different neutron energy regimes. **Table 3** summarizes the basic properties of the neutron as well as some useful relations regarding thermal neutrons.

Moderation of Neutrons

The energy spectrum of neutrons released from neutron sources is in the MeV range, whereas meV neutrons are required for scattering experiments in condensed matter research. Therefore, an energy shift of several orders of magnitude is necessary, which is accomplished by collisions with the atoms of a moderator substance. The goal in the layout of a moderator is to create the highest possible flux of moderated neutrons either in the shortest possible time (pulsed neutron sources) or in the largest possible volume (continuous neutron sources). This can be achieved by using moderators made of light atoms such as H_2O and D_2O. The time for slowing down the neutrons is $\sim 10^{-6}$ s after which the neutrons are in thermal equilibrium with the moderator kept at a constant temperature T according to the Maxwellian distribution

$$\Phi(\lambda) \propto \frac{1}{\lambda^3} \exp\left\{-\frac{h}{2k_B T m \lambda^2}\right\} \qquad [2]$$

where λ and m are the wavelength and the mass of the neutron, respectively. Moderators are generally kept at room temperature, and this is the reason why the corresponding neutrons are called thermal neutrons, with a maximum peak flux around the neutron wavelength $\lambda \approx 1$ Å, see **Figure 2**.

Scattering experiments which require cold or hot neutrons (i.e., neutrons with wavelengths considerably different from $\lambda \approx 1$ Å) would experience a tremendous flux penalty when working with the thermal neutron spectrum. However, the Maxwellian energy spectrum of the neutrons can be shifted by inserting either a cold source (e.g., a vessel containing D_2 at $T \geqslant 20$ K) or a hot source (e.g., a graphite block heated up to $T \leqslant 2000$ K) into the moderator; typical spectral shifts for cold and hot neutrons are displayed in **Figure 2**. By choosing the adequate neutron spectrum, the scattering experiments can be

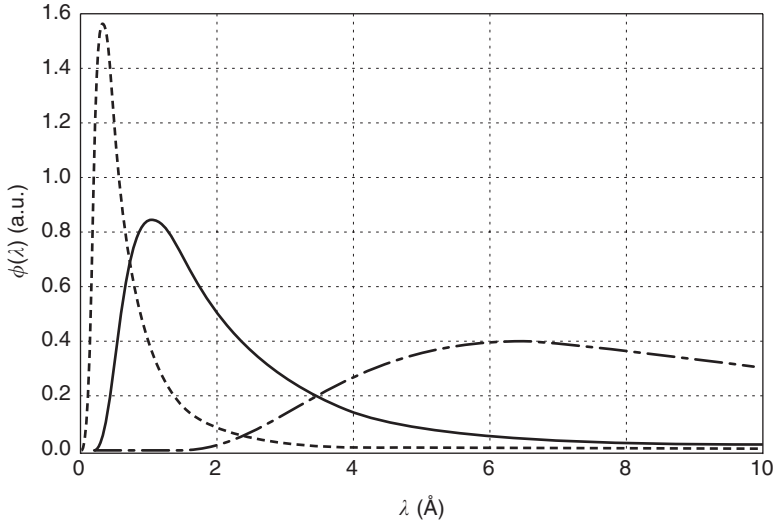

Figure 2 Wavelength distribution of neutrons from cold (dot dashed line, 50 K), thermal (solid line, 300 K), and hot (dashed line, 1000 K) moderators.

optimally tailored to the particular experimental requirements.

Neutron Beam Transport Devices

Once neutrons have been produced and moderated in the neutron source, it is still necessary to transport the neutrons to the experimental positions. Since neutron sources radiate isotropically, they must be surrounded by a heavy biological shielding. Beam tubes are inserted into the shielding to transport the neutron beam in a line-of-sight from the moderator surface to the instruments for neutron scattering. It is essential that these beam tubes are arranged tangentially to the core of the neutron source in order to reduce unwanted radiation significantly (e.g., fast neutrons). The angular acceptance of a neutron beam tube is determined strictly by the line-of-sight geometry between the source and the instrument. The beam divergence of a beam tube is normally $\sim 1^\circ$, so that the neutron flux available at the instrument position is drastically reduced by about six orders of magnitude as compared to the core flux.

The flux at the instrument position can be considerably improved by using neutron guides. A neutron guide works via total reflection of neutrons from the smooth walls of the guide material. This occurs for scattering angles less than the critical angle θ_c which is given by

$$\theta_c = 2\lambda\sqrt{\frac{\rho b}{2\pi}} \qquad [3]$$

where ρ and b are the atom number density and the coherent scattering length of the wall material, respectively. Among common materials, nickel is the best choice with critical angles $\theta_c(^\circ) = \lambda \cdot 10^{-1}$ (Å). The angular acceptance of a neutron guide can be dramatically increased by reflection from the so-called supermirrors which consist of a sequence of layers of variable thickness with alternatingly high positive and negative scattering length density. Supermirrors can be characterized by a number m defining the increase of θ_c compared to nickel. At present, $m = 3$ can be routinely achieved which results in an order of magnitude flux increase at the instrument position as compared to a conventional beam tube.

Prospects for Future Neutron Sources

An ever-growing scientific community uses neutrons in various disciplines of condensed matter research; however, the currently active neutron sources (see **Table 4**) will not be able to supply the future demand. In fact, some time between 2010 and 2020, the currently installed capacity of neutron sources serving the scientific community will decrease to a level below one-third that of today. Thus new neutron sources are indispensable to ensure the continuity and further developments in neutron scattering.

The history of the evolution of fission sources was impressive some decades ago, but progress was leveling off after the commissioning of the high-flux reactor at the ILL, Grenoble. This is clearly due to the technical difficulty of removing the heat from the reactor core. Another problem is the worldwide consciousness about the risk of installations based on nuclear fission. This makes it difficult to surpass the performance of existing high-flux reactors, so that one may conclude that fission sources do not have a serious prospect for the future.

Table 4 Currently active neutron sources offering access to the scientific community for condensed matter research (>100 users/year). The flux of pulsed sources corresponds to the peak flux

Location	*Country*	*Source*	*Type*	*Power* (MW)	*Thermal flux* (10^{14} n cm^{-2} s^{-1})
Lukas Heights	Australia	HIFAR	Fission/continuous	10	1.4
Chalk River	Canada	NRU	Fission/continuous	120	3.0
Grenoble	France	HFR	Fission/continuous	58	12.0
Saclay	France	Orphée	Fission/continuous	14	3.0
Berlin	Germany	BER-2	Fission/continuous	10	2.0
Geesthacht	Germany	FRG	Fission/continuous	5	0.8

Los Alamos	USA	LANSCE	Spallation/pulsed	0.056	34
Argonne	USA	IPNS	Spallation/pulsed	0.007	5

However, future progress can be expected for spallation sources which – unlike fission sources – offer the possibility of imposing a time structure on the neutron flux, so that the source performance depends on the peak flux in the pulse rather than on the time-averaged flux. The present spallation sources and spallation source projects are largely designed such as to create rather short neutron pulses $\sim 100\,\mu s$. A further increase of the power level beyond 1–2 MW (the envisaged power level for the spallation source projects in USA and Japan) may be difficult due to target problems. Nevertheless, an order of magnitude increase of the power level seems to be feasible for increased proton pulse lengths of the order of milliseconds duration, as obtainable from a linac without pulse compression. The European 5 MW spallation source project was partly based on such a concept, and it was demonstrated that significant advantages can be drawn from long proton pulses for certain categories of neutron scattering instruments. Although target problems become increasingly severe as the power goes up, it is probably realistic to see the ultimate limit of (long-pulse) spallation sources approaching a proton power level of 20 MW (i.e., 20 mA proton current at 1 GeV).

Nomenclature

E	neutron energy (MeV)
h	Planck's constant ($h = 6.626 \times 10^{-27}$ erg s)
k	neutron wave number (Å^{-1})
k_B	Boltzmann constant ($k_B = 1.381 \times 10^{-16}$ erg K^{-1})
m	mass of the neutron ($m = 1.675 \times 10^{-24}$ g)
λ	neutron wavelength (Å)
v	neutron velocity (km s^{-1})
Φ	neutron flux (n cm^{-2} s^{-1})

Neutrons and Neutron Scattering, History of

F Mezei, Hahn-Meitner-Institut, Berlin, Germany

Introduction

The expression "neutron scattering" commonly refers to the study of condensed or gaseous matter by observing the scattering of a neutron beam from a sample of the material in question. If the energy of the neutrons in the beam is much higher than the typical energy of the interactions of the atoms in the sample matter (e.g., the energy of chemical binding within constituent molecules), the collision of neutrons with the nuclei of the atoms depends only on the properties of the individual nuclei and carries no information on the properties of the material. Thus, the subject matter of this article is the history of using low-energy (typically less then 1 eV) neutron radiation for exploring what happens inside common materials.

The idea that neutrons can reveal precious information about the structure of such materials – solids, liquids, and to some extent also gases – was born shortly after neutrons were discovered by Chadwick in 1932. Practical neutron scattering started as a parasitic activity on research reactors built in the 1940s for developing nuclear energy. Since the 1960s, several facilities around the world have been specifically designed, built, and dedicated primarily for neutron scattering research to serve by the end of the twentieth century a worldwide community of about 7000 users of neutrons as one of their tools in the study of a vast variety of topics in condensed matter research, including physics, chemistry, biology, geology, archeology, and engineering. In 1994, Shull and Brockhouse, the two outstanding pioneers of neutron scattering in the 1950s, were awarded the Nobel prize in physics for discovering how the neutrons show "where the atoms are and what they do."

Establishing the Conceptual Foundations

As early as in 1936, Elsasser suggested that neutrons move as waves through matter and as these waves scatter on the nuclei of individual atoms, interference may occur between the partial waves scattered from different atoms, as was known since the 1910s for X-rays. This was demonstrated in the same year by observing the strong reflection of neutrons on large magnesium oxide single crystals. In this respect, the fundamental difference that neutrons scatter on the nuclei and X-rays on the electron cloud surrounding these nuclei in the atoms was of no principal consequence.

In 1936, Bloch also made a visionary proposition, which in contrast had no analogy in X-rays. Due to the fact that the neutron possesses a magnetic moment, Bloch realized that they could also feel the magnetic fields inside magnetic materials. The magnitude of the neutron magnetic moment is $\mu_n = 1.04 \times 10^{-3}\,\mu_B$, where the Bohr magneton μ_B essentially equals the magnetic moment of a free electron. The internal average magnetic field (induction) inside ferromagnetic iron is $B = 2.2\,\mathrm{T}$ and the energy of the Zeemann interaction in this field $E = -\mu_n B = 1.32 \times 10^{-7}\,\mathrm{eV}$ acts as a potential on the neutron (attractive if the neutron magnetic moment is parallel to the field B, and repulsive for antiparallel direction), which can measurably deflect a neutron beam. Bloch pointed out that, since the internal magnetic field distribution in a magnetic material is not homogeneous but shows strong maxima centered around the position of the nuclei, the internal magnetic field distribution shows a periodic structure in crystalline magnets and therefore with neutrons, not only the atomic structure determines the Bragg diffraction peaks well known for X-rays, but there is also a contribution from the magnetism of the atoms.

It is of particular historical interest that while Bloch's visionary recognition of the great potential of neutron scattering in the study of magnetic materials proved to be of outstanding importance in the investigation of magnetic phenomena, for example, the study of high-temperature superconductors in recent decades, he proposed a mathematical expression, which was debated for nearly 15 years and finally proved to be wrong. This controversy reflected a fundamental ambiguity of electromagnetic theory, which could finally be settled by the neutron reflectivity experiments of Hughes and Burgy (1951). In electromagnetic theory, two fields are associated with magnetic materials: the so-called magnetic field H and magnetic induction B. These two are equal outside the magnetized matter, the only place where one could place a measuring device. This was going to change with the neutrons: as neutral particles, neutrons interact weakly with most materials and can penetrate deep inside heavy objects (e.g., many centimeters in steel), and as a quantum mechanical particle wave, they can theoretically spread over an unlimited volume of the sample. So magnetism could, for the first time, be observed inside magnetic materials, with the

measuring probe, the neutron occupying the same space as the sample magnetic material. Although the details did not appear to be so clear at that time, Bloch's 1936 theory implied that the interaction between the neutron magnetic moment and magnetism corresponds everywhere, including the inside of matter, to the energy

$$E = -\mu_n H \qquad [1]$$

whereas the different formulas proposed by Schwinger in 1937 were shown to correspond to the general assumption

$$E = -\mu_n B \qquad [2]$$

The experiments of Hughes and Burgy, which could only be done when a few years after World War II intense neutron beams became available for research at nuclear reactors, settled the ambiguity in favor of eqn [2]. To overcome a repulsive energy barrier of ~ 100 meV corresponding to the magnetic induction B inside iron for the neutrons with magnetic moment opposite to the magnetization of the sample, the neutrons needed to have at least $5\,\mathrm{m\,s^{-1}}$ velocity perpendicular to the surface. Below this value, the neutron beam is totally reflected. Thus for typical velocities of the neutron beams available from reactors in the range of $2000\,\mathrm{m\,s^{-1}}$, the range of total reflection will extend up to grazing incident angles of $\sim 0.1^\circ$ (the so-called critical angle). Hughes and Burgy determined the potential energy by the observation of the critical angle in magnetized Fe films. Their conclusion that $E = -\mu_n B$ was shown to imply that the magnetic moment of the neutron should be considered as a microscopic Amperian current loop, and not as a dipole built by opposing charges.

Actually, the total potential energy at a surface is the sum of the magnetic and nuclear contributions, where the latter designates the average potential presented by the interaction between the neutrons and the nuclei of the atoms in the sample, and the detailed shape of the reflectivity curve above the critical angle of total reflection depends on the detailed profile of the potential, which can show considerable structure, for example, in surfaces consisting of a number of thin layers. Decades after the pioneering work of Hughes and Burgy, neutron reflectivity became a widely-used tool for the study of surfaces and thin film structures, in particular following Felcher's important study of the penetration depth of magnetic fields at the surface of superconductors in 1979.

Neutron Diffraction

Practical neutron scattering work started more than 10 years after the theoretical suggestions by Elsasser and Bloch, when nuclear fission reactors became available for research. The energy of fission neutrons is very high ($\sim$MeV), and they first need to be slowed down before they can be used in neutron scattering work. This was achieved by the thermalization process, in which neutrons are made to collide randomly with light, small absorbing nuclei (originally C in graphite) whereby after a few collisions a neutron gas with a temperature close to the temperature of the moderator is produced. The energy of the neutron emerging from a moderator

$$E = mv^2/2 \qquad [3]$$

(where m is the neutron mass, $m = 1.67 \times 10^{-24}$ g) is on average close to the thermal energy $k_B T$ at the temperature of the moderator, that is, 25 meV at room temperature. The corresponding neutron velocity $v = 2200\,\mathrm{m\,s^{-1}}$ is equivalent in quantum wave mechanics to a wavelength of $\lambda = 0.18$ nm, as given by the de Broglie relation

$$h/\lambda = mv \qquad [4]$$

where h is Planck's constant. This wavelength is comparable to the 0.154 nm of the Kα X-ray radiation of copper, mostly used for crystallographic studies at that time. However, the wavelength distribution in the neutron beam extracted from the moderator was very broad and to build the first neutron diffractometer in 1948, Shull and Wollan at Oak Ridge used a monochromator single crystal to obtain a neutron beam with a well-defined wavelength. The next step was to measure the neutron scattering power for a large number of atomic nuclei by studying the neutron diffraction pattern for many well-known crystals. It turned out that this power changes rather randomly from one nucleus to the other, and, in particular, in neutron diffraction one can see the contributions of light elements (e.g., hydrogen) also in the presence of much heavier ones. This is an important contrast of great practical utility to X-ray diffraction, where heavy elements in the crystals tend to mask the lighter ones.

The first decisive discovery by using neutron scattering was made by Shull and Smart in 1949 at Oak Ridge: they found a new Bragg peak in the neutron diffraction pattern of MnO at low temperatures, which could not be seen in X-ray studies (**Figure 1**). It was the first experimental evidence for antiferromagnetism, showing that the magnetic moments of the Mn atoms are aligned parallel for every second

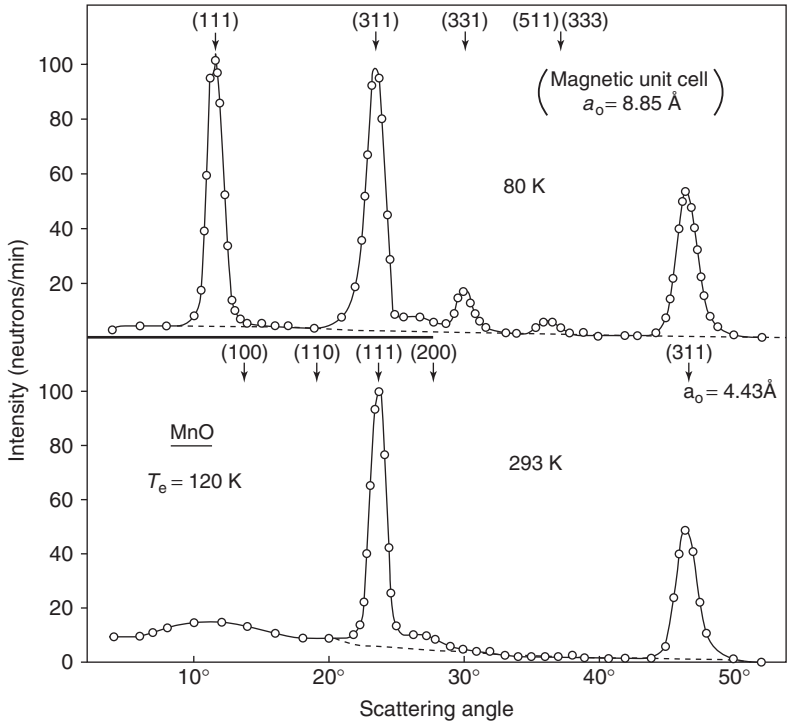

Figure 1 The first experimental evidence for antiferromagnetism by neutron diffraction. (Shull CG and Smart JS (1949) *Physical Review* 76: 1256.)

atom in certain lines and antiparallel for the atoms in-between. This breakthrough established neutron scattering as the preferred tool for the study of magnetism on the atomic scale. It is worth noting that this seminal discovery was made before the controversy on the coupling between neutron and magnetism had been settled. However, the existence of Bragg peaks in a sample without preferred magnetic orientation did not depend on the exact form of the interaction.

Neutron diffraction experiments can not only reveal crystalline long-range order, but also much less regular arrangements of atoms. In such cases the Bragg peaks are replaced by broad "diffuse scattering" structures in the scattering diagram (such as in the lower curve in **Figure 1** around 11° scattering angle), which carry information on a large variety of phenomena, such as the way in which one atom is surrounded by neighbors in a liquid or the size and arrangement of precipitates in an alloy. Information on larger structures shows up at smaller scattering angles, which gradually led (from the late 1950s) to the development of small angle neutron scattering (SANS) as a very special form of neutron diffraction.

Inelastic Scattering

The atoms and molecules inside condensed matter move around locally with energies comparable to k_BT. This leads to the appearance of the so-called inelastic scattering processes, in which the energy of the scattered particle is changed by an exchange with the kinetic energy of the atoms. Since for ordinary temperatures, the energy of the thermal motion of atoms in the sample is comparable to the energy of the neutrons from ambient moderators, the energy change of the neutron in the corresponding inelastic scattering processes can be quite substantial, and therefore readily measurable. In contrast, the quanta of X-rays with wavelength convenient for scattering work on condensed matter (i.e., in the range of atomic distances in the sample) are very high, and inelastic processes due to motion of atoms are difficult to observe. For example, the energy of the above-mentioned Kα X-ray radiation is 7.8 keV, ~300 000 times higher than energy of neutrons with similar wavelength. Since the early 1950s, several research groups have demonstrated the existence of such inelastic processes in neutron scattering. The decisive breakthrough came from Brockhouse at Chalk River by the introduction of triple-axis-spectroscopy in 1958, a technique to put these studies on firm grounds adequate for theoretical interpretation.

In 1954 van Hove developed a general theoretical framework for neutron (and other) scattering experiments in condensed matter. The particular significance of the van Hove theory for neutrons was that since the neutron interaction with most condensed

matter sample is weak (again a very important difference from X-rays), this theory applies with great precision in most cases. The theory allows us to calculate the probability for the neutron to scatter from an initial state with velocity $\boldsymbol{v}_i$ to a final state with velocity $\boldsymbol{v}_f$ for any complete model of the behavior of the sample, including both the arrangement of the atoms in space and their motion, for example, vibrations around steady equilibrium positions in solids, or the microscopic motion leading to fluidity in liquids. The van Hove scattering function $S(\boldsymbol{q}, E)$ is a function of two parameters, the momentum transfer vector $\boldsymbol{q}$ and the energy transfer E, which are defined in terms of the initial and final neutron velocities as follows:

$$\boldsymbol{q} = m\boldsymbol{v}_f/\hbar - m\boldsymbol{v}_i/\hbar \quad \text{and} \quad E = mv_f^2/2 - mv_i^2/2 \quad [5]$$

where $\hbar = h/2\pi$ and v_f and v_i are the absolute values of the velocity vectors $\boldsymbol{v}_f$ and $\boldsymbol{v}_i$. The triple-axis technique of Brockhouse allows us to select a well-defined pair of values $\boldsymbol{q}$ and E. This was a real breakthrough, since the computing power in theoretical calculations was rather limited at that time and model calculations such as the energy dispersion relation of a phonon or magnon excitation branch α in single crystals, $E_\alpha(\boldsymbol{q})$, could only be calculated for special momentum transfer vectors $\boldsymbol{q}$ in highly symmetric directions in the crystals.

The principle of triple-axis spectroscopy is very simple (**Figure 2**): both the initial and final neutron velocities can be selected with great flexibility, by a monochromator and an analyzer crystal, in order to fulfill both the equations in [5] for a wide range of desired values of the four parameters represented by the vector $\boldsymbol{q}$ and the scalar E. This requires calculating the three scattering angles for the monochromator, sample and analyzer, and automatically setting the spectrometer and the orientation of these three crystals in the right configuration. This was the key technical innovation behind the introduction of triple-axis spectroscopy. The most common mode of operation is to design scans of one of the abovementioned four parameters, for example, in "constant $\boldsymbol{q}$" scans a set of data points are taken at different E values, while the vector $\boldsymbol{q}$ is kept constant with respect to the sample. The diffractometer, or "two-axis" spectrometer, used by Shull and collaborators differs from the one in **Figure 2** only by the lack of the analyzer crystal: the detector only records the distribution of the scattered neutrons as a function of the scattering angle, without analyzing the magnitude of their velocity. This is done under the tacit and frequently valid assumption that the inelastic scattering is weak compared to the elastic one with $v_f = v_i$, and therefore it can be neglected.

An alternative approach to inelastic scattering is to produce pulses of neutrons with a constant initial velocity $\boldsymbol{v}_i$ and determine the final velocity vector $\boldsymbol{v}_f$ by recording the time of arrival of the neutrons at the immobile detector banks surrounding the sample, where the position of each detector corresponds to a given scattering angle. A 2–4 m flight path between the sample and the detectors is sufficient to determine the final neutron velocities with a reasonable precision. This "time-of-flight" (TOF) method was developed at several places in incremental steps parallel to the triple-axis technique, including early work with

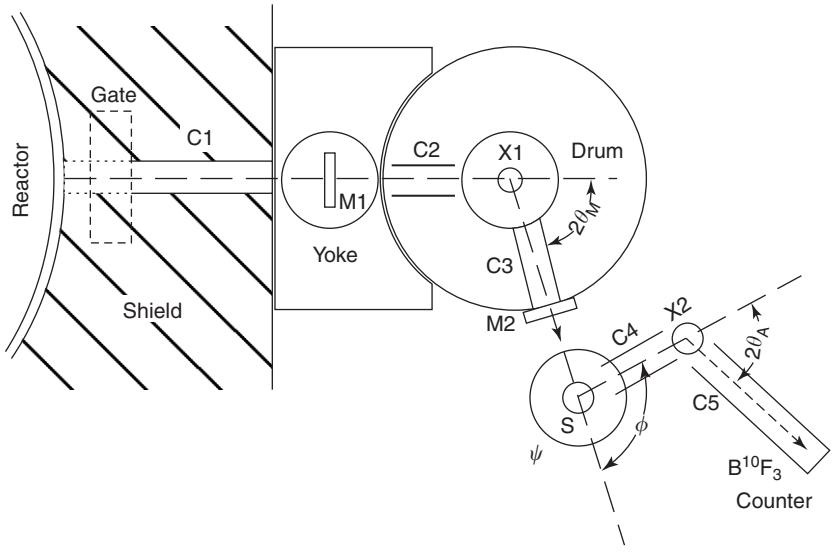

Figure 2 The basic layout of triple-axis spectrometers. The single crystals X1 and X2 are the monochromator and analyzer, respectively, and S is the sample. (Brockhouse BN and Stewart AT (1958) *Reviews of Modern Physics* 30: 236.)

mechanical choppers to produce neutron pulses by Jacrot at Saclay. TOF techniques are most often used for isotropic samples, for example, liquids, where only the absolute value of $\boldsymbol{q}$ matters, not its direction compared to the orientation of the sample. **Figure 3** shows the elementary excitation spectrum of superfluid ^{4}He below 2.17 K. The observation of the minimum in the $E(q)$ dispersion relation at $q = 19.3\,\mathrm{nm}^{-1}$ provided direct evidence for the theories of Landau and Feynman.

Polarized Neutrons

The van Hove scattering function as given above applies to the simplified situation of neglecting the neutron magnetic moment. While the initial and final states of the neutrons are only fully characterized by not only keeping track of the velocity but also of the direction of the magnetic moment vector $\boldsymbol{\mu}$ (or that of the associated neutron spin with $s = 1/2$), only the velocity has been considered so far. This corresponds to the real experimental situation in "unpolarized neutron scattering," where $\boldsymbol{\mu}$ is randomly oriented in the incoming beam and its orientation is not determined in the scattered beam. In the most general case, one needs to define both the initial and final states by the five parameters ($\boldsymbol{v}_\mathrm{i}$, $\boldsymbol{\mu}_\mathrm{i}$) and ($\boldsymbol{v}_\mathrm{f}$, $\boldsymbol{\mu}_\mathrm{f}$), respectively (vector $\boldsymbol{\mu}$ represents only two free parameters, since its magnitude is given). Thus, the van Hove scattering function will take the form $S_{\alpha,\beta}(\boldsymbol{q}, E)$, describing the scattering probability from an initial neutron state with magnetic moment direction α to a final one with magnetic moment direction β.

The two basic methods used nearly exclusively until now to produce polarized neutron beams were also discovered early on, in 1951. One of them is essentially the reflection of neutrons on magnetized mirrors used by Hughes and Burgy to identify the interaction of neutrons with magnetic fields, as discussed above. The potential in eqn [2] for the internal B field in the ferromagnetic mirror (Fe or Co or their alloys) makes the critical angle of total reflection different for neutrons with magnetic moment oriented parallel or antiparallel to the direction of the field magnetizing the mirror. Thus, in the angular range between these two critical angles (referred to as "spin up" and "spin down" critical angles), the reflectivity will be substantially larger for one direction of the neutron magnetic moment, and the mirror selects from the originally unpolarized beam a preferred magnetic moment (or spin) direction. This technique is simple and inexpensive; it has the disadvantage though that the difference between the "up" and "down" critical angles is rather small, and therefore it can only select a rather limited fraction of the neutrons emerging from the reactor in all directions. In 1976 Mezei introduced the "supermirrors" to enhance the angular range of efficient polarizing neutron mirrors by complementing the range of total reflection by a range of nearly total reflection by interference on a stack of up to ~ 500 thin layers of alternating magnetic and nonmagnetic layers with carefully designed sequence of thicknesses between ~ 3 and 50 nm. Most mirror-based neutron polarizers in operation today use supermirrors.

The other basic method of polarizing neutrons is to use an adequate Bragg reflection from a single

crystal. In ferromagnetic materials, unlike the case of antiferromagnets shown in **Figure 1**, the magnetism of the atoms leads to a magnetic contribution to the Bragg peaks corresponding to the atomic crystal structure. This makes the intensity of the reflection dependent on the relative direction of the neutron magnetic moment with respect to the magnetic field polarizing the sample. For a few special Bragg peaks in various materials, the intensity of the reflection can be two orders of magnitude different for neutron spins parallel or antiparallel to the crystal magnetization. This was first observed by Shull in 1950 for a reflection in magnetite, Fe_3O_4. He also pointed out that by observing the effect of the beam polarization on the scattered beam intensity in a magnetized sample one can increase the sensitivity of neutron scattering experiments in the study of weak signals from magnetic samples by orders of magnitude, for example, for detecting ordered magnetic moments in the range of $10^{-3}\,\mu_B$ per atom.

Polarization Analysis

For the unambiguous identification of the magnetic signals in complex magnets or inelastic scattering, in particular in paramagnetic or antiferromagnetic samples which cannot be magnetized in moderate fields, one needs to resort to polarization analysis. Here the scattered beam intensity might not depend on the initial beam polarization; instead, the scattered beam polarization needs to be determined. Experimentally this can be achieved by replacing both the monochromator and analyzer crystals on a triple-axis spectrometer by a crystal with a polarizing reflection and control the beam polarization between the polarizer and analyzer crystals, for example, by maintaining it in a given direction or "flipping" it. Several researchers have made important steps in this direction, in particular, Drabkin and collaborators at Gatchina. In 1969, Koehler, Moon, and Riste established the first experimental evidence for the characteristic polarization behavior of different scattering processes. In the approach, they established (what is now called "one-dimensional polarization analysis") that both the initial and final beam polarization can be either parallel ($+$ or "up") or antiparallel ($-$ or "down") to the field direction on the sample. Thus, the choice of α and β directions in the above general form of the van Hove scattering function reduces to the combinations: "$++$" for the probability of scattering from the $+$ neutron spin direction to the same one, $S_{++}(\boldsymbol{q}, E)$, and similarly "$--$," "$+-$," and "$-+$." The first two processes are without change of spin direction ("non-spin flip") and the last two ones involve the reversal of the neutron spin ("spin flip"). Later developments (primarily at Delft, Gatchina, and ILL, Grenoble) led to generalized or vectorial (3D) polarization analysis (or polarimetry), where α and β can be arbitrary directions. A historically important example of complex vectorial behavior of the scattered beam polarization is the early prediction by Halpern and Johnson in 1942 for the magnetic scattering in paramagnetic samples, giving the direction of the scattered beam polarization $\boldsymbol{P}_f$ (which is defined as the average of the individual neutron magnetic moment directions in the beam) as a function of the initial one $\boldsymbol{P}_i$ and the unit vector parallel to the momentum transfer $\hat{\boldsymbol{u}} = \boldsymbol{q}/q$ as

$$\boldsymbol{P}_f = -\hat{\boldsymbol{u}}(\boldsymbol{P}_i\hat{\boldsymbol{u}})$$

Special cases of this relation (when $\boldsymbol{P}_i$ and $\hat{\boldsymbol{u}}$ are either parallel or perpendicular) have been demonstrated in 1969 by Koehler, Moon, and Riste, while the full vectorial relation could only be verified later.

Neutron Spin Echo

The generic scheme of neutron scattering experiments consisting of preparation of an initial beam with more or less well-defined $\boldsymbol{v}_i$ and analysis of the final distribution of $\boldsymbol{v}_f$, as it is common, for example, for triple axis (**Figure 2**), TOF, and other techniques. It implies that for the observation of small changes, the initial and final velocities must be very well defined, that is, very few neutrons will be selected from

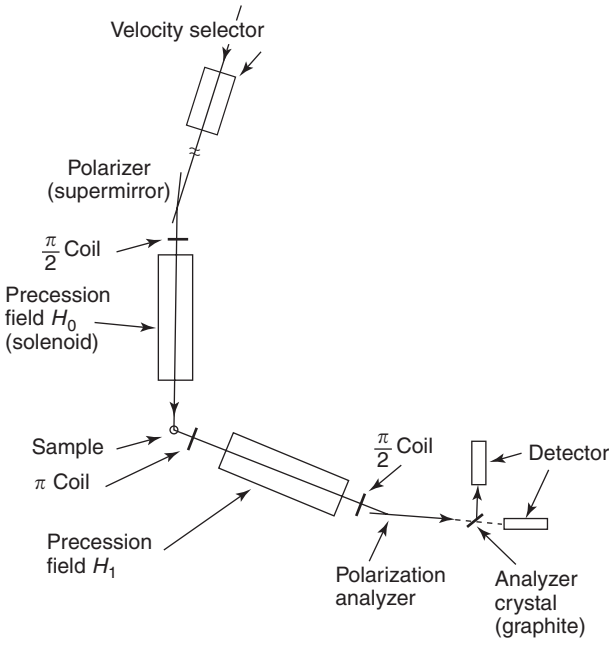

Figure 4 The layout of a neutron spin echo spectrometer. (Mezei F (ed.) (1980) *Neutron Spin Echo*. Berlin: Springer.)

a broad distribution in direction and absolute velocity. The neutron spin echo method, invented by Mezei in Budapest (1972) uses a drastically different paradigm. It consists in making each neutron effectively carry its own stopwatch and, using this, compare a selected component of v_i with another component of v_f. Thus, the determination of minute relative changes of the neutron energy in the 10^{-6} range can be measured at a rough monochromaticity of 10–20%. The Larmor precession of the magnetic moment of each neutron in well-defined magnetic fields serves as the clock attached to each neutron (**Figure 4**). Neutron spin echo thus allows to extend the upper limit of time domain 10^{-14}–10^{-9} s where atomic motions can be studied by methods of inelastic neutron scattering up to 10^{-6} s, making accessible many processes in macromolecular systems.

Steady-State and Pulsed Neutron Sources

The most recent revolution in neutron scattering is driven by the evolution of the methods of producing neutron beams. As we have seen, the need to select neutron beams with a more or less well-defined initial velocity v_i by some monochromator implies that one should throw away the vast majority of the neutrons produced with a broad velocity distribution and emitted in all directions by the moderators. Cutting out pulses of the beam by a mechanical chopper was found early on as an efficient way to select their velocity, for example, 0.2 ms pulses every 10 ms provide a suitable monochromatic beam for TOF spectroscopy over a typical flight path of 20 m. Such a monochromator only needs neutrons for a short time every 10 ms; for the rest the source could be switched off to save costs and heat production, the latter being the ultimate technical limitation. It is difficult but not impossible to operate reactors in a pulsed fashion, and this approach has been pioneered at Dubna near Moscow since the 1960s. The IBR-2 pulsed reactor source at Dubna today achieves 1500 MW instantaneous power (heat production) when switched on for about 0.3 ms, while steady-state reactors cannot practically surpass 100 MW.

Neutrons can also be produced by accelerators, that can easily operate in a pulsed mode. This approach was first pioneered by Tohuku University in the 1960s using electrons. The most efficient accelerator-based neutron production technique, the so-called "spallation," was established in Argonne near Chicago by Carpenter and collaborators in the 1970s. Here a pulsed proton beam is accelerated to typically 1 GeV energy, and each proton absorbed in a heavy-metal target sets free ~30 neutrons in a series of collisions with the nuclei. Thus, the energy needed per neutron produced (~30 MeV) is much less than the ~190 MeV heat accompanying the

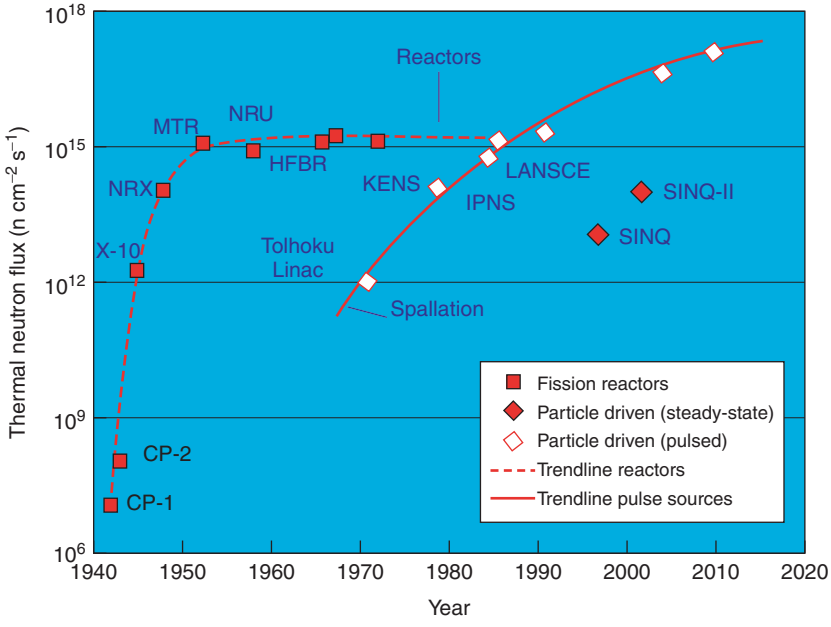

Figure 5 Evolution of the flux of neutron sources available for neutron scattering over the past decades at different facilities. The flux is defined here as the number of neutrons crossing unit area of the surface of the ambient temperature moderator in unit time. It is measured in units of $cm^{-2}s^{-1}$. For pulsed sources, the flux at the peak of the pulses is shown.

birth of a recoverable neutron in the fission process in reactors. The great new potential offered by high-power spallation sources, as illustrated in **Figure 5** by the peak instantaneous neutron flux they can produce during the pulse, is based on this double gain of efficiency: less heat is produced per usable neutron and the source is switched off for much of the time when no neutrons are needed. Although, by itself, the peak flux of a pulsed source compared to the time average flux of a steady-state reactor does not fully characterize its performance in all applications, the great potential of progress with future multi-MW spallation sources is well illustrated in **Figure 5**.

Neutron Optics

While source performance has not improved much since the 1950s in terms of number of neutrons produced, the intensity of neutron beams available in scattering experiments has steadily increased over the same period of time, in particular by the advent of Institut-Laue-Langevin (ILL) in Grenoble, the most powerful neutron scattering facility in the world operated through a European collaboration. At the 58 MW fission reactor at ILL three different moderator temperatures 25, 300, and 2000 K are available in order to provide the best-adapted neutron spectrum for the various instruments, and that has become a standard for more recent research reactors. The art of "neutron optics," the development of increasingly efficient components for transporting, shaping, monochromatizing, and analyzing neutron beams has also steadily progressed. One of the key inventions was the introduction of neutron guides by Maier-Leibniz in München in the early 1960s. Neutron guides are rectangular tubes with cross-section up to 100–200 cm^2 with the internal walls made of totally reflecting mirrors (usually highly polished glass coated with an adequate metallic layer). These guides can transport intense neutron beams over large distances with minimal losses with a beam divergence limited by the critical angle of total reflection (typically a few tenths of a degree). More recently, the divergence, and hence the intensity of the beam transported in the guides, is enhanced by using supermirror coating. The early single crystal monochromators are replaced by arrays of single crystals focusing the beam on the sample, and an increasingly larger fraction of the scattered neutrons is captured by using large position-sensitive area detectors. The combination of continuously advancing neutron optics with the enhanced neutron flux of the next-generation neutron sources means that the power of neutron scattering methods is increasing much faster than indicated by the trendline in **Figure 5** for spallation sources.

NMR Methods for the Determination of Local Structure

R Blinc and B Zalar, J. Stefan Institute, Ljubljana, Slovenia

Introduction

Ideal crystals exhibit perfect translational symmetry. The arrangement of the atoms in a unit cell repeats itself in one, two, and three dimensions. In disordered systems on the other hand, the translational symmetry is locally broken. It is only the average structure, which is translationally invariant.

Many physical properties of disordered systems are of great interest both for basic physics as well as applications. Generally, they are not determined by the average structure, but by the local structure. Examples of such systems are, for instance, relaxors, that is, perovskite solid solutions with exceptional dielectric and electromechanical properties, which are characterized both by substitutional site and charge disorder, and the formation of polar nanoclusters. It has been shown that disorder is important also in perovskites such as $BaTiO_3$ and $SrTiO_3$, which were long considered to be classical examples of displacive soft-mode type ferroelectrics or

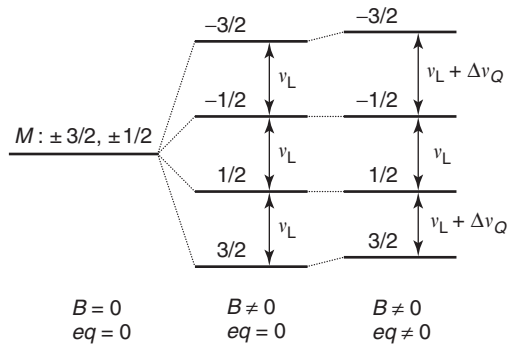

Figure 1 Shift of the Zeeman energy levels of a nucleus with a spin $I = 3/2$ in the presence of nonzero electric quadrupole coupling, $e^2qQ/h \neq 0$. Instead of a single Zeeman line now there are three lines: a central $1/2 \leftrightarrow -1/2$ transition and two satellite transitions, $3/2 \leftrightarrow -1/2$ and $-1/2 \leftrightarrow -3/2$. Here $eq = V_{zz}$ is the largest eigenvalue of the EFG tensor, e is the elementary charge, Q the nuclear quadrupole moment, and h Planck's constant.

ferroelastics, describable by anharmonic lattice dynamics. These are important in thin films and ferroelectric memory devices. The local rather than the average structure also determines the properties of hydrogen-bonded ferroelectrics such as KH_2PO_4, proton, and deuteron glasses as well as related H-bonded biomolecules and DNA. The same is true for many fullerenes as, for instance, for the purely organic ferromagnet TDAE-C_{60} or Cs_4C_{60}. Incommensurate systems, where one has perfect long-range order but no translational symmetry in one, two, or three dimensions, represent a special case. Here, the local structure is determined by the modulation wave, the periodicity of which is incommensurate to the periodicity of the basic lattice. Therefore, the translational periodicity is lost and the whole crystal is the unit cell. The small deviations from the average structure are hard to determine by X-ray or neutron scattering techniques, which depend on spatial averages. Local techniques, such as nuclear or electron magnetic resonance, on the other hand, directly reflect the local structure.

The relevant Hamiltonian is here, in the most general case, the sum of a Zeeman term, a chemical shift term, a dipole–dipole term, a nuclear quadrupole coupling term and a hyperfine coupling term

$$\mathcal{H} = \mathcal{H}_z + \mathcal{H}_{cs} + \mathcal{H}_{d-d} + \mathcal{H}_Q + \mathcal{H}_{hpf} \qquad [1]$$

The last four terms in expression [1] depend on the local structure and dynamics of the atomic surrounding of a given nucleus, and are very sensitive to small deviations from the average structure. The shifts of the Zeeman energy levels in case of a nonzero electric quadrupole coupling are schematically illustrated in **Figure 1**. The relation between the site symmetry and the quadrupole coupling term is shown in **Table 1**.

Table 1 EFG tensor and symmetry of the nuclear site

Site symmetry	*EFG tensor*
Cubic	0
Threefold, fourfold or higher symmetry rotational axis	Axially symmetric EFG tensor, asymmetry parameter $\eta = \frac{V_{xx} - V_{yy}}{V_{zz}} = 0$
Twofold axis	One principal axis of EFG tensor is parallel to the twofold axis

Disorder in Classical Perovskites

The question to be answered is whether the potential for Ti motion in the cubic phase of classical perovskites such as $BaTiO_3$ or $SrTiO_3$ exhibits a minimum at the center of the oxygen cage or whether the Ti ion is disordered between several off-center sites (**Figure 2**). Since the electric field gradient (EFG) tensor is zero by symmetry at the central position and nonzero at the off-center sites, the above problem can be solved by quadrupole perturbed Ti-nuclear magnetic resonance (NMR).

A recent NMR study indeed observed unresolved ^{47}Ti ($I = 5/2$) and ^{49}Ti ($I = 7/2$) first-order satellites indicative of nonzero quadrupole coupling in the cubic phase of $BaTiO_3$. This can only be understood if the Ti ions are off-center even in the cubic phase above the ferroelectric transition at T_c. Similar results have been obtained also in the cubic phases of $SrTiO_3$, ^{18}O enriched $SrTiO_3^{18}$, and $KTaO_3$ doped with Nb.

For the case that the EFG tensor at the Ti sites is nonzero, one expects $2I$ quadrupole perturbed NMR lines for each isotope in $BaTiO_3$. The frequency shift $\Delta\nu_m = \nu_{m-1 \leftrightarrow m} - \nu_L$ of the $m - 1 \leftrightarrow m$ transition is given by

$$\Delta\nu_m = -\nu_Q(m - 1/2)(3\cos^2\theta - 1 + \eta\sin^2\theta\cos 2\phi)/2 \qquad [2]$$

where $\nu_Q = 3K/[2I(2I-1)]$ is the quadrupole frequency, η is the asymmetry parameter of the EFG tensor, $K = e^2qQ/h$ is the electric quadrupole coupling constant, and θ and ϕ are the tilt and azimuthal angles, respectively, of the direction of the external magnetic field in the EFG tensor eigenframe xyz. Instead of sharp satellite lines, broad background components in addition to the two sharp $-1/2 \leftrightarrow 1/2$ central lines are observed, which are not affected by quadrupole coupling in the first order. The presence of the satellite background in $BaTiO_3$ and

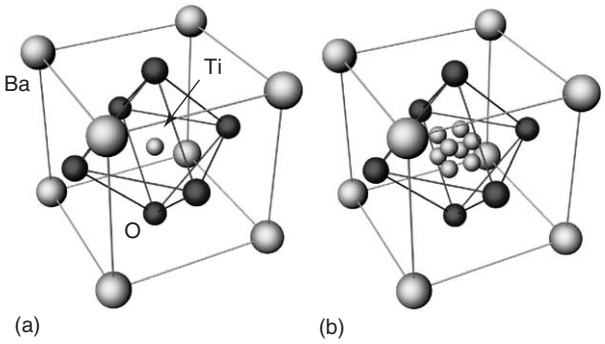

Figure 2 Possible Ti ion positions compatible with the cubic O_h symmetry of the paraelectric phase of $BaTiO_3$: (a) static Ti ion at the center of the oxygen cage of the ideal perovskite lattice, (b) Ti dynamically disordered among eight off-center sites displaced along the [111] body diagonals.

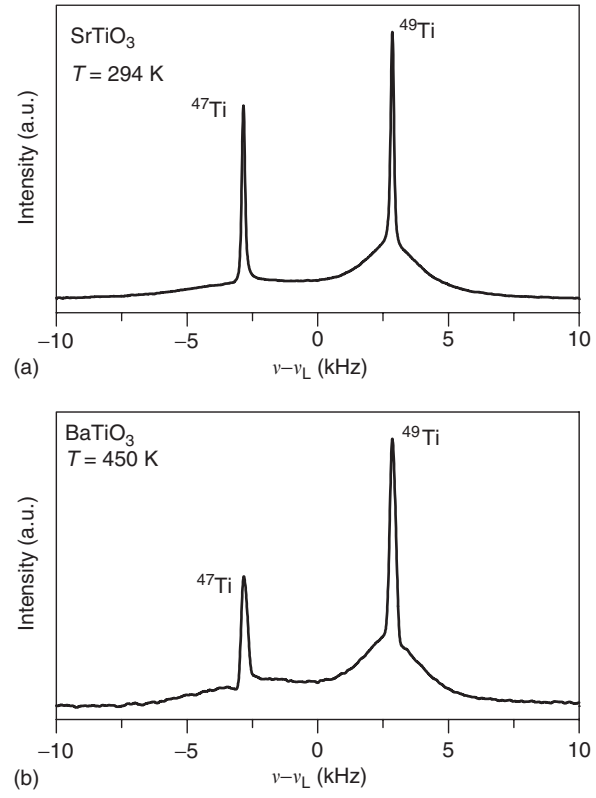

Figure 3 ^{47}Ti and ^{49}Ti NMR spectra of (a) $SrTiO_3$, and (b) $BaTiO_3$ single crystals in the cubic phase above T_c. The spectra show, in addition to the two central $1/2 \leftrightarrow -1/2$ lines, a broad background due to unresolved satellite transitions. The presence of these quadrupole-induced satellites demonstrates local tetragonal breaking of the macroscopic cubic symmetry.

$SrTiO_3$ demonstrates the local breaking of the O_h symmetry of the cubic phase. Without this breaking, there should be no satellite background around the central lines. The width of this unresolved satellite background shows that one has dynamic Ti

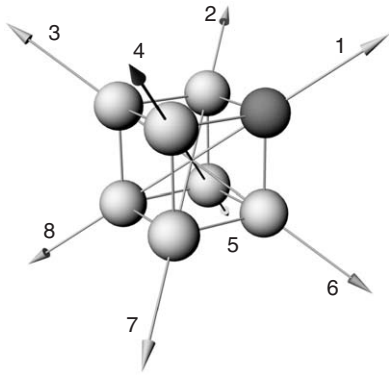

Figure 4 The eight site model of Ti disorder in $BaTiO_3$ and $SrTiO_3$.

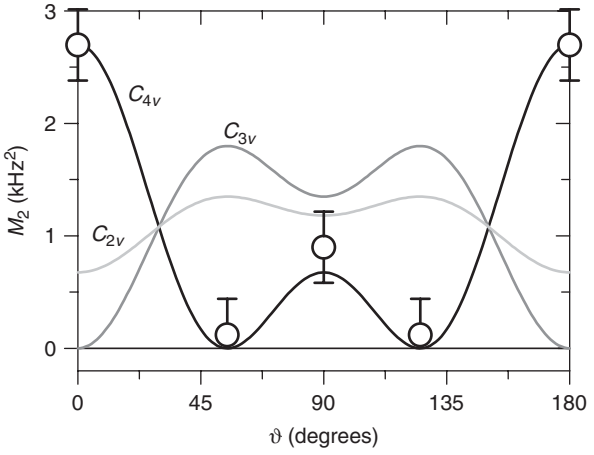

Figure 5 Angular dependence of the second moments M_2 of the ^{47}Ti quadrupolar background in $BaTiO_3$. For cubic symmetry there should be no angular dependence. The calculated values for tetragonal (C_{4v}), orthorhombic (C_{2v}), and rhombohedral (C_{3v}) local symmetry breaking in the paraelectric phase are shown as well. ϑ is the angle between the cubic direction [0 0 1] and the external magnetic field.

disorder among a subset of off-center sites (**Figures 3** and **4**).

The angular dependence of the second moments $M_2(\vartheta)$ of the ^{47}Ti spectra (**Figure 5**) shows that local tetragonal breaking of the cubic symmetry in $BaTiO_3$, $SrTiO_3$, and $SrTiO_3$[18] is dealt with.

The results can be understood within the eight-site order–disorder model (**Figure 4**). Sites 1, 2, 3, and 4 are each visited 25% of the time, whereas sites 5, 6, 7, and 8 are unvisited resulting in a local tetragonal state with a polarization along the [001] unit cell edge. The bias slowly switches so that after some time the sites 1, 2, 5, and 6 are visited 25% of the time and the polarization is along [010], etc. Thus, even in the cubic paraelectric phase, each unit cell is polarized. Only the time-averaged macroscopic polarization is zero. It should be stressed that two

distinct timescales as demonstrated by the T_2 data are dealt with here. On a short timescale, the Ti ions hop rapidly between four [111] off-center positions giving rise to a dipole moment along the cubic directions [100], etc. On a longer timescale, these tetragonal nanodomains can reorient between six equivalent directions.

Orthorhombic and rhombohedral symmetry breaking does not agree with the $M_2(\vartheta)$ data in the cubic phase. Below T_c the broad component (i.e., the unresolved satellite background) disappears and is replaced in $BaTiO_3$ by well-resolved satellites showing the presence of 90° ferroelectric domains. The tetragonal nanodomains become macroscopic and static below T_c.

One further point should be stressed. Assuming a fast motional exchange of the Ti ions among the off-center sites and site occupation probabilities n_i, one finds the motionally averaged EFG tensors for the cubic (O_h) and tetragonal (C_{4v}) phases as

$$\langle \underline{\underline{V}} \rangle = \sum_{i=1}^{8} n_i \underline{\underline{V_i}} \qquad [3]$$

leading to

$$\langle \underline{\underline{V}} \rangle_{O_h} = \frac{1}{2}(3\cos^2\theta - 1)\underline{\underline{V_0}}$$
$$\underline{\underline{V_0}} = eq \begin{pmatrix} -1/2 & 0 & 0 \\ 0 & -1/2 & 0 \\ 0 & 0 & 1 \end{pmatrix} \qquad [4]$$

and

$$\langle \underline{\underline{V}} \rangle_{C_{4v}} = 2(n_1 + n_5)(3\cos^2\theta - 1)\underline{\underline{V_0}} \qquad [5]$$

In the cubic phase $n_i = 1/8$, $i = 1,\ldots,8$, whereas in the tetragonal phase $n_1 = n_2 = n_3 = n_4 \neq n_5 = n_6 = n_7 = n_8$. In the undistorted cubic and tetragonal phases, the body diagonals [111] lie at the magic angle $\theta_M = 54.7°$ with respect to the cubic cell edges. As a result of this, $3\cos^2(\theta = \theta_M) - 1 = 0$, and the motionally averaged EFG tensor $\langle \underline{\underline{V}} \rangle$ vanishes though the EFG tensors at the eight off-center sites are different from zero. In fact, the tetragonal bias induces a slight deformation of the unit cell, $c/a \neq 1$, in the tetragonal nanodomains in the cubic phase so that $\langle \underline{\underline{V}} \rangle \neq 0$. The angle between the body diagonals and the unit cell edges deviates from the magic angle, $\theta = \theta_M + \delta$. In the tetragonal clusters inside the macroscopically cubic phase $\delta \approx 0.01°$. The situation is similar in $SrTiO_3$ and $SrTiO_3$[18].

On further cooling, $BaTiO_3$ undergoes a tetragonal–orthorhombic and at still lower temperatures, an orthorhombic–rhombohedral phase transition. These transitions are connected with a rotation of the spontaneous polarization due to changes in the site occupation probabilities n_i resulting from the biased freeze-out of dynamical Ti disorder. In the low T rhombohedral phase, the disorder is frozen out and only one of the eight sites is occupied.

Relaxors

"Weak" Relaxors

A well-known example of a prototype incipient ferroelectric or a "weak" relaxor is substitutionally diluted $KTa_{1-x}Nb_xO_3$. Pure $KTaO_3$ does not undergo any ferroelectric transition as $T \to 0$. On decreasing temperature, it shows a strong increase in the dielectric constant related to the softening of its ferroelectric phonon mode. $KNbO_3$, on the other hand, is a perovskite ferroelectric displaying transitions from the paraelectric cubic to the ferroelectric tetragonal, orthorhombic, and rhombohedral phases in complete analogy to $BaTiO_3$. Substituting Nb for Ta induces a diffuse ferroelectric phase transition in $KTa_{1-x}Nb_xO_3$ for $x > 0.008$, so that the transition temperature T_c varies with x as $T_c(x) = A(x - x_c)^{1/2}$. Within the experimental accuracy, the Ta ions occupy the center of symmetry position, whereas the Nb ions are off-center even in the cubic phase and move in a multiwell potential as in the case of $BaTiO_3$. For small x, one has a transition to a dipolar glass phase ($x \leqslant 0.06$) with no symmetry breaking. For larger x, one finds the same sequence of phase transitions as in $BaTiO_3$.

The breaking of the average cubic symmetry in $KTa_{1-x}Nb_xO_3$ far above $T_c \cong 150$ K can be easily seen

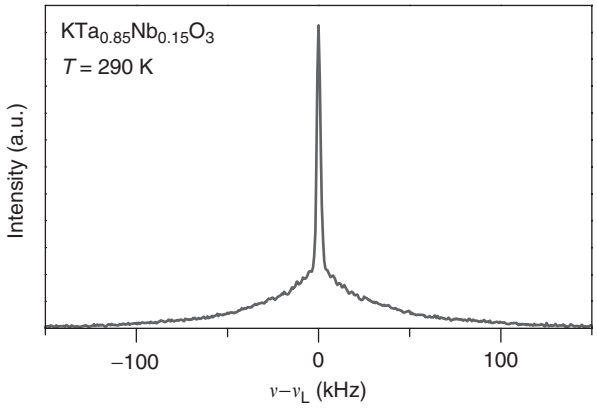

Figure 6 ^{93}Nb ($I = 9/2$) NMR spectrum of a $KTa_{0.85}Nb_{0.15}O_3$ single crystal in the cubic phase at room temperature. The presence of the quadrupole-coupling-induced unresolved satellite background demonstrates that the Nb ions are disordered between off-center sites in analogy to the Ti case in $BaTiO_3$.

from the nonzero Nb quadrupole coupling-induced unresolved satellite background for $x = 0.15$ (**Figure 6**).

"Strong" Relaxors

"Strong" perovskite relaxors such as $PbMg_{1/3}Nb_{2/3}O_3$ (PMN) are intermediate between dipolar glasses and classical ferroelectrics. They exhibit both site and charge disorder, and are therefore characterized by the presence of both random interactions and random fields. They show a broad and large, frequency-dependent peak in the dielectric constant (~ 300 K for PMN) and huge electro-mechanical coupling. In analogy to dipolar glasses, they show no macroscopic symmetry breaking and the structure remains cubic down to liquid helium temperatures. This is true even on the micrometric scale. On the nanometric scale, on the other hand, the local structure is different from the average structure. Burns and Dacol suggested that randomly oriented polar nanoclusters appear in PMN below 925 K so that one deals with a heterostructure consisting of two phases.

A characteristic difference between dipolar glasses such as $Rb_{1-x}(NH_4)_xH_2PO_4$ and relaxors is that, in relaxors a ferroelectric state appears for electric fields larger than a critical field, $E > E_c$, whereas this is not the case in dipolar glasses. This difference is obviously due to polar nanoclusters, which do not exist in dipolar glasses.

The local structure of PMN has been recently studied by field-cooled (FC) and zero field-cooled (ZFC) ^{207}Pb ($I = 1/2$) NMR. Since ^{207}Pb has no electric quadrupole moment, the dominant interaction which allows for the study of polar nanoclusters, is here the chemical shift. If the Pb nuclei in the polar clusters are displaced from their high-symmetry cubic perovskite sites, the ^{207}Pb chemical shift tensors become anisotropic. They can be written as a sum of a scalar part σ_0 and a traceless second-rank tensor part $\underline{\underline{\sigma_a}}$:

$$\underline{\underline{\sigma}} = \sigma_0 \underline{\underline{1}} + \underline{\underline{\sigma_a}} \qquad [6]$$

The eigenvalues of the traceless part are $-\sigma_a/2$, $-\sigma_a/2$, and σ_a. The largest principal axis of $\underline{\underline{\sigma_a}}$ should be parallel to the direction of the average shift of the Pb nucleus, that is, to the direction of the polarization p_i of a given polar cluster i.

For a general orientation of the crystal with respect to the direction of the magnetic field $\boldsymbol{B}_0$ specified by (θ,ϕ), the ^{207}Pb NMR transition frequency is given by

$$\nu_{Pb} = \nu_L[1 + \sigma_0(p) + \sigma_{ZZ}(p, \vartheta, \varphi, \theta, \phi)] \qquad [7]$$

where ν_L is the unperturbed Pb Larmor frequency, σ_0 is the isotropic part of the chemical shift tensor, and σ_{ZZ} is the component of $\underline{\underline{\sigma_a}}$ along the magnetic field direction. The angles (ϑ, φ) determine the orientation of the eigenframe of $\underline{\underline{\sigma_a}}$ with respect to the crystal fixed frame.

A simple nearly isotropic Pb spectrum of roughly Gaussian-line shape (**Figure 7**) is seen for both ZFC and FC spectra above 210 K. Its half-width at 410 K is ~ 30 kHz, that is, much larger than what can be accounted for by nuclear dipolar interactions. The line shape reflects a spherical shell-type distribution of chemical shift tensors due to nearly isotropic Pb displacements of various magnitudes from the cubic positions. The corresponding polarization distribution function is the one predicted by the spherical random bond–random field model. Below 210 K, an anisotropic line appears in addition to the isotropic component in both FC and the ZFC spectra. For $E > E_c$, a sudden increase in the intensity of the anisotropic component takes place (**Figure 7**) at 210 K. This signals a first-order type phase transition into an electric field-induced ferroelectric phase. The angular dependence of the anisotropic line shows that it corresponds to frozen-out Pb shifts along the [111] direction, that is, the direction of the spontaneous polarization. About 50% of the Pb nuclei still reside in the isotropic spherical glass matrix. The transition at T_c is thus an orientational percolation transition of frozen ferroelectric polar clusters with the polarization and the Pb shift parallel to the [111] direction. A similar though smaller increase in the concentration of frozen-out clusters with a Pb shift along [111] is seen also in the absence of an electric field. The concentration of ferroelectric clusters here does not seem to be large enough to induce a transition to the ferroelectric state. PMN thus seems to be an incipient ferroelectric.

The temperature dependence of the spin–spin relaxation time T_2 reflecting the nanocluster dynamics is shown in **Figure 8**. On cooling down from 400 K, T_2 decreases with decreasing temperature demonstrating the rapid slowing down of the nanocluster dynamics in the spherical glass matrix. A very pronounced T_2 minimum appears at ~ 255 K, that is, at the temperature where a maximum of the dielectric susceptibility is found. Here the inverse nanocluster correlation time is in the kHz range. The same mechanism, that is, fluctuations in the orientation of the nanocluster polarization, related to Pb jumping between several off-center sites, is responsible for the dielectric losses as well as for the T_2 behavior. The spin–lattice relaxation time T_1 is here by three orders of magnitude longer than T_2, demonstrating that one deals with a frequency distribution peaked at low frequencies. At $T > 250$ K, T_2 only weakly depends on the frequency offset, demonstrating that the

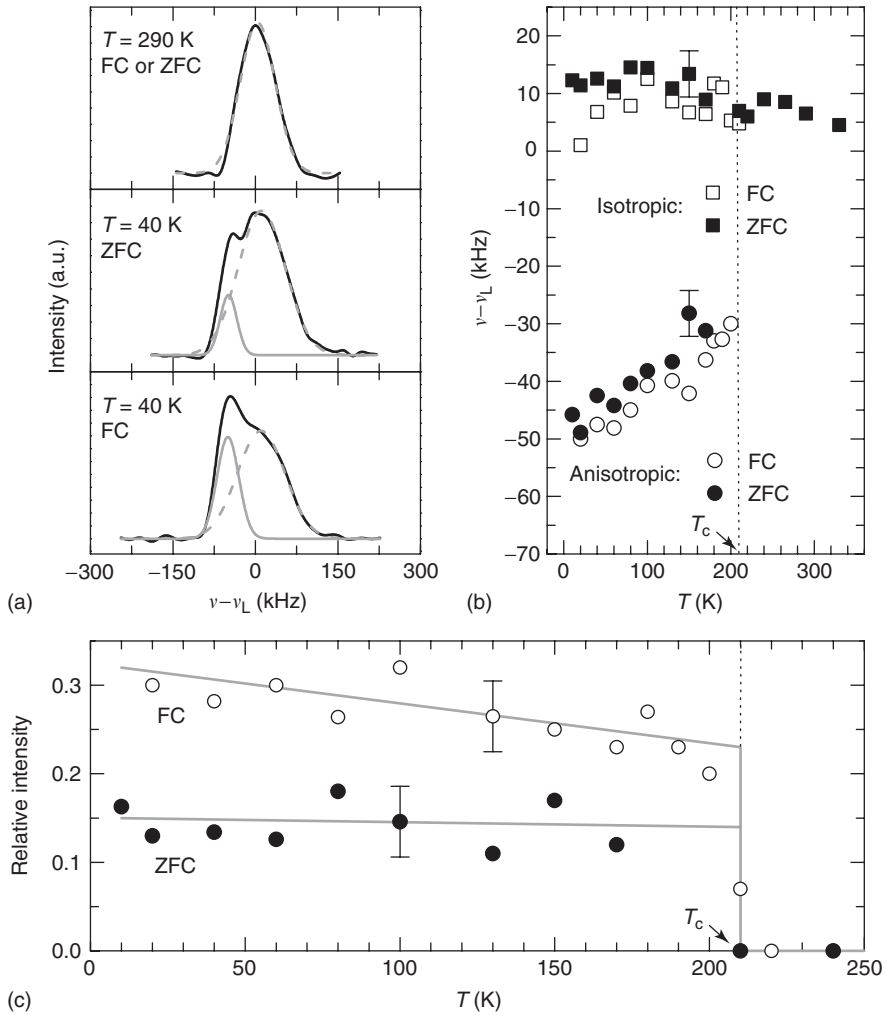

Figure 7 (a) Decomposition of the FC and ZFC ^{207}Pb NMR spectra of a PMN single crystal at 9.1 T and at $\boldsymbol{B}_0 \| \boldsymbol{E} \| [111]$ into isotropic and anisotropic components, (b) T-dependence of the positions of the isotropic and anisotropic ^{207}Pb NMR lines, (c) T-dependence of the relative intensity of the anisotropic component. Here $E = 3\,\mathrm{kV\,cm^{-1}} > E_c$.

nanocluster dynamics is similar in different parts of the crystal.

There is no difference in the FC and ZFC T_2 values above $T_c = 210\,\mathrm{K}$. Below the percolation transition at T_c, on the other hand, T_2 strongly depends on the frequency offset in the FC measurements, that is, the nanocluster dynamics is different in different parts of the crystal as expected for a two-component system. The FC and ZFC data differ significantly. A second rather flat T_2 minimum appears at $\sim$140–150 K in the FC data. It can be attributed to the ferroelectric [111] polarized clusters, whereas the first minimum is due to the spherical glass matrix.

H-Bonded Systems

The chemical, physical, and biological properties of H-bonded systems and biomolecules are determined by the local structure of the H-bonds, that is, by the position of the proton or deuteron in the hydrogen bonds and its dynamics. ^{17}O and deuteron quadrupole coupling, in particular, have been shown to be very sensitive indicators of that. The case of KH_2PO_4 is illustrated in **Figure 9**. Here, one has in the paraelectric phase, a fast exchange of the protons between the two equilibrium sites in the H-bond, ^{17}O–H…O and ^{17}O…H–O. These two sites correspond to the "close" respectively "far" positions of the proton with respect to a given ^{17}O ($I = 5/2$) nucleus. Due to fast exchange, only one averaged ^{17}O nuclear quadrupole resonance (NQR) line is seen in the paraelectric phase. In the ferroelectric phase below T_c, however, the proton motion is frozen out and one sees two separate ^{17}O NQR lines corresponding to the "close" and "far" proton positions. Still another technique, which allows for a very precise measurement of the ^{17}O–H distance, is

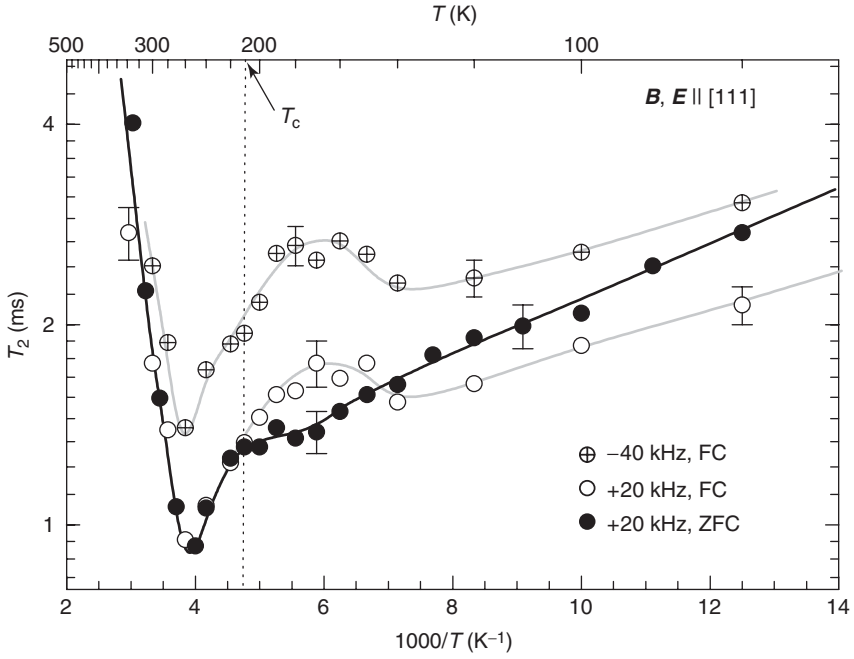

Figure 8 Temperature dependence of the ^{207}Pb spin–spin relaxation time T_2 in single crystal PMN reflecting the nanocluster dynamics in the FC and ZFC case.

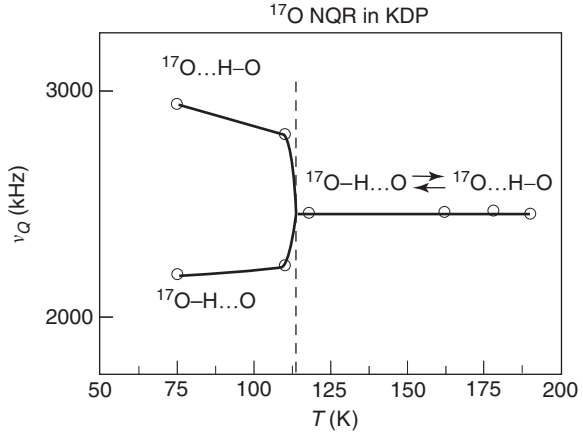

Figure 9 ^{17}O ($I = 5/2$) quadrupole resonance transitions in KH_2PO_4 obtained by the quadrupole double resonance technique. Below T_c are seen separate lines for the proton in the "far" ^{17}O…H–^{16}O and "close" ^{17}O–H…^{16}O positions whereas above T_c only one "average" line due to fast proton exchange between the two positions in the H-bond is seen. The ^{16}O nucleus has no quadrupole moment and does not contribute to the spectrum.

based on the measurement of the proton dipolar splitting of the ^{17}O NQR line by proton-^{17}O double resonance.

A significant progress in the understanding of the proton dynamics and proton transfer in solids has been recently achieved by two-dimensional (2D) deuteron and ^{31}P exchange NMR spectroscopy. Due to the so-called Pauling–Slater ice rules, only

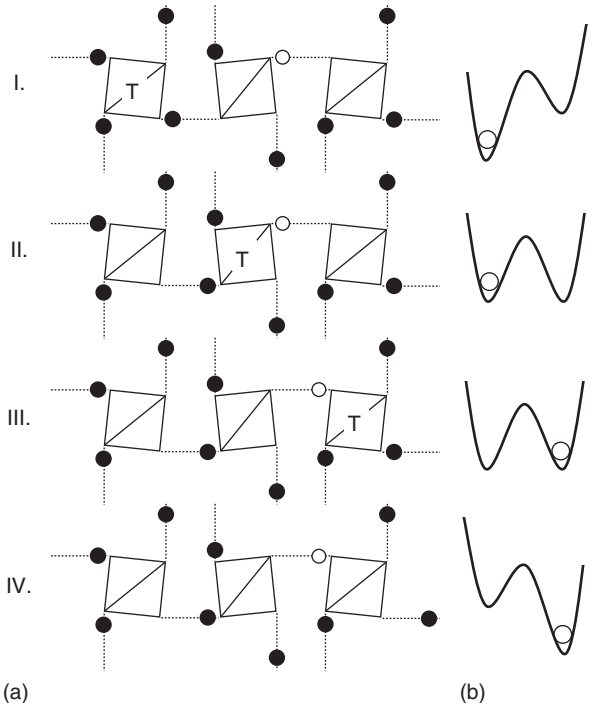

Figure 10 (a) Motion (steps I–IV) of Takagi H_3PO_4 defect (T) and (b) shape of the O–H…O H-bond potential in the proton (or deuteron) glass $Rb_{1-x}(NH_4)_xH_2PO_4$ or $Rb_{1-x}(NH_4)_xH_2AsO_4$. After several Takagi defect visits, the O–H…O potential linking different H_2PO_4 Slater groups becomes effectively of the symmetric double minimum type, thus explaining the tetragonal symmetry of these glasses and of the paraelectric phase of KH_2PO_4.

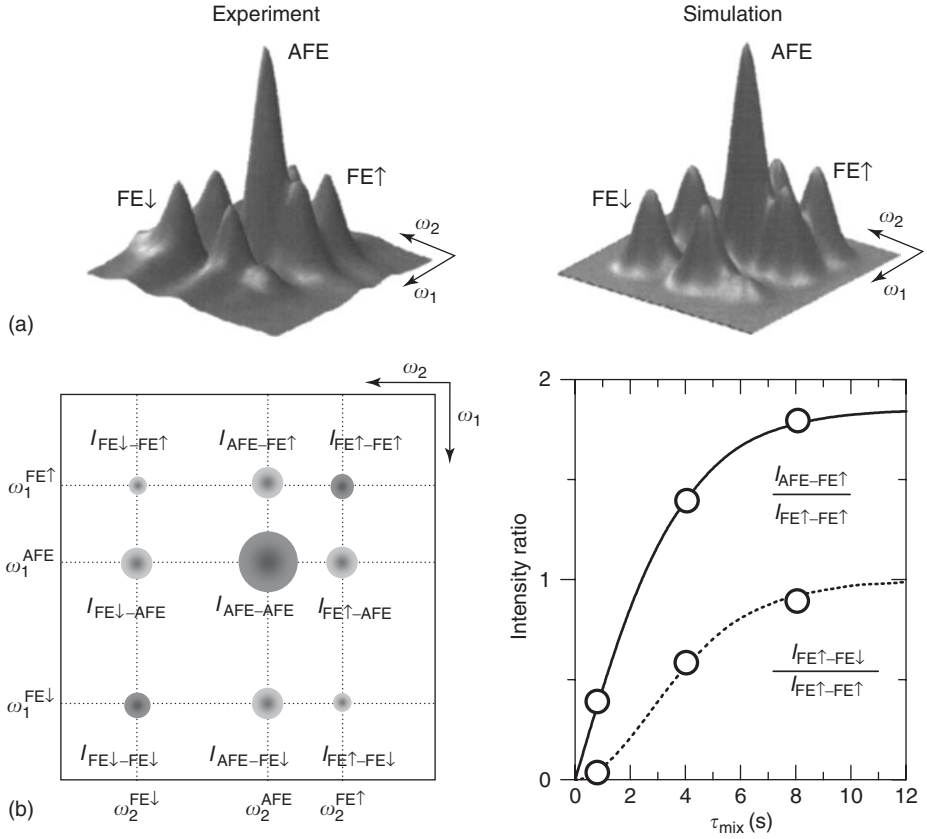

Figure 11 (a) ^{31}P 2D exchange NMR spectrum of $Rb_{1-x}(ND_4)_xD_2PO_4$ with $x = 0.5$ showing the exchange between the four antiferroelectric and the two ferroelectric Slater H_2PO_4 configurations due to the motion of Takagi defects, (b) Corresponding schematic 2D contour plot and dependence of the intensities of the 2D exchange peaks on the mixing time τ_{mix}.

two out of the four protons linking adjacent PO_4 groups via double minimum type O–H…O bonds, are close to each PO_4 ion in KH_2PO_4 type ferroelectrics and proton or deuteron glasses. The intrabond proton transfer from one well to another creates a Takagi HPO_4–H_3PO_4 defect pair which has a higher energy than the Slater pair H_2PO_4–H_2PO_4 it is originating from. In contrast to that, a H-bond linking an unpaired Takagi defect with a Slater group has a symmetric double-well potential (**Figure 10**). The visits of Takagi groups to a given Slater group invert the bias of the H-bonds (**Figure 10**), thus symmetrizing the double-well H-bond potential on a long enough timescale.

The switching among different Slater H_2PO_4 configurations induced by unpaired Takagi H_3PO_4 and HPO_4 diffusion has been indeed directly detected in a deuteron glass $Rb_{0.5}(ND_4)_{0.5}H_2P0_4$ by ^{31}P 2D exchange NMR (**Figure 11**). The resulting symmetrization of the O–H…O double minimum potential has been observed by 2D deuteron exchange NMR in $Rb_{0.68}(ND_4)_{0.32}H_2AsO_4$ (**Figure 12**). τ_{mix} is the mixing time of the 2D NMR exchange experiment pulse sequence, that is, the time over which the correlation of proton configurations in the H-bond network is measured.

Jahn–Teller Effect in C_{60}^-

Heisenberg predicted in 1928 that ferromagnetism is not expected to be found in organic systems made only of first row elements such as hydrogen, carbon, oxygen, and nitrogen. In view of that, it is rather remarkable that the C_{60}-based compound $TDAE^+$-C_{60}^- (here TDAE stands for tetrakis-dimethylaminoethylene) exhibits ferromagnetism below 16 K. This has been ascribed to the possible Jahn–Teller distortion of the spherical C_{60}^- ion into a rugby-like ball shape and the resulting redistribution of the unpaired electronic spin density into a belt-like form. The expected Jahn–Teller distortions are rather small (≈ 0.01 Å) and could not be observed by scattering techniques. Recently, however, ^{13}C NMR of the C_{60}^- ion provided for a direct evidence of this effect. The observation is made possible by the changes in the hyperfine Fermi electron–nuclear coupling shift of the ^{13}C NMR lines which accompany the Jahn–Teller distortion and act as a

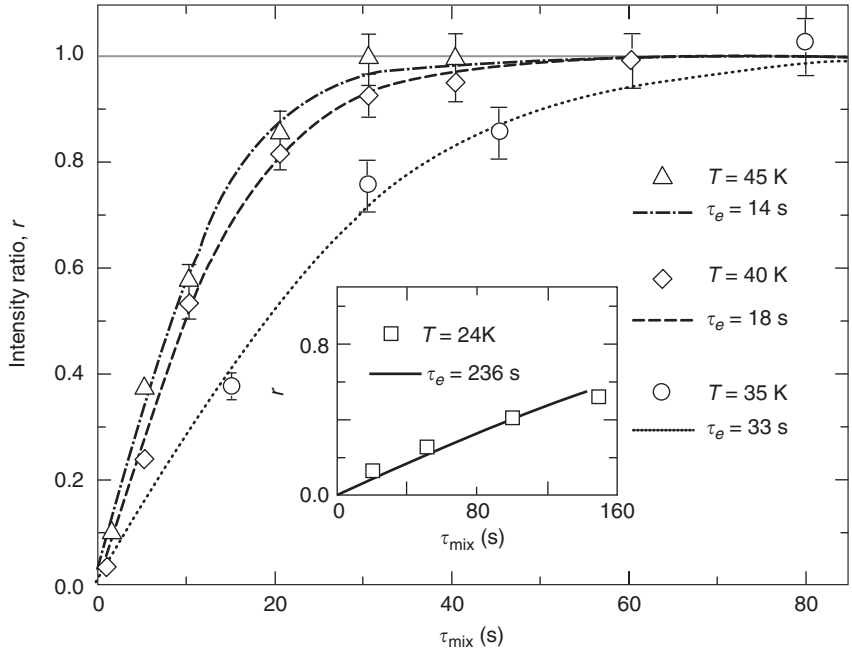

Figure 12 Dependence of the cross to diagonal peak intensity ratio r on the mixing time for 2D deuteron exchange NMR in $Rb_{0.68}(ND_4)_{0.32}D_2AsO_4$ showing the effective symmetry of the double minimum O–H…O potential as well as the exchange timescale τ_e. r should be smaller than 1 for an asymmetric potential and equal to 1 for a symmetric double minimum potential as indeed observed.

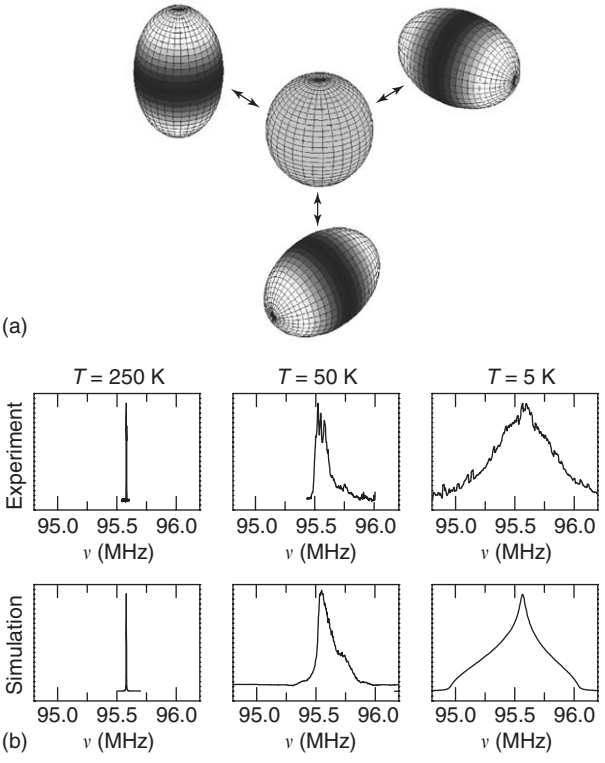

Figure 13 (a) Dynamic Jahn–Teller distortions of the C_{60}^- ion in the organic ferromagnet $TDAE^+$-C_{60}^-. The shaded areas show the belt-like concentration of the unpaired electron spin density around the equator in the distorted configurations, (b) ^{13}C NMR of the C_{60}^- ions in the temperature region of the freeze-out of the dynamic Jahn–Teller distortion, together with the theoretical simulations.

magnifying glass. In the undistorted C_{60}^- ion (or in a C_{60}^- ion exhibiting very fast exchange between different distorted configurations), all ^{13}C nuclei in the C_{60}^- ion are equivalent resulting in a narrow ^{13}C NMR line (**Figure 13**). In the frozen distorted case, on the other hand, the coupling Hamiltonian, which is a sum of the chemical shift term, the Fermi contact term and the electron nuclear dipole–dipole coupling term

$$\mathcal{H} = \mathcal{H}_{\mathrm{cs}} + \mathcal{H}_{\mathrm{hf,F}} + \mathcal{H}_{d_e,d_n} = \sum_j \boldsymbol{I}_j \underline{\underline{\mathcal{K}_t}} \boldsymbol{B}_0 \qquad [8]$$

becomes different for different nuclei.

This results in a huge increase in the width of the ^{13}C NMR spectrum when the dynamic Jahn–Teller distortions freeze out (**Figure 13**). The resulting belt-like distribution of the unpaired spin density enhances the ferromagnetic coupling between neighboring C_{60}^- ions (**Figure 14**), giving rise to an increase in T_c by three orders of magnitude. Similar Jahn–Teller distortions should take place in other fullerenes, for example, CsC_{60}.

Incommensurate Systems

In incommensurate (I) systems, the periodicity of at least one of the modulation waves cannot be expressed as a rational fraction of the periodicity of the underlying lattice. As a result of that, the translational

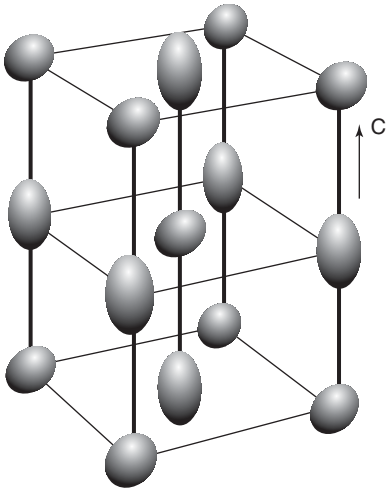

Figure 14 Lattice of Jahn–Teller distorted C_{60}^{-} ions leading to maximum ferromagnetic exchange interaction.

lattice periodicity is lost in spite of the existence of perfect long-range order. Phase transitions leading to such I phases are described by order parameters with a minimum dimensionality two ($n=2$), four ($n=4$), or six ($n=6$), resulting in systems with one (1-q), two (2-q), and three (3-q) I modulation waves. Examples of 1-q systems are, for example, Rb_2ZnCl_4, 2-q systems $AlPO_4$, and 3-q systems Ag_3AsS_3.

The modulation waves are independent if the modulation vectors $\boldsymbol{q}$ are independent and the corresponding phases are not correlated. If, however, the number of modulation waves is larger than the dimension of the space spanned by the corresponding wave vectors, and their phases are correlated, the modulation waves are not independent. The properties of such a system now strongly depend on the relative phases of the modulation waves. Such a situation occurs, for example, in quartz and berlinite ($AlPO_4$) where $n=6$, but the three modulation waves are coplanar, $D=2$, $\boldsymbol{q}_1+\boldsymbol{q}_2+\boldsymbol{q}_3=0$, and their relative phase is fixed, $\psi_1+\psi_2+\psi_3=0$, $\pm\pi/2$, or π, as well as in several charge density wave (CDW) systems, for example, in 2H-$TaSe_2$. It should be stressed that the properties of the above 3-q, $D=2$ systems should be qualitatively different from those of a noncoplanar 3-q, $D=3$ I system with three independent modulation waves.

NMR and NQR are ideally suited for a determination of the number of independent modulation waves in I systems and their nature, as well as for the determination of their relative phases if the modulation waves are correlated (**Figure 15**).

Solitons have been observed in 1-q insulators such as Rb_2ZnCl_4 and in a number of coplanar 3-q CDW systems, for example, in 2H-$TaSe_2$ by ^{77}Se NMR, as well as in proustite by ^{75}As NQR.

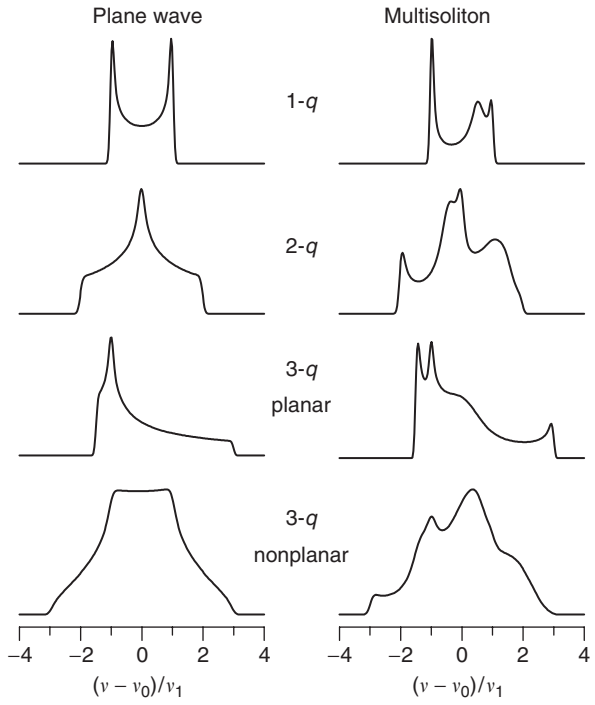

Figure 15 Theoretical NQR line shapes for the 1-q, 2-q, planar 3-q, and nonplanar 3-q incommensurately modulated systems in the plane wave and multisoliton lattice limits for a linear relation between the resonance frequency and nuclear displacement. The line shapes are obtained from eqn [13]. For the soliton limit, the phases are obtained as solutions of the sine-Gordon eqn [15]. In the planar 3-q case, the position of the central logarithmic singularity depends on the relative phases of the modulation waves even in the plane wave limit, while in this limit the spectrum is independent of the initial phases for the noncoplanar 3-q case.

The I state in proustite Ag_3AsS_3 can be described by a six-component order parameter

$$Q_{\pm l}=\rho_l \exp[\pm i\phi_l(x_l)], \quad l=1,2,3 \qquad [9]$$

where ρ_l stands for the amplitude and ϕ_l for the phase of the three independent I modulation waves. If the 1-q multidomain state is realized below T_I, then for a given domain, one of the following possibilities is realized:

$$\begin{aligned} &(1)\quad \rho_1=\rho_2=0, \quad \rho_3\neq 0 \\ &(2)\quad \rho_2=\rho_3=0, \quad \rho_1\neq 0 \\ &(3)\quad \rho_1=\rho_3=0, \quad \rho_2\neq 0 \end{aligned} \qquad [10a]$$

Each domain is here modulated in a single direction, but the direction of the modulation wave vector varies from one domain to another. For the genuine 3-q state, one has on the other hand a simultaneous I

modulation along three different directions

$$\rho_1 = \rho_2 = \rho_3 = \rho \neq 0 \qquad [10b]$$

In the general case, the dependence of the NQR resonance frequency ν_i on the nuclear displacements u_i in the I phase is nonlocal,

$$\nu_i = \nu[u_i(x_i), u_j(x_j), \ldots], \quad i \neq j \qquad [11]$$

where j runs over all ions that contribute to the resonance frequency at the ith site. Expanding the above relation in powers of the displacements, one finds for the ^{75}As NQR frequency in proustite in the 3-q case:

$$\nu_i(\phi_1, \phi_2, \phi_3) = \nu_0 + \nu_1 \sum_{l=1}^{3} \cos\,\phi_l + \nu_2 \sum_{l=1}^{3} \cos(2\phi_l + \phi_{20}) + \cdots \qquad [12]$$

where ν_1 is proportional to the amplitude of the modulation wave, that is, to the order parameter, $\nu_1 \propto \rho \propto (T_I - T)^{\beta}$, and $\nu_2 \propto (T_I - T)^{\tilde{\beta}}$ with $\tilde{\beta} \approx 2\beta$. ϕ_{20} describes the relative phase shift between the linear and quadratic terms. The I frequency distribution $f_{3\text{-}q}$ is now obtained in the constant amplitude approximation as

$$f_{3\text{-}q}(\nu) = K \iiint \delta\{\nu - \nu[\phi_1(x_1), \phi_2(x_2), \phi_3(x_3)]\}\, dx_1\, dx_2\, dx_3 \qquad [13]$$

where the x_l are variables along the directions of the modulation wave vectors. In the 1-q case, expression [13] simplifies to the well-known expression

$$f_{1\text{-}q}(\nu) = K \int \delta\{\nu - \nu[\phi(x)]\}\, dx = \frac{\text{const}}{d\nu/dx} = \frac{\text{const}}{(d\nu/d\phi)(d\phi/dx)} \qquad [14]$$

The resulting line shapes for 1-q, 2-q, planar 3-q, and noncoplanar 3-q cases are shown in **Figure 15** for the plane wave as well as for the multisoliton lattice limits. In the linear case ($\nu_2 = 0$), one finds, for a 1-q plane-wave type modulation, a frequency distribution limited by two edge singularities at $\nu - \nu_0 = \pm\nu_1$, where $d\nu/d\phi = 0$ (**Figure 15**). In the 2-q case, a line shape is found, characterized by a logarithmic singularity in the center. For the planar 3-q case, the line shape is similar to that of the 2-q case, but the position of the central singularity depends on the relative phases between the modulation waves. For the noncoplanar 3-q phase with three independent modulation waves, the NMR spectrum is bell-shaped and does not depend on the initial phases in the plane-wave limit. In contrast to the 1-q and 2-q cases and to the planar 3-q case, there are no singularities in the NMR spectrum but there are singularities in the derivative spectrum. As long as ϕ is a linear function of x, $d\phi/dx$ is nonzero and constant, and this term does not affect the spectral line shape. In the nonlinear case of a multisoliton lattice, on the other hand, $d\phi/dx \to 0$ in the commensurate regions, leading to the appearance of the characteristic "commensurate" lines in the spectrum.

From the Landau type free energy expansion model of Pokrovsky, one finds that in the simplest case the independent phases of the three modulation waves are obtained as solutions of the three

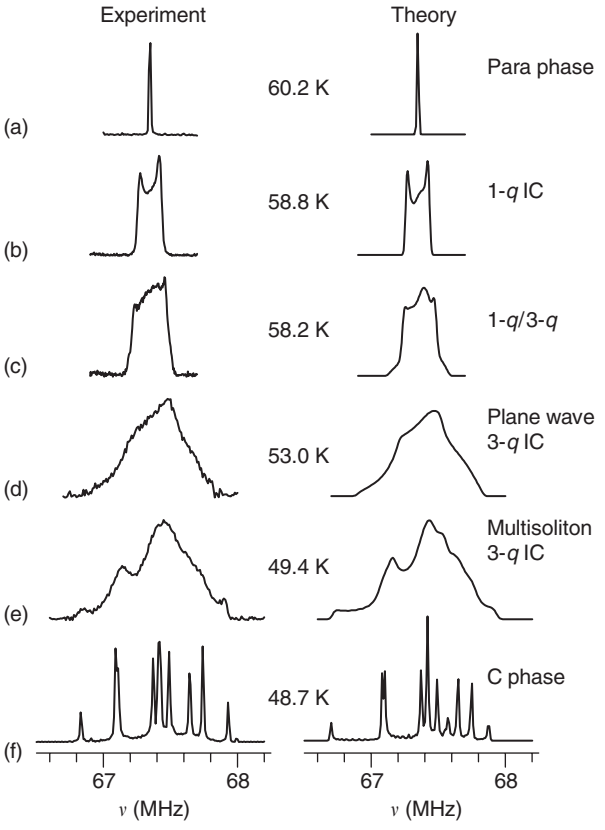

Figure 16 Comparison between the observed and theoretical ^{75}As NQR line shapes in proustite: (a) $T = 60.1$ K, para phase, (b) $T = 58.8$ K, 1-q I phase, (c) $T = 58.2$ K, coexistence of 1-q and 3-q phases, (d) $T = 53$ K, plane-wave regime of 3-q I phase, (e) $T = 49.4$ K, multisoliton regime of 3-q I phase and, (f) $T = 48.7$ K, commensurate phase.

uncoupled sine-Gordon equations:

$$\phi''(x_l) = -6Dt^2 \sin[6\phi(x_l)], \quad l = 1, 2, 3 \quad [15]$$

Here $t = 1 - T/T_I$ and D is a constant dependent on the parameters of the Landau free energy expansion first derived for proustite by Pokrovsky. The solutions for ϕ_l are elliptic amplitudes as in the 1-q case. The multisoliton line shapes in **Figures 15** and **16** are now obtained by inserting solutions of eqn [15] into eqn [13].

The temperature dependence of the soliton density n_{sl} on approaching T_I can be relatively well described by the Pokrovsky model, which in the simplest approximation predicts

$$n_{sl} = \frac{\pi}{2K(k)} \propto \frac{1}{\ln[(T - T_I)/T_I]}, \quad l = 1, 2, 3 \quad [16]$$

where $K(k)$ is a complete elliptic integral of the first kind. Here k, which depends on the amplitude of the modulation wave, is determined by a minimization of the free energy. The constant k is also directly related to the spatial derivative of the phase of the modulation wave $d\phi/dx$, and is thus experimentally accessible via NMR and NQR line shape measurements. A comparison between observed and theoretical ^{75}As NQR line shapes in proustite is presented in **Figure 16** and a good agreement is found.

Nonlinear Dynamics and Nonlinear Dynamical Systems

Remarks on Classical Chaos

Quantum chaos is a recent field of investigation of great importance for fundamental physics as well as in different research areas such as atomic physics, condensed matter, nuclear physics and, more recently, quantum computers. In order to understand the phenomena, it is necessary to start from the conception of dynamical chaos in classical mechanics. To simplify the discussion, only Hamiltonian (nondissipative) systems are considered as they are also more fundamental.

Dynamical chaos destroys the deterministic image of classical physics and shows that, typically, the trajectories of the deterministic equations of motion are, in some sense, random and unpredictable. Such surprising classical behavior is rooted in the

exponential instability of motion. The local instability is described by the linearized equations of motion:

$$\begin{aligned}\dot{\xi} &= \frac{\partial^2 H}{\partial q \partial p}\,\xi + \frac{\partial^2 H}{\partial p^2}\,\eta \\ \dot{\eta} &= -\frac{\partial^2 H}{\partial q^2}\,\xi - \frac{\partial^2 H}{\partial q \partial p}\,\eta\end{aligned} \qquad [1]$$

where $H = H(q, p; t)$ is the Hamiltonian, (q, p) are the coordinates of the $2f$-dimensional phase space and $\xi = \mathrm{d}q, \eta = \mathrm{d}p$ are f-dimensional vectors in the tangent space. The coefficients of the linear eqns. [1] are taken on the reference trajectory and, therefore, depend explicitly on time.

An important quantity characterizing the stability of the motion on the reference trajectory is the so-called Lyapounov exponent λ, which is defined as the limit

$$\lambda = \lim_{|t|\to\infty} \frac{1}{|t|} \ln \frac{d(t)}{d(0)} \qquad [2]$$

with $d^2 = \xi^2 + \eta^2$, the length of the tangent vector. The positivity of the Lyapounov exponent $\lambda > 0$ means exponential instability of motion.

The reason why exponentially unstable motion is called chaotic is due to the fact that almost all orbits, though deterministic, are unpredictable, in the framework of fixed finite precision for specifying data and doing calculations. Indeed, according to the Alekseev–Brudno theorem in the algorithmic theory of dynamical systems, the information $I(t)$ associated with a segment of trajectory of length t is equal, asymptotically, to

$$\lim_{|t|\to\infty} \frac{I(t)}{|t|} = h \qquad [3]$$

where h is the so-called KS (Kolmogorov–Sinai) entropy, which is positive when $\lambda > 0$. This means that in order to predict a new segment of a chaotic trajectory, one needs an additional information proportional to the length of this segment and independent of the previous length of the trajectory. In this situation, information cannot be extracted from the observation of the past history of motion. If, on the other hand, the instability is not exponential but power-law, the required information for unit time is inversely proportional to the previous length of the trajectory and, asymptotically, prediction becomes possible.

Quite clearly, prediction is possible even for a chaotic system inside a short time interval. More precisely, one can introduce the "randomness parameter" r,

$$r = \frac{h|t|}{|\ln \mu|} \qquad [4]$$

where μ is the accuracy at which a trajectory is recorded. Prediction is possible only inside the finite interval corresponding to $r < 1$ while, for $r > 1$, the motion is not distinguishable from a completely random motion.

Exponential instability implies a continuous frequency spectrum. Different parts of a trajectory are then statistically independent, and the latter property may be seen as the basis of statistical descriptions of chaotic many-body dynamics in terms of a few macroscopic variables, both with respect to equilibrium and effectively irreversible equilibration.

Is exponential instability necessary for a meaningful statistical description? While for integrable systems the instability is only linear in time, the converse is not true. On the contrary, examples of systems with linear instability have recently been found which exhibit normal diffusion and lead to normal transport coefficients.

Dynamical chaos represents a limiting case of classical motion. The opposite limiting case is given by completely integrable f-freedom systems, which possess f integrals of motion. Trajectories then wind around an f-torus with f discrete frequencies; the resulting quasiperiodic motion does not allow for "mixing": a cloud of points on a fixed f-torus draws out a bundle of trajectories such that close-by points separate only linearly. Nevertheless, the motion can be ergodic on the f-torus, provided the f frequencies are incommensurate.

Instead of using trajectories (in what might be called "Newton picture"), classical dynamics can be described in terms of distribution functions ("Liouville picture"). Distribution functions obey the linear Liouville equation. Therefore, the condition of nonlinearity for the dynamical chaos to occur refers to the description in terms of trajectories. Dynamical chaos implies the approach of any initially smooth distribution to a steady state: a cloud of points on the energy shell will start spreading out exponentially, and eventually cover that shell with uniform density. In particular, a chaotic evolution of the distribution function is nonrecurrent while, according to Poincaré's theorem, a single trajectory recurs to any neighborhood of some initial point infinitely many times.

Chaos in a Standard Model

The distinction of regular and chaotic motion survives quantization, even though the distinction

criteria change. In particular, the alternative of exponential or power-law divergence of trajectories disappears in quantum mechanics, Heisenberg's uncertainty principle forbidding the notion of trajectories. Conversely, genuine quantum criteria for chaos such as quantum dynamical localization or level repulsion which one is headed for, have no classical meaning. Not surprisingly, classical and quantum notions of chaos are complementary and reflect the basic particle–wave duality.

There is a common structure underlying both classical and quantum chaos, deeper than the more tangible but complementary phenomena. All autonomous single-freedom ($f = 1$) systems are integrable and show no chaos of any sort. For $f \geqslant 2$, integrability, and thus regular motion, requires that the dynamics can be split into f single-freedom ones; chaos can arise only if such reduction is impossible. The foregoing "definition" applies to classical point mechanics (where the issue is separability of, say, the Hamilton–Jacobi equation), to classical wave mechanics (where wave chaos comes with a nonseparable wave equation, see **Figures 5d–5f** below), and finally to quantum mechanics where Schrödinger's equation reigns.

For systems with a compact classical energy shell and, correspondingly, a discrete quantum energy spectrum, the complementarity mentioned brings about a conceptual difficulty worthy of brief discussion. How can the correspondence principle (which requires classical behavior to arise as a limiting case of quantum behavior) be reconciled with a discrete quantum energy spectrum when the limit is to be chaotic and thus characterized by a frequency continuum? The answer to that question must lie in the existence of $\hbar$-dependent timescales and, equivalently, energy scales. For quantum features to become manifest, one must resolve discrete energy levels (whose spacings vanish as $\hbar \to 0$), or sustain observation times which diverge in the formal limit $\hbar \to 0$. Examples are given below.

In order to illustrate quantum chaos, a simple model, the so-called kicked rotator is taken. Even though this model possesses a single pair of canonically conjugate variables, an angle θ and an angular momentum (alias action) p with the Poisson brackets $\{p, \theta\} = 1$, it allows for chaos due to periodic driving. Its classical Hamiltonian reads

$$H = \frac{p^2}{2I} + k\,\frac{I}{T}\cos\theta\;\delta_T(t) \qquad [5]$$

where k is the dimensionless strength and T the period of the perturbation, $\delta_T(t)$ a periodic δ-function of period T, and I a moment of inertia. The system [5] allows for a stroboscopic description by Chirikov's standard map

$$\begin{aligned} p_{\tau+1} &= p_\tau + k\,\frac{I}{T}\sin\theta_{\tau+1} \\ \theta_{\tau+1} &= \left(\theta_\tau + p_\tau\,\frac{T}{I}\right) \mathrm{mod}(2\pi) \end{aligned} \qquad [6]$$

where the integer τ counts the number of delta kicks. The motion [6] takes place on the cylindrical phase space $|p| < \infty,\ 0 \leqslant \theta \leqslant \pi$; alternatively, the motion can be restricted to the compact torus $-p_{\max}/2 < p \leqslant p_{\max}/2$, with $p_{\max}$ defining the "circumference" in the p direction. (Some authors employ the dimensionless action $P = (T/I)p$ to underscore the fact that the classical dynamics is controlled by the single parameter k.)

The kicked rotator allows for a convenient study of classical and quantum motion since it is simple and nevertheless displays the rich complexity and variety of time-dependent systems. Moreover, it provides a local description for a broad class of physical systems, including experimentally observed ones (see below).

For $k \gg 1$, the classical motion can be considered ergodic, mixing, and exponentially unstable with the Lyapounov exponent $\lambda \approx \ln(k/2)$, negligibly small stability islands apart. In particular, the action variable p displays a random-walk type of motion with $\langle p_\tau^2 \rangle = \langle p_0^2 \rangle + D\tau$ and the diffusion constant $D = (k^2/2)(I/T)^2$; of course, for the toroidal phase space, the foregoing diffusion law is valid only as long as the width in p remains smaller than the circumference, that is, up to a characteristic time $\tau_{\mathrm{cl}} \sim 2(p_{\max}T/I)^2/k^2$; thereafter, and indeed on that latter timescale, any nonsingular distribution function equilibrates to the ergodic state, $f(p, \theta, \tau) \to 1/2\pi p_{\max}$.

Quantum mechanically, the Hamiltonian [5] and the map [6] remain valid with p and θ operators. The one-step map for the wave function $\psi_\tau(\theta)$ reads $\psi_{\tau+1} = U\psi_\tau$ with the unitary Floquet operator

$$U = \exp\left(-\mathrm{i}\frac{kI}{T\hbar}\cos\theta\right)\exp\left(-\mathrm{i}p^2\frac{T}{2I\hbar}\right)\psi_\tau \qquad [7]$$

and $p = (\hbar/\mathrm{i})\partial/\partial\theta$. With the classical motion confined to a torus of volume $2\pi p_{\max}$, the wave function $\psi(\theta)$ lives in a Hilbert space whose dimension N is (the integer part of) $p_{\max}/\hbar$. (Authors employing $P = p(T/I)$ encounter the dimensionless variant $\hbar T/I$ of Planck's constant.)

Timescales of Quantum Chaos and Quantum Dynamical Localization

In order to understand the existence of different timescales, the classical and quantum evolution are compared starting from the same initial conditions. According to Ehrenfest's theorem, a quantum packet follows a beam of classical orbits as long as the packet remains narrow. During this time interval, the quantum motion is exponentially unstable and random as the classical one. However, the initial size of the quantum packet is bounded from below by the elementary quantum phase space cell of order $\hbar$, while the final size, for a bounded motion, is a characteristic value of the action variable, in this case of the order $p_{\max}$. Starting from an initial minimum-uncertainty wave packet of size $\Delta\theta_0 \Delta p_0 \backsim \hbar$, the time for exponential spreading is given by

$$\tau_r \sim \frac{\ln(p_{\max}/\hbar)}{\lambda} = \frac{\ln(p_{\max}/\hbar)}{\ln(k/2)} \qquad [8]$$

This is the random timescale introduced by Berman and Zaslavsky, often referred to as Ehrenfest time. Note that τ_r increases indefinitely as $\hbar \to 0$, in agreement with the correspondence principle.

Even after the random timescale, the quantum motion follows the classical diffusive energy growth

$$\left\langle \frac{p^2}{2I} \right\rangle_\tau - \left\langle \frac{p^2}{2I} \right\rangle_0 = \frac{1}{2I}\hbar^2 \sum_{n=-N/2}^{+N/2} n^2 |c_n|^2 \approx \frac{k^2}{4}\frac{I}{T^2}\tau \qquad [9]$$

up to some further timescale τ_b to be determined presently; here, c_n are the coefficients of the expansion of the wave function in the angular momentum representation, $p\varphi_n = \hbar n \varphi_n, -N/2 < n < N/2$.

The second timescale τ_b, at which the quantum evolution breaks away from the classical diffusion [9], is related to the phenomenon of quantum localization. The eigenvectors of the Floquet operator U given in [7] turn out localized in the p-representation with a width $\hbar\xi$; the dimensionless "localization length" ξ will be determined by a self-consistency argument presently, and self-consistency obviously requires $\xi \ll N$. Assuming localization, an initial minimum-uncertainty wave packet can involve only about ξ eigenstates of U with appreciable weight. Consequently, the width in p of the time-evolved packet $\psi_\tau = U^\tau \psi_0$ can never exceed the order of magnitude given by $\hbar\xi$; more quantitatively, the angular-momentum distribution reaches a steady state of approximately exponential form

$$|c_n|^2 \sim \exp(-2|n - n_0|/\xi) \qquad [10]$$

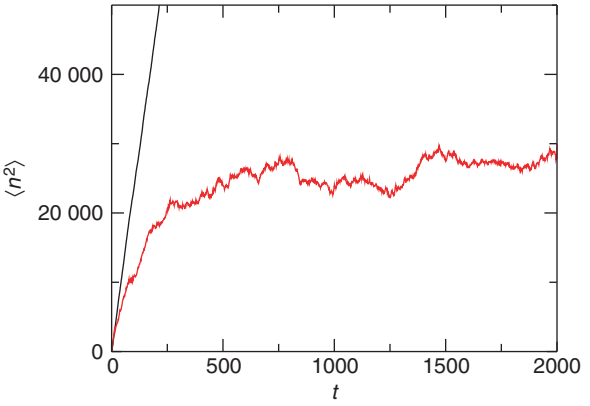

Figure 1 Classical (black) and quantum (red) mean energy as a function of time obtained by numerically iterating maps [6] and [7] for the same parameter values of **Figure 3**.

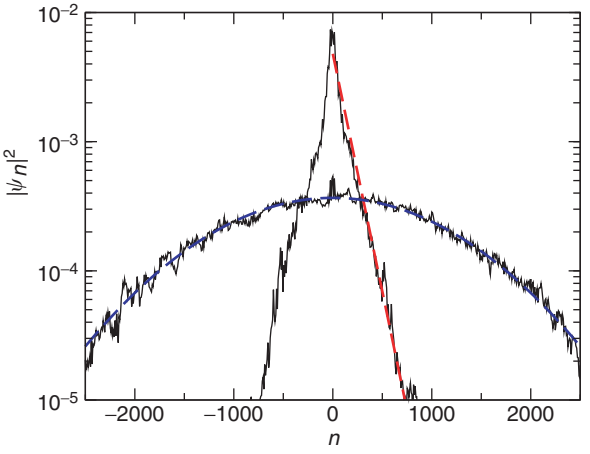

Figure 2 Quantum vs. classical probability distributions over the momentum basis at $t = 5000$. The blue curve gives the Gaussian classical distribution while the red line has slope $\xi = D$, according to [11].

In **Figures 1** and **2**, classical and quantum diffusive behavior obtained by numerical integration of the classical [6] and quantum [7] standard map are compared.

The "break time" τ_b can then be estimated as $D\tau_b \approx (\hbar\xi)^2$. An independent condition on τ_b is that the ξ eigenstates of U, appreciably excited in the wave packet in question, have a mean spacing $2\pi/\xi$ of the associated eigenphases of U. The quasiperiodic behavior of $\langle p^2 \rangle_\tau - \langle p^2 \rangle_0$ for times beyond τ_b can become manifest only for times larger than the inverse of the mean spacing mentioned, and the estimate $\tau_b \approx \xi$ thus results. The two conditions on ξ and τ_b reveal these two dimensionless quantities as roughly equal and given by the classical diffusion constant as

$$\tau_b = \xi = D/\hbar^2 \qquad [11]$$

Clearly, $\xi \ll N = p_{\max}/\hbar$ must hold for consistency (unless the classical phase space is left as the cylinder $|p| < \infty, 0 < \theta \leqslant 2\pi$). Note that both τ_b and ξ diverge in the classical limit and this is how the correspondence principle is satisfied.

Figure 3 shows the evolution of an initially narrow wave packet, demonstrating both the random (**Figures 3a–3c**) and the relaxation timescale (**Figures 3d–3f**) compared with the classical evolution.

The limitation of classical diffusion and randomness by quantum dynamical localization has been discovered in 1979 by G Casati *et al*. It can be shown that quantum dynamical localization is analogous to the famous Anderson localization of electronic motion in disordered solids. Interesting differences are that (1) in this case, localization takes place in angular-momentum space instead of coordinate space, and (2) no disorder is introduced in this model.

The above picture has been confirmed by a theoretical and experimental analysis of the microwave excitation and ionization of highly excited hydrogen atoms as well as in other atomic systems.

It is important to add that dynamical localization, even though one of the prominent manifestations of quantum chaos, is not shared by all chaotic dynamics. First of all, the rotator on the torus discussed above displays localization only under the condition $\xi \ll N$ already mentioned. Further below, the section on universality in quantum chaos will dwell on an important alternative to localization, that is, level repulsion. Here, it would be apt to point out that the kicked rotator on the "cylinder," as the prototype of dynamics with localization, can be seen as a limiting case of the so-called kicked top, which in general does not display localization. The kicked top features an angular-momentum vector $\boldsymbol{J}$ moving with conserved length, $\boldsymbol{J}^2 = \hbar^2 j(j+1) = \text{const.}$, with the quantum number j taking on integer or half-integer values; the classical limit is attained as j grows large. The classical phase space is a sphere (of radius $\sim \hbar j$). Suitable periodic kicking leads to globally chaotic classical motion on the sphere, islands of regular motion being of negligible size. Moreover, a small cloud of initial points spreads over the whole sphere within a few iterations of the classical stroboscopic map. Quantum mechanically, no localization arises: when the quasienergy eigenfunctions are visualized by their Wigner or Husimi functions, they all turn out to "live everywhere" on the sphere; the quasienergies (the eigenphases of the Floquet operator U) display level repulsion. Only very special choices of the angular-momentum dynamics entail a certain anisotropy, such that a cloud of points initially confined to an "equatorial waistband" rapidly spreads therein but diffuses only extremely slowly, by comparison, in the transversal directions. Under such conditions, the part of phase space actually explored within finite times is practically indistinguishable from the cylinder or the torus characterizing the kicked rotator. The quantum quasienergy eigenfunctions then become localized, as for the rotator, and the dimensionless localization length is much smaller than the size $2j + 1$ of the Hilbert space; conversely, no localization can be manifest when the localization length would not fit into the Hilbert space.

Dynamical Stability of Quantum Motion

In previous sections, it has been noted that analytical, numerical, and experimental results show that classical diffusive behavior can be suppressed or at least strongly inhibited by quantization. In addition to this, strong empirical evidence has been obtained that the quantum evolution is very stable, in sharp contrast to the extreme sensitivity to initial conditions and rapid loss of memory which is the very essence of classical chaos. In computer experiments, this effect leads to irreversibility. Indeed, even though the exact equations of motion are reversible, nevertheless any, however small, imprecision in solving them, such as computer round-off errors, is magnified by the exponential instability of orbits to the extent that initial conditions are effaced and reversibility is destroyed. **Figure 4** demonstrates the stability of quantum chaotic motion for the chaotic diffusive ionization of a Rydberg hydrogen atom in a microwave field. Here, the electron velocity was reversed after $\tau = 60$ periods of the microwave and the backward motion was observed. In both classical and quantum mechanics, the hydrogen atom would be expected to find its way back to the initial state. However, due to the finite computer precision, in the classical case such a return is not observed. The system retraces its history backward just for a few periods of the field and then, again, diffusive excitation occurs. Instead, in the quantum case, almost exact reversion is obtained. This result can be understood by taking into account that the random timescale is much shorter than the relaxation timescale. Yet, the accuracy of the reversal is surprising.

This property may turn out to be relevant in practical implementations of quantum computation, in which the stability of quantum computing in the presence of unavoidable imperfections in the quantum computer hardware is important for quantum information processing.

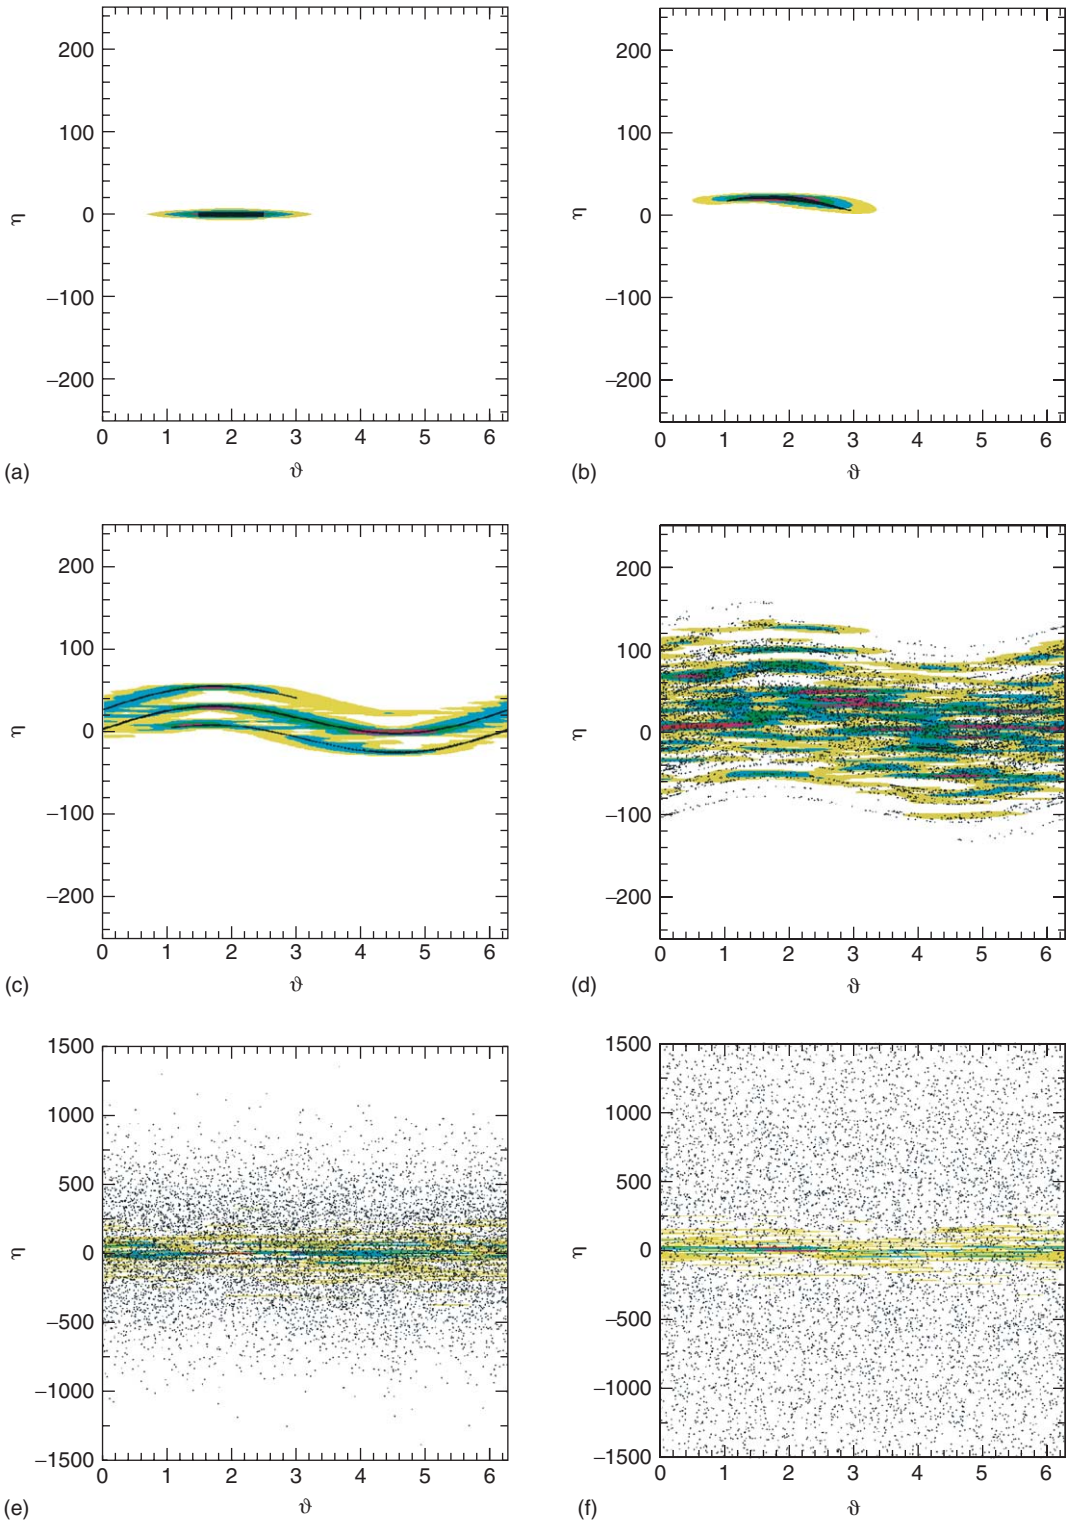

Figure 3 Classical and quantum evolution for the Chirikov standard map for parameter values $K = 5, L = 300, N = 2^{13} = 8192$. The classical evolution is computed by iterating the classical map [6] starting at time $t = 0$ with an ensemble of 10^4 orbits chosen in the interval $(\theta, n) \in [2 - 0.5, 2 + 0.5] \times [-2, 2]$. The quantum evolution is obtained by iterating the quantum map [7] starting from an initial least-spreading Gaussian wave packet of size $\Delta\theta_0 = (\Delta n_0)^{-1} \sim \sqrt{T} \approx 0.5$ centered on the initial classical density of points. The black dots represent the classical phase space density. In the quantum case, the Husimi function is plotted; different colors correspond to different intensity of the Husimi function: from red (maximum intensity) to white (zero intensity). The figure shows snapshots at different times: (a) $t = 0$, (b) $t = 1$, (c) $t = 3$, (d) $t = 10$, (e) $t = 500$, (f) $t = 5000$. Recall that the Husimi function on a given point is obtained by the projection of the evolving quantum state on the coherent state centered on that point.

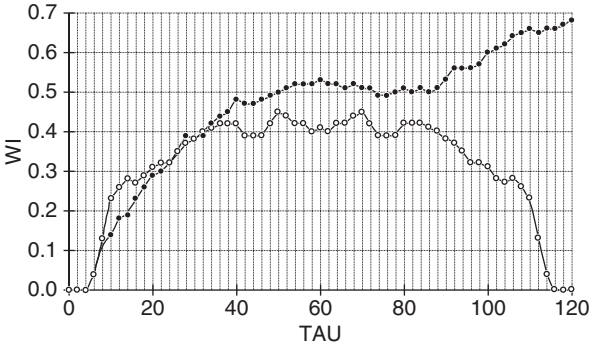

Figure 4 Classical (closed circles) and quantum (open circles) ionization probability as a function of time for a hydrogen atom under an external microwave field. Notice the perfect specular symmetry of the quantum curve about the time of reversal $\tau = 60$.

Universal Spectral Fluctuations

Interesting quantum signatures of classical chaos are encountered when quantum (quasi-) energy spectra of classically chaotic systems are scrutinized for fluctuations in the sequence of levels. One finds those levels correlated within local clusters, but statistically independent as their distance becomes much larger than the mean level spacing Δ. The correlation decay on the scale Δ is empirically found to be system-independent, within certain universality classes distinguished by symmetry. One speaks of universal spectral fluctuations.

A popular indicator of spectral universality is the level spacing distribution $P(S)$, obtained by throwing the spacings of neighboring energy levels into a histogram. **Figure 5** depicts such histograms for six different dynamics. In all cases, the histogram is a rugged variant of one and the same smooth curve, the so-called Wigner distribution which is discussed presently. One may note that this Wigner distribution rises linearly out of the origin and, with growing spacing S, passes through a maximum and eventually falls off like a Gaussian; negligible probability is thus assigned to spacings very small compared to the mean spacing, such that one can say that levels repel one another. Level repulsion is discussed below.

The dynamics referred to in **Figure 5** are all time-reversal invariant and belong to the so-called orthogonal universality class for which the antiunitary time-reversal operation squares to unity, $\mathscr{T}^2 = 1$. Two further universality classes are known as the symplectic ($\mathscr{T}$- invariance with $\mathscr{T}^2 = -1$, as typical for systems with half-integer spin) and the unitary (no $\mathscr{T}$- invariance) ones. More recently, seven more classes were discovered and shown to have realizations in disordered electronic systems, some of them superconducting. The classification is now considered complete inasmuch as the ten classes are one-to-one with the ten symmetric spaces sorted out by Cartan.

Universality goes further. As revealed by experiments and numerical work, fluctuations on the scale Δ turn out to be the same for the energy spectra of Hamiltonians as for the quasienergy spectra of Floquet operators, provided full classical chaos and the same symmetries reign. While proving that statistical similarity of autonomous and periodically driven dynamics is difficult, an intuitive understanding can be reached as follows. An energy spectrum of N levels E_n, $n = 1, \ldots, N$, of a Hamiltonian H corresponds to a quasienergy spectrum of the time evolution operator $e^{-iHt/\hbar}$, with quasienergies $E_n t/\hbar$. If the time t is chosen such that these N quasienergies just fit into the interval $[0, 2\pi]$, the quasienergy spectrum in question becomes similar to the Floquet spectra of periodically driven systems with period t. Only one difference is obvious: the lowest level E_1 of H gives rise to the lowest quasienergy $E_1 t/\hbar$, and similarly the highest energy E_N to the highest quasienergy $E_N t/\hbar$; even though close modulo 2π and being nearest neighbors as quasienergies, these two levels do not repel one another. In the quasienergy spectrum of a periodically driven system, on the other hand, there are no lowest and highest levels, and level repulsion is manifest for all neighboring levels. However, that difference can hardly be expected to play any role for the universal spectral fluctuations and correlations: as already emphasized, the universal fluctuations are of local character, that is, are supported by clusters of relatively few levels extending over a few mean level spacings. Many such local clusters exist for $N \gg 1$, such that exceptional ones at the edges of a spectrum have negligible weight. At any rate, with appeal to the statistical equivalence of energies and quasienergies, the subsequent discussion of universal spectral fluctuations is confined to energy spectra of autonomous dynamics (with finite N).

Experiments on microwave resonators and elastic vibrations of quartz blocks have brought into evidence fluctuations in the respective frequency spectra (see **Figures 5d–5f**) coinciding with the ones found for quantum chaos, the classical nature of the observed electromagnetic and elastic waves notwithstanding. This highly important finding suggests that one could see quantum chaos as a special case of a wider class of phenomena, wave chaos. Whichever wave phenomenon is looked at, as long as the pertinent ray limit (the classical limit in the case of quantum matter waves) displays chaos in the sense of positive Lyapounov exponents, it is now known to display universal fluctuations in the pertinent frequency or energy spectrum. The wave equations

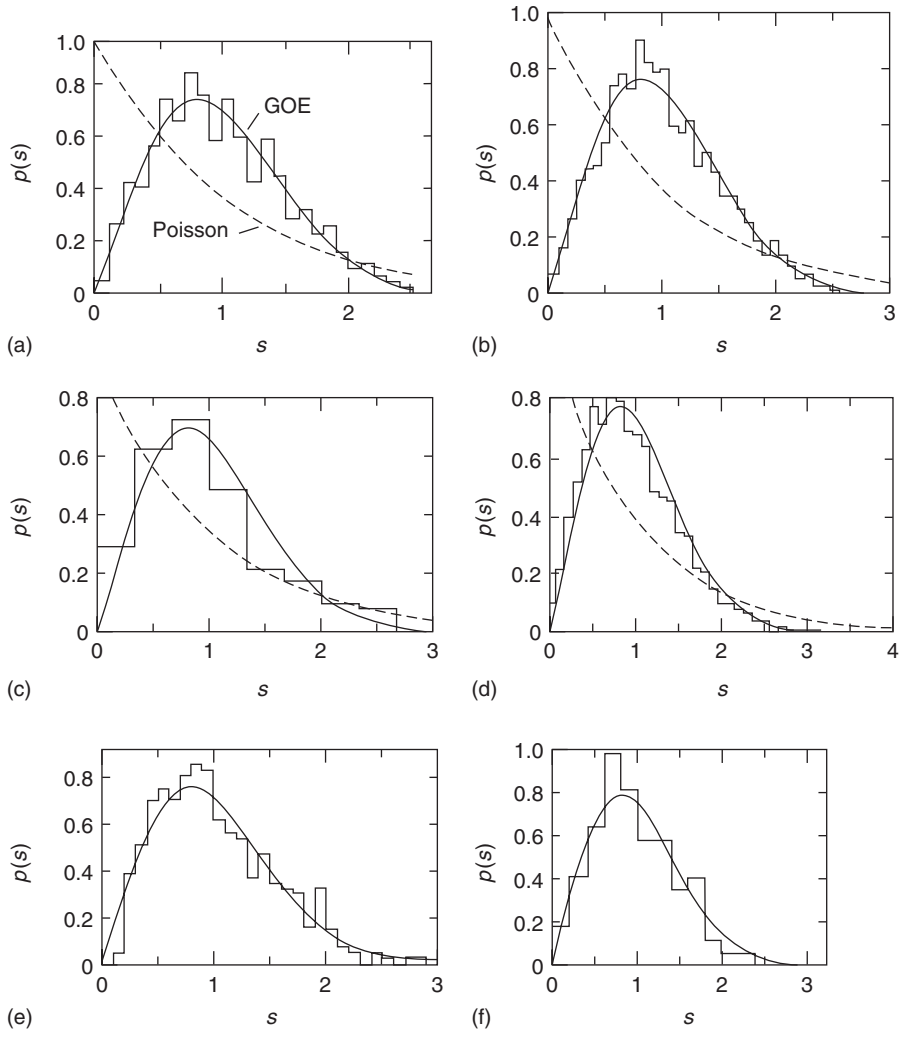

Figure 5 Level spacing distributions for (a) the Sinai billiard, (b) a hydrogen atom in a strong magnetic field, (c) an NO_2 molecule, (d) a vibrating quartz block shaped like a three-dimensional Sinai billiard, (e) the microwave spectrum of a three-dimensional chaotic cavity, (f) a vibrating elastic disk shaped like a quarter stadium. (Courtesy of Stöckmann H-J (1999) *Quantum Chaos*: *An Introduction*. Cambridge: Cambridge University Press.)

differ from case to case, but common to all chaotic waves is nonseparability: the respective boundary value problems defy solution by separation into one-dimensional problems. Such nonseparability is, of course, shared by wave and ray chaos, as well as by quantum and classical chaos.

Finally, and perhaps surprisingly, universal spectral fluctuations can also be found in a completely different context, for random matrices. Indeed, when throwing dice to specify the elements of Hermitian (or unitary) matrices, respecting nothing but symmetry (in the sense of the classes mentioned), one finds the level spacing distribution as well as other indicators of spectral fluctuations to be the same as for Hamiltonians (or Floquet operators) from the same symmetry class.

Random-Matrix Theory

Random matrices play an important role in the theory of quantum and wave chaos since certain random-matrix ensembles yield analytic expressions for many indicators of universal spectral behavior. For the three "classic" classes (orthogonal, unitary, symplectic), Wigner and Dyson have introduced the "Gaussian" ensembles (GOE, GUE, GSE) of Hermitian $N \times N$ matrices and the "circular" ensembles (COE, CUE, CSE) of unitary $N \times N$ matrices. The original motivation for investigating such random-matrix ensembles was unrelated to chaos since the latter notion had not yet seen the light of the world. Wigner and Dyson rather set out to understand the fluctuations in nuclear spectra and, for lack of good

Hamiltonians describing the innards of nuclei, resorted to random Hermitian matrices. Similarly, scattering processes involving nuclei and their constituents were modeled by means of random unitary matrices.

In respect of limits of space, this discussion is restricted to the three Gaussian ensembles GOE, GUE, and GSE which model Hamiltonians of the respective symmetries. The ensembles in question are defined by the following Gaussian density of the independent matrix elements of the Hermitian H,

$$W(H) = A\mathrm{e}^{-B\ \mathrm{Tr}\ H^2} \qquad [12]$$

where the constants A and B are fixed by normalization and the choice of a unit of energy.

The number $\mathcal{N}$ of independent elements in a matrix H differs for the three classes. In the orthogonal class, the matrices H are real symmetric and $N \times N$ such that $\mathcal{N} = N(N+1)/2$ independent real elements arise. The unitary class has complex Hermitian $N \times N$ matrices H, whose elements have $\mathcal{N} = N^2$ independent real and imaginary parts. Hamiltonians from the symplectic class have a more complicated matrix structure, often called quaternion real. Quaternion real $2N \times 2N$ matrices H consist of N^2 2×2 blocks; each block is formed with a pair of basis vectors $\{\psi_i, \mathcal{T}\psi_i, i = 1, \ldots, N\}$, which are orthogonal due to $\mathcal{T}^2 = -1$; eigenvectors forming different blocks are mutually orthogonal. All eigenvalues are doubly degenerate (Kramers' degeneracy follows from $\mathcal{T}^2 = -1$). To have N such pairs of levels, the matrix H must be $2N \times 2N$; its elements can be shown to have $\mathcal{N} = N(2N-1)$ independent real and imaginary parts. For all three ensembles, the normalization of the densities, $\int \mathrm{d}H\ W(H) = 1$, involves an $\mathcal{N}$-fold integral over the (real and imaginary parts of the) independent matrix elements with the measure $\mathrm{d}H$, the product of the respective differentials.

One may note that the aforementioned structures of H, that is, real symmetric, complex Hermitian, and quaternion real, as well as the distribution [12] are preserved under, respectively, orthogonal, unitary, and symplectic transformations of H. In fact, it is these invariances which have led to the names of the respective universality classes and their associated matrix ensembles.

The $\mathcal{N}$ independent real parameters in a random matrix H can be organized in two subsets, the N eigenvalues and $\mathcal{N} - N$ parameters, characterizing the eigenvectors (or, equivalently, the diagonalizing orthogonal, unitary or symplectic transformations). Upon integrating out the latter, one finds the eigenvalue distributions

$$\rho(E_1, \ldots, E_N) = A' \left(\prod_{i<j}^{1,\ldots,N} |E_i - E_j|^\beta \right) \times \exp\left(-B' \sum_{i=1}^{N} E_i^2 \right) \qquad [13]$$

here, the parameter β takes the values $1, 2, 4$ in the orthogonal, unitary, and symplectic class, respectively.

The simplest nontrivial ensemble average arises for the distribution of the level spacing for $N = 2$. One finds the "Wigner surmizes,"

$$P_\beta(S) = A'' S^\beta \mathrm{e}^{-B'' S^2} \qquad [14]$$

with the constants A'', B'' again fixed by normalization, $\int \mathrm{d}S\ P(S) = 1$, and the choice of a unit of energy, like $\int \mathrm{d}S\ SP(S) = 1$. The parameter β is now revealed as the degree of level repulsion, since the spacing distribution vanishes like S^β for $S \to 0$; one speaks of linear, quadratic, and quartic level repulsion in the orthogonal, unitary, and symplectic classes, respectively. The orthogonal case $P_1(S)$ is plotted as the smooth curve in **Figure 5**. Surprisingly, that curve turns out an excellent approximation to the spacing distribution of large spectra. Similarly good and surprising is the agreement of the Wigner surmizes $P_2(S)$ and $P_4(S)$ with the spacing distributions of large spectra in the unitary and symplectic class.

When the spacing distributions for $N > 2$ are calculated for the three Wigner–Dyson ensembles, no simple analytic expressions arise. In particular, the asymptotic densities for $N \to \infty$ are known, both as converging infinite products and series. In confirmation of numerical and empirical findings, the difference between the Wigner surmizes based on $N = 2$ and the asymptotic spacing distributions based on $N \to \infty$ is small: the integrated root-mean-square difference is found as

$$\left\{ \int_0^\infty \mathrm{d}S (P_\beta^{(N=2)}(S) - P_\beta^{(N\to\infty)}(S))^2 \right\}^{1/2} < 1.6 \times 10^{-4}$$

for all three Wigner–Dyson classes. Such insensitivity of the spacing distributions to the matrix size gives great practical importance to the Wigner surmizes. To verify that a single large spectrum is more faithful to the asymptotic distribution $P_\beta^{(N\to\infty)}(S)$ than to the Wigner surmize $P_\beta^{(N=2)}(S)$, several thousands of levels must be available.

In order to appreciate the faithfulness of large spectra to the predictions of the random-matrix theory (RMT) based on ensembles of two-level spectra,

the locality of correlations among levels may again be recalled. It appears that correlations between neighboring levels dominate the local correlations. It in fact turns out, that at least the universal small-S behavior, $P(S) \propto S^{\beta}$, can be understood by applying the familiar perturbation theory of nearly degenerate levels to pairs of neighboring levels.

Level repulsion of the various degrees just characterized is, in fact, a highly important quantum signature of chaos, since classically integrable dynamics with two or more freedoms usually display level clustering. The pertinent spacing distribution $P(S) = \mathrm{e}^{-S}$ is often referred to as Poissonian since a fully uncorrelated sequence of levels generated by a Poissonian random process would yield just that exponential.

Most classical dynamics have a mixed phase space, where chaotic and regular trajectories coexist. The universal spectral fluctuations prevail provided the classical islands of regular motion are overwhelmed in relative size by a single "chaotic sea."

Recently, exceptional dynamics were discovered that do display full classical chaos but no quantum level repulsion; they have quantum symmetries and conservation laws (the so-called Hecke symmetries), which disappear in the limit $\hbar \to 0$.

In contrast to the spectral fluctuations on the scale Δ, the energy dependence of the mean density of levels on larger scales is system specific, as is, of course, the precise location of the N levels.

This brief exposition of level repulsion and localization may be concluded by stating that these two quantum manifestations of chaos are, in a sense, mutually exclusive. Under conditions of localization, (quasi-)energy eigenfunctions, whose centers are much further apart than a localization length, have exponentially small overlap; their (quasi-)energies then have no reason to repel one another. When building up the spacing distribution $P(S)$ from all the nearest-neighbor spacings in the spectrum, one must expect and does indeed find the exponential distribution characteristic of statistically independent levels. However, upon building different distributions $P(S)$, each from a group of eigenfunctions with strong mutual overlap, those individual distributions do reveal universal level repulsion; by superposing the distributions from different groups, the statistical basis for comparing with RMT can be improved.

Why Universality?

Universal spectral fluctuations were conjectured early on in the development of the field of quantum chaos and later supported by a wealth of numerical and empirical data, and, as already indicated, confronted with exceptions. No mathematically hard formulation of the conjecture is available to date, leave alone proof. Nevertheless, some understanding has arisen along several lines of thought.

First progress was brought about by "parametric level dynamics," the change of energy levels $E_i(\lambda)$ and eigenfunctions $\psi_i(\lambda)$ under variation of the weight λ of a perturbation in the Hamiltonian $H = H_0 + \lambda H_1$. A closed system of $\mathcal{N}$ ordinary first-order differential equations for the N eigenvalues and $\mathcal{N} - N$ parameters representing the eigenfunctions can be established which, perhaps surprisingly, takes the form of classical Hamiltonian equations for a certain N-particle system of the Calogero–Moser–Wojciechowski type. The parameter λ plays the role of time, and the eigenvalues E_i are the coordinates of the fictitious particles. Such dynamics had been noted previously in the mathematical literature for being integrable, their nontrivial two-body interaction notwithstanding. Before their independent rediscovery in the context of parametric level dynamics, they were not paid much attention in physics; now, they may be seen as an elegant and closed form of the perturbation theory since indeed, their solution in terms of a power series in λ is nothing but the perturbation theory with respect to H_1. More importantly for the present context, the fictitious N-body system invites a statistical description. Inasmuch as the spectral fluctuations in the original quantum system do not change as λ varies, equilibrium statistical mechanics for the fictitious "gas" is called for. One may employ a generalized canonical ensemble which nails down all constants of the motion in the mean, through appropriate Lagrange parameters, and allows for equipartition otherwise. In fact, such a canonical ensemble turns out to yield the spacing distribution as coinciding with that of the RMT, up to corrections of the order $1/N$. One might argue that nothing is gained by replacing one ensemble (RMT) with another. However, the generalized canonical ensemble of level dynamics yields ensemble averages equalling λ averages, due to the ergodic behavior of the fictitious gas in the part of its phase space left accessible by the constants of the motion. For λ averages to equal ensemble averages, the λ averages must be extended over a sufficiently large parameter "window" $\delta\lambda$; that window must be taken somewhat larger than a collision "time" λ_{coll} for the fictitous gas, that is, the mean "temporal" separation between "avoided collisions" of neighboring particles in the fictitious gas; for the original quantum levels, λ_{coll} is the mean parameter distance between subsequent avoided crossings of neighboring levels. Inasmuch as that collision time is found to scale with the number N of "particles" such that $\lambda_{\mathrm{coll}} \to 0$ for $N \to \infty$, and since $N \to \infty$ in the classical

limit $\hbar \to 0$, one concludes that $\delta\lambda$ can be considered vanishingly small classically. Consequently, the canonical ensemble in question and thus RMT also have a status like that of equilibrium statistical mechanics for a stationary N-body system.

Further support for universality *à la* RMT comes from Gutzwiller's semiclassical periodic-orbit theory. The density of levels $\rho(E) = \sum_{i=1}^{N} \delta(E - E_i)$ is given there as a formal sum over classical periodic orbits, $\rho \sim \sum_\gamma A_\gamma \cos(S_\gamma/\hbar)$, where S_γ and A_γ are the action and stability coefficients of the γth orbit. The two-point correlator of the level density thus becomes a sum over pairs of orbits, each pair represented by a phase factor $e^{i(S_\gamma - S_{\gamma'})/\hbar}$. Since the action difference $S_\gamma - S_{\gamma'}$ "knows" no quantum unit $\hbar$, most pairs interfere destructively in their contribution to the correlation function. However, a paradigmatic discovery by Sieber and Richter as well as successive work brought to light families of pairs of orbits which do make finite contributions and, in fact, give the correlation function predicted by RMT.

The orbit pairs in question have periods of the order of the Heisenberg time T_H. The two orbits in a relevant pair are practically indistinguishable nearly everywhere. To understand the minute but consequential difference within a pair, it is useful to recall that an orbit cannot cross itself in phase space; however, a long orbit can, even must, have close "self-encounters," in which two orbit stretches come very close (possibly up to time reversal in $\mathscr{T}$-invariant systems). Given the fact that the smallest approaches that are discernible quantum mechanically have an order magnitude given by Planck's constant, the durations of such self-encounters have the typical order of the Ehrenfest time T_E'. On either side of a self-encounter, the orbits in a relevant pair have a long loop within which both orbits practically coincide; the two orbits differ in the order of traversals of the loops due to different connections within the short self-encounters. It is due to the relative smallness of the Ehrenfest time ($T_E/T_H \to 0$ in the limit $\hbar \to 0$) that the typical action difference can be of the order of the Planck's constant, thus enabling the orbit pairs to contribute constructively to the correlation function. The frequency of occurrence of such orbit pairs can be calculated by assuming ergodicity. It is thus clear that the latter universal property of classical chaos is intimately related to the universal spectral fluctuations characteristic of quantum chaos.

Conclusions

Chaos, both classical and quantum, requires two or more degrees of freedom and impossibility to reduce the dynamics to single-freedom ones.

From a quantum point of view, classical dynamical chaos appears as a transient, observable until quantum effects due to the discreteness of (quasi-)energy spectra take over. The correspondence principle is respected inasmuch as the breakaway from exponentially unstable classical motion to quantum quasiperiodicity takes place at a time formally diverging as $\hbar \to 0$. Quite analogous is the relation of classical waves to their ray limits.

Classical and quantum chaos have complementary manifestations reflecting the familiar particle–wave duality. Intrinsically quantum (or wave) manifestations of chaos are quantum dynamical localization and universal spectral fluctuations. Conditions under which these mutually exclusive phenomena arise have been discussed.

Universal spectral fluctuations can be modeled by suitable ensembles, of large random matrices. The status of random-matrix ensembles, relative to individual dynamics, bears analogies to the status of the ensembles, employed by equilibrium statistical mechanics, relative to individual many-body systems. Universal spectral statistics are beginning to be understood in terms of Gutzwiller's semiclassical "periodic-orbit theory."

Nonlinear Optics

V Degiorgio and I Cristiani, Università di Pavia, Pavia, Italy

Introduction

The propagation of optical waves inside a medium is described by the wave equation:

$$\nabla^2 \boldsymbol{E} = \frac{1}{c^2}\frac{\partial^2 \boldsymbol{E}}{\partial t^2} + \mu_o \frac{\partial^2 \boldsymbol{P}}{\partial t^2} \qquad [1]$$

where $\boldsymbol{E}(\boldsymbol{r}, t)$ is the electric field and $\boldsymbol{P}(\boldsymbol{r}, t)$ is the macroscopic polarization. Traditional optics is based on the simplified assumption that $\boldsymbol{P}$ is linearly related to $\boldsymbol{E}$ through a differential equation describing the noninstantaneous response of the medium. In the frequency domain, $\boldsymbol{P}(\boldsymbol{r}, \omega) = \varepsilon_0 \chi(\omega) \boldsymbol{E}(\boldsymbol{r}, \omega)$, where $\boldsymbol{E}(\boldsymbol{r}, \omega)$ and $\boldsymbol{P}(\boldsymbol{r}, \omega)$ are the electric field and polarization Fourier transforms, and $\chi(\omega)$ is the frequency -dependent electric susceptibility that is related to the index of refraction of the material through the expression: $n(\omega) = \sqrt{1 + \chi(\omega)}$. Actually the relation between $\boldsymbol{P}$ and $\boldsymbol{E}$ is intrinsically nonlinear and can be considered approximately linear when the optical field is much smaller than the internal field seen by the electron. Whereas in the past the optical intensities available with conventional sources were too weak to explore optical nonlinearities, it is now very easy to generate nonlinear optical effects by exploiting laser beams. The term nonlinear optics should apply to all the physical situations in which the linear approximation is not adequate. This article is limited to a treatment of those nonlinear optical interactions that are nonresonant. Resonant interactions, such as those responsible for laser behavior, optical bistability, or electromagnetically induced transparency, are discussed elsewhere in this encyclopedia.

Nonlinear optics has enhanced the understanding of fundamental light–matter interactions and provided new powerful methods for the investigation of materials. At the same time, nonlinear optics has a strong impact on technology as it offers the way to develop coherent radiation sources, emitting at new frequencies that are not usually available with lasers, and offering tunability from ultraviolet to visible and near infrared. Important applications also concern optical devices performing the same functions provided at radio frequencies by electronic devices, such as modulators, switches, and logical circuits.

Physical Origin of Nonlinearity

A simple physical model describing the relation between $\boldsymbol{P}$ and $\boldsymbol{E}$ is represented by the Lorentz model that treats a bound electron as a harmonic oscillator. Clearly, the assumption that the electron is in a parabolic potential well is valid only for small displacements from the equilibrium position. As shown in **Figure 1**, if the exciting field is strong enough, the electron displacement will also probe a range of distances over which the potential is no longer parabolic. The potential can be written as a Taylor expansion in the displacement x: $V(x) = V_0 + \alpha x^2 + (1/2)\beta x^3 + (1/3)\gamma x^4 + \cdots$. It can be easily seen by a perturbative approach that the

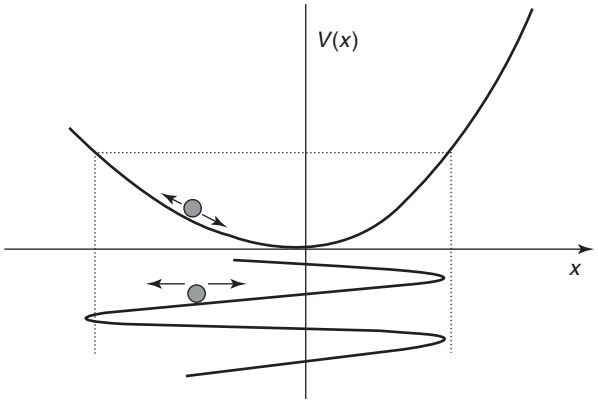

Figure 1 Particle motion in an asymmetric potential well under the action of a sinusoidal field: the oscillation is not symmetric; thus, it contains higher-harmonic contribution.

cubic term in $V(x)$ can give rise to a polarization term proportional to the square of the field, and the quartic term gives a term proportional to the cube of the field.

Note that a cubic term in $V(x)$ can exist only if the material structure is not centrosymmetric, as it happens with a crystal having a noncentrosymmetric unit cell or a system of oriented polar molecules. On the macroscopic scale the relation between $\boldsymbol{P}(\boldsymbol{r}, \omega)$ and $\boldsymbol{E}(\boldsymbol{r}, \omega)$ can be written as

$$\boldsymbol{P} = \varepsilon_0 \chi^{(1)} \boldsymbol{E} + \varepsilon_0 \chi^{(2)} \boldsymbol{E}^2 + \varepsilon_0 \chi^{(3)} \boldsymbol{E}^3 + \cdots \qquad [2]$$

Materials presenting a second-order nonlinearity, when illuminated with a beam at angular frequency ω, can generate a second-harmonic beam at frequency 2ω. If two beams at frequencies ω_1 and ω_2 are sent into the material, a third beam at the sum or difference frequency $\omega_3 = \omega_1 \pm \omega_2$ can be generated. Such a process is used in optical parametric amplifiers and oscillators. In the case of third-order materials, besides the generation of new frequencies through various frequency-mixing processes, phenomena such the optical Kerr effect, self-focusing, self-phase modulation, and optical phase-conjugation can be observed and exploited for the realization of optical devices. In addition, stimulated Raman and Brillouin scattering also belong to the family of third-order effects.

Second-Order Nonlinear Effects

Second-Harmonic Generation

In order to illustrate the basic aspects of nonlinear interactions, it is better to start with the simplest situation: a second-order material illuminated by a monochromatic plane wave propagating along the z-axis – $E_1 \exp[\mathrm{i}(\omega_1 t - k_1 z)]$. It is easy to see from eqn [2] that such a wave gives rise to a nonlinear polarization oscillating at $2\omega_1$. In turn, the nonlinear polarization, once inserted into eqn [1], behaves like a source for a second-harmonic (SH) optical wave. Limiting the consideration to stationary waves in the slowly-varying-envelope-approximation and expressing the pump and SH fields E_1 and E_2 as $E_1 = A_1(z)\exp(\mathrm{i}k_1 z)$ and $E_2 = A_2(z)\exp(\mathrm{i}k_2 z)$, respectively, the evolution of the SH generation phenomenon can be described through the following equations:

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}z} A_1(z) &= \mathrm{i}\frac{\omega_1}{cn_1} d_{\mathrm{eff}} A_2(z) A_1^*(z) \exp(-\mathrm{i}\Delta k z) \\ \frac{\mathrm{d}}{\mathrm{d}z} A_2(z) &= \mathrm{i}\frac{\omega_1}{cn_2} d_{\mathrm{eff}} A_1^2(z) \exp(\mathrm{i}\Delta k z) \end{aligned} \qquad [3]$$

where $d_{\mathrm{eff}} = \chi^{(2)}/2$ is called the effective nonlinear coefficient, $\Delta k = k_2 - 2k_1$ is the wave vector mismatch, c is the light velocity, and n_1 and n_2 represent the refractive indices experienced by the pump and SH fields during the propagation through the nonlinear medium. It is important to remark that, in scientific literature, the nonlinear properties of materials are usually expressed in terms of the d_{eff} coefficient values. It can be seen from eqns [3] that the condition for efficient SH generation is: $\Delta k = 0$. Such a condition is called the phase-matching condition. It expresses the requirement that the nonlinear polarization wave travels at the same phase velocity as the SH wave. It should be noted that the process consists in an exchange of energy (and momentum) between waves in which the nonlinear medium acts as a catalyst. If the process is described by a quantum-mechanical approach, two photons of the fundamental wave are converted into an SH photon; the phase-matching condition corresponds to momentum conservation in the nonlinear process.

In the case $\Delta k = 0$, the propagation equations can be solved analytically, giving the SH intensity as a function of the propagation distance z:

$$I_2(z) = I_1(0)\tanh(z/L_{\mathrm{SH}}) \qquad [4]$$

where the constant L_{SH} is inversely proportional to the nonlinear coefficient of the medium and to the square root of the input intensity. Equation [4] shows that the input intensity can be fully converted into the SH provided that the propagation distance is sufficiently long (the crystal length L should be larger than L_{SH}). As an example, by using a lithium niobate crystal with a second-order coefficient

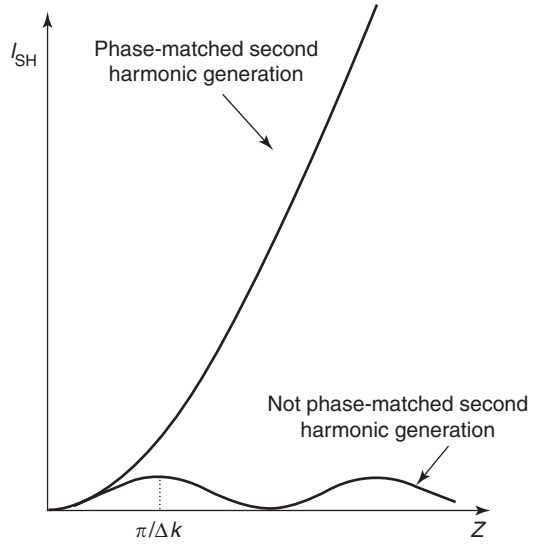

Figure 2 SH intensity as a function of propagation distance in a nonlinear crystal.

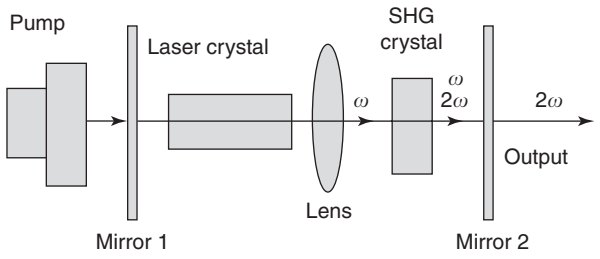

Figure 3 Scheme of an SH laser: mirrors 1 and 2 have high reflectivity for the frequency ω corresponding to the laser transition, but are transparent for 2ω.

$d_{\text{eff}} = 5\,\text{pm}\,\text{V}^{-1}$ and a neodymium laser ($\lambda = 1064$ *nm*) beam with an intensity of $10\,\text{MW}\,\text{cm}^{-2}$, $L_{\text{SH}} = 1\,\text{cm}$. When the phase-matching condition is not satisfied, $I_2(z)$ is an oscillating function of z (see **Figure 2**): the SH intensity achieves a maximum after a distance called coherence length $l_c = \pi/\Delta k$ and vanishes at $z = 2l_c$.

SH generation of a laser beam becomes particularly efficient if the nonlinear crystal is placed inside a laser cavity (see **Figure 3**). At present, such an approach represents one of the most convenient methods of generating coherent green and blue light by using near infrared solid-state lasers. As an example, a 532 nm green light is efficiently generated by intracavity frequency doubling of a neodymium laser.

Phase Matching

Recalling that the modulus of $\boldsymbol{k}$ is related to the angular frequency by the relation $k = (\omega/c)n(\omega)$, the phase-matching condition $\Delta k = 0$ requires that the index of refraction of the second harmonic be equal to that of the fundamental. In normal cases, n is an increasing function of frequency, so that phase matching is not satisfied for beams having the same polarization. A very clever method of obtaining phase matching is that of exploiting the crystal birefringence to compensate for the material dispersion (see **Figure 4**). Recall that, in a crystal possessing an optical axis, the propagation velocity of a linearly polarized plane wave depends on its polarization direction: a wave polarized perpendicularly to the optical axis sees the "ordinary" index of refraction n_o, whereas a wave polarized along the optical axis sees the "extraordinary" index n_e. A typical nonlinear crystal is lithium niobate, a uniaxial crystal presenting negative birefringence, that is, $n_o > n_e$. It can be shown that there is a frequency ω_{pm} for which $n_o(\omega_{\text{pm}}) = n_e(2\omega_{\text{pm}})$. In such a situation, an ordinary input beam at frequency ω_{pm}, propagating perpendicularly to the optical axis, can be efficiently converted into an extraordinarily polarized SH beam.

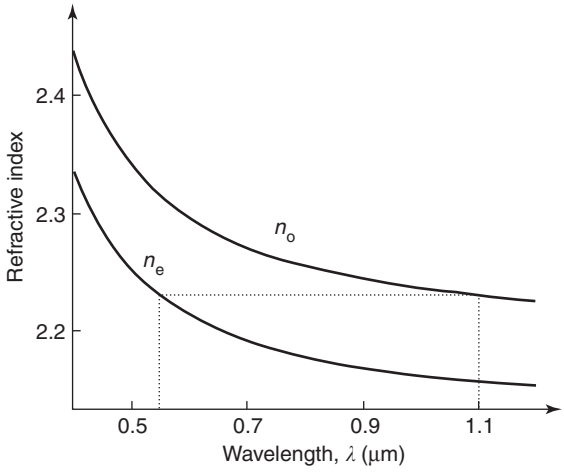

Figure 4 Birefringence phase matching.

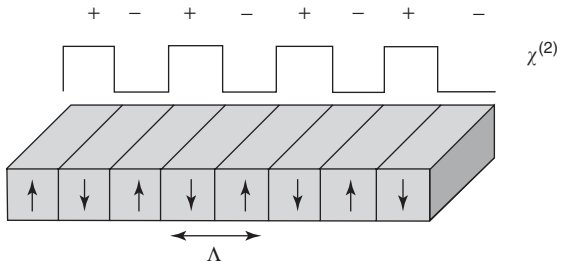

Figure 5 Periodically poled ferroelectric crystal presenting a uniform $\chi^{(1)}$ and an oscillating $\chi^{(2)}$.

Noting that the index of refraction of the extraordinary beam can be changed continuously between n_o and n_e by changing the angle θ between $\boldsymbol{k}$ and the optical axis, ω_{pm} can be tuned by appropriately rotating the crystal.

Since the indices of refraction depend on temperature, it is possible to tune ω_{pm} finely by varying T. More degrees of freedom are added to the SH experiment if two input beams having the same frequency, but different direction or different polarization, are considered.

From the point of view of applications, a very important trend that emerged in recent years is that of considering nonlinear interactions in microstructured materials and in waveguides. It goes beyond the scope of this article to approach such a subject; however, mention may be made here that a microstructured material, in which the value of the $\chi^{(2)}$ coefficient varies with a spatial periodicity Λ, can exchange momentum with the propagating waves in multiples of the unit $2\pi/\Lambda$, so that, in principle, phase matching can be achieved at any desired frequency by appropriately choosing the period Λ (see **Figure 5**). Concerning waveguided propagation, the main difference with respect to bulk propagation is that the

waveguide can support different spatial modes possessing different phase velocities even if they have the same frequency; such a "modal dispersion" also opens new possibilities of phase matching.

This section concludes with an important consideration: whereas the "ideal" phase-matching condition is $\Delta k = 0$, the "practical" condition in a crystal of finite length L is $\Delta kL < \pi$, or, equivalently, $l_c > L$. As a consequence, there is a frequency interval, centered on ω_{pm}, in which efficient SH generation can be achieved. The existence of a nonzero spectral acceptance makes it possible to use short pulses, instead of stationary beams, in nonlinear optical experiments.

Parametric Amplification and Oscillation

If two beams, possessing different frequencies ω_1 and ω_2, and different wave vectors $\boldsymbol{k_1}$ and $\boldsymbol{k_2}$, are sent into a second-order nonlinear crystal, the nonlinear polarization can give rise to new frequencies representing the SH of each beam or the sum/difference of the input frequencies. By choosing a specific phase-matching condition, only one process is selected among all possible processes. If the difference-frequency generation (DFG) is selected, and it is assumed that $\omega_1 > \omega_2$, a new beam at frequency $\omega_3 = \omega_1 - \omega_2$ and wave vector $\boldsymbol{k_3}$ is obtained, provided that the condition $\boldsymbol{k_3} = \boldsymbol{k_1} - \boldsymbol{k_2}$ is satisfied (see **Figure 6**).

All the phase-matching methods discussed in the previous section in connection with SH generation can also be applied to the sum/difference frequency generation. By using the same approach outlined for SH generation, it is easy to derive nonlinear propagation equations for the sum/difference fields having a structure similar to that of eqns [3]. In the DFG process, one photon at frequency ω_1 is annihilated and two photons at frequencies, respectively ω_3 and ω_2, are created, so that the process not only produces a new coherent beam at ω_3, but also amplifies the beam at ω_2. Such an amplification process is called parametric amplification. Whereas standard optical amplifiers work only at frequencies corresponding to transitions among energy levels, parametric amplifiers use transparent crystals and can work, in principle, over the whole transparency window of the crystal, provided that phase matching can be achieved (see **Figure 7**).

Recalling that an optical amplifier can become a laser oscillator once inserted into an optical cavity, a similar approach can transform the parametric amplifier into a parametric oscillator. Whereas in the laser case, the trigger to cavity oscillation comes from spontaneous emission from the upper level of the amplifying medium, the initial seed for parametric oscillation comes from parametric fluorescence, the process by which the "pump" photon at frequency ω_1 spontaneously breaks down into two photons at frequencies ω_2 (signal) and ω_3 (idler). Potentially, parametric fluorescence can yield any couple of frequencies satisfying energy conservation, the choice among all possible couples being determined by the phase-matching condition. The tuning of the parametric oscillator is generally achieved by rotating the crystal or by changing the operating temperature.

Nonlinear Optical Materials

The second-order processes described in the previous sections require the availability of noncentrosymmetric media. Such media are intrinsically anisotropic, so that the electric susceptibilities become tensorial quantities. In particular, $\chi^{(2)}$ is a third-order tensor, possessing 27 components χ_{ijk}. This fact makes the description of beam propagation inside the crystal and also the search for phase matching conditions rather complicated. Such descriptions are beyond the scope of this article; however, the following example is taken up: consider an input field polarized along the x-axis (this implies $j = k = 1$);

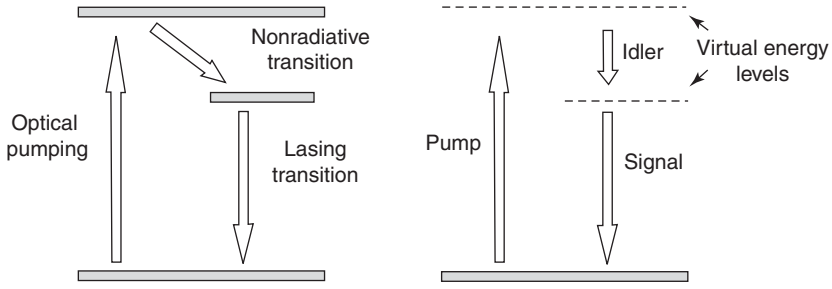

Figure 7 Comparison between the three-level laser, using real energy levels, and the optical parametric oscillator, using virtual levels.

birefringence phase matching requires that the generated nonlinear polarization lies along the z-axis (this implies $i = 3$), so that the useful component of the $\chi^{(2)}$ tensor is, in this case, χ_{311}. As a general consideration, the most powerful phase matching method, that is, birefringence phase matching, exploits nondiagonal components of $\chi^{(2)}$, whereas several interesting crystals present very large diagonal components of $\chi^{(2)}$. Such components can be exploited only if the phase-matching conditions are achieved by means of the periodical poling technique.

The commonly used second-order materials are inorganic crystals with oxygen polyedra, which can be viewed as ionic crystals where one of the ions is replaced by an oxygen polyedron in an ionized state, stabilized in a noncentrosymmetric configuration by the surrounding ions (usually of metal elements). Examples of such crystals are the ABO_3 type of ferroelectrics, such as $LiNbO_3$ and $KNbO_3$, borates, such as BaB_2O_4 and LiB_3O_5 (usually indicated, respectively, as BBO and LBO), and the isomorphic family with the generic formula $MTiOXO_4$, such as potassium titanyl phosphate $KTiOPO_4$ (usually indicated as KTP).

It is important to note that the requirements for nonlinear materials are not only suitable transparency and high nonlinearity, but also sufficient birefringence for phase-matching, high-optical-damage threshold, good thermal, mechanical, and chemical properties, and possibility of growing large crystals of good optical quality.

Families of crystals possessing a second-order nonlinearity larger than that of inorganic crystals are organic molecular crystals and heteropolar semiconductors. However, at present, they are less interesting for applications because the former has insufficiently good mechanical and chemical properties, whereas the latter is not birefringent. In addition, both families have a limited transparency range.

A possibility that is actively explored is that of starting from an amorphous material (such as a polymer or a silicate glass) and introducing an orientation of noncentrosymmetric molecular groups by heating at a temperature above the glass transition and applying an external field, usually an electric field (electrical poling).

Third-Order Nonlinear Effects

Optical Kerr Effect

If a third-order material illuminated by a monochromatic plane wave at frequency ω propagating along the z-axis is considered, it results from eqn [2] that such a wave gives rise to a nonlinear polarization oscillating at $3\omega_1$. In turn, the nonlinear polarization, once inserted into eqn [1], yields a third-harmonic (TH) optical wave. The entire treatment developed for SH generation, including the phase-matching considerations, can be easily translated to the TH case, and is not repeated here. Instead, the attention is on the polarization term having the expression

$$P(z,\omega) = \varepsilon_0[\chi^{(1)}E(z,\omega) + \chi^{(3)}\alpha|E(z,\omega)|^2E(z,\omega)] \quad [5]$$

where α is a numerical factor that can assume values ranging from 1/2 to 3/2, considering different third-order phenomena. From eqn [5], it is possible to define an intensity-dependent susceptibility: $\chi^{(1)}_{\text{eff}} = \chi^{(1)} + \chi^{(3)}\alpha|E(z,\omega)|^2$. By recalling the relation between index of refraction and electric susceptibility and assuming that the nonlinear contribution is small in comparison with the linear one, one obtains

$$n_{\text{eff}} = n + n_2|E|^2 \quad [6]$$

where $n_2 = \alpha\chi^{(3)}/(2\varepsilon_0 c\chi^{(1)})$. A more careful analysis shows that the overall effect consists in an intensity-dependent deformation of the index ellipsoid of the medium. In particular, an initially isotropic material becomes uniaxial in the presence of a strong linearly polarized optical beam.

Equation [6] expresses the optical Kerr effect. Some phenomena due to such an effect are briefly discussed below.

Optical switch The phase and the polarization of an optical signal going through a Kerr medium can be changed by illuminating the medium with a strong auxiliary (pump) beam. This opens the way to the realization of all-optical modulators and switches. If the Kerr effect is fast, as it happens when it is due to the displacement of electron clouds, the response time of the device can be as short as the duration of pump pulses (less than 1 ps).

Self-focusing Considering a pump with a Gaussian transverse intensity profile (this is the output beam from a single-mode laser), the optical Kerr effect produces a transverse index-of-refraction profile that follows the shape of the beam. If n_2 is positive, a greater index of refraction is induced on-axis than in the wings of the beam, creating in this way, a positive lens that tends to focus the beam. This effect is called self-focusing. If the input power is larger than a threshold value, self-focusing can exactly balance diffraction, so that the beam propagates without changing its profile. This phenomenon is called self-trapping. If the input power is further increased, the beam will catastrophically focus, causing in many cases optical damage inside the medium. To conclude this short discussion about self-focusing, it should be mentioned that the effect is very usefully exploited in the so-called Kerr-lens passive mode-locking method for the generation of ultrashort laser pulses.

Self-phase modulation Considering a beam with a time-dependent intensity profile (optical pulse), the optical Kerr effect gives rise to a self-induced nonlinear phase shift that is also time dependent. Generally speaking, this has the consequence of broadening the frequency spectrum of the optical pulse. It should be recalled that an optical pulse propagating in a linear dispersive medium has a time duration increasing progressively with the propagation distance. Among the various phenomena occurring during the nonlinear propagation of short pulses, it is worth mentioning the existence of optical solitons, that is, pulses of appropriate shape, intensity, and time duration that propagate without changing shape and duration in a medium presenting anomalous group-velocity dispersion. Such a phenomenon is made possible by a compensation between the effects of linear dispersion and self-phase modulation. Particularly important for applications to optical communications is the study of nonlinear propagation in single-mode optical fibers: although the nonlinearity of glass is very small, nonlinear effects can be significant because the intensity can be high and the propagation distance is very large.

Four-Wave-Mixing and Optical Conjugation

The term four-wave-mixing (FWM) refers to the interaction of four waves in a nonlinear medium via the third-order polarization. In the presence of three monochromatic beams at frequencies ω_1, ω_2, ω_3, a nonlinear polarization term oscillating at the frequency $\omega_4 = \omega_1 + \omega_2 - \omega_3$, with wave vector $\boldsymbol{k_4} = \boldsymbol{k_1} + \boldsymbol{k_2} - \boldsymbol{k_3}$, is generated:

$$P = \varepsilon_0 \chi^{(3)} A_1 A_2 A_3^* \ \exp[\mathrm{i}(\boldsymbol{k_1} + \boldsymbol{k_2} - \boldsymbol{k_3}) \cdot \boldsymbol{r}] \quad [7]$$

Among the various phenomena originated by the nonlinear polarization of eqn [7], two particularly interesting processes are selected (see **Figure 8**).

Frequency-shifting scheme In practical situations, a high-intensity beam (pump beam) at frequency $\omega_p = \omega_1$ is sent collinearly with the weak beam (signal beam) 2. The new beam 3 is also collinear, and has a frequency $\omega_3 = 2\omega_1 - \omega_2$. Note that $\omega_3 - \omega_1 = \omega_1 - \omega_2$, that is, ω_3 is the mirror image of ω_2 with respect to the pump frequency. If, for instance, the pump beam is continuous and the signal is a sequence of pulses, the frequency-shifted beam 3 is a temporal replica of the signal beam. It should be added that, in the absence of materials having a large $\chi^{(3)}$, it is usually more convenient to perform the same operation by using a cascade of two second-order processes in a $\chi^{(2)}$-material. Frequency-shifting devices can be usefully applied in optical communications systems.

Phase-conjugate mirror If a degenerate case in which all the frequencies coincide is considered, $\omega_1 = \omega_2 = \omega_3 = \omega$, the new field has frequency $\omega_4 = \omega$ and wave vector $\boldsymbol{k_4} = -\boldsymbol{k_3}$, that is, it counterpropagates with respect to beam 3. The nonlinear

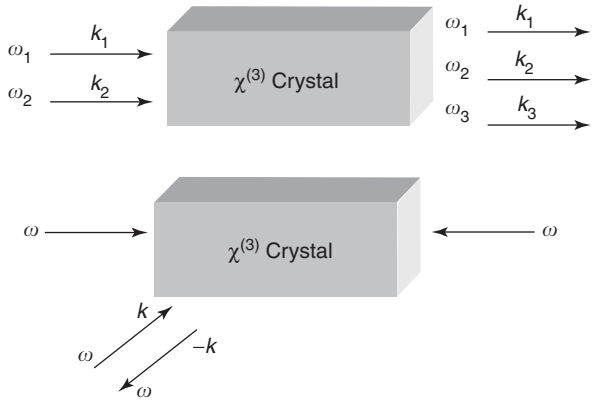

Figure 8 Schematic wave-mixing processes: frequency shifter and conjugated mirror.

medium illuminated by beams 1 and 2 acts as a mirror for beam 3: this is what is called a phase-conjugate mirror. Such a mirror has some unique properties compared to an ordinary mirror. First of all, it functions as a retroreflector for any incident angle θ, within the acceptance angle of the experiment. Any phase change $\phi(\boldsymbol{r})$ impressed on beam 3 by propagating, for example, through an inhomogeneous medium, will result in exactly the opposite phase $-\phi(\boldsymbol{r})$ impressed on the reflected wave, in this way correcting the phase distortion during the back-propagation. In terms of energy balance, the FWM process subtracts one photon from beam 1 and one photon from beam 2, and adds one photon to beam 3 and one photon to beam 4. As a consequence, the reflection coefficient of the conjugated mirror is proportional to the product of the intensities of beams 1 and 2 and can even become larger than 1.

This section concludes with a brief discussion on third-order nonlinear materials. It is useful to distinguish between slow and fast nonlinearities. Slow nonlinearities involve the rotation and alignment of molecular groups under the action of an optical field, such as it may happen in liquid crystals. The effects are large, but the response time can be of the order of milliseconds or even longer. Fast nonlinearities involve the displacement of electron clouds, response times can be in the range of picoseconds but the effects are small. In order to enhance electronic nonlinearities one can operate near a resonance, but the drawback is that response times are now controlled by the material decay time. The most interesting materials are semiconductors or conjugated polymers, but, in practice, the largest fast third-order nonlinearities are obtained by using a cascade of second-order processes in a noncentrosymmetric material.

Stimulated Raman and Brillouin Scattering

Raman scattering is an inelastic light scattering process in which a quantum of excitation is exchanged between the optical field and the scattering medium. A typical case is that of a molecule possessing a vibrational mode with angular frequency ω_v, illuminated by a light beam at frequency ω. The spectrum of scattered light, observed at any scattering angle, will contain, besides the unshifted Rayleigh line at ω, also an additional line, called Stokes line, at frequency $\omega_s = \omega - \omega_v$. The energy difference between the incident and scattered photon is taken to excite the molecular vibration. If the illuminated medium includes molecules that are already in an excited vibrational state, the spectrum of scattered light will contain a third line, called the anti-Stokes line, at frequency $\omega_{as} = \omega + \omega_v$, describing a scattering event in which the molecule has given its vibrational energy to the scattered photon. Raman scattering may exist also in association with rotational energy levels of molecules. Besides localized molecular excitations, there are also collective excitations producing Raman scattering, such as optical phonons in crystals or plasma waves in an electron gas. It should be noted that not all elementary excitations are Raman active; there are selection rules, usually different from those controlling radiative transitions.

Stimulated Raman scattering (SRS) is observed when two light beams, at frequencies ω and ω_s, are sent into the medium. The Stokes photons generated by SRS are emitted with the same wave vector as that of the incident Stokes field and added coherently to that field. The result is that the field at ω_s is amplified, and, at the same time, more molecules are excited to the vibrational level. SRS can be used not only to amplify a signal at ω_s, but also to generate a coherent wave at ω_s. In fact, if a powerful beam at ω is sent into the medium, it will create Stokes photons by spontaneous Raman scattering, and the created Stokes photons can constitute the seed for an amplification process yielding an intense coherent Stokes field. Note that the spontaneous Stokes photons are emitted isotropically in space, whereas the stimulated Stokes beam will appear in a specific direction satisfying the criterion of maximum overlap between the pump and the Stokes beam. In practice, SRS is observed only in the forward and backward directions.

The growth of the Stokes field along the direction z is described by the equation

$$P_S(z) = P_S(0)\exp\left[\int_0^z g_R P_p(z)\mathrm{d}z\right] \qquad [8]$$

where g_R (in units of $\mathrm{m\,W^{-1}}$) is called the Raman gain and $P_p(z)$ is the pump power. SRS is a third-order process; in fact, it can be shown that g_R is proportional to the imaginary part of $\chi^{(3)}$.

If the scattering medium is placed inside an optical cavity, one can build a Raman laser. The Raman laser is different from a normal laser because the pump frequency ω_p can be arbitrary, whereas in normal lasers ω_p must correspond to a transition between the ground level and an excited level of the active medium. As shown in **Figure 9**, the energy transfer between pump and Stokes can be so efficient that a sequence of Stokes lines of decreasing frequency can be coherently generated. Raman lasers utilizing

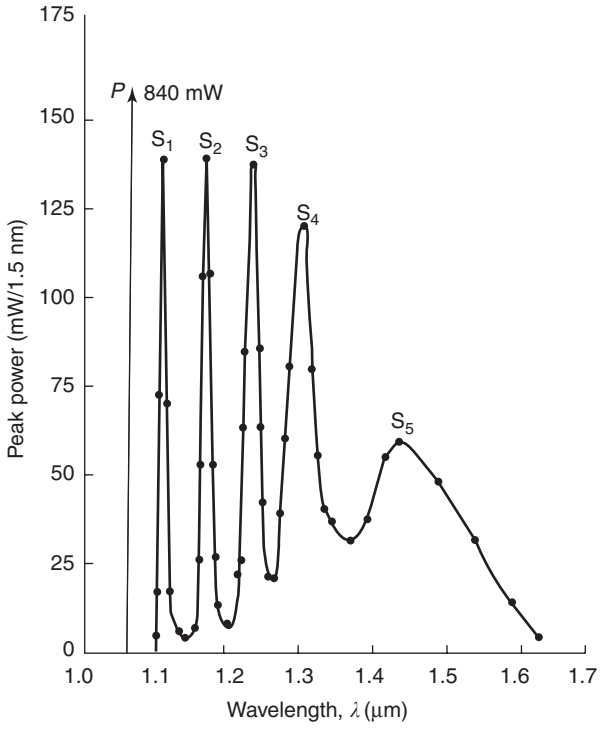

Figure 9 Generation of a sequence of Stokes lines in an optical fiber by stimulated Raman scattering. (Reproduced with permission from Cohen *et al.* (1978) *IEEE Journal of Quantum Electronics* QE-14(11): 855–859.)

optical fibers as active medium represent very efficient and powerful sources of coherent radiation: as an example, fiber Raman lasers pumped by a neodimium-laser ($\lambda = 1064\,\text{nm}$) and working on the fifth Stokes line can emit at a wavelength $\sim 1500\,\text{nm}$ with an overall efficiency of 30%.

Any medium at a nonzero temperature presents local fluctuations in the thermodynamic variables that give origin to light scattering. It is assumed that the incident light is characterized by a wave vector $\boldsymbol{k}$ and an angular frequency ω. In the case of a solid or liquid, the frequency spectrum of scattered light contains an unshifted line (due to nonpropagating density fluctuations) and two lines, called Brillouin lines, centered at frequencies $\omega \pm \omega_B$ that are due to density fluctuations propagating as spontaneous acoustic waves. If the scattering direction is fixed, hence the wave vector of the scattered field, $\boldsymbol{k}'$, only those spontaneous waves possessing a wave vector $\boldsymbol{K} = \pm(\boldsymbol{k}' - \boldsymbol{k})$ contribute to light scattering in that direction. The frequency shift ω_B of the Brillouin lines corresponds to the frequency of the acoustic phonon which is exchanged in the scattering process. Recalling that the velocity of acoustic waves is given by $u_a = \omega_B/K$, the Brillouin frequency shift can also be seen as a Doppler shift due to diffraction from a traveling phase grating. Although Raman shifts are typically in the range of several terahertz, Brillouin shifts are of the order of some gigahertz.

Stimulated Brillouin scattering (SBS) can occur in a way fully similar to that of SRS. Only the interaction $\boldsymbol{K} = -(\boldsymbol{k}' - \boldsymbol{k})$, corresponding to the situation in which the incident wave reinforces the spontaneous acoustic wave, can give rise to a stimulated effect, generating a coherent wave at the frequency $\omega - \omega_B$. In practice, SBS is observed only in the backward scattering direction. It is interesting to mention that the backward Brillouin wave behaves as the phase conjugate of the pump wave. Therefore SBS can create a phase-conjugate mirror, similar to FWM, but in a simpler way, because only one beam is required.

Nuclear Fission and Fusion

D M Brink, University of Oxford, Oxford, UK

Introduction

Nuclear fission is a process in which a heavy atomic nucleus divides into two massive fragments. The phenomenon was discovered by Hahn and Strassmann in 1938 in experiments with uranium (atomic number $Z = 92$). They noticed that radioactive products formed from uranium under neutron bombardment included isotopes of barium with atomic number $Z = 56$. Hahn and Strassmann sent their results to their collaborator Lise Meitner in December 1938 and within a few weeks Meitner and Frisch (1939) arrived at an interpretation. They wrote: "the particles in a heavy nucleus would be expected to move in a collective way which has some resemblance to the movement of a liquid drop. If the movement is made sufficiently violent by adding energy, such a drop may divide itself into two smaller drops." After division the drops would repel each other and gain an energy of $\sim$200 MeV.

Fission is an important source of energy and this article begins with a very short introduction to the physics of nuclear reactors. The main focus is on some advances in the understanding of nuclear fission which have been achieved over the past 65 years. Transuranic elements, for example, uranium, are produced in nuclear reactors. They are also created using fusion reactions with beams from heavy ion accelerators. A part of this article is devoted to the study of these nuclei and the quest for superheavy nuclei. The last part of the article is about fusion reactions with light nuclei.

Nuclear Reactors

The fissioning nucleus studied by Hahn and Strassmann was the isotope ^{235}U of uranium. As argued by Meitner and Frisch, the nucleus ^{236}U produced by absorbing a neutron is unstable and splits into two unequal fragments, for example

$$^{235}\mathrm{U} + \mathrm{n} \rightarrow {}^{236}\mathrm{U}^{*} \rightarrow {}^{93}\mathrm{Rb} + {}^{141}\mathrm{Cs} + 2\mathrm{n} \qquad [1]$$

Other similar decays occur but always with fragment mass numbers $A_1 \sim 95$ and $A_2 \sim 140$. The energy released can be calculated from the measured masses of the isotopes and is 196 MeV in the above example. There is a large energy release because the fragments are more strongly bound than the initial nucleus.

Nuclear power can be produced in fission reactors with the isotope ^{235}U as fuel. The process involves a chain reaction in which neutrons produced in the fission of one uranium nucleus can cause fission in other uranium nuclei. The fission cross section for neutrons on ^{235}U is a maximum for neutrons with energies of less than 1 eV, and in a thermal reactor the neutrons are slowed down by collisions with a moderator, such as carbon or hydrogen.

Natural uranium contains only 0.7% of the isotope ^{235}U. The major component is ^{238}U. This isotope absorbs neutrons but does not fission and instead produces the plutonium isotope ^{239}Pu. The isotope ^{239}U produced by neutron capture decays by beta decay, first to ^{239}Np and then to ^{239}Pu. Several transuranic elements are produced in reactors by further capture of neutrons followed by beta decay. These transuranic elements as well as the fission products are all radioactive and constitute an important component of "nuclear waste."

The plutonium isotope ^{239}Pu can also undergo fission when it absorbs neutrons and is a potential fuel for nuclear reactors. The fission cross section for plutonium is small for slow neutrons but becomes large for neutrons with energies greater than 1 keV. Plutonium burns best in a "fast reactor" where the fission neutrons are slowed down, but not too much.

Stability against Fission

Very soon after the discovery of the fission process, Bohr and Wheeler proposed a detailed theoretical treatment based on the comparison between the nucleus and a liquid drop. All subsequent developments preserve aspects of their model.

Bohr and Wheeler assumed that the liquid drop representing the nucleus passes through a sequence of shapes on the pathway to fission. Starting from the initial metastable equilibrium shape the nucleus becomes very deformed, then it develops into a dumbbell shape with two fragments joined by a neck. Finally the neck breaks, the fragments separate and are accelerated away from each other by the strong Coulomb repulsion acting between them.

In a simple picture one can introduce a parameter q associated with each of the shapes on the pathway to fission and function $V(q)$ representing the energy of the nucleus for each value of q. It is convenient to choose $q = 0$ for the initial shape and $q = R$, where R is the distance between the centers of mass of the fragments, when the two fragments are separated. For nuclei which are metastable against fission, $V(q)$ has a local minimum at $q = 0$, increases to a maximum $V(q_B)$ at the fission barrier $q = q_B$, and then decreases monotonically for $q > q_B$. When the fragments are separated, they are accelerated away from each other by the electrostatic repulsion acting between them.

The liquid drop model predicts that the equilibrium shape of a nucleus is spherical with $q = 0$. For a small deviation from the spherical shape along the fission path, the coordinate q represents a quadrupole deformation and $V(q) \approx V(0) + (1/2)Cq^2$, where

$$C \propto \tfrac{2}{5}\, a_s A^{2/3} - \tfrac{1}{5}\, a_c Z^2 A^{-1/3} \qquad [2]$$

where a_s and a_c are the surface energy and Coulomb energy parameters in the semi-empirical mass formula. The surface energy increases and the Coulomb energy decreases as the nucleus deforms. The stability of the spherical shape is determined by the balance between the surface energy and the Coulomb energy. The spherical shape is stable if the restoring force parameter $C > 0$ or

$$x = \frac{a_c}{2a_s}\,\frac{Z^2}{A} = \frac{2E_s(0)}{E_c(0)} < 1 \qquad [3]$$

The fissility parameter x was introduced by Bohr and Wheeler as a measure of the stability of a heavy nucleus. Using standard values for the parameters $a_s \approx 16.8$ MeV and $a_c \approx 0.72$ MeV, the liquid drop model predicts that a nucleus is unstable against fission when $Z^2/A > (Z^2/A)_{\text{limiting}} \approx 47$. There are important shell corrections to the liquid drop model but these simple arguments show there is a limit to the possibility of creating very heavy elements. The nucleus ^{235}U has $Z^2/A = 36$ while one of the heaviest known transuranic elements with $Z = 114$ and $A = 298$ has $Z^2/A = 44$.

Fission Barriers

When a nucleus is metastable against fission, the difference $V_B = V(q_B) - V(0)$ is called the fission barrier height or the fission activation energy. When the excitation energy E^* is less than V_B, then the nucleus can fission only by quantum tunneling through the barrier and the fission probability is very small. When $E^* > V_B$, then fission decay rate is large. This can be illustrated by the example of ^{236}U. Alpha decay is the dominant decay mode of the ground state of ^{236}U with a fission probability of only 10^{-7}%. When ^{236}U is formed by thermal neutron capture on ^{235}U, the compound nucleus, has an excitation energy of 6.5 MeV, which is greater than, the activation energy $V_B = 6.2$ MeV and fission is the dominant decay mode. Another example is ^{239}U, which can be formed by neutron capture on ^{238}U. When ^{238}U captures slow neutrons, then the excitation energy $E^* =$ 4.8 MeV is less than the activation energy 6.6 MeV and the fission probability is very small. On the other hand, when ^{238}U is bombarded with neutrons with an energy greater than 2 MeV, then the excitation energy of the ^{239}U is larger than V_B and the fission cross section is comparable with that for neutrons with the same energy on ^{235}U.

There is a general trend for fission barrier heights to decrease with Z for transuranic elements, but there are fluctuations. Nuclei with atomic numbers less than $Z = 92$ can undergo fission, provided the excitation energy is large enough. The fission barrier for ^{208}Pb is $\sim$28 MeV and for ^{216}Rn it is $\sim$13 MeV. Their fission probabilities are extremely small.

The Dynamics of Fission

In the previous sections, it was assumed that there was a unique path for the fission of a nucleus. The situation is more complicated than this for the liquid drop model and also for real nuclei. The fission of a nucleus such as ^{236}U does not lead to a unique pair of fission fragments. At the stage where the nucleus becomes very deformed and develops into a dumbbell shape, the number of nucleons on each side of the neck is not unique. When the neck breaks, there is a distribution in the partition of mass and charge

between the fragments and there is a high probability that the fragments will be left in excited states.

The distribution of mass and charge between the fragments can be measured by identifying the fission fragments. The liquid drop model predicts that, on the average, the mass is equally distributed between the two fragments, but in many cases the mass distribution is asymmetric. For example in the fission of ^{235}U by thermal neutron capture, the mass distribution has two peaks, one centered at $A \approx 95$ and the other at $A \approx 140$. This asymmetric fission is a shell effect and is discussed in the next section. Typically the spread of each peak in the mass distribution is in the range $\delta A \approx 10$–15 mass units.

The distribution in excitation energy of the fission fragments can be investigated by measuring the kinetic energy TKE of the fragments. The total energy released is equal to the Q-value, $Q = \delta M c^2$, where δM is the difference between the mass of the initial nucleus and the sum of the masses of the fragments. The total excitation energy of the fragments is given by $\delta E_{\text{exc}} = Q - \text{TKE}$. Some nuclei may have more than one fission barrier, each with its own characteristic mass distribution and TKE distribution. The existence of more than one barrier can often be detected by making a careful analysis of the mass and TKE distributions of the fragments.

Decay Rates

Any quasistationary state of a nucleus which can decay by fission may also have a branch for decay by α-emission, γ-emission, neutron emission, or various other processes. The decaying state has a total width Γ related to the mean life τ by $\Gamma = \hbar/\tau$. The total width is a sum of partial widths $\Gamma = \Gamma_{\text{f}} + \Gamma_{\alpha} + \Gamma_{n} + \cdots$ for each decay process and the fission probability or branching ratio is Γ_{f}/Γ. The mean life τ and fission branching ratio of the ground state of a nucleus can be measured directly. At higher excitation, energy states may appear as resonances in nuclear reactions, for example, low-energy neutron scattering reactions. Then Γ is the width of a resonance. At higher excitations resonances overlap and the width of a state is not a measurable quantity, but decay rates and branching ratios still have a meaning.

The fission width of a state can be estimated in various ways depending on the excitation energy of the nucleus. A nucleus in the ground state can decay by quantum tunneling through the fission barrier. The fission width is approximately

$$\Gamma_{\text{f}} \approx \frac{\hbar\omega_{\text{vib}}}{2\pi} P \qquad [4]$$

where ω_{vib} is a characteristic frequency for the oscillation of the fission coordinate q in the ground state and P is the transmission factor for penetrating the fission barrier along the tunneling path. A simple estimate for P is

$$P = \exp\left(-\frac{2\pi\Delta E}{\hbar\omega_{\text{B}}}\right) \qquad [5]$$

where ΔE is the energy of the decaying state below the top of the barrier and ω_{B} is related to the curvature of the top of the barrier. Typical values of ω_{B} lie in the range 0.5–1 MeV.

The states in nucleus with an excitation energy of several MeV have a complicated structure and statistical arguments can be used to estimate fission widths in terms of the average spacing $D(E^*)$ of levels of the excitation energy E^*. The quantity $\hbar/D$ represents the probability per unit time for concentrating the excitation energy into the motion of the fission coordinate. For excitation energies below the fission barrier, the width can be estimated from

$$\Gamma_{\text{f}} \approx \frac{D(E^*)}{2\pi} P \qquad [6]$$

The transition state theory of Bohr and Wheeler can be used to estimate fission decay rates of states well above the fission barrier. They assumed that internal degrees of freedom could be excited at the barrier and a formula can be obtained for the fission rate

$$\frac{\mathrm{d}N_{\text{f}}}{\mathrm{d}t} \approx \frac{D(E^*)}{2\pi\hbar} N^* \qquad [7]$$

Here $N^* \geqslant 1$ is the effective number of internal states available at the barrier.

Asymmetric Fission and Shell Effects

The shell model or independent-particle model of a nuclear structure assumes that a nucleon in the nucleus moves in a single-particle potential which represents its average interaction with other nucleons. Nucleons occupy single-particle levels in the shell model potential and fill up the lowest levels allowed by the Pauli exclusion principle. Closed shells occur when there is a rather large energy gap between the last filled level and the lowest available empty level. The ordering of single-particle levels is such that closed shells occur for neutron or proton numbers equal to 2, 8, 20, 28, 50, 82, … . Heavier nuclei with closed shells of neutrons and protons are ^{40}Ca, ^{48}Ca, ^{90}Zr, ^{132}Sn, and ^{208}Pb. Closed-shell nuclei and

especially double closed-shell nuclei are particularly stable and have binding energies larger than the predictions of the liquid drop model.

Taking fluctuations into account, the liquid drop model predicts that the mass distribution of fission fragments should be symmetric about the average value $A/2$, but in most cases the measured distribution is asymmetric. For example, the mass distribution ^{235}U has one peak centered at $A_1 \approx 95$ and another at $A_2 \approx 140$. The asymmetric distribution of fragments is very common when the excitation of the fissioning nucleus is less than ~ 6 MeV. There is remarkable systematics in the fragment mass distribution for the fission of nuclei with $256 > 228$. In all these cases, the average mass of the heavy fragment lies in the range 137–142. This is not so far from the mass of the double closed-shell nucleus ^{132}Sn. This systematics extends to the superheavy nuclei ^{286}112 and ^{292}114. In both these cases, the average mass of the light fragment is near to the mass of ^{132}Sn.

In 1966, Strutinsky invented a way of adding shell corrections to the liquid drop model. The total nuclear binding energy in the shell-correction approach is written as

$$E_{\text{tot}}(N, Z, \beta) = E_{\text{LDM}}(N, Z, \beta) + \delta E_{\text{n}}(N, \beta) + \delta E_{\text{p}}(Z, \beta) \qquad [8]$$

where β stands for a set of deformation parameters, E_{LDM} is the liquid drop energy as a function of deformation while δE_{n} and δE_{p} are shell corrections calculated for neutrons and protons moving in appropriate deformed single-particle potentials. This simple model was very helpful for understanding how shell effects influenced asymmetric fission and generalizes the simple argument of the dominance of the double closed-shell nucleus ^{132}Sn. Shell effects disappear in a nucleus with a large excitation energy and the asymmetry in the fission fragment distribution disappears.

Fission Isomers

Many different processes associated with fission have shown that the fission barrier does not always have a single maximum as predicted by the liquid drop model. According to present-day understanding, many nuclei have a double-humped fission barrier. The first minimum (I) in the double-humped potential $V(q)$ contains the ground state. Then there is a barrier followed by a second minimum (II) and finally another barrier which leads to fission. Quasi-stationary states in the second minimum are called fission isomers.

The ground state in the first minimum (I) is normally not spherical, but has a prolate equilibrium shape. The first minimum also contains type (I) excited states which have deformations similar to that of the ground state. Type (II) levels are located around the second minimum and are separated from the type (I) states by the first hump of the potential barrier. The type (I) states have deformations $\delta \sim 0.35$ while the deformations of the type (II) states are more than twice as large. Fission from a class (I) state occurs when the fission coordinate tunnels through the first barrier into the second minimum (II) and finally through the outer barrier.

The cross section for scattering of low-energy neutrons by ^{240}Pu has sharp resonances with a spacing ~ 10 eV. Each resonance corresponds to a state of the compound nucleus ^{241}Pu. The wave functions of the compound states are located around the first minimum in the double-humped potential. Most of the resonance states have a relatively small fission width, but there is a group of about seven resonances corresponding to neutron energies lying between 750 and 820 eV which have much larger fission widths. There is another group of resonances with large fission widths clustered around 1400 eV and a third at 1950 eV. This behavior can be explained by the double-humped potential. If the energy of a compound state in the first minimum is very close to the energy of a type (II) state, then there is a resonance effect which enhances the penetration of the double barrier. The penetration probability of the double barrier can be much larger than that for one of the individual barriers.

Fission isomers can be studied in other ways. For example, states in the second minimum of ^{239}U can be excited in the reaction ^{238}U(d, p) and γ-rays from the isomeric states observed. Superdeformed states have been observed in nuclei with mass numbers $A \sim 130$, 150, and 190. These have very similar properties to fission isomers.

Nuclear Fusion and Transuranic Elements

Bohr and Wheeler showed that elements with large enough atomic number must be unstable against fission because of the electrostatic repulsion between protons in the nucleus. For the past half century, there has been an intensive effort to create nuclei with larger and larger atomic number to try to reach the limit of stability. There have been suggestions that shell effects might give enough extra binding to elements with $Z \approx 114$ to make them more stable. There is strong evidence that the element with $Z = 114$ has already been produced in a collaboration between scientists from The Lawrence Livermore

Laboratory in California and the Dubna Laboratory in Russia. They bombarded a plutonium ^{244}Pu target with ^{48}Ca nuclei to create the new element.

To date, more than 20 transuranic ($Z > 92$) elements and 2000 isotopes have been discovered and various properties, including masses and lifetimes, have been studied. The names with atomic numbers and symbols of the first few new elements are neptunium (93Np), plutonium (94Pu), americium (95Am), curium (96Cm), berekelium (97Bk), californium (98Cf), einsteinium (99Es), and fermium (100Fm). Isotopes of these elements can be produced by a variety of reactions. For example, curium was first made in 1944 by the reaction

$$^{4}\mathrm{He} + ^{239}\mathrm{Pu} \rightarrow ^{265}\mathrm{Cm} + \mathrm{n} \qquad [9]$$

Isotopes up to ^{254}Fm and beyond can be produced by intense neutron irradiation of lower elements, such as plutonium, using a process of successive neutron capture interspersed with β-decays until these mass numbers and atomic numbers are reached.

Heavier elements are produced by fusion reactions. For example, the element hassium with $Z = 108$ is produced in the reaction

$$^{58}\mathrm{Fe} + ^{208}\mathrm{Pb} \rightarrow ^{265}\mathrm{Hs} + \mathrm{n} \qquad [10]$$

These reactions are very delicate because if the intermediate compound nucleus has too large an excitation energy, it will not survive. For the reaction to succeed, the incident energy of the projectile must be just large enough to cross the Coulomb potential barrier.

Fusion Reactions with Light Nuclei

Fusion reactions are the source of energy production in stars and are responsible for the conversion of protons into heavier elements. They are also a potential energy source for modern industrial society. Energy production in stars comes mainly from the conversion of hydrogen into helium. The overall result of a typical sequence of reactions is

$$4\,^{1}\mathrm{H} \rightarrow ^{4}\mathrm{He} + 2\mathrm{e}^{+} + 2\nu \qquad [11]$$

with the release of 27.7 MeV for each ^{4}He atom produced. Fission reactions in nuclear reactors are initiated by neutron absorption. The cross sections are large because the neutrons have no charge. Cross sections for reactions between charged nuclei are very small at low energies because of the electrostatic repulsive forces acting between them.

The first step in the production of helium from hydrogen in stars is the conversion of protons into deuterons:

$$^{1}\mathrm{H} + ^{1}\mathrm{H} \rightarrow ^{2}\mathrm{H} + \mathrm{e}^{+} + \nu \qquad [12]$$

This is a weak interaction process and the cross section is very small, but the reaction rate is significant because there are so many protons. After deuterons have been produced, other reactions can occur, for example

$$^{2}\mathrm{H} + ^{1}\mathrm{H} \rightarrow ^{3}\mathrm{He} + \gamma \qquad [13]$$

and

$$^{3}\mathrm{He} + ^{3}\mathrm{He} \rightarrow ^{4}\mathrm{He} + 2\,^{4}\mathrm{H} \qquad [14]$$

An accurate knowledge of thermonuclear reaction rates for reactions such as these is important for understanding the generation of energy and other physical processes in stars.

All the above reactions are inhibited by the Coulomb repulsion between the nuclei. The central temperature in a star such as the sun is $\sim 1.5 \times 10^{7}$ K which is equivalent to 1.3 keV. This is much less than the height of a typical Coulomb barrier and the reaction cross sections become very small. The cross section for a reaction between two charged nuclei for incident energies below the top of the Coulomb barrier can be written as [2]

$$\sigma(E) = \frac{S(E)}{E} \exp(-2\pi\eta) \qquad [15]$$

where the Sommerfeld parameter is given by

$$2\pi\eta = 2\pi Z_1 Z_2 (e^2/\hbar v) = 31.29 Z_1 Z_2 (\mu/E)^{1/2} \qquad [16]$$

The quantities Z_1 and Z_2 are the charges of the two nuclei, μ is the reduced mass in atomic mass units, and E is the center of mass energy in keV. The astrophysical S-factor $S(E)$ depends on the reaction and is normally a rather slowly varying function of energy at sub-barrier energies except for possible resonances. On the other hand, the exponential factor containing the Sommerfeld parameter is a very rapidly varying function of the energy, and cross sections become very small for low incident energies.

The reaction ^{3}He(^{3}He, ^{4}He)2p is a useful example to illustrate these points. The energy of the Coulomb barrier is ~ 2 MeV while the S-factor $S(E)$ lies in the range 4–8 MeV b as E varies between 1 MeV and 20 keV. The cross section for this reaction is ~ 10 mb when the relative energy is $E = 500$ keV, it drops to

about μb for $E = 100$ keV and to 0.3×10^{-12} b when $E = 20$ keV. One of the challenges for nuclear physicists is to measure these very small cross sections. The cross section has been measured at 20 keV and this is about the lower limit for present-day techniques.

Nuclear Models and Methods

R A Broglia, University of Milan, Milan, Italy

Independent-Particle Model

In classical mechanics, a system of particles of mass m which interact through a two-body force (particle–particle potential) of the type shown in **Figure 1** is described by the Hamiltonian

$$H = \frac{p^2}{2m} + v(r_{12}) \qquad [1]$$

The lowest-energy state occurs at zero temperature. It is obtained by minimizing, for each particle, its potential energy with respect to all the neighbors. Such static, localized particles provide the basic design for the ground state of molecules and crystals (**Figure 2**). While the laws governing the motion of these particles are invariant with respect to translation, in particular $v(r_{12})$, the solution of such equations violates translational and/or rotational invariance. In other words, the solution of the classical equations may display a lower symmetry than the original Hamiltonian. This phenomenon, known as "spontaneous symmetry breaking," is the basis of the "emergent properties" of the system of particles described by the Hamiltonian given in eqn [1]. In fact, the systems in **Figure 2a** display localization and rigidity, properties neither contained in each individual particle nor in H.

In quantum mechanics, momentum and coordinate are conjugate variables fulfilling Heisenberg's relation

$$\Delta x \Delta p_x \geqslant \hbar \qquad [2]$$

From this relation, one can calculate the (zero-point) energy associated with the localization

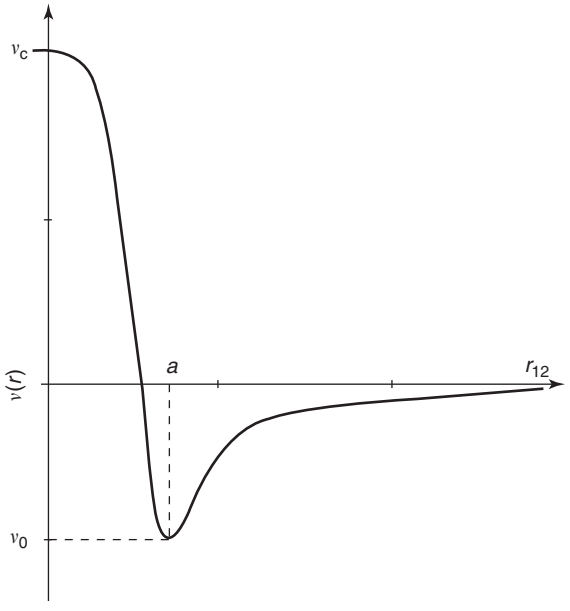

Figure 1 Schematic representation of a two-body force in a system of particles, displayed as a function of the relative particle–particle coordinate $r_{12} = |\boldsymbol{r}_1 - \boldsymbol{r}_2|$. It displays a repulsive core at $r_{12} = 0$ of strength v_c and an attractive minimum of strength v_0 at $r_{12} = a$.

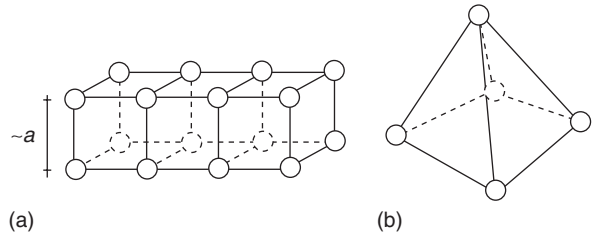

Figure 2 Examples of the state of minimum energy of a system of classical particles described by the Hamiltonian given in eqn [1].

of a particle within a volume of radius a, that is, $\sim\hbar^2/ma^2$. Thus, the particles described by the Hamiltonian given in eqn [1] may be delocalized because the potential energy gain of the classical (localized) configuration may be overwhelmed by the quantal zero-point energy. Consequently, systems for which the "quantality" parameter

$$Q = \frac{\text{zero-point energy of localization}}{\text{potential energy of localization}} \sim \frac{\hbar^2}{ma^2}\frac{1}{|v_0|} \quad [3]$$

is such that $Q \ll 1$ are expected to display particle localization, while systems associated with larger values of Q are expected to display particle delocalization. In the case of nucleons ($^1S_0$ nucleon–nucleon potential), $v_0 = -100$ MeV, $a \approx 1$ fm, $\hbar^2/M \approx 40$ MeV fm^2 ($m = M \approx 10^3$ MeV) and $Q = 0.4$. It is thus expected that nucleons, inside the nucleus, are delocalized.

Because nucleons do not occupy all the space available to them but are self-confined, it is said that the nucleus is a quantum liquid. This is not completely correct, in the sense that the nucleus behaves as a non-Newtonian solid. It deforms plastically under strain and reacts elastically to an instantaneous stress.

In the case where the particles under consideration are Ne_{20} atoms, $m = 20M$, $a \approx 3.1$ Å, and $v_0 = 3.1$ meV. Consequently, $Q \approx 0.007$ and N_{20} is, at $T = 0$, a solid, being a gas at room temperature.

Summing up, the fact that $Q \ll 1$ implies localization and thus spontaneous symmetry breaking, while $Q \sim 1$ does not, is an example of the fact that while potential energy always prefers special arrangements, fluctuations, quantum or classical, favor symmetry.

Mean Field

Because $Q \sim 1$ in the nuclear case, it is likely that the mean-field theory is applicable to the description of the motion of the nucleons. In fact, the marked variation of the binding energy per particle as a function of mass number $A = N + Z$ (cf. **Figure 3**) (where N and Z stand for the number of neutrons and protons, respectively), for specific values of N and of Z (magic numbers), testifies to the fact that nucleons in the nucleus display, in states close to the Fermi energy, a long mean free path, as compared to the size of the nucleus ($\approx$3–7 fm).

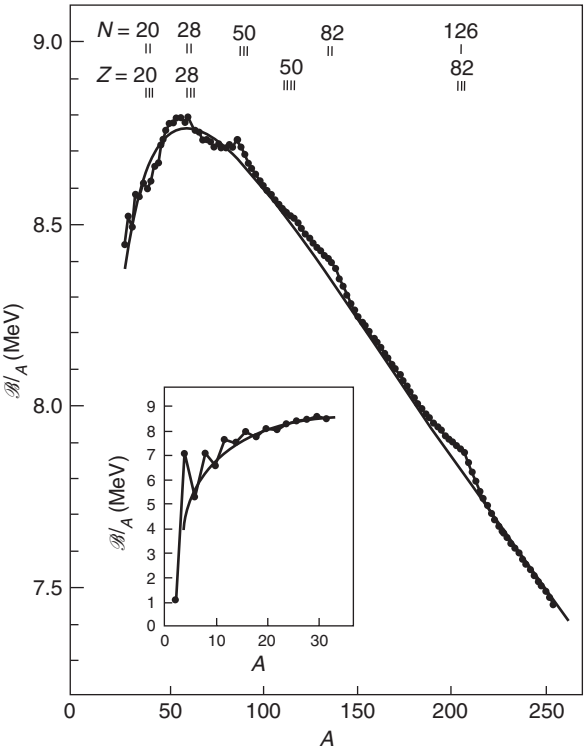

Figure 3 Binding energy per nucleon as a function of mass number.

Special stability is adscribed to nuclei displaying particular values of N and Z (magic numbers), in particular to $^{208}_{82}Pb_{126}$ containing 82 protons and 126 neutrons. In analogy with the atomic case in general, and with the noble gases in particular, this result is connected with the filling of shells, single-particle orbitals of a single-particle potential $U(r)$ generated by all the nucleons, and where each nucleon moves independently. The validity of the independent-particle model implies that the matrix elements of $U(r)$ are much larger than those of $(v(r_{12}) - U(r))$. In other words, that

$$H_{MF} = T + U(r) \quad [4]$$

is a good approximation to eqn [1].

Nucleon–nucleus elastic scattering data and one-particle stripping and pickup experiments provide the information needed to determine the parameter determining $U(r)$, and the energy and occupation probability of single-particle states.

The properties of the single-particle levels close to the Fermi energy, that is, with $E = |\varepsilon - \varepsilon_F| < 5$ MeV

(valence levels) can be quite accurately described by making use of a single-particle Saxon–Woods potential (a spin–orbit and a Coulomb term has to be added),

$$U(r) = \frac{U}{1 + \exp((r - R_0)/a)} \qquad [5]$$

where $R_0 = 1.2A^{1/3}$ fm is the nuclear radius and $a = 0.65$ fm the diffusivity of the potential, while the relation

$$U = U_0 + V_1 \frac{N - Z}{A} \tau_z \qquad [6]$$

defines the depth of the potential, with $U_0 = -45$ to -50 MeV. To describe the centroid of levels with $E > 5$–10 MeV, a term $0.4E$ has to be added to U, where $E = |\varepsilon - \varepsilon_F|$ is the absolute value of the single-particle energy measured from the Fermi energy. In other words, the depth of the empirical Saxon–Woods potential is

$$\begin{matrix} U & (E < 5\,\text{MeV}) \\ U + 0.4E & (E > 5 - 10\,\text{MeV}) \end{matrix} \qquad [7]$$

The last term in eqn [6] is closely related to the symmetry energy in the nuclear mass formula of Weizäcker $V_1 = 30$ MeV and $\tau_z = +1$ for neutrons and $\tau_F = -1$ for protons. This term expresses the fact that one has to pay a price to separate protons from neutrons, or to have a system with a neutron excess, needed in order to decrease the Coulomb repulsion among protons.

Hartree Theory

The mean-field theory, in the first version proposed by Hartree, finds that the energy of the system acquires a minimum by placing the nucleons in the potential

$$U_H(r) = \int d^3r' \rho(r') v(|\boldsymbol{r} - \boldsymbol{r}'|) \qquad [8]$$

where

$$\rho(r) = \sum_{i \in \text{occ}} |\varphi_i(\boldsymbol{r})|^2 \qquad [9]$$

is the density of the system, sum of the modulus squared of the single-particle wave functions, solutions of the Schrödinger equation

$$\begin{aligned} &\left(-\frac{\hbar^2}{2m} \nabla_r^2 + U_H(r) \right) \varphi_j(\boldsymbol{r}) \\ &\quad = -\frac{\hbar^2}{2m} \nabla_r^2 \varphi_j(r) + \sum_{i \in \text{occ}} \int d^3r' \varphi_i^*(\boldsymbol{r}') \\ &\qquad \times v(|\boldsymbol{r} - \boldsymbol{r}'|) \varphi_i(\boldsymbol{r}') \varphi_j(\boldsymbol{r}) \\ &\quad = \varepsilon_j \varphi_j(\boldsymbol{r}) \end{aligned} \qquad [10]$$

The sum in eqn [9] is over all the occupied states, while $v(|\boldsymbol{r} - \boldsymbol{r}'|)$ is the nucleon–nucleon potential (two-body interaction, cf. **Figure 1**). In other words, at equilibrium the system of particles displays a self-consistent relation between density $\rho(r)$ and potential $U(r)$, mediated by the two-body interaction $v(|\boldsymbol{r} - \boldsymbol{r}'|)$. The Hartree potential $U_H(r)$ reproduces rather well, the main features of the empirical Saxon–Woods potential for level close to ε_F.

Equations [9] and [10] are self-consistent partial differential equations, to be solved by iteration, starting from an ansatz for $U_H(r)$ (e.g., square well potential).

Constrained Hartree Theory

It is to be noted that in solving eqns [8]–[10], one has to specify the shape of the system, for example, whether the system is expected to be spherical or deformed. That is, the Hartree theory is always a constrained Hartree theory, in the sense that one looks for a minimum of energy for the particles moving in a potential whose density is either spherical symmetric or behaves as a tensor of rank L. It should be noted that not all shape constrains lead to a self-consistent solution.

For a closed-shell system, it is quite natural that the absolute minimum of the system is spherical (cf. **Figure 4a**), while a system with a number of nucleons outside the closed shell will deform under the polarization effect of these nucleons, just as the Moon and the Sun polarize the Earth (Jahn–Teller effect, cf. **Figure 4b**). In this case, and assuming a quadrupole, axial symmetric deformation,

$$R = R_0(1 + \beta_2 Y_{20}(\theta, \phi)) \qquad [11]$$

is the radius of the Saxon–Woods potential and the system defines a privileged direction in space, violating rotational invariance, in spite of the fact that all nucleons, as well as the Hamiltonian introduced in eqn [1] are invariant with respect to rotations. This result again is an example of the phenomenon of spontaneous symmetry breaking.

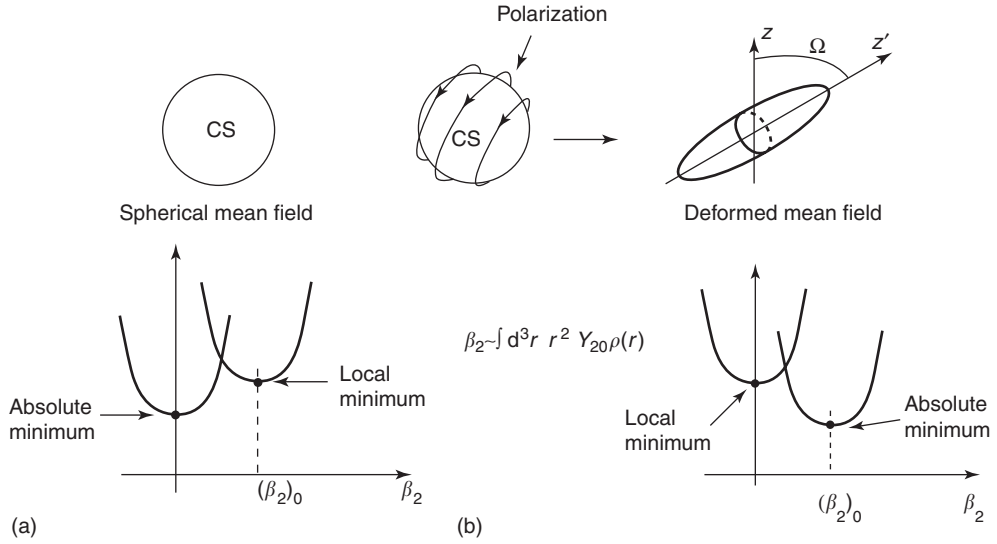

Figure 4 Schematic representation of the shapes of closed-shell (a) and open-shell (b) nuclei. The behavior of the total Hartree energy is also shown as a function of a deformation parameter, in this case the quadrupole deformation parameter.

The ground-state wave function, resulting from the filling of the lowest single-particle orbits of a deformed Saxon–Woods potential (eqns [5], [6] and [10], with $U_{\mathrm{H}}(r) = U(r)$ and [11]), can be written as

$$\Phi_0 = \prod_{i=1}^{A} \varphi_{\nu_i}(\boldsymbol{r}_i) \qquad [12]$$

It is a wave packet of different angular momenta, being associated with fixed values of the Euler angles Ω (**Figure 4b**), that is,

$$\Phi_0(\Omega) = \sum_I c_I \Psi_I \qquad [13]$$

It can be shown that there is a term in the residual interaction $(v - U)$, neglected in H_{MF}, which leads to zero-point fluctuations in the orientation of the system. Taking this term into account leads to solutions of H which transform in an irreducible way with respect to rotations, that is,

$$\Phi_{IMK}(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_A) \sim \int d\Omega \mathscr{D}^{I*}_{MK}(\Omega)\Phi_0(\Omega; \boldsymbol{r}_1, \ldots, \boldsymbol{r}_A) \qquad [14]$$

Here, $\mathscr{D}^{I*}_{MK}(\Omega)$ is a rotational matrix, $\Omega \sim (\theta, \phi, \psi)$ the corresponding Euler angles, K and M being the projections of the total angular momentum I on the intrinsic axis z' fixed to the body and on the laboratory axis z, respectively (cf. **Figure 5**). The states described by the wave function Φ_{IMK} are the members of a rotational band (**Figure 6**) associated with the different, quantized, frequencies of rotation. Rotational

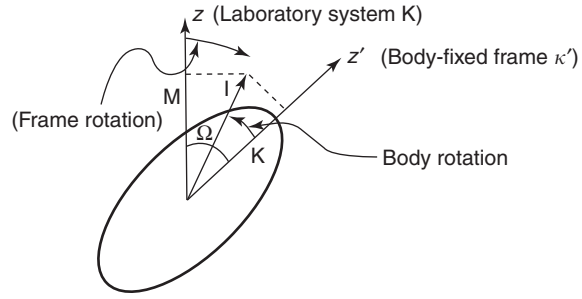

Figure 5 Schematic representation of a deformed rotating nucleus with angular momentum I, and with projection K on the body-fixed frame and M on the laboratory frame.

bands of this type have been observed systematically throughout the mass table.

The mean-field solutions Φ_{IMK} fulfill the requirement that the eigenfunctions of a Hamiltonian, which is invariant with respect to a group of symmetry (rotation group in the present case), should transform according to the irreducible representations of this group, that is, they must behave as a tensor with respect to rotations.

From a mathematical point of view, one can say that Ω and I being conjugate variables, one can choose which one to conserve in working out the solution of the problem. In the present case, it turns out that it is simpler to solve the problem in a representation in which Ω has a fixed value (and, consequently, I is completely indefinite, $\Delta\Omega\Delta I \geqslant \hbar$). Once this solution is found, one can, through a change of representation (Fourier transform), go to the representation in which I is a good quantum number. This is precisely what is accomplished through the integral (projection) given in eqn [14]; a projection which is

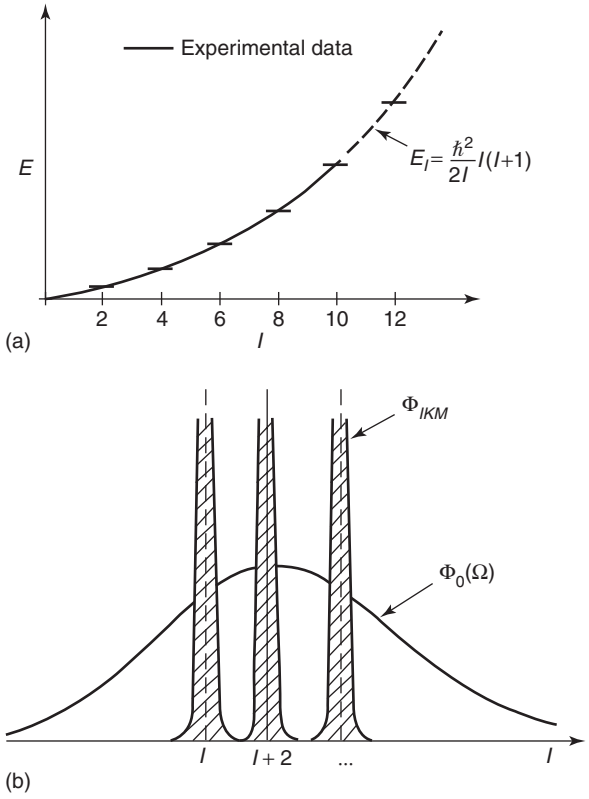

Figure 6 Schematic representation of nuclear rotational bands (a) and of the wave packet $\Phi_0(\Omega)$ of good angular momentum eigenstates Φ_{IKM}.

equivalent to

$$\Phi_{IMK} \sim \int \mathrm{d}\Omega \, \mathrm{e}^{-\mathrm{i}\boldsymbol{\Omega}\cdot\boldsymbol{I}} \Phi_0(\Omega) \qquad [15]$$

in keeping with the fact that

$$\mathscr{D}^{I*}_{MK}(\Omega) = \langle IK|\exp(-\mathrm{i}\boldsymbol{\Omega}\cdot\boldsymbol{I})|IM\rangle \qquad [16]$$

the operator

$$\mathscr{R}(\Omega) = \mathrm{e}^{-\mathrm{i}\boldsymbol{\Omega}\cdot\boldsymbol{I}}$$

generating a general rotation in space.

From a physical point of view, nuclear rotational motion is associated with a spontaneous breaking of rotational symmetry (deformation), a phenomenon which is at the basis of the variety of collective modes displayed by the nuclear many-body system.

In the description of many-body systems having a shape deviating from spherical symmetry (non-spherical nuclei, molecules, etc.), it is convenient to employ an intrinsic (or body-fixed) coordinate frame (**Figure 5**). The transformation of operators from the fixed frame (the laboratory system) to the intrinsic frame involves special features as a result of the fact that the orientation angles of the intrinsic frame are to be regarded as dynamical variables. The states of orientation can be specified by the angular variables or by the associated angular momenta.

In fact, the state of orientation of the body-fixed system is completely specified by the three angular momentum quantum numbers *IKM*, representing the conjugate variables of the three orientation angles $\Omega = (\phi, \theta, \psi)$.

Hartree–Fock Theory

Because nucleons are fermions, the product $\varphi_i(\boldsymbol{r}')\varphi_j(\boldsymbol{r})$ appearing in eqn [10] has to be replaced by the antisymmetric product $\varphi_i(\boldsymbol{r}')\varphi_j(\boldsymbol{r}) - \varphi_i(\boldsymbol{r})\varphi_j(\boldsymbol{r}')$. In this way, a particle does not interact with itself, and eqn [10] can be written as

$$\left[-\frac{\hbar^2}{2m}\nabla_r^2 + U_{\mathrm{H}}(r)\right]\varphi_j(\boldsymbol{r}) + \int \mathrm{d}^3r' U_x(\boldsymbol{r},\boldsymbol{r}')\varphi_j(\boldsymbol{r}') = \varepsilon_j\varphi_j(\boldsymbol{r}) \qquad [17]$$

where the nonlocal potential

$$U_x(\boldsymbol{r},\boldsymbol{r}') = -\sum_{i\in\mathrm{occ}} \varphi_i^*(\boldsymbol{r}')v(|\boldsymbol{r}-\boldsymbol{r}'|)\varphi_i(\boldsymbol{r}) \qquad [18]$$

is the so-called exchange or Fock potential.

It is, as a rule, not simple to deal numerically with nonlocal potentials. There are a number of ways in which one can make local U_x, for example in the LDA. Another way is through the so-called *k*-mass. In fact, for most purposes the effect of the term containing U_x in eqn [17] can be taken into account by replacing m in the kinetic energy term by

$$m_k = m\left(1 + \frac{m}{\hbar^2 k}\frac{\partial \tilde{U}_x}{\partial k}\right)^{-1} \qquad [19]$$

where $\tilde{U}_x(k)$ is the Fourier transform of the exchange potential. Making use of eqn [6] ($U = U_0 + V_1((N-Z)/A)\tau_z + 0.4E$) and of the fact that $E = (\hbar^2/2m)|k^2 - k_{\mathrm{F}}^2|$, one obtains

$$m_k \sim 0.7m \qquad [20]$$

The (local) equation

$$\left(-\frac{\hbar^2}{2m_k}\nabla_r^2 + U'(r)\right)\varphi_j(\boldsymbol{r}) = \varepsilon_j\varphi_j(\boldsymbol{r}) \qquad [21]$$

with $U'(r) = (m/m_k)U_H(r)$, leads to a set of levels which display the following properties:

1. the sequence of levels essentially coincides with those observed experimentally;
2. the density of levels coincide also with that observed experimentally for single-particle states with $E = |\varepsilon - \varepsilon_F| > 5$–10 MeV but is much lower for states with $E \leqslant 5$ MeV (valence levels); and
3. in the mean-field theory, all levels are sharp (infinite mean free path) while, experimentally, levels with $E > 5$–10 MeV display a damping width, that is, a finite lifetime.

The result (1) is quite natural, as $U_H(r)$ is quite similar to a Saxon–Woods potential with the parameters given in connection with eqns [5] and [6]. The property (2) emerges because a Schrödinger equation with $m = M$ (the bare nucleon mass) and a Saxon–Woods potential of depth $U + 0.4E$ gives essentially the same single-particle levels as a Schrödinger equation with $m \sim 0.7M$ and depth equal to $1.4U$ does. This result explains the agreement between theory and experiment concerning the density of levels with $E > 5$–10 MeV.

On the other hand, the density of levels of a Schrödinger equation with $m = M$ and depth U is much higher than the one with $m_k = 0.7M$, as the energy differences $\varepsilon - \varepsilon_F$ resulting from the m_k Schrödinger equation are $\sim(\varepsilon - \varepsilon_F)/0.7$.

Properties (2) and (3) are intimately connected with the fact that the mean-field theory defines a rigid surface, that is, where nucleons reflect elastically on it and each orbital closes on itself (cf. **Figure 7**), the resulting mean free path being infinite. In other words, when considering the motion of an individual nucleon, the self-consistency existing between density and potential (cf. eqn [8]), guarantees that the motions of the $A - 1$ remaining particles adjust at each instant of time to allow a nucleon to move independently of the others, filling their pushings and pullings to change momentum at the surface.

Now, the nuclear surface can be viewed as a quantal membrane with a surface tension $\gamma \approx 1$ MeV fm^{-2}. It is likely that it can fluctuate collectively, thus leading to an effective increase of the nuclear radius and thus to a decrease of the kinetic energy of the nucleons – in other words, to an effective increase of the single-particle level density.

Zero-point fluctuations are also expected to lead to a damping width of single-particle levels lying away from $\varepsilon_F (> 5$ MeV). In fact, assuming an orbital concentrated along the equator, the state will feel a wider and a narrower nucleus, as a function of time, thus giving rise to a distribution of the single-particle strength (cf. **Figure 8**).

Diagonalization of the Complete Hamiltonian

A possible way of obtaining the "exact" wave function of the system is to diagonalize the residual interaction $(v - U)$ in a complete basis of determinants $\Phi_n^0(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_A)$ built from single-particle wave functions $\varphi_\nu(\boldsymbol{r})$, solutions of the mean-field Hamiltonian $H_{MF} = T + U$ (cf. **Figure 9**). In other words, one first calculates the absolute and the local minima and associated wave functions of the constrained mean-field Hamiltonian. In this basis, one calculates the matrix elements of $(v - U)$, that is,

$$\int \mathrm{d}^3\{r_i\}\Phi_n^0(\{\boldsymbol{r}_i\})(v - U)\Phi_{n'}^0(\{\boldsymbol{r}_i\}) = \langle v_1 v_2|(v - U)|v_{1'} v_2\rangle O^{A-2} \qquad [22]$$

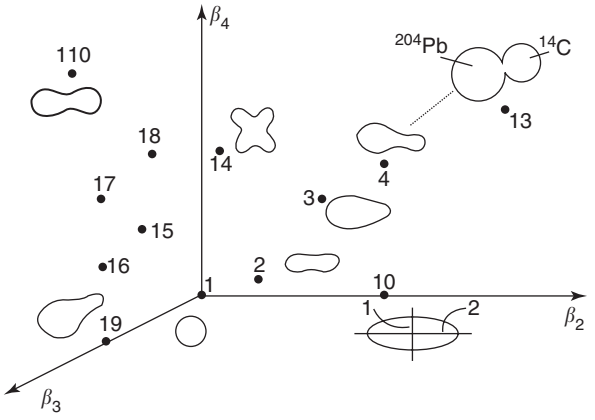

Figure 9 Schematic representation of the space of mean-field solutions of a (heavy) atomic nucleus as a function of the quadrupole (β_2), octupole (β_3), hexadecapole (β_4), etc., deformation parameters.

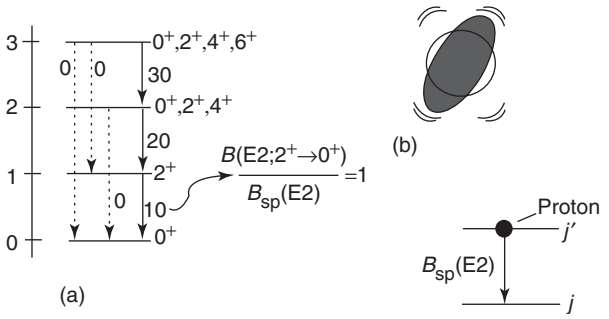

Figure 10 Schematic representation of harmonic quadrupole vibrations containing up to three phonons. The transition probabilities (e.g., $B(E2;2\rightarrow 0) = 10$) is measured in single-particle units implying that it is ten times stronger than a transition induced by the jump of a single proton from an excited state j' to a state j of lower energy.

where $O = \int \mathrm{d}^3 r(\varphi_\nu(\boldsymbol{r}))^*_n(\varphi_{\nu'}(\boldsymbol{r}))_{n'}$ is the overlap between two single-particle wave functions associated with the local minima n and n'. Diagonalizing the resulting matrix, one obtains

$$\Phi = \sum_n a^0_n \Phi^0_n \qquad [23]$$

which is the "exact" solution of the problem.

In fact, to obtain such a solution, one should, in principle, also include particle–hole (and eventually "many particle–many hole") states of the different local and the absolute minimum. In any case, the function Φ given above provides an accurate description of the exact ground state of the system.

Within this picture, the phenomenon of fission and of α- and exotic decay (e.g., of the process $^{223}\mathrm{Ra}\rightarrow{}^{209}\mathrm{Pb} + {}^{14}\mathrm{C}$) are associated with the probabilities $|a^0_{110}|^2$, $|a^0_4|^2$, and $|a^0_{13}|^2$, respectively, associated with conformations in space where a nucleus is necking in (• 1 1 0), or has a bulge of 2 protons and 2 neutrons (• 4), or corresponds to a ^{14}C nucleus on the surface of ^{209}Pb (•13). To achieve such conformations, the system has to move around a number of pairs of particles equal to the emitted particle (e.g., about half of the nuclear mass number in the case of symmetric fission). This corresponds to a crossing of the same number of empty and occupied states as a function of the deformations. The liquid-drop model (surface tension $\gamma = 1\,\mathrm{MeV\,fm^{-2}}$) can be used to calculate the restoring force associated with these deformations, while the inertia is determined by the pairing correlation (superfluidity) of the nucleons (see section on pairing).

Collective Vibration

In the nucleon–nucleus scattering experiments used to determine the (empirical) single-particle potential $U(r)$, one looks only at one reaction channel, namely, the elastic channel, where neither energy nor angular momentum is transferred between the projectile and the target, but only linear momentum is. Of course, there are, in general, other channels which are open at any given bombarding energy, and which act on the elastic (entrance) channel to drain intensity from it (absorption, imaginary part of the optical potential).

Now the focus is on the inelastic channel. Reactions of the type $A(p,p')A^*$, where not only linear momentum (elastic scattering) but also energy and angular momentum are exchanged (inelastic scattering) between a proton p and a nucleus A, which is left in an excited state A^*, have shown that the nuclear surface can vibrate as a whole in well-defined (normal) modes. In particular, quadrupole vibrations, of which states of up to three phonons have been observed (cf. **Figure 10**).

The experimental data can be parametrized at profit making use of the (empirical) harmonic oscillator Hamiltonian

$$H_{\mathrm{coll}} = \sum_{LM}\left(\frac{\pi^2_{LM}}{2D_L} + \frac{|\alpha_{LM}|^2}{2C_L}\right) \qquad [24]$$

where D_L and C_L are the inertia and the restoring forces of the mode with multipolarity L. Note that the static quadrupole deformation of the mean field (eqn [11] and **Figure 5**) can be viewed as a quadrupole vibration with a restoring force C_L that becomes zero.

The parameters C_L and D_L (which can also be calculated by making use of $(v - U)$, cf. the section

on collective vibrations), can be determined from the experimental data, that is, from the energy $\hbar\omega_L$ and the transition probability $B(EL; 0 \rightarrow L)$ of the modes, where

$$\hbar\omega_L = \hbar\sqrt{\frac{C_L}{D_L}} \qquad [25]$$

and

$$B(EL; 0 \rightarrow L) \sim |\langle n_L = 1|\alpha_{LM}|0\rangle|^2 = \frac{\hbar\omega_L}{2C_L} \sim \beta_L^2 \qquad [26]$$

in keeping with the fact that the coordinate operator of a harmonic oscillator can be written in second quantization as

$$\alpha_{LM} = \sqrt{\frac{\hbar\omega_L}{2C_L}}(\Gamma_{LM}^\dagger + \Gamma_{LM}) \qquad [27]$$

Here $|LM\rangle = |n_L = 1\rangle = \Gamma_{LM}^\dagger|0\rangle$ is the one-phonon state, $\Gamma_{LM}^\dagger$ and Γ_{LM} being the creation and annihilation boson operators fulfilling the commutation relation

$$[\Gamma_{LM}, \Gamma_{LM}^\dagger] = 1 \qquad [28]$$

In other words, α_{LM} is the coordinate of the harmonic oscillator (Dirac representation). The Hamiltonian H_{coll} (eqn [24]) can then be written as

$$H_{\text{coll}} = \sum_{LM}\left(\Gamma_{LM}^\dagger\Gamma_{LM} + \frac{1}{2}\right)\hbar\omega_L \qquad [29]$$

Consequently, with each degree of freedom there is associated a zero-point energy $\frac{1}{2}\hbar\omega_L$ and thus a zero-point fluctuation (cf. **Figure 10b**) leading to fluctuations of the nuclear radius (conserving volume so as to keep the density unchanged), which can be parametrized as (cf. also eqn [11])

$$R = R_0\left(1 + \sum_{LM}\alpha_{LM}Y_{LM}^*(\hat{r})\right) \qquad [30]$$

in keeping with the fact that the spherical harmonics provide a complete basis of eigenfunctions of angular momentum.

Beyond Mean Field: Particle–Vibration Coupling

Inserting the expression given in eqn [30] in the expression of the empirical potential given in eqn [5] and expanding to lowest order in α_{LM} (note that $\beta_L^2 \ll \beta_L$, where $\beta_L = \sqrt{2L+1}\sqrt{\hbar\omega_L/(2C_L)}$), one obtains

$$H = H_M + H_{\text{coupl}} + H_{\text{coll}} \qquad [31]$$

where

$$H_{\text{coupl}} = -\kappa\hat{\alpha}\hat{F} \qquad [32]$$

with

$$\hat{F} = \sum_{\nu_1\nu_2}\langle\nu_1|F|\nu_2\rangle a_{\nu_1}^\dagger a_{\nu_2} \qquad [33]$$

and

$$F = -\frac{1}{\kappa}R_0\frac{\partial U(r)}{\partial r}Y_{LM}^*(\hat{r}) \qquad [34]$$

The Hamiltonian H_{coupl} thus couples the motion of a single nucleon with the collective vibrations of the surface, with a matrix element (cf. **Figure 11**):

$$\langle n_\alpha = 1, \nu'|H_{\text{coupl}}|\nu\rangle = \Lambda_\alpha\langle\nu'|F|\nu\rangle = \langle n_\alpha = 1, \nu\nu'|H_{\text{coupl}}|0\rangle \qquad [35]$$

where

$$\Lambda_\alpha = -\kappa\sqrt{\frac{\hbar\omega_\alpha}{2C_\alpha}} \sim -\frac{\kappa\beta_\alpha}{\sqrt{2L_\alpha + 1}} \qquad [36]$$

is the particle–vibration coupling strength. Because $\beta_L^2 \ll \beta_L$, one can usually treat the particle–vibration coupling in the weak coupling situation. Consequently, H_{coupl} can be treated in the perturbation

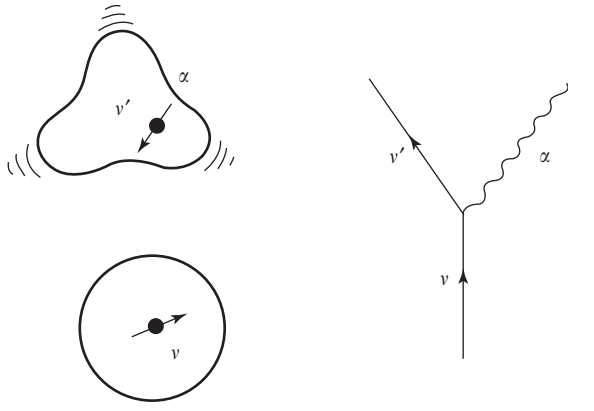

Figure 11 Schematic representation of the process by which a nucleon excites the vibrations of the surface.

theory. To second order, one finds

$$\left(-\frac{\hbar^2}{2m}\nabla_r^2 + U_{\mathrm{H}}(r)\right)\varphi_{\gamma}(r) + \int \mathrm{d}^3r' U_x(\boldsymbol{r},\boldsymbol{r}')\varphi_j(\boldsymbol{r}') + (\Delta E + \mathrm{i}W_j)\varphi_j(\boldsymbol{r}) \sim \left(-\frac{\hbar^2}{2m_k}\nabla_r^2 + U_{\mathrm{H}}''(r) + \Delta E_j + \mathrm{i}W_j\right)\varphi_j(\boldsymbol{r}) \quad [37]$$

$$= \varepsilon_j\varphi_j(\boldsymbol{r}), \quad \left(U_{\mathrm{H}}'' = \frac{m}{m_k}U\right) \quad [38]$$

where (cf. **Figure 12**) $\Delta E_j^{(\omega)}$ and $W_j^{(\omega)}$ are the real and imaginary contributions to the self-energy calculated in the second-order perturbation theory.

For most purposes, ΔE can be treated in terms of an effective mass

$$m_\omega = m(1+\lambda) \quad [39]$$

where

$$\lambda = -\frac{\partial \Delta E}{\partial \omega} \quad [40]$$

is the mass enhancement factor, while $Z_\omega = m/m_\omega$ is the quasiparticle strength (discontinuity of the Fermi energy).

Consequently, eqn [38] can be rewritten as

$$\left(-\frac{\hbar^2}{2m^*}\nabla_r^2 + U_{\mathrm{H}}' + \mathrm{i}W(\omega)\right)\varphi_j(\boldsymbol{r}) = \varepsilon_j\varphi_j(\boldsymbol{r}) \quad [41]$$

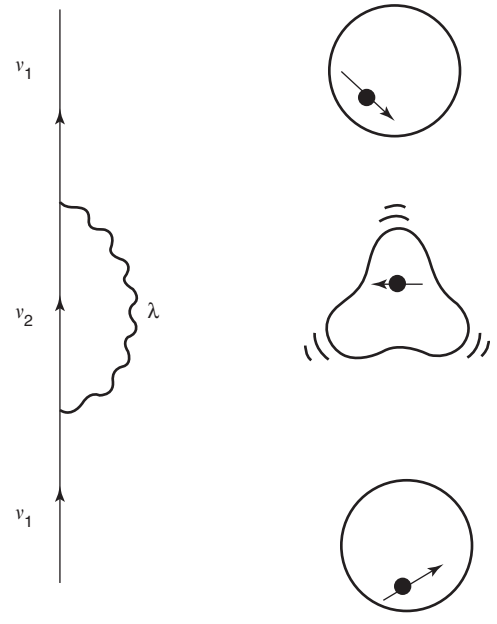

Figure 12 Self-energy graph for a single particle.

with

$$m^* = \frac{m_k m_\omega}{m} \quad [42]$$

and $U_{\mathrm{H}}' = (m/m^*)U$. Because $\lambda \sim 0.5$ (i.e., the dressed single-particle m_ω is heavier than the bare nucleon, as it has to carry a vibration along), $m^* \approx 1$, and $Z_\omega \approx 0.7$. Furthermore, due to the fact that $\hbar\omega_\alpha \approx 2$–$2.5$ MeV, the range of single-particle energy $E = |\varepsilon - \varepsilon_{\mathrm{F}}|$ over which the particle–vibration coupling processes displayed in **Figure 12** is effective and is approximately $\pm 2\hbar\omega_\alpha \sim 4$–$5$ MeV.

It should be noted that ΔE_j indicates the shift in energy of the energy centroid of the "dressed" single-particle state due to the coupling to the intermediate (more complex states) $\alpha' \equiv (\nu', \alpha)$, while $\Gamma = 2W$ measures the energy range over which the single-particle state spreads due to the coupling. While all states contribute to ΔE ("off the energy shell process," i.e., processes which do not conserve the energy), essentially only "on the energy processes," that is, processes which conserve the energy, contribute to Γ. The quantity $\hbar/\Gamma$ is the lifetime of the single-particle state, while Γ is the range of energy over which the single-particle state is distributed due to processes of the type shown in **Figure 12** (cf. also **Figure 8**).

Induced Interaction

A nucleon at the Fermi energy which creates, by bouncing inelastically off the nuclear surface, has no other choice but to reabsorb it at a later instant of time (virtual process, **Figure 12**). In the presence of another nucleon, the vibration excited by one nucleon may be absorbed by the second one (**Figure 13**),

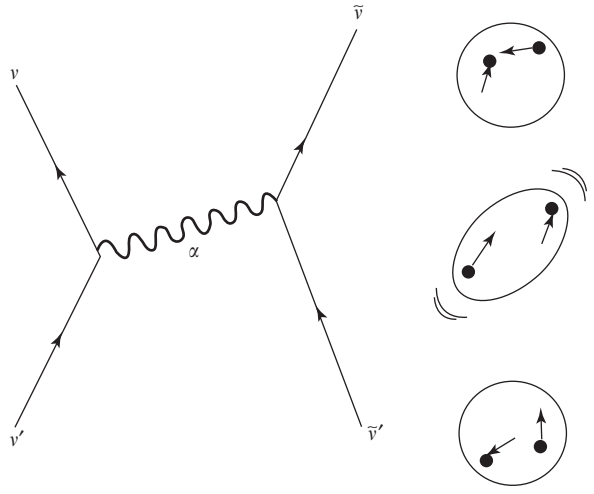

Figure 13 Schematic representation of the exchange of phonons between nucleons.

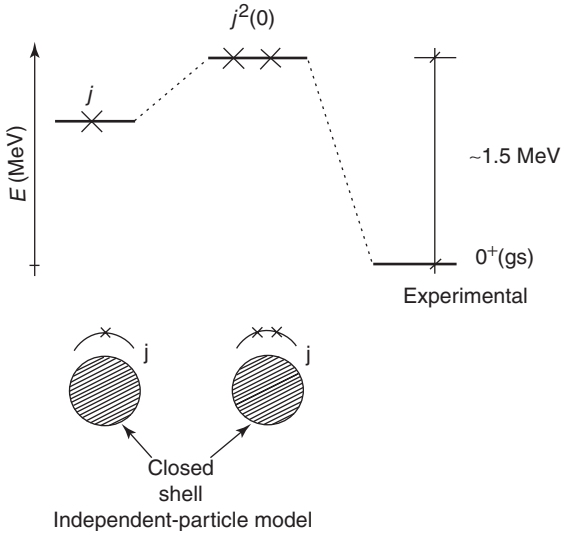

Figure 14 Schematic representation of the predictions of the independent-particle model for one and two particles outside the closed shell, in comparison with the experimental findings (e.g., for the case of ^{210}Pb, where $j = g_{9/2}$).

the exchange of a vibration leading to an (induced) interaction.

Simple estimates of this induced interaction lead to the case of, for example, ^{210}Pb, that is, of two neutrons outside the closed-shell nucleus ^{208}Pb, to values of the matrix element for pairs of particles coupled to angular momentum $J^\pi = 0^+$ of nearly -0.8 MeV, when summed over all the different multipolarities of low-lying collective surface vibrations which have been observed ($L^\pi = 2^+, 3^-, 5^-$). The fact that one considers particles coupled to angular momentum zero is because the associated orbitals have maximum overlap, which best considers the (pairing) interaction. In the case of two particles outside the closed shell, one would then expect the ground state to display, due to this mechanism, a correlation energy of 0.8 MeV larger than that predicted by the independent-particle model (cf. **Figure 14**). Experimentally, this correlation is ~ 1.5 MeV, indicating that the bare nucleon–nucleon interaction provides about half of the pairing interaction required by the experimental findings.

From this result, one can conclude that the pairing interaction induced by the process depicted in **Figure 13**, renormalizes the bare nucleon–nucleon potential significantly.

Collective Vibrations: Microscopic Description

In a self-substained vibration (normal mode), the variations of the potential must be self-consistent

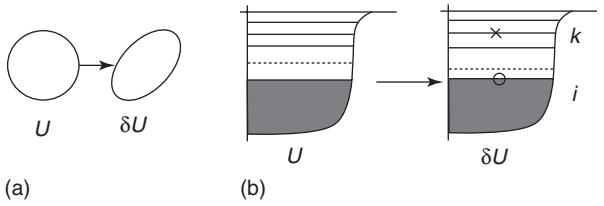

Figure 15 Complementary views of the nucleus: (a) as a system confined by an elastic surface, or (b) as a many-particle determinant.

with those of the density. In other words, the relation given in eqn [8] is also required to be valid for the dynamical situation, that is,

$$\delta U = \int \mathrm{d}^3 r' \delta\varrho v(|\boldsymbol{r} - \boldsymbol{r}'|) \qquad [43]$$

In fact, one can excite the system: (a) by acting collectively on the nucleus and deforming slightly the potential U (thus leading to δU), (b) promoting a particle from below to above the Fermi energy with a given probability (thus leading to $\delta\varrho$) (**Figure 15**), in keeping with the fact that a single-particle external field can change the state of motion of one particle at a time.

Consequently, collective vibrations in nuclei can be viewed as correlated particle–hole excitation, created by the operator

$$\Gamma^\dagger_\alpha = \sum_{ki} X^\alpha_{ki}\Gamma^+_{ki} + Y^\alpha_{ki}\Gamma_{ki} \qquad [44]$$

expressing the fact that while the collective modes look very simple in the collective representation of vibrations, they appear quite a bit more complicated (although entirely microscopic), in the particle–hole basis of the operators $\Gamma^+_{ki} = a^\dagger_k a_i$ and $\Gamma_{ki} = a^\dagger_i a_k$, where k denotes a level above the Fermi energy and i one below (cf. **Figure 15b**). Within the approximation where Γ^+_α and Γ_α fulfill boson commutation relation, Γ^+_{ki} and Γ_{ki} also are considered as (quasi-) boson operators. Within this approximation, and making use of the unitary transformation expressed by eqn [44], one can show that $\hat{\alpha} = \hat{F}$. Consequently,

$$H_{\mathrm{coupl}} = -\kappa\hat{\alpha}\hat{F} = -\kappa\hat{F}\hat{F} \qquad [45]$$

From the relations

$$[H_{MF} + H_{\mathrm{coupl}}, \Gamma^+_\alpha] = \hbar\omega_\alpha\Gamma^+_\alpha$$

and

$$[\Gamma_\alpha, \Gamma^+_{\alpha'}] = \delta(\alpha, \alpha')$$

valid for harmonic vibrations, one obtains, for the case of, for example, a dipole vibration

$$\hbar\omega_{\mathrm{D}} \sim \frac{80}{A^{1/3}}\ \mathrm{MeV} \sim \frac{100}{R}\ \mathrm{MeV} \qquad [46]$$

($R = 1.2A^{1/3}$ fm), a number which is very close to the experimental value (cf. **Figure 16**). The inverse dependence on the radius (momentum dependence) is typical of elastic vibrations.

In the case of quadrupole vibrations, one obtains

$$\hbar\omega_{\mathrm{Q}} = \frac{60}{A^{1/3}}\ \mathrm{MeV} \approx \frac{72}{R}\ \mathrm{MeV} \qquad [47]$$

which provides an overall account of the experimental findings.

In other words, the nucleus reacts elastically with a dipole mode of energy $\sim$16 MeV and carrying $\sim$100% of the energy weighted sum rule (EWSR) and with $\sim$l2 MeV and again $\sim$100% of the EWSR to an external quadrupole field.

While the mean-field theory predicts the states to be sharp, experimentally, they display a resonant behavior with a width of the order of 30% of the centroid energy. Similar to what was found in the case of single-particle motion, the coupling of the giant resonance to the zero-point fluctuations of the ground state accounts for the spreading width. This is because elastic vibrations are inversely proportional to the nuclear radius (cf. eqn [47]). In particular, in the case of the dipole resonance, quadrupole fluctuations of the nuclear surface are particularly effective (note that a 1^- can, to give again 1^-, couple only to 0^+ and to 2^+).

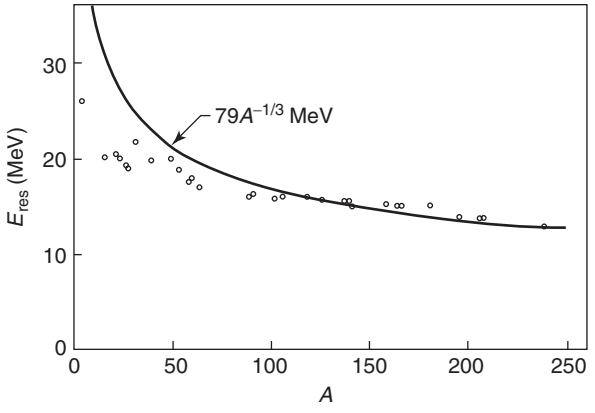

Figure 16 Schematic representation of the energy centroid of the GDR (giant dipole resonance). The open circles represent experimental data.

Pairing: Experimental Facts

The nuclear binding energy is found to exhibit a systematic variation, depending on the evenness or oddness of Z and N,

$$\delta\mathscr{B} = \begin{cases} \Delta & Z \text{ even}, N \text{ even} \\ 0 & A \text{ odd} \\ -\Delta & Z \text{ odd}, N \text{ odd} \end{cases} \qquad [48]$$

where

$$\Delta = -\frac{1}{2}\{\mathscr{B}(N-1,Z) + \mathscr{B}(N+1,Z) - 2\mathscr{B}(N,Z)\}$$

and $\mathscr{B}(N,Z)$ is the total binding energy and represents the difference between the observed mass $\mathscr{M}$ (or, equivalently, the total nuclear energy $\mathscr{E}$) in the ground state, and the masses of the separated nucleons,

$$\mathscr{M}(N,Z) = \frac{1}{c^2}\mathscr{E}(N,Z) = NM_n + ZM_p - \frac{1}{c^2}\mathscr{B}(N,Z)$$

The observed pairing energies (**Figure 17**) can be parametrized according to

$$\Delta \sim \frac{12}{\sqrt{A}}\ \mathrm{MeV} \qquad [49]$$

The large odd–even effect observed may be described in terms of pairwise correlations of identical particles coupled to angular momentum zero, which contribute an additional binding energy 2Δ per pair, for nucleons on top of the Fermi surface. Consistent with the above findings, the lowest noncollective excitations in even–even nuclei are found at an energy of $\sim 2\Delta$.

Pairing Interaction

A schematic interaction producing such an effect is the pairing force with constant matrix elements,

$$H_{\mathrm{p}} = -G \sum_{\nu_1 \nu' > 0} a^\dagger_\nu a^\dagger_{\bar{\nu}} a_{\bar{\nu}'} a_{\nu'} \qquad [50]$$

where the state $a^\dagger_{\bar{\nu}}|0\rangle = |\bar{\nu}\rangle$ is the time-reversal state to $a^\dagger_\nu|0\rangle = |\nu\rangle$.

The mean-field (BCS) solution leads to

$$(H_{\hat{p}})_{\mathrm{MF}} = U + H_{11} \qquad [51]$$

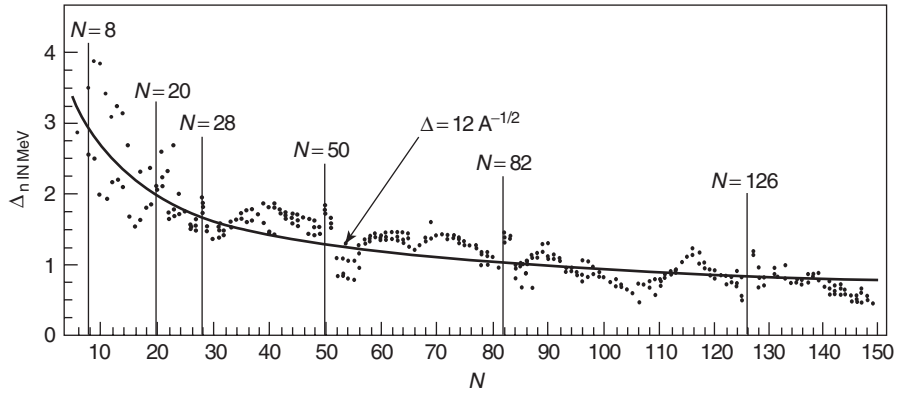

Figure 17 Odd–even mass difference for neutrons.

where

$$U = 2\sum_{v>0}(\varepsilon_v - \lambda)V_v^2 - \frac{\Delta^2}{G} \qquad [52]$$

and

$$H_{11} = \sum_{v>0} E_v \alpha_v^\dagger \alpha_v \qquad [53]$$

where

$$E_v = \sqrt{(\varepsilon_v - \lambda)^2 + \Delta^2} \qquad [54]$$

is the quasiparticle energy, while

$$\alpha_v^+ = U_v \alpha_v^+ - V_v \alpha_{\bar{v}}$$

is the quasiparticle creation operator. The occupation amplitudes U_v, V_v are

$$U_v = \frac{1}{\sqrt{2}}\left(1 + \frac{\varepsilon_v - \lambda}{E_v}\right)^{1/2}$$
$$V_v = \frac{1}{\sqrt{2}}\left(1 - \frac{\varepsilon_v - \lambda}{E_v}\right)^{1/2}$$

The parameters U_v and V_v which completely define the BCS mean-field solution of the pairing Hamiltonian depend on the Fermi energy λ and the gap parameter Δ. The equations determining these parameters are the number equation

$$N = \langle \mathrm{BCS}|\hat{N}|\mathrm{BCS}\rangle = 2\sum_{v>0} V_v^2 \qquad [55]$$

where

$$\hat{N} = \sum_{v>0} a_v^\dagger a_v \qquad [56]$$

is the particle-number operator, and the gap equation

$$\Delta = G\langle \mathrm{BCS}|P^+|\mathrm{BCS}\rangle = G\sum_{v>0} U_v V_v \qquad [57]$$

In other words, equations

$$\begin{aligned} N &= 2\sum_{v>0} V_v^2 \quad \text{(number equation)} \\ \frac{1}{G} &= \sum_{v>0}\frac{1}{2E_v} \quad \text{(gap equation)} \end{aligned} \qquad [58]$$

allow one to calculate λ and Δ from the knowledge of ε_v and G.

While the ground-state energy is equal to U, the energy of the lowest excited state, that is, that of a two-quasiparticle state, generalization of a particle–hole excitation in the case of normal ($G = 0$) systems, is

$$\begin{aligned} H_{11}|v_1 v_2\rangle &= H_{11}\alpha_{v_1}^\dagger \alpha_{v_2}^\dagger|\mathrm{BCS}\rangle \\ &= (E_{v_1} + E_{v_2})|v_1 v_2\rangle \end{aligned} \qquad [59]$$

Consequently, there are no excited states with energy less than 2Δ, the minimum value of $(E_{v_1} + E_{v_2})$.

By properly adjusting G for a given value of particles N, one can make this excitation coincide with twice the value given in eqn [49]. This value is

$$G \sim \frac{25}{A}\ \text{MeV} \qquad [60]$$

Making use of this value and of the empirical relation $\Delta = 12/\sqrt{A}$ MeV, one can write

$$\frac{\Delta^2}{G} \sim 5\ \text{MeV}$$

for the second term in eqn [52]. It should be noted that this gain in binding energy is partially compensated by an increase in single-particle energy

associated with the first term and by the fractional occupation of the single-particle levels around the Fermi surface. The summed effect amounts to only $\sim 1\,\text{MeV}$ ($\sim\Delta$) of extra binding energy acquired by the even–even system due to pairing with respect to the odd–even system. This quantity, which is very important to characterize the structure of a nucleus close to the ground state, is still very small compared to the total binding energy of the system ($\sim A \times 8\,\text{MeV} \approx 1\,\text{GeV}$).

In other words, a system of independent particles is affected only on a small region ($\sim 2\Delta$) around the Fermi energy as compared to this energy ($2\Delta/\lambda = 2\Delta/\varepsilon_F \sim 2-3\,\text{MeV}/36\,\text{MeV} \sim 0.1$). What is actually modified is the occupation of the single-particle levels around λ. For single-particle states fulfilling the condition $|\varepsilon_v - \lambda| \gg 1.5\Delta$, the system retains the single-particle properties. For single-particle states such that $|\varepsilon_v - \lambda| \lesssim 1.5\Delta$, the occupancy of the levels is strongly modified and the system is now made of nucleons coupled to angular momentum $J = 0$ (singlet states, i.e., $S = 0$ and $L = 0$, $J = L + S$). These pairs are known as Cooper pairs, and they behave like bosons. In nuclei, the number of Cooper pairs is small, typically 4–6. One would thus expect strong fluctuations of the associated pairing gap, fluctuations which may blur many of the sharp properties found in the case of infinite systems (bulk matter, thermodynamic limit).

BCS Wave Function

Because the wave function $|\text{BCS}\rangle$ is the quasiparticle vacuum, it does not have a fixed number of particles. In fact, making use of the gauge transformation

$$\mathscr{G}(\phi) = \mathrm{e}^{-(\mathrm{i}\hat{N}/2)\phi} \qquad [61]$$

which measures the particle-number properties associated with any operator or wave function, in the same way in which

$$\mathscr{R}(\Omega) = \mathrm{e}^{-\mathrm{i}\boldsymbol{I}\cdot\boldsymbol{\Omega}} \qquad [62]$$

probes the tensor properties of operators and of wave functions, one can determine the particle-number content of operators and wave functions. In particular,

$$a_v'^{\dagger} = \mathscr{G}(\phi) a_v^{\dagger} \mathscr{G}^{-1}(\phi) = \mathrm{e}^{-(\mathrm{i}/2)\phi} a_v^{\dagger} \qquad [63]$$

while

$$\begin{aligned} \mathscr{G}(\phi) H \mathscr{G}^{-1}(\phi) &= \mathscr{G}(\phi)(H_{\text{sp}} + H_{\text{p}})\mathscr{G}^{-1}(\phi) \\ &= H_{\text{sp}} + H_{\text{p}} \end{aligned} \qquad [64]$$

On the other hand,

$$\mathscr{G}(\phi) V_{\text{p}} \mathscr{G}^{-1}(\phi) = -\Delta(\mathrm{e}^{-\mathrm{i}\phi} P^{\dagger} + \mathrm{e}^{\mathrm{i}\phi} P) + \frac{\Delta^2}{G} \qquad [65]$$

and

$$a_v'^{\dagger} = \mathscr{G}(\phi) \alpha_v^{\dagger} \mathscr{G}^{-1}(\phi) = U_v \mathrm{e}^{(\mathrm{i}/2)\phi} a_v^{\dagger} - V_v \mathrm{e}^{(\mathrm{i}/2)\phi} a_{\bar{v}} \qquad [66]$$

In other words, while the total Hamiltonian $H_{\text{sp}} + H_{\text{p}}$ conserves the number of particles, neither the pairing mean field V_{p} nor the quasiparticle transformation does so. It is then not suprising that the wave function $|\text{BCS}\rangle$ is a wave packet in the number of particles and that the correct way to express it is in an intrinsic system of reference, that is,

$$\begin{aligned} &|\text{BCS}(\Phi = 0)\rangle_{\mathscr{K}'} \\ &\quad = \prod_{v>0} (U_v + V_v a_v'^{\dagger} a_{\bar{v}}'^{\dagger}) |0\rangle \\ &\quad = \prod_{v>0} (U_v + \mathrm{e}^{-\mathrm{i}\phi} a_v^{\dagger} a_{\bar{v}}^{\dagger}) |0\rangle \\ &\quad = \left(\prod_{v>0} U_v \right) \sum_n \mathrm{e}^{-\mathrm{i}n\phi} \left(\sum_{v>0} c_v a_v^{\dagger} a_{\bar{v}}^{\dagger} \right)^n |0\rangle \\ &\quad = |\text{BCS}(\Phi)\rangle_{\mathscr{K}} \end{aligned} \qquad [67]$$

The BCS state expressed in the intrinsic reference frame has gauge angle $\phi = 0$. It is equal to the BCS state referred to the laboratory system $|\text{BCS}(\phi)\rangle_{\mathscr{K}}$, which is then rotated by an angle ϕ. Consequently, the BCS wave function does not have a fixed number of particles, but a fixed orientation in gauge space (cf. **Figure 18**).

There is nothing wrong about this. In fact, one finds that it is easier to solve the pairing problem for fixed ϕ, and not N, in a similar way that another problem may be simpler to solve for fixed p instead of fixed r, or fixed Ω instead of I. Because ϕ and N are conjugate variables, in a similar way that p and x,

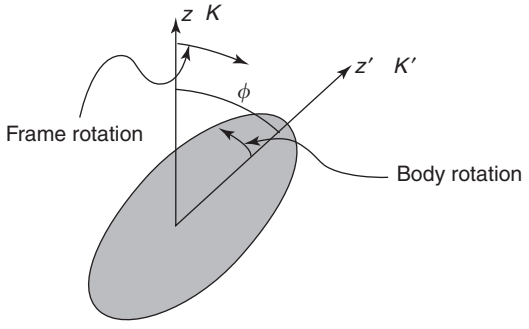

Figure 18 Schematic representation of the deformation in gauge space associated with the wave function $|\text{BCS}\rangle$ (eqn [67]).

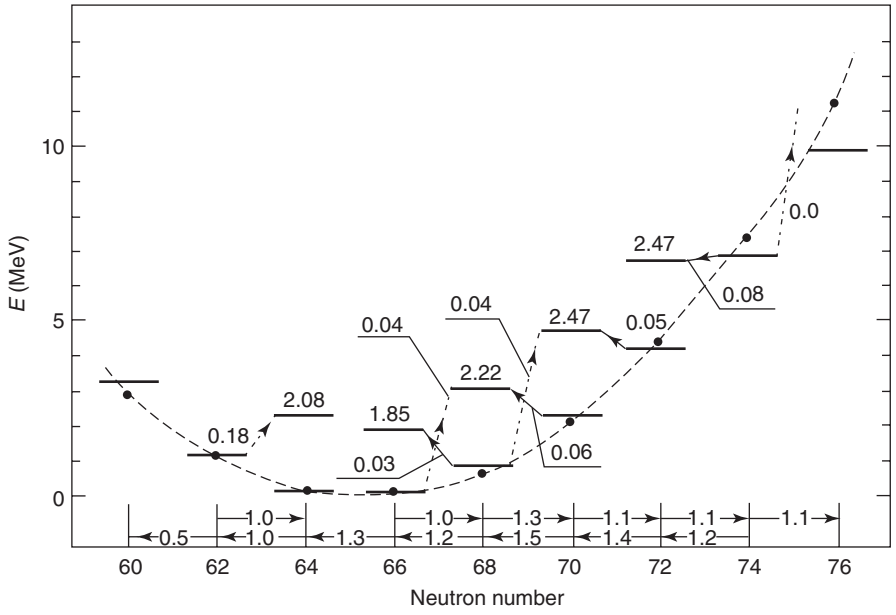

Figure 19 Experimental energies of the $J^{\pi} = 0^{+}$ states of the even Sn isotopes. The heavy drawn lines represent the values of the expression $E = -B(N) + E_{\text{exc}} + 8.58N + 45.3$ (MeV), $B(N)$ being the binding energies (in MeV) of the Sn isotopes. The dashed line represents the parabola $0.10(A - 65.4)^2$, which corresponds to a rotational energy parameter $\hbar^2/2\mathcal{J} = 0.10$ MeV. Also displayed is the excited pairing rotational band associated with the pairing vibrational mode. In all cases where more than one $J^{\pi} = 0^{+}$ state has been excited below 3 MeV in two-neutron transfer processes, the energy $\sum_i \sigma(0_i)E(0_i^+)/\sum_i \sigma(0_i^+)$ of the centroid is quoted, as well as the corresponding cross section $\sum_i \sigma(0_i^+)$. The quantity $\sigma(0_i^+)$ is the relative cross section with respect to the ground-state cross section. The numbers along the abscissa are the ground state (p, t) and (t, p) cross sections normalized to the ^{116}Sn(gs)$\leftrightarrow{}^{118}$Sn(gs) cross section.

and I and Ω are, one can transform the BCS solution so as to conserve the particle number through a Fourier transform. Thus, the solution of $H_{\text{sp}} + H_{\text{p}}$ with fixed particle number is then

$$|N_0\rangle_{\mathscr{K}} \sim \int \mathrm{d}\phi \mathrm{e}^{\mathrm{i}N_0/2}|\mathrm{BCS}(\phi)\rangle_{\mathscr{K}} \sim \left(\sum_{\nu>0} c_\nu a_\nu^\dagger a_{\bar{\nu}}^\dagger\right)^{N_0/2}|0\rangle \qquad [68]$$

These are the members of a pairing rotational band, that is, the ground states of a series of isotopes such as the Sn isotopes, which are strongly excited in two-particle transfer reaction (cf. **Figure 19**). In any case, the spontaneous symmetry breaking of particle conservation defines an emergent property in the nuclear system, not contained in the original Hamiltonian, namely, a generalized rigidity which defines a privileged orientation in gauge space, and which expresses itself in nature as a collective pairing rotational band.

Numerical Approximation and Analysis

C Brezinski, Université des Sciences et Technologies de Lille, Villeneuve d'Ascq, France

Introduction

When the solution of a mathematical problem cannot be obtained in an analytical form (e.g., the solution of a differential equation) or when it requires too many arithmetical operations (as the solution of a system of linear equations by Cramer's rule), then it is necessary to make use of a numerical method. Usually, such a method only provides an approximation of the solution. Numerical analysis is the branch of mathematics where constructive methods (that is methods able to construct effectively, numerically, the solution) are defined and studied.

Numerical approximation covers the approximation of functions in various senses (interpolation, best approximation, Padé approximation, etc.), the numerical solution of differential and integral equations, the computation of definite integrals, the solution of systems of linear and nonlinear equations, the computation of eigenelements, etc. It is beyond the scope of this article to enter into details and the aim of the article is to give a flavor of the domain and to describe the main ideas.

A numerical method is implemented on a computer. So, each arithmetical operation is affected by an error since computers work with numbers having a finite number of digits. So, the result which is finally obtained depends not only on the quality of the approximation used but also on the propagation of these rounding errors. Taking this point into account is fundamental when using a numerical method.

Approximation of Functions

In many situations, one needs to approximate a function f by another function g. The procedure to be used depends highly on the information on f and on the form of g. The function g can be a polynomial or a combination of given functions satisfying some conditions, or a rational function, or a spline (piecewise polynomials). If f is known at some given points x_i, then interpolation can be used. Interpolation determines the unknown parameters involved in g and provides approximations $g(x_i)$ of $f(x_i)$. If the numbers of parameters are less than the numbers of interpolation points, f can be approximated in the least squares sense. If the information on f is analytic, approximation in the sense of some norm can be used.

If the Taylor expansion of f around zero is known, a quite powerful procedure is Padé approximation. It is assumed that the formal expansion

$$f(z) = c_0 + c_1 z + c_2 z^2 + \cdots$$

is known. A rational approximation is derived with a numerator $N_p(z) = a_0 + \cdots + a_p z^p$ and a denominator $D_q(z) = b_0 + \cdots + b_q z^q$ so that the series expansion of $N_p(z)/D_q(z)$ agrees with the expansion of f as far as possible, which means

$$f(z)D_q(z) - N_p(z) = \mathcal{O}(z^{p+q+1})$$

Such a rational function is called a Padé approximant and it is denoted by $[p/q]_f(z)$. The coefficients of N_p and D_q given by

$$\begin{aligned} a_0 &= b_0 c_0 \\ a_1 &= b_0 c_1 + b_1 c_0 \\ &\vdots \\ a_p &= b_0 c_p + \cdots + b_q c_{p-q} \\ 0 &= b_0 c_{p+1} + \cdots + b_q c_{p-q+1} \\ &\vdots \\ 0 &= b_0 c_{p+q} + \cdots + b_q c_p a_0 \end{aligned}$$

with $c_i = 0$ for $i < 0$. Setting $b_0 = 1$ and solving the system formed by the last q equations gives the b_i. Then the a_i are directly obtained by the first p relations.

Padé approximants are widely used in many problems of mathematical physics.

Ordinary Differential Equations

Consider a Cauchy problem for a system of k ordinary differential equations

$$\begin{aligned} y'(x) &= f(x, y(x)), \quad x \in [a, b] \\ y(a) &= y_0 \end{aligned}$$

where $f : \mathbb{R} \times \mathbb{R}^k \mapsto \mathbb{R}^k$, $y \in \mathbb{R}^k$, and $y_0 \in \mathbb{R}^k$ is given.

A numerical method for the integration of this system consists in constructing approximations y_n of the exact solution $y(x_n)$ at some chosen points $a = x_0 < x_1 < \cdots < x_n < \cdots < x_N = b$ in the interval of integration. There are two types of procedures for obtaining these approximations: one-step methods (where y_{n+1} is deduced only from y_n) and multistep methods (where y_{n+1} depends on $y_n, \ldots, y_{n-p}$).

First choose a fixed step size $h = (b - a)/N$ and set $x_n = a + nh$ for $n = 0, \ldots, N$. Of course, for $y_0, \ldots,$

y_N to be approximations of $y(x_0), \ldots, y(x_N)$, the formula for computing y_{n+1} has to satisfy some properties, namely the consistency, the stability, and the convergence which means that the error tends to zero when h tends to zero. Another quite important property of a method is its order r which explains the behavior of the error with h, $y_n - y(x_n) = \mathcal{O}(h^r)$.

In a one-step method, the approximate solution is computed by

$$y_{n+1} = y_n + h\Phi(x_n, y_n, h), n = 0, \ldots, N-1$$

A Runge–Kutta method consists in

$$\begin{aligned} k_i &= f(x_n + \theta_i h, y_n + h\eta_i) \\ \eta_i &= a_{i1}k_1 + \cdots + a_{im}k_m \\ \Phi(x_n, y_n, h) &= c_1 k_1 + \cdots + c_m k_m \end{aligned}$$

If $a_{ij} = 0$ for $j \geqslant i$, the method is explicit (which means that each k_i can be computed separately) while, if not, it is implicit and the k_i are given as the solution of a system of (nonlinear) equations. Of course, an implicit method is much more difficult to implement but, in the case of a stiff differential equation (that is an equation whose solution varies rapidly), such an implicit method has to be used.

In a multistep method, $y_0, \ldots, y_{p-1}$ have first to be computed by a one-step method and then $y_p, \ldots, y_N$ are obtained by

$$a_0 y_n + \cdots + a_p y_{n+p} = h(b_0 f_n + \cdots + b_p f_{n+p})$$

for $n = 0, \ldots, N$–p, where $f_i = f(x_i, y_i)$. If $b_p = 0$ the method is explicit, otherwise it is implicit.

The main practical problem about the numerical integration of a differential equation concerns the precision of the approximate solution. If a desired precision has to be achieved, the first step is to choose the method. Then, h has to be chosen and adapted along the interval of integration in order to obtain the desired accuracy. This means, of course, that a procedure for estimating the error has to be implemented.

Integral Equations

Let g and K be two known functions. There are two kinds of integral equations depending whether the unknown function f appears only under the integral sign or also outside it. In these two kinds, two types arise depending on the interval of integration. If the interval of integration has fixed endpoints, a Fredholm equation is obtained.

$$\begin{aligned} \text{1st kind:} &\quad \int_a^b K(x,t)f(t)\,\mathrm{d}t = g(x) \\ \text{2nd kind:} &\quad f(x) - \lambda \int_a^b K(x,t)f(t)\,\mathrm{d}t = g(x) \end{aligned}$$

where $\lambda \neq 0$ is a parameter. If the right endpoint is a variable, a Volterra equation is obtained.

$$\begin{aligned} \text{1st kind:} &\quad \int_a^x K(x,t)f(t)\,\mathrm{d}t = g(x) \\ \text{2nd kind:} &\quad f(x) - \lambda \int_a^x K(x,t)f(t)\,\mathrm{d}t = g(x) \end{aligned}$$

Fredholm equations reduce to Volterra if the kernel K is such that $K(x, t) = 0$ for $x \leqslant t \leqslant b$.

To obtain approximations f_j of the function f at some points x_j, assume that the function g is known at some points x_i. So

$$g(x_i) = \int_a^b K(x_i, t)f(t)\,\mathrm{d}t, \quad i = 1, \ldots, N$$

and similarly for the other integral equations. The definite integral is evaluated by a quadrature formula

$$\int_a^b K(x_i, t)f(t)\,\mathrm{d}t \simeq \sum_{j=1}^{M} a_{ij} f(t_j)$$

Thus, the approximations $f_j \simeq f(t_j)$ is obtained by solving the system of linear equations

$$g(x_i) = \sum_{j=1}^{M} a_{ij} f_j, \quad i = 1, \ldots, N$$

If $N \neq M$, the system is solved in the least squares sense. Otherwise, a square system is obtained. However, it must be noticed that this system is usually ill-conditioned and thus preconditioning and/or regularization have to be used (see the next section). This is the case with the inversion of the Laplace transform, one of the most important integral equations.

Fredholm equations of the second kind can be solved by the method of successive approximations. If $\mathscr{K}$ denotes the integral operator which maps f into $\int_a^b K(x,t)f(t)$, then this integral equation is $(I - \lambda\mathscr{K})f = g$. So, f is given by its Neumann series

$$f = (I - \lambda\mathscr{K})^{-1} g = \left(I + \sum_{i=0}^{\infty} \lambda^i \mathscr{K}^i\right) g$$

In other terms, set $f_0 = g$ and then compute

$$f_i(x) = g(x) + \lambda \int_a^b K(x,t) f_{i-1}(t)\, \mathrm{d}t, \quad i = 1, 2, \ldots$$

This method converges if $\|\lambda \mathcal{K}\| < 1$.

Systems of Linear Equations

The choice of a method for solving a system of p linear equations in p unknowns, $Ax = b$, highly depends on the value of p. There are two classes of methods: direct methods and iterative methods.

When p is not too large (i.e., up to 10^4), an elimination procedure, such as Gaussian elimination, or Cholesky decomposition if the matrix is symmetric and positive definite, or Householder factorization, can be used. They all consist in transforming the system into an equivalent one (i.e., with the same solution) but with a matrix which is upper triangular. Then, such a system can be easily solved starting from the last equation.

When p is very large (several millions) and the matrix of the system comes out from the discretization, by finite differences or finite elements, of a partial differential equation, it is sparse (which means that most elements are zero). However, a direct method could not be used since the upper triangular matrix obtained by a direct method could be full. In that case, iterative methods are preferred. These methods split into two subclasses: relaxation methods and projection methods. Relaxation methods are nowadays mostly used as preconditioners (see below). Projection methods consist in generating a sequence of approximate solutions belonging to subspaces of increasing dimensions. Usually, these subspaces are Krylov subspaces and thus the name of such methods. Among them, the most popular are Lanczos method, the BiCGStab, and GMRES.

A fundamental topic of the solution of a system of linear equations is the condition number $\kappa(A) = \|A\| \cdot \|A^{-1}\|$ of the matrix A, a number greater than 1. If this number is large, then a small perturbation of the matrix A and/or the right-hand side b can produce a large variation in the exact solution of the system. The system is said to be ill-conditioned. Also, the speed of convergence of some Krylov subspace methods depends on the condition number: the larger it is the slower is the convergence. Thus, it is important, when a matrix is ill-conditioned to precondition the system, that is to consider the new system $M^{-1}Ax = M^{-1}b$, where the matrix M is an approximation of A easy to invert (or, equivalently, a system with M as its matrix is easy to solve) and chosen so that $\kappa(M^{-1}A)$is smaller than $\kappa(A)$. There is no universal preconditioner and almost each system is a particular case.

Another procedure for solving an ill-conditioned system is to use regularization. It consists in solving a perturbed system. A vector x which minimizes

$$\|Ax - b\|_2 + \lambda \|Hx\|$$

is derived where λ is a parameter and H a matrix. The solution x_λ depends on $\lambda \geqslant 0$ (and also on H). When λ is close to 0, x_λ is close to $x = A^{-1}b$ but, since A is ill-conditioned, it is badly computed. If λ is large, x_λ will be correctly computed but it will not be a good approximation of x. So, there is a balance to find between large and small values of λ, and this is the main difficulty of regularization. It can be avoided by using an extrapolation technique.

Onsager Relations

C Cercignani, Politecnico di Milano, Milan, Italy

Introduction

The second law of thermodynamics indicates that not all the processes compatible with the first law can actually occur. Whereas one can easily perform work to heat up the system, it is not always enough to supply heat to increase the mechanical energy. At least two heat sources at different temperatures are needed as shown by Carnot's argument (sometimes one of the sources may be naturally supplied by the environment). Essentially, the second law states that heat can never pass from a colder to a warmer body without some other related change occurring at the same time. The modern statement of this principle of dissipation is based upon the notion of entropy, introduced by Clausius in 1865. Clausius showed that for every thermodynamic system there exists a function of the state of the system, its entropy denoted by S. The latter is defined by a differential relationship for the increased $\mathrm{d}S$ of the entropy of the system in an infinitesimally short time interval, during which a time "reversible" process occurs:

$$\mathrm{d}S = \frac{\mathrm{d}^{*}Q}{T} \qquad [1]$$

where $\mathrm{d}^{*}Q$ is the heat supplied to the system and T is the absolute temperature. (The notation $\mathrm{d}^{*}Q$ emphasizes that Q is not a state function and hence, in mathematical language, $\mathrm{d}^{*}Q$ is not an exact differential; "time-reversible" means, of course, that the process formed by following the states in a reverse time order is also permissible). For processes that are irreversible, one can only state that the increase of entropy in a process leading from an equilibrium state to another is larger than the increase that would occur in a reversible process between the same two states:

$$\mathrm{d}S \geqslant \frac{\mathrm{d}^{*}Q}{T} \qquad [2]$$

In order to transform this meager statement into a useful tool, it is necessary to build some structure for the evolution of the thermodynamic state of a system.

The irreversible processes are also called transport processes because they arise from reversible motions at a molecular level, which transfer a quantity (mass, momentum, energy) in a way that is not recognized as a convection at a macroscopic level. Thus, the microscopic momentum flow splits into a macroscopic momentum flow (or convection of momentum) and a viscous stress; the microscopic energy flow splits into a macroscopic energy flow (or convection of energy), the work of viscous stresses, and heat conduction.

In the following sections, the microscopic theory of transport coefficients and reciprocity relations based on the Boltzmann equation, in the simple but important case of a mixture of ideal gases (which applies, with a few modifications, to the case of electrons as well) is first discussed. This is the only accurate way of proving the symmetry properties of the transport coefficients. Then, the macroscopic theory of the transport coefficients and their symmetry relations, due to Onsager, and usually called Onsager relations, is dealt with.

The Boltzmann Equation

The next step was provided by Boltzmann, who studied perfect gases with the tools of kinetic theory. To explain the mechanical origin of irreversibility, Boltzmann considered what happens to the distribution of velocities of gas molecules when collisions occur. This led him to formulate a kinetic equation, subsequently called the Boltzmann equation, in which two-body collisions (like those between two billiard balls) play a leading role. Certain collisions (called direct collisions) cause decreases in the number of molecules with a certain velocity, while other collisions (called restoring collisions) increase that number. The occurrence of both direct and restoring collisions corresponds to the inherent reversibility of molecular events. Not only did Boltzmann show that the equation bearing his name admits Maxwell's distribution as an equilibrium solution, he also gave a heuristic proof that it is the only possible

one. To this end he introduced a quantity, which he denoted by E and was later (as here) denoted by H, defined in terms of the molecular velocity distribution. He then demonstrated that, as a consequence of his equation, this function must always decrease in an isolated system or, at most, remain constant, the latter case occurring only if a state of statistical equilibrium prevails. Thus, the Boltzmann equation is not time reversible. Boltzmann's result is usually quoted as the "H-theorem" and indicates that H must be proportional to minus the entropy. H has an interesting interpretation as a measure of order in the molecular distribution; as a consequence, S is a measure of randomness or chaos.

Despite its successes, the Boltzmann equation involves conceptual difficulties. Because it is time irreversible, it violates the recurrence theorem of mechanics. This theorem says that the particles composing a system of finite energy and size will return, at some future time, to very nearly their initial condition. Boltzmann proposed the correct way out of this paradox: his equation should be interpreted as describing what happens to most, not all, of the initial data. To illustrate this, two former students of Boltzmann, Paul and Tatyana Ehrenfest, introduced a picturesque model, colloquially referred to as the dog-flea model. Consider two dogs lying next to one another, with a total of N fleas shared between them. If the fleas jump only from one dog to the next, then after a time, the number on each dog will have changed while the total number of fleas will be the same. If the dogs are identical, after a long period of time, it is expected that each dog will have on the average $N/2$ fleas. This will be true even if all the fleas originally resided on only one dog. However, if one waits a much longer time, all the fleas will be back on the original dog. Something similar holds for molecular dynamics; the recurrence time is, however, so long (extremely longer than the estimated age of the universe) that phenomena of this kind, which would violate the second law, are never witnessed. The advantage of the Boltzmann equation is that its rigorous derivation can only be obtained by a limiting procedure, according to which these paradoxical events disappear because they occur at a time $\bar{t}$ such that $\bar{t} \to \infty$, when the Boltzmann equation holds.

Moreover, it is possible to derive the laws of fluid flow, including the linear phenomenological equations, from the Boltzmann equation and to obtain explicit expressions for the heat conductivity and the viscosity of gases that agree with experimental measurements.

The quantity H was essentially defined by Boltzmann as the integral of $f \log f$ with respect to the molecular velocity, where log denotes the natural logarithm and f is the one-particle distribution function. The latter, in the case of a monatomic gas, is a function of time t, position $\boldsymbol{x}$, and molecular velocity $\boldsymbol{v}$ and gives the expected number density of molecules in the six-dimensional phase space described by position $\boldsymbol{x}$ and velocity $\boldsymbol{v}$. The distribution function f satisfies the Boltzmann equation that can be written in the following form:

$$\begin{aligned}&\frac{\partial f}{\partial t} + \boldsymbol{v} \cdot \frac{\partial f}{\partial \boldsymbol{x}} \\ &= \int_{\Re^3} \int_{S^2} [f(\boldsymbol{x}, \boldsymbol{v}', t) f(\boldsymbol{x}, \boldsymbol{v}'_*, t) - f(\boldsymbol{x}, \boldsymbol{v}, t) \\ &\quad \times f(\boldsymbol{x}, \boldsymbol{v}_*, t)] |\boldsymbol{V}| \sigma_{\mathrm{d}}(|\boldsymbol{V}|, \boldsymbol{V} \cdot \boldsymbol{n}) \mathrm{d}\boldsymbol{v}_* \, \mathrm{d}\boldsymbol{n} \end{aligned} \quad [3]$$

where $\boldsymbol{V} = \boldsymbol{v}_* - \boldsymbol{v}$ is the relative velocity and σ_{d} the differential cross section. The velocities before a collision, $\boldsymbol{v}'$ and $\boldsymbol{v}'_*$, are related to those after the same collision, $\boldsymbol{v}$ and $\boldsymbol{v}_*$, by

$$\boldsymbol{v}' = \tfrac{1}{2}(\boldsymbol{v} + \boldsymbol{v}_* + |\boldsymbol{V}|\boldsymbol{n}), \quad \boldsymbol{v}'_* = \tfrac{1}{2}(\boldsymbol{v} + \boldsymbol{v}_* - |\boldsymbol{V}|\boldsymbol{n}) \quad [4]$$

where $\boldsymbol{n}$ is a unit vector ranging over the unit sphere S^2, directed as the relative velocity after the collision.

For polyatomic gases, f depends on further variables describing the internal degrees of freedom of the molecule and the Boltzmann equation becomes more complicated.

By a detailed consideration of the properties of his equation, Boltzmann showed that the time derivative of H is never positive and vanishes if and only if the velocity distribution is a Maxwellian, provided the system cannot exchange heat with the surroundings. The proof of this result requires that the space derivatives give zero contribution (such is the case for a gas in a spatially homogeneous state or inside a box with specularly reflecting walls). It is clear that H corresponds to the entropy except for a negative constant factor. The extension of this result to non-isolated systems was only provided in the second half of the twentieth century and permits one to deal with heat sources.

The molecular description is complicated since it must cover situations varying from ordinary temperature and pressures to nearly vacuum conditions. The case when these conditions occur was studied already by Maxwell and Boltzmann and was systematized by Chapman and Enskog in the past century. The final result is better stated if one refers to the entropy per unit volume s:

$$\frac{\partial s}{\partial t} = \sigma = \sigma^{(r)} + \sigma^{(i)} \quad [5]$$

where σ is the entropy source per unit volume, decomposed into a reversible part

$$\sigma^{(r)} = -\nabla \cdot \left(s\boldsymbol{u} + \frac{\boldsymbol{q}}{T} \right) \quad [6]$$

and an irreversible one $\sigma^{(i)}$. Here, $\boldsymbol{q}$ is the heat flow vector and $\boldsymbol{u}$ the (bulk) velocity vector; $\sigma^{(i)}$ in turn must be decomposed into two parts: the entropy transfer associated with the irreversible processes and a volume source that is non-negative. This decomposition is discussed below.

According to the Chapman–Enskog solution of the Boltzmann equation for a simple gas (as opposed to a mixture) and in agreement with continuum mechanics, σ can be expressed as a sum of two terms, which can be written as a linear combination of $\sum_{ij} q_{ij}\eta_{ij}$ and $\sum_i q_i g_i$; here q_{ij}, η_{ij}, q_i, and g_i denote the components of the stress deviator, the rate of strain tensor, the heat flow vector, and the temperature gradient, respectively. The same theory shows that in each of the above pairs of tensors and vectors, the first element depends linearly on the second with coefficients which may only depend on temperature and number density. This result must be postulated in continuum mechanics. The extension of the theory to mixtures (see next section for details) shows that the pattern repeats itself: there are more gradients (the concentration densities also occur) and more quantities (such as the diffusion velocity) may depend on these quantities, but the entropy source is always a linear combination of terms which are products of two factors: a gradient and another factor describing a phenomenon typically associated with that gradient. New phenomena, such as thermal diffusion, were discovered by this kinetic theory approach, that has, however, the serious limitation of being essentially restricted to rarefie(l)d gases. During World War II, thermal diffusion, an example of a so-called cross-coupling in which a temperature gradient causes a diffusion flux, was used to separate fissionable isotopes of uranium.

Electric phenomena can also be studied by means of a Boltzmann equation describing the statistical behavior of electrons. Results qualitatively similar to those found for a gas can be proved in this case as well. In the next two sections, the Chapman–Enskog theory for the general case of a mixture is briefly described.

Transport Coefficients For Gaseous Mixtures

The transport coefficients of gas mixtures are derived below by using the Chapman–Enskog method. It is assumed that there are n gaseous species.

First of all, one must write the Boltzmann equation for a mixture:

$$\frac{\partial f_a}{\partial t} + \boldsymbol{v} \cdot \frac{\partial f_a}{\partial \boldsymbol{x}} = \sum_{b=1}^{n} \int (f'_a f'_b - f_a f_b) |V_{ba}| \sigma_{ab} \, \mathrm{d}\boldsymbol{n}_{ba} \, \mathrm{d}^3\boldsymbol{v}_b \quad [7]$$

where f_a is the one-particle distribution function for the ath species.

The one-particle distribution function of constituent a is written as

$$f_a = f_a^{(0)}(1 + h_a) \quad [8]$$

where $f_a^{(0)} h_a$ represents the deviation from the Maxwell distribution function:

$$f_a^{(0)} = n_a (2\pi RT)^{-3/2} \exp(-|\boldsymbol{v} - \boldsymbol{u}|^2 / 2RT) \quad [9]$$

where $\boldsymbol{u}$ is the bulk velocity with components u_i and R the gas constant.

Then, it is meaningful to assume that the local Maxwellian contains the entire information about the densities of all species, the bulk velocity, and the temperature. As a consequence, one obtains the following constraints for the deviation $f_a^{(0)} h_a$ from the Maxwell distribution function:

$$\int f_a^{(0)} h_a \, \mathrm{d}^3\boldsymbol{v} = 0 \quad [10]$$

$$\sum_{a=1}^{n} m_a \int \boldsymbol{v} f_a^{(0)} h_a \, \mathrm{d}^3\boldsymbol{v} = 0 \quad [11]$$

$$\sum_{a=1}^{n} m_a \int |\boldsymbol{v}|^2 f_a^{(0)} h_a \, \mathrm{d}^3\boldsymbol{v} = 0 \quad [12]$$

The Chapman–Enskog method can be presented in many ways; since most treatments restrict the computations to first-order perturbations, the simplest possible presentation is adopted. h_a is computed as a perturbation produced by the fact that the derivatives of $f_a^{(0)}$ with respect to time and space variables are nonzero, when these derivatives produce a small change on the scale of the mean free path and mean free time. Hence, if one inserts the distribution function [8] into the Boltzmann equation, one keeps the zeroth order terms on the left-hand size and the first-order terms on the right-hand side, thus obtaining

$$\partial_t f_a^{(0)} + \boldsymbol{v} \cdot \partial_{\boldsymbol{x}} f_a^{(0)} = \sum_{b=1}^{n} \int f_a^{(0)} f_b^{(0)} (h'_a + h'_b - h_a - h_b) |V_{ba}| \sigma_{ab} \times \mathrm{d}\boldsymbol{n}_{ba} \, \mathrm{d}^3\boldsymbol{v}_b \quad [13]$$

The left-hand side of [13] is transformed by inserting the Maxwell distribution function into the streaming term $\partial_t f_a + \boldsymbol{v}\cdot\partial_{\boldsymbol{x}} f_a$, which is written as

$$\frac{\partial f_a}{\partial t} + \boldsymbol{v}\cdot\frac{\partial f_a^{(0)}}{\partial \boldsymbol{x}} = f_a^{(0)}\left\{\boldsymbol{v}\cdot\partial_{\boldsymbol{x}}\left(\frac{\mu_a}{RT}\right) + \partial_t\left(\frac{\mu_a}{RT}\right) + \frac{|\boldsymbol{v}-\boldsymbol{u}|^2}{2RT^2}\boldsymbol{v}\cdot\partial_{\boldsymbol{x}}T + \frac{(\boldsymbol{v}-\boldsymbol{u})}{RT}\cdot(\boldsymbol{v}\cdot\partial_{\boldsymbol{x}})\boldsymbol{u} + \frac{|\boldsymbol{v}-\boldsymbol{u}|^2}{2RT^2}\partial_t T + \frac{(\boldsymbol{v}-\boldsymbol{u})}{RT}\cdot\partial_t\boldsymbol{u}\right\} \quad [14]$$

where, for convenience, the so-called chemical potential $\mu_a = RT\log n_a$ has been introduced. From [14] it follows that [13] reduces to

$$f_a^{(0)}\left\{\boldsymbol{v}\cdot\partial_{\boldsymbol{x}}\left(\frac{\mu_a}{RT}\right) + \partial_t\left(\frac{\mu_a}{RT}\right) + \frac{|\boldsymbol{v}-\boldsymbol{u}|^2}{2RT^2}\boldsymbol{v}\cdot\partial_{\boldsymbol{x}}T + \frac{(\boldsymbol{v}-\boldsymbol{u})}{RT}\cdot[\boldsymbol{v}\cdot\partial_{\boldsymbol{x}}\boldsymbol{u}] + \frac{|\boldsymbol{v}-\boldsymbol{u}|^2}{2RT^2}\partial_t T + \frac{(\boldsymbol{v}-\boldsymbol{u})}{RT}\cdot\partial_t\boldsymbol{u}\right\} = \sum_{b=1}^{n}\int f_a^{(0)}f_b^{(0)}(h'_a + h'_b - h_a - h_b)|V_{ba}|\sigma_{ab}\times \mathrm{d}\boldsymbol{n}_{ba}\,\mathrm{d}^3\boldsymbol{v}_b \quad [15]$$

It can be seen that the balance equations associated with eqn [13] (or [15]) are correct only to the zeroth order because the first-order terms on the left-hand side have been neglected. Thus, they do not contain the irreversible transport phenomena: they describe a mixture of Eulerian fluids (no viscosity, no heat conduction) with vanishing diffusion fluxes. In spite of that, they can be used correctly on the left-hand side, because this is correct to the zeroth order only. The procedure iterates on this to obtain the first terms which describe transport phenomena.

If one integrates eqn [15] over $\boldsymbol{v}$, one obtains the balance equation for the particle number density of constituent a that reads

$$\partial_t n_a + \partial_{\boldsymbol{x}}\cdot(n_a\boldsymbol{u}) = 0 \quad [16]$$

It has already been remarked that in a Eulerian fluid mixture, the pressure deviator and the heat flux of the mixture vanish. Hence, the balance equations for the momentum density and energy density of the mixture reduce to the balance equations for copies of a single Eulerian fluid that read

$$nc_v(\partial_t T + \boldsymbol{u}\cdot\partial_{\boldsymbol{x}}T) + p\partial_{\boldsymbol{x}}\cdot\boldsymbol{u} = 0 \quad [17]$$

$$nm(\partial_t\boldsymbol{u} + \boldsymbol{u}\cdot\partial_{\boldsymbol{x}}\boldsymbol{u}) = -\partial_{\boldsymbol{x}}p \quad [18]$$

where c_v is the heat capacity per particle at constant volume of the mixture.

Now the time derivatives $\partial_t(\mu_a/T)$, $\partial_t T$, and $\partial_t\boldsymbol{u}$ are eliminated from [15] by using eqns [16]–[18] and the following integral equation is obtained for h_a:

$$f_a^{(0)}\left\{-\boldsymbol{v}\cdot\sum_{b=1}^{n}(c_b-\delta_{ab})\partial_{\boldsymbol{x}}\left(\frac{\mu_b-\mu_a}{RT}\right) + \left(\frac{|\boldsymbol{v}|^2}{2RT} - \frac{5}{2}\right)\times\frac{\boldsymbol{v}}{RT^2}\cdot\partial_{\boldsymbol{x}}T + 2(\boldsymbol{v}-\boldsymbol{u})\cdot[(\boldsymbol{v}-\boldsymbol{u})\cdot\partial_{\boldsymbol{x}}]\boldsymbol{u} - \frac{2}{3}|\boldsymbol{v}-\boldsymbol{u}|^2\partial_{\boldsymbol{x}}\cdot\boldsymbol{u}\right\} = \sum_{b=1}^{n}\int f_a^{(0)}f_b^{(0)}(h'_a + h'_b - h_a - h_b)\times|V_{ba}|\sigma_{ab}\,\mathrm{d}\boldsymbol{n}_{ba}\,\mathrm{d}^3\boldsymbol{v}_b \quad [19]$$

where the particle fraction $c_a = n_a/n$ of constituent a is introduced.

The integral equation [19] has a solution of the form

$$h_a = A_a\frac{\boldsymbol{v}}{RT^2}\cdot\partial_{\boldsymbol{x}}T + \frac{\boldsymbol{v}}{k}\cdot\sum_{b=1}^{n}B_{ab}(c_b-\delta_{ab})\partial_{\boldsymbol{x}}\left(\frac{\mu_b-\mu_a}{RT}\right) + 2C_a(\boldsymbol{v}-\boldsymbol{u})\cdot[(\boldsymbol{v}-\boldsymbol{u})\cdot\partial_{\boldsymbol{x}}]\boldsymbol{u} - \tfrac{2}{3}C_a|\boldsymbol{v}-\boldsymbol{u}|^2\partial_{\boldsymbol{x}}\cdot\boldsymbol{u} \quad [20]$$

where A_a, B_{ab}, and C_a are determined from the integral equations that are obtained by inserting [20] into eqn [19], viz,

$$-\frac{\boldsymbol{v}}{R}(c_d-\delta_{ad}) = \sum_{b=1}^{n}\int f_b^{(0)}[B'_{ad}\boldsymbol{v}' + B'_{bd}\boldsymbol{v}'_b - B_{ad}\boldsymbol{v} - B_{bd}\boldsymbol{v}_b]\times|V_{ba}|\sigma_{ab}\,\mathrm{d}\boldsymbol{n}_{ba}\,\mathrm{d}^3\boldsymbol{v}_b \quad [21]$$

$$\frac{\boldsymbol{v}}{RT^2} = \sum_{b=1}^{n}\int f_b^{(0)}[A'_a\boldsymbol{v}' + A'_b\boldsymbol{v}'_b - A_a\boldsymbol{v} - A_b\boldsymbol{v}_b]\times|V_{ba}|\sigma_{ab}\,\mathrm{d}\boldsymbol{n}_{ba}\,\mathrm{d}^3\boldsymbol{v}_b \quad [22]$$

$$\frac{\boldsymbol{v}\boldsymbol{v}}{RT} = \sum_{b=1}^{n}\int f_b^{(0)}[C'_a\boldsymbol{v}'\boldsymbol{v}' + C'_b\boldsymbol{v}'_b\boldsymbol{v}'_b - C_a\boldsymbol{v}\boldsymbol{v} - C_b\boldsymbol{v}'_b\boldsymbol{v}_b]|V_{ba}|\sigma_{ab}\,\mathrm{d}\boldsymbol{n}_{ba}\,\mathrm{d}^3\boldsymbol{v}_b \quad [23]$$

Since one is interested only in general expressions for the transport coefficients, one need not solve the integral eqns [21]–[23]. The transport coefficients are expressed in terms of the functions A_a, B_{ab}, C_a, which can be obtained by solving the aforementioned integral equations.

It is remarked that the balance equations containing the irreversible transport phenomena, correct to first order, will occur as a compatibility condition for the equations at the next order. This is because of the iteration nature of the Chapman–Enskog procedure.

One can calculate the constitutive terms of a mixture of gases in the second Chapman–Enskog approximation. The constitutive terms are: the pressure deviator of the mixture q_{ij}, the heat flux of the mixture q_j, and the diffusion flux $\boldsymbol{J}_a$ of the constituent a.

To begin with, the constitutive equation is determined for the pressure deviator of the mixture, which can be obtained through the insertion of [8] together with [20] into its definition

$$q_{ij} = \sum_{a=1}^{n} m_a \int [(v_i - u_i)(v_j - u_j) - \tfrac{1}{3}|\boldsymbol{v} - \boldsymbol{u}|^2 \delta_{ij}] f_a \, \mathrm{d}^3\boldsymbol{v} \qquad [24]$$

yielding

$$q_{ij} = -\mu\left[\partial_{x_i} u_j + \partial_{x_j} u_i - \tfrac{2}{3}(\partial_{\boldsymbol{x}} \cdot \boldsymbol{u})\delta_{ij}\right] \qquad [25]$$

where the expression for the coefficient of shear viscosity μ is

$$\mu = \frac{1}{15}\sum_{a=1}^{n} \int |\boldsymbol{v} - \boldsymbol{u}|^4 f_a^{(0)} C_a \, \mathrm{d}^3\boldsymbol{v}_A \qquad [26]$$

Further, the heat flux of the mixture, defined by

$$q_j = \sum_{a=1}^{n} \frac{m_a}{2} \int (v_j - u_j)|\boldsymbol{v} - \boldsymbol{u}|^2 f_a \, \mathrm{d}^3\boldsymbol{v} \qquad [27]$$

can be shown to be

$$q_j = -\lambda \partial_{x_j} T \qquad [28]$$

The expressions of thermal conductivity λ reads

$$\lambda = \frac{1}{3}\sum_{a=1}^{n} \int |\boldsymbol{v} - \boldsymbol{u}|^2 f_a^{(0)} A_a \, \mathrm{d}^3\boldsymbol{v} \qquad [29]$$

The last constitutive equation to be determined is the one for the partial diffusion flux $\boldsymbol{J}_a$ with components J_{ai}, which is obtained by inserting [8] together with [20] into the definition of the partial flow:

$$J_{ai} = L_a \partial_{x_i} T + \sum_{b=1}^{n} L_{ab} \partial_{x_i}\left(\frac{\mu_b - \mu_a}{T}\right) \qquad [30]$$

In [30], the coefficients L_a and L_{ab} are related to the thermal-diffusion cross-effect and to the matrix of the diffusion coefficients, respectively. Their expressions are given by

$$L_a = \frac{1}{3}\int |\boldsymbol{v} - \boldsymbol{u}|^2 f_a^{(0)} A_a \, \mathrm{d}^3\boldsymbol{v} \qquad [31]$$

$$L_{ab} = \frac{1}{3}\int |\boldsymbol{v} - \boldsymbol{u}|^2 f_a^{(0)} B_{ab} \, \mathrm{d}^3\boldsymbol{v} \qquad [32]$$

Onsager's Reciprocity Relations from the Boltzmann Equation

In this section, one can analyze the relationships between the transport coefficients of a chemically reacting mixture of gases which are known as the Onsager reciprocity relations. The starting point is provided by the formulas derived in the previous section from the Boltzmann equation.

In order to determine the Onsager reciprocity relations, one needs the following relationship which is valid for arbitrary functions h and ψ:

$$\sum_{a,b=1}^{n} \int f_a^{(0)} f_b^{(0)} \psi_b (h'_a + h'_a - h_a - h_a) \times |V|\sigma_{ab} \, \mathrm{d}\boldsymbol{n} \, \mathrm{d}^3\boldsymbol{v}_a \, \mathrm{d}^3\boldsymbol{v}_b = \sum_{a,b=1}^{n} \int f_a^{(0)} f_b^{(0)} h_b (\psi'_a + \psi'_a - \psi_a - \psi_a) \times |V|\sigma_{ab} \, \mathrm{d}\boldsymbol{n} \, \mathrm{d}^3\boldsymbol{v}_a \, \mathrm{d}^3\boldsymbol{v}_b \qquad [33]$$

The above equation can be proved by using the symmetry properties of the elastic collision term and by interchanging the dummy indices a and b in the sums.

For the determination of the first Onsager reciprocity relation, it is first noted that due to the constraint $\sum_{a=1}^{n} \boldsymbol{J}_{ai} = 0$, one must have according to [30]–[32] that

$$\sum_{a=1}^{n} L_a = \frac{1}{3}\sum_{a=1}^{n} \int |\boldsymbol{v} - \boldsymbol{u}|^2 f_a^{(0)} A_a \mathrm{d}^3\boldsymbol{v} = 0 \qquad [34]$$

$$\sum_{a=1}^{n} L_{ab} = \frac{1}{3}\sum_{a=1}^{n} \int |\boldsymbol{v} - \boldsymbol{u}|^2 f_a^{(0)} B_{ab} \mathrm{d}^3\boldsymbol{v} = 0 \qquad [35]$$

Based on the above constraints, the two coefficients L_a and L_{ab} can be written as

$$L_a = -\frac{1}{3}\sum_{b=1}^{n} \int |\boldsymbol{v} - \boldsymbol{u}|^2 f^{(0)} A_a (c_b - \delta_{ab}) \, \mathrm{d}^3\boldsymbol{v} \qquad [36]$$

$$L_{ab} = -\frac{1}{3}\sum_{d=1}^{n} \int |\boldsymbol{v} - \boldsymbol{u}|^2 f_d^{(0)} B_{db} (c_d - \delta_{ad}) \, \mathrm{d}^3\boldsymbol{v} \qquad [37]$$

By multiplying [19] with $R(\boldsymbol{v}_a - \boldsymbol{u})f_a^{(0)}B_{ac}/3$, integrating the resulting equation over all values of $\mathrm{d}^3\boldsymbol{v}_a$, and after that summing over all constituents yields

$$
\begin{aligned}
&-\frac{1}{3}\sum_{a=1}^{n}\int |\boldsymbol{v}_a - \boldsymbol{u}|^2 f_a^{(0)} B_{ac}(c_d - \delta_{ad})\mathrm{d}^3\boldsymbol{v}_a = L_{dc} \\
&= \frac{R}{6}\sum_{a,b=1}^{n}\int f_a^{(0)} f_b^{(0)}(\boldsymbol{v}_a - \boldsymbol{u})B_{ac}\cdot[B'_{ad}(\boldsymbol{v}'_a - \boldsymbol{u}) \\
&\quad + B'_{bd}(\boldsymbol{v}'_b - \boldsymbol{u}) - B_{ad}(\boldsymbol{v}_a - \boldsymbol{u}) \\
&\quad - B_{bd}(\boldsymbol{v}_b - \boldsymbol{u})]|V|\sigma_{ab}\,\mathrm{d}\boldsymbol{n}\,\mathrm{d}^3\boldsymbol{v}_a\,\mathrm{d}^3\boldsymbol{v}_b \\
&= \frac{R}{6}\sum_{a,b=1}^{n}\int f_a^{(0)} f_b^{(0)}(\boldsymbol{v}_a - \boldsymbol{u})B_{ad}\cdot[B'_{ac}(\boldsymbol{v}_b - \boldsymbol{u}) \\
&\quad + B'_{bc}(\boldsymbol{v}'_b - \boldsymbol{u}) - B_{ac}(\boldsymbol{v}_a - \boldsymbol{u}) - B_{bc}(\boldsymbol{v}_b - \boldsymbol{u})] \\
&\quad \times |V|\sigma_{ab}\,\mathrm{d}\boldsymbol{n}\,\mathrm{d}^3\boldsymbol{v}_a\,\mathrm{d}^3\boldsymbol{v}_b = L_{cd}
\end{aligned}
\qquad [38]
$$

Hence, the first Onsager reciprocity relation which shows that the matrix of the diffusion coefficients is symmetric (i.e., $L_{cd} = L_{dc}$) has been proved.

The expression for the coefficient of the thermal-diffusion effect L_d^* is obtained through the multiplication of [20] by $R(\boldsymbol{v}_a - \boldsymbol{u})f_a^{(0)}A_a/3$, integration of the resulting equation over all values of $\boldsymbol{v}_a$, and subsequent summing over all constituents:

$$
\begin{aligned}
&-\frac{1}{3}\sum_{a=1}^{n}\int |\boldsymbol{v}_a - \boldsymbol{u}|^2 (c_d - \delta_{ad}) f_a^{(0)} A_a \mathrm{d}^3\boldsymbol{v}_a = L_d^* \\
&= \frac{R}{6}\sum_{a,b=1}^{n}\int f_a^{(0)} f_b^{(0)}(\boldsymbol{v}_a - \boldsymbol{u})A_a\cdot[B'_{ab}(\boldsymbol{v}'_a - \boldsymbol{u}) \\
&\quad + B'_{ba}(\boldsymbol{v}'_b - \boldsymbol{u}) - B_{ab}(\boldsymbol{v}_a - \boldsymbol{u})] - B_{ba}(\boldsymbol{v}_b - \boldsymbol{u})] \\
&\quad \times |V|\sigma_{ab}\,\mathrm{d}\boldsymbol{n}\,\mathrm{d}^3\boldsymbol{v}_a\,\mathrm{d}^3\boldsymbol{v}_b
\end{aligned}
\qquad [39]
$$

In the same way, it follows the expression for the coefficient of the diffusion-thermal effect L_d^*, that is, multiplying [23] by $R(\boldsymbol{v}_a - \boldsymbol{u})f_a^{(0)}B_{da}/3$, integrating the resulting equation over all values of $\mathrm{d}^3\boldsymbol{v}_a$ and thereafter summing over all constituents:

$$
\begin{aligned}
&\frac{1}{3T^2}\sum_{a=1}^{n}\int |\boldsymbol{v}_a - \boldsymbol{u}|^2\left(\frac{|\boldsymbol{v}_a - \boldsymbol{u}|^2}{2RT} - \frac{5}{2}\right) f_a^{(0)} B_{da}\mathrm{d}^3\boldsymbol{v}_a = L_d^* \\
&= \frac{R}{6}\sum_{a,b=1}^{n}\int f_a^{(0)} f_b^{(0)}(\boldsymbol{v}_a - \boldsymbol{u})\cdot B_{da}[A'_a(\boldsymbol{v}'_a - \boldsymbol{u}) \\
&\quad + A'_b(\boldsymbol{v}'_b - \boldsymbol{u}) - A_a(\boldsymbol{v}_a - \boldsymbol{u}) - A_b(\boldsymbol{v}_b - \boldsymbol{u})] \\
&\quad \times |V|\sigma_{ab}\,\mathrm{d}\boldsymbol{n}\,\mathrm{d}^3\boldsymbol{v}_a\,\mathrm{d}^3\boldsymbol{v}_b
\end{aligned}
\qquad [40]
$$

The first equality above can be written, thanks to the constraint [12] and to the definition of the thermal-diffusion coefficient [30].

One can compare now the expressions [39] and [40], and by using the property [33], one can infer the last Onsager reciprocity relation that relates the coefficients of the thermal-diffusion effect and of the diffusion thermal effect $L_d^* = L_d$.

The results obtained from the Boltzmann equation in this section suggests that one looks for an explanation of the general pattern, having in mind media more general than rarefie(l)d gases.

The Macroscopic Theory of Irreversible Processes

Recall that the entropy is a function of some local parameters x_k (number density, internal energy, etc.). As a consequence,

$$
\mathrm{d}s = \sum_k F_k\,\mathrm{d}x_k \qquad [41]
$$

where $F_k = \partial s/\partial x_k$ are the "thermodynamic forces," functions of the parameters x_k. The local parameters must be chosen suitably: they must satisfy some balance equations of the following form:

$$
\frac{\partial x_k}{\partial t} = \xi_k = \xi_k^{(\mathrm{r})} + \xi_k^{(\mathrm{i})} \qquad [42]
$$

where ξ_k is the source per unit volume, decomposed into a reversible part $\xi_k^{(\mathrm{r})}$ and an irreversible one $\xi_k^{(\mathrm{i})}$. The irreversible sources are due to transport phenomena and, hence, have the general expression:

$$
\xi_k^{(\mathrm{i})} = -\nabla\cdot\boldsymbol{J}_k^{(\mathrm{i})} \qquad [43]
$$

where $\boldsymbol{J}_k^{(\mathrm{i})}$ is the irreversible flux of x_k. The time derivative of the entropy is given by

$$
\begin{aligned}
\frac{\partial s}{\partial t} &= \sum_k F_k\frac{\partial x_k}{\partial t} = \sum_k F_k\xi_k \\
&= \sum_k F_k\xi_k^{(\mathrm{r})} - \sum_k F_k\nabla\cdot\boldsymbol{J}_k^{(\mathrm{i})}
\end{aligned}
\qquad [44]
$$

The part of the entropy source associated with irreversible processes is thus given by

$$
\begin{aligned}
\sigma^{(\mathrm{i})} &= -\sum_k F_k\nabla\cdot\boldsymbol{J}_k^{(\mathrm{i})} = -\sum_k \nabla\cdot(F_k\boldsymbol{J}_k^{(\mathrm{i})}) \\
&\quad + \sum_k \boldsymbol{J}_k^{(\mathrm{i})}\cdot\nabla F_k
\end{aligned}
\qquad [45]
$$

and decomposes naturally into a transport term related to the entropy flux $\sum_k F_k\boldsymbol{J}_k^{(\mathrm{i})}$ associated with irreversible processes, and a dissipation term

$$
\sigma^{(\mathrm{d})} = \sum_k \boldsymbol{J}_k^{(\mathrm{i})}\cdot\nabla F_k \qquad [46]
$$

which provides the volume source of entropy, that is frequently referred to as the entropy source, without any further qualification. The factor multiplying a flux $\boldsymbol{J}_k^{(\mathrm{i})}$, ∇F_k, is called a (generalized) force or affinity. The source $\sigma^{(\mathrm{d})}$ is non-negative for the second law to be satisfied; in fact, the transport term, being in the form of a divergence, transforms, upon integration, into a surface integral and is thus related to processes occurring on the boundary.

The fluxes must depend on the forces; otherwise one could reverse the fluxes, keeping the forces constant, and change the sign of $\sigma^{(\mathrm{d})}$. The dependence can be very general but in most cases it is Markovian, that is, the fluxes at a time-instant depend on the forces at the same time only. Further, in many cases, the relation is linear:

$$\boldsymbol{J}_k^{(\mathrm{i})} = \sum_j L_{jk} \nabla F_j \qquad [47]$$

This circumstance holds in many cases; the processes described by these laws can still be nonlinear because the coefficients L_{jk} (called kinetic coefficients) are functions of the thermodynamic forces F_l. In addition to the kinetic and transport equations that were established experimentally in the nineteenth century, the linear laws suggested new types of transport phenomena. Indeed, the chemist Lars Onsager and later the physicist Josef Meixner were led to a connection between the phenomenological kinetic coefficients and thermodynamics. Because the entropy source is positive, the kinetic coefficients are not arbitrary. In fact, the expression of the source

$$\sigma^{(\mathrm{d})} = \sum_{jk} L_{jk} \nabla F_j \cdot \nabla F_k \qquad [48]$$

indicates that all the diagonal kinetic coefficients, L_{jj}, must be positive. Furthermore, the off-diagonal kinetic coefficients $L_{jk}(j \neq k)$ must satisfy the inequalities that arise by the fact that the kinetic coefficients form a positive definite matrix. Thus, the second law constrains the size of the off-diagonal kinetic coefficients.

The Reciprocity Relations

In the case of linear relations, the coefficients L_{jk} are assumed to satisfy a symmetry relation

$$L_{jk}(\boldsymbol{B}) = \varepsilon_j \varepsilon_k L_{kj}(-\boldsymbol{B}) \qquad [49]$$

where $\boldsymbol{B}$ is a magnetic field that can act on the system. The factor ε_j is defined as follows: it equals 1 if the parameter F_j does not change when time is reversed, and -1 if the parameter F_j changes sign when time is reversed. Temperature and concentrations belong to the first class, velocity (or momentum) to the second. The extension to intermediate cases is not difficult, but does not occur in practice.

The coupling of a flux and a force corresponding to unequal values of j and k, occurring when the corresponding off-diagonal kinetic coefficient does not vanish, suggests the kind of irreversible phenomena that might occur: thus, a temperature difference might give rise not only to a heat flux but also to an electric current, while a potential difference can give rise to an electric current and a heat flux. Experimental measurements demonstrate not only that these phenomena, known as the Seebeck and Peltier effects, exist but that the two off-diagonal coupling coefficients are equal within experimental error.

The above symmetry conditions were first established by Onsager and further discussed by Casimir. They are called the Onsager–Casimir reciprocity relations. It must be stressed that the proof of these relations does not belong to standard thermodynamics, but requires a study of the microscopic theory and a number of assumptions. A careful analysis shows that the alleged proof can, at most, be considered as a plausibility argument.

Another condition on the off-diagonal kinetic coefficients, frequently called the Curie principle, dictates restrictions related to space symmetries. For example, it implies that the thermodynamic force for a chemical reaction in a fluid, which has no directional character, doe not contribute to the heat flux, which is a vector. Experiments to test the validity of the reciprocal relations are not always easy. Some of the most accurate deal with mass diffusion at uniform temperature. For example, in a solution of table salt (NaCl) in water, there is only a single thermodynamic force for diffusion (the gradient of the chemical potential of NaCl), but in an aqueous solution of NaCl and potassium chloride (KCl), gradients in the chemical potentials of both salts act as thermodynamic forces for diffusion. Within the limits of experimental uncertainty, the off-diagonal kinetic coefficients for diffusion in this and other three-component solutions have been shown to be equal. The magnitude of the off-diagonal kinetic coefficients is frequently comparable to the diagonal ones, which has made phenomena related to off-diagonal kinetic coefficients a significant tool in electrochemistry, membrane biology, and geophysics.

It would be useful to have a better theoretical justification of the Onsager–Casimir relations and a better discussion of their experimental validity, but these do not seem to be available. One observes that the modern thermomechanics of continua dispenses with the Onsager–Casimir relations and discusses

irreversible phenomena with the help of the Clausius–Duhem inequality

$$\frac{\mathrm{d}S}{\mathrm{d}t} \geqslant \int_{\partial\Omega} \frac{q}{T}\,\mathrm{d}A \qquad [50]$$

assumed to hold for an arbitrary region Ω, with boundary $\partial\Omega$, occupied by a continuous medium. The constitutive relations that relate the various state functions and the "fluxes" to the "forces" are assumed to obey the postulate of equipresence: each quantity which is not taken as basic depends upon all the basic ones, unless this is forbidden by the second principle. The basic quantities are usually the number (or mass) density, the velocity, the thermal energy, and the concentrations. The class of materials (elastic, viscous, viscoelastic, etc.) are defined by the type of constitutive relations that are admitted.

Optical Absorption and Reflectance

Y Toyozawa, University of Tokyo, Tokyo, Japan

Introduction

The interaction of electromagnetic waves with matter causes a variety of optical processes, such as reflection, refraction, transmission, absorption, elastic and inelastic scattering, and luminescence, which can be described in terms of relevant optical constants such as reflectivity, refractivity, absorption constant, scattering cross sections, quantum yield, and so on. The optical constants are related with more fundamental material constants: dielectric constant $\varepsilon(\omega)$ or electric conductivity $\sigma(\omega)$, which are response coefficients of matter to an incident electromagnetic wave of circular frequency ω. The real and imaginary parts of $\varepsilon(\omega)$ (and of $\sigma(\omega)$) are related through the Kramers–Kronig relations originating from the causality of the response against external force.

The dispersion, ω-dependence, of the dielectric constant provides one with detailed information on elementary excitations and their interactions. Thus, the spectroscopic study of matter not only brings a fundamental knowledge on microscopic motions taking place within the matter, but also provides a useful basis for a variety of optoelectronic applications of the material.

For the sake of better comprehensibility, the definition of dielectric constant is taken up first, and then, typical microscopic models for that are presented.

Electromagnetic Fields in a Medium

Maxwell equations for the electromagnetic fields in a medium are given by

$$\nabla \times \boldsymbol{E} + \partial \boldsymbol{B}/\partial t = 0, \quad \nabla \times \boldsymbol{H} - \partial \boldsymbol{D}/\partial t = \boldsymbol{J}_{\mathrm{ext}},$$

$$\nabla \cdot \boldsymbol{D} = \rho_{\mathrm{ext}}, \quad \nabla \cdot \boldsymbol{B} = 0$$

For weak electric and magnetic fields, linear relations hold for the electric flux density $\boldsymbol{D} = \varepsilon \boldsymbol{E}$, and the magnetic flux density $\boldsymbol{B} = \mu \boldsymbol{H}$, with dielectric constant ε and magnetic permeability μ. The difference of $\boldsymbol{D}$ from that in vacuum is due to the polarization of the medium: $\boldsymbol{P} = (\varepsilon - \varepsilon_0)\boldsymbol{E} = \chi \boldsymbol{E}$, where ε_0 is the dielectric constant of vacuum and χ is the electric susceptibility (polarizability). The convention followed is that only the foreign charge ρ_{ext} and foreign current $\boldsymbol{J}_{\mathrm{ext}} = \rho_{\mathrm{ext}} \boldsymbol{v}$ appear as inhomogeneous terms on the right-hand side with the understanding that ρ and $\boldsymbol{J}$ of internal origin (due to the constituent particles of the medium) have been removed to the left-hand side to be included as $-\rho = \nabla \cdot \boldsymbol{P}$ and $-\boldsymbol{J} = -\partial \boldsymbol{P}/\partial t$ in the third and second of the Maxwell

equations, respectively. The reason for doing this is that bound and mobile electrons in the medium are indistinguishable under an alternating electric field. For a weak field, a linear relation $\boldsymbol{J} = \sigma \boldsymbol{E}$ holds, where σ is the electric conductivity. ε, σ, χ, and μ are tensors in an anisotropic medium, but unless otherwise stated, the discussion is confined to the isotropic medium in which they can be treated as scalars.

Anticipating that the homogeneous set of Maxwell equations has a solution of a plane wave form, one expresses $\boldsymbol{E} = \boldsymbol{E}_0 \exp(\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r} - \mathrm{i}\omega t)$ and obtains

$$[(\varepsilon\mu\omega^2 - k^2) + \boldsymbol{k}\boldsymbol{k}\cdot]\boldsymbol{E}_0 = \boldsymbol{0}$$

There are two types of solutions. One is the transverse wave with $\boldsymbol{E}_0 \perp \boldsymbol{k}$, $\boldsymbol{H}_0 = (\mu\omega)^{-1}\boldsymbol{k} \times \boldsymbol{E}_0$, for which $\omega = ck$, $c = (\varepsilon\mu)^{-1/2}$. This is the electromagnetic wave in the medium with velocity c, which is different from $c_0 = (\varepsilon_0\mu_0)^{-1/2}$ in vacuum. Another is the longitudinal wave ($\boldsymbol{E}_0 \| \boldsymbol{k}$), which has to satisfy $\varepsilon\mu = 0$. If one confines to the nonmagnetic medium, it is possible to express $\mu = \mu_0$ (the same as in vacuum), but in general, the ω-dependence (dispersion) and $\boldsymbol{k}$-dependence (spatial dispersion) of the dielectric constant $\varepsilon(\omega, \boldsymbol{k})$ need to be assumed. It satisfies the relation $\varepsilon(-\omega, -\boldsymbol{k}) = \varepsilon(\omega, \boldsymbol{k})^*$, since $\boldsymbol{D}$ should be real when $\boldsymbol{E}$ is. Therefore, the longitudinal wave appears only at ω satisfying $\varepsilon(\omega, \boldsymbol{k}) = 0$, which means that $\boldsymbol{E} = -\varepsilon_0^{-1}\boldsymbol{P}$. Namely, this longitudinal oscillation arises due to the self-induced depolarizing electric field, being independent of the electromagnetic wave. A few examples are mentioned later.

For a spectral region below soft X-rays, the wavelength $\lambda = 2\pi/k$ is much greater than the interatomic distance of condensed matter, and the $\boldsymbol{k}$-dependence is hereafter ignored unless otherwise stated.

From the above argument with $\partial\boldsymbol{P}/\partial t \equiv \boldsymbol{J}$, one finds that $\varepsilon(\omega)$ and $\sigma(\omega)$ are not independent but are related by $(\varepsilon(\omega) - \varepsilon_0) = \sigma(\omega)/(-\mathrm{i}\omega)$, namely, $\varepsilon_1(\omega) - \varepsilon_0 = -\sigma_2(\omega)/\omega$ and $\varepsilon_2(\omega) = \sigma_1(\omega)/\omega$ where the suffixes 1 and 2 refer to real and imaginary parts. $\sigma_1(\omega)$, which is related to Joule's heat and $\varepsilon_2(\omega)$, represent the "dissipative" parts which are always non-negative as they should be, while $\varepsilon_1(\omega)$ and $\sigma_2(\omega)$ represent the "reactive" parts. Due to the causality between the electric field and its responses, the real and imaginary parts of $\varepsilon(\omega)$ are related by Kramers–Kronig relations:

$$\varepsilon_1(\omega) - \varepsilon_0 = \pi^{-1}P\int_{-\infty}^{\infty} \varepsilon_2(\omega')\,\mathrm{d}\omega'/(\omega' - \omega)$$

$$\varepsilon_2(\omega) = \pi^{-1}P\int_{-\infty}^{\infty} (\varepsilon_1(\omega') - \varepsilon_0)\,\mathrm{d}\omega'/(\omega' - \omega)$$

Classical Models for Mobile and Bound Charges, and Their Correspondence to Quantum Mechanical Systems

Consider free electrons in metals with scattering rate τ^{-1}. Under an oscillating electric field, the equation of motion for the velocity, $\mathrm{d}v/\mathrm{d}t - \boldsymbol{v}/\tau = (e\boldsymbol{E}/m)\exp(-\mathrm{i}\omega t)$, gives a forced oscillation solution:

$$\boldsymbol{v} = (e\boldsymbol{E}/m)(-\mathrm{i}\omega + \tau^{-1})^{-1}\exp(-\mathrm{i}\omega t)$$

from which follows the complex conductivity:

$$\sigma(\omega) = (ne^2/m)(-\mathrm{i}\omega + \tau^{-1})^{-1}$$

where n is the number density of electrons with charge e and mass m. While it gives a static conductivity $\sigma = ne^2\tau/m$, it gives an imaginary conductivity and hence, negative susceptibility

$$(\varepsilon(\omega) - \varepsilon_0) = \mathrm{i}\sigma(\omega)/\omega = -ne^2/m\omega^2$$

for high frequency of spectroscopic interest such that $\omega \gg \tau^{-1}$ ($\sim 10^{14}\ \mathrm{s}^{-1}$). Rewriting $\varepsilon_1(\omega)/\varepsilon_0 = 1 - \omega_\mathrm{p}^2/\omega^2$, one finds that $\varepsilon_1(\omega)$ is negative and $\varepsilon_2(\omega) = 0$ at $\omega < \omega_\mathrm{p}$, where ω_p defined by $\omega_\mathrm{p}^2 = ne^2/\varepsilon_0 m$ is the circular frequency of the plasma oscillation (the longitudinal charge density wave) satisfying $\varepsilon(\omega) = 0$ as mentioned before, and is $\sim 10^{16}\,\mathrm{s}^{-1}$ in normal metals.

As a classical model for a bound electron in an insulator, consider a set ($j = 1, 2, \ldots$) of damped harmonic oscillators with electric charge $\sqrt{f_j}e$, circular frequency ω_j, and damping constant γ_j. The equation of motion for each oscillator under an alternating electric field,

$$\mathrm{d}^2\boldsymbol{r}_j/\mathrm{d}t^2 + \gamma_j\mathrm{d}\boldsymbol{r}_j/\mathrm{d}t + \omega_j^2\boldsymbol{r}_j = \sqrt{f_j}(e/m)\boldsymbol{E}\exp(-\mathrm{i}\omega t)$$

leads to the electric polarizability

$$\begin{aligned}\chi(\omega) &= \varepsilon(\omega) - \varepsilon_0 \\ &= N_0\sum_{j(\neq 0)} (e^2/m)f_j/(\omega_j^2 - \omega^2 - \mathrm{i}\gamma_j\omega)\end{aligned}$$

where N_0 denotes the number of such sets of oscillators per unit volume of the medium.

The dimensionless constant f_j turns out to correspond to the quantum mechanical oscillator strength. In fact, the time-dependent Schrödinger equation for an electron starting from the ground state $j = 0$ of an atom subject to perturbation, $-\boldsymbol{m}\cdot\boldsymbol{E}\exp(-\mathrm{i}\omega t)$ with dipole moment $\boldsymbol{m} \equiv e\boldsymbol{r}$, gives

$$\langle \boldsymbol{m} \rangle_t = \boldsymbol{E}\exp(-\mathrm{i}\omega t)\sum_{j(\neq 0)} (2\omega_{j0}|\boldsymbol{m}_{0j}|^2/\hbar)(\omega_{j0}^2 - \omega^2)^{-1}$$

where $\hbar\omega_j \equiv \hbar\omega_{j0} \equiv E_j - E_0$ is the jth excitation energy of the atom. Comparison with the above expression for polarizability (γ_j being neglected) indicates that $f_j = f_{j0} = 2m\omega_{j0}|\boldsymbol{r}_{j0}|^2/\hbar$ is the oscillator strength of the transition $0 \rightarrow j$, satisfying the sum rule $\sum_{j(\neq 1)} f_{ji} = 1$ per one electron of the atom as can be derived from the commutation relation $xp - px \equiv [x, p] = i\hbar$ and the Heisenberg equation of motion, $p \equiv m\,\mathrm{d}x/\mathrm{d}t = m[x, H]/i\hbar$ (H is the Hamiltonian). Note that the (circular) frequency ω_j of the classical oscillation corresponds to the transition frequency ω_{j0} of the quantum mechanical system (correspondence principle). In the case of a harmonic oscillator, only the transition $i \rightarrow j = i \pm 1$ is allowed with $f_{i+1,i} = i + 1, f_{i-1,i} = -i$ and hence, $f_1 = 1$ and $f_0 = f_{i(\geqslant 2)} = 0$, in contradistinction to the case of an atom, which is so to speak, an anharmonic oscillator. This is the etymology of "oscillator strength" introduced above – the "oscillator equivalence" of the strength of transition. In the case of a medium consisting of N_0 identical atoms per unit volume, each with n_0 electrons, the sum rule can also be written as $\int_0^\infty \varepsilon_2(\omega)\omega\,\mathrm{d}\omega = \pi N_0 n_0 (e^2/m)$.

Transverse and Longitudinal Waves

It is to be noted that $\varepsilon_1(\omega)$ consists of a series ($j = 1, 2, \ldots$) of poles at $\omega_j^{\mathrm{t}} \equiv \omega_j$ representing transverse waves, each being followed by a zero at $\omega_j + \Delta_j \equiv \omega_j^{\mathrm{l}}$ representing longitudinal wave. The longitudinal–transverse ("lt") splitting is given by $\Delta_j = N_0 |\boldsymbol{m}_{0j}|^2/\hbar\varepsilon_j'$ with screening constant ε_j' for the dipole–dipole interaction being given by the "residual" dielectric constant as defined by

$$\varepsilon_j'(\omega) \equiv \varepsilon_0 + (N_0 e^2/m) \sum_{j'(\neq j)} f_{j'}/(\omega_{j'}^2 - \omega^2)$$

at $\omega = \omega_j^{\mathrm{l}}$. The free electron model for metal corresponds to the case with vanishing ω_j of the oscillator model with Δ being ω_{p}. The lt splitting Δ in either case originates from the depolarizing force as mentioned before. Thus, the dipole–dipole interaction energy $N_0|\boldsymbol{m}_{0j}|^2$ (note that $N_0 \sim r^{-3}$, where r is the interatomic distance) as well as the plasmon energy $\hbar\omega_{\mathrm{p}}$ have been obtained without explicit consideration of the Coulomb interaction between electrons to which they are to be attributed. In fact, the Coulomb interaction has been incorporated implicitly in the form of a depolarizing field. This phenomenological method allows one to give even the appropriate screening constant to be used for the dipole–dipole interaction, which belongs to a many-body effect of the higher-order perturbation theory.

Such conjugation of transverse and longitudinal waves holds not only for electronic excitation (transverse and longitudinal excitons) but also for lattice vibrations (transverse and longitudinal optical modes).

Quantization of Radiation Field and the Spontaneous Emission of Radiation

So far, the material system has been described, first by classical mechanics of harmonic oscillators and then by quantum mechanics of atoms, whereby the electromagnetic fields have been left as classical quantities. Historically, however, the quantum theory started with the quantization of an electromagnetic field, namely, with Planck's hypothesis on discrete energy levels of a radiation field, which was later substantiated by Einstein with his model of a quantum of the radiation field, that is, a photon. Einstein's argument on thermal equilibrium between a radiation field and two level atoms not only necessitated the spontaneous emission (as the consequence of quantization) in addition to the induced emission, but also related the rates B and A of absorption and emission of a photon in a way which proved to be correct even under the quantum mechanics established later than his prediction.

The intensity of a line spectrum is represented by the oscillator strength f_j as mentioned before, or by the rate of optical absorption per spectral density $w(\omega)$ of the incident radiation energy, $B_{0j} = \pi|\boldsymbol{m}_{0j}|^2/3\varepsilon_0\hbar^2$. According to Einstein, this B coefficient is related with his A coefficient,

$$A_{j0} = (g_0/g_j)B_{0j}\hbar\omega_{j0}^3/\pi^2 c_0^3 = \tau_j^{-1}$$

which is the rate of the spontaneous emission of a photon from the excited state j, where g_j is the degeneracy of the state j. The damping constant γ_j in the oscillator model introduced above and hence, the spectral width of the absorption line is given by the reciprocal of this natural (radiative) lifetime τ_j of the final state j in the case of an isolated atom, in accordance with the uncertainty principle between energy and time.

In the case of an atom or a molecule in a gas with density not too low, γ_j is dominated by larger rate processes, such as collision with other atoms or molecules. (In the case of a molecule, the excited states j are characterized not only by electronic but also by vibrational states, so that the absorption spectrum is much more complicated).

In insulators, the discrete lines in the absorption spectrum correspond to the transverse exciton states with γ_j being dominated by the rate of exciton

scattering by phonons, and the continuous spectra correspond to electronic transitions from filled bands to empty bands. In the spectral region of much lower frequency, there are discrete lines due to the excitation of a phonon of transverse optical modes, with γ_j being governed by the rate of phonon–phonon scattering due to the anharmonicity of lattice vibrations.

Relations between Optical Constants and Dielectric Constant

In order to experimentally obtain the complex dielectric function $\varepsilon(\omega)$, the basic quantity in which the dynamics of microscopic motions in the medium are directly reflected as mentioned above, one must resort to measurements of various optical constants which are functionally related with $\varepsilon(\omega)$ as follows.

When the electromagnetic wave comes from vacuum into a medium with dielectric constant $\varepsilon_1(\omega)+\mathrm{i}\varepsilon_2(\omega)$ $(\varepsilon_2(\omega)\geqslant 0)$, and magnetic permeability $\mu=\mu_0$ (the same as in vacuum), the wave vector becomes $\sqrt{(\varepsilon_1(\omega)+\mathrm{i}\varepsilon_2(\omega))/\varepsilon_0}\equiv\tilde{n}(\omega)\equiv n(\omega)+\mathrm{i}\kappa(\omega)$ times of its value k in vacuum (the square root with non-negative $n(\omega)$ and $\kappa(\omega)$ is to be chosen). This means that the amplitude of the electromagnetic wave decays as $\exp(-\kappa kx)$ in the medium with the extinction coefficient $\kappa(\omega)$, and the wavelength becomes n^{-1} times of its value $\lambda=2\pi/k$ in vacuum. n is the refractive index with which the angle θ_r of the refracted beam (measured from the perpendicular of the surface) is determined against the given angle θ_i of incidence through the Snell's law $n=\sin\theta_\mathrm{i}/\sin\theta_\mathrm{r}$. From this law, it also follows that the light beam incident from a medium of refractivity n' upon a medium of smaller refractivity n'' is subject to total reflection (because of no solution for θ_r), when the angle θ_i of incidence is greater than the critical angle θ_c, given by $\sin\theta_\mathrm{c}=n''/n'$. $\tilde{n}$ defined above, is called the complex refractive index.

For normal incidence, the reflectivity, the ratio of the electromagnetic energies of the reflected and incident waves, is given by

$$\begin{aligned}R(\omega)&=|(\tilde{n}-1)/(\tilde{n}+1)|^2\\&=\{(n-1)^2+\kappa^2\}/\{(n+1)^2+\kappa^2\}\end{aligned}$$

To be more elaborate, the ratios $H_\mathrm{r}/H_\mathrm{i}$ and $-E_\mathrm{r}/E_\mathrm{i}$ of the magnetic and electric fields between reflected and incident waves, inclusive of their phases, are given by the complex reflectivity $\tilde{r}(\omega)=(\tilde{n}-1)/(\tilde{n}+1)$. Rewriting this as $\tilde{r}(\omega)=\sqrt{R(\omega)}\exp[\mathrm{i}\theta(\omega)]$, one obtains the relations:

$$\begin{aligned}n(\omega)&=(1-R)/(1+R-2\sqrt{R}\cos\theta)\\\kappa(\omega)&=2\sqrt{R}\sin\theta/(1+R-2\sqrt{R}\cos\theta)\end{aligned}$$

From the analyticity of the complex refractivity $\tilde{n}(\omega)$, one obtains the Kramers–Kronig relations between its real and imaginary parts,

$$n(\omega)-1=\pi^{-1}P\int_0^\infty 2\omega'\kappa(\omega')\mathrm{d}\omega'/(\omega'^2-\omega^2)$$

and

$$\kappa(\omega)=-2\omega\pi^{-1}P\int_0^\infty (n(\omega')-1)\mathrm{d}\omega'/(\omega'^2-\omega^2)$$

Now the intensity of light in the medium with a complex dielectric constant decays as $\exp(-\alpha(\omega)x)$, and the so-defined absorption coefficient $\alpha(\omega)$ is related with the extinction coefficient by $\alpha(\omega)=2\omega c_0^{-1}\kappa(\omega)$, as mentioned before. If one measures the absorption coefficient $\alpha(\omega)$ over the entire region, one can obtain $n(\omega)$, $\kappa(\omega)$ and hence, the dielectric function $\varepsilon(\omega)$.

Another method of obtaining $\varepsilon(\omega)$ is the Kramers–Kronig analysis of reflectivity. Assuming the analyticity of the logarithm of the complex refractivity $\ln\tilde{n}(\omega)$ on the upper half of the complex ω-plain, one can derive

$$\theta(\omega)=-\omega\pi^{-1}\int_0^\infty \ln[R(\omega')/R(\omega)]\mathrm{d}\omega'/(\omega'^2-\omega^2)$$

where, $0\leqslant\theta(\omega)\leqslant\pi$. From the reflectivity spectrum $R(\omega)$ measured over the entire region, one obtains $\theta(\omega)$ and hence $n(\omega)$ and $\kappa(\omega)$, and finally $\varepsilon(\omega)$.

Polariton Picture for the Electromagnetic Wave in a Dispersive Medium, the Optical Absorption and the Reflectance

To see more clearly the behaviors of the electromagnetic wave with frequency near a pole ω_j^t of the lossless dispersion $\varepsilon(\omega)$, consider a single pole $\omega_\mathrm{t}\equiv\omega_j^\mathrm{t}$, which is well isolated from other poles. First invert the abscissa and the ordinate to show ω as a function of ε as shown in **Figure 1b**. Then plot in **Figure 1a** the real and imaginary parts of the complex wave vector $\tilde{n}(\omega)k\equiv n(\omega)k+\mathrm{i}\kappa(\omega)k\equiv k_\mathrm{r}+\mathrm{i}k_\mathrm{i}$ towards the right and left, respectively, of the abscissa k against ω as ordinate. Finally, one plots in **Figure 1c** the reflectivity $R(\omega)$ against ω in the same way. **Figure 1a** indicates that the ω–k dispersion of the electromagnetic wave is distorted as a result of resonant mixing with the polarization wave of the medium. A quantum of this mixed wave is called polariton. Note that the asymptotic light velocities of the upper and lower branches of the polariton are different due to the contribution of the resonance to the dielectric constant.

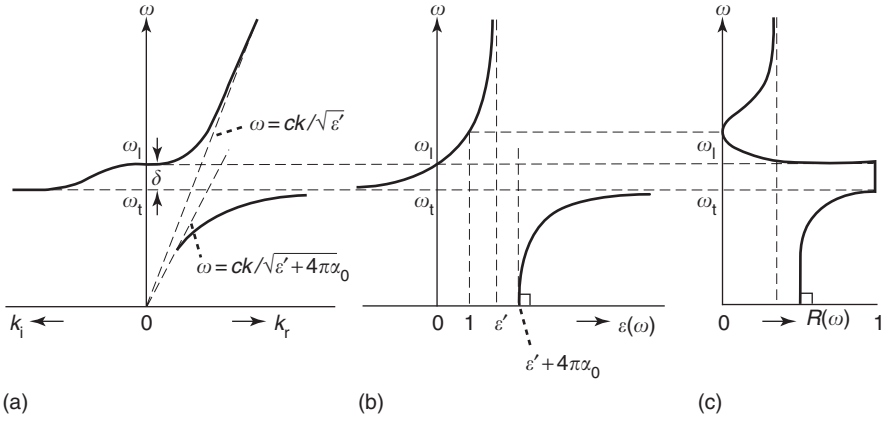

Figure 1 (a) Spatial dispersion of polariton, $\omega(k)$. (b) Dielectric dispersion, $\varepsilon(\omega)$. (c) Reflectivity, $R(\omega)$. (Reproduced with permission from Toyozawa Y (2003) *Optical Processes in Solids*. Cambridge: Cambridge University Press.)

There is no propagating wave in the medium between ω_t and ω_l, where the incident electromagnetic wave is totally reflected as shown in **Figure 1c**. Instead, there is an evanescent mode decaying as $\exp(-k_i x)$ toward the inside. The same holds in metals ($\omega_t = 0$) in much wider spectral regions, $\tau^{-1} \ll \omega < \omega_p$. Thus, the visible light is almost totally reflected on the metal surface, the reason why metals glitter.

Each pole in $\varepsilon_1(\omega)$ is blurred by the damping constants γ, and the corresponding resonance line in $\varepsilon_2(\omega)$ is broadened by γ. The spectrum of $\varepsilon_2(\omega)$ represents what is called absorption, but one must be careful in relating it with the spectrum of the absorption constant. The observed spectrum of $R(\omega)$ in some insulators shows strong resonance peaks often as high as almost reaching unity, and the dips as deep as nearly vanishing (as shown in **Figure 1c** in the idealistic situation of vanishing γ). In such a situation ($\gamma \lesssim \Delta$), the spectral shape of the absorption constant

$$\alpha(\omega) = (c_0 \varepsilon_0)^{-1} (\omega / n(\omega)) \varepsilon_2(\omega)$$

is significantly different from that of the basic quantity $\varepsilon_2(\omega)$, because of the factor $n(\omega)$ which varies significantly around the resonance. This is the reason why the Kramers–Kronig type analysis is necessary to obtain, from the observed optical constants, a more basic quantity $\varepsilon_2(\omega)$, so as to facilitate a quantitative comparison with particular theoretical models. For weak resonances (small oscillator strengths) such as weak exciton lines and impurity absorption bands, it is necessary to approximate $n(\omega)$ as a constant and to express

$$\alpha(\omega) = \text{const. } \omega \varepsilon_2(\omega) = \text{const. } \sigma(\omega)$$

If the lower branch of the polariton has a $\boldsymbol{k}$-dependence as in the case of an exciton with finite effective mass, one needs an additional boundary condition (abbreviated as ABC) besides the Maxwell boundary condition, in order to see how the incoming electromagnetic wave is converted to the lower and upper branch polaritons. More basically, this problem is to be studied in the context of a nonlocal theory with spatial dispersion $\varepsilon(\boldsymbol{k}, \omega)$ and surface structure being considered.

The Electric Quadrupole and Magnetic Dipole Transitions

So far, the discussion has been confined to the electric dipole allowed transitions. When the transition matrix elements μ_{j0} of the dipole moment between the states j and 0 vanish, one must explore the possible transitions due to higher multipoles. To see this, one starts with the canonical expression for the kinetic energy of an electron in an electromagnetic field, $(\boldsymbol{p} - \mathrm{e}\boldsymbol{A}(\boldsymbol{r}))^2/2m$, and takes the linear term in the vector potential $\boldsymbol{A}$, $H_1 = -(e/2m)[\boldsymbol{p} \cdot \boldsymbol{A}(\boldsymbol{r}) + \boldsymbol{A}(\boldsymbol{r}) \cdot \boldsymbol{p}]$ as the interaction of an electron with the electromagnetic field of which the electric field is given by $-\partial \boldsymbol{A}/\partial t = \boldsymbol{E} = \boldsymbol{E}_0 \exp(\mathrm{i}\boldsymbol{k} \cdot \boldsymbol{r} - \mathrm{i}\omega t)$, and hence, the amplitude of magnetic flux density by $\boldsymbol{B}_0 = \omega^{-1} \boldsymbol{k} \times \boldsymbol{E}_0$. Considering that the wave vector of the electromagnetic wave under consideration is much smaller than the reciprocal of atomic radius a, one takes the power series expansion $\exp(\mathrm{i}\boldsymbol{k} \cdot \boldsymbol{r}) = 1 + \mathrm{i}\boldsymbol{k} \cdot \boldsymbol{r}$ neglecting higher order terms, to obtain $H_1 = [-(e/\mathrm{i}m\omega)\boldsymbol{p} \cdot \boldsymbol{E}_0 - (e/\mathrm{i}m\omega)\mathrm{i}\boldsymbol{k} \cdot \boldsymbol{Q} \cdot \boldsymbol{E}_0 - (e/2m)\boldsymbol{l} \cdot \boldsymbol{B}_0] \exp(-\mathrm{i}\omega t)$, where $Q_{\alpha\beta} \equiv (1/2)(p_\alpha r_\beta + r_\beta p_\alpha)$ is the symmetric tensor, and $\boldsymbol{l} \equiv \boldsymbol{r} \times \boldsymbol{p}$ is the orbital angular momentum. Making use of the equation of motion, $\boldsymbol{p}/m = \mathrm{d}\boldsymbol{r}/\mathrm{d}t = (\mathrm{i}/\hbar)[H, \boldsymbol{r}]$, one can find that the transition matrix elements of the first and second terms of H_1 represent those of the interactions of electric dipole and electric quadrupole moments with

the electric field, respectively. The third term represents the Zeeman term for the orbital magnetic moment in the magnetic field as is obvious from the well-known magnetogyric factor $\gamma = (e/2m)$, and is to be combined with that for the spin magnetic moment, not considered so far, with twice as large a magnetogyric factor, to give $-(e/2m)(\boldsymbol{l} + 2\boldsymbol{s}) \cdot \boldsymbol{B}_0$, where $\boldsymbol{s}$ is the spin angular momentum.

When the electric dipole transition (E_1) is forbidden between states 0 and j, one must consider the electric quadrupole transition (E_2) and/or the magnetic dipole transitions (M_1), whose oscillator strengths are of the order $(ka)^2 \sim 10^{-6}$ in contrast to the order of unity in (E_1) transitions as explained above.

Optical Bistability

R Bonifacio and F Casagrande, Università degli Studi di Milano, Milan, Italy

Introduction

With the advent of the laser, in 1960, an entirely new field, nonlinear optics quickly developed, and progress in quantum optics and cavity quantum electrodynamics received a huge impulse. It was in this period that a great excitement was raised by optical bistability (OB), a phenomenon that can be described as a kind of passive counterpart of the laser.

In a laser system, an atomic medium is placed in an optical cavity where a transition is resonant with one cavity mode. Atoms are excited so that population inversion is created in the relevant levels, and the stimulated emission overcomes the absorption. If the resulting amplification can balance the cavity losses, a stationary oscillation establishes in the resonator, whose output is the laser field.

Consider a system of this kind, but with two main differences: the atomic medium is not pumped, but the optical cavity is driven by a coherent external field. This system can exhibit the phenomenon of "optical bistability": the intensity of the light transmitted from the resonator can take two different values corresponding to the same intensity of the incident field.

The first predictions of this effect were made in 1969 by Szöke, Daneu, Goldhar, and Kurnit, and independently by Seidel in an application for a US patent. The first experimental observation was achieved in 1975 by Mc Call, Gibbs, and Venkatesan, who used vapors of sodium atoms in a Fabry–Perot cavity driven by a CW dye laser. One year later a basic theoretical model of optical bistability was presented by Bonifacio and Lugiato.

The fundamental physics of this phenomenon is outlined, and the main developments in the theoretical understanding and the experimental implementations of OB and related applications are reviewed below.

Atomic Polarization and Dielectric Susceptibility

The main features of optical bistability can be understood by considering a semiclassical treatment.

A classical monochromatic radiation field, $\boldsymbol{E}(\boldsymbol{x}, t) = \boldsymbol{E}_0 \cos(\omega t - \boldsymbol{k} \cdot \boldsymbol{x})$, induces a polarization $\boldsymbol{P}(\boldsymbol{x}, t)$ in an ensemble of N two-level atoms in a volume V, where

$$\begin{aligned}\boldsymbol{P}(\boldsymbol{x}, t) &= \varepsilon_o \,\mathrm{Re}\{\chi \boldsymbol{E}_0 \exp[\mathrm{i}(\boldsymbol{k} \cdot \boldsymbol{x} - \omega t)]\} \\ &= \varepsilon_o [\chi_d \cos(\omega t - \boldsymbol{k} \cdot \boldsymbol{x}) \\ &\quad + \chi_a \sin(\omega t - \boldsymbol{k} \cdot \boldsymbol{x})] \boldsymbol{E}_0\end{aligned}$$

The complex dielectric susceptibility, $\chi = \chi_d + i\chi_a$, describes the response of the medium to the field. The induced atomic polarization exhibits two components, in phase and in quadrature with the field.

For weak atom–field interaction, the susceptibility is independent of the field amplitude, and this is the realm of linear optics. The dynamics of weakly excited atoms can be simply modeled by forced, harmonically oscillating dipoles. For a low-density atomic gas, where the refractive index $n = \sqrt{1+\chi} \cong 1 + \chi/2$, the real and imaginary parts of susceptibility, χ_d and χ_a, control the dispersive and absorptive effects via two parameters, the wave number κ and the absorption coefficient α, respectively, where

$$\kappa = \frac{\omega}{2c}\,\chi_d, \quad \alpha = \frac{\omega}{2c}\,\chi_a$$

For large enough field amplitude, however, the dielectric susceptibility becomes a nonlinear function of the field intensity $I = E_0^2/2$. In fact, the optical Bloch equations provide the following expression for the susceptibility:

$$\chi = \frac{N\mu^2}{V\varepsilon_0\hbar}\,\frac{\omega_a - \omega + i\gamma}{(\omega_a - \omega)^2 + \gamma^2 + (\mu^2/\hbar^2)I}$$

where μ is the modulus of the dipole matrix element for the relevant atomic transition, ω_a the Bohr transition frequency, and γ the spontaneous emission rate, here assumed as the only source of atomic decay, phenomenologically added to the Bloch equations.

The above result shows that both the dispersive (in phase) and the absorptive (in quadrature) components of induced polarization can exhibit a nonlinear dependence on the field amplitude, that is one of the clues to optical bistability in the corresponding dispersive or absorptive regimes.

Absorptive Optical Bistability: Steady-State Equation

In the case of resonance between the atomic transition and the radiation field, $\omega_a = \omega$, the dispersive component of susceptibility vanishes, $\chi_d = 0$, from the expression of the on-resonance absorptive component, χ_a, and one can write the absorption coefficient as

$$\alpha = \frac{\alpha_0}{1 + I/I_S}$$

where $\alpha_0 = \omega N\mu^2/2cV\varepsilon_0\hbar\gamma$ is the small signal value, and $I_S = \hbar^2\gamma^2/\mu^2$ the saturation intensity. The above expression shows that, for increasing field intensity, the absorption undergoes saturation: the coefficient α can decrease well below the small signal value α_0, until the absorber eventually becomes transparent. In this limit, the populations of the two relevant levels are equal. The saturation of absorption is a basic ingredient for the occurrence of absorptive optical bistability, and is the passive equivalent of gain saturation in laser systems.

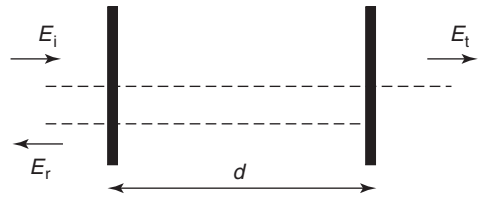

Figure 1 Fabry–Perot cavity with two partially reflecting mirrors at a distance d. The incident field E_i is partially reflected (E_r) and partially transmitted (E_t) by the optical cavity.

Absorptive OB can be observed when, for example, the atomic system fills a Fabry–Perot cavity (**Figure 1**), which is driven by a coherent incident field, E_i, oscillating at the same frequency ω of both the cavity mode and the atomic transition. The cavity mirrors provide an intrinsic feedback mechanism, by which the reflected cavity field recombines with the injected driving field. Feedback adds to nonlinearity for the occurrence of OB.

In the semiclassical treatment of system dynamics, the optical Bloch equations which describe the atomic polarization and the level of populations induced by the cavity field, are self-consistently coupled to the Maxwell equation for the cavity-field amplitude, generated by the atomic polarization as well as by the injected field, which acts as a source term. At steady state, the field propagation equation can be integrated with respect to the relevant space coordinate and with proper boundary conditions. When standing-wave effects can be averaged, the treatment for a Fabry–Perot cavity becomes equivalent to the simpler one of a unidirectional ring cavity. In this case a simple analysis shows that, at steady state, in the small absorption limit $\alpha d \ll 1$, where d is the cavity length, the ratio of transmitted to incident field amplitude can be written as

$$\frac{E_t}{E_i} = \frac{1}{1 + \alpha d/T}$$

where $T = I_t/I$ is the mirror transmittivity. By inserting the expression for the absorption coefficient α, and solving for the incident field amplitude, one derives the stationary state equation for

absorptive OB:

$$y = x + 2C\frac{x}{1+x^2}$$

It provides a nonlinear relation between the dimensionless transmitted field amplitude, x, and incident field amplitude, y, defined as $x \equiv E_t/\sqrt{I_S T}$, $y \equiv E_i/\sqrt{I_S T}$. One can notice the two contributions to the transmitted field, due to the injected field, and to radiation from the absorptive component of atomic polarization in quadrature with the field. The latter contribution is an atomic cooperative one. Actually, the steady-state equation is ruled by a single parameter, the cooperation parameter C, which can be written in terms of both macroscopic and microscopic system parameters as follows:

$$C = \frac{\alpha_0 d}{2T} = \frac{Ng^2}{2k\gamma}$$

where g is the atom–cavity mode coupling frequency, and k the cavity line width.

Absorptive Optical Bistability: Hysteresis Cycle

In **Figure 2**, the transmitted field amplitude x is plotted as a function of the incident field amplitude y, obtained by inverting the steady-state relation $y = y(x)$, for different values of the cooperation parameter C.

The dashed line for $C = 0$ (**Figure 2a**) shows for reference the empty cavity limit, $x = y$. For $0 < C < 4$ (**Figure 2b**), the curve exhibits a nonlinear monotonic behavior. It connects a cooperative, low-transmission linear regime, where $x \approx y/(1 + 2C)$ for $x^2 \ll 1$, with a one-atom, high-transmission linear regime, where $x \approx y$ for $x^2 \gg 1$. In between, $y(x)$ exhibits a region with a steep slope where the system can operate as an optical transistor, since a small amplitude incident field is transformed into a large amplitude output field.

$C = 4$ (**Figure 2c**) is a critical value. For $C > 4$ (**Figure 2d**), the curve exhibits the characteristic S-shaped behavior which is the signature of bistability. In fact, for $C > 4$ the equation $x = x(y)$ admits three real solutions on a range of input values, however, the portion of the curve with negative slope is unstable, that is, the corresponding states are unphysical. Though this instability may be easily checked mathematically, it can be readily understood in physical terms by realizing that on the negative-slope portion of $x(y)$ a decrease of the incident field would correspond to an increase of the transmitted one. Hence, there are only two accessible stationary states, corresponding to a single output value (bistability).

Which is really the state of the system depends on its history, as illustrated in **Figure 3**. For example, consider a value $y = y_1$ in the bistable range, $y_d < y_1 < y_u$. Depending on whether y_1 is approached for increasing or decreasing values of y, the system will be in the state (x_1, y_1) on the lower branch of the hysteresis cycle, or in state (x_3, y_1) on the upper branch, respectively.

In general, starting with a small incident field amplitude, the system remains on the lower branch for increasing y, up to $y = y_u$, at this value the system jumps on the upper branch. Conversely, starting with large incident amplitude, the system remains on the upper branch for decreasing y, until $y = y_d < y_u$,

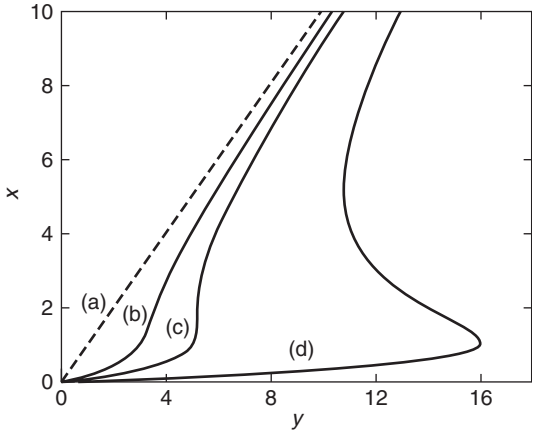

Figure 2 Dimensionless transmitted field amplitude x vs. incident field amplitude y in the stationary state of absorptive optical bistability. (a) $C = 0$, (b) $C = 2$, (c) $C = 4$, (d) $C = 15$.

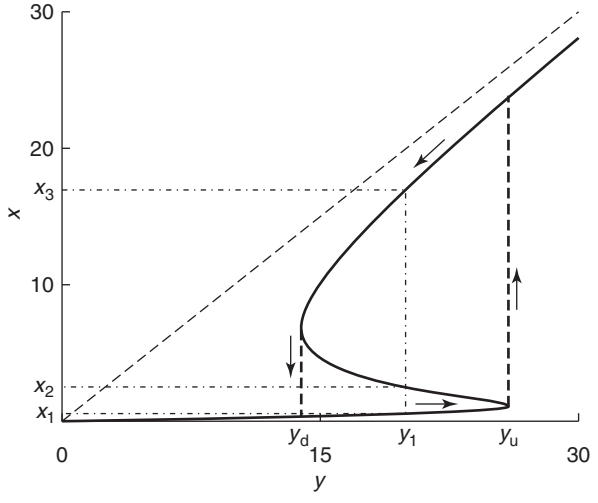

Figure 3 Hysteresis cycle in absorptive optical bistability for transmitted field amplitude x vs. incident field amplitude y, for cooperation parameter $C = 25$.

when it jumps down to the lower branch and thus closes the cycle.

The physical mechanism is as follows. For small intensity, the incident field is mostly reflected due to strong atomic absorption in the cavity. By increasing the incident field intensity, the absorption decreases, until the atomic transition is saturated, and suddenly the transmittivity approaches the empty cavity limit. If the incident intensity is decreased from this limit, the absorber remains bleached well below the upper transition value $y = y_u$, until at $y = y_d$ the intensity is so low that the transmitted field comes back to the small initial values.

The main theoretical predictions were confirmed in a series of experiments by Kimble and co-workers, culminating in a quantitative test by Orozco, Kimble, and Rosenberger in 1987.

Though hysteresis effects are quite familiar in condensed matter physics, for example, in magnetism and ferroelectricity, the relevant point here is that optical bistable systems are open systems driven out of thermodynamical equilibrium. In particular, if one considers the steady-state curves $y(x)$ for different values of C, instead of the curves $x(y)$ as in **Figure 2**, they closely resemble the van der Waals curves which describe the transition from gas to liquid in a system at thermodynamical equilibrium. More precisely, x, y, and C play the role of pressure, volume, and temperature, respectively, and the curve for $C = 4$ is equivalent to the critical isotherm. Hence, just like the laser is a prototype of a first-order phase transition in out-of-equilibrium (dissipative) systems, OB represents a prototype of second-order phase transition in the same framework.

Dispersive Optical Bistability

A similar behavior also shows up in the dispersive regime of optical bistability, though the underlying physical mechanism is different. In this regime, the system operates well off-resonance, so that the atomic response is ruled by the dispersive component χ_d of dielectric susceptibility, whereas the absorptive part χ_a is negligible. Hence, the saturation of dispersion is crucial in this case. If one evaluates the expression of χ_d in a large detuning limit, where in the denominator γ^2 is negligible and $(\omega_a - \omega)^2 \gg (\mu^2/\hbar^2)I$, then the dispersive susceptibility can be approximated as follows:

$$\chi_d \cong \frac{N\mu^2}{V\varepsilon_0\hbar}\frac{1}{\omega_a - \omega}\left[1 - \frac{(\mu^2/\hbar^2)I}{(\omega_a - \omega)^2}\right] \equiv \chi_0 + \chi_2 I$$

In this limit, the (real) refractive index of the atomic medium can be written in the characteristic form of an optical Kerr medium: $n = n_0 + n_2 I$, where $n_0 = 1 + \chi_0/2$ and $n_2 = \chi_2/2$. The atoms thus behave as a nonlinear dielectric medium with a third-order susceptibility.

Kerr nonlinearity and intrinsic feedback conspire for the occurrence of dispersive OB in a coherently driven optical cavity, where at steady state the transmitted field intensity can assume two different values for the same incident intensity.

The jump, for example, from low to high transmission branch of the hysteresis cycle is explained as follows: for increasing intensity of the incident field, the variation of the refractive index, hence the effective wave number, can shift the cavity frequency ω to coincide with the driving field frequency ω_0, that is, on resonance, where the transmission is suddenly raised. The reverse process is similarly explained by a return to off-resonance conditions.

Just dispersive effects allowed the mentioned first observation of optical bistability.

Dynamical Effects

The dynamics of optical bistable systems has been the object of careful investigation since the early days, especially after the predictions of instabilities of different kinds in the late seventies. McCall predicted regenerative pulsations in the presence of nonlinearities with some specific features, and demonstrated their occurrence with a hybrid electrooptical device.

Bonifacio and Lugiato showed by a many-mode model that, under proper conditions, a portion of the high-transmission branch of the hysteresis cycle can be unstable. In this case, the system can operate as a kind of transformer of continuous light into pulsed light, where the self-pulsing oscillation occurs with a period equal to the cavity round-trip time.

Another instability mechanism was suggested by Ikeda in 1979 by investigating dispersive bistability with time delay effects, namely, when the time spent by radiation to propagate from the output to the input end of the nonlinear medium is longer than the atomic decay time. This instability can lead to period doubling and chaos, as first observed in 1981 by Gibbs, Hopf, Kaplan, and Shoemaker. It was then shown that the Ikeda instability emerges in a suitable limit of the general treatment by Bonifacio and Lugiato.

A number of other instabilities were investigated, including those due to the transverse structure of the cavity field, or originated by counter-propagating radiation beams in bidirectional ring cavities containing a saturable absorber and driven by an external coherent field. These features stimulated further studies in nonlinear and chaotic dynamics as well as in nonequilibrium statistical mechanics.

Quantum Treatment and Experiments in Cavity Quantum Electrodynamics

Quantum statistical treatments of optical bistability allowed a proper description of system dynamics, including fluctuations, which are especially relevant near the switching conditions. Purely quantum features could be investigated, such as the photon number distribution, and nonclassical effects could show up in the statistical properties of the transmitted field. The semiclassical treatment corresponds to an approximate approach, at the level of the expectation values of the relevant system operators and where all correlations are neglected.

First of all, the quantum approach showed that, in fact, only one of the two accessible stationary states of the system is absolutely stable, the other one is a metastable state, that is physically accessible only for limited time intervals. Hence, in the bistable parameters range the system switches from one to the other state, and the corresponding switching time is one of the main parameters for practical applications of optical bistable devices.

The quantum theory also showed that the spectrum of transmitted light from an optical bistable system exhibits remarkable features. In the low-transmission branch, for instance, the spectrum is narrower than the natural line, in agreement with the cooperative nature of the emission process. Near the switch-up region, the spectrum is broadened by the onset of large fluctuations. In the high-transmission branch, for large driving field intensity, the spectrum approaches the three-peaked structure characteristic of resonance fluorescence, in agreement with the one-atom nature of system behavior in that limit. Hence, the switching represents a transition between cooperative and non-cooperative radiation processes.

Progress in cavity quantum electrodynamics in the strong coupling regime, where the coherent atom–field interaction dominates the incoherent decay processes, has allowed the experimental investigation of absorptive OB in the limit of a few atoms and photons in a high-finesse cavity, much like it has allowed achieving maser and laser operation with single atoms in microwave and optical resonators, respectively.

In 1991, Rempe, Thompson, Brecha, Lee, and Kimble could observe optical bistability with a number $N \geqslant 15$ of cesium atoms in the cavity, and cooperation parameter $C \geqslant 30$. For smaller numbers of atoms, they reported the breakdown of the semiclassical approximation and the onset of a purely quantum regime, where fluctuations play a basic role, and a single atomic emission has a relevant effect on system dynamics. In this regime, they could observe the occurrence of the effects of photon antibunching and sub-Poissonian photon statistics, as first predicted by Casagrande and Lugiato in 1980.

Semiconductors and Optical Bistable Devices

The first demonstrations of optical bistability raised great hopes in a new all-optical technology based on the transmission, control, and manipulation of light. Optical bistable devices were potentially considered as new kinds of chips for the ultimate goal to control light by light. Actually, they can operate as optical memory elements, transistors, logical gates, and switches, and can perform other basic operations for communications and computation, where photons are used instead of electrons.

After some experiments with solid (ruby) atomic samples and with Kerr liquids in Fabry–Perot resonators, relevant advances were readily achieved in experiments with semiconductors, starting around 1980 from gallium arsenide (GaAs) and indium antimonide (InSb). In bulk GaAs, for instance, the optical Fabry–Perot cavity was reduced to a microcavity, only a few micrometers long, simply consisting of a semiconductor layer with two partially reflecting faces. Under coherent excitation, the material provides strong nonlinearities due to excitonic effects at wavelengths near the bandgap. An exciton is an electron–hole pair bound system. Exciton resonances are responsible for sharp peaks in the absorption edge. The mechanism for absorption saturation is the creation of an increasing number of partially overlapping excitons, such that the Coulomb potential responsible for their bonding is eventually screened and their lifetime shortened by ionization.

Optical bistability with InSb was based on different mechanisms than excitonic absorption. The use of this material allowed the first observation of the effect of optical multistability. Optical bistable devices with semiconductors exhibited quite smaller dimensions, much shorter switching times, and much lower power levels, than with atomic systems. Switch-on times of a few picoseconds were soon reached, though switch-off times were longer due to slower recombination dynamics. Operation at room temperature with remarkably low power was obtained with GaAs super-lattice devices, based on multiple quantum well structures with alternating layers of GaAs and $Al_xGa_{1-x}As$. Many other bulk or low dimensional semiconductor structures, as well as organic materials, liquid crystals, not to mention hybrid electrooptical devices, were tested to implement optical bistable devices.

The dream of all-optical computers, however, slowly faded for the difficulties, with respect to electronic technology, in the realization of high-density arrays of fast optical gates able to operate at low enough switching energies and powers. On the other hand, increasing attention has been paid to the potentiality for applications in optical communications and in specific sectors of computing such as the interconnections.

The subsequent explosive progress in microstructured materials has however opened, again, very promising perspectives to optical bistability and related applications, mainly related to the so-called photonic crystals, composite periodic dielectric materials, where, for example, dielectric rods of high refractive index are embedded in a low refractive index material. Photonic crystals appear as the analog of semiconductors for photons, exhibiting photonic bandgaps like the electronic bandgaps in semiconductor materials. Their properties can be engineered with great flexibility. At present, optical bistable devices based on photonic bandgap microstructures are expected to exhibit quite remarkable properties, such as sizes on the order of a radiation wavelength, switching times shorter than 1 ps, and dissipation of power not larger than a few milliwatts.

The progress in optics and material sciences really seems to renew the expectations raised in the early days of optical bistability, perhaps even as regards all-optical computing.

Optical Fibers

V Degiorgio and I Cristiani, Università degli Studi di Pavia, Pavia, Italy

Introduction

Immediately after the laser invention, it was realized that laser beams with a carrier frequency of some 10^{14} Hz have the potential to transport information with a much larger frequency band than either radio or microwaves. Atmospheric transmission is limited to line-of-sight communications and is strongly dependent on visibility conditions. It was, therefore, natural to think about a waveguide having the function of creating a protected path for the light beam, and also of compensating diffraction by optical confinement. Indeed, an optical wave having a finite transversal size broadens during propagation in free space. If one considers the output of a typical laser working at the wavelength λ, this is represented by a Gaussian wave with a beam diameter $d \sim 1$ mm. The diffraction angle θ (also called the divergence of the beam) is of the order of λ/d. Taking $\lambda = 1\,\mu$m, it is found that at the distance $L = 1$ km the beam diameter becomes 1 m. At present, guided-wave optics is an important technology with applications that are not limited to the transmission of optical signals, but also involve the fabrication of integrated optical and optoelectronic devices, such as lasers and modulators. The basic concept of optical confinement is simple. A dielectric medium of refractive index n_1, embedded in a medium of lower refractive index n_2, acts as a light trap within which optical rays remain confined by multiple internal reflections at the boundaries. The optical waveguide may have the shape of a slab, strip, or cylinder. The most widely

used is the optical fiber, which is made of two concentric cylinders of glass or polymeric material. Silica glass fibers represent, by far, the most important family of fibers, because they can transmit optical pulses over long distances with small attenuation and limited pulse broadening. The fibers made of polymeric material, called plastic optical fibers (POF), although presenting much larger losses than silica fibers, have the advantage of a much cheaper fabrication process, and can be competitive for the short links required in a variety of applications, including communication networks inside a building or a vehicle.

Structure and Modes

The structure of an optical fiber is shown in **Figure 1**. Typically, the cladding is made of pure silica, whereas the core is doped with germania during manufacturing in order to increase its refractive index and introduce a positive index step between core and cladding. In many cases, instead of having a step in the refractive index profile, the refractive index of the core is graded from a maximum value at its center to a minimum value at the core-cladding boundary. The fiber is then called a graded-index fiber, whereas the fiber shown in **Figure 1** is called a step-index fiber. For optical-communication fibers, the cladding diameter is typically 125 μm, and the core diameter can vary from 9 to 50 μm depending on the application.

An elementary description of light trapping in the core of a step-index fiber can be based on total internal reflection: since $n_1 > n_2$, when the angle of incidence β on the core-cladding interface is larger than the limit angle $\beta_c = \arcsin(n_2/n_1)$, total internal reflection occurs, so that the beam can propagate for an indefinite distance within the fiber core without radiating outside any optical power. If an optical ray whose propagation direction forms an angle α with the axis of the fiber is considered, it is easy to derive that the maximum acceptance angle, α_{max}, is given by

$$\sin \alpha_{max} = n_1 \sqrt{1 - \sin^2 \beta_c} = \sqrt{n_1^2 - n_2^2} \qquad [1]$$

The quantity $\sin \alpha_{max}$ is called numerical aperture of the fiber, and is indicated with the symbol *NA*. Considering a realistic case in which $n_1 = 1.48$, $n_2 = 1.46$, one finds that the numerical aperture is 0.24, and $\alpha_{max} = 14°$.

The geometrical picture of light guidance by multiple reflections is not adequate to explain the propagation properties of the fiber. In particular, geometrical optics suggests a complete confinement

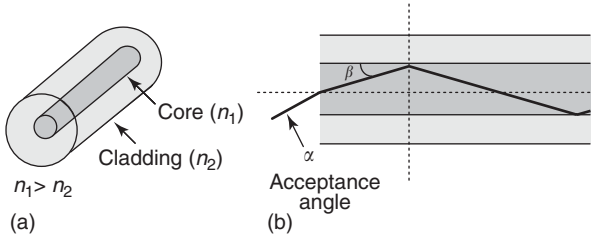

Figure 1 (a) Scheme of an optical fiber; (b) Waveguiding effect by total internal reflection.

of the light beam within the core, whereas wave optics predicts a nonzero intensity in the cladding region (evanescent wave). The general treatment requires solving the wave equation with the appropriate boundary conditions. Since it goes beyond the scope to discuss such a treatment, the article is limited to a description of the main results. Assuming that the electromagnetic wave is monochromatic (i.e., it contains a single frequency ν) and that nonlinear optical effects are negligible, it is found that there is a set of field configurations, called fiber modes, which can propagate without attenuation maintaining the same transversal distribution and the same polarization at all distances along the waveguide axis. In most practical cases, the full set of modes can be approximated by the so-called linearly polarized (LP_{mn}) modes. An LP_{mn} mode has n field maxima along a radius vector and $2m$ field maxima round a circumference. By calling E_{mn} the electric field associated to the mode mn, where the indices m and n are integer numbers, and choosing the z-axis coincident with the fiber axis, the fiber mode is characterized by a transversal field distribution $A_{mn}(x, y)$ and a propagation constant β_{mn}, both depending on m and n:

$$E_{mn}(x, y, z, t) = A_{mn}(x, y) e^{i(\beta_{mn} z - \omega t)} \qquad [2]$$

where $\omega = 2\pi\nu$ is the angular frequency. **Figure 2** shows the amplitude profile of the fundamental mode LP_{01} that is approximately described by a Gaussian function:

$$A_{01}(r) = A_o \exp\left(-\frac{r^2}{w^2}\right) \qquad [3]$$

where $r = (x^2 + y^2)^{1/2}$ is the distance from the fiber axis. It is seen that the field amplitude $A_{01}(x,y)$ is mainly concentrated inside the core, but presents exponentially decaying tails extending into the cladding region. Higher-order modes present more complicated profiles extending more and more deeply into the cladding as the indices m and n become larger and larger.

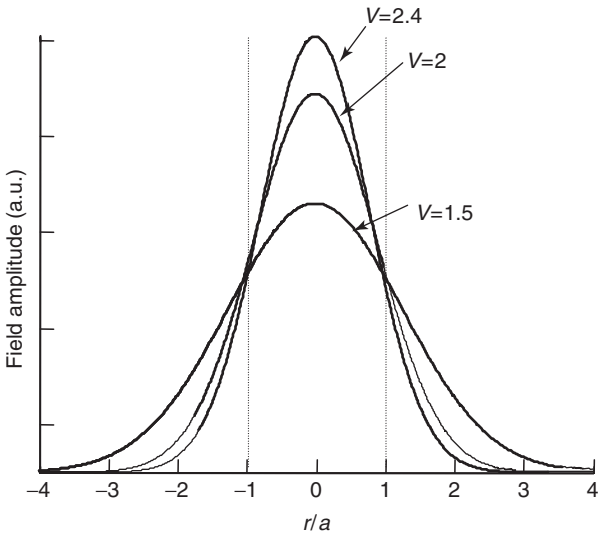

Figure 2 Field profile of the fundamental propagation mode LP_{01} for various values of the normalized frequency V.

In order to discuss fiber properties, it is helpful to introduce the dimensionless parameter V, called normalized frequency, defined as

$$V = \frac{2\pi a}{\lambda}\sqrt{n_1^2 - n_2^2} \qquad [4]$$

where $\lambda = c/v$ is the wavelength. The plots in **Figure 2** indicate that the beam size w is a decreasing function of V. This can be easily understood if one notes that the beam is more tightly confined when the core size is large in comparison with the wavelength, and when the difference in refractive index between core and cladding is large.

From the propagation constant β_{mn}, one can derive the effective index of refraction n_{mn} seen by the mode mn, by using the relation: $\beta_{mn} = 2\pi n_{mn}/\lambda$. The value of n_{mn} will be clearly intermediate between n_1 and n_2, approaching n_1 more closely when the field mode is more tightly confined.

A very important general property of waveguides is that, for a fixed waveguide configuration and a fixed λ, a fundamental mode always exists, whereas higher-order modes can be sustained only under specific conditions. In the case of optical fibers, the parameter controlling the single-mode or multimode behavior is the normalized frequency V. If V is sufficiently small, the fiber is single-mode. When V becomes larger than a critical value V_c, the second mode can also be sustained. By progressively increasing V, more and more modes can be guided. For $V \gg 1$, the number N of guided modes is given by: $N \cong V^2/2$.

The value of V_c is dependent on the fiber structure. In the case of the step-index fiber, $V_c = 2.405$. Fibers that are single-mode at $\lambda = 1500\,\text{nm}$ are usually designed with values of V close to 2, by choosing a core radius $\sim 4.5\,\mu\text{m}$ and a difference $n_1 - n_2 \sim 5 \times 10^{-3}$. It is to be noted that, since V is inversely proportional to λ, a fiber that is single-mode in the near infrared will be multimode in the visible.

Multimode fibers have typically a core diameter $\sim 50\,\mu\text{m}$. They are easier to align and less expensive than single-mode ones. However, as discussed later in the section "Dispersion," they are not fit for pulse transmission over long distances because pulse-broadening effects are large.

Attenuation

In principle, a guided mode can propagate in an optical fiber for arbitrary distances without suffering radiation losses. In practice, however, the propagating wave is always attenuated. Assuming that the losses are linear, the optical power P_o launched into the fiber decays exponentially along the fiber following the law:

$$P(z) = P_o e^{-\alpha_o z} \qquad [5]$$

where α_o, expressed in km^{-1}, is the attenuation coefficient. The quantity normally given in fiber specifications is the coefficient $\alpha = 4.34\ \alpha_o$ expressing the attenuation in dB km^{-1}.

The attenuation is due to two phenomena, light scattering and absorption. Light scattering is originated by the microscopic inhomogeneities that exist in the glass at the drawing temperature because of thermal fluctuations. Such inhomogeneities are frozen during the rapid cooling process, and give rise to spatial fluctuations of the refractive index over a submicrometric scale. Rayleigh scattering from these fluctuations has a cross section that scales according to λ^{-4}. As a consequence, scattering losses rapidly decrease as a function of wavelength.

Optical fibers are usually made of fused silica glass (SiO_2). This material has two strong absorption bands, an ultraviolet band $\sim 0.3\,\mu\text{m}$ due to electronic transitions and an infrared band $\sim 1.7\,\mu\text{m}$ due to the vibrational mode of the Si–O bond. The presence of water impurities gives other absorption peaks due to vibrations of the OH^- ion, the most important one near 1370 nm. Because of the combined effect of scattering and absorption, the attenuation curve for silica glass, as shown in **Figure 3**, has an absolute minimum at 1550 nm and a secondary minimum $\sim 1300\,\text{nm}$. The earliest optical communication schemes were working at $\sim 800\,\text{nm}$, where the attenuation has a local minimum, not apparent in **Figure 3**. The value of the attenuation at the absolute

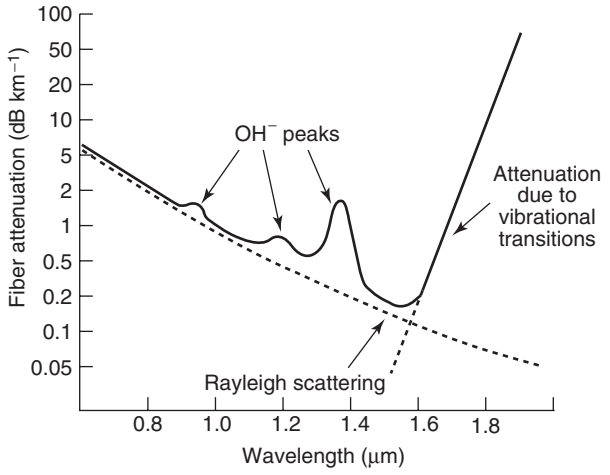

Figure 3 Dependence of the attenuation coefficient α of silica glass on the wavelength λ.

minimum, α_{min}, is $\sim 0.15\,dB\,km^{-1}$, corresponding to a reduction of the input power by a factor of 2 after a propagation length of 20 km. Optical communication systems operate at the wavelength corresponding to the minimum attenuation.

If different oxides are added to SiO_2, the position of α_{min} is only slightly changed because essentially all oxides present vibrational transitions in the range 1.5–2 μm. A significant shift of the minimum attenuation can be obtained by using glasses made with mixtures of fluorides, such as the so-called ZBLAN glasses that contain Zr, Ba, La, Al, and Na fluorides. Since vibrational levels of fluorides are localized in the range 5–8 μm, ZBLAN glasses present the attenuation minimum at $\sim 3\,\mu m$, with a value of α_{min} one order of magnitude smaller that of silica glasses. It is, however, rather difficult to draw ZBLAN fibers of good optical quality.

It should be mentioned that fiber losses increase considerably if the fiber is curved. This can be easily understood in the frame of geometrical optics: if the fiber is curved, there is a change of the incidence angle at the core-cladding interface and some rays may not be totally reflected. Such a radiation loss affects, in particular, the modes presenting a field distribution that extends considerably into the cladding, as it happens when the normalized frequency V is small.

Dispersion

In optics, the term dispersion indicates that the index of refraction of the medium changes with the frequency of the propagating wave, $n = n(\omega)$. An optical pulse with duration Δt has a spectral broadening $\Delta\omega \geqslant \Delta t^{-1}$, and cannot be treated as a monochromatic wave. Each frequency component travels in the dispersive medium with a different phase velocity $v_\phi = c/n(\omega)$. As a consequence, the pulse shape changes during propagation. If it is assumed that the input pulse is transform-limited, which means that all the frequency components have the same phase, the effect of dispersion is a progressive increase of the pulse duration as the propagation length increases.

If the wave propagates along an optical fiber, its velocity is determined by the effective index of refraction n_{mn} defined above. It is to be noted that, even in the absence of material dispersion, the effective index of refraction changes with frequency because the mode profile is frequency-dependent. Therefore, the fiber is dispersive even in the absence of dispersion of the materials constituting the fiber. This results in a waveguide contribution that must be added to the material contribution to obtain the total fiber dispersion.

Laser pulses have a spectral broadening $\Delta\omega$, normally much smaller than the central frequency ω_0. This allows one to treat the wave propagation in a dispersive medium by using a perturbative approach. The propagation constant $\beta(\omega)$ is expanded in a power series around ω_o, and the series is truncated to the quadratic term:

$$\beta(\omega) = \beta_o + \beta_1(\omega - \omega_o) + \tfrac{1}{2}\beta_2(\omega - \omega_o)^2 \qquad [6]$$

where β_j is the jth derivative of $\beta(\omega)$ evaluated at $\omega = \omega_o$. By using eqn [6] inside the propagation equation, it can be shown that the reciprocal of β_1 is the group velocity (i.e., the velocity of the pulse envelope) and that β_2 is the parameter responsible for pulse broadening, usually called group-velocity dispersion (GVD). If it is assumed that the input pulse is a transform-limited Gaussian pulse having full-width at half maximum equal to Δt_o, the pulse duration Δt after a path length z is given by

$$\Delta t = \sqrt{(\Delta t_o)^2 + \left(\frac{|\beta_2|z}{\Delta t_o}\right)^2} = \Delta t_o\sqrt{1 + \left(\frac{z}{L_D}\right)^2} \qquad [7]$$

where $L_D = (\Delta t_o)^2/|\beta_2|$ is called the dispersion length. Equation [7] indicates that dispersion effects become more and more important as the pulse duration becomes shorter and shorter. Considering, for instance, a standard single-mode optical-communication fiber at 1550 nm, $\beta_2 = -20\,ps^2\,km^{-1}$, and $\Delta t_o = 10\,ps$, one finds $L_D = 5$ km. This means that the pulse duration is more than doubled when $z = 10$ km. Clearly, pulse broadening can be very detrimental in long communication links because it produces a smearing out of individual bits, leading to higher bit error rates. In order to reduce such an effect, fibers with low value of

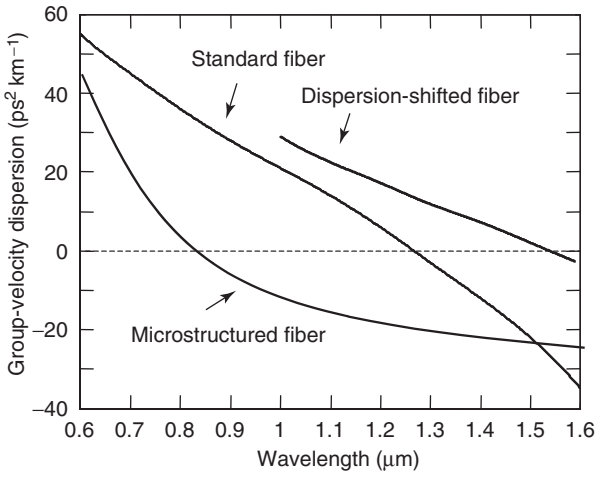

Figure 4 The dispersion parameter β_2 plotted as a function of wavelength for a standard single-mode fiber, a dispersion-shifted fiber, and a microstructured fiber.

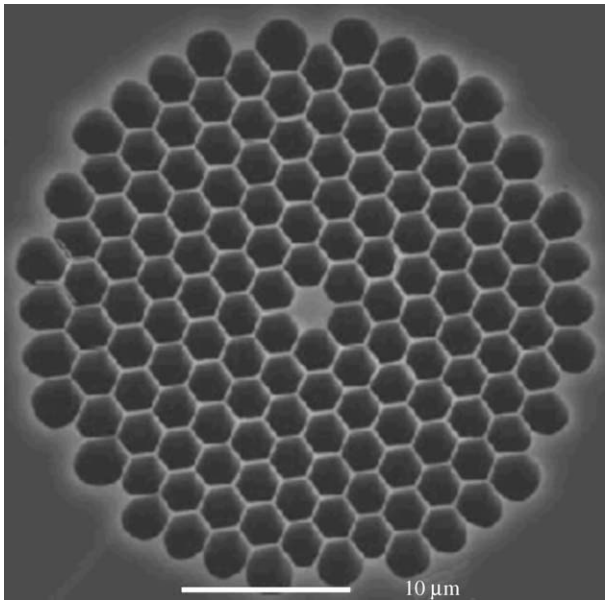

Figure 5 Cross section of a microstructured fiber made of silica with air holes running along the fiber axis. The silica core has a diameter of $\sim 2\,\mu$m.

β_2 have to be used. These special fibers, called dispersion-shifted fibers, are fabricated by an appropriate choice of refractive-index profile. **Figure 4** shows the behavior of β_2 as a function of λ for a standard single-mode fiber and for a dispersion-shifted fiber.

Multimode fibers present an additional dispersion mechanism due to the fact that different modes, even if oscillating at the same frequency, have different field profiles, hence different effective refractive indices. Therefore, if the pulse input power is coupled simultaneously to several modes, modal dispersion gives a contribution to pulse broadening that can be larger than that due to material and waveguide dispersion.

It should be noted that in this section, the refractive index has been considered as a real quantity, whereas the presence of attenuation would imply that the refractive index, hence the propagation constant, is a complex quantity.

Special Fibers

Besides step-index and graded-index fibers, other types of fibers having a more complicated index profile are used for special purposes. The previous section mentioned dispersion-shifted fibers, designed to present a reduced dispersion in a specific wavelength range. Another useful category is that of polarization-maintaining fibers, fibers presenting some anisotropy in the index profile that makes them birefringent. A very recent development consists in fibers presenting air holes running along the fiber axis. An example is shown in **Figure 5**. These are called microstructured fibers, and may have a variety of applications connected with the fact that the air–silica structure allows single-mode behavior over a very wide wavelength range and gives more freedom in choosing the area of the propagating mode or the shape of the dispersion curve.

Fiber Bragg Gratings

It is very helpful to be able to manipulate optical signals traveling inside fibers without extracting them from the fiber. This not only reduces losses, but also makes the optical system more flexible. Following the all-fiber approach, various optical components and devices have been conceived and built in order to perform a variety of functions, such as beam splitters and combiners, mirrors, filters, polarizers, amplifiers, and even lasers. This section describes frequency-selective mirrors obtained by introducing inside the fiber core, a modulation of the refractive index with a given periodicity. Such a modulation acts as a phase grating and the structure is indeed called "fiber Bragg grating" (FBG). The behavior can be understood by similarity with a multilayer dielectric mirror: a sequence of weakly reflecting surfaces can become a high-reflectivity structure if a constructive interference condition is established among all the reflected fields. Calling Λ the grating period, such a condition requires that the phase shift suffered by the field propagating over the distance Λ be π (or a multiple of π). The condition is satisfied for the wavelength λ_o given by

$$\lambda_o = 2n\Lambda \qquad [8]$$

where n is the average refractive index of the fiber core. If Δn is called the amplitude of the refractive-index modulation and N the number of grating periods, the peak reflectivity is given by

$$R_{\max} = \tanh^2\left(N\frac{\Delta n}{n}\right) \qquad [9]$$

Typically the grating length L is of the order of millimeters, that is, $N = L/\Lambda$ is in the range 10^3–10^4. Therefore, $R_{\max}$ can be close to 100%, even if Δn is small. The bandwidth of the FBG mirror is a decreasing function of Δn, so that the reflectivity peak can become very narrow for small Δn.

FBGs are fabricated by exploiting the photosensitivity of the Ge-doped core of silica fibers. The presence of Ge atoms leads to the formation of oxygen-deficient bonds that represent defects in the silica matrix. The energy required to break the bond is ~ 5 eV. The absorption of a 244 nm photon from an excimer laser can break the defect-bond, resulting in a change of absorption spectrum and in a corresponding change in the refractive index. Since index changes occur only in the regions where ultraviolet light is absorbed, by illuminating the fiber core with a periodic intensity pattern, an index-of-refraction grating is generated.

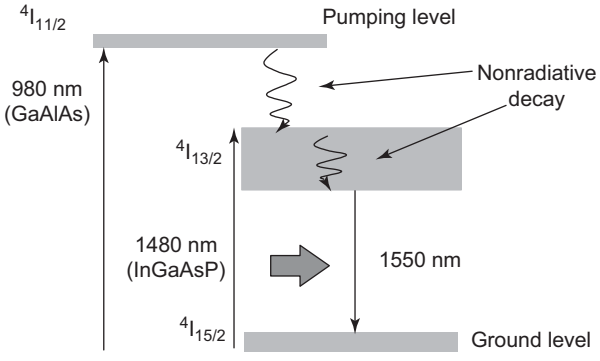

Figure 6 Energy levels of the Er^{3+} ion.

Fiber Amplifiers and Lasers

An important family of materials used for optical amplification is represented by dispersions of rare-earth ions, such as neodymium or erbium or ytterbium, in a solid matrix that can consist of a crystal or a glass. An interesting extension of the idea of the rare-earth solid-state optical amplifier is the fiber amplifier, which utilizes silica fibers doped with rare-earth ions. Optical amplification is extremely important in long-distance optical-communication links in order to compensate for fiber attenuation, so that the optical power can be maintained at sufficiently high levels along the path to ensure a satisfactory signal-to-noise ratio. Doped fibers can provide wide-band amplification at wavelengths ~ 1550 nm, corresponding to the attenuation minimum for silica fibers.

The most common fiber amplifier is based on erbium-doped silica fibers and uses a transition of the Er^{3+} ion in a wavelength range extending from 1530 to 1560 nm. The energy level diagram of the ion Er^{3+} is shown in **Figure 6**. The upper level of the 1530 nm transition is metastable (with a lifetime of 12 ms), thus permitting one to easily achieve population inversion by exciting the ion with radiation at 980 or 1480 nm. The pump field comes from a semiconductor laser, either InGaAs (980 nm) or InGaAsP (1480 nm). A scheme of the amplifier configuration is shown in **Figure 7**. The pump field and the signal field are injected into the single-mode doped fiber by using a dichroic coupler. After the doped fiber, an optical isolator is inserted in order to eliminate back-reflections. The length of the amplifying fiber is typically ~ 10 m, and the optical gain can be as large as 10 000. The efficiency of the amplifier is large

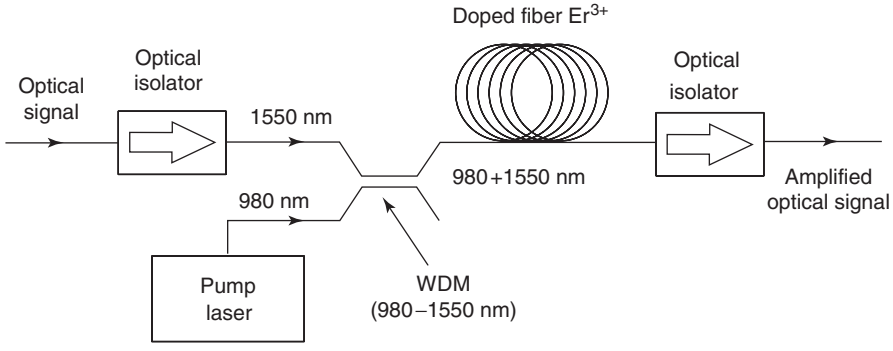

Figure 7 Scheme of an Erbium-doped fiber amplifier, pumped by a semiconductor laser. WDM (Wavelength Division Multiplexer) indicates a wavelength dependent combiner.

because the single-mode fiber ensures a very good spatial overlap between pump field and signal field. The conversion efficiency can be further improved by using a mixed erbium–ytterbium doping.

Any optical amplifier can be converted into a laser oscillator if a positive feedback scheme is provided. The fiber amplifier can become a fiber laser by placing the amplifier in between two mirrors, constituted, for instance, by two FBGs. Fiber lasers can work either continuously or pulsed, with a large power output. Since the fiber is very thin, the surface-to-volume ratio is large, thus permitting very efficient heat dissipation without using the water-circulation cooling system typical of power lasers. In order to improve the coupling between the semiconductor pump laser and the amplifier, a new fiber geometry involving a double cladding was introduced. A very successful fiber laser using such a geometry is the ytterbium laser, which is pumped at 920 nm and can emit in a wide band centered $\sim$1100 nm. Continuous-wave Yb fiber lasers with an output power larger than 100 W and efficiency of 75–80% are now available.

Nonlinear Fiber Optics

Nonlinear optical effects are particularly efficient in single-mode optical fibers despite the relatively small third-order susceptibility of silica glass. The reason for this is that the spot size of the propagating beam is small and the interaction length can be very long due to waveguiding and low losses. A point of great conceptual relevance is that most of the treatments of nonlinear propagation are developed for plane waves, whereas experiments in bulk materials are performed with laser beams that can be considered as Gaussian waves. Therefore, diffraction can play a significant role in the experiments, making the comparison with the plane-wave theory sometimes difficult. The nonlinear propagation inside the optical fiber can be treated in most cases by assuming that the transversal field distribution is invariant along the propagation distance, so that the propagation problem becomes spatially unidimensional as in the case of the plane-wave approach. This makes the comparison between theory and experiment much simpler.

The two most important nonlinear phenomena in nonlinear fiber optics are the optical Kerr effect and stimulated Raman scattering (SRS).

The optical Kerr effect, that is, the linear dependence of the index of refraction on the beam intensity, gives rise to a self-induced phase shift experienced by the optical field during its propagation, called self-phase modulation (SPM). SPM is responsible for the spectral broadening of optical pulses. In normal dispersion, the consequence is that SPM gives an additional contribution to the spreading out in time of the pulse. There is, however, an interesting situation, corresponding to positive Kerr effect and negative GVD, in which there is a compensation between the two effects, so that an optical pulse of appropriate intensity and shape (optical soliton) can propagate with constant shape and amplitude over a distance that is limited in practice only by the linear attenuation in the fiber. Indeed, several beautiful experiments showing the onset and development of solitonic propagation have been performed. With standard fibers, the wavelength range of negative GVD is above 1.3 μm, but the new fibers presenting an air–silica microstructure (see the section "Special fibers") can shift the negative GVD region to lower wavelengths, as shown in **Figure 4**, so that solitonic propagation in the visible can be observed.

Concerning SRS, it is recalled that, starting from a pump wave at frequency ν_p, the effect of SRS is that of generating a strong signal, called the Stokes wave, at a frequency $\nu_s = \nu_p - \nu_v$, where ν_v is a vibrational frequency typical of the considered medium. In the case of silica fibers, the main effect is associated with vibrations of the Si–O bond, occurring at $\nu_v =$ 12 THz. SRS can be used to amplify a weak signal at frequency ν_s in presence of a pump ν_p. Raman amplification is very attractive for applications in optical communications because, at variance with what happens in erbium-doped fiber amplifiers, it is nonresonant, so that it can be used for any ν_s, provided the appropriate pump is available.

Introduction

This article describes some complex devices which are commonly used in the laboratory for analysis of condensed matter, instruments which measure the fundamental quantity of light, and use the interaction between light radiation and matter. It is assumed, that the reader is confident with simple optical instruments such as lenses, mirrors, prisms, and diffraction gratings. A complete description of the fundamental optical phenomena is given elsewhere in this encyclopedia and can be easily found in literature on fundamental optics. Before describing optical instruments in detail, a brief overview of light behavior is given. Among the instruments commonly used in the laboratory, the spectrometer or devices based on scattering, absorption, and reflection are widely described in other sections of this encyclopedia. Also interferometric methods used in microscopy are illustrated elsewhere. Here, the focus is on the following instruments: refractometer, interferometer, polarimeter, ellipsometer, and radiometer.

Optical Terminology and Fundamental Optical Phenomena

Light is an electromagnetic wave with wavelengths between 0.1 nm and 100 μm. Visible light corresponds to wavelength in the range of 400–700 nm, vacuum ultraviolet light is in the range 0.1 μm to 10 nm; at the other end of the wavelength scale between 100 and 1000 μm is the microwave region. **Figure 1** shows electromagnetic wavelength regions and **Table 1** shows important parameters that are used to characterize light and the media through which it passes. At this point, a few comments are necessary. First of all in free space, light behaves like a transverse wave which means that the variations of the electric vector $\boldsymbol{E}$, are perpendicular to the propagation direction. In electromagnetic waves, the electric field $\boldsymbol{E}$ and magnetic field $\boldsymbol{B}$ are perpendicular to each other and to the propagation vector $\boldsymbol{k}$ (**Figure 2**). The simplest case of a three-dimensional wave is the plane wave in which all the surfaces upon which a disturbance has a constant phase form a set

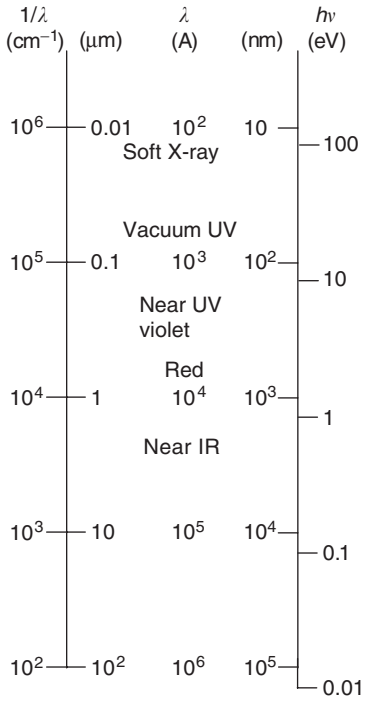

Figure 1 Diagram relating wave number, photon energy, and wavelength in light radiation.

of planes, each generally perpendicular to the propagation direction. There are quite practical reasons for studying this sort of wave, one of which is that by using optical devices, one can readily produce light resembling plane waves, and this case is taken up in detail in the following.

The mathematical expression for a plane wave that is perpendicular to a given vector $\boldsymbol{k}$ in complex representation is

$$\boldsymbol{E} = \boldsymbol{E}_0 \mathrm{e}^{\mathrm{i}(\boldsymbol{k}\cdot\boldsymbol{r}\pm\omega t)} \qquad [1]$$

The vector $\boldsymbol{k}$ whose magnitude is the propagation number k is called the propagation vector, and it is linked to the wave quantity by the following useful relations:

$$k = \frac{2\pi}{\lambda} = \frac{2\pi n}{\lambda_0} \qquad [2]$$

where λ is the wavelength, and n is the refractive index of light. The speed of light is

$$v = \lambda\nu = n\lambda_0\nu = nc \qquad [3]$$

where c is the velocity of light in vacuum

$$c = 2.997\,924\,58 \times 10^8 \mathrm{m\,s^{-1}} \qquad [4]$$

Table 1 Fundamental parameters of electromagnetic radiation and optical media

Parameter	*Symbol*	*Value*	*Units*
Velocity of light in vacuo	$c_0 = \sqrt{\mu_0 \varepsilon_0}$	2.997 924 58 x 10^8	$m\,s^{-1}$
Permeability of free space	μ_0	4π x 10^{-7}	henry m^{-1}
Permittivity of free space	ε_0	8.854 16 x 10^{-12}	farad m^{-1}
Velocity of light in a medium	$c = \sqrt{\mu_r \mu_0 \varepsilon_r \varepsilon_0} = c_0/n$		$m\,s^{-1}$
Refractive index	$n = \sqrt{\mu_r \varepsilon_r}$		dimensionless
Relative permeability of a medium	μ_r	usually 1	dimensionless
Dielectric constant of a medium	ε_r		dimensionless
Frequency	$\nu = c/\lambda$		Hz
Wavelength in vacuo	$\lambda_0 = c_0 \nu$		m
Wavelength in a medium	$\lambda = c\nu = \lambda_0/n$		m
Wave number	$\bar{\nu} = 1/\lambda$		cm^{-1}
Wave vector	$k = 2\pi/\lambda$		m^{-1}
Photon energy	$E = h\nu$		J (1.6×10^{-19} J = 1 eV)
Electric field of wave	$\boldsymbol{E}$		$V\,m^{-1}$
Magnetic field of wave	$\boldsymbol{B}$		$A\,m^{-1}$
Poynting vector	$\boldsymbol{S} = \boldsymbol{E} \times \boldsymbol{B}$		$W\,m^{-2}$
Intensity	$I = \langle \boldsymbol{S} \rangle_{av} = \lvert E \rvert^2 \varepsilon_0 c^2$		$W\,m^{-2}$

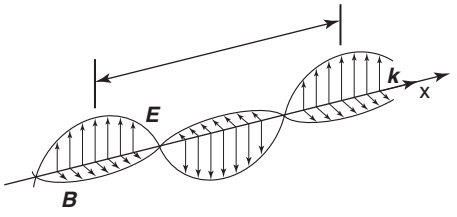

Figure 2 Picture of a plane polarized light. For plane polarized light, the ***E*** and ***B*** vector remain in perpendicular planes to the propagation vector ***k***.

and where the wave frequency

$$v = \omega/2\pi \qquad [5]$$

It is to be noticed that at any given time the surfaces joining all points of equal phase are known as wave fronts.

The velocity of light in vacuum is $c = \sqrt{\mu_0 \varepsilon_0}$; in a medium, it depends both on the relative magnetic permeability μ_r and dielectric constant ε_r of the medium, $\mu_r = 1$ for all practical optical materials so that the refractive index and the dielectric constant are related by $n = \sqrt{\varepsilon_r}$. When light propagates in a non-isotropic medium, such as a crystal, n and ε_r will generally depend on the direction of the wave propagation and its polarization state.

The Poynting vector

$$\boldsymbol{S} = c^2 \varepsilon_0 \boldsymbol{E} \times \boldsymbol{B} \qquad [6]$$

is a vector that points in the direction of energy propagation of the wave. The local direction of the Poynting vector at a point in a medium is called the ray direction. The time-averaged value of the magnitude of the Poynting vector is the irradiance and is given by

$$I = \langle S \rangle = \varepsilon_0 c \langle E^2 \rangle \qquad [7]$$

where ε_0 is the permittivity of free space, $8.8542 \times 10^{-12}\,F\,m^{-1}$.

Since light in vacuum is a transverse wave, an appreciation of its vectorial nature is of great importance, which means that all phenomena of optical polarization should be treated in terms of a vector wave picture. Before going into details of optical devices, two things should be noted. One is that electromagnetic waves propagating in real material media are generally not transverse. Another is that for unpolarized light, in which the wave vector changes direction randomly and rapidly, or in some other cases, scalar approximation becomes useful, as in the theory of interference and hence the simpler scalar representation of the light wave is considered wherever possible.

The parameter used to describe the interaction of light with the material is the complex index of refraction $\tilde{n}$, which is a combination of a real part and an imaginary part and is given by

$$\tilde{n} = n + i\kappa \qquad [8]$$

The real part is called the index of refraction and the imaginary part the extinction coefficient. For a dielectric material such as glass, none of the light is absorbed and $\kappa = 0$; in this case the concern is only n, as previously defined. In an absorbing medium, κ describes the attenuation of the wave field in the

medium and it is related to the absorption linear coefficient. A complex index of refraction is a characteristic of an absorbing medium.

Real and imaginary parts of the index of refraction are, in fact, functions of the wavelength λ; this is why when white light enters a prism, it emerges with the various colors separated. This phenomenon is called dispersion and is described by the Kramers–Kronig equations for both the real and imaginary part of the complex index of refraction or by an approximated expression by power series of $1 = \lambda$ using Cauchy coefficient. For optical materials, the change of index with wavelength is very gradual, and often negligible, unless the wavelength approaches a region where the material is not transparent. For this reason, in this article the description of optical systems is simplified assuming that the light is monochromatic. When light is reflected by a plane boundary between two media of different refractive index, the three rays, that is, incident, reflected, and refracted lie in the same plane and the angle of incidence is always equal to the angle of reflection as shown in **Figure 3**. When a light ray crosses the boundary, the angle of refraction θ_2 is related to the angle of incidence accordingly to Snell's law

$$\frac{\sin\theta_1}{\sin\theta_2} = \frac{n_2}{n_1} \qquad [9]$$

If $n_2 < n_1$, there is a maximum angle of incidence for which there can be a refracted wave because $\sin\theta_2$ cannot be greater than unity for a real angle. This is called the critical angle θ_c and is given by $\sin\theta_c = n_2/n_1$. Total internal reflection is illustrated in **Figure 3** when θ_1 exceeds θ_c and the boundary acts as a very good mirror.

One or both the media in **Figure 3** may be anisotropic. The incident wave will then generally split into two components, and assist a double-refraction phenomenon. One of the components obeys Snell's law directly (the ordinary wave) while for the other component, Snell's law is modified (the extraordinary wave).

Looking at the wave field at a boundary between two media, it can be seen that there is still an interdependence sheared by the amplitudes which can be evaluated and which depends on polarization as in a case in which E is perpendicular as well as parallel to the plane of incidence. There are two expressions that are general statements that apply to all linear, isotropic, and homogeneous media; they are called Fresnel equations. For electric field of the wave field perpendicular to the plane of incidence (S polarization)

$$r_s = \left(\frac{E_{0r}}{E_{0i}}\right)_s = \frac{n_i\cos\theta_i - n_t\cos\theta_t}{n_i\cos\theta_i + n_t\cos\theta_t} \qquad [10]$$

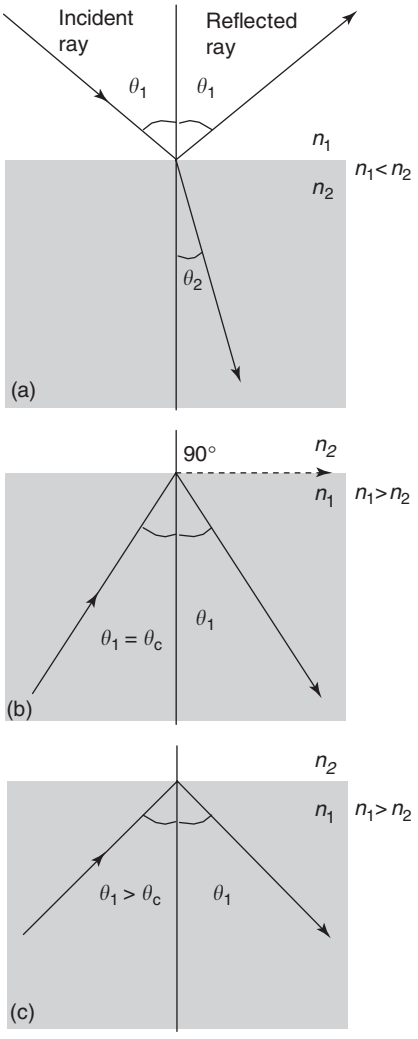

Figure 3 (a) Reflection and refraction of a light ray at the boundary between two different isotropic media of refractive index n_1 and n_2. The case shown is for $n_2 > n_1$. (b) Critical angle and (c) total internal reflection for $n_1 > n_2$.

$$t_s = \left(\frac{E_{0t}}{E_{0i}}\right)_s = \frac{2n_i\cos\theta_i}{n_i\cos\theta_i + n_t\cos\theta_t} \qquad [11]$$

Here r_s denotes the amplitude reflection coefficient and t_s is the amplitude transmission coefficient.

For electric field of the wave field parallel to the plane of incidence (P polarization)

$$r_p = \left(\frac{E_{0r}}{E_{0i}}\right)_p = \frac{n_t\cos\theta_i - n_i\cos\theta_t}{n_i\cos\theta_t + n_t\cos\theta_i} \qquad [12]$$

$$t_p = \left(\frac{E_{0t}}{E_{0i}}\right)_p = \frac{2n_i\cos\theta_i}{n_i\cos\theta_t - n_t\cos\theta_i} \qquad [13]$$

When the reflecting surface is not a dielectric and κ is nonzero, the index of refraction in the Fresnel equations is the complex index of refraction and the Fresnel equations are in general complex number.

Refractometer

The index of refraction is a topical parameter for isotropic material. Most of the refractive index measurements are based on "prism refraction." Since the angle of deviation between the incident beam and the refracted beam from a prism varies with the angle of the prism, with the angle of incidence of the ray on the prism, and with the refractive index of the prism, measuring angles involved in the process gives the value of the refractive index of the prism. The deviation of a ray of light passing through a simple prism can be described with the aid of **Figure 4**. The various angles α, i, r, and θ satisfy Snell's law irrespective of the polarization state of the input beam, provided the prism is made of an isotropic material. The deviation θ of a ray depends on the incidence angle i and increases as the angle of incidence is increased. From the symmetry of the system, it follows that the deviation is minimum for the ray that passes through the prism symmetrically. When the prism is used in the position of minimum deviation

$$i = \tfrac{1}{2}\alpha + \tfrac{1}{2}\theta \qquad [14]$$

Hence, in the minimum deviation condition, the prism index of refraction is

$$n = \frac{\sin(\alpha + \theta)/2}{\sin \alpha/2} \qquad [15]$$

When θ and α have been measured, the refractive index of the prism material can be calculated. If the angles are measured to about one second, n can be found to $\sim \pm 0.000\,01$.

The configuration can be used to determine the refractive index of a liquid by employing a hollow prism whose faces are parallel-sided plates of glass. The walls of such a vessel have no effect on the angle of deviation, and the angle of the liquid prism is the same as that of the vessel. Hence, α and θ can be measured in the usual way. It is important to point out that the refractive index of liquid varies rapidly with temperature, and there is usually no point in attempting an accuracy better than 0.0001 in the refractive index unless special care is given to temperature control.

Widely used is the "critical angle prism refractometer" which uses a critical angle configuration: the idea is to look at the light totally reflected by the internal prism wall. An alternative method is to position the incident beam so that rays fall on the prism at grazing or near-grazing incidence. The rays falling on the face BA of **Figure 4b** at grazing incidence emerge from face AC at angle ϕ, and those rays incident on BA at angles less than 90° emerge from AC at an angle greater than ϕ. No light emerges at angles less than ϕ. When a detector is placed in front of the AC plane, with the arrangement shown in the figure, the right-hand side of the field view is dark and the left-hand side of the field view is bright; the edge between the bright and dark zones is used to measure ϕ. In this configuration

$$n^2 = 1 + \left(\frac{\sin\phi + \cos\alpha}{\sin\alpha}\right)^2 \qquad [16]$$

gives the refractive index of the prism material.

The same method may be employed to determine the refractive index of a liquid of which only a small

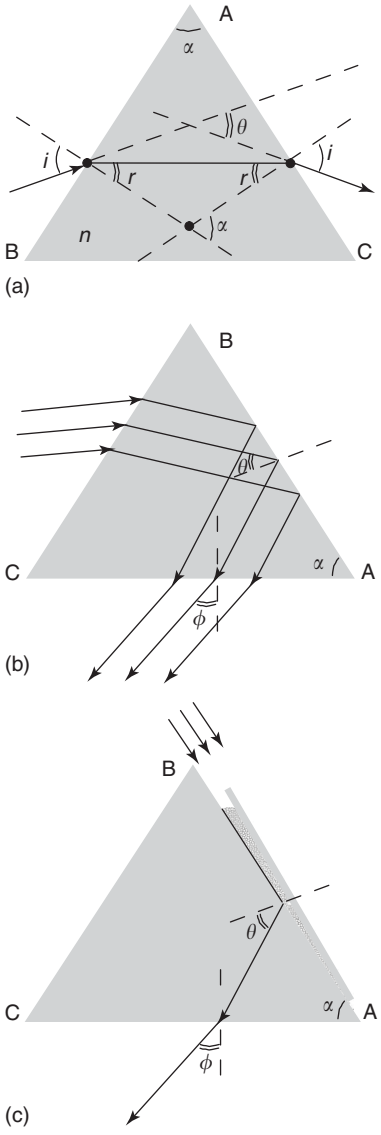

Figure 4 (a) Symmetrical path of a ray through a prism. (b) Critical angle prism refractometer with light at grazing incidence. (c) Critical angle method for liquid sample.

quantity is available, provided the index of the prism is greater than that of the liquid. A drop of the liquid is placed on the face BA and a thin glass plate is placed over it. If necessary, it is possible to have a wedge form of the liquid to be examined, and the glass is held in position by a capillary action. In this case, the refraction index of the liquid is

$$n_0 = \sin\alpha\sqrt{n^2 - \sin^2\phi} - \cos\alpha\sin\phi \qquad [17]$$

It should be noted that the maximum possible value of r is the critical angle, and that there is a grazing incidence and a grazing emergence. Hence, the angle of a prism used in the upper configuration must not be greater than twice the critical angle, otherwise it is impossible for rays to be transmitted through the prism.

A two-prism configuration with the critical-angle method is used in the Abbe refractometer, shown in **Figure 5a**. The liquid under test is placed between two prisms of high refractive index. The prism P corresponds to the prism to be used in the total reflection configuration. Light that strikes P in grazing incidence emerges at the angle ϕ to be measured. The measurement of the emerging angle would enable one to determine the refractive index of the liquid, if α and the refractive index n of P are known.

Critical-angle based refractometers have three main disadvantages: (1) they measure light rays coming from the prism on a field view where bright and dark areas have to be separated and measured, which is a basically asymmetric system, (2) the refractive index of the glass prism must be greater than that of the specimen under test, and (3) the measured index corresponds to a surface layer and may differ from that of the main bulk of the specimen. The Hilger–Chance instrument (**Figure 5b**) was developed to overcome these difficulties. The composite glass block is made by combining two prisms as indicated. Monochromatic collimated light passes through the V-block and specimen. The direction of the emergent light depends upon the refractive index of the specimen. It will be seen that two perpendicular plane surfaces must be produced on the specimen, but it is not necessary for these to be of the highest quality since a film of liquid can be placed between the faces of the specimen and the V-block. Since the method is not a critical-angle method, the refractive index of the specimen can be greater than or less than that of the V-block. The accuracy found with this instrument is 0.000 01. The instrument can be used for liquids if the V-block is provided with side plates to form a trough, but 2–3 cc of liquid are required.

Finally, accurate measurements of the index of refraction up to 0.000 001 can be done using interferometry which measures the optical path difference (geometrical difference per index of refraction), and hence provides the index of refraction of the sample under test if the geometric path (usually thickness of the sample) is well known. The interferometric technique is widely used for several samples, isotropic or not, also for polarizing active material. Ellipsometry remains at the moment the most powerful method for investigating complex systems, such as nonisotropic multilayered samples or gradient varying samples.

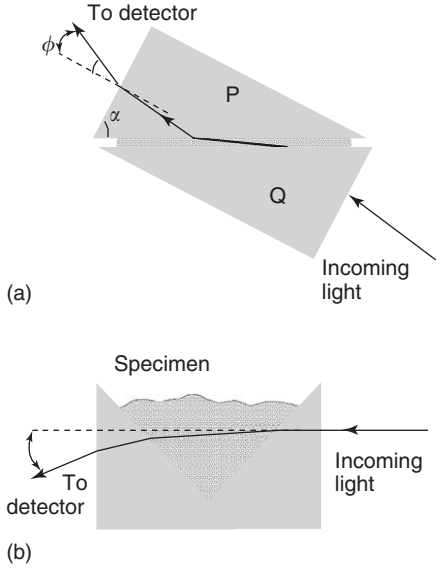

Figure 5 (a) Abbe refractometer and (b) Hilger–Chance instrument.

Interferometers

Interferometers are complex optical devices based on interference phenomenon. Optical interference occurs when two or more light waves interact yielding a resultant irradiance that deviates from the sum of the component irradiances.

A few of the more important interferometric systems will be examined here. Interferometric devices are divided into two groups: wave front splitting and amplitude splitting. In the first case, portions of the primary wave front are used as sources to emit secondary waves, or in conjunction with optical devices to produce virtual sources of secondary waves. These secondary waves are then brought together to interfere. In the case of amplitude splitting, the primary wave itself is divided into two segments, which travel different paths before recombining and interfering.

In accordance with the principle of superposition, the light field or the electric field intensity $\boldsymbol{E}$, at a

point in space, arising from the separate field $\boldsymbol{E}_1, \boldsymbol{E}_2, \ldots$ of various contributing sources is given by

$$\boldsymbol{E} = \boldsymbol{E}_1 + \boldsymbol{E}_2 + \cdots \qquad [18]$$

Taking the time average of both sides, one finds that the irradiance in the case of two superposed fields becomes $I = I_1 + I_2 + I_{12}$ provided that $I_1 = \langle \boldsymbol{E}_1^2 \rangle$, $I_2 = \langle \boldsymbol{E}_2^2 \rangle$, and $I_{12} = 2\langle \boldsymbol{E}_1 \cdot \boldsymbol{E}_2 \rangle$, where $\langle\ \rangle$ is the time average over a time interval T much greater than the period of the harmonic function. The latter expression is known as the interference term and is $I_{12} = \langle \boldsymbol{E}_{01} \cdot \boldsymbol{E}_{02} \cos\delta \rangle$, and $\delta = (\boldsymbol{k}_1 \cdot \boldsymbol{r} - \boldsymbol{k}_2 \cdot \boldsymbol{r} + \phi_1 - \phi_2)$ is the phase difference arising from a combined path length and initial phase-angle difference.

The most common situations correspond to $\boldsymbol{E}_{01}$ parallel to $\boldsymbol{E}_{02}$. In that case, the irradiance reduces to the value found in the scalar case: $I_{12} = E_{01}E_{02}\cos\delta$ and the total irradiance is

$$I = I_1 + I_2 + 2\sqrt{I_1 I_2}\cos\delta \qquad [19]$$

If a screen is placed in the region of interference, bright and dark zones would be visible, which are known as interference fringe pattern.

At various points in space, the resultant irradiance can be greater, less than, or equal to $I_1 + I_2$, depending on δ. When $\delta = 0, \pm 2\pi, \pm 4\pi, \ldots, \cos\delta = 1$ and maximum of irradiance is obtained. The waves are said to be in phase and one speaks of this as total constructive interference. When $0 < \cos\delta < 1$, the waves are out of phase. As $\delta = \pi/2,\ \cos\delta = 0$ the optical disturbance is said to be 90° out of phase, and $I = I_1 + I_2$. For $-1 < \cos\delta < 0$, one has the condition of destructive interference. The minimum in the irradiance results when the waves are 180° out of phase, $\cos\delta = -1$. This occurs when $\delta = \pm\pi, \pm 3\pi, \pm 5\pi, \ldots$, and it is referred to as total destructive interference.

A special case arises when $I_1 = I_2 = I_0$, the two sources have equal irradiance and

$$I = 2I_0(1 + \cos\delta) = 4I_0\cos^2\frac{\delta}{2} \qquad [20]$$

for which it follows that $I_{\min} = 0$ and $I_{\max} = 4I_0$.

When two beams interfere to produce a stable pattern, they must have very nearly the same frequency. A significant frequency difference would result in a rapidly varying, time-dependent phase difference, which in turn would cause I_{12} to average to zero during the detection interval. The most common means of overcoming this problem is to make one source serve to produce two coherent secondary sources.

It is to be remembered that because of the granular nature of the emission process, conventional quasi-monochromatic sources produce light that is a mix of photon wave trains. At each illuminated point in space, there is a net field that oscillates for less than 10 ns or so before it randomly changes phase. This interval over which the lightwave resembles a sinusoid is a measure of what is called its temporal coherence t_c. The average time interval during which the lightwave oscillates in a predictable way is designated as the coherence time of the radiation. The longer the coherence time, the greater the temporal coherence of the source. The corresponding spatial extent over which the lightwave oscillates in a regular, predictable way is called the coherence length $l_c = c \times t_c$, where c is the velocity of light. The most common means to produce interference, as will be seen, is to make one source serve to produce two coherent secondary sources that will interfere. An interference fringe pattern will be seen as long as the difference between the optical paths of the two secondary sources is no longer than the coherence length of the lightwave. Nowadays, laser sources are quite cheap and easier to use than lightwave sources with a temporal coherence ranging up to at least 1 ms, corresponding to Km of coherence length.

Wave Front Splitting Interferometer

A hypothetical monochromatic plane wave illuminating two parallel narrow closely spaced slits, S_1 and S_2 is to be considered. This is shown in a two-dimensional view in **Figure 6**. When symmetry exists, the segments of the primary wave front arriving at the two slits will be exactly in phase, and the slits will constitute two coherent secondary sources. One expects that the two waves coming from S_1 and S_2 overlap, interference will occur (provided the optical path difference is less than the coherence length, $c \cdot t_c$). In a realistic physical situation, the distance between the screen and the slits will be very large in comparison with the distance a between the two slits, and all the fringes would be fairly close to the center O of the screen. One can express the path difference as

$$r_1 - r_2 = a\theta \qquad [21]$$

since $\theta \backsim \sin\theta$.

Following this approximation $\theta = y/s$, $r_1 - r_2 = ay/s$. Constructive interference will occur when $r_1 - r_2 = m\lambda$; thus from the last two relations, one obtains

$$y_m = \frac{s}{a}m\lambda \qquad [22]$$

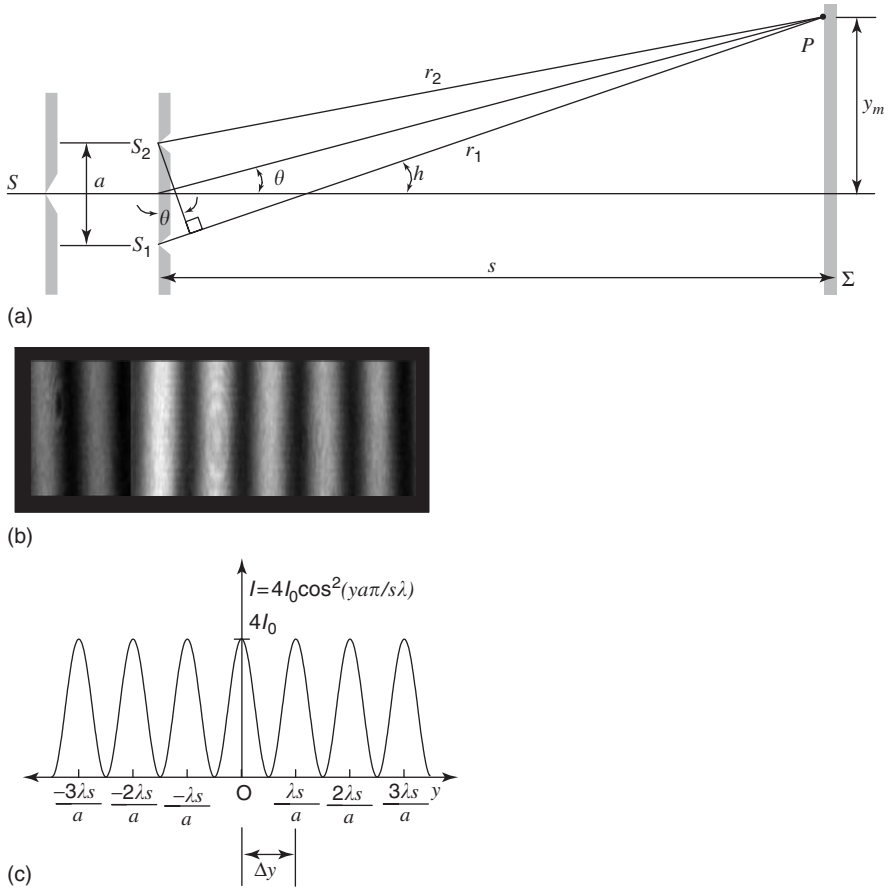

Figure 6 (a) Geometry of Young's experiment which is the most pedagogical example of wave-front splitting interferometer. A path-length difference of one wavelength corresponds to $m = \pm 1$ and to the first maximum. (b) Irradiance on a photoplate or a CCD camera is shown together with (c) the idealized irradiance vs. distance curve.

This gives the position of the mth bright fringe on the screen, if the maximum at 0 is counted as the zeroth fringe.

The interferometric configuration discussed above is known as Young's experiment. The same physical and mathematical considerations apply directly to a number of other wavefront splitting interferometer. Most common among these are Fresnel double mirror, Fresnel double prism, diffraction grating, and mirror configuration.

Amplitude Splitting Interferometer

Suppose that a light wave was incident on a semi-transparent mirror, or simply a sheet of glass. Part of the wave is transmitted and another part is reflected. Both the transmitted and the reflected waves will have lower amplitudes than the original one. When the two separate waves are brought together again at the detector, interference results as long as the original coherence between the two are not destroyed and if the path length differs by a distance lower than the coherence length.

Dielectric films The simpler amplitude splitting interference effects are observable in sheet transparent materials. Consider the simple case of a transparent parallel plate of dielectric material having a thickness d (**Figure 7**). Suppose that the film is nonabsorbing and that the amplitude–reflection coefficients at the interfaces are so low that only the first two reflected beams E_{1r} and E_{2r} need be considered. One may consider S to be a monochromatic point source. The film serves as an amplitude-splitting device, so that E_{1r} and E_{2r} are parallel on leaving the film and can be brought together at a point P on the focal plane of a lens. From **Figure 7**, the optical path length difference for the two reflected beams is given by

$$\Lambda = 2n_s d \cos\theta_t \qquad [23]$$

The corresponding phase difference associated with the optical path-length difference is then just the product $k_0\Lambda$, where $k_0 = 2\pi/\lambda_0$. If the film is immersed in a single medium $n_1 = n_2 = n$ and there

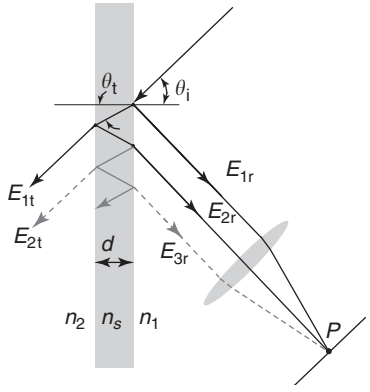

Figure 7 Thin layer interference.

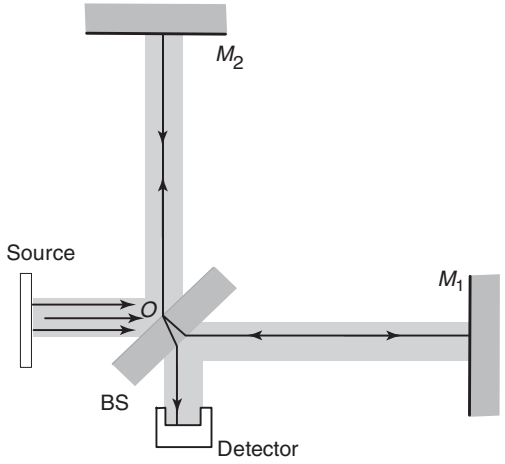

Figure 8 Michelson interferometer.

is an additional phase shift arising from the reflections between the two light beams themselves, one internally and one externally reflected, there will be a relative phase shift of π radians. Accordingly, $\delta = k_0\Lambda \pm \pi$. In the reflected light, an interference maximum, a bright spot appears at P when δ is an even multiple of π. In that case

$$d\cos\theta = (2m+1)\frac{\lambda_0}{4n_s} \qquad [24]$$

This also corresponds to a minima in the transmitted light. Interference minima in reflected light (maxima in transmitted light) result when δ is an odd multiple of π. For such cases

$$d\cos\theta = 2m\frac{\lambda_0}{4n_s} \qquad [25]$$

The thickness of sheet transparent materials commonly used in optics, varies from films less than the length of a light wave, to plates several centimeters thick. A layer of material is referred to as a thin film for a given wavelength of electromagnetic radiation when its thickness is of the order of that wavelength. The applications of thin dielectric films are manifold, as are their structures which extend from the simplest single coatings to intricate arrangements of hundreds of layers. Coatings for high reflecting mirrors, to eliminate unwanted reflections, nonabsorbing beamsplitters, dichroic mirrors, multilayer broad, and narrow bandpass filters are examples of the thin film optical devices.

Mirrored interferometer Among the amplitude-splitting interferometers that utilize mirrors and beam splitters, the best known and historically most important is the Michelson interferometer. Its configuration is illustrated in **Figure 8**: a quasimonochromatic source emits a wave, part of which travels to the right. The beam splitter O divides the wave into two, one segment traveling to the right and one up into the background. The two waves are reflected by mirrors M_1 and M_2 and return to the beam splitter. Part of the wave coming from M_2 passes through the beam splitter going downward, and part of the wave coming from M_1 is deflected by the beam splitter toward the detector. Thus the two waves are united, and interference can be expected. The optical path difference for these rays is $2d$, where d is the difference length between the two interferometer arms (OM_1 and OM_2), which represents a phase difference of $k_0 2d$. There is an additional phase term arising from the fact that the wave traversing the arm OM_2 is internally reflected in the beam splitter, whereas the OM_1 wave is internally reflected at O. If the beam splitter is simply uncoated, the relative phase shift resulting from the two reflections will be π radians. Destructive rather than constructive interference will occur when $2d = m\lambda_0$, where m is an integer. If the light source is slightly divergent, an observer will see a circular fringe system. When the mirrors of the interferometer are inclined with respect to each other, making a small angle (i.e., when M_1 and M_2 are not quite perpendicular), a pattern of straight parallel fringes is visible.

It is apparent that the Michelson interferometer can be used to make extremely accurate length measurements. As the movable mirror is displaced by $\lambda_0/2$, each fringe will move to the position previously occupied by an adjacent fringe. One need only count the number of fringes N, or a portion of a fringe, that has moved past a reference point to determine the distance traveled by the mirror $\Delta d = N(\lambda_0/2)$.

Very accurate measurements of wavelengths are also performed using the Michelson interferometer. The beam of a reference light source, usually a very stable and well-known wavelength λ_r laser, and the beam within the unknown wavelength λ_x are aligned into the interferometer with identical paths but opposite directions. This produces two different fringe systems to be revealed by two different detectors. While the movable mirror is displaced, sinusoidal signals are visible by the detectors: the rates of the interference maxima are counted by the detectors for both the known and unknown wavelengths. From the ratio of both counting rates, the unknown wavelength λ_x can be obtained by $\lambda_x/\lambda_r = N_r/N_x$.

The Twyman–Green interferometer is essentially a variation of the Michelson interferometer. It is an instrument of great importance in the domain of modern optical testing. Illustrated in **Figure 9**, the setup has a lens L_1, used to provide a source of incoming plane waves, and a lens L_2, which permits all the light, from the aperture to enter the detector so that the entire field can be seen.

Twyman–Green interferometers are used to test the quality of a surface or of a lens with respect to a reference wave front. For instance, if a reference flat high-quality surface is used for mirror M_1, the mirror M_2 can be tested and any wave front distortions produced by the surface of M_2 will appear in the final interferogram, provided that high-quality low-deformation lenses L_1 and L_2 have been used.

The Mach–Zehnder interferometer shown in **Figure 10** consists of two beamsplitters and two totally reflecting mirrors. The two waves within the apparatus travel along separated paths. A difference between the optical paths can be introduced by a slight tilt of one of the mirrors. Since the two paths are separated, the interferometer finds myriad applications. An object interposed in one beam will alter the optical path-length difference, thereby changing the fringe pattern. This results in a very accurate determination of the index of refraction of the sample and its local variations. For these reasons, a common application of the device is to observe the density variations in liquid or gas flow patterns.

Another amplitude-splitting device is the Sagnac interferometer shown in **Figure 11**. It is to be noticed that the main feature of the device is that there are two identical but oppositely directed paths taken by the beams that form closed loops before they are united to produce interference. A slight shift in the orientation of one of the mirrors will produce a path-length difference and a resulting fringe pattern changing. When the entire interferometer (mirrors, source, and detector) rotates about a perpendicular axis passing through its center, the rotation effectively shortens the path taken by one beam in comparison to that of the other. In the interferometer, the result is a fringe shift proportional to the angular

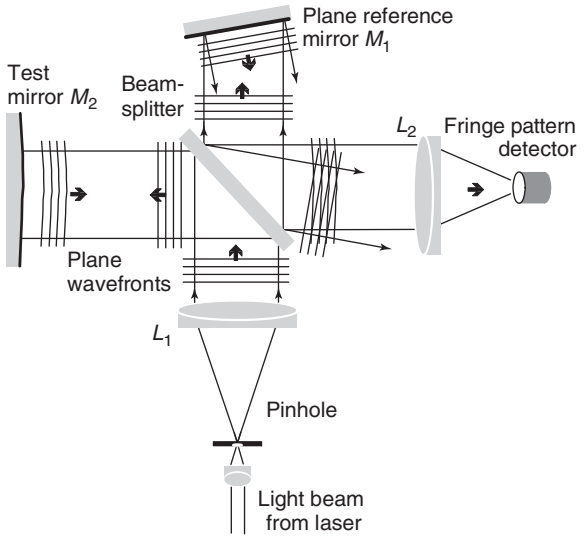

Figure 9 Twyman–Green interferometer and arrangement for a mirror test.

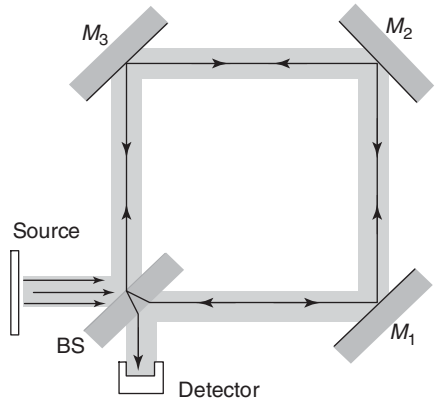

Figure 10 Mach–Zehnder interferometer.

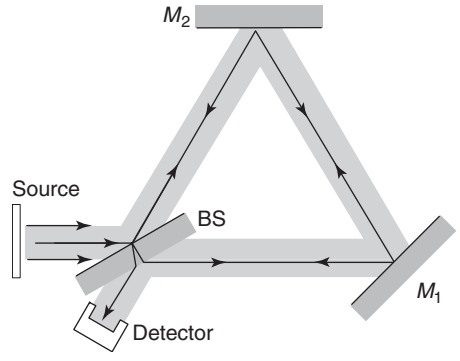

Figure 11 Sagnac interferometer.

speed of rotation $\Omega : \Delta N = 4A\Omega/c\lambda$, where A is the area formed by the beams of light.

Shearing interferometer The method of lateral shearing interferometry consists of displacing the light beam wave front laterally by a small amount and obtaining the interference pattern between the original and the displaced wave fronts. **Figure 12** schematically illustrates the principle in one of the simpler experimental configurations, based on a plane parallel plate. There are many physical arrangements to obtain lateral shear. The most popular arrangements derive from the use of beam dividers, that means, of amplitude splitting interferometers. In this way, the amplitude of the incident wave front is divided, but the shape of the wave front does not change. If the wave front is considered nearly planar, it can be expressed as $W(x, y)$, where (x, y) are the coordinates of point P. When this wave front is sheared in the x direction by an amount s, the sheared wave front is expressed by $W(x - s, y)$. The resultant path difference at P between the original and the sheared wave front is:

$$\Delta W = W(x - s, y) - W(x, y) \qquad [26]$$

The path difference ΔW may be obtained at various points on the wave front from the relation: $\Delta W = m\lambda$, where m is an integer indicating the order of the interference fringe. It is expected that for a perfect, plane wave $\Delta W = 0$ a null fringe will occur, but as soon as the wave front is distorted and ΔW is not zero, a fringe system, sometimes rather complicated, is visible. When the wave front is laterally sheared, normally it is assumed that the new wave front is not tilted with respect to the original one. It is possible to obtain a known amount of tilt between the two wave fronts by using a wedge with a small angle instead of a parallel plate in **Figure 12** setup. In such a case, the optical path difference associated with this tilt may be presented as a linear function of the coordinate along the tilt, and a system of straight fringes is generated. A deviation from the straight fringe system is a measure of the wave front deformation.

Lateral shearing interferometers are commonly used for checking the collimation of a lens, or measuring lens parameters such as focal length or the refractive index, for studying of homogeneity of transparent solid samples, and for flow studies. Another application involves the measurement of surface imperfections of concave or convex surfaces.

Here, it is important to note that Mach–Zehnder, Twyman–Green, and shearing interferometers are widely used in noncontact measurement of surface height profiles. They can be used to determine surface roughness or geometries of small features. All these interferometric profile measurements are noncontact and therefore do not harm the surface under test. They are very sensitive and can measure heights with a precision of up to 0.1 Å RMS (root mean square). Quantitative phase-measurement techniques are generally used to determine the phase difference between an object point and a reference. This phase is then converted into height information. Because of

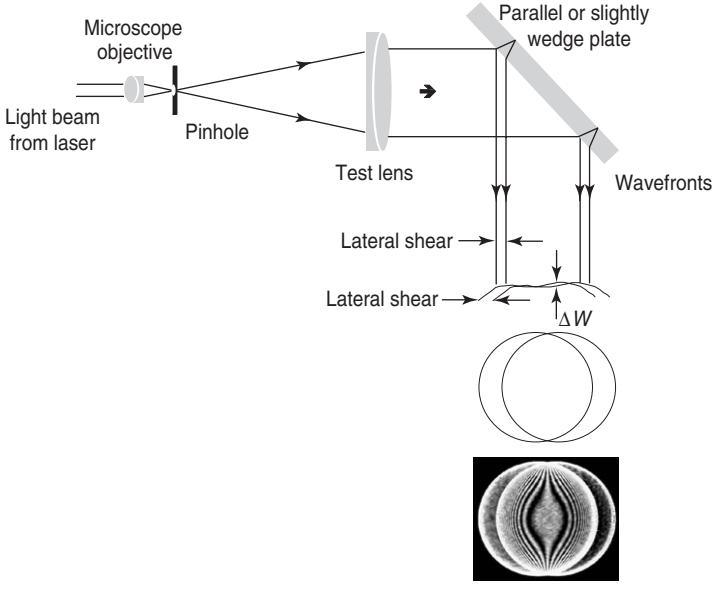

Figure 12 Schematic diagram of a lateral shearing interferometer using a plane parallel plate of glass. Diagram also illustrates the original and the sheared wave front, and lateral shearing interferogram of a wave front distorted by spherical aberration.

the precision in measurement and noncontact configuration, interferometric optical profilometers are appropriate for on-line process control. All these instruments measure heights relative to a reference surface rather than absolute distance. All profiling instruments can be calibrated relative to an existing, traceable standard; however, most of these instruments are better than existing standards, so it is hard to determine their absolute accuracy.

The main limitation of interferometric optical profilers is due to the phase shift induced by reflection of the object beam from the test surface. Every material induces a phase shift depending on its complex index of refraction. As long as a surface comprises of a single material and does not have a transparent coating on it, the phase shift does not cause a problem. When two dissimilar materials are next to each other on the surface, they will have different phase shifts upon reflection and the height difference at the boundary will be incorrect. This problem can be overcome using a coating with an opaque material, or by knowing the optical constants of the different materials.

Multiple beam interferometer The multiple beam interferometer (also known as Fabry–Perot interferometer after its inventors) consists of two plane parallel highly reflecting surfaces or mirrors separated by some distance d (**Figure 13**). Light coming in the volume between the mirrors can be partly reflected and transmitted by the surfaces. The distance d generally ranges from several millimeters to several centimeters when the apparatus is used interferometrically, and to few tens of centimeters or more when it serves as a laser resonant cavity. Consider a point source S_1 and one ray emitted, entering by way of the partially reflecting plate, it is multiply reflected within the gap. The transmitted rays are collected by a lens and brought to a screen. The multiple waves generated in the cavity, arriving at P from S_1 are coherent among themselves. All the rays incident on the parallel plates at a given angle will result in a circular fringe of uniform irradiance. The interference bands will be narrow concentric rings, corresponding to multiple-beam transmission pattern. The phase difference between two successively transmitted waves is

$$\delta = \frac{4\pi n}{\lambda_0} d \cos\theta_t + 2\phi \qquad [27]$$

where ϕ is an additional phase shift introduced by metallic films at the surfaces, if present. ϕ can be considered constant and, in general, d is so large and λ_0 so small that ϕ can be neglected. One can consider that reflectance R is the fraction of the flux density reflected at each incidence and T the transmittance. One can neglect absorption from the metal films that are used to increase the reflectance, and consider $R + T = 1$. The irradiance of the transmitted beam is

$$I_t = I_0 \frac{(1 - R^2)}{(1 - R^2) + 4R \sin^2(\delta/2)} \qquad [28]$$

and the irradiance of the reflected beam is

$$I_t = I_0 R \frac{4 \sin^2(\delta/2)}{(1 - R^2) + 4R \sin^2(\delta/2)} \qquad [29]$$

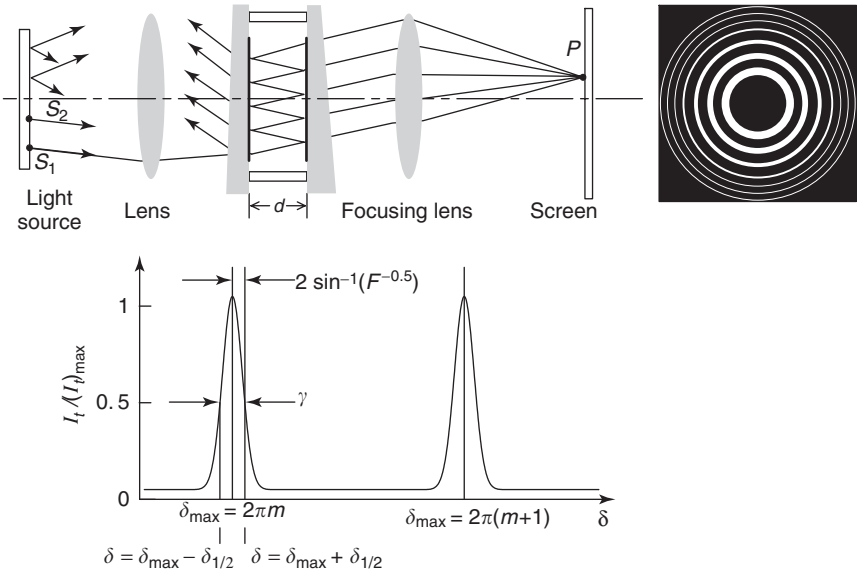

Figure 13 Multiple beam interferometer and intensity profile of Fabry–Perot fringes.

Multiple-beam interference has resulted in a redistribution of the energy density in comparison to the sinusoidal two-beam pattern. Peaks in the transmission occur at specific values of the phase difference $\delta = 2\pi m$. The frequency range δv between two maxima is the free spectral range of the interferometer. For normal incidence, the free spectral range becomes $\delta v = c/2nd$. Accordingly, the irradiance will drop to half of its maximum value whenever δ shifts from $\delta_{\max}$ of $2(1-R)/\sqrt{R}$. In frequency units, the halfwidth becomes $\Delta v = (c/2nd)((1-R)/(\pi\sqrt{R}))$. The ratio $\delta v/\Delta v$ to the free spectral range δv and the halfwidth Δv is called the finesse F of the interferometer:

$$F = \frac{\Delta v}{\delta v} = \frac{\pi\sqrt{R}}{1-R} \qquad [30]$$

The finesse is determined only by the reflectivity R of the surfaces.

The Fabry–Perot interferometer is frequently used to examine the detailed structure of spectral lines. Two incident waves with frequencies v_1 and $v_2 = v_1 + \Delta v$ produce two systems of fringes partly superimposed. This will traduce into two transmitted irradiances corresponding to the two different wavelengths. The spectral resolution $v/\Delta v$ of the interferometer is determined by the free spectral range δv and by the finesse F. A Fabry–Perot interferometer with $d = 1$ cm, $R = 0.98$ for a wavelength light in the visible range, that is, $\lambda = 500$ nm, having negligible wedge and high-quality surfaces, so that the finesse is mainly determined by the reflectivity, achieves $F = 155$, a resolving power $\Delta\lambda/\lambda = 10^{-7}$. This means that the line width of the instrument is $\delta\lambda = 5 \times 10^{-5}$ nm and in frequency unit, $\delta v = 60$ MHz.

Both the applications and configurations of the Fabry–Perot interferometer are numerous indeed. Solid etalon, or air-spaced plane parallel reflecting surfaces are used as transmission filters. Using spherical mirrors where the demand for parallelism is dropped, with high-reflectivity dielectric coating can achieve high large finesse $F > 10\,000$. Spherical mirror Fapry–Perot configurations are also used for laser cavities.

As a final comment on interferometers, it needs to be pointed out that nowadays much of the progress in the field of interferometry has come not from inventing new forms of interferometers, but from powerful fringe analysis methods, such as phase-shift interferometer analysis in optical testing, mostly helped by computer data treatment, and from making user-friendly instruments. Interferometry has the great advantage of a high-precision and noncontact capability in measurement. Commercial interferometric systems can achieve a resolution in the direction of propagation of the light beams of 2 nm and in the transversal plane ten times larger. This corresponds also to a resolution in the index of refraction measurement resolution of 10–6 and in highly controlled laboratory experiments in a 10–8 resolution. The major impediment of interferometry is its sensitivity: because of this, instruments tend to measure the whole surrounding environment, which can adversely affect accuracy.

Polarimeter and Ellipsometer

As discussed above, light may be treated as transverse electromagnetic waves. Thus far, only linear polarized light has been considered, that is, light for which the orientation of the electric field is constant, although its magnitude and sign vary in time. The electric field, therefore, resides in a fixed plane that contains both $\boldsymbol{E}$ and $\boldsymbol{k}$, the electric field vector and the propagation vector in the direction of motion, and is known as the plane of vibration.

One can resolve any plane polarized wave into two orthogonal components with the appropriate relative phase difference. For a wave propagation along the z axis, the two orthogonal electric field components can be represented in the form

$$\boldsymbol{E}_x(z,t) = \mathbf{i}\cos(kz - \omega t) \qquad [31]$$

$$\boldsymbol{E}_y(z,t) = \mathbf{j}\cos(kz - \omega t + \varepsilon) \qquad [32]$$

If ε is equal to zero or an integral of $\pm 2\pi$, the resultant electric field becomes

$$\boldsymbol{E} = (\mathbf{i}E_{0x} + \mathbf{j}E_{0y})\cos(kz - \omega t) \qquad [33]$$

and has a fixed amplitude. If ε is an odd integer multiple of $\pm\pi$, the electric field is again linearly polarized but the plane of vibration has been rotated. Circular polarization occurs when both constituent waves have equal amplitudes and their relative phase difference $\varepsilon = \pm\pi/2 + 2m\pi$, where $m = 0, \pm 1, \pm 2, \ldots$ the consequent wave is given by

$$\boldsymbol{E} = E_0[\mathbf{i}\cos(kz - \omega t) \pm \mathbf{j}\cos(kz - \omega t)] \qquad [34]$$

The amplitude is constant but the electric field $\boldsymbol{E}$ is time varying and it rotates clockwise (right-circularly polarized light) or counterclockwise (left-circularly polarized) at an angular frequency ω.

Both linear and circular polarized light may be considered to be special cases of elliptically polarized light. This means that, in general, the resultant electric field vector will rotate and change its magnitude as well. In such cases, the endpoint of

$\boldsymbol{E}$ will trace out an ellipse in a fixed space perpendicular to $\boldsymbol{k}$.

Instruments employed to measure polarization of a light beam after its interaction with a sample are commonly known as polarimeters or ellipsometers. A polarimeter is used when a light beam is transmitted through the sample whereas an ellipsometer is commonly used when a light beam is reflected by the sample. Both, the polarimeter and ellipsometer, use polarizers and retarders.

An optical device with an input of nonpolarized light and an output of some form of polarized light is known as a polarizer. For instance, an instrument that separates the two linear orthogonal components of electric field, discarding one and passing on the other, is a linear polarizer. Depending on the output it could also be classified as circular or elliptical polarizer. Polarizers come in many different configurations, but they are all based on one of the four fundamental physical mechanisms: dichroism or selective absorption, reflection, scattering, and birefringence or double refraction.

Polarizers are used in two different ways. If the polarizer is used to convert unpolarized light to polarized light, it is called the "polarizer." If it is used to determine the state of polarized light (usually by locating the null), it is called the "analyzer."

The next optical element to be considered is called the "retarder" or "quarter-wave-plate." The wave plate, in general, is an anisotropic optical element with a fast axis and a slow axis, both of which are perpendicular to each other and to the direction of propagation of light. The component of the wave which is aligned with the fast axis passes through the optical element faster than the component aligned with the slow axis. The thickness of the wave plate can be chosen such that the phase difference is exactly 90°.

Polarimeter

Polarimeters are optical instruments used for determining the polarization properties of light beams and samples. Light-measuring polarimeters determine the polarization state of a beam of light and give its polarization characteristics. Sample-measuring polarimeters are used in light–matter interaction in which an incident beam can be transmitted, reflected, diffracted, or scattered by the sample. Polarimeters are used to determine the relationship between the polarization states of incident beams and output beam. Polarimeters are composed of a polarization generator consisting of all elements needed to produce a beam of a known polarization state, and a polarization analyzer to perform a particular polarization component in the output light beam.

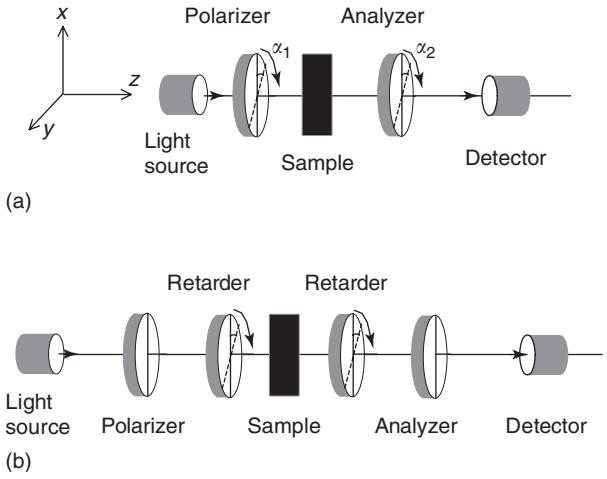

Figure 14 (a) The dual rotating polarizer polarimeter consists of a source, a linear polarizer which rotates, the sample, a second linear polarizer with a varying angular orientation, and the detector. (b) The dual rotating retarder polarimeter consists of a source, a fixed linear polarizer, a retarder which rotates, the sample, a second retarder with a varying angular orientation, a fixed linear polarizer, and the detector. The polarimeter measures, in a complete way, all the polarization characteristics.

A common polarimetric configuration is shown in **Figure 14a**. Light from the source passes through a linear polarizer whose orientation α_1 is adjustable. The generated linearly polarized light interacts with the sample and is analyzed by a second linear polarizer whose orientation α_2 is also adjustable. This polarimeter is sufficient only when linear polarization effects are dominant. Whenever circular polarization effects are present in the sample, elliptical properties of the output light must be considered and a more complete polarimeter is needed as shown in **Figure 14b**.

Typical applications of polarimeters include calibration of polarization elements for optical systems, but they are also widely used to analyze any optically active substances. There is a large number of organic and inorganic substances that are optically active in their crystalline, liquid, or dissolved state. Being optically active means that these substances are able to rotate the direction of oscillation of polarized light around a determined angle. A well-known optical substance is sugar: if it is dissolved in an optically inactive liquid like water, the degrees of angle of rotation depend – amongst other factors – on the concentration of the solution. This angle of rotation can be determined by a polarimeter with the highest possible precision. Analysis of active sugar solutions, and of any active solutions, is the most important application of polarimeters in the quality control, determination of concentration, and purity control in food, chemical, and pharmaceutical industries.

Ellipsometer

In ellipsometry, a collimated beam of a well-known polarized and monochromatic light is incident on a sample surface and the state of polarization of the reflected light is analyzed. In a typical scheme shown in **Figure 15a**, light is linearly polarized at a known but arbitrary plane of vibration identified by angle θ_i with the plane of incidence. The two components of polarization being *S* and *P*, are taken respectively parallel and perpendicular to the plane of incidence. For optically isotropic structures, ellipsometry is carried out at oblique incidence and reflected light results to be elliptically polarized. For incident electric field components E_{is} and E_{ip}, the corresponding field components of the reflected light are given by

$$E_{rs} = r_s E_{is}, \quad E_{rp} = r_p E_{ip} \qquad [35]$$

where r_p and r_s are the complex Fresnel reflection coefficients of the sample for *P* and *S* polarized light.

By taking the ratio of the respective sides of the two equations, one gets

$$\rho = r_p/r_s = \frac{E_{is}/E_{ip}}{E_{rs}/E_{rp}} \qquad [36]$$

The second term in the equation describes the incident and reflected polarization states of light. Therefore, pure polarization measurements determine the ratio of the complex reflection coefficient for the *S* and *P* polarizations. These ratios are subsequently related to the structural and optical properties of the ambient–sample interface region by invoking an appropriate model and the electromagnetic theory of reflection.

The ellipsometric measurement is normally expressed in terms of Ψ and Δ:

$$\tan\Psi\, e^{i\Delta} = \rho = \frac{r_p}{r_s} \qquad [37]$$

Referring to **Figure 15**, the phase difference between the parallel component and the perpendicular component of the incoming wave is denoted as δ_1, and the phase difference between the parallel and the perpendicular component of the outgoing wave as δ_2. It results that the parameter $\Delta = \delta_1 - \delta_2$ is the change in phase difference that occurs upon reflection and its value can be from 0° to 360°. Without regard to phase, the amplitude of both perpendicular and parallel components may change upon reflection, their ratio represented by the tan Ψ.

As ellipsometry measures a ratio quantity, the measurement is potentially more precise and accurate than a traditional intensity reflectance or transmission measurement. On the other hand, since ellipsometry is a polarization-based measurement, relatively complex optical instrumentation is required. Spectroscopic ellipsometry measures the complex ratio ρ as a function of wavelength, whereas variable angle spectroscopic ellipsometry performs the above measurement as a function of both wavelength and angle of incidence.

In case multiple interfaces have to be analyzed, it is possible to derive the ratio of the amplitude of the resultant reflected wave to the amplitude of the incident wave as a function of the Fresnel reflection coefficients for the single interfaces, wavelength of light, and thickness of layers.

For many instruments used today, the intensity measurement of the reflected light is related to

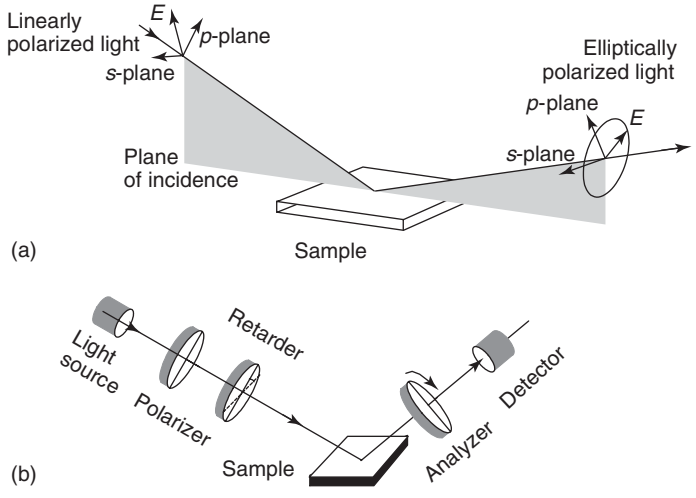

Figure 15 (a) Interaction of polarized light with a sample. (b) A rotating element ellipsometer. In this ellipsometer, only the analyzer rotates. The intensity measurement can be made with the quarter-wave-plate retarder either in the beam or outside it.

rotation of the analyzer of polarization on the reflected beam. This instrument is shown schematically in **Figure 15b**. In this case the polarizer on the incident beam is set at a fixed angle, usually 45°. The quarter wave plate (QWP) is fixed with the fast axis perpendicular to the plane of incidence and can be placed in the beam or removed from it. Only one of the polarizing elements (the analyzer) is rotated. The intensity I measured as a function of time t by the light detector can be expressed as

$$I(t) = I_0[1 + \alpha\cos 2A(t) + \beta\sin 2A(t)] \qquad [38]$$

where $A(t) = 2\pi ft + A_c$ with f being the angular frequency of the rotation and A_c being a constant phase offset. I_0 is the average intensity, and α and β are the Fourier coefficients. For a rotating analyzer instrument, the optimum precision is obtained when the light incident on the rotating analyzer is circularly polarized. If the phase shift induced by the reflection is $\sim 90°$, the optimum precision would be realized by using linearly polarized light (no QWP). The light starts out linearly polarized (components in phase) and the reflection changes it into near-circularly polarized light. If, on the other hand, the phase shift due to the reflection is either none or $\sim 180°$ without the QWP, the light incident on the analyzer would be almost linearly polarized. In this case the QWP is used. Typically, Ψ is measured without the QWP in place and Δ is measured both with and without the QWP. Depending on the value obtained, one or the other of the measurements is used.

The Fourier coefficients α and β are given by

$$\alpha = -\cos 2\Psi \quad \text{and} \quad \beta = \sin 2\Psi \cos \Delta_m \qquad [39]$$

where Δ_m is the measured phase difference between the parallel and the perpendicular components of the light at the analyzer. These equations can be inverted to give

$$\cos \Delta_m = \pm\sqrt{\frac{\beta^2}{1-\alpha^2}} \qquad [40]$$

and

$$\tan \Psi = \sqrt{\frac{1+\alpha}{1-\alpha}} \qquad [41]$$

If the QWP is not used, the phase shift induced by the reflection is given by $\Delta = \Delta_m$. If the QWP is in place and the light incident on the sample is circularly polarized, then it is necessary to add the retardation of the QWP to the measured value. If the QWP is perfect, then $\Delta = \Delta_m + 90°$.

Many desired material parameters can be extracted by this technique, including layer thickness, surface and/or interfacial roughness, and optical constants.

$$n = n_0 + \mathrm{i}n_1 \qquad [42]$$

where $n_0 = c/v$ is the index of refraction and n_1 is the extinction coefficient and takes care of absorption phenomena. The ellipsometric data measured on a bulk sample can be directly inverted into the optical constants of the material, assuming that surface oxide or roughness effects are negligible:

$$\begin{aligned}\tilde{n} &= n_0 + \mathrm{i}\kappa \\ &= \sin\phi^2\left[1 + \tan\phi^2 \times \left(\frac{1-\rho}{1+\rho}\right)^2\right]\end{aligned} \qquad [43]$$

where ϕ is the angle of incidence and ρ is measured by an ellipsometer.

This equation gives the averaged and a first appreciation of physical parameters under test. A full optical and microstructure analysis of real materials including multilayer structures, requires use of an appropriate model and regression analysis. It should be noted that ρ is the quantity measured by an ellipsometer and, assuming the instrument is operating properly, it is correct. The calculated sample parameters, such as thickness and index of refraction are correct, depend on whether the model assumed is correct. Typical examples of applications are determination of thickness and index of refraction of thin-film stacks up to five layers, material, optical constant of photoresist which is critical for industrial lithography, measurement of thickness and compositions of complex compound semiconductor structures, optical multilayer coatings, and variation in optical coating index.

Radiometer

Radiometry deals with the measurement of amounts of light. Photometry takes into account the response of the human eye which rises to a nonlinear and wavelength-dependent subjective impression of radiometric quantities.

Radiant power W, measured in watts, is the total amount of energy emitted by a light source per second. The spectral variation of radiant power can be specified in terms of the radiant power density per unit wavelength interval W_λ

$$W = \int_0^\infty W_\lambda \, \mathrm{d}\lambda \qquad [44]$$

If the light source emits radiation only for some specific duration, it is more useful to specify the source in terms of its radiant energy output Q_e, measured in joules. If the source emits radiation for a time T, one can write

$$Q_e = \int_0^T W(t)\,dt \qquad [45]$$

The amount of power emitted by a source in a particular direction per unit solid angle is called radiant intensity I_e, and is measured in watts per steradian. In general,

$$W = \oint I_e(\Omega)\,d\Omega \qquad [46]$$

where the integral is taken over a closed surface surrounding the source. If I_e is the same in all directions, the source is said to be an isotropic radiator. At distance r from such a source, if r is much greater than the dimension of the source, the radiant flux crossing a small area ΔS is

$$\phi_e = \frac{I_e \Delta S}{r^2} \qquad [47]$$

The irradiance at this point, measured in $W\,m^{-2}$, is

$$E_e = \frac{I_e}{r^2} \qquad [48]$$

which is equal to the average value of the Poynting vector measured at that point. The radiant flux emitted or reflected or scattered per unit area of a surface is called the radiant emittance M_e, and it is measured in $W\,m^{-2}$. For an extended source, the radiant flux emitted per unit solid angle per unit area of the source is called its radiance or brightness L_e:

$$L_e = \frac{\delta I_e}{\delta S_n} \qquad [49]$$

where the area δS_n is the projection of the surface element of the source in the direction being considered. When the light emitted from a source or scattered from a surface has a radiance that is independent of the viewing angle, the source or surface is called a perfectly diffuse or Lambertian radiator. For such a source, the radiant intensity at an angle θ to the normal to the surface is clearly

$$I_e(\theta) = I_e(0)\cos\theta \qquad [50]$$

The total flux emitted per unit area of such a surface is its radiant emittance, which, in this case, is $M_e = \pi I_e(0)$.

For plane waves, since all the energy in the wave is transported in the same direction, it is customary to specify the radiant flux crossing unit area normal to the direction of propagation, and call this the intensity I of the plane wave. Because lasers emit radiation into an extremely small solid angle, they have very high radiant intensity, and it is once again more usual to refer simply to the intensity of the laser beam at a point as the energy flux per second per unit area. Presently, radiometry involves the measurement of the energy content of electromagnetic radiation fields and the determination of how this energy is transferred from a source, through a medium, and to a detector, independently of its effect on a particular detector. The measurement of the effect of the transfer of radiation, such as absorption, reflection, or scatter is usually called spectrophotometry.

In common practice, radiometry is divided according to regions of the spectrum in which the same experimental technique can be used. Thus, vacuum ultraviolet, visible and near visible, intermediate-infrared, far infrared, and microwave regions are considered separate fields in radiometry.

Photometry concerns radiometry related to human vision, and measurement of the ability of electromagnetic radiation to produce a visual sensation in a physically realizable manner. The response of the human eye gives rise to a nonlinear and wavelength-dependent subjective impression of radiometric quantities. The response function of the human eye extends roughly from 400 to 700 nm with a peak at 555 nm. In photometry, radiometric quantities are used with different names and units. The luminous intensity, for instance, is the equivalent of the radiometric quantity, radiant intensity, and in photometry is measured as candela where 1 candela = 1 lumen str^{-1}.

Today, measurement of the energy content of electromagnetic radiation is performed with an electrically calibrated detector, which is a device for measuring absolute radiant power in comparison to electrical power. It consists of a thermal detector that has a radiation-heater within the surface, or the heater is in good thermal contact with the surface. When the device is irradiated, the detector senses the temperature of the radiantly heated surface. The radiation source is then blocked and the power to the electrical heater adjusted to reproduce the temperature of the radiantly heated surface. The electrical power to the heater is measured and equated to the radiant power on the surface. As the measurement has to be accurate, differences between the radiant and the electrical heating modes must be evaluated.

Detectors are distinguished by two types of radiant power absorber configurations: a flat surface coated

with a highly absorbing material or a cavity-shaped, light-trapping detector. Cavity-shaped radiometers are usually more accurate over a greater spectral range than flat-surface radiometers. However, a flat-surface receiver can be fabricated with less thermal mass than a cavity-shaped receiver, and, therefore, may have greater sensitivity and a faster response time.

Electrically calibrated detectors are in widespread use today; they are commercially available and are calibrated in the factory with a calibration lamp. They use either a thermocouple, a thermopile, or a bolometer. They operate at ambient temperature and are commonly used for solar/artificial lighting and for laser power measurements.

Optical Microscopy

G F Vander Voort, Buehler Ltd., Lake Bluff, IL, USA

Metallurgical microscopes differ from biological microscopes primarily in the manner by which the specimen is illuminated due to the opacity of metals. Unlike biological microscopes, metallurgical microscopes must use reflected light, rather than transmitted light. **Figure 1** is a simplified ray diagram of a metallurgical microscope. The prepared specimen is placed on the stage with the surface perpendicular to the optical axis of the microscope and is illuminated through the objective lens by light from a lamp or arc source. This light is focused by the condenser lens into a beam that is made approximately parallel to the optical axis of the microscope by a half-silvered mirror. The light then passes through the objective onto the specimen. It is then reflected from the surface of the specimen, back through the objective, the half-silvered mirror, and then to the eyepiece to the observer's eye, or to a camera port or a film plane.

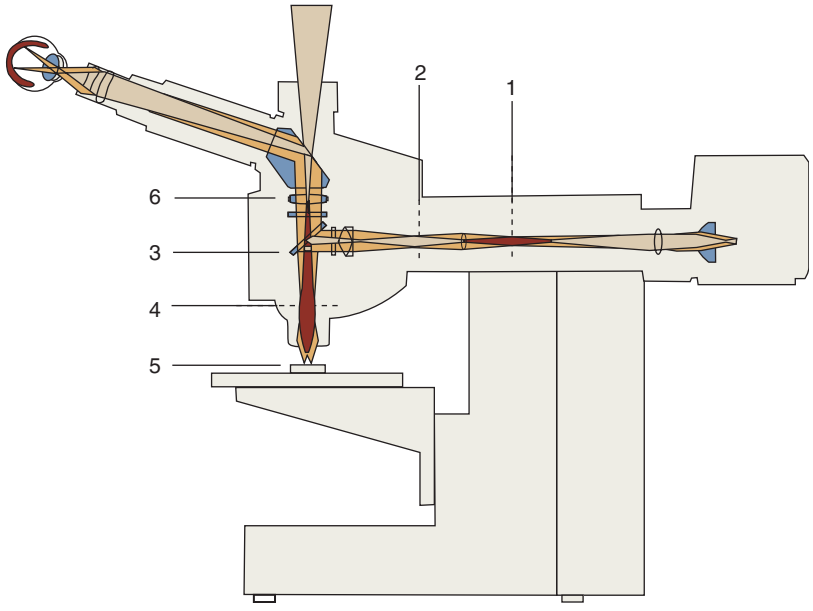

Figure 1 Schematic showing the light path in an upright reflected light microscope using bright-field illumination (1. aperture diaphragm; 2. luminous-field diaphragm; 3. reflector; 4. objective pupil; 5. sample surface; 6. tube lens). (Reproduced with permission of Buehler, Ltd.)

After the specimen has been properly sectioned and polished, it is ready for examination. However, in many cases, it is important to begin the examination with an as-polished specimen, particularly for quality control or failure analysis work. Certain microstructural constituents, such as nonmetallic inclusions, intermetallic phases, nitrides, cracks, or porosity, are best evaluated in the as-polished condition as etching reveals other microstructural features that may obscure such details. In the as-polished condition, there is a minimum of extra information for the observer to deal with which makes examination of these features most efficient. Some materials do not require etching and, in a few cases, examination is less satisfactory after etching.

For most metals, etching must be used to fully reveal the microstructure. A wide range of processes are used, the most common being etching with either acidic or basic solutions. For most metals and alloys, there are a number of general-purpose etchants that should be used first to reveal the microstructure. Subsequent examination may indicate that other more specialized techniques for revealing the microstructure may be useful. For example, the examination may reveal certain constituents that the metallographer may wish to measure. Measurements, particularly those performed with automatic image analyzers, will be simpler to perform and more reliable if the desired constituent can be revealed selectively, and numerous procedures are available to produce selective phase contrasting.

Henry Clifton Sorby

When Henry Clifton Sorby made his first examination of the microstructure of iron on 28 July 1863, he was using a transmitted light petrographic microscope made by Smith, Beck, and Beck of London that he had purchased in 1861. Although capable of magnifications up to 400×, most of his examinations were conducted at 30, 60, or 100× and his first micrographs were produced at only 9×. The objective lenses of this microscope were equipped with Lieberkühns silvered concave reflectors for focusing light on opaque specimens.

Sorby quickly realized that reflected light produced with the Lieberkühns reflectors was inadequate and he developed two alternate methods for this purpose. Subsequently, others developed vertical illuminators using prisms or plane glass reflectors and Sorby's systems were not further developed. In 1886, Sorby reported on the use of "very high power" (650×) for the study of pearlite. This was accomplished using a 45° cover glass vertical illuminator made for him by Beck.

For many years, photomicroscopy was conducted using specially built reflected microscopes known as metallographs. These devices represented the "top-of-the-line" in metallurgical microscopes and were essential for quality work. In the late 1960s and early 1970s, manufacturers developed metallographs that were easier to use from the eyepiece viewing position. The temperamental carbon-arc light sources were replaced by xenon-arc lamps. The unwieldy bellows systems for altering magnification were replaced by zoom systems. Vertical illuminators, previously using single-position objectives, were equipped with four-to-six position rotatable nosepiece turrets to minimize objective handling. The light path was deflected so that the film plane was conveniently near at hand. Universal-type vertical illuminators and objective lenses were introduced so that the illumination mode could be readily switched from bright field to dark field, polarized light, or differential interference contrast (DIC). Such systems were very attractive in that separate vertical illuminators and objectives were no longer needed for each illumination mode and handling was eliminated. Exposure meters were also added at this time, chiefly as a result of the rising popularity of instant films where such devices are needed to minimize film wastage. However, by the late 1970s, these large metallographs had become very expensive, too expensive for most laboratories.

In 1979, microscope manufacturers began to introduce very high quality, reasonably priced, compact metallographs. These microscopes can be obtained with a wide variety of objective lens types and auxiliary accessories to meet the metallographer's needs. They are available with universal vertical illuminators that permit easy switching from one illumination mode to another using the same set of objective lenses. Furthermore, the manufacturers have introduced new glass compositions and lens formulations, generally by computer-aided design, for improved image contrast and brightness. Tungsten–halogen filament lamps have largely replaced xenon-arc lamps as the preferred light source.

Microscope Components

Light Sources

The amount of light lost during passage from the source through a reflecting-type microscope is appreciable because of the intricate path the light follows. For this reason, it is generally preferable that the intensity of the source be high, especially for photomicroscopy. Several types of light sources are used including tungsten-filament lamps, tungsten–halogen lamps, quartz–halogen lamps, and xenon-arc bulbs.

Tungsten-filament lamps generally operate at low voltage and high current. They are widely used for visual examination because of their low cost and ease of operation.

Tungsten–halogen lamps are the most popular light source today due to their high light intensity. They produce good color micrographs when tungsten-corrected films are employed. Light intensity can be varied easily to suit the viewing conditions by adjusting a rheostat, a distinct advantage over arc lamps.

Xenon-arc lamps produce extremely high intensity, and their uniform spectra and daylight color temperature makes them suitable for color photomicrography. The first xenon lamps produced ozone, but modern units have overcome this problem. Light output is constant and can only be reduced using neutral-density filters.

Condenser

An adjustable lens free of spherical aberration and coma is placed in front of the light source to focus the light at the desired point in the optical path. A field diaphragm is placed in front of this lens to minimize internal glare and reflections within the microscope. The field diaphragm is stopped down to the edge of the field of view.

A second adjustable-iris diaphragm, the aperture diaphragm, is placed in the light path before the vertical illuminator. Opening or closing this diaphragm alters the amount of light and the angle of the cone of light entering the objective lens. The optimum setting for the aperture varies with each objective lens and is a compromise among image contrast, sharpness, and depth of field. As magnification increases, the aperture diaphragm is stopped down. Opening this aperture increases image sharpness, but reduces contrast; closing the aperture increases contrast, but impairs image sharpness. The aperture diaphragm should not be used for reducing light intensity. It should be adjusted only for contrast and sharpness.

Filters

Light filters are used to modify the light for ease of observation, for improved photomicroscopy, or to alter contrast. Neutral-density filters are used to reduce the light intensity uniformly across the visible spectrum. Various neutral-density filters, with a range of $\sim$85% of to 0.01% transmittance, are available. Most light microscopes offer selection of at least two such filters.

Selective filters are used to balance the color temperature of the light source to that of the film. This is often necessary for faithful reproduction of color images, depending on the light source used and the film type. A green or yellow-green filter is widely used in black-and-white photography to reduce the effect of lens defects on image quality. Most objectives, particularly the low-cost achromats, require such filtering for best results.

Polarizing filters are used to produce plane-polarized light (one filter) or crossed-polarized light (two filters rotated to produce extinction) for examinations of metals with noncubic crystallographic structures.

Objectives

The objective lens forms the primary image of the microstructure and is the most important component of the light microscope. The objective lens collects as much light as possible from the specimen and combines this light to produce the image. The numerical aperture (NA) of the objective, a measure of the light-collecting ability of the lens, is defined as

$$\mathrm{NA} = n \sin \alpha$$

where n is the minimum refraction index of the material (air or oil) between the specimen and the lens, and α is the half-angle of the most oblique light rays that enter the front lens of the objective. Light-collecting ability increases with α. The setting of the aperture diaphragm will alter the NA of the condenser and therefore the NA of the system.

The most commonly used objective is the achromat, which is corrected spherically for one color (usually yellow-green) and for longitudinal chromatic aberration for two colors (usually red and green). Therefore, achromats are not suitable for color photomicroscopy, particularly at higher magnifications. Use of a yellow-green filter yields optimum results. However, achromats do provide a relatively long working distance, that is, the distance from the front lens of the objective to the specimen surface when in focus. The working distance decreases as the objective magnification increases. Most manufacturers make long-working-distance objectives for special applications, for example, in hot-stage microscopy. Achromats are usually strain free, which is important for polarized light examinations. Because they contain fewer lenses than other more highly corrected lenses, internal reflection losses are minimized.

Semiapochromatic or fluorite objectives provide a higher degree of correction of spherical and chromatic aberration. Therefore, they produce higher quality color images than achromats. The apochromatic objectives have the highest degree of correction, produce the best results, and are more expensive. Plano objectives have extensive correction for flatness

of field, which reduces eyestrain, and are often found on modern microscopes.

With parfocal lens systems, each objective on the nosepiece turret will be nearly in focus when the turret is rotated, preventing the objective front lens from striking the specimen when lenses are switched. Many objectives also are spring loaded, which helps prevent damage to the lens. This is more of a problem with high-magnification objectives, because the working distance can be very small.

Certain objectives are designed for use with oil between the specimen and the front lens of the objective. However, oil-immersion lenses are rarely used in metallography, because the specimen and lens must be cleaned after use. However, they do provide higher resolutions that can be achieved when air is between the lens and specimen. In the latter case, the maximum possible NA is 0.95; oil-immersion lenses produce a 1.3 to 1.45 NA, depending on the lens and the oil used. Objective magnifications from $\sim$25 to 200$\times$ are available, depending upon the manufacturer. Use of oil also improves image contrast, which is valuable when examining low-reflectivity specimens, such as coal or ceramics.

Eyepieces

The eyepiece, or ocular, magnifies the primary image produced by the objective; the eye can then use the full resolution capability of the objective. The microscope produces a virtual image of the specimen at the point of most distinct vision, generally 250 mm (10 in.) from the eye. The eyepiece magnifies this image, permitting achievement of useful magnifications. The standard eyepiece has a 24-mm-diameter field of view, whereas wide-field eyepieces for plano-type objectives have a 30-mm-diameter field of view, which increases the usable area of the primary image. Today, the wide-field plano-objective is standard on nearly all metallurgical microscopes.

The simplest eyepiece is the Huygenian, which is satisfactory for use with low- and medium-power achromat objectives. Compensating eyepieces are used with high NA achromats and the more highly corrected objectives. Because some lens corrections are performed using these eyepieces, the eyepiece must be matched with the type of objective used. The newer, infinity-corrected microscopes do not perform corrections in the eyepieces, but in a tube lens. So, eyepieces are simpler in the infinity-corrected microscopes.

Eye clearance is the distance between the eye lens of the ocular and the eye. For most eyepieces, the eye clearance is 10 mm or less – inadequate if the microscopist wears glasses. Simple vision problems, such as near-sightedness, can be accommodated using the fine focus adjustment. The microscope cannot correct vision problems such as astigmatism, and glasses must be worn. High-eyepoint eyepieces are available to provide an eye clearance of $\sim$20 mm, necessary for eyeglasses.

Eyepieces are commonly equipped with various reticles or graticules for locating, measuring, counting, or comparing microstructures. The eyepiece enlarges the reticle or graticule image and the primary image. Both images must be in focus simultaneously. Special eyepieces are also produced to permit more accurate measurements than can be made with a graticule scale. Examples are the filar-micrometer ocular or screw-micrometer ocular. Such devices can be automated to produce a direct digital readout of the measurement, which is accurate to $\sim$1 μm.

A 10$\times$ magnification eyepiece is usually used, to obtain standard magnifications; some systems require other magnifications; such as 6.3$\times$. However, higher power eyepieces, such as 12, 15, 20, or 25$\times$, are also useful in certain situations. The overall magnification is found by multiplying the objective magnification, M_o, by the eyepiece magnification, M_e. If bellows or a zoom system is also used, the magnification should be altered accordingly.

Stage

A mechanical stage is provided for focusing and moving the specimen, which is placed on the stage and secured using clips. The stage of an inverted microscope has replaceable center-stage plates with different size holes. The polished surface is placed over the hole for viewing. However, the entire surface cannot be viewed, unless the specimen is smaller than the hole and it is mounted. At high magnifications, it may not be possible to focus the objective near the edge of the hole due to the restricted working distance.

Using the upright microscope, the specimen is placed on a slide on the stage. Because the polished surface must be perpendicular to the light beam, clay is placed between the specimen bottom and the slide. A piece of lens tissue is placed over the polished surface, and the specimen is pressed into the clay using a leveling press. However, pieces of tissue may adhere to the specimen surface. An alternative, particularly useful with mounted specimens, is to use a ring instead of tissue to flatten the specimen. Aluminum or stainless steel ring forms of the same size as the mounts (flattened slightly in a vise) will seat on the mount rather than on the specimen.

The upright microscope allows viewing of the entire surface with any objective, and the operator can

see which section of the specimen is being viewed – a useful feature when examining specific areas on coated specimens, welds, and other specimens where specific areas are to be examined. For mounted specimens, an auto-leveling stage holder can eliminate leveling specimens on clay.

The stage must be rigid to eliminate vibrations. Stage movement, controlled by *x*- and *y*-micrometers, must be smooth and precise; rack and pinion gearing is normally used. Many stages have scales for measuring the distances in the *x*- and *y*-directions. The focusing controls often contain rulings for estimating vertical movement. Some units have motorized stages and focus controls.

A circular rotatable stage plate may facilitate polarized light examination. Such stages, common for mineralogical or petrographic studies, are graduated to permit measuring the angle of rotation. A rectilinear stage is generally placed on top of the circular stage.

Stand

Bench microscopes require a rigid stand, particularly if photomicroscopy is performed on the unit. The various pieces of the microscope are attached to the stand when assembled. In some cases, the bench microscope is placed on a separate stand that also holds the photographic system.

Resolution

To see microstructural detail, the optical system must produce adequate resolution, or resolving power, and adequate image contrast. If resolution is acceptable but contrast is lacking, detail cannot be observed. In general, the ability to resolve two points or lines separated by distance d is a function of the wavelength, λ, of the incident light and the numerical aperture, NA, of that objective.

$$d = \frac{k_\lambda}{\text{NA}}$$

where k is 0.5 or 0.61. **Figure 2** illustrates this relationship for $k = 0.61$ and four light wavelengths. Other formulas have also been reported. This equation does not include other factors that influence resolution, such as the degree of correction of the objectives and the visual acuity of the microscopist. It was based on the work of Abbe under conditions not present in metallography, such as self-luminous points, perfect black-white contrast, transmitted-light examination, an ideal point-light source, and absence of lens defects.

Using the above equation, the limit of resolution for an objective with an NA of 1.3 is $\sim 0.2\,\mu\text{m}$. To see lines or points spaced 0.2 μm apart, the required magnification must be determined by dividing the resolving power of the human eye, which is difficult to determine under observation conditions. Abbe used a value of 0.3 mm at a distance of 250 mm – the distance from the eye for optimum vision. For light with a mean wavelength of 0.55 μm, the required magnification is 1100 times the NA of the objective. This is the origin of the $1000 \cdot \text{NA}$ rule for the maximum useful magnification. Any magnification above $1000 \cdot \text{NA}$ is termed "empty," or useless.

Strict adherence to the $1000 \cdot \text{NA}$ rule should be questioned, considering the conditions under which it was developed, which are certainly far different

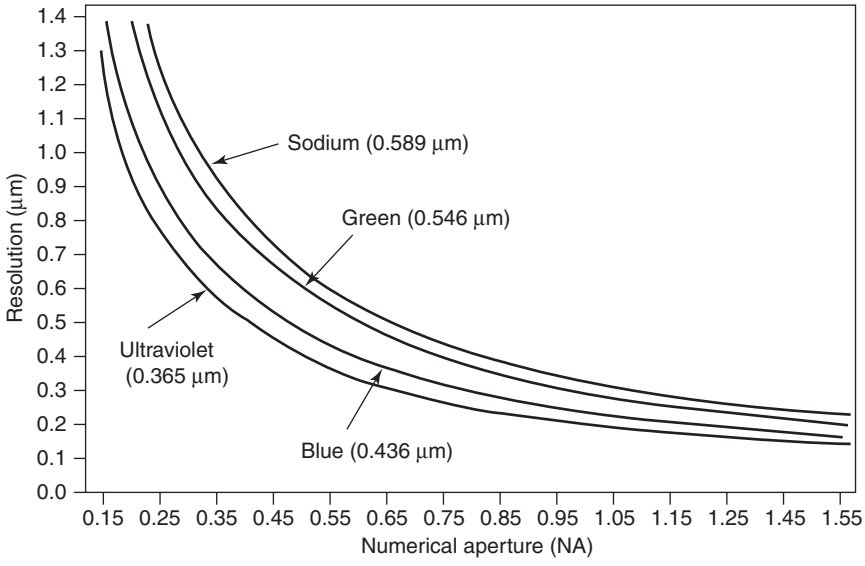

Figure 2 Influence of objective numerical aperture and wavelength on the resolution of the light microscope. (Reproduced with permission from Buehler, Ltd.)

from those encountered in metallography. According to the Abbe analysis, for a microscopist with optimum 20/20 vision and for optimum contrast conditions and a mean light wavelength of 550 nm, the lowest magnification that takes full advantage of the NA of the objective is 500 times the NA. This establishes a useful minimum magnification to be used with a given objective. It has been suggested that the upper limit of useful magnification for the average microscopist is $2200 \cdot \text{NA}$, not $1000 \cdot \text{NA}$.

Depth of Field

Depth of field is the distance along the optical axis over which image details are observed with acceptable clarity. Those factors that influence resolution also affect depth of field, but in the opposite direction. Therefore, a compromise must be reached between these two parameters, which is more difficult as magnification increases. This is one reason light etching is preferred for high-magnification examination. The depth of field, d_f, can be estimated from:

$$d_f = \lambda \frac{(n^2 - \text{NA}^2)^{1/2}}{\text{NA}^2}$$

where n is the refractive index of the medium between the specimen and the objective ($n \approx 1.0$ for air), λ is the wavelength of light, and NA is the numerical aperture. This equation shows that depth of field increases as the NA decreases and when longer wavelength light is used, as shown in **Figure 3**.

Imaging Modes

Most microscopical studies of metals are made using bright-field illumination. In addition to this type of illumination, several special techniques (oblique illumination, dark-field illumination, DIC microscopy, and polarized-light microscopy) have particular applications for metallographic studies.

Nearly all microscopes using reflected or transmitted light employ Köhler illumination because it provides the most intense, most even illumination possible with standard light sources. The reflected light microscope has two adjustable diaphragms: the aperture diaphragm and the field diaphragm, located between the lamp housing and the objective. Both are adjusted to improve illumination and the image. To obtain Köhler illumination, the image of the field diaphragm must be brought into focus on the specimen plane. This normally occurs automatically when the microstructural image is brought into focus. The filament image must also be focused on the aperture diaphragm plane. This produces uniform illumination of the specimen imaged at the intermediate image plane and magnified by the eyepiece.

Bright Field

In bright-field illumination, the surface of the specimen is normal to the optical axis of the microscope, and white light is used. A ray diagram for bright-field illumination is illustrated in **Figure 4**. Light that passes through the objective and strikes a region of the specimen surface that is perpendicular to the beam will be reflected back up the objective through the eyepieces to the eyes where it will appear to be bright or white. Light that strikes grain boundaries, phase boundaries, and other features not perpendicular to the optical axis will be scattered at an angle and will not be collected by the objective. These

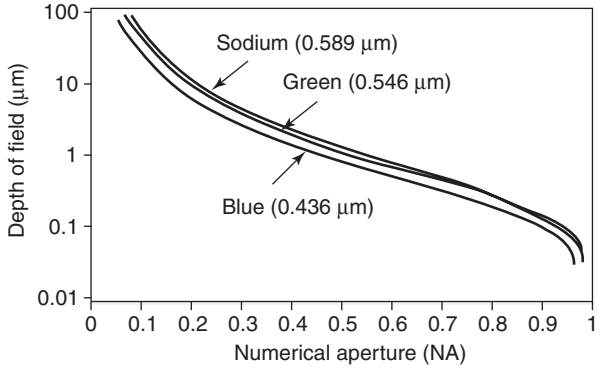

Figure 3 Influence of the objective numerical aperture and wavelength on the depth of field of the light microscope. (Reproduced with permission from Buehler, Ltd.)

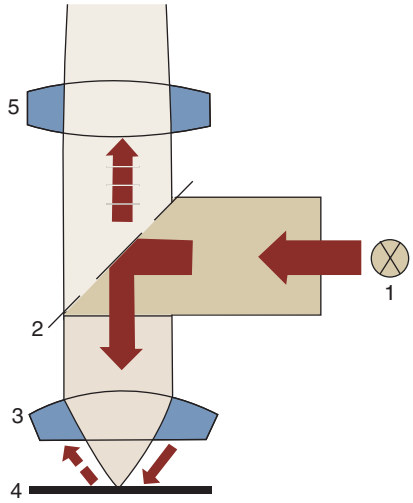

Figure 4 Schematic showing the light path in bright-field illumination (1. light source; 2. color-neutral beam splitter; 3. reflected-light objective; 4. sample surface; 5. tube lens). (Reproduced with permission from Buehler, Ltd.)

regions will appear to be dark or black in the image. Bright-field is the most common mode of illumination used by metallographers.

Oblique Illumination

The surface relief of a metallographic specimen can be revealed using oblique illumination. This involves offsetting the condenser lens system or, as is more usually done, moving the condenser aperture to a position slightly off the optical axis. Although it should be possible to continually increase the contrast achieved by oblique illumination by moving the condenser farther and farther from the light axis, the numerical aperture of a lens is reduced when this happens because only a portion of the lens is used. For this reason, there is a practical limit to the amount of contrast that can be achieved. Illumination also becomes uneven as the degree of "obliqueness" increases. Since DIC systems have been available, oblique illumination is rarely offered as an option on new microscopes.

Dark Field

Another method that can be used to distinguish features not in the plane of the polished-and-etched surface of a metallographic specimen is dark-field (also called dark ground) illumination. This type of illumination (see **Figure 5** for a ray diagram) gives contrast completely reversed from that obtained with bright-field illumination – the features that are light in bright-field will be dark in dark-field, and those that are dark in bright-field will be light, appearing to be self-luminous, in dark-field. This highlighting of angled surfaces (pits, cracks, or etched grain boundaries) allows more positive identification of their nature than can be derived from a black image with bright-field illumination. Due to the high image contrast obtained and the brightness associated with features at an angle to the optical axis, it is often possible to see details not observed with bright-field illumination.

Polarized-Light Microscopy

Because many metals and metallic and nonmetallic phases are optically anisotropic, polarized light is particularly useful in metallography. Polarized light is obtained by placing a polarizer (usually a Polaroid filter) in front of the condenser lens of the microscope and placing an analyzer (another Polaroid filter) before the eyepiece, as illustrated in **Figure 6**. The polarizer produces plane-polarized light that strikes the surface and is reflected through the analyzer to the eyepieces. If an anisotropic metal is examined with the analyzer set 90° to the polarizer, the grain structure will be visible. However, viewing of an isotropic metal (cubic metals) under such conditions will produce a dark, "extinguished" condition (complete darkness is not possible using Polaroid filters). Polarized light is particularly useful in metallography for revealing the grain structure and twinning in anisotropic metals and alloys and for identifying anisotropic phases and inclusions.

DIC Microscopy

When crossed polarized light is used along with a double quartz prism (Wollaston prism) placed between the objective and the vertical illuminator (**Figure 7**), two light beams are produced which exhibit coherent interference in the image plane. This leads to two slightly displaced (laterally) images differing in phase ($\lambda/2$) that produces a height contrast. The image produced reveals topographic detail somewhat similar to that produced by oblique illumination but without the loss of resolution. Images can be viewed with natural colors similar to those observed in bright-field, or artificial coloring can be introduced by adding a sensitive tint plate.

As an example of the use of these different imaging modes, **Figure 7** shows the microstructure of an aluminum bronze specimen that was water-quenched from the beta field forming martensite. The specimen was prepared but not etched. A minor amount of relief was introduced in final polishing. **Figure 8a** shows the surface in bright-field illumination. Due to the relief present, a faint image of the structure is visible. Dark-field (**Figure 8c**) and DIC (**Figure 8d**) make use of this relief to reveal much more detail than in bright-field. However, as the martensite is noncubic in crystal structure, it responds well to crossed-polarized light (**Figure 8b**). Of course, not every material can be examined using all four illumination modes, but there are many cases where two or more modes can be effectively utilized to reveal more information than given by bright-field alone.

Optical Properties of Materials

G Guizzetti and M Patrini, Università degli Studi di Pavia, Pavia, Italy

Introduction

The optical properties of materials are of major interest from both the applicative and the fundamental points of view. They are indeed quantified by macroscopic functions, such as the refractive index, the absorption coefficient and reflectivity, a knowledge of which is necessary in designing and implementing optic or optoelectronic components and devices. They explain the nature of the material (e.g., allowing the distinction between metals, semiconductors, and insulators), and of the material homogeneity, crystal structure, and composition. Moreover, the macroscopic optical response should be related to microscopic properties, such as the electronic and vibrational structures, by means of classical models (e.g., Drude–Lorentz model) and quantum treatments (e.g., for interband and intraband optical transitions).

In this article, the optical properties of macroscopic materials based only on classical arguments are described. Starting from Maxwell's equations in a medium, the propagation of electromagnetic (em) waves in isotropic, linear, and homogeneous materials is treated. To this aim, complex macroscopic quantities as the dielectric function, the optical conductivity, and the refractive index are introduced, together with the dispersion relations which they obey. Some hints at their extensions to anisotropic and nonlinear materials are given.

The reflection and transmission properties of em waves are then analyzed at the interface between different materials, and the appropriate functions are defined for unpolarized light waves. Their extension for polarized waves follows, with the addition of the ellipsometric functions which are particularly interesting from the application point of view. Finally, links between the different optical functions and brief hints at their measurement techniques are given.

Maxwell's Equations in a Medium

The theoretical framework for the optical properties of a material is given by Maxwell's equations which describe the propagation of an em wave in a medium and which in SI units are

$$\nabla \cdot \boldsymbol{D} = \rho, \qquad \nabla \cdot \boldsymbol{B} = 0$$
$$\nabla \times \boldsymbol{E} = -\frac{\partial \boldsymbol{B}}{\partial t}, \qquad \nabla \times \boldsymbol{H} = \boldsymbol{j} + \frac{\partial \boldsymbol{D}}{\partial t} \qquad [1]$$

where $\boldsymbol{E}$ and $\boldsymbol{H}$ are the electric and magnetic fields, $\boldsymbol{D}$ the electric displacement, $\boldsymbol{B}$ the magnetic induction, ρ the external introduced charge density, $\boldsymbol{j}$ the current density.

The relations between the electric and magnetic fields are

$$\boldsymbol{D} = \varepsilon_0 \boldsymbol{E} + \boldsymbol{P}, \qquad \boldsymbol{H} = \frac{\boldsymbol{B}}{\mu_0} - \boldsymbol{M}\partial \qquad [2]$$

where $\boldsymbol{P}$ is the polarization (electric dipole moment per unit volume) and $\boldsymbol{M}$ the magnetization (magnetic moment per unit volume), ε_0 and μ_0 the vacuum permittivity and magnetic permeability.

The current density $\boldsymbol{j}$ in the more general case contains two terms

$$\boldsymbol{j} = \boldsymbol{j}_{\text{ext}} + \boldsymbol{j}_{\text{cond}} \qquad [3]$$

where $\boldsymbol{j}_{\text{ext}}$ is the current density introduced into the medium from an external source and $\boldsymbol{j}_{\text{cond}}$ is the conduction current which is induced by a driving em field and which arises from the motion of charges in phase with the field.

All these quantities are macroscopic, that is, the average of their microscopic counterparts over a volume ΔV with linear dimensions small compared to the wavelength λ of the em wave, but large enough to contain many atoms. Then the medium can be treated as continuous from the viewpoint of optical properties, although an ideally perfect crystal is not rigorously homogeneous on a microscopic scale. For instance, the internal charge density has crystal periodicity and varies sharply in the unit cell.

In the following, homogeneous, isotropic, nonmagnetic ($\boldsymbol{B} = \mu_0 \boldsymbol{H}$) materials are treated in the absence of external charges ($\rho = 0$) and currents ($\boldsymbol{j}_{\text{ext}} = 0$). Moreover, the linear response regime is considered, that is, the variations in the internal charge density and in the current density induced by a driving em field of small intensity are proportional to the field. In these assumptions, the appropriate constitutive equations of the medium are:

$$\boldsymbol{P} = \varepsilon_0 \chi \boldsymbol{E}, \qquad \boldsymbol{j}_{\text{cond}} = \sigma \boldsymbol{E} \qquad [4]$$

where χ is the electric susceptibility and σ is the conductivity. The susceptibility χ and the conductivity σ

contain the response of the medium to the em field E. They both appear at the right-hand side of the last of Maxwell's equations [1] and represent two different currents, the conduction current $\boldsymbol{j}_{\text{cond}}$ and the polarization current $\boldsymbol{j}_{\text{pol}} = \partial \boldsymbol{P}/\partial t = \varepsilon_0 \chi(\partial \boldsymbol{E}/\partial t)$. Since periodic solutions of Maxwell's equations are considered, $\boldsymbol{j}_{\text{cond}}$ and $\boldsymbol{j}_{\text{pol}}$ are $\pi/2$ out-of-phase: $\boldsymbol{j}_{\text{cond}}$ is in-phase with $\boldsymbol{E}$ and gives a time-average power absorption per unit volume $\boldsymbol{P}_{\text{a}} = \langle \boldsymbol{j} \cdot \boldsymbol{E} \rangle = \sigma \langle \boldsymbol{E}^2 \rangle$; $\boldsymbol{j}_{\text{pol}}$, instead, is $\pi/2$ out-of-phase with $\boldsymbol{E}$ and does not provide any absorption. It is stressed that $\boldsymbol{j}_{\text{cond}}$ and $\boldsymbol{j}_{\text{pol}}$, and thus χ and σ, are not independent quantities because they have the same origin: the motion of charges (free or bound) induced by the em field. As it is shown below, the real quantities χ and σ are better represented by the real and imaginary parts of a single complex quantity. Moreover, the conductivity σ which appears in eqn [4] is sometimes called optical conductivity, which in the limit of zero-frequency equals the usual DC electrical conductivity, that is, for a static field $\boldsymbol{E}\,\sigma \neq 0$ only in conductors, while for time-variable fields $\boldsymbol{E}(t)\,\sigma \neq 0$ for both conductors and insulators.

An alternative parameter which characterizes a material is defined through eqn [2] by

$$\boldsymbol{D} = \varepsilon_0 \boldsymbol{E} + \boldsymbol{P} = \varepsilon_0 \boldsymbol{E} + \varepsilon_0 \chi \boldsymbol{E} = \varepsilon \boldsymbol{E} \qquad [5]$$

where the quantity $\varepsilon = \varepsilon_0(1 + \chi)$ is termed the dielectric constant or dielectric function (as is evident below, the second nomenclature is more appropriate when dealing with time-dependent fields). The dimensionless quantity $\varepsilon_{\text{r}} = \varepsilon/\varepsilon_0 = (1 + \chi)$ is the relative dielectric function.

ε and σ are the parameters which allow one to completely characterize the optical response of the material. They describe the velocity of the wave in the medium and its spatial attenuation, that is, the energy absorbed by the medium, respectively. ε and σ are functions of frequency (this property is called time dispersion) and the wave vector (spatial dispersion) of the em wave. Moreover, they depend also on internal/external physical parameters, such as temperature, pressure, magnetic or electric static fields.

In the aforementioned hypotheses and from Maxwell's equations, the following wave equation can be derived:

$$\nabla^2 \boldsymbol{E} = \varepsilon_{\text{r}} \varepsilon_0 \mu_0 \frac{\partial^2 \boldsymbol{E}}{\partial t^2} + \sigma \mu_0 \frac{\partial \boldsymbol{E}}{\partial t} \qquad [6]$$

This is the so-called d'Alembert equation for a wave propagating in a generic absorbing medium. Solutions of eqn [6] are necessarily restricted to transverse waves because $\nabla \cdot \boldsymbol{E} = 0$ in the absence of a net charge density ρ. In vacuum ($\varepsilon_{\text{r}} = 1,\ \sigma = 0$), the wave velocity coincides with the velocity of light $c = (\sqrt{\varepsilon_0 \mu_0})^{-1}$, while in a nonabsorbing medium ($\sigma = 0$) the phase velocity is $v = (\sqrt{\varepsilon_{\text{r}} \varepsilon_0 \mu_0})^{-1} = c/\sqrt{\varepsilon_{\text{r}}} = c/n$, where $n = \sqrt{\varepsilon_{\text{r}}} = c/v$ is the refractive index of the medium. The wave amplitude attenuation is described by the second term on the right-hand side of eqn [6].

The Complex Dielectric Function

It must be emphasized that, in the case of time-dependent em fields, there is generally a phase shift between the motion of the charge carriers and the electric field $\boldsymbol{E}$ (similar to what happens in AC circuits). In such cases the complex formalism is particularly convenient to describe these phase shifts, in addition to describing dispersion and absorption effects at the same time. Complex fields are usually defined, the real parts of which have physical meaning and are the ones involved in Maxwell's equations. For instance, $\boldsymbol{E}(\boldsymbol{r}, t) = \text{Re}[\tilde{\boldsymbol{E}}(\boldsymbol{r}, t)]$, where the tilde distinguishes the complex quantity from its real counterpart.

Since the experimental measurements of the optical properties of solids are usually conducted with monochromatic light, a solution of eqn [6] is considered in the form of a monochromatic plane wave:

$$\tilde{\boldsymbol{E}}(\boldsymbol{r}, t) = \tilde{\boldsymbol{E}}_0 \exp[\text{i}(\tilde{\boldsymbol{q}} \cdot \boldsymbol{r} - \omega t)] \qquad [7]$$

where $\tilde{\boldsymbol{E}}$ is the complex electric field, $\tilde{\boldsymbol{E}}_0 = \boldsymbol{E}_0 \text{e}^{\text{i}\varphi_0}$ is the polarization vector with an arbitrary phase φ_0, $\boldsymbol{r}$ is the position vector with respect to an arbitrary coordinate system, $\omega = 2\pi v$ is the angular frequency, and $\tilde{\boldsymbol{q}} = \boldsymbol{q}_1 + \text{i}\boldsymbol{q}_2$ is the complex wave vector of the em wave in the medium. The absolute value of the wave vector in vacuum is $q = 2\pi/\lambda = \omega/c$. In fact, $\tilde{\boldsymbol{q}}$ describes the phase and spatial attenuation of the em wave, its explicit form being written as

$$\begin{aligned} \boldsymbol{E}(\boldsymbol{r}, t) &= \text{Re}\ \tilde{\boldsymbol{E}}(\boldsymbol{r}, t) \\ &= \text{Re}\left[\tilde{\boldsymbol{E}}_0 \exp[\text{i}(\tilde{\boldsymbol{q}} \cdot \boldsymbol{r} - \omega t)]\right] \\ &= \text{Re}\left[\tilde{\boldsymbol{E}}_0 \exp[\text{i}(\boldsymbol{q}_1 \cdot \boldsymbol{r} - \omega t)]\right] \exp(-\boldsymbol{q}_2 \cdot \boldsymbol{r}) \\ &= \boldsymbol{E}_0 \cos(\boldsymbol{q}_1 \cdot \boldsymbol{r} - \omega t + \varphi_0) \exp(-\boldsymbol{q}_2 \cdot \boldsymbol{r}) \end{aligned} \qquad [8]$$

In general, $\boldsymbol{q}_1$ and $\boldsymbol{q}_2$ are perpendicular to the constant phase planes and to the constant amplitude planes, respectively. If $\boldsymbol{q}_1 || \boldsymbol{q}_2$, the wave is homogeneous.

By inserting the monochromatic plane wave expression (eqn [7]) in eqn [6], the wave dispersion relation is obtained:

$$\tilde{\boldsymbol{q}} \cdot \tilde{\boldsymbol{q}} = \mu_0 \left(\varepsilon + \text{i}\frac{\sigma}{\omega}\right) \omega^2 = \mu_0 \tilde{\varepsilon} \omega^2 \qquad [9]$$

where a complex dielectric function $\tilde{\varepsilon}$ has been introduced as

$$\tilde{\varepsilon} \equiv \varepsilon_1 + i\varepsilon_2 = \varepsilon + i\frac{\sigma}{\omega} \quad [10]$$

The real part $\varepsilon_1 = \varepsilon$ describes the wave dispersion while the imaginary part $\varepsilon_2 = \sigma/\omega$ accounts for the dissipation of energy by the material. Alternatively, the complex conductivity $\tilde{\sigma} \equiv \sigma_1 + i\sigma_2 = -i\omega\tilde{\varepsilon} = \sigma - i\omega\varepsilon$ is sometimes used instead of $\tilde{\varepsilon}$.

The possibility of a phase shift between $\tilde{\boldsymbol{D}}$ (or $\tilde{\boldsymbol{j}}$) and $\tilde{\boldsymbol{E}}$ is now easily included by defining $\tilde{\boldsymbol{D}} = \tilde{\varepsilon}\tilde{\boldsymbol{E}}$ (or $\tilde{\boldsymbol{j}} = \tilde{\sigma}\tilde{\boldsymbol{E}}$). Moreover, when considering an em field given by eqn [7], the displacement current $\partial\boldsymbol{D}/\partial t$ and the conduction current $\boldsymbol{j}_{\text{cond}}$ which appear in Maxwell's equations can be combined as follows:

$$\begin{aligned}\boldsymbol{j}_{\text{cond}} + \frac{\partial \boldsymbol{D}}{\partial t} &= \sigma\boldsymbol{E} + \varepsilon\frac{\partial \boldsymbol{E}}{\partial t} = \text{Re}[(\sigma - i\omega\varepsilon)\tilde{\boldsymbol{E}}] \\ &= \text{Re}[\tilde{\sigma}\tilde{\boldsymbol{E}}] = \text{Re}[-i\omega\tilde{\varepsilon}\,\tilde{\boldsymbol{E}}]\end{aligned} \quad [11]$$

Thus the response function $\tilde{\varepsilon}$ accounts not only for the displacement current $\partial\boldsymbol{D}/\partial t$, which is $\pi/2$ out-of-phase with $\boldsymbol{E}$ and does not dissipate energy, but also, in its imaginary part, for the conduction current $\boldsymbol{j}_{\text{cond}}$, which is in-phase with $\boldsymbol{E}$ and dissipates energy. The same holds for $\tilde{\sigma}$. When the optical response of a medium is calculated according to a specific model, either $\tilde{\varepsilon}$ or $\tilde{\sigma}$ must be introduced (but not both), since each one already includes both the in-phase and out-of-phase components.

In a general treatment, ε and σ are functions of space and time since the space–time representation of Maxwell's equations has been adopted. They are response functions or linear integral operators that connect the fields $\boldsymbol{D}(\boldsymbol{r}, t)$ and $\boldsymbol{j}(\boldsymbol{r}, t)$ with the electric field $\boldsymbol{E}(\boldsymbol{r}', t')$ at all other positions and all earlier times. Thus, in general,

$$\boldsymbol{D}(\boldsymbol{r}, t) = \int \mathrm{d}\boldsymbol{r}' \int_{-\infty}^{t} \varepsilon(\boldsymbol{r}, \boldsymbol{r}', t, t')\boldsymbol{E}(\boldsymbol{r}', t')\mathrm{d}t' \quad [12]$$

that is, $\boldsymbol{D}$ $(\boldsymbol{r}, t)$ and $\boldsymbol{E}$ $(\boldsymbol{r}, t)$ are not proportional to each other, while this is true for their Fourier components. In fact, fields and sources should be decomposed into a complete set of monochromatic plane waves, for example

$$\begin{aligned}\boldsymbol{E}(\boldsymbol{r}, t) = \int_{-\infty}^{+\infty} \mathrm{d}\boldsymbol{q} \int_{-\infty}^{+\infty} \tilde{\boldsymbol{E}}(\boldsymbol{q}, \omega) \\ \times \exp[i(\boldsymbol{q}\cdot\boldsymbol{r} - \omega t)]\mathrm{d}\omega\end{aligned} \quad [13]$$

where $\tilde{\boldsymbol{E}}$ $(\boldsymbol{q}, \omega)$ is the Fourier transform of $\boldsymbol{E}(\boldsymbol{r}, t)$, with

$$\begin{aligned}\tilde{\boldsymbol{E}}(\boldsymbol{q}, \omega) = \left(\frac{1}{2\pi}\right)^4 \int_{-\infty}^{+\infty} \mathrm{d}\boldsymbol{r} \int_{-\infty}^{+\infty} \boldsymbol{E}(\boldsymbol{r}, t) \\ \times \exp[-i(\boldsymbol{q}\cdot\boldsymbol{r} - \omega t)]\mathrm{d}t\end{aligned} \quad [14]$$

Operating the Fourier transform of eqn [12] and utilizing the convolution theorem, one obtains

$$\tilde{\boldsymbol{D}}(\omega, \boldsymbol{q}) = \tilde{\varepsilon}(\omega, \boldsymbol{q})\tilde{\boldsymbol{E}}(\omega, \boldsymbol{q}) \quad [15]$$

where the complex dielectric function $\tilde{\varepsilon}(\omega, \boldsymbol{q})$, Fourier transform of $\varepsilon(\boldsymbol{r}, t)$, shows up as the proportionality constant between the complex field components. An analogous relation $\tilde{\boldsymbol{j}}(\omega, \boldsymbol{q}) = \tilde{\sigma}(\omega, \boldsymbol{q})\tilde{\boldsymbol{E}}(\omega, \boldsymbol{q})$ can be obtained.

The frequency and wave vector dependence of $\tilde{\varepsilon}(\omega, \boldsymbol{q})$ and $\tilde{\sigma}(\omega, \boldsymbol{q})$ describe the time and the spatial dispersion of the material, respectively. The spatial dispersion is associated with the presence of natural lengths in the medium, such as the dimension of atoms and interatomic spacings; its effect is weak for wavelengths which are long as compared to the natural lengths. In the optical spectral range, the spatial dispersion should be neglected and $\tilde{\varepsilon}(\omega, \boldsymbol{q}) = \tilde{\varepsilon}(\omega)$; this is not possible at X-ray wavelengths. Moreover, it may be noted that the wave dispersion relation (eqn [9]), which binds ω and $\boldsymbol{q}$, does not imply, in general, a connection between time dispersion and spatial dispersion. In principle, it is possible to investigate separately the temporal response of a medium (and hence the time dispersion in ω) by subjecting it to a spatially uniform field that oscillates in time, or the spatial response (and hence the spatial dispersion in $\boldsymbol{q}$) with a static field that is spatially periodic.

In an anisotropic medium, the polarization $\boldsymbol{P}$ and $\boldsymbol{j}_{\text{cond}}$ generally lie in a direction different from that of $\boldsymbol{E}$. This situation can be handled by representing the complex dielectric function as a tensor $\tilde{\varepsilon}_{ij}$. The real and imaginary parts of $\tilde{\varepsilon}_{ij}$ are symmetric also for an anisotropic medium; thus, it is possible to put each of them into diagonal form in an appropriate set of coordinate axes (principal axes). The two sets do not coincide in general, until the crystal has symmetry at least as high as an orthorhombic one. ln the particular case of cubic crystal symmetry, $\tilde{\varepsilon}_{ij}$ reduces to a scalar quantity.

In a nonlinear dielectric medium, it is possible to expand the relation between $\boldsymbol{P}$ and $\boldsymbol{E}$ in a Taylor series about $\boldsymbol{E} = 0$. Thus $\boldsymbol{P} = \varepsilon_0(\chi\boldsymbol{E} + \chi^{(2)}\boldsymbol{E}^2 + \chi^{(3)}\boldsymbol{E}^3 + \cdots)$, where the $\chi^{(n)}$ coefficient describes the nth order nonlinear effect. The eqn [6] is not applicable to em waves in nonlinear media. However, Maxwell's equations can be used to derive a

nonlinear partial differential equation that these waves obey.

Finally, the real and imaginary parts of $\tilde{\varepsilon}$ are not independent quantities, being related to one another by the integral relations, the so-called Kramers–Kronig relations. These relations follow rigorously from the requirement of causality (i.e., there can be no effect before the cause) and apply to the real and imaginary part of whatever linear response function. Thus, the complex dielectric function $\tilde{\varepsilon}(\omega)$ obeys the following relations:

$$\begin{aligned}\varepsilon_1(\omega) &= \varepsilon_0 + \frac{2}{\pi}P\int_0^\infty \frac{\omega'\varepsilon_2(\omega')}{\omega'^2-\omega^2}\,\mathrm{d}\omega' \\ \varepsilon_2(\omega) &= -\frac{2\omega}{\pi}P\int_0^\infty \frac{\varepsilon_1(\omega')-\varepsilon_0}{\omega'^2-\omega^2}\,\mathrm{d}\omega'\end{aligned} \qquad [16]$$

where P stands for the principal value of the integral.

It may be recalled that $\tilde{\varepsilon}$ and $\tilde{\sigma}$ describe the macroscopic properties of materials, but they can be related to polarizabilities on the atomic scale and give reasons for the microscopic properties of condensed matter, for example, electronic and vibrational structures.

Complex Refractive Index

In analogy with the statement $n^2(\omega) = \varepsilon_\mathrm{r}(\omega)$ valid in nonabsorbing media, where n is the refractive index, it is useful to define a complex quantity, the so-called complex refractive index $\tilde{n}(\omega)$ that is related to the relative complex dielectric function $\tilde{\varepsilon}_\mathrm{r}(\omega) = \tilde{\varepsilon}(\omega)/\varepsilon_0$ by the relation:

$$\tilde{n}^2(\omega) = \tilde{\varepsilon}_\mathrm{r}(\omega) \qquad [17]$$

The real part of $\tilde{n}(\omega)$ coincides with the usual refractive index while the imaginary part is the extinction coefficient of the medium. Thus

$$\tilde{n}(\omega) = n(\omega) + \mathrm{i}k(\omega) \qquad [18]$$

and then the real and imaginary parts of $\tilde{\varepsilon}$, including the absorption contribution, should be written as

$$\varepsilon_{\mathrm{r}1} = n^2 - k^2, \qquad \varepsilon_{\mathrm{r}2} = 2nk \qquad [19]$$

Also, the inverse relations are derived as

$$n = \left\{\frac{1}{2}\left[\varepsilon_{\mathrm{r}1} + (\varepsilon_{\mathrm{r}1}^2 + \varepsilon_{\mathrm{r}2}^2)^{1/2}\right]\right\}^{1/2}, \qquad k = \frac{\varepsilon_{\mathrm{r}2}}{2n} \qquad [20]$$

The dispersion relation of eqn [9] assumes the following expression:

$$\tilde{\boldsymbol{q}}\cdot\tilde{\boldsymbol{q}} = \mu_0\tilde{\varepsilon}\omega^2 = \mu_0\varepsilon_0\tilde{\varepsilon}_\mathrm{r}\omega^2 = \frac{\omega^2}{c^2}\tilde{n}^2 \qquad [21]$$

If the wave is homogeneous, that is, $\boldsymbol{q}_1 \| \boldsymbol{q}_2$, it holds $\tilde{\boldsymbol{q}} = (\omega/c)\tilde{n}\boldsymbol{u}_q$, where $\boldsymbol{u}_q$ is the unit vector parallel to $\tilde{\boldsymbol{q}}$, and then $\boldsymbol{q}_1 = (\omega/c)n\boldsymbol{u}_q, \boldsymbol{q}_2 = (\omega/c)k\boldsymbol{u}_q$. Thus, eqn [7] should be written as

$$\begin{aligned}\tilde{\boldsymbol{E}}(\boldsymbol{r},t) = \tilde{\boldsymbol{E}}_0 &\exp\left[-\frac{\omega}{c}k\boldsymbol{u}_q\cdot\boldsymbol{r}\right] \\ &\times\exp\left[\mathrm{i}\left(\frac{\omega}{c}n\boldsymbol{u}_q\cdot\boldsymbol{r}-\omega t\right)\right]\end{aligned} \qquad [22]$$

The extinction coefficient k measures the attenuation of the wave amplitude with the propagation distance inside the medium, while n determines the phase velocity c/n in the medium. The penetration depth δ or classical skin depth, defined as the distance at which the field amplitude drops by $1/e$, is $\delta = c/\omega k$.

In anisotropic material, $\tilde{n}(\omega)$ is no more a scalar quantity, and as it is stated for $\tilde{\varepsilon}$, it should be a tensor. For example, in a uniaxial crystal (i.e., $\tilde{\varepsilon}_{xx} = \tilde{\varepsilon}_{yy} \neq \tilde{\varepsilon}_{zz}$) ordinary ($n_\mathrm{o}$) and extraordinary ($n_\mathrm{e}$) refractive indexes are defined, for light propagation in the xy plane and along the z direction, respectively.

Just as ε_1 and ε_2, n and k also satisfy Kramers–Kronig relations.

An additional important macroscopic quantity of the medium is the absorption coefficient α, which describes the relative decrease in the wave intensity I with unit distance (in the propagation direction, i.e., $\boldsymbol{u}_q \| \mathrm{d}\boldsymbol{r}$). Since the wave intensity (i.e., the power which is incident on the unit area perpendicular to $\boldsymbol{u}_q$) is $I = nc\varepsilon_0 E^2/2$, from eqn [22] it follows that

$$\alpha(\omega) = \frac{2k\omega}{c} = \frac{4\pi k}{\lambda} = \frac{\omega\varepsilon_{\mathrm{r}2}}{nc} \qquad [23]$$

The exponential attenuation of I after a propagating distance d accounts for the phenomenological Lambert–Beer law:

$$I = I_0\mathrm{e}^{-\alpha d} \qquad [24]$$

where I_0 is the incident wave intensity. Differently from n and k, α is a dimensional quantity and is normally measured in cm^{-1}. The αd coefficient that reflects both the physical and chemical properties, and the geometry of the medium is referred to as optical density.

Reflection and Transmission Properties

Unpolarized Light

While the refractive index n is measurable with a high degree of accuracy through experimental techniques that do not require absolute intensity measurements, such as minimum deviation, Brewster angle and interferometric techniques, the complete

determination of n and k (or α) of a medium generally requires the measurement of the intensity reflected I_r, transmitted I_t, and/or absorbed I_a with respect to the intensity I_0 of an em wave incident on the material surface. From the energy conservation law, it follows that

$$I_0 = I_r + I_t + I_a \qquad [25]$$

Dividing both sides by I_0, one obtains:

$$\mathscr{R} + \mathscr{T} + \mathscr{A} = 1 \qquad [26]$$

where $\mathscr{R}$, $\mathscr{T}$, and $\mathscr{A}$ are the reflectance, the transmittance and the absorbance of the medium, respectively. The connection between these quantities and the optical functions of the medium can be obtained by Maxwell's equations with appropriate surface boundary conditions, that is, the tangential components of $\boldsymbol{E}$ and $\boldsymbol{H}$ and the normal components of $\boldsymbol{D}$ and $\boldsymbol{B}$ at the surface of the material are continuous.

Hereafter, only specularly reflected light is dealt with: this condition is well matched when surface irregularities and roughness have length scales much smaller than the light wavelength λ. In this case, diffuse reflection losses are negligible.

Consider the simplest case of a plane monochromatic wave, propagating in a medium with refractive index $\tilde{n}_0$, which is normally incident on the surface of a semi-infinite medium with refractive index $\tilde{n}$ giving rise to the phenomena of reflection and refraction. Applying the boundary conditions both to the electric field $\boldsymbol{E}$ and to the magnetic field $\boldsymbol{H}$ (with $\boldsymbol{E} = \mu_0 \boldsymbol{H} \times \boldsymbol{v}$ in a transverse electromagnetic wave), the tangential components of the incident (0), reflected (r) and refracted (i.e., transmitted, t) fields must obey

$$\begin{aligned} \tilde{E}_t &= \tilde{E}_0 + \tilde{E}_r \\ \tilde{n}\tilde{E}_t &= \tilde{n}_0\tilde{E}_0 - \tilde{n}_0\tilde{E}_r \end{aligned} \qquad [27]$$

By solving for $\tilde{E}_r$ and $\tilde{E}_t$, one has

$$\begin{aligned} \tilde{r} &= \frac{\tilde{E}_r}{\tilde{E}_0} = \frac{\tilde{n}_0 - \tilde{n}}{\tilde{n}_0 + \tilde{n}} \\ \tilde{t} &= \frac{\tilde{E}_t}{\tilde{E}_0} = \frac{2\tilde{n}_0}{\tilde{n}_0 + \tilde{n}} \end{aligned} \qquad [28]$$

where $\tilde{r}$ and $\tilde{t}$ are complex quantities in the more general case, and are named reflection and transmission Fresnel coefficients, respectively. Then, the reflected and transmitted waves change in amplitude and phase with respect to the incident one, and while $\tilde{r}$ change only in sign inverting the propagation direction, $\tilde{t}$ changes the absolute value. It is noted that $\tilde{t} = 1 + \tilde{r}$ and its value should exceed unity. Moreover, in transparent media (n_0 and n real) the phase change in reflection is π when $n_0 < n$.

At the interface of the two media, the reflected and transmitted intensity relative to the incident one are called reflectivity R and transmittivity T, and are given by:

$$\begin{aligned} R = \frac{I_r}{I_0} = |\tilde{r}|^2 &= \left|\frac{\tilde{n}_0 - \tilde{n}}{\tilde{n}_0 + \tilde{n}}\right|^2 \\ &= \frac{(n - n_0)^2 + (k - k_0)^2}{(n + n_0)^2 + (k + k_0)^2} \end{aligned} \qquad [29]$$

$$\begin{aligned} T = \frac{I_t}{I_0} &= \mathrm{Re}\left(\frac{\tilde{n}}{\tilde{n}_0}\right)|\tilde{t}|^2 \\ &= \mathrm{Re}\left(\frac{\tilde{n}}{\tilde{n}_0}\right)\left|\frac{2\tilde{n}_0}{\tilde{n}_0 + \tilde{n}}\right|^2 \end{aligned}$$

It may be noted that R and T are $\leqslant 1$ with $R + T = 1$, as expected by the energy conservation at the interface between different media.

When considering the reflection, absorption, and transmission properties of optical materials, care must be taken to differentiate between reflectivity and reflectance, transmittivity and transmittance. To make the distinction between these terms clear, consider a sample of material with $\tilde{n}$ and thickness d, immersed in air ($\tilde{n}_0 = 1$), as shown in **Figure 1**. Coming from air, the near-normally incident beam is split into reflected and transmitted fractions (as determined by R and T) at each interface, giving rise to secondary beams: reflectance and transmittance are obtained by summing up all the multiple-reflected and multiple-transmitted elements, which account also for light absorption along the thickness d. The

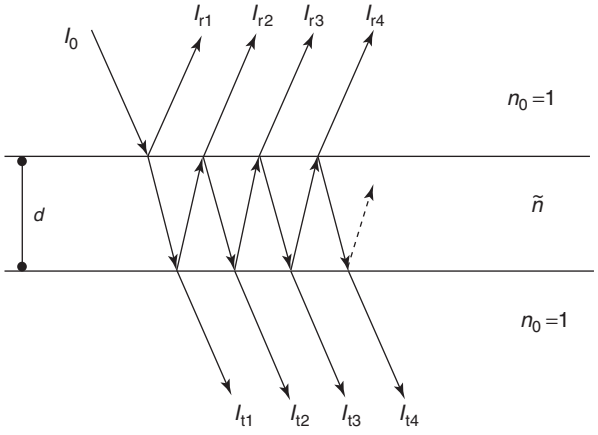

Figure 1 Reflected and transmitted beams generated by an em wave with intensity I_0 near-normally incident on a layer with complex refractive index $\tilde{n}$ immersed in air. Refracted and reflected angles are exaggerated for clearness.

total intensity reflected from the front surface is

$$I_r = I_{r1} + I_{r2} + \cdots + I_{rn} + \cdots$$
$$= (R + RT^2 e^{-2\alpha d} + R^3 T^2 e^{-4\alpha d} + \cdots) I_0 \quad [30]$$

Then, since $T = 1 - R$, the reflectance $\mathscr{R}$ is

$$\mathscr{R} = \frac{I_r}{I_0} = R + \frac{(1-R^2) R\, e^{-2\,\alpha d}}{1 - R^2\, e^{-2\,\alpha d}} \quad [31]$$

Similarly the transmittance $\mathscr{T}$ results in

$$\mathscr{T} = \frac{(1-R)^2\, e^{-\alpha d}}{1 - R^2\, e^{-2\alpha d}} \quad [32]$$

and the absorbance $\mathscr{A} = 1 - \mathscr{R} - \mathscr{T}$ is equal to

$$\mathscr{A} = \frac{(1-R)(1 - e^{-\alpha d})}{1 - R\, e^{-\alpha d}} \quad [33]$$

In the only case when the optical density $\alpha d \gg 1$, the reflectance $\mathscr{R}$ has only the first term in eqn [31] and coincides with the reflectivity R of the material; there is no more intensity transmitted. If the thickness of the sample is sufficiently low to allow transmittance, $\mathscr{T}$ depends on α, d, and R.

Polarized Light

In order to evaluate the Fresnel coefficients in the general case of a plane wave propagating in a medium with refractive index $\tilde{n}_0$ and incident at an angle ϕ_0 on a semi-infinite medium with refractive index $\tilde{n}$, it is convenient to consider separate cases with the electric vector polarized perpendicular to and parallel to the plane of incidence. There is no loss of generality in doing so, since any electric or magnetic vector may be resolved into components normal to and parallel to this plane. The subscripts s and p normally refer to the normal and parallel component, respectively.

The electric field $\tilde{\boldsymbol{E}}_0(\boldsymbol{r}, t)$ associated to an incident plane wave propagating in the z direction of a local coordinate system xyz (**Figure 2**) can be represented as

$$\tilde{\boldsymbol{E}}_0(\boldsymbol{r}, t) = \mathrm{Re}\{(\mathbf{i}\tilde{E}_{0s} + \boldsymbol{j}\tilde{E}_{0p}) \times \exp[\mathrm{i}(\tilde{\boldsymbol{q}} \cdot \boldsymbol{r} - \omega t)]\} \quad [34]$$

where $\tilde{E}_{0p}$ and $\tilde{E}_{0s}$ are the complex field components of $\tilde{\boldsymbol{E}}_0$ that describe both amplitude and phase dependence along the x (s direction) and y (p direction) axes of the system. The electric field of the reflected wave can be represented in another local coordinate system as

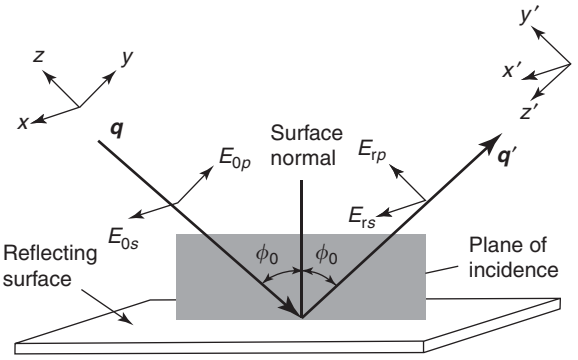

Figure 2 Reflection of an em wave from a surface. The field components E_s and E_p are shown, together with the coordinate axes for the incident and reflected waves. The plane of incidence contains the incoming wave vector $\boldsymbol{q}$ and the specularly outgoing $\boldsymbol{q}'$, as well as the surface normal.

$$\tilde{\boldsymbol{E}}_r(\boldsymbol{r}', t) = \mathrm{Re}\{(\mathbf{i}'\tilde{r}_s\tilde{E}_{rs} + \boldsymbol{j}'\tilde{r}_p\tilde{E}_{rp}) \times \exp[\mathrm{i}(\tilde{\boldsymbol{q}}' \cdot \boldsymbol{r}' - \omega t)]\} \quad [35]$$

An analogous expression holds for the transmitted electric field. As in the previous case, by imposing the surface boundary conditions for the electric and magnetic fields at the interface, the complex Fresnel coefficients in reflection ($\tilde{r}_p$ and $\tilde{r}_s$) and transmission ($\tilde{t}_p$ and $\tilde{t}_s$) are obtained:

$$\tilde{r}_p = \frac{\tilde{E}_{rp}}{\tilde{E}_{0p}} = \frac{\tilde{n}_0 \cos\tilde{\phi} - \tilde{n}\cos\tilde{\phi}_0}{\tilde{n}_0 \cos\tilde{\phi} + \tilde{n}\cos\tilde{\phi}_0}$$
$$\tilde{t}_p = \frac{\tilde{E}_{tp}}{\tilde{E}_{0p}} = 1 + \tilde{r}_p$$
$$\tilde{r}_s = \frac{\tilde{E}_{rs}}{\tilde{E}_{0s}} = \frac{\tilde{n}_0 \cos\tilde{\phi}_0 - \tilde{n}\cos\tilde{\phi}}{\tilde{n}_0 \cos\tilde{\phi}_0 + \tilde{n}\cos\tilde{\phi}} \quad [36]$$
$$\tilde{t}_s = \frac{\tilde{E}_{ts}}{\tilde{E}_{0s}} = 1 + \tilde{r}_s$$

where $\tilde{\phi}_0$ and $\tilde{\phi}$ are the incident and refraction complex angles which are no more purely geometrical quantities. The refracted em wave is generally inhomogeneous, that is, it is characterized by different directions for planes of constant phase (parallel to the interface and perpendicular to $\boldsymbol{q}_2$) and for planes of constant amplitude (perpendicular to $\boldsymbol{q}_1$). In particular, the generalized Snell law at the interface between two absorbing media is written as

$$\tilde{n}_0 \sin\tilde{\phi}_0 = \tilde{n}\sin\tilde{\phi} \quad [37]$$

If the ambient medium is transparent, such as vacuum or air, the quantity $n_0 \sin\phi_0 = \tilde{n}\sin\tilde{\phi}$ is real, and then $\tilde{\phi}$ is determined starting from $\tilde{n}$ and

ϕ_0. At normal incidence the distinction between parallel and perpendicular components disappears and $\tilde{r}_s = \tilde{r}_p = \tilde{r}$ and $\tilde{t}_s = \tilde{t}_p = \tilde{t}$, that is, eqns [36] reduce to eqns [28].

From the Fresnel coefficients in eqn [36] and the energy conservation at the interface, reflectivity R_j and transmittivity $T_j (j = s, p)$ are derived as

$$R_j = |\tilde{r}_j|^2, \qquad T_j = \mathrm{Re}\left(\frac{\tilde{n}\cos\tilde{\phi}}{\tilde{n}_0\cos\tilde{\phi}_0}\right)|\tilde{t}_j|^2 \quad [38]$$

Again it is verified that $R_s + T_s = 1$ and $R_p + T_p = 1$. For normal incidence, eqns [38] reduce to eqns [29]. In case of unpolarized waves, it holds

$$R = \tfrac{1}{2}(R_p + R_s), \qquad T = \tfrac{1}{2}(T_p + T_s) \quad [39]$$

At any angle of incidence ϕ_0 (except for $\phi_0 = 0$ or $\phi_0 = \pi/2$), it is $R_s > R_p$. Moreover, when both materials are transparent ($k_0 = k = 0$), and when $\phi_0 + \phi = \pi/2$ (i.e., the reflected and refracted waves are perpendicular), it follows that $R_p = 0$. The p component is refracted without losses, while the s component is only partially refracted. This particular value of ϕ_0 is called the Brewster angle ϕ_B, and from the Snell law it follows that $\tan\phi_B = n/n_0$. In **Figure 3**, R_p and R_s components versus the angle of incidence for bulk silicon immersed in air and in the transparent wavelength region ($n \cong 3.42$) are reported. The Brewster angle value is $\phi_B \cong 73.7^\circ$. If $k \neq 0$, R_p goes through a nonzero minimum in correspondence of a different value of $\phi > \phi_B$ which is called the pseudo-Brewster angle.

Ellipsometric Functions

An alternative way to describe the optical response of a material is based on the variation of the state of polarization of an em wave produced by reflection on the surface. The polarization state of an em wave is expressed by $\tilde{\chi}$, defined as

$$\tilde{\chi} = \frac{\tilde{E}_p}{\tilde{E}_s} \quad [40]$$

Since $\tilde{E}_p$ and $\tilde{E}_s$ are complex, $\tilde{\chi}$ is, in general, a complex quantity: if $\tilde{E}_p$ and $\tilde{E}_s$ are in-phase, $\tilde{\chi}$ is real and the em wave is linearly polarized. In the case of $\tilde{E}_p$ and $\tilde{E}_s$ $\pi/2$ out-of-phase, $\tilde{\chi}$ is purely imaginary; if, in addition, $|\tilde{E}_p| = |\tilde{E}_s|$ then $\tilde{\chi} = \pm i$ and the wave is circularly polarized. Elliptical polarization is obtained when $\tilde{E}_p$ and $\tilde{E}_s$ are out-of-phase by $\pi/2$ and have different amplitudes, or in the more general case when the phase angle has any value different from 0 and $\pi/2$.

The incident and reflected waves are characterized by the polarization states $\tilde{\chi}_0$ and $\tilde{\chi}_r$, respectively, that are connected by the following relationship:

$$\tilde{\chi}_r = \frac{\tilde{E}_{rp}}{\tilde{E}_{rs}} = \frac{\tilde{r}_p\tilde{E}_{0p}}{\tilde{r}_s\tilde{E}_{0s}} = \frac{\tilde{r}_p}{\tilde{r}_s}\tilde{\chi}_0 \quad [41]$$

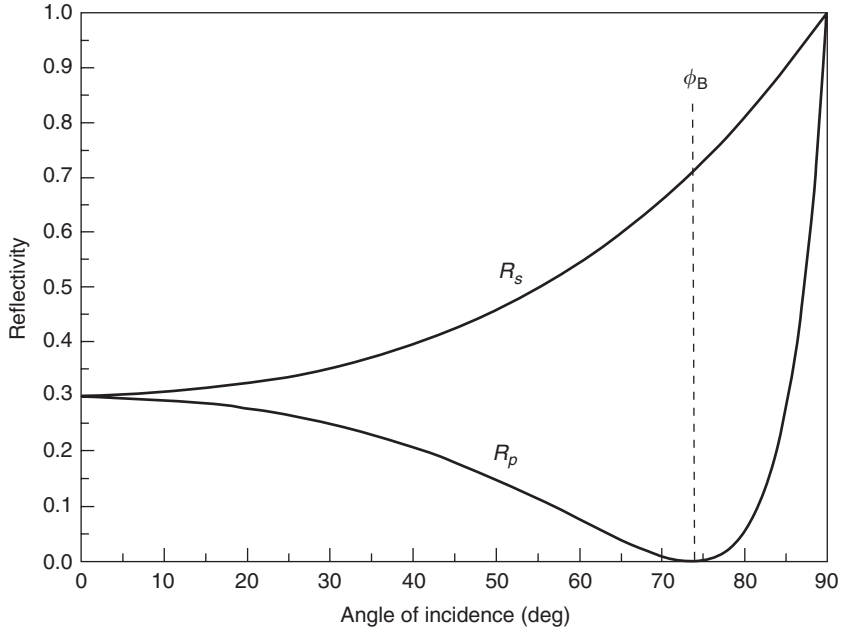

Figure 3 Polarized reflectivities R_s and R_p as a function of the angle of incidence for silicon in the subgap transparency spectral region ($n = 3.42$). R_p reaches zero value at the Brewster angle $\phi_B = 73.7^\circ$.

where $\tilde{r}_p$ and $\tilde{r}_s$ are defined in eqns [36]. Since $\tilde{r}_p$ and $\tilde{r}_s$ are complex quantities (i.e., $\tilde{r} = |\tilde{r}|e^{i\theta}$), it is evident that the reflected wave has a different polarization state with respect to the incident one.

When linearly polarized light impinges on a material surface, the reflected light is generally elliptically polarized. This ellipse of polarization is completely characterized by the ratio of the two axes and by the orientation of the major axis. From this fact, the name ellipsometry is given to the experimental technique which allows one to determine the variation in the polarization state by reflection on a sample surface.

In ellipsometry the crucial quantity is the ratio $\tilde{\rho}$, defined as the ratio between $\tilde{\chi}_r$ and $\tilde{\chi}_0$:

$$\tilde{\rho} = \frac{\tilde{\chi}_r}{\tilde{\chi}_0} = \frac{\tilde{r}_p}{\tilde{r}_s} = \left(\frac{E_{rp}}{E_{rs}}\right)\left(\frac{E_{0s}}{E_{0p}}\right)\exp\{i[(\beta_p - \beta_s)_r - (\beta_p - \beta_s)_0]\} \quad [42]$$

Here $(\beta_p - \beta_s)$ is the phase difference between p and s field components. The absolute value of $\tilde{\rho}$ gives information on the amplitude ratio of the reflected to the incident E_p and E_s, while the phase of $\tilde{\rho}$ is given by the variation of the phase difference caused by reflection. The quantity $\tilde{\rho}$ is normally written in the compact form

$$\tilde{\rho} = \tan\psi e^{i\Delta} \quad [43]$$

where

$$\tan\psi = \rho = \frac{|\tilde{r}_p|}{|\tilde{r}_s|} = \frac{r_p}{r_s} \qquad \Delta = (\beta_p - \beta_s)_r - (\beta_p - \beta_s)_0 \quad [44]$$

A single ellipsometric measurement gives $\tilde{\rho}$, that is, the ellipsometric functions $\tan\psi$ and $\cos\Delta$, which allow one to determine the optical properties of a material. As an example, in the case of a semi-infinite material with complex dielectric function $\tilde{\varepsilon}$, assuming that the ambient medium is void ($\tilde{\varepsilon}_o = 1$) and ϕ_0 is the angle of incidence, it is possible to obtain a simple relation which binds $\tilde{\rho}$ and $\tilde{\varepsilon}$:

$$\tilde{\varepsilon} = \sin^2\phi_0 + \sin^2\phi_0 \tan^2\phi_0 \left|\frac{1-\tilde{\rho}}{1+\tilde{\rho}}\right|^2 \quad [45]$$

It is then immediate to derive the real and imaginary part of $\tilde{\varepsilon} = \varepsilon_1 + i\varepsilon_2$. In addition, in transparent media, ellipsometry is widely used to determine the refractive index and the thickness of a thin film layer deposited on a substrate with known optical properties.

In conclusion, it is noted that the reflection/transmission properties of a medium are of major interest from the application point of view. Moreover, they allow a complete optical characterization of a homogeneous, isotropic medium, that is, the determination of ε_1 and ε_2 or n and k. Since there are two unknown parameters, at least two independent measurements are needed. In transparent materials, R and T should be used, or R measurements at different angles of incidence. In semi-infinite media (or with finite thickness but opaque), only reflection and ellipsometric measurements should be performed.

Moreover, the Fresnel coefficient $\tilde{r} = |\tilde{r}|e^{i\theta}$ expresses the linear relation between incident and reflected electric field amplitudes which obey causality. As stated above, it follows that a dispersion relation exists which connects its real and imaginary parts. Using the normal incidence reflectivity $R = |\tilde{r}|^2$, the dispersion relation between the absolute value R and the phase angle θ should be written as

$$\theta(\omega) = -\frac{\omega}{\pi} P \int_0^\infty \frac{\ln R(\omega')}{\omega'^2 - \omega^2}\, d\omega' \quad [46]$$

Then θ should be determined, in principle, at whatever frequency if $R(\omega)$ is known over the whole spectral interval. In practice, $R(\omega)$ is measured over a finite spectral range and some means of extrapolating experimental results over inaccessible spectral ranges are necessary. Finally, n and k are calculated on the basis of eqns [28] and [29].

Optical Properties of Surface Layers Enhanced Raman Scattering

G Mattei, CNR, Istituto dei Sistemi Complessi, Rome, Italy

Introduction

The subject of this article is the description of the properties of metal surfaces and metal particles that are sources of strong enhancement of the intensity of the scattered Raman light from molecules and thin films, which are in contact with them or in their close vicinity in the nanoscale range. First, the origin of the enhancement of the Raman intensity is discussed showing that the main source of the effect is the amplification of the electromagnetic (e.m.) field at the interface of two media (e.g., metal/dielectric), when surface e.m. waves and/or surface or localized plasmons are excited. The cases of flat and corrugated metal surfaces, single metal particles, and metal clusters are discussed. The last section is devoted to the illustration of the surface-enhanced Raman scattering (SERS), commonly characterized by enhancement of the Raman intensity of 4–8 orders of magnitude, and originated from metal (e.g., Au, Ag, Cu) surfaces which are rough on nanoscale (10–100 nm) and from metal nanoparticles and nanoclusters. Not all the subjects are treated in detail since some of them are presented exhaustively in other articles of this encyclopedia.

The Origin of the Enhancement of Raman Intensities

As it is well known, Raman scattering is a nonlinear process (e.g., two photons and one quantum of vibration are involved) which is characterized by a very low cross section σ (in m^2) defined by the relation: $P_{sc} = \sigma I_{in}$, where P_{sc} is the power (in W) of the scattered light and I_{in} is the intensity of the exciting light (in Wm^{-2}). For the normal Raman scattering, the cross section (average value $\approx 10^{-33}$ m^2) is nine orders of magnitude smaller than that of the infrared absorption process and this prevents the detection of a very small amount of material as it is necessary, for example, in surface science. To achieve the surface

sensitivity (detection limit of a fraction of the monolayer), some enhancement in the process is necessary. Two mechanisms are possible sources of this enhancement. The first one is related to the cross section itself. In some systems, molecules as well as crystals and films, at special frequencies σ present a resonant behavior due to the direct absorption of the incident photons by suitable electronic levels coupled with vibrational states. In this condition, that is, resonant Raman scattering, the intensity of the scattered light can be enhanced up to six orders of magnitude. In some cases, chemisorption on metal is accompanied by the formation of new electronic levels in the visible range for the adsorbate/metal system, allowing the resonant Raman scattering to occur. Of course, this resonant process (average enhancement factor 100), often indicated as "chemical effect," is strongly dependent on the frequency of the exciting light and is specific to the excited system. The second source of Raman intensity amplification is related to the enhancement of the local electric field seen by the excited medium (e.g., adsorbed molecules on a metal surface or on a small metal particle). Indeed I_{in} being proportional to the square of the electric field amplitude of the excitation light, an increase of this amplitude by a factor 10^2 implies an enhancement of the Raman intensity by a factor 10^4, for example. This enhancement mechanism of the Raman intensity, called "electromagnetic effect," is somehow independent of the excited system and presents some specificity that allows one to discriminate it from the "chemical effect." Of course, in some cases both the effects can contribute to the total Raman enhancement. The following sections illustrate the e.m. effect through the use of system models, namely various metal surfaces. Undoubtedly, the properties of the surface itself play an important role in the Raman enhancement. Among them, the surface shape and size, and also the frequency-dependent dielectric function of the metal, have to be considered.

Flat Metal Surface: Raman Enhancement and Surface Selection Rules

Consider the case of molecules adsorbed (or in the near proximity) on a flat metal mirror where an e.m. wave, impinging on with an angle of incidence θ, is reflected (**Figure 1**).

The molecules see a local electric field at surface, $\boldsymbol{E}^{su}$, that is due to the coherent superposition of the electric fields $\boldsymbol{E}^{i}$ and $\boldsymbol{E}^{r}$ of the incident and the reflected e.m. waves. Considering the two polarizations, s (TE) and p (TM), one has, for the x, y, and z

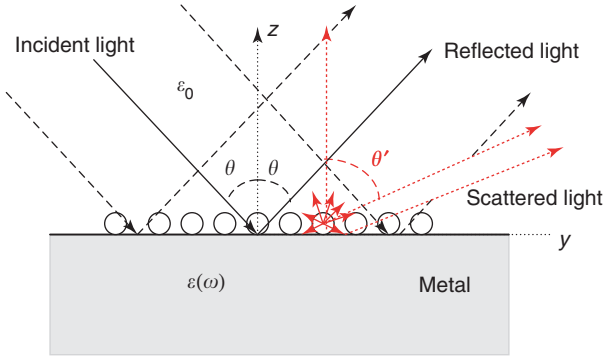

Figure 1 Scheme of the Raman scattering of molecules (circles) adsorbed on the flat interface between a dielectric and a metal.

components of the local field,

$$E_x^{su} = E_{s,0}^{i}(1 + r_s)$$
$$E_y^{su} = E_{p,0}^{i}(1 - r_p)\cos(\theta)$$
$$E_z^{su} = E_{p,0}^{i}(1 + r_p)\sin(\theta)$$

where $E_{s,0}^{i}$ and $E_{p,0}^{i}$ are the components of the incident electric field of s (TE) and p (TM) polarization, and r_s and r_p are the Fresnel coefficients, being:

$$r_s = [\cos(\theta) - (\varepsilon - \sin^2(\theta))^{1/2}]/[\cos(\theta) + (\varepsilon - \sin^2(\theta))^{1/2}]$$

$$r_p = [\varepsilon\cos(\theta) - (\varepsilon - \sin^2(\theta))^{1/2}]/[\varepsilon\cos(\theta) + (\varepsilon - \sin^2(\theta))^{1/2}]$$

It is to be noted that the dielectric function $\varepsilon(\omega)$ is a complex function of the frequency ω (here the dependence on the wave vector of the light is neglected). In the case of metals, the real part $\mathrm{Re}[\varepsilon(\omega)]$ can be strongly negative below the plasma frequency ω_p and almost zero around ω_p. It is easy to demonstrate that when $|\varepsilon|$ is very large, $r_s \to -1$ and $r_p \to +1$; it is just the opposite in the limit of very small $|\varepsilon|$, $r_s \to +1$ and $r_p \to -1$.

In the light scattering process, the local electric field $\boldsymbol{E}^{su}(\omega_{ex})$ induces on the molecules at the surface a dipole moment $\boldsymbol{\mu}$, given by: $\boldsymbol{\mu}(\omega_{sc}) = \alpha\boldsymbol{E}^{su}(\omega_{ex})$, $\hat{\alpha}$, the polarizability of the molecules being a tensor of the second rank. The frequencies ω_{ex} and ω_{sc} are those of the incident and scattered light, respectively. $|\omega_{ex} - \omega_{sc}| = \omega_{vibr}$ is the frequency of the normal vibrational mode of the molecule involved in the scattering process. The scattered light, collected along a direction θ' far away from the surface, is then the superimposition of the light emitted directly in this direction together with the scattered light directed toward the metal surface and then reflected in the same direction (**Figure 1**). Hence, the intensity of

the scattered light, that is proportional to the square of the amplitude of the scattered electric field, will be affected by two surface contributions due to the reflection of the incident and of the scattered light as well. From the above expressions, the Raman intensities for the possible polarization (s and/or p) of the incident and scattered light can be obtained:

$$I_{ss} \propto \omega_{sc}^4 |\alpha_{xx}(1+r_s)(1+r'_s)|^2$$

$$I_{ps} \propto \omega_{sc}^4 |\alpha_{xy}(1-r_p)(1+r'_s)\cos(\theta) + \alpha_{zy}(1+r_p)(1+r'_s)\sin(\theta')|^2$$

$$I_{sp} \propto \omega_{sc}^4 |\alpha_{yx}(1+r_s)(1-r'_p)\cos(\theta') + \alpha_{zx}(1+r_s)(1+r'_p)\sin(\theta')|^2$$

$$I_{pp} \propto \omega_{sc}^4 |[\alpha_{yy}(1-r_p)\cos(\theta) + \alpha_{yz}(1+r_p)\sin(\theta)](1-r'_p)\cos(\theta') + [\alpha_{zy}(1-r_p)\cos(\theta) + \alpha_{zz}(1+r_p)\sin(\theta)](1+r'_p)\sin(\theta')|^2$$

In these equations, all the quantities including the Raman polarizability components are referred to the frame of axis indicated in the figure with z along the metal surface normal. The primes indicate those quantities that are to be evaluated at the frequency and angle of the scattered light. It is clear that the observed scattered intensity depends in a quite complex way on the chosen scattering geometry (through the angles, the polarizations, and the Fresnel coefficients), the optical properties of the metal (through its frequency-dependent dielectric function), the symmetry of the molecular vibration, and the orientation of the molecule with respect to the surface (through the α_{ij} components of the polarizability). These relations determine the surface selection rules that control the Raman scattering of molecules adsorbed or posed on a flat metal surface. According to these selection rules, the Raman spectra can be very different from those of free molecules: the relative band intensities can be altered, some band can be strongly attenuated, others can be enhanced with respect to the free molecules. Even the dependence on the scattering frequency of the Raman intensity for single modes can deviate significantly from the ω^4 rule typical of the Raman scattering of free molecules. Finally, it is easy to verify that the maximum expected enhancement of the Raman intensity for any mode is 16 but for real systems, this value is seldom obtained, while enhancement values around 6–10 can be usually measured on flat metal mirrors.

Electromagnetic Enhancement due to Surface Plasmons and Surface Electromagnetic Waves: Flat and Roughed Surfaces

As it is well known, at the vacuum/metal interface, surface collective charge modes, named surface plasmons (sp), polaritons do exist. They are evanescent waves produced by the oscillations of the surface charges, and propagate along the interface with a real wave vector K, given by

$$K = (\omega/c)\sqrt{\varepsilon_0\varepsilon/(\varepsilon_0+\varepsilon)}$$

In this equation, which represents the sp dispersion curve (ω vs. K), ε_0 and ε are the dielectric function of the dielectric (e.g., the air) and of the metal, respectively. No radiation is emitted from the surface in the two semispaces. The electric field that can be very intense at the surface, decays exponentially with the distance from the interface. Indeed, the components of the wave vector perpendicular to the surface are basically purely imaginary being: $K_\perp = \mathrm{i}(\omega/c)|\varepsilon_i^2/(\varepsilon_0+\varepsilon)|^{1/2}$, where ε_i is equal to ε_0 in the dielectric medium and to ε in the metal, respectively.

The sp condition of existence and their dispersion curve are illustrated in **Figure 2**, where for simplicity the metal dielectric function, ε, has been approximated with that of a free electron gas, namely: $\varepsilon = 1-(\omega_p/\omega)^2$. In the figure, "reduced" adimensional quantities have been used for frequency, ω/ω_p, and surface wave vector, cK/ω_p.

It is clear from the comparison of the frequency dependences of the dielectric function and of the sp dispersion that sp do exist only for $\omega<\omega_p$, where the bulk modes cannot propagate in the metal, being $\varepsilon<0$. For large K values, the sp polaritons dispersion curve tends to frequency $\omega_p/(1-\varepsilon_0)^{1/2}$ for which it is $\varepsilon = -\varepsilon_0$. Since the sp are not radiative modes, they cannot be directly excited by light propagating in one of the two media. Indeed, for a given frequency ω, the component parallel to the surface, $k_{||}$ of the light wave vector will be always smaller than the corresponding component, K, of the sp wave vector. As a matter of fact, it is always $k_{||} = (\omega/c)\varepsilon_0^{1/2}\sin\theta_i < (\omega/c)\varepsilon_0^{1/2} < K$, where θ_i is the angle of incidence of the light on the metal surface.

Hence, the conditions for the energy and wave vector conservation cannot be simultaneously satisfied. Nevertheless, sp excitation by light can be obtained in special conditions, namely: by grating coupling and in attenuated total reflection (ATR) geometry.

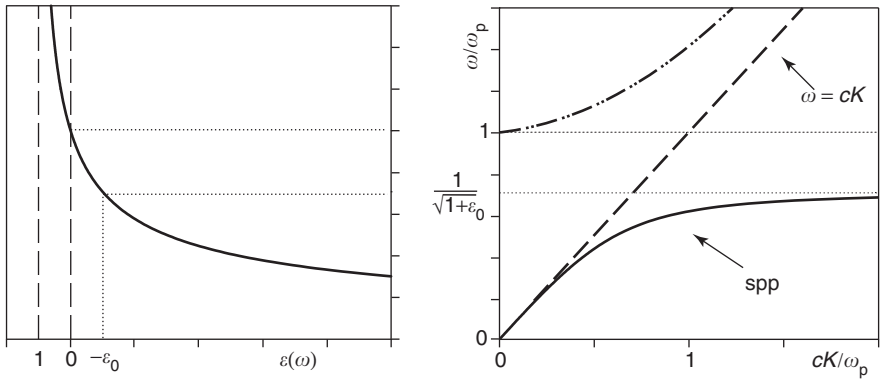

Figure 2 On the left, dielectric function vs. reduced frequency, ω/ω_p, (ω_p is the plasma frequency) for a metal in the free electron gas approximation; on the right, surface plasmon polaritons (spp) dispersion curve for the metal/dielectric interface. K is the real wave vector parallel with the surface. The dashed straight line represents the photon dispersion in vacuum.

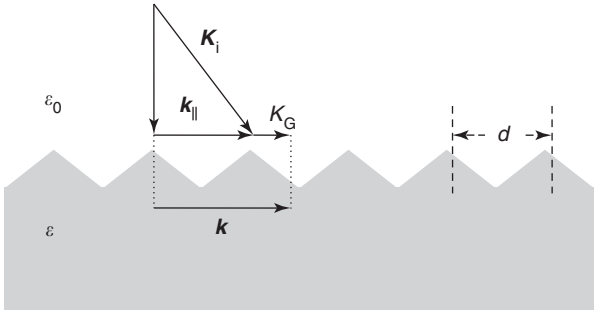

Figure 3 Scheme of the spp excitation of a metal grating of period d by incident light of wave vector K_i. $K_G = (2\pi n/d)$ is the surface wave vector due to the grating. $k_{||}$ and K are the surface wave vectors parallel to the surface of the incident light and of the spp excitations.

When a metal surface is sinusoidally modulated with a period d to form a grating, if the amplitude of the modulation is small compared with the wavelength of light, there is a modification of the light wave vector parallel to the surface, $k_{||}$, into $K_n = (k_{||} + 2\pi n/d)$ with $n = 0, \pm 1, \pm 2$, etc. It is then possible that, for suitable value of θ and n, the coupling condition, $K_n = K$, be satisfied, allowing the sp excitation by light radiation (**Figure 3**).

Wood anomalies in gratings, experimentally well known since the beginning of the twentieth century, can be attributed to this effect. Besides, sp can have their wave vector modified by a surface modulation and become radiative waves. On this basis, it is clear that a rough metal surface can allow to some extent the excitation of sp waves by light and their radiative emission.

Another way to excite sp is the use of a prism in total reflection condition to generate surface e.m. evanescent waves that can couple with the spp modes. The ATR in the so-called "Otto configuration" is illustrated in **Figure 4a**, where a prism

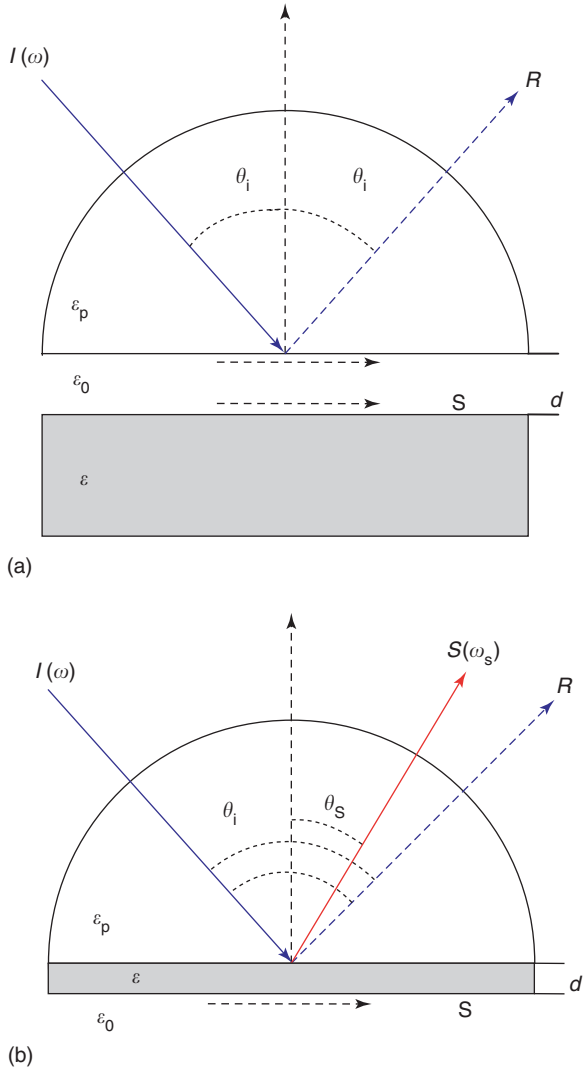

Figure 4 ATR geometries: (a) Otto configuration, (b) Kretschmann configuration: I, R and S represent the incident, the reflected, and the scattered beams, respectively; d is the thickness of the interlayer between prism and metal (a) or of the metal film (b).

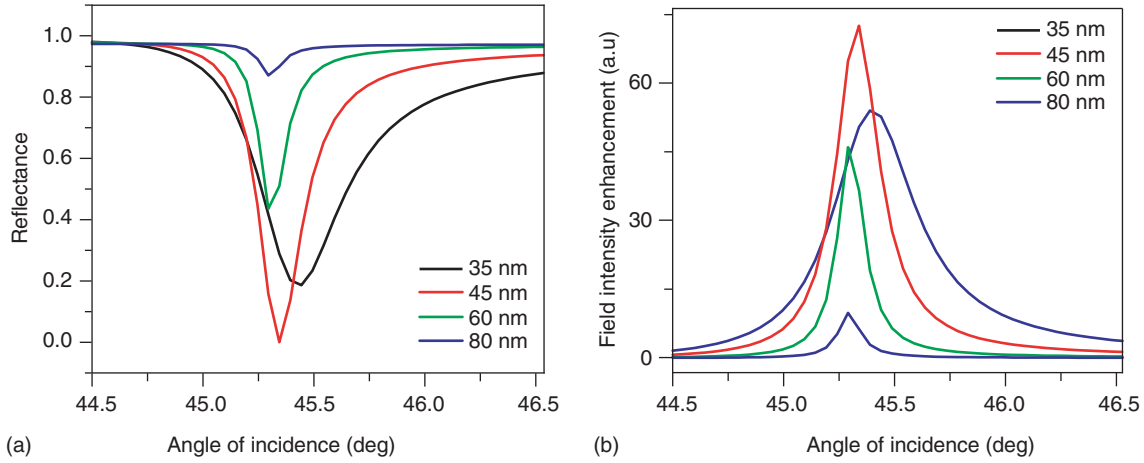

Figure 5 ATR in the Kretschmann configuration, wavelength 530 nm. (a) Angular dependence of the reflectivity in the prism for various Ag film thicknesses. (b) Angular dependence of the electric field intensity at the air/metal interface for various Ag film thicknesses.

(dielectric constant ε_p) is separated by a thin layer of thickness d and dielectric constant $\varepsilon_0 < \varepsilon_p$ from a metal surface S. If a light beam strikes the interface prism/interlayer at an angle of incidence θ_i greater than the critical angle $\theta_c = \arcsin(\varepsilon_0/\varepsilon_p)^{1/2}$, total reflection occurs: no light is transmitted in the ε_0 medium. At the interface, an evanescent e.m. wave is produced with real wave vector parallel to the surface $k_{||} = (\omega/c)\varepsilon_p^{1/2} \sin\theta_i > (\omega/c)\varepsilon_0^{1/2}$ and perpendicular wave vector component purely imaginary in the ε_0 media. The amplitude of the electric field decays rapidly in the interlayer, but, if the thickness d is of the order of the wavelength, the surface e.m. waves can interact with the sp evanescent waves generated at the interface metal/interlayer when the wave vector ($k_{||} = k$) and the frequency ($\omega_{light} = \omega_{spp}$) conservation laws are satisfied. When this resonant coupling occurs, the intensity of the reflected beam, R, is attenuated or "frustrated" allowing the detection of sp modes.

Since both the Snell's law (i.e., the conservation of the parallel component of the wave vector at the interface) and the dispersion relation of sp are symmetrical with respect to ε_0 and ε, it is possible to interchange the role of these two media with respect to the prism. This is shown in **Figure 4b** where the ATR in the so-called "Kretschmann configuration" is illustrated. The thickness d of the thin metal film must be sufficiently small to allow enough energy to reach the metal/dielectric interface. Again, attenuation of the intensity of the reflected light as a function of the frequency and of the angle of incidence allows the detection of sp waves.

Calculated angular dependence of the reflectivity at 530 nm as a function of the angle of incidence in the Kretschmann configuration (prism ($\varepsilon_p = 2.1$), metal film ($\varepsilon = \varepsilon' + i\varepsilon'' = -17.35 + i0.56$), air ($\varepsilon_0 = 1$)) are presented in **Figure 5a** for different values of d. The minimum of the reflectivity, corresponding to the excitation of the sp at the interface metal/air, is deepest for an optimal film thickness. Note that the angle and the angular width of this minimum depend on the thickness, because in the case of thin film the sp modes of the two interfaces fill each other, and influence and modify the corresponding dispersion curves depending on the distance d between the interfaces.

An important consequence of the excitation of the sp waves by ATR is that the intensity of the electric field at the metal/dielectric (metal/air, in this case) interface can be significantly larger than that of the incident e.m. wave. As an example, in **Figure 5b**, the field intensity enhancement, namely the ratio between the intensity of the electric field at the metal/air interface and the one of the incident wave at the prism/metal interface, is reported as a function of the angle of incidence, for the case of **Figure 5a**. As it is clear, in the optimal condition, an enhancement of two orders of magnitude can be achieved. As a consequence, enhanced Raman scattering from molecules adsorbed on the metal/air interface can be excited in this configuration. Considering that the scattered light can be also converted in sp excitations and, through the ATR system, into light emitted in the prism at a suitable angle, a final enhancement of about four orders of magnitude can be obtained. Indeed, in the literature several experimental evidences of enhanced Raman scattering using ATR configuration, with the enhancement factor ranging from a few tens to ten thousand, have been reported. For example, studies by enhanced Raman spectroscopy of metal/liquid interfaces and Langmuir–Blodget

layers on smooth Ag surfaces have been reported. Besides, a combination of ATR spp excitation and near-field Raman spectroscopy has been used to scan, with high sensitivity, the species present on the electrode surfaces.

Finally, for completeness, it is important to note that the conversion of traveling e.m. waves into surface evanescent e.m. waves can be used to enhance Raman scattering intensity at the interface between two dielectric media, when the exciting light strikes the interface from the denser medium in total reflection condition. As a matter of fact, the Raman scattering excited in a total reflection condition has been used for studying adsorbates, films, and even the surface phonon-polaritons dispersion at the interface between a prism and a transparent crystal.

Electromagnetic Enhancement due to Metal Particles

The following case is considered first, that is, the case of single isolated metal sphere of radius R, small with respect to the light wavelength λ: that is, $R \ll \lambda$ ("Rayleigh limit" or "electrostatic approximation"). If such a sphere, of dielectric function $\varepsilon(\omega)$ and embedded in a medium of dielectric function ε_0, is irradiated by an e.m. wave with electric field amplitude E_i polarized in the z direction (see scheme in **Figure 6**), a dipole moment $p = gR^3E_i$ is generated inside the sphere. The potential, V, outside the sphere, due to the incident electric field and the electric dipole p, expressed in spherical coordinates (r, θ, φ), is

$$V(r,\theta) = E_i(r - gR^3/r^2)\cos(\theta)$$

where $g = (\varepsilon - \varepsilon_0)/(\varepsilon + 2\varepsilon_0)$. The radial, E_n, and tangential, E_t, components of the electric field at the surface of the sphere can be obtained in a standard way from the potential. The intensity of the two electric components, averaged over all the solid angle, are proportional to

$$\bar{E}_n^2 \propto |1 + 2g|^2$$
$$\bar{E}_t^2 \propto 2|1 - g|^2$$

Because of the resonant denominator in g, when it is $\mathrm{Re}[\varepsilon(\omega)] = -2\varepsilon_0$ (condition of excitation of localized sp of the metal sphere) and the $\mathrm{Im}[\varepsilon(\omega)]$ is small (as in the case of coinage metals), the electric field intensity at the surface of the metal particle can be much larger that that of the incoming radiation.

Let the light scattering process be considered now, assuming that the molecules are adsorbed on the spherical metal particle with the z-axis of the molecule-fixed coordinate frame along the normal to the surface. The average Raman intensity can be simply considered as dependent on the average intensity of the incident and scattered fields. The metal particle enhances not only the incident electric field on the molecule, but also the Raman scattered field. It acts as an antenna, through the dipole induced in it by the molecular dipole, which amplifies the scattered light intensity. Considering the polarizability tensor of the molecule, three kinds of vibrations can be distinguished. The α_{zz}-type modes require a radial field, E_n, to be excited and produce an induced dipole with only a radial component. Hence, the average intensity due to only the radial electric field will contribute twice to the detected Raman intensity: once in excitation and once again in emission. Similar considerations can be made for the other two kinds of modes, $\alpha_{xx}, \alpha_{yy}, \alpha_{xy}$ (only tangential components), and α_{xz}, α_{yz}, (mixture of tangential and radial components).

The intensity of enhanced Raman spectra of these kinds of modes will therefore depend on the frequency through the following functions:

α_{zz}-type

$$\bar{E}_n^2 \bar{E}_n'^2 \propto |1 + 2g|^2 |1 + 2g'|^2$$

$\alpha_{xx}, \alpha_{yy}, \alpha_{xy}$, -type

$$\bar{E}_n^2 \bar{E}_n'^2 \propto 4|1 - g|^2 |1 - g'|^2$$

α_{xz}, α_{yz}-type

$$\tfrac{1}{2}(\bar{E}_n^2 \bar{E}_t'^2 + \bar{E}_t^2 \bar{E}_n'^2) \propto [|1 + 2g|^2 |1 - g'|^2 + |1 - g|^2 |1 + 2g'|^2]$$

where the prime indicates quantities to be evaluated at the frequency of the scattered light. In **Figure 7** the dependence on the frequency of these functions is

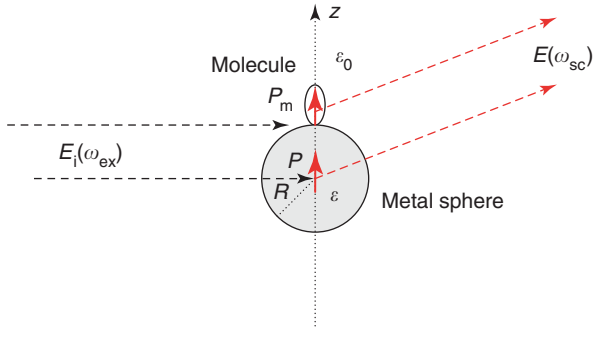

Figure 6 Scheme of the Raman scattering from a molecule adsorbed on a metal spherical particle of radius R. E_i and E indicate the electric field of the incident and of the scattered light, respectively; p_m and p are the electric dipole induced in the molecule and in the metal particle, respectively.

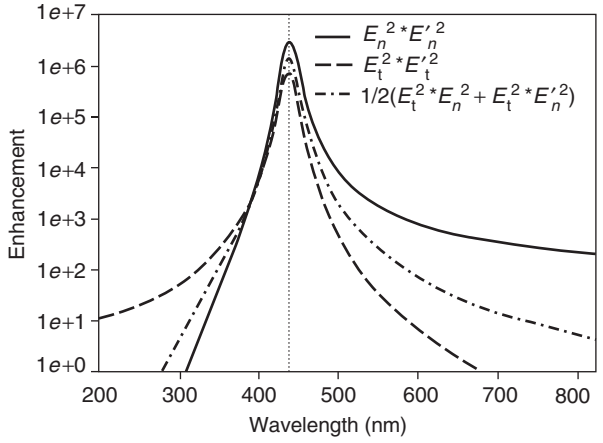

Figure 7 Wavelength dependence of the enhancement factors for the three kinds of molecular modes for a molecule adsorbed on a metal particle of radius R in the Rayleigh limit ($R \ll$ wavelengthof the exciting light).

presented for a fictitious free-electron metal particle. For simplicity, it has been considered that $\varepsilon_0 = 1$ and $g = g'$.

As expected, all three functions have a sharp maximum (corresponding enhancement factor 10^6) at a wavelength for which $\mathrm{Re}[\varepsilon(\omega)] = -2$. Besides, at longer wavelengths the α_{zz}-type modes dominate in the Raman spectrum, whereas at lower wavelengths all the modes are almost equally enhanced. It is clear that the number and the relative intensity of the bands present in the enhanced Raman spectrum can vary significantly with the frequency of the excitation light. Indeed, often very rich spectra can be measured with the distribution of the intensity that apparently violates the surface selection rules.

The model discussed above, although quite simple, provides the main features associated with the enhanced Raman scattering of molecule adsorbates on small metal particles. A more realistic model must include the effects of the particle shape and size distribution.

As the particle size increases beyond the Rayleigh regime, the used electrostatic approximation is not longer valid. The computer-intensive Lorenz–Mie or electrodynamics formalism, which accurately accounts for the effects due to the phase retardation and the quadrupole and higher order poles, must be used to obtain an exact solution. Also the conversion of the near-field electric field due to the molecule through the metal particle acting as an antenna into far-field radiation must be then taken into account. Generally, as a consequence, the intensity enhancement of the Raman scattered radiation can be significantly reduced.

Considering the shape effect, in the case of an isolated spheroid of eccentricity b/a (a and b being the length of the short and the long principal axis, respectively), in presence of an external electric field (due to an e.m. wave) oriented along the b-axis, it can be demonstrated that the Raman enhancement is always larger for the more aspherical particles. In the limiting case of $(b/a) \to \infty$, the calculated enhancement at the tip positions can be of some order of magnitude larger than for the case of spherical particles ("lightning rod effect").

Finally, to treat the case of interacting metal particles and of metal clusters that are also of great practical relevance, various model systems have been considered, for example, two interacting metal spherical particles ("bispheres"), aggregates of metal spheres, set of parallel metal cylinders of variable diameter and interdistance, etc. The calculation of the optical properties of these systems and of the effects on the Raman scattering is generally quite complex and can include retardation effects and high-order multipoles. The general result is that the interaction between two plasmon-resonant nanoparticles leads to additional resonances (at longer wavelengths) for the coupled system. Besides, the electric field in the gap between the particles or around the contact region (for two contacting particles) can be much strong in other places near the particles and stronger than in any place around an isolated particle. Hence, the Raman enhancement can be much larger than for isolated metal nanoparticles. Indeed, enhancement value as large as 10^8–10^9 has been predicted for such metal systems.

It has been recognized early that small-particle composites, or disordered clusters present in metal colloidal solution, as well as some rough metal surface have a fractal character. Studies have been developed to relate the enhancement of the local electric fields in these systems with their fractal dimension. An interesting example is illustrated in **Figure 8**, where the calculated dependence on the wavelength, λ, of the local electric field enhancement factor for three systems made by 500 metal spherical nanoparticles ($d \ll \lambda$) is presented.

In the case of a gas of spherical particles (RGP curve), the characteristic sharp feature due to the excitation of the sp in isolated spheres is clearly observed below 400 nm. The absence of other features above that wavelength indicates a very lithe interaction among the particles. For the ordered particle aggregate (CPSP curve), the single-particle excitation is attenuated and the enhancement increases in the long-wavelength region of the spectrum as a result of the mutual particle interactions. Clearly, the largest enhancement in the local field, up to 10^3 times the one of isolated particle, is predicted for the fractal system (CCA curve). On this basis, huge

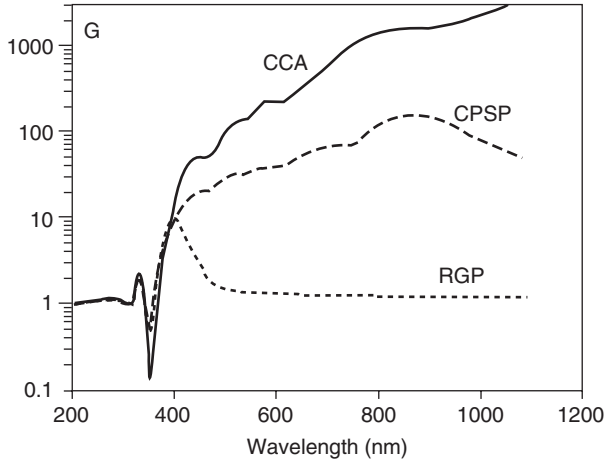

Figure 8 Wavelength dependence of the averaged local field intensity for a gas of spherical particles (RGP), a close-packed crystal of spherical particles (CPSP), and a fractal aggregate (CCA). (Reproduced from Shalaev VM (1996) *Physics Reports* 272: 61–137, with permission from Elsevier.)

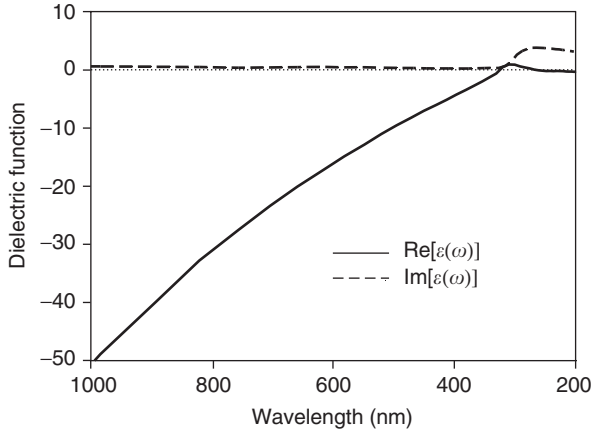

Figure 9 Experimental dielectric function, $\varepsilon(\omega)$, of a silver film. The combined contributions of the free electron and interband transitions cause $\mathrm{Re}[\varepsilon(\omega)]$ of Ag to approach 0 in the visible range even though the free electron plasma frequency is in the ultraviolet. In the same range $\mathrm{Im}[\varepsilon(\omega)]$ is quite small.

enhancement factors for the intensity of Raman scattering from molecules on fractal systems can be expected.

Surface-Enhanced Raman Scattering

SERS was discovered, although not recognized as such, by M Fleishman and co-workers in 1974. They observed an intense Raman signal from pyridine adsorbed onto a roughened silver electrode surface from an aqueous solution. They attributed, erroneously, the observed enhancement of the Raman signal to an increase of the surface area due to the roughening process. In 1977, the nature of this enhancement was attributed by D L Jeanmair and R V Van Duyne, and independently by M G Albert and J A Creighton to a new phenomenon related with the increase of the effective Raman cross section of adsorbates on some rough metal surfaces. Since then, many studies and works have being carried out to understand the fundamental aspects as well as to exploit all the applicative potentialities related with SERS. A wide variety of metal substrates have been found to exhibit SERS: electrochemically roughened electrodes, chemically etched surfaces, colloids (especially aggregated colloids), island films, particles grafted on silanized glasses, regular particle arrays, etc. The dominant metals in SERS are the coinage (Cu, Au, Ag) and alkali (Li, Na, K) metals. Moreover, although with lower enhancement, transition metals (e.g., Pt, Ru, Rh, Pd, Fe, Co, Ni and their alloys) have also been used. Generally, the observed enhancement ranges for 10^4 up to 10^8 in standard SERS measurements. The largest enhancement occurs for surfaces which are rough on the nanoscale (10–100 nm).

The main observed features of SERS spectra are the followings: (1) the intensities of the bands generally fall off with increasing vibrational frequency (e.g., C–H stretching vibrations are relatively weak, overtones and combination bands are seldom observed), (2) selection rules are relaxed, even forbidden Raman modes can be detected, (3) the spectra tend to be completely depolarized, (4) excitation profiles differ from the dependence on the fourth power of the frequency, ω_{in}^4, typical of nonresonant Raman scattering, and (5) although the enhancement is mainly concentrated on the first layer of adsorbates, often the effect can extend to a quite long range (up to tens of nanometers).

As suggested before, two mechanisms must be considered to explain SERS, namely the e.m. and the chemical effects. Previous sections describe the foundation of the e.m. effect of the SERS, since the behavior and the properties of metal substrates and particles that sustain the SERS effect can be described using the models presented there. First of all, the dominance of the coinage metals arises from the optical properties of these metals as indicated for Ag in **Figure 9**.

Indeed, the resonance condition with the sp (e.g., $\mathrm{Re}[\varepsilon(\omega)] = -2\varepsilon_0$) is satisfied at visible frequency generally used for Raman spectroscopy. Besides, the imaginary part of the dielectric function, $\mathrm{Im}[\varepsilon(\omega)]$, which is related with losses in the material, is very small at the resonance frequency, thus allowing strong enhancement of the local electric field on the rough surface and colloidal particle made with these metals.

The e.m. model explains many of the experimental features of SERS listed above, including the order of magnitude of the observed enhancement of the Raman intensities. For example, in feature (1), the need to have simultaneously the frequency of the incident and of the scattered light as close as possible to the resonance frequency implies a more effective enhancement for the vibrations with lower Raman shift. The modification of the Raman selection rules as well as the deviation from the ω_{in}^4 dependence of the Raman intensity for SERS are also suggested from the model. The dipole decay law with the distance explains the long-range effect of the SERS enhancement often observed. Finally, the observed depolarization can be easily explained considering that a SERS-active surface is a collection of roughness features of different sizes and shapes into which the molecules adsorb in a variety of orientations and the occurrence of multiple scattering.

Although the e.m. model is able to explain most of the experimental SERS features, some observations strongly support the existence of a second mechanism of Raman enhancement of adsorbates on metal, namely the "chemical effect." Synonyms found in literature for chemical effect in SERS are charge-transfer excitations, short-range effects, atomic-scale roughness, SERS-active sites, adatoms, and energy-transfer excitations. Some SERS measurements indicate a dependence of the observed signal on the special studied adsorbates that cannot be explained by an e.m. effect. For example, the SERS spectra of CO and N_2 molecules that exhibit near identical polarizability differ from a factor 200, hard to explain invoking only the e.m. enhancement. A second evidence supporting the chemical effect is the potential dependence of SERS measured in electrochemical experiments. When the potential is scanned at a fixed laser frequency, or the laser frequency is scanned at a fixed potential, broad resonances are observed.

A simple Raman resonance mechanism can provide the explanation of this chemical effect. It is not unusual that the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) of the adsorbate, which arise from the chemisorption, are symmetrically positioned in energy with respect to the Fermi level of the metal, as indicated in **Figure 10**.

Since for molecules normally studied by SERS the LUMO is typically in the ultraviolet, the charge transfer excitations (either from the metal to the molecule or vice versa) can occur at about half the energy of the intrinsic intramolecular excitations, namely in the visible region of the spectrum.

In recent years, the advent of new very sensitive Raman instrumentation with high spatial resolution,

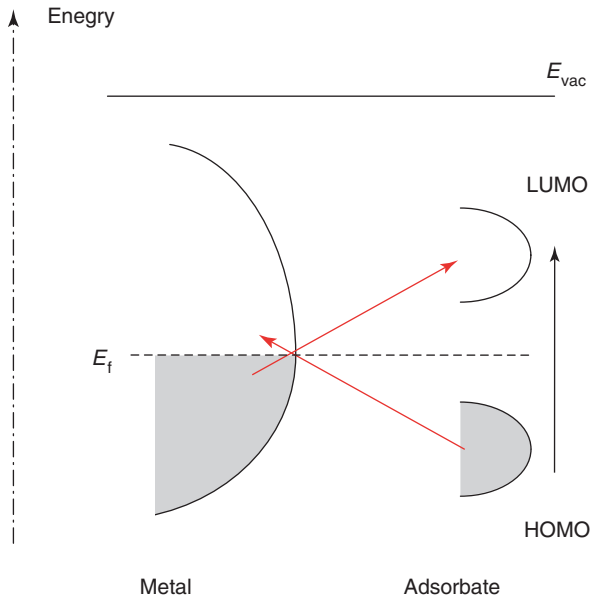

Figure 10 Typical energy level diagram for a molecule adsorbed on a metal surface. Possible charge transfer excitations are shown.

for example, micro-Raman and near-field systems, allowed the selective observation of single particles by SERS. Those experiments demonstrated that SERS from adsorbed species on metal particles show huge enhancement, around 10^{12}–10^{15}, allowing the detection of the Raman signal from a single molecule and opening new fields of applications. In the case of experiments performed on aggregate clusters of colloidal particles, their fractal nature has been invoked to explain the observed enhancement whereas in the case of single particles (in the dimension range of 100–500 nm), the multiplicative effect of resonance Raman enhancement of the molecule and surface enhancement at the metal surface has been considered the main source of the effect. Besides, not all the particles showed an efficient enhancement but only a few called "hot spots" did so. In most cases there is a time dependence of the intensity of every Raman band, which is called "blinking." Finally, this huge Raman enhancement can be reconciled with the more commonly observed value (10^6–10^8) for SERS considering the particles population averaging that occurs in conventional experiments (macro-Raman). These last findings have attracted considerable attention from both basic and practical viewpoints. Indeed, a detailed understanding of the mechanisms operating to generate such a huge local Raman enhancement is not achieved yet and, hence, represents a very interesting area for study. Potential applications are, for example, in analytical chemistry as an ultrasensitive detection technique and in the

development of micro-instrumentation, by combining scanning near-field microscopy with SERS.

Optical Sum Rules and Kramers–Kronig Relations

F Bassani, Scuola Normale Superiore, Pisa, Italy

Introduction

The optical properties of atoms, molecules, and solid materials have been an active field of research for the past two centuries and have given the most precise information on the microscopic structure of matter. Since the early nineteenth century, it was known that absorption peaks in the light intensity occur at specific frequencies and that a corresponding dispersion occurs in the frequency dependence of the dielectric function $\varepsilon(\omega)$ (or in the refractive index $n(\omega)$).

It may be recalled that in any medium all the optical functions (dispersion, absorption, reflection, etc.) depend on the frequency ω and on the momentum of the photon $\hbar\boldsymbol{k} = \hbar(2\pi/\lambda)$, $\hbar$ being the reduced Planck constant. They can all be expressed in terms of the dielectric functions $\tilde{\varepsilon}(\boldsymbol{k}, \omega)$ extended to the complex plane. From Maxwell equations, it can be seen that its imaginary part can be expressed in terms of the conductivity σ, so that

$$\tilde{\varepsilon}(k,\ \omega) = \varepsilon_1(k,\ \omega) + \mathrm{i}\varepsilon_2(k,\ \omega) = 1 + 4\pi\chi(\boldsymbol{k},\ \omega) + \frac{4\pi\sigma(\boldsymbol{k},\ \omega)}{\omega}\mathrm{i} \qquad [1]$$

where the real susceptibility χ is defined in terms of the polarization $\boldsymbol{P}$ (dipole moment per unit volume) and of the electric field $\boldsymbol{E}$ by

$$\chi(k,\ \omega) = \frac{\boldsymbol{P}(\boldsymbol{k},\ \omega)}{\boldsymbol{E}} \qquad [2]$$

If the susceptibility is also extended to the complex plane to include the conductivity, so that

$$\tilde{\chi}(\boldsymbol{k},\ \omega) = \chi(k,\ \omega) + \frac{\mathrm{i}\sigma(\boldsymbol{k},\ \omega)}{\omega} = \chi_1 + \mathrm{i}\chi_2 \qquad [3]$$

where the subscripts 1 and 2 denote the real and imaginary parts, respectively, the usual expression for the complex dielectric function obtains $\tilde{\varepsilon}(\boldsymbol{k},\ \omega) = 1 + 4\pi\tilde{\chi}(\boldsymbol{k},\ \omega)$. This also defines a complex

refractive index

$$\tilde{n}(\boldsymbol{k}, \omega) = \sqrt{\tilde{\varepsilon}}(k, \omega) = n(\boldsymbol{k}, \omega) + \mathrm{i}\kappa(\boldsymbol{k}, \omega) \qquad [4]$$

The absorption of radiation can be related to the conductivity induced by the electric field by considering the energy lost per unit time per unit volume

$$\frac{\mathrm{d}W}{\mathrm{d}t} = \boldsymbol{J}\cdot\boldsymbol{E} = \frac{\mathrm{d}\boldsymbol{P}}{\mathrm{d}t}\cdot\boldsymbol{E} = \sigma E^2 \qquad [5]$$

so that the absorption coefficient $\eta(\omega)$, defined as $\mathrm{d}W/\mathrm{d}x = -\eta W = (\mathrm{d}W/\mathrm{d}t)\ (n/c)$, is given by

$$\eta = \left|\frac{\mathrm{d}W}{\mathrm{d}t}\right| \frac{n}{Wc} = \frac{4\pi\sigma}{nc} = \frac{\omega\varepsilon_2}{nc} = \frac{2\omega\kappa}{c} \qquad [6]$$

Also the reflection and transmission amplitudes can be obtained from the dielectric function through Fresnel relations, which in the case of normal incidence from vacuum to a medium are

$$\frac{E_r}{E_0} = r = \frac{\tilde{n}-1}{\tilde{n}+1}, \qquad \frac{E_t}{E_0} = t = \frac{2}{\tilde{n}+1} \qquad [7]$$

$R = |r|^2$ and $T = n|t|^2$ being the reflectivity and the transmittance, respectively.

In crystalline materials, the optical constants are tensors (second-rank tensors in the linear approximation), but this aspect may be neglected and isotropic media may be considered for the purpose. The results obtained will apply to all tensorial components.

For electromagnetic waves, the magnetic susceptibility is considered unitary and one can also use the dipolar approximation ($\hbar\boldsymbol{k} \simeq 0$) because of the very small light momentum (neglect of spatial dependence).

The above-described optical functions give the electromagnetic properties of matter. Their detailed dependence on frequency is related to the microscopic structure of the material considered and to its interaction with the radiation field. Here, the general properties of the optical functions that depend only on time causality are considered.

Elementary Description of Sum Rules

The traditional phenomenological model for the optical constants is the Lorentz oscillator model, where the equation of motion from the equilibrium position of any specific electron in terms of any oscillator frequencies ω_j and of damping γ_j, is given by

$$\frac{\mathrm{d}^2x}{\mathrm{d}t^2} + \omega_j^2 x + \frac{\gamma_j\,\mathrm{d}x}{\mathrm{d}t} = \frac{e\boldsymbol{E}}{m} \qquad [8]$$

From this, for the complex dielectric function in a volume V for a number of resonance frequencies ω_j, one obtains

$$\tilde{\varepsilon}(\omega) = 1 + \frac{4\pi e^2}{mV}\left(\sum_j \frac{f_j}{(\omega_j^2 - \omega^2) - \mathrm{i}\gamma_j\omega}\right) \qquad [9]$$

where the oscillator strength f_j gives the intensity of the resonance frequency ω_j with damping constant γ_j. The conservation of the electron number and the asymptotic behavior ($\omega \to \infty$) of [9], made to coincide with that of any free electrons ($f_i = 1,\ \omega_j = 0,\ \gamma_j = 0$), immediately gives the f-sum rule, first demonstrated in 1925 by W Thomas, F Reiche, and W Kuhn, and called the TRK sum rule:

$$\sum_j f_j = n \qquad [10]$$

This states that the sum of the oscillator strengths of all optical transitions is equal to the total number of electrons n.

Although the TRK sum rule was derived with classical mechanics, it is worth mentioning that the quantum description of the oscillator strength implies that, for the sum rule to hold, the commutation relations between momentum and position operator must also hold, as pointed out by Heisenberg. In fact one can see, by expressing the optical functions in terms of the transition probability rates, observing that electrons are excited from state i to state f, with a probability rate given by the Fermi golden rule

$$P_{if} = \frac{2\pi}{\hbar}|\langle f|eEx|i\rangle|^2\delta(E_f - E_i - \hbar\omega) \qquad [11]$$

that the quantum mechanical expression for the imaginary part of the dielectric function is

$$\varepsilon_2(\omega) = 4\pi^2 \sum_{ij} |\langle f|ex|i\rangle|^2\delta(E_f - E_i - \hbar\omega) \qquad [12]$$

Considering in expression [9] that

$$\lim_{\gamma\to 0} \frac{\gamma}{(\omega_j - \omega)^2 + (\gamma/2)^2} = 2\pi\delta(\omega_j - \omega) \qquad [13]$$

and comparing with [12] it is obtained that the quantum mechanical expression for the oscillator strength is

$$f_{fi} = \frac{2m}{\hbar^2}|\langle f|x|i\rangle|^2(E_f - E_i) \qquad [14]$$

Taking into account the general Heisenberg expression for the time dependence of the displacement x,

$$m\dot{x} = \frac{m}{\mathrm{i}\hbar}[x, H] \qquad [15]$$

where the square brackets denote commutators, and considering the expression for eigenstates,

$$H|j\rangle = E_j|j\rangle \qquad [16]$$

one obtains for the oscillator strength

$$\begin{aligned} f_{fi} &= \frac{2m}{\hbar^2}\langle i|x|f\rangle\langle f|x|i\rangle(E_f - E_i) \\ &= \frac{1}{\mathrm{i}\hbar}(\langle i|x|f\rangle\langle f|p_x|i\rangle \\ &\quad - \langle i|p_x|f\rangle\langle f|x|i\rangle) \end{aligned} \qquad [17]$$

which, summing over the final states, gives

$$\sum_f f_{fi} = \frac{1}{\mathrm{i}\hbar}\langle i|[x, p_x]|i\rangle = 1 \qquad [18]$$

because of Heisenberg commutation rules $[x, p_x] = \mathrm{i}\hbar$. Summing over all occupied initial states, one obtains immediately the TRK sum rule [10].

In general, the oscillator strength depends continuously on the frequency, so that the TRK sum rule can be expressed in terms of the imaginary part of the dielectric function as

$$\int_0^\infty \omega\varepsilon_2(\omega)\,\mathrm{d}\omega = \frac{2\pi^2 e^2}{m}\,\varrho \qquad [19]$$

which relates the total radiation absorbed to the total electron density $\varrho = n/V$.

This is a very important property, because it gives a general constraint which the absorption of the medium must obey. When the sum rule [19] is saturated at a given frequency, no further absorption can occur at higher frequencies. This explains why in light elements (low electron density) hard X-rays are not absorbed and hard γ-rays pass through all materials. The sum rule [19] is also useful to check the results of approximate calculations or experiments. It must always be obeyed by the exact optical functions.

Kramers–Kronig Dispersion Relations

A connection between sum rules and the causality principle was established on the basis of the relation between the real and the imaginary parts of the susceptibility $\tilde{\chi}(\omega)$. This can be obtained by considering the complex ω plane and observing that the susceptibility does not have poles on the upper plane because the polarization can be expressed from the time-dependent response operator $G(\tau)$ as

$$P(t) = \int_{-\infty}^{+\infty} G(\tau)E(t-\tau)\,\mathrm{d}\tau \qquad [20]$$

with the condition $G(\tau) = 0$ for $\tau < 0$ due to time causality. Then, taking the Fourier transform, one obtains

$$\tilde{P}(\omega) = \tilde{\chi}(\omega)E(\omega) \qquad [21]$$

with

$$\tilde{\chi}(\omega) = \int_0^\infty G(\tau)\exp(\mathrm{i}\omega\tau)\,\mathrm{d}\tau \qquad [22]$$

The fact that $\tilde{\chi}(\omega)$ is analytic in the upper complex plane gives, using the Cauchy theorem on a contour closed to infinity where $\tilde{\chi}(\omega)$ goes to zero (see **Figure 1**)

$$\tilde{\chi}(\omega) = \frac{1}{\pi\mathrm{i}}\fint_{-\infty}^{+\infty} \frac{\tilde{\chi}(\omega')}{\omega' - \omega}\,\mathrm{d}\omega' \qquad [23]$$

where the line on the integral denotes that the principal part must be considered. Since $\chi(-\omega) = \chi^*(\omega)$, the standard form of Kramers–Kronig (KK) relations is obtained:

$$\chi_1(\omega) = \frac{2}{\pi}\fint_0^\infty \frac{\omega'\chi_2(\omega')}{\omega'^2 - \omega^2}\,\mathrm{d}\omega' \qquad [24a]$$

$$\chi_2(\omega) = \frac{-2\omega}{\pi}\fint_0^\infty \frac{\chi_1(\omega')}{\omega'^2 - \omega^2}\,\mathrm{d}\omega' \qquad [24b]$$

In the case of metals, besides the pole at ω, the function $\tilde{\chi}(\omega')/(\omega' - \omega)$ has an additional pole at $\omega' = 0$ because $\sigma(0) \neq 0$. This can be taken into account by considering the function $\tilde{\chi} - (\sigma(0)/\omega)\mathrm{i}$, which does not have such a pole and is analytic

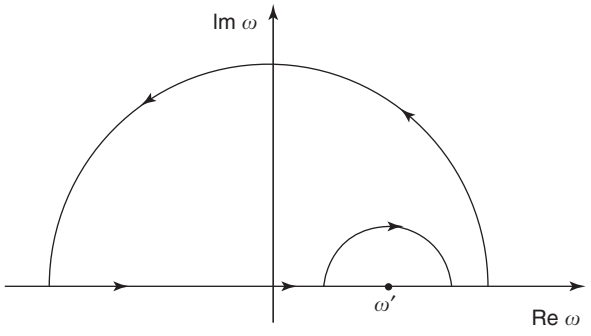

Figure 1 Indication of the contour on the complex plane where the integral of the function $\chi(\omega')/(\omega' - \omega)$ by Cauchy theorem is equal to $\mathrm{i}\pi\chi(\omega)$.

on the upper plane. Then dispersion relations [23] and [24] apply, provided the term $-\sigma(0)/\omega$ is added to the imaginary part of $\tilde{\chi}(\omega)$ and the principal part of the integrals is considered along the entire real axis, including the point at $\omega = 0$, where $\tilde{\chi}_2(\omega')$ has a pole.

The above KK relations are very useful because they relate the dispersion to the absorption. Similar relations can be obtained for the other optical constants $\tilde{\sigma}$, $\tilde{n}(\omega)$, r, and $\mathrm{Im}(1/\varepsilon)$.

They can all be connected to specific sum rules by considering the asymptotic behavior which can be obtained from the KK relations, and comparing it to that which is obtained from a specific model of the material system. Since the asymptotic behaviors must coincide, sum rules are obtained. It can be seen immediately that the TRK sum rule [10] or [19] can be obtained when one considers the asymptotic behavior from [24a] by using the so-called super-convergence theorem, which amounts to letting $\omega' \to 0$ in the denominator, and comparing it with the asymptotic behavior from expression [9] ($\omega_j \to 0$ in the denominator).

As a consequence of the above discussion, one can conclude that sum rules and KK dispersion relations derive from the causality principle only, and from a knowledge of the short-time (or high-frequency) behavior of the system. Complicated properties due to electron–electron interaction or external potentials are not relevant for sum rules and Kramers–Kronig relations. Also the quantum mechanical approach is not essential.

A revival of the field of sum rules started in the early 1970s after the discovery of the refractive index sum rule by Altarelli, Dexter, Nussezveig, and Smith (ADNS), which states for the real part of the refractive index

$$-\!\!\!\!\!\!\int_0^\infty (n(\omega) - 1)\, \mathrm{d}\omega = 0 \qquad [25]$$

After that new sum rules and more KK-type relations were derived for all optical functions and are now being used to interpret a variety of effects. New KK relations and sum rules have also been found in nonlinear optics. Sum rules can now be explored in the entire frequency range using the properties of synchrotron radiation. They are also being used as stringent tests for approximate theories.

KK Relations and Linear Sum Rules

The KK relations [24] for the complex susceptibility function have been derived by direct integration, but causality and KK relations have more direct implications; they can be summarized in what is known as a Titchmarsh theorem, which states the following: any square integrable function $f(\omega)$ which fulfills one of the three conditions below fulfills all three of them:

1. the inverse Fourier transform $F(t)$ of $f(\omega)$ vanishes for $t < 0$,
2. $f(\omega)$ is the limit for $\varepsilon \to 0^+$ of a function $\tilde{f}(\omega + \mathrm{i}\varepsilon)$ that is analytic in the upper half plane and square integrable on the real axis and on any line parallel to it, and
3. $\tilde{f}(\omega)$ verifies the KK identity

$$\tilde{f}(\omega) = \frac{1}{\pi \mathrm{i}} -\!\!\!\!\!\!\int_{-\infty}^{\infty} \frac{\tilde{f}(\omega')}{\omega' - \omega}\, \mathrm{d}\omega' \qquad [26a]$$

or equivalently for $F(t)$ real,

$$f_1(\omega) = \frac{2}{\pi} -\!\!\!\!\!\!\int_0^\infty \frac{\omega' f_2(\omega')}{\omega'^2 - \omega^2}\, \mathrm{d}\omega'$$
$$f_2(\omega) = -\frac{2\omega}{\pi} -\!\!\!\!\!\!\int_0^\infty \frac{f_1(\omega')}{\omega'^2 - \omega^2}\, \mathrm{d}\omega' \qquad [26b]$$

The above theorem proves that KK relations are a direct consequence of time causality, but it also implies that any combinations of analytic functions satisfy KK relations if they are square integrable. For establishing KK relations, it is not necessary to know the explicit form of the causal response function, which is determined by the specific operator being considered, by the Hamiltonian, and by the time-dependent perturbing potential. One only needs to know its asymptotic behavior which can be obtained in the classical approximation from the Lorentz oscillator model, or in the quantum theory from the quantum expression of the response function at time zero. The same holds for the sum rules, which are obtained by comparing the above described asymptotic behavior with that obtained from KK relations.

Consider the optical case in the dipole approximation. The interaction Hamiltonian can then be written as

$$H' = -\boldsymbol{P} \cdot \boldsymbol{E}(t) \qquad [27]$$

where $\boldsymbol{P} = \sum_i e\boldsymbol{r}_i$ is the polarization (it can be used as an operator in quantum mechanics) and $\boldsymbol{E}(t)$ is the electric field, which is taken as a sinusoidal function. While in the classical approximation one considers directly the time dependence of the $\boldsymbol{P}_+$ (Lorentz oscillator model), in the quantum mechanical approach the response function can be obtained from the trace of the density matrix operator ϱ_0 on the ground state

of the system, and to the first order is given by

$$G_p(\tau) = \mathrm{Tr}\left\{\frac{1}{-\mathrm{i}\hbar}\,[P(-\tau),\ \varrho_0]P\right\} \qquad [28]$$

where $P(\tau)$ is defined in the interaction representation. This gives, for the susceptibility, the expression

$$\chi(\omega) = \frac{1}{\hbar}\sum_n |\langle 0|P|n\rangle|^2 \times\left\{\frac{1}{\omega-\omega_{n0}+\mathrm{i}\varepsilon}-\frac{1}{\omega+\omega_{n0}+\mathrm{i}\varepsilon}\right\} \qquad [29]$$

where ε is an arbitrarily small frequency which accounts for the adiabatic switching of the perturbation.

The sum rules can now be obtained from the two expressions of the asymptotic behavior, which must coincide. The first is given by the zero-time response function and its derivatives, and can be obtained integrating by part the Fourier transform of $G(\tau)$, with $G(\infty) = 0$:

$$\underset{\omega\to\infty}{\chi}(\omega) = \int_0^\infty G(\tau)\exp(-\mathrm{i}\omega\tau)\,\mathrm{d}\tau = \frac{G(0^+)}{-\mathrm{i}\omega}+\frac{G'(0^+)}{-\omega^2}+\frac{G''(0^+)}{-\mathrm{i}\omega^3} + \frac{G'''(0^+)}{\omega^4}+\cdots \qquad [30]$$

where the time derivatives are denoted with the apex. The second is obtained from the KK relations [24] with the superconvergence theorem,

$$\underset{\omega\to\infty}{\chi_1} = -\frac{2}{\pi\omega^2}\int \omega'\chi_2(\omega')\,\mathrm{d}\omega' + O(\omega^{-2}) \qquad [31a]$$

$$\underset{\omega\to\infty}{\chi_2} = -\frac{2}{\pi\omega}\int \chi_1(\omega')\,\mathrm{d}\omega' + O(\omega^{-1}) \qquad [31b]$$

By computing the limits of expression [30], it can be seen that $G(0^+) = 0$, $G'(0^+) = \omega_\mathrm{p}^2/4\pi$, etc. One can see immediately that two sum rules are obtained: The first from the asymptotic behavior of the real part is the TRK sum rule

$$\int_0^\infty \omega'\chi_2(\omega')\,\mathrm{d}\omega' = \frac{\pi}{2}\frac{\mathrm{d}}{\mathrm{d}t}G(t)|_{t=0^+} = \frac{1}{8}\omega_\mathrm{p}^2 \qquad [32]$$

where $\omega_\mathrm{p}^2 = 4\pi e^2\varrho/m$. The second refers to the asymptotic behavior [31b] of the imaginary part of the susceptibility which, by comparing with [30] is

$$\int_0^\infty \chi_1(\omega')\,\mathrm{d}\omega' = \frac{\pi}{2}G(t)|_{t=0^+} = 0 \qquad [33]$$

where the second equality can be obtained from the quantum mechanical expression [28] of $G(t)$ or from the Lorentz oscillator model.

In the case of metals, the imaginary part of $\chi(\omega)$ has a pole $\omega = 0$ due to the fact that the conductivity $\sigma(\omega)$ is different from zero at zero frequency. As shown for the KK relations, this can be handled by adding to $\tilde{\chi}(\omega)$ the term $(-(\sigma(0)/\omega)\mathrm{i})$ which cancels the pole, preserving the properties of the function. This is the dominant term in the asymptotic behavior for $\omega\to\infty$, so that, by comparing with [31b] the sum rule for metals is obtained:

$$\int_0^\infty \chi_1(\omega')\,\mathrm{d}\omega' = \frac{\pi}{2}\sigma(0) \qquad [34]$$

Other similar sum rules can be obtained for all optical constants (conductivity σ, refractive index $\tilde{n}$, $\varepsilon^{-1}(\omega)$) in the same way as described above, because they are all related to the real and imaginary parts of the susceptibility. Since conductivity is related to the susceptibility by $\sigma(k,\omega) = -\mathrm{i}\omega\chi$, the sum rule [32] gives directly

$$\int_0^\infty \mathrm{Re}\ \sigma(k,\ \omega)\,\mathrm{d}\omega' = \frac{\omega_\mathrm{p}^2}{8} \qquad [35]$$

which has been used in superconductors. Analogous to eqn [33] is the ADNS sum rule [25] for the real part of the index of refraction, which can be obtained immediately from the observation that the dispersion relations [26b] apply to $\tilde{n}(\omega) - 1$ for both the metallic and nonmetallic media, and that the asymptotic behavior of the complex refractive index is

$$\underset{\omega\to\infty}{\tilde{n}}(\omega) \simeq 1 - \frac{\omega_\mathrm{p}^2}{2\omega^2} + O(\omega^{-2}) \qquad [36]$$

As a consequence, the ADNS sum rule [25] is obtained for both metallic and nonmetallic media.

Longitudinal Sum Rules

Sum rules can also be obtained for the longitudinal dielectric function $\varepsilon_\mathrm{l}(\boldsymbol{k}, \omega)$. This is given by the response of the electron density to an external scalar perturbation, which in $\boldsymbol{k}$ space takes the form

$$\Delta\varrho(\boldsymbol{k}, \omega) = \chi_\mathrm{l}(\boldsymbol{k}, \omega)\phi(\boldsymbol{k}, \omega) \qquad [37]$$

The relation between $\chi_\mathrm{l}(\boldsymbol{k}, \omega)$ and $\varepsilon_\mathrm{l}(\boldsymbol{k}, \omega)$ is obtained from the Maxwell equations

$$\varepsilon_\mathrm{l}^{-1}(k,\ \omega) = 1 + \frac{4\pi e}{k^2}\chi_\mathrm{l}(\boldsymbol{k}, \omega) \qquad [38]$$

A number of phenomena are related to the longitudinal dielectric function, such as the screening of charges, the scattering of electrons, with the expression for the probability for unit time and unit volume that an electron transfers momentum $\boldsymbol{k}$, and energy $\hbar\omega$ to the medium:

$$P(\boldsymbol{k}, \omega) = -\frac{8\pi e^2}{k^2 \hbar V} \operatorname{Im} \varepsilon_{\mathrm{l}}^{-1}(\boldsymbol{k}, \omega) \qquad [39]$$

The sum rules for $\varepsilon_{\mathrm{l}}^{-1}(\boldsymbol{k}, \omega)$ can be obtained with the same procedure used for the optical susceptibility and are

$$\int_0^\infty [\operatorname{Re} \varepsilon_{\mathrm{l}}^{-1}(k, \omega) - 1] \, \mathrm{d}\omega = 0 \qquad [40]$$

and

$$\int_0^\infty \omega \operatorname{Im} \varepsilon_{\mathrm{l}}^{-1}(k, \omega) \, \mathrm{d}\omega = \frac{\pi}{2} \omega_{\mathrm{p}}^2 \qquad [41]$$

where $\omega_{\mathrm{p}}^2 = (4\pi e^2/m)\varrho$ is the plasma frequency. This can be referred to the density of the valence electrons to give the contribution of plasma resonances in metals, but when ϱ includes all the electrons of the medium the sum rule is saturated for $k \to 0$ so that no other longitudinal excitations are present.

Relativistic and Spatial-Dependent Corrections

One can extend the sum rules beyond the dipole approximation, by considering spatial dispersion and the relativistic definition of the current from the Dirac equation. One must consider the fact that $\boldsymbol{k}$ is related to ω by the expression $\varepsilon(k, \omega)\omega^2 = k^2(\omega)c^2$ so that one must take this into account when performing the integration over frequency.

One can be limited to first-order contributions because of the small value of $|\boldsymbol{k}|$ in optics. The lowest-order contribution is of order k^2 because the linear term vanishes due to time reversal. Following Ginzburg and Meiman, a Taylor expansion about $k = 0$ can be obtained as

$$\varepsilon\left(\frac{\partial^2 \varepsilon}{\partial k^2} \frac{\omega\sqrt{\varepsilon}}{c}, \, \omega\right) \simeq \varepsilon(0, \omega) + \frac{\omega^2}{2c^2} \varepsilon\left(\frac{\omega\sqrt{\varepsilon}}{c}, \, \omega\right) \frac{\partial^2 \varepsilon}{\partial k^2}\bigg|_{t=0} \qquad [42]$$

which gives

$$\varepsilon\left(\frac{\omega\sqrt{\varepsilon}}{c}, \, \omega\right) \simeq \frac{\varepsilon(0, \omega)}{1 - (\omega^2/2c^2)\,(\partial^2 \varepsilon/\partial k^2)|_{k=0}} \qquad [43]$$

The calculation of the second derivative of the dielectric function with an inclusion of relativistic corrections has been carried out by Scandolo, Bassani, and Lucarini; it is rather complex and is not to be reported here. When the result is substituted in the frequency dependence [43], its asymptotic behavior is obtained, and the sum rules can be derived in the usual way with spatial dispersion and relativistic corrections. The sum rule on the real part of the susceptibility is unchanged and gives zero, and that on the imaginary part is modified by a contribution which depends on the expectation value of the kinetic energy of the electrons on the total ground state of the system $T_0 = \langle 0|\frac{1}{2}mv^2|0\rangle$. The result is

$$\int_0^\infty \omega' \varepsilon_2(\omega') \, \mathrm{d}\omega' = \frac{\pi}{2} \omega_{\mathrm{p}}^2 \left(1 - \frac{2}{3} \frac{T_0}{mc^2}\right) \qquad [44]$$

This correction is very small, of the order of $\approx 10^{-3}$ in Al, where tests of the sum rule have been made, but it may be easily detected in heavy materials using synchrotron radiation up to very high frequencies.

Applications

Applications of the above described sum rules and KK relations are innumerable and have been of great help in understanding the basic properties of optics in condensed matter. They explain immediately why above a given frequency, all materials are transparent to the electromagnetic radiation.

They show immediately the strict connection between the absorption edge in solids and the value of the static dielectric constant.

The KK dispersion relations have allowed the determination of the optical constants from the measurements of only one of them on the entire optical spectrum (for instance, the reflectivity in semiconductors, where the transmittance cannot be measured because it is too small). In that case, KK dispersion relations can be derived for the reflectivity amplitude. They connect the measured reflectivity R to the phase θ through the function

$$\ln r = \ln |r| + \mathrm{i}\theta = \tfrac{1}{2} \ln R(\omega) + \mathrm{i}\theta(\omega) \qquad [45]$$

which has been proven to have the required analytic behavior in the upper half of the complex ω plane. One can then obtain the phase, and from eqn [7] the complex refractive index and all optical constants. This has allowed the knowledge of the optical transitions in solids, and consequently of the electronic band structure over an extended energy range.

The availability of synchrotron radiation of frequency over a very extended range has furthermore

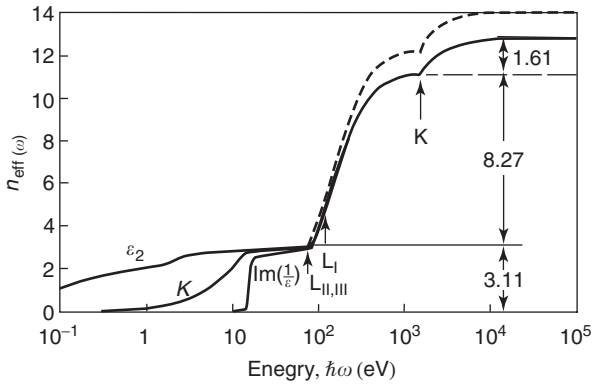

Figure 2 Sum rule for ε_2, κ, and $-\text{Im}(\varepsilon_l^{-1})$: in Al, the solid line shows the saturation at $n = 13$. (E Shiles, T Sasaki, M Inokuti, and DY Smith (1980) *Physical Review B* 22: 1612.)

allowed the direct verification of the sum rules. **Figure 2** reports the results obtained on the metal Al. Further, more detailed analysis on heavy materials would allow the verification of the relativistic and spatial dispersive correction given by expression [44].

Organic Semiconductors

R Scholz, Technische Universität Chemnitz, Chemnitz, Germany

Introduction: Materials

Organic semiconductors are molecular materials with vanishing density of states around the Fermi energy and an energetic gap of ~ 1–5 eV between the highest occupied and the lowest unoccupied states. Contrary to inorganic semiconductors, the optical and transport gaps may differ by more than 1 eV because they are related to different kinds of crystal excitations: the optical response is dominated by Frenkel excitons arising from neutral molecular excitations, and the transport gaps refer to charge transfer (CT) between different molecular sites in the limit of infinite intermolecular distance.

The highest valence band results from the highest occupied molecular orbital (HOMO), and the lowest conduction band from the lowest unoccupied molecular orbital (LUMO). Two contributions to the band dispersion have to be distinguished: strong interactions between adjacent covalently bound building blocks in long oligomers or polymers, and weak intermolecular interactions. The latter give rather small transfer matrix elements between adjacent molecules, restricting the bandwidths of the charge carriers to typically less than 0.5 eV.

Three material classes can be distinguished: polymers, crystalline or amorphous solids composed of identical polycyclic molecules, and organic salts composed of two different kinds of molecules. In the last case, the condensed phase favors electron transfer from the sites with the smaller ionization potential toward the molecules with the stronger electron affinity. The electronic states of polymers and oligomers with a large number of repeating units are covered elsewhere in the encyclopedia (refer "See also" section), and the present article concentrates on the properties of solids composed of identical molecules. Some prototypic planar molecules forming one or several semiconducting crystal phases are discussed, compare **Figure 1**. The optical properties of the monomers are related to the electronic orbitals involved in the dipole-allowed transitions, highlighting the importance of the deformation in the relaxed excited state of the molecule both for the optical response and for resonant Raman spectra.

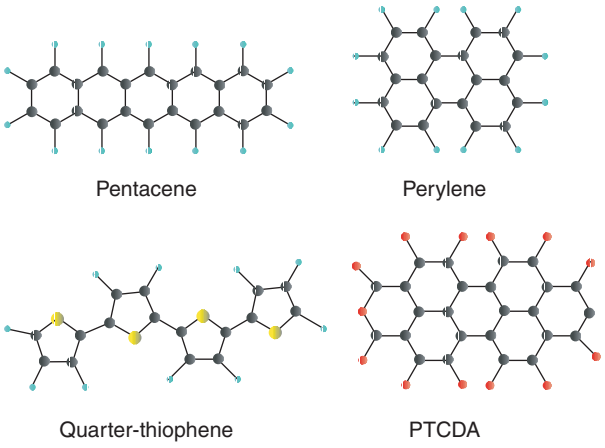

Figure 1 Molecular semiconductors discussed in the present article: pentacene as an example for the polyacene series, perylene, quarter-thiophene (T4), and PTCDA with geometries optimized at the B3LYP/6-31G(d) level.

Based on these ingredients for a single molecule, it is shown that a neutral molecular excitation can be transferred between different sites in the crystal, resulting in excitonic Bloch waves known as Frenkel excitons. For the particular case of 3,4,9,10-perylene, tetracarboxylic dianhydride (PTCDA), it is demonstrated that the anisotropy of the dielectric tensor in the visible and the dominating low-temperature photoluminescence (PL) band can be related quantitatively to the dispersion of the Frenkel excitons arising from the molecular HOMO–LUMO transition.

If CT excitations between adjacent sites in the molecular crystal are energetically below the Frenkel excitons, self-trapped excitons may form, resulting in PL bands with long radiative lifetimes corresponding to the small intermolecular transition dipoles. Two microscopic models can be distinguished: excimers composed of two neutral molecules sharing an electronic excitation, and pairs of oppositely charged molecules. In both cases, the self-trapped excitons can be assigned to pairs of internally deformed molecules involving a reduced intermolecular distance with respect to the crystal geometry.

The electronic band structure of a molecular solid is related to the overlap between the frontier orbitals on adjacent molecules. Starting from a tight-binding approach, it is shown that key parameters such as the bandwidth of the charge carriers show a pronounced temperature dependence, an important ingredient for the interpretation of the observed temperature-dependent mobilities.

Concerning devices based on organic semiconductors, the two major applications are organic field effect transistors and organic light emitting diodes. In the latter case, the disadvantage of rather low-charge carrier mobilities with respect to inorganic semiconductors is counterbalanced by favorable molecular properties such as the tunability across the visible by choosing suitable compounds, the high-internal quantum efficiency, and a relatively low power consumption.

Intermolecular Interactions and Crystal Phases

Several organic crystals with semiconducting properties are composed of planar molecules (see the examples in **Figure 1**), and different polymorphs have been observed for various species. In molecules with partly ionic bonds such as PTCDA, the net charges on the atoms surrounding these bonds result in a large electric quadrupole moment of the entire molecule, determining, in turn, preferential geometries for neighboring molecules in the solid. This quadrupole moment favors an orthogonal arrangement of the two basis molecules in the crystal unit cell, and as a consequence, the unit cell should be quadratic. In both crystal phases of this compound, a symmetry breaking toward a rectangular unit cell allows an interaction of coplanar molecules in the neighboring unit cells via hydrogen bridges, increasing the number of neighbors with similar intermolecular binding energies from 4 to 6.

The oblique orientation of the third lattice vector with respect to the molecule normal reduces the Coulomb repulsion between the stack neighbors, favoring instead short distances between oppositely charged C and O atoms in consecutive crystal planes. The precise stacking geometry results from a combination of the Coulomb interaction between the atomic net charges, a repulsive potential arising from the intermolecular overlap of the π orbitals, and an attractive van der Waals tail determined by the interactions between the molecular polarizabilities. The latter part cannot be obtained by summing over pairs of independent atoms, but the polarizability of each molecule has to be related to the molecular orbitals and the electronic excitations between them. Therefore, a realistic estimate of the interaction energy between the stack neighbors requires advanced quantum chemical approaches such as the second-order Møller–Plesset perturbation theory where the dispersion interaction involving excited Slater determinants is included.

For the case of α-PTCDA (see **Figure 2**), the interactions between neighboring molecules in the crystal are summarized in **Table 1**. The results have been obtained with B3LYP, Hartree–Fock (HF) and the second-order Møller–Plesset perturbation theory (MP2) in the 3–21G variational basis set. In all cases, the

molecular geometries rely on the atomic positions obtained with X-ray diffraction and a readjustment of the hydrogen atoms with a DFT calculation for the three-dimensional crystal. As the elimination of the basis set superposition error results in substantial changes of the interaction energies, only the counterpoise corrected energies are discussed in the following. For the coplanar neighbors, the binding energies depend only weakly on the microscopic approach used, but especially for the stack neighbors, the interaction at the HF and B3LYP level remains repulsive, whereas an MP2 calculation including dispersion interactions gives an overall negative binding energy. From an estimate of the basis set limit of the repulsive HF interaction between two stack neighbors and of their dispersion interaction, it can be concluded that the basis set limit of the MP2 calculation gives a binding energy of -0.91 eV for the stack. Without further modifications of the other intermolecular interactions reported in **Table 1**, this increases the cohesive energy in α-PTCDA at the MP2 level from -2.14 to -3.36 eV. Despite the large size of the PTCDA molecule, the estimated basis set limit of the MP2 binding energy in a stacked dimer is only about twice as large as the MP2 basis set limit obtained for a slipped naphthalene dimer in a stacked geometry, indicating that this energetic range for the van der Waals interaction is typical for various molecular crystals forming stacks. On the other hand, the large intermolecular binding energy between coplanar PTCDA neighbors is a pecularity of the large quadrupole moment and the vicinity of oxygen and hydrogen atoms in both molecules. The strength of these interactions is only weakly dependent on the quantum chemical approach used. Therefore, it can be concluded that the partly ionic carboxylic bonds with negatively charged oxygens and positively charged carbons are of crucial importance for the specific arrangement of the two basis molecules in the unit cell. For molecules without such dipolar groups in the periphery, the interaction between coplanar neighbors would be much smaller, so that noncoplanar arrangements may be more favorable, as observed, for example, for the polyacene series.

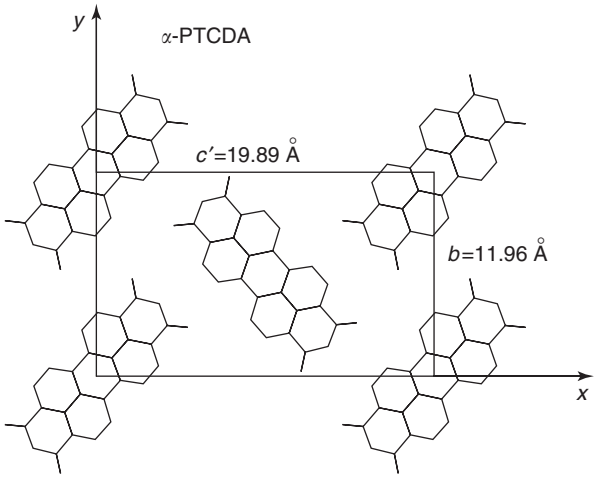

Figure 2 Unit cell of the monoclinic α phase of PTCDA, in the projection coinciding most closely with the molecular orientation. The lattice vectors are $a = 3.72$ Å, $b = 11.96$ Å, and $c = 17.34$ Å, and the direction c' visualized is a linear combination of the lattice vectors c and $2a$.

Frontier Orbitals and Relaxed Excited State of a Single Molecule

The electronic states of polycyclic molecules can be calculated with a large variety of quantum chemical techniques. In this section, the molecules shown in **Figure 1** are investigated with the B3LYP approach in the 6–31G(d) variational basis set as implemented in the GAUSSIAN98 program package. The HOMO and the LUMO are π states resulting from the atomic $2p_z$ orbitals oriented along the normal of the molecular plane. They are composed of lobes with alternating

Table 1 Total energy of different molecular dimers in α-PTCDA

Geometry	*Distance* (Å)	*Type*	*Sites*	*B3LYP* (eV)	*HF* (eV)	*MP2* (eV)
b	11.96	*AA*	2	-0.24 (-0.52)	-0.30 (-0.49)	-0.23 (-0.50)
$a+(b+c)/2$	11.60	*AB*	4	-0.18 (-0.47)	-0.21 (-0.40)	-0.20 (-0.50)
a	3.72	*AA*	2	$+0.76$ ($+0.21$)	$+0.94$ ($+0.41$)	-0.30 (-1.02)
$(b+c)/2$	10.53	*AB*	4	$+0.01$ (-0.13)	$+0.03$ (-0.08)	-0.06 (-0.19)
$a-(b+c)/2$	13.64	*AB*	4	-0.01 (-0.03)	-0.02 (-0.02)	-0.02 (-0.02)
Total			16	$+0.33$ (-3.15)	$+0.48$ (-2.16)	-2.14 (-5.88)

Both for the nearly coplanar molecules (first two lines) and for the interactions between consecutive layers of the crystal (next three lines), the type of the basis molecules involved is indicated by *AA* or *AB,* respectively. Multiplied by the number of the respective neighboring sites and summed over the five types of dimers investigated, these dimer energies result in an estimate for the total cohesive energy in the crystalline phase (last line). All results have been obtained with the GAUSSIAN98 software package using the 3–21G variational basis set, with (without) counterpoise corrections of the basis set superposition error.

sign, and as both orbitals are in the central energetic region of all the π states, each lobe is typically delocalized over two atomic sites (cf. **Figures 3–6**). For perylene and PTCDA, in each half of the molecule the higher-lying LUMO has one node plane and one lobe more than the HOMO, so that the energetic ordering is in accordance with the well-known node counting rules.

The deformation patterns shown in **Figures 3–6** correspond to the difference between a CIS/6–31G(d) calculation for the minimum of the excited state potential and the HF/6–31G(d) geometry for the electronic ground state. In all cases, the $S_0 \rightarrow S_1$ excitation arises from the dipole-allowed HOMO–LUMO transition. For quarter-thiophene, perylene, and PTCDA, the transition dipole moment is oriented along the long axis of the molecules, whereas the lowest electronic transition in pentacene has a transition dipole moment along the short axis.

The deformation pattern in the relaxed excited state of each molecule can be understood from the bonding regions and nodal planes of HOMO and LUMO: for bonds where a bonding region of the HOMO is replaced by an antibonding node of the LUMO, the bond length increases, whereas nodes of the HOMO replaced by a bonding region of the

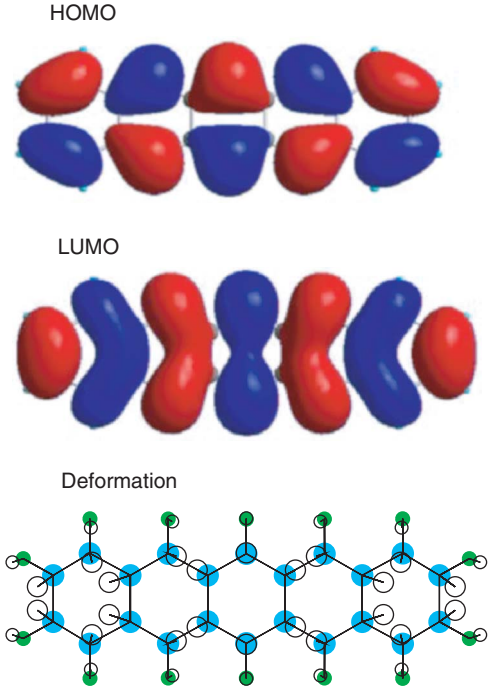

Figure 3 HOMO, LUMO, and deformation in the relaxed excited state of pentacene, multiplied by 20. The orbitals have been calculated with B3LYP/6–31G(d) in the geometry optimized with the same method, and the deformation is the difference between geometry optimizations using CIS/6–31G(d) for the excited state and HF/6–31G(d) for the ground state.

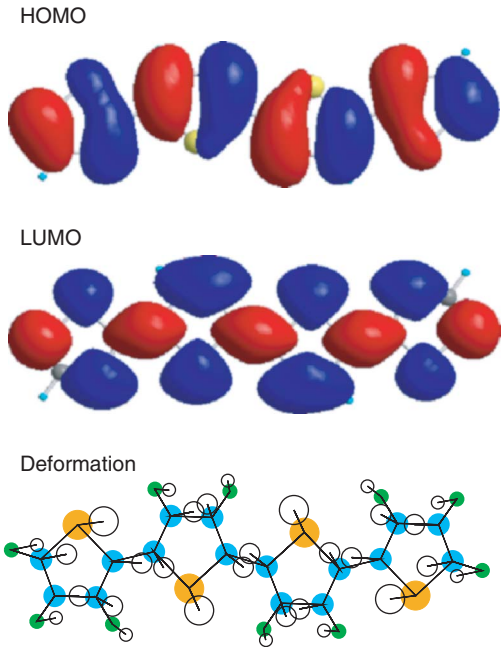

Figure 4 HOMO, LUMO, and deformation in the relaxed excited state of quarter-thiophene.

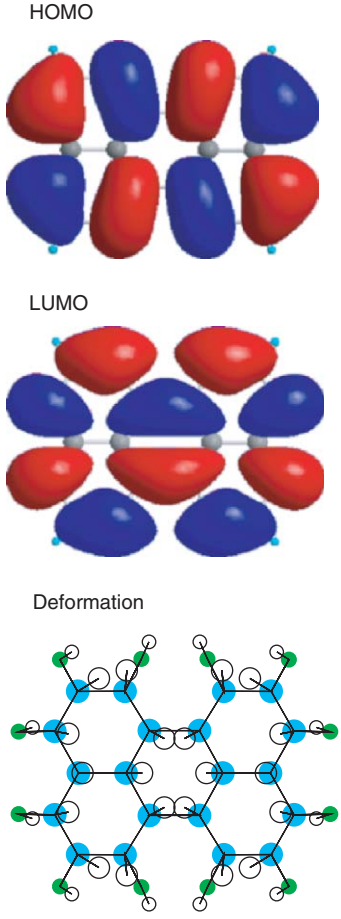

Figure 5 HOMO, LUMO, and deformation in the relaxed excited state of perylene.

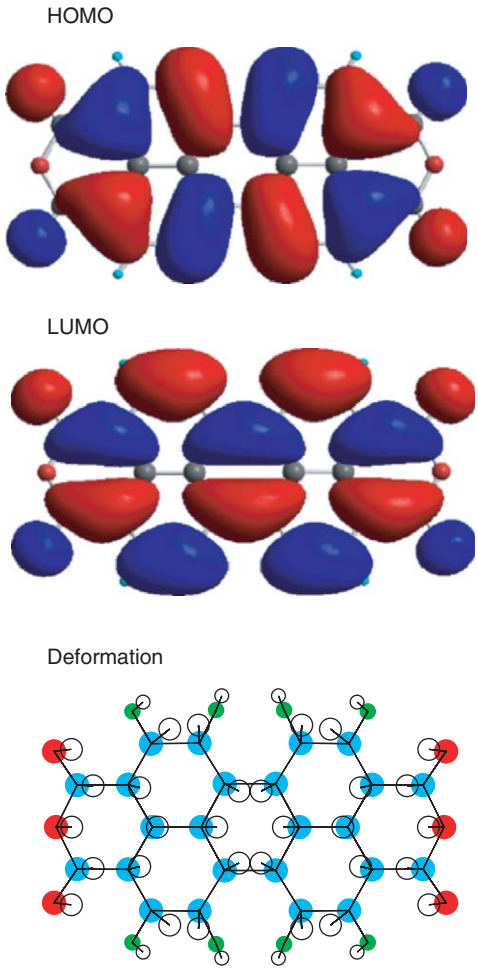

Figure 6 HOMO, LUMO, and deformation in the relaxed excited state of PTCDA.

LUMO result in a shorter bond. As the commutative point groups of the four molecules shown contain the inversion, the charge density of each orbital transforms according to the totally symmetric representation A_g, restricting the deformation in the relaxed excited state to the same symmetry.

Vibrational Spectroscopy

Infrared Spectroscopy

For each molecular species, the vibrational properties of the molecules give a unique fingerprint related to the specific bonding mechanisms involved. The strongest response of the infrared (IR)-active modes arises from bonds with a significant ionic CT, so that IR spectroscopy gives direct insight into the charge distribution over the molecule, and as discussed in an earlier section, the resulting molecular quadrupole moment has a significant influence on the intermolecular interactions in the condensed phase.

In **Figure 7**, the calculated IR spectra of the molecules visualized in **Figure 1** are reported on the same scale. This comparison reveals that the covalent bonds in pentacene and perylene result in quite small net charges on the constituting atoms. The calculated IR activity of quarter-thiophene arises mainly from two out-of-plane C–H bending modes at 696 and 802 cm^{-1}, a symmetric C–S–C in-plane stretch mode at 830 cm^{-1}, a mode at 1245 cm^{-1} where the pattern is a superposition of C–S stretching and C–C stretching of the bonds between pentagons, and a mode at 1557 cm^{-1} dominated by C–C stretching in the pentagons and C–H bending. The most interesting case is PTCDA, where the vibrational fingerprint is largely determined by the O=C–O–C=O end groups. The asymmetric C–O–C stretch contributes strongly to the modes at 1070 and 1173 cm^{-1}, the symmetric C–O–C stretch to the modes at 1151 cm^{-1}, 1171 cm^{-1}, and 1323 cm^{-1}, where in each group the mode with the highest frequency has significant contributions from C–C stretching modes involving the carbon atoms of the carobxylic groups. Among the IR modes with the highest frequencies, the one at 1645 cm^{-1} has mainly elongations of the carbon atoms, and the two strong modes at 1821 cm^{-1} and 1854 cm^{-1} are C=O stretching modes. Even though the 6–31G(d) basis set used for the calculation of the vibrational properties is reasonably well converged, the calculated IR activity of the out-of-plane modes below 1000 cm^{-1} is far below the observed spectra for crystalline material, indicating that in the free molecule the most strongly elongated H-atoms do not carry a significant charge. However, in the crystalline phase, the CT between oxygen and hydrogen atoms of neighboring molecules results in small positive net charges on the hydrogens, with a strong impact on the IR activity of the out-of-plane C–H wagging modes.

Resonant Raman Spectroscopy and Vibronic Progressions in Absorption and PL

For the Raman-active breathing modes, the elongation in the relaxed excited state of each molecule can be obtained from a projection of the deformation pattern in **Figures 3–6** on the complete set of vibrational eigenvectors of each molecule. As a result, for each of the A_g-symmetric breathing modes $\hbar\omega_j$, the corresponding reorganization energies

$$\lambda_j = g_j^2 \hbar\omega_j \qquad [1]$$

can be expressed in terms of a dimensionless vibronic coupling constant g_j^2. This quantity determines the transition probabilities from the electronic and vibrational ground state $|0_g\rangle$ to the different vibronic

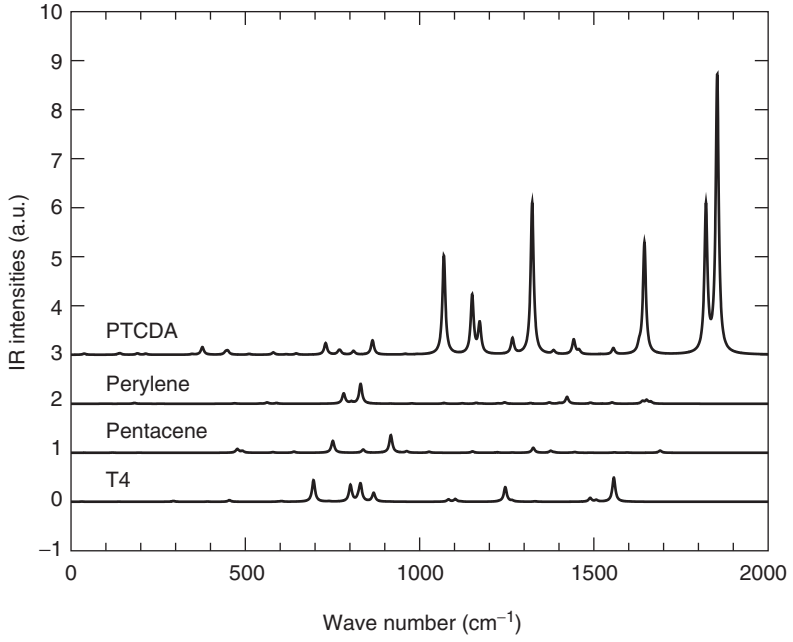

Figure 7 IR intensities calculated at the B3LYP/6–31G(d) level. For visualization purposes, the IR-active modes are broadened with Lorentzian lineshapes with a full width half maximum (FWHM) of 10 cm^{-1}, and all curves are reported on the same but arbitrary scale. From bottom to top: quarter-thiophene, pentacene, perylene, and PTCDA, as annotated. Due to inherent approximations of the B3LYP method, the calculated mode frequencies shown in this figure are too high by ~4%, and as a consequence, it is common practice to rescale them by a factor of ~0.96. The reference lines of the different molecules have been shifted for clarity.

levels $|v_e\rangle$ associated to the excited state potential:

$$P(|0_g\rangle \rightarrow |v_e\rangle) \propto \langle v_e|0_g\rangle^2 = P_v(g_j^2) = \frac{g_j^{2v}}{v!}e^{-g_j^2} \qquad [2]$$

where $P_v(g_j^2)$ is a Poisson distribution. If several internal modes are elongated in the relaxed excited state geometry, the calculation of the linear optical response requires the multiplication of the transition probabilities associated to the transitions $|0_g\rangle \rightarrow |v_e\rangle$ of different breathing modes $\hbar\omega_j$. The transition probabilites $P(|0_e\rangle \rightarrow |v_g\rangle)$ observed in PL can be described by a similar equation:

$$P(|0_e\rangle \rightarrow |v_g\rangle) \propto \langle v_g|0_e\rangle^2 = P_v(g_j^2) = \frac{g_j^{2v}}{v!}e^{-g_j^2} \qquad [3]$$

To leading order, the resonant Raman cross section of each mode is proportional to the vibronic coupling constant g_j^2,

$$\sigma_R(\hbar\omega_j) \propto g_j^2(\hbar\omega_j)^2[1 + n_{th}(\hbar\omega, k_BT)] \qquad [4]$$

where n_{th} $(\hbar\omega_j, k_BT)$ is the number of thermally excited vibrational quanta at temperature T according to Bose–Einstein statistics. Equations [2] and [4] reveal that the linear optical properties, PL and resonant Raman spectra give complementary information on the coupling between electronic excitations and vibrational modes.

Albeit the experimental Raman spectra are usually obtained from the crystalline phase, calculations for a single molecule remain a reasonable approximation because the intermolecular influence on the internal vibrational properties is rather weak.

Clear vibronic progressions can be obtained from the absorption spectra of frozen solutions, laser-induced fluorescence spectra in weakly interacting solvents such as superfluid helium, and PL at low temperature. For excitations to higher vibronic levels, nonradiative recombination mechanisms may reduce the laser-induced fluorescence signals with respect to the absorption coefficient so that the PL excitation spectra deviate considerably from the absorption coefficient. **Figure 8** shows the PL spectra of quarter-thiophene in a frozen solution of tetradecane at a temperature $T = 4.2$ K, allowing a clear assignment of the elongations of various internal breathing modes.

For more strongly interacting solvents and higher temperature, the absorption and PL spectra of dissolved monomers are considerably broadened, so that individual vibronic lines merge into broader bands. An example of this behavior is dissolved PTCDA, where the most strongly elongated breathing modes between 1100 and 1700 cm^{-1} merge into a vibronic progression with a spacing of ~1400 cm^{-1},

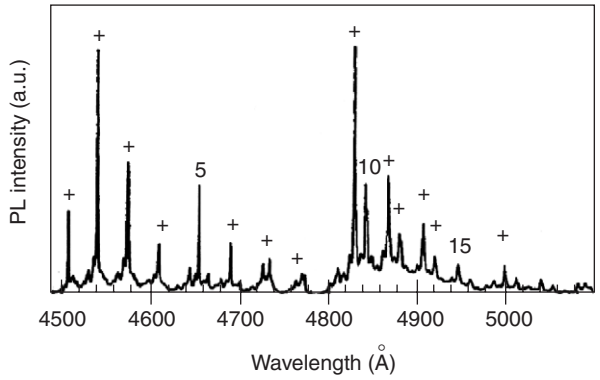

Figure 8 PL spectrum of a frozen solution of quarter-thiophene in tetradecane at $T = 4.2$ K, as a function of wavelength. The PL has been excited selectively on the lowest transition of one of the four different sites resolved in PL excitation spectra. The difference of 1478 cm^{-1} between the peaks 9 and 1 corresponds to the calculated mode at 1503 cm^{-1} in **Figure 9**. (After Birnbaum D, Fichou D, and Kohler BE (1992) The lowest energy singlet state of tetrathiophene, an oligomer of polythiophene. *Journal of Chemical Physics* 96: 165.)

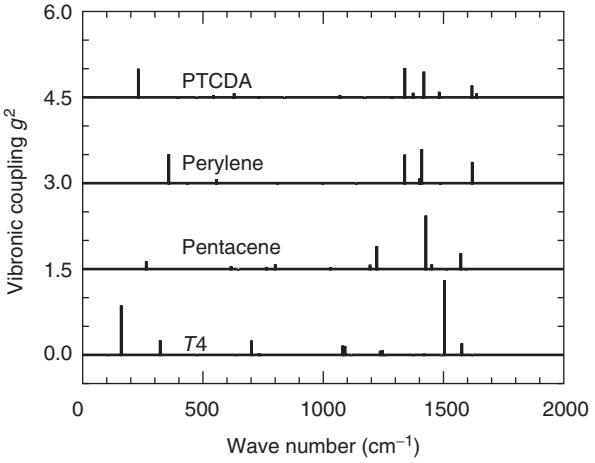

Figure 9 Vibronic coupling constants g_j^2 for the internal breathing modes $\hbar\omega_j$, calculated from a projection of the deformation between the CIS/6–31G(d) relaxed excited state geometry and the HF/6–31G(d) ground-state geometry on the librational eigenvectors obtained for the ground-state potential energy surface with B3LYP/6–31G(d). The reference lines for the different molecules have been shifted for clarity.

interpreted as the elongation of an effective internal vibration.

Figure 9 shows the vibronic coupling constants g_j^2 of the breathing modes in the ground-state potential related to the reorganization energy of each mode according to eqn [1]. As PL and resonant Raman spectroscopy probe the vibrational properties on this potential surface, both spectra can be calculated with these parameters according to eqns [2] and [4].

On the other hand, the modeling of vibronic progressions in optical absorption requires a knowledge of the vibrational properties in the excited state potential. Especially for floppy molecules such as quarter-thiophene, the breathing modes may be quite different, partly due to changes of the potential curvature, and partly due to Dushinksy rotations between the vibrational eigenvectors on the ground- and excited-state potential surfaces.

For all the four molecules visualized in **Figure 9**, a low-frequency mode below 400 cm^{-1} is strongly elongated. In each case, it corresponds to a compressive in-phase movement of all atoms, with the elongations oriented mainly along the long axis of the molecule. The modes in the region 500–800 cm^{-1} have a similar in-phase pattern oriented along the short axis. In quarter-thiophene, the dominating mode at 1503 cm^{-1} is a combination of C–C stretching with a symmetric C–S–C bending motion. For the other three molecules, the breathing modes between 1100 and 1700 cm^{-1} involve a combination of C–C stretching modes and C–H bending modes, and their elongation is driven by the modulation of the C–C bond lengths in the relaxed excited state geometry. The similarity between the modes contributing to perylene and PTCDA is a direct consequence of the similarity of the HOMO and LUMO in both compounds, and of the fact that the terminal O = C–O–C = O groups of PTCDA produce vibrational modes with very small elongations in the perylene core where the differences between the HOMO and LUMO patterns provide the driving force for the elongations.

Absorption and PL Spectra in the Crystalline Phase

For molecular crystals with weak intermolecular interactions such as quarter-thiophene, the low-temperature absorption and PL spectra show clear vibronic progressions of internal vibrations resembling dissolved monomers, (see **Figure 10**). On the other hand, in crystals with strong intermolecular interactions such as PTCDA, the optical excitation induces large elongations of external phonon modes which can be mapped with resonant Raman spectroscopy. It can be shown that these elongations of the librational phonons and the lowest internal breathing modes allow a quantitative assignment of the large broadenings of the absorption spectra observed even at low temperature. As a matter of fact, already at low temperature the fine structure of the vibronic progression is hidden under a line width with FWHM of $\sim$80 meV, so that the high-frequency breathing modes dominating the resonant Raman

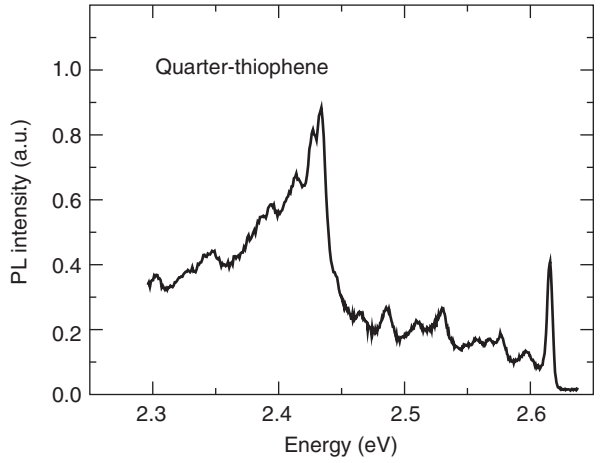

Figure 10 PL spectrum of a 25 Å thick film of quarter-thiophene on highly oriented pyrolitic graphite recorded at $T = 20$ K. The difference of 1469 cm^{-1} between the two most prominent peaks corresponds to the calculated mode at 1503 cm^{-1} in **Figure 9**. (After Gebauer W, Väterlein C, Soukopp A, Sokolowski M, and Umbach E (1996) High-resolution optical spectra from ultrathin quaterthiophene films. *Thin Solid Films* 284–285: 576.)

spectra merge again into an effective high-frequency internal vibration. In the solid phase, the higher harmonics of the internal vibrations are subject to additional broadening mechanisms induced by a combination of exciton transfer and spreading of the internal deformation over molecules surrounding the optically excited site.

The stronger intermolecular interactions in crystalline PTCDA reduce the PL efficiency with respect to the monomer. On the other hand, these interactions are also responsible for the fact that single crystals of α-PTCDA show a large variety of radiative recombination channels (see **Figure 11**). For the four strongest PL bands, the observed decay time τ can be fitted to a simple model for radiative recombination with nonradiative PL quenching at higher temperatures:

$$\frac{1}{\tau} = \gamma = \gamma_{\mathrm{rad}} + \gamma_{\mathrm{nrad}} \exp\left[\frac{-\Delta_{\mathrm{act}}}{k_{\mathrm{B}} T}\right] \qquad [5]$$

where $\gamma_{\mathrm{rad}} = \tau_{\mathrm{rad}}^{-1}$ is the inverse of the radiative lifetime, γ_{nrad} a nonradiative recombination rate, and Δ_{act} the corresponding activation barrier (see **Figure 12**).

As discussed in the next section, the fastest recombination channel with a radiative decay time of 13 ns arises from a vertical recombination starting at the dispersion minimum of the Frenkel excitons. The three PL bands with longer radiative lifetimes can be assigned to self-trapped excitons involving molecular dimers with internal deformations and a modified intermolecular distance (for further details see the section "Slow PL channels: self-trapped excitons").

Exciton Models for the Crystalline Phase

Optical Cycle of Frenkel Excitons

In the solid phase, the molecular HOMO–LUMO excitations can be transferred to different molecules, resulting in neutral crystal excitations called Frenkel excitons. The transfer matrix elements arise from the interaction between the molecular HOMO–LUMO transition dipoles, and for a quantitatively meaningful description, it is important to go beyond the point dipole approximation by including the delocalization of HOMO and LUMO over the entire molecular area, compare **Figures 3–6**. This can be achieved by discretizing the HOMO–LUMO transition dipole moment into a distribution of atomic overlap charges.

As the deformation in the relaxed excited state has a major impact on the absorption spectrum of the monomer, a simple scheme for the internal deformation has to be merged with the possibility of transferring molecular excitations. If the relevant breathing modes cluster in a narrow range as for a PTCDA molecule, it is convenient to introduce an effective internal mode $\hbar\omega_{\mathrm{eff}} = \sum_j g_j^2 \hbar\omega_j / \sum_j g_j^2$ with an effective vibronic coupling constant $g_{\mathrm{eff}}^2 = \sum_j g_j^2$, where the sum may be restricted to the most strongly elongated modes, for example, in the range 1100–1700 cm^{-1}. It has been shown that for crystalline PTCDA, an effective mode described by $\hbar\omega_{\mathrm{eff}} = 0.17\,\mathrm{eV} = 1370\,\mathrm{cm}^{-1}$ and $g_{\mathrm{eff}}^2 = 1.0$ gives a realistic description. Within this effective mode model, the elementary molecular excitations can be described by Bosonic creation and annihilation operators $b_{n\alpha\nu}^{+}$ and $b_{n\alpha\nu}$, respectively, where

$$b_{n\alpha\nu_{\mathrm{e}}}^{+} = |n\alpha\nu_{\mathrm{e}}\rangle\langle n\alpha 0_{\mathrm{g}}| \qquad [6]$$

excites the basis molecule α in the unit cell at the lattice site n from the electronic and librational ground state $|0_{\mathrm{g}}\rangle$ to the vibronic sublevel $|\nu_{\mathrm{e}}\rangle$ on the excited state potential. Based on these operators, a Hamiltonian including the possibility of transferring neutral excitations between different molecules can be written in the following form:

$$H^{\mathrm{e}} = \sum_{n} \sum_{\alpha=A,B} \sum_{\nu_{\mathrm{e}}} E_{0_{\mathrm{g}}\nu_{\mathrm{e}}} b_{n\alpha\nu_{\mathrm{e}}}^{+} b_{n\alpha\nu_{\mathrm{e}}} + \sum_{n\alpha\nu_{\mathrm{e}}} \sum_{m\beta\mu_{\mathrm{e}}} t_{n\alpha\nu_{\mathrm{e}};m\beta\mu_{\mathrm{e}}} b_{n\alpha\nu_{\mathrm{e}}}^{+} b_{m\beta\mu_{\mathrm{e}}} \qquad [7]$$

where the transfer matrix elements $t_{n\alpha\nu_{\mathrm{e}};m\beta\mu_{\mathrm{e}}}$ are the product of an electronic and a vibronic part,

$$t_{n\alpha\nu_{\mathrm{e}};m\beta\mu_{\mathrm{e}}} = T_{n\alpha;m\beta} S_{\nu_{\mathrm{e}}0_{\mathrm{g}}} S_{\mu_{\mathrm{e}}0_{\mathrm{g}}} \qquad [8]$$

$S_{\nu_{\mathrm{e}}0_{\mathrm{g}}} = \langle \nu_{\mathrm{e}}|0_{\mathrm{g}}\rangle$ and $S_{\mu_{\mathrm{e}}0_{\mathrm{g}}} = \langle \mu_{\mathrm{e}}|0_{\mathrm{g}}\rangle$ are the vibronic Franck–Condon factors of the effective internal

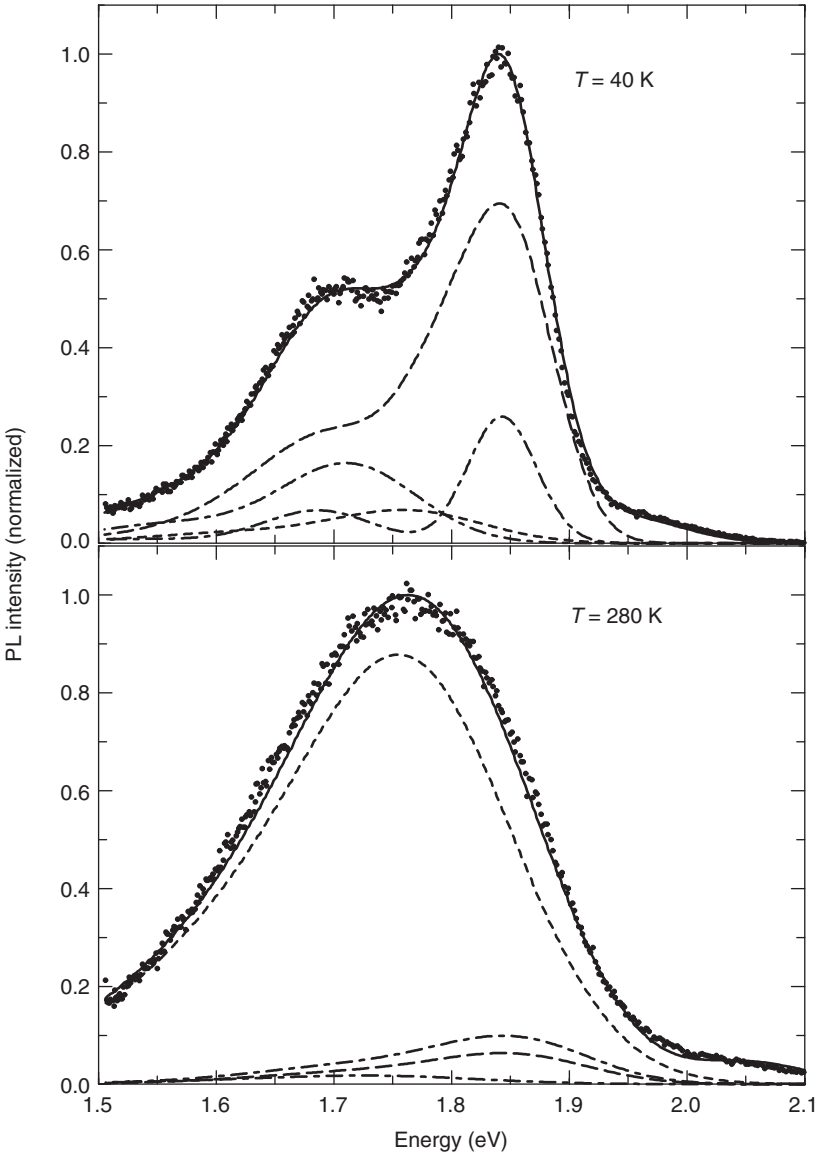

Figure 11 Decomposition of the measured time-integrated PL spectra (dots) at $T = 40$ K (upper) and $T = 280$ K (lower) into contributions from Frenkel excitons (long-dashed), excimers (short-dashed), and two CT channels assigned to recombination between an anionic and a cationic molecule (dash-dotted). The time-integrated spectra include a high-energy satellite ~ 1.95 eV at $T = 40$ K and ~ 2.05 eV at $T = 280$ K (not shown separately). mode, and their squares follow a Poisson progression $S^2_{v_e 0_g} = P_{v_e}(g^2_{\text{eff}})$ according to eqn [2]. As the transfer matrix elements result from the interaction of the molecular transition dipoles, the neighboring molecules in the crystal give the largest values. For pairs of equivalent basis molecules in α-PTCDA, it can be shown that the stack neighbors exceed all other transfer matrix elements by more than one order of magnitude. Even though the transfer between both types of basis molecules remains much smaller, it induces a pronounced difference between the lineshapes of the diagonal components of the frequency-dependent dielectric tensor.

The above Hamiltonian equation [7] is based on the simplifying approximation that the electronic excitation and the deformation reside on the same molecule, so that they are transferred together. It can be block-diagonalized by a Fourier transformation to k-space, resulting in dispersion relations for the different vibronic levels of the Frenkel exciton. In the usual approximation of a vanishing photon wave vector with respect to the size of the Brillouin zone, the optical excitation results in a Frenkel exciton at the Γ point. The HOMO–LUMO transition dipole moments are oriented along the long axes of the two basis molecules, defining the plane where this transition

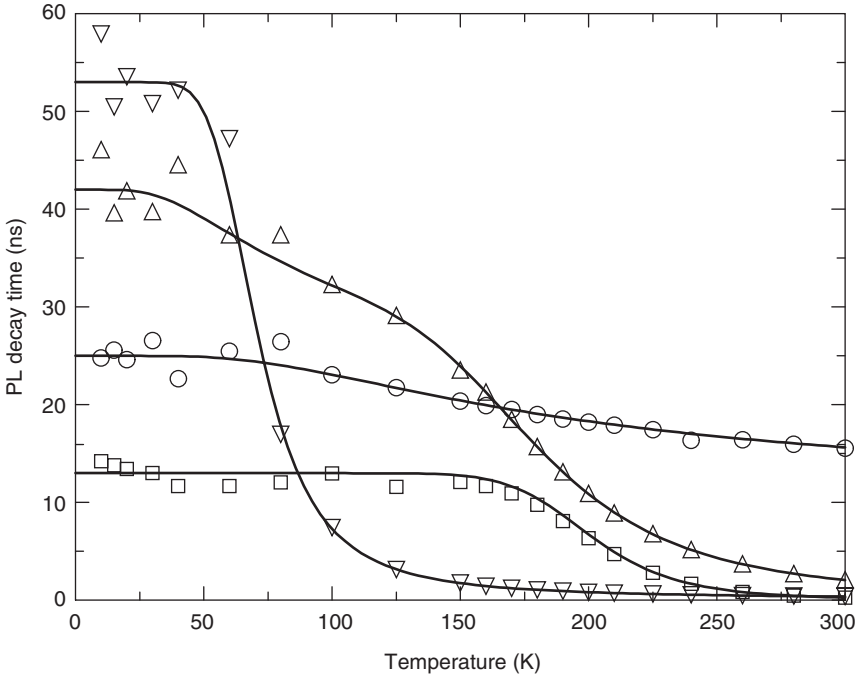

Figure 12 Lifetimes of the different PL bands, where the model curves according to eqn [5] are calculated with $\tau_{rad} = 13$ ns for the Frenkel excitons, 42 ns for the high-energy CT band around $\langle E_{PL} \rangle = 1.78$ eV, 53 ns for the low-energy CT band around $\langle E_{PL} \rangle = 1.67$ eV, and 25 ns for the PL arising from the stacked excimer. The model curve for the higher CT band involves two nonradiative decay mechanisms. (After Kobitski A Yu, Scholz R, Wagner HP, and Zahn DRT (2003) *Physical Review B* 68: 155201.)

contributes to the optical response. Due to the specific arrangement of the two molecules in the unit cell, this plane is very close to the plane visualized in **Figure 2**.

The dielectric tensor resulting from the above Hamiltonian equation [7] and realistic transfer matrix elements is visualized in **Figure 13**. In addition to the molecular ingredients discussed above, the two crystal parameters determining the optical response are the sum over all transfer matrix elements between equivalent lattice sites, $T_{AA} = 150$ meV, and the sum over all transfers between inequivalent basis molecules, $T_{AB} = 46$ meV. The redistribution of oscillator strength between the different vibronic sublevels is governed by $T_{AA} - T_{AB} = 104$ meV for ε_{xx}, and by $T_{AA} + T_{AB} = 196$ meV for ε_{yy}. These values result in different lineshapes of the two diagonal elements of the dielectric tensor, but the Davydov splitting between the vibronic sublevels remains rather small. For polycrystalline films with random azimuthal orientation of the crystallites, the average $\varepsilon_{||}(\omega)$ can be used for the definition of the refractive index $n_{||}(\omega)$, (see **Figure 14**).

The above approach to exciton transfer can easily be generalized to the exciton dispersion in the entire Brillouin zone displayed in **Figure 15**. After the optical excitation toward the dispersion maximum at Γ, the Frenkel excitons can be scattered by librational modes, resulting eventually in a thermalized exciton population around the dispersion minimum at the boundary of the Brillouin zone. These low-lying exciton states are obvious candidates for a strongly redshifted PL band.

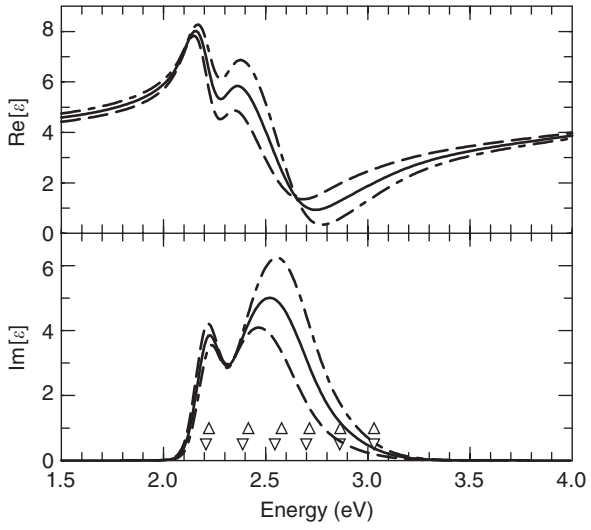

Figure 13 Calculated diagonal components of the frequency-dependent dielectric tensor in α-PTCDA. Dashed: $\varepsilon_{xx}(\omega)$, dash-dotted: $\varepsilon_{yy}(\omega)$, solid: average $\varepsilon_{||}(\omega)$. The △ and ▽ signs indicate the positions of the upper and lower Davydov components, contributing to $\varepsilon_{yy}(\omega)$ and $\varepsilon_{xx}(\omega)$, respectively. Figure 15 Schematic model of the optical excitation and recombination cycle in crystalline PTCDA at low temperature. Vibronic levels ν_g not involved in the absorption and PL transitions are visualized as dashed lines. (After Vragović I and Scholz R (2003) *Physical Review B* 68: 155202.)

Assuming a vertical PL transition, the final state after recombination has to conserve the wave vector of the thermalized Frenkel exciton, so that the electronic and vibronic ground state with a vanishing wave vector can be excluded as an acceptable final state. This lack of the lowest final state gives the largest contribution of 0.17 eV to the overall Stokes shift of 0.41 eV between the lowest absorption subband and the highest PL feature, followed by the dispersion of the Frenkel excitons extending over a range of 0.12 eV. A Stokes shift of 0.09 eV related to the low-frequency internal vibrations and to the external phonons can be estimated from resonant Raman spectra, and the correlation between different vibronic sublevels of the final states induced by exciton transfer is about 0.03 eV. The observed radiative lifetime of $\tau_{rad} = 13$ ns can be reproduced quantitatively, and the slowing down with respect to dissolved monomers with $\tau_{rad} = 4$ ns results from the lack of the dipolar coupling to the final state $|0_g\rangle$. Electron energy loss spectroscopy can be used to map the dependence of the dipolar coupling strength on the wave vector, corroborating the validity of the excitonic dispersion in **Figure 15** and the calculated distribution of the vibronic overlap factors over the different branches.

Slow PL Channels: Self-Trapped Excitons

In several organic crystals with small intermolecular distances, PL channels with decay times exceeding 20 ns have been observed (see **Figures 11** and **12** for α-PTCDA). As this range for the radiative recombination time is far above the PL decay time observed on dissolved monomers of the same species, the molecular HOMO–LUMO transition dipole can be ruled out as a possible assignment. On the other hand, intermolecular CT transitions are expected to have very small transition dipoles, and for α-PTCDA, it can be shown that the three slower PL channels arise from different types of deformed excited dimer states: The dominating high-temperature PL band results from an excimer in a stack geometry, the lower CT band from the corresponding anion–cation pair, and the higher CT band from the two basis molecules in the unit cell involving an anionic and a cationic molecule. In each case, the Stokes shift with respect to the corresponding CT transition in the undeformed crystal is composed of three contributions: an internal deformation of the two constituting molecules, an elongation of the external librational phonon modes, and self-trapping along the intermolecular distance.

For the stack excimer, the internal deformation of the two molecules can be defined in accordance with the deformation pattern in **Figure 6**, and as both molecules share the electronic excitation, the minimum on the excited state potential obtained with the time-dependent density-functional theory (TD-DFT) corresponds to about 45% of the deformation of the relaxed excited state of the monomer, giving a contribution of 0.21 eV to the Stokes shift.

From their resonant Raman intensities, the librational phonons are expected to contribute 0.04 eV to

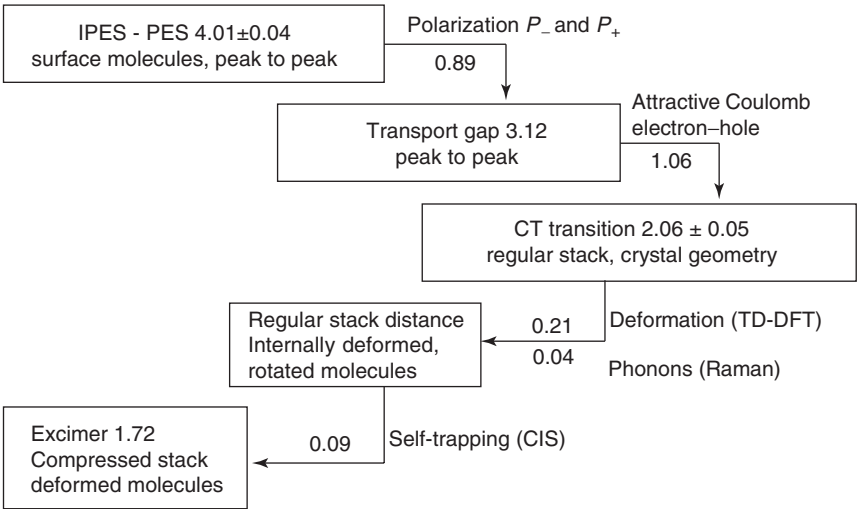

Figure 16 CT energies related to the stack geometry, in eV. The energies for the stack excimer and the undeformed stack are derived from the dimer model for a self-trapped exciton discussed in the main text, and the Coulomb attraction between the electron and hole is taken from previous microelectrostatic calculations. (Tsiper EV and Soos ZG (2001) *Physical Review B* 64: 195124.) The difference of 0.89 eV between the polarization energies for surface molecules and for molecules inside the bulk can be estimated from the difference of photoemission spectroscopy (PES) and inverse photoemission spectroscopy (IPES). (Hill IG, Kahn A, Cornil J, dos Santos DA, and Bredas JL (2000) Occupied and unoccupied electronic levels in organic π-conjugated molecules: comparison between experiment and theory. *Chemical Physics Letters* 317: 444 and Park S, Kampen TU, Braun W, and Zahn DRT (2001) *Applied Surface Science* 175–176: 249.) The experimental uncertainty of the energetic difference between PES and IPES is derived from a fit to experimental data, and the uncertainty of the CT energy in the undeformed stack is estimated from the three ingredients of the excimer red shift.

the reorganization energy in the absorption spectra of the Frenkel excitons. The internal deformation of the molecules in the stacked excimer geometry gives a Stokes shift half as large as for the monomer, so that it is reasonable to assume that the contribution of the librational phonons is reduced by the same amount. The self-trapping of the excimer along the stack distance can be investigated with a combination of configuration interaction of singles and the second-order Møller–Plesset theory, resulting in a Stokes shift of 0.09 eV. These red shifts with respect to the CT transition between stack neighbors in the geometry of the crystal ground state are summarized in **Figure 16**. The resulting estimate of 2.06 eV for the CT transition in the crystal geometry is ~ 0.25 eV below previous calculated values, and this deviation can be rationalized from the fact that the gas-to-crystal shift of the CT transition is in the same range as for the Frenkel exciton, a contribution to the CT energy not included in previous microscopic models.

The CT gap can be defined as the energy of a pair of oppositely charged molecules at infinite distance inside the crystal. It arises from polarization corrections of the energetic difference between ionization potential I and electron affinity A in vacuum:

$$E_t = I - A - P_+ - P_- \qquad [9]$$

where P_+ and P_- contain polaronic contributions due to intramolecular deformations and lattice phonons, and the energy related to the polarization induced by the charges on the ionized molecules. At finite distance, the electron–hole attraction reduces this energy,

$$E_{\text{pair}}(\boldsymbol{r}) = E_t + V(\boldsymbol{r}) < E_t \qquad [10]$$

and for stack neighbours, micro-electrostatic calculations gave $V(\boldsymbol{r}) = -1.06$ eV, resulting in an estimate of 3.12 eV for the transport gap inside the crystal. Due to smaller polarization energies for the surface molecules involved in measured photoemission and inverse photoemission spectra, the difference between the resulting HOMO and LUMO states of the surface molecules is much higher than the transport gap, (see **Figure 16**).

Electronic Band Structure and Mobility of Charge Carriers

Tight-Binding Approach

The transfer of positive or negative charges between adjacent sites in the crystal results from the overlap between the electronic π orbitals of the respective molecules. The exponential decay of the wave functions results in rather small intermolecular matrix elements, and even for the neighboring molecules, they are only of the order of $T = 0.1$ eV. The electronic band structure for a molecular crystal with

two basis molecules can be written as

$$E_{\pm}(\boldsymbol{k}) = \left(\frac{T_{\mathrm{AA}}(\boldsymbol{k}) + T_{\mathrm{BB}}(\boldsymbol{k})}{2}\right) \pm \sqrt{\left(\frac{T_{\mathrm{AA}}(\boldsymbol{k}) - T_{\mathrm{BB}}(\boldsymbol{k})}{2}\right)^2 + V_{\mathrm{AB}}^2(\boldsymbol{k})} \quad [11]$$

where the wave-vector-dependent matrix elements are given by a Fourier transform of the intermolecular transfer integrals $t_{\mathrm{AA}}(\boldsymbol{R}_n)$, $t_{\mathrm{BB}}(\boldsymbol{R}_n)$, and $t_{\mathrm{AB}}(\boldsymbol{R}_n)$:

$$T_{\mathrm{AA}}(\boldsymbol{k}) = E_{\mathrm{A}} - 2\sum_{\boldsymbol{n}} t_{\mathrm{AA}}(\boldsymbol{R}_{\boldsymbol{n}})\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{R}_n} \quad [12]$$

$$T_{\mathrm{BB}}(\boldsymbol{k}) = E_{\mathrm{B}} - 2\sum_{\boldsymbol{n}} t_{\mathrm{BB}}(\boldsymbol{R}_{\boldsymbol{n}})\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{R}_n} \quad [13]$$

$$V_{\mathrm{AB}}(\boldsymbol{k}) = -2\sum_{\boldsymbol{n}} t_{\mathrm{AB}}(\boldsymbol{R}_{\boldsymbol{n}})\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{R}_n} \quad [14]$$

For crystals with the monoclinic centrosymmetric space group $P2_1/c(C_{2h}^5)$ containing two equivalent molecules such as naphthalene, anthracene, and PTCDA, $E_{\mathrm{A}} = E_{\mathrm{B}}$ and $T_{\mathrm{AA}}(\boldsymbol{k}) = T_{\mathrm{BB}}(\boldsymbol{k})$, whereas for triclinic crystals with two inequivalent basis molecules such as tetracene and pentacene, these energies and transfer matrix elements differ. The values of the transfer matrix elements such as $t_{\mathrm{AA}}(\boldsymbol{R}_n)$ can be obtained with quantum chemical approaches or with density-functional calculations of the periodic solid. **Figure 17** shows a calculated electronic band structure for naphthalene. For the polyacene series, the total bandwidths of the HOMO and LUMO bands increase monotonously from naphthalene to pentacene.

Band Narrowing due to Polaronic Effects

Within a mixed Holstein–Peierls approach, the coupling between tightly bound electrons and phonons can be written as

$$H = \sum_{mn} \varepsilon_{mn} a_m^+ a_n + \sum_q \hbar\omega_q \left(b_q^+ b_q + \frac{1}{2}\right) + \sum_{mnq} \hbar\omega_q g_{qmn}\left(b_q^+ + b_{-q}\right) a_m^+ a_n \quad [15]$$

where $a_m^{(+)}$ annihilates (creates) an electron at the site $\boldsymbol{R}_m$ with energy ε_{mm}, and $b_q^{(+)}$ annihilates (creates) a phonon with wave vector $\boldsymbol{q}$ and energy $\hbar\omega_q$. The site indices m are a shorthand notation including both the cell index and the basis molecule. In order to keep the notation readable, a sum over different local and nonlocal (librational) phonon modes λ is suppressed.

In the noninteracting system, that is, $g_{qmn} = 0$, the electronic band structure would be determined by the transfer matrix elements ε_{mn} alone. An approximate solution of the coupled Hamiltonian [15] can be achieved by a nonlocal canonical transformation according to

$$H \rightarrow \tilde{H} = e^S A e^{S+} \quad [16]$$

$$S = \sum_{mnq} g_{qmn}(b_q^+ - b_{-q}) a_m^+ a_n \quad [17]$$

By an application of the Baker–Campbell–Hausdorff theorem and the Wick theorem, the transformed Hamiltonian decouples into independent electron and phonon contributions,

$$\tilde{H} = \sum_{mn} \tilde{E}_{mn} a_m^+ a_n + \sum_q \hbar\omega_q \left(b_q^+ b_q + \frac{1}{2}\right) \quad [18]$$

where the on-site energies $\tilde{E}_{mm}$ and transfer integrals $\tilde{E}_{mn}$ are renormalized by the presence of local and nonlocal phonon couplings:

$$\langle \tilde{E}_{mm} \rangle = \varepsilon_{mm} - \Delta_{mm} \quad [19]$$

$$\langle \tilde{E}_{mn} \rangle = \varepsilon_{mn}\mathrm{e}^{-X_{mn}} - \Delta_{mn}\frac{1 - \mathrm{e}^{-X_{mn}}}{X_{mn}} \quad [20]$$

The polaron shifts Δ_{mn} are given by

$$\Delta_{mn} = \sum_{qj} \hbar\omega_q g_{qmj} g_{-qjn} \quad [21]$$

and X_{mn} stands for

$$X_{mn} = \sum_q \left(\frac{1}{2} + N_q\right) G_{qmn} \quad [22]$$

where N_q is the thermal occupation of the phonon mode according to Bose–Einstein statistics. G_{qmn} summarizes both local and nonlocal phonon couplings:

$$G_{qmn} = |g_{qmm} - g_{qnn}|^2 + \sum_{l \neq m,n} (|g_{qml}|^2 + |g_{qnl}|^2) \quad [23]$$

For practical calculations, the phonons can be approximated by dispersionless branches λ, simplifying the above expression [22] to

$$X_{mn} = \sum_{\lambda} \left(\frac{1}{2} + N_\lambda\right)(G_{\lambda mm} + G_{\lambda nn} - g_{\lambda mn}^2) \quad [24]$$

$$G_{\lambda jj} = g_{\lambda jj}^2 + \frac{1}{2}\sum_{l \neq j} g_{\lambda jl}^2 \quad [25]$$

For the polyacene series, this formalism has been applied to the temperature dependence of the polaron bandwidth (see **Figure 18** for naphthalene and tetracene). At zero temperature, the local part of eqns [24] and [25] gives a reduction of the transfer matrix

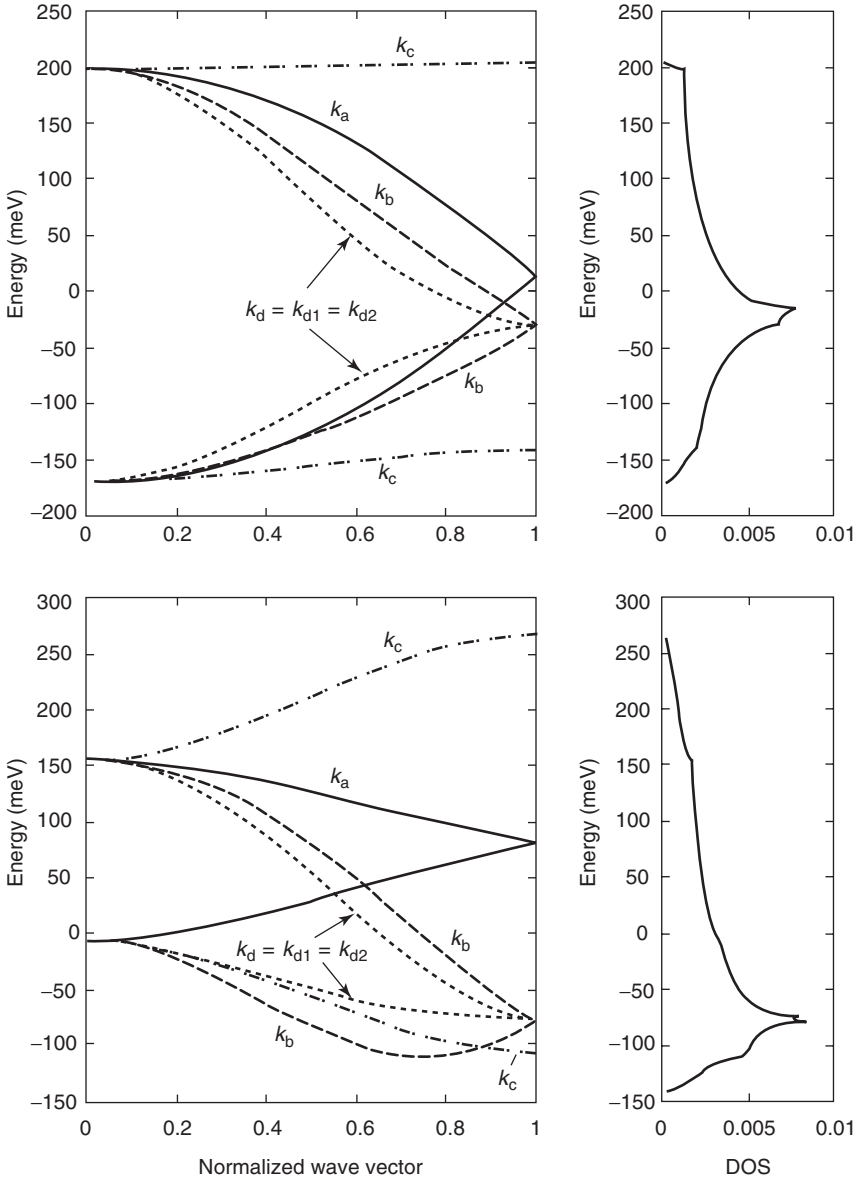

Figure 17 Shape of the LUMO band (upper panel) and the HOMO band (lower panel) of naphthalene in the major crystal directions within the first Brillouin zone, with the corresponding density of states (DOS) (right panels). (After Cheng YC, Silbey RJ, da Silva Filho DA, Calbert JP, Cornil J, and Bredas JL (2003) *Journal of Chemical Physics* 118: 3764.)

elements in eqn [20] resembling the exponential prefactor $S_{00}^2 = e^{-g^2}$ in the Poisson distribution [2]. In this regime, only this lowest vibronic level is occupied by charge carriers, reducing the bandwidth of the lowest vibronic branch by S_{00}^2. Therefore, already at low temperature, the polaron bandwidths reported in **Figure 18** are far below the purely electronic bandwidth shown in **Figure 17**. Due to the low energies of the phonon modes coupling to the electron transfer, at higher temperature the thermal occupation numbers N_λ may become rather large, resulting in a further reduction of the polaron bandwidth with respect to low temperature.

Temperature Dependence of the Charge Carrier Mobilities

Figure 19 reports the measured mobility of electrons and holes in naphthalene. In each crystal direction, the holes show higher mobilities than electrons, but the temperature dependence is quite different: for holes, the exponent n in $\mu_h(T) \propto T^{-n}$ increases with rising temperature, whereas for electrons it decreases.

In thermal equilibrium, the mobility μ_α in the direction $\boldsymbol{e}_\alpha$ can be obtained from the Kubo formula based on the current–current correlation function. The current is composed of a pure electronic part $\boldsymbol{j}^{(I)}$

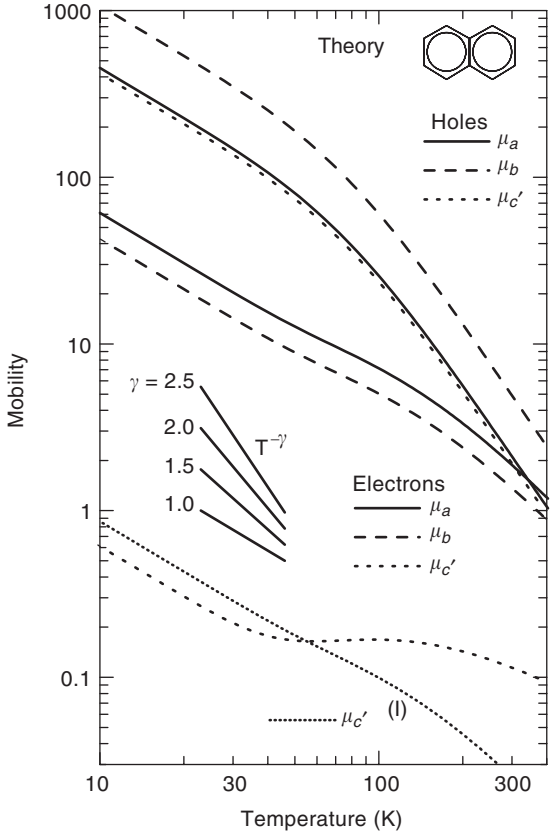

Figure 20 Calculated charge carrier mobilities vs. temperature for naphthalene crystals, as obtained from eqns [28] and [30] in arbitrary units. (After Hannewald K and Bobbert PA (2004) *Ab initio* theory of charge-carrier conduction in ultrapure organic crystals. *Applied Physics Letters* 85: 1535.)

and a phonon-assisted part $\boldsymbol{j}^{(II)}$, given by

$$\boldsymbol{j}^{(I)} = \frac{e}{i\hbar}\sum_{mn}(\boldsymbol{R}_m - \boldsymbol{R}_n)\varepsilon_{mn}a_m^+ a_n \qquad [26]$$

$$\boldsymbol{j}^{(II)} = \frac{e}{i\hbar}\sum_{mnq}(\boldsymbol{R}_m - \boldsymbol{R}_n)\hbar\omega_q g_{qmn}(b_q^+ + b_{-q})a_m^+ a_n \qquad [27]$$

The mobility $\mu_\alpha^{(I)}$ can be cast into the following form:

$$\mu_\alpha^{(I)} = \frac{e}{2k_B T\hbar^2}\sum_{m\neq n}(R_{m\alpha} - R_{n\alpha})^2\varepsilon_{mn}^2 \times \int_{-\infty}^{\infty} dt \left[e^{-\sum_\lambda G_\lambda[1+2N_\lambda-\phi_\lambda(t)]}\right]^2 e^{-\Gamma^2 t^2} \qquad [28]$$

where $R_{m\alpha}$ is the Cartesian component α of the molecular site, G_λ is defined as in eqn [25], Γ is a phenomenological broadening parameter, and

$$\phi_\lambda(t) = (1+N_\lambda)e^{-i\omega_\lambda t} + N_\lambda e^{i\omega_\lambda t} \qquad [29]$$

The bandwidth narrowing of eqn [20] is represented by the exponential of $-\sum_\lambda G_\lambda[1+2N_\lambda]$ in eqn [28]. It accounts for coherent scattering processes, whereas the part of the exponent containing $\phi_\lambda(t)$ describes

incoherent scattering processes involving changes in the phonon occupation.

The total mobility μ_α including the phonon-assisted current $\boldsymbol{j}^{(II)}$ can be obtained from an expression of the same form as eqn [28], with the replacement

$$\varepsilon_{mn}^2 \rightarrow (\varepsilon_{mn} - \Delta_{mn})^2 + \frac{1}{2}\sum_\lambda (\hbar\omega_\lambda g_{\lambda mn})^2 \phi_\lambda(t) \qquad [30]$$

In **Figure 20**, the calculated electron and hole mobilities are reported as a function of temperature. The experimental observation that the hole mobilities are larger than the electron mobilities is reproduced, together with a qualitatively reasonable temperature dependence of the exponent n in $\mu_h(T) \propto T^{-n}$. For temperatures above $T = 50\,\mathrm{K}$, the phonon-assisted electron current $\boldsymbol{j}^{(II)}$ along c' increases, resulting in a saturation of the mobility at higher temperatures, as observed experimentally.

However, for electrons the anisotropy of the mobility is severely overestimated. As the electronic transfer matrix elements and the electron–phonon couplings were determined with density-functional methods, this deficiency can be related to the lack of van der Waals corrections in the definition of the total energy of the molecular crystal.

Summary

From the experimental point of view, the field of organic semiconductors is now approaching a mature state, and the first technological applications including organic light emitting devices and organic field effect transistors are already emerging in the market. However, due to the size of the molecules involved, quantitatively reliable model calculations concerning spectroscopic properties and charge carrier mobilities are just emerging. For practical applications, it remains a major challenge to suppress unwanted impurities in the organic host which can act as traps for charge carriers, and to introduce dopants in a controlled way. Concerning optoelectronic applications, the possibility of using electrophosphorescent molecules has allowed the design of light emitting devices with highly competitive efficiencies with respect to inorganic semiconductors and gas discharge tubes.

Orientation Texture

S I Wright, TSL/EDAX, Draper, UT, USA

Introduction

Many single crystals exhibit properties that vary with direction (anisotropy). For example, consider the elastic modulus of a copper single crystal. The elastic modulus measured for an applied uniaxial tensile stress parallel to the $\langle 1\,1\,1 \rangle$ crystal direction (i.e., the body diagonal) is nearly three times larger than the modulus measured with a stress axis parallel to $\langle 1\,0\,0 \rangle$ (i.e., normal to the cube faces) (**Figure 1**).

Most materials are not single crystals but polycrystals. To first order, a given property that varies

with direction, such as the elastic modulus, can be approximated for a polycrystal by averaging the property for each constituent crystal. For example, if the elastic stiffness of a single crystal is represented as a fourth-order tensor – C_{ijkl}, then one approximation of the average elastic stiffness tensor ($\bar{C}_{ijkl}$) for the polycrystal is given as follows:

$$\bar{C}_{ijkl} = \frac{1}{V}\sum_{n=1}^{N} v(\boldsymbol{g}^n) g^n_{ip} g^n_{jq} g^n_{kr} g^n_{ls} C_{pqrs} \qquad [1]$$

where V is the total volume of the polycrystal, $\boldsymbol{g}^n$ is the orientation, $v(\boldsymbol{g}^n)$ is the volume of the nth grain in the polycrystal in matrix form, and N is the total number of grains.

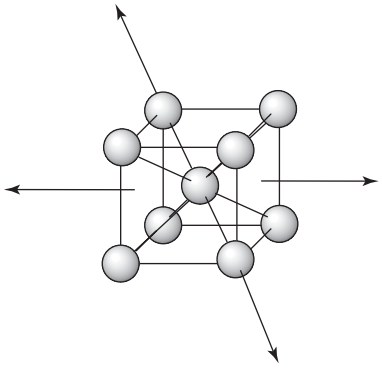

Figure 1 Schematic of elastic moduli measured for stresses applied along the ⟨1 1 1⟩ (body diagonal) and ⟨1 0 0⟩ (normal to the cube faces) crystal directions in a body-centered cubic crystal.

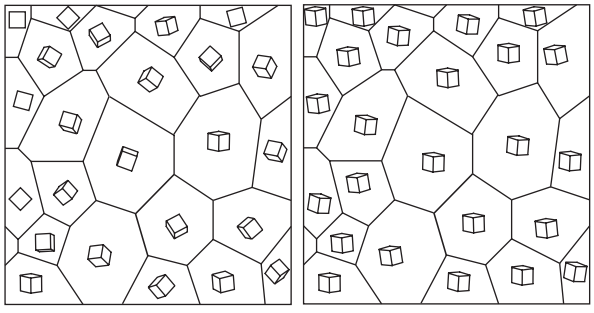

Figure 2 Schematic of a polycrystal with a random texture and a polycrystal with a strong texture.

If a polycrystal is composed of grains where the crystal lattices are all in similar orientations, then the properties of the polycrystal would mimic the inherent anisotropy of the constituent crystals. If the grains were all oriented randomly, then the properties of the polycrystal would not reflect the anisotropy of the constituent crystals, but would instead be isotropic (i.e., the properties would not vary with direction) (**Figure 2**).

Real polycrystals may vary between these two extremes depending on the processing route used to form the material. The terms crystallographic texture, orientation texture, or simply texture are used to describe the statistical distribution of grain orientations (the terms lattice preferred orientation (LPO) or fabric are also used within the geological community). In fact, the term grain (in most cases) generally describes a spatial domain where the orientation of the crystal lattice is the same or at least very nearly the same. A grain boundary is then an interface between two crystal lattices of different orientation.

As nearly all materials forming processes produce textured materials, the characterization of texture is an important element to understanding the relationship between microstructure and properties as well as the evolution of microstructure during processing. This article reviews the definition of crystallographic orientation and graphical representations of orientations, techniques for the measurement of texture, the mathematical formalism used in processing texture data, and a few examples of texture analysis.

Crystallographic Orientation

Orientation Descriptions

In order to describe a crystallographic orientation, two coordinate systems must be defined: one for the sample, referred to as $\boldsymbol{X}^{\mathrm{S}}$ and one for the crystallite, $\boldsymbol{X}^{\mathrm{C}}$ (**Figure 3**). The choice of sample axes is somewhat arbitrary; however, the choice usually follows

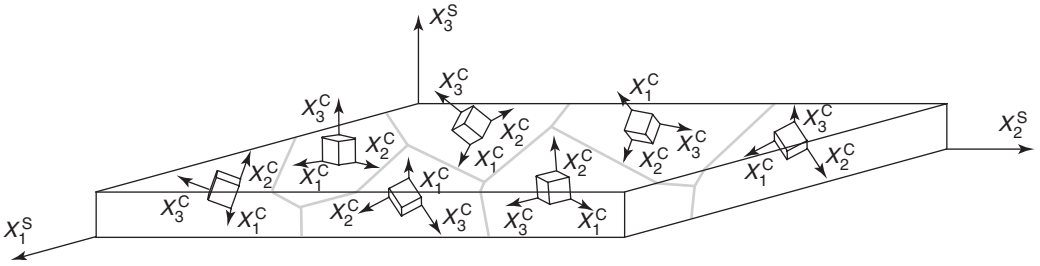

Figure 3 Schematic of the coordinate system fixed to the sample, $\boldsymbol{X}^{\mathrm{S}}$ and the coordinate system fixed to the crystals, $\boldsymbol{X}^{\mathrm{C}}$.

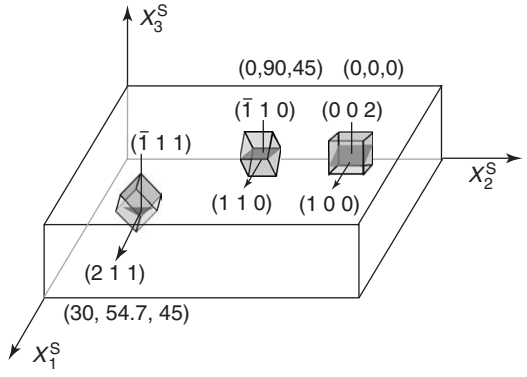

Figure 4 Two equivalent descriptions of crystallographic orientation: Euler angles and standard plane normal and crystal direction notation (i.e., (*hkl*)[*uvw*]).

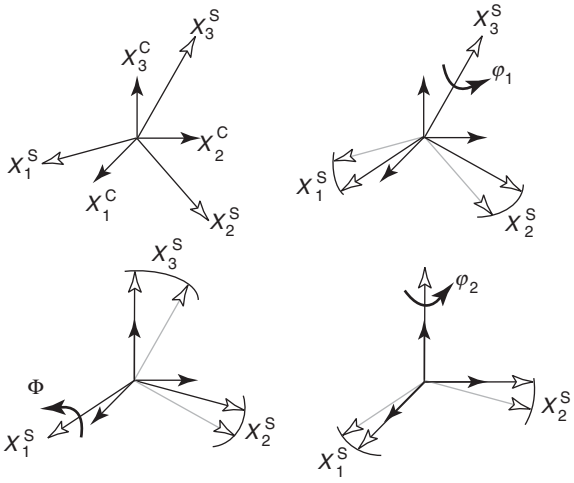

Figure 5 Schematic showing the definition of the three Euler angles, φ_1, Φ, φ_2.

the sample shape or processing used to form the sample. For example, consider a coupon obtained from a rolled sheet. It is common to assign X_1^S to the rolling direction, X_2^S to the transverse direction, and X_3^S to the sample normal direction. The coordinate system for the crystallite generally follows that traditionally used in defining the unit cell, that is, X_1^C is assigned to the [1 0 0] crystal direction, X_2^C to [0 1 0], and X_3^C to [0 0 1]. Both coordinate systems are right-handed Cartesian coordinate systems. While the assignment of the reference frame to a cubic crystal, as given here, is fairly straightforward, the assignment is less straightforward for other crystal systems such as hexagonal ones. Nonetheless, a Cartesian system can be assigned, for example, for a hexagonal crystal the convention is $X_1^C || [2\,\bar{1}\,\bar{1}\,0]$, $X_2^C || [0\,1\,\bar{1}\,0]$, and $X_3^C || [0\,0\,0\,1]$.

There are many ways to describe the orientation of a crystal with respect to the coordinate system of a sample. The most common is the (*hkl*)[*uvw*] notation where (*hkl*) are the Miller indices of the plane perpendicular to the sample normal (generally X_3^S) and [*uvw*] describes the crystal direction parallel to X_1^S (**Figure 4**). However, as integers are used, this description is not as convenient for describing any arbitrary orientation. In texture analysis, a common way to describe the orientation of the crystal lattice with respect to a sample reference frame is to use three Euler angles (**Figure 5**). In this case, the Euler angles describe three successive rotations that bring the sample reference frame into coincidence with the crystal reference frame.

The various descriptions are equivalent and can be converted from one description to another. A matrix, ***g***, can also be used to describe the orientation. It can be derived from the Euler angles according to

$$\begin{bmatrix} \cos\varphi_1\cos\varphi_2 - \sin\varphi_1\sin\varphi_2\cos\Phi & \sin\varphi_1\cos\varphi_2 + \cos\varphi_1\sin\varphi_2\cos\Phi & \sin\varphi_2\sin\Phi \\ -\cos\varphi_1\sin\varphi_2 - \sin\varphi_1\cos\varphi_2\cos\Phi & -\sin\varphi_1\sin\varphi_2 + \cos\varphi_1\cos\varphi_2\cos\Phi & \cos\varphi_2\sin\Phi \\ \sin\varphi_1\sin\Phi & -\cos\varphi_1\sin\Phi & \cos\Phi \end{bmatrix} \quad [2]$$

The matrix representation is particularly useful for describing orientations in computer algorithms.

The rotation of the sample reference frame into coincidence with the crystal reference frame is termed a passive rotation. Conversely, rotating the crystal reference frame into coincidence with the sample reference frame is termed an active rotation.

Symmetry

The three Euler angles form a bounded space: $0 \leqslant \varphi_1 < 2\pi,\ 0 \leqslant \Phi < \pi,\ 0 \leqslant \varphi_2 < 2\pi$. As most crystals exhibit some degree of symmetry, for any given crystallographic orientation, there exist other symmetrically equivalent orientations. For example, consider a material with cubic crystal symmetry. There are 24 symmetry elements for a cube: the fourfold rotations about axes normal to the faces of the cube (i.e., 90° rotations about the $\langle 0\,0\,1 \rangle$ crystal directions), the twofold rotations about the face diagonals

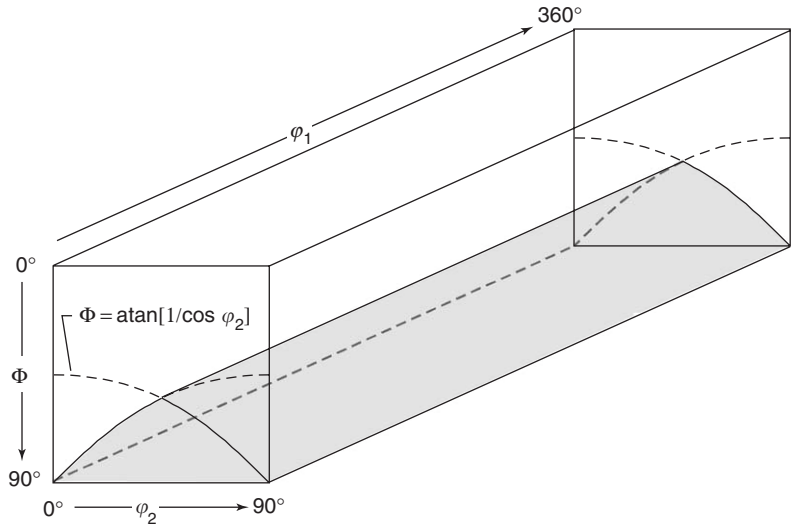

Figure 6 The asymmetric domain for cubic crystal symmetry.

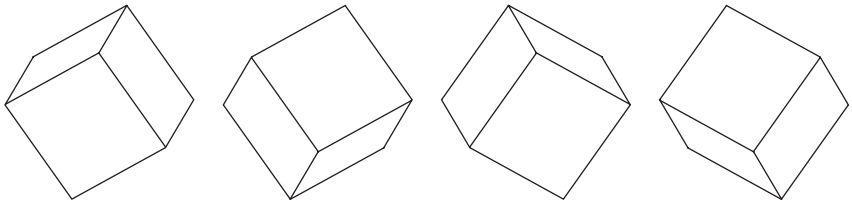

Figure 7 Four orthotropically equivalent orientations.

(180° rotations about $\langle 1\,1\,0 \rangle$), and the threefold rotations about the body diagonals (120° about $\langle 1\,1\,1 \rangle$). Thus, for any orientation of a cubic crystal, there are 24 equivalent orientations within the Euler space. A space can be defined within Euler space containing only asymmetric orientations. This subspace is termed the asymmetric domain or fundamental zone (**Figure 6**). Since texture is a statistical distribution of orientations, another type of symmetry must also be considered, namely, sample symmetry. Sample symmetry arises from the symmetry inherent to the forming process. Consider, for example, the rolling of sheet metals. This forming operation has orthotropic symmetry. For a rolled cubic material, the four orientations shown in **Figure 7** would appear with the same statistical frequency in the microstructure. Thus, the term statistical symmetry is a more accurate description. If the matrix notation is used, then the symmetry operations can be applied as follows:

$$\boldsymbol{g}^{\text{e}} = \boldsymbol{L}_i \boldsymbol{g} \boldsymbol{R}_j \qquad [3]$$

where $\boldsymbol{g}^{\text{e}}$ denotes an equivalent orientation, $\boldsymbol{L}_i$ is one of the crystal symmetry elements, and $\boldsymbol{R}_j$ is one of the statistical symmetry elements. Because of the form of this relation, the crystal symmetry is sometimes referred to as left-handed symmetry, and the statistical symmetry as right-handed.

Graphical Descriptions

Pole figures can be used to provide a graphical representation of orientation. A pole figure is a two-dimensional graphical representation of orientation, showing the orientation of a selected plane normal (a pole) with respect to the sample reference frame. The pole is a vector in three-dimensional space. If one imagines a hemisphere surrounding a crystal unit cell, then a pole would intersect the hemisphere at some location in three-dimensional space. The intersection location can be projected into a two-dimensional plot using a variety of projection schemes. An example of a pole figure is shown in **Figure 8**, this pole figure shows the $(0\,0\,0\,1)$ and $(1\,0\,\bar{1}\,0)$ poles for a hexagonal crystal, note that there is only one pole for the $(0\,0\,0\,1)$ plane and three for the $(1\,0\,\bar{1}\,0)$ plane. The additional poles in the $(1\,0\,\bar{1}\,0)$ case arise from crystal symmetry. In the pole figures, poles from the negative hemisphere are shown in gray.

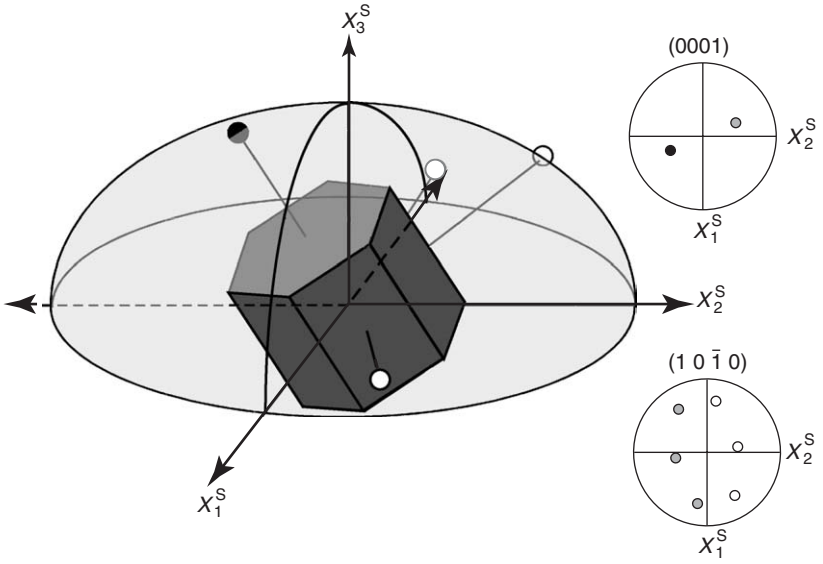

Figure 8 Schematic showing the orientation of a hexagonal crystal and the corresponding (0 0 0 1) pole figure.

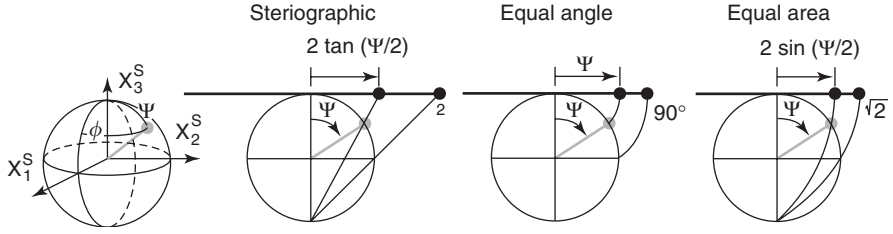

Figure 9 Stereographic, equal-angle, and equal-area pole figure projections.

Displaying the negative poles is sometimes referred to as including inversion symmetry. **Figure 9** shows three common "projection schemes" found in the literature (the equal angle is not a true projection; but, rather, a mapping of the polar angle).

A complement to the pole figure is the inverse pole figure. An inverse pole figure shows the location of a sample direction relative to the crystal reference system. For pole figures the plane of interest is selected, whereas in inverse pole figures the sample direction of interest is selected. It is a bit more intuitive to think of an inverse pole figure as showing which plane normal in the crystal is parallel to the selected sample direction. **Figure 10** shows an example. In this case, it shows the poles aligned with the sample normal for three different orientations as well as the poles aligned with the X_1^S sample direction. Because of crystal symmetry, the full circle need not be displayed; only the asymmetric portion is needed.

While pole figures and inverse pole figures are useful representations of orientations, they only provide a partial description of orientation. For example, consider the (0 0 0 1) pole figure shown in **Figure 8**. While the orientation of the (0 0 0 1) pole is known, the rotation of the crystal about this pole is unknown. A second pole figure (such as the (1 0 $\bar{1}$ 0)) is needed to completely fix the orientation. When the orientations of many crystallites are displayed, the use of multiple pole figures is quite limited. In this case, it is more productive to show the orientations in constant angle sections of the Euler space. **Figure 11** shows 30 000 discrete orientations from rolled copper in a portion of the Euler space along with the corresponding (1 1 1) pole figure.

Misorientation

To this point, the orientation of a crystal has been described relative to the sample coordinate system. However, the orientation of one crystal could also be described relative to the coordinate system associated with a neighboring crystal. Such a description is often denoted a misorientation (or alternatively, a disorientation or orientation difference). While misorientations can be described similar to orientations, that is, in terms of the Euler angles or matrices, it is

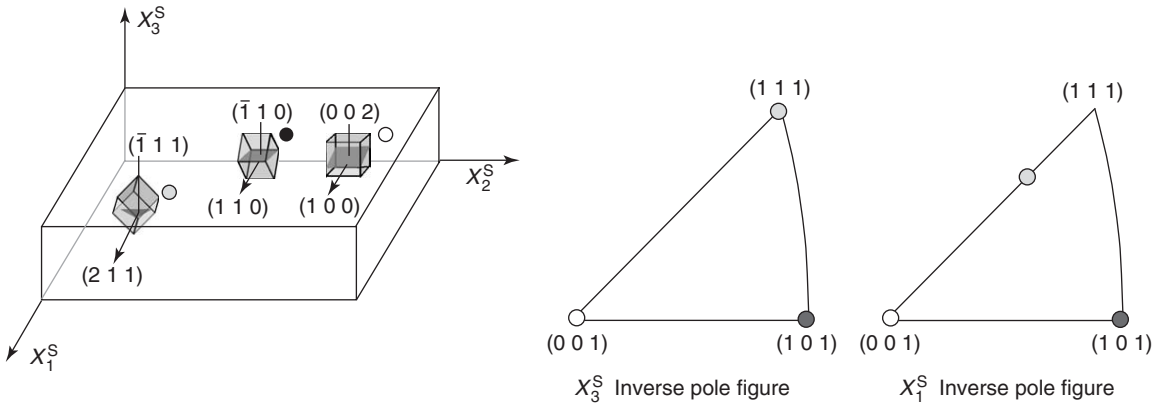

Figure 10 Schematic showing the representation of orientation in inverse pole figures.

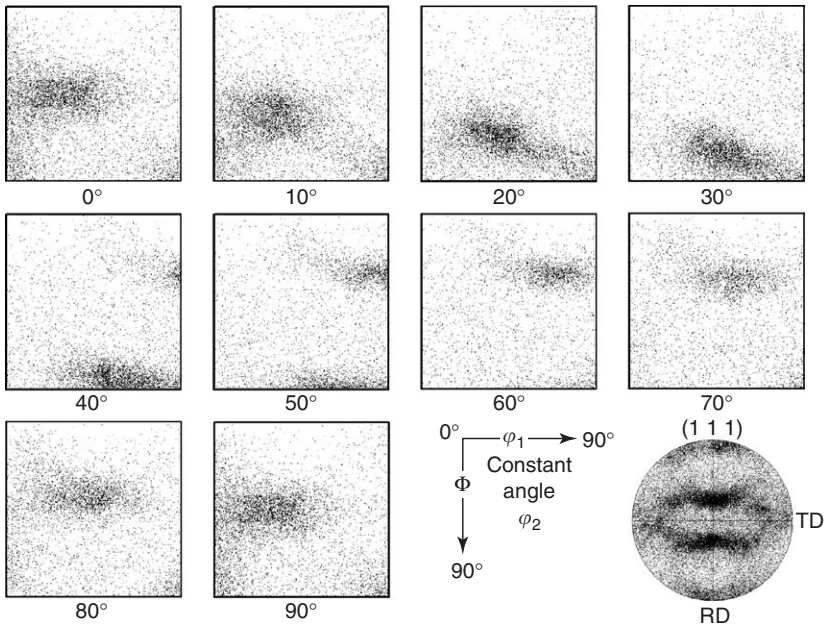

Figure 11 Plot of 30 000 discrete orientations from rolled copper in constant-angle sections through Euler space accompanied by a (1 1 1) pole figure of the same data.

usually more convenient to describe them in terms of axis–angle pairs. For two crystals in any two orientations, it is always possible to find a common axis around which one crystal can be rotated until it is in coincidence with the other. The misorientation can thus be described as a rotation about the common axis. As with orientations, crystal symmetry plays a role in the description of misorientations. For example, for a crystal with cubic symmetry there are 24 symmetrically equivalent orientations. Thus for a misorientation between two cubic crystals, there are 576 (24×24) symmetrically equivalent misorientations. This is realized in the axis–angle space as essentially 24 axes of rotation, each with a specific angle of rotation associated with it and 24 different permutations of the indices describing the axes. Generally, the angle of a permutation with minimum misorientation is used to describe the misorientation.

Texture Measurement Techniques

X-Ray Diffraction

There are essentially two ways of measuring textures, measuring pole figures or measuring the orientations of individual grains. Until recently, most textures have been measured using pole figures obtained by X-ray or neutron diffraction. The governing equation for a pole figure is Bragg's law:

$$\lambda = 2d_{hkl} \sin \theta \qquad [4]$$

where λ is the wavelength of the X-rays, d_{hkl} is the interplanar spacing of the pole figure to be measured (recall that the pole is the normal to a (hkl) plane), and θ is the Bragg angle as shown in **Figure 12**. In a pole figure measurement, a sample is placed in a goniometer so that the sample can be rotated while under the X-ray beam. For each rotation (in both Ψ and ϕ as shown in **Figure 12**), the signal from those grains satisfying Bragg's law is measured as shown in **Figure 13**. An intensity value is measured at successive tilts (Ψ) and rotations (ϕ) of the sample. This is typically done for a series of pole figures. For example, for a base-centered cubic material, the (1 1 0), (2 0 0), and (1 1 2) pole figures are typically measured. A similar approach is employed for neutron diffraction. The major difference is that X-ray pole figures are typically measured in a reflective mode, whereas neutron diffraction is done in transmission. Thus, neutron measurements have the advantage of providing a volumetric measure of texture, whereas the signal for X-rays comes from the surface of the sample. Various corrections must be applied to the pole figures to account for defocusing and absorption effects.

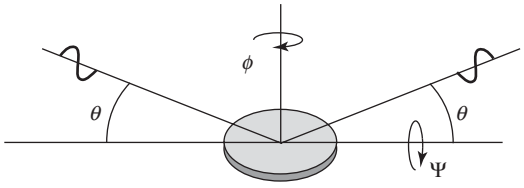

Figure 12 Diagram showing the pole figure measurement geometry.

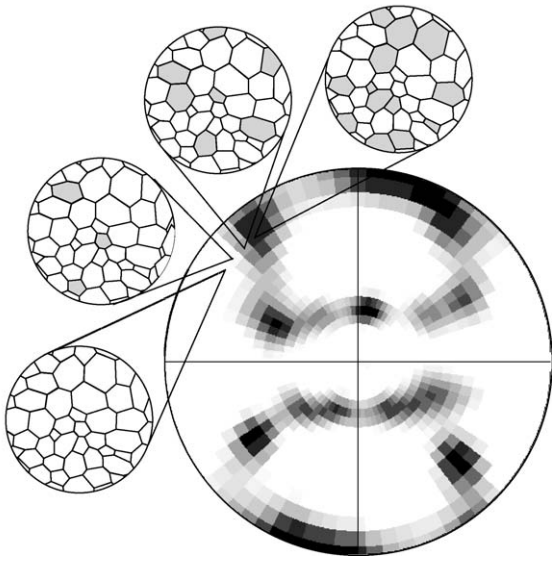

Figure 13 Schematic showing grains satisfying the Bragg condition for successive 5° rotations about the sample normal (ϕ).

Electron Backscatter Diffraction

In the last decade, the automation of electron backscatter diffraction (EBSD) in the scanning electron microscope (SEM) has made it practical to measure textures using the orientations of individual grains. Other methods for measuring individual orientations exist, including using X-rays from synchrotron radiation, optical microscopy using etch pits, or selected area or Kikuchi diffraction patterns in the transmission electron microscope. However, EBSD has become the most practical method for texture measurements via individual orientations.

In EBSD, a highly tilted sample ($\sim 70^\circ$) is placed in the SEM. When a stationary electron beam impinges on a grain in the sample, a diffraction pattern is generated as shown in **Figure 14**. The pattern is a function of the orientation of the lattice within the diffracting volume. As the beam is moved from grain to grain, the diffraction pattern changes.

The pattern is imaged on a phosphor screen and transmitted to a computer using a high-gain camera, typically a CCD camera. The orientation of the lattice in the diffracting volume can be derived from the pattern. This can be done automatically in the computer. The computer also controls the location of the beam on the sample. Typically, the beam is stepped across the sample to form a regular scan grid. An orientation measurement is made at each point in the grid (**Figure 15**). This process is fully automated and current rates exceed 50 measurement points per second. Despite the rapid measurement provided by automation, EBSD does not generally sample as

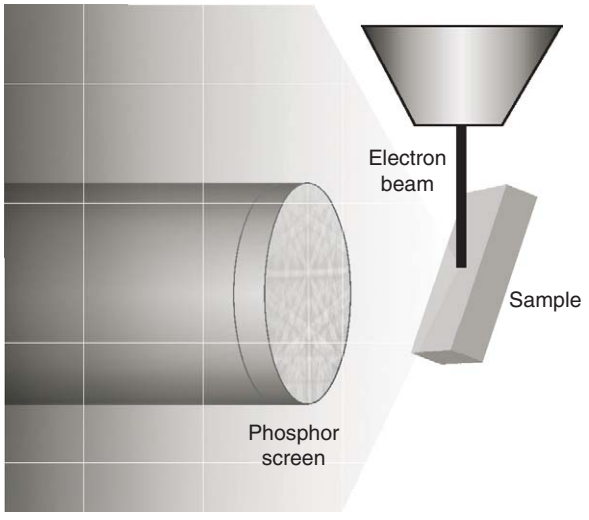

Figure 14 Schematic of EBSD.

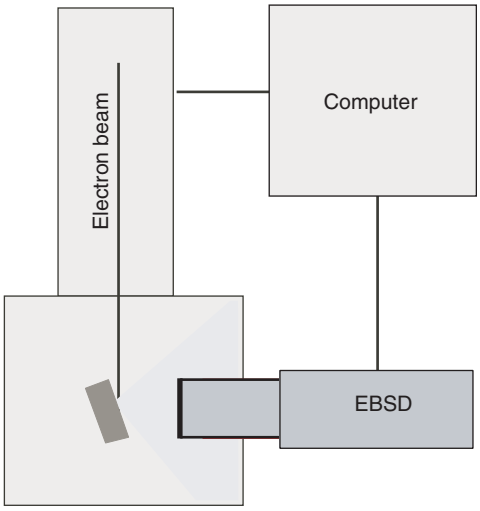

Figure 15 Schematic of automated EBSD.

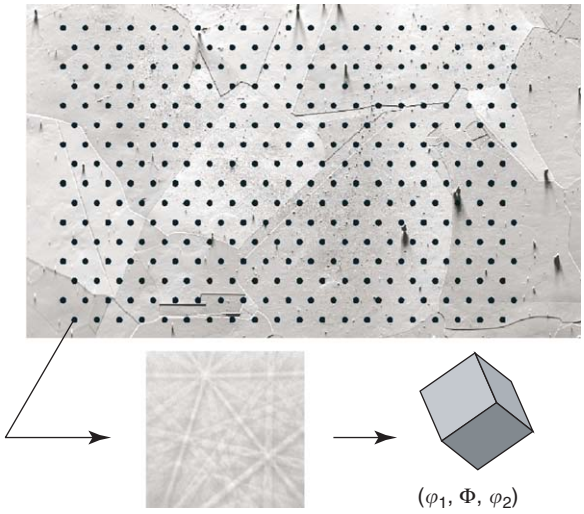

Figure 16 Schematic of the determination of the ODF from individual orientation measurements.

many grains as the conventional X-ray pole figure technique. However, EBSD has the advantage of spatially specific measurements of orientations allowing not only the distribution of orientations to be characterized, but misorientations and local texture gradients as well.

Mathematical Constructs

Basic Equation

The basis of texture analysis is the orientation distribution function or ODF. The ODF is a probability density function describing the probability of finding a grain with an orientation, g, within a given angular distance, Δg, of a specified orientation, g_o, in a polycrystal; or, alternatively, the volume fraction of material oriented within Δg of g_o. These two descriptions are related through the following equation:

$$\frac{\Delta V_{(g_o+\Delta g)}}{V} = \oint_{g\in(g_o+\Delta g)} f(g)\,\mathrm{d}g \qquad [5]$$

where the quantity to the left of the equals sign is the volume fraction of material oriented within Δg of g_o, and the function $f(g)$ is the ODF. It should be noted that the following condition must be met for a density function:

$$\oint f(g)\,\mathrm{d}g = 1 \qquad [6]$$

where the integration is carried out through all of the orientation space. The ODF gives the probability of finding a grain in a polycrystal with a specific orientation. If, for example, $f(g)$ is 3, then the chance of finding a grain with orientation, g, would be three times greater than that expected in a polycrystal with a random distribution of orientations.

The objective of texture analysis is to process the pole figures or the individual orientation measurements to determine the ODF. It is easiest to conceptualize the ODF determination using the individual orientation measurements. Consider a set of orientation measurements, where the orientations can be described as points on a number line as shown schematically in **Figure 16**. If the line is partitioned into a finite set of bins, then the number of orientations in each box can be counted and a histogram constructed as shown. A curve can then be fit to the histogram. The resulting curve is essentially the ODF.

It should be noted that the distribution of orientations shown schematically in **Figure 16** could be described using other distributions as shown in **Figure 17** depending on the size of the bins used to form the histogram. The choice is somewhat arbitrary; however, the choice can depend on the property being studied. For example, elastic anisotropy could be studied using the lower-order curve, whereas piezoelectricity requires a higher-order description of texture.

While there are multiple methods of performing the data reduction from the pole figures or discrete orientation data, two have emerged as the most common: the so-called harmonic and the WIMV methods. The WIMV (an acronym formed from the names of the originators of the technique) is essentially a binning method as outlined previously, whereas the harmonic method uses a series expansion approach, converting the orientation measurements directly to an ODF.

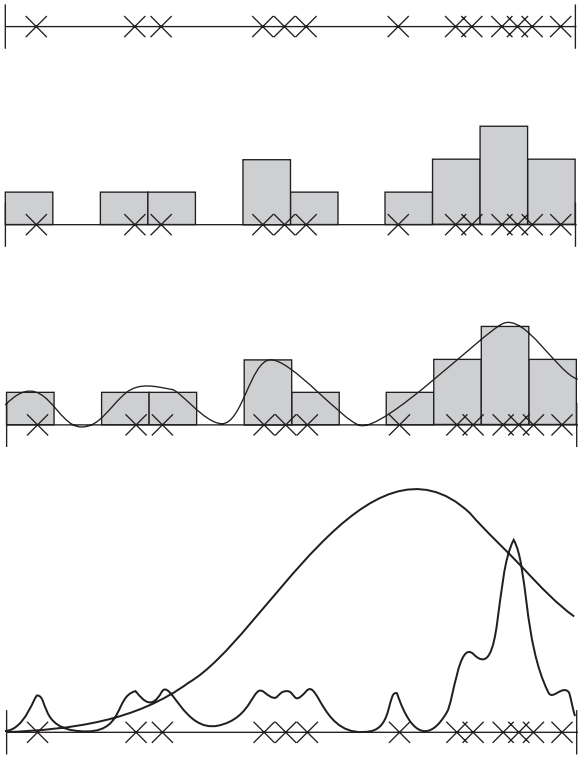

Figure 17 Schematic showing lower- and higher-order descriptions of the texture shown in **Figure 16**.

WIMV Method

A pole figure can be derived through integration of the ODF along a specific path in the orientation space according to

$$P_h(\boldsymbol{y}) = \frac{1}{2\pi}\int_{h\|y} f(g)\ \mathrm{d}\chi \qquad [7]$$

where $P_h(\boldsymbol{y})$ is the pole figure, $\boldsymbol{h}$ represents the (hkl) of the pole figure (a vector in the crystal reference frame), $\boldsymbol{y}$ is a vector in the pole figure (i.e., a vector in the sample reference frame represented by the rotation and tilt angles, ϕ and Ψ introduced previously). The integration is carried out along the path, χ, where $\boldsymbol{h}$ and $\boldsymbol{y}$ are coincident.

Pole figures are measured on discrete grids (typically 5° steps in ϕ and Ψ). If the ODF is also discretized into an array (e.g., in 5° steps in φ_1, Φ, and φ_2), then a matrix can be determined using an iterative process relating the intensities at the grid points in the measured pole figures with the ODF through eqn [6]. The mapping of the pole figure measurement grid to the ODF array is not one-to-one; thus, some interpolation techniques must be employed. One nice feature of this technique is that the resulting ODF is "smoothed" to the same degree as the measured pole figures. Thus a choice of the degree of smoothing to be applied is not required as in the other methods. The smoothness of the pole figure measurements is a function of the grid selection as well as the experimental setup (e.g., slit sizes).

Analogous to the WIMV pole figure inversion procedure, the ODF can be calculated from single orientation measurements using a binning approach. The Euler space is divided up into bins (e.g., $5^\circ \times 5^\circ \times 5^\circ$). For each orientation in the set, the corresponding bin is incremented. In addition, the symmetrically equivalent bins must also be incremented. Once all orientations have been accounted for, the values in the bins must be modified so that the normalization condition in eqn [5] is satisfied. Generally, the ODF is smoothed using a Gaussian filter. One of the challenges of this technique is the ambiguity of the Euler space at $\Phi = 0^\circ$. At $\Phi = 0$, φ_1 and φ_2 are not fully defined but rather governed by $\varphi_1 + \varphi_2 = C$. The volume of the bins vary as a function of Φ, bins centered on $\Phi = 2.5^\circ$ have a volume of $0.044\,\mathrm{rad}^3$, and bins centered on $\Phi = 87.5^\circ$ have a volume of $0.999\,\mathrm{rad}^3$ assuming they are $5^\circ \times 5^\circ \times 5^\circ$ bins. In addition, artifacts can arise simply due to the artificial boundaries introduced in the ODF by the binning technique. Lower- and higher-order descriptions of the ODF can be achieved through smoothing or by adjusting the size of the bins.

Harmonic Method

The ODF can be described by a series of generalized spherical harmonics (similar to the Fourier series expansion method used in many areas of physics). There are various ways of performing the series expansion, the most common method is that introduced by Bunge, namely,

$$f(g) = \sum_{l=0}^{\infty}\sum_{m=-l}^{l}\sum_{n=-l}^{l} C_l^{mn} T_l^{mn}(g) \qquad [8]$$

where the $T_l^{mn}(g)$ are the spherical harmonic functions and are known. The C_l^{mn} coefficients are a function of the texture, and can be calculated from pole figures or individual orientation measurements. If the crystal and statistical symmetries are enforced on the calculation, then the number of C_l^{mn} coefficients is greatly reduced. For an expansion carried out to $l = 22$, a sample with cubic crystal symmetry and orthotropic sample symmetry would have 179 coefficients compared to 16 215 coefficients if the symmetry is not applied.

Pole figures can be calculated from the C coefficients using a series of spherical surface harmonics

according to

$$P_{h_i}(\boldsymbol{y}) = \sum_{l=0}^{\infty} \frac{4\pi}{2l+1} \sum_{m=-l}^{l} \sum_{n=-l}^{l} C_l^{mn} k_l^{*m}(\boldsymbol{h}_i) k_l^n(\boldsymbol{y}) \quad [9]$$

where $\boldsymbol{h}_i$ represents the (hkl) of the ith pole figure (a vector in the crystal reference frame), $\boldsymbol{y}$ is a vector in the pole figure (i.e., a vector in the sample reference frame represented by the rotation and tilt angles, ϕ and Ψ introduced previously), and the k functions are spherical surface harmonics. Since the surface harmonics and the pole figures are known quantities, the C coefficients can be obtained by finding the solution to a large number of linear equations.

The calculation of the coefficients using single orientation measurements is somewhat simpler, namely,

$$C_l^{mn} = \frac{2l+1}{N} \sum_{i=1}^{N} K T_l^{mn}(g_i) \quad [10]$$

where g_i represents one orientation from a set containing N individual orientation measurements. K is a smoothing factor. If single orientation measurements are made where only one measurement per grain is recorded, then a weighting factor proportional to the grain area must also be introduced.

One disadvantage of the harmonic method is the presence of negative values in the ODF. Negative values are not allowed for density functions but can arise from the series expansion, particularly when the textures are very sharp. As with any series expansion, truncation errors arise. However, the rank (l) of the series expansion has some correlation to physical properties. For example, the elastic constants of a crystal can be described using a fourth-order tensor. Thus, for characterizing elastic anisotropy arising from texture, the harmonic series need only be expanded out to $l = 4$.

The choice of the degree of the Gaussian smoothing is somewhat arbitrary. Generally, it is assumed that a sharper texture requires a smaller filter (say, 1–2°), whereas larger values (say 5–10°) are suggested for more random distributions. In addition, the greater the orientation measured, the smaller the Gaussian can be as well. Some comparisons between X-ray data and EBSD data suggest a value of 7.5°. However, with the increased speed in modern EBSD systems, larger data sets are being measured and therefore smaller values of 3–5° are now more appropriate.

Examples

Thin Films

Thin films are typically characterized by the alignment of a particular crystallographic axis with the sample normal. **Figure 18** shows a (1 1 1) pole figure for an aluminum thin film. The axisymmetric character of this material is sometimes called a (1 1 1) fiber texture. Some thin film properties (such as, the mean time to failure in microelectronic devices) have been correlated to the sharpness of the fiber texture. An axisymmetric texture can be more simply analyzed by a pole plot as shown in **Figure 18**. The pole plot is essentially a slice through the pole figure as shown. For more accurate results, the pole plot can be improved by averaging azimuthally.

While the pole plot is helpful for analyzing thin film textures, calculating the pole figures to verify that the texture is truly axisymmetric is always recommended. For example, in a copper thin film, a

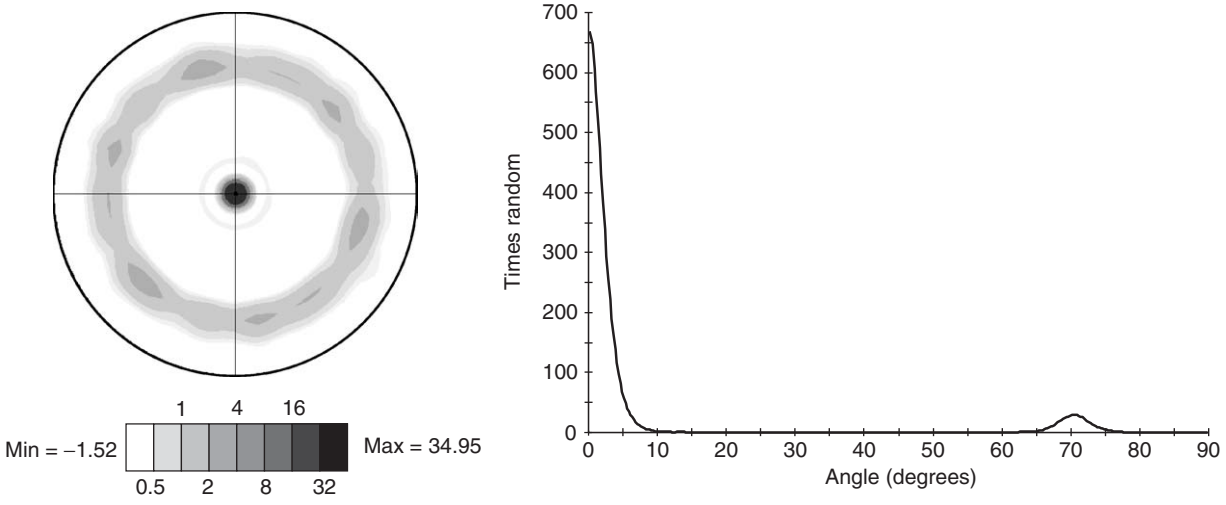

Figure 18 (1 1 1) pole figure and corresponding pole plot from an aluminum thin film.

(1 1 1) fiber texture is expected. However, other fibers may also be present. The axisymmetric nature of the texture can be confirmed using a pole figure, and the presence of other fibers discovered using an inverse pole figure as shown in **Figure 19**.

Rolled Sheet

One of the most studied materials using texture analysis is the rolled aluminum sheet for beverage cans. The texture of this material must be as well controlled as possible in order to produce stock well suited for the deep drawing of cans. Typical (1 1 1) pole figures for rolled aluminum are shown in **Figure 20**.

The bulk of the orientations typically lie within a "fiber" in the Euler space as shown in **Figure 21**. In order to simplify the analysis of rolled face-centered cubic materials such as aluminum, components associated with key locations along this fiber have been identified. These key components are shown in the Euler space and in a (1 1 1) pole figure.

A rolling texture can then be simply characterized by the intensities of these ideal components. This approach has been successfully used in developing thermomechanical processes to achieve textures that optimize the deep-drawing performance of beverage can stock.

P

Paramagnetism

P F de Châtel, New Mexico State University, Las Cruces, NM, USA

Paramagnetic materials do not order magnetically and have a positive magnetic susceptibility, which means the magnetization is pointing in the same direction as the magnetic field. Inevitably, there is also a diamagnetic susceptibility. The material is classified as paramagnetic if the sum of the two contributions is positive. Nevertheless, the paramagnetic susceptibility can be determined in both kinds of materials. In addition, the paramagnetic susceptibility of magnetically ordered materials (ferro-, ferri-, and antiferromagnets) above the transition temperature can be a subject of study.

In the most common paramagnetic materials, the response to an external magnetic field is due to the alignment of atomic magnetic moments under the torque exerted by the field. The potential energy of the moment $\boldsymbol{m}_{\mathrm{at}}$ in a field $\boldsymbol{B}$ is

$$V = -\boldsymbol{m}_{\mathrm{at}} \cdot \boldsymbol{B} \qquad [1]$$

The magnitude of the atomic moment is of the order of the Bohr magneton, $\mu_{\mathrm{B}} = e\hbar/2m_{\mathrm{e}} = 9.27\times 10^{-24}\ \mathrm{J\ T^{-1}}$, where e is the electron charge, $\hbar = h/2\pi$ the Planck constant, and $\boldsymbol{m}_{\mathrm{e}}$ the electron mass. Equation [1] shows that $\boldsymbol{m}_{\mathrm{at}}$ tends to align parallel to the magnetic field and the energy gained by alignment in a field of 1 T is $\sim 10^{-23}$ J, less than 1% of the thermal energy per degree of freedom, $\frac{1}{2}k_{\mathrm{B}}T$, at room temperature ($k_{\mathrm{B}}$ is the Boltzmann constant). At ambient temperature, in a regular electromagnet, one should not expect a substantial paramagnetic magnetization. On the other hand, if the moments are free, that is, no interaction hampers their rotation, lowering the temperature can reduce the thermal fluctuations, whereupon the paramagnetic susceptibility will increase. If none of the constituent atoms of a material has a magnetic moment, there can still be a paramagnetic moment, due to moments induced by the magnetic field. The resulting Van Vleck susceptibility is independent of temperature (see below).

The value of the atomic moment depends on the number of electrons and on their angular momentum. The filled shells of the ion cores and of fully ionized species, like O^{2-} or Cu^{+}, have zero angular momentum and hence no magnetic moment. The outermost electron shells are often but partially occupied and can carry a magnetic moment. However, in crystalline solids, these shells provide the delocalized Bloch states and contribute to the cohesive energy of the crystal. This requires a considerable overlap of the atomic wave functions on neighboring sites. The corresponding states are severely perturbed and cannot be labeled by the angular momentum quantum numbers ℓ and m_ℓ. In the case of transition metals, lanthanides, and actinides, under certain circumstances, there is a distinction between the outermost s and p states and the more localized states in the d and f shells, which are not fully occupied either. The former are responsible for the cohesion and determine the interatomic distances, while the latter remain localized and can form localized moments. This subtle division of electronic states makes transition and rare-earth metals and their compounds the most important ordered magnetic materials and also the strongest paramagnets.

A given number of d or f electrons will form a total angular momentum in accordance with Hund's rules, which require that (1) the total spin angular momentum S be as large as possible without violating the Pauli principle; (2) the total orbital angular momentum L be as large as possible without violating the Pauli principle and requirement (1); and (3) S and L be aligned antiparallel and form the total angular momentum, $J = |L - S|$, if the shell is less than half filled, and parallel, $J = L + S$, if it is more than half filled.

The hierarchy of the three rules of Hund reflects a hierarchy among the interactions involved. Of these, the exchange interaction, which favors the parallel-spin arrangement, rule (1), is the strongest. The preference for the alignment of orbital moments, rule (2), is dictated by the less important correlation energy, while the spin–orbit coupling, responsible for rule (3), is ineffective in transition metals and quite important in the rare earths. **Table 1** shows the ground states

following from the three rules for transition-metal ions in the conventional notation $(2S+1)X_J$, where $X = S$, P, D, and F stand for $L = 0$, 1, 2, and 3, respectively. Also shown are the effective moments, calculated for the $L-S$ coupled as well as spin-only states, which will be discussed below. **Table 2** gives the corresponding data for the tripositive rare-earth ions (H and I stand for $L = 5$ and 6, respectively).

If the quantum numbers of the ground state are known, the atomic magnetic moment can be calculated as $m_{\text{at}} = g_J \mu_{\text{B}} J$, where

$$g_J = 1 + \frac{J(J+1) + S(S+1) - L(L+1)}{2J(J+1)}$$

is the Landé g factor.

There is no classical analog of the above procedure of determining the magnitude of the atomic moments as there should not be one, considering that the Bohr–van Leeuwen theorem precludes orbital magnetism in a classical system. What is often referred to as the classical derivation of the paramagnetic magnetization is the application of classical statistics to the quantum mechanical objects $\boldsymbol{m}_{\text{at}}$. In the context of classical statistics, the partition function involves the potential energy (eqn [1]), where $\boldsymbol{m}_{\text{at}} \cdot \boldsymbol{B} = m_{\text{at}} B \cos \vartheta$, where ϑ is a continuous variable and integration is to be performed over φ and ϑ, the angular coordinates of the vector $\boldsymbol{m}_{\text{at}}$. In the proper quantum mechanical description, a summation over the possible values of the z component of $\boldsymbol{m}_{\text{at}}$ is required and the partition function takes the form

$$Z = \left(\sum_{M_J=-J}^{J} \exp(g_J \mu_{\text{B}} B M_J / k_{\text{B}} T) \right)^{N_{\text{at}}} \qquad [2]$$

where N_{at} is the number of atoms or ions. Summation of the geometrical series leads to

$$Z = \left(\frac{\sinh\left(g_J \mu_{\text{B}} B (J + 1/2)/k_{\text{B}} T\right)}{\sinh(g_J \mu_{\text{B}} B / 2 k_{\text{B}} T)} \right)^{N_{\text{at}}}$$

Deriving the free energy as $F = -(1/k_{\text{B}}T) \ln Z$ and using $M = (-1 \partial F / V \partial B)$, the magnetization is found in the form

$$M = \frac{N_{\text{at}}}{V} g_J \mu_{\text{B}} B_J (g_J \mu_{\text{B}} B)$$

where

$$B_J(x) = \frac{2J+1}{2J}\coth\frac{2J+1}{2J}x - \frac{1}{2J}\coth\frac{1}{2J}x$$

is the Brillouin function. For large values of J, $B_J(x)$ approaches the Langevin function, $L(x) = \coth x - 1/x$ which is the result of the classical treatment outlined above. The susceptibility is found to obey Curie's law,

$$\chi_C = \left(\frac{\partial M}{\partial H}\right)_{H=0} = \frac{N_{at}}{V}\mu_0\frac{(g_J\mu_B)^2 J(J+1)}{3k_BT} = \frac{C}{T} \quad [3]$$

where $\mu_0 = 4\pi \times 10^{-7}$ T mA^{-1} is the permeability of free space and the Curie constant, C, is implicitly defined by this equation. The Curie law is well obeyed by various salts and other compounds, where the atoms or ions carrying magnetic moments are far enough from each other, so that their interaction, the exchange interaction, is negligible. In these cases the effective magnetic moment, $\mu_{eff} = g_J\mu_B\sqrt{J(J+1)}$, can be determined from the slope of χ^{-1} versus T plots. In paramagnetic rare-earth materials, the measured μ_{eff} values agree with the Hunds rule values listed in **Table 2**. In most transition-metal oxides and salts, however, the μ_{eff} values calculated from the Hunds rule spin quantum numbers alone are closer to the measured values than the ones involving J, indicating that crystal fields are strong enough to suppress ("quench") the orbital angular moment. If the exchange interaction between magnetic moments is not negligible, the Curie–Weiss law, $\chi_{CW} \propto (T-\theta)^{-1}$, often holds. To account for the interaction, whose source was unknown at that time (1907), Weiss has introduced the molecular field H_m, which acts, in addition to the external field H, on each atomic magnetic moment. As H_m is supposed to describe the tendency of atomic moments to point in the same direction, it is assumed to be proportional with the magnetization, $H_m = \lambda M$. Substituting this expression in the expression for the magnetization in the total field,

$$M = \chi_C(H + H_m) = \frac{C}{T}(H + \lambda M)$$

the magnetization can be expressed as $M = \chi_{CW}H$ with

$$\chi_{CW} = \frac{\chi_C}{1 - \lambda\chi_C} = \frac{C}{T-\theta} \quad [4]$$

where $\theta = C\lambda$ is the paramagnetic Curie temperature. It is seen that the slope of χ_{CW}^{-1} versus T plots are determined by the effective moment the same way as in the case of the Curie law, but the straight lines representing the measured data do not go through the origin. Deviations from the straight-line behavior may be due to crystal fields.

In most metals, the effect of the crystalline environment is so strong that all couplings imposed by Hund's rules are broken and all but the ion-core electrons are delocalized. In rare-earth materials, the f electrons are localized and form magnetic moments conforming to Hund's rules. In insulators, the d electrons of transition-metal cations remain localized, but the spin–orbit coupling is broken and the orbital angular momentum itself is destroyed. The latter process is called the quenching of angular momentum, not a particularly enlightening term. What it stands for is that, the spherical symmetry around a particular ion being broken by its neighbors in the crystal, the stationary states are no more eigenstates of the angular momentum. Due to the symmetry of the crystalline environment, some degeneracy of the eigenstates may remain. However, if all matrix elements of the three components of the angular momentum, $\hat{L}_x$, $\hat{L}_y$, and $\hat{L}_z$, between the degenerate wave functions vanish, its expectation value vanishes for any linear combination of these functions; the angular momentum is "quenched." If that is not the case, the angular momentum may be partially quenched and can be described by an effective angular momentum operator working within the multiplet of the lowest-lying crystal-field level.

Partial or complete quenching of the orbital angular momentum influences the temperature dependence of the paramagnetic susceptibility if the temperature is high enough for the thermal energy k_BT to be comparable to the splitting between the lowest and next-to-lowest crystal-field levels. At temperatures exceeding Δ/k_B, Δ being the total splitting of the ground-state multiplet, the Curie or Curie–Weiss susceptibility is recovered with the effective moment appropriate to that multiplet.

Higher-lying crystal-field states can influence the paramagnetic susceptibility also at very low temperatures, $T \ll \Delta/k_B$. Even though the thermal occupancy of such states is negligible in this limit, the magnetic field will mix them into the ground state via the perturbing Hamiltonian (eqn [1]). Taking account of this perturbation to second order, the corresponding contribution to the susceptibility, the Van Vleck paramagnetic susceptibility, is found to be

$$\chi_{VV} = \frac{N_{at}}{V}\mu_0 2\sum_i \frac{\left|\int \psi_0^*(\hat{m}_{at})_z\psi_i d\tau\right|^2}{\varepsilon_i - \varepsilon_0} \quad [5]$$

independent of temperature. Here ψ_0,ψ_i are the wave functions and ε_0,ε_i the energies of the ground state and higher-lying crystal-field states, respectively. The

operator representing the atomic magnetic moment is

$$\hat{\boldsymbol{m}}_{\mathrm{at}} = \mu_{\mathrm{B}}(\hat{\boldsymbol{L}} + 2\hat{\boldsymbol{S}})$$

evidently not proportional to $\hat{J}$. Therefore, $(\hat{m}_{\mathrm{at}})_z$ has nonvanishing matrix elements between the Hund's rule ground state and higher-lying eigenstates of different J values as well. In fact, Van Vleck derived eqn [5] for that case, with ions having small spin–orbit splitting in mind. However, the term "Van Vleck susceptibility" is used with reference to any temperature-independent contribution to the paramagnetic susceptibility due to the quantum-mechanical admixture of higher-lying states.

As mentioned above, crystal-fields in insulators constitute a subtle effect, compared to the full delocalization of conduction electrons in metals. The consequence of the latter for the paramagnetic response is indeed drastic. The conduction electrons, instead of following the Curie law (eqn [3]) with $g = 2$ and $S = 1/2$, contribute only the Pauli paramagnetism, a small, temperature-independent susceptibility,

$$\chi_P = \mu_0 \mu_{\mathrm{B}}^2 \rho(\varepsilon_{\mathrm{F}}) \qquad [6]$$

where $\rho(\varepsilon_{\mathrm{F}})$ is the density of states per unit volume at the Fermi energy. It is indeed the Pauli principle that suppresses the $1/T$ divergence of χ: most of the electrons are unable to flip their spin, because the opposite-spin state of the same energy is occupied. Only the electrons in states with energies within $k_{\mathrm{B}}T$ from the Fermi energy are given the choice of m_{s} values implied by eqn [2]. As the density of such electrons is about $k_{\mathrm{B}}T\rho(\varepsilon_{\mathrm{F}})$, the temperature in the denominator of the Curie susceptibility is canceled out and eqn [6] can be seen to follow from eqn [3].

In the alkali metals, $\rho(\varepsilon_{\mathrm{F}}) \approx 10^{47}\ \mathrm{J}^{-1}\ \mathrm{m}^{-3}$ whence from eqn [6] $\chi_P \approx 10^{-5}$, in good agreement with the paramagnetic susceptibility derived from experiment. In transition metals, the density of states is about one order of magnitude larger, but even so, eqn [6] underestimates the paramagnetic susceptibility, which is enhanced by the exchange interaction between the d electrons. Like in the derivation of the Curie–Weiss law, here too the effect of this interaction can be described by the molecular field. The result,

$$\chi = \frac{\chi_P}{1 - \lambda\chi_P} \qquad [7]$$

is formally similar to eqn [4], but it should be noted that it is independent of temperature in this case. Equation [7] gives the exchange-enhanced paramagnetic susceptibility, $S = (1 - \lambda\chi_P)^{-1}$ is the Stoner enhancement factor. Among the transition metals, the largest value of S is observed in palladium, where $S = 10$.

Periodicity and Lattices

F J Lamelas, Boise State University, Boise, ID, USA

Lattices in Two and Three Dimensions

A lattice is a periodic array of points generated by translation vectors (quasiperiodic lattices are discussed separately later). As an example, consider a two-dimensional rectangular lattice generated by the orthogonal vectors $\boldsymbol{a}_1$ and $\boldsymbol{a}_2$ (**Figure 1**).

The lattice is assumed to be infinite in extent. Points on this lattice have position vectors

$$\boldsymbol{R} = n_1\boldsymbol{a}_1 + n_2\boldsymbol{a}_2 \qquad [1]$$

where n_1 and n_2 are integers.

Lattices can be classified according to their symmetry properties. For example, the rectangular lattice in **Figure 1** has reflection lines which pass through the vertical and horizontal rows of points, and twofold rotation points coincident with the lattice points. Additional symmetry elements occur between the lattice points, as shown in **Figure 2**.

According to the lattice condition, all points of the lattice must have the same environment; therefore, not all regular arrays of points are lattices. For example, in one dimension there is only one possible lattice: an array of equally spaced points, as shown in **Figure 3**.

If one classifies all two-dimensional lattices according to their symmetry elements, it is possible to show that there are only five distinct types, as shown in as **Figure 4**.

The translation vectors define the edges of unit cells which are building blocks of the lattice. In two dimensions, the shape of the unit cell is specified by three lattice parameters: the magnitudes a and b of the translation vectors, and γ, the angle between the vectors (the magnitudes of the translation vectors are typically defined as $a = |\boldsymbol{a}_1|$, $b = |\boldsymbol{a}_2|$, and, in three dimensions, $c = |\boldsymbol{a}_3|$).

The choice of the unit cell is by no means unique. One could, for example, double the unit cells of **Figure 4** and generate the same lattices. Unit cells containing only one lattice point are primitive; in this case, the positions of all lattice points can be written as integer sums of the translation vectors, as in eqn [1]. For the centered unit cell of **Figure 4c**, the lattice points at the centers are given by half-integer sums of the translation vectors:

$$\boldsymbol{R}_{\text{center}} = (n_1 + 1/2)\boldsymbol{a}_1 + (n_2 + 1/2)\boldsymbol{a}_2 \qquad [2]$$

Even primitive cells are not unique, since one could, for example, define an oblique primitive cell for the square lattice, as shown in **Figure 5**.

In general, the conventional unit cell is chosen so as to be as small as possible, consistent with the underlying symmetry of the lattice. For example, the centered rectangular lattice (**Figure 4c**) could be generated by an oblique primitive cell, but its symmetry elements are more obviously related to a rectangular unit cell (the symmetry elements of the

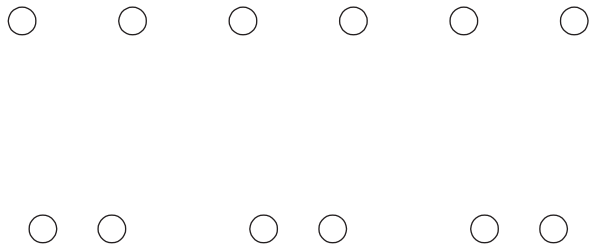

Figure 3 Two periodic one-dimensional arrays of points. The lower example does not satisfy the lattice condition since some points have their nearest neighbor on the right, and some on the left.

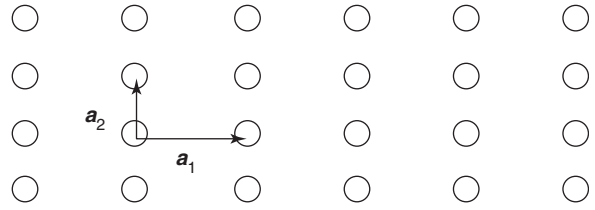

Figure 1 Rectangular lattice with translation vectors $\boldsymbol{a}_1$ and $\boldsymbol{a}_2$.

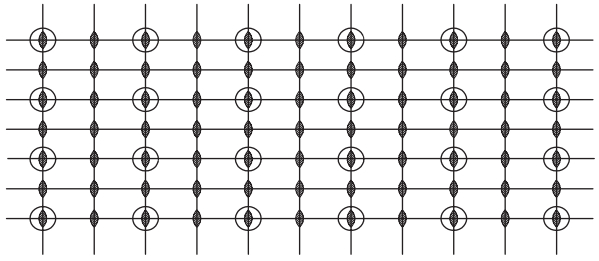

Figure 2 Symmetry elements of the rectangular lattice. The points of the lattice are indicated by open circles, reflection lines by solid lines, and twofold rotation points by lens-shaped symbols.

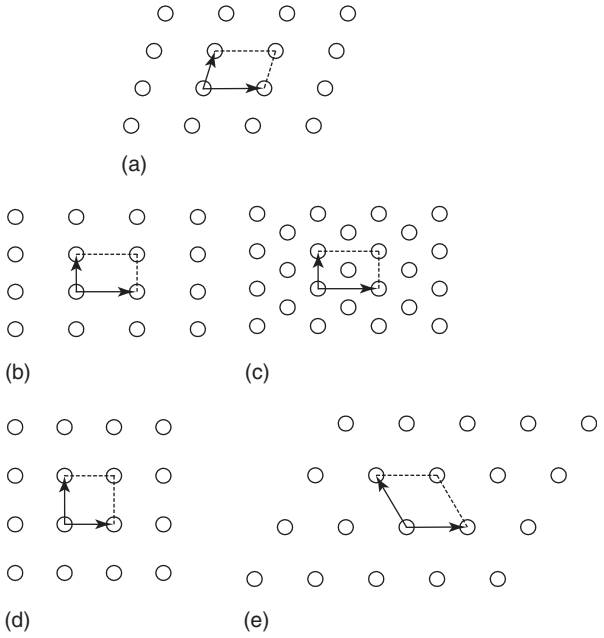

Figure 4 The five two-dimensional lattices: (a) oblique, (b) rectangular, (c) centered rectangular, (d) square, and (e) hexagonal. Outlines of unit cells are shown by the dashed lines. Except for (c), all of the unit cells shown here are primitive.

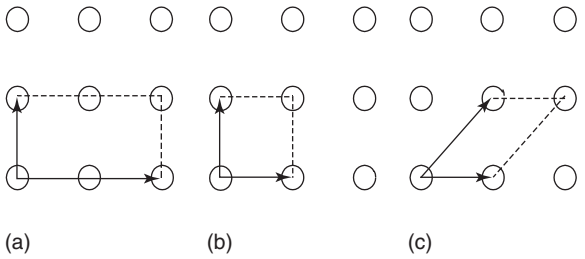

Figure 5 Several unit cells which can generate a square lattice, including (a) a nonprimitive cell containing two lattice points, (b) a conventional primitive cell, and (c) an oblique primitive cell. In counting the number of lattice points assigned to a cell, points at corners, on sides, and within the cell are given weights of 1/4, 1/2, and 1.

Table 1 The four two-dimensional systems

System	*Lengths*	*Angle* (°)
Oblique	$a \neq b$	$\gamma \neq 90$
Rectangular	$a \neq b$	$\gamma = 90$
Square	$a = b$	$\gamma = 90$
Hexagonal	$a = b$	$\gamma = 120$

centered rectangular lattice are identical to those of **Figure 2**, with additional twofold rotation points along the cell diagonal). In other words, symmetry considerations can lead one to choose a conventional cell that is larger than a primitive cell.

The two-dimensional lattices of **Figure 4** can be grouped within four systems based on the relative magnitudes of the translation vectors and the angle between them, as shown in **Table 1**.

Note that the number of lattices (five) is not equal to the number of systems (four), since there are two rectangular lattices (primitive and centered).

A periodic physical system such as a naturally occurring crystal can be described as a lattice with repeating units known as a basis attached to each lattice point. The basis may consist of a single atom, a molecule, or a larger assembly. The space group that characterizes the entire structure results from the combined symmetries of the lattice and the basis. Since bases with different symmetries can be attached to a given lattice, one expects a greater number of space groups than lattices. In two dimensions, there are 4 systems, 5 lattices, and 17 space groups. An example of two structures with the same lattice but different space groups is given in **Figure 6**.

Different space groups also arise according to the arrangement of asymmetric molecules on similar lattices. For example, if every other molecule is flipped after displacement along a lattice translation vector, then a glide-reflection symmetry element is produced. (In the glide-symmetry operation, the structure is translated along the glide line and then reflected across the line.) Examples of two space groups with and without glide symmetry are shown in **Figure 7**.

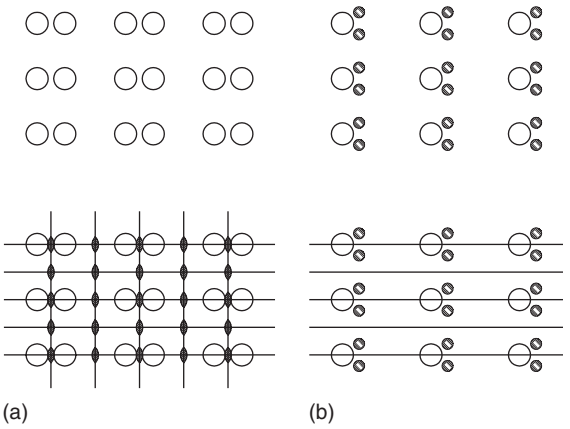

Figure 6 Upper drawings: two structures with identical rectangular lattices but different bases. Lower: the same structures repeated with symmetry elements superimposed. (a) Space group *p2mm*, indicating a primitive lattice (*p*) with twofold rotation points (2), and two sets of mirror lines (*mm*), (b) space group *pm*, indicating a primitive lattice with a single set of mirror lines.

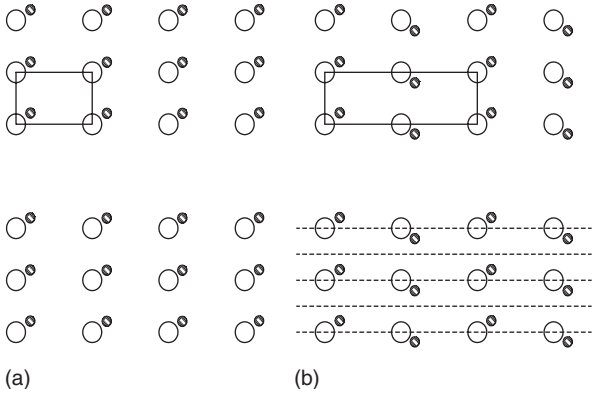

Figure 7 Upper drawings: arrangements of identical molecules with and without glide-line symmetry. Unit cells are shown by the solid rectangles. Lower: the same structures with symmetry elements superimposed. (a) Space group *p*1: primitive lattice with no rotational, mirror, or glide symmetry. (b) Space group *pg*: primitive lattice with glide-line symmetry. (Note: the unit cell contains two molecules but only one lattice point, and is therefore primitive.)

In three dimensions, lattices are generated by three translation vectors: $\boldsymbol{a}_1$, $\boldsymbol{a}_2$, and $\boldsymbol{a}_3$. It can be shown that there are 14 symmetrically distinct lattices which satisfy the lattice condition. These are the Bravais lattices; the conventional unit cells are shown in **Figure 8**. The shapes of the unit cells are characterized by six lattice parameters: the magnitudes a, b, and c of the translation vectors, and the angles α, β, and γ, shown in **Figure 9**.

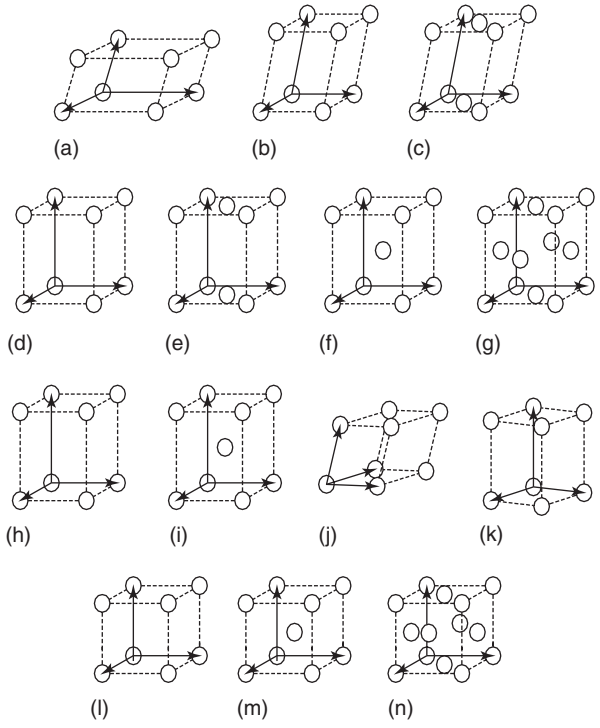

Figure 8 The 14 Bravais lattices, with lattice translation vectors shown as solid arrows. (a) triclinic, (b) monoclinic, (c) base-centered monoclinic, (d) orthorhombic, (e) base-centered orthorhombic, (f) body-centered orthorhombic, (g) face-centered orthorhombic, (h) tetragonal, (i) body-centered tetragonal, (j) trigonal, (k) hexagonal, (l) cubic, (m) body-centered cubic, and (n) face-centered cubic.

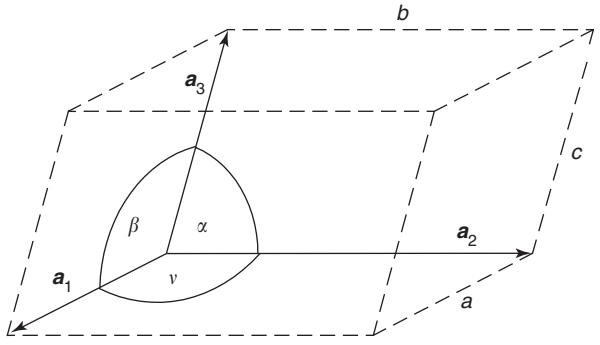

Figure 9 Three-dimensional lattice parameters. The lengths of the cell edges are the magnitudes of the translation vectors *a*, *b*, and *c*. The interaxial angles $\boldsymbol{a}_2 \wedge \boldsymbol{a}_3$, $\boldsymbol{a}_3 \wedge \boldsymbol{a}_1$, and $\boldsymbol{a}_1 \wedge \boldsymbol{a}_2$ are given by α, β, and γ.

The 14 Bravais lattices are distributed among seven crystal systems, with relative lattice parameters given in **Table 2**.

The combined symmetries of the 14 Bravais lattices and all possible bases lead to 230 space groups in three dimensions, first enumerated late in the nineteenth century and described explicitly in the International Tables for X-ray Crystallography. The classification of

Table 2 The seven three-dimensional crystal systems

System	*Lengths*	*Angles*
Triclinic	$a \neq b \neq c$	$\alpha \neq \beta \neq \gamma$
Monoclinic	$a \neq b \neq c$	$\alpha = \beta = 90^\circ \neq \gamma$
Orthorhombic	$a \neq b \neq c$	$\alpha = \beta = \gamma = 90^\circ$
Tetragonal	$a = b \neq c$	$\alpha = \beta = \gamma = 90^\circ$
Trigonal	$a = b = c$	$\alpha = \beta = \gamma \neq 90^\circ$
Hexagonal	$a = b \neq c$	$\alpha = \beta = 90^\circ,\ \gamma = 120^\circ$
Cubic	$a = b = c$	$\alpha = \beta = \gamma = 90^\circ$

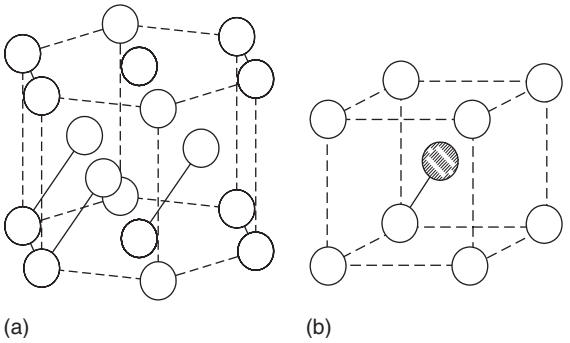

Figure 10 Examples of structures produced by adding a basis to a Bravais lattice. (a) h.c.p cobalt. Pairs of atoms in the basis are connected by solid lines. The dashed lines show the edges of a hexagonal repeating structure with three times the volume of the conventional unit cell of **Figure 8k**. (b) Cesium chloride. Open and filled circles represent oppositely-charged ions. The primitive cubic unit cell (also known as a simple cubic unit cell) is identical to that of **Figure 8l**.

periodic structures as members of specific space groups is important in predicting properties, such as allowed reflections in X-ray diffraction, and allowed vibrational modes in optical spectroscopy.

A three-dimensional crystal can be "constructed" by placing a specific basis at each of the points of one of the 14 Bravais lattices. In the simplest case, the basis consists of a single atom and the full structure is simply that of the Bravais lattice. An example is face-centered cubic (f.c.c.) aluminum, which has the unit cell shown in **Figure 8n**. As the complexity is increased, the basis can include more than one atom of the same element, as in hexagonal close-packed (h.c.p.) cobalt. In this structure, a basis consisting of two cobalt atoms is attached to the hexagonal lattice points, as shown in **Figure 10a**. In the case of compounds, the basis contains two or more elements, as in cesium chloride, where the two-ion basis is attached to a primitive cubic lattice, as in **Figure 10b**.

In all cases, it is the Bravais lattice (rather than the details of the basis) which determines the translational symmetry of the structure. That is, the crystal is invariant after a translation by a Bravais lattice vector, no matter what the basis is. This spatial

periodicity results in the great utility of Fourier methods, as shown in the next section.

The Reciprocal Lattice, Diffraction, and Electronic Band Structure

A signal which is periodic in time can be conveniently described in terms of the strength of its harmonics. The signal can be defined completely in either the time or the frequency domain, using variables which have dimensions of time or inverse time. Similarly, a property such as the electron density of a spatially periodic structure can be described directly, in a space which has dimensions of length, or by a Fourier expansion in reciprocal lattice vectors, which have dimensions of inverse length. Many of the properties of a solid, such as its electronic band structure, are formulated most easily in reciprocal space (rather than direct space). Even from a purely structural standpoint, the reciprocal-space description is essential in the diffraction techniques which are used to solve crystal structures.

If one wishes to use the reciprocal lattice in order to describe physical properties, it is useful to define the reciprocal lattice as follows (in crystallography, the definition of the reciprocal lattice may differ slightly from that given here, for example, by the omission of the factors of 2π). Consider a solid with lattice translation vectors $\boldsymbol{a}_1$, $\boldsymbol{a}_2$, and $\boldsymbol{a}_3$. The reciprocal lattice vectors are defined by

$$\boldsymbol{b}_1 = 2\pi \frac{\boldsymbol{a}_2 \times \boldsymbol{a}_3}{\boldsymbol{a}_1 \cdot \boldsymbol{a}_2 \times \boldsymbol{a}_3}, \quad \boldsymbol{b}_2 = 2\pi \frac{\boldsymbol{a}_3 \times \boldsymbol{a}_1}{\boldsymbol{a}_1 \cdot \boldsymbol{a}_2 \times \boldsymbol{a}_3}, \quad \boldsymbol{b}_3 = 2\pi \frac{\boldsymbol{a}_1 \times \boldsymbol{a}_2}{\boldsymbol{a}_1 \cdot \boldsymbol{a}_2 \times \boldsymbol{a}_3} \qquad [3]$$

The denominator of these expressions $(\boldsymbol{a}_1 \cdot \boldsymbol{a}_2 \times \boldsymbol{a}_3)$ is the volume of the unit cell in direct space. The vectors $\boldsymbol{b}_1$, $\boldsymbol{b}_2$, and $\boldsymbol{b}_3$ are the translation vectors which define the reciprocal lattice, just as $\boldsymbol{a}_1$, $\boldsymbol{a}_2$, and $\boldsymbol{a}_3$ define the Bravais lattice in direct space. An arbitrary translation vector, which connects two points of the Bravais lattice, has the form

$$\boldsymbol{R} = n_1\boldsymbol{a}_1 + n_2\boldsymbol{a}_2 + n_3\boldsymbol{a}_3 \qquad [4]$$

where n_1, n_2, and n_3 are integers. Similarly, an arbitrary reciprocal lattice vector can be written as

$$\boldsymbol{G} = m_1\boldsymbol{b}_1 + m_2\boldsymbol{b}_2 + m_3\boldsymbol{b}_3 \qquad [5]$$

The form of the numerators in eqn [3] leads to a compact expression for dot products between direct-space and reciprocal-space translation vectors. Note, for example, that $\boldsymbol{a}_2 \cdot \boldsymbol{b}_1 = \boldsymbol{a}_3 \cdot \boldsymbol{b}_1 = 0$, and $\boldsymbol{a}_1 \cdot \boldsymbol{b}_1 = 2\pi$. In general,

$$\boldsymbol{b}_i \cdot \boldsymbol{a}_j = 2\pi\delta_{ij} \qquad [6]$$

This implies that any function of the form $e^{i\boldsymbol{G}\cdot\boldsymbol{r}}$ will have the translational symmetry of the Bravais lattice, because, for an arbitrary lattice translation vector $\boldsymbol{R}$,

$$\begin{aligned} e^{i\boldsymbol{G}\cdot(\boldsymbol{r}+\boldsymbol{R})} &= e^{i\boldsymbol{G}\cdot\boldsymbol{r}} e^{i\boldsymbol{G}\cdot\boldsymbol{R}} \\ &= e^{i\boldsymbol{G}\cdot\boldsymbol{r}} e^{i(m_1\boldsymbol{b}_1+m_2\boldsymbol{b}_2+m_3\boldsymbol{b}_3)\cdot(n_1\boldsymbol{a}_1+n_2\boldsymbol{a}_2+n_3\boldsymbol{a}_3)} \\ &= e^{i\boldsymbol{G}\cdot\boldsymbol{r}} e^{2\pi i(m_1n_1+m_2n_2+m_3n_3)} = e^{i\boldsymbol{G}\cdot\boldsymbol{r}} \end{aligned} \qquad [7]$$

For a Bravais lattice where the translation vectors $\boldsymbol{a}_1$, $\boldsymbol{a}_2$, and $\boldsymbol{a}_3$ are all perpendicular (these are the orthorhombic, tetragonal, and cubic cases), the corresponding reciprocal lattice can be immediately determined by inspection of eqn [3]. In this case, $\boldsymbol{b}_1 \parallel \boldsymbol{a}_1$, and $b_1 = 2\pi/a_1$. Similar relations hold for $\boldsymbol{b}_2$ and $\boldsymbol{b}_3$, that is, the reciprocal-space translation vectors are parallel to those in direct space, with magnitudes which are inversely proportional.

If the direct-space lattice vectors are not all perpendicular, then the reciprocal lattice vectors are not, in general, parallel to them, because, for example, $\boldsymbol{a}_2 \times \boldsymbol{a}_3$ may not be parallel to $\boldsymbol{a}_1$. Nonetheless, the reciprocal lattice vectors still have a straightforward interpretation in terms of lattice planes.

Lattice planes are labeled using Miller indices, which are assigned by taking the reciprocal of the intersection of the plane with each of the direct-space axes, as shown in **Figure 11**.

In **Figure 11a**, the first (1 0 0) plane which does not contain the origin, intersects the x-axis at a distance a from the origin. The plane is also parallel to the y and z axes; intersections with those axes are at infinity. Taking the reciprocal of these distances in lattice-parameter units, one obtains the Miller indices $(hkl) = (1\,0\,0)$ for these planes. Similarly, in **Figure 11b** the intersections at (a, a, ∞) give $(hkl) = (1\,1\,0)$. In **Figure 11c**, the intersections are $(\infty, a, a/2)$, giving Miller indices $(hkl) = (0\,1\,2)$.

If h, k, and l are integers, it can be shown that in any of the crystal systems a reciprocal lattice vector of the form

$$\boldsymbol{G}_{hkl} = h\boldsymbol{b}_1 + k\boldsymbol{b}_2 + l\boldsymbol{b}_3 \qquad [8]$$

will be normal to the lattice planes with indices (hkl). The magnitude will be inversely proportional to the spacing of the planes, specifically,

$$\boldsymbol{G}_{hkl} = \frac{2\pi}{d_{hkl}} \qquad [9]$$

where d_{hkl} is the spacing of the (hkl) planes.

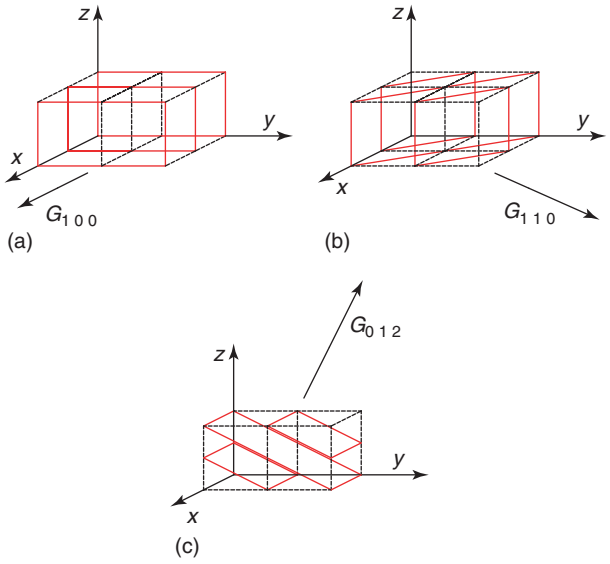

Figure 11 Several examples of sets of planes in a cubic crystal, including (a) (1 0 0) planes, (b) (1 1 0) planes, and (c) (0 1 2) planes. Unit cells are shown with dashed lines and the sets of planes are in red. The corresponding reciprocal lattice vectors are normal to the planes and have magnitudes inversely proportional to the plane spacing.

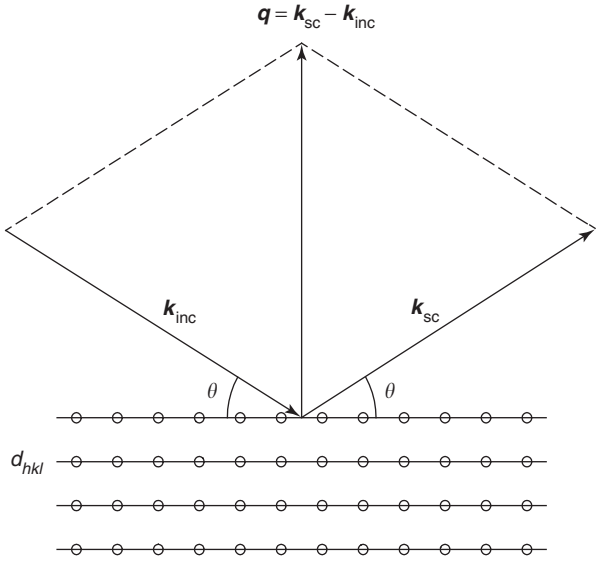

Figure 12 Bragg scattering geometry. A beam with wave vector $\boldsymbol{k}_{inc}$ is incident with angle θ upon a set of atomic planes with spacing d_{hkl}. The scattered wave vector is $\boldsymbol{k}_{sc}$ and the scattering vector is $\boldsymbol{q}$. The small circles represent atoms or lattice points in direct space.

The relationship between $\boldsymbol{G}_{hkl}$ and the (hkl) planes leads to an important formulation of the diffraction condition in the reciprocal space of the crystal. **Figure 12** shows the geometry of the Bragg diffraction. The incident beam has wavelength λ and propagates along the direction given by the wave vector $\boldsymbol{k}_{inc}$. The magnitude of the wave vector is defined by

$$k_{inc} = k_{sc} \equiv k = \frac{2\pi}{\lambda} \qquad [10]$$

where the first equality indicates that the scattering is elastic. By setting the phase shift between waves scattered from neighboring planes equal to 2π, one obtains the Bragg condition for constructive interference (or diffraction) from the hkl planes:

$$\lambda = 2\, d_{hkl} \sin\theta \qquad [11]$$

By inspection of **Figure 12**, and using eqns [10], [11], and [9], one obtains

$$q = 2k \sin\theta = 2\pi \frac{2 \sin\theta}{\lambda} = \frac{2\pi}{d_{hkl}} = G_{hkl} \qquad [12]$$

In other words, Bragg's law (eqn [11]) can be reformulated as eqn [12], which indicates that if constructive scattering from the (hkl) planes is to occur, then the magnitude of the scattering vector is equal to the magnitude of the corresponding reciprocal lattice vector. Since both $\boldsymbol{q}$ and $\boldsymbol{G}_{hkl}$ are normal to the scattering planes, eqn [12] holds for the vector quantities as well:

$$\boldsymbol{q} = \boldsymbol{G}_{hkl} \qquad [13]$$

Equation [13] is the basis of the Ewald sphere representation of the diffraction condition, shown in **Figure 13**. In an X-ray, electron, or neutron diffraction measurement, one maps out intensities associated with specific reciprocal lattice points. In essence, a diffraction measurement yields an image or a projection of the reciprocal lattice, and indirectly, information on the actual atomic ordering in the direct-space lattice.

The motion of an electron in a crystal is strongly affected by the periodic nature of the lattice. A nearly free valence electron interacts with relatively-fixed ion cores and experiences a potential, which can be written as an expansion in reciprocal-lattice vectors:

$$U(\boldsymbol{r}) = \sum_j c_j e^{i\boldsymbol{G}_j \cdot \boldsymbol{r}} \qquad [14]$$

As shown by eqn [7], a potential-energy function written in this form will have the periodicity of the Bravais lattice:

$$U(\boldsymbol{r} + \boldsymbol{R}) = U(\boldsymbol{r}) \qquad [15]$$

for any lattice vector $\boldsymbol{R}$. One might expect that the electron would be scattered erratically during its interaction with the ions; however, this is not the case. It can be shown that solutions of the Schrödinger equation in a periodic potential, such as that of

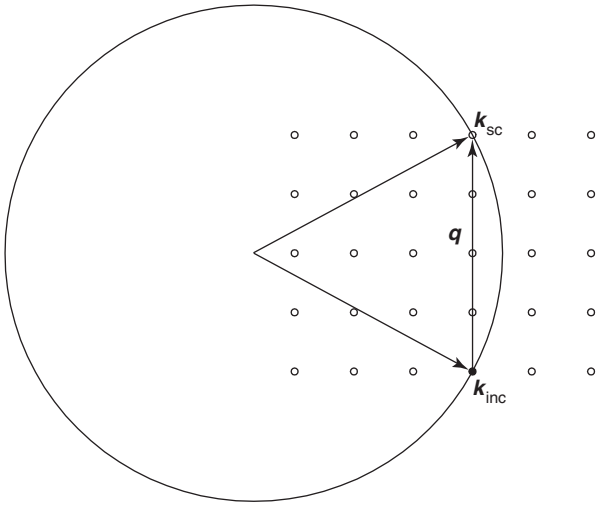

Figure 13 The Ewald sphere construction of the diffraction condition $\boldsymbol{q} = \boldsymbol{G}_{hkl}$. This figure is drawn in reciprocal space; the small circles represent reciprocal lattice points, not atoms. The tip of the incident wave vector is placed at the origin, shown as a filled circle. The surface of the sphere gives the possible locations of the tip of an elastically scattered wave vector. When the diffraction condition is met, the scattered wave vector coincides with a reciprocal lattice point. In the example shown here, if the *z*-axis is assumed to be vertical, the Bragg condition for the (0 0 4) reflection is met, that is, $\boldsymbol{q} = \boldsymbol{G}_{004}$.

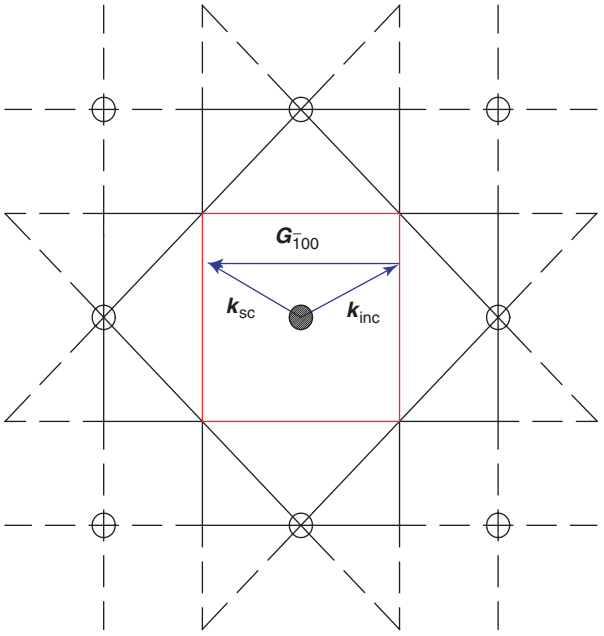

Figure 14 Construction of Wigner–Seitz cells by drawing perpendicular bisectors of reciprocal lattice vectors. The first Brillouin zone is shown in red. Electron wave vectors and a scattering vector are shown in blue. The notation $\boldsymbol{G}_{\bar{1}00}$ indicates that the scattering vector runs from the origin to the first point to the left of the origin.

eqn [14], are Bloch functions:

$$\Psi(\boldsymbol{r}) = u_{\boldsymbol{k}}(\boldsymbol{r})\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}} \qquad [16]$$

where $\hbar\boldsymbol{k}$ is the momentum of the electron, $\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}}$ is a plane wave propagating in the direction of $\boldsymbol{k}$, and $u_{\boldsymbol{k}}(\boldsymbol{r})$ is a function which has the periodicity of the Bravais lattice, that is,

$$u_{\boldsymbol{k}}(\boldsymbol{r} + \boldsymbol{R}) = u_{\boldsymbol{k}}(\boldsymbol{r}) \qquad [17]$$

Equation [16] indicates that electrons can propagate freely through the lattice as plane waves modulated by the lattice. The energy $\varepsilon(\boldsymbol{k})$ of an electron in a particular momentum state will have a specific form that depends on the potential energy function $U(\boldsymbol{r})$. (For a free electron (when $U = 0$), $\varepsilon \propto k^2$.)

The effect of the lattice on the electron becomes very strong when the wave vector $\boldsymbol{k}$ takes on particular values. In order to see how this comes about, consider the region of reciprocal space near the origin. Then draw a series of lines which bisect the reciprocal-lattice vectors, starting with the shortest ones, as shown in **Figure 14**. This construction divides the reciprocal space into Wigner–Seitz cells. In reciprocal space, the central cell which surrounds the origin is known as the first Brillouin zone (Wigner–Seitz cells can also be drawn in direct space. As an example, a primitive unit cell can always be constructed by generating such a cell about a Bravais lattice point).

Electrons with wave vectors within the Brillouin zone have propagating Bloch wave functions and can move through the lattice. However, if the wave vector $\boldsymbol{k}_{\mathrm{inc}}$ terminates anywhere on the zone boundary, the electron can undergo Bragg diffraction to a new state $\boldsymbol{k}_{\mathrm{sc}}$, since the difference between these wave vectors is equal to a reciprocal lattice vector. One can see the that $\boldsymbol{k}_{\mathrm{inc}}$ satisfies the condition for Bragg diffraction by comparing **Figure 14** to the Ewald sphere construction of **Figure 13**.

When the Schrödinger equation is solved in a periodic potential (one of the simplest examples being the one-dimensional Kronig-Penney model), one finds that diffraction at the Brillouin zone boundary is accompanied by a discontinuity in the energy $\varepsilon(\boldsymbol{k})$, which is otherwise continuous within the zone. That is, a fundamental property of electrons in solids - the bandgap - follows directly from the periodicity of the Bravais lattice.

Variations of Lattices: Superlattices, Surface Structures, and Quasicrystals

The discussion so far is suited to the description of three-dimensional crystalline elements and simple compounds. Also, the structures are assumed to be

infinite in extent and periodic. This section will briefly consider several departures from these assumptions.

A superlattice is a periodic structure which has a somewhat large or complex unit cell composed of smaller building blocks, something like a pedestrian walk made of a sequence of concrete and asphalt blocks, as shown in **Figure 15**.

If all of the blocks were concrete, the structure could be described by a unit cell consisting of one block. However, with the arrangement shown here, the unit cell is lengthened to four blocks.

Several examples of superlattices, which are important in condensed matter physics, are shown schematically in **Figure 16**. In an ordered metallic alloy, specific elements (shown as open and filled circles in **Figure 16a**) occupy specific sites on a lattice. The ordering produces a unit cell which is larger than that which would characterize a pure element, or a random alloy (from a diffraction point of view, a random alloy can be approximated as a single element with scattering properties intermediate between those of the individual elements). According to eqn [3], if the unit cell in direct space is enlarged, that is, if the translation vectors $\boldsymbol{a}_1$, $\boldsymbol{a}_2$, and $\boldsymbol{a}_3$ increase in length, then the corresponding reciprocal lattice vectors $\boldsymbol{b}_1$, $\boldsymbol{b}_2$, and $\boldsymbol{b}_3$ decrease in length. The reciprocal lattice points become denser and more peaks appear in the diffraction pattern. The new peaks are known as superlattice reflections.

Superlattices can also be produced by the intercalation of a foreign substance in a layered structure, such as graphite or one of the clay minerals, as shown in **Figure 16b**. As with the ordered alloy, the enlargement of the unit cell (relative to that of the pure host) leads to additional superlattice reflections. As in the alloy, the increase in cell size often occurs in more than one direction; therefore, the array of new reflections can be one-, two-, or three-dimensional.

An artificial superlattice, such as a semiconductor quantum-well structure or a magnetic multilayer, is prepared by the sequential deposition of thin layers of dissimilar materials onto a substrate (**Figure 16c**). In this case, the unit cell is enlarged in only one direction and the corresponding new features in the reciprocal lattice would be rows of points normal to the layers.

Two-dimensional lattices known as surface reconstructions are often formed on clean metals and semiconductors. Although the reconstruction resides on a bulk solid, its structure and reciprocal lattice can, to a certain extent, be considered as that of a very thin isolated layer. The main features of the diffraction pattern can be understood by considering the reconstruction as a limiting case: a three-dimensional structure where the interlayer spacing has become very large, as shown in **Figure 17**. If the unit cell is very large in the vertical direction (**Figure 17a**), the corresponding reciprocal lattice points become dense (**Figure 17b**). In the actual limit of a two-dimensional layer, the reciprocal lattice becomes a series of rods normal to the surface, and in diffraction one observes a set of streaks, rather than the discrete peaks which occur with a three-dimensional structure. One can also see that streaks arise by considering the exponential terms that occur in a structure-factor calculation of the diffraction intensity: $\exp(\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}) = \exp(\mathrm{i}(k_x x + k_y y + k_z z))$. If the surface layer lies in the $z = 0$ plane, then the scattering intensity has no k_z dependence, that is, the diffraction features consist of streaks of uniform intensity normal to the surface. One also obtains streak-like

Figure 15 A one-dimensional superlattice.

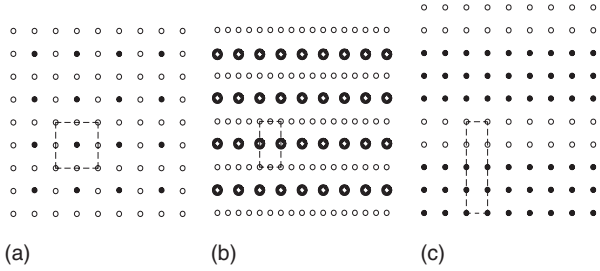

Figure 16 Examples of superlattices, including (a) an ordered alloy, (b) an intercalated layered structure, and (c) a superlattice prepared by the sequential deposition of two compounds. In all cases, the unit cell is indicated by dashed lines.

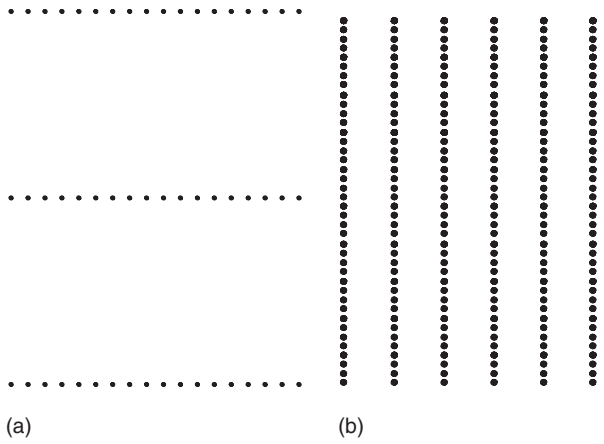

Figure 17 Isolated layers in a solid in the limit where the interlayer spacing becomes very large in direct space (a). The corresponding reciprocal lattice is shown in (b).

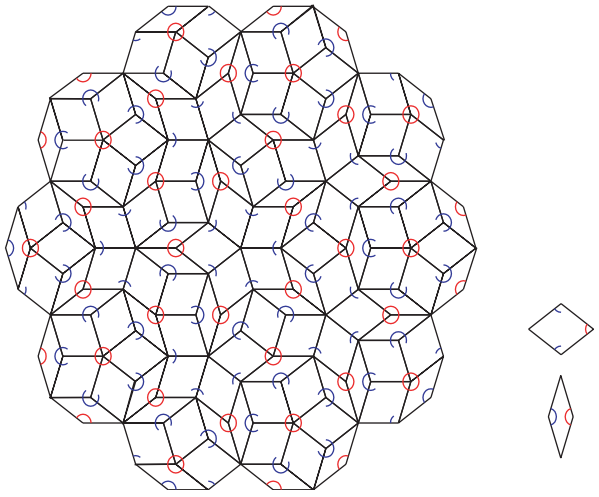

Figure 18 Portion of a Penrose tiling made with the two decorated building blocks shown to the right. The large and small building blocks are rhombuses with angles of 72° and 36°. The tiling was constructed subject to the rule that the decorations (colored arcs) on adjoining blocks must match.

diffraction features in scattering from the surface of a perfectly terminated (atomically-flat) crystal. However, in contrast to the case of the two-dimensional layer, the intensity of the streaks falls off quickly.

Finally, consider quasicrystalline ordering, where a solid is assembled according to a prescription which is ordered, but not periodic. A one-dimensional example is a Fibonacci lattice, where two building blocks A and B are repeated in the sequence

A BA ABA BAABA ABABAABA…

where the spaces are included for clarity. Each succeeding cluster of blocks is the sum of the two previous clusters. In practice, such a structure can be assembled by the sequential deposition of layers of two distinct materials. The structure is not periodic, since the pattern does not repeat, but it is ordered and it can be shown that it gives rise to a characteristic diffraction pattern with sharp peaks.

A two-dimensional example of a quasicrystal is a Penrose tiling, made up of two building blocks as shown in **Figure 18**. A fivefold symmetry does not occur among the periodic two-dimensional lattices (**Figure 4**), but the Penrose tiling of **Figure 18** has a fivefold symmetry about its central point. Like the Fibonacci lattice, the Penrose tiling is aperiodic, in that there is no repeating unit cell, yet it is ordered, as is clear from the perfect symmetry of **Figure 18**.

Quasiperiodic lattices are more than an interesting exercise in mathematical crystallography, since in the 1980s it was discovered that certain metallic alloys crystallize with icosahedral symmetry. These alloys yield diffraction patterns with a fivefold symmetry, which is forbidden for an untwinned crystal with translational symmetry. The icosahedral alloys are thought to be three-dimensional quasicrystals with an ordered aperiodic structure, formed by the optimization of near-neighbor packing during solidification. Although the actual physical structures are aperiodic, they can be represented as projections into three-dimensional space of periodic structures in a higher-dimensional space. Therefore, an understanding of the symmetry properties of periodic structures turns out to be very useful, even when the physical system is not periodic.

Phase Transformation

J H Perepezko, University of Wisconsin, Madison, WI, USA

Introduction

A central focus of phase transformation thermodynamics is the examination of relative phase stability. Under most conditions, phase stability is considered in terms of the response of a material to changes in temperature, pressure, composition, and size scale. The changes are often applied rapidly in order to establish undercoolings, overpressures, and supersaturations that place the initial stable phase in a metastable (or energized) condition. The relaxation of a metastable state to the stable state can proceed through a succession of various other metastable states, but the rate of the relaxation processes is usually limited by diffusional kinetics for thermally activated reactions. In general, it is often worthy to also identify the rate-limiting stage of a phase transformation reaction as either the nucleation or the growth stage, since the thermodynamic analysis for each stage can be different.

The essential thermodynamics that governs the relative phase stability for phase transformation reactions can be represented in analytical expressions for the Gibbs free energy as a function of temperature, pressure, composition, size scale, and other appropriate variables. These relationships can also be presented in a graphical form that facilitates the interpretation and visualization of the free energy changes, the metastable phase options, and various reaction pathways that often occur in kinetic competition.

A useful concept for the study of phase transformation processes is the distinction between closed and open system processes. In a closed system, an energized state is achieved through a rapid temperature, pressure, or composition change to create a certain level of undercooling or supersaturation (i.e., a metastable state), which then releases the excess free energy during relaxation toward the equilibrium stable state. With an open system, the energized state is often attained by a continuous incremental excess energy input to an initial state through the incorporation of excess lattice defects or solute on a localized spatial scale and time interval that is short compared to the relaxation time so that the relaxation process can be influenced by external factors. Regardless of the type of phase transformation or synthesis method, there are some common themes in the phase stability. The fundamental issues include the phase selection during the initial synthesis and the phase stability after synthesis and during subsequent treatment.

In order to treat the basic issues in phase stability within the limited coverage that is available, some of the key points are examined by considering selected thermodynamic relations for macroscopic systems and their modification for high interfacial area nanoscale systems. A central issue is the free-energy change (i.e., driving free energy) associated with a phase transformation reaction. As a means of illustrating the use of the relevant thermodynamic concepts, some examples are considered for the evaluation of the driving free energy and the ranking of different levels of metastability.

Phase Stability Thermodynamics

Equilibrium

There are a number of essentially equivalent approaches to describe thermodynamic equilibrium. For a closed system, the general conditions for equilibrium are represented by a maximum in entropy, S, or a minimum in free energy, G, with respect to a system variable z, where z is a variable such as pressure P, temperature T, or volume V as given by

$$\frac{dS}{dz} = 0 \quad \text{and} \quad \frac{d^2S}{dz^2} \leqslant 0 \qquad [1]$$

or

$$\frac{dG}{dz} = 0 \quad \text{and} \quad \frac{d^2G}{dz^2} \geqslant 0 \qquad [2]$$

These conditions prevail either for local minima/maxima that represents a metastable equilibrium or for an absolute minima/maxima that holds for a stable equilibrium as illustrated in **Figure 1**.

Pure Components

In the analysis of relative phase stability and the driving forces for different phase transformation reactions, the Gibbs free energy G is the main quantity of interest. By definition, $G = H - TS = E + PV$, where H is the enthalpy, E is the internal energy, and PV represents the system work. For reactions between two phases, the free energy change is the difference, $\Delta G = \Delta H - T\Delta S$. For example, during solidification of a liquid, $G_s - G_1 = (H_s - H_1) - T(S_s - S_1)$ or $\Delta G_f = H_f - T\Delta S_f$. At equilibrium, $\Delta G_f = 0$ so that $\Delta S_f = \Delta H_f / T_m$. If ΔS_f is taken as

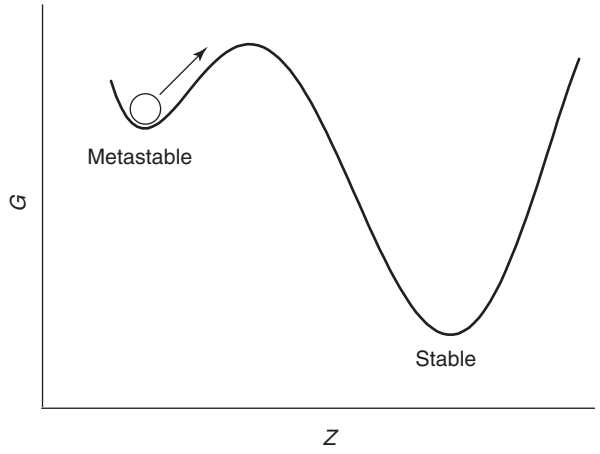

Figure 1 Schematic comparison of metastable (i.e., local) and stable (i.e., absolute) equilibrium.

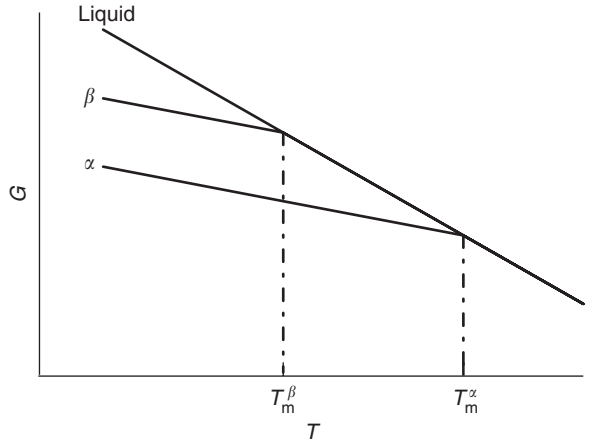

Figure 2 Molar free energy as a function of temperature for a single component. The melting point of the stable α-phase $T_m\alpha$ and the metastable β-phase $T_m\beta$ is indicated.

independent of T (i.e., neglecting the small heat capacity correction), then $\Delta G_f = \Delta H_f[1 - (T/T_m)] = \Delta H_f(T_m - T)/T_m = \Delta H_f \Delta T/T_m$, so that the driving free energy (i.e., driving force) available to accomplish the reaction is proportional to the undercooling, ΔT. The dependence of the molar free energy on temperature is illustrated in **Figure 2** for a liquid, a stable α-phase and a metastable β-phase, where it is evident that the formation of the metastable β-phase requires a minimum liquid undercooling below the stable α-phase melting point of $\Delta T = T_m^\alpha - T_m^\beta$.

From the second law of thermodynamics, several differential relations can be developed (i.e., Maxwell relations). The relation for the Gibbs free energy for a single phase is

$$dG = VdP - SdT \qquad [3]$$

For the liquid–solid case at equilibrium, $dG = 0$ and

$$V_s dP - S_s dT = V_1 dP - S_s dT \qquad [4]$$

or

$$\left(\frac{dP}{dT}\right)_{eq} = \frac{S_s - S_1}{V_s - V_1} = \frac{\Delta S_f}{\Delta V_f} = \frac{\Delta H_f}{\Delta V_f T_m} \qquad [5]$$

which is the Clapeyron equation for the pressure dependence of the melting point. When eqn [3] is applied to other two-phase coexistence such as solid–liquid, solid–vapor, and liquid–vapor equilibrium, the pressure–temperature phase diagram for a single component is developed as shown in **Figure 3**. The solid lines represent the two-phase coexistence conditions, where there is one degree of freedom according to the phase rule (i.e., $p + f = c + 2$, where

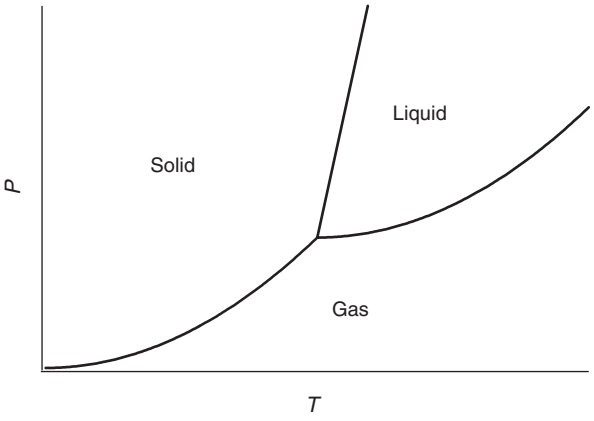

Figure 3 A schematic pressure vs. temperature diagram for a single component.

p is the number of phases, f is the number of degrees of freedom, and c is the number of components). The lines intersect at an invariant triple point where $f = 0$. It is worth noting that $(\partial G/\partial T)_P = -S$ and $(\partial G/\partial P)_T = V$ as illustrated in **Figure 2**.

Classification of Phase Transformations

The pure component reactions that are depicted in **Figure 3** are often classified as first-order phase transformations. At the equilibrium transformation temperature T_e, $G^\alpha = G^\beta$, but the slopes are different (i.e., $dG^\alpha/dT \neq dG^\beta/dT$). This gives rise to a discontinuity in S, V, and H at T_e and a singularity in heat capacity $C_p = T(dS/dT) = T(d^2G/dT^2)$ as illustrated in **Figure 4**.

During a second-order phase transformation, S, V, and H are continuous at the transformation temperature or critical temperature, T_c (i.e., there is no

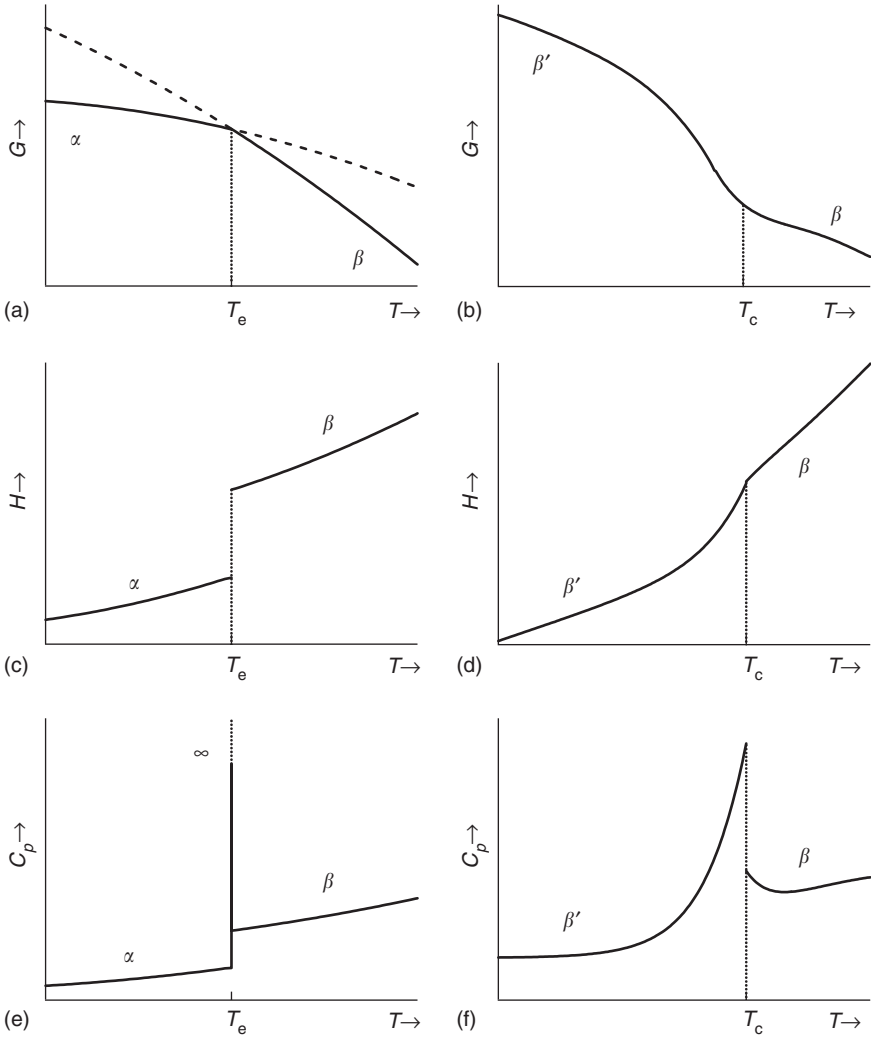

Figure 4 The thermodynamic characteristics of (a, c, and e) first-order and (b, d, and f) second-order phase transformations.

latent heat), but there is a discontinuity in heat capacity as indicated in **Figure 4**. Second-order phase transformations are often associated with electronic effects such as the paramagnetic/ferromagnetic transition, but they are also observed for certain order–disorder changes in alloys.

The distinction between first- and second-order phase transformations also has an impact on the presentation of the equilibria in a phase diagram and the progress of the phase transformation. For example, long-range ordering of unlike atoms in a crystal lattice develops due to an attractive interaction between unlike atoms. During a first-order reaction, the development of an ordered atomic arrangement initiates at separate regions as the temperature falls below T_e as shown in **Figure 5**. A sharp interface separates the transformed (i.e., ordered) regions and the untransformed (i.e., disordered) regions. Across this interface, there is a jump in the long-range order parameter, η that varies from zero for a random arrangement to unity for a perfectly ordered arrangement. The coexistence at T_e is represented on the phase diagram as a two-phase field between the ordered and the disordered phase. In contrast, during a second-order reaction, the development of an ordered arrangement initiates throughout the volume at the critical temperature T_c and progressively develops with increasing values of η as the temperature is lowered below T_c. There is no two-phase coexistence of an ordered and a disordered phase, so that the phase diagram does not display a two-phase field. Instead, the phase diagram shows the locus of T_c as a function of composition.

Alloy Solutions

For alloy solutions, the chemical terms for the free energy are included by adding the partial molar free

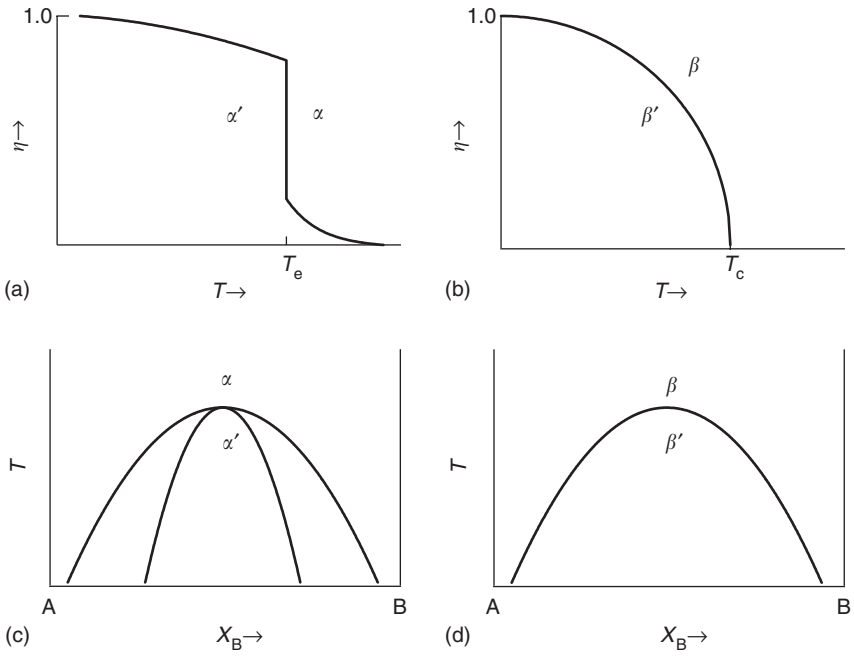

Figure 5 Schematic illustration of the temperature dependence of η (a and b) and the phase diagram characteristics (c and d) for (a and c) first-order and (b and d) second-order phase transformations.

energy for each component, i or j to eqn [3] as

$$dG = VdP - SdT + \left(\frac{\partial G}{\partial n_i}\right)_{T,P,nj} dn_i + \left(\frac{\partial G}{\partial n_j}\right)_{T,P,ni} dn_j \quad [6]$$

where n is the number of moles. The partial molar free energy represents the chemical potential, μ_i, that is defined as

$$\left(\frac{\partial G}{\partial n_i}\right)_{T,P,nj} = \mu_i = \mu_i^0 + RT \ln a_i \quad [7]$$

where μ_i^0 is the standard state chemical potential, R is the gas constant, and a_i is the activity which is the product of an activity coefficient γ_i and the mole fraction, X_i (note that for a binary solution $X_i + X_j = 1$). For alloy solution at constant T and P with a given composition X_0 in an A–B system, the molar free energy is

$$G = (1 - X_0)\mu_A + X_0\mu_B \quad [8]$$

and as indicated in **Figure 6**, eqn [8] describes the tangent to the G versus X_B curve at X_0. For reaction between two coexisting solution phases such as liquid and solid in an alloy with overall composition X_0

$$\Delta G = (1 - X_0)(\mu_A^s - \mu_A^1) + X_0(\mu_B^s - \mu_B^1) \quad [9]$$

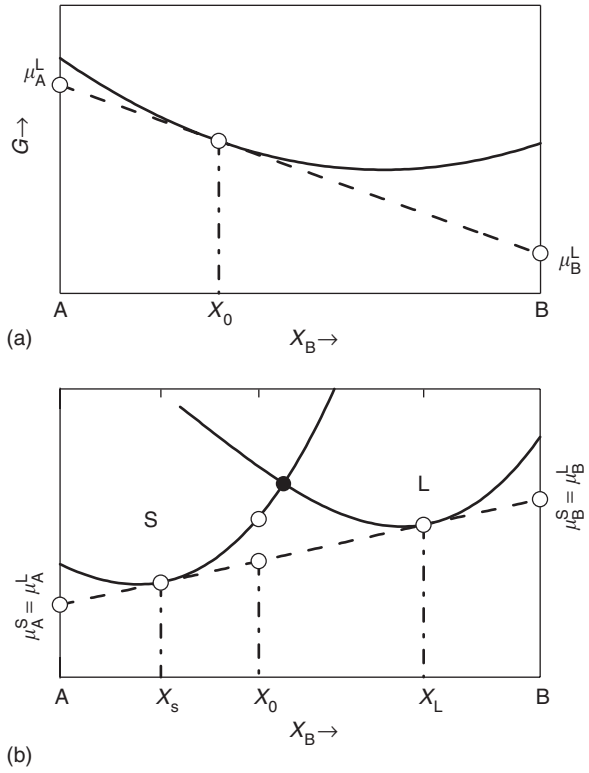

Figure 6 Schematic free energy vs. composition diagrams for a binary alloy of (a) a single-phase liquid solution with the component chemical potentials μ_A^L and μ_B^L determined by the pure component intersections with the tangent to the G vs. X_B curve at X_0 and of (b) a two-phase liquid–solid equilibrium with common tangent points at X_s and X_L.

At equilibrium, $\Delta G = 0$, so that $(\mu_A^s = \mu_A^1) = (\mu_B^s = \mu_B^1)$ and the two phases share a common tangent.

For the examination of interactions in solutions, it is often useful to represent the free energy change for mixing of pure components to form a solution ΔG_m in terms of an enthalpy of mixing ΔH_m and a mixing entropy ΔS_m. The simplest model is based upon an ideal solution where there are no nearest neighbor interactions, so that $\Delta H_m = 0$ and $\gamma_i = 1$ and the ideal entropy of mixing is given by

$$\Delta S_m = -R[(1 - X_B)\ln(1 - X_B) + X_B \ln X_B] \quad [10]$$

Most real solutions are not ideal. When the departure from ideal behavior is modest so that the molar volume change upon mixing to form a solution is negligible, the enthalpy of mixing can be represented in terms of the nearest neighbor pairwise interaction energies E_{AA}, E_{BB}, and E_{AB} as

$$\Delta H_m = ZN_a X_A X_B[E_{AB} - 0.5(E_{AA} + E_{BB})] \quad [11]$$

or

$$\Delta H_m = \Omega X_A X_B \quad [12]$$

where Z is the lattice coordination number, N_a is Avogadro's number and $\Omega = ZN_a[E_{AB} - 0.5(E_{AA} + E_{BB})]$ is a constant for a regular solution. The entropy of mixing is given by the ideal solution expression eqn [8] to yield

$$\Delta G_m = \Delta H_m - T\Delta S_m = \Omega X_A X_B + RT \times [(1 - X_B)\ln(1 - X_B) + X_B \ln X_B] \quad [13]$$

The composition dependence of ΔG_m is shown in **Figure 7** for different values of Ω and temperature. For exothermic solutions, $\Omega < 0$ and mixing results in a free energy decrease at all temperatures. In this case, the preference for unlike atom pairings results in a tendency for the development of ordering in the solid solution. When $\Omega > 0$, however, the behavior changes with temperature. At high temperatures, $T\Delta S_m$ is greater than ΔH_m for all compositions and the free energy curve has a positive curvature at all points. At low temperatures, however, $T\Delta S_m$ is smaller than ΔH_m for the central composition range and ΔG_m displays a change in curvature with a negative curvature near the pure component compositions that changes to a positive curvature (i.e., unstable solutions) in the central composition range. The positive value of Ω indicates a preference for pairings of like atoms and results in a tendency for the development of clustering in the solid solution.

The composition dependence of ΔG_m yields a concave curve when $\Delta H_m < 0$ as illustrated in **Figure 6a**. In addition, in **Figure 6b**, the equilibrium condition of the equality of the chemical potential for each component in the coexisting phases is illustrated by the common tangent construction. The various phase equilibria that are defined by a collection of free energy versus composition diagrams at different temperatures are the basis of the equilibrium phase diagram. As demonstrated in the schematic diagram in **Figure 8**, the common tangent points on the free energy versus composition diagram define the tie lines between coexisting phases at each temperature on the phase diagram. Within the two-phase regions defined by the common tangents, the free energy curves intersect. The point of intersection defines the limit to partitionless transformation. For liquid compositions to the left of the intersection (i.e., A-rich compositions), there is a free energy decrease for a composition invariant or partitionless solidification. For liquid compositions to the right of the intersection, a partitionless solidification is impossible since the free energy would increase. The locus of the intersection points as a function of temperature is often called a T_0 curve.

When $\Delta H_m > 0$, the composition dependence of ΔG_m displays a change in curvature as noted in **Figure 7d** and illustrated in more detail in **Figure 9**. As shown in **Figure 9**, the phase diagram for a solution with $\Delta H_m > 0$ exhibits a miscibility gap at low temperature where a homogeneous solution, α, decomposes into two solutions α_1 and α_2 without overcoming an activation energy barrier. Due to the change in curvature of the G versus X_B curve, there is a fundamental change in the stability of solutions within the miscibility gap and a resultant change in the mechanism of the decomposition. For example, solutions with compositions between X_1 and the turning point (i.e., where $d^2G/dX_B^2 = 0$) or between the turning point and X_2 are metastable, since $d^2G/dX_B^2 > 0$. This signifies that fluctuations in composition that are necessary to accomplish the decomposition reaction result in an increase in free energy that represents a barrier to the reaction. For these solutions, a nucleation process is required to initiate the decomposition reaction. In contrast, solutions with compositions between the turning points are unstable, since $d^2G/dX_B^2 < 0$. In this case, fluctuations in composition are spontaneous, since they lead to a reduction in free energy. The demarcation between metastable and unstable solutions within the miscibility gap is represented by the spinodal curve that refers to the locus of temperatures and compositions, where $d^2G/dX_B^2 = 0$.

Phase Transformation Energetics

An important application of the thermodynamic description of phase stability is the representation of the free energy change that accompanies a phase transformation (i.e., the driving free energy). A change of phase requires a departure from equilibrium as the system develops a supersaturation or an undercooling that represents the driving free energy as indicated in **Figure 10**. For a dilute solution where the activity is represented by the mole fraction, the free energy change associated with a precipitation reaction where the α-phase composition changes from X_0 to X_α as pure β develops at temperature T_1 is given by

$$\Delta G = RT_1 \ln\left(\frac{X_0}{X_\alpha}\right) \qquad [14]$$

Since the solvus phase boundary composition, X_s, is represented as

$$X_S = \exp(\Delta S_S)\exp\left(-\frac{\Delta H_S}{RT}\right) \qquad [15]$$

where ΔS_s is the entropy of solution and ΔH_s is the enthalpy of solution, the free energy change for precipitation is expressed as

$$\Delta G = \frac{\Delta H_S \Delta T}{T_S} \qquad [16]$$

demonstrating again that a supersaturation can be expressed in terms of an equivalent undercooling. It is to be noted that the expressions in eqns [12] or [14] refer to the overall ΔG for the reaction, $\alpha(X_0) \rightarrow \alpha(X_\alpha) + \beta(X_\beta)$. During the initial nucleation

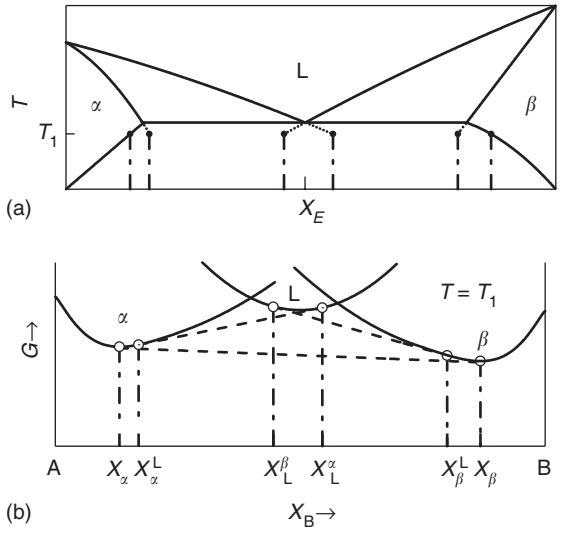

Figure 8 (a) Schematic phase diagram and (b) free energy vs. composition diagram for a binary alloy that exhibits a eutectic reaction: $L \rightarrow \alpha + \beta$. The relationship between the phase boundaries on the phase diagram and the common tangents is illustrated for a temperature T_1, where both a stable $\alpha + \beta$ and the metastable $L + \alpha$ and $L + \beta$ two-phase equilibria could occur for different kinetic conditions. The location of the T_0 points are indicated by filled circles.

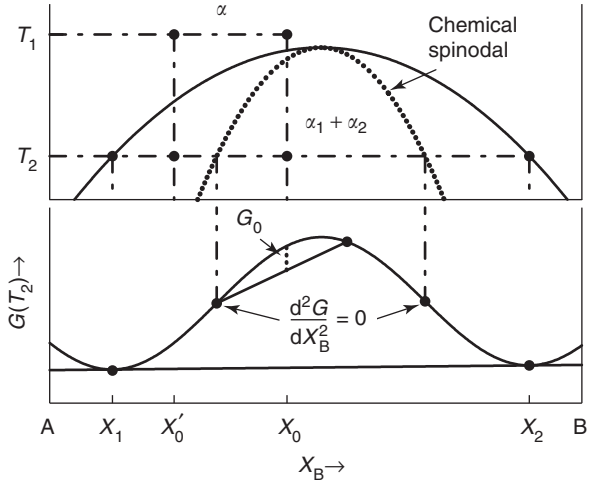

Figure 9 (a) Schematic phase diagram and (b) free energy vs. composition diagram for alloys between the spinodal points, which are unstable and can decompose into two coherent phases α_1 and α_2 without overcoming an activation energy barrier. Alloys between the miscibility gap and the spinodal are metastable and can decompose only after nucleation of the other phase.

stage when a small quantity of β forms, the α-matrix composition is not changed much from the X_0 value. In this case, the maximum driving free energy for nucleation of β, ΔG_N, is given by the separation between the tangent to the G_α curve at X_0 and a parallel tangent to the G_β curve as illustrated in **Figure 10**. The tangent to the G_β curve occurs at the

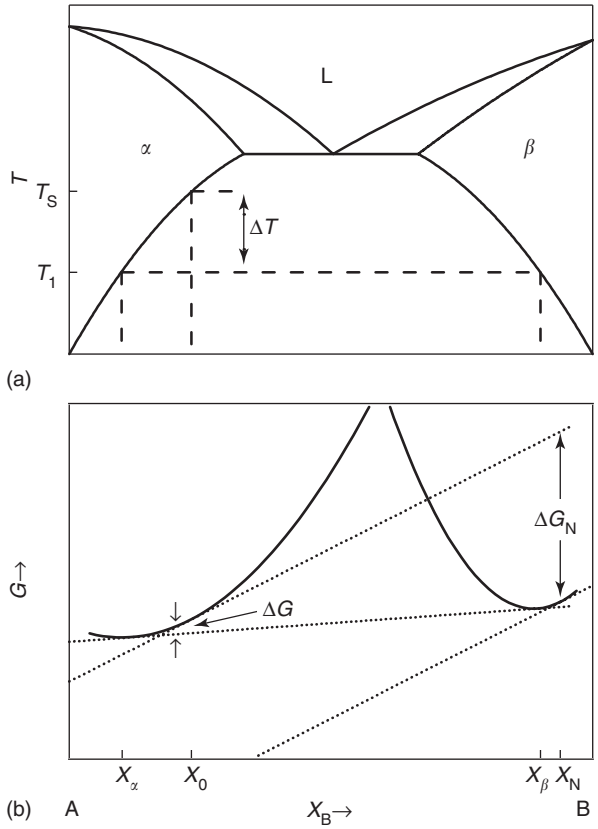

Figure 10 (a) Schematic phase diagram and (b) illustration for the development of a supersaturation $[X_0/X_\alpha]$ as an α- phase alloy of composition X_0 is undercooled by an amount ΔT below the α- phase solvus boundary. During the initial formation of a β-phase precipitate, the maximum driving free energy for nucleation, ΔG_N is given by the parallel tangent construction.

composition X_N, which is the favored composition for a β-nucleus (i.e., the composition with the largest driving free energy).

Similarly, for a phase transformation involving the decomposition of an initial phase such as the liquid with composition X_E in **Figure 8** into two phases such as α of composition X_α and β of composition X_β, the ΔG for reaction can be evaluated from eqn [8]. The free energy change is given by the separation between the tangent to the G_L curve at X_E and the common tangent to the G_α and G_β curves as

$$\Delta G = (\mu_\alpha^B - \mu_L^B)X_E + (\mu_\alpha^A - \mu_L^A)(1 - X_E) \quad [17]$$

Phase Stability Hierarchy

Nucleation-Controlled Reactions

Throughout the analysis of transformation behavior, it is commonly recognized that nucleation control is an important part of the initial stage of a reaction. Under nucleation control, a strong temperature

dependence of the product phase selection and number density is developed, which leads to a nanoscale microstructure. Nucleation limitations in diffusion reactions, especially those involved in reactive diffusion, also represent a form of nucleation control that is important in nanostructure synthesis. In terms of alloy metastability, nucleation control is important in allowing access to metastable states. In effect, the observation of nucleation control is directly related to the factors that promote the development of large undercooling or supersaturation which enables the expression of kinetic transitions through competitive phase selection resulting in the refinement of the product size to the nanoscale level.

Competitive Phase Selection and Metastability

A common theme in the development of new microstructural options by phase transformations is the occurrence of metastable structural states. Often, the reactions that occur during the freezing of undercooled liquids or during other rapid transformations are viewed as nonequilibrium processes. However, it is also evident that some of the departures from full equilibrium can be considered in terms of different levels of metastability. In fact, a hierarchy of equilibrium is identified based upon the severity of the kinetic constraints that affect the capability of a material to relax toward full equilibrium during processing. As the rate of reaction becomes faster, kinetic constraints that arise from nucleation and growth limitations associated with an equilibrium product phase formation develop and expose alloy metastability that often coincides with nanostructure synthesis. For the suppression of the equilibrium phase or the formation of a kinetically favored metastable phase, it is still possible to analyze reactions in terms of a metastable equilibrium that is used locally at interfaces. The transition from stable to metastable equilibrium is illustrated in **Figure 11** where the kinetic suppression of an equilibrium γ-phase (see **Figure 11a**) yields a metastable eutectic involving the α- and β-phases. Moreover, it is expected that the application of the appropriate local equilibrium is used when the processing involves nanoscale structures. Under extreme conditions, loss of interfacial equilibrium for either a stable or metastable phase is developed even when interfacial

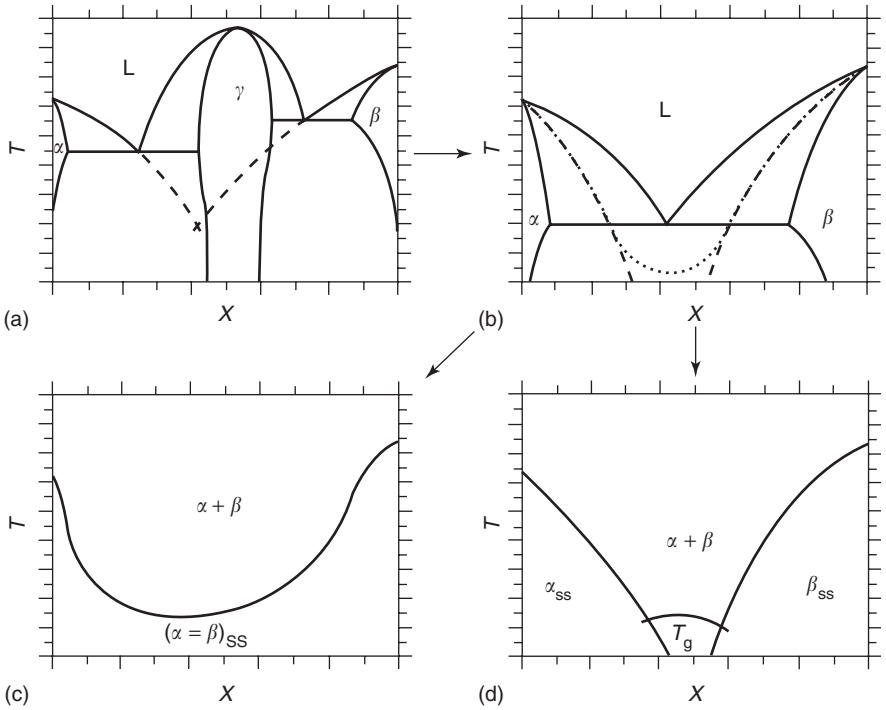

Figure 11 Schematic illustration of temperature vs. composition diagram for some of the levels in the hierarchy of equilibrium. (a) The equilibrium phase diagram of a system with an intermediate phase; dashed lines represent the metastable extensions of the liquidus and solidus curves for the primary solution phases. Solidification under metastable equilibrium conditions can result in a bypassing of the intermediate phase to yield a metastable eutectic phase diagram between α and β. (b) The T_0 curves for the primary solutions. The extensions of these curves to temperatures below the metastable eutectic are indicated as dashed curves. (c) If the primary phases have different crystal structures and low mutual solubility, then the T_0 curves might not intersect. Such a situation favors glass formation in the composition range, where the T_g curve is greater than the T_0 curves. (d) For alloys based upon components with different structures each crystal phase has a T_0 curve.

relaxation becomes too slow. With the loss of interfacial equilibrium, thermodynamics can still be used to restrict the possible range of compositions that exists at an interface at various temperatures, since the selection must yield a net reduction in the free energy of the system. One way to represent the thermodynamic restrictions is based upon the application of T_0 curves which represent the locus of temperatures and compositions, where the free energies of two phases are equal (as illustrated in **Figure 6**) for liquid and solid phases, and thus define the limiting condition for partitionless transformation. For example, as interfacial equilibrium is lost, the liquidus and solidus boundaries in **Figure 11b** collapse to the T_0 curves. With isomorphous systems that exhibit complete solubility, the T_0 curve is continuous with composition (see **Figure 11c**) while for alloys based upon components with different structures, each crystal phase has a T_0 curve (see **Figure 11d**). At temperatures and compositions above the T_0 curves, solute partitioning is required for solidification (see **Figure 11d**). Because of the diffusional constraint due to solute partitioning, a crystallization reaction can be inhibited by quenching to promote glass formation. Within the overall hierarchy of stability, the systematic examination of the different levels of kinetic constraints provides useful insight into the thermodynamic analysis of alloy metastability and phase selection.

Constrained Equilibrium

There are a number of important cases, where phase transformation reactions proceed under various constraints that involve externally imposed conditions or internally generated limitations. A common example is the development of a metastable phase because of favorable nucleation and growth kinetics compared to the stable phase. This is a kinetically constrained equilibrium. Another kinetically constrained equilibrium can be developed in alloys, where one component exhibits a significantly higher diffusivity than the other components. This is commonly observed in alloy steels where the high diffusivity component is an interstitial component such as carbon and the other slow diffusivity components are substitutional species. The high diffusivity component is able to establish an equality of the chemical potential in the coexisting phases before the slow diffusivity components. This is called "paraequilibrium." Of course, since paraequilibrium is constrained kinetically, it

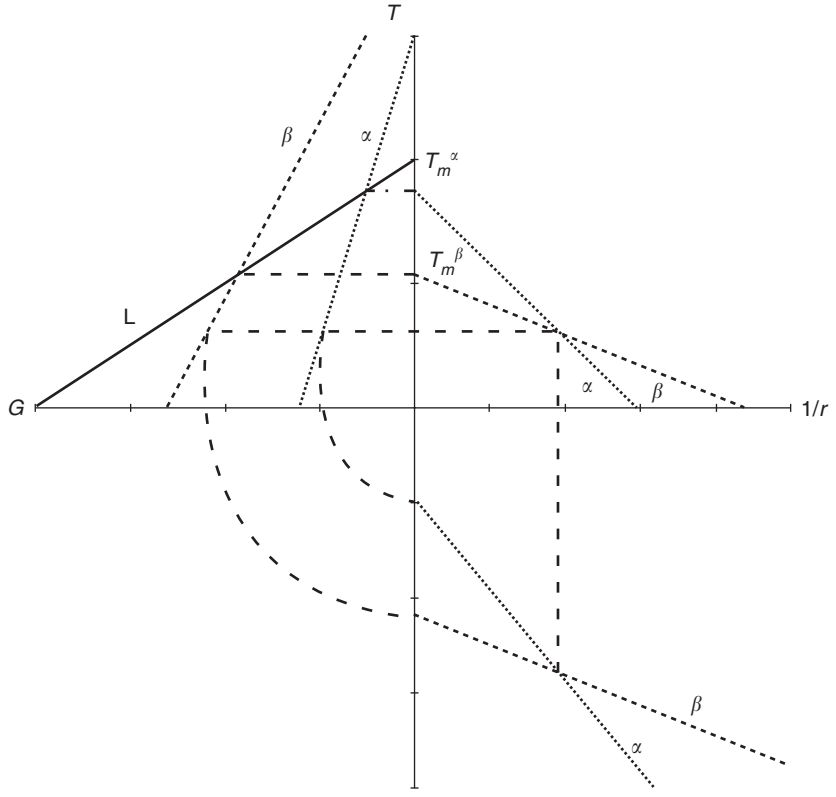

Figure 12 Schematic illustration of the influence of curvature (1/*r*) on the melting point of the α-phase and the β-phase and on the relative phase stability when $\sigma_{\alpha L} V_m / \Delta S_f^{\alpha} > \sigma_{\beta L} V_m / \Delta S_f^{\beta}$.

will dissipate with time as the alloy approaches the stable equilibrium.

During the initial stages of a phase transformation reaction in the solid state or during deposition from the vapor, it is often observed that the product phase exhibits an epitaxial crystallographic relationship with the transforming phase or the substrate involving the interfacial matching of lattice planes and directions. The appearance of a crystallographic matching results in a reduction of the interfacial energy that in turn yields favorable nucleation kinetics. However, the matching is rarely perfect so that there remains a residual interfacial strain. The resulting elastic strain energy represents another component to the free energy. With the progress of the reaction, the product phase grows and there is a loss of coherency and elastic strain energy.

The elastic strain energy is usually not partitioned equally between the transforming, and product phase so that the constraint of lattice matching across the interphase interface alters the phase equilibrium. This constrained equilibrium is designated as "coherent equilibrium." Because the level of elastic strain energy depends on the volume, the influence of coherent equilibrium is a function of composition in the two phase regions (i.e., relative amounts of phases). This yields new behavior that is beyond the scope of coverage in this discussion.

Thermodynamics of Nanoscale Systems

The nanoscale is often reported as a linear dimension but the important interfacial effects should be considered in terms of the interfacial area per unit volume (A/V). For example, for a sphere: $A/V = 3/r = 3 \times 10^7\ \mathrm{m}^{-1}$ for $r = 100$ nm. This is very significant.

Interfacial effects can be included in the free energy as

$$\mathrm{d}G = V\mathrm{d}P - S\mathrm{d}T + \sum \mu_i \mathrm{d}n_i + \sum \sigma_i \mathrm{d}A_i \qquad [18]$$

where σ_i is the interfacial energy and A_i is the interfacial area.

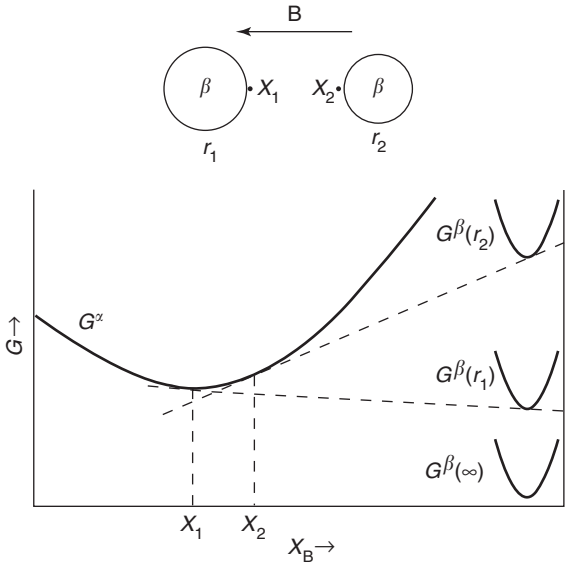

Figure 14 Schematic free energy vs. composition diagram demonstrating the influence of interface curvature of a β-phase particle on the solubility.

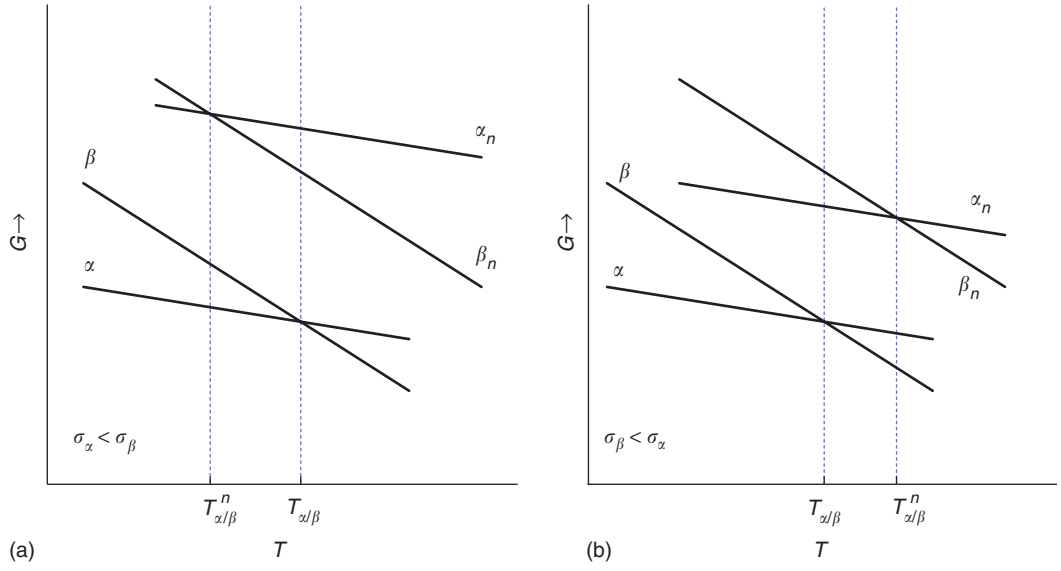

Figure 13 Schematic Illustration of the modification of the stability of the α-phase at the nanoscale. (a) when $\sigma_\alpha < \sigma_\beta$, there is an enhancement of α-phase stability and (b) when $\sigma_\beta < \sigma_\alpha$, there is a reversal of phase stability between the α-phase and the β-phase.

Table 1 Comparison of the driving free energies for some phase transformation reactions

Reaction process	*Free energy*	*Typical value*[a] ($J\,mol^{-1}$)	*Remarks*
Crystallization polymorphic transition	$\Delta H_f \Delta T/T_m$	3×10^3	
Mixing/Interdiffusion	$RT(X_A \ln X_A + X_B \ln X_b)$	5×10^3	Ideal solution behavior
Oxidation	$\Delta G^0 = -RT \ln K$	$5 \times 10^4 - 5 \times 10^6$	ΔG^0 – Formation of oxide K – Equilibrium constant
Sublimation/condensation	$\Delta H_v\ \Delta T/T_s$	10^4–10^5	ΔH_v – Sublimation enthalpy T_s – Sublimation temperature
Grain growth, coarsening	$2\sigma/r$	20 for $r = 1\,\mu m$ 2×10^3 for $r = 10\,nm$	$\sigma = 1\,J\,m^{-2}$
Precipitation	$RT\ln(X_\alpha/X_0)$	10^4	$X_\alpha/X_0 = 10$
Cold work (stored energy)	$\rho G\boldsymbol{b}^2$	10^2–10^3	G – Shear modulus b – Burgers vector ρ – Shear modulus

[a]Typical value at $T = 1000\,K$.

The increment in free energy due to interfaces is represented by the Gibbs–Thomson relation in terms of the interface curvature κ that is determined by the principal radii, r_i , as

$$\Delta G = \kappa\sigma V_m = (r_1^{-1} + r_2^{-1})\sigma V_m \qquad [19]$$

where V_m is the molar volume.

For a sphere, $\Delta G = 2\sigma V_m/r$. The effect of curvature on the melting point and the relative phase stability is indicated in **Figure 12** where the dependence of melting point on curvature can be expressed from eqns [3] and [13] as

$$T_m(r) = T_m(\infty) - \frac{2\sigma_{SL} V_m}{r\Delta S_f} \qquad [20]$$

There are two key points that are illustrated in **Figure 12**. First, the macroscopic melting points for the α- and β-phases, that is, T_m^α and T_m^β, decrease with increasing curvature. Second, the β-phase that is metastable for macroscopic sizes becomes the stable phase with respect to α-phase at high curvature values. Furthermore, the phase stability relations for a macroscopic scale system can be modified in different ways depending on the relative magnitude of σ for each phase for a nanostructured system. As illustrated in **Figure 13**, when $\sigma_\alpha < \sigma_\beta$, the stability of α is enhanced at the nanoscale. However, when $\sigma_\beta < \sigma_\alpha$, there is a reversal of phase stability at the nanoscale. There are a number of examples of the reversal in relative phase stability when the size scale changes from macroscopic to nanostructured.

The excess free energy due to curvature that acts to control the relative phase stability in nanoscale materials also acts to modify other thermodynamic behavior. For example, with the same analysis that was applied to express the curvature dependence of the melting point, the dependence of the solubility may be represented in terms of particle size. This behavior is illustrated in **Figure 14**, where it is evident that the increase in chemical potential with decreasing particle size will act to drive a diffusive flux between neighboring particles in a particle-size distribution such as that produced by a precipitation reaction. An important consequence of the interparticle transport is the dissolution of the finest particles along with a concomitant increase in the average particle size in the distribution. This coarsening behavior is central to the kinetic stability of a nanoscale microstructure.

A useful perspective on the different phase transformation reactions can be developed by considering the relative magnitudes of the driving free energies associated with each of the reactions. A partial summary of the representative magnitudes for the driving free energies for a selection of reactions is presented in **Table 1**. The listings in **Table 1** indicate that for typical processes involving chemical changes or phase transitions, the driving free energies range from a few to $100\,kJ\,mol^{-1}$. While the excess free energy associated with a nanoscale microstructure is only a few $kJ\,mol^{-1}$, this level is sufficient to alter the relative phase stability and to modify the path of kinetic reactions.

Phase Transformations, Mathematical Aspects of

J-C Tolédano, Ecole Polytechnique, Palaiseau, France

Introduction

Phase transformations occur in a large variety of systems subjected to a change in temperature or pressure, for example, fluids, liquid crystals, crystalline or noncrystalline solids, magnetic compounds, superconductors, and quasicrystals. Their existence is often revealed by subtle effects, which are characteristic of the system considered: progressive or sudden onset of magnetization, small mechanical shear, an optical rotatory power, additional X-ray or neutron scattering directions of diffraction, etc.

Except within simplified microscopic models of physical systems, the occurrence of a phase transformation at a given temperature T_c is taken as an experimental fact and as a starting point of the theory. The objective is then to relate the atomic-scale configuration of the system to the laws governing the more or less abrupt variations of physical properties, which are observed experimentally. The standard framework of these so-called phenomenological theories corresponds to the situation of continuous phase transformations, that is, transformations in which, although sharp anomalies of certain physical quantities are observed, the atomic (and magnetic) configuration undergoes infinitesimal modifications at T_c (or p_c) and changes in a continuous manner on either sides of the transformation point (in the following, the temperature T will be assumed to be the only relevant intensive thermodynamic quantity).

The fundamental mathematical quantity in a physical theory of continuous phase transformations is the order parameter. The concept of order parameter was introduced by L D Landau in 1935 in the first unified theory of phase transformations, which not only addresses the interpretation of physical phenomena out of the so-called critical range of temperatures of the transformation, but also is relevant to the more recent renormalization group theory of the critical phenomena. The next section introduces this concept and specifies its mathematical properties with reference to the mathematical theory of group representations. The following sections describe the implications of these properties for the prediction of symmetry breaking at a phase transformation, or for the form of the invariant polynomials involved in the expression of the free energy, or alternatively in the effective Hamiltonian density appearing in the phenomenological theories. Attention is also given to criteria excluding the continuous character of a phase transformation. For a discussion of other important aspects, for example, methods of analysis of the minima of the free energy, extensions of the theory to the cases of discontinuous and reconstructive transitions, and the prediction of domain/variant orientations resulting from the breaking of symmetry, the reader is referred to the Further reading section.

The Order Parameter and Its Mathematical Symmetry Properties

The introduction of an order parameter relies on the following remarks.

First, it is observed that the values of thermodynamical functions defined for a system, such as the free energy F, can be formally expressed, for any state of the system (equilibrium or nonequilibrium), as a function $F(x_i|T)$ of the various degrees of freedom x_i specifying an atomic (or magnetic) configuration (e.g., a set of values of the coordinates of all the atoms and their spin orientations), the temperature being an externally controlled parameter. At a given temperature T, the equilibrium values $x_i^{\mathrm{eq}}(T)$ of these degrees of freedom are determined by locating the absolute minimum of $F(x_i|T)$. One has

$$F_{\mathrm{eq}}(T) = F(x_i^{\mathrm{eq}}|T) = \min|x_i\ F(x_i|T) \qquad [1]$$

Hence $F(x_i|T)$ serves as a variational function to determine the thermodynamic equilibrium of the system.

Second, it is emphasized that, for a continuous phase transformation, $x_i^{\mathrm{eq}}(T)$ vary continuously across the transformation temperature T_{c}, and therefore, their values in the vicinity of T_{c} are close to their equilibrium values, $x_i^* = x_i^{\mathrm{eq}}(T_{\mathrm{c}})$. Consequently, one can restrict the study of $F(x_i|T)$ and of its minima to values of the x_i close to x_i^*. Moreover, if $F(x_i|T)$ is assumed to be a function without mathematical singularities at T_{c}, it can be expressed as a Taylor expansion of the small increments of the degrees of freedom $\delta x_i = x_i - x_i^*$:

$$\begin{aligned} F(x_i|T) = {} & F(\delta x_i|x_i^*, T) = F_0(x_i^*, T) \\ & + F_1(\delta x_i|x_i^*, T) + F_2(\delta x_i|x_i^*, T) \\ & + \cdots + F_p(\delta x_i|x_i^*, T) + \cdots \end{aligned} \qquad [2]$$

where F_p is a homogeneous polynomial of degree p in the increments δx_i with coefficients depending on the parameters x_i^* and T.

The mathematical formulation of the theory is based on two additional observations. The first concerns the invariance (i.e., the unchanged expression) of F when certain geometrical operations are applied to the degrees of freedom x_i. Indeed, the free energy being a function of the relative positions of the microscopic constituents of the system (or the relative orientation of the magnetic moments), and not of their absolute position in space, its expression $F(x_i|T)$ as a function of x_i must be invariant under any orthogonal transformation or translation acting globally on the system. However, if F is considered as a function of the increments δx_i, and can therefore be written as $F = F(\delta x_i|x_i^*, T)$, it will only be invariant under the restricted set of the former transformations which also preserve the parameters x_i^* implied in this function. This restricted set consists of the operations that leave unchanged the equilibrium atomic (and spin) configuration $x_i^* = x_i^{\mathrm{eq}}(T_{\mathrm{c}})$ of the system at the temperature T_{c}. These operations represent the symmetries of the considered configuration. This set forms a mathematical group $\mathscr{G}^{\bigstar}$. It can be shown that the $\mathscr{G}^{\bigstar}$-invariance of $F(\delta x_i|x_i^*, T)$ holds necessarily for each of the homogeneous polynomials $F_p(\delta x_i|x_i^*, T)$ of degree p of its Taylor expansion (eqn [2]).

The second key aspect of the mathematical theory concerns the replacement of the increment variables δx_i by their linear combinations, which have the property of being adapted to the group $\mathscr{G}^{\bigstar}$. Specifically, if, for the sake of simplicity, a single increment variable δx is considered, it is written as

$$\delta x = \sum_{\alpha,j} \eta_j^{\alpha} \cdot \xi_j^{\alpha} \qquad [3]$$

where, for a given value of an index α, the m degrees of freedom ξ_j^{α} $(j = 1, 2, \ldots, m)$ form a basis of an m-dimensional vector space $\mathscr{E}^{\alpha}$ invariant and irreducible under the action of $\mathscr{G}^{\bigstar}$. This property means, first, that each operation g belonging to $\mathscr{G}^{\bigstar}$ acts on a given ξ_i^{α} by transforming it into a linear combinations of the m variables ξ_j^{α} (same index α), and that, therefore, the space $\mathscr{E}^{\alpha}$ is globally invariant under this action. In addition, $\mathscr{E}^{\alpha}$ does not contain any subspace possessing this property of global invariance under the set of all elements of $\mathscr{G}^{\bigstar}$. The index α labels the set of irreducible representations Γ^{α} of this group, which is established once and for all on the basis of the mathematical structure of a group. This index specifies a "simple and standard" mode of action of $\mathscr{G}^{\bigstar}$ on an invariant vector space. For any group, one of the irreducible representations, Γ^0, of dimension $m = 1$, is the trivial representation whose unique basis vector is unchanged by the action of any element $\mathscr{G}$ of the group.

The action of $\mathscr{G}^*$ on δx can, in fact, be considered on the basis of eqn [3] in two equivalent ways: either by considering, as assumed above, that the η_j^{α} are mere coefficients unchanged by this action and that $\mathscr{G}^{\bigstar}$ only acts on the ξ_j^{α}, or, alternatively, that the ξ_j^{α} constitute a given set of fixed degrees of freedom and that the η_j^{α} are transformed by the action of $\mathscr{G}^{\bigstar}$ according to the representation Γ^{α}. The latter option is retained in the following. It has the advantage that the ξ_j^{α} can be chosen as fixed quantities with finite and normalized values and that both the symmetry properties and the infinitesimal character of δx are attributed to the η_j^{α} coefficients.

The preceding statements on the irreducibility of Γ^{α} and of $\mathscr{E}^{\alpha}$ need to be completed, because the mathematical theory of group representations considers vector spaces, and representations, based on complex numbers. Since the degrees of freedom are real quantities, it must be stated that Γ^{α} is either a real irreducible representation or a direct sum of two

complex conjugate irreducible representations. The action of $\mathcal{G}^\star$ on the $\eta_{\alpha,j}$ coefficients, for given α, is then defined by a set of orthogonal matrices $M^\alpha(\mathcal{G})$ associated with the various elements $_\mathcal{G} \in \mathcal{G}^\star$.

A series of central results can be derived from the $\mathcal{G}^*$ invariance of F and by using the variables η_j^α in $F(\eta_j^\alpha | x_i^*, T)$:

- For the theory, the very definition of a continuous phase transformation at T_c is based on the occurrence of a change in the symmetry of the equilibrium atomic configuration. Namely, the symmetry group $\mathcal{G}$ of the equilibrium configuration $x_i^{eq}(T)$ is $\mathcal{G} = \mathcal{G}^*$ on one side of T_c (generally for $T \geqslant T_c$) and $\mathcal{G} \subset \mathcal{G}^*$ on the other (for $T < T_c$). In other terms, in the situation generally encountered (which will be considered as always realized in the following), there is a breaking (also referred to as lowering) of the symmetry on decreasing the temperature across T_c.
- The trivial representation Γ^0 is not present in the linear expansion of δx (eqn [3]) and, accordingly, there is no term F_1 of degree one in the Taylor expansion of F.
- The term F_2 of degree two in this expansion necessarily has the form

$$F_2(\eta_j^\alpha | x_i^*, T) = \sum_\alpha A_\alpha(x_i^*, T) \left[\sum_j (\eta_j^\alpha)^2 \right] \quad [4]$$

  where all the variables η_j^α relative to each irreducible representation α contribute to a single sum of squares with coefficient A_α.
- In the neighborhood of T_c, $A_\alpha > 0$ for all A_α except one which vanishes and changes sign at T_c. Namely, if the corresponding index is written as $\alpha = \alpha^*$, then, with $a > 0$,

$$A_{\alpha^*} = a(T - T_c) \quad [5]$$

The m-dimensional set of m degrees of freedom $(\eta_j^{\alpha^*})$ associated with the vanishing coefficient A_{α^*} is called the order parameter of the phase transformation.

- Whenever an A_α is strictly positive at a given temperature, the equilibrium values of the corresponding components $(\eta_j^\alpha)^{eq}(T)$ are necessarily equal to zero, as straightforwardly deduced by minimizing the leading term in the Taylor expansion (eqns [2] and [4]). Hence, for $T > T_c$, all the components vanish. For $T < T_c$, in the approximation where just the leading term is considered, the only degrees of freedom which can take nonzero equilibrium values are the m components of the order parameter. This result implies that the change in atomic configuration as well as the main physical anomalies induced by the phase transformation can be studied by considering the free energy as a function of the sole components of the order parameter. The other variables (η_j^α), with $\alpha \neq \alpha^*$, can be ignored, in the first place, since their equilibrium values are equal to zero at any temperature. For the sake of simplicity, the index α can then be dropped. The free energy, whose minima determine the equilibrium configuration of the system at each temperature, is given by

$$F(\eta_j | T) = F_0 + a(T - T_c) \left[\sum_j (\eta_j)^2 \right] + \cdots + F_p(\eta_j | T) + \cdots \quad [6]$$

In summary, given the symmetry group $\mathcal{G}^*$ of the equilibrium configuration of a system at the transformation temperature T_c (and above it), the order parameter of a phase transformation is a set of m degrees of freedom $(\eta_1, \eta_2, \ldots, \eta_m)$ whose symmetry properties, that is, changes under the action of the elements of $\mathcal{G}^*$, are defined by the type of irreducible representation Γ^{α^*} associated with it. Physically, η_j are linear combinations of increments δx_i of the degrees of freedom of the system (e.g., atomic position, orientations of magnetic moments). The specificity of this combination is that its second-degree contribution to the Taylor expansion (eqn [2]) has a coefficient A_{α^*} that vanishes and changes sign at T_c.

$\mathcal{G}^\star$ Groups

The groups $\mathcal{G}^\star$ of operations encountered in the study of real physical systems are of various types. A standard situation of reference is that of phase transformations taking place in crystalline solids. $\mathcal{G}^*$ is then one of the 230 crystallographic space groups, obtained by combining specific orthogonal transformations (among which rotations through a restricted set of angles), an infinite discrete set of lattice translations, and certain fractions of these translations. The irreducible representations Γ^α of these groups, denoted $\Gamma^{\boldsymbol{k},n}$, form an infinite set, where the index $\boldsymbol{k}$ is a vector of the reciprocal space, whose three components can take a continuous set of values, and n is an integer taking a finite number of values. It can be shown that if the considered phase transformation leads to a low symmetry phase which is also crystalline, not all the irreducible representations $\Gamma^{\boldsymbol{k},n}$ are acceptable to describe the symmetry properties of the order parameter (Lifshitz criterion). The vector $\boldsymbol{k}$ must end on the so-called high-symmetry points of the Brillouin zone of the crystal, its components

being a few specific fractions of the reciprocal lattice vectors. For a given group $\mathcal{G}^*$, the task of enumerating the possible symmetry properties of order parameters of phase transformations between crystalline phases is then a finite one. Order parameter dimensions range from $m = 1$ to $m = 8$.

The irreducible representations $\Gamma^{k,n}$ with k different from the above restricted set of vectors, in particular when their projections on the reciprocal lattice vectors are not all rational numbers, are not devoid of physical interest. The corresponding order parameters describe phase transformations between a crystalline phase and a so-called incommensurately modulated crystal phase. In these phases, atomic positions deviate slightly from their positions in a perfect crystal, the deviations being periodic in space; further, the ratio of atomic periods in these phases to those in the reference crystal lattice are irrational numbers.

Another standard situation is that of phase transformations in crystals involving the onset of an organized configuration of magnetic moments. The symmetry group $\mathcal{G}^*$ then includes, in addition to the translations and orthogonal transformations already considered for crystals, the time-reversal operation $\mathcal{R}$ which reverses the directions of magnetic moments. This operation is of a specific mathematical nature because, unlike the geometrical operations considered above, it is associated with an antilinear operator. This feature introduces differences in the formulation of the order parameter symmetry that cannot be simply associated with an irreducible representation of $\mathcal{G}^*$.

Liquid crystals represent another class of substances that undergo a large variety of phase transformations. The relevant $\mathcal{G}^*$ groups are, as for crystalline solids, combinations of orthogonal transformations and translational. However, in this case, the orthogonal transformations generally involve a continuous set of rotations around an axis, and the translational operations form continuous sets at least in one direction.

$\mathcal{G}^*$-Invariant Free Energy

Within the framework of Landau's phenomenological theory, it can be shown that the presence of a term F_3 of degree three in the expansion (eqn [6]) is incompatible with the continuous character for the phase transformation. Imposing the absence of such a term (Landau criterion) puts a mathematical restriction on the irreducible representations Γ^α acceptable to describe the symmetry properties of an order parameter. Its mathematical formulation states that the symmetrized third power of the representation Γ^α must not contain the trivial representation of $\mathcal{G}^\bigstar$. Certain irreducible representations of the crystallographic groups do not comply with this criterion and are, therefore, not eligible for describing the symmetry properties of order parameters.

One fourth-degree term, at least, F_4 is always present in the F-expansion. Indeed, for any irreducible representation Γ^α, the term $[\sum_j (\eta_j)^2]^2$ is $\mathcal{G}^*$-invariant, being the square of the invariant second-degree term. In general, the $\mathcal{G}^*$-invariant fourth-degree term is a linear combination:

$$F_4(\eta_j, \beta_k) = \sum_k \beta_k f_4^{(k)}(\eta_j) \qquad [7]$$

where the β_k are arbitrary coefficients and each $f_4^{(k)}$ is $\mathcal{G}^*$-invariant and can be considered as a basis vector of the vector space $\mathcal{P}_4$ of $\mathcal{G}^*$-invariant fourth-degree polynomials. An example is given in a later section.

Symmetry Breaking

The restriction of the sum in eqn [3] to only the components η_j of the order parameter shows that the equilibrium configuration of the system, defined by the $\delta x^{\mathrm{eq}}(T)$, is determined by

$$\delta x^{\mathrm{eq}}(T) = \sum \eta_j^{\mathrm{eq}}(T)\xi_j \qquad [8]$$

where the η_j^{eq} are the values of the η_j that minimize the free energy (eqn [6]). At least one of the η_j^{eq} components has nonzero value below T_c. The nonzero components are specified by the terms $F_p(\eta_j|T)$ of degrees greater than 2. In most cases, the fourth-degree term is sufficient to determine them.

Equation [8] can be interpreted in the following manner: the equilibrium configuration $\delta x^{\mathrm{eq}}(T)$ is a nonzero vector with components η_j^{eq} in the m-dimensional space $\mathcal{E}^\alpha$ of the order parameter. While this space is globally invariant under the group $\mathcal{G}^*$, a given vector of this space, with components η_j, cannot be invariant under all the elements of this group (due to the irreducibility and the nontrivial character of $\mathcal{E}^\alpha$). Only a subgroup $\mathcal{G} \subset \mathcal{G}^*$ leaves this vector unmoved. $\mathcal{G}$ is therefore, the symmetry group of the equilibrium atomic (or spin) configuration $(x^* + \delta x^{\mathrm{eq}})$ below T_c (since x_i^* is invariant under $\mathcal{G}^* \supset \mathcal{G}$). The symmetry breaking occurring at T_c is, therefore, $\mathcal{G}^* \to \mathcal{G}$.

For a given irreducible representation Γ^α of $\mathcal{G}^\bigstar$, there is a finite number of these subgroups that can be systematically enumerated. They are called the small groups or isotropy groups of the vector defined by the η_j. Enumerating the set $\{\mathcal{G}\}$ of these small groups $\mathcal{G}$, for all directions in $\mathcal{E}^\alpha$, provides a collection of the potential symmetry changes which may be observed across a continuous phase transformation, for the considered order parameter symmetry. The

actual symmetry change is associated with the vector direction (η_j^{eq}) that minimizes F (eqn [6]).

It has been conjectured that the step of minimizing F could be avoided by relying on a group-theoretical rule: the maximal small-group rule. Thus, the "equilibrium direction" (η_j^{eq}) can be assumed to define necessarily a small group $\mathcal{G}_m \in \{\mathcal{G}\}$ complying with the condition that if $\mathcal{G}$ is any other small group ($\mathcal{G} \in \{\mathcal{G}\}$) distinct from $\mathcal{G}_m$, then

$$\mathcal{G}_m \not\subset \mathcal{G} \qquad [9]$$

This conjecture, although verified in most current situations (in particular for order parameter dimension $m = 1-3$), has been invalidated by a few theoretical examples of order parameter symmetries for which the calculated minimum of the free energy corresponds to a direction (η_j^{eq}) with a nonmaximal small group $\mathcal{G}$.

Intrinsic Symmetries of the Order Parameter and of the Free Energy

The "physical" groups $\mathcal{G}^\star$ are not the ones most effectively involved in the mathematical procedure exploiting the symmetry properties of the order parameter. Indeed, the action of the group $\mathcal{G}^\star$ in the space $\mathcal{E}^\alpha$ (i.e., the manner by which $\mathcal{G}^\star$ acts on η_j) is entirely specified by the set of matrices $M^\alpha(g)$ expressing this action. These matrices themselves form a group G^* which generally has a different structure than $\mathcal{G}^\star$, the correspondence $\mathcal{G}^\star \to G^*$ being only a homomorphism. G^* is often simpler than $\mathcal{G}^\star$. While $\mathcal{G}^\star$ is, for instance, an infinite crystallographic space group involving orthogonal transformations and translations, G^* can be a finite group of orthogonal transformations. G^* is, therefore, a subgroup of the so-called full orthogonal group in m dimensions, denoted $O(m)$. In addition, it is an irreducible subgroup, that is, one that leaves no subspace of $\mathcal{E}^\alpha$ invariant. The subgroups G^* can be enumerated for each order parameter dimension m, while $\mathcal{G}^\star$ also depends on the nature of the system. The G^* groups characterize the intrinsic symmetry of the order parameter. Their enumeration is easy for small values of m. Hence, for $m = 1$, $\mathcal{E}^\alpha$ is a line containing the origin O, and G^* is one of the two possible groups denoted as C_1 and $\overline{C_1}$, where C_1 is the trivial group reduced to the sole identity and $\overline{C_1}$ is the group of order 2 generated by the symmetry about the origin O. For $m = 2$, $\mathcal{E}^\alpha$ is a plane. There are two infinite discrete sets of groups G^*: groups C_n generated by the rotations of angle $2\pi/n$ around the origin O (with n a finite or infinite integer), and groups C_{nv} products of C_n by a reflection in a line passing through the origin. For $m = 3$, $\mathcal{E}^\alpha$ is the three-dimensional space, and G^* is either identical to $O(3)$ or to one of its irreducible subgroups, namely, the full symmetry groups of a cube, a regular tetrahedron, and a regular icosahedron. The Landau criterion, which forbids the existence of a third-degree term in the free energy, has the effect of reducing the number of acceptable intrinsic symmetries. Hence, for $m = 1$, among the two groups considered, only $\overline{C_1}$ is relevant. For $m = 2$, C_3 and C_{3v} are not acceptable, and for $m = 3$, the symmetry of the tetrahedron is excluded. Once the homomorphism between $\mathcal{G}^\star$ and G^* has been specified, the determination of the small groups $\mathcal{G} \subset \mathcal{G}^\star$ of the various directions in $\mathcal{E}^\alpha$ can be replaced by the working out of the small groups $G \subset G^*$ in $\mathcal{E}^\alpha$. This task can be achieved in a unified way for all the transformations sharing the same intrinsic order parameter symmetry.

Another type of intrinsic symmetry can be defined for the $\mathcal{G}^\star$-invariant polynomials of a given degree belonging to the free energy. Hence, one can define a homomorphism $G^* \to G^*_{(4)}$ in which the latter group acts in the vector space $\mathcal{P}_4$ of $\mathcal{G}^\star$-invariant fourth-degree polynomials defined by eqn [7]. Again, the set of $G^*_{(4)}$ groups is more restricted than the set of G^* groups. Since the entire Taylor expansion F is G^*-invariant, one has necessarily $G^* \subset G^*_p \subset O(m)$. There are only three distinct forms of fourth-degree terms for $m = 2$, corresponding to $G^*_{(4)} = C_4, C_{4v}$, or $O(2)$, and two for $m = 3$ corresponding to $G^*_4 = O_H$ (cubic symmetry) and $O(3)$. To each of these groups corresponds a general expression of fourth-degree contribution to the free energy. For instance, for $m = 3$ and $G^*_{(4)} = O_H$, this is given by

$$F_4 = \beta_1(\eta_1^2 + \eta_2^2 + \eta_3^2)^2 + \beta_2(\eta_1^4 + \eta_2^4 + \eta_3^4) \qquad [10]$$

Similar results can be derived for other values of m, and for terms of degree higher than 4.

Extension to the Formulation of the Renormalization-Group Hamiltonian

The so-called renormalization-group theory in reciprocal space, which deals with the critical behavior at a continuous phase transformation, relies on an "effective Hamiltonian density" which is given by

$$H(r) = \alpha \sum_j \phi_j^2(r) + \sum_k \beta_k f_4^{(k)}(\phi_j) + \sum (\nabla \phi_j)^2 \qquad [11]$$

Its spatially homogeneous terms, with coefficients α and β_k, are identical to the fourth-degree Taylor expansion (eqn [6]). Hence, the intrinsic symmetries G^* and $G^*_{(4)}$ defined earlier can be fully utilized to establish a set of relevant Hamiltonian densities.

In this theory, one generates a flow of Hamiltonian densities all given by eqn [11] and characterized by α and β_k coefficients which may converge toward a "stable fixed-point Hamiltonian" defined by the set of coefficients α^* and β_k^* and associated with a given physical critical behavior. The existence of such stable fixed points is considered as a requirement for the occurrence of a continuous transformation in the system.

A mathematically formulated criterion forbidding such an occurrence has been stated. It relies on consideration of groups acting in the vector space $\mathscr{P}_4$ of polynomials earlier. Let G_C be the small group of the direction (β_k^*) in this space. It may also be the invariance group of other directions in $\mathscr{P}_4$. Let $\{(\beta_j)\}$ represent their set (obviously containing the (β_k^*)). One can define a group G_N acting in $\mathscr{P}_4$ and leaving globally invariant the set $\{(\beta_j)\}$ (while G_C leaves every direction unmoved). The criterion states that a necessary condition for the stability of the considered fixed-point Hamiltonian (β_k^*) is that $G_C = G_N$.

Nomenclature

E^α	vector space of the order parameter
F	variational free energy
$f_4^{(k)}$	$\mathscr{G}^\star$-invariant fourth-degree independent polynomial
$F_{\text{equilibrium}}$	equilibrium free energy
$\mathscr{G}$	low-symmetry group
G	subgroup of G^* and small group of a direction in the order parameter space
$\mathscr{G}^\star$	high-symmetry group
G^*	intrinsic symmetry-group of the order parameter
$G^*_{(4)}$	intrinsic symmetry group of fourth-degree polynomials
$\mathscr{P}_4$	vector space of fourth-degree polynomials
T_c	transformation temperature
α	label of an irreducible representation
β_k	coefficient of the fourth-degree expansion
$\Gamma^{k,n}$	irreducible representation of a crystallographic space group
Γ^α	irreducible representation of a group
η_j	components of the order parameter

Phases and Phase Equilibrium

M A White, Dalhousie University, Halifax, NS, Canada

Introduction

A phase is a homogeneous region of matter, separated from other homogeneous regions by phase boundaries. The different regions (phases) will have different physical and/or chemical properties. For example, the contents of a beaker with ice cubes floating in water form a two-phase system, as the ice and water are two separate phases. When more than one phase exists, the material is heterogeneous, but the length scale of heterogeneity can vary from nanometer to macroscopic dimensions.

Although phase equilibria can involve many types of phases, this article concentrates on solid–solid and solid–liquid equilibria.

Phase Stability for Pure Materials

If more than one phase of a pure material is possible, the phase with the lowest energy will be stable with respect to all others. The stability condition can

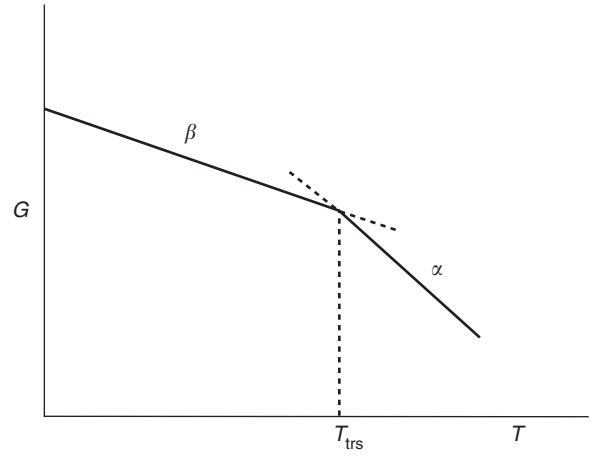

Figure 1 Gibbs energy as a function of temperature, showing a phase transformation at T_{trs}. The stable phase, shown by a solid line, is the one with the lowest G. For $T < T_{trs}$, phase α would be metastable with respect to phase β.

change as the temperature, or pressure, or volume, or other variables change.

If the temperature and pressure are the important variables, as in most laboratory conditions, then the phase with the lowest Gibbs energy (also commonly referred to as "Gibbs free energy"), G, will be the stable phase for those conditions. Since G is a state function of T and P such that

$$dG = V\,dP - S\,dT$$

it follows that

$$\left(\frac{dG}{dT}\right)_P = -S$$

so, for a given phase, G decreases as the temperature increases. If the $G(T)$ curve for two phases, α and β, cross (see **Figure 1**), the phase with the lower G will be stable. At the temperature where phases α and β are in equilibrium, $G_\alpha = G_\beta$. At a temperature at which $G_\alpha > G_\beta$, phase β is more stable than phase α. However, in these circumstances, α could exist in favor of β if the kinetic barrier for $\alpha \rightarrow \beta$ is too high. In that case, α would be metastable with respect to β because it is at a local energy minimum, but not at the global energy minimum. For example, liquid water can be supercooled below 0°C and is metastable with respect to ice for $T < 0$°C. Supercooled water owes its existence to the kinetic barrier to ice formation.

Polymorphism

For many pure materials, different phases are stable, depending on the temperature, pressure, electric field, magnetic field, etc.

Just within the temperature parameter, complex materials can show intermediate phases (known as mesophases) with intermediate amounts of disorder. In general, materials become more disordered as the temperature increases. For molecular materials with particular molecular shapes, two general categories of mesophases are possible.

If the material is composed of molecules which could easily glide past one another, because they are either rod-shaped or disk-shaped, at some intermediate temperature the material could form a liquid crystal. In the liquid crystalline mesophase, the molecules can glide past one another easily, and the material will conform to the shape of its container, making it appear liquid-like. However, if the molecules are aligned, there will be some crystal-like properties as well, for example, diffraction of light. Therefore, the term "liquid crystal" is quite apt. However, this is a mesophase: at lower temperatures the material will form a normal ordered solid, and at higher temperatures it will form an isotropic liquid.

On the other hand, if the molecules are nearly spherical, the barrier to reorientation can be so low that an orientationally disordered mesophase is possible. C_{60} is known to form such a phase: the C_{60} molecules are on the lattice points of a face-centered-cubic lattice, but they rotate rather freely so that they are orientationally disordered. At lower temperatures, the C_{60} molecules become more ordered.

Liquid crystals and orientationally disordered solids are two examples of polymorphism, which is literally the existence of more than one type of solid phase for a given composition. Polymorphism is quite common. Molecular materials are particularly prone to polymorphism because the Gibbs energy surface can have many energy minima, which can be explored as the external parameters (T, P, etc.) are varied. Even ionic materials can exhibit polymorphism due to phase changes related to electronic, magnetic, and structural properties. Examples include metal → superconductor transitions, ferromagnetic → paramagnetic transitions, and transitions with changes in crystal structure. Polymorphism plays an important role in many materials, from pharmaceuticals, where different polymorphs might have different biological activity, to geological materials, where polymorphism can be induced by extremes of temperature and pressure.

A phenomenon related to polymorphism is the existence of glass phases. A glass can be formed by supercooling a liquid. Below the glass transition temperature, T_g, the supercooled liquid becomes a rigid glass. Glass is essentially a "frozen liquid" in that its atoms are not ordered. However, the glass phase is almost always metastable with respect to a stable crystalline phase.

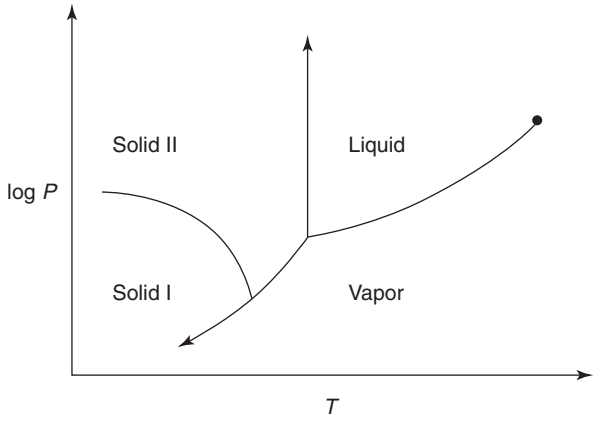

Figure 2 Schematic phase diagram for a pure (one-component) material, showing two different stable solids, labeled as I and II.

A schematic, equilibrium P–T phase diagram for a pure component with two stable solid phases is shown in **Figure 2**.

The Phase Rule

The phase rule, first devised by J Willard Gibbs, relates the number of degrees of freedom in a system, f, to the number of phases, p, and number of chemical components, c. Thus far, only single-component (i.e., pure, $c = 1$) systems have been considered, but many materials are composed of more than one component. The number of degrees of freedom is given by:

$$f = c - p + n$$

where n is the number of externally controllable variables (T, P, etc.) which can, in principle, be varied and change the state of the system.

For a pure system, $c = 1$, and if T and P can vary, $n = 2$. If a solid and liquid are in equilibrium, $p = 2$ and thus $f = 1$. This indicates that there is only one degree of freedom, and T and P cannot be varied independently while maintaining the two-phase equilibrium. This is apparent from the two-phase coexistence lines in **Figure 2**.

Phase Equilibria for Pure Materials

From the fact that two phases in equilibrium have the same value of G, and if the equilibrium is shifted by changing P and T such that equilibrium is maintained, the changes in G for the two phases are equal:

$$\mathrm{d}G^{\alpha} = \mathrm{d}G^{\beta}$$

and both can be represented by the corresponding pressure and temperature contributions:

$$\mathrm{d}G^{\alpha} = V^{\alpha}\,\mathrm{d}P - S^{\alpha}\,\mathrm{d}T = V^{\beta}\,\mathrm{d}P - S^{\beta}\,\mathrm{d}T$$

leading to the Clapeyron equation

$$\frac{\mathrm{d}P}{\mathrm{d}T} = \frac{\Delta_{\mathrm{trs}}S}{\Delta_{\mathrm{trs}}V} = \frac{\Delta_{\mathrm{trs}}H}{T_{\mathrm{trs}}\Delta_{\mathrm{trs}}V}$$

which quantifies the slopes of the phase equilibrium lines in **Figure 2** in terms of the changes in the thermodynamic properties due to the change in phase.

For the special case of the liquid–vapor equilibrium line, the Clapeyron equation can be simplified by taking into account that the molar volume of the gas is much greater than that of the liquid, and, since the vapor pressure is low the gas is likely to be ideal, that is, $\Delta_{\mathrm{trs}}V = V_{\mathrm{gas}} - V_{\mathrm{liquid}} \approx V_{\mathrm{gas}} = RT/P$ (where R is the gas constant); thus, for two liquid–vapor equilibrium points, (P_1, T_1) and (P_2, T_2),

$$\ln\left(\frac{P_2}{P_1}\right) = -\frac{\Delta_{\mathrm{vap}}H}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)$$

which is known as the Clausius–Clapeyron equation. For the liquid–vapor equilibrium, the P–T lines, as shown in **Figure 2**, can be known from the enthalpy change on vaporization, $\Delta_{\mathrm{vap}}H$, and vice versa.

Chemical Potential

For any multicomponent system, an important consideration for phase equilibrium is the chemical potential for component i, μ_i:

$$\mu_i = \left(\frac{\partial G}{\partial n_i}\right)_{T,P,n_{j\neq i}}$$

where n_i is the number of moles of component i. At equilibrium, for each component i:

$$\mu_i^{\alpha} = \mu_i^{\beta} = \cdots$$

where α, β,… represent the phases. In general, the chemical potentials of different components are different. The Gibbs energy is then given by

$$G = \sum_i X_i\mu_i$$

where $X_i = n_i/n_{\mathrm{tot}}$ and n_{tot} is the total number of moles. At equilibrium, the Gibbs–Duhem relation holds:

$$S\,\mathrm{d}T - V\,\mathrm{d}p + \sum_i n_i\,\mathrm{d}\mu_i = 0$$

Binary Systems

General Concepts

To describe a binary (two-component) mixture, three variables are required to describe the equilibrium phases: composition (usually expressed as mass percent or mole fraction), temperature, and pressure.

Although pressure can change the equilibrium phases, it is the most difficult variable to manipulate experimentally, and small pressure changes usually have little influence on phase equilibria, so binary phase diagrams are generally expressed as the isobaric presentation of temperature as a function of composition.

For a system composed of two components A and B, such that $n_A + n_B = 1$ mole, the Gibbs–Duhem equation becomes

$$S_{total}\,dT - V_{total}\,dP + X_A\left(\left(\frac{\partial\mu_A}{\partial T}\right)_P dT + \left(\frac{\partial\mu_A}{\partial P}\right)_T dP + \left(\frac{\partial\mu_A}{\partial X_B}\right)_{T,P} dX_B\right) + X_B\left(\left(\frac{\partial\mu_B}{\partial T}\right)_P dT + \left(\frac{\partial\mu_B}{\partial P}\right)_T dP + \left(\frac{\partial\mu_B}{\partial X_B}\right)_{T,P} dX_B\right) = 0$$

and with

$$d\mu_A = \left(\frac{\partial\mu_A}{\partial T}\right)_P dT + \left(\frac{\partial\mu_A}{\partial P}\right)_T dP + \left(\frac{\partial\mu_A}{\partial X_B}\right)_{T,P} dX_B$$

it follows that

$$(1 - X_B)\left(\frac{\partial\mu_A}{\partial X_B}\right) + X_B\left(\frac{\partial\mu_B}{\partial X_B}\right) = 0$$

which is a general binary solution result. For $X_B = 1 - X_A$, the Gibbs energy is given by

$$G = \mu_A + X_B(\mu_B - \mu_A)$$

which is the equation for a straight line for $G(X_B)$ with slope $(\mu_B - \mu_A)$ and intercept μ_A. Such a line would be a tangent in a graph of $G(X_B)$. Recalling that the phase equilibrium condition is the equivalence of μ_i, the chemical potential of each component i in each phase, it follows that the $G(X)$ curves for the phases in equilibrium must share a common tangent. This concept will prove useful in the analysis of $G(X)$ for binary phase diagrams (*vide infra*).

Solid Solutions

One of the simplest binary phase diagrams is one in which both components are completely miscible in each other in all proportions, forming a solid solution. Examples include metals which form alloys and many mineral systems. In general, solid solutions require the two components to have very similar interatomic interactions (similar types of atoms, and similar sizes). A generalized binary phase diagram showing formation of a solid solution is shown in **Figure 3**.

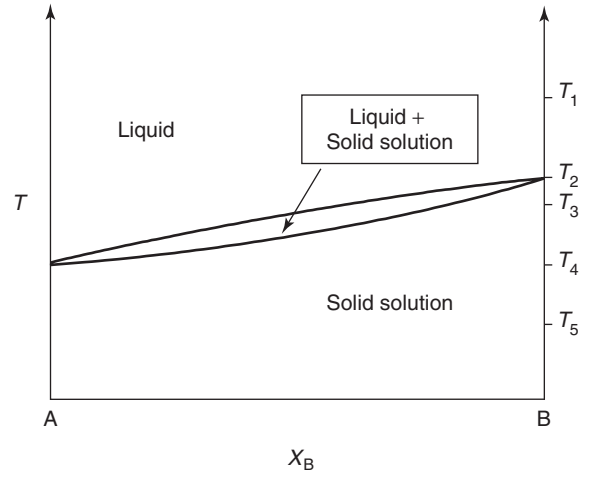

Figure 3 A schematic binary phase diagram showing complete miscibility of both components to form a solid solution.

The corresponding Gibbs energy diagrams for solid solution formed under various isobaric, isothermal conditions are shown in **Figure 4**. At temperatures below the melting point of either component, the solid solution is the most stable phase, due to favorable enthalpic effects and/or entropic considerations.

A consideration of the Phase Rule for the various regions of **Figure 3**, with $c = 2$ and $n = 1$, indicates that $f = 2$ in the single-phase regions (i.e., T and X can vary independently) and $f = 1$ in the two-phase regions (i.e., T and X are no longer independent variables).

Immiscible Solids

At the other extreme, sometimes components in a binary system are completely immiscible in the solid state. This would give rise to a phase diagram such as the one illustrated schematically in **Figure 5**. The depressed freezing point of component A on the addition of component B is given by T in

$$\ln X_A = \frac{\Delta_{fus}H_A}{R}\left(\frac{1}{T_A} - \frac{1}{T}\right)$$

where $\Delta_{fus}H_A$ is the enthalpy change on melting (fusion) of the pure component A, T_A is the melting temperature of pure A, and R is the (ideal) gas constant. Similarly, the freezing point of B is depressed on the addition of A, and where they meet is a special point, called the eutectic. At the eutectic composition, immiscible solids melt to directly give the liquid, whereas at off-eutectic compositions melting leads to a temperature range over which solid and liquid coexist.

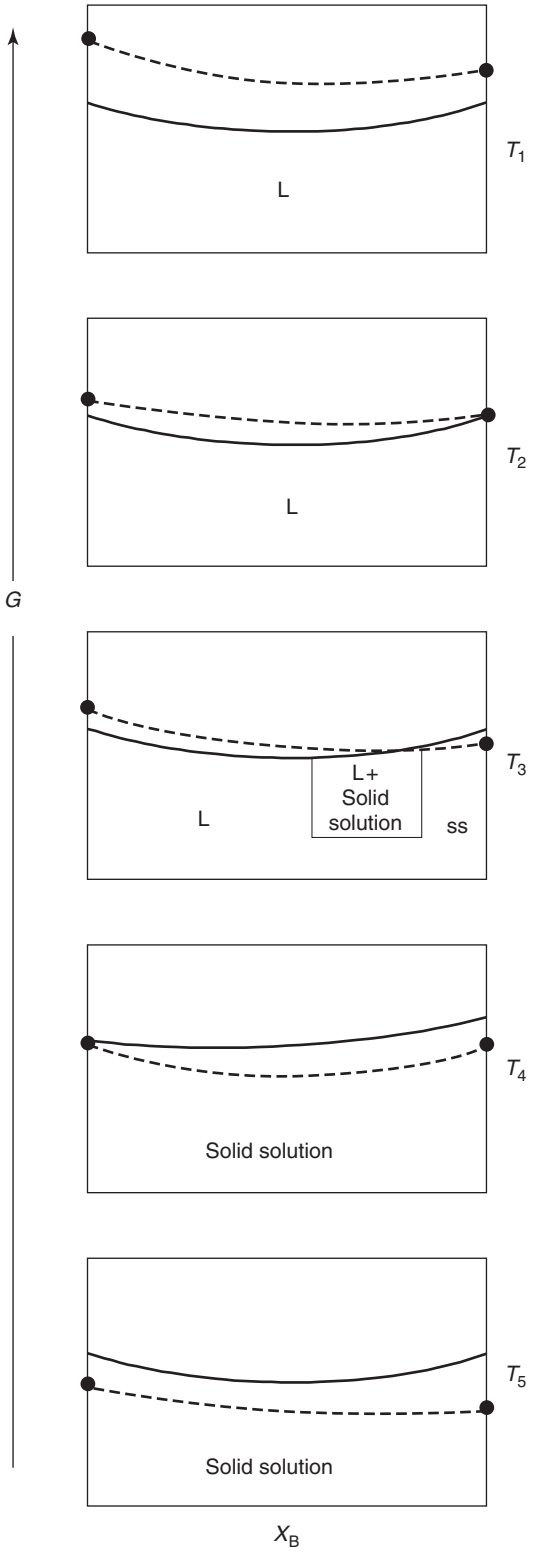

Figure 4 Gibbs energy as a function of composition for a binary system which forms a solid solution, with the temperature as indicated in **Figure 3**. The dots indicate Gibbs energies for fixed compositions, the solid curves indicate G for the liquid, and the dashed line is G for the solid solution. Note that the stable phase has the lowest value of G. When two phases are in equilibrium, their $G(X_B)$ curves share a common tangent, as at T_3.

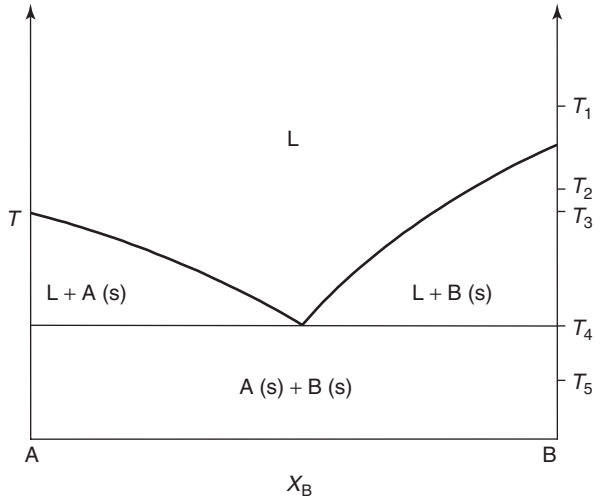

Figure 5 A schematic binary phase diagram showing complete immiscibility of the components.

In the case of immiscible solids, the components would be very dissimilar in their packing and/or interaction energies, making it more favorable for the solid to be a heterogeneous mixture of the two pure (solid) components. The corresponding Gibbs energy diagrams for immiscible solids under various isobaric, isothermal conditions are shown in **Figure 6**.

Again, the Phase Rule for the various regions of **Figure 5**, with $c = 2$ and $n = 1$, gives $f = 2$ in the single-phase regions, $f = 1$ in the two-phase regions, and now $f = 0$ at the eutectic (three phases). The invariance of the eutectic makes it useful for thermometry calibration, as are triple points in single-component systems ($f = 0$ also).

Congruently Melting Compounds

Often the two components in a binary mixture have sufficiently favorable interactions that a stoichiometric compound is formed at a certain composition. An example of a 1:1 compound of component A and component B, of empirical formula AB, is shown in **Figure 7**. This particular compound melts directly at a fixed temperature to give a liquid of the same composition, a feature known as congruent melting.

In some ways, the phase diagram of **Figure 7** is like two **Figure 5** phase diagrams, side by side. However, there is a distinction in the slope of the liquid line: at the compound composition, the slope is zero, whereas the slope is nonzero at the components (A or B in both **Figures 5** and **7**). The reason for the difference stems from the difference in composition of the liquid: pure A melts to give liquid A, and likewise for pure B, but compound AB melts to give A(liq) miscible with B(liq), and the freezing point depression equation given above no longer holds.

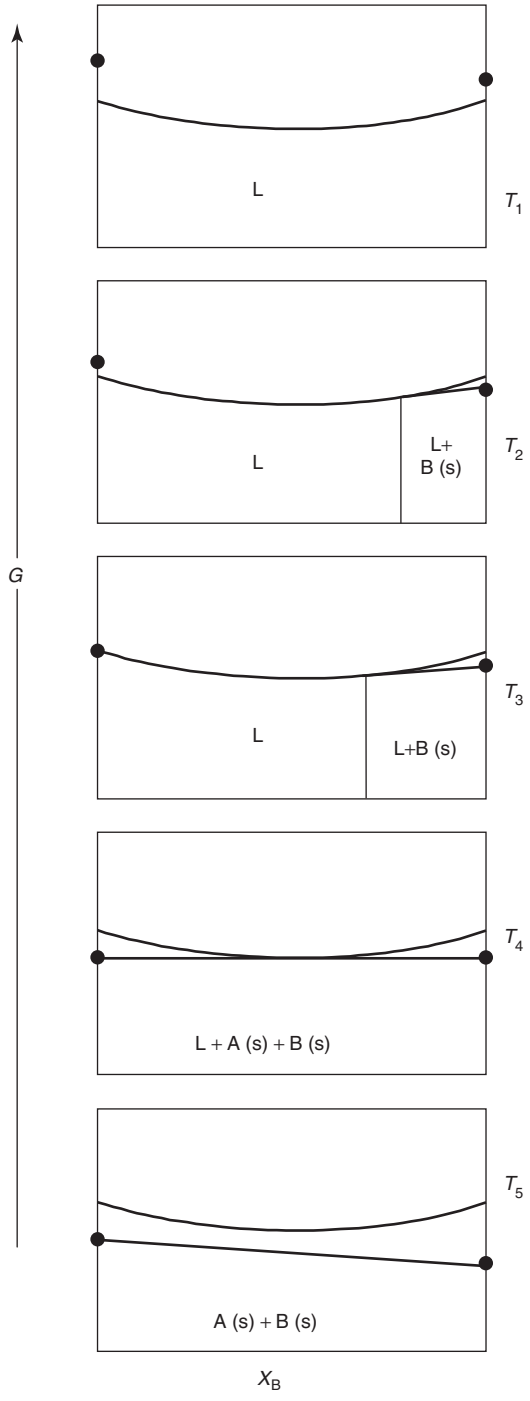

Figure 6 Gibbs energy as a function of composition for a binary system in which the solids are immiscible, with the temperatures as indicated in **Figure 5**. The dots indicate Gibbs energies for fixed compositions and the solid curves indicate *G* for the liquid.

The Gibbs energy diagrams corresponding to **Figure 7** under various isobaric, isothermal conditions are shown in **Figure 8**. Here there is a new feature compared with the previous $G(X)$ curves, the compound AB, since it is sufficiently stable to influence the phase diagram.

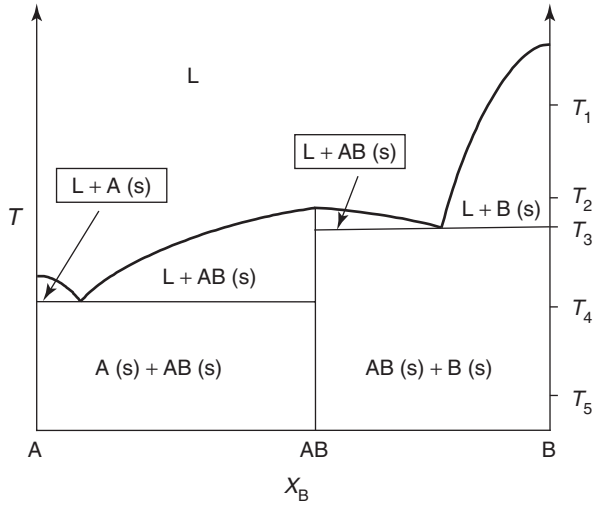

Figure 7 A schematic binary phase diagram showing the formation of a congruently melting compound of empirical formula AB.

As for the other isobaric binary phase diagrams, $f = 2$ in the one-phase regions, $f = 1$ in the two-phase regions, and $f = 0$ at the eutectic. Note that at the melting point of the congruently melting compound, $c = 1$, $n = 1$ so $f = 0$ as for a pure compound.

Incongruently Melting Compounds

Not all compounds melt congruently. Some melt with decomposition of the compound to form a liquid and one of the components, as shown in **Figure 9**. In this case, heating AB leads to

$$\mathrm{AB\ (s)} \rightarrow \mathrm{liquid} + \mathrm{B(s)}$$

and AB is said to melt incongruently.

Compounds which melt incongruently do so because the relatively low (i.e., favorable) Gibbs energy of one of the components (see **Figure 10**), and especially its rapid change with temperature.

Since

$$\left(\frac{\partial G_\mathrm{A}}{\partial T}\right)_P = -S_\mathrm{A}$$

it follows that a highly entropically stabilized component could favour incongruent melting.

Again, from the Phase Rule, $f = 2$ in the one-phase regions, $f = 1$ in the two-phase regions. Now, $f = 0$ at the incongruent melting point of the binary compound. (This is called the peritectic temperature, and the peritectic point is shown in **Figure 9**.) For a warming curve at the composition of the incongruently melting compound, the otherwise increasing temperature will halt at the peritectic temperature ($f = 0$) until the solid (AB in the case of **Figure 9**) has converted to liquid + B(s).

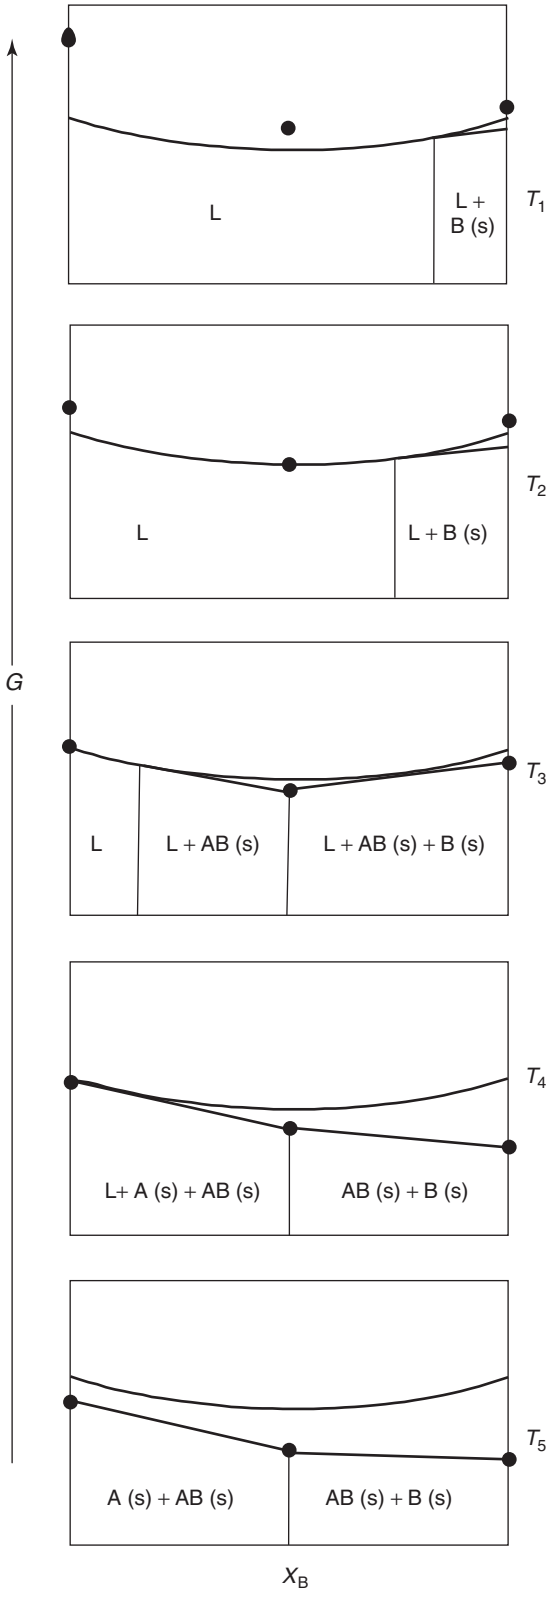

Figure 8 Gibbs energy as a function of composition for a binary system in which a congruently melting compound, AB, forms. The temperatures are as indicated in **Figure 7**. The dots indicate Gibbs energies for fixed compositions and the solid curves indicate *G* for the liquid.

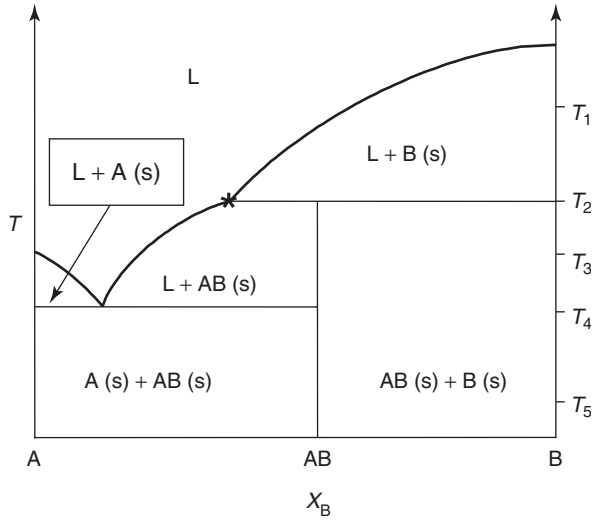

Figure 9 A schematic binary phase diagram showing the formation of an incongruently melting compound of empirical formula AB. The peritectic is shown as ✶.

Proportions of Phases in Binary Systems

In any binary system, the phases present can be surmised from the ends of an imaginary horizontal line, called a tie line. The relative proportions of the phases are inversely proportional to the distances from the ends of the tie line, given as a lever with the fulcrum at the composition under consideration. For example, at the composition shown by X_B^* in **Figure 11**, two phases coexist at temperature T*, liquid of composition X'_B, and solid B ($X_B = 1$). The relative molar proportions of liquid and B at X_B^* are given by

$$\frac{n_{liq}}{n_B} = \frac{1 - X_B^*}{X_B^* - X'_B}$$

This lever rule is a general relationship: the closer to the phase, the higher the proportion. Furthermore, the lever rule applies to both mole fraction (for a diagram expressed in *X* as for **Figure 11**), and mass fraction or mass percent (for a phase diagram expressed in mass fraction or mass percent, respectively).

Ternary Systems

When three components are mixed, making a ternary system, there are now four independently manipulable variables, *viz*. *T*, *P*, and two mole fractions (the third being given by difference). For ease of presentation, ternary phase diagrams are normally shown as isothermal isobaric slices, with the compositions given by triangular coordinates, as shown in **Figure 12**.

The sides of the triangle represent isobaric, isothermal slices of the binary system represented by the ends of the sides. For example, the side opposite the

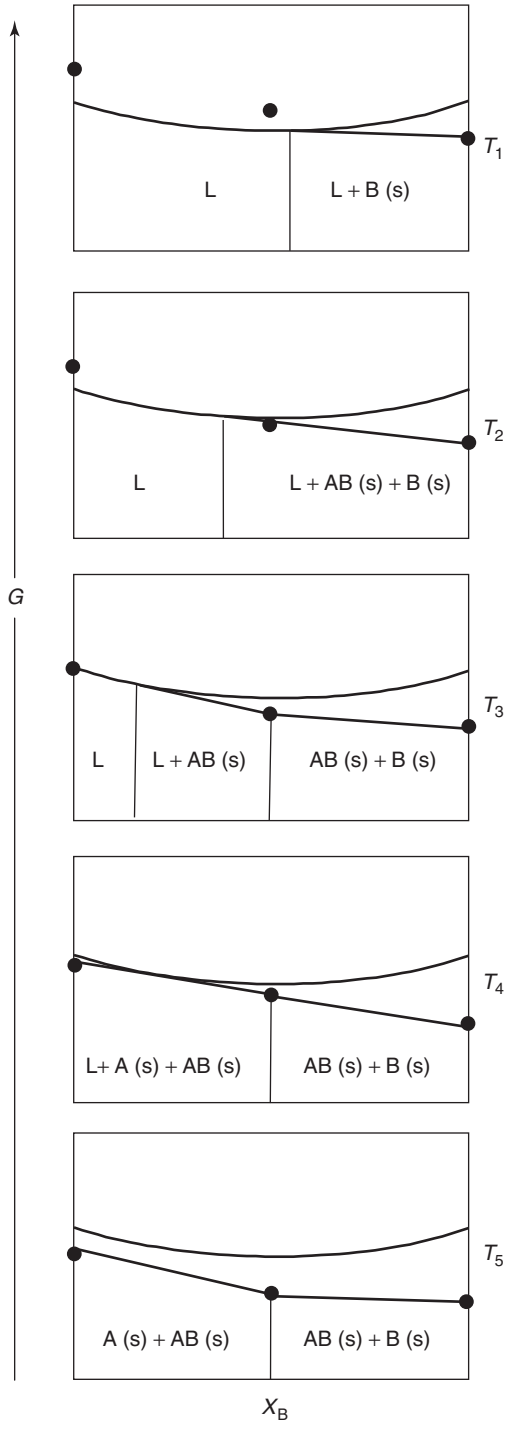

Figure 10 Gibbs energy as a function of composition for a binary system in which an incongruently melting compound, AB, forms. The temperatures are as indicated in **Figure 9**. The dots indicate Gibbs energies for fixed compositions and the solid curves indicate *G* for the liquid.

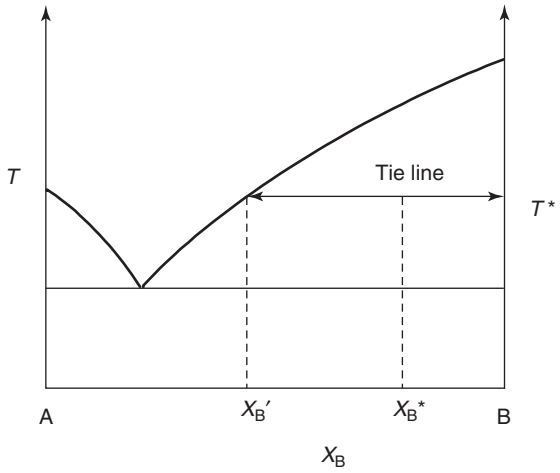

Figure 11 Illustration of the lever principle. See the text for details.

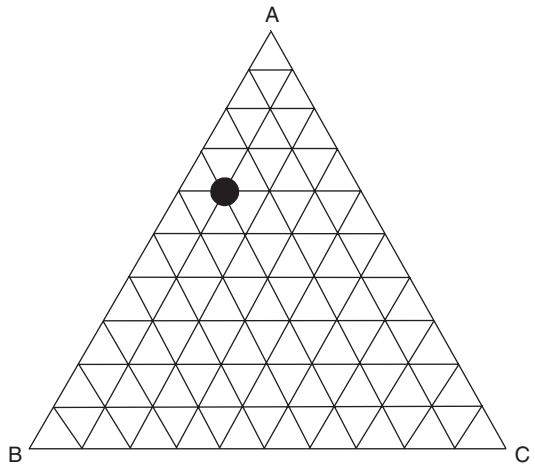

Figure 12 Graphical representation of compositions for a ternary (three-component) phase diagram. The lines correspond to constant composition in a single component. The distance from a component (A, B, or C) is inversely proportional to its concentration. For example, the B–C line at the bottom corresponds to $X_A = 0$. Each line parallel to that is at a different composition in A, at 10% steps in A. Similarly, the lines leading away from the B and C vertices correspond to constant composition in B and C, respectively. The point shown by • corresponds to 60% A, 30% B, 10% C. The ternary diagram can be expressed as mole fraction, or mass percent.

C vertex corresponds to $X_C = 0$, that is, the A–B binary system.

An example of a ternary phase diagram is shown in **Figure 13**. Here there is partial solubility of each of the components in the other. In general, ternary phase diagrams can illustrate all the features discussed so far, namely solid solution, solid immiscibility, congruently melting compound formation, and incongruently melting compound formation. Again, the number of degrees of freedom in the system is specified by the Phase Rule. In particular, note that for an isothermal, isobaric ternary system, that is, $c = 3$, $n = 0$, the maximum number of phases is three.

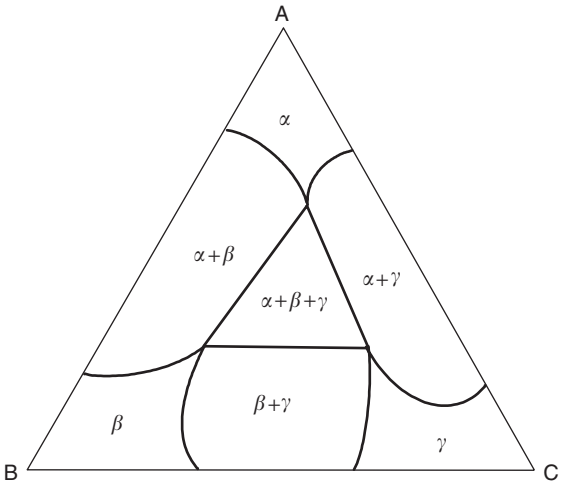

Figure 13 A schematic isobaric, isothermal ternary phase diagram, showing partial miscibility. The phases α, β, and γ are solid solutions rich in A, B, and C, respectively. Note that no more than three phases coexist.

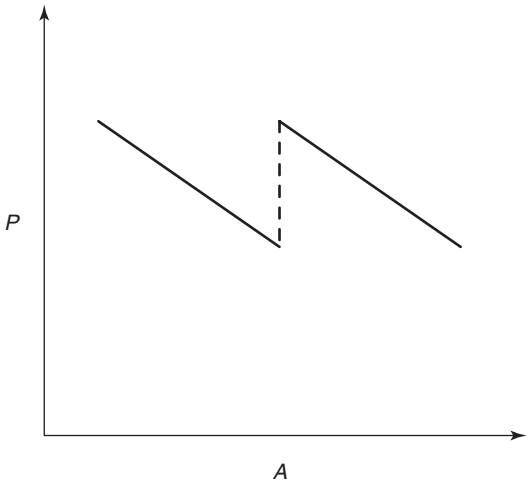

Figure 14 The pressure as a function of surface area, *A*, for a Langmuir–Blodgett film on a liquid surface. At low surface coverage (large *A*), the coverage is less than a monolayer. As the area is decreased, the pressure increases until the monolayer coverage and then at lower surface area the layer collapses, as shown by drop in *P*. At still lower surface areas, the film is greater than a monolayer thick and still shows compressibility.

Other Phase Equilibria

Thus far, only bulk phases of matter have been considered. However, if the material was two-dimensional, such as in a Langmuir–Blodgett film on a liquid surface, other phase equilibria would need to be considered. The pressure–surface area graph of **Figure 14** indicates this concept.

In the case of micelle formation by amphoteric molecules, the important phase equilibrium parameters are temperature and micelle concentration.

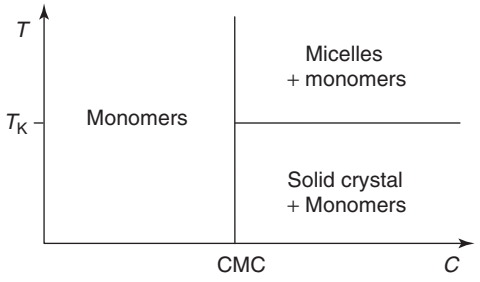

Figure 15 Phase diagram showing the temperature–concentration relationships for amphoteric molecules in solution. At low concentration, the molecules do not aggregate and appear as monomers. Above the critical micellar concentration (CMC), the molecules aggregate into micelles if the temperature is above the Krafft temperature, T_K. At high concentrations and low temperatures, a crystalline solid prevails.

This is illustrated in the phase diagram shown in **Figure 15**.

One might expect quite a different phase behavior when matter is finely divided (e.g., nanoparticle sized) due to the large surface-to-volume ratio. This can change phase stability in the presence of thermal, pressure, and other influences.

Furthermore, even within bulk materials, many other factors can influence phase behavior, including electric field, magnetic field, and strain field.

Photoelectron Spectromicroscopy

G Margaritondo, Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

Spectromicroscopy is the class of experimental techniques that combine spectroscopic performances with high spatial resolution. The name is most commonly used for photoelectron spectromicroscopy, which is based on the different spectroscopic techniques exploiting the photoelectric effect. Two different approaches are discussed: photon-focusing photoelectron spectromicroscopy and electron-optics spectromicroscopy. The discussion includes a few selected examples and an analysis of relevant performances. Finally, other types of spectromicroscopy are briefly reviewed.

Spectromicroscopy

The term "spectromicroscopy" broadly applies to all cases in which a spectroscopic technique is implemented with high spatial resolution. Therefore, many techniques can be technically considered under the term "spectromicroscopy." The discussion is focused on a leading subset of this class: spectromicroscopy techniques related to the photoelectric effect.

Besides photoemission spectromicroscopy, the important types of spectromicroscopy are: (1) electron energy loss spectroscopy (EELS), which can be performed with high lateral resolution providing local information on the electronic and chemical structure of surfaces; (2) auger spectroscopy, a leading chemical probe, can also achieve high lateral resolution; (3) X-ray-excited fluorescence, a powerful and relatively straightforward technique for chemical analysis. When performed with a high-brightness synchrotron source and an X-ray lens, the technique can achieve high lateral resolution becoming a powerful microchemical probe called fluorescence microprobe.

Near-field microscopy is a well-known approach that beats the diffraction limits of far-field microscopy by working with evanescent waves. In some cases, the technique can be implemented in a spectroscopic mode. For example, a near-field infrared microscope can perform vibrational spectroscopy in localized areas while still beating the diffraction limit. **Figure 1** shows an example of this approach.

The Development of Photoelectron Spectromicroscopy

Photoelectron spectroscopy, the class of experimental techniques based on the photoelectric effect, has emerged since the late 1960s as a leading probe of the electronic structure in condensed matter systems. The progress in the experimental tools progressively eliminated the historical limitations of such techniques, enhancing their impact and expanding their field of application. In this evolution, the development of photoelectron spectromicroscopy is one of the milestones.

Until the late 1980s, photoemission experiments were performed without lateral resolution – whereas the natural surface sensitivity of the photoelectron emission process automatically provided atomic-scale resolution in the direction perpendicular to the emitting surface. Technical problems, primarily related to the low signal level, forced the photoemission experiments to probe a sample area of the order of $1 \times 1\,\text{cm}^2$ or even larger. This was a severe limitation in the study of laterally inhomogeneous systems and processes.

In 1988–89, the first example of photoemission experiment with high lateral resolution was presented (see, e.g., **Figure 2**), opening up new opportunities in

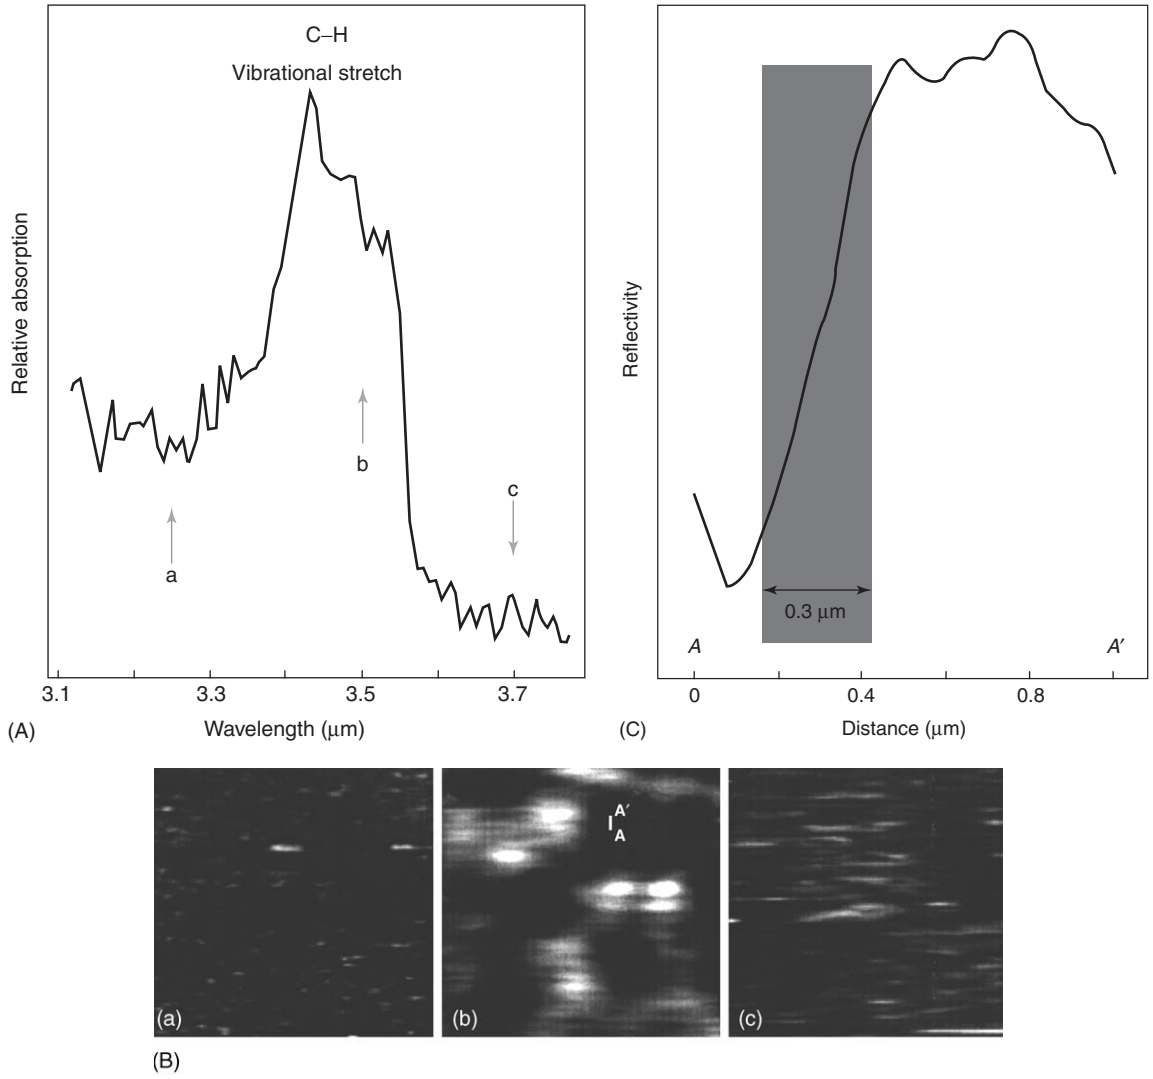

Figure 1 One of the first examples of near-field spectromicroscopy: (A) the optical absorption band corresponding to the C–H stretch vibrational mode; (B) $10 \times 10\,\mu m^2$ near-field images taken with the photon wavelengths labeled as (a), (b), and (c) in **Figure 9a**, inside and outside the C–H absorption band. The central image shows H-related features revealing an unexpected hydrogen contamination of the examined diamond film. (C) The intensity line scan along the *AA′* line of **Figure 9b** demonstrates a lateral resolution well below the diffraction limit. The data were obtained at the Vanderbilt University Free Electron Laser. (Results derived from Cricenti A, Generosi R, Luce M, Perfetti P, Margaritondo G, *et al.* (2001) Spectroscopic scanning near-field optical microscopy with a free-electron laser: CH_2 bond imaging in diamond films. *Journal of Microscopy* (Oxford) 202: 446.)

the general field of photoemission techniques. Lateral resolution could be achieved thanks to the advent of high-brightness synchrotron radiation sources such as the undulators. In the subsequent years, photoemission spectromicroscopy in different forms rapidly expanded becoming one of the most prolific subdomains of photoelectron spectroscopy.

One important aspect of this evolution was the impact on the life sciences. Without lateral resolution, photoelectron spectroscopy had been almost useless in biology, biophysics, and the medical research. Spatial dimensions such as the size of cells and cell components determine in fact the minimum spatial resolution to provide experimental information in these domains. Before the late 1980s, photoelectron spectroscopy was, as mentioned, very far from such lateral resolution levels.

After the advent of photoelectron spectromicroscopy, photoelectron-based probes became instead quite important in biology and medical research. They provide in fact very valuable microchemical information without requiring extensive sample preparation and the consequent possibility of artifacts. On the other hand, photoelectron spectromicroscopy requires ultrahigh vacuum and this constitutes a severe limitation in biological applications.

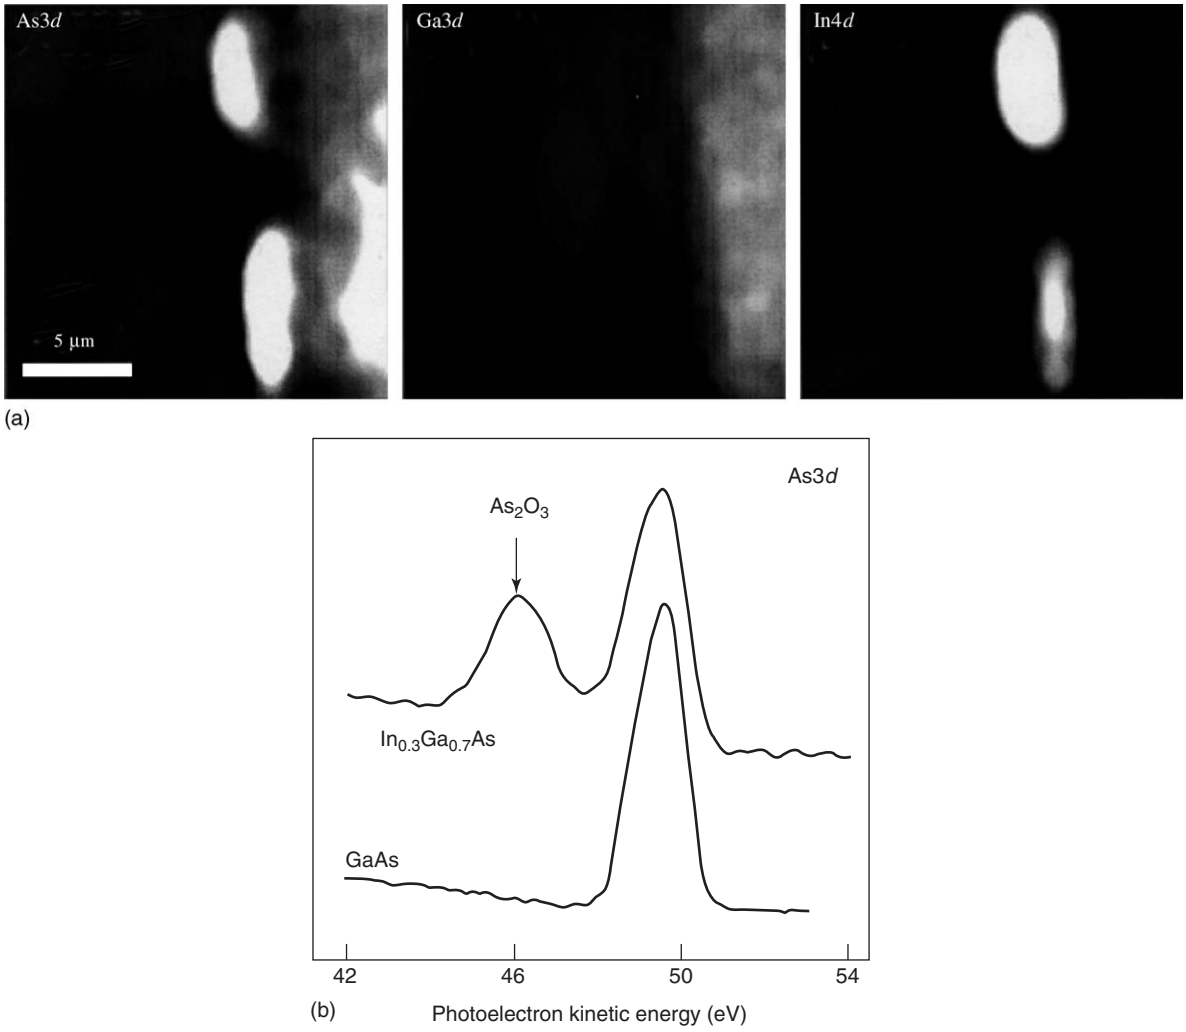

Figure 2 One of the first results of photoelectron spectromicroscopy, obtained at the University of Wisconsin Synchrotron Radiation Center with the "MAXIMUM" spectromicroscope. (Results derived from Ng W, Ray-Chaudhuri AK, Liang S, Singh S, Solak H, *et al.* (1994) Photoemission spectroscopy reaches the 1000 Å scale. *Nuclear Instruments and Methods* A347: 422.) (a) Two-dimensional photoemission intensity maps across a GaAs-$In_{0.3}Ga_{0.7}As$ interface for the As3*d*, Ga3*d*, and In4*d* core-level peaks. (b) Local As3*d* spectra taken in two spots at the two sides of the interface. Note the As_2O_3 component present on the $In_{0.3}Ga_{0.7}As$ side but not on the GaAs side.

Two Approaches to Photoelectron Spectromicroscopy

There exist basically two approaches to achieve lateral resolution in a photoemission experiment (**Figure 3**). In the first case, the primary photon beam is focused into a small sample area and photoelectrons are excited only from that area. This approach leads to two complementary data-taking procedures. In the first procedure, the photon beam is kept in a constant position on the sample surface and photoemission data are taken from that small spot. In the second case, the focused beam is scanned on the sample surface (or, rather, the samples are scanned with respect to the beam) while photoelectrons are collected for a constant set of parameters. This produces two-dimensional "images" of the photoemission intensity.

Consider (**Figure 4**) the case in which the focused spot is scanned while the collected photoelectron energy corresponds to photoelectrons emitted from a given core level to a given element. The photoemission intensity roughly corresponds to the concentration of the corresponding element. Therefore, the "images" provide two-dimensional chemical maps of the lateral distribution of different component elements.

Furthermore, a core-level energy for a given element changes slightly depending on the oxidation state of the element. Therefore, by fine-tuning the collected photoelectron energy one can obtain chemical maps of a given element in different chemical

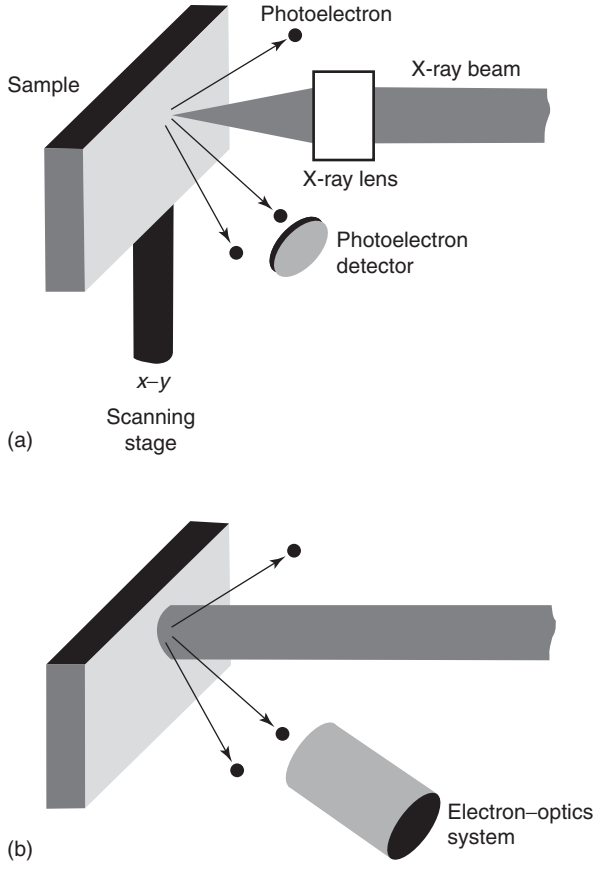

Figure 3 The two implementation modes of photoelectron spectromicroscopy: in (a) the lateral resolution is achieved by focusing the photon beam. In (b) the resolution is given by an electron lens system.

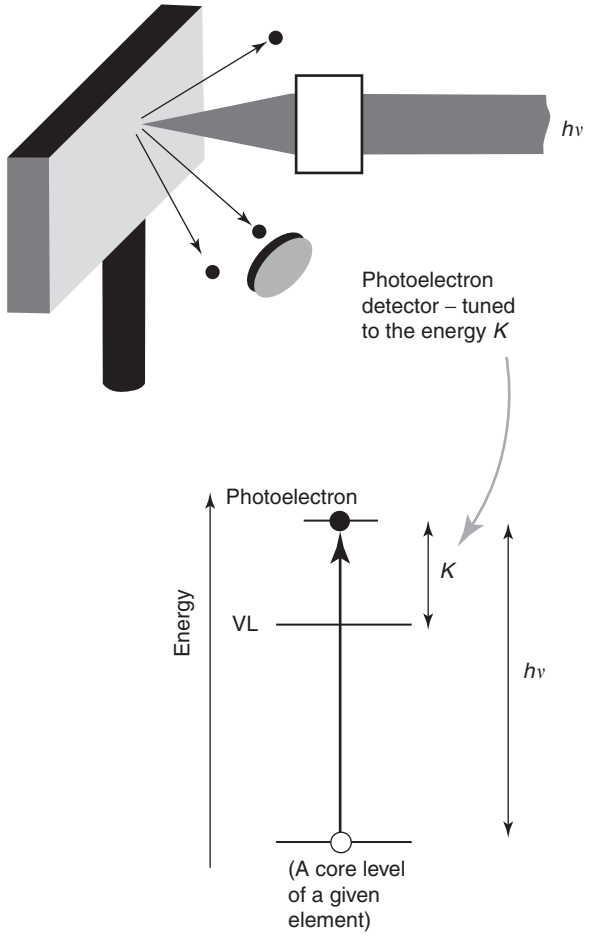

Figure 4 Chemical microanalysis with the photon-focusing mode of photoelectron spectromicroscopy. The photoelectron detector is tuned to a kinetic energy corresponding to the photoelectron emission from a given core level of a given chemical element. The corresponding photoemission intensity reveals the presence and concentration of that element.

environments. Since photoelectron spectromicroscopy has the high surface sensitivity typical of nearly all photoemission experiments, the chemical maps concern the region near the sample surface and provide extremely valuable information on surface processes such as corrosion, passivation, and catalysis.

The second approach to photoelectron spectromicroscopy (see again **Figure 3**) does not require focusing the photon beam. Lateral resolution is achieved by processing the emitted photoelectrons with an electron–optical system roughly equivalent to an electron microscope. Several years of practical experience demonstrated that the two approaches have advantages and disadvantages with respect to each other, and are largely complementary.

Practical Implementation: Photon-Focusing Spectromicroscopy

Focusing photon beams is – or at least was – a major technical problem in the implementation of the first of the above two approaches to photoelectron spectromicroscopy. The photons must have sufficient energy to enable electrons inside the solid to overcome the surface energy barrier and become photoelectrons. The corresponding smallest photon energies fall in the ultraviolet range.

Furthermore, the energy of the photons must be sufficient to extract photoelectrons from the core levels of relevant chemical elements. The corresponding photon energies range from the vacuum ultraviolet to the hard X-rays.

Focusing is a relatively easy task only in a very small portion of this spectral range, corresponding to its lowest photon energies (a few eV). For higher photon energies (X-rays), focusing is a difficult task.

The reasons are quite simple: (1) solid materials absorb photons in a large portion of the vacuum ultraviolet and soft-X-ray ranges, making it impossible to use transmission optical devices similar to optical lenses. (2) Hard X-rays can travel through solid materials, but the X-ray refractive index is very

close to that of vacuum ($n = 1$), drastically limiting the effectiveness of refractive focusing devices. (3) The reflection of X-rays is extremely limited except at near-grazing incidence, and this tendency becomes stronger when the wavelength decreases. This rules out reflection-focusing devices working at near-normal incidence.

Effective technical solutions for these problems have been conceived and implemented. **Figure 5** shows a series of X-ray-focusing devices suitable for different spectral domains.

Focusing Mirrors

Mirrors can provide X-ray focusing as long as the angle of incidence is sufficiently close to grazing incidence. This, however, complicates the fabrication of mirrors and makes them quite expensive. The surface profile must in fact meet stringent requirements over a large area.

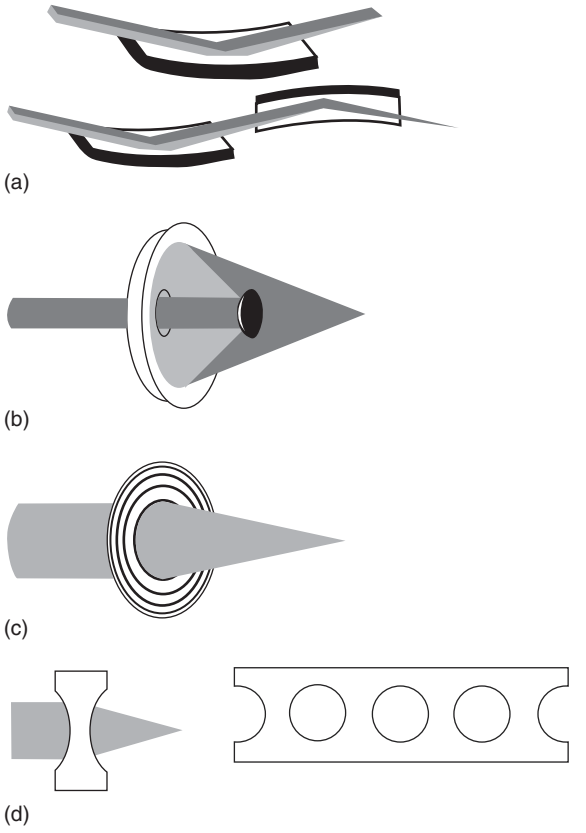

Figure 5 Different X-ray focusing devices. (a) A single grazing-incidence mirror (top) focuses only in one direction, whereas (bottom) a combination of two mirrors (Kirkpatrick–Baez lens) provides bidirectional focusing. (b) The Schwarzschild objective is formed by a convex spherical lens and a concave spherical lens, with nongrazing-incidence reflection enhanced by multilayer coatings. (c) A Fresnel zone plate (FZP). (d) (Left) a single biconcave refractive lens for hard-X-rays, and (right) a compound refractive lens (CRL).

The focusing surface can be toroidal, parabolic, or spherical (with some degree of aberration). Machining such surfaces with the required accuracy is technically difficult. It is possible to use cylindrical surfaces that are easier to fabricate (e.g., bent mirrors), but they focus only in one direction. Bidirectional focusing requires therefore a pair of mirrors combined together in a "Kirkpatrick–Baez" lens (**Figure 5a**).

Schwarzschild Objectives

These devices (**Figure 5b**) focus visible light as well as X-rays, and this facilitates the alignment of the X-ray optical system. The objective is the combination of two reflecting spherical surfaces. Note that the reflection is not at grazing incidence and this would limit the throughput.

The problem can be solved by a suitable multilayer coating that enhances reflection. The corresponding technology is, however, quite sophisticated. Furthermore, these lenses can only work in a limited spectral range that is typically located below 100 eV of photon energy. Even with these limitations, the Schwarzschild objectives did play a significant role in the development of photoelectron spectromicroscopy.

Fresnel Zone Plates

The fresnel zone plates (FZPs) are widely used as focusing devices in different spectral ranges. As illustrated in **Figure 5c**, the working principle is based on the interference of rays passing through a series of alternating transmitting and blocking circular zones. The blocking zones are supported by a very thin substrate to provide reasonable transmission in the X-ray domain.

The main difficulty in fabricating FZPs for X-rays is related to the dimension of the zones. The radial size of the zones decreases on going from the center to the periphery of the plate; furthermore, the size decreases as the wavelength decreases. For X-ray wavelengths, the outermost-zone size is in the order of hundreds of angstroms. The fabrication requires sophisticated – and expensive – electron-beam lithography techniques. These problems notwithstanding, FZPs are extensively used in X-ray microscopy and spectromicroscopy.

Refractive Lenses and Compound Refractive Lenses

For hard X-rays, the difficulties related to the limited transmission become progressively less important and it is possible to use refractive lenses. There exist, however, significant differences between the refractive lenses for visible light and those for X-rays. The refractive index for X-rays is smaller in a

material than in vacuum, whereas the contrary is true for visible light. An X-ray focusing lens, therefore, is not biconvex but biconcave (**Figure 5d**).

As already mentioned the refractive index differences between a material and vacuum are extremely limited. As a consequence, the focal length of a single biconcave refractive lens would be unreasonably large. The solution is provided by a series of lenses in the form of spherical concavities inside a block, as also shown in **Figure 5d**. Such a device is known as "compound refractive lens" or CRL.

Practical Implementation: Electron-Optics Spectromicroscopy

Figure 6 shows a typical electron-optics system for the implementation of this second approach to photoelectron spectromicroscopy. The standard name for this type of instrument is photoelectron emission microscope (PEEM).

Without photon focusing, it becomes easier to perform photoemission techniques that require changing the photon energy. The most frequent way to use a PEEM is to perform "partial yield" (PY) measurements with high lateral resolution. A PY experiment is implemented by taking the intensity of the "secondary" photoelectrons as a function of the photon energy – see **Figure 7**.

The secondary photoelectrons are the low-kinetic-energy electrons emitted from the sample after a loss of energy with respect to the sum of the initial energy in the sample plus the photon energy. Such losses are typically due to multistep phenomena. The yield of secondary photoelectrons is proportional to the number of absorbed photons. Therefore, a PY curve closely resembles the plot of the X-ray absorption coefficient as a function of the photon energy.

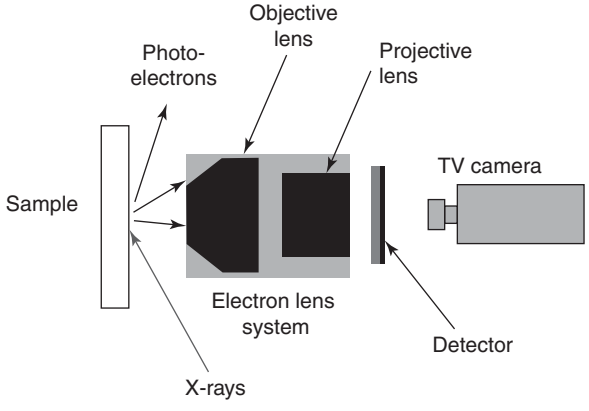

Figure 6 Schematic experimental setup of a photoelectron emission microscope (PEEM) for the second mode of photoelectron spectromicroscopy.

Note, however, that the PY technique is surface sensitive – although the surface sensitivity is not as high as for other photoemission techniques due to the low kinetic energy of the secondary photoelectrons. Therefore, a PY curve primarily reflects the absorption coefficient of the surface rather than that of the bulk.

With a PEEM, PY curves can be taken from small sample areas. This is a very powerful way to explore the local chemical composition and chemical properties. An X-ray absorption spectrum is dominated by the absorption threshold of the component elements in the specimen and reveals their presence and chemical status. This approach is particularly convenient when local chemical information must be obtained rapidly.

The technique is typically implemented by first taking overall images corresponding to the partial-yield intensity emitted from different sample areas with a fixed photon energy (or with a "white" photon

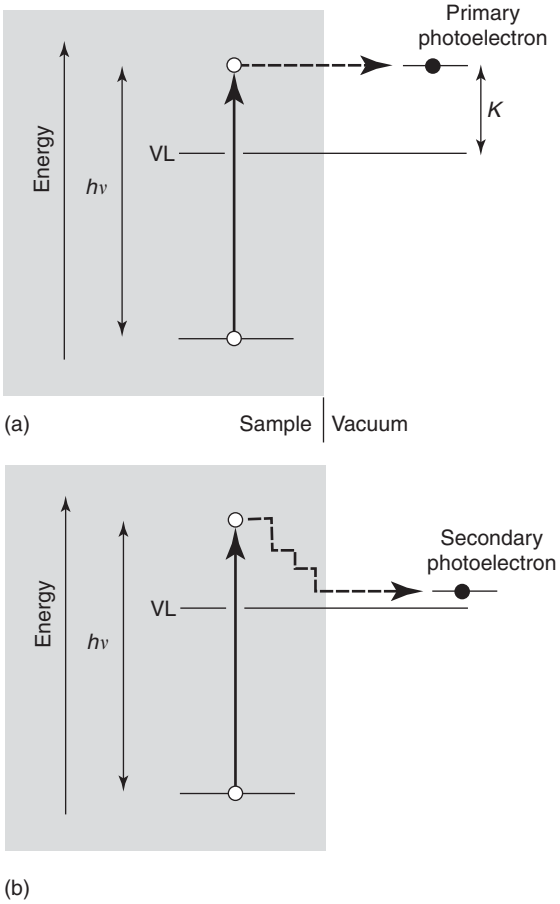

Figure 7 (a) Primary photoelectrons are emitted with an energy (above the vacuum level VL) corresponding to the initial energy in the solid plus the photon energy, without losses. (b) A secondary photoelectron loses part of its energy, typically through multiple losses, before leaving the sample. The partial yield (PY) mode of photoelectron spectroscopy and spectromicroscopy is based on the detection of secondary photoelectrons.

beam). Such images reveal the overall morphology of the specimen. Then, specific areas are selected for a more detailed analysis and PY spectra are taken from them.

Selected Examples and Performances

Figure 8 shows an example of photoelectron spectromicroscopy in the photon-focusing mode. The spectra illustrate a specific core level (Ge3*d*) of a metal–semiconductor interface (a thin germanium film on a semiconductor substrate).

This particular system has been considered as a typical example of nonreactive interface in which no chemical reaction takes place. On the contrary, spectra taken in different parts of the interface show clear differences, providing evidence for local chemical reactions that were not visible in a normal photoemission experiment.

Figure 9 shows an example of electron-optics photoelectron spectromicroscopy obtained with a PEEM operating in the PY mode. Note that the experiment concerns a biological sample: the PEEM technique is in fact particularly suited for studies in the life sciences and in medical research.

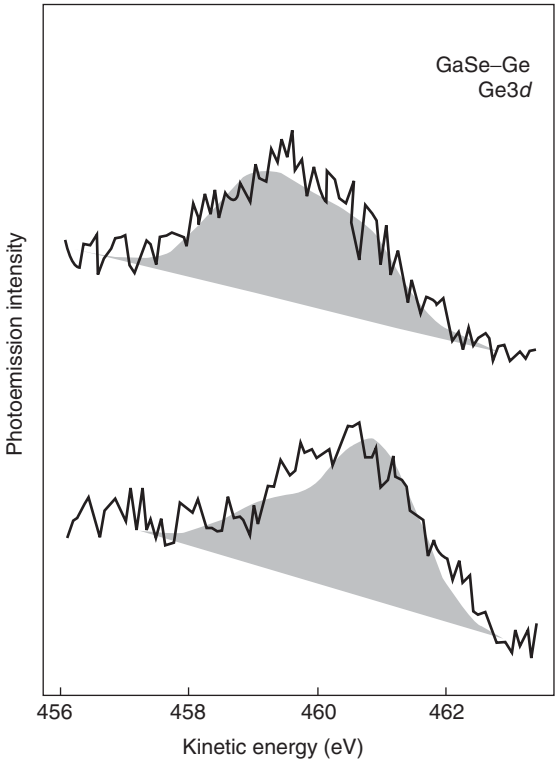

Figure 8 An example of photon-focusing photoelectron spectromicroscopy result (from Almeida J, Vobornik I, Berger H, Kiskinova M, Kolmakov A, *et al.* (1997) Spectromicroscopic evidence of Ge–GaSe chemical reactions: not a Schottky system. *Physical Review B* 55: 4899): two spectra taken at two different spots of a thin Ge overlayer on a GaSe substrate reveal different spectral line shapes for the Ge3*d* peak – and put in evidence unexpected local chemical reactions. The results were obtained at the Elettra synchrotron in Trieste.

Resolution and Sensitivity

The most relevant performances for photoelectron spectromicroscopy are the lateral resolution and the

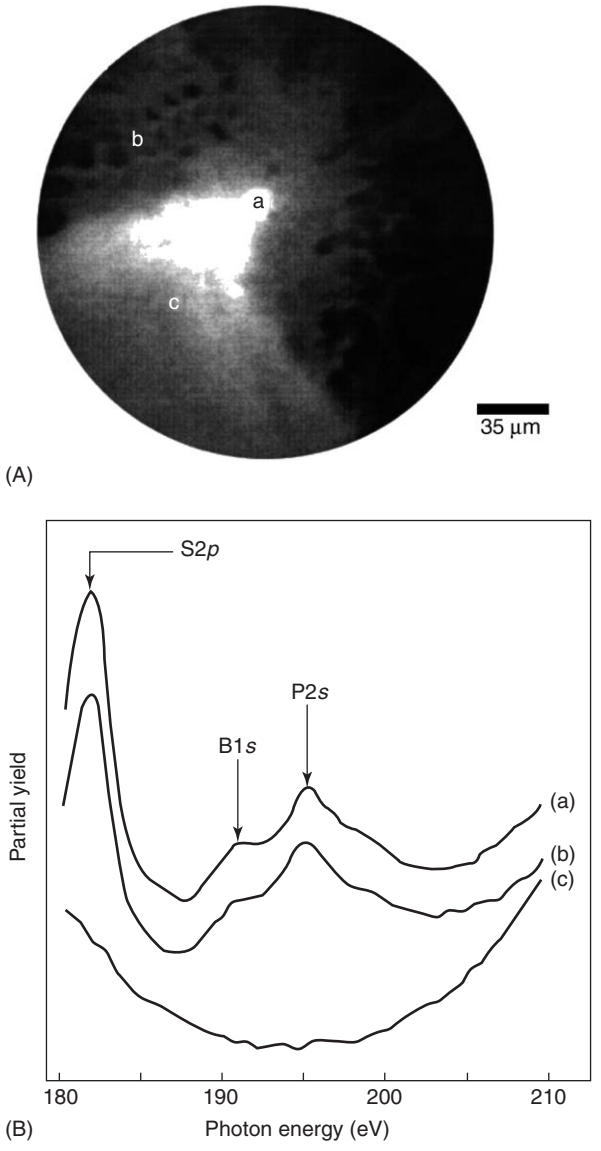

Figure 9 (a) PEEM microimage taken for a cancerous brain cell specimen with pre-injected boron, as required for the BNCT (boron neutron capture therapy). (b) PEEM PY spectra taken in specific spot reveal the localization of boron from the corresponding signal. The data were obtained with the PEEM-class spectromicroscope "MEPHISTO" at the University of Wisconsin Synchrotron Radiation Center. (Data derived from Gilbert B, Redondo J, Baudat P-A, Lorusso GF, Andres R, *et al.* (1998) Spectromicroscopy of boron for the optimization of boron neutron capture therapy (BNCT) for cancer. *Journal of Physics D* 31: 2642.)

sensitivity to trace chemicals. Concerning lateral resolution, for both approaches to photoelectron spectromicroscopy it is necessary to distinguish between the "system" (optical or electron–optical) resolution and the real resolution that can be obtained while performing spectromicroscopy.

In the spectromicroscopy mode the resolution is in fact also limited by practical factors such as the signal level. Consider for example the comparison between the resolution delivered by an electronic lens system used as an electron microscope and the corresponding resolution when the system is used in a PEEM. In the first case, the lateral resolution can reach a few nanometers. In the spectromicroscopy mode, the best practical resolution is ~ 20 nm. The standard resolution in most PEEM experiments is worse than this optimal value.

Likewise, X-ray focusing devices can deliver a lateral resolution better than the corresponding real resolution in spectromicroscopy. Consider for example a Fresnel zone plate: its optical resolution depends on the size of the outermost zone, and can be better than 10 nm. The corresponding "spectromicroscopy" resolution, although at the submicron level, does not reach comparable values – and is typically limited to 100 nm.

Note that the actual lateral resolution in a spectromicroscopy experiment is often the result of a compromise between conflicting requirements. For example, lateral resolution can be limited in order to achieve a good energy resolution while keeping the signal at a reasonable level.

Chemical sensitivity is an important point for spectromicroscopy. In a normal photoemission experiment without lateral resolution, the minimum detectable relative concentration is 0.01–0.001. This is, of course, the local concentration in the near-surface region probed by photoemission. If the minority species is concentrated in that region, the equivalent relative concentration limit for the entire specimen is much lower.

Spectromicroscopy concentrates the analysis to areas of $\sim 1\,\mu m^2$ or less. If the minority species is not homogeneously distributed, by focusing on high-concentration areas the equivalent detectable concentration limit can be lowered.

Future Developments

Spectacular improvements in the instrumentation and in particular in the photon sources open up many new avenues. On the one hand, additional spectroscopy techniques can be implemented with high lateral resolution becoming spectromicroscopies. Furthermore, it becomes increasingly possible to simultaneously achieve high lateral resolution and other extreme performances such as ultrahigh energy resolution. One of the most attractive possibilities is the coupling of time resolution and lateral resolution to study dynamic phenomena on a microscopic scale.

Photon Statistics and Coherence Theory

P Mataloni, Università di Roma "La Sapienza," Rome, Italy

Introduction

The study of optical fluctuations represents an important tool in understanding the fundamental properties of light. One can distinguish among different types of light sources. In a common spectroscopic source, such as a gas discharge lamp, the different atoms are excited by an electrical discharge and emit their radiation independently of one another. The radiation produced by this source is called chaotic light. Several varieties of light, as those produced by a thermal cavity or a filament lamp, be-long to the same class. A second type is the coherent light, the best approximation of which is given by a single-mode laser operating well above the threshold at a single frequency and in a well-defined spatial direction.

Chaotic and coherent light have quite different statistical properties. These are measured by first- and second-order optical interference experiments that allow one to study the electric field intensity correlations between different portions of the light beam, with different coordinates in time and/or space. The fundamental component for optical interference is represented by the optical beam splitter, present in several kinds of interferometers, such as the Mach–Zehnder (MZ) and the Brown–Twiss (BT) interferometer. A beam splitter is basically a semitransparent mirror with, in general, equal probability to reflect or transmit the light beam, $R = T$. MZ is an example of first-order interferometer, while the BT represents the typical scheme for experiments of second-order interference.

Depending on its nature, the light can show either a classical or nonclassical behavior. Classical and quantum theories predict identical interference effects for coherent and chaotic light, or light with intermediate coherence properties. Exclusively quantum effects occur with other kinds of light that cannot be classically described. No difference is found between classical and quantum predictions for first-order interference experiments, while a second-order interference allows one to distinguish between classical and nonclassical light.

Chaotic Light

This article starts by examining some phenomena related to the behavior of chaotic light by looking at the time dependence of the amplitude or intensity of the light beams. It is known from spectroscopy that the line broadening processes present in a source are responsible for the fluctuations of the electric field and intensity occurring around an average value, on a timescale which is inversely proportional to the bandwidth of the spectrum. The unpredictable temporal fluctuations and the frequency spectrum of a source are complementary manifestations of the same physical properties of the radiating atoms that constitute the light source. The superposition of emission of many independent atoms that radiate with different frequencies and phases, is responsible for the generation of the chaotic light.

The temporal fluctuations of chaotic light can be investigated by considering the model of an N-excited-atom source which is broadened by collisions occurring at a rate $\gamma_{\text{coll}}[\text{s}^{-1}]$, that is, with an average time $\tau_c = 1/\gamma_{\text{coll}}$. The wave train radiated by a single atom is shown in **Figure 1**, where the electric field amplitude is schematically represented as a function of time. The total electric field radiated by the source is expressed as

$$E(t) = \sum E_i(t) = E_0 \exp(-2\pi i \nu_0 t) \times [\exp(i\phi_1(t)) + \exp(i\phi_2(t)) + \cdots + \exp(i\phi_N(t))]$$

where E_0 and ν_0 represent the characteristic amplitude and frequency of the field radiated by every atom and $\phi_i(t)$ $(i = 1, 2, \ldots, N)$ represents the random phase of each one of the uncorrelated atoms. The average spectrum is obtained by the Fourier decomposition of $E(t)$ and consists of a set of frequencies centered at ν_0.

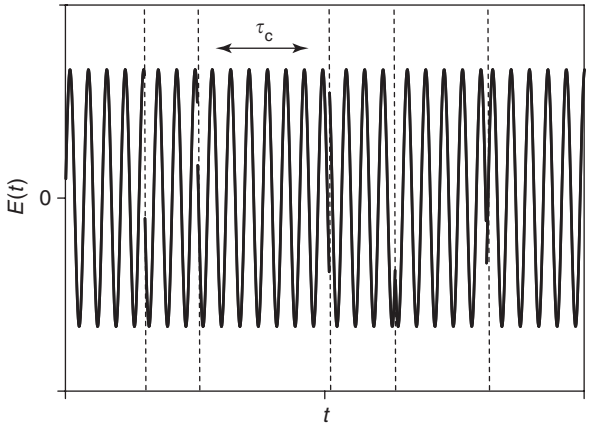

Figure 1 Sequence of wave trains for chaotic light.

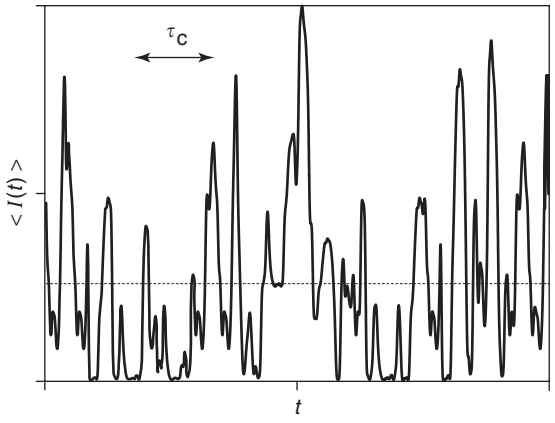

Figure 2 Temporal evolution of chaotic light.

The intensity of the beam is proportional to $|E(t)|^2$. It is a random function of time, varying on a timescale of the order of τ_c. The cycle-averaged intensity $I(t)$ is defined as the average of the intensity over a cycle of the oscillation at frequency v_0. In many cases, the corresponding fluctuations are too rapid to be detected, so that one is able to measure the average of the fluctuations over the response time of the detector. **Figure 2** shows the computer simulation of a typical temporal evolution of the cycle-averaged intensity for a chaotic light beam. The timescale is normalized to the coherence time τ_c. The average intensity $\langle I(t) \rangle$ is the result of the ensemble average over a large number of values of $I(t)$, measured over a period of time much longer than τ_c:

$$\begin{aligned}\langle I(t) \rangle &= \langle |E(t)|^2 \rangle \\ &= E_0^2 \langle |\exp(i\phi_1(t)) \\ &\quad + \exp(i\phi_2(t)) + \cdots \\ &\quad + \exp(i\phi_N(t))|^2 \rangle = NE_0^2\end{aligned}$$

This result is a consequence of the zero average contribution of the cross-terms between the phase factors of different radiating atoms. The dotted line in **Figure 2** indicates the value of $\langle I(t) \rangle$ for the fluctuating intensity.

First-Order Coherence

The first-order correlation function of the electric field at times t and $t + \tau$ is defined as

$$G^{(1)}(\tau) = \langle E^*(t)E(t+\tau) \rangle$$

It expresses how the fluctuations of the field $E(t + \tau)$ are affected by the value of field E at time t. It is found that $G^{(1)}(0) = I$ at $\tau = 0$. Furthermore, $G^{(1)}(-\tau) = G^{(1)*}(\tau)$, because of its Hermitian symmetry.

The degree of first-order temporal coherence is defined as

$$\begin{aligned}g^{(1)}(\tau) &= G^{(1)}(\tau)/G^{(1)}(0) \\ &= \langle E^*(t)E(t+\tau) \rangle / \langle E^*(t)E(t) \rangle\end{aligned}$$

a complex function, independent of the intensity, with the properties: $g^{(1)}(-\tau) = g^{(1)*}(\tau)$ and $0 \leqslant |g^{(1)}(\tau)| \leqslant 1$. The value of $|g(\tau)|$ is a measure of correlation between $E(t)$ and $E(t + \tau)$. In the ideal case of a monochromatic plane wave of amplitude $E_0, E(t) = E_0 \exp(2\pi i v_0 t)$. The degree of first-order temporal coherence becomes

$$g^{(1)}(\tau) = \exp(-2\pi i v_0 t)$$

and $|g(\tau)| = 1$, then $E(t)$ and $E(t + \tau)$ are completely correlated for all the values of τ.

The model of a collision-broadened light source can be assumed to calculate the degree of first-order coherence. The correlation function of the whole light beam is obtained from the single-atom contribution,

$$\langle E^*(t)E(t+\tau) \rangle = NE_0^2 \exp(-2\pi i v_0 \tau - \tau/\tau_c)$$

As a consequence the first-order coherence degree is

$$\begin{aligned}g^{(1)}(\tau) &= \exp(-2\pi i v_0 \tau - \tau/\tau_c) \\ &= \exp(-2\pi i v_0 \tau - |\tau|/\tau_c)\end{aligned}$$

with modulus

$$|g^{(1)}(\tau)| = \exp(-|\tau|/\tau_c)$$

Note that the exponential shape of $|g^{(1)}(\tau)|$ is consistent with the characteristic Lorentzian frequency spectrum valid for a collision-broadening mechanism, with coherence time τ_c.

Insofar as other broadening mechanisms are concerned, one can consider the case of chaotic light generated by atoms in a gas characterized by a spread in their velocities. The consequent Doppler effect leads to a Gaussian distribution of the emission frequencies. In this case the degree of first-order coherence is

$$g^{(1)}(\tau) = \exp[(-2\pi i v_0 \tau - \pi/2(\tau/\tau_c)^2]$$

with $\tau_c = \sqrt{\pi}/\Delta$ (Δ^2 corresponds to the variance of the Gaussian distribution).

The modulus of $g^{(1)}(\tau)$ for chaotic light, calculated in the two cases of Lorentzian and Gaussian frequency spectrum, is shown in **Figure 3**. The dashed line $g^{(1)}(\tau) = 1$ represents the case of a plane wave.

Light emitted from a partially coherent source is modeled as a sequence of random, uncorrelated wave packets, each one with a characteristic coherence length $l_c = c\tau_c$. The coherence times and the corresponding values of l_c are shown in **Table 1** for different

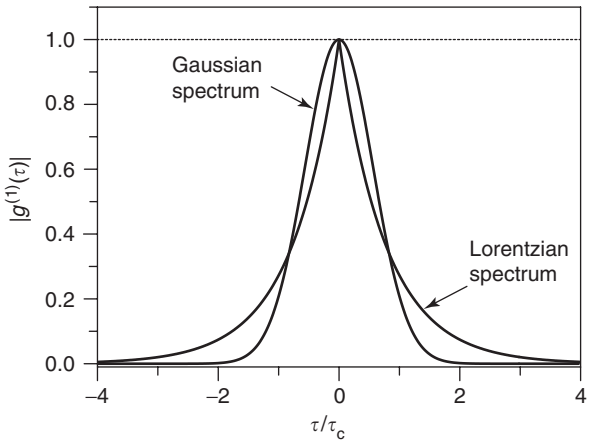

Figure 3 First-order coherence degree expressed as a function of units of τ_c for collision-broadened and Doppler-broadened chaotic light. Dashed line corresponds to the case of coherent light.

Table 1 Coherence times and coherence length of different light sources

Source	τ_c	l_c
White light (400–700 nm)	3.6 fs	1.08 μm
LED ($\lambda = 800$ nm, $\Delta\lambda = 50$ nm)	43 fs	0.01 mm
Spectral lamp (Hg)	10 ps	3 mm
Multimode CW He–Ne laser ($\lambda = 633$ nm)	0.67 ns	20 cm
Single-mode Nd : YAG laser ($\lambda = 1.06$ μm)	3 ms	900 m

light sources. The case of a single-mode laser, whose coherence length is of the order of several hundreds of meters, represents the best approximation of a monochromatic plane wave with $l_c = \infty$.

Similarly to the case of temporal correlation, one can adopt the same formalism to investigate the degree of first-order correlation of two different spatial points of the wave front, with coordinates $\boldsymbol{r}_1$ and $\boldsymbol{r}_2$,

$$g^{(1)}(\boldsymbol{r}_1, \boldsymbol{r}_2) = G^{(1)}(\boldsymbol{r}_1, \boldsymbol{r}_2)/\sqrt{[I(\boldsymbol{r}_1)I(\boldsymbol{r}_2)]}$$

with $0 \leqslant |g^{(1)}(\boldsymbol{r}_1, \boldsymbol{r}_2)| \leqslant 1$. For a given value of $\boldsymbol{r}_2$ and varying $\boldsymbol{r}_1$, the spatial extent of the region where $|g^{(1)}(\boldsymbol{r}_1, \boldsymbol{r}_2)|$ is greater than a reference value (e.g., 1/2 or 1/e) uniquely determines the radius of the coherence area. In the ideal case of a coherent plane wave $|g^{(1)}(\boldsymbol{r}_1, \boldsymbol{r}_2)| = 1$, whatever the distance $\boldsymbol{r}_1 - \boldsymbol{r}_2$. In this case the coherence area is infinitely large. In the general case, the first degree of coherence $g^{(1)}(\boldsymbol{r}_1, t_1, \boldsymbol{r}_2, t_2)$ can be defined for any pair of space–time points.

Depending on the value of $|g^{(1)}|$, a light can be classified as coherent ($|g^{(1)}| = 1$), incoherent ($|g^{(1)}| = 0$), or partially coherent ($0 \leqslant |g^{(1)}| \leqslant 1$). The coherence degree of a light beam is measured by first-order interferometry.

So far, a classical model of light has been adopted to describe first-order coherence processes. Also, in the case of light beams that need to be described in terms of quantum states of radiation, no difference is found between classical and quantum predictions for first-order interference experiments, as already stated. The possibility of distinguishing between classical and nonclassical light resides on second-order interference experiments.

Interference of Two Partially Coherent Waves

Consider two partially coherent waves $\boldsymbol{E}_1(\boldsymbol{r}, t)$ and $\boldsymbol{E}_2(\boldsymbol{r}, t)$, with intensities $\langle |\boldsymbol{E}_1(\boldsymbol{r}, t)|^2 \rangle$ and $\langle |\boldsymbol{E}_2(\boldsymbol{r}, t)|^2 \rangle$. The two waves correspond, for example, to the fields coming out of a two-arm interferometer, such as a Mach–Zehnder or Michelson scheme. A Mach–Zehnder interferometer, composed of two equal beam splitters (BS) and two total reflecting mirrors (M), is sketched in **Figure 4**. The light beam is incident on one of the two input ports of the first BS and is divided into two equal beams, with electric field $\boldsymbol{E}_1(t)$ and $\boldsymbol{E}_2(t)$, traveling through the two optical paths 1 and 2. The two beams meet together in the second BS, where interference between the two electric fields can occur, depending on the mutual phase conditions.

By the above assumptions, one has

$$g_{12} = \langle \boldsymbol{E}_1^* \cdot \boldsymbol{E}_2 \rangle / \sqrt{(I_1 I_2)}$$

The average intensity corresponding to the two-wave superposition is

$$\begin{aligned} I &= \langle |E_1 + E_2|^2 \rangle \\ &= I_1 + I_2 + 2\sqrt{(I_1 I_2)}\ \mathrm{Re}(g_{12}) \\ &= I_1 + I_2 + 2\sqrt{(I_1 I_2)}|g_{12}|\ \cos\phi \end{aligned}$$

where ϕ is the phase of g_{12}. It can be suitably adjusted by varying, within half of the wavelength $\lambda = c/\nu$, the delay between the two optical paths 1 and 2. Optical interference arises exactly from the third term of the above expression, that is, from the value of the mutual correlation degree, g_{12}. Two important cases are considered, depending on the limit values of g_{12}.

1. $|g_{12}| = 1$ (coherent waves) $\Rightarrow$ $I = I_1 + I_2 + 2\sqrt{(I_1 I_2)}\cos\phi$,
2. $|g_{12}| = 0$ (incoherent waves) $\Rightarrow$ $I = I_1 + I_2$.

In the general case of partially coherent waves, the intensity I is a sinusoidal function of ϕ; the larger the $|g_{12}|$, the larger the amplitude of the oscillation. In this case, the measurement of the interference

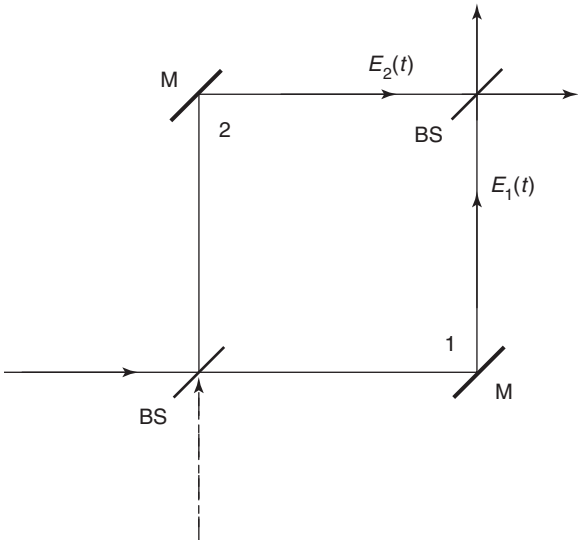

Figure 4 Mach–Zehnder interferometer.

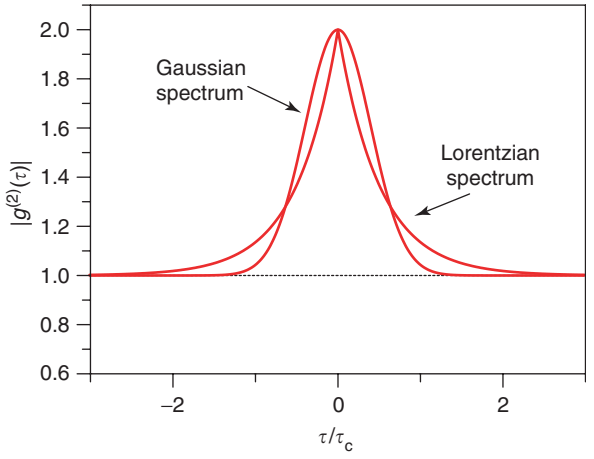

Figure 5 First-order coherence degree expressed as a function of units of τ_c for collision-broadened and Doppler-broadened chaotic light. Dashed line corresponds to the case of coherent light.

strength as a function of the optical path delay gives us all the necessary information about the temporal or spatial behavior of the correlation degree, allowing the measurement of the temporal coherence length or the coherence radius of the light beam. One can express the modulation depth by the visibility parameter,

$$V = (I_M - I_m)/(I_M + I_m)$$

with I_M and I_m corresponding to the maximum ($\phi = 0$) and minimum ($\phi = \pi$) value of the intensity, respectively.

By expressing the visibility as a function of $|g_{12}|$, one has

$$V = [2\sqrt{(I_1 I_2)}/(I_1 + I_2)]|g_{12}|$$

In a symmetrical interferometer ($I_1 = I_2$), $V \equiv |g_{12}|$. In this case, for $|g_{12}| = 1$, $I_M = 4I$ and $I_m = 0$.

Second-Order Coherence

As for the first-order coherence, consider two time measurements in which many pairs of samples of the cycle-averaged intensity are measured at a fixed delay τ. The classical definition of the intensity correlation function, valid either for chaotic or coherent light, corresponds to the average of the products of each pair of samples:

$$\begin{aligned} G^{(2)}(\tau) &= \langle I(t)I(t+\tau)\rangle \\ &= \langle \boldsymbol{E}^*(t)\boldsymbol{E}^*(t+\tau)\boldsymbol{E}(t+\tau)\boldsymbol{E}(t)\rangle \end{aligned}$$

The correlation function $G^{(2)}(\tau)$ can be normalized to the square of the long-time-averaged intensity $\langle I(t)\rangle$ in order to obtain the degree of second-order temporal coherence:

$$\begin{aligned} g^{(2)}(\tau) &= G^{(2)}(\tau)/G^{(2)}(0) \\ &= \langle I(t)I(t+\tau)\rangle / \langle \boldsymbol{E}^*(t)\boldsymbol{E}(t)\rangle^2 \end{aligned}$$

Because of symmetry properties, $g^{(2)}(\tau) = g^{(2)}(-\tau)$. It can be demonstrated that $g^{(2)}(\tau)$ satisfy the following relation at zero time delay, $\tau = 0$:

$$1 \leqslant g^{(2)}(0) \leqslant \infty$$

Since $g^{(2)}(\tau)$ is a positive function, for a finite time delay, $\tau \neq 0$, one has

$$0 \leqslant g^{(2)}(\tau) \leqslant \infty$$

Furthermore, since $\langle I(t)I(t+\tau)\rangle \leqslant \langle I(t)^2\rangle$, the degree of second-order coherence never exceeds its value for zero time delay. Hence, the following inequality holds:

$$g^{(2)}(\tau) \leqslant g^{(2)}(0)$$

For a large number N of radiating atoms, it can be demonstrated that

$$g^{(2)}(\tau) = 1 + |g^{(1)}(\tau)|^2$$

By considering the limiting values of $|g^{(1)}(\tau)|$ for $\tau = 0$ and $\tau \gg \tau_c$, for chaotic light, $g^{(2)}(0) = 2$ and $g^{(2)}(\tau \gg \tau_c) = 1$.

In the two cases of collision and Doppler-broadened light, one can write, respectively,

$$g^{(2)}(\tau) = 1 + \exp(-2|\tau|/\tau_c)$$

$$g^{(2)}(\tau) = 1 + \exp[-\pi/(\tau/\tau_c)^2]$$

Figure 5 shows the behavior of $g^{(2)}(\tau)$ of both the chaotic lights with Lorentzian and Gaussian frequency

distribution. Starting from $g^{(2)}(0) = 2$ at zero time delay, the intensities $I(t)$ and $I(t+\tau)$ become more and more uncorrelated by increasing τ and $g^{(2)}(\tau) \to 1$. In contrast to chaotic light, in the case of a classical stable wave, one has $g^{(2)}(\tau) = 1$ for any value of τ. This case is represented by the horizontal dashed line in **Figure 5**.

Similarly to the case of first-order coherence, the definition of second-order coherence degree is generalized to the spatial case,

$$g^{(2)}(\boldsymbol{r}_1, \boldsymbol{r}_2) = \langle \boldsymbol{E}^*(\boldsymbol{r}_1)\boldsymbol{E}^*(\boldsymbol{r}_2)\boldsymbol{E}(\boldsymbol{r}_1)\boldsymbol{E}(\boldsymbol{r}_2)\rangle / \langle |\boldsymbol{E}(\boldsymbol{r}_1)|^2\rangle \langle |\boldsymbol{E}(\boldsymbol{r}_2)|^2\rangle$$

and, in general, $g^{(2)}(\boldsymbol{r}_1, t_1, \boldsymbol{r}_2, t_2)$ can be defined for any pair of space–time points.

All the measurements of $g^{(2)}(\tau)$ are based on the original experimental apparatus invented by Brown and Twiss (BT) and are illustrated in **Figure 6**. Quasi-monochromatic radiation, properly selected in the single spatial mode, is incident upon a symmetric ($R = T$) optical beam splitter, so that half of the original intensity $I(t)$, $I_1(t)$, is directed to detector D_1, the other half, $I_2(t)$, to detector D_2. The electric signals of the detectors are used to determine the average of the product of $I_1(t)$ and $I_2(t+\tau)$ by means of a correlator. This operation allows to measure the intensity fluctuations. By making the assumption of a stationary field, $\langle I_1(t)\rangle = \langle I_2(t+\tau)\rangle$, and detectors with instantaneous response time, if these are placed at the same distance from the beam splitter, one has

$$g_{12}^{(2)}(\tau) = \langle I_1(t) I_2(t+\tau)\rangle / [\langle I_1(t)\rangle \langle I_2(t)\rangle] = \langle I(t) I(t+\tau)\rangle / \langle I(t)\rangle^2$$

By this scheme, any measurement affected by the temporal or spatial coherence of the light can be performed. Indeed, the original BT experiment was carried out to measure the angular diameter of stars by the observation of spatial coherence effects.

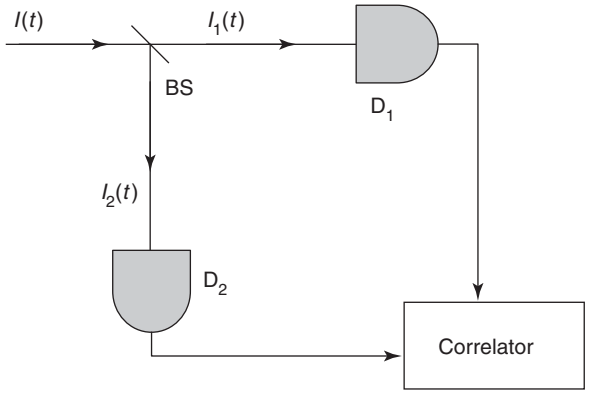

Figure 6 Brown–Twiss interferometer.

Photon Statistics of Coherent and Chaotic Light

The peculiar significance of all the measurements of degrees of second-order coherence resides on the correspondence between the classical and nonclassical radiation. So far the main aspects of optical coherence have been introduced in terms of the classical wave theory of light. The particle aspect of light is considered whenever it is possible to count photons (or rather, the photoelectrons ejected from a photoemissive surface by the absorption of photons). It is possible to demonstrate that in a typical photon-counting experiment, which allows one to measure the number of photoelectrons ejected by a light beam with average number of photons $\langle n\rangle$ during an appropriate time interval ΔT, the probability distribution $P_n(\Delta T)$ for n photoelectrons counted during the time ΔT is the Poisson distribution

$$P_n(\Delta T) = (\langle n\rangle^n / n!) \exp(-\langle n\rangle)$$

This expression applies either to a stationary coherent (laser) beam or to a chaotic radiation with coherence time $\tau_c \ll \Delta T$, in order to average the intensity fluctuations. In the opposite case, $\Delta T \ll \tau_c$, the probability of finding exactly n photons in the field, in thermal equilibrium at some temperature T, is governed by the Boltzmann factor

$$p(n) = \frac{[\exp(-nh\nu/k_B T)]}{[\sum_m \exp(-mh\nu/k_B T)]}$$

In this case, one obtains the so-called Bose–Einstein distribution,

$$P_n(\Delta T) = \langle n\rangle^n / (\langle n\rangle + 1)^{\langle n\rangle + 1}$$

It is clear from the above equations that a laser and a chaotic source may be characterized by the same average number, $\langle n\rangle$, of photons, the same frequency and bandwidth, and the same first-order coherence properties, but will have completely different photon statistics.

The mean square deviation of the photon number for the Poisson distribution is given by

$$\langle \Delta n^2\rangle = \langle n\rangle$$

while, for the Bose–Einstein distribution,

$$\langle \Delta n^2\rangle = \langle n\rangle^2 + \langle n\rangle$$

Chaotic light belongs to the category of super-Poissonian light, because it presents additional fluctuations to those of coherent light. One may ask if sub-Poissonian light ($\langle \Delta n^2\rangle < \langle n\rangle$) exists. This is the case of number state light; its genuine quantum properties will be illustrated in the next section. The

relative root mean square distributions for coherent and chaotic light are

$$\Delta n_{\text{rms}}/\langle n\rangle = 1\sqrt{\langle n\rangle}$$
$$\Delta n_{\text{rms}}/\langle n\rangle = \sqrt{(1+1/\langle n\rangle)}$$

From the above two expressions, one can conclude that the photon number fluctuations for a chaotic field can be much more pronounced than in the case of a laser field with increasing of $\langle n\rangle$.

Brown–Twiss Correlations and Nonclassical Light

The quantum definition of the degree of second-order coherence is defined analogously to the classical case by correlating two intensities at two different space–time points. Consider a light beam containing a mean number, $\langle n\rangle$, of photons, traveling in a single mode of the electromagnetic field, incident upon the BS (**Figure 6**). The degree of second-order coherence is expressed in terms of the mean and mean square photon number as

$$g^{(2)}(\tau) = \langle n(n-1)\rangle/\langle n\rangle^2$$
$$= [\langle n^2\rangle - \langle n\rangle]/\langle n\rangle^2$$

This expression can be explained as follows: the probability of counting a photon is proportional to the number of photons, n, in the field. Since the number of photons available in a second measurement is reduced by one unit, the probability of counting a second photon is proportional to $n-1$. As a consequence, the two-photon counting probability is proportional to $\langle n(n-1)\rangle = \langle n^2\rangle - \langle n\rangle$. Since the photon number variance is $(\Delta n)^2 \equiv \langle n^2\rangle - \langle n\rangle^2$, one can express the degree of second-order coherence as

$$g^{(2)}(\tau) = 1 + [\langle \Delta n\rangle^2 - \langle n\rangle]/\langle n\rangle^2$$

Since $(\Delta n)^2 \geqslant 0$, it must be that $\langle n^2\rangle \geqslant \langle n\rangle^2$. Hence, the following inequality holds:

$$g^{(2)}(\tau) \geqslant 1 - 1/\langle n\rangle \quad (\langle n\rangle \geqslant 1)$$

a result independent of the value of τ, including $\tau = 0$. It follows that one can write $g^{(2)}(0)$ instead of $g^{(2)}(\tau)$.

The signature of nonclassical light is given by the range of values, $1 - 1/\langle n\rangle \leqslant g^{(2)}(0) < 1$ accessible to the degree of second-order coherence, with $g^{(2)}(0) = 0$ for $\langle n\rangle < 1$.

For $\langle n\rangle = 1$, $g^{(2)}(0) = 0$, a result arising from the impossibility of the incident photon to be splitted by the beam splitter. As a consequence, no correlation exists between the signals of detectors D_1 and D_2 in this case. In the limit case of a beam with exactly n photons (photon number state), one has $\langle n\rangle = n$, and

$$g^{(2)}(0) = (n-1)/n \quad (n \geqslant 2)$$
$$g^{(2)}(0) = 0 \quad (n = 0, 1)$$

Figure 7 shows the degree of second-order coherence as a function of $\langle n\rangle$ for different kinds of light.

Finally, consider once more the theoretical predictions for chaotic and coherent light, **Figure 5**. The Brown–Twiss correlation at $\tau = 0$ for chaotic light, $g^{(2)}(0) > 1$ is also referred to as photon bunching, a term which indicates that photons tend to arrive simultaneously at detectors D_1 and D_2. Note that no photon bunches occur for coherent light, $g^{(2)}(0) = 1$. On the contrary, photon antibunching occurs for nonclassical light, such as photon number states, which lies in the region $0 \leqslant g^{(2)}(0) < 1$. In this case photons tend to arrive well spaced in time.

Quantum light has great importance in modern quantum optics because of its applications whenever transmission of signals through single photons is required, as in quantum cryptography and quantum computing. The single-photon regime can be attained by strongly attenuating a laser beam to ensure that the probability of having more than one photon becomes negligible. However, such attenuated beams differ from true single photons because of the intrinsic Poissonian statistics of the photon. Significant advances in the generation of single-photon states have been obtained in recent years, such as quantum dots in microcavities, parametric down-converters, falling neutral atoms and trapped ions in cavities, defects in diamond nanocrystals, and single molecules in a solid matrix.

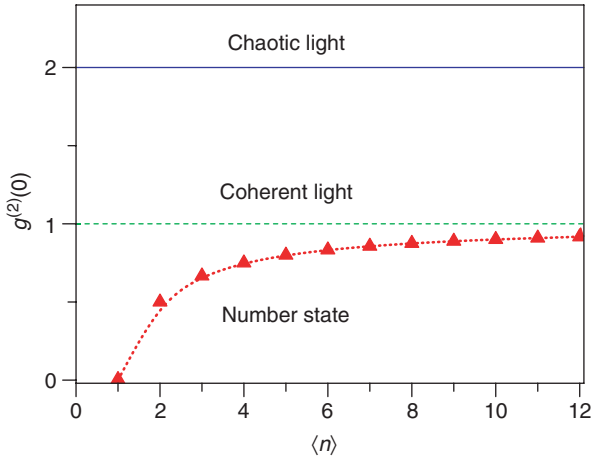

Figure 7 Degree of second-order coherence expressed as a function of $\langle n\rangle$ for chaotic light, coherent light, and quantum light.

Two-Photon States

As noted already, the optical beam splitter is the fundamental element for analyzing the statistical properties of light. Interesting interference effects occur when radiation given by two-photon states enters a beam splitter. These states, of high relevance for quantum information applications, can be generated by the nonlinear optical process of parametric down-conversion. Here two photons of frequency ν_1 and ν_2, also called as the signal and idler, are created by the annihilation of a "pump" photon of higher frequency ν_p, belonging to a laser beam which shines a crystal with no inversion symmetry, that is, with nonlinear dielectric susceptivity $\chi^{(2)} \neq 0$. Two-photon generation must obey the energy and momentum conservation laws:

$$\nu_p = \nu_1 + \nu_2; \qquad \boldsymbol{k}_p = \boldsymbol{k}_1 + \boldsymbol{k}_2$$

where $\boldsymbol{k}_p$, $\boldsymbol{k}_1$, and $\boldsymbol{k}_2$ correspond to the wave vectors of the pump, signal, and idler photons, respectively. Depending on the characteristics of the crystal, signal and idler photons can travel along the same direction or along different directions, and may have parallel or orthogonal polarizations.

The partition process on a beam splitter of two equal photons ($\nu_1 = \nu_2 = \nu_p/2$) traveling along two symmetric directions, a and b, can be studied by means of the Ou–Mandel interferometer, which is shown in **Figure 8**. Two cases are possible:

1. The two photons meet the beam splitter at different times. In this case, the probability $P(n_c, n_d)$, of finding n_c photon on mode c and n_d photons on mode d follows the classical binomial distribution,

   $$P(2,0) = R^2, \quad P(1,1) = 2RT, \quad P(0,2) = T^2$$

   For a symmetric beam splitter, $P(0,2) = P(2,0) = \frac{1}{2}P(1,1)$.
2. The two photons arrive simultaneously at the beam splitter. In this case, the output probability distribution is completely different:

   $$P(2,0) \equiv P(0,2) = 2RT, \quad P(1,1) = (R-T)^2$$

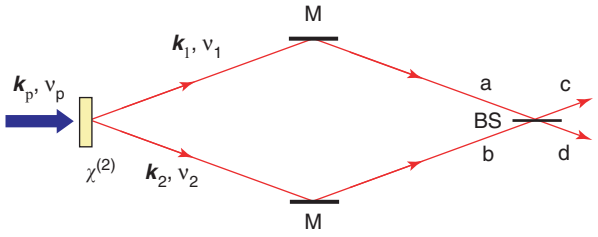

Figure 8 Ou–Mandel interferometer.

It is interesting to note that, for $R = T$, $P(1,1) = 0$, that is, in this particular case the photons emerge together in the same output arm, either c or d. The case of two-photon interference has no analog in the classical theory of light. Indeed, with two laser beams the partition probability is always binomial.

Photonic Bandgap Materials, Electronic States of

M Agio and L C Andreani, Università degli Studi di Pavia, Pavia, Italy

Introduction

Photonic crystals are materials whose dielectric function is periodic in one, two, or three spatial dimensions (1D, 2D, 3D). The propagation properties of photons in periodic media are analogous to those of electrons in crystalline solids, as covered by several sections of the encyclopedia. Translational invariance leads to the validity of the Bloch theorem (called Floquet theorem in optics) and to the formation of allowed and forbidden frequency regions. The allowed states of the electromagnetic field are organized into "photonic

bands," in analogy to electron bands in periodic solids. A frequency window for which light cannot propagate is named a "photonic gap" and periodic dielectric media are often called "photonic bandgap materials."

The concept of a 1D periodic dielectric medium has been a familiar one in optics, where it is known as a distributed Bragg reflector (or dielectric mirror) with well-defined stop bands. However, a stop band (or photonic gap) in 1D forbids propagation of light only in a limited angular cone. The field of photonic crystals is considered to have started in 1987 with seminal papers dealing with the control of spontaneous emission and with light localization in three dimensions. Indeed, the presence of a full photonic bandgap in 3D leads to the suppression of vacuum fluctuations of the electromagnetic field and, therefore, to the inhibition of spontaneous emission of a light source at frequencies within the bandgap. Moreover, the presence of disorder may lead to a weak localization of light at frequencies close to a band edge. Photonic crystals are now of great interest for basic physical properties related to the control of light propagation, radiation–matter interaction and quantum electrodynamic effects, localization and microcavities, nonlinear properties as well as for applications to optoelectronic and photonic devices such as lasers, optical fibers, filters, dispersion compensators, and integrated optical interconnects.

The article starts with the general properties of the photonic band structure and discusses the main theoretical approaches for calculating photonic bands and optical properties. Then photonic bands in three and two dimensions as well as photonic crystals embedded in planar waveguides (also known as photonic crystal slabs) are described. Defect states in photonic crystals are then considered. This section concludes with a few remarks about methods for measuring the photonic band dispersion.

Photonic Band Structure: General Properties

Maxwell equations for the electromagnetic field in matter with neither free charges nor currents can be cast into a second-order equation for the harmonic components of the electric field

$$\nabla \times \nabla \times \boldsymbol{E}(\boldsymbol{r}) = \left(\frac{\omega^2}{c^2}\right)\varepsilon(\boldsymbol{r})\boldsymbol{E}(\boldsymbol{r}) \qquad [1]$$

or of the magnetic field

$$\nabla \times \left[\frac{1}{\varepsilon(\boldsymbol{r})}\nabla \times \boldsymbol{H}(\boldsymbol{r})\right] = \frac{\omega^2}{c^2}\boldsymbol{H}(\boldsymbol{r}) \qquad [2]$$

Here, nonmagnetic media ($\mu(\boldsymbol{r}) = 1$) are assumed. The first equation should be combined with the divergence equation $\nabla \cdot \varepsilon(\boldsymbol{r})\boldsymbol{E}(\boldsymbol{r}) = 0$, while the second one requires $\nabla \cdot \boldsymbol{H}(\boldsymbol{r}) = 0$. The equation for the magnetic field is normally taken as the starting point for photonic band structure computations for two reasons. First, it has the form of an eigenvalue problem $\boldsymbol{\Theta}\boldsymbol{H}(\boldsymbol{r}) = (\omega^2/c^2)\boldsymbol{H}(\boldsymbol{r})$, with $\boldsymbol{\Theta}$ being a Hermitian operator. Second, the divergence equation for the magnetic field does not contain the dielectric function and is easier to implement. Working with a Hermitian eigenvalue problem is convenient from a computational point of view and has strong analogies with the matrix formulation of quantum mechanics.

The basic electromagnetic equations have a very useful property of "scale invariance." If $\boldsymbol{H}(\boldsymbol{r})$ is a solution at frequency ω corresponding to the dielectric constant $\varepsilon(\boldsymbol{r})$, then the scaled system with dielectric constant $\varepsilon'(\boldsymbol{r}) = \varepsilon(\boldsymbol{r}/s)$ has a solution $\boldsymbol{H}'(\boldsymbol{r}) = \boldsymbol{H}(\boldsymbol{r}/s)$ with frequency $\omega' = s\omega$. Reducing the length scale of the system by a factor s leads to eigenfrequencies that are multiplied by the same factor. Thus, there is no fundamental length scale for the photonic problem (unlike for electrons in solids, for which the Bohr radius is the natural unit of length).

A periodic dielectric medium (in 3D, say) is invariant under translations by vectors $\boldsymbol{R} = n_1\boldsymbol{a}_1 + n_2\boldsymbol{a}_2 + n_3\boldsymbol{a}_3$ ($n_1, n_2, n_3 \in Z$), where $\boldsymbol{a}_1$, $\boldsymbol{a}_2$, and $\boldsymbol{a}_3$ are primitive vectors and the set of all $\boldsymbol{R}$'s forms a "Bravais lattice." The dielectric constant satisfies the relation

$$\varepsilon(\boldsymbol{r} + \boldsymbol{R}) = \varepsilon(\boldsymbol{r}) \qquad [3]$$

and the magnetic field has the form implied by the Bloch–Floquet theorem:

$$\boldsymbol{H}_{n\boldsymbol{k}}(\boldsymbol{r} + \boldsymbol{R}) = \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}}\boldsymbol{H}_{n\boldsymbol{k}}(\boldsymbol{r}) \qquad [4]$$

where $\boldsymbol{k}$ is the Bloch vector (which may be restricted to the first Brillouin zone or Wigner–Seitz cell of the reciprocal lattice) and n is a discrete band index. The frequency eigenvalues have the form $\omega = \omega_n(k)$ and the set of all frequencies for $\boldsymbol{k}$ spanning the first Brillouin zone is called a photonic band. In addition to translational invariance leading to Bloch vector conservation, discrete rotational symmetries of the lattice may also be used to analyze the photonic bands, again in close similarity to the electronic problem. The density of states (DOS) is defined as

$$N(\omega) = \sum_n \int_{\mathrm{BZ}} \delta(\omega - \omega_n(\boldsymbol{k}))\mathrm{d}^3\boldsymbol{k} \qquad [5]$$

and is strongly modified as compared to the photonic DOS in vacuum or in a homogeneous medium, which increases with the square of the frequency.

Theoretical Methods

The most common method for calculating photonic band structures consists of expanding the magnetic field on a basis of plane waves that satisfy the Bloch theorem and the divergence equation:

$$\boldsymbol{H}_{n\boldsymbol{k}}(\boldsymbol{r}) = \sum_{\boldsymbol{G},\lambda} c_n(\boldsymbol{k}+\boldsymbol{G},\lambda)\hat{\varepsilon}(\boldsymbol{k}+\boldsymbol{G},\lambda)\mathrm{e}^{\mathrm{i}(\boldsymbol{k}+\boldsymbol{G})\cdot\boldsymbol{r}} \quad [6]$$

where G are reciprocal lattice vectors and $\hat{\varepsilon}(\boldsymbol{k}+\boldsymbol{G},\lambda), \lambda = 1,2$ are unit and mutually orthogonal polarization vectors perpendicular to $\boldsymbol{k}+\boldsymbol{G}$. The second-order eqn [2] is transformed into the matrix equation

$$\sum_{\boldsymbol{G}'\lambda'} \boldsymbol{H}_{\boldsymbol{G}\lambda,\boldsymbol{G}'\lambda'} c_n(\boldsymbol{k}+\boldsymbol{G}',\lambda') = \frac{\omega^2}{c^2} c_n(\boldsymbol{k}+\boldsymbol{G},\lambda) \quad [7]$$

where

$$\boldsymbol{H}_{\boldsymbol{G}\lambda,\boldsymbol{G}'\lambda'} = |\boldsymbol{k}+\boldsymbol{G}||\boldsymbol{k}+\boldsymbol{G}'| \times \varepsilon^{-1}(\boldsymbol{G},\boldsymbol{G}') \begin{bmatrix} \hat{\varepsilon}_2\cdot\hat{\varepsilon}'_2 & -\hat{\varepsilon}_2\cdot\hat{\varepsilon}'_1 \\ -\hat{\varepsilon}_1\cdot\hat{\varepsilon}'_2 & \hat{\varepsilon}_1\cdot\hat{\varepsilon}'_1 \end{bmatrix} \quad [8]$$

and $\varepsilon^{-1}(\boldsymbol{G},\boldsymbol{G}') \equiv \varepsilon^{-1}(\boldsymbol{G}-\boldsymbol{G}')$ is the Fourier transform of $\varepsilon^{-1}(\boldsymbol{r})$. Numerically, the linear eigenvalue problem is solved by retaining a finite number of reciprocal lattice vectors and using standard matrix diagonalization routines or more efficient methods based on fast Fourier transforms and iterative eigensolvers. The accuracy of the method depends on the number of plane waves in the basis and on their ability to reproduce the spatial variations of the magnetic field in the periodic structure and Maxwell boundary conditions when dielectric discontinuities are present. It turns out that convergence of the method is substantially improved when $\varepsilon^{-1}(\boldsymbol{G},\boldsymbol{G}')$ is obtained by first calculating $\varepsilon(\boldsymbol{G},\boldsymbol{G}') \equiv \varepsilon(\boldsymbol{G}-\boldsymbol{G}')$ as the Fourier transform of $\varepsilon(\boldsymbol{r})$ and inverting the resulting matrix numerically. Still, convergence of the method should always be checked and it may become problematic in special situations (e.g., high dielectric discontinuities and/or complex bases in the unit cell with close-packing dielectric spheres).

Just like plane-wave expansion, other techniques for photonic band structure calculations are borrowed from corresponding methods for the electronic problem. For example, in the case of spherical (for 3D) or circular bases (for 2D), the Korringa–Kohn–Rostoker method based on expanding the Green function in the basis of symmetry-adapted functions satisfying appropriate boundary conditions can be applied. This method has the advantage that it can easily incorporate frequency dispersion of the dielectric function (thus it can be used, for example, for photonic crystals containing metallic components), but it can be applied easily only to structures with bases of special symmetry.

The calculation of photonic bands assumes ideal structures, that is, infinitely extended in space and without imperfections. On the other hand, real samples are always finite and carry a certain degree of imperfection. Furthermore, there are quantities such as the transmission and reflection coefficients that manifest the existence of photonic bandgaps and are relatively easy to obtain experimentally. Among the numerical methods that are able to compute transmission and reflection, the most widely used are the transfer matrix, the scattering matrix, and the finite-difference time-domain method.

The transfer matrix method works in real space. The Maxwell curl equations are discretized on a mesh of subcells, so that the field propagation in the structure is defined by a nearest-neighbor interaction. The matrix of the resulting linear system of equations is called a "transfer matrix," as it transfers the fields from a subcell to another. Since the interaction is limited to the first neighbors, the matrix is sparse. Propagation across the whole structure is obtained by multiplication of sparse matrices. Once the transfer matrix is obtained, the calculation of transmission and reflection is straightforward. It is worth mentioning that when the system is periodic, the eigenvalues of the transfer matrix of a single unit cell yield an alternative method for computing the photonic band structure. This is especially useful when dealing with dispersive media.

The scattering matrix method is more suitable for the study of photonic crystal slabs (see description below). It computes reflection, transmission, and diffraction coefficients for propagation along a direction perpendicular or parallel to the waveguide plane. Maxwell equations are first solved in each layer by plane wave expansion. Then, using the scattering matrix (S), instead of the transfer matrix, boundary conditions are imposed at each interface. The S-matrix connects the ingoing amplitudes to the outgoing amplitudes. The scattering matrix $S(0,N)$ of the whole structure is constructed starting from the scattering matrix of the first interface $S(0,1)$, by applying the recursion formula $S(0,l) -> S(0,l+1)$. The S-matrix yields better numerical stability than the transfer matrix.

When working with more complex systems, with imperfections or explicitly designed defects, a more flexible numerical approach is required. This is fulfilled by the finite-difference time-domain (FDTD) method. The derivatives in the Maxwell curl equations

$$\nabla\times\boldsymbol{E} = -\frac{1}{c}\frac{\partial\boldsymbol{B}}{\partial t}, \qquad \nabla\times\boldsymbol{H} = +\frac{1}{c}\varepsilon(\boldsymbol{r})\frac{\partial\boldsymbol{E}}{\partial t} \quad [9]$$

are discretized by central finite differences, both in space and time. The electromagnetic field is thus defined on two meshes in space and time, one for the $\boldsymbol{E}$ field and one for the $\boldsymbol{H}$ field. These meshes are interlaced in order to have each $\boldsymbol{E}$ field position surrounded by nearest neighbor $\boldsymbol{H}$ field positions and vice versa. The equations are recast in the so-called "Yee algorithm," which is illustrated here for a two-dimensional case:

$$\boldsymbol{E}_x|_{i,j+1/2}^{n+1/2} = \boldsymbol{E}_x|_{i,j+1/2}^{n-1/2} + \frac{c\Delta t}{\varepsilon_{i,j+1/2}\Delta y}\left(\boldsymbol{H}_z|_{i,j+1}^{n} - \boldsymbol{H}_z|_{i,j}^{n}\right) \quad [10]$$

$$\boldsymbol{E}_y|_{i+1/2,j}^{n+1/2} = \boldsymbol{E}_y|_{i+1/2,j}^{n-1/2} - \frac{c\Delta t}{\varepsilon_{i+1/2,j}\Delta x}\left(\boldsymbol{H}_z|_{i+1,j}^{n} - \boldsymbol{H}_z|_{i,j}^{n}\right) \quad [11]$$

$$\begin{aligned}\boldsymbol{H}_z|_{i,j}^{n+1} = \boldsymbol{H}_z|_{i,j}^{n} &- \frac{c\Delta t}{\Delta x}\left(\boldsymbol{E}_y|_{i+1/2,j}^{n+1/2} - \boldsymbol{E}_y|_{i-1/2,j}^{n+1/2}\right) \\ &+ \frac{c\Delta t}{\Delta y}\left(\boldsymbol{E}_x|_{i,j+1/2}^{n+1/2} - \boldsymbol{E}_x|_{i,j-1/2}^{n+1/2}\right)\end{aligned} \quad [12]$$

Looping on i, j (space), and n (time) simulates the propagation of the electromagnetic field through the structure. Once the Yee algorithm has been implemented, the discretization of the dielectric constant $\varepsilon(r)$ is the only step that needs to be adapted to the specific simulation. This is a great advantage of FDTD with respect to the transfer matrix method. A Gaussian pulse is sent along a chosen direction, while detection lines collect the incident and outgoing power. The transmission coefficient is simply the ratio of outgoing to incident power. The reflection coefficient can be obtained in a similar manner. When the system is periodic, it is also possible to obtain the band structure from an FDTD simulation. Specific implementations of the FDTD method have been developed to treat media with strong frequency dispersion, such as metallic or metallo-dielectric systems.

Three-Dimensional Photonic Crystals

The first photonic structure that has been shown to possess a complete bandgap in three dimensions is the diamond lattice of dielectric spheres in air or air spheres in a dielectric material. The photonic gap opens provided the dielectric constant is large enough and it exists in a wide range of filling factors. Another simple 3D structure with a complete bandgap is the f.c.c. lattice of air spheres in a dielectric material: this is often called the "inverse opal" structure. An example of photonic bands and DOS for this structure is shown in **Figure 1**. The frequencies are given in dimensionless units $\omega a/(2\pi c) \equiv a/\lambda$, where a is the lattice constant, and as such they are invariant under a scale transformation. A full bandgap forms between the eighth and ninth bands with a relative width $\Delta\omega_g/\omega_g \approx 4\%$. On the other hand, no gap is formed between lower-lying bands, but a pseudogap with low photonic DOS occurs around $a/\lambda = 0.52$: a degeneracy between the second and the third bands at the W point and along the XU line prevents a gap from opening.

The inverse opal is derived from the (direct) opal structure, that is, an f.c.c. lattice of dielectric spheres in air: indeed, the opal is a natural gem consisting of a close-packed lattice of silica spheres with an f.c.c. arrangement. Artificial opals can be obtained

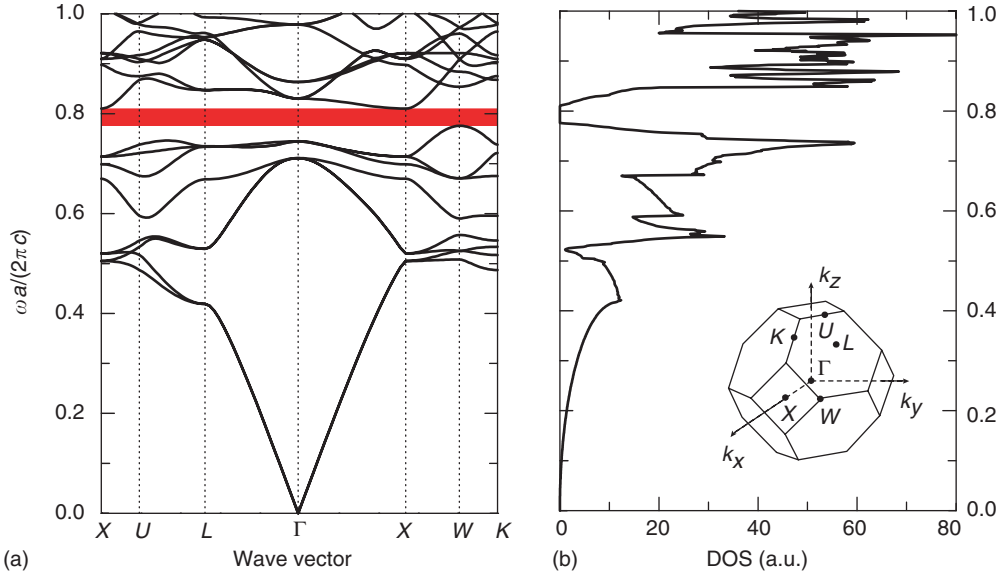

Figure 1 (a) Photonic bands and (b) DOS for an f.c.c. structure of close-packing air spheres in a dielectric material with $\varepsilon = 12$. The shaded area in (a) denotes the photonic gap. Inset: Brillouin zone and symmetry points of the f.c.c. lattice.

by self-assembling of spheres in a colloidal solution. The voids are then filled with a high-index material (Si or TiO_2) and the template is subsequently removed to obtain the inverse structure. This procedure allows one, in principle, to realize a photonic crystal with a complete bandgap in the optical region. In real systems, however, a small amount of disorder is always present: the gap shown in **Figure 1** is not very robust as it is relatively narrow and is formed between higher-lying bands, which are very sensitive to disorder.

Many other structures possessing a complete photonic gap in three dimensions have been studied. Two of them are shown in **Figure 2**. The structure in **Figure 2a**, called the "Yablonovite" (from the name of its proponent, E Yablonovitch) is obtained by drilling three sets of cylindrical holes with a triangular pattern, at 35.26° from the surface normal and at 120° with respect to each other. It represents a distortion of the diamond structure of air spheres in a dielectric material, where the surface is a (1 1 1) plane of the crystal and the holes correspond to [1 1 0] open channels of the diamond structure. The Yablonovite can be realized, in principle, at infrared and optical wavelengths by deep lithography. The structure in **Figure 2b**, often called "woodpile," is obtained by stacking four alternate layers of dielectric rods: starting from a first layer, the second layer is rotated by 90° with respect to the first, and the third layer is shifted by $a/2$ (a is the lattice constant) with respect to the first one. The woodpile structure can be realized by a series of stacking steps. The fabrication procedures of Yablonovite and of woodpile are examples of "top-down" and "bottom-up" approaches, respectively.

Two-Dimensional Photonic Crystals

2D photonic crystals have a dielectric constant that is periodic in a plane (xy) and homogeneous in the third (z) direction. The most interesting situation is when light propagates in the xy plane, that is, for a vertical wave vector $k_z = 0$. The system is invariant under specular reflection with respect to the mirror plane xy; thus the electromagnetic eigenmodes can be classified as even or odd with respect to this mirror symmetry. Even states have nonvanishing field components (E_x, E_y, H_z) and are called H- (or TE-) polarized modes, while odd states have nonzero field components (H_x, H_y, E_z) and are called E- (or TM-) polarized. Unlike in the 3D case, there is a strong polarization dependence of the photonic bands.

Most 2D structures that have been studied are based on a square or on a hexagonal Bravais lattice. In general, the most favorable situation for a complete photonic gap is to have a structure with the highest possible rotational symmetry: this helps in achieving an overlap between bandgaps along different directions of the Brillouin zone. The square Bravais lattice has a fourfold symmetry axis, while the hexagonal lattice has a sixfold rotational axis that is the maximum possible symmetry for periodic Bravais lattices. Higher rotational symmetries are possible for nonperiodic structures, such as quasicrystals.

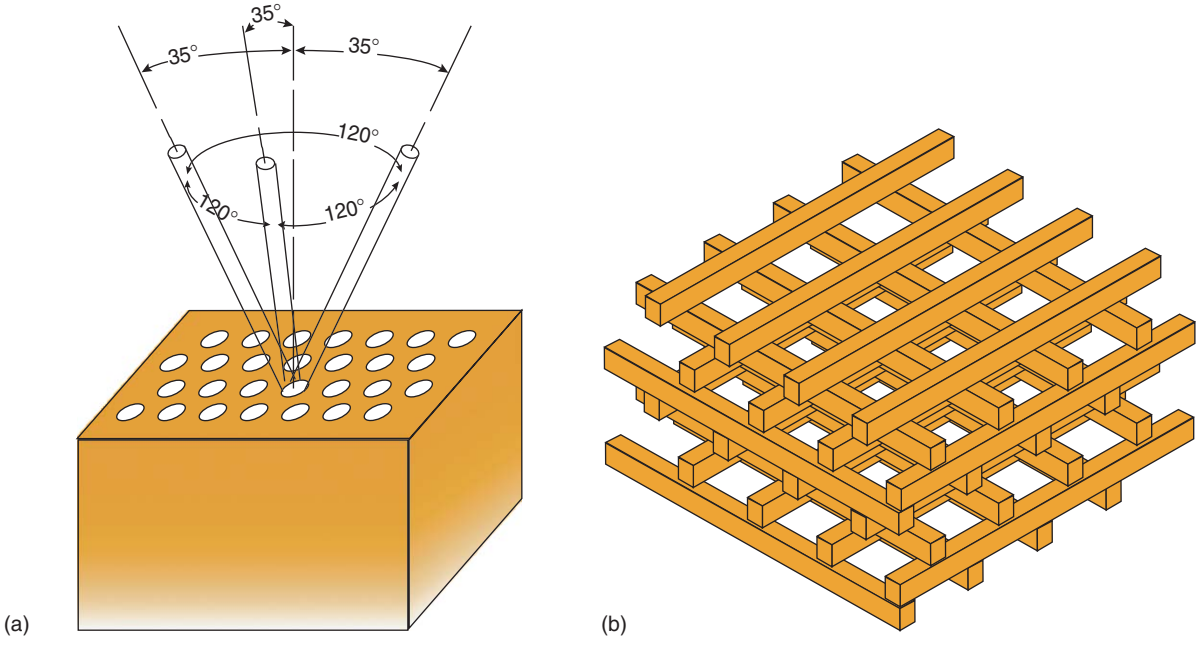

Figure 2 Schematic plots of the Yablonovite (a) and woodpile (b) photonic structures.

Figure 3 shows two examples of 2D photonic bands in structures with a full bandgap for all directions and polarizations, namely the triangular lattice of air holes in a dielectric medium (**Figure 3a**) and the graphite or honeycomb lattice of dielectric pillars in air (**Figure 3b**). Both structures are based on the 2D hexagonal Bravais lattice. The triangular lattice of holes has a large gap between the first and the second

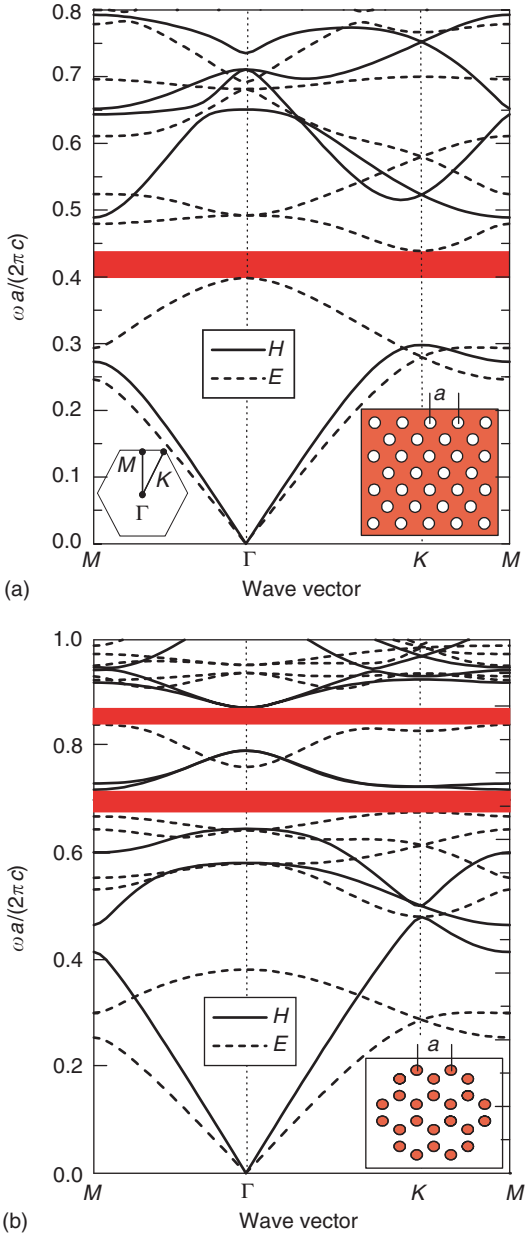

Figure 3 Photonic bands of (a) a triangular lattice of air holes with radius $r/a = 0.45$ in a dielectric material and (b) a graphite lattice of dielectric pillars with radius $r/a = 0.18$ in air. The dielectric material has $\varepsilon = 12$ in both cases. Solid (dashed) lines represent *H*- (*E*-) polarized modes: they are even (odd) with respect to a horizontal mirror plane. The shaded areas denote the photonic gaps. Insets: structures and 2D Brillouin zone.

H-band and a smaller gap between the second and the third *E*-band, which overlap in the region shown by a dashed area in **Figure 3a**. For the assumed value of the dielectric constant ($\varepsilon = 12$), the *H*-gap is found to open for hole radii $r/a > 0.16$, while the *E*-gap opens only for hole radii $r/a > 0.4$; therefore, a polarization-independent gap exists only for relatively high values of the air fraction. The graphite lattice of pillars, instead, has two complete bandgaps between higher-lying bands. Notice that the graphite lattice of pillars supports a large gap between the second and third *E*-bands, which however does not overlap any *H*-gap.

As a general rule, structures with a connected dielectric lattice (like that of **Figure 3a**) tend to have larger gaps for *H*-polarization, while structures with disconnected dielectric pillars (like that of **Figure 3b**) tend to support larger *E*-gaps. This criterion, which can be traced back to Maxwell boundary conditions for the nonvanishing field components, is generally followed for both square and hexagonal Bravais lattices. The overlap of *H*- and *E*-gaps is a stronger condition that occurs only in a few cases, those shown in **Figure 3** being the most common examples. In real systems, the complete gap shown in **Figure 3a** is easier to realize, because it is lower in frequency and less sensitive to disorder. For technological applications, a polarization-sensitive gap is often sufficient and the commonly used structure is the triangular lattice of air holes for smaller air fractions than shown in **Figure 3a**, in order to reduce radiation losses.

2D photonic structures can be defined by a top-down procedure based on lithography and etching. The prototype of a 2D photonic crystal is macroporous silicon, which is obtained by wet etching of Si in an electrochemical cell. It should be remembered that the photonic bands such as those shown in **Figure 3**, refer only to propagation in the *xy* plane: in a system that can be considered as homogeneous in the *z*-direction, the bands retain an out-of-plane dispersion and light is free to propagate in the vertical direction. This mechanism is exploited in a new class of optical fibers, which are known as holey- or photonic crystal fibers.

Photonic Crystal Slabs

In order to achieve a better control of light propagation, a 2D photonic structure can be embedded in a planar (slab) dielectric waveguide, thereby realizing a "photonic crystal slab." A few possible structures are shown in **Figure 4**. The theoretically simplest system is the "air bridge" (**Figure 4a**), which consists of a self-standing patterned dielectric membrane surrounded

by air. The air bridge has the highest refractive index contrast between the core and the cladding. **Figure 4b** exemplifies the silicon-on-insulator (SOI) structure, consisting of an air/Si/SiO_2 waveguide in which only the Si layer is patterned. A system with a weak refractive index contrast is shown in **Figure 4c**, and it can be realized with GaAs/AlGaAs or with InP/InGaAsP waveguides: both the core and the cladding need to be patterned in order to maintain the guiding properties of the slab. The fabrication of photonic crystal slabs requires epitaxial growth, lithography, and dry (reactive-ion) etching steps.

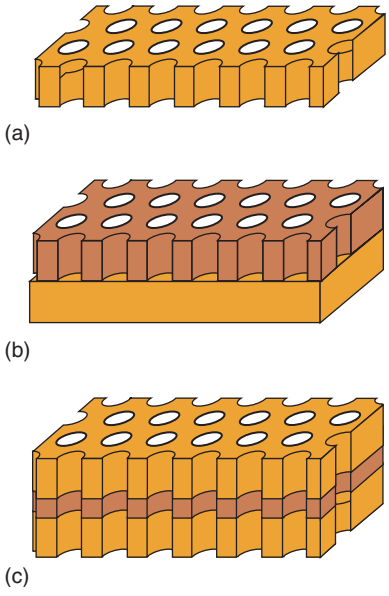

Figure 4 Schematic plots of photonic crystal slabs: (a) air bridge, or self-standing membrane, (b) SOI, where only the Si core layer is patterned, and (b) AlGaAs/GaAs/AlGaAs, where all layers are patterned.

Photonic crystal slabs are characterized by the light-line issue. Only photonic modes that lie below the light dispersion of the cladding material(s) in the $k-\omega$ plane are truly guided and stationary, while modes that lie above the cladding light line(s) are radiative and only quasi-guided. For a specified value of the in-plane wave vector, the truly guided modes lie in a frequency region of the discrete spectrum, while quasi-guided modes lie in the region of the continuous spectrum and appear as resonances: their line width can be related to an imaginary part of the mode frequency.

An example of mode dispersion in a photonic crystal slab is shown in **Figure 5** and it refers to an air bridge patterned with a triangular lattice of holes. **Figure 5a** shows the real part of the frequency dispersion in the Γ–K direction. The cladding light line (dotted line in the figure) separates the regions of guided and quasi-guided modes. The planar waveguide is monomode up to a frequency $\omega a/(2\pi c) \cong 0.61$, where a second-order mode appears. $\mathrm{Re}(\omega)$ is generally larger than for the ideal 2D case due to a vertical confinement in the slab waveguide: this effect is particularly pronounced for a strong

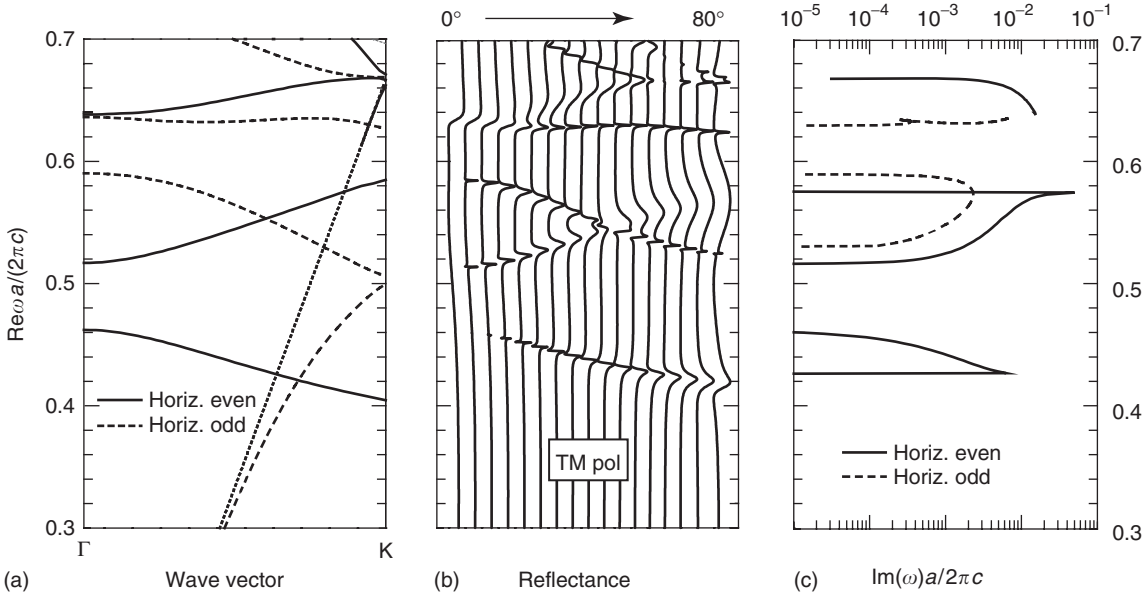

Figure 5 (a) Real part of the frequency; (b) specular reflectance from the surface at angles of incidence from 0° to 80° in steps of 5°; and (c) imaginary part of the frequency for a photonic crystal slab with a triangular lattice of air holes of radius $r/a = 0.3$ patterned in a membrane with core thickness $d/a = 0.3$ and dielectric constant $\varepsilon = 12$. All curves calculated for TM polarized (even) modes with respect to the plane of incidence along the Γ–K orientation. Solid (dashed) lines in (a) and (c) correspond to even (odd) modes with respect to a horizontal symmetry plane. The dotted line in (a) represents the dispersion of light in air.

index-contrast slab. **Figure 5b** displays the calculated reflectance of a plane wave incident on the surface of the slab, for increasing values of the angle of incidence. Spectral structures appear in reflectance spectra, which mark the excitation of photonic modes and whose evolution as a function of the incidence angle corresponds to the $\omega(k)$ dispersion of **Figure 5a**: the wave vector parallel to the surface is conserved and it equals $k = (\omega/c)\sin\theta$ (modulo a reciprocal lattice vector). **Figure 5c** shows the imaginary part of the frequency of quasi-guided modes plotted as a function of the real part. The imaginary part depends strongly on the mode index and on the wave vector, and it vanishes when the real part of the dispersion crosses the light line and goes into the guided mode region. It can be seen that an increasing imaginary part in **Figure 5c** corresponds to an increasing line width of the reflectance structure in **Figure 5b**.

The imaginary part of the mode frequency leads to an imaginary part of the wave vector through the relation $\mathrm{Im}(k) = \mathrm{Im}(\omega)/v_g$, where $v_g = \mathrm{d}\omega/\mathrm{d}k$ is the group velocity. Physically, a propagating quasi-guided mode in an ideal photonic crystal slab is subject to intrinsic radiative losses due to diffraction out of the 2D plane. In real systems, extrinsic diffraction losses related to fabrication aspects (insufficient hole depth, nonvertical profile, roughness of the sidewalls) are present for both guided and quasi-guided modes.

Defect States

It is well known in the electronic structure theory that localized defects introduce impurity states in the gap. An analogous phenomenon takes place in photonic crystals. A common example is a planar defect in a 1D photonic crystal, which is known as a planar (or Fabry–Pérot) microcavity. Linear and point defects in photonic crystals of higher dimensionality also give rise to defect modes within the photonic bandgap. The simplest kinds of defects can be treated with the methods introduced for bulk photonic crystals, provided the defect is repeated with supercell periodicity.

An example of photonic bands for a line defect, or channel waveguide in a photonic crystal slab is shown in **Figure 6**. The structure consists of a single missing row of holes in the Γ–K direction of the triangular lattice (see inset). The defect modes are found outside the projections of the 2D bands onto the Γ–K direction, which are denoted by shaded regions. The defect mode that falls below the photonic gap of the triangular lattice is called "index-guided," because it is laterally confined by the dielectric discontinuity between the channel region and the surrounding photonic crystal. The modes that exist only within the bandgap of the 2D lattice are called "gap-guided" and are laterally confined by the photonic gap, that is, by the lack of electromagnetic eigenmodes in the surrounding material. Both index- and gap-guided modes can be seen in **Figure 6**. Notice that the defect modes can be either guided or quasi-guided, according to their frequency with respect to the cladding light line. Truly guided defect modes allow, in principle, for straight propagation without losses.

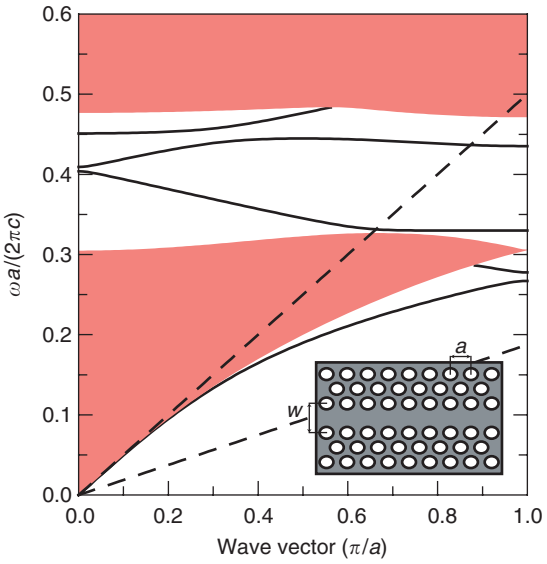

Figure 6 Dispersion of defect modes of a linear waveguide in a membrane with thickness $d/a = 0.3$ and dielectric constant $\varepsilon = 12$. The structure is shown in the inset and the holes in the triangular lattice have a radius $r/a = 0.36$. Only horizontally even and vertically odd modes are shown. The shaded regions correspond to the projected bands of the periodic lattice and the dashed lines denote the light dispersion in the dielectric material and in air.

The linear defect structure in a photonic crystal lends itself to the realization of ultra-compact waveguides with sharp bends, which cannot be obtained with conventional dielectric waveguides based on total internal reflection. **Figure 7** shows an example of wave propagation through a 120° bend in the triangular lattice of holes – the electromagnetic pulse is guided through the bend by the existence of a photonic gap in 2D. The FDTD method is particularly useful to model this kind of structures.

Measuring the Photonic Band Structure

In conclusion, a few experimental methods for measuring the photonic band structure are mentioned. The frequency window of a photonic bandgap can be obtained by transmission (or reflection) measurements.

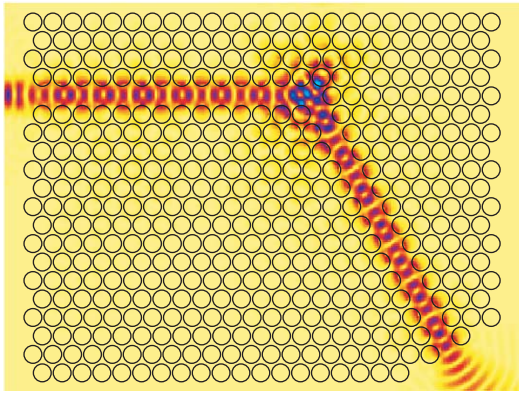

Figure 7 Electric field profile for an electromagnetic wave propagating through a 120° bend designed in a triangular lattice of air holes (FDTD calculation in two dimensions). The modulus of the field is represented in a linear scale.

The conceptually simplest method for obtaining the photonic band dispersion in the direction of light propagation is to measure the phase delay $\phi(\omega)$ of an electromagnetic wave through the photonic crystal: if d is the thickness of the sample, the wave vector at any given frequency can be obtained from the relation $\phi(\omega) = k(\omega)d$. This method has been applied by means of phase-sensitive measurements, first in the microwave spectral region and later in the near infrared and visible regions. The band dispersion in the direction of light propagation can also be obtained by analyzing Fabry–Pérot fringes in reflection or transmission through a sample of finite size. The photonic dispersion in two or three dimensions can also be derived by measuring the beam propagation (i.e., the refraction) of a light beam impinging on the photonic crystal at nonnormal incidence. The 2D band dispersion above the light line in photonic crystal slabs can be obtained by variable-angle reflectance measurements from the crystal surface. The principle is apparent from **Figure 5b**: the spectral position of a resonant structure in reflectance yields both the frequency and the parallel wave vector of a photonic mode. The same variable-angle reflectance technique can be applied to 2D and 3D photonic crystals, and in this case, it leads to the dispersion of photonic bands in a plane parallel to the crystal surface. Finally, the photonic dispersion can also be obtained by angle-resolved luminescence measurements in the far field: this is the photonic analog of angle-resolved photoemission spectroscopy for electronic systems.

Photosynthesis, Physics of

J L Herek, FOM Institute for Atomic and Molecular Physics, Amsterdam, The Netherlands

Introduction

Photosynthesis is the transformation of light energy into fuel that drives essential life processes in a variety of organisms. The physics of photosynthesis is photophysics: the collection and handling of sunlight and its conversion to a more stable form of energy. The subsequent utilization of this light energy involves a series of chemical reactions, which taken together comprise the global biological function of photosynthesis. In this article, the focus is on the fundamental steps of photosynthesis. The article begins by looking at the nanoscale machines involved, and then follows the path of an absorbed photon of sunlight as it journeys through the photosystem until eventually being converted into chemical potential.

It is worth bearing in mind that the total time of this phase of photosynthesis is no more than 100 ps, yet it is packed with numerous small steps, each of which has now been resolved in exquisite detail. Since the 1980s, photosynthetic complexes have been crystallized and analyzed to the atomic level. At the same time, lasers have been replacing the Sun in laboratory studies with increasingly better time resolution, such that one can now initiate and follow the flow of energy and charge in real time. This combination of detailed structural and dynamic information has opened a new window on photosynthesis, revealing the importance of these fundamental physical processes on the overall biological function.

Photosynthetic Machinery

Photosynthesis occurs in plants, algae, and some bacteria. The photosynthetic apparatus of all these organisms contains two key components responsible for the primary photophysics: light-harvesting (LH) complexes and reaction centers (RCs). Both are sophisticated pigment–protein structures located within cell membranes, and while they are necessarily coupled, each has a unique task. The light-harvesting complexes capture photons and transfer the solar energy both within and between complexes until it reaches the reaction centers, where this energy is then used to shuttle electrons across the photosynthetic membrane.

The essential components of photosynthesis can be viewed as nanoscale machines arranged in a complex web (rather than a linear assembly line operation) for optimal performance. **Figure 1** shows the photosynthetic apparatus responsible for collection and conversion of solar energy for the case of purple nonsulfur bacteria. These primitive organisms serve as prototype species for studies of the physics of photosynthesis. Unlike plant systems, the various components of the photosynthetic apparatus in these bacteria can be easily isolated and purified. In some

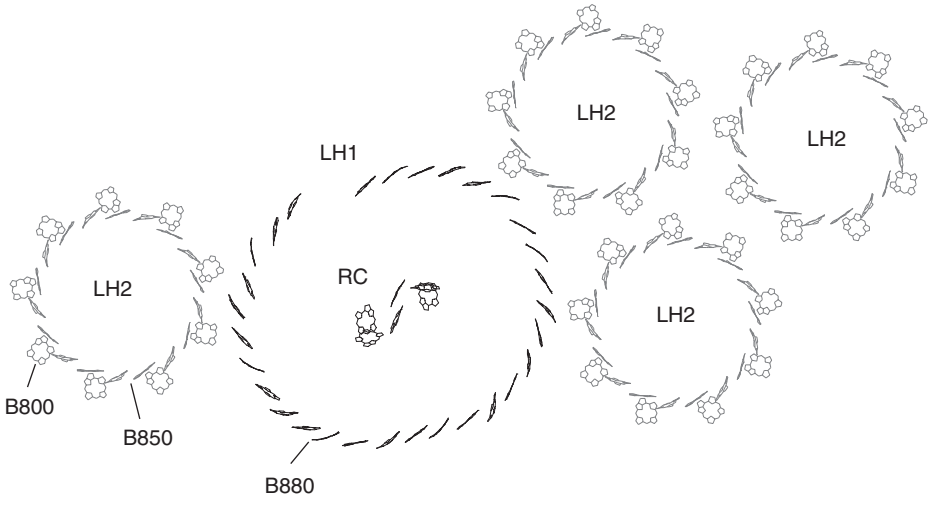

Figure 1 Schematic representation of the photosynthetic machinery of purple nonsulfur bacteria, based on crystallographic data. For clarity, the protein and carotenoid molecules are omitted. The peripheral light-harvesting complex LH2 contains two circular aggregates of bacteriochlorophyll molecules, labeled B800 and B850 according to their characteristic absorption maxima at 800 nm and 850 nm. Likewise, the larger core light-harvesting complex LH1 contains a broken ellipse of aggregated bacteriochlorophylls, the B880 ring. Nestled within the LH1 complex is the photosynthetic reaction center (RC). The supramolecular aggregate of LH2, LH1, and RC complexes is called the photosynthetic unit.

species, these components have been crystallized, allowing atomic-level structural information to be extracted. Also, the genetic makeup of these systems is known, allowing site-specific mutagenesis in which individual amino acids in the protein matrix can be altered. Such mutants are invaluable in studies aimed at detailed structure–function relations.

Figure 1 shows schematically a top-down look at the photosynthetic membrane of purple bacteria, based on real structural data. The ring-like structures are light-harvesting (LH) complexes. These complexes contain cylindrical aggregates of alpha-helical proteins (not shown) that span the lipid bilayer membrane and noncovalently bind the pigment molecules in circular or elliptical arrays. Nestled within one of these rings is another pigment–protein complex, the so-called reaction center (RC). This complex contains two branches with near mirror symmetry, also spanning the photosynthetic membrane. The overall supramolecular aggregate of peripheral light-harvesting complexes LH2 and core complexes containing the RC and surrounding LH1 complex is called the photosynthetic unit (PSU), though the ratio of LH2 to LH1-RC varies according to growth conditions such as temperature and light intensity.

In the intricate network of molecules arranged within the protein matrix, the function is determined by the location. While a chlorophyll molecule in the reaction center plays an essential role in photochemistry, a chlorophyll molecule located in an antenna complex functions in a completely different manner. These functions are described in the following sections.

Harvesting Light

The first step of photosynthesis is the collection of sunlight. How is light captured by living things? Illuminated molecules may either reflect or absorb incident light. Molecules that are especially capable of absorbing light in the visible region of the spectrum and give color to living things are called pigments. The pigments of photosynthesis are primarily chlorophylls, of which there are many different varieties. These molecules efficiently absorb light in the red and blue regions of the solar spectrum, while reflecting away most of the green (hence the predominance of this color in Nature). In addition, a variety of other less-abundant pigments enhance the light-absorbing capabilities of photosynthetic organisms by capturing other regions of the visible spectrum. Carotenoids, for example, have strong absorption in the blue-green region, but reflect away the yellow to red wavelengths. These pigments are largely responsible for the autumn "colorama," showcasing the presence of the carotenoids that becomes gloriously apparent as the chlorophyll in the leaves of the trees begins to break down.

When a molecule absorbs a photon of visible light, one of its electrons is promoted to a higher energy state. The molecule is then said to be in an electronic excited state. The wavelengths of light that are capable of creating excited states for a given molecule are given by an absorption spectrum. In **Figure 2**, the absorption spectra of chlorophyll and carotenoid molecules are shown, in comparison with the solar irradiance spectrum on Earth. The entire visible range of light (400–700 nm) as well as much of the near-infrared (up to 1000 nm) is used to drive photosynthesis in different organisms.

Understanding the excited states in photosynthesis is a key area of biophysics research, as it is from these states that all physical processes such as energy transfer and trapping as well as chemical reactions may occur. The nature of the excited state depends not only on the characteristic properties of the individual molecule, but also on its specific location within the photosynthetic complex. Interactions between neighboring pigments and, to some extent, the surrounding protein can shift the excited-state energies and thereby affect dynamics. For example, in photosynthetic purple bacteria, the primary pigment is bacteriochlorophyll. The main absorption of this pigment when isolated in solution is at $\sim$780 nm. In the photosynthetic unit, however, the absorption band shifts according to its location (and corresponding function): in the peripheral light-harvesting complex (LH2),

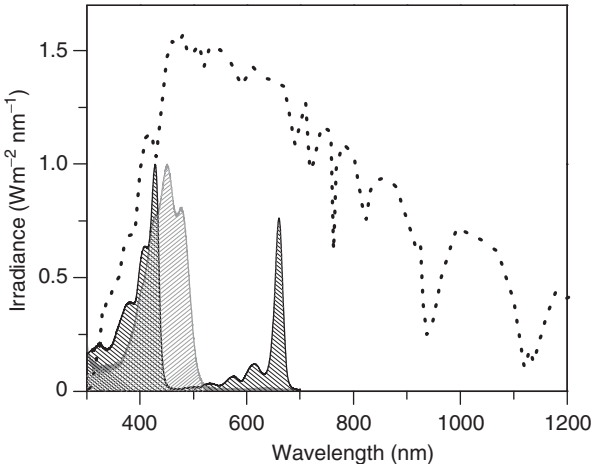

Figure 2 Solar irradiance spectrum and absorption spectra of photosynthetic pigments. Dotted curve: Intensity profile of sunlight measured on the Earth's surface. Black hatch: Absorption spectrum of chlorophyll, the most abundant photosynthetic pigment in Nature. Grey hatch: Absorption spectrum of the carotenoid beta-carotene, an accessory pigment. The spectra of the pigments are in absorption units (scale not shown).

there are two distinct binding sites for bacteriochlorophyll, giving rise to absorption bands at 800 and 850 nm, respectively. These binding sites are correspondingly labeled B800 and B850; see **Figure 1**. In the B800 ring, the individual pigments are well separated (by $\sim$20 Å), and the spectral properties are determined mainly by weak interactions with the protein environment. In the B850 ring, however, the pigments are tightly packed in a "waterwheel" arrangement; the further red-shifted absorption of the molecules here is due to the much stronger excitonic coupling between adjacent pigments. The ring structure also enhances absorption and acts as an energy storage unit. In the LH1 core light-harvesting complex, which directly couples to the reaction center, the bacteriochlorophyll absorb at 880 nm, and have an arrangement similar to the B850 ring. This tuning of absorption properties with location is crucial to the overall function of photosynthesis, creating an energy hierarchy that efficiently funnels light energy into the reaction center.

Antenna Action: Energy Transfer

While the reaction center is the hotspot for photosynthetic energy conversion, by itself it can only capture a few photons per second (given its absorption cross section, the solar flux, and its overlap with the solar irradiance spectrum). Yet, the turnover time of the reaction center function is of the order of 10 ms, that is, it is capable of a much higher throughput. Hence, an antenna system evolved to catch extra photons and feed them to the reaction center.

Antenna networks are highly regulated to maximize the efficiency of energy collection while at the same time avoiding photodamage that can occur when too much light is absorbed. These functions occur by rapid and directional energy transfer reactions. Following absorption of solar light, the pigment molecules are in electronically excited states. In principle, this excitation energy may then be used directly to drive a chemical reaction. However, in photosynthesis, the energy is first transferred between many molecules, over quite large distances, before it arrives at the site of action.

The antenna system increases the amount of sunlight that can be absorbed compared to a single pigment, thereby increasing the number of photons available for photochemistry. A photosynthetic antenna is analogous to a satellite dish, collecting energy from a large area and concentrating it at a small receiver site (the reaction center), thereby greatly increasing the signal strength. Antenna networks contain an additional 100–10 000 pigments per reaction center. Molecules located in the antenna do not perform any chemistry, but simply transfer the collected energy between each other in a well-defined and efficient manner. For optimal functioning, energy collected by the antenna pigments must reach the reaction center within $\sim$100 ps; hence, the transfer between individual pigments should be of the order of 1 ps or less. This transfer process is purely physical and is governed by the energetic interactions between molecules.

Advances in ultrafast laser spectroscopy have allowed detailed measurements of these energy transfer dynamics in real time. In the laboratory, a femtosecond laser replaces the sun and initiates the process of interest. As the absorption of the antenna pigments is determined by their location, the laser may be tuned to be resonant with a given molecule, thereby isolating a specific energy transfer step. For example, in the LH2 complex of purple bacteria, the B800 to B850 energy transfer can be targeted by tuning an excitation pulse to 800 nm, and then probing the arrival of energy by monitoring the buildup of the transient absorbance signal at 850 nm with a second delayed femtosecond pulse. By varying the timing of the probe pulse, the dynamics of the process may be followed at discrete time steps, which, when combined, yield a kinetics trace.

All photosynthetic systems have an inherent energy gradient that dictates the flow of energy among the pigments. In purple bacteria, this is given by B800 $\rightarrow$ B850 $\rightarrow$ B880 $\rightarrow$ RC (note that the valuable contributions of carotenoids, which perform accessory light harvesting in addition to other important functions, are ignored). The associated time constants for these transfer steps are shown in **Figure 3**. The lifetime of an isolated antenna complex, decoupled from the reaction center, is of the order of 1 ns. During this time, the excitation energy moves freely among the lowest-energy pigments of the antenna network, until eventually dissipated by nonradiative relaxation processes. In the full photosynthetic unit, where antennas are connected to reaction centers, the excitation is trapped within 30–50 ps. Hence under physiological conditions, nearly all the energy is utilized for photochemistry.

Excitation transfer in biological systems has usually been described as an incoherent hopping process following the theory of Förster. It is hard to overestimate the physical insight obtained by this approach. At the same time, a number of experimental observations for photosynthetic pigment–proteins do not fit into this picture and call for a more general description of the problem. The incoherent Förster description of electronic energy transfer assumes that the interaction between the involved molecules is very weak. In the opposite limit of strong interaction between the molecules, a molecular exciton description

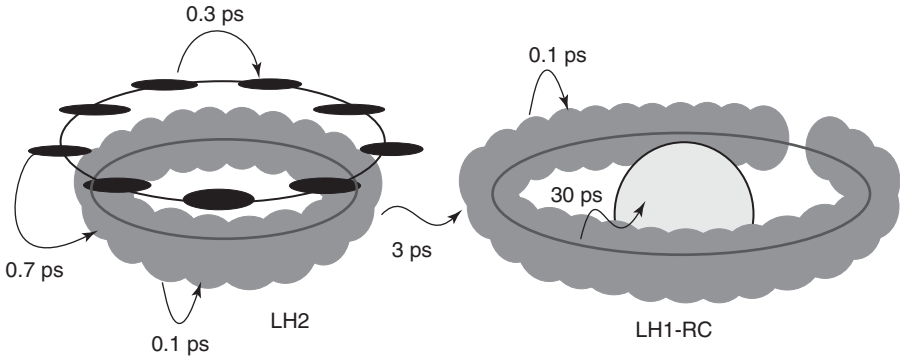

Figure 3 Energy transfer times between the various pigments in the photosynthetic units of purple bacteria.

is appropriate. In this limit, the excited states of the individual molecules combine to exciton states common for all the interacting molecules (the aggregate), the excitation is coherently delocalized over a number of pigment molecules and the absorption spectrum exhibits a prominent exciton band structure. Time evolution in the exciton picture occurs via phonon-induced relaxation between exciton levels. These two descriptions, incoherent hopping and exciton relaxation, are the two qualitatively different limiting cases of the general process of excitation dynamics. What description should be chosen for a particular observation depends on the system properties and the experimental conditions. It may happen that the real situation is somewhere in between these two limiting cases, in which case the analysis is particularly challenging.

The important factor in deciding which process(es) occur is the ratio of the coupling between electronic transitions (V) and the disorder (Δ). The disorder may be either static (spectral inhomogeneity) or dynamic (electron–phonon interaction). If V/Δ is much less than unity, then the interactions are considered very weak and energy transfer occurs in the incoherent Förster hopping regime. In the opposite case, if $V/\Delta \gg 1$, the interaction is very strong and the exciton picture is used. In both cases, the transfer rate can be calculated using the first-order perturbation theory leading to the Fermi Golden rule. In the hopping description, the electronic coupling (V) acts as a perturbation; in the exciton picture, an electron–phonon coupling (dynamic disorder) is the perturbation.

In the weak coupling incoherent limit, the rate of energy transfer (energy hopping) from a donor to an acceptor molecule is determined by three different molecular properties: the electronic coupling between donor and acceptor (V), the overlap of donor fluorescence and acceptor absorption spectra (J), and the relative orientation of the molecules (κ), and given by

$$K_{\mathrm{ET}} \sim V^2 J \kappa^2$$

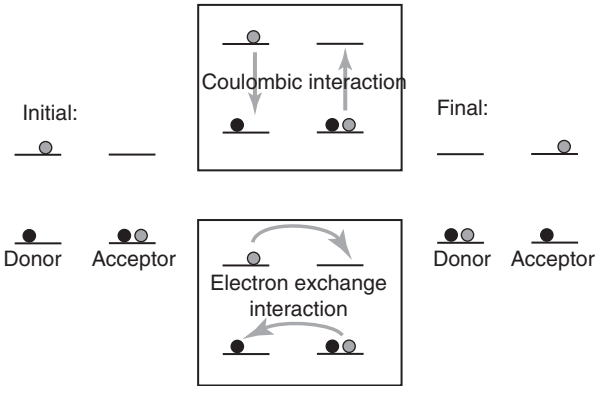

Figure 4 Interactions governing excitation energy transfer. The Coulombic interaction promotes simultaneous deactivation of the donor and excitation of the acceptor. The electron exchange interaction involves transfer of excitation energy via direct exchange of electrons between donor and acceptor molecules.

A few things should be noted. The electronic coupling (V) has two contributions, one short-range electron-exchange interaction (which decays exponentially with the intermolecular distance R) and one long-range Coulombic interaction (which scales as R^{-6}). These two cases are described in **Figure 4**. The interaction accounted for in the Förster mechanism and implicated by the transition dipoles is the generally dominating dipole–dipole contribution to the Coulombic interaction; higher multipole terms are also generally present, but of much less importance for molecules with strong transition dipole moments (e.g., strongly allowed optical transitions). The electron exchange term in the interaction may become important at very short distances, when there is overlap of the donor and acceptor molecular orbitals. This is the so-called Dexter mechanism, and in particular for molecules with forbidden optical transitions, it may become important. Energy transfer in photosynthetic antenna complexes between the lowest forbidden excited state of carotenoid molecules and the lowest excited state of chlorophyll molecules has been discussed in terms of the Dexter mechanism.

In the exciton picture, the excitation energy is delocalized over the interacting pigment molecules. However, the extent of delocalization is determined by the V/Δ ratio, and in a real system, exciton delocalization is generally smaller than the physical size of the molecular aggregate. The localization process may also have a dynamic part due to the dynamic contribution to the disorder Δ, and the exciton thereby changes its size in time. The relevant aspects of the energetics and dynamics in the exciton limit are the exciton level structure, the dynamics of exciton relaxation among the set of exciton levels, the extent and dynamics of delocalization of the exciton, and the motion of the whole exciton over the aggregate of interacting molecules. The energies of the exciton states are obtained from the Hamiltonian of the interacting molecules and the dynamics may be obtained from the density matrix of the system.

Energy Conversion and Storage

Electron transfer reactions are Nature's solution to the problem of converting the short-lived energy of electronically excited molecules into a more stable form of energy, which can, in addition, be transformed into various energy-rich substances with practically unlimited storage potential. Nature has devised highly efficient systems that optimize electron transfer processes while at the same time avoiding back-reactions and quenching processes.

When the excitation energy reaches the photosynthetic reaction center, it launches a sequence of electron transfer reactions that create a charge-separated state in which positive and negative charges are separated over the lipid bilayer membrane. Energy stored in this manner can then be used to pump protons across the membrane. The resulting proton motive force drives the synthesis of energy-rich compounds such as adenosine triphosphate (ATP). ATP is thermodynamically stable for a sufficiently long time to serve as the "fuel" for many subsequent biochemical processes. Once stored in the form of ATP, the energy can be used in the cell at any arbitrary instant for transport, synthesis, or other chemical reactions that require input energy.

Again, of all the photosynthetic organisms, the reaction center of anoxygenic purple bacteria is best understood. Though in contrast to the wide variety in the configurations of antenna complexes, the reaction centers of bacteria and plants share a rather common structural and functional motif. The reaction center consists of a number of protein subunits that form a scaffold (not shown) to hold the photochemically active molecules. While a number of these molecules are identical or similar to the (bacterio)chlorophyll pigments found in the antenna, here the molecules are called cofactors to distinguish their different function. The structure of the reaction center from *Rhodobacter sphaeroides* is shown in **Figure 5**. The cofactors are bacteriochlorophylls (P and B in **Figure 5**), bacteriopheophytins (H), quinones (Q), and an iron atom (located between the quinones; not shown). The cofactors are arranged into two nearly symmetric branches (A and B), joined at the top by the so-called "special pair" of bacteriochlorophyll molecules that are located so close together as to form a super molecule or dimer.

When the excitation energy collected by the antenna network finally arrives at the reaction center, it initiates a cascade of electron transfer reactions. These reactions have been visualized by a variety of spectroscopic techniques, in particular ultrafast transient absorption spectroscopy, often combined with genetic manipulations of the native structure to better elucidate structure–function relations. Upon light irradiation, the excited dimer (P^*) transfers an electron to the bacteriochlorophyll (B_A) and the bacteriopheophytin (H_A) on the A side of the branch within a few ps. The resulting radical pair ($P^+H_A^-$) decays in about 200 ps moving the electron onward to the quinones.

The most striking feature of the reaction center activity is the unidirectional transport down branch A (the active branch), despite the apparent twofold symmetry of the structure. The electron is 200 times

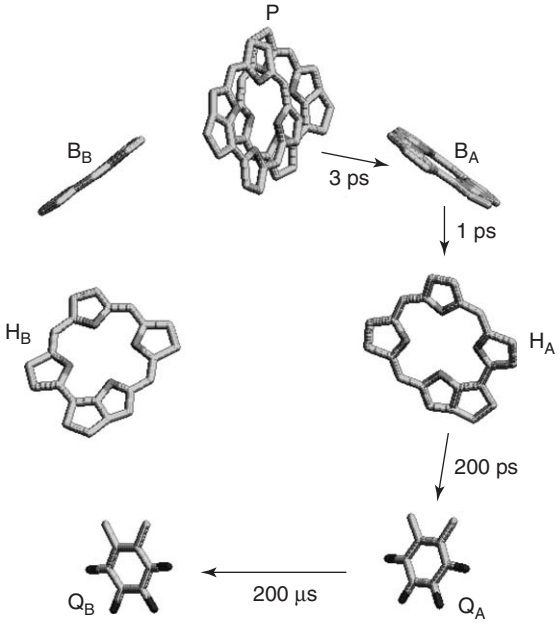

Figure 5 X-ray structure of the active molecules in the reaction center from the photosynthetic purple bacteria *Rhodobacter sphaeroides*, showing the pathway and time constants of electron transport via the active branch A.

more likely to follow branch A than branch B. While considerable experimental and theoretical efforts have tackled this discrepancy, it remains as one of the most intriguing puzzles in the primary processes of photosynthesis.

The high quantum yield of primary charge separation (as much as 0.95 in some systems) comes with a price: a lower energetic yield. The final radical pair state of the bacterial RC contains 0.55 eV, which is only 40% of the excited state energy of the primary electron donor (or around a third of the average photon energy absorbed by the antenna). Perhaps the energetic efficiency of the RC could be improved upon in synthetic RC-like structures, though model systems (consisting of electron donor and acceptor molecules connected by covalent links) have shown quantum efficiencies of 30% or less. Most likely, the rigidity of the protein surrounding the donor and acceptor pigments is essential to achieve such high quantum efficiency.

From Natural to Artificial Photosynthesis

An understanding of how Nature works will allow one to use the basic principles for other purposes. The most obvious application of artificial photosynthesis is the conversion of sunlight to useful forms of energy, such as electricity by photovoltaic devices or fuel by photochemical reactors. Modern solar cells are already being built on principles gleaned from natural photosynthesis. Sensitized semiconductor materials are environmentally friendly and becoming cost-effective alternatives to silicon. Solar cells based on this material utilize sensitizer molecules that act as antenna pigments to collect sunlight in a wide spectral region and funnel the solar energy into the semiconductor by way of an electron transfer process. Ongoing research will lead to the development of new, more efficient solar light-harvesting technologies that not only mimic Nature, but perhaps also surpass it.

Piezoelectricity

D Damjanovic, Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

The piezoelectric effect describes the linear relationship between the mechanical (stress σ and strain x) and electrical (electric field E, and electric displacement D or polarization P) fields that is observed in certain classes of materials. The "direct" piezoelectric effect, which describes an electric field or electric displacement generated by mechanical stress or strain, was discovered by Pierre and Jacques Curie in 1880. The so-called "converse" effect, which describes mechanical strain or stress generated by an electric field or charge was theoretically predicted by G Lippmann in 1881 and confirmed experimentally by the Curies in 1882. The term "piezo" has its origin in the Greek word for pressure (e.g., piezoelectricity which means electricity produced by pressure) and was proposed by W Hankel in 1881. The formulation of piezoelectricity in tensor form followed the 1894 work of Voigt.

Thermodynamic Formulation of the Piezoelectricity

A convenient way to formally derive piezoelectric effect is by using thermodynamics of polarizable, elastically deformable solids. The reversible change dU in the internal energy U of an elastic, dielectric material that is subjected to a small change of the strain dx_{ij}, electric displacement dD_i, and entropy dS is given by $dU = T\,dS + \sigma_{ij}\,dx_{ij} + E_i\,dD_i$, where T is the

temperature of the material, indices $i, j = 1, 2, 3$ indicate components of the tensors, and summation over repeated indices is assumed. The choice of the independent variables is arbitrary, and for experimental convenience one generally chooses the set T, σ_{ij}, E_i instead of S, x_{ij}, D_i used above to formulate dU. The change of independent variables from one set to another is accomplished by performing a Legendre transformation of U by adding to it, the expression $-TS - x_{ij}\sigma_{ij} - E_iD_i$. The resulting free energy function $G = U - TS - \sigma_{ij}x_{ij} - E_iD_i$ is known as the Gibbs free energy. The differential of G is $dG = -S\,dT - x_{ij}\,d\sigma_{ij} - D_i\,dE_i$ and, therefore, $x_{ij} = -(\partial G/\partial\sigma_{ij})_{T,E}$ and $D_i = -(\partial G/\partial E_i)_{T,\sigma}$. The subscripts indicate that the variables are kept constant. The derivatives $d_{ijk}^{\text{converse}} = (\partial x_{ij}/\partial E_k)_T = -(\partial^2 G/\partial E_k\partial\sigma_{ij})$ and $d_{kij}^{\text{direct}} = (\partial D_k/\partial\sigma_{ij})_T = -(\partial^2 G/\partial\sigma_{ij}E_k)$ define the converse and the direct piezoelectric effect, where d_{ijk} are elements of the tensor of the piezoelectric coefficient. Since the order in which the second derivatives are taken is irrelevant, one obtains the following Maxwell relations:

$$d_{kij}^{\text{direct}} = \left(\frac{\partial D_k}{\partial\sigma_{ij}}\right)_T = -\left(\frac{\partial^2 G}{\partial\sigma_{ij}\partial E_k}\right)$$
$$= -\left(\frac{\partial^2 G}{\partial E_{ik}\partial\sigma_{ij}}\right) = \left(\frac{\partial x_{ij}}{\partial E_k}\right)_T = d_{ijk}^{\text{converse}}$$

which demonstrate the thermodynamic equivalence of the converse and the direct piezoelectric effect. The piezoelectric effect can be formulated in integrated form as

$$D_k = d_{kij}^T\sigma_{ij}$$

and

$$x_{ij} = d_{ijk}^T E_k$$

The superscript T indicates that the piezoelectric coefficient is considered under isothermal conditions and is usually not written explicitly. In nonpolar materials, adiabatic and isothermal coefficients are identical while in polar (pyroelectric) materials their difference is usually negligible.

The piezoelectric tensor equations are generally written in reduced matrix form, according to the following convention by Voigt: $d_{ijk} = d_{im}$, where $m = 1, 2, 3$ for $jk = 11, 22, 33$, and $d_{ijk} = 1/2\,d_{im}$, where $m = 4, 5, 6$ for $jk = 23$ or 32; 13 or 31; and 12 or 21, respectively. The piezoelectric effect is thus expressed in reduced form as $x_m = d_{mi}E_i$ and $D_i = d_{im}\sigma_m$. Note that while d_{ijk} transforms as tensor, d_{im} does not.

The signs of the piezoelectrically generated charge D (or polarization P) and strain x depend on the direction of applied mechanical and electric fields, respectively. This distinguishes the piezoelectric effect from electrostriction in which the electric field of either sign produces the same sign of the strain. This sign of a piezoelectric coefficient is a matter of convention. For example, a d_{kk} is defined as positive, if tension σ_k parallel to X_k axis causes a potential difference on two parallel faces perpendicular to X_k, such that the positive terminal coincides with the face of the crystal on which $+X_k$ points from inside the crystal. A given piezoelectric coefficient d_{ij} can be either positive or negative, and can change the sign with temperature or frequency. It is common to call piezoelectric coefficients measured in the direction of the applied field, longitudinal coefficients (d_{11}, d_{22}, d_{33}), and those measured in the direction perpendicular to the field, transverse coefficients (e.g., d_{31}, d_{23}). Other piezoelectric coefficients are known as shear coefficients (e.g., d_{15}, d_{26}) (**Figure 1**).

The remaining combinations of the electric and mechanical variables (E, x;D, x;D, σ) define additional thermodynamic functions from which the following pairs of direct and converse piezoelectric relations can be derived: $\sigma_m = -e_{im}E_i$ and $D_i = e_{im}x_m$; $\sigma_m = -h_{im}^x D_i$ and $E_i = -h_{im}x_m$; $x_m = g_{im}D_i$; and $E_i = -g_{im}\sigma_m$, where e, g, and h are the piezoelectric coefficients. The relationships among the four piezoelectric

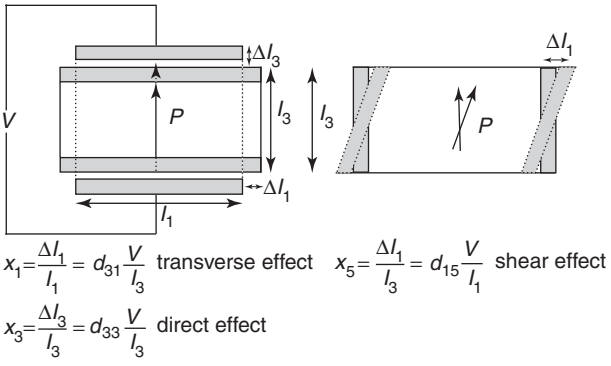

Figure 1 Illustration of the converse longitudinal, transverse, and shear piezoelectric effect in a polar material. The shaded areas indicate conductive layers (electrodes) applied on the sample surfaces to collect charge or apply electric field.

coefficients in reduced matrix notation are given by

$$d_{im} = e_{in}s^E_{nm} = \varepsilon^\sigma_{ij}g_{jm} \ \ (\mathrm{m\,V^{-1}\ or\ C\,N^{-1}})$$
$$e_{im} = d_{in}c^E_{nm} = \varepsilon^x_{ij}h_{jm} \ \ (\mathrm{C\,m^{-2}\ or\ N(V\,m)^{-1}})$$
$$g_{im} = h_{in}s^D_{nm} = \beta^\sigma_{ij}d_{jm} \ \ (\mathrm{m^2\,C^{-1}\ or\ V\,m\,N^{-1}})$$
$$h_{im} = g_{in}c^D_{nm} = \beta^x_{ij}e_{jm} \ \ (\mathrm{N\,C^{-1}\ or\ V\,m^{-1}})$$

The units of each coefficient are indicated in parentheses. The difference between the coefficients can be illustrated by taking as an example g and d coefficients. The matrix indices are omitted for simplicity. Relation $D = d\sigma$ describes the piezoelectric charge measured on electrically shorted samples, with free flow of the charge into the external electric circuit. If the sample is open circuited, this piezoelectric charge will accumulate on the sample surface and generate a voltage (or electric field E) across the sample. The field depends on the capacitance (i.e., dielectric permittivity ε) of the sample (charge = capacitance × voltage) and is related to the stress by $E = -g\sigma$, where $g = d/\varepsilon$.

Piezoelectric Constitutive Equations and Electromechanical Coupling Factors

Following the thermodynamic approach given above, the total strain in a piezoelectric material under the combined influence of electric and mechanical fields, under isothermal conditions and in the limit of the linear response, is given by

$$x_m = s^E_{mn}\sigma_n + d_{im}E_i \qquad [1]$$

where the first term denotes the Hook's law. Under the same conditions, the total charge density (or dielectric displacement) generated by a piezoelectric material is given by

$$D_i = d_{im}\sigma_m + \varepsilon^\sigma_{ij}E_j \qquad [2]$$

where the second term indicates polarization of the material by an electric field. The pairs of equations of this type are known as the piezoelectric constitutive equations. Terms describing coupling to thermal, magnetic, and other effects can be added to constitutive relations as necessary. Analog constitutive equations can be written for g, e, and h coefficients.

Analysis of any problem involving piezoelectric effect must usually involve full constitutive equations and not just its piezoelectric part. A common experimental situation is illustrated in **Figure 2**, where an external stress σ_3 is applied on a piezoelectric sample and the generated charge is collected on the top and bottom surfaces of the sample. Application of a stress deforms the sample both longitudinally and laterally. If the sample is short-circuited and free to deform laterally, the only stress present is the applied stress, and the piezoelectric charge collected from the electroded top and bottom faces is given by $D_3 = d_{33}\sigma_3$ (e.g., the case of a ferroelectric sample poled along its thickness as shown in **Figure 2**). However, if the sample is clamped laterally (e.g., a piezoelectric thin film deposited on a thick, perfectly rigid substrate), the clamping will be equivalent to having additional, effective stresses, σ_1 and σ_2, opposing the lateral deformation of the sample. The piezoelectric charge is then given by $D_3 = d_{31}\sigma_1 + d_{32}\sigma_2 + d_{33}\sigma_3$. The lateral stresses can be calculated from the clamping condition $x_1 = x_2 = 0 = s^E_{1n}\sigma_n = s^E_{2n}\sigma_n$. The effective piezoelectric coefficient is then given by $d^{\mathrm{eff}}_{33} = d_{33} + f(s_{mn}, d_{im})$. In many cases, function $f(s_{mn},d_{im})$ is negative so that the effective d^{eff}_{33} can be as much as 50% smaller than the true piezoelectric coefficient. In practice, the boundary conditions can be more complex and it is often necessary to consider constitutive equations with mixed independent variables (e.g., strain and stress). This is the case when the substrate also deforms, in which case f includes elastic properties of the substrate, and can become positive, increasing the apparent piezoelectric response. The influence of function f can be minimized by changing the aspect ratio of the sample.

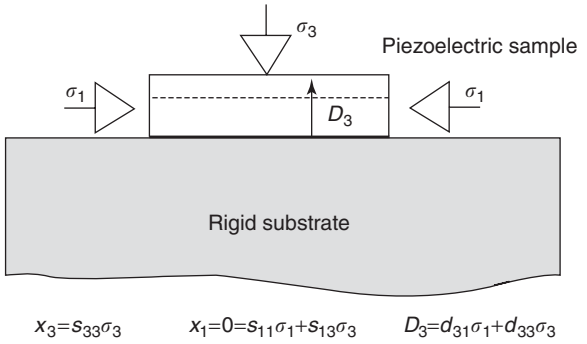

Figure 2 Illustration of the clamping effect and use of both pairs of constitutive equations for a two-dimensional piezoelectric material. The only externally applied stress is σ_3, whereas the lateral stress σ_1 is a consequence of the clamping.

Because of the piezoelectric coupling between the electrical and elastic variables, the values of the dielectric permittivity and elastic compliance (or stiffness) in piezoelectric materials will not be the same if measured under different experimental conditions. If an electric field is applied on a clamped one-dimensional sample, the resulting piezoelectric stress is $\sigma = -eE = -(d/s^E)E$. Replacing this stress into expression $D = d\sigma + \varepsilon^\sigma E$ for the dielectric displacement, one obtains $D = (\varepsilon^\sigma - d^2/s^E)E = \varepsilon^x E$ where $\varepsilon^x = \varepsilon^\sigma(1 - d^2/s^E\varepsilon^\sigma) = \varepsilon^\sigma(1 - k^2)$ is called the clamped (zero strain) dielectric constant. The parameter k, defined by $k^2 = d^2/s^E\varepsilon^\sigma$, is known as the electromechanical

coupling coefficient. In some ferroelectrics, k may be as large as 0.7–0.9 leading to as much as 50–80% difference between the free (zero stress) and clamped (zero strain) dielectric constant. It can be shown in a similar way that the elastic compliance s^D, measured under open circuit conditions (zero or constant D), and compliance s^E, measured under short circuit conditions (zero or constant E), are related by $s^D = s^E(1 - d^2/s^E\varepsilon^X) = s^E(1 - k^2)$. The coupling coefficients depend on measurement direction. In many applications, the coupling coefficients are the most important figure of merit of a piezoelectric material.

The coupling coefficients may be related to the ratio of the input mechanical (or electrical) energy and the stored electrical (or mechanical) energy. However, when defined as the energy ratio, the coupling coefficient is well defined only for simple geometries. For more complex shapes, this energy ratio depends on external variables and thus cannot represent a property of the material.

Symmetry Relations and Piezoelectricity

Because the strain and stress are symmetrical tensors, the piezoelectric-coefficient tensor is also symmetrical with respect to the same indices, $d_{ijk} = d_{ikj}$. The number of independent piezoelectric coefficients is thus reduced from 27 to 18. The number of independent elements of d_{ijk} may be further reduced by the symmetry of the material.

By using Neumann and Curie principles, it is possible to predict which materials can exhibit piezoelectric effect. The application of an electric field (which is a vector – a first rank tensor – and thus possesses noncentrosymmetric symmetry) changes dimensions of any insulating material by separating the centers of the negative and positive charges. The stress field (a tensor of fourth rank, with center of symmetry), can polarize a material (separate centers of positive and negative charges) only if there is at least noncentrosymmetric distribution of charges in the material. It is straightforward to see why piezoelectric effect cannot exist in a centrosymmetric material. If stress (which is centrosymmetric) is applied on a centrosymmetric material and the crystal gets polarized, then inversion of the crystal and stress will lead to the same crystal-stress state, but polarization would be reversed. This is possible only if the polarization is zero. Thus, the piezoelectric and other effects described by odd-rank tensors are forbidden by the symmetry in crystals that belong to 11 centrosymmetric groups and in noncentrosymmetric point group 432. Crystals that belong to the remaining 20 noncentrosymmetric groups can exhibit the piezoelectric effect. These 20 point groups are sometimes called piezoelectric point groups. Ten of the piezoelectric point groups possess a unique polar axis and may exhibit, in the absence of an external field, a spontaneous polarization vector, P_s. All ferroelectric crystals, which exhibit the largest piezoelectric coefficients (see the next section), belong to these ten polar point groups. Ferroelectric materials are different from other polar materials in the fact that their spontaneous polarization can change direction under external fields. This feature (see the next section) is essential in obtaining piezoelectric effect in polycrystalline ferroelectric materials. Thus, some piezoelectrics are pyroelectric and some pyroelectrics are ferroelectrics, while all pyroelectrics and ferroelectrics are piezoelectric. For example, SiO_2 is a piezoelectric but nonpolar material. ZnO is a polar, thus pyroelectric and piezoelectric material, but is not ferroelectric (direction of P_s cannot be switched by an external field). $BaTiO_3$ is a piezoelectric, polar (pyroelectric), and ferroelectric material. It should be emphasized that the value of a piezoelectric coefficient can still be zero even if the symmetry of the material allows for its presence.

Crystallographic point groups with discrete symmetry elements are insufficient to describe polycrystalline and noncrystalline materials. Properties of a ceramic with a random orientation of crystallites (or grains) are, for example, identical in all directions and may be described by introducing the symmetry axis of an infinite order, whose symbol is ∞. The point groups that contain infinity symmetry axes are called the limit groups of symmetry or Curie groups. Ceramic materials with a random orientation of grains possess spherical symmetry, $\infty\infty m$, which is centrosymmetric, and cannot exhibit piezoelectric effect even if the symmetry of each grain belongs to one of the piezoelectric or polar point groups. If the ceramic is, however, ferroelectric, the spontaneous polarization direction in each grain may be reoriented by an external electric field. Such poled or polarized ceramic possesses symmetry of a cone, ∞m, and exhibits piezoelectric effect.

Since the piezoelectric effect is a tensor, its properties are dependent on the orientation of the material. A triclinic material belonging to point group 1 exhibits 18 different piezoelectric coefficients, whereas poled ferroelectric ceramics, which can be described by point group *6mm*, possess only three independent piezoelectric coefficients: d_{33}, $d_{31} = d_{32}$, and $d_{24} = d_{15}$.

Microscopic Origin of the Piezoelectricity and Contributions to the Piezoelectric Effect

As the piezoelectric effect is present in a vast number of compounds, ranging from simple compositions

such as quartz to complex solid-state solutions, natural and synthetic organic and biological materials to many heterogeneous materials, it is clear that there are many different microscopic mechanisms that can lead to a piezoelectric response. The first theory of the piezoelectric effect in crystals was proposed by Born in 1933. In his theory of dynamics of crystal lattices, he formulated the piezoelectric effect in terms of displacement of positive and negative charges but the quantitative agreement of the calculated response and experimental values was unsatisfactory, especially for crystals with a mixed covalent–ionic bonding.

Theoretically, there was for some time a disagreement in the literature even about the formal proof that piezoelectricity is a well-defined bulk property. Presently, the most advanced theoretical approach in describing the piezoelectric response of both compositionally simple piezoelectrics and complex perovskite solid solutions, is based on first-principle calculations. In perovskite ferroelectrics, the strain coefficient e_{ij} can be calculated as

$$e_{im} = \frac{1}{2\pi\Omega}\sum_{\alpha} R_{\alpha,i}\frac{\mathrm{d}}{\mathrm{d}x_m}(\Omega G_{\alpha,l}P_l)$$
$$= e_{im,c} + \sum_{k}\frac{ea_i}{\Omega}Z^*_{k,ii}(k)\frac{\mathrm{d}u_i(k)}{\mathrm{d}x_m}$$

where P_l are components of the total polarization calculated as a Berry phase of the wave functions resulting from first-principle calculations, Ω is the cell volume, and $R_{\alpha,j}$ and $G_{\alpha,l}$ are components of three ($\alpha = 1, 2, 3$) real-space and reciprocal lattice vectors, respectively. $e_{im,c}$ is the so-called clamped-ion or homogeneous-strain contribution that corresponds to applied macroscopic strain and zero internal strain (internal coordinates are scaled with cell size and shape). The last term corresponds to change in polarization induced by internal distortions only; it is related to the effective charge tensor Z^* and to the response of the internal atomic coordinates to a macroscopic strain ($\mathrm{d}u_i/\mathrm{d}x_j$). k runs over all atoms of the cell, e is the electronic charge, and a_i are lattice constants along the i-direction. It is the last term in the above expression that is of most interest in identifying the contribution of each atom in the piezoelectric response of a crystal.

Piezoelectric d_{im} coefficients can be calculated from first-principle approaches by considering the free energy $F = U - P_iE_i$. The internal energy U is obtained from first-principle calculations, P_i as a Berry phase, and E_i are components of the external field. The piezoelectric d coefficient can be calculated as a slope of strain versus electric field, where the strain is calculated from the free energy. These first-principle calculations lead not only to a satisfactory agreement between calculated and experimental piezoelectric coefficients, but can, in principle, be used to predict new materials with predefined piezoelectric properties.

From the phenomenological point of view, the piezoelectric effect in ferroelectric materials may be described reasonably well by the Landau–Ginzburg–Devonshire approach. In this framework, the piezoelectricity has its origin in electrostriction biased by the spontaneous polarization. The d coefficient can, for example, be expressed as $d = 2\varepsilon QP_s$ where Q is an electrostrictive coefficient.

Recently, a high piezoelectric or piezoelectric-like response was discovered in materials in which no piezoelectric effect would be expected. Strontium titanate, $SrTiO_3$, is a simple cubic centrosymmetric perovskite at room temperature; however, high piezoelectric response ($d_{31} > 1000\,\mathrm{pm\,V^{-1}}$) was discovered at cryogenic temperatures. The mechanism of the piezoelectric response in $SrTiO_3$ is presently not understood, but its divergence as $T \to 0\,\mathrm{K}$ suggests that it could be associated with a quantum critical point and field-induced phase transition into a piezoelectric and possibly ferroelectric phase at $\mathrm{T} \approx 0\,\mathrm{K}$. A piezoelectric-like response, where strain is reversibly proportional to charge, has been reported in the platinum metal with nanoporosity when submerged in an electrolyte, and an electric potential is applied between the metal and electrolyte. The piezoelectricity is related to the charge-induced strain at the interface (metal/pores) layer, and strain levels comparable to those in the best piezoelectric ceramics have been observed.

Polyvinylidene fluoride (PVDF) is a semicrystalline polymer, consisting of basic CH_2–CF_2 units which form a head-to-tail structure CH_2–CF_2–$(CH_2$–$CF_2)_n$–CH_2–CF_2. The crystalline part consists of a nonpolar phase and a highly polar phase, in which dipoles are due to the distribution of H^- and F^+ ions on opposite sides of the polymer chain. As grown, PVDF is macroscopically nonpolar due to random orientation of polymer chains, but can be rendered polar by the application of mechanical stress and electric field.

In some materials, the piezoelectric effect can be due to several processes. In ferroelectric $AgNa(NO_2)_2$, for example, the piezoelectric effect consists of two contributions: one related to ionic and electronic polarizations of the lattice, and the other to ordering of NO_2 radicals. The contribution of radicals relaxes at relatively low frequencies (30 kHz), so that the piezoelectric response exhibits a strong Debye-like relaxation.

Besides the piezoelectric response arising from the molecular or atomistic mechanisms (sometimes called intrinsic response), there are a number of the so-called

extrinsic contributions to the piezoelectric response whose value can be comparable to that of the intrinsic effect. In ferroelectric materials, for example, the displacement of ferroelectric-ferroelastic domain walls (e.g., 90° domain walls) at weak electric and elastic fields will modify both the polarization and shape of the sample, and thus contribute to the piezoelectric response. Both theoretical estimates and experimental studies show that this contribution of moving domain walls can account for as much as 50–70% of the total piezoelectric response. The movement of domain walls is nonlinear and hysteretic even at relatively weak fields, so that the piezoelectric response in ferroelectric materials often exhibits a charge–pressure and strain–electric field hysteresis (**Figure 3**). The piezoelectric hysteresis and nonlinearity are undesirable in many high-precision applications such as piezoelectric actuators used in scanners.

Besides the nonlinearity, the piezoelectric response in many ferroelectric materials exhibits a frequency dependence and creep. In heterogeneous materials, the dielectric (or elastic) dispersion may couple with elastic (or dielectric) and piezoelectric properties through the piezoelectric effect leading to dispersion of the latter. Interestingly, the charge–pressure or strain–electric field relationship can exhibit clockwise or counterclockwise hysteresis. This is possible because the strain and electric field, and charge density and pressure, are not conjugate work variables, and the corresponding hystereses do not possess energy units.

In complex materials, such as lead zirconate titanate, $Pb(Zr,Ti)O_3$ or PZT, it is possible to design properties to enhance or reduce extrinsic contributions, thus arriving at materials that possess either higher (but less stable) or more stable (but generally lower) properties. The former materials are called soft, and latter hard. Typical soft PZT is obtained by doping the ceramic with donor cations (e.g., replacing part of $(Ti,Zr)^{+4}$ with Nb^{+5}), whereas hard characteristics are obtained by doping the ceramics with acceptor cations (e.g., replacing part of $(Ti,Zr)^{+4}$ with Fe^{+3}). The amounts of dopants necessary to significantly change the properties are small, in the order of 0.5–2%. However, commercial hard and soft compositions differ also in composition, structure, and contain large concentrations of other additives, besides containing acceptor and donor dopants.

Piezoelectric Materials

The piezoelectric effect is widely encountered in nature and many synthetic materials. The best known natural piezoelectric material is quartz, SiO_2, while

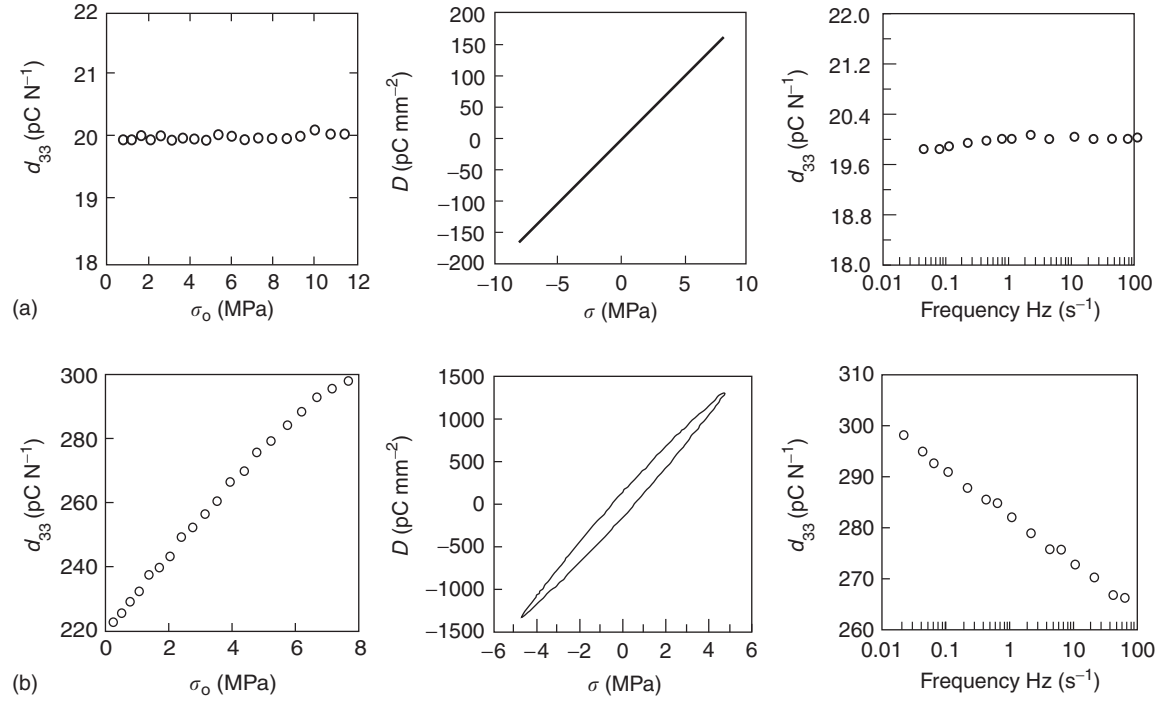

Figure 3 (a) Linear, nonhysteretic, and dispersion-free direct piezoelectric effect in $SrBi_4Ti_4O_{15}$ ceramics. (b) The direct piezoelectric effect in soft $Pb(Zr,Ti)O_3$ ceramics exhibits strong nonlinearity, charge–pressure hysteresis, and frequency-dependent response. σ_o indicates amplitude of the dynamic pressure. The charge–pressure curve is centered numerically whereas the sample is always under compressive stress during the measurements.

among thousands of synthetic materials, the most widely used and best understood are ferroelectric ceramics belonging to solid solutions of lead zirconate and lead titanate, $Pb(Zr,Ti)O_3$ (PZT). Quartz exhibits nearly perfect, unhysteretic, linear and stable, but a weak piezoelectric response. The piezoelectric coefficients of PZT are about two orders of magnitude higher than in quartz (**Table 1**). At present, PZT is not available in single crystal form; it is prepared as ceramics that need to be poled to exhibit the piezoelectric response. The best piezoelectric properties in PZT are observed near 1:1 Zr : Ti ratio. In this region (called morphotropic phase boundary region or MPB), the crystal structure of PZT changes from tetragonal ($PbTiO_3$-rich side) to rhombohedral ($PbZrO_3$-rich side) via an intermediary monoclinic structure (**Figure 4**). The following arguments are used to interpret the origin of exceptionally large piezoelectric properties in the MPB region: (1) because the free energies of the rhombohedral, tetragonal, and monoclinic phases at MPB are close to each other, there is a large number of available directions (6 tetragonal, 8 rhombohedral, 22 monoclinic) along which the polarization vector can reorient during the poling process; thus, a ceramic can be poled more efficiently, (2) at MPB, which represents a composition-induced phase transition region, some piezoelectric coefficients exhibit a maximum, just as in the vicinity of a temperature-induced phase transition, (3) those grains whose polar direction is oriented along an oblique direction with respect to the measuring field will, in general, exhibit a piezoelectric response which combines longitudinal, transverse, and shear effects; this increases the piezoelectric response because shear effects tend to be large at the MPB.

Recently, a new class of piezoelectric crystals was discovered with longitudinal and transverse piezoelectric coefficients reaching, along certain crystallographic directions, values of 1000–2500 $pC\,N^{-1}$ with shear coefficients in the range 4000–5000 $pC\,N^{-1}$, and coupling coefficients as large as 0.95. These crystals are solid solutions of a relaxor ferroelectric, such as $Pb(Zn_{1/2}Nb_{2/3})O_3$ or $Pb(Mg_{1/2}Nb_{2/3})O_3$, and ferroelectric $PbTiO_3$. As in PZT, the properties are maximized in the vicinity of the MPB (**Figure 4**), and along certain crystallographic directions, as shown in **Figure 5**. When a crystal is poled along a nonpolar direction, a special domain structure results, which is referred to as "engineered domain structure." In some

Table 1 Piezoelectric properties of selected materials

Material	*Piezoelectric coefficient* ($pC\,N^{-1}$)	*Coupling coefficient*	*Comment*
Soft PZT	$d_{33} = 600$	$k_{33} = 0.75$	Poled ceramic
Hard PZT	$d_{33} = 200$ $d_{15} = 500$	$k_{33} = 0.67$	Poled ceramic
PMN-PT	$d_{33} = 2500$ $d_{15} = 4900$	$k_{33} = 0.93$	Single crystal; d_{33} long [0 0 1] pseudocubic direction
SiO_2	$d_{11} = 2.3$	$k_{11} = 0.1$	Single crystal
PVDF	$d_{31} = 30$ $d_{33} = -15$	$k_{33} = 0.2$	Poled polymer

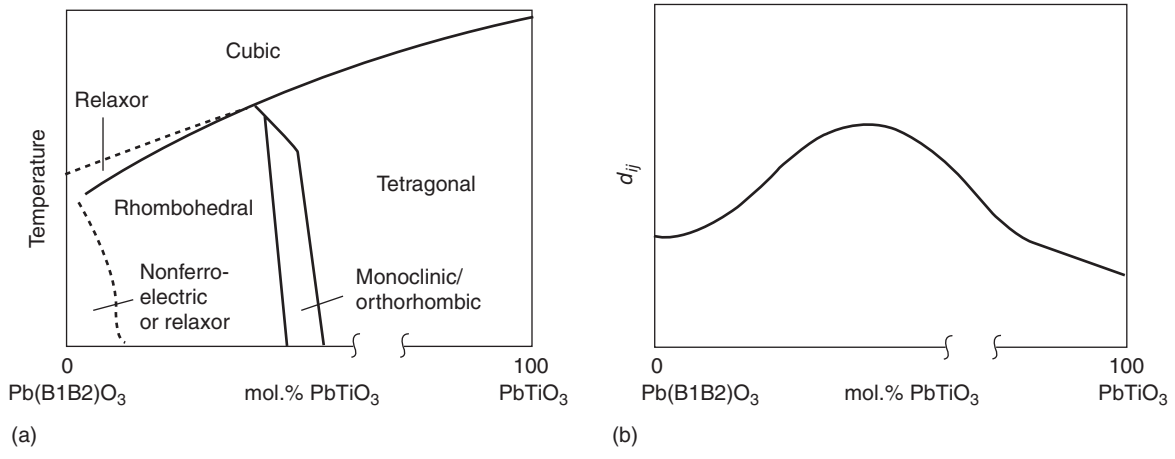

Figure 4 Schematic illustration of (a) temperature-composition phase diagram, and (b) piezoelectric coefficient–composition dependence, as observed in many solid solutions of simple and complex perovskites (e.g., $PbZrO_3$ and $Pb(Mg_{1/2}Nb_{2/3})O_3$) with $PbTiO_3$.

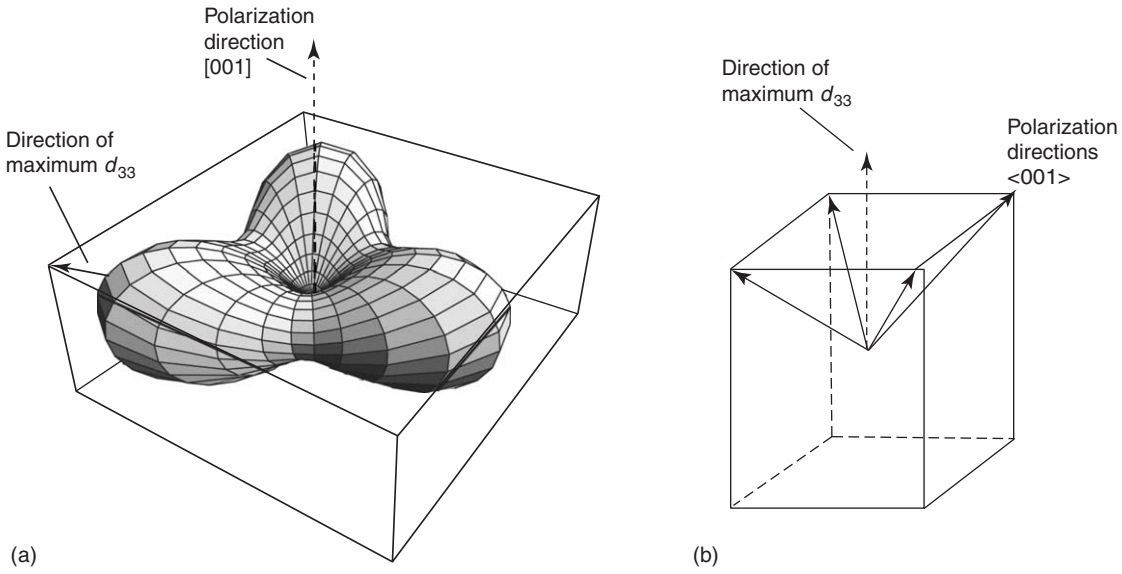

Figure 5 Dependence of the longitudinal d_{33} piezoelectric coefficient on crystal orientation for (a) crystals belonging to point group *3m*, such as rhombohedral PZT, $BaTiO_3$, or $Pb(Zn_{1/2}Nb_{2/3})O_3$-$PbTiO_3$, (b) the four domain states in such a crystal poled along pseudocubic [0 0 1] direction.

cases (e.g., rhombohedral crystals poled along $\langle 0\,0\,1 \rangle$ pseudocubic direction, **Figure 5**), the engineered domain state not only gives a large piezoelectric response but is also stable and hysteresis free.

Polymer–ceramic piezoelectric composites, which have been developed during the 1970s and 1980s, are now routinely used for medical imaging and underwater (SONAR) applications. The polymer phase is nonpiezoelectric while ceramic is a PZT composition. Different connectivities of the two phases are used. The role of the polymer is mainly to reduce the density and thus improve acoustical impedance matching to human body and water, and to reduce transverse piezoelectric effect and thus reduce cross-talk of elements in transducer arrays. The most important synthetic organic piezoelectric is PVDF.

PZT, quartz, and PVDF are the most widely used piezoelectric materials. Other than these materials, $LiNbO_3$ and $LiTaO_3$, tourmaline, modified $PbTiO_3$, lead metaniobate $PbNb_2O_6$, $BaTiO_3$, and materials belonging to the family of bismuth titanate-based aurivillius structures are used for special applications. There are some attempts to partly replace quartz by crystals belonging to the langasite $La_3Ga_5SiO_{14}$ family, and $GaPO_4$, both of which exhibit a higher piezoelectric response than quartz, temperature-stable properties and operating temperatures significantly higher than quartz. Recent developments in the area of piezoelectric thin films have raised interest in PZT and AlN films. Presently, there are attempts to develop lead-free piezoelectric materials (e.g., $KNbO_3$, $Na_{0.5}Bi_{0.5}TiO_3$ based compositions) with properties comparable to those of PZT. The *ab initio* theories appear to be a promising approach in predicting new materials with high piezoelectric properties.

Many organic, synthetic and natural, and biological materials are piezoelectric, including nylon, wood, hair, bones, and eye tissue. The piezoelectric effect in bovine eyes is several times higher than in quartz. The origin of piezoelectricity in animal and human tissue can be traced to collagen. However, presently, it is not clear whether the piezoelectric effect in living tissue has any physiological role.

Applications of Piezoelectric Materials

Piezoelectric applications can be divided into three general categories: sensors, actuators, and high-frequency transducers. The piezoelectric sensors are based on the direct effect and are used to measure and detect force, acceleration, and vibration by transforming them into electric (charge or voltage) signals. A typical PZT ceramic with d_{33} of 300 $pC\,N^{-1}$ will generate 3 nC when pressed with 10 N, an easily measured quantity. If short circuited, a cube of PZT with side 1 cm and with relative dielectric constant of 1000 will give voltage of $\sim$30 V when pressed with 10 N. The piezoelectric sensors are thus very sensitive. They are not effective at constant or very slowly varying forces, since all materials possess some conductivity and piezoelectric charge will eventually leak leading to drift and loss of the signal.

The actuators are based on the converse piezoelectric effect and are used to generate force and small displacement. The same PZT cube as above will change its size by only 0.3 nm when subjected to

100 V. This is excellent for small displacement control, for example, in atomic force and electron microscope scanners, but different schemes have to be worked out to amplify displacements of piezoelectrics for applications where μm range movement or higher is required (e.g., actuators for fuel injection).

Piezoelectric materials can be forced into mechanical resonance if driven by an electric field with the same frequency as the natural mechanical resonance frequency of the piezoelectric sample. A case which can be considered is that of a thin bar made of ferroelectric ceramics and poled along thickness direction, such that length ≫ thickness, width > thickness (**Figure 6a**). This reduces the problem to a one-dimensional case. An electric field is applied along the thickness (X_3 direction). At low frequencies of the driving field, the piezoelectric strain inside the sample can be considered to be homogeneous. However, as the wavelength of an electrically generated acoustical wave becomes comparable to the dimensions of the sample, strain becomes nonuniform. The Newton equation for a longitudinal wave propagating along X_1 direction is given by $\rho(\partial^2\delta_1/\partial t^2)\,\mathrm{d}V = F$, where δ_1 is the displacement of an elemental volume dV, and $F = (\partial\sigma_1/\partial X_1)\,\mathrm{d}V$ is the force. However, due to piezoelectric coupling, the stress depends on the electric field. The Newton equation then becomes modified by the piezoelectric constitutive eqn [1] resulting in the wave equation:

$$\begin{aligned}\partial^2\delta_1/\partial t^2 &= (1/s_{11}^E\rho)(\partial^2\delta_1/\partial X_1^2)\\ &= (v^E)^2\partial^2\delta_1/\partial X_1^2\end{aligned} \qquad [3]$$

which is obtained considering that $\partial E_3/\partial X_1 = 0$ and $x_1 = \partial\delta_1/\partial X_1$, where v^E is the velocity of the longitudinal elastic waves in the bar. For simple harmonic motion, $\delta_1 = \delta_0 e^{i\omega t}$. Taking into account the boundary

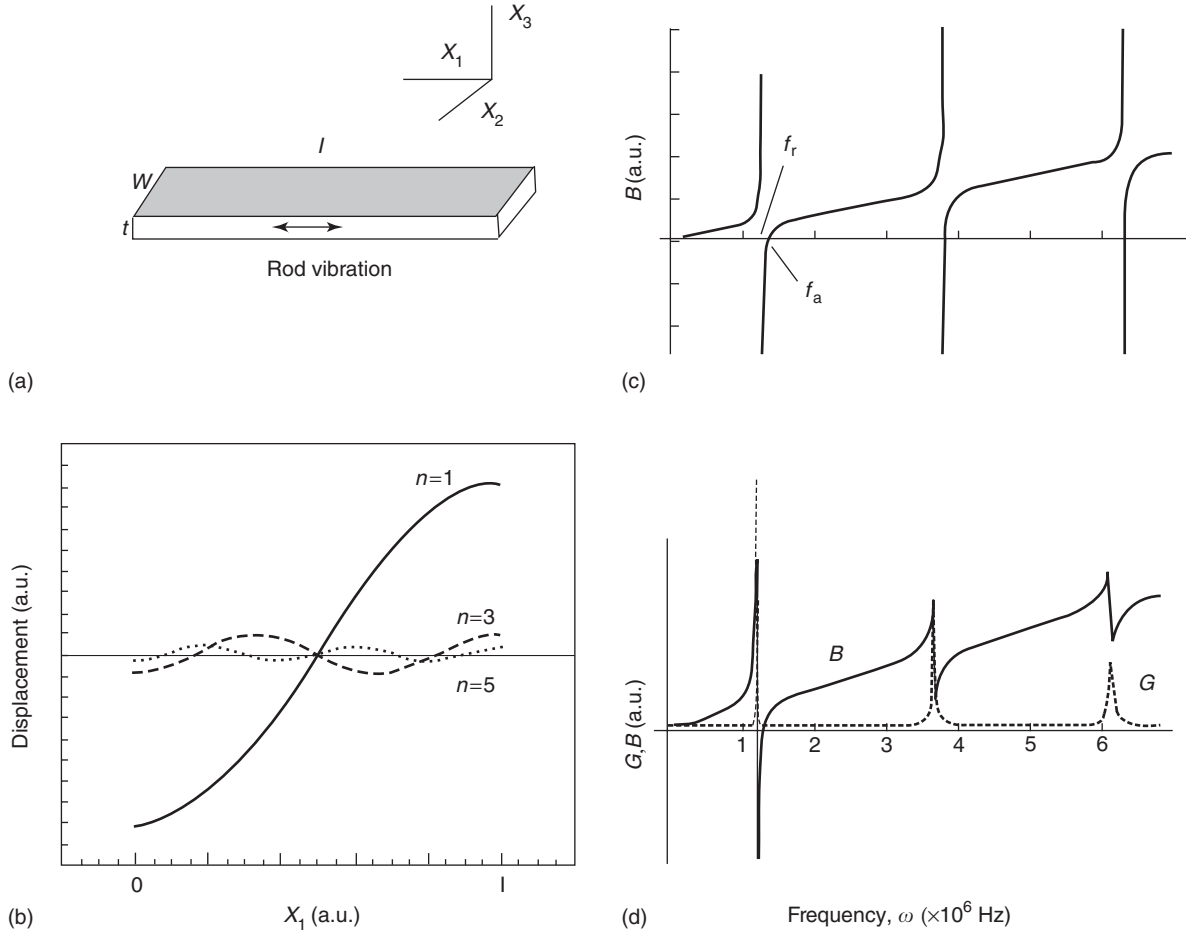

Figure 6 (a) Piezoelectric bar resonator made of a ferroelectric ceramic and poled along thickness. The shaded area indicates the electrode. Another electrode is placed on the bottom surface of the sample and the electric field is applied on these electrodes. (b) Mechanical longitudinal displacement as a function of position for the bar in transverse resonant mode (controlled by d_{31}). Admittance (Y) as a function of frequency for (c) lossless ($Y = iB$) and (d) lossy resonator ($Y = G + iB$). Resonant (f_r) and antiresonant (f_a) frequencies are marked in (c).

condition $\sigma_1 = 0$ at $X_1 = 0, l$ and eqn [1], expression [3] can be solved for δ_1 (**Figure 6b**). On the other hand, the electrical admittance Y of the vibrating bar is obtained from the ratio of the current I and voltage V across the vibrating bar $Y = I/V = w \int(\partial D_3/\partial t)\, \mathrm{d}X_1 / \int E_3\, \mathrm{d}X_3$, and can be calculated explicitly as a function of materials coefficients d, s, and ε using relations [1]–[3].

$$Y = \mathrm{i}\frac{\omega w l}{t}\left(\varepsilon_{33}^{\sigma} - \frac{d_{31}^2}{s_{11}^E}\right) + \mathrm{i}\frac{2wd_{31}^2}{(\sqrt{\rho s_{11}^E})s_{11}^E t}\tan\frac{\omega l(\sqrt{\rho s_{11}^E})}{2} \qquad [4]$$

Resonance (admittance becomes infinite) occurs when $\omega = n\pi/(l\sqrt{\rho s_{11}^E})$, where $n = 1, 3, 5, \ldots$. This is the same frequency at which mechanical resonance of an unloaded frictionless bar occurs. Resonances for $n > 1$ are called overtones.

In the presence of losses, purely imaginary admittance $Y = \mathrm{i}B$, where B is called susceptance and is shown in **Figure 6c**, will exhibit a real part, G, called conductance, $Y = G + \mathrm{i}B$, **Figure 6d**. Using characteristic resonant frequencies, the material coefficients can be calculated. For example, at resonance, f_r, admittance $Y \to \infty$, so that $\tan\lfloor \omega l(\sqrt{\rho s_{11}^E})/2 \rfloor \to \infty$ and $f_\mathrm{r} = 1/(2l\sqrt{\rho s_{11}^E})$, which can be used to calculate the elastic constant. At antiresonance, f_a, admittance $Y = 0$ and therefore

$$\tan[(\pi/2)(f_\mathrm{a}/f_\mathrm{r})]/[(\pi/2)(f_\mathrm{a}/f_\mathrm{r})] = (k_{31}^2 - 1)/k_{31}^2$$

which permits calculation of k_{31} and thus $d_{31} = k_{31}\sqrt{s_{11}^E \varepsilon_{33}^{\sigma}}$. The permittivity can be measured separately at subresonant frequencies. Values of the characteristic frequencies are modified in the case of lossy resonators.

High-frequency and resonant properties of piezoelectric materials have been widely used in many high-frequency applications, including ultrasonic medical and nondestructive imaging, frequency control (time measurements), filters, for chemical, biological and thickness monitoring, and in piezoelectric transformers.

Introduction

Consider a metal whose conduction electrons move freely. In equilibrium, the negative electronic charge is balanced by the positive charge of the ionized metal atoms. If this balance is somehow disturbed by perturbing the electron density, increasing it within some region $\mathscr{R}$ which becomes thus negatively charged, the electrons would be subsequently driven away from that region by their mutual repulsion. Equilibrium is however not restored immediately, as the electrons have inertia and would keep on moving away from $\mathscr{R}$ even after the system becomes neutral. Thus, after some time interval, $\mathscr{R}$ would become positively charged. The electrons would then be attracted to this positive charge, arresting their outward motion and inducing an inward motion. By overshooting the equilibrium situation again, $\mathscr{R}$ would become negative again and the whole cycle would repeat itself until the energy associated with the perturbation is lost through Joule heating or some other dissipative process. Thus, an oscillation of the charge carrier density may be established within conductors. Due to the analogy between the electronic dynamics within a metal and the motion of charged ions within a plasma, the charge oscillations described above are known as plasma oscillations, and they have a characteristic frequency ω_p which depends on the mass, density, and charge of the carriers, known as the plasma frequency. Typically, this frequency is much higher than the thermal frequency $k_B T/\hbar$, where k_B is Boltzmann's constant, T is the temperature, and $\hbar$ is Planck's constant, so that the quantization of the plasma oscillations has to be taken into account when describing the electronic dynamics of solids. A quantized plasma oscillation of a conductor, with a typical energy $E_p = \hbar\omega_p$, is known as a "plasmon."

Simple Models

To estimate the plasma frequency, consider the most simple model of a conductor: that of a gas of electrons of number density n_0 moving freely in a homogeneous positively charged background and interacting with the self-consistent field $\boldsymbol{E}$. If somehow, a charge accumulation Q localized in a given region $\mathscr{R}$ is produced due to a compression or a rarefaction of the electron gas (**Figure 1**), it produces a Coulomb field $E(\boldsymbol{r}) = Q\boldsymbol{r}/r^3$ far away, where the vector $\boldsymbol{r}$ goes from $\mathscr{R}$ toward the observation position. Each electron becomes accelerated according to Newton's second law, $m\mathrm{d}^2\boldsymbol{r}/\mathrm{d}t^2 = -e\boldsymbol{E}(\boldsymbol{r},t)$, where m and $-e$ are the electronic mass and charge, respectively, so that $\partial\boldsymbol{j}(\boldsymbol{r},t)/\partial t = (n_0e^2/m)\boldsymbol{E}(\boldsymbol{r},t)$, where $\boldsymbol{j} = -n_0e\mathrm{d}\boldsymbol{r}/\mathrm{d}t$ is the electric current density at $\boldsymbol{r}$. Integrating over a large closed surface Σ that surrounds the charge completely, one obtains $(\mathrm{d}/\mathrm{d}t)\int_\Sigma \mathrm{d}\boldsymbol{a}\cdot\boldsymbol{j} = (ne^2/m)\int_\Sigma \mathrm{d}\boldsymbol{a}\cdot\boldsymbol{E}$, which becomes a simple differential equation for the charge

$$\frac{\mathrm{d}^2Q}{\mathrm{d}t^2} = -\frac{4\pi ne^2}{m}Q \qquad [1]$$

by introducing the continuity equation $\int_\Sigma \mathrm{d}\boldsymbol{a}\cdot\boldsymbol{j} = -\mathrm{d}Q/\mathrm{d}t$ and Gauss' law $\int_\Sigma \mathrm{d}\boldsymbol{a}\cdot\boldsymbol{E} = 4\pi Q$. Its solution $Q(t) = Q(0)\mathrm{e}^{-\mathrm{i}\omega_p t}$ oscillates with the bulk plasma frequency

$$\omega_p = \left(\frac{4\pi ne^2}{m}\right)^{1/2} \qquad [2]$$

Typical values for the energy of a quantized plasma wave or plasmon are $E_p = \hbar\omega_p \sim 5$–$15$ eV.

If the charge were located at the surface of a semi-infinite conductor, half of the field lines would be in vacuum and would induce no electric current

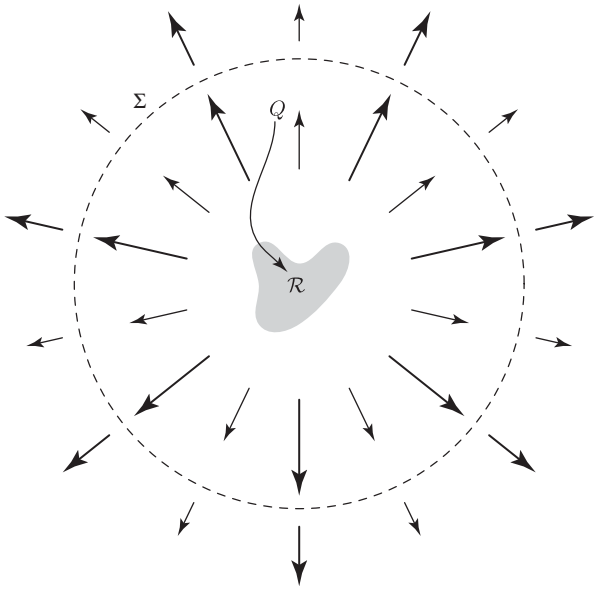

Figure 1 Charged region $\mathscr{R}$ (gray) in a homogeneous conductor. The charge Q contained within the Gaussian surface Σ (dashed circle) produces a field $\boldsymbol{E}(\boldsymbol{r},t)$ (wide arrows) which induces a current density $\boldsymbol{j}(\boldsymbol{r},t)$ (thin arrows) which flows across Σ, modifying Q over time t and yielding a plasma oscillation.

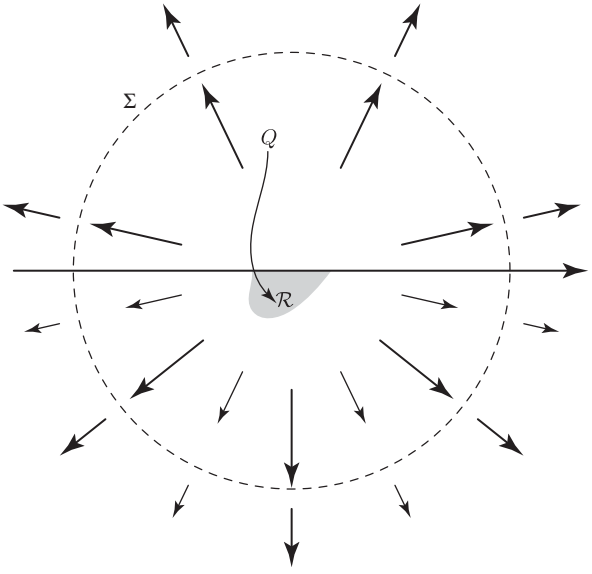

Figure 2 Charged region $\mathscr{R}$ at the surface of a semi-infinite conductor. The field $\boldsymbol{E}(\boldsymbol{r}, t)$ (wide arrows) is as in **Figure 1** but the current density $\boldsymbol{j}(\boldsymbol{r}, t)$ (narrow arrows) is only induced in the half space within the conductor. Thus, there is charge flow only across half the Gaussian surface Σ (dashed circle).

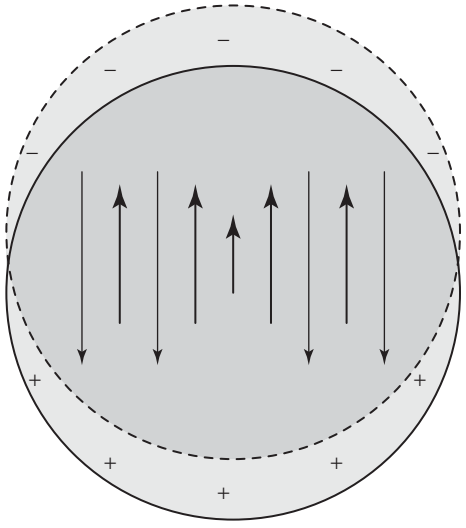

Figure 3 Metallic sphere (solid circle) all of whose electrons are displaced the same distance ζ (short arrow), occupying a displaced region (dashed circle), producing negative (top) and positive (bottom) surface charges (light gray). The interior (dark) remains neutral. The polarization (narrow arrows) and electric field (wide arrows) within the sphere are shown schematically.

(**Figure 2**), the current flow across the surface Σ would then be cut in half, and the charge would obey

$$\frac{\mathrm{d}^2 Q}{\mathrm{d}t^2} = -\frac{\omega_\mathrm{p}^2}{2} Q \qquad [3]$$

instead of eqn [1]. The solution $Q(t) = Q(0)\mathrm{e}^{-\mathrm{i}\omega_\mathrm{s} t}$ is an oscillation with the surface plasma frequency

$$\omega_\mathrm{s} = \frac{\omega_\mathrm{p}}{\sqrt{2}} \qquad [4]$$

As a last simple example, consider a small spherical metallic particle which is initially perturbed by displacing all of its electrons by a distance $\boldsymbol{\zeta}$ (**Figure 3**). Thus, by a distance there would be an accumulation of electrons on one hemisphere and a deficiency of electrons on the other hemisphere. The ensuing surface charge $\sigma = \boldsymbol{P} \cdot \hat{\boldsymbol{n}}$ produces a homogeneous electric depolarization field $\boldsymbol{E} = -(4\pi/3)\boldsymbol{P}$, where $\boldsymbol{P} = -n_0 e\boldsymbol{\zeta}$ is the electric polarization. This field accelerates the charges, according to $m\mathrm{d}^2\boldsymbol{\zeta}/\mathrm{d}t^2 = -e\boldsymbol{E}$, which becomes

$$\frac{\mathrm{d}^2}{\mathrm{d}t^2}\boldsymbol{\zeta} = -\frac{\omega_\mathrm{p}^2}{3}\boldsymbol{\zeta} \qquad [5]$$

upon substitution. Its solution $\boldsymbol{\zeta}(t) = \boldsymbol{\zeta}(0)\mathrm{e}^{-\mathrm{i}\omega_\mathrm{d} t}$ oscillates with the dipolar surface plasma frequency

$$\omega_\mathrm{d} = \frac{\omega_\mathrm{p}}{\sqrt{3}} \qquad [6]$$

These examples show that different systems may have plasmons, that is, collective excitations that involve fluctuations in the charge density, with different frequencies which depend not only on the properties of the material but also on geometrical properties such as size and shape.

Dispersion Relations

The previous section discussed a few simple models that predict charge oscillations of frequencies ω_p, ω_s, and ω_d at infinite, semi-infinite, and small conductors. In this section, these quantities will be calculated in a more general context, and expressions which are independent of the particular model made for the system will be obtained.

Bulk Plasmons

According to Gauss law,

$$\nabla \cdot \boldsymbol{D} = 0 \qquad [7]$$

in the absence of external charge, where $\boldsymbol{D} = \boldsymbol{E} + 4\pi\boldsymbol{P}$ is the displacement field and $\boldsymbol{P}$ the polarization. Within a linear homogeneous isotropic material, the displacement may be written in terms of the electric field,

$$\boldsymbol{D} = \varepsilon\boldsymbol{E} \qquad [8]$$

where the dielectric function ε is a property of the material. Thus, Gauss law implies that $\varepsilon\nabla \cdot \boldsymbol{E} = 0$. The trivial solution $\nabla \cdot \boldsymbol{E} = 4\pi\rho = 0$ corresponds to the null charge density ρ within a homogeneous system and a transverse electric field. However, there is

a second frequently overlooked possibility, namely, that $\nabla \cdot \boldsymbol{E} = 4\pi\rho \neq 0$ but $\varepsilon = 0$. Thus, the electric field may have a longitudinal contribution, and charge fluctuations may appear within a solid, but only if the dielectric function is null.

Matter responds differently to electromagnetic fields of different frequencies or colors, as demonstrated by Newton's prism experiments. Consequently, the dielectric function depends on the frequency, that is, $\varepsilon \rightarrow \varepsilon_\omega$. According to the discussion above, charge oscillations may exist but only for those frequencies for which

$$\varepsilon_\omega = 0 \qquad [9]$$

This result may be applied to the Drude model, in which electrons are assumed to respond freely and independently to a perturbing electric field. One would expect that independent electrons would be unable to support collective oscillations. However, the electron–electron interaction is partially incorporated into the Drude model by identifying the perturbing field with the self-consistent electric field $\boldsymbol{E}$, which includes the mean value of the field produced by the electrons themselves, and not as an external field. The Drude dielectric function is

$$\varepsilon^{\mathrm{D}}_\omega = 1 - \frac{\omega_{\mathrm{p}}^2}{\omega^2} \qquad [10]$$

and leads to plasma oscillations at its zero

$$\omega^{\mathrm{D}} = \omega_{\mathrm{p}} \qquad [11]$$

Dissipation may be incorporated by changing $\omega^2 \rightarrow \omega^2 + \mathrm{i}\omega/\tau$ in eqn [10] where τ is the mean time between electronic collisions.

Plasmon excitations within a solid are possible only due to the temporal dispersion of the dielectric function, as the dielectric constant may only vanish at some finite frequencies but never in the static limit. The meaning of dispersion may be understood if the frequency dependence is introduced explicitly into eqn [8] (i.e., $\boldsymbol{D}_\omega = \varepsilon_\omega \boldsymbol{E}_\omega$), which is then Fourier transformed using the convolution theorem, becoming

$$\boldsymbol{D}(t) = \int \mathrm{d}t' \varepsilon(t - t')\boldsymbol{E}(t') \qquad [12]$$

The Fourier transform of ε_ω yields the delay-dependent dielectric function $\varepsilon(t - t')$, which is a measure of the response $\boldsymbol{D}(t)$ of the system at time t to a perturbing field $\boldsymbol{E}(t')$ which acts at a time t'. Causality demands $\varepsilon(t - t') = 0$ whenever $t' > t$. Just as the response of the system at a given time depends on the excitation at previous times, it is also the case that the response of the system at a given position $\boldsymbol{r}$ depends on the excitation at nearby positions $\boldsymbol{r}'$, and not only at $\boldsymbol{r}$. Thus, eqn [12] should be generalized to become

$$\boldsymbol{D}(\boldsymbol{r}, t) = \int \mathrm{d}t' \int \mathrm{d}^3 r' \varepsilon(\boldsymbol{r}, \boldsymbol{r}', t - t')\boldsymbol{E}(\boldsymbol{r}', t') \qquad [13]$$

The dependence of ε on $\boldsymbol{r}$ and $\boldsymbol{r}'$ is known as spatial dispersion or nonlocality. Within a homogeneous system, ε depends only on the interval $\boldsymbol{r} - \boldsymbol{r}'$ between the excitation and the observation point, so that the RHS of eqn [13] becomes a convolution. A space and time Fourier transform then yields a simple algebraic relation

$$\boldsymbol{D}_{q\omega} = \varepsilon_{q\omega}\boldsymbol{E}_{q\omega} \qquad [14]$$

in which nonlocality is equivalent to a dependence of the dielectric response $\varepsilon_{q\omega}$ on the wave vector $\boldsymbol{q}$ besides the frequency ω. Within nonlocal media, $\boldsymbol{q}$ defines a preferred direction even within isotropic media. Therefore, the nonlocal response of the system to a transverse field $\boldsymbol{E}^{\mathrm{T}}_{q\omega} \perp \boldsymbol{q}$ and to a longitudinal field $\boldsymbol{E}^{\mathrm{L}}_{q\omega} \parallel \boldsymbol{q}$ might differ; hence,

$$\boldsymbol{D}^{\mathrm{T}}_{q\omega} = \varepsilon^{\mathrm{T}}_{q\omega}\boldsymbol{E}^{\mathrm{T}}_{q\omega} \qquad [15]$$

$$\boldsymbol{D}^{\mathrm{L}}_{q\omega} = \varepsilon^{\mathrm{L}}_{q\omega}\boldsymbol{E}^{\mathrm{L}}_{q\omega} \qquad [16]$$

instead of the single eqn [14].

Identifying $\nabla \rightarrow \mathrm{i}\boldsymbol{q}$ in Fourier space, the dispersion relation $\omega = \omega_q$ versus $\boldsymbol{q}$ of bulk plasmons is deduced from eqn [7] and is expressed implicitly by

$$\varepsilon^{\mathrm{L}}_{q\omega} = 0 \qquad [17]$$

that is, for a given wave vector $\boldsymbol{q}$, longitudinal waves may propagate provided their frequency ω_q is such that the longitudinal dielectric function vanishes.

Notice that plasmons do not propagate within local media as their group velocity $\boldsymbol{v}_{\mathrm{g}} = \nabla_q \omega_q$ vanishes, but in a spatially dispersive medium, the frequency of the plasmon does depend on the wave vector and plasmons may propagate and transport energy. A simple model that illustrates plasmon propagation is the hydrodynamic model, a generalization of the Drude model, in which the conduction electrons feel the forces due to variations of the pressure beyond their interaction with the self-consistent field. The pressure is mainly due to the Pauli principle which allows only one fermion to occupy each electronic state. To increase the density of an electronic fluid, higher energy levels have to be occupied and this requires work. The hydrodynamic longitudinal dielectric function is

$$\varepsilon^{\mathrm{H}}_{q\omega} = 1 - \frac{\omega_{\mathrm{p}}^2}{\omega^2 - \beta^2 q^2} \qquad [18]$$

where β is a measure of the compressibility of a Fermion gas of density n_0. A calculation of β assuming local equilibrium of the electron gas yields

$\beta = \sqrt{1/3}v_F$, where $v_F = \hbar k_F/m$ is the Fermi velocity, $\hbar k_F = \sqrt{2mE_F}$ is the Fermi momentum, and E_F is the Fermi energy, that is, the kinetic energy of the highest occupied state. More elaborate calculations are consistent with a frequency-dependent β with the value $\beta = \sqrt{3/5}v_F$ at typical plasmon frequencies. The dispersion relation [17] of bulk plasmons becomes

$$\omega = (\omega_p^2 + \beta^2 q^2)^{1/2} \qquad [19]$$

which is illustrated schematically in **Figure 4**.

Notice that eqn [19] may also be solved for q, given the value of ω. For $\omega < \omega_p$ the solution is imaginary, meaning that charge fluctuations may exist for frequencies below ω_p, but they do not propagate. Rather, they decay exponentially within a distance $\lambda_s = 1/|q|$. In the static limit, one obtains $\lambda_s = \lambda_{TF}$ from eqn [19], where $\lambda_{TF} = \beta/\omega_p$ is the Thomas–Fermi screening length.

One of the main drawbacks of the hydrodynamic model is that it ignores the single-particle excitations. For a free-, independent-electron conductor, these consist of electrons which are taken from occupied states with momentum $\hbar\boldsymbol{k}$ within the Fermi sphere (i.e., $\hbar k < \hbar k_F$) and excited into empty states with momentum $\hbar(\boldsymbol{k} + \boldsymbol{q})$ outside of the Fermi sphere, leaving a hole in the initial state. The momentum of these electron–hole (e–h) pairs is $\hbar\boldsymbol{q}$ and its energy $\hbar^2[(\boldsymbol{k} + \boldsymbol{q})^2 - k^2]/2m$ may take a quasicontinuum of values bounded by $\hbar^2(q^2 \pm 2qk_F)/2m$. Plasmons with wave vector q and energy $\hbar\omega$ within these bounds, displayed in **Figure 4** by dashed lines, are short-lived as they may decay through the excitation of e–h pairs, a mechanism known as Landau damping. Thus, plasmons may exist as well-defined collective excitations only within a short range of wave vectors and frequencies.

An alternative formulation for the calculation of the plasmon dispersion may be obtained from the inhomogeneous Gauss' law, which may be written in Fourier space with the help of eqn [16] as

$$\rho_{q\omega} = \frac{\rho^{ext}_{q\omega}}{\varepsilon^{L}_{q\omega}} \qquad [20]$$

where $\rho^{ext} = i\boldsymbol{q} \cdot \boldsymbol{D}_{q\omega}/4\pi$ is the external, and $\rho = i\boldsymbol{q} \cdot \boldsymbol{E}_{q\omega}/4\pi$ the total charge density within the conductor. Thus, the inverse dielectric function $1/\varepsilon^{L}_{q\omega}$ may be interpreted as a charge–charge response function. A finite response may be obtained from an infinitesimal excitation, that is, the system may oscillate spontaneously, only when the response function has a pole. Thus, the plasmon dispersion relation is given by the pole of $1/\varepsilon^{L}_{q\omega}$, which, naturally, coincides with eqn [17].

Surface Plasmons

As suggested by the remarks above, the normal modes of an arbitrary system may be obtained by searching for the poles of its response functions. Consider an electromagnetic wave of amplitude E^i impinging on the surface of an isotropic semi-infinite conductor (**Figure 5**). The wave sets in motion the charges within the conductor which radiates a reflected wave of amplitude E^r. For s (transverse electric) and p (transverse magnetic) incident polarizations, the reflected wave has the same polarization, so one may define scalar reflection amplitudes $r_s = E^r_s/E^i_s$ and $r_p = E^r_p/E^i_p$, given by Fresnel's formulas:

$$r_s = \frac{q_\perp - k_\perp}{q_\perp + k_\perp} \qquad [21]$$

$$r_p = \frac{\varepsilon_\omega q_\perp - k_\perp}{\varepsilon_\omega q_\perp + k_\perp} \qquad [22]$$

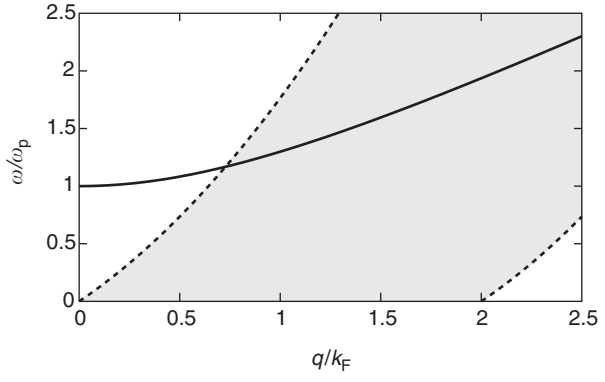

Figure 4 Dispersion relation for bulk plasmons calculated for Na within the hydrodynamic model (solid). The shadowed area between dashed lines corresponds to the region where plasmons might decay due to excitation of electron–hole pairs.

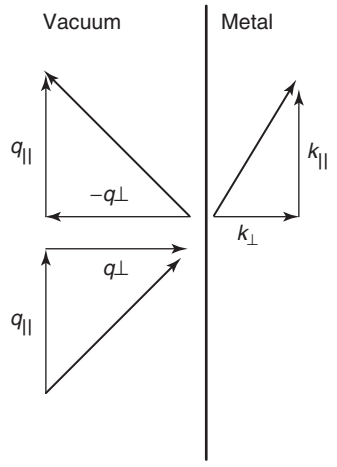

Figure 5 Electromagnetic wave incident on the surface of a semi-infinite system. The wave vectors of the incident, reflected, and transmitted waves, and their perpendicular and parallel components are shown.

where $\boldsymbol{q} = (\boldsymbol{q}_\parallel, q_\perp)$ is the wave vector of the incident wave in vacuum, and $\boldsymbol{k} = (\boldsymbol{k}_\parallel, k_\perp)$ is the wave vector of the transmitted wave into the metal. Snell's law requires that $\boldsymbol{k}_\parallel = \boldsymbol{q}_\parallel$ and the electromagnetic wave equations in vacuum and within the metal require

$$q_\perp = \left[\left(\frac{\omega}{c}\right)^2 - q_\parallel^2\right]^{1/2} \qquad [23]$$

and

$$k_\perp = \left[\varepsilon_\omega\left(\frac{\omega}{c}\right)^2 - q_\parallel^2\right]^{1/2} \qquad [24]$$

The reflection amplitudes [21] and [22] have the nature of surface response functions and therefore, their poles yield the surface normal modes of the system. One may note first that conservation of energy apparently implies that the reflectances $R_s = |r_s|^2$ and $R_p = |r_p|^2$ ought to be smaller than unity, as it is not possible to reflect more energy than is incident upon the surface. Thus, it would seem that r_s and r_p can have no pole. However, if $q_\parallel > \omega/c$, that is, outside of the light cone, eqn [23] yields an imaginary value for $q_\perp$. In this case, the incident and reflected waves do not propagate but are rather evanescent waves, each of which carries no energy along the normal to the surface. Only in this situation can the reflection amplitudes display poles. As both the reflected and transmitted waves should decay away from the surface, the signs of Im $q_\perp$ and Im $k_\perp$ should be equal to each other. Equations [21] and [22] imply that there is no *s*-polarized mode and that a *p*-polarized mode is only possible if $\varepsilon_\omega < 0$. Substituting eqns [23] and [24] into the normal mode condition $\varepsilon_\omega q_\perp + k_\perp = 0$, one obtains the surface plasmon dispersion relation

$$q_\parallel = \frac{\omega}{c}\left(\frac{\varepsilon_\omega}{\varepsilon_\omega + 1}\right)^{1/2} \qquad [25]$$

Figure 6 shows the dispersion relation of surface plasmons (SP) calculated from eqn [25] with a Drude dielectric function. The dispersion relation lies outside of the light cone. For large $q_\parallel$, ω approaches asymptotically a constant frequency given by ω_s (eqn [4]), while for small $q_\parallel$ it approaches the light cone.

For very large wave vectors $q_\parallel \gg \omega/c$, the phase velocity of the SP, $v = \omega/q_\parallel$, becomes much smaller than the speed of light c, so that the retardation of the electromagnetic field may be ignored. It is common to set $c = \infty$ in this nonretarded region and treat the problem as quasistatic, that is, solving the equations of electrostatics. In this limit, $q_\perp \approx k_\perp \approx iq_\parallel$, and therefore the reflection amplitude [22] becomes

$$r_p \approx -g = \frac{\varepsilon_\omega - 1}{\varepsilon_\omega + 1} \qquad [26]$$

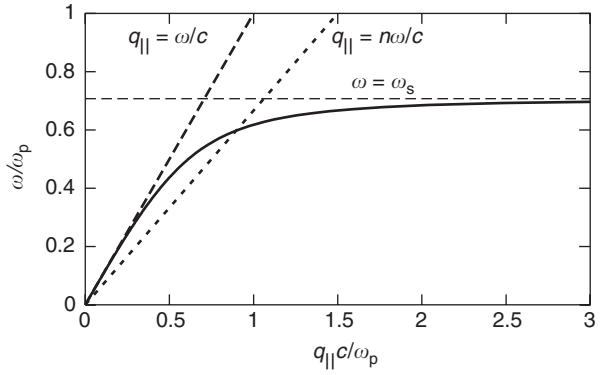

Figure 6 SP dispersion relation calculated within the Drude model (solid). The asymptotic frequency $\omega_s = \omega_p/\sqrt{2}$, the vacuum light cone $q_\parallel = \omega/c$, and the light cone of glass ($n = 1.5$) are indicated by dashed lines.

The nonretarded surface response function g is the quotient between the external and the induced scalar potentials, and its expression [26] may be recognized as the image charge induced within a conductor by the presence of a unit point charge within vacuum. The pole of g,

$$\varepsilon_\omega = -1 \qquad [27]$$

yields the nonretarded SP frequency. This equation generalizes the previous nonretarded result [4] to arbitrary materials.

More refined microscopic theories of metallic surfaces should account for the thin but finite transition region or selvedge where the properties change smoothly from those of the bulk metal to those of vacuum, and for the spatial dispersion of the metal. Their effect may be characterized within the semi-infinite jellium model by the distance from the nominal surface of the metal to the centroid of the induced charge density,

$$d_\perp \equiv \frac{\int \mathrm{d}z z\rho(z)}{\int \mathrm{d}z \rho(z)} \qquad [28]$$

The response function g depends on $\boldsymbol{q}_\parallel$ and ω and may be written as

$$g_{q_\parallel \omega} \approx \frac{1 - \varepsilon_\omega + (1 - \varepsilon_\omega) q_\parallel d_\perp}{1 + \varepsilon_\omega + (1 - \varepsilon_\omega) q_\parallel d_\perp} \qquad [29]$$

with poles at

$$\varepsilon_\omega + 1 = (\varepsilon_\omega - 1) q_\parallel d_\perp \qquad [30]$$

Using the Drude model for the local limit ε_ω of the bulk dielectric function, one obtains

$$\omega = \omega_s \sqrt{1 - q_\parallel d_\perp} \approx \omega_s - \omega_s q_\parallel d_\perp / 2 \qquad [31]$$

Thus, instead of reaching an asymptotic value ω_s, which is actually a bulk property determined by ε_ω,

the nonretarded SP has a dispersion determined by $d_\perp$, a quantity that is very sensitive to the surface condition. The sign of the dispersion is positive or negative corresponding to whether the induced surface charge lies inside ($d_\perp < 0$) or outside ($d_\perp > 0$) of the metal. The latter is the case for simple metals.

Thin Films

The reflection amplitude of a thin film may be calculated from that of each of its surfaces by summing the amplitudes of the multiply reflected waves. Thus, for the thin film of **Figure 7**

$$r = r_{12} + t_{12}r_{23}t_{21}e^{2ik_\perp d}\sum_{n=0}^{\infty}(r_{21}r_{23}e^{2ik_\perp d})^n \quad [32]$$

$$= r_{12} + \frac{t_{12}r_{23}t_{21}e^{2ik_\perp d}}{1 - r_{21}r_{23}e^{2ik_\perp d}} \quad [33]$$

where each successive term in the geometric series corresponds to an additional trip from the 1–2 interface toward the 2–3 interface and back, $k_\perp$ is the normal wave vector within the film, and r_{ab} and t_{ab} denote the reflection and transmission amplitudes of the surface ab for a wave moving from medium a toward b. The dispersion relation of the thin film SP is then given implicitly by the poles of r:

$$r_{21}r_{23}e^{2ik_\perp d} = 1 \quad [34]$$

For an unsupported film $r_{21} = r_{23} = -r_{12}$, and in the unretarded regime, using eqn [26] for r_{21},

$$\left(\frac{\varepsilon_\omega - 1}{\varepsilon_\omega + 1}\right)^2 = e^{2q_\parallel d} \quad [35]$$

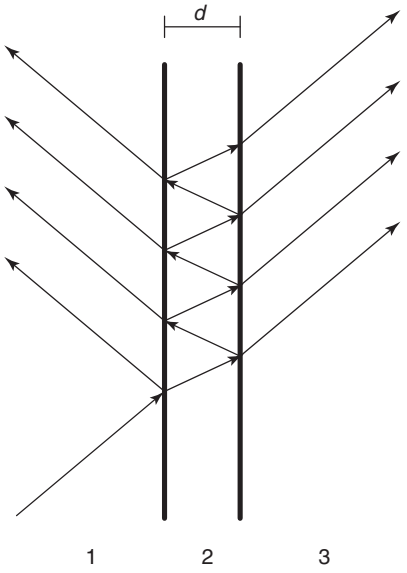

Figure 7 Reflection of an electromagnetic wave from a thin film 2 of width d bounded by media 1 and 3.

with solutions

$$\varepsilon_\omega = -\begin{cases} \coth(q_\parallel d/2) & \text{(even)} \\ \tanh(q_\parallel d/2) & \text{(odd)} \end{cases} \quad [36]$$

according to the parity of the surface charge. **Figure 8** illustrates the dispersion relation of unretarded SPs within a thin unsupported film described by the Drude model. Each surface supports by itself an SP of frequency ω_s. However, the field of each SP penetrates the film a distance $1/q_\parallel$ and thus may couple to the SP on the opposite surface, lifting the degeneracy. For small wave vectors, the odd coupled mode oscillates with the bulk plasma frequency ω_p, while the even coupled mode acquires an acoustical dispersion propagating with speed $v_s = \omega/q_\parallel = \omega_p d/2 = 2\pi n_0 de^2/m$, that is,

$$v_s = 2\pi n_s e^2/m \quad [37]$$

where $n_s = n_0 d$ is the number of electrons per unit area in the film.

Spherical Particles

The scalar potential $\psi_{lm}^{ind}(r,\theta,\phi) = C_{lm}^{ind}Y_{lm}(\theta\phi)r^{-l-1}$ produced at $r > a$ by the charges induced at the surface of a metallic sphere of radius a, subject to an external potential $\psi_{lm}^{ext}(r,\theta,\phi) = C_{lm}^{ext}Y_{lm}(\theta,\phi)r^l$ with angular momentum lm may be obtained in the nonretarded limit by solving Laplace's equation $\nabla^2\psi = 0$ within the sphere, and in the surrounding vacuum and imposing boundary conditions at $r = a$. This procedure yields the response function of the sphere,

$$S_{lm} \equiv \frac{C_{lm}^{ind}}{C_{lm}^{ext}} = -\frac{\varepsilon_\omega - 1}{\varepsilon_\omega + (l+1)/l}\,a^{2l+1} \quad [38]$$

for each value of l and m. Thus, the collective normal modes of the sphere, that is, its multipolar

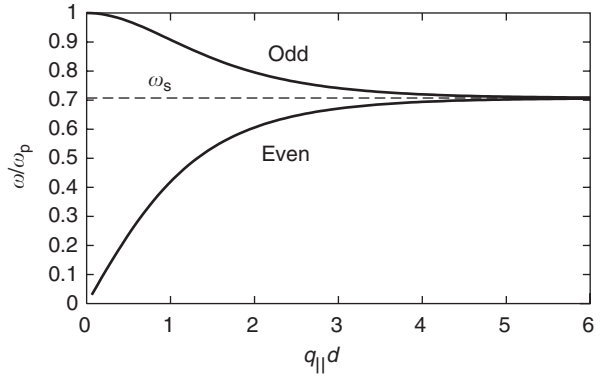

Figure 8 Dispersion relation of the odd and even SPs of a thin metallic film described by the Drude model. The SP frequency of a single surface is indicated by a dashed line.

surface plasmons, are given by the zeroes of the denominator:

$$\varepsilon_\omega = -\frac{l+1}{l} \qquad [39]$$

For the Drude model without dissipation,

$$\omega = \sqrt{\frac{l}{2l+1}}\,\omega_p \qquad [40]$$

This result yields ω_d for the case $l=1$. Thus, eqn [39] is a generalization of eqn [6] to conductors with arbitrary dielectric function, and yields modes with arbitrary angular momentum l. Notice that in the limit $l \to \infty$, eqn [39] coincides with the SP relation for a flat surface [27].

Observation

As plasmons are charge oscillations, they may couple to charged particles. A charged particle shot through the bulk of a conductor with velocity $\boldsymbol{v}$ induces screening charges of the opposite sign in its neighborhood. However, as the projectile is in motion and there is some delay before the screening is fully developed, the center of the screening charge lags behind the position of the projectile, as shown schematically in **Figure 9**. Thus, the attraction force toward the screening charge slows down the projectile, taking energy and momentum from it. Quantum mechanically, the particle loses energy $\hbar\omega$ and momentum $\hbar\boldsymbol{q}$ due to the emission of plasmons with frequency ω and wave vector $\boldsymbol{q}$. Only plasmons with velocities that match that of the particle, that is, with $\omega = \boldsymbol{q}\cdot\boldsymbol{v}$ are emitted, and with a probability per unit time which is proportional to the loss function $-\mathrm{Im}(1/\varepsilon^{L}_{q\omega})$. The loss function displays a sharp peak whenever $(\boldsymbol{q},\omega)$ approaches the plasmon dispersion relation [17]. For example, plasmon excitation may be observed with electron energy loss spectroscopy (EELS), in which high-energy electrons are shot into a metallic thin film in a transmission electron microscope, and the intensity of the electrons which are inelastically scattered into different directions is measured.

Consider now a relatively low-energy electron which collides with the surface of a conductor where it is specularly reflected. On its way toward the surface and back, it induces screening charges which produce a field that acts back on the projectile. According to the image theory, the field may be calculated in terms of a fictitious image charge within the metal. The image charge is not a point charge and it lags behind the ideal image position due to the delay in the development of the screening. Thus, the energy and momentum gained from the image force as the projectile approaches the surfaces are smaller than those lost as the projectile rebounds (**Figure 10**). Quantum mechanically, the electron loses energy $\hbar\omega$ and momentum $\hbar\boldsymbol{q}_\parallel$ along the surface by emitting SPs with a probability proportional to the surface loss function $-\mathrm{Im}\, g_{q_\parallel \omega}$. The loss function displays a sharp peak whenever $(\boldsymbol{q}_\parallel,\omega)$ approaches the SP dispersion relation [30], which may therefore be measured with low-energy reflection EELS.

Besides being excited by external charges, plasmons may also be excited by electromagnetic fields. The electric field of p-polarized light impinging on the surface of a metal may push the charge against the surface, and the resulting charge accumulation may subsequently propagate toward the bulk as a plasmon or along the surface as an SP. In the former case, the reflectance is slightly reduced below that given by the Fresnel amplitude [22] at frequencies above ω_p. In order to couple to SPs, the

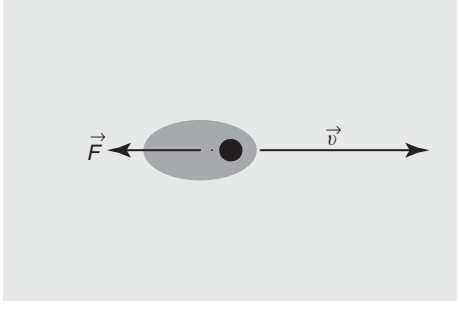

Figure 9 An external charge (black dot) moving with speed $\boldsymbol{v}$ within the bulk of a conductor (light gray), induces an excentric screening charge (dark gray) which produces a decelerating force $\boldsymbol{F}$.

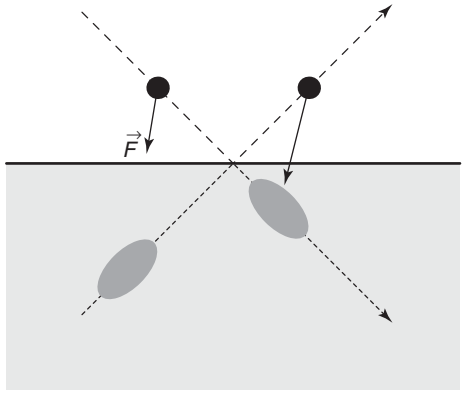

Figure 10 An external electron (black dot) collides with the surface of a metal (light gray) where it is specularly reflected. Along its trajectory (dashed), it interacts with its image (dark gray) being accelerated before the collision and decelerated afterwards by different forces (arrows), losing energy and momentum in the process.

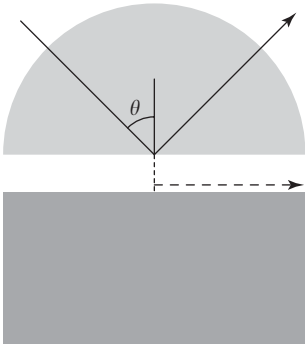

Figure 11 ATR experiment. *P* polarized light is incident at an angle θ on the surface of a glass semicylinder where it is totally reflected (solid arrow). The evanescent transmitted field (short dashes) reaches the surface of the metal, where it may excite an SP (dashed), attenuating the total reflection.

incoming wave should have a wave vector $q_{\parallel} > \omega/c$. This may be accomplished in an attenuated total reflection (ATR) experiment in which the surface is illuminated through a glass prism with an index of refraction $n > 1$ (**Figure 11**), in which the light line $n\omega/c$ extends beyond that of vacuum (**Figure 6**). By varying θ and/or ω, the region $\omega/c \leqslant q_{\parallel} = n(\omega/c)\sin\theta \leqslant n\omega/c$ may be explored (**Figure 6**). The reflectance of the system is close to 1 due to total reflection in the glass–air interface, except for a sharp dip when $(\boldsymbol{q}_{\parallel}, \omega)$ crosses the dispersion relation of the SP [25]. SPs may also be excited at a rough surface, where $\boldsymbol{q}_{\parallel}$ is no longer a conserved quantity and SPs may couple to ordinary light. The electric field close to the surface may be amplified several orders of magnitude due to SP excitations. This amplification is partly responsible for the enhanced Raman scattering by molecules adsorbed at rough metallic surfaces.

Final Remarks

Plasmons are present and have been studied in manifold systems: quasi-two-, one-, and zero-dimensional structures, in the presence of strong static electric and magnetic fields, in small particles of various shapes, etc. Their frequency may be obtained from the poles of appropriate response functions, typically, the total charge–external charge response, commonly identified with the inverse dielectric operator $\rho = \hat{\varepsilon}^{-1}\rho^{\text{ext}}$. The operator $\hat{\varepsilon}^{-1}$ may be represented by a matrix (ε^{-1}) introducing a suitable basis $|\alpha\rangle$, and each of the matrix elements $(\varepsilon^{-1})_{\alpha\beta}$ depends on frequency and may depend on other conserved quantities, such as momentum or angular momentum, if they are present. Plasmons are then given by the poles of the (ε^{-1}), or equivalently, from $\det(\varepsilon_{\alpha\beta}) = 0$. Plasmons play a fundamental role in the screening of electromagnetic fields within matter, and may be detected through inelastic scattering of charged particles or through resonant scattering of light.

Point Defects

W B Fowler, Lehigh University, Bethlehem, PA, USA

Introduction

As its name implies, a "point defect" is an atomic-scale imperfection in an otherwise perfect crystal. In this respect, it may be contrasted with an "extended defect," which extends through a large portion of the crystal. Much of solid-state technology is associated with point defects, and indeed this topic is central to many of the articles in this encyclopedia. Hence, this article will address general properties of point defects in condensed matter, while other articles delve into more specific properties and applications.

Types of Point Defects

In a solid that contains no chemical impurities, the fundamental intrinsic point defects are vacancies, interstitials, and antisites. A "vacancy" (also called a "Schottky defect") is a missing atom from a normally occupied site, while an "interstitial" is an extra atom in a normally unoccupied site. A "Frenkel defect" results when an atom is moved from a normal site to an interstitial site. In compound solids (e.g., GaAs), an "antisite" defect exists when an atom of one of the elements is located at a site normally occupied by that of another element.

A compound solid has another degree of freedom that can lead to vacancies and interstitials, namely chemical stoichiometry. A slight abundance of one component can lead to vacancies of another component, for example. This issue is particularly relevant in complex oxides in which standard preparations often yield nonstoichiometric crystals, such as the perovskite crystal, strontium iron niobium oxide.

Chemical impurities may be present substitutionally (taking the place of a normal atom) or interstitially. Furthermore, certain chemical impurities may induce the existence of vacancies or interstitials. For example, if a second-row impurity ion such as Ca^{2+} substitutes for Na^{+} (a first-row ion) in an insulating ionic solid such as NaCl, it is likely that there will be an Na^{+} vacancy nearby, in order for overall charge conservation to occur.

Particularly in semiconductors, but also in insulators, specific point defects may exist in different charge states. The charge states will clearly influence the electrical and optical properties of the solid. Charge states may be changed by varying the chemical potential (Fermi energy) of the solid, by various photoionization processes, or by charge injection.

While the simplest notion of atoms in solids is that of spheres of different sizes, an understanding of point defects (especially in nonmetals), in fact, relies heavily on chemical bonding ideas. For example, interstitials in semiconductors almost never simply sit at empty sites, interacting weakly with their neighbors. Rather, the interstitial atom and its neighbors reorganize their bonding and their positions, often forming the so-called split interstitial whose structure is governed by chemical bonding concepts.

Control of Point Defects

The control of point defects in solids is a central role of materials physics, and indeed, it is often the ultimate source of success or failure in a particular application.

The first step in point defect control is in the crystal growth process. It is at this point that desired impurities may be introduced and undesired impurities may be avoided. The outcome depends on the purity of the starting material, the detailed growth process, and the growth environment.

Even an elemental solid such as silicon, prepared with care, will contain intrinsic defects as a consequence of thermal equilibrium. Although a perfect crystal structure represents the most stable arrangement energetically, in thermal equilibrium a number of defects will exist as determined by Boltzmann statistics:

$$N_{\mathrm{D}} = BN \exp(-AE/kT) \qquad [1]$$

Here N_{D} is the number of defects, N the number of atomic sites, and A and B are dimensionless factors of order 1. E is the energy required to create the defect, k is Boltzmann's constant, and T is the kelvin temperature. If, for example, the creation energy is 0.35 eV, the room-temperature equilibrium fraction of defects can be $\sim 10^{-6}$, large enough to have noticeable effects. Commonly, the creation energy is larger, but even then, exposure of the solid to high temperatures during growth or processing can lead to a significant fraction of intrinsic defects, which, if cooling occurs faster than thermal equilibrium can be established, and can be "frozen in" at concentrations appropriate to the higher temperature.

In some cases, additional thermal processes may reduce the defect concentration through annealing. On the other hand, thermal treatments that are necessary for the construction of complex semiconductor

devices may yield unwanted outcomes relative to the point defects in portions of the device, such as thermally stimulated diffusion of impurity atoms from one region of the device to another.

In thin films, as those that occur for example in semiconductor devices, applied electric fields may also lead to changes in the location or configuration of point defects. Electric field-induced diffusion of atoms or ions may occur. Or, trapping of electrons or holes may lead to changes in defect configurations.

Point defects may be created or modified by external ionizing irradiation, either by photons or by high-energy particles. A number of detailed processes may take place, depending on the solid and the properties of the radiation. Heavy particles (such as neutrons or α-particles) of sufficient energy can displace atoms in the crystal by momentum- and-energy-conserving "billiard-ball" collisions. For lighter particles such as electrons or γ-rays, the requirements of both energy and momentum conservation require very high energies for the lighter particle.

In some nonmetallic crystals, irradiation can introduce point defects by simply ionizing atoms or ions, in which case the energy required is the bandgap, of the order of several electronvolts. In such cases, the defect creation occurs via a chemical reaction between the ionized atom, or the atom in an excited state, and other atoms in its vicinity.

Point Defect Diffusion

Point defect diffusion is a process in which a defect moves a macroscopic distance as the result of a series of short-range, statistical motions. Many specific mechanisms of defect diffusion may exist, depending on the defect or defects, the host, and other conditions such as temperature and external fields. The interaction of point and extended defects may lead to large enhancements of point defect diffusion.

An impurity at an interstitial site is considered, for example. Thermally activated motion over a potential barrier will be required for the impurity to move to an equivalent nearest-neighbor site. If there is just one impurity and there are no additional fields, its net motion will be a "random walk"; its long-range displacement will be hampered by its tendency to jump back toward, in addition to away from, the initial site, and no particular direction of motion will be favored. Calculations using statistical methods show that the net distance traveled by the impurity will vary as the square root of time.

If, however, an external field yields a net force in one direction, then the probability of jumps in that direction will be greater than the probability of jumps in the reverse direction; so, there will be a net motion of the impurity in the direction of the net force.

Furthermore, diffusion can take place in the absence of external fields if there is a concentration gradient of impurity atoms. An impurity will tend to jump from a region of higher concentration to a region of lower concentration, since in a direction of higher concentration the neighboring interstitial sites are more likely to be already occupied. This effect is described by Fick's first law:

$$J(x) = -D\frac{\partial C(x)}{\partial x} \qquad [2]$$

Here $J(x)$ is the impurity flux in the x-direction, $C(x)$ is the impurity concentration, and D is the diffusion coefficient. The diffusion coefficient D contains all the material properties, and it is also a function of temperature. Since the diffusion process involves thermal motion over a barrier, the diffusion coefficient D often varies with temperature, T, in a way similar to eqn [1]:

$$D = D_0 \exp(-\Delta E/kT) \qquad [3]$$

Here, ΔE is the height of the potential barrier and k is Boltzmann's constant.

Point Defects in Normal Metals and Superconductors

Because metals contain nearly free electrons, charge neutrality in the region of a point defect will automatically be satisfied. Hence, issues such as charge-compensating defects or charge-state effects, which are of major importance in nonmetals, are not relevant in metals. Nevertheless, point defects are still of importance in affecting the properties of metals. Two examples are briefly mentioned here: electrical properties and magnetic properties.

Even though charge neutrality in the region of point defects in metals exists, point defects still scatter conduction electrons. This is particularly important at low temperatures, where phonon scattering in the perfect crystal is reduced while impurity scattering remains.

Magnetic impurities can be important in both magnetic and nonmagnetic metals. In the latter case, the magnetic moment of the impurity is partially, but not completely, screened by the conduction electrons. In the former case, interactions between the magnetic atoms are important and will help determine the magnetic properties of the defective material.

In most cases, point defects have negative effects on superconductivity, since superconductivity involves coherent effects between charged particles. In high-T_c superconductors, however, impurities can

increase the number of electrons or holes. Furthermore, impurities have been of some use in studying the mechanisms for superconductivity.

Point Defects in Semiconductors

Semiconductors are useful in electronics because it is possible to add impurities in a way that leads to specified concentrations of electrons or holes that, in turn, can carry current. This is called "doping." In the simplest elemental semiconductors, such as silicon (a group IVb element), each atom has four valence electrons and forms bonds to four neighbors. If a phosphorus (a group Vb element) atom replaces a silicon atom, four of the phosphorus valence electrons form bonds, and the fifth is only weakly bound to the phosphorous atom. This weakly bound electron can be thermally ionized at normal temperatures, yielding a conduction electron. The result is *n*-type conduction.

If, on the other hand, a boron (a group IIIb element) atom replaces a silicon atom, a valence electron is needed to form bonds with the four neighbors, leaving a missing electron – a hole – in the valence band, weakly bound to the boron. This hole can be thermally ionized at normal temperatures, yielding a positively charged conducting "particle" – a "hole." The result is *p*-type conduction.

This simple picture does not always hold. For example, nitrogen is also a group Vb element, but a nitrogen atom substituting for a silicon atom does not yield a weakly bound electron. Rather, the nitrogen relaxes from the center of the substitutional site and forms bonds with the neighboring silicons in which all the electrons are involved and none are left to be weakly bound. This example shows that, in general, localized ("deep") and delocalized ("shallow") defect states may coexist, and which one is more stable depends on details.

In some cases, doping in compound semiconductors (such as GaAs) follows similar logic. Silicon in GaAs is amphoteric; if Si replaces Ga the system is *n*-type, whereas if it replaces As the system is *p*-type. In principle, *n*- or *p*-type conductivity may also be associated with intrinsic defects. For sometime, it was thought that *n*-type GaN resulted from nitrogen vacancies, but eventually it was realized that the origin of the conduction electrons – at least in most cases – comes from Si replacing the Ga.

It has been found difficult to achieve *p*-type doping in a number of compound semiconductors, and success has required some "tricks." For example, Mg on an N site will yield *p*-type GaN, but it is difficult to prepare GaN:Mg. The trick here is to include hydrogen in the processing; it is possible to prepare GaN with an Mg:H complex on the N site. Subsequent irradiation or heat treatment then removes the hydrogen, leaving behind the desired structure.

Along with deliberately introduced dopants, many other kinds of defects may occur in semiconductors. Some are relatively benign; for example, substitutional C in Si does not trap electrons or holes; so it may occur in a relatively large concentration and have little effect on the electronic properties of Si. Others may themselves trap electrons or holes, or they may combine with dopants in a way that "passivates" the electrical activity of the defect. For example, substitutional B in Si may combine with an H atom, resulting in a B–H pair in which the H is bond-centered (i.e., located within a B–Si bond) in the positive or the neutral charge state. In this configuration, the H supplies the fourth bonding electron, so there is no weakly bound hole and *p*-type conduction is suppressed.

In general, hydrogen is a common and significant impurity in semiconductors. Semiconductor processing involves compounds that contain hydrogen, so it is commonly present. Hydrogen is also amphoteric; it may passivate both donors and acceptors. In fact, hydrogen is, in most cases, a "negative-U" defect. This means that it will never occur as a neutral atom in thermal equilibrium; for any pair of hydrogen atoms (in general, well-separated), the sum of the energies of H^+ and H^- is lower than the energy of two neutral H's. If in fact the H's are mobile, it is likely that interstitial H_2 molecules will form, whose energy is still lower and thus represents the most stable state.

In general, defect motion is of great importance in semiconductor technology, and it has been widely studied. As noted earlier, atomic diffusion may occur during high-temperature processing, and in semiconductors this may yield deleterious effects on resulting devices. Processes that involve impurities coupled with intrinsic defects are common. For example, a substitutional Au atom in Si can switch places with an interstitial Si, forming an interstitial Au, which in turn has a very high diffusivity.

An important phenomenon in optical and some electrical applications is recombination-enhanced diffusion. In some situations, the energy gained from the recombination of an electron and a hole is sufficient to allow atomic motion over potential barriers. For example, optical excitation in ZnSe can induce a diffusion jump of an interstitial Zn atom.

Diffusion of impurity atoms in semiconductors may be enhanced by electric fields. For example, N and B may be induced to diffuse in SiC under high-temperature conditions in the presence of a field associated with a built-in *p*–*n* junction in the material.

Another important issue is the effect of charge states on diffusion. Because the structure and energetics of

defects may be strongly dependent on charge states, so may be the diffusion coefficient. Hence, atomic diffusion phenomena observed in *n*-type and *p*-type semiconductors may be quite different.

Point Defects in Insulators

Insulating solids share with semiconductors the existence of a bandgap; a region of forbidden energy between filled and empty electronic states. They also share some physics, such as the possible existence of defect states of different charge.

A fundamental distinction between insulators and semiconductors is that defect states in insulators are almost never sufficiently shallow in energy to provide charge carriers at normal temperatures. Hence, defects in insulators are almost always "deep."

There are many distinctions between insulators and semiconductors concerning important properties and applications. For example, the bandgaps of insulators span the energy range of visible photons, so defects in insulators may have important optical properties. Indeed, in the early German literature on defects in alkali halides (e.g., NaCl), such defects were called "farbzentren" (or "color centers"). Many precious gems have significant colors because of naturally occurring point defects in an insulating host. One result of these properties was the invention of the ruby laser, and insulator hosts have proven useful in connection with other optical devices and lasers as well.

Point defects in nonmetallic crystals will, if they have energy levels within the gap between the valence and conduction bands, lead to characteristic optical absorptions that involve the excitation of electrons or holes from a ground to an excited state. In many cases, there is also luminescence as the excited defect returns to the ground state.

The general theory of optical absorption, as well as some aspects of luminescence, is similar for deep semiconductor and insulator defects. In both cases, the electron–phonon interaction is involved. The defect in its ground electronic state has neighboring atoms that vibrate about sites whose equilibrium positions are determined, in part, by the defect wave function. When the defect is electronically excited, the neighboring atoms, responding to a new defect wave function, relax to new equilibrium positions. This process may be represented by a configuration coordinate diagram (**Figure 1**) of energy, E, versus an average position of the neighboring atoms, R. This idealized case consists of two displaced parabolas representing the harmonic energy of the vibrating atoms in ground (m) and excited (k) states. η and γ denote the quantized vibrational levels associated with the parabolas. An optical transition, in general, involves a change of both electronic and vibrational quantum numbers.

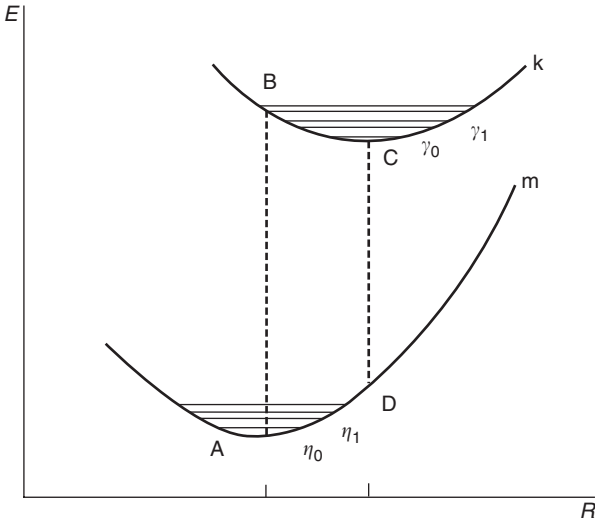

Figure 1 Configuration coordinate diagram for a model system.

In the weak-coupling limit, where the excited-state parabola is nearly above that of the ground state, the strongest transitions involve no change in the vibrational quantum number. In this case, at low temperature, if only the zero-point vibrational level of the ground state is occupied, the strongest transition will be a sharp "zero-phonon" transition from A to C to the zero-point level of the excited state.

In the strong-coupling limit shown in **Figure 1**, with both horizontal and vertical displacements of the parabolas, the zero- and few-phonon transitions are weak because the vibrational wave functions of the low-lying displaced oscillators do not overlap strongly, and the optical absorption is characterized by a broad multiphonon transition A to B which is approximately vertical in the configuration coordinate R.

In the absence of nonradiative processes, the excited defect will luminesce, emitting a photon as it returns to the ground state. In general, the radiative lifetime is at least several orders of magnitude longer than the vibrational relaxation rates, so the excited defect will relax to its lowest vibrational state, for example, at low temperature it will relax to the zero-point state C before the defect radiates. In the weak-coupling limit, the zero-phonon line C to A will be identical to that for absorption, while few-phonon lines will lie at lower photon energy (in contrast to absorption, where they lie at higher energies). In the strong-coupling limit, the broad multiphonon emission C to D will be "Stokes-shifted" to lower photon energy from that for absorption, as shown in **Figure 1**.

In the strong-coupling limit, then, the electron–phonon coupling has substantial effects. For example, for an electron trapped at a Cl^- vacancy in KCl (an F

center), the optical absorption peak at low temperature is at 2.3 eV with a width at half-maximum of 0.16 eV, while the luminescence peak is at 1.2 eV with a width of 0.26 eV.

Summary

Point defects in solids are of great importance and can have a wide variety of properties and applications. Other articles cited in the "See also" section delve more deeply into these topics. The books listed in the "Further reading" section treat the properties and effects of point defects in considerable depth and breadth. Internet searches under "crystal point defect" will provide up-to-date connections, as well.

Glossary

Antisite defect	an atom on the "wrong" site in a crystal that contains more than one type of chemical constituent.
Atomic diffusion	the motion of an atom over a macroscopic distance as the result of a series of individual microscopic motions which are statistical in nature.
Chemical impurity	an atom, ion, or (small) molecule that is chemically different from the perfect-crystal constituents.
Color centers	point defects in insulators that generate optical activity in the visible.
Configuration coordinate diagram	plot of energy versus atomic position for a molecule or defect.
Deep defects	defects in semiconductors or insulators in which the electron or hole is strongly bound and is not likely to be unbound at room temperature.
Doping	the introduction of chemical impurities into a crystal during the growth process.
Extended defect	an imperfection that extends through a large portion of a crystal.
F center	an electron trapped at a halogen-ion vacancy in an alkali halide crystal.
Fermi energy	the chemical potential of a solid.
Frenkel defect	a vacancy-interstitial pair.
Hydrogen passivation	the change of the nature of the electrical properties of defects by the incorporation of hydrogen into the defect.
Interstitial	an atom or ion at a position other than a perfect-crystal site.
n-Type	a semiconductor with an excess of donors.
Negative-U	a situation in which the "effective" Coulomb interaction between electrons or holes is negative.
p-Type	a semiconductor with an excess of acceptors.
Perfect crystal	a periodically repeated array of identical building blocks such as atoms or arrays of atoms.
Point defect	an imperfection in a perfect crystal that is of the order of atomic size.
Schottky defect	an isolated vacancy in an otherwise perfect crystal.
Shallow donors and acceptors	defects in semiconductors in which the electron (donor) or hole (acceptor) is weakly bound and is likely to be unbound at room temperature.
Stokes shift	the energy difference between absorption and emission bands.

Substitutional defect	a defect that occurs on a perfect-crystal atom site.
Vacancy	the absence of an atom or ion from its perfect-crystal site.
Zero-phonon transition	an optical transition from the zero-point vibrational level of one electronic state to the zero-point level of another state.

Point Groups

H Klapper, Mineralogisch-Petrologisches Institut, Universität Bonn, Bonn, Germany
Th Hahn, Institut für Kristallographie, RWTH Aachen, Germany

Brief Review of Groups

Definition: A group $\mathcal{G}$ is a set of N elements g_i with a composition law ("multiplication" $g_i \circ g_j$) of any two elements g_i and $g_j \in \mathcal{G}$ obeying the following four group axioms:

1. The "product" of any two group elements g_i and $g_j \in \mathcal{G}$ is again an element of the group: $(g_i \circ g_j) = g_k \in \mathcal{G}$ (axiom of closure).
2. There exists always a neutral element (identity) e, such that $(e \circ g_i) = (g_i \circ e) = g_i$ for any $g_i \in \mathcal{G}$.
3. For every $g_i \in \mathcal{G}$, there exists an inverse element $g_i^{-1} \in \mathcal{G}$ such that $(g_i \circ g_i^{-1}) = (g_i^{-1} \circ g_i) = e$.
4. For any three elements g_i, g_j, $g_k \in \mathcal{G}$, the associative law holds: $(g_i \circ g_j) \circ g_k = g_i \circ (g_j \circ g_k)$.

The finite number N of (different) elements of a group is the order of the group (finite groups). If the group contains infinitely many (different) elements, the group is said to be of infinite order (infinite group).

A finite group $\mathcal{G}$ is called cyclic, if it can be generated by one element g: $g^1 = g, g^2, g^3, \ldots, g^N = e$ and is of order N.

If the relation $(g_i \circ g_k) = (g_k \circ g_i)$ holds for all pairs g_i, $g_k \in \mathcal{G}$, the group is called commutative or Abelian. All groups containing only binary elements g_i (i.e., $g_i \circ g_i = g_i^2 = e$, or equivalently, $g_i = g_i^{-1}$) and all cyclic groups are commutative.

A subset $\mathcal{H}$ of a group $\mathcal{G}$, $\mathcal{H} \subset \mathcal{G}$, is called a subgroup of $\mathcal{G}$, if $\mathcal{H}$ obeys the group axioms. In this case, $\mathcal{G}$ is a supergroup of $\mathcal{H}$. For finite groups, the ratio of the orders of group and subgroup, $N(\mathcal{G})$ and $N(\mathcal{H})$, is the index $[i]$ of $\mathcal{H}$ in $\mathcal{G}$: $[i] = N(\mathcal{G})/N(\mathcal{H}) = |\mathcal{G}|/|\mathcal{H}|$. According to the theorem of Lagrange, for finite groups the index $[i]$ is always an integer.

An illustrative representation of a finite group $\mathcal{G}$ of order N is the multiplication table or group table of $\mathcal{G} = \{e, g_2, g_3, g_4, \ldots, g_N\}$. It is an $(N \times N)$ square array of all products according to the abstract scheme of **Table 1**. Note that in each of the N rows and N columns of the table, each group element appears exactly once.

Groups of the same order and with the same structure of the group table, that is, with strict correspondence of their ordered elements and their products (irrespective of the names and symbols of the group elements), are isomorphic. If the group table is symmetric with respect to the main diagonal, the group is commutative.

In crystallographic groups, the group elements are symmetry operations (motions, isometries). The "multiplication" is the successive application of two operations. As an example, the group tables of the two crystallographic point groups 4 (fourfold 90° rotations, tetragonal) of order 4 (**Table 2**) and $2_x/m_x\, 2_y/m_y\, 2_z/m_z$ (short *mmm*, orthorhombic) of order 8 (**Table 3**) are discussed. **Table 3** illustrates the

Table 1 Multiplication table of a group $\mathcal{G} = \{e, g_2, g_3, g_4, \ldots, g_N\}$ of order N

	e	g_2	g_3	...	g_N
e	e	g_2	g_3	...	g_N
g_2	g_2	g_2^2	$g_2 g_3$	...	$g_2 g_N$
g_3	g_3	$g_3 g_2$	g_3^2	...	$g_3 g_N$
⋮	⋮	⋮	⋮	⋮	⋮
g_N	g_N	$g_N g_2$	$g_N g_3$	...	g_N^2

Table 2 Group table (4×4) of the tetragonal crystallographic point group 4: successive 90° rotations forming a cyclic group of order 4, i.e., $4^4 = 1$ (this group is commutative)

	1	4^1	$4^2 = 2$	$4^3 = 4^{-1}$
1	1	4^1	2	4^3
4^1	4^1	2	4^3	1
$4^2 = 2$	2	4^3	1	4^1
$4^3 = 4^{-1}$	4^3	1	4^1	2

There is one subgroup of order $N = 2$ and index $[i] = 2$ with elements {1,2} (180° rotation).

Table 3 Group table (8×8) of the orthorhombic crystallographic point group $2_x/m_x\,2_y/m_y\,2_z/m_z$ (short *mmm*) of order $N = 8$

	1	2_y	m_y	$\bar{1}$	⋮	2_x	m_x	2_z	m_z
1	1	2_y	m_y	$\bar{1}$	⋮	2_x	m_x	2_z	m_z
2_y	2_y	1	$\bar{1}$	m_y	⋮	2_z	m_z	2_x	m_x
m_y	m_y	$\bar{1}$	1	2_y	⋮	m_z	2_z	m_x	2_x
$\bar{1}$	$\bar{1}$	m_y	2_y	1	⋮	m_x	2_x	m_z	2_z
...	...	...	...	...					
2_x	2_x	2_z	m_z	m_x		1	$\bar{1}$	2_y	m_y
m_x	m_x	m_z	2_z	2_x		$\bar{1}$	1	m_y	2_y
2_z	2_z	2_x	m_x	m_z		2_y	m_y	1	$\bar{1}$
m_z	m_z	m_x	2_x	2_z		m_y	2_y	$\bar{1}$	1

The top left (4×4) array (separated by dotted lines) is the group table of the subgroup $2_y/m_y$ of order $N = 4$ and index $[i] = 2$. The group *mmm* can be obtained from the subgroup $2_y/m_y$ by "extension" of its (4×4) group table by any of the additional operations 2_x, m_x, 2_z, or m_z (here by 2_x as the fifth element), each leading to the same supergroup *mmm* of index $[i] = 2$. Both, group and supergroup, are commutative, because all group elements g_i are binary.

various group–subgroup relations within this group: there are seven subgroups of order $N = 4$ and index $[i] = 2$. One of these subgroups, $2_y/m_y$, is displayed in the upper left (4×4) array in **Table 3**. The full (8×8) group table of $2_x/m_x\,2_y/m_y\,2_z/m_z$ is obtained from this $2_y/m_y$ subtable by adding any of the operations 2_x, m_x, 2_z, or m_z. From **Table 3**, it is easily derived that the seven subgroups of order 4 are $2_x/m_x$, $2_y/m_y$, $2_z/m_z$, $2_x2_y2_z$, $2_xm_ym_z$, $m_x2_ym_z$, and $m_xm_y2_z$, which are all isomorphic. There are seven further isomorphic subgroups of order 2 and index 4.

Introduction to Point Groups

Three kinds of three-dimensional groups are fundamental to the study of crystals: point groups, translation groups, and space groups. This article deals with the first type of groups, the point groups. These groups describe and govern the symmetry of finite (nonperiodic, i.e., not containing translations) objects, such as molecules, crystals, flowers, and objects of art, as well as the local symmetries ("site symmetries") of points in a periodic pattern (ornament, wallpaper, crystal structure).

In a more subtle fashion, one can distinguish two kinds of point-group symmetries:

1. Symmetry in "vector space": symmetry of a set of vectors, for example, of the face normals of a crystal ("crystal form"), of the translation vectors of a crystal lattice, and of the interatomic vectors of a crystal structure (Patterson vectors). These symmetries are visualized best as vector bushels originating from a common origin.
2. Symmetry in "point space": symmetry of any finite polyhedron, of a molecule, or of an atomic group; symmetry around an arbitrary point in an infinite crystal structure ("site symmetry") or around a lattice node in an infinite point lattice ("lattice point group").

It should be noted that in many textbooks on crystals, two terms are in general use: "point group" as the symmetry of a particular crystal and "crystal class" as the set of all crystals with the same point-group symmetry. Both receive the same symbol. It is of interest that the 32 three-dimensional crystallographic point groups were derived already around 1830.

General and Crystallographic Point Groups

Point groups can be subdivided into crystallographic and noncrystallographic point groups. Both together are called general point groups.

General Point Groups

A "general point group" is a group of rigid motions (symmetry operations, isometries) which all leave at least one point of space invariant.

This definition leads to infinitely many mono-axial point groups, because it admits infinitely many rotation groups with rotation angles $\varphi = 360°/n$ for all integer values of n. All these rotation groups are of finite order $N = n$. Furthermore, there are some point groups of order $N = \infty$, because they contain rotations (or rotoinversions) of order infinity, that is, rotations with all possible (including arbitrarily small) rotation angles. These rotation groups of infinite order are symbolized as ∞ and $\overline{\infty} = \infty/m$ in Hermann–Mauguin notation and as C_∞ and $C_{\infty h} = C_{\infty i} = S_\infty$ in Schoenflies notation. They appear as symmetry elements of cones, cylinders, circles, and spheres. For details see the "Further reading" section, especially Vol. A of the *International Tables*.

The condition "leave at least one point of space invariant" means that all symmetry elements of the group (axes, planes, and point) intersect at this one point, thus excluding any translations among the symmetry operations. Invariance of more than one point is of course possible, but always leads to infinitely many invariant points. Examples are all "mono-axial" groups n (one rotation axis only), which have an invariant line, and the reflection group m, which has an invariant plane. The intersection of several

rotation axes in one point or the presence of a center of symmetry $\bar{1}$, leads to only one invariant point which represents the center of the object.

Crystallographic Point Groups

A "crystallographic point group" is a group of rigid motions which all leave at least one point of space invariant and, in addition, map a point lattice onto itself ("crystallographic restriction").

As described elsewhere in this encyclopedia, the crystallographic restriction (lattice condition) restricts the permissible rotation angles to multiples of 180°, 120°, 90°, and 60° (two-, three-, four-, and sixfold axes). This reduces the infinitely many point groups to 10 for two dimensions and to 32 for three dimensions. The highest group orders are $N = 12$ for two and $N = 48$ for three dimensions.

Among the 32 three-dimensional crystallographic point groups, there are 11 centrosymmetric groups (so-called Laue groups), which are important in X-ray diffraction, and seven lattice point symmetries (holohedries), defining the seven crystal systems. It should be noted that the 32 three-dimensional crystallographic point groups discussed below can be attributed to 18 isomorphism classes (abstract point groups). A classification of the crystallographic point groups with respect to physical properties is given in **Table 5**.

Among the three-dimensional noncrystallographic point groups there are the two icosahedral point groups, which contain 6 fivefold, 10 threefold, and 15 twofold rotation axes. They have recently received particular attention due to their occurrence in quasicrystals and fullerenes.

In modern crystallography, point groups in four, five, and six dimensions have been derived and are used for the treatment of incommensurate and quasicrystals. There are 271 point groups in four, 955 in five, and 7104 in six dimensions, with highest orders $N = 1152$, 3840, and 51840, respectively.

Symbols of the 32 Crystallographic Point Groups

The two systems of symbols for the crystallographic point groups are briefly reviewed here:

1. Schoenflies symbols, first presented in 1891 in Schoenflies' classical book, are based on capital letters for rotation groups C, D, S, T, O with subscripts s, h, v, d for mirror planes in various orientations, and subscript i for an inversion center. The noncrystallographic icosahedral and sphere groups are denoted by letters I_h and K_h (for German "Kugelgruppe").
2. The Hermann–Mauguin or international symbols are based on the "blickrichtungen" (symmetry directions) of the various lattices (holohedries), with specific numbers 2, 3, 4, 6 for symmetry axes, m for a mirror plane, and $\bar{1}$ for an inversion center. The Hermann–Mauguin symbols for the icosahedral and the sphere groups are $2/m\bar{3}\bar{5}$ (often written as $\bar{5}\bar{3}2/m$) and $2/m\overline{\infty}$ (often written as $\infty\,\infty m$).

Symbols and groups orders of the 32 three-dimensional crystallographic point groups, both in Schoenflies and Hermann–Mauguin notation, are illustrated in **Figure 1**.

Description of Point Groups

A formal description of point groups is already given by their group tables, in the section "Brief review of groups" and in **Tables 1–3** of this article.

Algebraically, the point groups are usually represented by matrix groups, that is, by the set of (3×3) matrices $\boldsymbol{W}$ of their point group operations (motions, isometries) with determinants $+1$ and -1 or, in a more condensed form, by either the N (contravariant) coordinates x, y, z, of the symmetrically equivalent points, or the N (covariant) Miller indices $\{hkl\}$ of the symmetrically equivalent faces of the "general face form" (crystal form). N is the order of the point group.

Example: point group $2_y/m_y$ (cf. subgroup in **Table 3**), consisting *of* $N = 4$ group elements 1, 2_y, m_y, $\bar{1}$:

1. coordinates of equivalent general points: x, y, z (1), $-x, y, -z$ (2_y), $x, -y, z$ (m_y), $-x, -y, -z$ $(\bar{1})$;
2. Miller indices of equivalent general faces: (hkl) (1), $((\bar{h}, k, \bar{l})$ (2_y), $(h\bar{k}l)$ (m_y), $(\bar{h}\bar{k}\bar{l})(\bar{1})$.

A complete algebraic representation of the 10 two- and the 32 three-dimensional crystallographic point groups, as well as of the two icosahedral groups is given in Vol. A of the *International Tables* (cf. "Further reading" section).

Geometrically, a point group is normally represented by means of the stereographic projection of its "framework of symmetry," that is, the spatial assemblage of its symmetry elements (rotation axes, mirror planes, and center of symmetry).

Figure 1 shows the stereographic projections of the symmetry frameworks of the 32 three-dimensional crystallographic point groups, as well as the two icosahedral groups. The graphical symbols of rotation

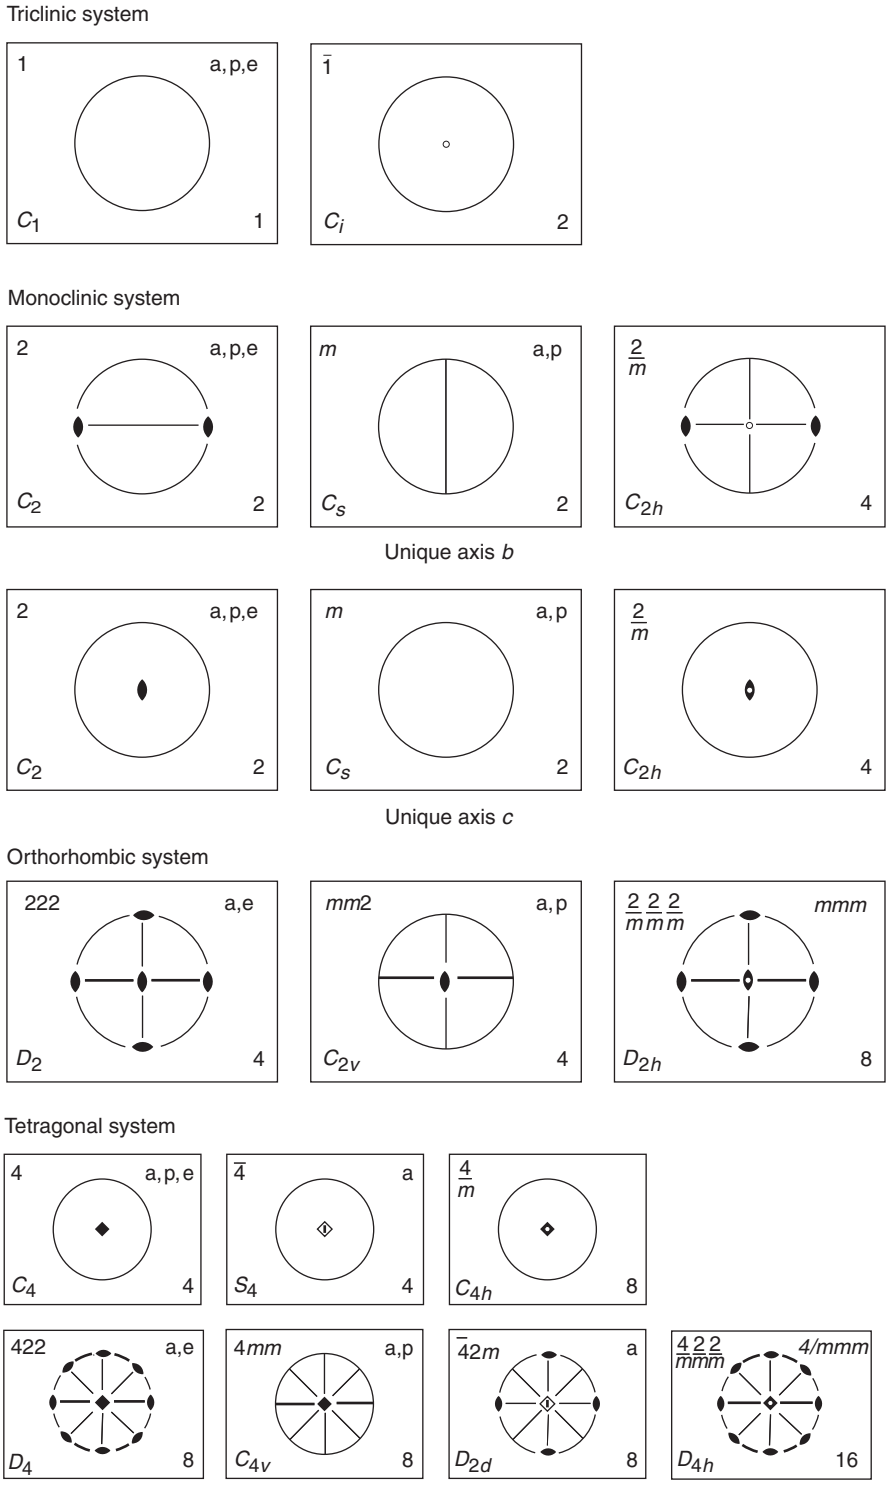

Figure 1 Stereographic projections of the symmetry elements of the 32 crystallographic point groups and the two icosahedral groups. Heavy solid lines or circles indicate mirror planes, thin lines are used for the projection circle and for auxiliary lines. Around each projection, the full (top left) and short (top right, if different) Hermann–Mauguin symbols, the Schoenflies symbol (bottom left) and the group order *N* (bottom right) are given. In the top right position the letters "a", "p", and "e" indicate that the point group is acentric (noncentrosymmetric), polar (pyroelectric) and enantiomorphic, respectively (cf. **Table 5**). No letter indicates a centrosymmetric point group. (Reproduced with permission from Hahn Th and Klapper H (2002) *International Tables for Crystallography*, Vol. A, *Space-Group Symmetry*, 5th edn. Dordrecht: Kluwer Academic; © International Union of Crystallography.)

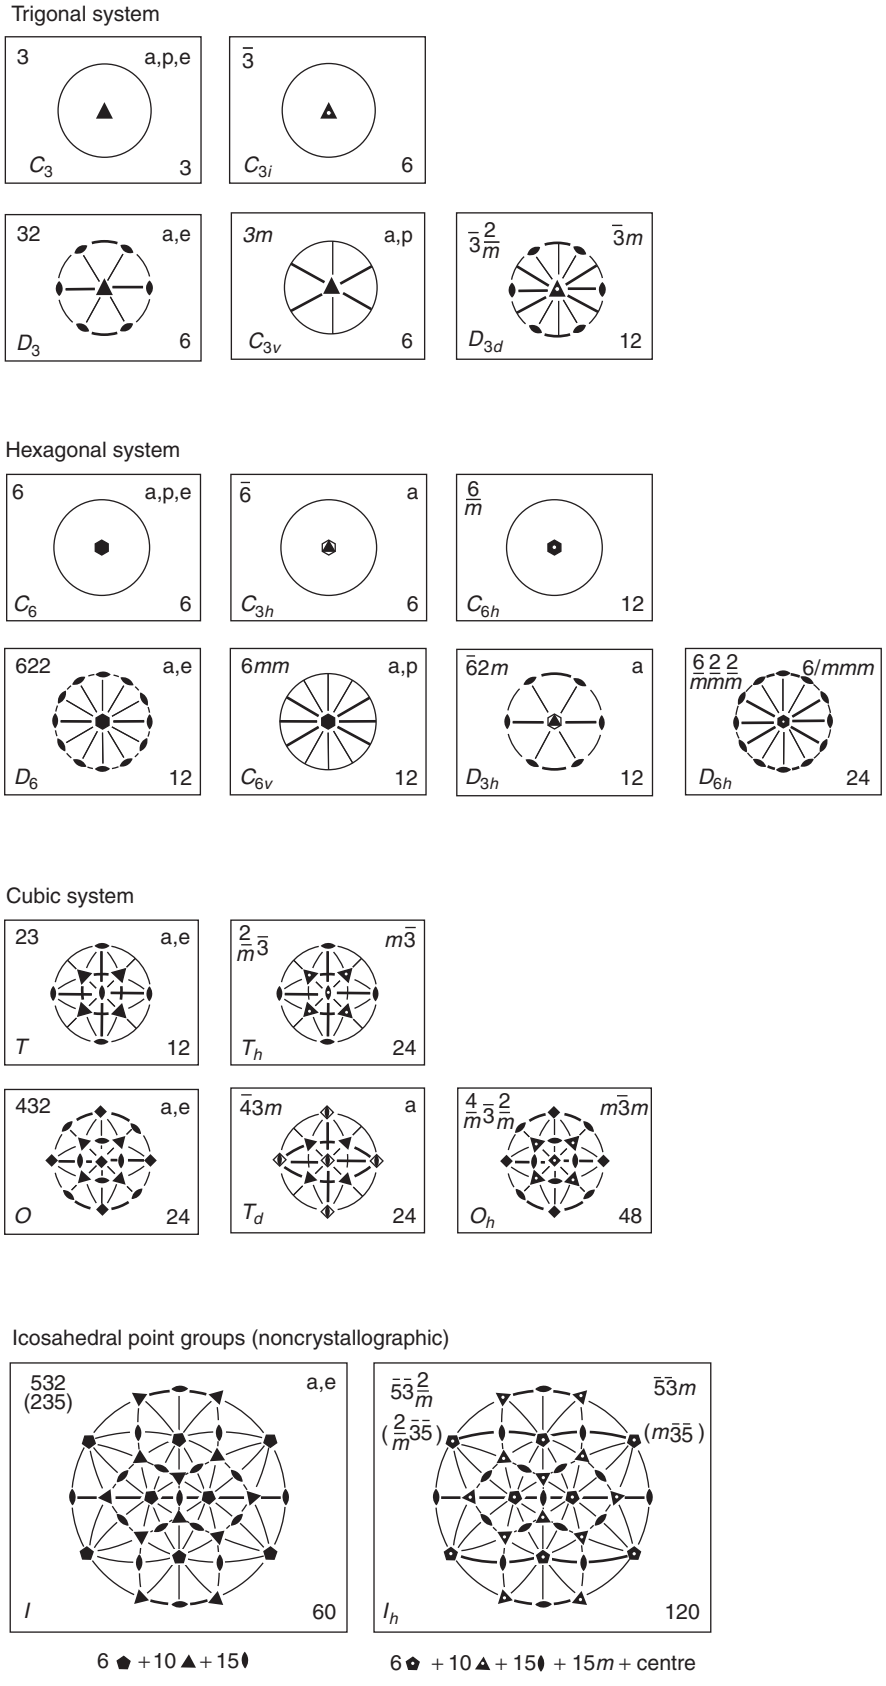

Figure 1 Continued.

and rotoinversion axes, mirror planes, and inversion centers are explained elsewhere in this encyclopedia.

The most frequent use of these stereographic projections in mineralogy and crystallography is the characterization of the crystal morphology by the normals of the crystal faces (face poles), leading to the face forms (crystal forms), that is, sets of symmetrically equivalent faces. Each point group (order N) has a "general" face form $\{hkl\}$ with N faces, each one of "face symmetry" 1, and up to six "special" face forms with N/q faces with "face symmetry" >1 of order q, for example, $\{hk0\}$, $\{1\,1\,1\}$, $\{1\,0\,0\}$. Example: the face form cube $\{1\,0\,0\}$ has six faces with "face symmetry" $4\,mm$ (order 8) in point group $4/m\,\bar{3}2/m$ (order $6 \times 8 = 48$).

Complete listings of all general and special face forms of the crystallographic point groups and the icosahedral groups are presented in Vol. A of the *International Tables* (see the "Further reading" section).

Subgroups of the Crystallographic Point Groups

Group–subgroup relations, as defined in the first section, are of particular importance for physical phenomena such as phase transitions (symmetry breaking in the Landau theory), twinning, and domain structures. In solid-state chemistry, they are widely used for the classification of structural relations in families of related compounds (structure types).

Figure 2 displays the sub- and supergroups of the two- and three-dimensional crystallographic point groups in the form of two "family trees." Each tree has two "summits": for two dimensions (**Figure 2a**) the hexagonal holohedry $6mm$ (order $N = 12$) and the tetragonal holohedry $4mm$ ($N = 8$), for three dimensions (**Figure 2b**) the cubic holohedry $4/m\bar{3}\,2/m$ ($N = 48$) and the hexagonal holohedry $6/m\ 2/m\ 2/m$ ($N = 24$). Their subgroups "mix" on the levels $N = 4$ (**Figure 2a**) and $N = 12$ (**Figure 2b**), where common subgroups of both branches appear first. Reading the diagrams downward, solid and dashed lines connect a point group $\mathcal{G}$ with all its maximal subgroups $\mathcal{H}$. The subgroup index $[i]$ is given by the ratio of the group orders of $\mathcal{G}$ and $\mathcal{H}$: $[i] = N(\mathcal{G})/N(\mathcal{H})$. If the diagrams are read upward, the lines connect a point group $\mathcal{H}$ with all its minimal supergroups $\mathcal{G}$, with supergroup index $[i] = N(\mathcal{G})/N(\mathcal{H})$. The index $[i]$ is always an integer, according to the theorem of Lagrange.

In the diagrams, solid lines refer to normal subgroups, dashed lines to sets of conjugate subgroups. Two subgroups $\mathcal{H}_1$ and $\mathcal{H}_2$ are conjugate in $\mathcal{G}$, if (at least) one symmetry operation g_j of $\mathcal{G}$ exists which maps $\mathcal{H}_1$ onto $\mathcal{H}_2$: $g_j^{-1} \circ \mathcal{H}_1 \circ g_j = \mathcal{H}_2$. Conjugate subgroups are "symmetrically equivalent" in $\mathcal{G}$. If a subgroup $\mathcal{H}$ is equivalent only to itself (self-conjugate) and to no other subgroup, $\mathcal{H}$ is a normal (invariant) subgroup of $\mathcal{G}$.

Example: the cubic point group $2/m\bar{3}$ (short : $m\bar{3}$) has six maximal subgroups. They are:

- two normal subgroups, one 23 (cubic) of index [2], and one $2/m2/m2/m$ (short: mmm, orthorhombic) of index [3];
- one set of four conjugate subgroups $\bar{3}$ (trigonal) of index [4]. They are symmetrically equivalent (conjugate) under the "lost" twofold rotations of $2/m\bar{3}$.

In three dimensions, [4] is the largest index of a maximal subgroup of a crystallographic point group. In two dimensions, it is [3]. Note that orthorhombic $2/m2/m2/m$ has three normal (nonconjugate) subgroups of the same type, $mm2$, $m2m$, and $2mm$, whereas the cubic point group 23 has four conjugate (symmetrically equivalent) subgroups of type 3.

When a crystal of symmetry $\mathcal{G}$ undergoes a (displacive) phase transition to a lower point group symmetry $\mathcal{H}$, it splits into (twin) domains which are related by the lost symmetry operations of $\mathcal{G}$. The number of domain states (orientation states) equals the subgroup index $[i] = N(\mathcal{G})/N(\mathcal{H})$.

Examples

1. Quartz (SiO_2) possesses the point group 32 of order $N = 6$ at room temperature. Upon heating above $T_c = 573°C$, it transforms into "high-quartz" with point group 622 and order 12. Upon cooling back below T_c, it loses the twofold axis 2 (contained in the hexagonal axis 6) and returns to "low-quartz" with symmetry 32, whereby it splits into domains of $[i] = 2$ orientation states ("Dauphiné twin"). This is an example of a nonferroelastic transition and merohedral twinning.

2. Barium titanate ($BaTiO_3$) (and other perovskite compounds) undergoes, by cooling below 125°C, a ferroelastic and ferroelectric cubic-to-tetragonal phase transition from point group $4/m\bar{3}\,2/m$ (order 48) to $4\,mm$ (order 8) of index $[i] = 6$. This one-step transformation can be rationalized as a succession of two maximal-subgroup steps:

(a) Reduction from $4/m\bar{3}\,2/m$ to $4/m2/m2/m$ (order 16), both centrosymmetric, with subgroup index [3]. This leads to a set of three conjugate tetragonal subgroups with their tetragonal axes oriented along the former three fourfold cube axes as well as to three ferroelastic 90° domain states.

(b) Further reduction of each of the three conjugate $4/m2/m2/m$ subgroups to its normal subgroup

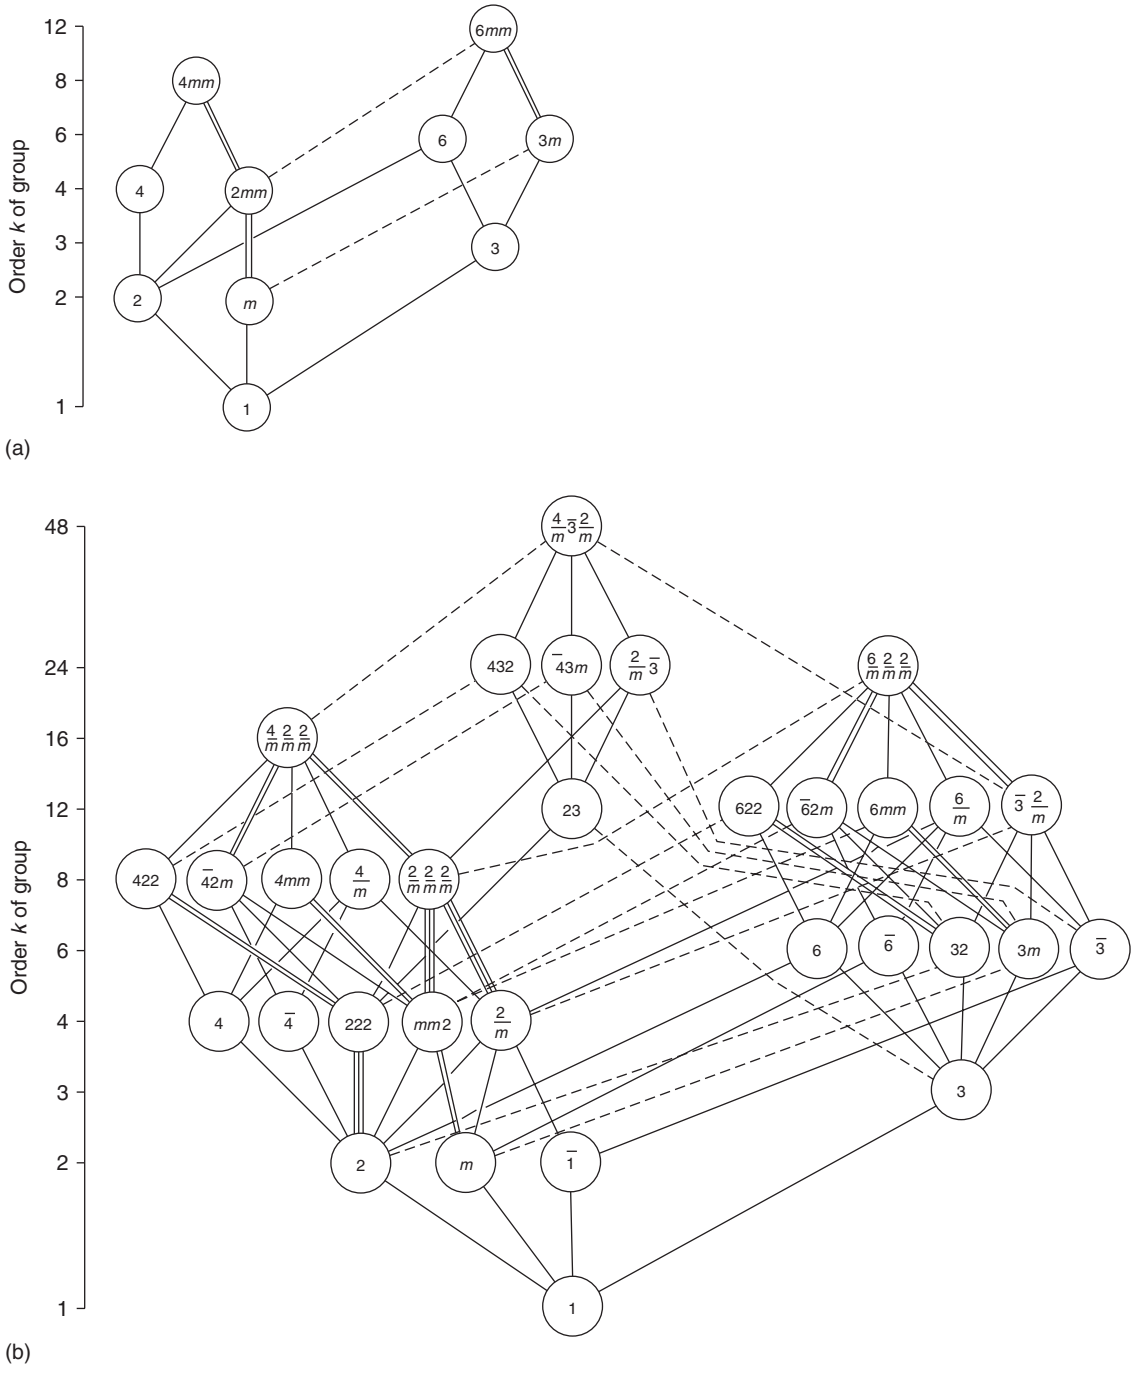

Figure 2 Sub- and supergroup relations of the crystallographic point groups for (a) two and (b) three dimensions. The group orders N are given at the left margin of the diagrams. Solid lines refer to normal subgroups, dashed lines to sets of conjugate subgroups. (Reproduced with permission from Hahn Th and Klapper H (2002) *International Tables for Crystallography*, Vol. A, *Space-Group Symmetry*, 5th edn. Dordrecht: Kluwer Academic; © International Union of Crystallography.)

4*mm* of index [2], leading to two antiparallel ferroelectric domain states (180° domains).

The total index of both transition steps is $[3] \times [2] = [6]$. As a result, six different "orientation states" (domain states) are generated: three ferroelastic 90° domain states (pseudo-merohedral twins) [due to step (1)], each one being further split into two ferroelectric 180° domain states (merohedral inversion twins) [result of step (2)].

Symmetry of Physical Properties

Definition of Tensor Symmetry

Physical properties of crystals are strongly governed by symmetry. This holds in particular for the (non-scalar) anisotropic properties described by tensors, and for nontensorial properties such as cleavage and plasticity for which a comprehensive mathematical treatment does not exist. The components of the tensors describing crystal properties are usually referred to a Cartesian coordinate system, that is, three orthogonal axes X_1, X_2, X_3 with equal unit lengths.

Whereas the anisotropic properties themselves are independent of the choice of the coordinate system, their representation by tensors is not, that is, the tensor components change if the coordinate system is transformed. As a consequence, the symmetry of a physical property can be defined in two alternative, but equivalent ways:

1. a rigid motion (rotation, reflection, and inversion), represented by a unitary matrix W ($\det W = \pm 1$), is applied to the crystal, whereby the coordinate system is kept stationary. All motions, for which the tensor components of the transformed crystal are unchanged, are symmetry operations of the tensor property $\mathscr{P}$;
2. alternatively, an arbitrary motion W is applied to the coordinate system with the crystal kept stationary. All motions, for which the tensor components are unchanged under the coordinate transformations W, are symmetry operations of the tensor property $\mathscr{P}$. In both cases the rotation matrices are inverse to each other.

As a consequence of this invariance, some of the tensor components are equal or even zero. The number of independent components is decreased when the symmetry of the crystal increases. Thus, an increase of the point-group symmetry from 1 (triclinic) to $4/m\bar{3}\ 2/m$ (cubic) or to the sphere group $\infty\,\infty m$ (i.e., isotropy) reduces the number of tensor components for symmetrical second-rank tensors from 6 to 1, and for double-symmetrical fourth-rank tensors (e.g., elasticity) from 21 to 3 (cubic) and 2 (isotropy). Even more drastic is this reduction for all tensors of odd rank (such as pyroelectricity and piezoelectricity): all components are zero if an inversion center is present, that is, properties described by odd-rank tensors do not exist in centrosymmetric crystals. This is further elucidated below.

Neumann's Principle

A useful group–subgroup relation between physical and crystallographic symmetries is provided by "Neumann's principle" (first stated in 1833). It states that the symmetry of all physical properties of a crystal is higher than (or at least equal to) its crystallographic point-group symmetry, or in the language of groups: the crystallographic symmetry $\mathscr{G}$ is a proper or improper subgroup of any physical symmetry $\mathscr{P}$, $\mathscr{G} \subseteq \mathscr{P}$. This is illustrated in **Table 4** for second-rank tensors which are, as all even-rank tensors, centrosymmetric. Their symmetries can be recognized by their representation surfaces, which are always ellipsoids or hyperboloids. The symmetry of a general ellipsoid or hyperboloid is $2/m\ 2/m\ 2/m$, but it degenerates to cylindrical and spherical symmetries with point groups $\infty/m\ 2/m$ ($\overline{\infty}2/m$) and $\infty\,\infty m$ ($2/m\,\overline{\infty}$) for uniaxial (i.e., tetragonal, trigonal, hexagonal) and cubic crystals. It is obvious that in all cases the crystallographic symmetry is a proper subgroup of the "physical symmetry," except for the orthorhombic holohedry, for which they are identical. Note that all point groups within the same crystal

Table 4 Symmetry of second-rank polar tensor properties and optical birefringence (refractive-index ellipsoids) in the seven crystal systems

Crystal system	*Holohedry*	*Type of ellipsoid or hyperboloid*	*Symmetry of tensor property*	*Optical birefringence (index ellipsoid)*
Triclinic	$\bar{1}$	General	$2/m\ 2/m\ 2/m$	Biaxial
Monoclinic	$2/m$	General	$2/m\ 2/m\ 2/m$	Biaxial
Orthorhombic	$2/m\ 2/m\ 2/m$	General	$2/m\ 2/m\ 2/m$	Biaxial
Tetragonal	$4/m\ 2/m\ 2/m$	Rotational	$\infty/m\ 2/m$	Uniaxial
Trigonal	$\bar{3}\,2/m$	Rotational	$\infty/m\ 2/m$	Uniaxial
Hexagonal	$6/m\ 2/m\ 2/m$	Rotational	$\infty/m\ 2/m$	Uniaxial
Cubic	$4/m\,\bar{3}\,2/m$	Spherical	$\infty\,\infty m(2/m\,\overline{\infty})$	Isotropic

In column 5 the terms "biaxial" and "uniaxial" refer to the number of "optical axes", i e., of circular sections through the index ellipsoid. For uniaxial crystals, the rotation axis of the tensor surface coincides with the main crystallographic symmetry axis. For orthorhombic crystals, the three principal tensor axes and the crystallographic symmetry axes are parallel. For monoclinic crystals, one principal tensor axis is fixed by symmetry; it is parallel to the monoclinic symmetry axis. For triclinic crystals, none of the principal tensor axes is fixed by symmetry, allowing their "orientation dispersion", e.g., with temperature.

Table 5 The 21 noncentrosymmetric crystallographic point groups (crystal classes) and the occurrence (+) of specific crystal properties

Crystal system	*Noncentrosymmetric point group*	*First-rank tensor (e.g., pyroelectricity)*	*Third-rank tensor (e.g., piezoelectricity)*	*Enantiomorphism*	*Optical activity (opt. gyration)*
Triclinic	1	+ (3) [*uvw*]	+ (18)	+	+ (6)
Monoclinic	2	+ (1) [0 1 0][a]	+ (8)	+	+ (4)
	m	+ (2) [*u* 0 *w*][a]	+ (10)	−	+ (2)
Orthorhombic	222	−	+ (3)	+	+ (3)
	*mm*2	+ (1) [0 0 1]	+ (5)	−	+ (1)
Tetragonal	4	+ (1) [0 0 1]	+ (4)	+	+ (2)
	$\bar{4}$	−	+ (4)	−	+ (2)
	422	−	+ (1)	+	+ (2)
	4*mm*	+ (1) [0 0 1]	+ (3)	−	−
	$\bar{4}$ 2*m*	−	+ (2)	−	+ (1)
Trigonal	3	+ (1) [0 0 1][b]	+ (6)	+	+ (2)
	32	−	+ (2)	+	+ (2)
	3*m*	+ (1) [0 0 1][b]	+ (4)	−	−
Hexagonal	6	+ (1) [0 0 1]	+ (4)	+	+ (2)
	$\bar{6}$	−	+ (2)	−	−
	622	−	+ (1)	+	+ (2)
	6*mm*	+ (1) [0 0 1]	+ (3)	−	−
	$\bar{6}$ 2*m*	−	+ (1)	−	−
Cubic	23	−	+ (1)	+	+ (1)
	432	−	−	+	+ (1)
	$\bar{4}$ 3*m*	−	+ (1)	−	−
Icosahedral	532 (235)	−	−	+	+ (1)
Spherical	$\infty\,\infty$ (2∞)	−	−	+	+ (1)

The number of nonzero independent tensor components is given in parentheses. For comparison, the noncentrosymmetric icosahedral and the sphere group (isotropy) are added. For first-rank tensors the direction [*uvw*] of the property vector is given. There are 10 pyroelectric, 20 piezoelectric, 11 enantiomorphic and 15 optically active crystal classes.
[a] Unique axis *b*
[b] Hexagonal axis.

system (e.g., orthorhombic 222, *mm*2, 2/*m*2/*m*2/*m*) exhibit the same second-rank tensor symmetry.

The more the physical symmetry approximates the crystallographic symmetry, the higher the rank of its tensor. For example, in cubic crystals tensor properties of second rank are isotropic, whereas fourth-rank tensors (e.g., linear elasticity) are not isotropic; they exhibit cubic crystallographic symmetry. For hexagonal crystals, on the other hand, the sixfold axis is still a continuous rotation axis also for fourth-rank tensors.

Tensors of Odd Rank

Physical properties represented by odd-rank tensors are of particular importance for technological applications. Pyroelectricity and piezoelectricity under hydrostatic pressure are properties of first rank, represented by maximally three independent coefficients (i.e., by a vector). Important third-rank properties are piezoelectricity (under general stress), optical second-harmonic generation, and linear electrooptics. Odd-rank tensors are subject to strong constraints by symmetry, in particular by an inversion center which renders all tensor components zero, that is, properties of odd rank do not exist in centrosymmetric crystals.

Pyroelectricity and ferroelectricity Pyroelectricity originates from a permanent electric dipole moment of the unit cell of the crystal structure or, in macroscopic terms, from an intrinsic ("spontaneous") electrical polarization. This polarization is changed by heating and cooling, thus giving rise to electric charges on certain crystal faces.

In a crystal, a spontaneous polarization can be present only along a polar direction which has no

symmetrically equivalent directions. (In the literature, the condition for the occurrence of pyroelectricity is frequently expressed as "a unique (or singular) polar axis." This term, however, is misleading for point groups *m* and 1.) Such polar directions occur in the following ten ("pyroelectric") point groups: 6, 4, 3, 2, 1, and their combination with a "parallel" mirror plane: *6mm*, *4mm*, *3m*, *mm2*, *m* (**Table 5**). In point groups with a rotation axis, the electric polarization ("pyroelectric vector" $\boldsymbol{p}$) is fixed parallel to this polar axis. For point group *m*, the pyroelectric vector $\boldsymbol{p}$ is oriented parallel to the mirror plane, and for point group 1 any direction of $\boldsymbol{p}$ is possible.

A polar crystal is ferroelectric if the direction of the spontaneous polarization can be reversed ("switched") by an electric field, leading to a hysteresis behavior. Thus, ferroelectricity can only occur in the ten pyroelectric point groups.

Piezoelectricity Among the third-rank property tensors, piezoelectrity and its converse effect, the piezoelectric strain ("linear electrostriction"), are the most important properties for technological applications (pressure sensors, resonators, etc.). Well-known examples are single crystals of quartz (SiO_2) and textured ("poled") ceramics of barium titanate ($BaTiO_3$). Of similar significance are, nowadays, the third-rank tensors of optical second-harmonic generation (for optical frequency doubling, for example, potassium dihydrogen phosphate, KDP) and of linear electrooptics (Pockels effect) (for light modulation, e.g., KDP).

Third-rank properties occur in all noncentrosymmetric crystal classes, except for the cubic class 432, where the combination of three perpendicular equivalent fourfold axes causes all tensor components to vanish. The combination of three equivalent twofold axes, present in the two cubic classes 23 and $\bar{4}3m$, however, still admits one independent nonzero component. The tensor is the same for both classes and exhibits the symmetry $\bar{4}3m$ (**Table 5**).

Piezoelectricity under hydrostatic pressure is possible only in the ten pyroelectric crystal classes (see **Table 5**). An example for use of this effect for pressure sensors (e.g., formerly for submarines) is provided by $Li_2SO_4 \cdot H_2O$ (point group 2) single crystals.

Enantiomorphism and Optical Activity (Optical Gyration)

Enantiomorphism is a qualitative property stating that an object (molecule, crystal) may have a right- and a left-handed ("mirror image") form or structure. This feature requires the absence of any "hand-changing" operation ($\det \boldsymbol{W} = -1$), such as a reflection or rotoinversion (including the inversion $\bar{1}$). Thus, only the 11 non-centrosymmetric crystal classes containing only proper rotations ($\det \boldsymbol{W} = +1$) allow enantiomorphism (**Table 5**). Enantiomorphism, of course, is also possible in noncrystallographic symmetry groups without mirror planes and rotoinversion axes.

Optical gyration is described by a second-rank tensor, but in contrast to the polar tensors of second rank shown in **Table 4**, it has an axial character, that is, it exhibits the features of a screw. Thus, the components of the axial gyration tensor change their signs if the handedness of the coordinate system is changed from right to left, and vice versa. Consequently, the invariance condition for tensor components g_{ij} under symmetry transformations, as described in the section "Definition of tensor symmetry" for polar tensors, has to be modified as follows: for all "hand-changing" symmetry operations $\boldsymbol{W}$ (i.e., $\det \boldsymbol{W} = -1$), the transformed components $\tilde{g}_{ij}$ must equal their negative counterparts: $\tilde{g}_{ij} = (-1)g_{ij}$. From this, it follows directly that optical activity is forbidden in all centrosymmetric crystal classes. For proper rotations which preserve the handedness, a change of sign does not occur. Thus, all symmetry groups allowing enantiomorphism also permit optical activity. Crystals belonging to one of the enantiomorphic crystal classes may occur in two forms, either left- or right-handed, which exhibit opposite senses of rotation of the plane of polarization. A well-known example is provided by quartz SiO_2 (enantiomorphic crystal class 32), which crystallizes in a right- and a left-hand form with opposite senses of optical activity.

In addition to the 11 enantiomorphic crystal classes, there are four nonenantiomorphic classes exhibiting optical activity: *m*, *mm2*, $\bar{4}$, $\bar{4}2m$. In these cases, optical activity does not occur for all directions of light propagation, viz. not those parallel to the $\bar{4}$ axis and parallel or normal to the mirror plane *m*. All other propagation directions exhibit activity, whereby directions symmetrical with respect to $\bar{4}$ and *m* show opposite rotation senses. Thus, the four symmetry groups above show both (right and left) rotation senses in one and the same crystal.

The optical activity is isotropic in cubic crystals, as it is in optically active liquids (e.g., in solutions of dextro- or levo-sugar). In this case, the symmetry of the optical activity is described by the noncentrosymmetric sphere group $\infty\infty(2\infty)$. Geometrically, this symmetry group can be represented by a (right- or left-hand) rotating sphere or by a sphere which is densely covered with either right- or left-hand swirls.

Curie's Principle

Until now the symmetry group $\mathcal{G}_P$ of physical properties of a "free" macroscopic crystal *C* with point

group $\mathcal{G}_C$ was discussed. Now, the symmetry $\mathcal{G}_{CF}$ of a crystal C which is subject to an external influence F, for example, to an electric field, to uniaxial stress, to temperature changes, etc., is considered. For this treatment, point-group symmetries $\mathcal{G}_F$ of the external influences (Curie groups) are defined as follows:

1. Homogeneous electric field $\boldsymbol{E}$: ∞m (polar continuous rotation axis with "parallel" mirror planes, that is, symmetry of a stationary cone). Note that a rotating cone (left- or right-hand) represents geometrically the polar enantiomorphous group ∞; a stationary cone represents the polar group ∞m with "vertical" mirror planes.
2. Homogeneous magnetic field $\boldsymbol{H}$: ∞/m (symmetry of a rotating cylinder).
3. Uniaxial stress σ_{ii}: $\infty/m\ 2/m$ (symmetry of a stationary centrosymmetric cylinder).
4. Temperature change ΔT or hydrostatic pressure $-\sigma$ (scalars): $\infty\ \infty\ m$ (symmetry of a stationary centrosymmetric sphere).
5. Shear stress σ_{ij}: $2/m\ 2/m\ 2/m$ (orthorhombic).

According to Curie's principle of 1894, the point-group symmetry $\mathcal{G}_{CF}$ of the crystal under the external field is the intersection symmetry of the symmetry $\mathcal{G}_C$ of the crystal without field and the symmetry $\mathcal{G}_F$ of the field without crystal: $\mathcal{G}_{CF} = \mathcal{G}_C \cap \mathcal{G}_F$; that is, $\mathcal{G}_{CF}$ is a (proper or improper) subgroup of both groups $\mathcal{G}_C$ and $\mathcal{G}_F$.

As examples, consider the effect of an electric field ($\mathcal{G}_F = \infty m$) and a uniaxial stress ($\mathcal{G}_F = \infty/m\ 2/m$) along one of the (four) threefold rotoinversion axes $\bar{3}$ of cubic crystals with point groups $\mathcal{G}_C = 2/m\bar{3}$ and $\mathcal{G}_C = 4/m\bar{3}\,2/m$

- Electric field parallel [1 1 1]:

$$2/m\,\bar{3} \cap \infty m:$$
$$\mathcal{G}_{CF} = 3 \quad \text{along } [1\,1\,1]$$
$$\text{(pyroelectric, optically active)}$$

$$4/m\,\bar{3}\,2/m \cap \infty m:$$
$$\mathcal{G}_{CF} = 3m \quad \text{along } [1\,1\,1]$$
$$\text{(pyroelectric)}$$

- Uniaxial stress parallel [1 1 1]:

$$2/m\bar{3} \cap \infty/m\,2/m:$$
$$\mathcal{G}_{CF} = \bar{3} \text{ along } [1\,1\,1]$$
$$4/m\bar{3}\ 2/m \cap \infty/m\,2/m:$$
$$\mathcal{G}_{CF} = \bar{3}2/m \quad \text{along } [1\,1\,1]$$

Note that, in contrast to uniaxial stress, the electric field destroys centrosymmetry, leading to pyroelectricity and even optical gyration. The polarity and the gyration sense are reversed upon reversal of the electric field. If the electric field and the uniaxial stress were applied to an arbitrary (nonsymmetry) direction of the above cubic crystals, point groups 1 and $\bar{1}$ would result in the two cases.

If a scalar influence, which is represented by the centrosymmetric sphere group $\mathcal{G}_E$, for example, a temperature change ΔT, is applied to a crystal, its symmetry is not changed, $\mathcal{G}_{CF} = \mathcal{G}_C$, provided that no phase transition is induced. Nomenclature

e	neutral element, identity
F	external physical influence (external field) on a crystal
g_i	element of $\mathscr{G}$
$\mathscr{G}$	point group of a crystal
$\mathscr{H}$	subgroup
$[i]$	index of a subgroup or supergroup; number of orientation states of domains
$N(\mathscr{G}) = \lvert\mathscr{G}\rvert$	order of group $\mathscr{G}$
$\boldsymbol{p}$	electric polarization vector, pyroelectric vector
P	physical (tensor) property of a crystal
$\mathscr{P}$	symmetry group of the property P
W	(3×3) matrix of a point-group operation
σ_{ii}, σ_{ij}	uniaxial stress, shear stress
$-\sigma$	hydrostatic pressure

Polaritons

M Litinskaya, Institute of Spectroscopy, Troitsk, Russia

Introduction

Definition

By definition, polaritons are quasiparticles in a medium that form as a result of interaction and mixing of light with dipole active transitions of the medium. The classical theory of light waves in ionic crystals near optical phonon frequencies was proposed by K B Tolpygo and K Huang in the early 1950s. Later, the quantum theory of light waves near excitonic resonances and the concept of polaritons were developed in works by U Fano, J J Hopfield, and V M Agranovich.

Consider an electromagnetic wave propagating in a medium, and let the frequency of the wave be close to some resonance frequency of the medium. These frequencies are generally associated with some quasiparticles. They can be of electronic nature, such as Frenkel or Wannier–Mott excitons, or related to lattice vibrations, such as optical phonons in ionic crystals. The electromagnetic field polarizes the medium. The polarization, which is high near the resonance frequency, in turn influences the electromagnetic field. One can regard it as an interaction between the "bare" photon and "bare" medium excitation ("light–matter interaction"). When the interaction is strong enough, the excitation spectrum of the medium essentially changes. Near the resonance between the light mode and the mode of the medium excitation, their dispersion curves transform into two – the "lower" and the "upper" – split polaritonic branches showing anticrossing behavior. In other words, a gap of the size 2Δ, where Δ is the coupling strength defined below, opens in the excitation spectrum. This situation is referred to as the strong coupling regime. Roughly speaking, polaritons possess the properties of both "bare" photons and "bare" medium excitations. This mixed character of polaritons leads to many interesting physical properties.

Usually, one indicates the type of crystal excitations which participates in the formation of polaritons by adding prefixes: "exciton–polaritons," "plasmon–polaritons," and "optical phonon–polaritons." The quasiparticles, which appear as a result of interaction between an electromagnetic field and the resonances of magnetic permeability, are known as "magnetic polaritons."

Theoretical Approaches

Many of the physical processes concerning polaritons, as well as their dispersion law, can be described by means of the macroscopic (semiclassical) approach. It utilizes the system of Maxwell's equations for the fields in the medium. For spatially restricted systems, the problem must be supplemented by the fields outside the crystal and by proper boundary conditions. These equations must be combined with the material equation, which relates the fields $\boldsymbol{D}$ and $\boldsymbol{E}$ through the tensor of dielectric permeability $\varepsilon_{ij}(\omega, \boldsymbol{k})$. The tensor $\varepsilon_{ij}(\omega, \boldsymbol{k})$ can be obtained from the microscopic theory or from experiment. In an isotropic medium with the account of spatial dispersion,

$$\varepsilon_{ij}(\omega, \boldsymbol{k}) = \varepsilon_{\mathrm{t}}(\omega, k)\left(\delta_{ij} - \frac{k_i k_j}{k^2}\right) + \varepsilon_{\mathrm{l}}(\omega, k)\frac{k_i k_j}{k^2} \qquad [1]$$

where $\varepsilon_{\mathrm{t}}(\omega, k)$ and $\varepsilon_{\mathrm{l}}(\omega, k)$ are, respectively, transverse and longitudinal dielectric permeabilities, and δ_{ij} is the Kronecker symbol. The condition $\varepsilon_{\mathrm{l}}(\omega, k) = 0$ determines the dispersion $\omega = \omega_{\mathrm{l}}(k)$ of a longitudinal wave, which does not interact directly with the transverse photons. In turn, the poles $\omega = \omega_{\mathrm{t}}(k)$ of the function $\varepsilon_{\mathrm{t}}(\omega, k)$ determine the transversal "bare"

excitations of the medium. As shown below, polaritons are just the transverse normal modes in the medium near these frequencies. The macroscopic description is effective as far as the wavelength of light exceeds the lattice constant and the excitonic Bohr radius strongly.

In the framework of the microscopic (quantum) approach, polaritons appear as a result of the account of retardation. It is well-known that excitons are the excitations in a medium in the approximation when only the instantaneous Coulomb interaction between the molecules (or atoms) is taken into account (i.e., in the limit $c \to \infty$). The inclusion of retardation, as known from quantum electrodynamics, is equivalent to taking into account the interaction with a transverse electromagnetic field. Hence, polaritons appear as a result of interaction between excitons and transverse photons. Such a description can also be applied to low-dimensional structures (such as, a monolayer or a chain of molecules), when a dielectric tensor cannot be introduced and the macroscopic description is not valid. This approach utilizes the second-quantization formalism, and polaritons appear as a result of diagonalization of the full Hamiltonian of the crystal, which is a sum of Hamiltonians of "bare" transverse photons, "bare" excitons, and the Hamiltonian of their interaction. The total Hamiltonian can be diagonalized by operators that are linear combinations of the operators of "bare" photons and "bare" excitons. Near the resonance, these operators are of the form

$$\begin{aligned} \xi^{+}_{\boldsymbol{k},\rho} &= C^{(\rho)}_{\text{phot}}(k) a^{+}_{\boldsymbol{k}} + C^{(\rho)}_{\text{exc}}(k) B^{+}_{\boldsymbol{k}} \\ \xi_{\boldsymbol{k},\rho} &= C^{(\rho)*}_{\text{phot}}(k) a_{\boldsymbol{k}} + C^{(\rho)*}_{\text{exc}}(k) B_{\boldsymbol{k}} \end{aligned} \qquad [2]$$

where $a^{+}_{\boldsymbol{k}}$, $a_{\boldsymbol{k}}$ and $B^{+}_{\boldsymbol{k}}$, $B_{\boldsymbol{k}}$ are, respectively, the creation and annihilation operators of photons and excitons, and $\rho = \text{U}, \text{L}$ denote the upper or the lower polaritonic branch, respectively. The coefficients $C^{(\rho)}_{\text{phot}}(k)$ and $C^{(\rho)}_{\text{exc}}(k)$ define, respectively, the amplitudes of the photon and the exciton in the polaritonic states. Their squared modules give the weights of the "bare" excitations in the polaritonic states. With the change of the wave vector k, they vary between 0 and 1. At the resonance $|C^{(\text{U,L})}_{\text{phot}}(k_{\text{res}})|^2 = |C^{(\text{U,L})}_{\text{exc}}(k_{\text{res}})|^2 = 1/2$.

Within linear optics, these two approaches yield identical results, and the choice between them is just a matter of convenience. Quite often, a semiclassical (macroscopic) approach is used to calculate the optical response of a system. Quantum (microscopic) formalism describes polaritons as quasiparticles, and can be used to discuss the collective properties of polaritons and their statistics. It is convenient for a discussion on nonlinear processes, and allows one to describe the eigenfunctions of the crystal (in particular, the polaritonic vacuum state is not equivalent to an independent-particle vacuum).

When Strong-Coupling Regime Is Destroyed

The strong-coupling regime can be destroyed by different dephasing processes. Many of them (such as, exciton–phonon interactions and scattering by sample disorder) influence polaritons through their excitonic components. In semiconductor microcavities, the lifetime of polaritons is also restricted by the finite lifetime of the cavity photon within the cavity due to a finite transmission of the cavity mirrors. Roughly, the strong-coupling regime holds when the exciton–photon coupling strength Δ is larger than all the involved dephasing rates of polaritons. If this condition is violated, the system is in a so-called weak-coupling regime, when the gap in the spectrum of elementary excitations does not form.

The role of phonons can be diminished by decreasing the temperature. One can say, for instance, that in good GaAs crystals, the strong-coupling regime holds below 20 K in bulk, and below 70 K in microcavities.

Disorder appears as impurities in bulk crystals, and interface roughnesses and/or alloy fluctuations for cavity and surface polaritons. Bulk polaritons are very sensitive to the disorder. In turn, in state-of-the-art nanostructures, the role of disorder can be brought almost to nothing. The main effect of disorder is that it introduces local excitonic levels, which trap polaritonic states and eventually destroys them.

Polaritons in Bulk

Dispersion Equation

In the framework of the macroscopic approach, the dispersion equation for polaritons in a bulk medium can be obtained by solving the wave equation for the fields $\boldsymbol{D}$ and $\boldsymbol{E}$:

$$\Delta \boldsymbol{E} + \frac{\omega^2}{c^2} \boldsymbol{D} - \text{grad div } \boldsymbol{E} = 0 \qquad [3]$$

combined with the material equation. In an isotropic medium, neglecting dissipation, the dielectric permeability $\varepsilon_{\text{t}}(\omega, k)$ is

$$\varepsilon_{\text{t}}(\omega, k) = \varepsilon_{\text{b}} + \frac{A}{\omega^2_{\text{t}}(k) - \omega^2} \qquad [4]$$

where ε_{b} is the background dielectric constant, and A is proportional to the oscillator strength f_{osc} of the transition. Omitting the resonance term yields "bare" photon approximation. Further, $\omega_{\text{t}}(k)$ is the dispersion of the crystal excitation, which, for small k, can

be written in the effective-mass approximation:

$$\omega_t(k) = \omega_t + \frac{\hbar k^2}{2m_t}, \quad \omega_t \equiv \omega_t(k=0) \qquad [5]$$

Here, m_t is the effective mass of the excitation, and it determines the curvature of the exciton dispersion. If the dependence of the dielectric permeability on the wave vector (i.e., spatial dispersion) is neglected, then $\omega_t(k) = \omega_t$ and $\varepsilon_t(\omega, k) \equiv \varepsilon(\omega)$. This usually applies to optical phonon–polaritons and some of Frenkel exciton–polaritons, while for Wannier–Mott exciton–polaritons, the dependence of $\varepsilon_t(\omega, k)$ on k is usually important.

In an infinite isotropic medium, the wave eqn [3] has three solutions. One is a longitudinal wave, and its dispersion law $\omega = \omega_l(k)$ is determined by $\varepsilon_l(\omega, k)$. In addition, there are two twice-degenerate (corresponding to two possible polarizations) transverse waves, which are polaritons. Their dispersion law can be found from the equation

$$\frac{c^2k^2}{\omega^2} = \varepsilon_t(\omega, k) = \varepsilon_b + \frac{A}{\omega_t^2(k) - \omega^2} \qquad [6]$$

Solving this equation for $\omega \sim \omega_t$, one finds

$$(\omega - \omega_{phot}(k))(\omega - \omega_t(k)) = \Delta^2 \qquad [7]$$

where $\Delta = \sqrt{A/(4\varepsilon_b)} \propto \sqrt{f_{osc}}$ is the coupling strength, and $\omega_{phot}(k) = ck/\sqrt{\varepsilon_b}$ is the photon dispersion in the bulk. Near the resonance (i.e., for $\omega \sim \omega_t(k) \approx \omega_{phot}(k)$), the polaritonic branches split. The smallest separation between them is at the resonance, and is equal to 2Δ. Far from the resonance, the polaritonic effect is usually not important, and polaritonic dispersion curves tend to that of the photon and the exciton. The solutions of [7] $\omega = \omega_{U,L}(k)$ are

$$\omega_{U,L}(k) = \frac{1}{2}\left[\omega_{phot}(k) + \omega_t(k) \pm \sqrt{(\omega_{phot}(k) - \omega_t(k))^2 + 4\Delta^2}\right] \qquad [8]$$

The dispersion curves of bulk excitations (including the longitudinal wave, which does not couple to light) are plotted in **Figure 1** ((**a**) without and (**b**) with spatial dispersion).

The dispersion of bulk exciton–polaritons has been measured for many semiconductors (such as, CuCl, GaAs, CdS) in a variety of optical experiments (for instance, two-photon absorption measured at different angles or hyper-Raman scattering measurements).

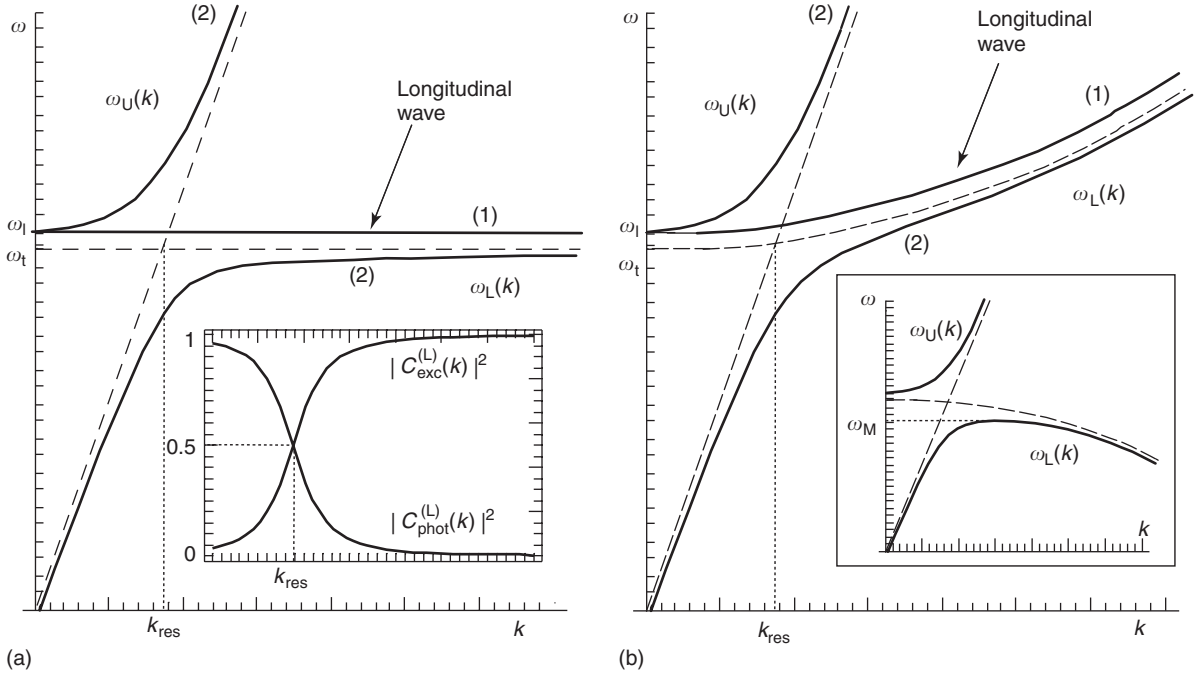

Figure 1 Dispersion of bulk polaritons and of the longitudinal wave (solid lines). The numbers in brackets show the degeneracy of each mode. Dashed lines correspond to the dispersions of "bare" photon and "bare" transverse exciton. (a) Spatial dispersion is neglected. The inset shows the dependence on the wave vector of the exciton and photon weight coefficients $|C_{exc}^{(L)}(k)|^2$ and $|C_{phot}^{(L)}(k)|^2$ defined in eqn [2] for the lower branch. (b) Spatial dispersion is taken into account, and $m_t > 0$, $m_l > 0$. The inset shows the spectrum of transverse waves for $m_t < 0$.

Anisotropic Media

The properties of polaritons in anisotropic crystals (e.g., organic crystals) are determined by the structure of the dielectric tensor $\varepsilon_{ik}(\omega, \boldsymbol{k})$ (see [1]), which relates the fields as

$$D_i(\omega, \boldsymbol{k}) = \varepsilon_{ik}(\omega, \boldsymbol{k}) E_k(\omega, \boldsymbol{k})$$

Then the equation analogous to [6], which yields the dispersion of polaritons $\omega = \omega(k)$, can be obtained from the zeros of the following determinant:

$$\left| \frac{\omega^2}{c^2} \varepsilon_{ik}(\omega, \boldsymbol{k}) - k^2 \delta_{ik} + k_i k_k \right| = 0 \qquad [9]$$

For an arbitrary direction of the wave vector $\boldsymbol{k}$, polaritons in anisotropic crystals have a mixed longitudinal–transverse character.

Spatial Dispersion and Additional Waves

Spatial dispersion is a result of the ability of excitations to propagate in the crystal due to internal interaction forces. As mentioned already, it results in the dependence of dielectric permeability on the wave vector.

If spatial dispersion is neglected, then there are no bulk waves in the interval $\omega_t < \omega < \omega_l = \omega_l(0)$, and for every other frequency, there exists only one propagating bulk wave (see **Figure 1a**).

Spatial dispersion results in the appearance of the so-called "additional waves" (waves with the same energy $\hbar\omega$, but different wave vectors $k(\omega)$), first noticed by S I Pekar. Near a resonance, it is enough to take into account the dispersion of the excitonic resonance, as it is done in [5] for an isotropic medium. Then the curve $\omega_t(k)$ bends up or down, depending on the sign of m_t. The curve $\omega_l(k)$ also bends depending on the sign of the effective mass m_l of the longitudinal exciton, since in the general case, $m_l \neq m_t$. Several examples are given below. First, in an isotropic nongyrotropic medium with $m_t > 0$, for $\omega > \omega_l$, there exist two propagating transverse waves, which are the lower and the upper polaritons (see **Figure 1b**). In the "forbidden" region ($\omega_t < \omega < \omega_l$), there appears a state of the lower polaritonic branch. In **Figure 1b**, m_l is also positive, that is typical for inorganic semiconductors. Then, for $\omega > \omega_l$, the longitudinal wave also exists. Second, if $m_t < 0$, as it is in some molecular crystals, there exist two propagating transverse waves (both are lower-branch polaritons) for $\omega < \omega_M < \omega_t$ (see the inset in **Figure 1b**). As regards the longitudinal wave, if $m_l > 0$, then it exists for $\omega > \omega_l$, together with the upper polaritonic branch, and if $m_l < 0$, then the longitudinal wave is the third wave for $\omega < \omega_M$, and it is the only one wave for $\omega_M < \omega < \omega_l$. Third, in a cubic gyrotropic crystal, the dispersion curve of the exciton splits into two branches with linear dispersion: $\omega_t(k) = \omega_t \pm \alpha k + O(k^2)$. The corresponding polaritonic spectrum with three propagating waves for $\omega < \omega_G < \omega_t$ and one propagating wave for $\omega > \omega_G$ is shown in **Figure 2**.

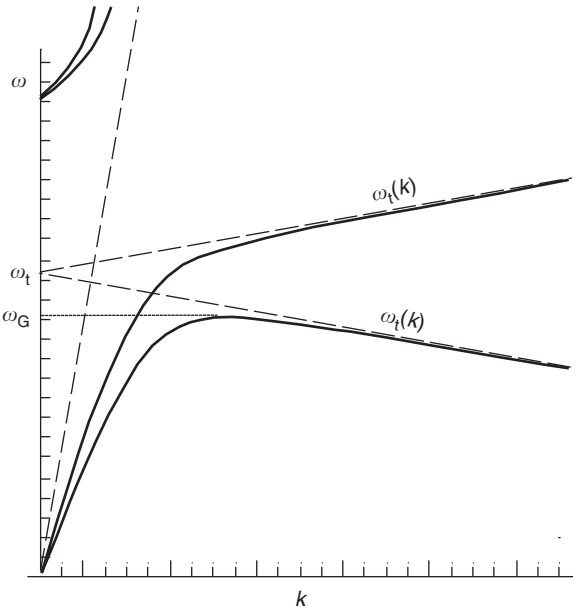

Figure 2 Dispersion of bulk polaritons (thick solid lines) in a gyrotropic cubic crystal. Dashed lines show the dispersion of "bare" excitons and "bare" photon.

For spatially restricted media (e.g., when calculating reflectance of a bulk crystal) at the frequencies where the additional waves exist, one has to introduce the so-called additional boundary conditions (ABCs), since the usual Maxwell's boundary conditions are not sufficient to find the relation between the amplitudes of the waves. From a microscopic point of view, ABCs describe the behavior of the fields close to the surface. The character of ABCs essentially depends on the properties of the medium, its surface, and on the properties of excitons. In the most general case, in the framework of linear optics, ABCs are constructed as some linear combinations of the fields $\boldsymbol{E}$, $\boldsymbol{P}$, and their derivatives. The first ABC proposed by S I Pekar is $\boldsymbol{P} = 0$ at the boundary of the medium. It is good for molecular crystals, but is often suitable for semiconductors also. A widely used approach proposed by J J Hopfield and D G Thomas introduces a "dead layer" of some thickness l near the surface, where excitons cannot penetrate. The thickness l and other phenomenological constants entering ABCs are to be determined from a microscopic theory or from comparison with experiment.

Surface Polaritons

In a medium with a surface, specific surface states, known as surface polaritons, exist in certain (ω, k) regions. Surface polaritons are normal modes that propagate along the medium surface (or along an interface between two media, or along interfaces of layered structures). The electromagnetic field in these modes decays exponentially with the distance from the surface. It will be shown below that surface polaritons are usual solutions of Maxwell's equations applied to the case when the dielectric permeability is negative (the situation realizable near a resonance frequency of the medium). Surface polaritons yield information on the surface of the crystal. They may also be important as possible final states in the different processes of interaction of electromagnetic waves in crystals.

Surface Polaritons at the Interface between Two Semi-Infinite Media

Let a semi-infinite isotropic medium with the dielectric permeability $\varepsilon(\omega)$ (spatial dispersion is neglected) be contiguous with an isotropic half-space with dielectric constant ε_{out}. Let $\boldsymbol{k}_{\parallel}$ be a two-dimensional wave vector parallel to the surface. The surface mode is TM-polarized (see the inset in **Figure 3**) and has the following dispersion relation:

$$\frac{\varepsilon(\omega)}{\sqrt{k_{\parallel}^2 - \omega^2\varepsilon(\omega)/c^2}} = -\frac{\varepsilon_{\text{out}}}{\sqrt{k_{\parallel}^2 - \omega^2\varepsilon_{\text{out}}/c^2}} \quad [10]$$

For $\varepsilon_{\text{out}} > 0$, the dispersion equation of surface polaritons has solutions only if $\varepsilon(\omega) < 0$. The dispersion equation can be rewritten in a more convenient form:

$$k_{\parallel}^2 = \frac{\omega^2}{c^2}\frac{\varepsilon(\omega)\varepsilon_{\text{out}}}{\varepsilon(\omega) + \varepsilon_{\text{out}}} \quad [11]$$

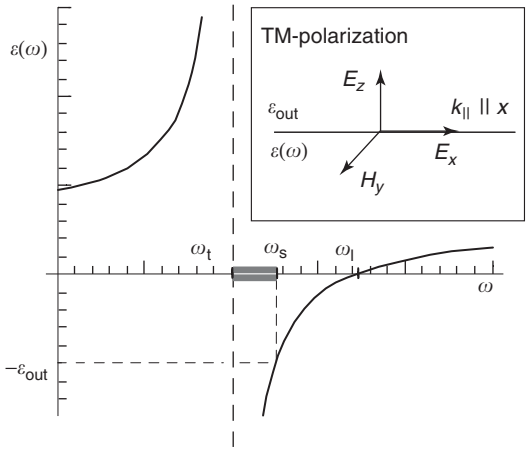

Figure 3 A graph of the function $\varepsilon(\omega)$. The frequencies marked in gray correspond to the interval of existence of surface polaritons at the interface with a material with a dielectric constant ε_{out}.

From here, it is seen that the permissible interval of the surface polariton frequencies is more narrow, since for real $k_{\parallel}$ and negative dielectric permeability, $\varepsilon(\omega)$, in fact, must be less than $-\varepsilon_{\text{out}}$. Let ω_S denote the upper boundary of the existence of surface polaritons: $\varepsilon(\omega_S) = -\varepsilon_{\text{out}}$. When ε_{out} approaches ε_b, $\omega_S \to \omega_l$. For a dielectric material, the function $\varepsilon(\omega)$ is given by [4]; it is shown in **Figure 3**, and the frequency interval where a surface polariton exists is marked in gray. For a metal, when $\varepsilon(\omega) = 1 - \omega_p^2/\omega^2$ (ω_p is the plasma frequency), surface plasmon–polariton exists for $0 < \omega < \omega_p/\sqrt{1 + \varepsilon_{\text{out}}}$.

Figure 4a shows the dispersion of surface polaritons without spatial dispersion. The thin dashed line shows the dispersion of light outside the crystal (propagating parallel to the crystal surface), and the thick dashed lines show bulk polariton dispersion curves. All these dispersion curves do not intersect with the dispersion curve of the surface polariton, hence surface polaritons cannot be excited by an incident photon (or, once excited, cannot transform into bulk polaritons or leave the crystal as photons) – the laws of conservation of energy and wave vector cannot be simultaneously fulfilled for such processes. To excite surface polaritons, one has to make use of a prism (attenuated total-reflection technique) or a grating on the crystal surface. Surface polaritons have been seen as dips in the total reflection of TM-polarized light in many such experiments.

Spatial dispersion complicates the problem, because then a lower "bulk" polariton appears for large wave vectors in the frequency interval where a surface polariton exists (see **Figure 4b**). As discussed above, it requires introduction of ABCs, which mix surface polaritons with bulk lower polaritons. The mixing leads to leakage of the energy of the surface wave into the interior of the crystal, providing a new (nonradiative and nondissipative) damping mechanism for surface polaritons.

Surface Polaritons in Presence of a Transition Layer

The presence of a surface transition layer can essentially alter the dispersion of surface polaritons. The transition layer may be either natural or artificial (a thin film on a substrate). As shown by V M Agranovich and A G Mal'shukov, if an oscillation in the layer is resonant with the surface polariton, a gap with a magnitude Δ_S opens in the surface polariton spectrum. This is similar to what happens to bulk electromagnetic waves near the resonance frequency with the difference that both, the excitation

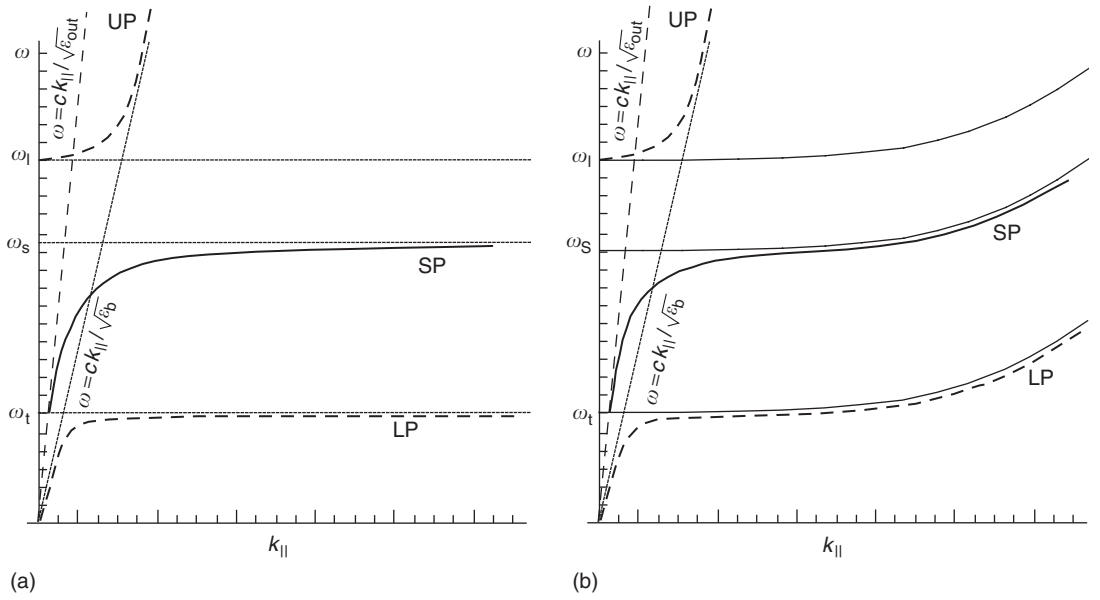

Figure 4 Dispersion of surface polariton (solid line) at an interface between a resonant isotropic crystal with dielectric function $\varepsilon(\omega)$ and an isotropic material with a dielectric constant ε_{out} (a) without and (b) with spatial dispersion. The thick dashed lines show the dispersions of bulk polaritons, and the thin dashed line shows the dispersion of the photon outside of the crystal. UP, LP, and SP denote, respectively, the upper, lower, and the surface polariton branches.

in the layer and the surface electromagnetic wave, have a two-dimensional character. While usually the effects of a thin layer are of the order of $d/\lambda \ll 1$ (d is the layer thickness, λ is the wavelength of the light), here $\Delta_S \propto \sqrt{d/\lambda} \gg d/\lambda$, and therefore the gap had been observed in a number of experiments, both in the infrared spectral region and in the spectral region of electronic transitions.

Polaritons in Nanostructures with Reduced Dimensionality

From the above discussion, it follows that in bulk crystals the interaction of excitons with an electromagnetic field does not give rise to radiative decay of the exciton. Instead, the energy oscillates back and forth between exciton and photon states, and there is no radiative decay. It happens because the total wave vector conserves (an exciton with a given wave vector interacts with only one photon with the same wave vector) and there is no density of states for radiative decay.

Another situation occurs in two- and one-dimensional (1D) crystals, where an exciton has less degrees of freedom than a photon. As noted by V M Agranovich and O A Dubovsky, in such crystals the radiative decay is restored, since in these cases only two or one of the components of the total wave vector, respectively, are conserved.

Consider polaritonic effects in quasi-2D quantum wells and quasi-1D quantum wires described elsewhere in this encyclopedia. The translation symmetry is preserved (and, consequently, the wave vector $\boldsymbol{k}_{||}$ of the exciton is a good quantum number) only in the plane of the quantum well in the first case, and only along the quantum wire in the second case. The component of the total wave vector perpendicular to $\boldsymbol{k}_{||}$ is denoted by $\boldsymbol{k}_{\perp}$. Photons are 3D, as before.

There are two kinds of states. Consider first the states with small values of the wave vector $k_{||} < k_0 \equiv \omega\sqrt{\varepsilon_b}/c$. They are degenerate with photons and can decay into them. One can regard it as a coupling of an exciton with a wave vector $\boldsymbol{k}_{||}$ with photons with the same component $\boldsymbol{k}_{||}$ parallel to the quantum well or the quantum wire, but with all possible values of $\boldsymbol{k}_{\perp}$. These photons act as a dissipative bath, and instead of forming stable states similar to polaritons in bulk, the exciton decays irreversibly.

The corresponding radiative lifetimes can be calculated treating exciton–light coupling as a perturbation. For Frenkel exciton–polaritons, the decay times in 1D and 2D are, respectively, $\tau_{1D}^{(F)} \sim (2\pi a/\lambda)\tau_0, \tau_{2D}^{(F)} \sim (2\pi a/\lambda)^2\tau_0$, where $\tau_0 \sim 10^{-9}$–10^{-8} s is the radiative lifetime of the excitation of an isolated molecule, and a is the lattice constant (i.e., the radiative decay is enhanced proportionally to the number of molecules within the wavelength of light, λ). The radiative lifetime of exciton–polaritons in 2D is then $\sim 10^{-12}$ s, and such "superradiant decay"

had been observed in anthracene. For Wannier–Mott exciton–polaritons, the lifetime of 2D exciton–polariton for $k_{\|}=0$ was found to be $\tau_{2D}^{(WM)} = m_t c\sqrt{\varepsilon_b}/(2\pi e^2 f_{osc})$. For ideal situations, such as in GaAs, it is $\sim$10 ps. The account of the effects of thermalization and disorder-induced partial localization of polaritons considerably complicates the picture both in 1D and 2D cases.

For $k_{\|} > k_0$, the modes are nonradiative. In quantum wells, to some extent, they are similar to surface polaritons, since the electromagnetic field in them decays exponentially outside of the quantum-well plane. Similarly, the propagating modes can be excited using a prism or with surface gratings. Radiative polaritons with $k_{\|} < k_0$ can be excited directly by incident light and have been observed in many semiconductor nanostructures in absorption, photoluminescence, and reflectivity spectra.

Cavity Polaritons

In multilayered nanostructures called semiconductor microcavities, both excitons and photons have a 2D character. The interaction between them leads to formation of states similar to bulk polaritons known as cavity polaritons. These states are stable in the sense that the exciton with a given 2D wave vector $\boldsymbol{k}_{\|}$ interacts with only one cavity photon with the same $\boldsymbol{k}_{\|}$, and the energy oscillates back and forth between these states. In other words, in contrast to the nanostructures where photons are 3D, there is no density of states for the radiative decay of the exciton. After several oscillations, light waves escape the cavity due to a finite transmission of the cavity mirrors. Cavity polaritons had, for the first time, been observed by C Weisbuch, M Nishioka, A Ishikawa, and Y Arakawa. The important difference with bulk polaritons is, first, that as result of a reduction of the excitonic Bohr radius due to the confinement, both the oscillator strength and the binding energy of the exciton are enhanced. As a consequence, Wannier–Mott exciton–polaritons become considerably more stable than in the bulk. Second, lower polaritons have a finite energy at vanishing $k_{\|}$, and this lowest-energy state may, in principle, work as a "trap" for relaxing polaritons.

The properties of cavity polaritons are discussed below in the context of well-investigated examples of isotropic inorganic material, such as, GaAs. However, exciton–polaritons in organic microcavities have recently attracted attention due to their large oscillator strengths (and, consequently, very large values of the splitting Δ at room temperature) in some of these materials.

The dispersion equation of cavity polaritons can be accurately obtained from Maxwell's equations with the help of the transfer-matrix method, which relates the transmission and reflectance at each interface of the layered structure. Near the resonance, one obtains the dispersion equation of the type [7] with solutions similar to [8], with the energies of "bare" exciton and photon dependent on the in-plane wave vector $k_{\|}$. A significant difference arises for the cavity photon dispersion, since the perpendicular component of its total wave vector is fixed by the boundary conditions at the microcavity mirrors, leading to parabolic (for small $k_{\|}$) dispersion of the cavity photon:

$$\omega_{phot}(k_{\|}) = \omega_c + \frac{\hbar k_{\|}^2}{2\mu} \qquad [12]$$

where $\omega_c \equiv \omega_{phot}(0) = \pi c/(L_c\sqrt{\varepsilon_b})$, L_c is the microcavity thickness, and $\mu = \pi\hbar\sqrt{\varepsilon_b}/(cL_c)$ is its effective mass, which is very small ($\sim 10^{-5} m_e$, m_e is the electron mass). The dispersion curves of cavity polaritons are plotted in **Figure 5**.

The detuning between the cavity photon and quantum-well exciton $u = \omega_c - \omega_t$ determines the ratio between exciton and photon weights in the polaritonic states for each $k_{\|}$. The value of detuning is determined by the cavity thickness and, due to a wedge-shaped microcavity profile, can be varied in experiments.

The relaxation of polaritons into the ground state $\omega_L(0)$ is impeded due to the so-called bottleneck effect observed in photoluminescence experiments. Polaritons gather near the "knee" at the lower polariton dispersion curve just below the exciton energy (near the point A in **Figure 5**), since there the acoustic

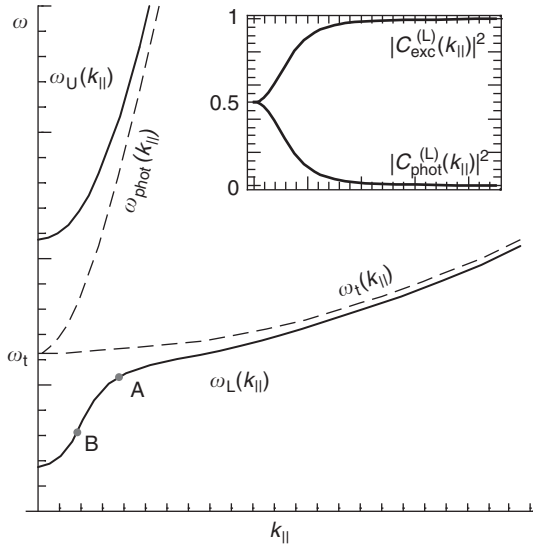

Figure 5 Dispersion of cavity polaritons (solid lines) for zero detuning. Dashed lines correspond to the dispersions of "bare" photon and "bare" exciton. The inset shows the dependence on the wave vector of the exciton and photon weight coefficients $|C_{exc}^{(L)}(k_{\|})|^2$ and $|C_{phot}^{(L)}(k_{\|})|^2$ defined in eqn [2] for the lower branch.

phonon-assisted relaxation is not effective due to an abrupt decrease of the density of final states. Qualitatively, at this point lower-branch polaritons change their character from exciton-like to photon-like, which essentially impedes the relaxation.

Much attention at the moment is devoted to the possibility of collecting a macroscopic number of polaritons in $\omega_L(0)$ state, exploiting the bosonic nature of cavity polaritons. Bosonic effects have manifested themselves in the experiments on stimulated scattering of cavity polaritons. In these experiments, lower-branch polaritons were excited resonantly near the inflection point of their dispersion curve (point B in **Figure 5**). A convex–concave character of the dispersion curve at this point allows the polariton–polariton scattering process, when one polariton is scattered into the state with $k_{\|} = 0$ ("signal"), and one is scattered to a higher-energy state ("idler"). A weak stimulation of $k_{\|} = 0$ state by a probe beam leads to a giant ($\sim$100-fold) amplification of the "signal" due to the fact that the scattering rate of bosons is proportional to $n_i(1 + n_f)$, where n_i and n_f denote, respectively, the populations of the initial and final states. It suggests a tempting possibility of Bose–Einstein condensation or Kosterlitz–Thouless transition to the superfluid phase of cavity polaritons.

Polarizabilities

K Cho, Osaka University, Osaka, Japan

Introduction

Electromagnetic (EM) field in the presence of a matter is described by the Maxwell equations with the source terms of charge and current densities. One of the components of the current density is the time derivative of polarization, which plays a central role in the optical response of matter. The charge and current densities to be used in the Maxwell equations should be determined from the motion of the matter system in the EM field. This means that the motions of EM field and matter should, in principle, be determined self-consistently, as explicitly done usually in quantum electrodynamics.

A conventional way to avoid the tedious process of self-consistent solution was invented in the macroscopic theory of optical (or EM) response, where a polarizability constant was assigned to each material as a parameter, describing the induced polarization as a function of the incident EM field. This has allowed an easy access to the solution of the Maxwell equations in a matter system. Namely,

one looks for a solution in each part of the material with the same polarizability, and then, these solutions are connected with one another via the so-called Maxwell boundary conditions (the continuity of the normal or tangential components of EM field across a surface/interface). This determines the response of matter to an incident EM field uniquely. Another name also used for polarizability is "electric susceptibility."

Polarizability can be calculated quantum mechanically by evaluating the induced polarization from $\mathrm{Trace}\{\rho_{\mathrm{M}}\hat{\boldsymbol{P}}\}$ in the presence of an incident EM field, where ρ_{M} is the density matrix of the matter and $\hat{\boldsymbol{P}}$ the polarization (or dipole density) operator. In the semiclassical framework, an EM field is treated as a c-number, and the induced polarization defined above is usually chosen as a c-number of the matter side, to be related with the EM field. The optical processes to be covered by such a description include reflection, absorption, transmission, refraction, diffraction of macroscopic scale, and various nonlinear processes. However, in optical processes where the matter states are different before and after the process, such as Raman scattering or luminescence, one needs a more detailed treatment of induced polarization, such as the transition polarizability introduced by Born and Huang.

Macroscopic Polarizability

In macroscopic (local) theory of optical response, the polarizability relates a source electric field $\boldsymbol{E}(\boldsymbol{r},\omega)$ with the induced polarization $\boldsymbol{P}(\boldsymbol{r},\omega)$ of a matter as

$$\begin{aligned} P_\xi(\boldsymbol{r},\omega) = {} & \varepsilon_0 \sum_\eta \bar{\chi}^{(1)}_{\xi,\eta}(\omega) E_\eta(\boldsymbol{r},\omega) \\ & + \varepsilon_0 \sum_\eta \sum_\zeta \bar{\chi}^{(2)}_{\xi,\eta,\zeta}(\omega',\omega'') \\ & \times E_\eta(\boldsymbol{r},\omega') E_\zeta(\boldsymbol{r},\omega'')|_{\omega'+\omega''=\omega} \\ & + \cdots \end{aligned} \qquad [1]$$

where $\boldsymbol{r}$ and ω are position and frequency, respectively, (ξ,η) stand for the Cartesian coordinates, ε_0 the dielectric constant of vacuum, and $\bar{\chi}^{(N)}$ the polarizability of the Nth-order process. These $\{\bar{\chi}^{(N)}\}$ are tensor quantities because they give relationships between different vectors. $N=1$ corresponds to a linear process, and $N=2$, 3, etc. to the nonlinear ones of the second-, third-order, etc., respectively.

These polarizabilities are allowed to have dependence, not on position, but on frequencies, within the framework of macroscopic response. A typical way leading to the frequency dependence is the so-called Lorentz oscillator model, which regards matter as an assembly of charged oscillators. Using a model of "damped harmonic oscillator in a vibrating force" of classical mechanics, one can derive a simple expression of the frequency dependence of, for example, linear polarizability as

$$\bar{\chi}^{(1)}(\omega) = \frac{N_0 Q^2}{M} \frac{1}{\omega_0^2 - \omega^2 - \mathrm{i}\gamma\omega} \qquad [2]$$

where N_0, Q, M, ω_0, and γ are the number density, charge, mass, resonant frequency, and the damping parameter, respectively, of the oscillators. By appropriately choosing these parameters for a given material, one can rather well describe the ω-dependence of the optical spectrum. This is because the ω-dependence of $\bar{\chi}^{(1)}(\omega)$, apart from the parameter values, is essentially correct in comparison with the quantum mechanically calculated polarizability, as shown below. For a given material, there can be many different types of oscillators with different parameters.

The frequency ω_0 corresponds to the excitation energy of the matter, so that there are infinitely many of them in general. For an optical process near a resonance, it is often the case that this particular one is treated as a Lorentz oscillator explicitly and all the others as a frequency-independent background medium. Thus, the $\bar{\chi}^{(1)}$ to be used in such a treatment is the resonant term [2] plus a constant background polarizability χ_{b}. The idea of introducing background medium is a kind of "wisdom" to circumvent the tremendous complexity arising from the infinite number of freedom.

Microscopic Polarizability

Polarizabilities can be calculated quantum mechanically by evaluating the induced polarization as a functional of source electric field via a time-dependent perturbation calculation with respect to the light–matter interaction. If one does it properly, there arises a peculiarity of the microscopic response, namely, a nonlocal relationship between $\boldsymbol{P}$ and $\boldsymbol{E}$ as

$$\begin{aligned} P_\xi(\boldsymbol{r},\omega) = {} & \varepsilon_0 \sum_\eta \int \mathrm{d}\boldsymbol{r}' \chi^{(1)}_{\xi,\eta}(\boldsymbol{r},\boldsymbol{r}',\omega) E_\eta(\boldsymbol{r}',\omega) \\ & + \varepsilon_0 \sum_\eta \sum_\xi \int \mathrm{d}\boldsymbol{r}' \int \mathrm{d}\boldsymbol{r}'' \chi^{(2)}_{\xi,\eta,\zeta} \\ & \times (\boldsymbol{r},\boldsymbol{r}',\boldsymbol{r}'';\omega',\omega'') \\ & \times E_\eta(\boldsymbol{r}',\omega') E_\eta(\boldsymbol{r}'',\omega'')|_{\omega'+\omega''=\omega} \\ & + \cdots \end{aligned} \qquad [3]$$

The integral kernels $\chi^{(1)}$ and $\chi^{(n)}$ $(n=2,3,\ldots)$ are the nonlocal polarizabilities of the linear and the nth-order nonlinear processes, respectively. The

quantum mechanical expressions of, for example, the linear susceptibility at absolute zero temperature is given as

$$\chi^{(1)}_{\xi,\eta}(\boldsymbol{r},\boldsymbol{r}',\omega) = \sum_{v}\left\{\frac{\langle 0|\hat{P}_{\xi}(\boldsymbol{r})|v\rangle\langle v|\hat{P}_{\eta}(\boldsymbol{r}')|0\rangle}{E_v - E_0 - \hbar\omega - \mathrm{i}\gamma} + \frac{\langle 0|\hat{P}_{\eta}(\boldsymbol{r}')|v\rangle\langle v|\hat{P}_{\xi}(\boldsymbol{r})|0\rangle}{E_v - E_0 + \hbar\omega + \mathrm{i}\gamma}\right\} \quad [4]$$

where v runs over all the excited states of the matter from the groundstate $|0\rangle$. The parameter γ is, for idealized systems, a positive infinitesimal (0^+) representing the adiabatic switching of light–matter interaction, and for realistic systems, it is the self-energy of the excitation $E_v - E_0$, caused by nonradiative scattering, and is often approximated as a phenomenological parameter. The effect of radiative damping appears automatically by solving the coupled equations for $\boldsymbol{E}$ and $\boldsymbol{P}$, and therefore should not be included in γ. Otherwise, one would make a double counting of the interaction. The introduction of the background polarizability can be done similarly as before, by specifying the resonant frequency of interest and the rest.

Local versus Nonlocal (Macro- vs. Microscopic) Description

The nonlocal relationship between the polarization and electric field in the above expression is due to the coherence of the relevant wave functions and also to the intention to consider the spatial structure down to the subatomic scale. In the macroscopic response theory, it is approximated to be a local one as in eqn [1]. The simplified scheme of local response has been largely successful in calculating the EM or optical response of bulk matter. The validity condition for this approximation has not been discussed in detail.

A frequently encountered description for the macroscopic local theory is that it is a scheme for "the field components averaged over a region which is much larger than atomic size but much smaller than light wavelength." This means that a point in macroscopic theory has a volume satisfying the condition in the quotation marks. By this coarse graining, one loses certain information, but gains a simplified mathematical scheme. Thus, in order to judge whether or not a local description is all right for a given problem, one has to check two conditions: (1) if one can define a macroscopic "point" in the system of interest, and then (2) if the lost information by averaging is serious or not. For most nonresonant processes, local approach will be all right, because the long-wavelength approximation (LWA) is valid. For resonant processes, a nonlocal description should generally be chosen. But the case of excitations localized in a region much smaller than the macroscopic point mentioned above can be treated locally. In this case, the nonlocal polarizability [4] can be reduced to a local one [2] through the replacement

$$\hbar\omega_0 \to E_{v0}, \qquad \frac{Q^2}{M} \to \frac{2E_{v0}}{\hbar}|M_{v0}|^2 \qquad [5]$$

where M_{v0} is the electric dipole moment of the transition with the excitation energy E_{v0}.

The characteristic point of the local theory is that only electric dipole transitions can contribute to the polarization because of its essential assumption of LWA. In the nonlocal theory, there is also a possibility for other types of transitions to contribute because it takes the spatial variation of the EM field in a self-consistent way. Especially in the case of nanostructured materials, this possibility can lead to remarkable effects with respect to the size and frequency dependence of nonlinear responses. This is a reflection of the coherence of size-quantized excited states of matter, which are the counterparts of their size-quantized energy levels. In this sense, the nonlocal polarizability plays an important role for nanoscale materials.

In a microscopic description, polarizability is not a quantity to facilitate the calculation of optical response as in the macroscopic theory. The practical way of calculating optical response is rather different in the microscopic theory. Namely, it is not the polarizability itself but its components such as the matrix elements of dipole density and energy denominators that appear in the description of optical response, as shown below.

The main difference between the macroscopic and microscopic response theories lies in whether or not the boundary condition for an EM field is required. The reason why it is required in the macroscopic theory is that a medium is defined in terms of a set of position-independent polarizabilities, and that the boundaries of various optical media are introduced separately.

On the other hand, the microscopic polarizabilities include the position dependence reflecting the boundaries of matter through the boundary conditions for electrons and nuclei. Since the boundary conditions are already taken into account in the quantum mechanics of matter, it is no more necessary to consider the boundary conditions again for the EM field. The way of obtaining an optical response is the self-consistent solution of the two relations between polarization and EM field obtained from the Maxwell equations and Schrödinger equation, as shown below.

Determination of Microscopic Response

If all the matter states are included in the polarizabilities, the electric field produced by the polarization is obtained from the Maxwell equations as

$$E_\xi(\boldsymbol{r},\omega) = E_{0,\xi}(\boldsymbol{r},\omega) + \sum_\eta \int \mathrm{d}\boldsymbol{r}' G_{\xi,\eta}(\boldsymbol{r},\boldsymbol{r}',\omega) P_\eta(\boldsymbol{r}',\omega) \quad [6]$$

where $\boldsymbol{E}_0$ is an incident field, and $G_{\xi,\eta}(\boldsymbol{r},\boldsymbol{r}',\omega)$ is the (ξ,η)-tensor component of the radiation Green's function of vacuum, which satisfies the differential equation

$$\left(\nabla\times\nabla + \frac{\omega^2}{c^2}\right)\boldsymbol{G}(\boldsymbol{r},\boldsymbol{r}',\omega) = \mathbf{1}\,\delta(\boldsymbol{r}-\boldsymbol{r}') \quad [7]$$

The self-consistent solution of the EM field and the induced polarization is obtained by solving [3] and [6] simultaneously. For this purpose, one introduces the new variables

$$F_{\mu\nu}(\omega) = \int \mathrm{d}\boldsymbol{r}\, \boldsymbol{E}(\boldsymbol{r},\omega)\cdot\langle\mu|\hat{\boldsymbol{P}}(\boldsymbol{r})|\nu\rangle \quad [8]$$

The induced polarization $\boldsymbol{P}$ is written as a polynomial series of these variables, which together with eqn [6] gives $\boldsymbol{E}$ also in a polynomial series of these $\{F\}$'s. Substituting the latter into eqn [8], one obtains a set of polynomial equations to determine $\{F\}$'s. For a given order of optical process, linear or Nth order nonlinear one, the solution of these simultaneous polynomial equations determines the response for a given incident field $\boldsymbol{E}_0$.

For linear process, one has a set of linear equations for $\{F\}$'s. The condition for the existence of nontrivial solution in the absence of incident field $\boldsymbol{E}_0$ is given as the vanishing of the determinant of the coefficient matrix, $\det|\boldsymbol{S}| = 0$. This is the equation for the eigenmode of the light–matter coupled system. In the rotating wave approximation, where only the first term on the right-hand side of eqn [4] is retained, one has

$$S_{\mu\nu} = (E_\mu - \hbar\omega)\delta_{\mu\nu} + A_{\mu 0,0\nu}(\omega) \quad [9]$$

The quantity $A_{\mu 0,0\nu}(\omega)$ represents the interaction energy between the induced polarization components via a transverse EM field (vacuum photons) with frequency ω as

$$A_{\mu 0,0\nu}(\omega) = -\int \mathrm{d}\boldsymbol{r}\int \mathrm{d}\boldsymbol{r}'\langle\mu|\hat{\boldsymbol{P}}(\boldsymbol{r})|0\rangle \cdot \boldsymbol{G}(\boldsymbol{r},\boldsymbol{r}',\omega)\cdot\langle 0|\hat{\boldsymbol{P}}(\boldsymbol{r})|\nu\rangle \quad [10]$$

which is a complex quantity. Since the eigenmode of the coupled system gives the resonant structure in an optical spectrum, the real and imaginary parts of $A_{\mu 0,0\nu}(\omega)$ represent the radiative shift and width of the matter excitation energy, if its frequency dependence is negligible as usually is the case. In this sense, the eigenmodes in the regime of nonlocal response are extended Lorentz oscillators, that is, a matter is an assembly of oscillating dipole densities with finite spatial extension and radiative shift and width, which can be defined precisely on a quantum mechanical basis. In atomic systems, this radiative correction is very small, but in nanoscale systems and in the bulk, this correction can be comparable to or even exceeds the level spacing of matter. For example, the difference between the dispersion curves of an exciton and polariton is just the radiative shift defined above.

Different Definitions of χ and Corresponding Matter Hamiltonians

The definition of polarizability depends on what the polarizing field is. When light is incident on an isolated matter, it polarizes the matter, and the induced oscillating polarization emits an EM field with the same frequency, and this EM field polarizes the matter further, and so on. Even if a polarizing field is purely transverse (T), the induced polarization can generally contain both longitudinal (L) and T components. Both of them act as the source term in the Maxwell equations, leading to the Maxwell field with both T and L components. Since the L component of the Maxwell field is caused by the induced charge density, the interaction of this L field with the matter polarization is a part of the Coulomb interaction among the charged particles, that is, the Coulomb interaction among the induced charge densities H_{cc}. ("Electron–hole exchange interaction" can also be rewritten in such a form.) Namely, the LT splitting of polarization waves in a crystal may be expressed as a part of matter excitation energy, but it could also be ascribed to the interaction energy of a polarization wave with an induced depolarization field.

There are two points of view about the treatment of H_{cc}, that is, as a part of (A) matter Hamiltonian, or (B) the interaction between matter and external field. For each viewpoint, there is a suitable set of "matter Hamiltonian, an external EM field, the interaction between them, and polarizability." Namely, H_{A} should contain the full Coulomb interaction, while H_{cc}, a part of the Coulomb interaction, should be excluded from H_{B}, that is, $H_{\mathrm{B}} = H_{\mathrm{A}} - H_{\mathrm{cc}}$. The fields inducing the polarization should be chosen as the full Maxwell field $\boldsymbol{E}$ in scheme (B), while it is only the T component of $\boldsymbol{E}$ in scheme (A). The linear polarizability in each case is given in the same form as eqn [4], but the energy eigenvalues and the matrix elements of polarization operator are different

because of the difference in the matter Hamiltonian. One can show the equivalence of these two points of view, at least for linear response. Depending on the problem to be considered, one can choose either of them with proper consideration of the matter Hamiltonian to be used.

As a simple example, let the electronic excitations in a crystal be considered, that is, the case where a wave vector is a good quantum number. Neglecting the effect of finite reciprocal wave vectors (Umklapp processes), one can treat $\chi^{(1)}$ as a function of $\boldsymbol{r}-\boldsymbol{r}'$ alone. Its Fourier transform $\chi^{(1)}(\boldsymbol{k},\omega)$ has a different relationship, depending on the scheme (A) and (B), with dielectric function defined as $\boldsymbol{D}(\boldsymbol{k},\omega)=\varepsilon_0\varepsilon(\boldsymbol{k},\omega)\boldsymbol{E}(\boldsymbol{k},\omega)$. From $\nabla\cdot\boldsymbol{D}=0$ and $\boldsymbol{P}=\varepsilon_0\chi_{\mathrm{A}}^{(1)}\boldsymbol{E}_{\mathrm{T}}=\varepsilon_0\chi_{\mathrm{B}}^{(1)}\boldsymbol{E}$, one can derive

$$\varepsilon=1+\chi_{\mathrm{B}}^{(1)} \qquad [11]$$

and

$$\chi_{\mathrm{B}}^{(1)}=\chi_{\mathrm{A}}^{(1)}+\chi_{\mathrm{A}}^{(1)}\cdot\frac{\boldsymbol{k}\boldsymbol{k}}{k^2}\cdot\chi_{\mathrm{B}}^{(1)} \qquad [12]$$

The excitation energies of the matter Hamiltonian appear as the poles of $\chi^{(1)}$. Therefore, all the matter excitation energies of both T and L characters in the scheme (A) appear as the poles of $\chi_{\mathrm{A}}^{(1)}$. The matter Hamiltonian in the scheme (B) does not contain H_{cc}, so that its T and L levels are degenerate. The interaction with the external L field lifts the degeneracy and gives an additional energy to the L state alone, which finally leads to the same resonant positions of the T and L levels of the light–matter coupled system. This situation in the scheme (B) is reflected in the above relationship, namely, the L mode excitations appear as the zeros of the dielectric function $\varepsilon=1+\chi_{\mathrm{B}}^{(1)}$, and the T mode excitations as the poles of $\chi_{\mathrm{B}}^{(1)}$.

The above relationship between $\chi_{\mathrm{A}}^{(1)}$ and $\chi_{\mathrm{B}}^{(1)}$ can be generalized to the case without translational symmetry. If one denotes the $(\boldsymbol{k},\boldsymbol{k}')$-Fourier components of the linear polarizabilities as $\chi_{\mathrm{A}}^{(1)}(\boldsymbol{k},\boldsymbol{k}';\omega)$ and $\chi_{\mathrm{B}}^{(1)}(\boldsymbol{k},\boldsymbol{k}';\omega)$, respectively, their relationship is generally given as

$$\chi_{\mathrm{B}}^{(1)}(\boldsymbol{k},\boldsymbol{k}')=\chi_{\mathrm{A}}^{(1)}(\boldsymbol{k},\boldsymbol{k}')+\frac{1}{2\pi^2}\int \mathrm{d}\boldsymbol{q}\,\chi_{\mathrm{A}}^{(1)}(\boldsymbol{k},\boldsymbol{q})\cdot\frac{\boldsymbol{q}\boldsymbol{q}}{q^2}\cdot\chi_{\mathrm{B}}^{(1)}(\boldsymbol{q},\boldsymbol{k}') \qquad [13]$$

with the omission of the common variable ω.

Polariton Dispersion Equation

Polarizability plays an essential role in determining the eigenmodes of light–matter coupled systems. Among various examples of such an eigenmode, the case of an exciton in a three-dimensional crystal is taken. The eigenmode of the coupled light–matter system is an exciton–polariton, whose dispersion equation is obtained from the coupled linear equations

$$0=\boldsymbol{k}\times\boldsymbol{k}\times\boldsymbol{E}(\boldsymbol{k},\omega)+\frac{\omega^2}{c^2}(1+\chi_{\mathrm{B}}^{(1)})\boldsymbol{E}(\boldsymbol{k},\omega) \qquad [14]$$

If symmetry allows pure T modes, this leads to the polariton dispersion equation $1+\chi_{\mathrm{B}}^{(1)}=(ck/\omega)^2$. A more general dispersion equation for crystal excitations is obtained from the eigenmode equation $\det|S|=0$ mentioned in connection with eqn [9]. In this generalized scheme, the Umklapp effect can easily be included through the Fourier components of the induced microscopic polarization. This effect is important for the X-ray propagation in a crystal in the dynamical scattering regime. The generalized dispersion equation has the form

$$0=\det|\{|\boldsymbol{k}+\boldsymbol{g}|^2-q^2\}\delta_{i,j}\delta_{g,g'}-q^2\hat{\boldsymbol{e}}_i(\boldsymbol{k}+\boldsymbol{g})\cdot\chi_{\mathrm{A}}^{(1)}\cdot\hat{\boldsymbol{e}}_j(\boldsymbol{k}+\boldsymbol{g}')| \qquad [15]$$

where $q=\omega/c$, $\{\boldsymbol{g}\}$ are reciprocal lattice vectors, and $\{\hat{\boldsymbol{e}}_i(\boldsymbol{k}+\boldsymbol{g});\ i=1,2\}$ are the mutually orthogonal unit vectors perpendicular to $\boldsymbol{k}+\boldsymbol{g}$. The polarizability $\chi_{\mathrm{A}}^{(1)}$ is the $\{\boldsymbol{k}+\boldsymbol{g},\boldsymbol{k}+\boldsymbol{g}'\}$ Fourier components of the polarizability of the scheme (A) mentioned before, which can contain all the resonances of the crystal.

If one neglects the matrix elements with subscripts of finite reciprocal lattice vectors in eqn [15], the reduced equation can be shown to be equivalent to the general dispersion equation obtained from eqn [14], which allows the LT mixed mode polaritons.

From the fact that the generalized dispersion equation [15] contains the effect of both resonance and Bragg scattering, it can be used in diverse situations such as polaritons, X-ray dynamical scattering, and photonic crystals in extended frameworks.

Oscillator Strength and Its Size Dependence

There is a quantity closely related with polarizability, namely, oscillator strength, which characterizes the coupling strength of a matter excitation with an EM field. It is defined as

$$f_{v0}=\frac{2mE_{v0}}{\hbar^2e^2}|M_{v0}|^2\cos^2\theta \qquad [16]$$

where θ is the angle between the transition dipole moment vector and light polarization direction. This factor is proportional to the numerator of the resonant polarizability in eqn [2], as shown in [5]. Namely, this is a useful concept within LWA. In nanoscale systems, there can be a quantum state

extending over the whole sample region, which may exhibit size-linear enhancement of its oscillator strength. As a sample size approaches the wavelength of resonant light from below, this size enhancement tends to saturate. This enhancement is not reflected on the linear polarizability, because induced (linear or nonlinear) polarization is defined as the induced dipole moment per unit volume. Following this definition, however, it has an effect on nonlinear polarizability. For example, $\chi^{(3)}$ for macroscopic response can exhibit size-linear enhancement, which is of course valid only in LWA.

Beyond the size region of LWA, oscillator strength is no more an appropriate measure of the coupling strength. As a more general measure, one could use the radiative width of each excitation, that is, the imaginary part of $A_{v0,0v}$ defined in eqn [10]. This quantity can be used irrespective of LWA. Since it is proportional to $|M_{v0}|^2$, that is, to oscillator strength, in LWA, it can be used more generally than oscillator strength.

The size dependence of the radiative width is very sensitive to the spatial structure of size-quantized excitations. Following the size evolution of a given excitation, one can observe, not only the size-linear enhancement in an LWA regime, but also size-resonant enhancement beyond the LWA. For each type of excitation, there is a characteristic size where the coupling with an EM field becomes maximal.

If the coupling with an EM field becomes very large as, for example, in a resonant Bragg reflector consisting of, for example, regular arrays of quantum wells (QWs) with electronic resonances, where the resonant light satisfies the Bragg condition, it is no more appropriate to neglect the frequency dependence of radiative correction, eqn [10]. In this situation, the coupling of the light–matter system is so strong that it is no more valid to regard its eigenmode as a matter oscillator corrected with radiative shift and width. In the above example, there is formation of photonic bands with a gap mode branch by increasing the number of QWs.

Cancellation Problem in Evaluating Nonlinear Polarizabilities

For the calculation of polarizabilities in eqn [3], the time-dependent perturbation theory with light–matter interaction is used:

$$H_{\text{int}} = -\int \mathrm{d}\boldsymbol{r}\, \hat{\boldsymbol{P}}(\boldsymbol{r}) \cdot \boldsymbol{E}(\boldsymbol{r}, t) \qquad [17]$$

as the perturbation Hamiltonian. The nth-order nonlinear polarizability is expressed as the n-fold time integral of the n-fold commutator of polarization operators in interaction representation. For an explicit calculation, one expands the n-fold commutator into the sum of various products of the polarization operators, and carries out the time integrations. When one sums up these integrated terms, there occurs partial or total cancellation among them for n larger than or equal to 2. A typical example is the polarization made of pure bosons such as harmonic oscillators. In this case, the innermost commutator of two polarization operators in the interaction representation at different times becomes a c-number, so that its commutator with another operator turns out to be zero. This means that all the nonlinear polarizabilities should be zero for this model. However, each of the contributions from the expanded terms of the n-fold commutator is generally nonvanishing, which means that the complete cancellation occurs in summing up these expanded terms. For general cases of light–matter interaction, matter excitations are not pure bosons, and there is interaction among them, which leads to finite nonlinear polarizability. But there always exists a partial cancellation in summing up the expanded terms.

This feature is important when one considers the size enhancement of nonlinear polarizabilities for a nanoscale matter. As mentioned above, this enhancement tends to saturate as sample size grows to be comparable to the resonant wavelength. However, each of the expanded terms of the n-fold commutator is kept enhanced also beyond LWA. The saturation occurs only through the cancellation among such terms. This means that beyond LWA the leading order terms are cancelled out, leaving the next order terms as a finite contribution. Therefore, it is essential to make a very careful treatment of cancellation in the calculation of nonlinear polarizabilities. Otherwise, one would be left with a large error in the values.

Nomenclature

$A_{\mu 0,0\nu}(\omega)$	radiative interaction between induced polarizations
$\boldsymbol{D}$	displacement field
$\{\hat{\boldsymbol{e}}_i(\boldsymbol{k}+\mathbf{g})$; i-1,2\}	mutually orthogonal unit vectors perpendicular to $\boldsymbol{k}+\boldsymbol{g}$
$\boldsymbol{E}$	(Maxwell) electric field
$\boldsymbol{E}_0$	incident electric field
$\boldsymbol{E}_{\mathrm{T}}$	transverse component of Maxwell field
E_v	energy eigenvalue of matter, with $v=0$ for ground state
E_{v0}	excitation energy of transition $\|v\rangle \leftarrow \|0\rangle$
f_{v0}	oscillator strength of transition $\|v\rangle \leftarrow \|0\rangle$
$F_{\mu\nu}$	expansion coefficient of induced polarization
$\boldsymbol{g}$	reciprocal lattice vector
$\boldsymbol{G}(\boldsymbol{r},\boldsymbol{r}',\omega)$	radiation Green function in vacuum
H_{A}	matter Hamiltonian for the scheme (A)
H_{B}	matter Hamiltonian for the scheme (B)
H_{cc}	Coulomb interaction among induced charge densities
H_{int}	interaction Hamiltonian between light and matter
$\boldsymbol{M}_{v0}$	transition dipole moment for $\|v\rangle \leftarrow \|0\rangle$
$N_0, Q, M, \omega_0, \gamma$	number density, charge, mass, resonant frequency, and damping parameter, respectively, of Lorentz oscillator
$\hat{\boldsymbol{P}}(\boldsymbol{r})$	polarization (dipole density) operator
$q=\omega/c$	wave number in vacuum
$\boldsymbol{r}$	position vector
$S_{\mu\nu}$	coefficient matrix to determine $F_{\mu\nu}$
ε_0	dielectric constant of vacuum
$\varepsilon(\boldsymbol{k},\omega)$	dielectric function for a crystal
θ	angle between $\boldsymbol{M}_{v0}$ and light polarization direction
ξ, η, ζ	running indices for Cartesian coordinates
ρ_{M}	density matrix of matter
$\chi_{\mathrm{A}}^{(1)}$	linear polarizability defined with respect to the transverse component of Maxwell field
$\chi_{\mathrm{B}}^{(1)}$	linear polarizability defined with respect to Maxwell field
χ_{b}	background polarizability
$\chi^{(n)}$	nth-order nonlocal nonlinear polarizability ($n=2, 3, \ldots$)
$\bar{\chi}^{(N)}$	local polarizability of the Nth order ($N=1, 2, \ldots$)
ω	frequency

Polarons

E I Rashba, Harvard University, Cambridge, MA, USA

Introduction

Charge carriers, electrons and holes, moving across a semiconductor or an insulator experience interaction with phonons. This interaction has two major effects. First, it causes electron scattering and, therefore, electrical resistance. Second, it changes the properties of electrons. Indeed, an electron deforms the lattice around it. This deformation can be described as a cloud of virtual phonons. When the electron moves, the cloud follows it. Such an electron dressed by a cloud of virtual phonons is called a polaron. The polaron concept, as applied to an electron coupled to optical phonons in a polar crystal, was introduced by Pekar in 1946. It is currently applied to electrons (holes) coupled to various types of phonons and to magnons. This concept has also been generalized as applied to electrons coupled to the fluctuations of the chemical content or the order parameter. The properties of polarons depend on the type of the phonons to which the electron is coupled, on the coupling strength, and also on the dimensionality, D, of the space. In the strong coupling regime, the deformation inside a polaron is usually large and its ability to move is suppressed. This limit corresponds to the Landau's concept of the self-trapping of electrons in a perfect lattice. Both terms, polaron and self-trapping, will be used in what follows. Similar to electrons, excitons are also coupled to phonons and dressed by them; such dressed excitons are sometimes called "excitonic polarons polaritons." While electron and hole polarons are investigated mostly through transport phenomena, excitonic polarons are observed primarily by spectroscopy. However, transport of excitonic polarons has also been investigated, especially in alkali halides.

Basic Classification of Polarons

Depending on the number N of phonons in the cloud, polarons are termed strong-coupling or weak-coupling polarons, for $N \gg 1$ and $N \ll 1$, respectively. Polarons are termed small polarons when their size r_p is close to the lattice constant a, $r_p \approx a$, and large polarons when $r_p \gg a$. Depending on the ratio of the half-width W of the electron band to the characteristic phonon frequency $\hbar\omega_{ph}$, polarons are termed adiabatic (when $W \gg \hbar\omega_{ph}$) and antiadiabatic (when $W \ll \hbar\omega_{ph}$). Free electrons and holes are always dressed by the electronic polarization of closed atomic (ionic) shells. When they move slowly, this polarization follows them nearly without retardation; therefore, it is included in the band energy of free particles. To emphasize this dressing, a term "electronic polaron" is sometimes used: "electronic polarons" are a specific type of antiadiabatic polarons.

In what follows, mostly adiabatic polarons are considered.

Polarons can also be classified by the electron–phonon coupling mechanisms. The standard Hamiltonian of this coupling is

$$H_{e-ph} = \frac{1}{N^{1/2}} \sum_{kq} \gamma_q a^+_{k+q/2} a_{k-q/2} (b_q + b^+_{-q})$$

where a_k and b_q are electron and phonon operators, respectively, $\boldsymbol{k}$ and $\boldsymbol{q}$ are their quasimomenta, and N is the number of unit cells in the normalization volume. Various mechanisms of electron–phonon coupling are discerned by the momentum dependence of the coupling constant γ_q and the phonon frequency ω_q. For the polarization coupling to optical phonons, $\omega_q = \omega_0 = \text{const.}$ and

$$\gamma_q = \frac{\sqrt{\alpha}\hbar}{q} \left(\frac{2\pi\omega_0}{v} \sqrt{\frac{2\hbar\omega_0}{m}} \right)^{1/2}$$

$$\alpha = \frac{e^2}{\hbar\kappa} \sqrt{\frac{m}{2\hbar\omega_0}},$$

$$\frac{1}{\kappa} = \frac{1}{\kappa_\infty} - \frac{1}{\kappa_0}$$

where e is the elementary charge, m is the electron effective mass, v is the unit cell volume, κ_0 and κ_∞ are the low- and high-frequency dielectric constants, respectively, and α is the Fröhlich coupling constant. In the equation for the Pekar factor $1/\kappa$, taking difference of inverse dielectric constants eliminates the fast "electronic polaron" polarization of atomic shells and retains only the polarization due to slow ionic displacements. Because of the factor q in the denominator of γ_q, the coupling to long-wavelength polar phonons, $qa \ll 1$, dominates. For nonpolar coupling to optical phonons $\gamma_q = \text{const.}$, $\omega_q = \text{const.}$, for the deformation potential coupling to acoustic phonons $\omega_q \propto q$, $\gamma_q \propto q^{1/2}$, and for piezoelectric coupling to acoustic phonons $\omega_q \propto q$, $\gamma_q \propto q^{-1/2}$.

Pekar–Fröhlich Polaron

In a Pekar–Fröhlich polaron, an electron is coupled to dispersionless optical phonons by polarization interaction. Because of the role of long-wavelength phonons, the theory is outlined in terms of an electron coupled to a dielectric continuum. This model can be solved in both limits: weak, $\alpha \ll 1$, and strong, $\alpha \gg 1$, coupling. Dressing of the electron renormalizes its spectrum; in particular, it lowers the bottom of the band and increases the effective mass. The effect is most drastic for $\alpha \gg 1$. In this limit, lattice polarization is nearly static and produces a potential well for an electron. The ground state for an electron in this well can be found from a nonlinear integral–differential Schrödinger equation

$$-\frac{\hbar^2}{2m} \nabla^2 \psi_0(r) + V[\psi_0, r]\psi_0(r) = E_0 \psi_0(r)$$

$$V[\psi_0, r] = -\frac{e^2}{\kappa} \int \frac{\psi_0^2(r')}{|\boldsymbol{r} - \boldsymbol{r}'|} \, d\boldsymbol{r}'$$

This equation is self-consistent: an electron that is self-trapped in the ψ_0-state produces a dielectric polarization that supports, by its Coulomb field, this quantum state. It can be derived as a minimum of a functional

$$\mathcal{H}[\psi] = \min_\Psi \langle \psi | - (\hbar^2/2m)\nabla^2 + \tfrac{1}{2} V[\psi, r] | \psi \rangle$$
$$= K + V/2$$

K and V being the mean values of the kinetic energy and the energy of electron–phonon interaction. The factor 1/2 appears because the Schrödinger equation is nonlinear, and $\mathcal{H}[\psi]$ equals the total energy of the system, including the electron energy E_0 and the polarization energy $E_P = -V/2$, $\mathcal{H} = E_0 + E_P$. A scaling transformation $\psi_v(r) = v^{3/2}\psi_0(vr)$ results in

$$\mathcal{H}[\psi_0] = \min_v \{v^2 K + vV/2\}$$

Because ψ_0 is the exact ground state, the minimum of $\mathcal{H}[\psi_v]$ is achieved at $v = 1$. This equation relates K to V and leads to Pekar's virial theorem

$$K : E_P : |E_0| : |V| = 1 : 2 : 3 : 4$$

The eigenvalue $E_0 \approx -0.16 me^4/\kappa^2\hbar^2$ and the polaron radius $r_p \approx 3\kappa\hbar^2/me^2$ does not depend on ω_0. The number of phonons in the cloud $N = 2|E_0|/3\hbar\omega_0$. The strong coupling theory is applicable when $|E_0| \gg \hbar\omega_0$, and the continuum approximation when $r_p \gg a$.

The function $\psi_0(r)$ describes a strictly self-trapped electron. The translational symmetry of the problem and the finite phonon frequency ω_0 result in polaron motion: it acquires a finite effective mass m_p. Three phonon degrees of freedom are absorbed by the polaron and transformed into three zero modes of its translational motion. This results in the energy gain of $3\hbar\omega_0/2$ that, together with electron–phonon correlations, lowers the polaron energy as compared with $\mathscr{H}[\psi]$. Finally, the ground-state energy and the polaron mass are

$$E(k=0) \approx -(0.1085\alpha^2 + 2.836)\hbar\omega_0$$
$$m_p \approx 0.023\alpha^4 m$$

Landau–Pekar effective mass m_p increases steeply with α because a moving polaron drags a phonon cloud whose energy E_P grows with α, and m_p diverges when $\omega_0 \to 0$ because the number of the phonons in the cloud diverges, $N = E_P/\hbar\omega_0 \to \infty$.

In the weak coupling limit, $\alpha \ll 1$, the perturbation theory results in

$$E(k=0) \approx -\alpha\hbar\omega_0, \quad m_p \approx m/(1-\alpha/6)$$
$$N = \alpha/2$$

Because the numerical coefficients in the strong-coupling equations are small, the asymptotic expressions for $E(k=0)$ and m_p match at large α values, $\alpha \gtrsim 5$. Smooth matching can be achieved by different analytical intermediate-coupling methods, of which Feynman method has been the most widely used. More recently, numerical approaches based on the Monte Carlo method have been developed. Nevertheless, the basic physical insight into the polaron energy spectrum including its excited states is based on analytical results.

An estimate of α in terms of fundamental constants suggests that the strong coupling should be a typical one. With $m \approx m_0$, where m_0 is the electron mass in a vacuum, $\kappa \approx 1$, and $\hbar\omega_0$ estimated through the adiabatic parameter as $\hbar\omega_0/E_a \approx \sqrt{m_0/M}$, where $E_a \approx 10$ eV is an atomic scale energy and $M \approx 10^4 m_0$ is an atomic mass, one gets $\alpha \approx 10$. This estimate underscores the importance of the polaron effect in solid-state physics and chemistry of electrolytes. However, in many semiconductors α is small because of a small electron mass, $m \ll m_0$, and a large dielectric constant, $\kappa \gg 1$. For example, $\alpha \approx 0.02$ in InSb, 0.06 in GaAs, 0.6 in CdS, 1.8 in AgCl, and 4.1 in RbCl. Therefore, electron polarons are weakly coupled in most of the semiconductors and intermediately coupled in ionic insulators. In many crystals, hole polarons are coupled strongly; in these cases, they usually are small Jahn–Teller polarons.

Excited States of a Polaron

For $r \gtrsim r_p$, the potential $V[\psi_0, r]$ decreases by a Coulomb law, $V[\psi_0, r] \approx -e^2/\kappa r$. Therefore, excited states form a Rydberg-type series, their energies being scaled by $|E_0| \sim \alpha^2\omega_0$. These states have considerable widths due to multiphonon decay. According to the Franck–Condon principle, optical transition of an electron in a strong-coupling polaron can be found at a fixed lattice polarization. Such a polaron possesses an absorption spectrum that begins near the energy $\sim 3|E_0|/4$, consists of strongly overlapping bands, and is extended to high energies. While the absorption shape depends on a specific model, appearance of a peak ("polaron peak") instead of a Drude spectrum is a fingerprint of a strong-coupling polaron. A related but independent signature of a polaron is a Stokes shift caused by the polaron relaxation into a self-consistent excited state.

A different sequence of the excited states of a strong-coupling polaron has excitation energies below $\hbar\omega_0$; they cannot decay and are stable. These states develop due to the polarization of the $\psi_0(r)$-state by a fluctuating electric field of optical phonons and can be considered as polaron–phonon bound states or as local phonon modes near a polaron. A typical binding energy for these states is $\sim 0.1\hbar\omega_0$. In the $\alpha \to \infty$ limit, bound states form an infinite sequence converging to $\hbar\omega_0$. Practically, the sequence is cut by the magnitude of α and by phonon dispersion. The energy spectrum of a strong-coupling polaron is shown schematically in **Figure 1**.

For a weak-coupling polaron, the spectrum $E(k)$ has a termination point at $k_{th} \approx \sqrt{2m_p\omega_0/\hbar}$ that is the threshold for the emission of a real phonon by a fast polaron. The states with $E(k) > \hbar\omega_0$ have a finite width. For $\alpha \ll 1$, electron–phonon coupling

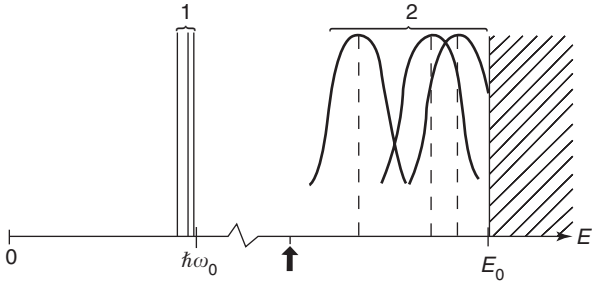

Figure 1 Schematics of the electron energy spectrum of a Pekar–Fröhlich polaron. The bottom of the polaron spectrum is chosen as an origin, polaron momentum $k = 0$. (1) polaron–phonon bound states with energies $E < \hbar\omega_0$. (2) high-energy excited states in the potential $V[\psi_0, r]$; their widths are shown schematically. The lower Stokes-shifted relaxed excited state is shown by the arrow. Two energy scales are used: $\hbar\omega_0$ on the left and E_0 on the right of the break in the E-axis. Free electron band is hatched.

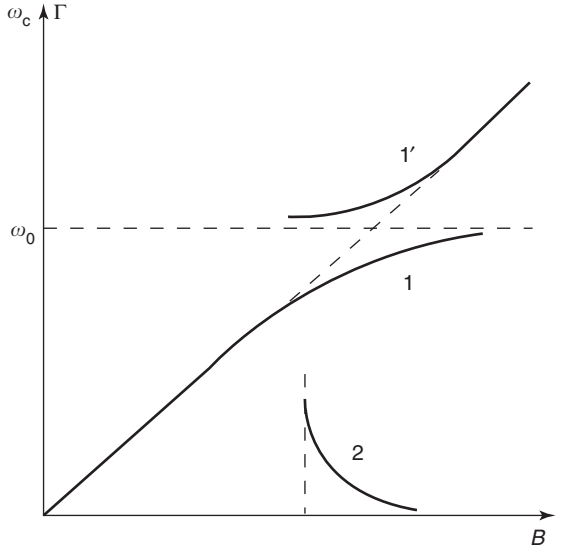

Figure 2 Dependence of the cyclotron resonance frequency $\omega_c(B)$ and the level width $\Gamma(B)$ on magnetic field B near the magneto-phonon resonance in the spectrum of a weak-coupling polaron. 1 and 1′ – the lower and upper branches of the spectrum, respectively; 2 – the width $\Gamma(B)$ of the upper branch.

manifests itself dramatically in a magneto-phonon resonance when the cyclotron frequency eB/m_pc of the polaron approaches ω_0, B being a magnetic field. The dependence $\omega_c(B)$ is shown in **Figure 2**. Near the resonance, the curve $\omega_c(B)$ splits into two branches. The lower branch is stable and is pinned to ω_0 when B increases. The upper branch is unstable because of the phonon emission, and the level width $\Gamma(B)$ reaches its maximum near the threshold. The effect is observed experimentally as the cyclotron resonance band splitting. This splitting is $\sim\alpha^{2/3}\omega_0$ near the resonance and allows direct measuring of α. The phenomenon results from the resonance enhancement of the electron–phonon coupling near the resonance that also manifests itself in the increase of N from $N\approx\alpha/2$ to $N\approx 1/2$.

Nonpolar Electron–Phonon Coupling

This problem applies to electrons and holes in nonpolar compounds, and also to excitons, because of their electrical neutrality, in any kind of crystals. In a continuum approximation, both mechanisms of nonpolar coupling (to acoustic and optical phonons) result in the same expression $V[\psi_0, r]\propto -\psi_0^2(r)$ in the strong coupling limit. The scaling transformation $\psi_v(r) = v^{D/2}\psi_0(vr)$ of a trial function $\psi_0(r)$, where D is dimensionality, leads to the functional $\mathscr{H}$:

$$\mathscr{H}[\psi_0] = \min_v \mathscr{H}(v), \quad \mathscr{H}(v) = v^2K + v^DV$$

where K and $V<0$ are kinetic and potential energies, respectively. The result depends on D critically.

$D = 1$, One-Dimensional Systems

With $D = 1$, $\mathscr{H}(v)$ reaches its minimum at a finite value of v, just as in the case of a three-dimensional (3D) large polaron. The self-trapped state can be found from a nonlinear Schrödinger equation

$$-\frac{\hbar^2}{2m}\frac{d^2\psi_0}{dx^2} - 2c\psi_0^3 = E_0\psi_0$$

Its only normalizable solution is

$$\psi_0(\xi) = (1/\sqrt{2})\text{sech}\ \xi, \quad \xi = mcx/\hbar^2$$
$$E_0 = -mc^2/2\hbar^2$$

For coupling to nonpolar optical phonons of the frequency ω_0, the dimensionless coupling constant α is usually chosen in such a way that in the weak coupling regime the energy equals $E(k=0) = -\alpha\hbar\omega_0$. Then $E_0 \approx -\alpha^2\hbar\omega_0$, and

$$E(k=0)\approx -(\alpha^2/3 + 0.955)\hbar\omega_0$$
$$m_p \approx 32\alpha^4 m/15$$

As distinct from the large 3D polaron, there is no small numerical factors in $E(k=0)$ and m_p. Therefore, strong coupling sets in at $\alpha\gtrsim 1$. As a result, 1D geometry is favorable for large strong-coupling polarons and excitons. This is an important property of various quasi-1D-compounds, including polyacetylenes.

Similarly to a large 3D polaron, there exists an infinite sequence of stable excited states below $\hbar\omega_0$. However, as distinct from a large 3D polaron, the potential $V[\psi_0, x]$ does not support excited bound states above the $\hbar\omega_0$ threshold.

$D = 2$, Two-Dimensional Systems

Both terms in $\mathscr{H}(v)$ show the same dependence on v; hence, there exists a critical value of the coupling strength. Below it only a weak-coupling polaron exists, above it a self-trapped state is the polaron's ground state; its size is about a lattice spacing a.

$D = 3$, Three-Dimensional Systems: Holstein Polaron

There is no minimum at the curve $\mathscr{H}(v)$; hence, nonpolar coupling cannot support large strong-coupling polarons. Different options are shown in **Figure 3**.

If the coupling is strong enough, $\mathscr{H}(v)$ changes sign for a state whose size is still larger than the lattice constant (curve 1). In this case, a self-trapped state exists and is the polaron ground state. When the coupling strength decreases, the self-trapped state becomes metastable, its energy being higher than the

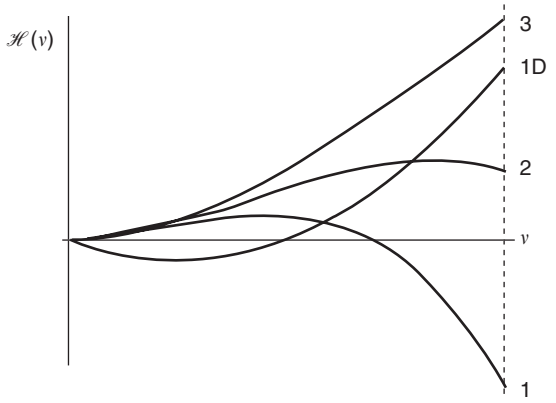

Figure 3 Different types of the dependence of the energy functional $\mathscr{H}(v)$ on v, the inverse size of a local state. 1 – strong coupling; a self-trapped state is the polaron ground state. 2 – intermediate coupling; a self-trapped state exists but is metastable. 3 – weak coupling; there is no self-trapped states. The dashed line indicates the size of the local 3D state of about a lattice constant a. For comparison, a $\mathscr{H}(v)$ curve for a strong-coupled 1D system is shown; position of its minimum indicates the size of a self-trapped state.

electron band bottom (curve 2). When coupling is weak, there is no self-trapped states (curve 3). The classification of states based on the functional $\mathscr{H}(v)$ is tantamount to the original Landau argument and is exact in the strictly adiabatic limit, $\omega_0 \to 0$. This argument says that, in a 3D quantum well, a bound state appears only when the well depth V and radius R obey the criterion $V \gtrsim \hbar^2/2mR^2$, and a self-trapped state is stable when the binding energy is large enough to ensure that the total energy of the system is lower than the bottom of the free-electron band.

Properties of small polarons depend on the crystal geometry and the details of chemical bond. Holstein model provides important insight into some of their general properties. In the lattice-site representation, the Holstein Hamiltonian reads

$$H = -t\sum_{n} a_n^+ a_{n+\delta} + \gamma \sum_{n} a_n^+ a_n (b_n + b_n^+) + \hbar\omega_0 \sum_{n} b_n^+ b_n$$

The first term is the electron kinetic energy, vectors $\boldsymbol{\delta}$ point to all nearest neighbors of the site $\boldsymbol{n}$. The second term describes intrasite electron coupling to dispersionless optical phonons through deformation potential. This Hamiltonian depends on two dimensionless constants. The ratio $\gamma/\hbar\omega_0$ measures the electron–phonon coupling strength, while the ratio $t/\hbar\omega_0$ controls the polaron evolution from the adiabatic ($t \gg \hbar\omega_0$) to antiadiabatic ($t \ll \hbar\omega_0$) limit.

For arbitrary parameter values, the problem can be solved only numerically. The results show convincingly, in a qualitative agreement with the adiabatic theory, that the switching between the weak- and strong-coupling regimes is smooth for $D = 1$ and rather sharp for $D = 3$. This is true for the dependence of both $E(k = 0)$ and m_p on $\gamma/\hbar\omega_0$. The changeover between the free and self-trapped electron regimes, which is abrupt in 3D in the adiabatic limit (and sometimes, rather improperly, termed a "phase transition"), is getting smoother when the ratio $\hbar\omega_0/t$ increases. This smoothening reflects a strong mixing of the free and self-trapped states when they are close to a resonance.

Holstein model is well suited for investigating the strong coupling regime when γ is large as compared with t and $\hbar\omega_0$, while the ratio $\hbar\omega_0/t$ can be arbitrary. Applying the Lang–Firsov transformation $\exp\{\gamma(b_n^+ - b_n)/\hbar\omega_0\}$ to all lattice sites, one eliminates the second term in H. The transformed Hamiltonian $\tilde{H}$ shows a general polaron shift of the spectrum by $-\gamma^2/\hbar\omega_0$ and a renormalization of the bandwidth, $t \to \tilde{t} = t\exp\{-(\gamma/\hbar\omega_0)^2\}$. After the transformation, the kinetic energy acquires factors dependent on phonon operators. The basic conclusions are as follows. Because the translational symmetry is not violated, the band spectrum is retained. However, the polaron band becomes exponentially narrow; therefore, band transport of polarons is easily destroyed by defects and thermal phonons. If the temperature T is not too low, the polaron transport is dominated by thermoactivated diffusion, $D \propto \exp(-E_a/k_B T)$ with $E_a \approx \gamma^2/\hbar\omega_0$, k_B being the Boltzmann constant. Activational T-dependence of the mobility is the basic transport fingerprint of small electronic and excitonic polarons.

It is a general property of polarons that their mass increases with the coupling constant by a power law in continuum models, and exponentially in lattice models.

The lattice models are especially useful for antiadiabatic polarons. Under these conditions the number of phonons in the system is nearly conserved. As a result, the lower part of the spectrum is described by the band of a dressed polaron, and the excited states by a few-particle theory as a polaron interacting with real phonons through a renormalized electron–phonon interaction. Such an approach is highly efficient in the spectroscopy of molecular excitons coupled to intra-molecular phonons where one distinguishes exciton–phonon bound states and a two-particle continuum.

Some Specific Types of Small Polarons

Strong-coupling polarons of the Holstein Hamiltonian are single-site polarons. Meantime, two-site hole polarons are typical of many solids. These are

quasimolecular ions of Xe_2^+ type in rare gas solids and of Cl_2^- type in alkali halides. While the van der Waals forces dominate in the cohesion energy of rare gas solids, such ions are bound chemically. As a result, atomic displacements are large in self-trapped states, and electron–phonon interaction is strongly nonlinear. Quasimolecular self-trapped excitons in these crystals have the same symmetry as hole polarons, with Xe_2-type self-trapped excitons mimicking excimers. Side-by-side with them, quasi-atomic self-trapped excitons usually also exist; however, they are metastable and decay into quasimolecular states. Quasimolecular hole polarons are a special case of Jahn–Teller polarons whose symmetry is broken because of the atomic level degeneracy.

Electron bubbles in liquid He and metal–ammonia solutions are different examples of nontrivial small polarons. Because of the negative work function of He, electrons injected into He produce vacuum bubbles and become self-trapped inside them. Holes in liquid He appear as positive ions surrounded by "icebergs" of solid phase.

Self-Consistency of the Adiabatic Concept of Self-Trapping

An important feature of the adiabatic concept of self-trapping is the coexistence of extended and localized states. The extended states are weakly coupled to phonons, while the localized states are strongly coupled to the same phonons. In order to prove the self-consistency of this concept, one has to check that the corrections to the energy of free states are really small, to be specific, small as compared with the self-trapping energy. The standard expression for the electron coupling constant to acoustic phonons is

$$\gamma_q = Cq\sqrt{\hbar/2\rho v\omega_q}, \quad \omega_q = sq$$

where C is the deformation potential, ρ is the density, v is the unit cell volume, and s is the sound velocity. Then the second-order correction $\delta_2 E(k=0)$ to the position of the electron band bottom and the energy of a strong-coupled single-site polaron E_p, with the accuracy to numerical factors, are

$$\delta_2 E(k=0) \approx -mC^2/\hbar\rho sa^2, \quad E_p \approx -C^2/\rho s^2 a^3$$

In both cases, the main contribution comes from short wavelength phonons. Their ratio

$$\delta_2 E(k=0)/E_p = msa/\hbar \approx \hbar\omega_D/W$$

ω_D being the Debye frequency. Therefore, this ratio equals the small parameter of the adiabatic theory of polarons. When W is of the atomic scale, $W \sim 10$ eV, this ratio is about $\sqrt{m/M}$, the basic parameter of the adiabatic theory of solids. Under the same conditions, $\delta_2 E(k=0) \sim \hbar\omega_D$ when C is of atomic scale.

A similar estimate for nonpolar coupling to optical phonons shows that $\delta_2 E(k=0) \approx -\gamma^2/W$, $E_p \approx -\gamma^2/\hbar\omega_0$, and their ratio $\delta_2 E(k=0)/E_p \approx \hbar\omega_0/W$.

Therefore, the coupling energies for nearly free and self-trapped states differ by the adiabatic parameter $\hbar\omega_{ph}/W$; hence, whenever it is small, the adiabatic theory of polarons is self-consistent.

Self-Trapping Barrier and Self-Trapping Rate

The self-consistency of the adiabatic theory suggests description of self-trapping in systems with wide electron bands, $W \gg \hbar\omega_{ph}$, in terms of the adiabatic potential surfaces $U(\ldots Q_i \ldots)$, where Q_i are phonon coordinates. With a single phonon coordinate symbolizing both the spatial extension and the magnitude of the lattice deformation, the dependence $U(Q)$ is shown in **Figure 4** for an electron (exciton) coupled to a 3D crystal lattice by a nonpolar interaction. The branching point where a local level first appears in the potential well produced by a growing lattice deformation is shown by BR; at this point the lower

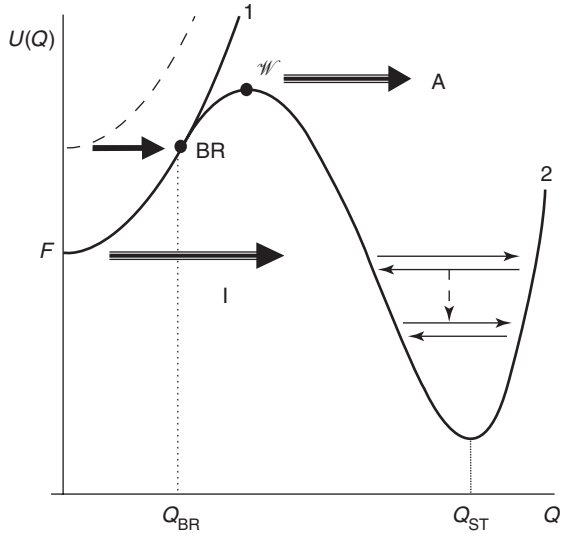

Figure 4 Adiabatic potential surfaces $U(Q)$ for a particle coupled to a 3D crystal by a nonpolar interaction. 1 – energy of the lattice deformation with a particle in a free state F at the bottom of the band. 2 – the split-off sheet of the adiabatic potential originating at the branching point BR. $\mathscr{W}$ shows the lowest saddle point of the sheet 2 that plays a role of the self-trapping barrier. Arrows I and A symbolize the instanton and activational (Arrhenius) self-trapping trajectories, respectively. A heavy arrow symbolizes self-trapping of a fast particle whose energy is shown by a dashed parabola. Oscillations around the point Q_{ST} in the self-trapped state and energy relaxation are also shown.

sheet 2 of the adiabatic potential surface splits off the free-particle surface 1. A distinctive feature of nonpolar coupling in 3D is the existence of the barrier for self-trapping shown by $\mathscr{W}$ ($\mathscr{W}$ is the lowest saddle point of the surface 2 in the multidimensional Q-space). Its energy equals

$$\mathscr{W}_{\mathrm{ac}} = 44(\hbar^3\rho s)^2/m^3C^4$$
$$\mathscr{W}_{\mathrm{op}} = 11\hbar^8/m^3(\gamma^2\omega_0 v)^2$$

for the coupling to acoustic and optical phonons, respectively. In both cases, the spatial extention of the barrier $r_{\mathrm{b}} \sim a(E_{\mathrm{p}}/W)$. Therefore, when coupling is strong, $E_{\mathrm{p}} \gg W$, the spatial extention of the barrier is large as compared with a, and the expressions for $\mathscr{W}$ in terms of macroscopic parameters are valid. The adiabatic theory is applicable when $\mathscr{W} \gg \hbar\omega_{\mathrm{ph}}$. Because $\mathscr{W}/\hbar\omega_{\mathrm{ph}} \sim (W/\hbar\omega_{\mathrm{ph}})(W/E_{\mathrm{p}})^2$, both criteria are compatible if the adiabatic parameter is large enough, $W/\hbar\omega_{\mathrm{ph}} \gg 1$. When $\mathscr{W} \lesssim \hbar\omega_{\mathrm{ph}}$, the notion of the barrier has no sense.

Free states are self-consistent solutions of the adiabatic problem, and the barrier protects free particles from fast self-trapping. Therefore, free and self-trapped states can coexist. Of course, free states are metastable, and self-trapping is sometimes considered as a decay of a "false vacuum." Self-trapping rate w is controlled by the penetration of the particle through the barrier. Thermoactivated tunneling and the activational (Arrhenius) mechanism dominate at $T < T_{\mathrm{c}}$ and $T > T_{\mathrm{c}}$, respectively. The critical temperature $T_{\mathrm{c}} \sim \hbar\omega_{\mathrm{ph}}/k_{\mathrm{B}}$, the numerical factor in it depends on specific properties of the system. In the framework of the semiclassical theory, thermoactivated tunneling can be considered as a collective tunneling of the lattice and the particle described technically as an instanton. Instanton is a notion adopted from the quantum field theory where it describes a trajectory of a classical field in imaginary time that possesses a finite Euclidean action. As applied to the self-trapping problem, an instanton begins with the tunneling of the free lattice that prepares a potential well for the particle, then the particle is trapped to a shallow energy level emerging in this well in the vicinity of the branching point, and the process is completed by joint tunneling of the coupled particle–lattice system. The probability $w(T) \propto \exp[-S(T)]$, where $S(T)$ is the semiclassical (Euclidean) action of the instanton that it acquires during its motion in imaginary time; this is a convenient way for describing the tunneling motion of the system under the barrier. The action decreases monotonically with T at $T < T_{\mathrm{c}}$ and equals $S(T) = \mathscr{W}/k_{\mathrm{B}}T$ in the Arrhenius region. Self-trapping through a $T = 0$ instanton and the Arrhenius process are shown schematically in **Figure 4**. When the particle has an initial energy E larger than $k_{\mathrm{B}}T$, which may be the case for excitons produced by light, this energy can contribute to w by reducing S. A coherent energy transfer from a particle to the tunneling lattice is suppressed by the small mass ratio; it is most efficient for $E \lesssim \mathscr{W}$.

After the instanton passes the barrier, it turns into a wave packet that oscillates between the turning points of the well with a frequency of a local mode and relaxes by emitting lattice phonons (**Figure 4**). For excitons, this dynamics can be detected by the oscillations and decay of light emission because it comes mostly from the turning points of the semiclassical lattice motion. If the energy of the packet is concentrated at a single or a few degrees of freedom, self-trapping results in lattice defect production.

Self-trapping of charged particles, electrons and holes, in ionic crystals into the Pekar–Fröhlich polaron states, and also self-trapping of electrons (holes) and excitons in 1D conductors, proceeds fast because there is no barrier for them. For example, (i) self-trapping of holes in alkali halides proceeds much faster than self-trapping of excitons, and (ii) oscillations and decay of the exciton emission from quasi-1D Pt complexes begin immediately after the excitation pulse.

Because of the atomic size of self-trapped states, calculating numerical values of their parameters, especially the self-trapping probability, is a formidable task. However, the basic qualitative predictions of the adiabatic theory are confirmed by extensive experimental data, especially as applied to excitons because they are detected optically. Coexistence of free and self-trapped states has been established in alkali halides, rare gas solids, and molecular crystals. Branching of the hot-exciton self-trapping in pyrene, including the bypassing flow of excitons that avoided the intraband energy relaxation, directly to the self-trapped states, has been observed.

Self-Trapping in Peierls Insulators

According to the Peierls theorem, a 1D metal with a single electron per lattice site is unstable and undergoes a phase transition into an insulating phase by lattice deformation. The scheme of alternating single and double bonds after the Peierls transition in a conducting polymer *trans*-polyacetylene is shown in **Figure 5**. Because double bonds are slightly shorter than single bonds, the lattice period doubles, from a to $2a$, and a gap $2\Delta = 1.8$ eV opens in the spectrum. Because a- and b-configurations of **Figure 5** have the same energy, there are two ground states, or two vacuums. A defect shown in **Figure 5** c is a kink

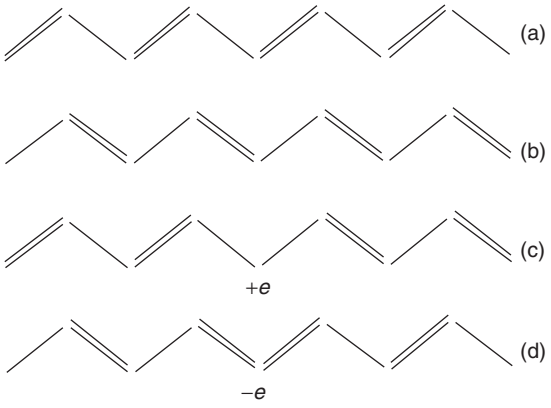

Figure 5 Schematics of valence bonds in the carbon backbone of *trans*-polyacetylene and topological solitons. (a) and (b) Two degenerate ground states with alternating bonds; (c) a soliton; (d) an antisoliton.

separating two vacuums – the *a*-vacuum on the left and the *b*-vacuum on the right; it is called a soliton, *S*. In the Heeger–Schrieffer–Su model, the energy of a deformed carbon backbone of *trans*-polyacetylene is

$$H_{\mathrm{el-ph}} = \alpha \sum_{n,s} (u_{n+1} - u_n)(a^{+}_{n+1,s} a_{n,s} + a^{+}_{n,s} a_{n+1,s})$$

where n numerates lattice sites and s spin projections. In this theory, solitons and antisolitons ($\bar{S}$) are extended defects of the size $2x_0 \approx 13a$. Their energies $\approx 0.6\Delta$ are less than Δ; hence, they are the basic low-energy excitations of the electron system. Because lattice displacements in solitons are small, only $\sim 0.03a$, soliton masses are also small, $m_S \approx 6m_0$. In the continuum approximation, the lattice displacement in a soliton, $u(x) = u_0 \tanh(x/x_0)$, creates a midgape state with the energy $E = 0$ that can be populated by one or two electrons.

There are two basic differences between solitons and polarons. First, the usual spin–charge relation is reversed in solitons. S has spin $s = 0$ when charged positively, $+e$, and spin $s = 1/2$ in the neutral state when a single electron is trapped at the midgape level. Second, a soliton is a topological excitation because a kink separates two vacuums, while a polaron only produces a local lattice distortion and does not change the vacuum. In this system, a polaron is a midgape electron bound to an $S\bar{S}$ pair; binding energy equals $\Delta/\sqrt{2}$. Because a single injected electron cannot change the vacuum, it relaxes into a polaron. However, an electron–hole pair relaxes into an $S\bar{S}$ pair.

Because the deformations are small and smooth, $u_0 \ll a$ and $x_0 \gg a$, the theory is rather accurate, and comparison with experiment is extensive and successful.

Polarons in Strongly Correlated Electron Conductors

Historically, polarons were devised for insulators and semiconductors. More recently, they were invoked in physics of strongly correlated electronic conductors, in particular, high-T_c superconductors and colossal magnetoresistance materials (cuprates, perovskite manganites, EuB_6, etc.). These materials are unstable, close to metal–insulator and magnetic transitions, show strong electron correlations, and contain $\sim 10^{-1}$–10^{-2} carriers per formula unit. Because of the presence of ions with partially filled atomic shells, they are candidates for Jahn–Teller polarons, and optical signatures of such polarons are present in the spectra. Strong correlations of Jahn–Teller polaron pairs result either in their bound states (bipolarons) or resonances inside the Fermi sea that manifest themselves in a pseudo-gap, believed to be a precursor of the superconductor gap still in the normal state. They are believed to enhance T_c over the canonical BCS mechanism.

The interplay of several competing mechanisms makes it difficult to isolate polaron effects; however, their role is well documented already.

Polymer Structures

R A Pethrick, University of Strathclyde, Glasgow, UK

Introduction

In order to understand the structure of a polymeric material, it is important to recognize the subclass of macromolecular materials to which the substance belongs. In principle, there are many features which are common to naturally occurring and synthetic polymers. The former is usually produced via a "step growth" process and hence has atoms other than carbon in their backbone, one of the exceptions to this generalization being natural rubber, which has an all-carbon backbone. Associated with the heteroatom incorporation are the amide, urea, ester, lactone, lactam, ether, etc. functions upon which so many of the structures are based. The polymer backbones or side groups may contain hydrogen-bonded entities and their interactions build the hierarchal structures that are so important in biological polymer systems. Many synthetic polymers are produced via "addition" reactions in which an active center created by a radical, cation, or anion adds to an unsaturated carbon–carbon bond and propagates the growth of a polymer chain. This type of chemistry is responsible for many of the highly used polymers, for example, poly(ethylene), poly(propylene), poly(vinylchloride), and poly(styrene). Polymers such as poly(ethyleneterephthalate) are produced via a step-growth process similar to that used by nature in much of its macromolecular synthesis. Polymers produced by addition reactions can have chain lengths that are all very similar, whereas the very nature of the step-growth process will tend to generate a broad distribution of chain lengths. The difference in the distribution of chain lengths can have a significant effect on the structures created by these polymers. A narrow distribution of chain lengths will allow a level of organization that is not observed in the broader distribution.

Influence of Molecular Structure on Morphology

Polymer materials can be divided into two types: those produced with two functions per repeat unit and form linear structures, and those which have functionality greater than 2 and form branched or cross-linked structures. The latter are often "thermoset" materials and may not be reprocessed by heating, whereas the former linear chain polymers are "thermoplastic" and can be reprocessed into new structures by heating or dispersion in a solvent. The ability for thermoplastic polymers to generate organized structures depends very much on the balance between the inherent entropy, associated with the conformational distribution between the various stable states possible for the polymer chain. For instance, in the case of poly(ethylene), there are two possible states: gauche and trans, the latter having lower energy and hence a higher probability of occurrence (**Figure 1a**).

In terms of structure building, the trans structures are ideally suited for packing into a regular crystalline ordered arrangement and creating domains which are highly ordered within the solid. The gauche structures will disrupt this packing and the crystallization processes proceed with the clustering of these higher-energy states into regions which are disordered or amorphous in nature. Certain polymers which possess bulky side chains, polystyrene being a classic example (**Figure 1b**), are unable to pack and hence the dominant structure is amorphous. If the monomers are multifunctional, then network formation leading to a thermoset structure is possible (**Figure 1c**). It is, therefore, possible to divide polymer materials into three general classes of materials: amorphous, crystalline, and network structures. In the content of networks and amorphous materials, it is important to recognize that the dynamics of the polymer chains can influence the perception of the material without requiring a major redefinition of the overall structure. In the case of an amorphous

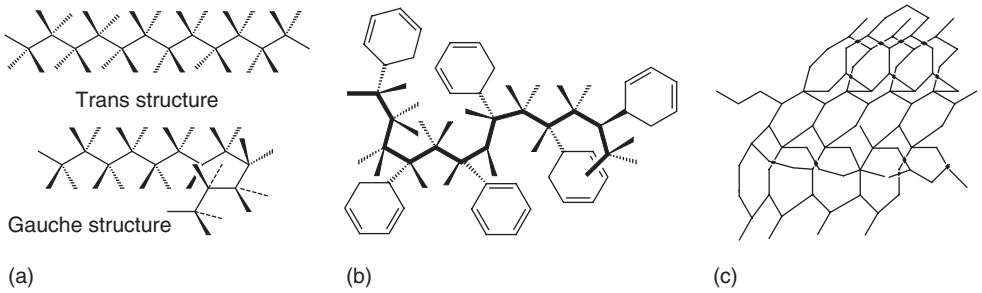

Figure 1 Possible structures for (a) poly(ethylene) chain, (b) poly(styrene), and (c) a network based on multifunctional monomers.

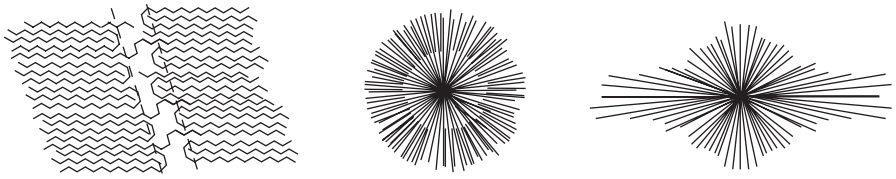

Figure 2 Chain folding in poly(ethylene) leading to lamellae formation and a pictorial representation of spherulitic growth.

polymer, if the interactions between neighboring polymer molecules are strong, then it is unlikely that there will be sufficient volume for the chains to readily change their conformations. The matrix distribution is, therefore, essentially frozen and the material is a glass. Heating the material can cause an expansion to occur, reducing the chain–chain interactions and producing sufficient volume between the chains for conformational change to occur. Creation of the "free volume" allows conformational changes, which involve cooperative motions of the polymer backbone and the material becomes flexible. This rubbery or elastomeric structure has been created without significant redistribution of the chains within the structure and can still be considered to be amorphous. It is also possible to see the same changes from glassy to rubbery behavior in a network structure.

Crystalline Polymer Structure

Only in solution-grown polymer single crystals will perfect, often rhombohedral, crystal structures be observed. In general, the structures obtained from processing crystallizable polymeric materials will reflect the thermal history associated with solidification of the material. In the melt phase, the polymer will adopt a configuration that the ideal flexible polymer would have in dilute solution and corresponds to the so-called random coil structure. The coiling behavior is a direct reflection of the gauche content in the conformational distribution. As the polymer cools down, the proportion of the trans content in the conformational distribution increases and the possibility of the alignment of these units necessary for crystal growth is encouraged. The consequence of the residual gauche content is that the elements of the chains will be disordered and can even loop back on themselves. The looping back creates a hairpin-like organization (**Figure 2**), which aids further packing of subsequent chains. The result of the folding is that the lamellae-type of structure is generated. The thickness of the lamellae, L_{lam}, is dictated by the temperature at which the crystallization process and the growth mechanism take place. The lamellae for poly(ethylene) are typically between 10 and 18 nm, for poly(4-methylpentene-1) between 11 and 15 nm, and for poly(oxymethylene) between 6 and 10 nm. If the surface energy of the fold surface is σ_f, the enthalpy for melting of the crystal phase is ΔH_M^0, and the melt temperature is T_M^0, then

$$(L_{\text{lam}})_{\text{theor}} = \frac{2\sigma_f T_M^0}{(\Delta H_M^0)(T_M^0 - T_{\text{cryst}})}$$

where T_{cryst} is the temperature to which the melt has been supercooled before crystallization occurs. The ratio of the instantaneous volume fraction ϕ of the crystalline material in the total sample to the value after infinite time ϕ_∞ indicates a randomly distributed nuclei. The probability p that a point does not lie in any one entity is proportional to the fraction:

$$p = 1 - \left(\frac{\phi}{\phi_\infty}\right)$$

If all the entities are formed simultaneously, the density of nuclei is a constant and the probability depends on the mean volume $\bar{V}_i$ and the number of entities N. The concentration of entities then becomes $v = N/V$, where V is the total volume. This leads to

$$\phi = \phi_\infty [1 - \exp(1 - v\bar{V}_i)]$$

The growth is controlled by the following factors: whether or not the nucleation is spontaneous; and the form of the growth, that is, rod, disk, or spherical. This leads to the Avrami equation which has the form

$$\phi = \phi_\infty [1 - \exp(1 - zt^n)]$$

where z and n are constants, characteristic of the particular growth mechanism. While the theoretical predictions and practical observations do not show a strong correlation, the theory has been useful for rationalizing the growth observed in similar systems.

Spherulites

Electron microscopic examination indicates that the lamellae will tend to cluster from the nucleation point and form into a floret- or spherulite-like structure (**Figure 2**), which has an interface with the growth boundary of a neighboring cluster. These boundary layers are important as they represent regions of potential weakness and can develop on cold-drawing of the polymer. Cold-drawing of predominantly isotactic poly(propylene) creates fibers with strength significantly greater than those of the originally extruded sheet of polymer (**Figure 3**).

The cold-drawing creates alignment of the lamellae and allows development of anisotropic mechanical properties. The modulus in the draw direction is significantly increased, whereas it decreases in the transverse direction due to the creation of voids. Spherulites make films opaque when their dimensions are greater than half the wavelength of light and when, in addition, inhomogeneities exist in relation to the density or the refractive index. Spherulitic poly(ethylene) is opaque, but spherulitic poly(4-methyl-pentene-1) is glass clear even when both have the same number of spherulites with the same dimensions.

Dendrites and Epitaxial Growth

Spherulites are produced because the overall crystallization rate is approximately the same in all directions. However, the growth rates of crystals in the spherulite may be directionally dependent. Conversely, if the overall crystallization rate is also direction dependent, then what are called dendrites are produced. A low-temperature solution-growth process often produces these structures. Acid etching of the polymer indicates that the interior contains a polymer chain that can be oxidized and represent an amorphous component. The remaining crystalline component has a lamellar structure of regular thickness.

Shish Kebab

High-temperature solution growth can generate a structure that resembles a "shish kebab," (from the Armenian dish) structure. When crystallization from dilute solution occurs with strong stirring, these structures are produced (**Figure 4**). The macromolecules are orientated along the direction of flow and settle out perpendicular to each other. X-ray scattering, electron diffraction, and birefringence measurements show that the chains lie parallel to the fiber axis. The fibrils produced order themselves into nucleation bundles, but the shear gradient is strongly reduced between the fibrils crystallizing out on these in the form of folded chain lamellae. The lamellae here lie vertical with respect to the fibrils. The shish kebab formation is a special case of epitaxial growth.

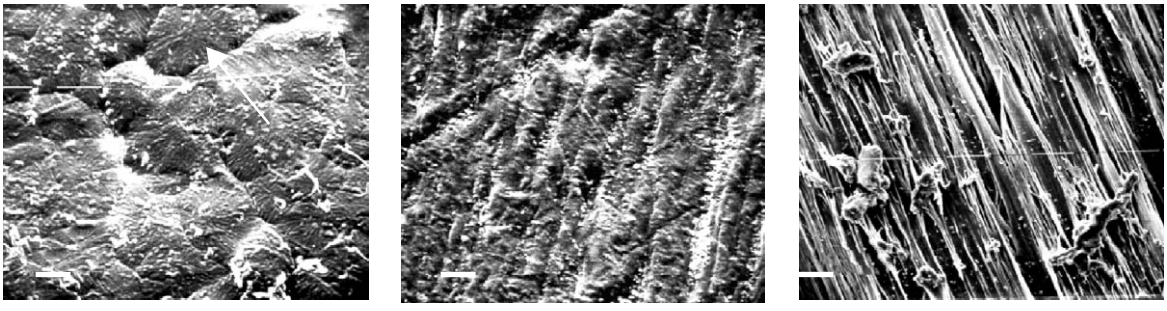

Figure 3 Electron micrographs of cold-drawn polypropylene indicating the alignment of the crystal structure, the bar is 1 μm, λ = draw ratio: $\lambda = 1$, a domain is identified by the arrow; $\lambda = 6$, the parallel texture is a consequence of the lamellae aligning in the draw direction; $\lambda = 12$, the process of drawing has generated fibers and the bridging polymer fragments are clearly seen between the fibers.

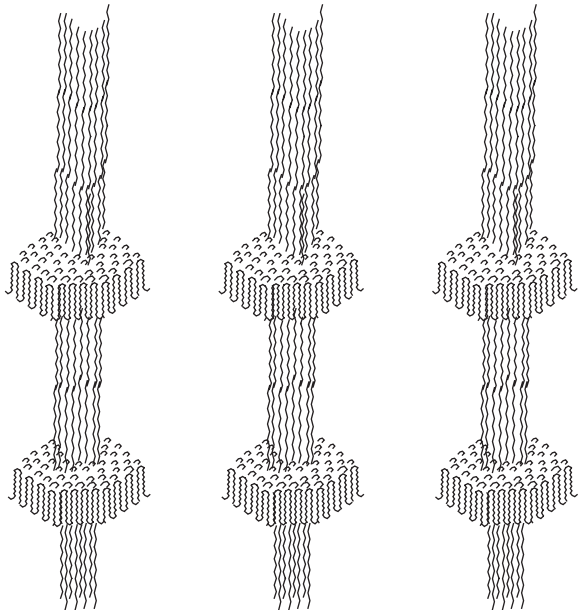

Figure 4 Schematic representation of the arrangement of chains that form a shish kebab structure.

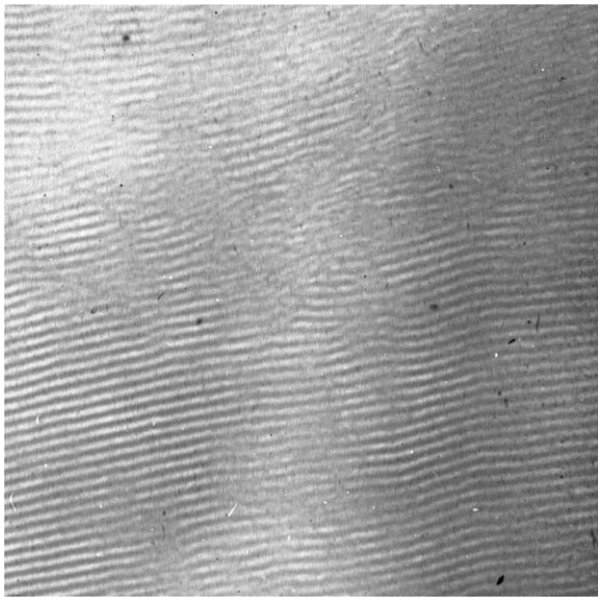

Figure 5 Transmission electron micrograph of styrene–butadiene–styrene triblock copolymer stained with osmium tetroxide. The domain sizes are 10 μm in width.

The orientated growth of one crystalline substance on another is defined as epitaxy.

Amorphous Polymer Structure

The amorphous state is characterized by a complete lack of structure or organization of the polymer chains. The chains that form this disorganized state will have trapped a certain amount of volume – "free volume." It is possible to probe this free volume using positron annihilation lifetime spectroscopy and to show that at the glass–rubber transition, T_g, there is an increase in the volume that liberates the backbone motions of the polymer chain and allows it to demonstrate a rubbery character. The polymer chains in the amorphous state will have a size which is similar to that found at the theta temperature in solutions. The theta temperature corresponds to a thermodynamic state in which the interaction of the polymer segments with one another is identical to the solvent when the polymer is in dilute solution. Most amorphous polymers and crosslinked networks do not show any structure when observed using X-ray diffraction or electron microscopy.

Block Copolymers

Due to thermodynamic incompatibility of the segments of a styrene–butadiene–styrene tri-block, copolymer phase separation can be observed in styrene (light colored) and butadiene (dark colored) phases. The different colors in the electron micrography are achieved by using osmium tetroxide that adds to the butadiene double bonds, and the osmium generates the scattering contrast (**Figure 5**).

Extrusion of the block copolymer can generate an aligned material in which the styrene and butadiene phases, orientated with the flow and perpendicular to the flow direction, form a regular ordered structure (**Figure 6**). The result of this alignment is that the modulus in the direction of the flow is dominated by the styrene phase and has a value at room temperature close to that of poly(styrene). In the transverse direction, the material exhibits a much lower modulus which is close to that of poly(butadiene), which is a rubber at room temperature. Phase separation has a dominating effect on the physical properties of a number of polymer systems, and many of the useful characteristics to be found in polyurethanes are a consequence of phase separation of the hard aromatic urethane phase from the flexible poly(ether) or poly(ester) phases.

Phase separation is very important in thermoset resins. Rubber toughening in epoxy resin can be achieved by the addition of carboxy terminated butadiene–acrylonitrile copolymer – CTBN. The CTBN is initially compatible with the epoxy amine mixture but as cure proceeds, the rubber phase separates out and forms rubbery domains (**Figure 7**). It is interesting to note that the white specs within the rubbery phases are epoxy resin, which is incorporated in the phase as it separates but subsequently is precipitated as it cures. However, since it is now in the rubbery phase, it is occluded in that phase rather than forming part of the main matrix structure.

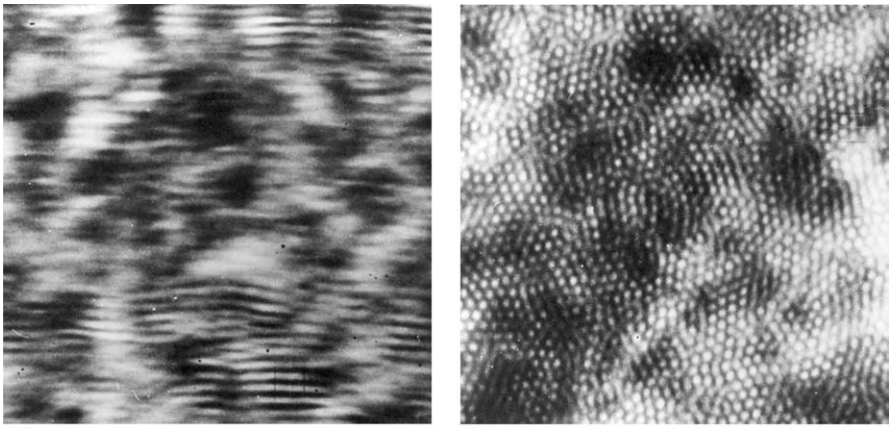

Figure 6 Electron micrographs (a) parallel and (b) perpendicular to the extrusion direction for an osmium tetroxide strained styrene–butadiene–styrene triblock copolymer. The light colored domains are ~10 nm in size.

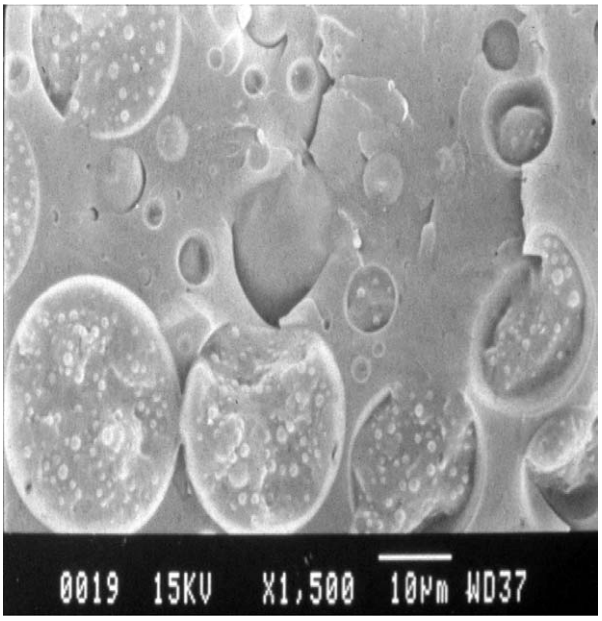

Figure 7 Electron micrograph of a carboxyl terminated butadiene–acrylonitrile copolymer phase dispersed in a thermoset amine cured epoxy resin.

These rubbery phases impart toughening to the epoxy resin by providing a mechanism for energy dissipation. Although amorphous polymers are not normally considered to exhibit structures, phase separation does create features that are important in understanding the mechanical properties of the polymers.

Liquid Crystalline and Related Structures

Polymers, like small molecules, are observed to exhibit partial ordered structures. Like their low-molar-mass analogs, polymers also exhibit the optical birefringence that is characteristic of partial degrees of alignment: nematic, smectic, and/or cholesteric organization (**Figure 8**).

These structures are distinguished on the basis of the extent to which they exhibit coherent alignment and dimensional order. In the nematic phase, the species are aligned in one direction, designated as the director. The smectic phase has alignment in at least

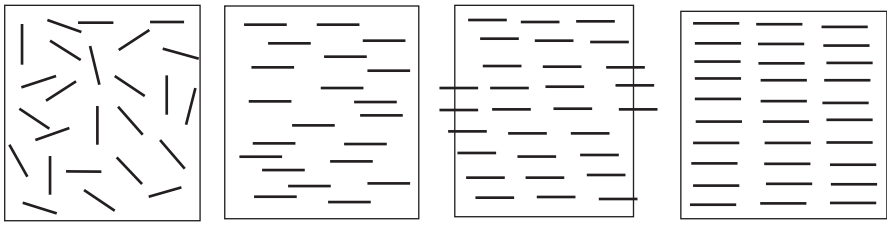

Figure 8 Schematic representation of the alignment and order in nematic and smectic phases.

two directions and may also exhibit order in a third phase depending on its designation. In the smectic A phase, the director is parallel to the plane normal, whereas in the smectic C phase the director is inclined along the plane but the perfection approaches that of the crystalline state. In the cholesteric phase, entities exhibit a regular register from plane to plane and there is a helical twist developed through the volume as the planes rotate (**Figure 9**).

In addition to these idealized structures, there are a number of characteristic features that reflect the influence of various types of characteristic defects on the material. Because the ordered domain has dimensions of the order of the wavelength of light (~ 500 nm), dramatic birefringent optical images can be observed when crossed polarization is used for the microscopic examination. These structures are rarely uniform and the director will vary slowly through space. Different phases have different characteristic textures that arise from the permitted symmetry of the defects that occur in the packing process. The textures can be used to identify the phases. However, in the case of the "fingerprint" texture seen in cholesteric liquid crystals, the texture arises simply from its helical structure as indicated in **Figure 9**. Light is rotated by the director as long as the rate of twist is not too great compared with the wavelength of light, λ.

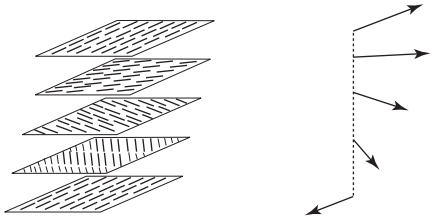

Figure 9 Schematic of the order and relative rotation of parallel planes in a cholesteric liquid crystalline phase.

Defects

Within a particular plane it is possible to envisage a twist, splay, or slow bend of the director and these structures will all have characteristic optical birefringence. Dislocations are discontinuities in the translation of atoms in a crystalline phase; however, in a liquid crystalline phase the discontinuities are in orientation, within the director field. There are various types of disclinations characterized by their "strengths." The term "strength" indicates the number of multiples of 2π that the director rotates in a complete circuit around the disclination core.

Under crossed polars, four dark "brushes" are seen where the director is parallel to one of the polarizers, and extinction occurs. The defect may be either a line or a point defect. A variety of different defects can be identified which are characteristic of a particular liquid crystalline phase.

It is not very surprising to find that polymer films can exhibit liquid crystalline order. Polymeric liquid crystallines are usually divided into main chain (MCPLC) and side chain polymer liquid crystals (SCPLC). The liquid crystalline character of the main chain polymers reflects the correlation of regular kinks in the backbone allowing organized regions to be developed. Examples of this type are poly(ethyleneterephthalate) and poly(hydroxynaphthalenic acid).

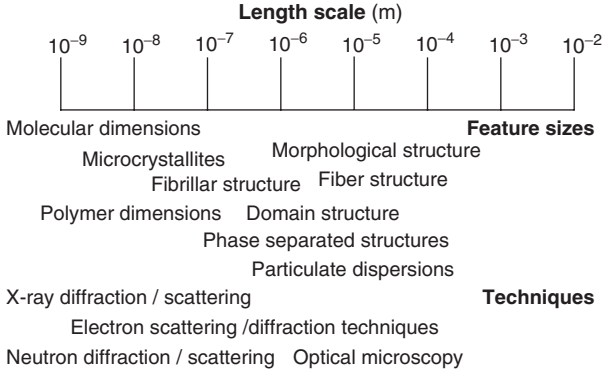

Figure 11 Length scale variations and visualization techniques.

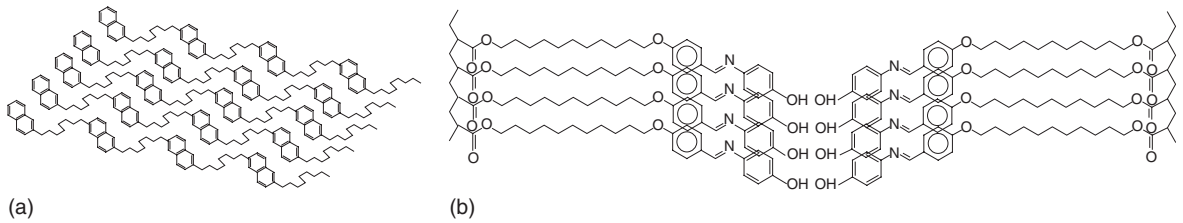

Figure 10 Schematic of backbone and side chain liquid crystalline polymers: (a) main chain liquid crystal order and (b) side chain liquid crystal order.

The flexible ethyleneoxide spacer allows the relative alignment of neighboring chains and the polymer to display liquid crystalline order. Kinks in the backbone structure of the poly(hydroxynaphthalenic acid) allows a similar alignment to be achieved and liquid crystal behavior to be observed. There has also been considerable interest in side chain liquid crystalline polymers, where the pendant entities are designed to be flexibly attached to the backbone and can themselves align to give ordered structures (**Figure 10**).

Liquid crystalline structures have been detected in a wide range of polymers including poly(ether imides), poly(4,4′-dioxy-2,2′-dimethyl-azoxybenzene dodecanedioyl)-co-polyoxyethylene 400 (PMABD-co-POE), poly(didocecyl-*p*-phenylene), poly(diacetylene) P-4BCMU, poly(*p*-phenylene terephthalamide), and aromatic polyesters. It is clear that organization ion polymer systems not only have to be considered at a molecular level, but also in terms of nano- and micro-length-scales. **Figure 11** indicates how length scales can be studied.

Biopolymeric Structures

It is well known that various cellulose derivatives can exhibit a liquid crystalline behavior; however, it is appropriate to consider how the organization can be mapped between the molecular chain and the macrostructure of a cotton fiber (**Figure 12**). Cellulose has a 1,4-β-D-linked polyanhydropyranose structure. In order to understand the physical properties, one has to be able to distinguish the principal structure at three different levels.

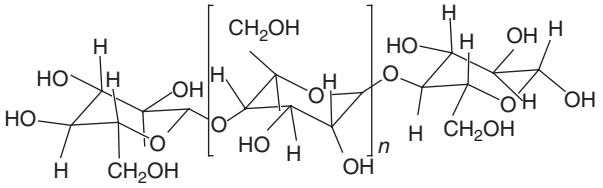

Figure 12 Structure of the cellulose molecule.

The Molecular Level

At a molecular level, the chains that consist of β-D-glucose existing in the pyranose form adopt a $^4C^1$ (chair conformation $^4C^1$ denotes that the ring which is attached through the 1- and 4-carbons is in the chair configuration), which is the lowest energy conformation. The presence of intramolecular hydrogen bonding between the hydroxyl group in the 3 position and the ring ether oxygen in the 5 position imposes a twist on the C(1)–O(1) and the C(4)–O(4) glucosidic bonds which results in the chain adopting a helical conformation.

The possibility of polymorphic forms being obtained depends on how the rigid chains pack together. The study of these forms has been the subject of active study for many years. Native cellulose exhibits the cellulose I structure. The mercerized or regenerated cellulose exhibits a different structure designated as cellulose II. Of the two forms, the latter is considered to be more thermodynamically stable. The average hydrogen bond length in the case of cellulose II is 2.72×10^{-10} m, which is remarkably shorter than the value of 2.80×10^{-10} m in cellulose I. The denser structure and greater involvement in the hydrogen bonding are reflected in the lower susceptibility of the regenerated cellulose to reaction. The polymer chains, although aligned, also exhibit

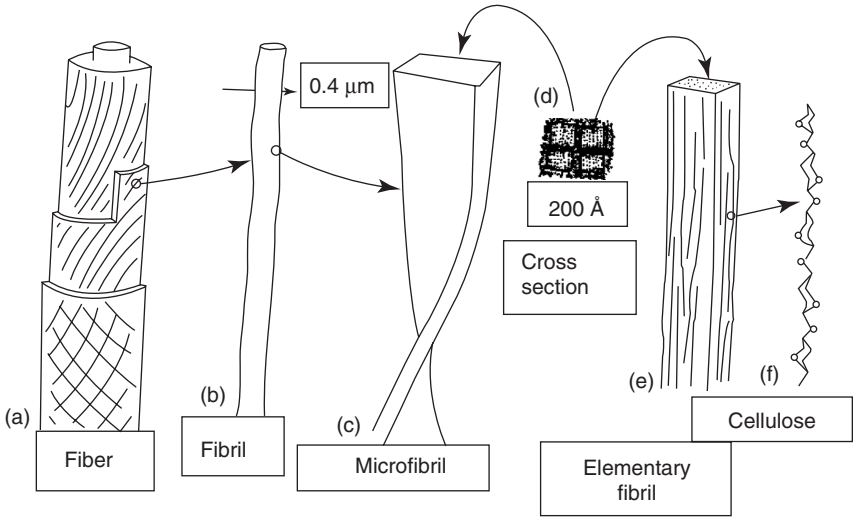

Figure 13 Morphology of a cellulose fiber showing the various levels of organization.

disorder that leads to the creation of amorphous regions and disrupts the perfection of the crystal structure.

The Supermolecular Level

The crystalline regions will organize themselves into larger structures, and the number and form that they take is dictated by a variety of factors which reflect the processes involved in the formation of the macrostructures (**Figure 13**). The crystallites are organized into the microfibrils that pack to form the fibril. This packing, however, is not random, and the microfibril having a twisted structure itself aids the formation of the fibril.

Macrostructural Level

The fibrils are themselves packed into a layered structure that reflects the twisted nature of the fibrils. The center of the cotton fiber is a hollow structure formed by the criss-crossing of the fibers to generate a tube-lumen upon which the other layers are formed. The subsequent layers adopt a common alignment of the fibers and form the so-called secondary wall structure. The outer layer of cellulose is the winding layer that is also composed of a criss-crossed layer. Outside this layer, the primary wall and the cuticle are to be found, and these often contain noncellulose materials such as lignin.

The morphology of biopolymers is dominated by hydrogen bonding and self-assembly, and there is a rich spectrum of level of structures which can be observed.

Polymers and Organic Compounds, Optical Properties of

T Koda, University of Tokyo, Tokyo, Japan
K Kajikawa, Tokyo Institute of Technology, Yokohama, Japan

Introduction

This article deals with the optical properties of organic substances, which are by far rich in diversity and make the reductionalist view point of physics quite hard to apply. Nevertheless, during the latter half of the twentieth century, considerable progress has been made in establishing the simplest possible physical pictures, such as excitons, phonons, polaritons, and so on. This trend is still underway, aiming at the goal which may be best expressed by the following words of Mott in the preface of a book by Pope and Swenberg: "The reasons are many, but certainly the most important is that new things are to be found, which is rarely the case in the well-explored field of inorganic crystals. —and perhaps the distant dream of a new technology and one possible application to the understanding of such biological processes as do involve electronic motion."

Structures of Organic Materials

In the following, organic opto-electronic materials composed of conjugated molecules are considered. Starting from an ethylene molecule, $H_2C=CH_2$, and connecting it with another ethylene molecule one by one, either an open-end linear conjugated system or a closed-ring conjugated system is obtained, which are named in chemistry as aliphatic and aromatic molecules, respectively. In the limit of infinite chain length, the former system becomes a prototype of conjugated polymers. Typical molecular structures of the conjugated molecules are listed in **Figure 1**.

Assemblies of these conjugated molecules can be further classified into two major types, according to the nature of dominant intermolecular cohesive interaction: (1) Molecular crystals, composed of electrically neutral molecules. The van der Waals interaction between the molecules with no net charge and permanent electric dipole moment is responsible for the cohesive force. Most of the mono-molecular crystals of aromatic molecules belong to this type. (2) The charge-transfer (CT) complex crystals composed of two kinds of molecules having electric charges of opposite sign due to the intermolecular electron transfer. The effective molecular charge ρ (the degree of CT) is determined by the trade-off relation between the Coulombic energy gained by the long-range electrostatic interactions in the whole molecular assembly and the energy needed for the CT process, similar to the case of a bimolecular donor (D)-acceptor (A) CT complex $D^{+\rho}A^{-\rho}$.

There are other kinds of organic materials, though not so major in numbers. Among them, hydrogen

(a) Aromatic (ring-like) and related molecules

Family of polyacenes

Name	Structure	λ_m(nm)
Benzene		259
Naphthalene		310
Anthracene		380
Naphthacene (tetracene)		471
Pentacene		575

Some related molecules

Phenanthrene		293
Pyrene		336
Perylene		437
Porphyrine		400 (Soret band) 700 (Q-band)
Phthalocyanine		400~700 (depending on the ligand metal at the center of the ring)

(b) Aliphatic (linear) and related molecules

Family of polyenes

Name	Structure	λ_m(nm)
Ethylene		~162
Butadiene		~220
Hexatriene		~260
Octatriene		~300

Some related molecules

β-Carotene (all-trans)		~480
Trans-retinal		~370
Polyacetylene (trans-form)		~690
Poly-(*p*-phenylenevinylene) (PPV)		~430

Figure 1 Typical conjugated molecules; (a) for ring-like molecules, and (b) for chain-like molecules. Molecular structures are shown according to the IUPAC notations. λ_m represents approximate wavelength (in nm) of the lowest main absorption band.

(H)-bonded molecular crystals are important. Two atoms X, Y having electro-negativities larger than the H atom, are connected like –X–H–Y– (X, Y = N, O, P, S, …) to form a weakly coupled molecular crystal-like crystalline H_2O (ice). In organic materials and polymers, there are several important H-bonded substances including bio-polymer DNA, for instance. Often the H atom has bi-stable or multi-stable positions, showing interesting optical and dielectric phenomena due to the proton transfer. Besides, noncrystalline assembly of organic molecules is also important for technological applications. Conjugated polymer films having a spaghetti-like irregular structure of entangled fibrils may be regarded as a quasi-one-dimensional (1D) electronic system with a mixed character of amorphous and crystalline structures. Another important disordered molecular assembly is liquid crystals. These topics are described in the last part of this article.

Simple Model for π-Electron Systems

The conjugated molecules shown in **Figure 1** exhibit an obvious trend of increasing wavelengths of absorption bands as the repetition number N of the conjugation unit increases (**Figure 2**). The first theoretical model for this is known as the Kuhn model. It is assumed that the total $2N$ π-electrons including the spin freedom are confined in a 1D potential well, having width equal to the conjugation length $L(= aN)$. When the potential is flat and the wall height is infinite, it is an elementary task to calculate the quantized states for each π-electron in the Hückel approximation, neglecting the electron correlation effect. The photoexcitation of an electron takes place from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO), the HOMO–LUMO gap corresponding to the lowest absorption energy due to the spin-singlet $\pi-\pi^*$ transition. To improve this simplest possible model, the flat potential may be replaced by a weak periodic potential as a perturbation. The same model is applicable to the ring-shaped molecules by using the cyclic boundary condition. This model leads to a theoretical expression for the lowest singlet $\pi-\pi^*$ transition energy ΔE as follows:

$$\Delta E = \left(\frac{\hbar^2}{2m}\right)\left(\frac{2N+1}{L^2}\right) + V_0\left(1 - \frac{1}{2N}\right)$$

Here, $\hbar$ and m are conventional fundamental constants, V_0 ($\sim 2\,\text{eV}$) is an empirical parameter for the amplitude of sinusoidal periodic potential. The first term on the right side is the increment of kinetic energy when an electron is photoexcited, while the second term is due to the perturbation of the periodic potential. In the limit of infinite length L, the first term vanishes, so that the π-electron system must exhibit a free-electron-like (metallic) behavior if $V_0 = 0$. But, when $V_0 \neq 0$, the second term remains finite in the same limit, which implies that the long conjugated molecules and polymers must be a semiconductor with a finite excitation gap.

Though the Kuhn model is useful for providing an intuitive physical picture, like the Kronig–Penny model in semiconductor physics, it has an obvious fault of completely ignoring the electron-correlation effect, which is evidently unrealistic for the π-electron systems confined within a low-dimensional molecular geometry. In the opposite limit of the strongly correlated π-electron systems, the $2N$ π-electrons may be better treated as a Fermion gas, instead of the one-electron model in the Hückel approximation. In the Fermion gas model, the finite excitation energy in the limit of $N \to \infty$ is interpreted as due to the plasma oscillation of the π-electron gas. However, the underlying physics is much more complicated than depicted by either models. In the subsequent course of studies, it has been widely accepted that the origin of finite excitation energy in long conjugated linear-chain molecules and polymers is due to the bond-alternation caused by the structural instabilities inherent in a 1D electron-lattice system and in a 1D spin-lattice system. The energy gap due to the former is called the Peierls gap, and the latter the Hubbard gap. The charge density wave (CDW) excitation, and the spin density wave (SDW) excitation are responsible for the opening of the respective gaps. The actual conjugated molecular systems have a mixed character to be treated as a 1D Hubbard–Peierls system.

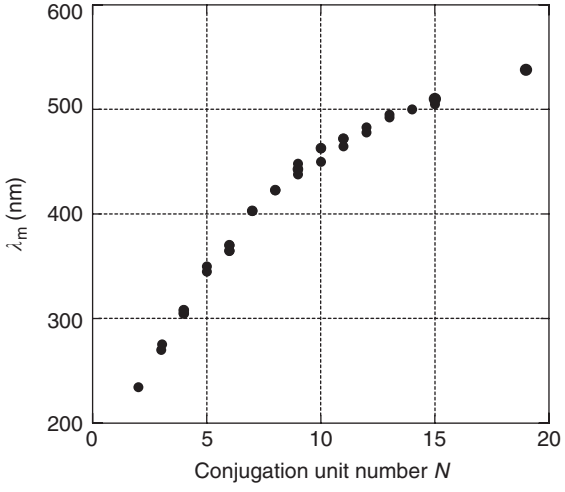

Figure 2 The absorption peak wavelength λ_m vs. conjugation unit number N for transpolyenes $[–HC=CH–]_N$. Filled circles are experimental data for specific molecules (not indicated here) in solution. (Due to H Suzuki and S Mizuhashi.)

So far, the spin-singlet excited states were considered. In the early stage of study, it had been suggested that the spin-triplet excited states were responsible for phosphorescence in organic phosphors. In subsequent studies, photoinduced transient effects in magnetic, ESR, and optical properties had confirmed that the triplet excited states are certainly photo-generated in various organic molecules and crystals. The singlet-triplet splittings are fairly large ($\leqslant 1$ eV), indicating a strong electron correlation effect in the π-conjugated organic systems.

Vibronic Spectra of Organic Molecules

The energies for the ground and excited states, E_g and E_{ex}, of a π-electron system can be expressed as a function of so-called configuration-coordinates (CC), Q_iLs, in a general form of E_i (i= g, ex)(Q_1, Q_2, … Q_i …). For simplicity, one assumes that a particular mode Q (usually of the totally symmetric breathing mode) is dominant, so that the vibronic energies for the ground and excited states (singlet and triplet) are depicted by three curves, as illustrated in **Figure 3**. Photoexcitation takes place from the vibronic levels of the ground state to those of the singlet excited state, with relative intensities depending on the Boltzmann distribution in the vibronic states of the ground states and on the Franck–Condon factor, which is defined as the overlapping integral squared of the vibrational wave functions for the ground and excited states having displaced equilibrium points. The excited electron releases the extra vibrational energy into the surroundings within a time of several vibration periods (a few picoseconds). During this relaxation process, the electron may undergo spin-flip, and makes a radiationless jump (intersystem crossing) to the triplet excited state. Under the steady photoexcitation, excited molecules find themselves near the bottom of either the singlet excited-state curve or the triplet excited-state curve. The radiative decay from the singlet excited state is observed as fluorescence with a fast decay (a few nanoseconds or less), while that from the triplet excited state as phosphorescence with a slow decay (a few milliseconds or more). The phosphorescence band is considerably red-shifted from the fluorescence band, which is usually not the case in inorganic phosphors. The excitation spectra for the phosphorescence are often useful in detecting the triplet excited state and other forbidden excited states, which are hard to observe directly by absorption.

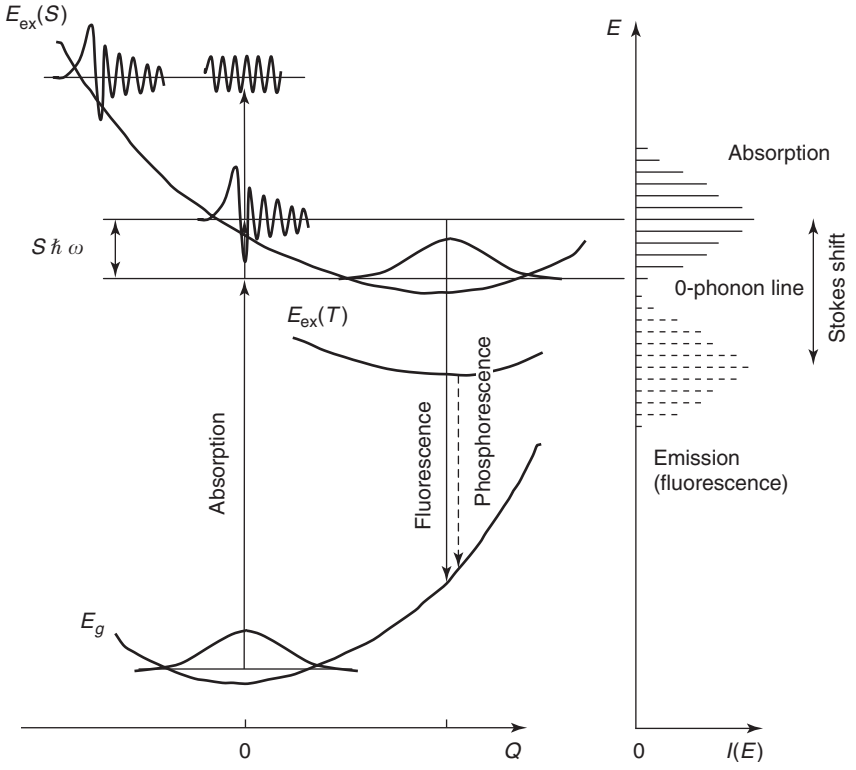

Figure 3 CC model for optical transitions in a conjugated molecule; the curves denoted E_g, $E_{ex}(S)$, and $E_{ex}(T)$ are the CC curves for the ground state, singlet, and triplet excited states, respectively. On the right, vibronic structures in the absorption and fluorescence bands are schematically shown. Those for the phosphorescence band appearing in the lower energy region are not shown.

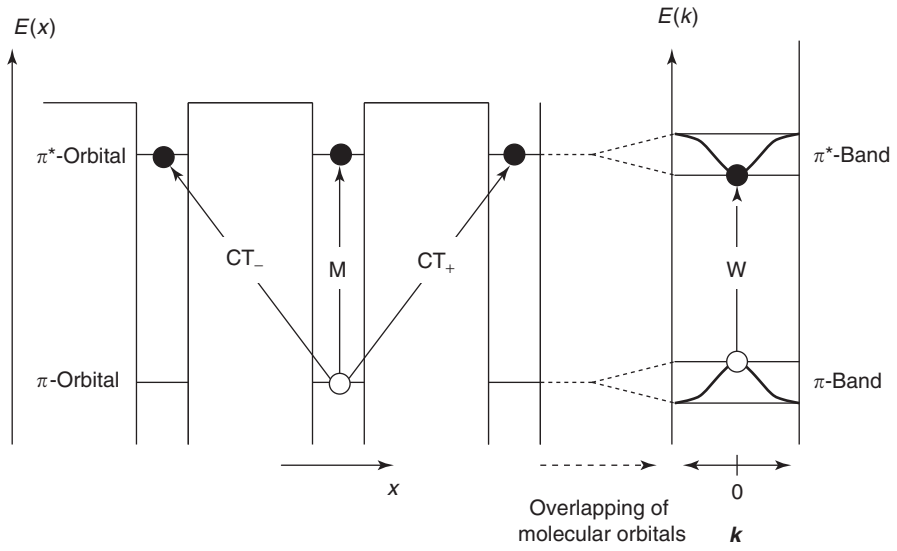

Figure 4 Schematic illustrations for elementary excitations in molecular exciton (M), charge-transfer exciton ($CT_{\pm}$), and Wannier (W) exciton. The transnational motion of respective excitons is not depicted. The filled and open circles represent electrons in the LUMO π^*-orbital (or conduction band) and holes in the HOMO π-orbital (or valence band), respectively.

According to the adiabatic (Born–Oppenheimer) approximation, the absorption spectrum at sufficiently low temperatures is composed of a series of narrow lines (o, n), corresponding to the transitions from the lowest vibronic state ($m = 0$) of the ground state to the vibronic states $n \geqslant 0$ of the singlet excited state, m and n being the vibrational quantum numbers for the ground and excited states. The relative intensity for the (o, n) components is given by the Franck–Condon factor. The result is expressed by the Poisson distribution, $I(0, n) = e^{-S}S^n/n!$, provided that both states have the same vibration frequencies. Here, S is the Huang–Rhys factor, defined as the average number of vibration quanta emitted in the thermal relaxation process after photoexcitation. In the strong vibronic coupling regime ($S \gg 1$), the absorption spectrum approaches a broad Gaussian shape, while in the weak or intermediate coupling regime ($S \leqslant 1$), the spectrum shows a sharp zero-phonon line which is followed by a series of equidistant vibronic lines on the higher energy sides. In the same way, the emission (fluorescence) spectrum at low temperatures is composed of vibronic components (m, o) approximately in a mirror-image of the absorption spectrum. The red-shift of the emission band peak from the absorption band peak is called the Stokes shift.

Exciton Concepts in Organic Crystals

Detailed optical studies of molecular crystals had started at the beginning of the twentieth century. Subsequently in the 1920s to the 1940s of the last century, further extensive studies had been made using extremely thin flakes of aromatic molecular crystals, until the conventional Kramers–Kronig analysis of reflection spectra became available in the late 1960s. From a careful comparison of absorption spectra in solutions and crystals, it had been recognized that some notable features show up when molecules are condensed into a crystalline structure. To interpret these features, a quantum mechanical picture of molecular excitons had been proposed upon the concept of the Frenkel exciton. Later on, more profound studies had been explored on the optical properties related with excitons in organic crystals. In contrast to the predominant character of 3D Wannier excitons in inorganic semiconductors, excitons in organic crystals and polymers have three different faces like Hekate, a goddess in ancient Greek mythology. They are named as molecular (Frenkel) exciton, charge-transfer (CT) exciton, and Wannier exciton, which are schematically illustrated in **Figure 4**.

Molecular (Frenkel) Excitons

The name "molecular exciton" comes from its origin in the intra-molecular $\pi - \pi^*$ excitation in the isolated molecule, while the Frenkel exciton is a theoretical concept of propagating excited states in a crystal as a linear combination of localized excitations. The character of the molecular exciton in a crystal is schematically illustrated in **Figure 5**. When a large number (N) of identical conjugated molecules are placed with sufficiently large separation from each other, the photoexcited states have the N-fold

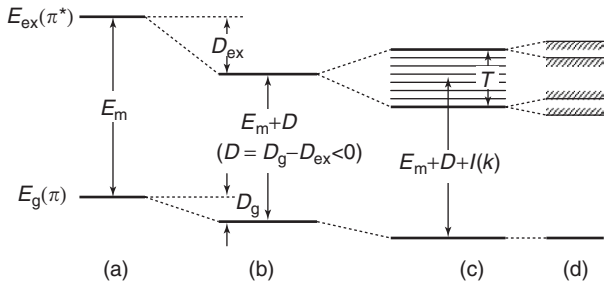

Figure 5 Schematic illustration of the energy levels for the ground and excited states in a conjugated molecule: (a) for an isolated molecule, (b) for the same molecule in solution, (c) and (d) for the excitons in the molecular crystal without and with the Davydov splitting. As for the various notations, see the text.

degeneracy with the same excitation energy E_m (**Figure 5a**). As the inter-molecular distance becomes smaller, the excitation energy is reduced to $E_m - D(>0)$, where D is the reduction in E_m due to the inter-molecular interaction (the site-shift effect). When molecules are condensed to a crystalline structure, the photo-excited state is no longer localized on a specific molecule and begins to propagate in the crystal due to the resonant energy transfer leading to formation of the Frenkel exciton band with $E(k)(= E_m - D + I(k))$.

So far, an ideal case of a rigid crystal has been considered, where all molecules are supposed to be frozen up at their equilibrium sites. Actually, the free excitons are significantly influenced by the dynamical fluctuation of potential due to the molecular vibrations. The vibronic spectra of such molecular excitons can be analyzed by the theoretical model called the dynamical coherent potential approximation (DCPA). Important parameters in this model are the exciton-bandwidth T, representing the delocalized nature of the exciton, and the Huang–Rhys factor S, representing the localized nature of the vibronic state. An example of theoretical absorption spectra by the DCPA model is shown in **Figure 6**. For simplicity, it is assumed here that the exciton is interacting with a single molecular vibration with the energy of $\hbar\omega$ by the Huang–Rhys factor S, which is taken to be unity. A series of spectra in **Figure 6** illustrate the tendency of exciton delocalization as T is increased. In the case of $T = 0$ (top of **Figure 6**), the absorption spectrum is that of an isolated molecule given by the CC model (**Figure 3**). As T increases, the intensities of phonon-side-bands are decreased, and an intense sharp line evolves at the low-energy side of the vibronic spectra. This absorption peak corresponds to the transition to the $k = 0$ edge of the exciton band under the influence of the exciton–polaron effect. It is interesting to note that such behavior of the absorption spectra

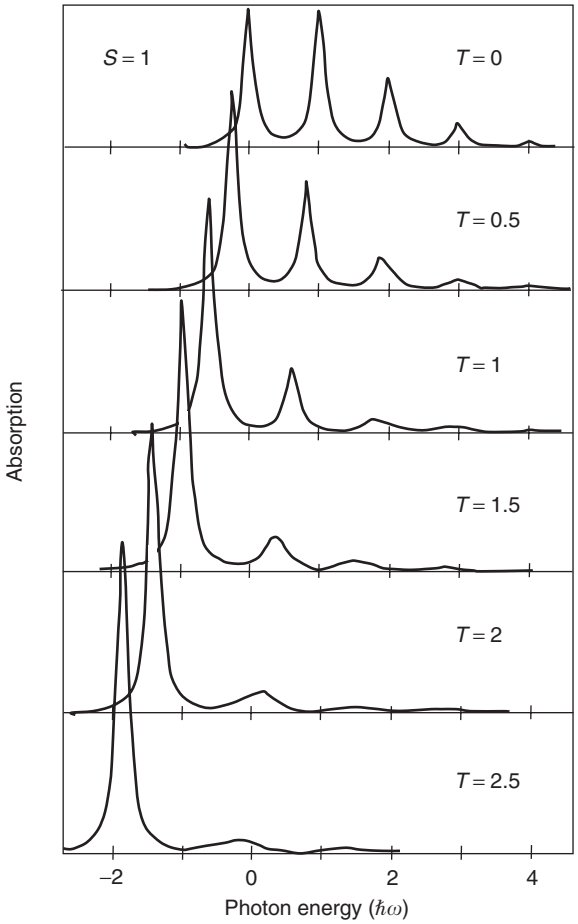

Figure 6 Theoretical spectra at a temperature of 0 K for a vibronic exciton interacting with a molecular vibration with the energy of $\hbar\omega$. The Huang–Rhys factor S is taken to be unity here, and the exciton band-width T is varied from $T = 0$ to 2.5 (in units of $\hbar\omega$). A semicircular curve with the radius of T is adopted for the density-of-state model. The $T = 0$ spectrum at the top corresponds to the localized exciton, those for $T = 0.5-2$ to the intermediate excitons, and that for $T = 2.5$ at the bottom to the nearly free exciton influenced by the polaron effect. The sharp peaks in the $T = 2-2.5$ spectra correspond to the optical transition to the $k = 0$ state of the exciton band. (Due to H Sumi.)

predicted by the DCPA is quite similar to the spectral change observed in the solutions of some organic dyes, where a single intense peak (called the J-band) appears on the low energy side of the broad molecular absorption band as the dye concentration is increased. The formation of microcrystalline aggregates and mobile molecular excitons therein are suggested to be responsible for this remarkable change.

To summarize, complicated optical properties of molecular excitons are interpreted as due to the competing trends of excitons, either being free or self-trapped. For a free exciton, the absorption intensity is concentrated on a single intense line, because very quick exciton motion tends to smooth out the local-molecular deformation (the motional narrowing).

When excitons are localized (self-trapped), the spectra become very broad and Stokes-shifted. There are a number of interesting optical phenomena related with the dynamical behavior of molecular excitons. For instance, it has been demonstrated that a fusion–fission process takes place between mobile singlet and triplet excitons in the following way: 2 triplet excitons $\rightarrow$1 singlet exciton in fusion, and vice versa in fission. In the former case, a delayed fluorescence component is observed with the same slow decay time as phosphorescence.

The prototype of molecular exciton spectra is shown in **Figure 7** for an anthracene crystal. There are two molecules at translationally nonequivalent sites, A and B, as shown in the inset. There can be two kinds of degenerate excitons propagating in the sublattices for the A and B sites. They are actually split into two polarized components due to the interaction between excited molecules on the A and B sites (the Davydov splitting). The transition dipole moment vectors for the Davydov components are suitable linear combinations of the transition moment vectors of the A and B molecules depending also on the wave vector of the exciton. The characteristic polarization dependence of the exciton spectra in **Figure 7** are due to the Davydov splitting of vibronic structures, which correspond to the intermediate coupling regime in the DCPA model (**Figure 6**). The Davydov splittings are also observed in the triplet exciton located at $\sim$1.8 eV. The Davydov splitting energies are 220 cm^{-1} (27 meV) and 21.5 cm^{-1} (3 meV), respectively, for the lowest singlet and triplet excitons. Extensive studies have been made on the various aspects of the molecular exciton in an anthracene crystal, including the fission–fusion process between the singlet and triplet excitons, the exciton polaritons, the surface excitons, and the exciton dynamics in the mixed crystals with deuterium-substituted anthracene molecules and so forth. On the higher energy side of the vibronic exciton bands, there are a series of weak features due to the intermolecular CT excitons, as mentioned in the next section. They are supposed to be responsible for the photocarrier generation process.

Aside from standard aromatic molecules shown in **Figure 1**, there are many important families of molecular crystals, such as phthalocyanines and other cyanine dyes. The molecular excitons in these crystals have a very large oscillator strength ($f \geqslant 1$), which is responsible for the remarkable metallic reflection bands due to the wide polariton-gap. Excitonic states are also supposed to play an important role in the primary stage of the photosynthesis process within the regularly arrayed chlorophyll molecules.

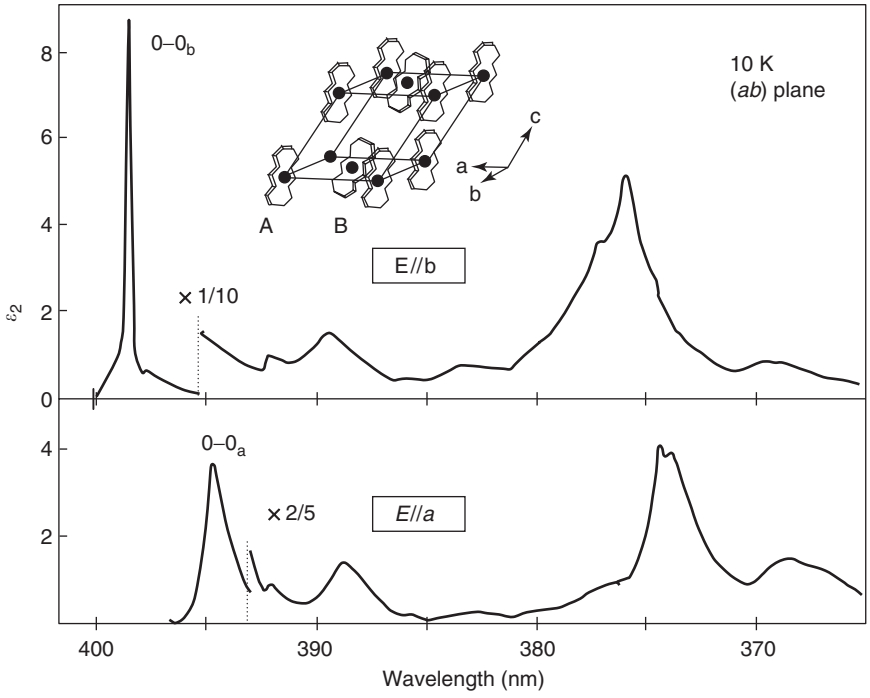

Figure 7 Polarized absorption spectra of anthracene crystal, shown by the imaginary part of complex dielectric constant $\tilde{\varepsilon}$ obtained from the Kramers–Kronig analysis of polarized reflection spectra on the (*ab*) plane at 10 K. The vibronic structures are due to the molecular excitons showing Davydov splittings due to the interaction between excited molecules in the sublattices A and B (see the inset). (Due to Y Tokura and T Koda.)

Charge-Transfer Excitons

In the CT complex crystals, the optical spectra are predominated by the CT excitations, whereas the molecular excitons play only a minor role. According to the characters of CT excitations, the CT crystals are further classified into the following three groups (**Figure** 8); (1) metal–tetracyanoquinodimethane (TCNQ) complex M^+–$TCNQ^-$ (M = K, Rb, Cu, Ag…), (2) halogen-bridged mixed-valent metal–organic complex $-M^{2+}-X-M^{4+}-X-M^{2+}-$ (M = Pt, Pd, Ni; X = Cl, Br), and (3) mixed-stack donor–acceptor (DA) complex, including anthracene–PMDA, TTF–chloranil(CA), etc. In the group (1) crystals, the electron transfer is schematically written as $TCNQ^- \cdot TCNQ^- \rightarrow TCNQ^0 \cdot TCNQ^{2-}$. This needs a finite excitation energy, ~ 1.0 eV in K–TCNQ, due to the Coulomb repulsion between the two electrons on the $TCNQ^{2-}$ molecule. For this CT process to occur, the crystal must have antiferromagnetic spin ordering on the anion sites. Such a spin-ordering occurs below T_c (~ 400 K in K^+–$TCNQ^-$), where the crystal undergoes a structural phase transition (the spin-Peierls transition) into the dimerized antiferromagnetic phase. Similar instabilities in the crystal structure are also observed in group (2) and (3) crystals due to the 1D character of the electron-lattice combined system (the Hubbard system).

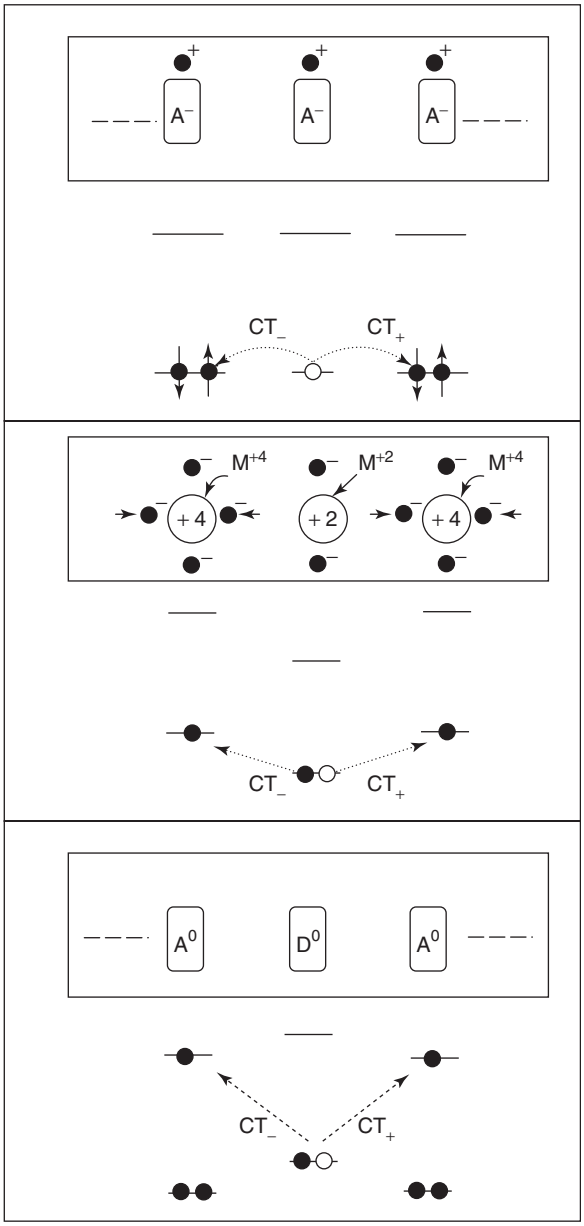

Figure 8 Schematic illustration of elementary CT excitations in three kinds of CT crystals; the top for the family of metal(monovalent)–TCNQ complex crystal, the middle for the halogen-bridged mixed-valence metal complex crystal, and the bottom for the mixed-stack donor (D)–acceptor (A) complex crystal (in the neutral phase denoted D^0A^0). The elementary CT exciton transitions are shown by arrows with dotted lines. All of these CT excitons have a quasi-1D character.

The CT exciton bands are strongly polarized along the 1D stacking axis of molecules in sharp contrast to the intra-molecular absorption bands which are polarized in the directions specified by the molecular axes. In the elementary CT process, an electron is transferred to the adjacent molecules with equal energies for the back- and force-CT excitations (CT_+, CT_-), when the crystal is not dimerized. The eigen CT states are the symmetric and antisymmetric combinations of CT_+ and CT_- states, one being optically allowed and the other forbidden. The photogenerated CT state is unstable against the local deformation and is apt to be self-trapped by the dimerization of adjacent molecules. The forbidden CT state which is not observable in ordinary absorption spectra becomes optically active, either by applying an electric field or by the lattice dimerization below T_c. It is suggested that the forbidden CT state plays an important role as an intermediate state for the large third-order nonlinear optical response of some CT crystals with $\chi^{(3)} \sim 10^{-9}$ esu ($\sim 1\,\mathrm{nm^2\,V^{-2}}$ in MKS). When the CT bands are close to the molecular exciton bands, the intensity of CT transitions is considerably enhanced. This "intensity-borrowing" effect is responsible for the high photoconductivity in some molecular crystals, such as phthalocyanine and other organic photoconductors.

As a prototype of CT crystals, a mixed-stack complex crystal composed of anthracene (An) and PMDA, which belongs to the group (3) CT crystal with a weak degree of CT of $\rho \sim 0.05$ is chosen somewhat arbitrarily. Needle-like crystals of An–PMDA show a bright red color, though the starting materials in the vapor-phase reaction are white powders of An and PMDA. This bright red color of the

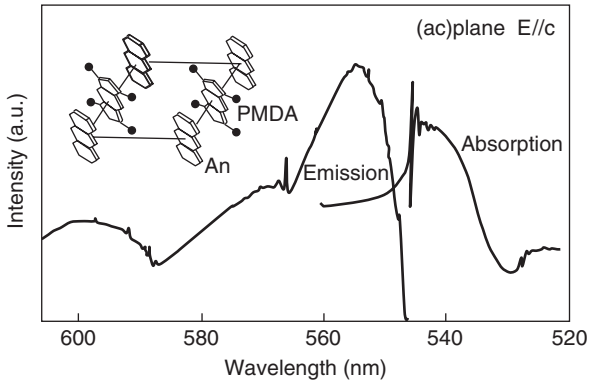

Figure 9 The absorption (obtained by Kramers–Kronig transformation) and emission spectra of An–PMDA crystal at 2 K, polarized with *E*//*c*. The *c*-axis is parallel to the mixed-stack molecular column and is the direction of preferential polarization for both spectra. The sharp absorption line at ~546 nm is due to the 0–0 component of vibronic structures. Broad and sharp features in the emission spectra are due to the free and self-trapped CT excitons coexisting at low temperatures (see the text). (Due to Y Tokura and T Koda.)

crystal is due to the strong CT band at ~540 nm, which is preferentially polarized along the stacking axis (*c*-axis) (**Figure 9**). A sharp absorption peak at ~546 nm is the zero-phonon (0–0) component of the vibronic series $(0-n)$. The emission band is not mirror-symmetric to the absorption band, indicating that the emission is due to the radiative decay of the self-trapped CT exciton. However, when the temperature is lowered near 2 K, a weak 0–0 emission line appears at the energy of 0–0 absorption line, indicating that a part of photo-generated CT excitons are moving freely in the crystal before being self-trapped. This is a rather rare case, and usually the CT excitons are promptly self-trapped after the photogeneration. In An–PMDA and other CT crystals, a weak phosphorescence band due to the radiative decay of the triplet CT excitons is also observed. They are self-trapped too by local displacement of molecules.

In other mixed-stack CT crystals with larger ρ, the CT exciton bands are shifted to the near infrared region. Hence, these crystals are not so colorful as the An–PMDA crystal. Nevertheless, they do exhibit even more interesting characteristics in the dielectric, magnetic, and structural properties, which are related with the so-called neutral–ionic (NI) instability. When the degree of CT approaches a certain critical value, the crystal ground state becomes unstable and undergoes a phase-transition from the neutral (N) phase to the ionic (N) phase. In the vicinity of the NI phase boundary, a number of novel phenomena, such as reversible photochromism, bistable electric conductivity, antiferroelectric ordering, appearance of spin- and charged-solitons, and so forth, have been observed in several mixed-stack CT crystals, in particular in TTF–chloranil crystals. Another important type of CT complex crystal is the family of segregated-stack CT crystals, such as TTF–TCNQ and BEDT–TTF–TCNQ, showing high (metallic) conductivity and even super-conductivity. Interdisciplinary studies have been extended on these "synthetic metals," forming an important field of condensed matter physics.

Wannier Excitons

The Wannier exciton is quite familiar in inorganic semiconductors, but not so much in organic molecular crystals, because of the localized nature of the π, π^* orbitals. In the case of the CT bands in anthracene crystals, spectral features detected by the electromodulation spectroscopy are assigned to the Rydberg series $E_{CT} = E_G - e^2/(4\pi\varepsilon R_{CT})$, R_{CT} being the supposed distance for the CT jump. As the limit of this series, "the bandgap energy" E_G has been estimated to be $E_G = 3.2$ eV for anthracene crystals. But this picture of CT states is considerably different from the Wannier exciton picture in the one-electron band regime, and is more properly represented by a pair of localized π^*-electron and π-hole, each located on the separated sites.

The most typical Wannier exciton in organic solids may be found in organo-silicon polymers (polysilanes) with a structure of [–RSi–SiR′-], R, R′ being organic side-group molecules. They are regarded as the σ-conjugated analog of the π-conjugated polymers, having the HOMO (σ) and LUMO (σ^*) orbitals extended along the conjugated polymer chains. Taking advantage of much easier preparation of oriented thin films by spin-coating, extensive studies have been made on the ordinary absorption, electroabsorption, two-photon excitation of luminescence, third-harmonic generation (THG) and electric-field-induced second-harmonic generation (EFISHG). Based on these experimental results, a theoretical model of quasi-1D Wannier exciton has been constructed (**Figure 10**). This model is essentially based upon a 1D-hydrogen model given by,

$$\left(-\frac{\hbar^2}{2m}\frac{d^2}{dx^2} - \frac{e^2}{4\pi\varepsilon_0|x|}\right)\psi_n(x) = E_n\psi_n(x)$$

where $x = x_e - x_h$, x_e, x_h being the electron and hole coordinates. Exciton states for $n = 1,2,3$ have been calculated assuming a finite potential at $x = 0$ due to the on-site Coulomb repulsion. According to this model, the exciton wave functions $\psi_n(x)$ are spread over a considerable range of the Si-chain (shown on the top of **Figure 10**). Various linear and nonlinear

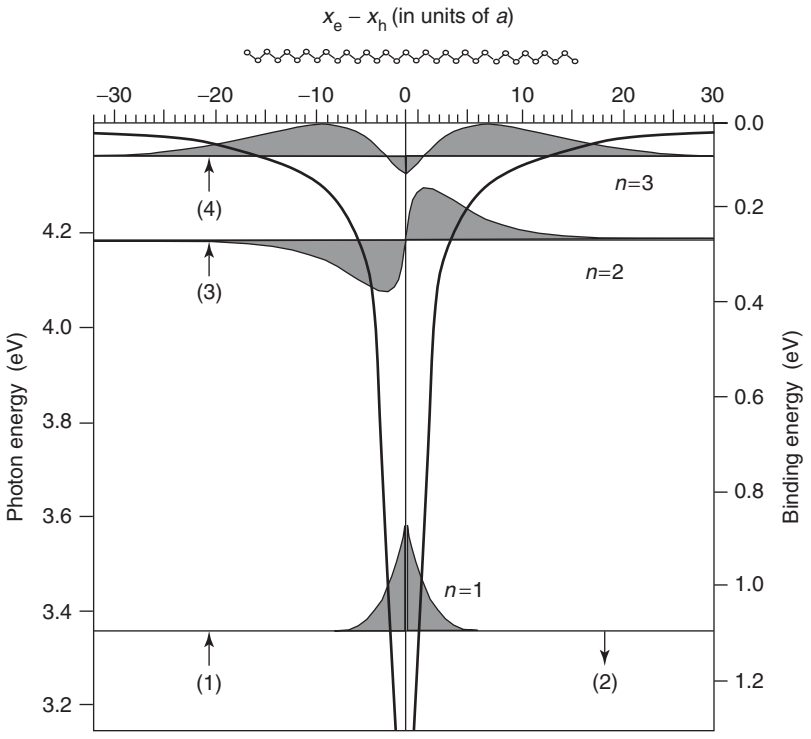

Figure 10 The quasi-1D Wannier exciton model for a polisilane (trans-polydihexylsilane: PDHS). The abscissa is the electron–hole distance along the polymer chain in units of the lattice constant (a= 2.0 Å). The energies shown on both sides of ordinates represent the photon energy from the ground state (left) and the exciton binding energy from the band edge at E_g= 4.43 eV (right). The on-site energy U at the origin ($x = 0$) of the 1D potential (solid curve) is taken as U= −5.18 eV from E_g. The envelope functions for the n = 1,2,3 excitons are indicated by curves surrounding shadowed areas. The upward arrows indicate the resonant transitions; (1) for the one- and three-photon absorptions, (2) for emission (fluorescence), (3) for two-photon absorption and electric-field-induced SHG, and (4) for three-photon absorption, respectively. The multi-photon absorptions were measured by the excitation spectra for fluorescence (2). On the top, a Si-chain structure of *trans*-PDHS is depicted. (The organic side-groups are omitted). (Due to T Hasegawa, T Koda, *et al.*)

optical transitions are indicated by vertical arrows. Observed spectra for respective transitions are in very good agreement with the theoretical results calculated by this model, indicating that trans-PDHS is an ideal molecular quantum wire having the band-gap E_g ~4.4 eV and the exciton binding energy as large as 1.1 eV.

As an example of Wannier exciton spectra in π-conjugated polymers, **Figure 11** shows the experimental results for a PDA–TS crystal obtained by the solid-state polymerization of a crystal of the diacetylene monomer R–C≡C–C≡C–R with the side group R = toluenesulfonate (TS), $-SO_3C_6H_4CH_3$. The monomer crystal is transparent in the visible region showing a pale pink color due to a small amount of short conjugated chains (origomers) generated by room light. The absorption bands (1 ~ 4) in the higher energy region are due to the $\pi-\pi^*$ transitions in the DTS monomer. After polymerization, the crystal surface turns to show a brilliant golden color in reflection. This is due to the wide polariton-gap associated with an intense absorption line at ~2 eV which is strongly polarized along the backbone chain of a conjugated polymer. This absorption line is assigned to the photogeneration of an electron–hole pair in the quasi-1D π^*-conduction and π-valence bands. Detailed studies have been made so far to elucidate the nature of the exciton states in PDA–TS and other PDAs as well by means of various linear and nonlinear spectroscopies. Similar quasi-1D Wannier exciton models are also likely to be valid in other π-conjugated polymers such as PPV (polyphenylene-vinylene). As for trans-polyacetylene, however, there is still controversy on whether the 1D Wannier exciton or the band-to-band transition is responsible for the absorption peak. It is likely that the 1D character of the π-electron system in polyacetylene is considerably modified by the 3D interchain interaction because of the very close distance between the polymer chains.

Organic Nonlinear Optical Materials

The nonlinear optical (NLO) response of organic materials is due to the fairly large anharmonicity in the

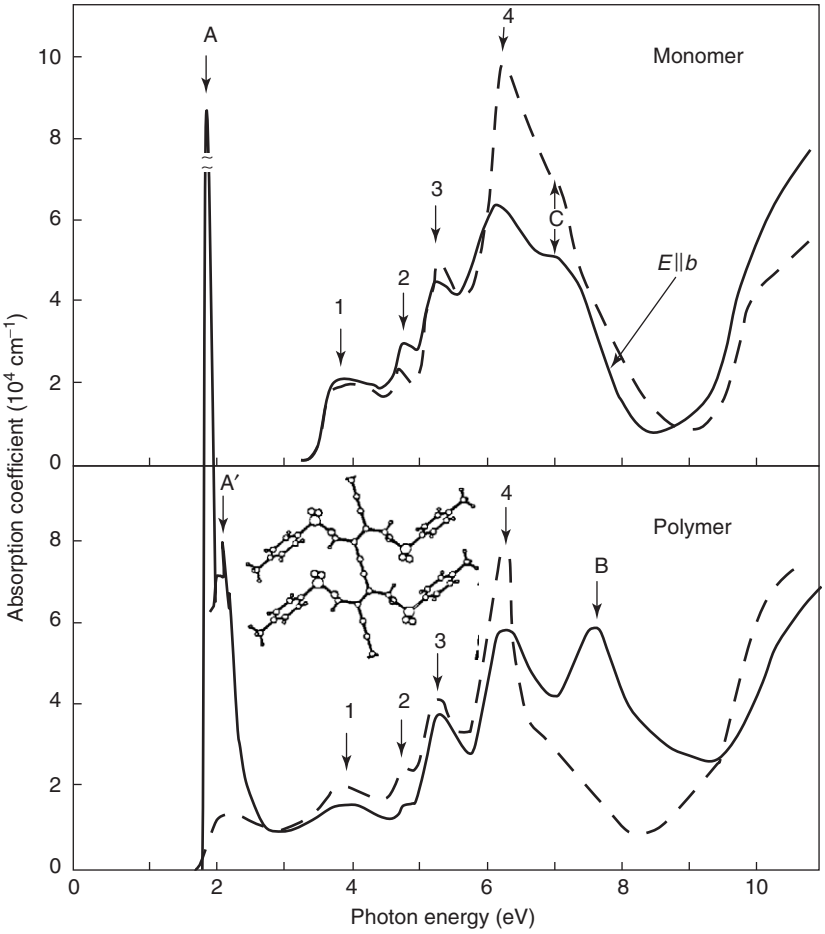

Figure 11 Polarized absorption spectra of monomeric and polymeric crystals of diacetylene (DA) with the side-group (TS); the upper part for the monomer crystal (DATS) and the lower part for the polymer crystal (PDA–TS) after thermal polymerization of the monomer crystal, both obtained by the Kramers–Kronig analysis of the reflection spectra at RT. The solid and dashed curves represent the polarized components with $E \| b$ and $E \perp b$, respectively. Absorption peak A and probably the band B are due to the Wannier excitons associated with the extended π and π^* bands on the conjugated polymer chains oriented along the *b*-axis, while the broad absorption bands (1–4) are due to the $\pi-\pi^*$ transitions within the side-group molecules. The band C in monomer crystal is assigned to the $\pi-\pi^*$ transition in the conjugated bonds of diacetylene monomer. (Due to Y Tokura, T Koda, *et al.*)

photoinduced polarization of the π-electrons, which are delocalized in the low-dimensional structures of conjugated molecules and polymers. This makes NLO spectroscopy a powerful tool for the studies of organic materials. Among others, the NLO spectroscopy for quasi-elastic and inelastic light scattering processes, such as Raman and Brillouin scattering, have been extensively employed in the studies of the structure and dynamics of organic materials. In addition, the NLO spectroscopy provides an indispensable means of detecting the forbidden electronic excited states in organic molecules and polymers. An example was shown before for the quasi-1D Wannier exciton in a σ-conjugated polymer (**Figure 10**). Another example is the two-photon excitation spectroscopy for the optically forbidden 2^1A_g state in finite linear polyenes. Also electro-absorption (reflection) spectroscopy, which is essentially due to the third-order NLO process (Kerr effect), has been widely used to detect the symmetry-forbidden excited states in conjugated polymers and CT crystals. The large third-order electric susceptibility $\chi^{(3)} \simeq 10^{-9}$ esu ($\sim 1\,\mathrm{nm^2\,V^{-2}}$ in MKS) in some low-dimensional organic materials is deemed to arise from the resonant intermediate transition between the closely separated allowed and forbidden excited states. Regarding the second-order NLO phenomena, measurement of the second-harmonic generation (SHG) from centrosymmetric organic molecules is useful for a sensitive probe to the local distortions near the surface, interface, and in other kinds of anisotropic environments which activate normally forbidden SHG of the molecule by breaking the symmetry of the local field. By scanning the laser beam, one can obtain an *in situ* image of the microscopic anisotropy in the structures.

The NLO properties of organic materials are also attractive for feasible applications in opto-electronics. The hope conceived there is multiple: the large and ultrafast NLO response, the robustness against irradiation damage, the on-demand designability of efficient organic NLO materials, and so on, which are promising for the fabrication of, for instance, optical switches or modulators in optical IC devices and the blue-emitting LEDs by efficient up-conversion of the near IR light from semiconductor lasers by the SHG process. It has been shown that, by introducing suitable bulky side-groups at both ends of conjugated molecules, the second-order electric susceptibility $\chi^{(2)}$ can be considerably enhanced owing to the push–pull effect on the distribution of the delocalized π-electrons. Many kinds of newly synthesized NLO molecules are to be found in literature. Some of these organic NLO materials may be brought into the spotlight in future technology. To bring this dream into reality, closer multidisciplinary collaborations will be essential.

Liquid Crystals

Liquid crystals (LCs) will be the most familiar functional organic materials used in various hi-tech products surrounding us. The history of LCs goes back to the discovery of a curious optical property in cholesterol. Below a certain critical temperature T_c, cholesterol shows an optical anisotropy (birefringence) like a crystal, despite the appearance of a cloudy fluid. Due to such an intermediate character, the name of "liquid crystals" was given to these novel materials. Ever since, steady and patient efforts have been devoted to the basic studies of LCs, until the boom came in 1970s to develop LC panels for watches, calculators, and so forth. The research and development of LC technology may be one of the most happy marriages between scientific curiosity and technological quest supported by active multidisciplinary collaborations.

The LC molecules are characterized by the large anisotropic shapes with either rod-like or disk-like contours. The key parameters specifying the liquid-crystalline order are the director, that is, the unit vector representing spatial orientation of the molecule, and the center position of each molecule. To elucidate the physical nature of characteristic behaviors of liquid crystals, efforts had been made early in the 1930s and the 1940s by a Russian group, and more lately by de Gennes *et al*. in the 1970s. The basic principle in most LCDs is the external control of the directors with an electric field. An LC film sandwiched by a pair of polarizers acts as an optical valve with a low working voltage, leading to yet growing applications of low-power LCDs to flat panel displays, mobile computers, LC projectors, and so on. Aside from such commercial applications, the optical properties of LCs are important and interesting subjects in soft-matter science. The NLO spectroscopy of LCs is another subject of current interest. Various NLO phenomena such as harmonic generations, optical wave-mixing, self-focusing, and the external control of these NLO properties by an electric field are being extensively investigated in LCs. Also, mixed systems of a liquid crystal and a solvent (called lyotropic liquid crystals) are interesting as a mimic biomembrane system.

Organic Electroluminescence Devices

An important application of optical properties of polymers and organic compounds, next to LCDs, will be the organic light emitting devices (organic EL or organic LED). After extensive R&D efforts in the last two decades, the efficiency, the lifetime, and color performance of these devices have been improved far beyond previous expectations even by the experts. The pioneering challenges to organic EL devices were initiated in the early 1980s to meet the increasing need of a flat display for laptop computers and other hi-tech devices. However, the way to the state-of-the-art organic EL devices has been quite hard, because of the severe working conditions such as very high electric current and harmful influence of oxidizing atmosphere. A number of breakthroughs must have been made, until an innovative idea was presented for the fabrication of a *pn*-junction type multilayer structure. The point of this idea is to split the device into essentially three separate regions, each taking part in the transport of electrons and holes and in their efficient recombination process, so as to attain better performance by means of the optimum design of the materials and device structure.

A typical structure of the EL cell is schematically illustrated in **Figure 12**. The cell consists of three layers; an Alq (an Al-chelate compound) layer, another Alq layer doped with phosphorescent $Ir(ppy)_3$ (an Ir-chelate compound of a few %), and a TPD (an aromatic diamine molecule) layer. These layers are sandwiched between the anode made of a transparent conducting film of indium–tin oxide (ITO) and the cathode made of an Mg–Ag alloy metal film. When an AC bias voltage of ~ 10 V or less is applied across the electrodes, carrier injection takes place from both electrodes into the cell: the electrons from the metal cathode with a low work-function and the holes from the ITO anode with a larger work-function. The electrons and holes are transported, respectively, across the Alq layer and the TPD layer, and

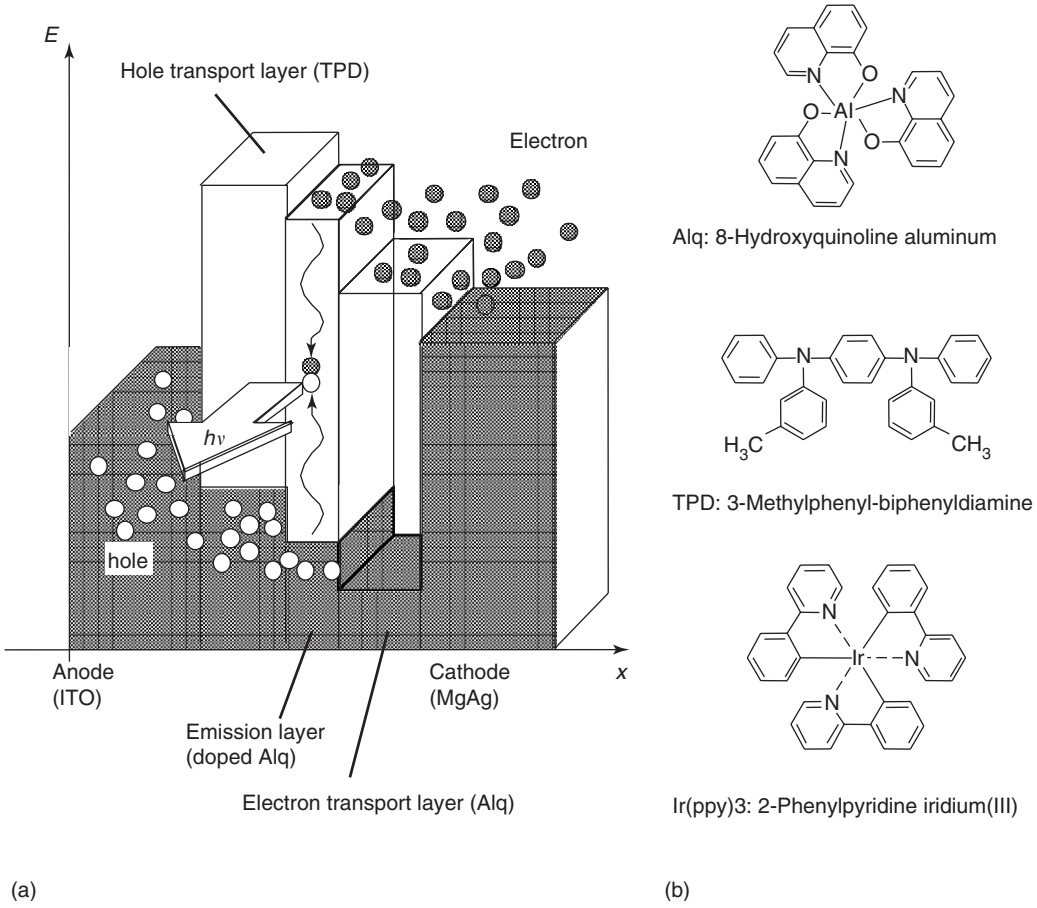

Figure 12 Schematic illustration of a typical organic electro-luminescent (EL) cell and the structures of component molecules. The EL cell shown in (a) has a *pn*-junction-type multilayer structure, composed of the transparent anode (an ITO film), the hole-injection layer (a TPD layer), the emission layer (an $Ir(ppy)_3$-doped Alq layer), the electron-transport and emission layer (an Alq film), and metal cathode (an Mg/Ag alloy film), each ~10 nm thick. The structures and the names of the component molecules (abbreviated above as Alq, TPD and $Ir(ppy)_3$) are shown in (b). The EL light is composed of two components; one being fluorescence due to the recombination of the singlet excitons in the Alq molecules and the other being phosphorescence by the recombination of the triplet excitons trapped in the $Ir(ppy)_3$ molecules. The EL light (shown by an arrow in (a) for illustration) is actually emitted out of the cell through the ITO layer vertically to the layer surface. See the text for details.

then are blocked by the layer interface forming a space charge layer near the boundary. A part of holes in the TPD layer goes through the potential barrier by tunneling into the doped Alq layer. They are bound by the electrons on the Alq molecules near the interface and form molecular excitons in either singlet or triplet state with a ratio of 1:3. These excitons diffuse into the doped Alq layer and further to the Alq layer. By the radiative decay of the singlet excitons, fluorescence is emitted from the Alq molecules, while the triplet excitons are trapped by the $Ir(ppy)_3$ molecules and are efficiently converted to the phosphorescent light due to the enhanced singlet–triplet mixing in the iridium-ligand. Other kinds of organic dye molecules can also be incorporated in the doped-Alq layer in order to give full color performance of the EL cell. As a result, the net efficiency of the EL is now approaching the level of practical light sources not only for displays but also for illumination.

Apart from these multilayer EL cells, diode-type organic EL devices (organic LEDs) have been also developed using thin films of PPV as the active layer. This type of organic EL devices has an advantage of application to the flexible and large-area EL films. In conclusion, the future scope of both types of organic EL devices is quite promising, complementing the established technology of LCDs.

Conclusion

To conclude this article, a Haiku is quoted: "Oh, how many of them are there in the fields! But each flower in its own way— In this is the highest achievement of

flower!" (Matsuo Basho, 1644–1694, translated by Maradudin A A). Simplicity and diversity may be the key words for the attractive world of polymers and organic compounds, and of their optical properties in particular. For progress in the future, one will have to go beyond reductionism in traditional condensed matter physics. Last but not the least, the authors would like to express their sincere thanks to many researchers whose names should have been quoted for their excellent pioneering works concerning the subjects dealt with in this article.

Polymers and Organic Materials, Electronic States of

E Zojer* and J-L Brédas, Georgia Institute of Technology, Atlanta, GA, USA

Introduction and Overview

In this article, the results of quantum-chemical calculations will be used to provide an introductory overview on the electronic structure of organic semiconductors. The focus is on phenylene-based materials since these form a highly attractive class of π-conjugated systems. These materials can be exploited in organic photodetectors, solar cells, transistors, and electronic circuits; their main application relates to organic light emitting devices and displays, where they serve as blue emitters. Apart from their practical relevance, polyphenylenes also serve as ideal model systems to discuss the electronic properties of organic semiconductors and conjugated polymers and allow the description of general concepts that can then be applied to more complex systems.

Here, a start is made from the simple benzene molecule to show how its molecular orbitals are related to the conduction and valence bands of the corresponding polymer, poly(*p*-phenylene) (PPP) (see **Figure 1** for the chemical structure of the corresponding ten-ring oligomer 10PP).

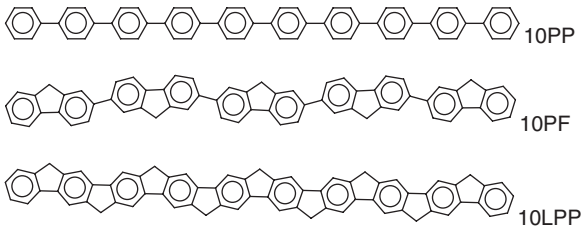

Figure 1 Chemical structures of the ten-ring oligomers of poly(*p*-phenylene) (10PP), poly(fluorene) (10PF), and ladder-type poly(*p*-phenylene) (10LPP).

*At the time of publication E Zojer was on leave from the Graz University of Technology.

In this way, a number of general properties of the excited states in phenylene-based materials can be derived. To bridge the gap between a molecular description usually found in quantum chemistry and the band structure picture prevalent in condensed matter physics, it will be shown how the molecular orbitals of phenylene chains of increasing length adopt a Bloch-type structure. A similar band-like behavior is found when considering the exciton states of extended π-conjugated molecules. To discuss the influence of molecular conformation, the electronic properties of "regular" poly(fluorene) – a partly bridged derivative of PPP – will be compared to those of its planarized conformation (the so-called β-phase) as well as of the fully bridged ladder-type PPP (see **Figure 1**). To address the role played by inter-chain interactions, the excited states of an oligophenylene dimer will be investigated. To complete the description of low-lying excited states in phenylene-based materials, excited states of different spin multiplicities will be compared. Finally, the impact of chemical defects on the electronic and optical properties of conjugated polymers will be examined by discussing the example of the ketonic defects in poly(fluorene)-type materials.

Basic Electronic Structure and Band Structure Description

To understand the electronic structure of phenylene-based materials, it is useful to start with discussing the properties of benzene rings that constitute the fundamental building blocks of these systems. (In the course of this discussion, D_{6h} symmetry is assumed for benzene.) The two highest-lying occupied and two lowest-lying unoccupied π-orbitals of benzene are shown in the left part of **Figure 2**. In a linear combination of atomic orbitals (LCAO) picture, these orbitals can be regarded as linear combinations of the p_z orbitals of the six sp^2-hybridized carbon atoms forming the ring (note that, as a result, there are two more molecular π-orbitals in benzene; their energies are, however, so different from the highest occupied molecular orbit (HOMO) and lowest unoccupied molecular orbit (LUMO) energies that they usually

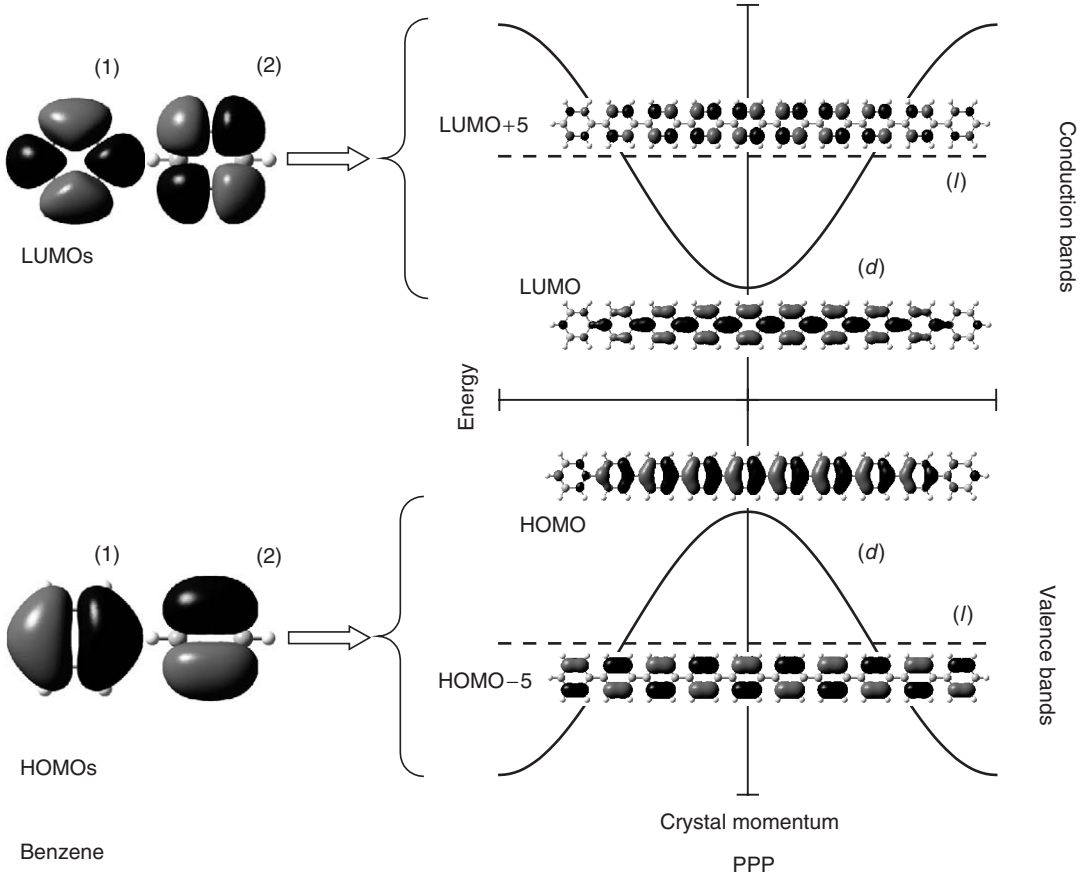

Figure 2 Left: Doubly degenerate HOMO and LUMO orbitals of benzene. Right: Hückel-type dispersed (solid lines) and nondispersed (dashed lines) conduction and valence bands of poly(*p*-phenylene). The insets show the localized and delocalized orbitals in a ten-ring oligomer, which can be associated with the four different types of bands.

do not influence the electronic and optical properties of interest).

Although the two HOMOs and LUMOs of benzene are degenerate (**Figure 2**) the molecular orbitals that derive from them display distinctively different properties when several phenylene units are linked in *para*-position to form oligo- or poly-phenylene chains. As an illustration, the HOMO and HOMO-5 of a coplanar ten-ring oligomer (10pPP) are shown on the right side of **Figure 2**. In the context of a Hückel (tight-binding) approach, the HOMO of 10pPP can be regarded as a linear combination of the benzene HOMOs of type-(1) (see **Figure 2**), while the HOMO-5 of 10pPP is a linear combination of type-(2) benzene HOMOs. The one-electron eigenstates of an infinitely long, periodic PPP chain that are similar to the HOMO of 10pPP, form the strongly dispersed valence band shown as a solid line in the Hückel-type band structure of **Figure 2**. Eigenstates like the HOMO-5 build the flat band depicted as a dashed line in the band structure. The reason for this different behavior is that for the type-(1) benzene HOMO, one finds high electron density at the carbon atoms which link the individual phenylene units to their neighbors. In contrast, the electron density on the connecting carbons vanishes for the type-(2) HOMO of benzene. Therefore, in the former case, the individual rings interact strongly in a polymer chain, while in the latter case there is only very little interaction. A strong interaction results in a large energy splitting and consequently in a strongly dispersed (wide) band; one then speaks of delocalized (d) orbitals/electronic states. The orbitals/electronic states derived from the type-(2) HOMOs are referred to as localized (l). The same reasoning also applies to the unoccupied orbitals (conduction bands) shown in the top part of **Figure 2**.

Some basic aspects regarding the optical properties of phenylene-based materials can be derived from the orbitals and the band description discussed above: The lowest energy transitions involve excitations between delocalized bands ((d)–(d) transitions) and are polarized parallel to the chain axis. Their energetic positions are strongly influenced by parameters like conjugation length and molecular conformation (*vide infra*). Experimental investigations of compounds in solution as well as quantum-mechanical calculations yield energies for the lowest optical transitions (absorption maximum) ranging from around 5.0 eV for biphenyl to about 3.7 eV for PPP (note that the latter value is extrapolated from the results obtained for finite-size systems, assuming a linear dependence of the excitation energy on the inverse number of repeat units). Transitions from delocalized into localized [(d)–(l)] and from localized into delocalized bands [(l)–(d)] are found at higher energies (around 6.2 eV according to inelastic electron scattering investigations on sexiphenyl thin films). Their dependence on the conjugation length is less pronounced than for the (d)–(d) excitations; for coplanar oligomers, they are polarized within the plane of the molecule along the short molecular axis. At higher energies (around 7.2 eV in sexiphenyl), one finds excitations involving transitions among localized levels [(l)–(l)]; these are polarized again along the long molecular axis.

The respective polarizations of these excitations can be easily understood from the symmetries of the molecular orbitals when recalling that the electric transition dipole M_{ge} for excitation from the ground state Ψ_g to the excited state Ψ_e is given by $\boldsymbol{M}_{ge} = -e\langle \Psi_g|\boldsymbol{R}|\Psi_e\rangle$. Taking (1) the center of the molecule as the origin of the coordinate system; (2) the long molecular axis as the x-axis; and (3) the molecular plane as the xy-plane, all delocalized orbitals are symmetric with respect to the xz-mirror plane. Therefore, the M_{ge} matrix element will be identically zero for a y-polarized electric field. The same applies to the (l)–(l) transitions, as here all orbitals are antisymmetric with respect to the xz-mirror plane; it also holds for z-polarized light, as all π-orbitals are antisymmetric with respect to the molecular plane. For x-polarized light and a (d)–(d) or (l)–(l) excitation, whether the M_{ge} matrix element vanishes or not, depends on the change of the orbital symmetry when going from an occupied to an unoccupied orbital. According to **Figure 2**, the HOMO is antisymmetric with respect to the yz-mirror plane while the LUMO is symmetric. Thus, the lowest-lying excited state, which is dominated by a HOMO→LUMO excitation, is optically allowed for x-polarized light. Similar arguments can be applied to show that d–l excited states can be optically allowed only for light polarized in the y-direction.

From Molecular Eigenstates to Continuous Bands

As becomes clear from the discussion, the description of π-conjugated organic materials is at the interface between condensed matter physics, molecular physics, and physical chemistry. Consequently, terms derived from each of these fields are often used simultaneously and sometimes synonymously. To bridge the gap between, on the one hand, molecular eigenstates and, on the other hand, bands, which are continuous in k-space, it is useful to consider oligomers with a relatively large, but finite, number of repeat

units. These can be described in the framework of the so-called quasiband structure model, which has been studied both theoretically and experimentally via inelastic electron scattering. The basic idea of the quasiband structure model in finite-size systems is to distribute the discrete molecular levels in k-space along the continuous bands of the parent polymers. As the crystal momentum is no longer a good quantum number for a system with finite size, a given range of $\boldsymbol{k}$-vectors has to be associated with each molecular eigenstate. In fact, the "band-like" nature of the electronic states in conjugated oligomers becomes obvious when looking at the shape of the orbitals. For 10pPP, the five highest occupied and five lowest unoccupied orbitals are shown in **Figure 3**.

Figure 3 also illustrates that the molecular orbitals adopt a Bloch-like character, that is, they can be regarded as periodically modulated plane waves. The plane-wave character is indicated by the sine-functions in **Figure 3** and the periodic modulation is given by the type-(1) occupied and unoccupied benzene orbitals from **Figure 2**. For molecular crystals based on oligomers, the quasiband structure description of the individual building block can be reconciled with the full three-dimensional band structure of the molecular crystal by going from a reduced zone scheme (relying on the crystal unit cell as a repeat unit) to an extended zone scheme, which is then consistent with assuming that the individual molecular building block (e.g., the phenylene ring) is the repeat unit.

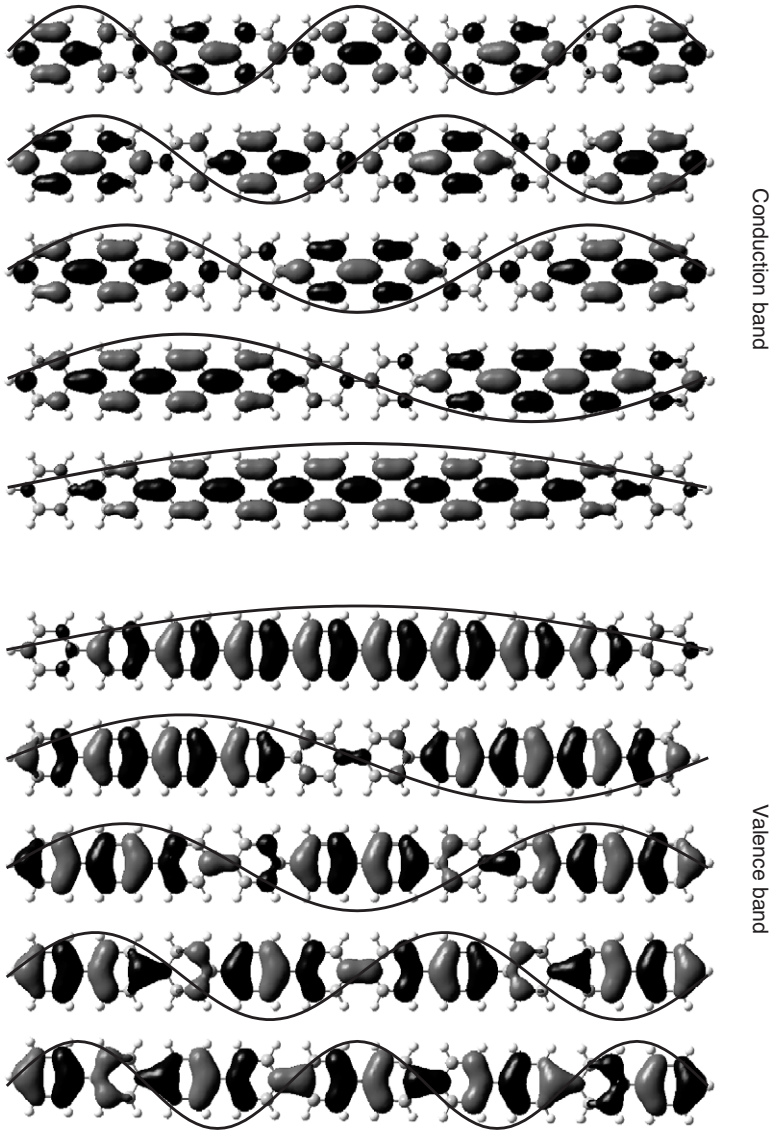

Figure 3 INDO-calculated five highest-lying occupied orbitals and five lowest-lying unoccupied orbitals of a planar ten-ring oligophenylene. The sine-wave envelope functions illustrate the Bloch-type character of the molecular orbitals.

This general evolution of the electronic states for long (periodic) chains does hold not only for one-electron eigenstates (orbitals), but also for excited states taking account of electron-correlation effects. This is shown in **Figure 4**, where the electron–hole two-particle wave functions for the lowest-lying excited states of (d)–(d) type in 10pPP are displayed.

Such plots illustrate the probability of finding the hole on atom x, while the electron is on atom y. They are calculated here for the excited states in 10pPP described by linear combinations of singly excited Slater determinants (this is referred to as a single configuration-interaction (SCI) approach, usually adequate to describe the low-lying optically allowed

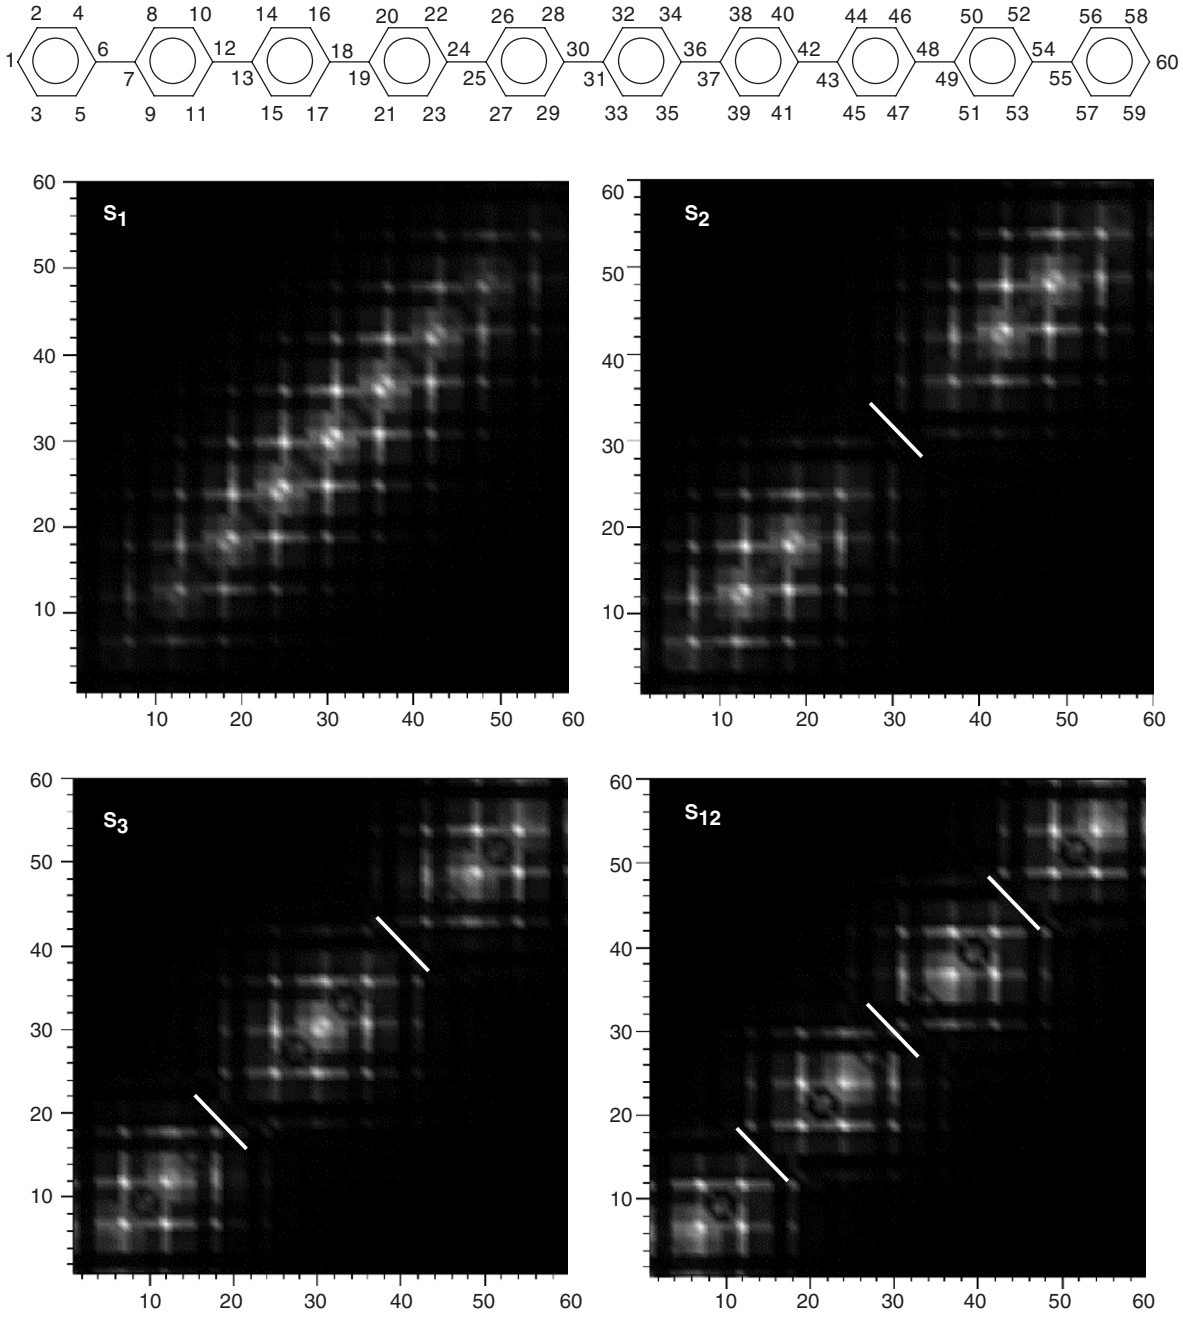

Figure 4 INDO/SCI-calculated electron–hole two-particle wave functions for the four lowest-lying (d–d) excited states in a planar ten-ring oligophenylene. The shading is proportional to the probability of finding the hole on the atom whose number is given at the horizontal axis, while the electron is at the atom whose number is given at the vertical axis. The numbers of the atoms are indicated in the molecular structure shown at the top of the graph. The diagonal white lines are a guide to the eye to show the increasing number of nodes for higher-lying states.

excited states in π-conjugated materials). In the context of the quasiband model, it is interesting to note that the S_1 state (of (d)–(d) character) presents no node. For S_2, there occurs one node (the diagonal white line in **Figure 4** is a guide to the eye); for S_3, there are two nodes, and for S_{12}, 3 nodes, etc. (the excited states from S_4 to S_{11} are of (d)–(l), (l)–(d) character). Therefore, it appears that the quasiband structure picture also holds for exciton bands, which are relevant for a comparison with spectroscopic data. This behavior is not restricted to the (d)–(d) bands; as a typical representative of a (d)–(l) excitonic state, the electron–hole wave function of S_6 is shown in **Figure 5**. The momentum-value associated with S_6 (as determined from the number of nodes) is equivalent to that of S_3 in the (d)–(d) band.

Another interesting property of the excited states that can be derived from the electron–hole wave functions is the localization of the electron–hole pair. The graphs shown in **Figure 4** indicate that the electron–hole pair is delocalized over the whole chain, as the shading goes along the full diagonal of the plots. The average electron–hole separation is, however, relatively small (calculated as 3.9 Å for the S_1 state). This is the consequence of the significant correlation of the electron and hole motions and can be seen by the relatively fast decrease of the electron–hole wave function when going away from the diagonal in the plots.

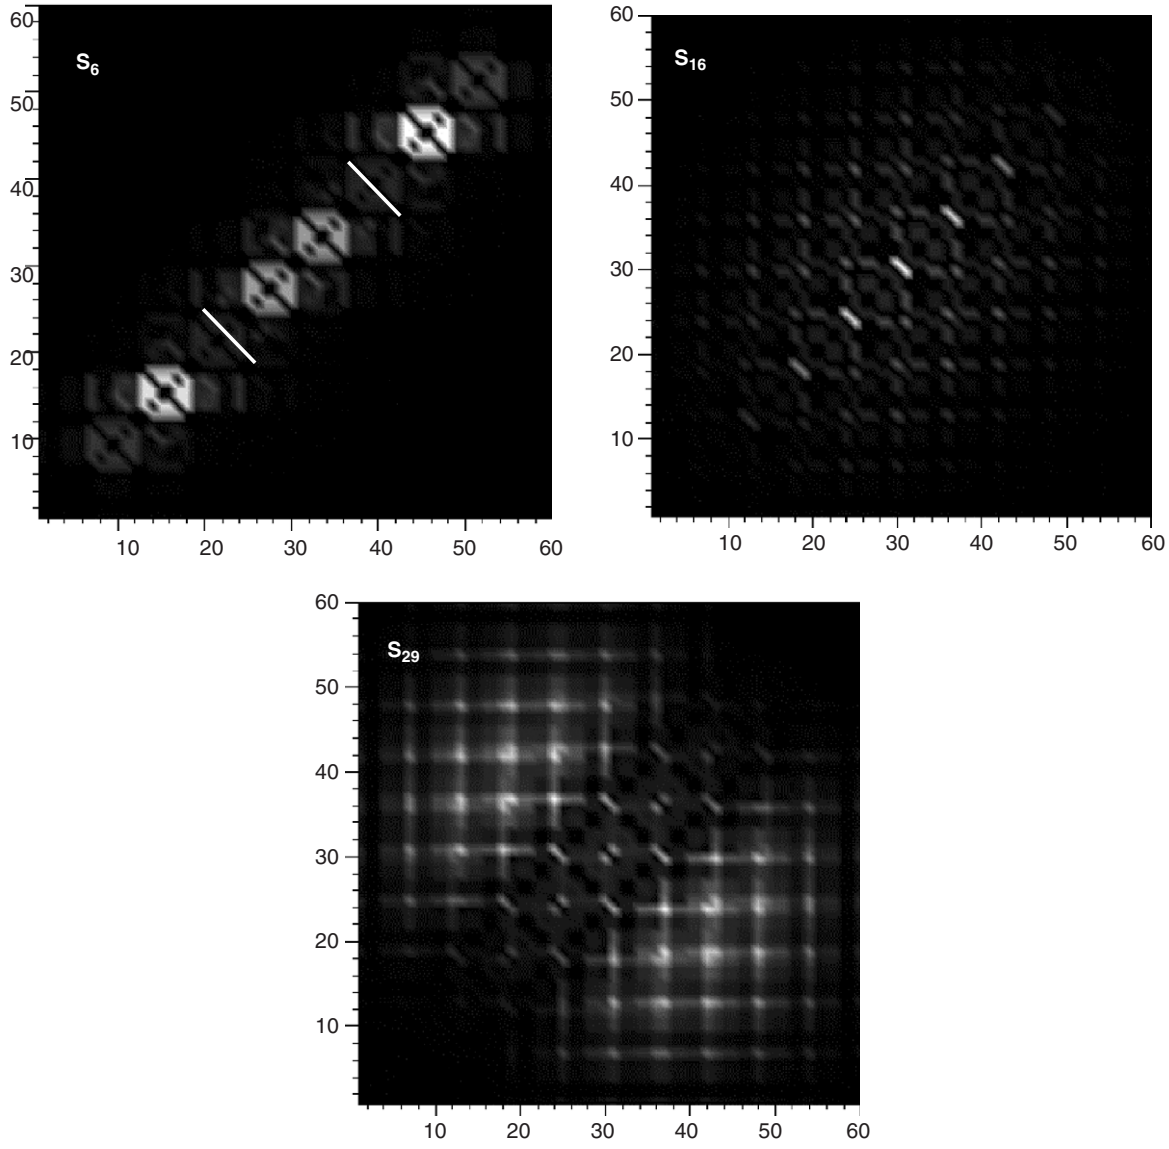

Figure 5 INDO/SCI-calculated electron–hole two-particle wave functions for some representative examples of higher-lying excited states in a planar ten-ring oligophenylene (see text). The numbering of the atoms is the same as in **Figure 4**.

As excitation energy increases, one finds exciton bands presenting a much larger electron–hole separation. An excited state representative of such bands is S_{16} at 4.8 eV (see central part of **Figure 5**). The average electron–hole separation for S_{16} is calculated to be 7.5 Å, which is more than twice as large as that for S_1. At higher energies, states with a clear charge-transfer character are found; this is illustrated by the electron–hole wave function of S_{29} in **Figure 5**: when the electron is on one half of the molecule, the hole is on the other (here, the average electron–hole separation is 14.9 Å). States like S_{16} and S_{29} are of considerable relevance for excited-state dissociation, which is found for high-energy photons in pump-probe experiments. Charge dissociation is critical, for example, in solar cells and photodetectors.

To link the properties of the exciton bands to those of the orbitals, it is useful to examine the configuration interaction description of the excited states (i.e., how the excited Slater determinants couple). For the four (d)–(d)-band states discussed above, one qualitatively obtains (writing only the dominant determinants):

$$
\begin{aligned}
|S_1\rangle &= a_1|\mathrm{HOMO}\rightarrow\mathrm{LUMO}\rangle \\
&\quad + b_1|\mathrm{HOMO}-1\rightarrow\mathrm{LUMO}+1\rangle + \cdots \\
|S_2\rangle &= a_2|\mathrm{HOMO}\rightarrow\mathrm{LUMO}+1\rangle \\
&\quad + b_2|\mathrm{HOMO}-1\rightarrow\mathrm{LUMO}\rangle + \cdots \\
|S_3\rangle &= a_3|\mathrm{HOMO}\rightarrow\mathrm{LUMO}+2\rangle \\
&\quad + b_3|\mathrm{HOMO}-2\rightarrow\mathrm{LUMO}\rangle \\
&\quad + c_3|\mathrm{HOMO}-1\rightarrow\mathrm{LUMO}+1\rangle + \cdots \qquad [1] \\
|S_4\rangle &= a_{12}|\mathrm{HOMO}\rightarrow\mathrm{LUMO}+3\rangle \\
&\quad + b_{12}|\mathrm{HOMO}-1\rightarrow\mathrm{LUMO}+2\rangle \\
&\quad + c_{12}|\mathrm{HOM}-2\rightarrow\mathrm{LUMO}+1\rangle \\
&\quad + d_{12}|\mathrm{HOMO}-3\rightarrow\mathrm{LUMO}\rangle + \cdots
\end{aligned}
$$

A most interesting aspect of these CI expansions is that the determinants that strongly mix are those for which the sum of the numbers of nodes for the occupied and unoccupied orbitals involved in the excitation are the same. (For example for S_3, a determinant in which an electron has been excited from an orbital with no node (HOMO) into an orbital with two nodes (LUMO + 2) is coupled to a determinant where both orbitals have one node (HOMO − 1 and LUMO + 1) and a determinant with two nodes for the HOMO + 2 and no nodes for the LUMO. Only the significant contribution of $|\mathrm{HOMO}-1\rightarrow\mathrm{LUMO}+1\rangle$ to the S_1 state somewhat deviates from this behavior.) In the quasiband model, this can be interpreted as momentum-conservation. This also allows one to rationalize why the states depicted in **Figure 4** apart from S_1 are either optically forbidden or have a small oscillator strength since for optical excitations the momentum transfer has to be negligibly small.

The Effect of Molecular Conformation and Intermolecular Interactions

So far, for the sake of simplicity, the oligophenylene chains have been assumed to be coplanar. However, in a nonbridged chain, this is not necessarily the case because the tendency to maximize conjugation by planarizing the (macro)molecule is counteracted by steric interactions between adjacent rings. Quantum-mechanical calculations on isolated oligophenylene chains, for example, give an inter-ring torsion angle of 40° as the optimal compromise between these two driving forces. This is confirmed by measurements on biphenyl, which displays an inter-ring twist angle of 42° in the gas phase. In solution and the molten state, the angle is found to be *c.* 32°; similar twists can be assumed for amorphous materials. These angles can also be affected when long aliphatic side chains are attached to the conjugated backbones. In the crystalline state, biphenyl has been found to be planar on average, but more recent data on terphenyl indicate an inter-ring twist of 12° in the solid state.

To address the influence of the inter-ring twist on the excited states, several PPP derivatives are discussed and their results for fully geometry-optimized and coplanar chains are compared; The systems under consideration are ten-ring oligomers of poly(*p*-phenylene) (10PP), poly(fluorene) (10PF), and ladder-type poly(*p*-phenylene) (10LPP); their chemical structures are shown in **Figure 1**. In poly(fluorene), every other connection between rings is bridged by a saturated carbon atom forming a fluorene unit that is coplanar. The torsion angle between consecutive fluorene units is similar to that in oligophenylenes. In 10LPPP, all phenylene rings are linked by a carbon bridge, which leads to a fully planar conformation of the backbone. For 10PP and 10PF, conformers forced into a coplanar conformation were also studied; in polyfluorenes a (near) coplanar conformation is in fact found for systems with nonbranched aliphatic side chains attached to the bridging carbon atoms, as a result of crystallization of these side chains (this phase is usually referred to as the *β*-phase). The transition energies and oscillator strengths for the lowest-energy absorption maxima are listed in **Table 1**.

As expected, the material with the largest bandgap is 10PP, for which the conjugation is most strongly

Table 1 INDO/SCI-calculated $S_0 \rightarrow S_1$ transition energies in ten-ring oligomers of fully geometry-optimized poly(*p*-phenylene) (10PP), poly(fluorene) (10PF), and ladder-type PPP (10LPP), as well as the coplanar conformations of poly(*p*-phenylene) (10pPP) and polyfluorene (10pPF)

Material	$E_{S_0 \rightarrow S_1}$ (eV)	*Oscillator strength*
10PP	3.84	4.52
10PF	3.58	4.34
10pPP	3.36	4.93
10pPF	3.31	4.54
10LPP	3.20	4.32

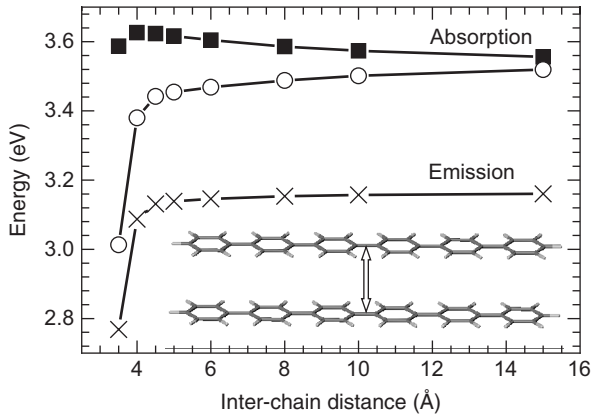

Figure 6 INDO/SCI-calculated dependence of the energies of the lowest-lying excited states in a dimer consisting of two cofacial coplanar sexiphenyl chains. The filled squares and open circles correspond to the two lowest-lying excited states for the ground-state geometry (absorption process). The crosses represent the energy of the lowest-lying excited state of the dimer in which one of the chains is in the relaxed excited-state conformation (emission process).

disturbed by the twists between all rings. The bandgap in 10PF where every other inter-ring bond is twisted, is significantly reduced by ~ 0.26 eV; for coplanar conformations (10pPP, 10pPF, and 10LPP), the energy gap is between 0.48 eV and 0.64 eV lower than in 10PP. The smallest gap is obtained for the fully bridged 10LPP system although the rings themselves are significantly distorted by the presence of the bridges. These findings are fully consistent with the experimental observations, which show that the emission and absorption maxima for the β-phase of poly(fluorene) are red-shifted by some 0.2 eV to 0.4 eV relative to regular poly(fluorene). The absorption and emission peaks in ladder-type poly(*p*-phenylene) are red-shifted by another 0.1 to 0.2 eV relative to the β-phase.

The description of excited states in phenylene-based materials given so far applies to isolated chains and also holds for molecules and polymers in solution and in amorphous films. (This is especially true for polymers with long aliphatic side chains, whose primary role is to provide solubility.) In crystals with well-ordered building blocks and short inter-chain distances, inter-molecular interactions can start to play a significant role. These have been studied by full 3D band structure calculations or by looking the properties of large molecular clusters. (Such studies show for instance that the l-bands also display significant dispersion in the direction perpendicular to the chain-axis.) When dealing with excited states, the situation quickly becomes rather complex; one then usually relies either on band structure calculations including correlation effects (e.g., by solving the Bethe–Salpeter equation) or on a correlated description of molecular clusters in a super-molecular approach. In addition, it has been recently suggested that in molecular crystals the exciton–exciton coupling is of similar magnitude as the exciton–phonon coupling; this would require a simultaneous treatment of the electronic and vibrational parts of the Schrodinger equation. Wave-propagation and polariton effects have also been found to significantly influence the optical properties of crystalline organic thin films.

In the following, the impact of intermolecular interactions on the optical properties by considering a simple model system consisting of a cofacial sexiphenyl dimer, shown in the inset of **Figure 6**, is discussed. The interaction between the two molecules results in a splitting of the molecular-orbital and exciton-state energies due to symmetric and antisymmetric linear combinations of the eigenstates of the individual molecules. The evolution of the excited-state energies related to the splitting of the lowest excited states of an individual oligomer is shown in **Figure 6**. As expected, at large inter-chain distances, the splitting is small; when the two molecules approach and start interacting significantly, the lowest excited state of the dimer gets stabilized while the next state is destabilized. Only for very short intermolecular distances (below 4 Å) would the energies of both states decrease.

For the absorption process (note that in this case the molecules in the cofacial-dimer conformation have identical geometries), the lowest-lying excited state (given by the open circles in **Figure 6**) is optically forbidden for symmetry reasons; thus a blue-shift of the absorption maximum is expected (the energy of the lowest optically allowed excited state is given by the filled squares in **Figure 6**). These selection rules relax when the symmetry is broken, for instance, when rotating one of the molecules (in such a way that the long molecular axes of the individual

oligomers are no longer parallel). Whether such symmetry-breaking occurs in molecular crystals critically depends on the space group of the system.

For the emission process, one encounters a different situation: As a result of the strong geometry relaxation that follows the excitation of a conjugated organic molecule, the symmetry of the dimer can be broken even in the cofacial conformation (i.e., when the geometry modification is centered on one of the two molecules). In this case, the lowest-lying excited state becomes optically allowed (although the oscillator strength might be relatively weak). Therefore, one has to expect a red-shift of the emission maximum upon decreasing the intermolecular distance (crosses in **Figure 6**).

Electronic Nature of the Lowest-Lying Excited States

It is important to point out that the lowest optically allowed state (usually mainly described by a HOMO→LUMO excitation) is not necessarily the lowest-lying excited state even in an isolated chain. For instance, it is well established that for polyenes (longer than butadiene) a highly correlated Ag state (with the same symmetry as the ground state) comes to lie below the optically allowed 1Bu state. This is the reason why polyacetylene does not luminesce. To describe such effects properly, it is necessary to go beyond a single configuration interaction description, since the low-lying Ag states have strong contributions from multiply excited determinants. In the case of phenylene-based materials (due to the large effective degree of bond-length alternation), the HOMO→LUMO excited state is the lowest-lying state within the singlet manifold; this is confirmed by the high luminescence quantum yields of oligo- and polyphenylenes and their bridged derivatives.

The ordering of the excited states also has to take account of triplet states. It is in fact a common feature in organic semiconductors that T_1, the lowest-lying triplet state, lies at significantly lower energies than the S_1 state. As an example, the energy diagram for a (coplanar) *p*-sexiphenyl (6PP) molecule is shown in **Figure 7** (here, the geometries and energies of the S_0 and T_1 states are obtained from density-functional theory (DFT) calculations and the transition energies to S_1 and T_n are calculated using time-dependent DFT). The T_1 state is seen to lie more than 1.3 eV below the S_1 state; there are several other excited triplet states present between T_1 and T_n (where T_n is the triplet excited state presenting the largest oscillator strength for a transition from T_1), some of which also lie below S_1. Note that

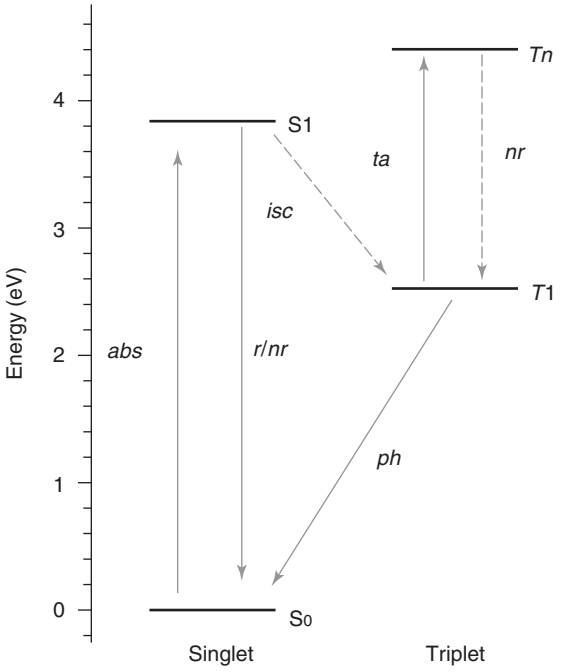

Figure 7 DFT- and TD-DFT-calculated (Jablonski) energy diagram for the low-lying optically active excited states in the singlet and triplet manifolds of coplanar sexiphenyl. The energies in the singlet manifold are given for the relaxed ground-state (S_0) geometry, while those for the triplet manifold are calculated for the relaxed T_1 geometry. The arrows represent processes coupling these excited states: *abs* – absorption; *r/nr* – radiative or nonradiative recombination; *isc* – inter-system crossing; *ta* – triplet absorption; *nr* – nonradiative recombination; *ph* – phosphorescence.

the energy of T_1 relative to S_0 and S_1 is an important factor when studying singlet/triplet formation rates in organic light emitting devices, or when adding organometallic dyes as phosphorescent triplet harvesting molecules to increase device efficiencies.

The Jablonski-diagram in **Figure 7** illustrates the typical photophysical processes linking the ground state and the various low-lying excited states. (In **Figure 7**, the relaxed S_0 geometries for the singlet and T_1 geometries for the triplet manifold is dealt with. Therefore, the energies are a proper description only for the $S_0 \rightarrow S_1$ and $T_1 \rightarrow T_n$ absorption processes. For the other processes, the energies have to be corrected by the respective relaxation energies.) Starting from the ground state S_0, the molecule can be excited via optical absorption (*abs*) into the one-photon allowed state S_1; from there, it can decay back to the ground state either radiatively or nonradiatively (*r/nr*), dissociate into positive and negative charge carriers (polarons), be excited into higher-lying singlet states S_n, or switch to the triplet manifold either via inter-system crossing (*isc*) or exciton-dissociation and subsequent nongeminate

polaron-pair recombination. Within the triplet manifold, the excited state will readily relax to the T_1 state from where the molecule can decay into the S_0 state either via phosphorescence processes (*ph*) or through the emission of phonons. Due to spin-selection rules, the T_1 state is usually long-lived. Therefore, absorption processes within the triplet manifold (*ta*) can have practical relevance for optical limiting applications and also need to be considered when designing materials for organic-laser applications.

The Role of Chemical Defects

An aspect of importance with regard to applications is the role chemical and structural defects play for the electronic and optical properties of conjugated materials. As in the inorganic semiconductor industry, great efforts have to be and are being made to eliminate chemical impurities and defects. In many instances, charge transport in organic circuits is critically influenced by charge-carrier trapping at grain boundaries and other morphological and chemical defects and the emission properties of light emitting devices can be strongly modified by sub-percent concentrations of impurities due to long-range energy migration and carrier trapping. Although "impurities" can be added intentionally as electronic dopants or emissive guest-molecules, they are usually detrimental for the performance of the device.

An example of the impact of chemical impurities is the recent understanding that the green shift of the emission in poly(fluorene) LEDs is not a consequence of aggregate or excimer formation (structural "defects"), but rather a result of chemical oxidation leading to the formation of fluorenone defects along the poly(fluorene) chains. The consequences of this type of defect for the optical properties of poly(fluorene) are now briefly discussed.

In **Table 2**, the properties of the lowest-lying excited states in a pristine ten-ring fluorene oligomer (10PF from **Table 1**) are compared with those of a model system in which the central fluorene unit has been replaced by a fluorenone (10PFK) (see chemical structure on top of **Figure 8**). Note that very similar results are obtained for ketonic defects at the end of the chain. The lowest-lying excited state in 10PF is a $\pi-\pi^*$ excited state at 3.58 eV, which is delocalized over the whole chain and is dominated by a HOMO to LUMO excitation, much like the S_1 state in coplanar poly(*p*-phenylene) discussed above. Upon geometry relaxation in the excited state, the transition energy is reduced to 3.12 eV.

In the ketone-containing molecule, 10PFK, a similar excited state, S_3, is found at an energy ~ 0.1 eV higher than that of S_1 in 10PF. There are, however, two excited states below the $\pi-\pi^*$ state in 10PFK. The lowest-lying state at 2.77 eV displays an $n-\pi^*$ character (i.e., its CI-description is dominated by an excitation from a σ-orbital localized at the C═O group to the π^* LUMO). The $S_0 \rightarrow S_1$ transition is optically forbidden due to symmetry reasons. S_2 is a weakly allowed charge-transfer $\pi-\pi^*$ (CT-$\pi-\pi^*$) state. Interestingly, in the relaxed excited-state geometry, which is relevant for emission, S_2 becomes the lowest excited state. Thus, the CT-$\pi-\pi^*$ state becomes responsible for the green emission in degraded poly(fluorene) (see right part of **Table 2**). To better understand the electronic nature of the $\pi-\pi^*$ and CT-$\pi-\pi^*$ states, it is useful to look at the orbitals involved in their CI-description and at the corresponding electron–hole two-particle wave functions. These are displayed in **Figure 8** for the relaxed excited-state geometry (the electron–hole wave function of the $n-\pi^*$ state, which is not shown here, is completely localized on the C and O atoms of the ketonic defect).

The strongest contribution to the description of the CT-$\pi-\pi^*$ state comes from a HOMO to LUMO excitation. These orbitals are shown in the inset of the upper electron–hole plot in **Figure 8**. The HOMO of 10PFK is strongly reminiscent of that of pristine poly(fluorene). The LUMO has no equivalent in pristine poly(fluorene) and is strongly localized on

Table 2 INDO/SCI-calculated excitation energies and oscillator strengths for a ten-ring poly(fluorene) chain without (10PF) and with (10PFK) a ketonic defect on the central fluorene unit. A chiral conformation is chosen and the ground-state geometry is optimized with the semi-empirical AM1 Hamiltonian, which is coupled to multi-electron CI to optimize the relaxed excited-state geometry.

	Ground-state geometry			*Excited-state geometry*		
	Type	*E* (eV)	*Oscillator strength*	*Type*	*E* (eV)	*Oscillator strength*
10PF						
S_1	$\pi-\pi^*$	3.58	4.34	$\pi-\pi^*$	3.12	3.91
10PFK						
S_1	$n-\pi^*$	2.77	0.00	CT-$\pi-\pi^*$	2.45	0.47
S_2	CT-$\pi-\pi^*$	3.05	0.42	$n-\pi^*$	2.64	0.00
S_3	$\pi-\pi^*$	3.68	3.88	$\pi-\pi^*$	3.44	3.08

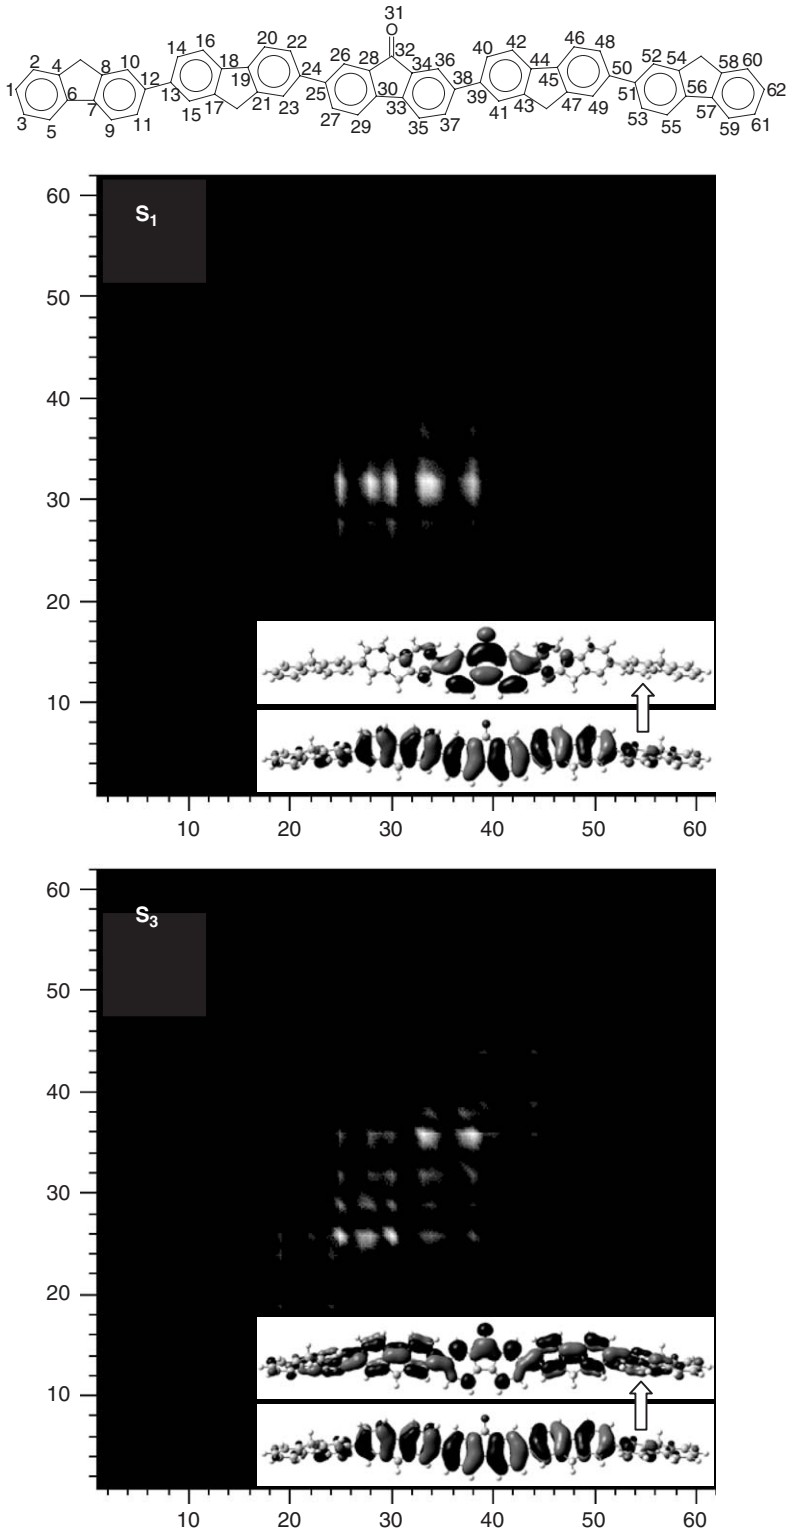

Figure 8 INDO/SCI-calculated electron–hole wave functions for the S_1 and S_3 states in a ten-ring oligofluorene in which the central fluorene unit has been replaced by a fluorenone. As the ketonic defect mainly affects the emission properties of poly(fluorene), the calculations have been performed for the relaxed S_1 geometry obtained from the AM1/CI approach. The atom site numbers used in the electron–hole plots are shown in the molecular structure at the top of the graph. The inset in the top graph shows the HOMO and LUMO orbitals which dominate the CI description of the S_1 state; the HOMO and LUMO + 1 are shown in the inset of the bottom graph.

the fluorenone unit. As a result, the electron–hole pair describing the CT-$\pi-\pi^*$ state is also localized on the fluorenone unit. The $\pi-\pi^*$ state (S_3) is delocalized over the whole chain and is dominated by a HOMO to LUMO + 1 excitation, with the latter orbital being strongly reminiscent of the LUMO in pristine polyfluorene.

This example clearly shows that the green-shifted emission in degraded poly(fluorene) stems from localized excited states resulting from the fluorenone chemical defect. Considering the fact that in poly(fluorenes) with ketonic defects, a new orbital (the LUMO from top of **Figure 8**) appears below the LUMO of pristine poly(fluorene), one can expect that this type of defect influences charge-carrier transport by acting as an electron-trap; this has been recently confirmed by experimental studies and *ab initio* calculations of ionization potentials and electron affinities in poly(fluorene) chains with and without ketonic defects.

To summarize, in this article, the example of phenylene-based materials is taken: (1) to derive the basic electronic structure of π-conjugated materials; (2) to describe the relation between molecular wave functions and band structure-type eigenstates; (3) to illustrate the impact of inter-chain interactions; (4) to examine the ordering of the excited states in the singlet and triplet manifolds; and (5) to discuss the role of chemical defects on the electronic properties.

Polymers, History of

M M Coleman and P C Painter, The Pennsylvania State University, University Park, PA, USA

Introduction

Although this article presents only a very brief history of polymers, it would be remiss if it did not open by acknowledging that without polymers this encyclopedia would not have been written! Mother Nature, with ingenious dexterity, used "natural" organic polymers such as proteins, polypeptides, carbohydrates, and DNA, to build the structural elements of life itself. Long before there was any fundamental understanding of the macromolecular nature of materials such as cotton, silk, wool, wood, leather, bone, and ivory, humankind found ways to use and modify these materials to produce articles for clothing, utensils, and shelter. One could write books on this subject alone, so in this short history the focus

is on how the foundations of our understanding of the nature of polymer materials were laid. In doing so, a lot of important and interesting things have been left out. Accordingly, the focus is on the history of semisynthetic and synthetic polymers, mentioning natural rubber only in passing. (Rubber actually deserves a history of its own and the interested reader is encouraged to consult the sources listed at the end of this review.)

To many people, the birth of polymer science as a discipline starts with Hermann Staudinger and his assertion that materials such as natural rubber are covalently bonded long-chain molecules, as opposed to some sort of colloidal aggregate. Jumps such as this in our understanding of nature do not occur in a vacuum, however. Staudinger was building on a wealth of work by nineteenth-century chemists and entrepreneurs, whose goal was to produce substitutes for various types of increasingly expensive or difficult to obtain natural materials such as ivory and silk.

Early History: Developments in the Nineteenth Century

Perhaps the most enduring images of the industrial revolution of the nineteenth century are those provided by the ironmasters and engineers. One thinks of a world of railways, "dark, satanic mills," and the social and political consequences of the division of labor and the creation of an urban working class. It is the world according to Charles Dickens, built on iron, steel, coal, and the power of steam. Natural polymers, such as cotton and wool, were, of course, key materials and after Charles Goodyear's discovery of vulcanization, natural rubber would join them. But, from about the middle to the end of the nineteenth century onward, various synthetic and semisynthetic polymer materials were also introduced and these were to have a profound social and economic impact.

In 1845, common household items such as combs and toothbrushes were often laboriously fashioned from bone or ivory and were thus expensive and unavailable (except in crude wooden forms) to most people. This was to change, although not immediately, with the work of the Swiss chemist, Christian Schönbein. The story (perhaps apocryphal) has it that he used his wife's apron to wipe up some spilled concentrated nitric and sulfuric acid while conducting experiments in his home. After washing the apron, he put it in front of the fire to dry, upon which it immediately flared brightly and disappeared. Schönbein had discovered guncotton, formed by nitrating the cellulose in the apron. Not only did guncotton have more explosive power than gunpowder, it gave off far less smoke. This was considered a major advance, because it lessened the confusion of the battlefield and generals could now see the people they were slaughtering. Advances in military technology were often spin-off materials and processes that are useful in everyday life, however, and this was to be no exception. Cellulose in its native form is both insoluble and infusible and cannot be cast from solution or molded to make useful objects. However, a French doctor, Louis Menard, found that nitrated cellulose would dissolve in a mixed solvent of alcohol and ether and cast to form a transparent film, called collodion. This was used to dress cuts and wounds. Crucially, it was also found that at levels of nitration of $\sim$13% or less, nitrated cellulose is no longer explosive, although still highly flammable.

Alexander Parkes, a prolific English inventor and true material scientist, had already achieved considerable fame as a metallurgist when he found that the addition of castor oil and camphor to nitrated cellulose lowered its softening temperature. The resulting material, which he modestly called Parkesine, could then be molded. Various objects made from this new material were displayed at the Great Exhibition at the Crystal Palace in 1862, where it won a medal for excellence of product. Parkes seems to have been unaware of the special role of camphor as a plasticizer, however. In some of his publications he omitted reference to it completely and the commercial exploitation of Parkesine was ultimately a failure. Nevertheless, it marked the beginning of the plastics industry.

This history now shifts across the Atlantic, where the next development came as a direct consequence of a shortage of elephants and rhinoceroses. It is a classic case of a short supply of one material, in this case ivory, providing the impetus for the development of another. The American billiard ball manufacturing company, Phelan and Callendar, offered a prize of $10 000 (a very large sum in those days) to anyone who could invent a substitute for ivory billiard balls. John Hyatt took up the challenge and chose to experiment with Parkesine. One can speculate that Hyatt might have misspent his youth in pool halls, because he was intrigued by the problem and spent several years of his life working toward a solution. He did not win the prize, but did establish the Albany Billiard Ball Company, which used a mixture of gum shellac and wood pulp to make the bulk of the ball. This was coated with nitrocellulose, which gave this new ball some interesting properties. Hyatt later reported, "We had a letter from a billiard saloon proprietor in Colorado mentioning that occasionally the violent contact of the balls would produce a mild explosion and saying that he did not care so much about it, but that instantly every man in

the room pulled a gun." It seems that controlling the degree of nitration remained a problem.

This experience with nitrocellulose prompted Hyatt to investigate its properties in more detail. He eliminated castor oil from his formulations, using only camphor, and, with good old-fashioned Yankee ingenuity, solved the manufacturing problems that had plagued Parkes. He produced a hard material that could be softened by heating to 90°C and called it celluloid. Celluloid was an enormous success. Many common objects that were previously expensive could now be mass-produced cheaply. These ranged from knife handles to false teeth, from combs to that symbol of Victorian rectitude, the stiff celluloid collar. It also provided film for the fledgling movie industry, whose stars became known as the "celluloid kings and queens."

Celluloid was not a true synthetic polymer, of course, but a chemically modified natural polymer. Its central significance to the development of the field was not so much the nature of the objects produced, although these had an important social and economic impact, but the engineering techniques and machines developed to produce these goods. An example is the artificial silk fiber produced by Count Hilaire de Chardonnet, who developed an extrusion process in which a nitrocellulose solution was forced through a small orifice producing a lustrous thread. Unfortunately, nitrocellulose lost none of its incendiary qualities in this process. The workers in Chardonnet's factory quickly dubbed the product "mother-in-law silk" (buy your mother-in-law this nice blouse and stand her in front of the fire), thus revealing an interesting, though morbid, sense of humor. Chardonnet overcame this problem by "denitrating" the fibers by passing them through a solution of aqueous ammonium hydrogen sulfide and, in effect, regenerating cellulose.

There are easier ways to make regenerated cellulose and in the early 1890s Cross, Bevan, and Beadle discovered that cellulose could be rendered soluble by sodium hydroxide and carbon disulfide. A basic solution of cellulose xanthate is formed, which regenerates cellulose upon acidification. Fibers from regenerated cellulose were called rayon, while films were known as cellophane. By the 1930s cellophane was being used to wrap an enormous range of goods, not only to protect them from spoilage, but also because they had customer appeal. A grocery chain reported an increase in sales of an astonishing 2100% in two weeks once their doughnuts were wrapped in cellophane. In a mid-twentieth century poll by the *New York Times*, cellophane was considered to be one of the key discoveries of the century to that date and was even included in a Cole Porter song (You're the Top). The impact of these materials was enormous, but cheaper synthetic polymers have now largely replaced them.

The First Synthetic Plastic

The first truly synthetic polymer materials are the "phenolic resins," originally synthesized by reacting phenol (or, as it was called at the time, carbolic acid, a compound that was, and still is, commonly used as a disinfectant) and formaldehyde (an aqueous solution of which, formalin, had been used in the embalming business for thousands of years). It was actually an Englishman, Arthur Smith, who in 1899 was awarded the first patent for the application of phenol/formaldehyde resins as electrical insulators. But it was Dr. Leo Hendrik Baekeland, a Belgium chemist born in Gent and living in the US, who made the big breakthrough.

Baekeland was an interesting man. He graduated with a Ph.D. degree, "maxima cum laude" and then taught at the University of Gent until 1889. He then left for the US, where he quickly invented Velox, a photographic paper superior to anything else then available. George Eastman, who in 1888 introduced the Kodak camera with the slogan "you press the button, we do the rest," made up his mind to buy Velox and invited Baekeland to Rochester. Baekeland had decided to ask for what was then the very large sum of $50 000, but had it in the back of his mind that he would settle for $25 000. Eastman offered him a million, allowing Baekeland to retire to his laboratory in Yonkers, New York, and look for new chemical worlds to conquer.

Baekeland decided to try and develop a less flammable replacement for shellac, a natural coating derived from the resinous secretions of tiny lac beetles. According to one source, his immediate goal was to develop a wood varnish for bowling alleys, all the rage at that time. Other sources state that Baekeland perceived the growing impact of electricity on everyday life and his goal was to produce a new synthetic insulator. It took roughly 150 000 beetles ~6 months to produce enough resin to make one pound of shellac and the demands of the fledgling electrical industry had created a shellac shortage.

Although Baekeland is given the credit for the discovery of phenolic resins, there were significant contributions from many others including Adolf Baeyer, Arthur Smith, Adolf Luft, and James Swinburne. Baekeland's key discovery (made in 1907), one that set him apart from the competition, was that phenolic resins could be made in two parts. In essence, he developed a process where a polycondensation reaction was carried out at an elevated temperature.

He then stopped the reaction at an intermediate point by cooling to ambient temperature, where the partially reacted resin solidified. In the second stage, this reasonably stable intermediate material was placed into a mold and heated under enormous pressure. This transformed the material (by continued polymerization and cross-linking reactions) into a hard, shiny, intractable, relatively brittle solid. Bakelite, as Baekeland called his new material, could be molded and machined; it was hard, relatively strong, lightweight, and resistant to heat. It was the first true synthetic polymer and there was nothing else like it on the face of the planet. It found use not only in electrical fixtures, but also in knife handles, buttons, cameras, radio, and telephone equipment, essentially anything that required a molded part. It was advertised as the "Material of a Thousand Uses." And it was.

The Dawn of Understanding

The polymeric materials discussed so far were developed in a largely "Edisonian" fashion, by trial and error, and in the absence of any fundamental understanding of the macromolecular nature of polymers. In fact, the prevailing view at that time was that materials like silk, cellulose, and natural rubber were colloidal aggregates of small molecules. Not only that, the chemistry of what were then called "high molecular compounds," which could not be purified by crystallization or distillation, was regarded with disdain by the academic chemical community and referred to as "grease chemistry."

It was therefore an act of considerable courage for Hermann Staudinger to decide to devote the bulk of his efforts to these "high molecular compounds." He asserted in lectures and papers (published in the period 1917–1920) that these materials were covalently bonded long-chain molecules. Although Staudinger, at the ripe old age of 39, was a distinguished chemist, holding academic positions at prestigious universities in Karlsruhe, Zurich, and Freiburg, convincing his colleagues was to be no easy matter. For example, Staudinger recollects in *Arbeitserinnerungen* (Working Memoirs) that he was advised in the 1920s by a famous organic chemist of the day, H Wieland, "My dear chap, give up your ideas on big molecules. There are no organic molecules with a molecular weight of more than 5000. Just clean up your products and they will crystallize and reveal themselves as low molecular weight compounds." In 1925, after giving a lecture at the Zurich Chemical Society, he was attacked by a number of leading scientists and in frustration quoted Martin Luther, "Here I stand and can do no other."

Staudinger could not accept that the physical properties of rubber, proteins, cellulose, and the like could be explained by the idea that they consisted of associations of small molecules held together by some unknown force. (It was speculated at the time that some undiscovered "vital" or life force could be involved.) Staudinger maintained that the atoms in these molecules were connected by covalent chemical bonds, as in low molecular weight materials like benzene, but these molecules just happened to be incredibly large! Despite the apparent reasonableness of this position, the dispute became almost theological in its intensity. Von Baeyer had it right when he pronounced his "Three Stages of a Triumphant Theory": First it is dismissed as untrue; second it is rejected as contrary to religion; and third it is accepted as dogma and every scientist claims to have long appreciated its truth! Staudinger was, of course, correct, and he was belatedly recognized for his achievements in 1953, when he was awarded the Nobel Prize in chemistry. Sometimes you have to outlive your enemies!

Numerous experiments performed by the late 1920s and early 1930s provided accumulating evidence in favor of the existence of macromolecules. Particularly important were Staudinger's work on polyoxymethylenes, where he systematically studied changes in the physical and chemical properties of this polymer and a homologous series of its oligomers; the X-ray diffraction studies of Meyer and Mark, establishing the chain structure of cellulose; and the molecular weight measurement made possible by Svedberg's development of the ultracentrifuge. However, it was the brilliant experimental studies of Wallace Hume Carothers, which were to remove any lingering doubt about the macromolecular, long-chain nature of polymers.

Carothers obtained his doctorate from the University of Illinois, and then took up a teaching position at Harvard. In 1928, Charles Stine persuaded Carothers to leave his teaching post and join the DuPont Company to head a newly formed fundamental research laboratory. He was given wide discretion and he clearly stated at the outset that his goal was to tackle the problem of macromolecules from a chemical approach, by synthesizing compounds of high molecular weight and known constitution. Carothers is best known for the discoveries of nylon and neoprene, but his general contributions to polymer synthesis and polymer structure/property relationships were truly seminal.

Wallace Carothers was probably the first to appreciate the enormous importance of monomer functionality in the production of condensation or step-growth polymers. Amongst many other things Carothers is also credited with categorizing the two major classes

of polymerization: condensation or step-growth (which he referred to as "C" type polymerization) and addition (called "A" type). Carothers' crowning glory, one of the major outcomes from his fundamental studies of polymerization, was the discovery of polyamides, or as they are now known universally, nylons. The first major market was ladies' stockings, introduced in the early 1940s. There was a huge demand for this product, which in these days of less formal wear is hard to imagine. Nylon production was co-opted for the war effort after Pearl Harbor was bombed (replacing silk in parachutes and so on), but when nylon stocking production was resumed in 1945 there were actually so-called nylon riots among people lining up to purchase the limited supply. This is a great story, one that would take more space than available here, but it is also a tragic one. Carothers never lived to see the extraordinary success of nylon. The bouts of depression, to which he had long been subject, became increasingly frequent after 1935 and he began to believe he was a failure as a scientist. He left his home in Wilmington, Delaware, on April 28, 1937 and checked into a Philadelphia hotel room, where he swallowed lemon juice laced with potassium cyanide.

The Post 1930s

Following Staudinger and Carothers, the synthesis of polymer materials would become based on chemical principles, rather than empirical trial and error. It was now understood what types of functional groups could react to form polymers and chemists set about making them. Nevertheless, it took years of effort by many scientists to achieve a firm understanding of the details of reaction mechanisms and their kinetics. For example, industrial scale polymerization of vinyl monomers in Germany by what became recognized as a free radical mechanism was in early work (late 1920s) initiated by exposure to sunlight. Initiation also played a crucial role in the development of a high-pressure process for the polymerization of ethylene by Fawcett and Gibson at ICI (Imperial Chemical Industries) in England in the 1930s. While trying to react benzaldehyde with ethylene at high pressure, a waxy solid was formed which they recognized to be a polymer of ethylene. A subsequent experiment blew up the apparatus and ICI banned high-pressure studies until stronger reaction vessels could be constructed. Fawcett left to join Carothers' group in America, but Perrin continued work in secret after normal working hours, risking both his life and his job. By 1936, it was recognized that small amounts of oxygen could initiate the reaction and by 1939, production of significant quantities was achieved. This turned out to be crucial for the war effort. Because polyethylene turned out to have an extremely low dielectric loss, it was ideal for radar cable insulation. As Robert Wattson Watts, the British inventor of radar, stated, "The availability of polyethylene transformed the design, production, installation and maintenance of airborne radar from the most insoluble to the comfortably manageable. And so, polyethylene played an indispensable part in the long series of victories in the air, on the sea and the land, which were made possible by radar."

By 1950, significant advances in understanding free radical polymerization, the nature of copolymerization, emulsion polymerization, etc., had been achieved. At the same time, the period between the first and second World Wars had seen the introduction of a number of important condensation polymers, which included not only nylon, but also the polyurethanes. Otto Bayer, who just happened to have the same name as the large German company for whom he worked, became head of the Central Scientific Laboratory at the ripe old age of 31. He was aware of the work of Staudinger and Carothers and reasoned that a superior "condensation" polymerization would be one where a small molecule (such as water) was not split off. He had worked on isocyanate chemistry and perceived that diisocyanates might form the basis for making such polymers. Synthesizing diisocyanates is hard and dangerous chemistry and one of Bayer's closest colleagues remarked, "If you had ever tried to make a monoisocyanate, you would not have come up with the mad idea of trying to produce diisocyanates. The reaction of phosgene on diamines would result in almost anything except diisocyanate, and would probably be thoroughly unstable, anyway." Others added, "It will explode!" This is another great story, which too cannot be told properly for want of space, but needless to say, Bayer succeeded.

Although some addition polymerizations involving catalysts and ionic initiators were performed between the two World Wars, it was not until the early 1950s that things really took off, when catalysts for the low pressure polymerization of ethylene were discovered, independently and almost simultaneously in the early 1950s, by Karl Ziegler in Germany and Robert Banks and Paul Hogan at the Phillips Petroleum company in the USA. These were not the only scientists involved, as workers at Standard Oil of Indiana were pursuing similar goals, while Giulio Natta, a Professor at the Politecnico di Milano, had become interested in the field after he heard a lecture given by Ziegler. Natta had sent some of his collaborators to work in Ziegler's laboratory to learn the art and craft of the technique and upon their return, Natta set out to synthesize polypropylene,

which could not be made free radically. They succeeded and filed for a patent just days before Ziegler's group, who by then had also succeeded in polymerizing propylene. Although Ziegler and Natta were jointly awarded the 1963 Nobel Prize in chemistry, they were no longer speaking to one another. Polypropylene also became the subject of one of the longest patent cases in history.

There is much more to this story, and the history of the development of many other major polymers and classes of polymers is equally fascinating. But although a history of polymer materials naturally focuses on how these materials were discovered and synthesized, an understanding of the physics and physical chemistry of these materials was equally important. It was Carothers, looking for a physical chemist to join his group, who hired the newly graduated Paul Flory in 1934. Carothers encouraged Flory to carry out mathematical investigations of polymerization and the subsequent impact that Flory was to have on the field of polymer science is difficult to overstate. Flory's book, *Principles of Polymer Chemistry*, is still a classic 50 years after publication and essential reading for anyone starting out in this field. In 1974, he was awarded the Nobel Prize in chemistry for his fundamental achievements, both theoretical and experimental, in the physical chemistry of macromolecules. While many other notable scientists have contributed to the theory of polymers, Pierre-Gilles de Gennes has a knack for seeing commonalities in wildly different physical systems and then reducing these observations to simple scaling arguments. His book, *Scaling Concepts in Polymer Physics*, is also a required reading for aspiring polymer physicists. In 1991, his peers recognized de Gennes' accomplishments and he was awarded the Nobel Prize in physics.

Final Words

There is much that has been omitted and many great scientists have been slighted by these omissions. The authors can only suggest that if they have sparked any interest in the reader that he or she refers to the references cited below.

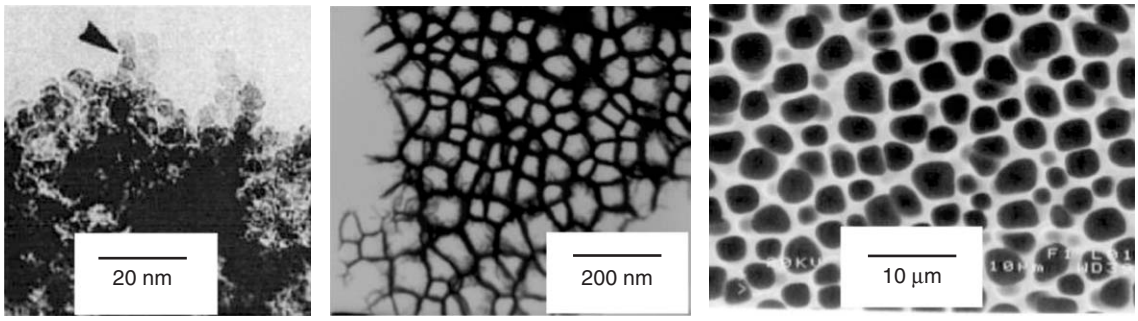
Porous Silicon

Z Gaburro, N Daldossoh, and L Pavesi, Università di Trento, Povo (Trento), Italy

This article deals with generalities and definitions of porous silicon (PSi): fabrication techniques, structural properties, chemical properties, electronic properties, electrical properties, optical properties, and actual or potential applications of PSi. Optical properties include light transport, photoluminescence, and electroluminescence.

Generalities and Definitions

PSi was discovered by Uhlir in 1956 while performing electrochemical etching of silicon. In 1990, Canham showed that certain PSi materials can have large photoluminescence (PL) efficiency at room temperature in the visible: a surprising result, since the PL efficiency of bulk silicon (Si) is very low, due to its indirect energy bandgap and short nonradiative lifetime. The reason for this was the partial dissolution of silicon, which causes (1) the formation of small silicon nanocrystals in the PSi material; (2) the reduction of the effective refractive index of PSi with respect to silicon, and hence an increased light extraction efficiency from PSi; and (3) the spatial confinement of the excited carriers in small silicon regions where nonradiative recombination centers are mostly absent. In general, PSi is an interconnec ted network of air holes (pores) in Si. PSi is classified according to the pore diameter, which can vary from



(a) (b) (c)

Table 1 IUPAC classification of porous materials

Dominant pore width (nm)	*Type of material*
$\leqslant 2$	Microporous
2–50	Mesoporous
>50	Macroporous

a few nanometers to a few micrometers depending on the formation parameters (**Figure 1**). According to the general classification of porous materials, three size regimes are defined as in **Table 1**.

The word "nanoporous" is sometimes used for the smallest-pore regime to emphasize the nanometric dimension. The volumetric fraction of air of the material is called porosity (P). The internal surface of PSi per unit volume can be very large, of the order of $500\,m^2\,cm^{-3}$. The enhanced photoluminescence efficiency of PSi – compared to Si – has motivated research toward other porous semiconductor materials. For example, highly porous SiC, GaP, $Si_{1-x}Ge_x$, and Ge structures have been investigated.

Fabrication Procedures

Anodization

PSi is mostly fabricated by electrochemical anodization – often referred to as electrochemical etching – of bulk Si wafers in diluted aqueous or ethanoic hydrofluoric acid (HF). Ethanol is often added to facilitate evacuation of H_2 bubbles, which develop during the process. Typical anodization arrangements are schematically shown in **Figure 2**. Another much less common technique is stain etching, or chemical etching (with no current flow), performed with HF–HNO_3 solution.

The anodization can be performed either in potentiostatic (voltage-controlled) or in galvanostatic (current-controlled) mode. The latter is normally preferred, because it supplies the required charge for the reaction at constant rate, regardless of any evolution – during anodization – of the cell electrical impedance, ultimately leading to more homogeneous and reproducible material. The typical values of the most important anodization parameters, along with their impact on the anodization process, are reported in **Tables 2** and **3**. Three sample setups for fabrication of different PSi structures are shown in **Table 4**. The anodization can be modulated. The modulation is most easily achieved by varying the applied current density. Modulation results in controlled changes of the microstructure and the porosity of PSi along the growth direction. For example, PSi multilayer films can be simply created by varying the current density in time.

The position of pore nucleation can be controlled by etch pits, defined by a lithographic step before the anodization (**Figure 3**). This option is in practice limited to macroporous PSi, since present lowest lithographic resolution limits are in the range of a hundred nanometers. For example, ordered two-dimensional periodical matrices of pores can be formed, leading to materials with remarkable optical transport properties (2D photonic crystals, see **Figure 4**). PSi singlelayers or multilayers can be fabricated as free-standing samples. The detachment from the substrate can be achieved by applying a short pulse of high current density, that is, exceeding the electropolishing threshold, typically some hundreds of $mA\,cm^{-2}$.

Anodization Mechanisms

Typical current–voltage (I–V) characteristics of the electrochemical cell are shown in **Figure 5**. It should be stressed that the quantity having physical meaning is the current density J (at the Si/electrolyte interface),

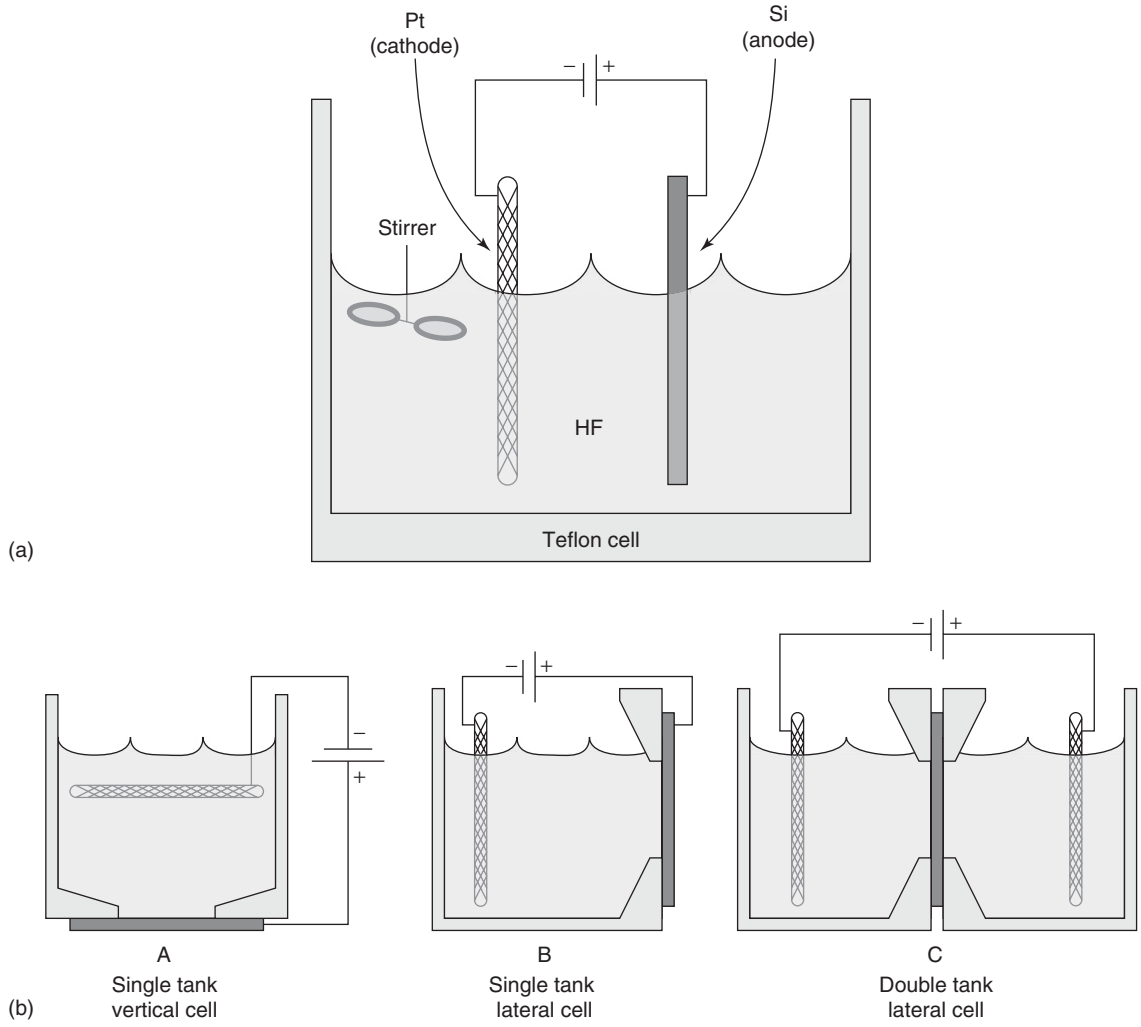

Figure 2 Schematic anodization arrangements: (a) principle and (b) practical examples (A, B, and C). Platinum and Teflon are mostly used because of their chemical resistance to HF. In the practical arrangements A, B, and C, the Si area exposed to the solution – typically $\sim 1\,cm^2$, circular – is well defined by the Teflon cell. Rubber gaskets between Si and Teflon can easily avoid spills. Type A is easier to design, type B is convenient when Si illumination is desirable (e.g., for *n*-type Si, see section "Fabrication procedures"), and type C does not require electrical contacts on Si. An optional stirrer is sometimes used to improve diffusion of HF during the anodization and H bubbles removal.

Table 2 Critical parameters of the anodization procedure

Parameter	*Typical range*	*Unit*
HF concentration	2–40	% (in weight)
Current density	0.5–150	$mA\,cm^{-2}$
Anodization time	5–1800	s
Temperature	250–300	K
Wafer resistivity (*p*-type)	0.001–100	Ω cm
Wafer resistivity (*n*-type)	0.001–100	Ω cm

A typical electrochemical solution can include, e.g., water (H_2O) in an approximately equal amount of HF, the rest being ethanol.

rather than the absolute current I. J and I scale with a fixed constant for a given cell, provided that the area of the Si sample exposed to the electrolyte is well defined and fixed.

In order to form PSi, the current at the Si side of the Si/electrolyte interface must be carried by holes, injected from the bulk toward the interface. The current must be kept between zero and the electropolishing threshold, which can be identified as the value of the first maximum of the anodic regime in the I–V curve. Useful regimes are included in the hashed region of **Figure 5**, where the electropolishing threshold voltage (for the curve marked with open circles) is $V \sim 1.3\,V$. In order to achieve significant hole current in *n*-type Si, external illumination of the sample is required, depending on the doping level. If the current exceeds the electropolishing threshold, the anodization results in a progressive, complete removal of Si. The wafer then has a mirror-like appearance.

Table 3 Effect of anodization parameters on PSi formation

An increase of	*Porosity*	*Etching rate*	*Electropolishing threshold*
HF concentration	Decrease	Decrease	Increase
Current density	Increase	Increase	
Anodization time	Increase	Almost constant	
Temperature			Increase
Wafer doping (*p*-type)	Decrease	Increase	Increase
Wafer doping (*n*-type)	Increase	Increase	

As an approximate rule of thumb, the etch rate is of the order of 1 nm s^{-1} for each mA cm^{-2} of the anodization current density.

Table 4 Three sample sets of anodization parameters, for *p*-type Si substrates, resulting in the three different structural regimes described in **Table 1**

HF concentration (%)	15	15	2
Current density (mA cm^{-2})	50	50	5
Wafer resistivity (Ω cm)	5	0.01	10
Resulting structure	Microporous	Mesoporous	Macroporous

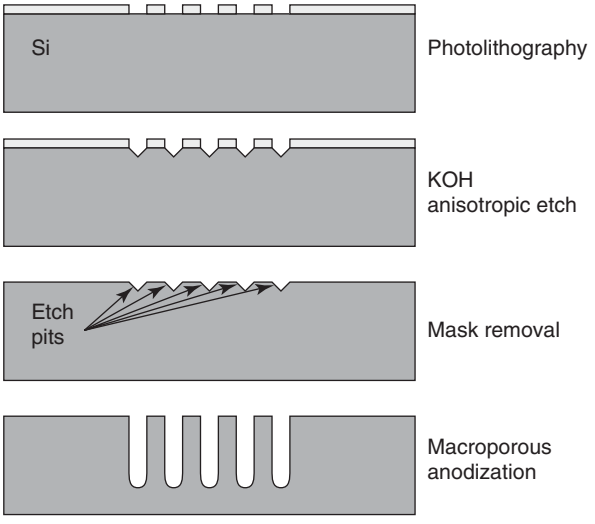

Figure 3 Schematic lithographic procedure resulting in the definition of pore-starting etch pits.

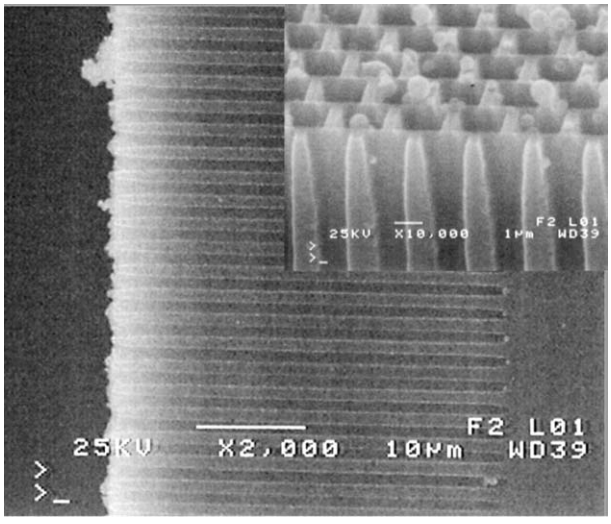

Figure 4 Example of a photonic crystal (cross section and top-view images of the same sample) realized with ordered macroporous PSi in a *p*-type doped silicon substrate. This photonic crystal has a photonic bandgap at 3.5 μm.

A hypothesized chemical reaction which could describe the anodization is

$$Si + 6HF \rightarrow H_2SiF_6 + H_2 + 2H^+ + 2e^- \qquad [1]$$

The last term – a negative charge at the interface, to be neutralized by the current flow – would explain the need of hole injection from the substrate toward the Si/electrolyte interface. Similar to most semiconductor junctions, at the Si/electrolyte interface a depletion zone is formed. The width of this depletion zone depends on the doping and may explain the different pore sizes found in p^--and p^+-type doped silicon. In addition, the depletion layer width depends on the surface curvature: the anodization preferentially occurs at the pore tips where the curvature is largest. Moreover, when the depletion zones of adjacent pores meet each other, the current flow is suddenly pinched off. Further Si etching is blocked, and pore collapsing is prevented. For this reason, the reaction is self-limited in the hashed anodization regimes of **Figure 5**, and leads to a porous structure rather than to electropolishing. As further practical consequence, in stationary conditions, the porosity remains approximately constant, whereas the overall thickness of the PSi layer grows essentially linearly in time.

Back-side illumination (most conveniently achieved using cells of type B, **Figure 2**) in potentiostatic

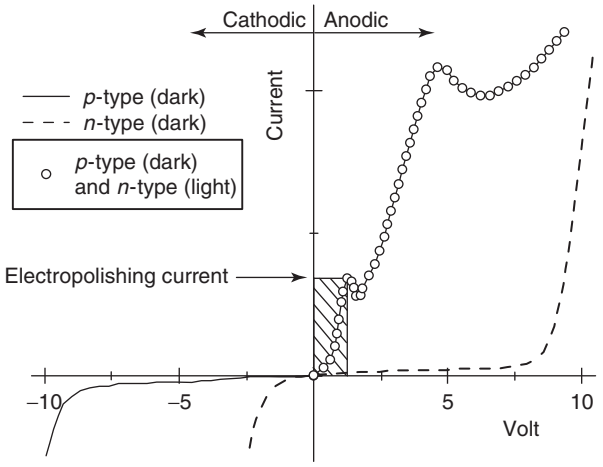

Figure 5 Typical *I–V* characteristics of an electrochemical cell for PSi fabrication (**Figure 2**). The hashed region corresponds to the useful regime where PSi can be achieved, assuming the *I–V* characteristic marked with hollow circles. In the anodic regime, the characteristics of a cell with *n*-type Si will lie in the region bounded by the characteristic in dark (dashed line) and in full light (hollow circles).

regime, with *n*-type Si, allows a useful, further control on the hole injection, both in terms of carrier flux (which is proportional to illumination intensity) and of localization of the injection, which is concentrated in the region of the pore tips, acting as hole collectors. The etching process leads to a very regular pore growth, which is most effectively exploited to fabricate macroporous photonic crystal devices (**Figure 4**).

Drying Techniques

Due to large capillary stress, drying of samples is a critical step and can result in extended cracking if special procedures are not followed. Methods to reduce or eliminate the capillary stress include pentane drying, supercritical drying, freeze drying, and slow evaporation rates. Pentane drying is the easiest to implement. Pentane has a very low surface tension, and shows no chemical interaction with PSi (unlike ethanol). Using pentane as drying liquid enables to strongly reduce the capillary tension, but since water and pentane are nonmiscible liquids, ethanol or methanol have to be used as intermediate liquids. Using this drying technique, PSi layers with porosity values up to 90% and thickness up to 5 μm exhibit no cracking pattern after drying. Supercritical drying requires a specific apparatus but is more effective in preventing cracking of the film so that PSi layers of porosity values up to 95% were demonstrated.

Oxidation Techniques

As soon as PSi samples are dried, hydrogen surface passivation is gradually replaced by native oxide. This chemical change affects most PSi properties, for example, photoluminescence and electrical conductivity. Since the characteristics of the native oxide strongly depend on many factors such as the storage conditions, evolution of sample properties is often poorly characterizable. To stabilize PSi properties, oxidation is often used. Oxidation implies the formation of a layer containing the original Si atoms. Therefore, it also reduces the nanocrystallite size, with remarkable impact on photoluminescence emission energy (blue-shift). The employment of controlled oxidation procedures is therefore a valuable post-anodization option toward a better control of PSi properties and stabilization.

Tested oxidation procedures on PSi include anodic oxidation, chemical oxidation, thermal oxidation, plasma-assisted oxidation, and irradiation-enhanced oxidation. Anodic oxidation is an electrochemical process, in which oxide layers are formed with current injection. As such, the technique is structurally selective: more conductive paths get more oxidized. This selectivity is particularly interesting for light-emitting diode (LED) applications, where more conductive paths are usually associated to large injection channels, which are poorly luminescent, and their oxidation results in enhanced electroluminescence quantum efficiency. Another application of controlled oxidation – mostly thermal – is the fabrication of small, blue-luminescent PSi nanocrystallites.

Structural Properties

Structural properties of PSi have been investigated by electron microscopy, scanning probe microscopy, X-ray scattering techniques, X-ray absorption techniques, and Raman spectroscopy. In particular, X-ray absorption spectroscopy can be performed not only by extended X-ray absorption fine structure (EXAFS) analysis, but also by X-ray excitation of optical luminescence (XEOL), a convenient tool for luminescent samples, in which absorption is probed via the measurement of the corresponding optical emission. A general feature resulting from the comparison of these techniques is that highly luminescent PSi is a composition of extensively connected Si crystals of nanometric dimensions (typically, 1–5 nm in radius). Sizes smaller than Si Bohr radius ($\sim$4.9 nm), imply significant quantum confinement effects. Raman measurements are also often used to demonstrate crystallinity in PSi skeleton and infer information on the size of Si nanocrystals.

Accurate determination of pore size distribution in mesoporous Si is usually given by the analysis of adsorption isotherms of gases at low temperature (Brunauer–Emmett–Teller, or BET, method). The

physical adsorption by a porous surface is increased relative to a nonporous one because of capillary condensation in pores. This increase in adsorption starts when the gas pressure is high enough to fill the smallest pores.

Chemical Properties

Surface chemical composition of PSi is best probed with Fourier transform infrared (FTIR) spectroscopy. FTIR signal in PSi is larger and easier to measure than in bulk Si due to much larger specific area. Chemical bonds and their IR resonance positions detected in PSi are shown in **Table 5**. In fresh, as-prepared samples, oxygen is normally absent, the dominant bonds being $Si–H_x$ groups ($x = 1$, 2, or 3). Aging is observed as a slow replacement of H by O bonds in PSi. Also, luminescence fatigue is explained by photochemical reactions occurring on the surface of the Si nanocrystals.

Electronic Properties

The first and most favorable explanation for the visible emission in PSi is the quantum confinement of excitons in nanometer-sized silicon. An empirical law, based on the effective mass approximation, links the energy gap E_g of silicon nanocrystals with their sizes $\ell : E_g(\ell) = E_g^{Si} + 88.34/(\ell)^{1.37}(\text{eV})$, when ℓ is given in Å. The energy gap opening is given by an equal energy shift of the bottom of the conduction band to high energy and of the top of the valence band to low energy. The nature of the energygap is still indirect even though a quasidirect bandgap can be formed in ultrasmall Si nanocrystals.

Electrical Properties

Electrical resistivity in PSi is five orders of magnitude higher than in intrinsic Si, because PSi is depleted of free carriers. Depletion can occur either because of the energy gap widening from quantum confinement which reduces the thermal generation of free carriers, or because of trapping of free carriers. Trapping can occur during the preparation of PSi either because the binding energy of dopant impurities are increased or because of the formation of surface states. It has been demonstrated that the dopants are still present in essentially unchanged concentration after the etching, but are in a neutral state.

The electrical transport is mainly affected by the disordered structure of the Si skeleton which restricts the conductive paths to a highly constrained geometry, which for certain porosities forms a percolated or fractal geometry. As a consequence, conductivity is thermally activated, strongly frequency dependent, and highly dispersive. Several models have been proposed to explain the electrical transport properties. They differ on the transport paths and mechanisms. The proposed transport paths range from transport in the Si nanocrystals (with diffusion or tunneling between the Si nanocrystals or at their surface) to transport in the amorphous and disordered matrix surrounding the nanocrystals, or through both. The suggested mechanisms are band transport, activated hopping in band tail, trap-controlled hopping through nanocrystals, activated deep states hopping, Pool–Frenkle processes, and activated hopping in fractal networks.

Given the large specific area per unit volume, the electrical transport is strongly influenced by external factors such as residual electrolyte and ambient atmosphere. The latter property is very interesting for sensor applications. Certain gases – for example, NO_2 – have the capability of modifying the free carrier population. Changes in the electrical conductivity in the presence of sub-ppm concentrations of such gases can be detected at room temperature operation. Other gaseous species (e.g., polar liquid vapors) also affect electrical transport via electric field interactions with charge carriers.

Optical Properties

Light Diffusion and Scattering

The dimension l of the PSi structures (i.e., the pore size and the porous layer thickness), compared to the optical wavelengths λ, can range from $l \ll \lambda$ all the way to $l \approx \lambda$. There are accordingly two different regimes of light propagation and interaction with PSi.

The first regime is $l \ll \lambda$. The radiation fields cannot resolve the PSi structures, and the interaction can be conveniently described by means of an "effective medium approximation," where a macroscopic dielectric constant (or a refractive index) is evaluated as a suitable combination of the dielectric constants of Si and air. The result is, in general, a complex dielectric function of space. Effective medium theories, which are routinely used for PSi, are enumerated in **Table 6**. Refractive index values are reported in **Figure 6**.

The second regime is $l \sim \lambda$. These kinds of structures are called mesoscopic: the structural size is small compared to the wave coherence length, that is, the maximum length along which phase memory and coherent phenomena are observable. The porous geometrical structure strongly influences light transport and interaction. Useful mathematical models take advantage either of the Bloch theorem (in the case of periodical structures (photonic crystals)), or of statistical and Green's function methods (in the case of aperiodic or random structures).

Mixed regimes are also possible in PSi. The most important case is the one-dimensional (1D) mesoscopic structure: the anodization parameters are set to achieve microporous PSi (size of pores $\ll \lambda$, first regime), but the anodizing current density is modulated to obtain periodical or aperiodical thin layer structures (thickness $\sim \lambda$, second regime along the PSi growth direction). Each layer is different from adjacent layers in terms of porosity and thus of effective dielectric constant (and effective refractive index). Compared to other thin-film growth techniques, PSi has the advantage of allowing a continuous tuning of the refractive index over a wide range ($1.4 \leqslant n_{\text{eff}} \leqslant 2.4$), and of being a fast and cheap technique that can lead to structures of several hundreds of layers, with typical fabrication times ranging from few minutes to few hours.

In the presence of high-index liquids (and/or their vapors), the refractive index of the porous layer changes, affecting light transport properties. The effect can be exploited for gas sensors and biosensors applications.

Table 6 Useful effective medium approximation for the dielectric function of PSi

Theory	*Formula*
Bruggeman	$P\frac{\varepsilon_M - \varepsilon_{\text{eff}}}{\varepsilon_M + 2\varepsilon_{\text{eff}}} + (1-P)\frac{\varepsilon - \varepsilon_{\text{eff}}}{\varepsilon + 2\varepsilon_{\text{eff}}} = 0$
Maxwell Garnett	$\frac{\varepsilon_{\text{eff}} - \varepsilon_M}{\varepsilon_{\text{eff}} + 2\varepsilon_M} = (1-P)\frac{\varepsilon - \varepsilon_M}{\varepsilon + 2\varepsilon_M}$
Looyenga	$\varepsilon_{\text{eff}}^{1/3} = (1-P)\varepsilon^{1/3} + P\varepsilon_M^{1/3}$

ε, dielectric function of Si; ε_M, dielectric function of host material (normally: air); ε_{eff}, calculated effective dielectric function; P, porosity.

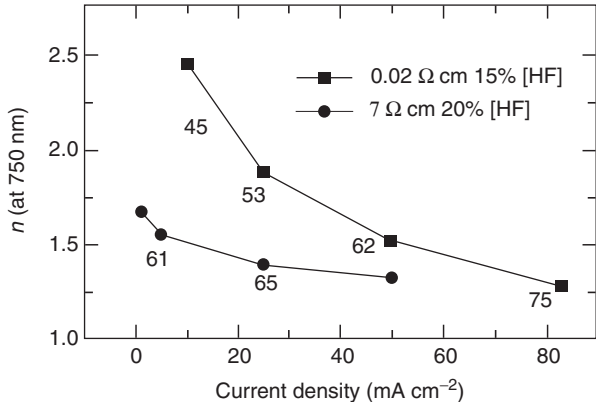

Figure 6 Refractive index as a function of current density and porosity for two different substrate doping levels.

Photoluminescence

Microporous PSi structures have been reported to luminesce efficiently in the near infrared (IR) (0.8 eV), in the whole visible range, and in the near ultraviolet (UV) (**Figure 7**).

Such a broad range of emission energies arises from a number of clearly distinct luminescent bands, which are listed in **Tables 7–9**. In addition, PSi has been used as an active host for rare-earth impurities, for example, Nd or Er, or dye solutions. Direct energy transfer between PSi and the impurity or dye is demonstrated. The most efficient and studied emission is the slow (S) band because it can be excited by electrical injection. The most popular model for the photoluminescence – especially for the S-band – is excitonic radiative recombination subject to quantum confinement. Other models are surface states models, the siloxene model, defect models, the surface hydrides model, and the hydrogenated amorphous silicon model. Coexistence of more than one mechanism is likely.

S-Band It can be tuned from close to the bulk silicon bandgap through the whole visible range. The large spectral width comes from inhomogeneous broadening and vibronic coupling of the radiative transitions. The S-band efficiency is not proportional to the inner surface area: a "threshold" porosity has

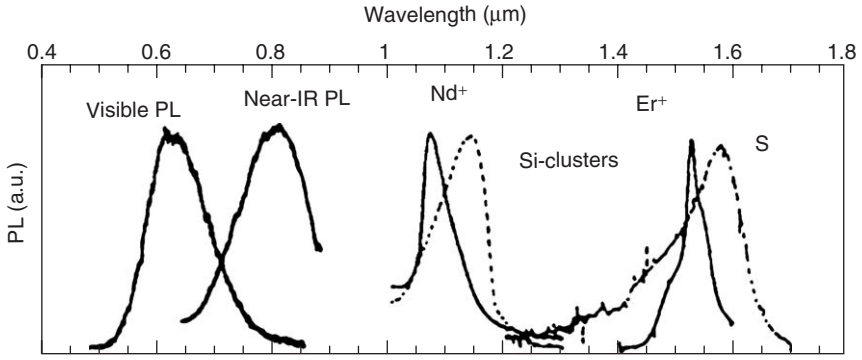

Figure 7 Room temperature photoluminescence spectra for various PSi structures which have been oxidized or implanted with some selected impurities. (Reproduced from Fauchet PM, Tsybeskov L, Duttagupta SP, and Hirschman KD (1997) Stable photoluminescence and electroluminescence from porous silicon. *Thin Solid Films* 297(1–2): 254–260, with permission from Elsevier.)

Table 7 PSi luminescence bands

Spectral range	*Peak wavelength* (nm)	*Label*
UV	~350	UV band
Blue-green	~470	Fast (F) band
Blue-red	400–800	Slow (S) band
Near IR	1100–1500	IR band

to be exceeded to achieve an efficient luminescence. Postanodization chemical etching in HF, corresponding to a porosity increase, results in a strong rise in PL efficiency and a blue shift of the visible band. External quantum efficiencies higher than 0.1% are obtainable from high-porosity PSi layers of all types, but efficiency normally decreases in the order n^--type, p^--type, n^+-type, and p^+-type doped PSi. High porosity is essential for high visible PL efficiency. The inefficient luminescence observed from inhomogeneous material of low porosity originates from microscopic areas of high porosity. Isolated nanocrystals, produced by dispersing a colloidal suspension of PSi fragments on a glass coverslip, show external quantum efficiencies $\geqslant 88\%$, with a number of bright-to-dark nanocrystals in the suspension of only 2.8%. Thus, the average quantum efficiency of a PSi layer of 1% results from a statistical distribution of high and low quantum efficiency nanocrystals.

Phonon-assisted luminescence (vibronic-coupled transitions) is demonstrated by fine structure in resonantly excited photoluminescence at low temperature. Thus, the electronic and the vibronic structure of the luminescence of PSi are similar to crystalline Si, with an energy shift consistent with quantum confinement. At large confinement energies (>0.7 eV), no-phonon quasidirect transitions dominate, because of the breakdown of k-conservation under strong confinement.

The luminescence is polarized parallel to the exciting light. This is measured by recording the polarization ratio $\rho = (I_\parallel - I_\perp)/(I_\parallel + I_\perp)$. ρ is zero on the IR band and nonzero on the S-band (tending to zero as the energy approaches that of the Si bandgap). The interpretation is that PSi is an ensemble of randomly oriented aspherical nanocrystals, preferentially aligned along the $\langle 1\,0\,0 \rangle$ direction. Recombining carriers have bulk-like wave functions which are sensitive to the shape of the nanocrystals.

Aging effects include a blue shift in the S-band and changes in the photoluminescence efficiency (both increasing and decreasing have been observed), which can be explained in terms of surface oxidation. Anticorrelation exists between the dangling bond density and the luminescence efficiency; thus, the effect of the oxidation depends on its passivation properties.

Other Bands The F-band is observed only in oxidized PSi, and it is probably originated from contaminated or defective Si oxide. Annealing in water vapor activated the blue emission indicating a possible major role of adsorbed hydroxyls in the emission process. The IR band is weak at room temperature, and becomes much stronger at cryogenic temperatures. Its origin seems to be related to dangling bonds, although no direct correlation has been demonstrated.

Absorption

The absorption coefficient has been measured in PSi by optical transmission, photoluminescence excitation (PLE), and photothermal deflection spectroscopy (PDL). Transmission spectra are shifted toward higher energy compared to bulk Si with a shift, which increases with increasing porosity. This observation is consistent with quantum confinement model. The line shape analysis of the absorption coefficient shows that its energy dependence follows a trend like that of an indirect gap semiconductor similar to Si, but displaced to higher energy.

Table 8 Some spectral characteristics of the S-band

Property	*Typical values*	*Comments*
Peak wavelength	1100–400 nm	At 300 K, depends on porosity
PL external quantum efficiency	$\geqslant$5%	At 300 K, depends on porosity
FWHM	0.3 eV	At 300 K (8 meV in PSi microcavities)
PL decay times	$\simeq 10\,\mu s$	Strongly dependent on wavelengths, temperature and aging condition
Polarizability ratio	$P \leqslant 0.2$	
Fine structure under resonant excitation	Phonon replica at 56 and 19 meV	Heavily aged PSi, energies consistent with Si phonons

Table 9 Some spectral characteristics of the F-band

Property	*Typical values*	*Comments*
Peak wavelength	480 nm	UV excitation at 300 K
PL efficiency	$\geqslant$0.1%	External quantum efficiency UV excitation at 300 K
FWHM	0.4 eV	UV excitation at 300 K
PL decay times	1 ns	Independent on wavelength and excitation conditions

A characteristic feature of PSi is the large displacement (Stokes shift) between the absorption edge and the emission peak energy (see **Figure 8**). The existence of localized states that can account for the observed shift has been demonstrated. Such states can lead to self-trapped excitons at some surface bonds of Si crystallites, such as Si–Si dimers and Si–O double bonds, giving reduced dependence of the luminescence energy on size, and a very large Stokes shift. Other models for the Stokes shift are based on Si quantum dot relaxation from distorted configurations, giving rise to new transitions involving localized states that lower the emission threshold with respect to the absorption.

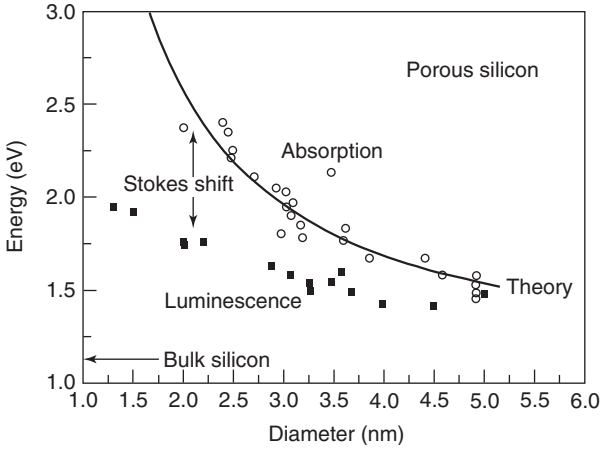

Figure 8 Compilation of optical bandgaps of PSi samples obtained from optical absorption (unfilled symbols) and luminescence (filled symbols). The lines represent calculated values with the empirical law reported in the text.

Applications

Important actual or perspective applications of PSi are shown in **Table 10**.

Light Emitting Diodes (LEDs)

Si *p*/*n* junction emits light both in forward and in reverse bias conditions. Power efficiency is $\sim 10^{-4}$ (10^{-8}) at 1.1 μm wavelength in forward (reverse) bias. Also in PSi based devices, electroluminescence (EL) is observed both in the IR and in the visible. Efficiency is higher than in bulk Si diodes, depending on the diode structure and on the PSi contact method. Initially, EL was observed with wet contacts and later with solid contacts. Major achievements in terms of quantum efficiency are summarized in **Figure 9**.

Sensors, Biosensors, Medical Applications

PSi is a twofold promising material for sensor applications. On one side, its electrical and optical properties strongly depend on the environment, because of its large specific area. Useful sensing parameters include, for example, the electrical conductivity and photoluminescence. Most sensing parameters can effectively work at room temperature. On the other side, it supplies a handy template to hold chemical and biological species. Target species can be immobilized in the PSi matrix, a practice which is especially useful for biological samples – such as oligonucleotides, biotin, or antibodies. Techniques for immobilization range from physical adsorption to the replacement of hydride bonds with Si alkyls, and to antibody bonding at functionalized PSi surface with subsequent antibody–antigen interactions. Species identification can be performed by probing optical, electrical, or chemical properties. Examples include, respectively, reflectivity or wave-guiding measurements (which depend on the dielectric constant of the species, as already discussed), conductance measurements, and

Table 10 Potential application areas of PSi

Application area	*Role of PS*	*Key property*
Optoelectronics	LED	Efficient electroluminescence
	Waveguide	Tunability of refractive index
	Field emitter	Hot carrier emission
	Optical memory	Nonlinear properties
Micro-optics	Fabry-Perot filters	Refractive index modulation
	Photonic bandgap structures	Regular macropore array
	All optical switching	Highly nonlinear properties
Energy conversion	Antireflection coatings	Low refractive index
	Photo-electrochemical cells	Photocorrosion cells
	Solar cells	
Environmental monitoring	Gas sensing	Ambient sensitive properties
Microelectronics	Micro-capacitor	High specific surface area
	Insulator layer	High resistance
	Low-k material	Electrical properties
Wafer technology	Buffer layer in heteroepitaxy	Variable lattice parameter
	SOI wafers	High etch selectivity
Micromachining	Thick sacrificial layer	Highly controllable Etching parameters
Biotechnology	Tissue bonding	Tunable chemical reactivity
	Biosensors	Enzyme immobilization

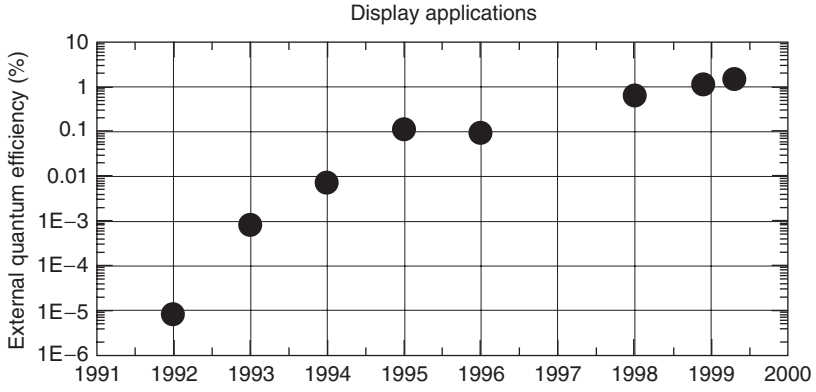

Figure 9 Time evolution of the external quantum efficiency of porous silicon-based LEDs for display applications.

pH measurements. Biocompatibility of PSi has suggested medical applications, such as *in vivo* slow release of drugs, *in vivo* diagnostic tests, and template for bone growth.

Powder Processing: Models and Simulations

A B Yu, The University of New South Wales, Sydney, NSW, Australia

Introduction

Granular materials, which can be either wet or dry and range in size from nanometers to centimeters, are widely encountered as particles or powder in industries and in nature. As with solids, they can withstand deformation and form heaps; as with liquids, they can flow; as with gases, they exhibit compressibility. Corresponding to the fluid- and solid-like modes, they show different flow regimes: quasi-static regime, rapid flow regime, and a transitional regime that lies in between. These features give rise to another state of matter that is poorly understood. The development of a general theory to describe the packing (statics) and flow (dynamics) of granular materials has been a problem challenging the scientific community for years.

Essentially, the existing approaches to modeling granular materials can be classified into two categories: the continuum approach at a macroscopic level and the discrete approach at a microscopic level. In the continuum approach, the macroscopic behavior is described by balance equations, for example, mass and momentum as used in the two fluid model (TFM), closed with constitutive relations together with initial and boundary conditions. This approach is preferred in process modeling and applied research because of its computational convenience. However, its effective use depends heavily on constitutive or closure relations and the momentum exchange between particles of different type. In the past, different theories have been devised for different materials and for different flow regimes. For example, models have been proposed to derive the constitutive equations for the rate-independent deformation of granular materials based on either the plasticity theory or the double shearing theory; the rapid flow of granular materials has been described by extending the kinetic theory of dense gases; the transitional regime that involves both collisional and frictional mechanisms is studied by use of the kinetic theory combined with the Mohr–Coulomb quasi-static theory. However, to date, there is no accepted continuum theory applicable to all flow conditions. As a result, phenomenological assumptions which have very limited application are necessary to obtain the constitutive relations and boundary conditions.

The discrete approach is based on the analysis of the motion of individual particles and has the advantage that there is no need for global assumptions on solids such as steady-state behavior, uniform constituency, and/or constitutive relations. Various methods have been developed in the past. A major type of discrete approach is based on the so-called discrete element method (DEM), originally developed for rock mechanics. The method considers a finite number of discrete particles interacting by means of contact and noncontact forces, and every particle in a considered system is described by Newton's equations of motion. In principle, it is similar to molecular dynamic simulation (MDS) but the forces involved differ because of the difference in

time and length scales. DEM-based simulation has been recognized as an effective method to study the fundamentals of granular materials and assess the performance of industrial processes. By means of a proper average method, it can also generate information to support continuum modeling.

This article is focused on the discrete approach. It first describes the principles and key features of the simulation method, and then discusses its application to the study of a few typical static and dynamic particle systems. Emphasis is given to the validity analysis and the usefulness of the resulting particle scale information in elucidating the fundamentals of granular materials, achieved through illustrative results.

Simulation Method

Governing Equations

A particle in a considered system can have two types of motion: translational and rotational, determined by Newton's second law of motion. During its movement, the particle may collide with its neighbor particles or wall at the contact points and interact with the surrounding fluid, through which the momentum and energy are exchanged. For the systems considered in this article, at any time t, the equations governing the translational and rotational motions of particle i are

$$m_i \frac{\mathrm{d}\boldsymbol{v}_i}{\mathrm{d}t} = \boldsymbol{f}_{\mathrm{pf},i} + m_i\boldsymbol{g} + \sum_{j=1}^{k_i}\left(\boldsymbol{f}_{\mathrm{c},ij} + \boldsymbol{f}_{\mathrm{d},ij} + \boldsymbol{f}_{\mathrm{v},ij}\right) \quad [1]$$

and

$$I_i \frac{\mathrm{d}\omega_i}{\mathrm{d}t} = \sum_{j=1}^{k_i}\left(\boldsymbol{T}_{\mathrm{c},ij} + \boldsymbol{T}_{\mathrm{r},ij}\right) \quad [2]$$

where m_i, I_i, $\boldsymbol{v}_i$, and $\boldsymbol{\omega}_i$ are, respectively, the mass, moment of inertia, translational, and rotational velocities of the particle. The forces involved are: the particle–fluid interaction force, $\boldsymbol{f}_{\mathrm{pf},i}$, gravitational force, $m_i\boldsymbol{g}$, and interparticle forces between particles i and j. The torques include the interparticle torque $\boldsymbol{T}_{\mathrm{c},ij}$ and rolling friction torque $\boldsymbol{T}_{\mathrm{r},ij}$. For multiple interactions, the interparticle forces and torques are summed for k_i particles interacting with particle i.

Particle flow is often coupled with fluid (gas and/or liquid) flow. Various approaches have been proposed to simulate such a coupled particle–fluid flow. The time and length scales for fluid flow can range from discrete (MDS, lattice Boltzmann (LB), pseudo-particle (PP)) to continuum (direct numerical simulation (DNS), large eddy simulation (LES)), and other conventional techniques such as the TFM described above. Relative to particle phase, they can also be categorized into three groups: sub-particle, pseudo-particle, and computational cell. **Table 1** lists a few representative combinations of different length scales for fluid and particle phases and their relative merits in different aspects.

At this stage of development, the difficulty in particle–fluid flow modeling is mainly related to the solid phase rather than the fluid phase. Therefore, the

Table 1 Typical models for particle–fluid flow and their relative merits

Model type				
Length scale for fluid phase	Sub-particle (discrete or continuum)	Pseudo-particle (discrete)	Computational cell (continuum)	Computational cell (continuum)
Length scale for particle phase	Particle (discrete)	Particle (discrete)	Particle (discrete)	Computational cell (continuum)
Nature of coupling	Discrete + discrete or continuum + discrete	Discrete + discrete	Continuum + discrete	Continuum + continuum
Example	LB-DEM or DNS	PP-DEM	CCDM or CFD-DEM	TFM
Closure of equations	Yes (but may experience numerical difficulty for systems with strong particle–particle interactions)	No (difficulty to determine physical properties of a pseudo-particle)	Yes	No (constitutive relation for solid phase and phase interactions not generally available)
Incorporation of distribution effects of dispersed, solid phase	Yes	Yes	Yes	No
Computational effort	Extremely demanding	Very demanding	Demanding	Acceptable
Suitability for engineering application in relation to process modeling and control	Extremely difficult	Very difficult	Difficult	Easy
Suitability for fundamental research in relation to fluid physics	Most acceptable ($\boldsymbol{f}_{\mathrm{pf}}$ can be used for CCDM)	Acceptable (but only valid for well-defined PP system)	Acceptable	No

so-called combined continuum and discrete model (CCDM) or CFD–DEM is attractive because of its computational convenience as compared to DNS or LB–DEM, and capability to capture particle physics as compared to TFM. In CCDM, the continuum fluid field is calculated from the continuity and the Navier–Stokes equations based on the local mean variables over a computational cell, which are given by

$$\frac{\partial \varepsilon}{\partial t} + \nabla \cdot (\varepsilon \boldsymbol{u}) = 0 \qquad [3]$$

and

$$\frac{\partial (\rho_f \varepsilon \boldsymbol{u})}{\partial t} + \nabla \cdot (\rho_f \varepsilon \boldsymbol{u}\boldsymbol{u}) = -\nabla p - \boldsymbol{F}_{pf} + \nabla \cdot (\varepsilon \boldsymbol{\tau}) + \rho_f \varepsilon \boldsymbol{g} \qquad [4]$$

where $\boldsymbol{u}$, p, and $\boldsymbol{\tau}$ are, respectively, the fluid velocity, pressure, and viscous stress tensor; $\boldsymbol{F}_{pf} = \left(\sum_{i=1}^{k_c} \boldsymbol{f}_{pf,i}/\Delta V\right)$ is the particle–fluid interaction force, and ε, ΔV, and k_c are respectively the porosity, volume, and number of particles in a computational cell.

Models for Particle–Particle and Particle–Fluid Interactions

The forces acting on a particle result from particle–particle and particle–fluid interactions. For particles, these interactions include the forces due to direct or nondirect contacts between particles, as shown in **Figure 1**. The direct contact forces include the contact force and viscous contact damping force. The nondirect contact forces include the forces associated with fine particles such as the van der Waals force, electrostatic force, capillary and viscous forces, and solid-bonding forces. Particle–fluid interactions include buoyancy, drag force, and so on. These forces have been implemented by various investigators in various ways. To date, the equations to determine some of the forces are not fully developed. Therefore, development of a more comprehensive theory and experimental techniques to quantify the interaction forces between particles and between particle and fluid under various conditions will continue to be an active research area for years to come. **Table 2** lists the equations employed to calculate the forces and torques for the particle systems considered in this article; they are also commonly used in the literature.

Numerical Solution and Boundary Treatments

Equations [1] and [2] for solid flow can be solved by an explicit time integration method, and eqns [3] and [4] for fluid flow by use of a standard computational fluid dynamics (CFD) algorithm, facilitated with suitable boundary conditions. For fluid phase, the no-slip boundary condition often applies to bed walls, together with other (inlet or outlet) conditions specified. For particle phase, the interparticle force models are also applied to the interaction between a particle and a wall, with the corresponding wall properties used; however, the wall is assumed to be so rigid that no displacement and movement of the wall result from this interaction. Depending on the geometry and flow conditions, periodic boundary conditions can be implemented to reduce the computational effort. If fluid flow is negligible, simulations can be conducted without the need for solving eqns [3] and [4].

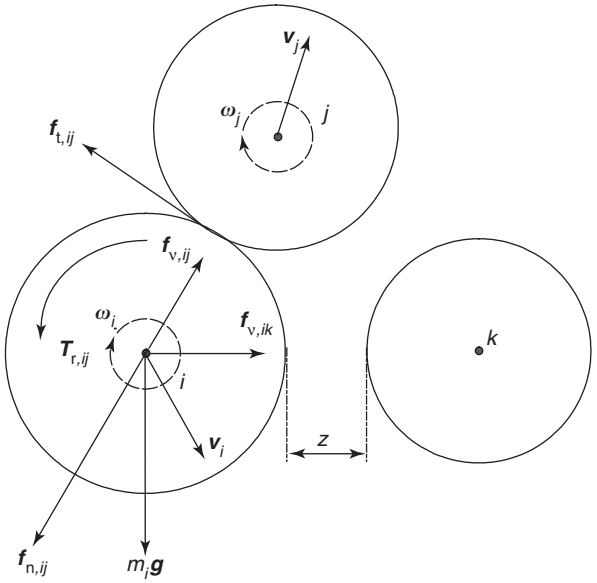

Figure 1 Schematic illustration of the forces acting on particle *i* from contacting particle *j* and noncontacting particle *k*. (Modified with permission from Yang RY, Zou RP, and Yu AB (2000) Computer simulation of the packing of fine particles. *Physical Review E* 62: 3900–3908; © American Physical Society and Yang RY, Zou RP, and Yu AB (2003) Effect of material properties on the packing of particles. *Journal of Applied Physics* 94: 3025–3034; © American Institute of Physics.)

The modeling of the solid flow by DEM is at the individual particle level, whilst the gas flow by CFD is at the computational cell level. As shown in **Figure 2**, their coupling is numerically achieved as follows. At each time step, DEM will give information, such as the positions and velocities of individual particles, for the evaluation of porosity and volumetric fluid drag force in a computational cell. CFD will then use these data to determine the gas flow field which then yields the fluid drag forces acting on individual particles. Incorporating the resulting forces into DEM will produce information about the motion of individual particles for the next time step. The fluid drag force acting on individual particles will react on the fluid phase from the particles, so that Newton's third law of motion is satisfied.

Table 2 Components of forces and torque acting on particle *i*

Force or torque	*Symbol*	*Equation*
Normal forces		
Contact	$\boldsymbol{f}_{\mathrm{cn},ij}$	$-\kappa_i \boldsymbol{\delta}_{\mathrm{c},ij}$
Damping	$\boldsymbol{f}_{\mathrm{dn},ij}$	$-\eta_i \boldsymbol{v}_{\mathrm{n},ij}$
Tangential forces		
Contact	$\boldsymbol{f}_{\mathrm{ct},ij}$	$\min\left(\gamma_{\mathrm{s}} \boldsymbol{f}_{\mathrm{cn},ij}, \kappa_i \boldsymbol{\delta}_{\mathrm{t},ij}\right)\dfrac{\boldsymbol{\delta}_{\mathrm{t},ij}}{\delta_{\mathrm{t},ij}}$
Damping	$\boldsymbol{f}_{\mathrm{dt},ij}$	$-\eta_i \boldsymbol{v}_{\mathrm{t},ij}$
Torques		
Interparticle	$\boldsymbol{T}_{\mathrm{c},ij}$	$\boldsymbol{R}_i \times (\boldsymbol{f}_{\mathrm{ct},ij} + \boldsymbol{f}_{\mathrm{dt},ij})$
Rolling friction	$\boldsymbol{T}_{\mathrm{r},ij}$	$-\gamma_{\mathrm{r}} R_i \boldsymbol{f}_{\mathrm{cn},ij} \hat{\boldsymbol{\omega}}_i$
Gravity force	$\boldsymbol{G}_i$	$m_i\, \boldsymbol{g}$
van der Waals force	$\boldsymbol{f}_{\mathrm{v},ij}$	$\dfrac{\mathrm{H}d}{6[\max(z, z_0)]^2}\dfrac{\boldsymbol{R}_i}{R_i}$
Fluid drag force	$\boldsymbol{f}_{\mathrm{pf},i}$	$0.5 c_{d0,i} \rho_f \pi \boldsymbol{R}_i^2 \varepsilon_i^2 \lvert\boldsymbol{u}_i - \boldsymbol{v}_i\rvert (\boldsymbol{u}_i - \boldsymbol{v}_i) \varepsilon_i^{-(\chi+1)}$

where: $\boldsymbol{V}_{ij} = \boldsymbol{V}_j - \boldsymbol{V}_i + \omega_j \times \boldsymbol{R}_j - \omega_i \times \boldsymbol{R}_i$, $\boldsymbol{V}_{n,ij} = (\boldsymbol{V}_{ij} \cdot n) \cdot n$, $\boldsymbol{V}_{t,ij} = (\boldsymbol{V}_{ij} \times \boldsymbol{n}) \times \boldsymbol{n}$, $\hat{\omega}_i = \dfrac{\boldsymbol{\omega}_i}{\omega_i}$,

$n = \dfrac{\boldsymbol{R}_i}{R_i}$, $\chi = 3.7 - 0.65 \exp\left[-\dfrac{(1.5 - \log_{10}\mathrm{Re}_{p,i})^2}{2}\right]$, $c_{d0,i} = \left(0.63 + \dfrac{4.8}{\mathrm{Re}_{p,i}^{0.5}}\right)^2$, $\mathrm{Re}_{p,i} = \dfrac{2\rho_f R_i \varepsilon_i \lvert\boldsymbol{u}_i - \boldsymbol{v}_i\rvert}{\mu_f}$

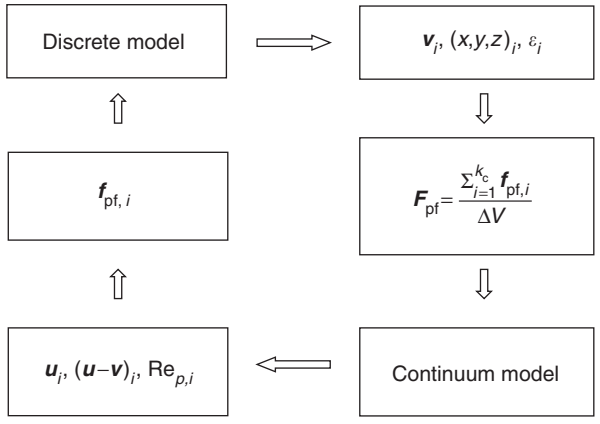

Figure 2 Coupling and information exchange between continuum and discrete models.

Model Validity and Application

Particle Packing

Random packing of particles, as a core research area in particle science and technology, is fundamental to many operations in powder processing and is useful in modeling some physical systems. Its formation is a dynamic process involving various interparticle forces as discussed above. Therefore, a successful simulation method must take into account all dynamic factors related to both geometry and force. Most of the previous methods only consider the former and ignore the latter, and hence fail to generate realistic packing structure, particularly when forces rather than the gravity are dominant. DEM-based simulation offers a promising way to overcome this difficulty.

Table 3 Parameters for glass beads

Parameter	*Symbol*	*Base value*
Particle density	ρ_{p}	$2.5 \times 10^3\,\mathrm{kg\,m^{-3}}$
Young's modulus	Y	$1.0 \times 10^7\,\mathrm{N\,m^{-2}}$
Poisson's ratio	$\tilde{\sigma}$	0.29
Sliding friction coefficient	γ_{s}	0.3
Rolling friction coefficient	γ_{r}	0.005
Normal damping coefficient	η_{i}	$2 \times 10^{-5}\,\mathrm{s^{-1}}$
Hamaker constant	H	$6.5 \times 10^{-20}\,\mathrm{N\,m}$
Minimum separation	z_0	$1 \times 10^{-20}\,\mathrm{m}$

Simulation conditions can vary to represent different packing processes, for example, the spherical growth of a packing under a centripetal force such as that used in isotropic compression or the vertical growth under gravity and other forces. Treatment such as vibration or compaction can also be implemented in a simulation. Here, only packing with vertical growth, which is typically conducted as follows, is considered. First, particles are randomly generated without overlap in a cylindrical or rectangular container. Then, the particles are allowed to settle down under gravity and other forces. This dynamic process proceeds until all particles reach stable positions with an essentially zero velocity as a result of the damping effect for energy dissipation. This packing process is equivalent to a physical operation to transform a gas-fluidized bed to a fixed bed by stopping the gas supply. Periodical boundary conditions can be applied to avoid the effect of sidewalls. **Table 3** lists the parameters normally used to simulate the packing of glass beads. Note that Young's modulus is smaller than the

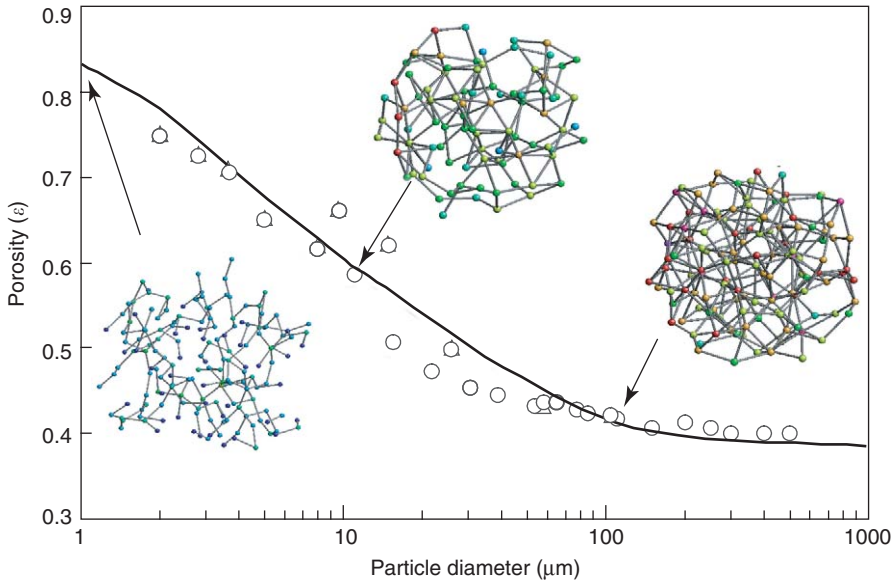

Figure 3 Porosity vs. particle size for glass beads: points, measured; line, simulated; and insets, packing structures taken from spherical samples for different sized spheres. Figure 4 The radial distribution function for packings of different sized particles. (Reprinted with permission from Yang RY, Zou RP, and Yu AB (2000) Computer simulation of the packing of fine particles. *Physical Review E* 62: 3900–3908; © American Physical Society.)

actual value in order to reduce the stiffness of particles and hence the computational effort.

The validity of the simulation technique can be assessed at both macroscopic and microscopic levels. **Figure 3** shows the relationship between porosity and particle size for mono-sized spheres. The good agreement between the measured and simulated results confirms macroscopically the validity of the DEM and the important role of the van der Waals force in governing the behavior of fine spheres ranging from 1 to 100 μm. The split-second peak in the radial distribution function has been recognized as a key feature for coarse spheres with negligible effect of the van der Waals force. For years, many investigators have struggled to reproduce this feature by computer simulation. As shown in **Figure 4**, it can be readily generated with the present simulation technique. The results also show that the radial distribution function varies with particle size or porosity. The coordination number is a more sensitive parameter in characterizing the packing structure. **Figure 5** shows that the simulated coordination number distributions for a particle mixture are quantitatively comparable to those measured, confirming the validity of the DEM approach from the viewpoint of microstructure.

Further comparison can be made in terms of interparticle forces. There is a good agreement between the simulated and measured distributions of normal contact forces between particles for a packing formed under gravity (**Figure 6**). This demonstrates the capability of the DEM in generating quantitative force information which is difficult, if not impossible, to obtain with the current experimental technique.

The validated DEM model offers a convenient way to carry out controlled numerical experiments to

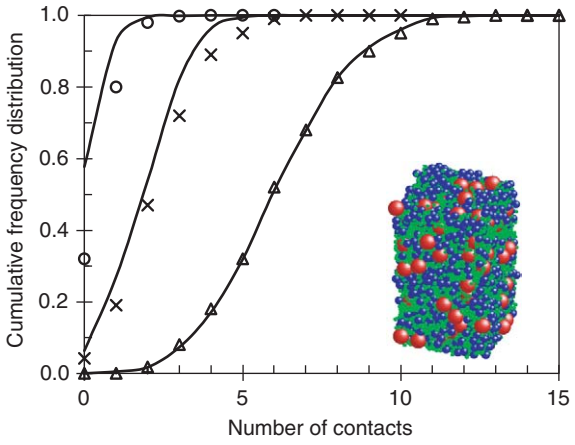

Figure 5 Distribution of coordination numbers for the packing of a ternary mixtures of spheres (inset) when the size ratios are 4:2:1 and the volume fractions are 0.25, 0.50, and 0.25 for large (red), medium (purple), and small (green) components: o, measured contacts between medium and large components; x, measured contacts between medium and medium components; Δ, measured contacts between medium and small components; lines, simulated.

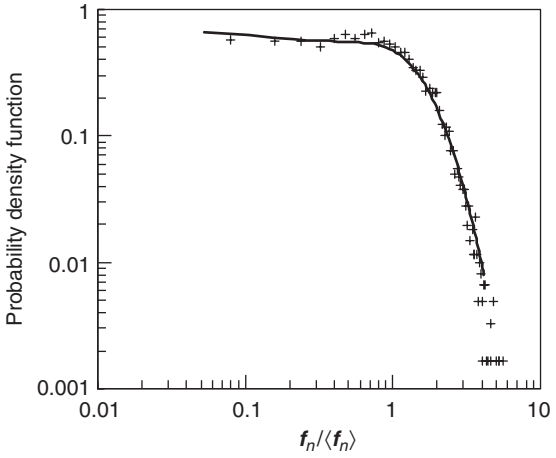

Figure 6 Frequency probability distribution of normalized normal contact forces between particles for the packing of 1 mm spheres: +, measured; −, simulated.

study the packing of particles under various conditions. For example, it has been used to quantify the effects of material properties such as the sliding and rolling friction coefficients related to the surface forces, the Hamaker constant, and the particle density related to the body forces acting on a particle, as shown in **Figure 7**. Correlations between macroscopic and microscopic or structural variables such as porosity, radial distribution function, and coordination number can be established based on DEM simulations. An important finding from this type of study is that macroscopic properties, for example, porosity, can be described as a function of interparticle forces, that is, the force ratio of the average van der Waals force and gravity force on a particle, as shown in **Figure 8**. This relationship, as an equation of state, can be generalized in terms of cohesive force relative to effective gravity force, although further work is necessary to understand its dependence on variables related to surface forces.

Structural analysis is the key to elucidating the packing mechanisms and the underlying physics. Realistic simulation of particle packing is crucial to such an analysis. In fact, the resulting structural information can be directly used to study the structural properties of porous media, including, for example, permeability related to pore-to-pore connectivity and effective thermal conductivity related to particle-to-particle connectivity. DEM-based microstructural study will play a key role in quantifying the governing mechanisms and generate reliable predictive methods for engineering application.

Particle Flow in a Horizontal Rotating Drum

Particle flow, coupled with fluid (gas and/or liquid) flow, is a very common feature in almost all operations or processes in powder processing. Understanding the fundamentals governing the flow and formulating suitable governing equations and constitutive relationships are of paramount importance to the development of better strategies for process and/or quality control. Previous studies are largely at a macroscopic or global scale, the resulting information being helpful in developing a broad understanding and design of a process of particular interest. However, the lack of quantitative fundamental understanding makes it difficult to generate a general method for reliable scaleup, design, and control/optimization of processes of different types. The bulk behavior of a particle system depends on the collective interactions of individual particles, and hence research on a particle scale has been recognized as a promising approach to overcome this difficulty. The CCDM method described above plays a very important role in this connection. This is demonstrated by the following two examples: particle flow in a rotating drum and gas fluidization of cohesive powders.

Rotating drums are widely used in various industries for various purposes including, for example, granulation/agglomeration, mixing, drying, milling, and coating. A comprehensive understanding of the flow of particles in a drum under different conditions is essential for process control and optimization. It is also very much related to the physics of granular matter, for example, particle avalanche in relation to heap formation or transition between fluid-like and

solid-like modes. This example illustrates how such a process can be simulated and analyzed.

Simulated here is the flow of glass beads in a horizontal drum of diameter 100 mm and thickness 16 mm. The drum is 35% filled with spheres of diameter 3 mm and rotates at various pre-set speeds. Periodic conditions apply axially to reduce the number of particles used; for simplicity the analysis is two-dimensional, achieved by averaging the data along the axial direction. Depending on the rotation speed, different flow regimes have been identified; but the cases considered here are in the so-called rolling regime that is commonly used in practice. The flow of particles in this regime has been well documented in the literature. Driven by the rotating drum, particles participate in collective solid rotation, reaching the filling surface inclined at an angle of repose from the rotating bulk at the bottom, pouring down this surface and getting mixed at the same time and then being re-trapped into the rotating bulk. This is indeed what is observed in the simulation, as shown in **Figure 9**.

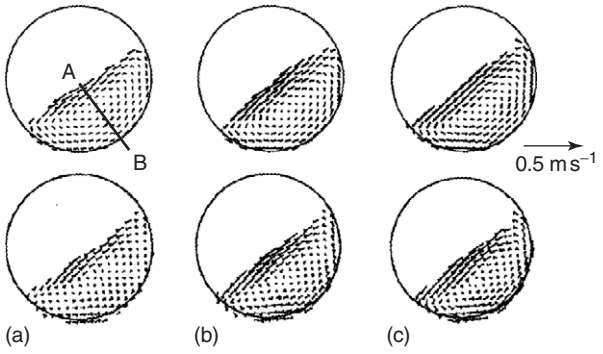

Figure 9 Velocity fields in a plane section taken from DEM simulation (top) and PEPT experiment (bottom) at rotation speeds of: (a) 20 rpm; (b) 42 rpm; and (c) 65 rpm. (Reproduced from Yang RY, Zou RP, and Yu AB (2003) Microdynamic analysis of the flow of particles in horizontal rotating drum. *Powder Technology* 130: 138–146, with permission from Elsevier.)

(Reproduced from Yang RY, Zou RP, and Yu AB (2003) Microdynamic analysis of the flow of particles in horizontal rotating drum. *Powder Technology* 130: 138–146, with permission from Elsevier.)

The validity of the simulation technique can be assessed by directly comparing the simulated and measured results. It is very useful to do so at a particle scale. One of the experimental techniques to produce such data is the so-called positron emission particle tracking (PEPT). **Figure 10** shows the dependence of the dynamic angle of repose on rotation speed. The agreement between the DEM simulation and PEPT measurement is good, both indicating that the angle increases linearly with the speed of rotation for the range considered.

Figure 9 also shows that the flow patterns produced by the DEM are comparable to those generated

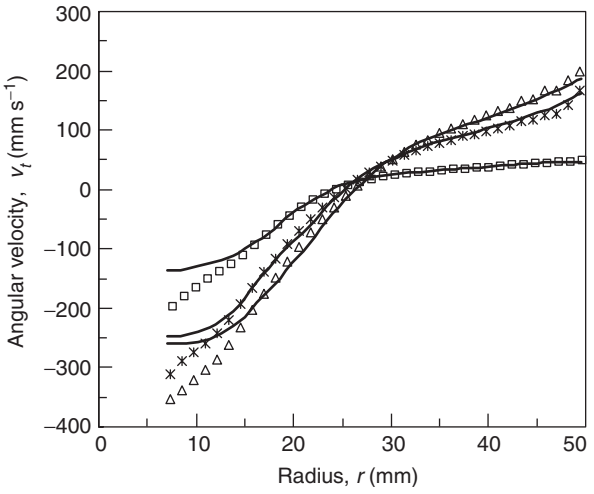

Figure 11 Angular velocity along the radius perpendicular to the flowing surface at rotation speeds of: □, 20 rpm; ✳, 42 rpm; and Δ, 65 rpm. Points are the PEPT measurements and solid lines are the simulated results. (Reproduced from Yang RY, Zou RP, and Yu AB (2003) Microdynamic analysis of the flow of particles in horizontal rotating drum. *Powder Technology* 130: 138–146, with permission from Elsevier.)

by PEPT for different rotation speeds. To be more quantitative, **Figure 11** plots the angular velocity along the radius perpendicular to the flowing surface, that is, line $\overline{AB}$ in **Figure 9**. Obviously, the agreement between the simulation and experiment is good. Satisfactory agreement between DEM and PEPT can also be observed for other processes such as bladed mixer and gas fluidization. It is noticed that the simulated velocity near the flow surface is higher than the PEPT velocity. This difference is mainly because the DEM simulation may not fully represent the PEPT experimental conditions, for example, the wall properties are simply assumed to be the same as those of particles in the DEM simulation. The selection of parameters for simulation is important to generate results matching physical experiment. The different sampling methods used in the simulation and experiment may also contribute to this observed discrepancy. Unlike PEPT, which determines the velocity field using the trajectory data of a single particle, the velocity field obtained from the DEM simulation is the average of the instantaneous velocities of all particles in the system.

The dynamics of particle flow includes at least three aspects: velocity, structure, and force. Previous studies had to be largely limited to velocity field because of the difficulty in obtaining information for the other two. Consequently, there have been problems in probing the underlying mechanics and solving practical problems reliably. DEM is an effective technique that can overcome this problem. Its results

can be readily used to establish the spatial and statistical distributions of important variables related to flow and force structures such as porosity, coordination number, and various forces acting on particles. These variables can be treated as local average variables. As an example, **Figure 12** shows some typical results when the rotation speed is 42 rpm. Nonuniformity is obvious. For example, the bottom part, that is, the rotating solid bed, has a lower porosity while the top part, that is, the flow layer, a higher porosity (**Figure 12a**). The normal contact force is important as other contact forces (e.g., tangential contact force) are directly related to it. **Figure 12b** shows the force network in terms of this force, where each stick represents one connection between two particles with its thickness representing the magnitude of the force. As expected, large forces occur to particles at the bottom wall region to provide support to the top particles. However, relatively large forces can also be found at the lower joint region between the flow layer and the rotating solid bed where particles of high velocity pouring down the bed surface impact the particles of low velocity waiting to start the bed rotation movement. Particles at the top have minimum contact forces. Notably, the force network actually also represents the flow structure of particles.

Understanding the interactions among particles is important for such a dynamic system. For example, the size enlargement or reduction process depends on two important factors: the effectiveness of a collision and the frequency of collisions between particles. The effectiveness is mainly related to the so-called initial kinetic energy or impact energy, which is proportional to the square of the relative collision velocity between two particles v_{ij} ($=|v_i - v_j|$). **Figure 12c** shows the spatial distribution of relative collision velocity. It demonstrates that the most vigorous interaction between particles is at the lower joint point between the flow layer and the rotation solid bed. It then propagates into the bed mainly along the shear band between the flow layer and rotation solid bed. As shown in **Figure 12d**, the spatial distribution of collision frequency has a similar pattern. A region of high relative collision velocity corresponds to a region of high-collision frequency, or vice versa. Note that the concept of collision differs from that of contact between particles. The contact or coordination number is determined by "freezing" the bed. In contrast, particle collision is a dynamic process and a collision must be from two noncontacting particles. **Figure 12d** is obtained when two particles collide from a gap of at least 1% of particle diameter.

The resulting information can be used to understand the performance of industrial operations. Here, particle size enlargement by agglomeration is taken as an example. Increasing rotation speed can increase the impact energy per collision and the collision frequency, giving two opposite effects on agglomeration

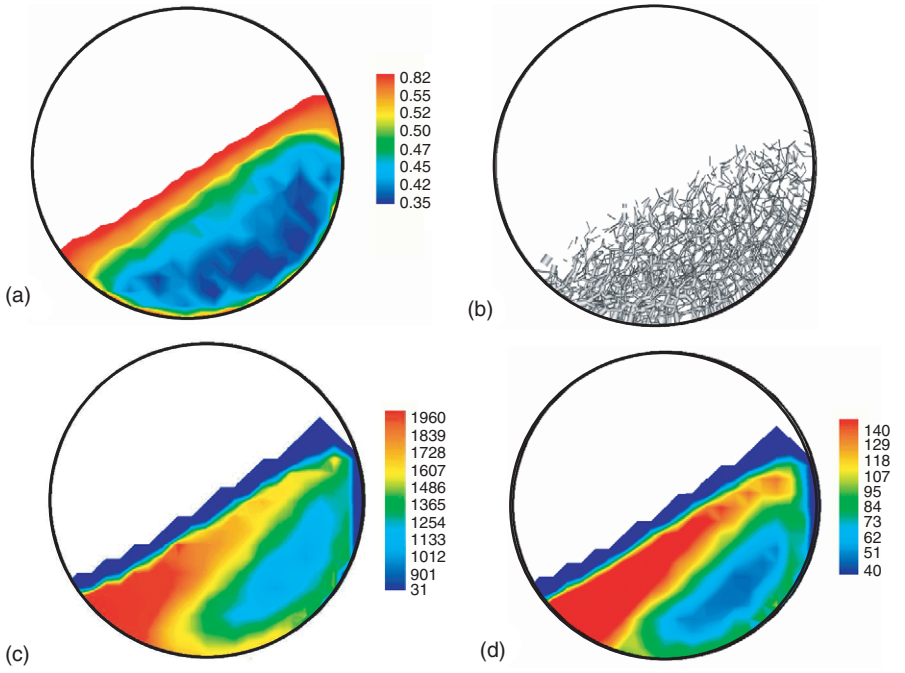

Figure 12 Spatial distribution of: (a) porosity; (b) (snapshot) force network, total force (mg); (c) collision velocity ($m\,s^{-1}$); and (d) collision frequency (s^{-1}) when the rotation speed is 42 rpm. in a drum. The increased kinetic energy will promote the breakage, crushing, and abrasion of agglomerates, decreasing the growth rate. On the other hand, the increased collision frequency means more contacts or coalescences among particles within a given time period, leading to an increased growth rate. Consequently, as schematically shown in **Figure 13**, depending on the rotation speed and operational conditions, various growth kinetics can result from the two opposite effects.

Gas Fluidization of Cohesive Powders

It has long been recognized in practice that powders show four distinct behaviors, that is, cohesive, aeratable, sand-like, and spoutable, when fluidized. Theoretically, these behaviors must be related to particle–particle and particle–fluid interactions. Through controlled numerical experiments, the role of various interparticle forces can be examined. The simulations are carried out in a rectangular packed bed. Gas is then introduced uniformly at the bottom of the bed at a specified velocity to start a coupled gas–solid flow. **Table 4** lists the physical parameters used in this work. Different from the above two examples, it is assumed that

$$\gamma_r = \sqrt{R_i^2 - (R_i - 0.5\delta_{ij})^2}/R_i$$

Figure 14 summarizes the gas and solid flow patterns in the sequence of increasing gas velocity, with particles colored in a layered pattern according to their initial positions in the bed to demonstrate the particle rearrangement and solid mixing. Three states can be seen in this figure: fixed bed, expanded bed, and fluidized bed. In the fixed bed, there is no observable structural change in the bed. Gas simply flows through interstices among stationary particles.

Table 4 Parameters used for the present simulation

Solid phase		*Gas phase*	
Particle shape	Spherical	Type of gas	Air
Number of particles, N	45 000	Viscosity, μ_f	$1.8 \times 10^{-5}\,\mathrm{kg\,m^{-1}\,s^{-1}}$
Particle diameter, d	$1.0 \times 10^{-4}\,\mathrm{m}$	Density, ρ_f	$1.205\,\mathrm{kg\,m^{-3}}$
Particle density, ρ_p	$1440\,\mathrm{kg\,m^{-3}}$	Bed width	$2.5 \times 10^{-2}\,\mathrm{m}$
Spring constant, κ	$50\,\mathrm{N\,m^{-1}}$	Bed height	$4.5 \times 10^{-2}\,\mathrm{m}$
Sliding friction coefficient, γ_s	0.3	Bed thickness	$1.0 \times 10^{-4}\,\mathrm{m}$
Contact damping coefficient, η	$1.65 \times 10^{-5}\,\mathrm{kg\,s^{-1}}$	Cell width	$1.0 \times 10^{-3}\,\mathrm{m}$
Hamaker constant, H	$2.10 \times 10^{-20}\,\mathrm{N\,m}$	Cell height	$1.0 \times 10^{-3}\,\mathrm{m}$

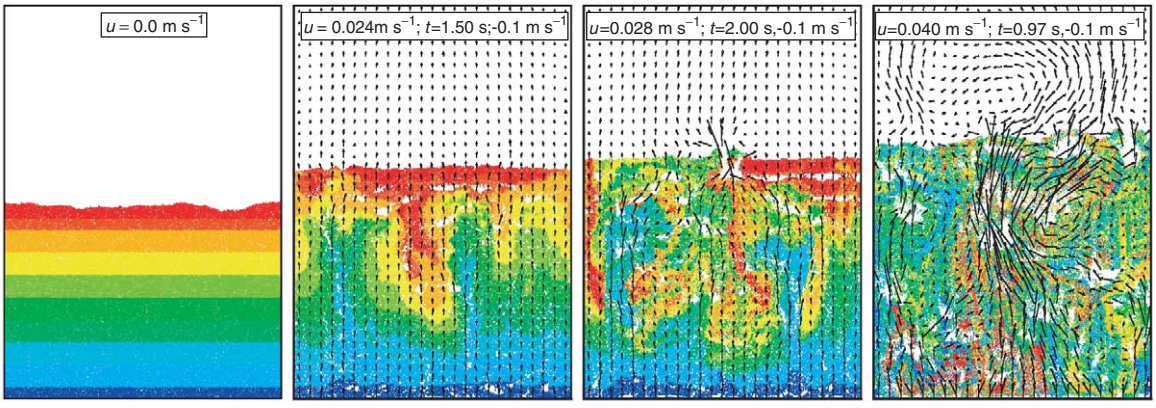

Figure 14 Particle configurations and gas flow fields for different superficial gas velocities, showing the existence of fixed ($u = 0.0\,\mathrm{m\,s^{-1}}$), expanded ($u = 0.024\,\mathrm{m\,s^{-1}}$), and fluidized beds ($u \geqslant 0.028\,\mathrm{m\,s^{-1}}$).

In the expanded bed, cavities or large pores of different size and orientation are formed. Generally speaking, the cavities show an elongated shape and are predominantly horizontal. The expanded bed terminates at the so-called minimum bubbling velocity, which is $\sim 0.028\,\mathrm{m\,s^{-1}}$ from the simulation. In the fluidized bed, sustainable bubbles appear in the bed. The predicted trends are qualitatively in good agreement with those observed.

The analysis of the forces acting on individual particles is important to understand the phenomena observed. This can be demonstrated in the analysis of the origin of bed expansion. **Figure 15** shows the variation of the overall averaged contact force, van der Waals force, and fluid drag force relative to particle gravity during the transition from a fixed bed to an expanded bed when $u = 0.024\,\mathrm{m\,s^{-1}}$. Three stages, that is, startup, transient, and stable, can be

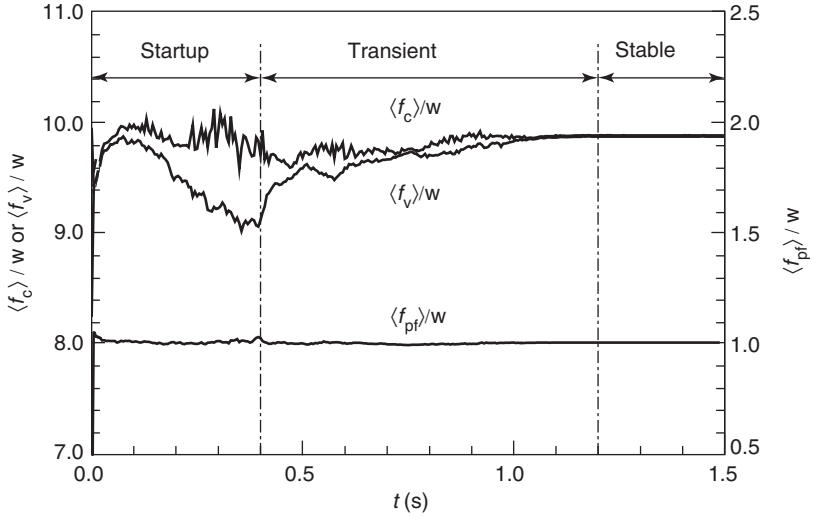

Figure 15 Variation of dimensionless ensemble-averaged contact force, van der Waals force, and fluid drag force with time when $u = 0.024\,\mathrm{m\,s^{-1}}$.

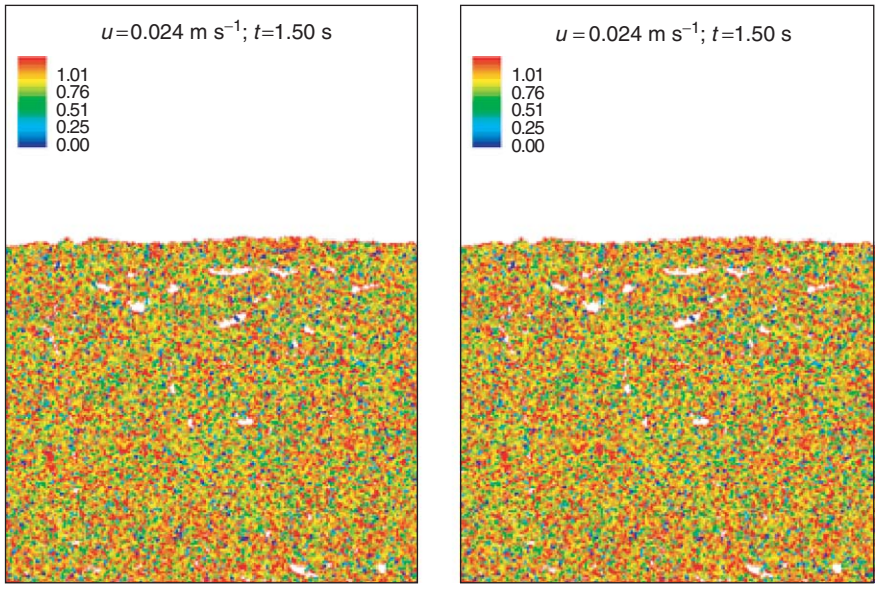

(a) (b)

Figure 16 Spatial distribution of the magnitudes of: (a) contact force; (b) van der Waals force acting on individual particles in an expanded bed when $u = 0.024\,\mathrm{m\,s^{-1}}$. The forces relative to the gravity of a particle are shown in a logarithm scale.

identified in this figure. In the startup stage, both the contact and van der Waals forces increase sharply within a short time. The two forces reach their maximum and then the contact force fluctuates at this level while the van der Waals force decreases. In the transient stage, the fluctuation in contact force is attenuated and the van der Waals force starts increasing. In the stable stage, the contact force and van der Waals force balance each other. The fluid drag force is virtually maintained at a value just balancing the weight of the bed during all three stages, a fact that highlights the rapid response from the solid phase, by changing its porosity, to the fluid drag force induced by gas flow. Clearly, the contact force must be balanced by the van der Waals force to form a stable expanded bed. Further analysis of the spatial distributions of the two forces indicates that the balance between them is observed not only at a bulk average scale but also at an individual particle scale, as shown in **Figure 16**. If the van der Waals force is unable to balance the contact force after initial disruption of the fixed bed, instability and then fluidization result.

Figure 17 shows the sequences of gas–solid flow patterns with increasing magnitude of the van der

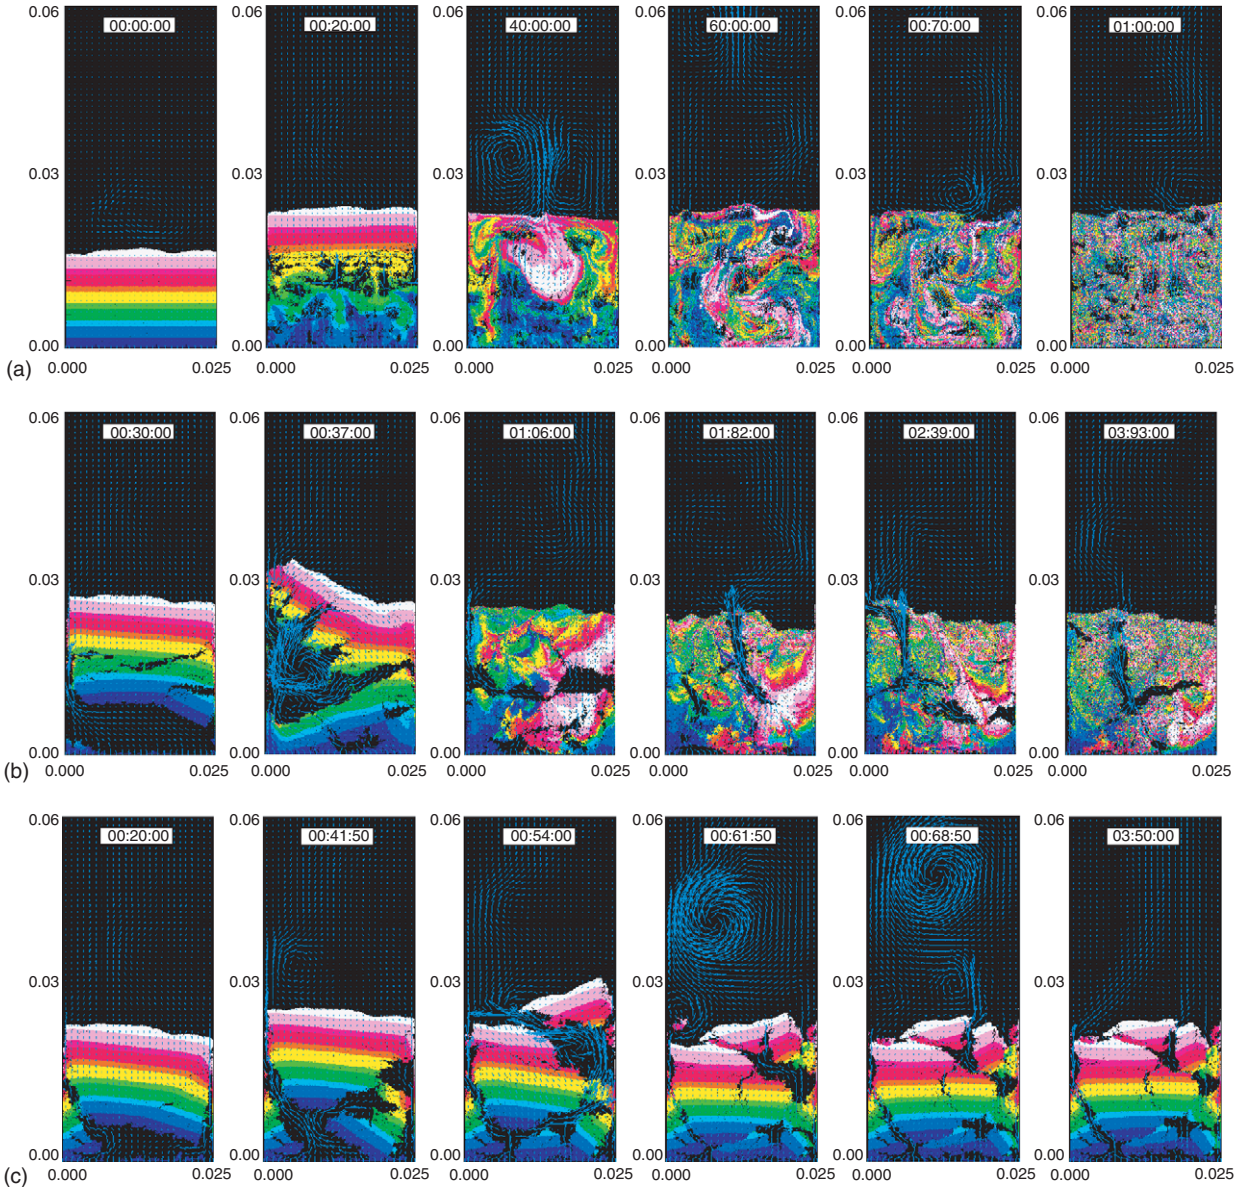

Figure 17 Gas–solid flow patterns when the ratio of superficial gas velocity to minimum fluidization velocity is 4.8 and the ratio of van der Waals force to particle weight is (a) 10, (b) 70, and (c) 300. The particles are colored according to their initial heights in the bed to visualize the solid mixing.

Waals force, where the change of the van der Waals force is achieved by adjusting the Hamaker constant. Three regimes of fluidization can be identified from this figure: good fluidization, quasi-fluidization, and defluidization. When the ratio of the maximum van der Waals force (determined when $z = z_0$) to particle gravity is less than ~ 30, good fluidization is obtained with continuous bubbles of relatively small sizes rising through the bed. When the force ratio is in the range of ~ 40–100, the fluidization quality deteriorates significantly and severe channeling occurs although the bed is still fluidizable at higher gas velocities. When the force ratio is greater than ~ 300, the fluidization is impossible by normal means. The simulation reasonably reproduces the experimentally observed phenomena, leading to the quantification of the roles of various particle–particle and particle–fluid interaction forces for this gas–solid flow system.

Concluding Remarks

The bulk behavior of granular materials depends on the collective interactions among individual particles. Particle scale modeling and analysis is therefore a key to elucidating the underlying physics and linking fundamental to applied research, particularly in developing from know-how to know-why knowledge. The examples discussed in this article clearly demonstrate that discrete particle simulation, although not perfect at this stage of development, does capture the main features and is an effective way to achieve this goal. With the rapid development of the computer technology, it offers a cost-effective way to meet the challenge of understanding the ever-changing particle science and technology resulting from the continuing development of new processes and products.

Protein Folding and Aggregation

R A Broglia and G Tiana, Università degli Studi di Milano, Milan, Italy

Introduction

The protein folding problem concerns understanding how a protein of specified amino acid sequence ends up in a unique configuration which, among other things, determines its biological function. In physical terms: how does the one-dimensional information provided by the sequence of 20 different types of amino acids encodes for a unique and stable three-dimensional equilibrium conformation.

This problem has a clear biological and medical importance. The sequencing of the human genome provides information on the sequence of amino acids forming each of the hundreds of thousands of proteins which build our cells. The acquisition of sequence data by DNA sequencing is relatively quick, and vast quantities of data have become available through international efforts. On the other hand, the acquisition of three-dimensional data is still slow and is limited to proteins that either crystallize in a suitable form or are sufficiently small and soluble so that their structure can be determined by NMR in solution. Algorithms are thus required to translate the linear information into spatial information.

But the protein folding problem is quite intriguing also from a physical point of view. A protein is a system which is in a nearly-zero-entropy equilibrium state (usually referred to as "native" state; cf., e.g., **Figure 1**) in a wide range of temperatures (typically from 0°C to 60°C). Such equilibrium state has essentially no symmetries. The interactions within the protein are noticeably complicated and heterogeneous. Nonetheless, the protein does not display, as a rule, any competing low-energy states or kinetic

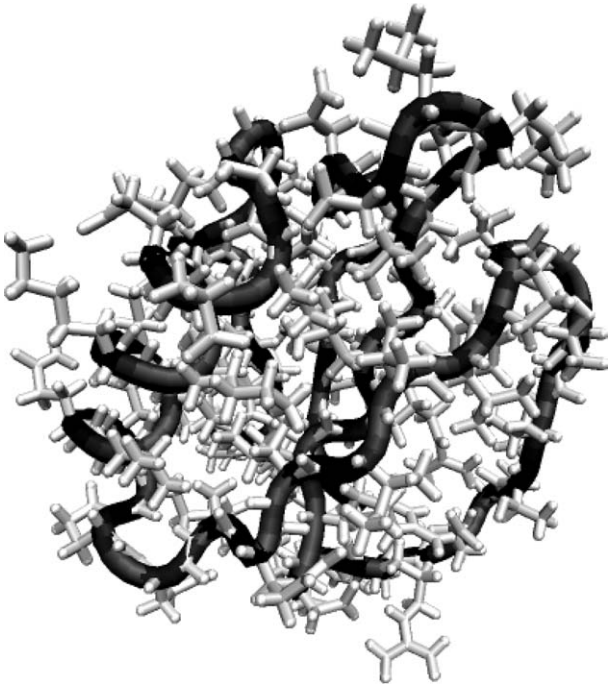

Figure 1 The native conformation of chymotrypsin inhibitor 2. The light gray parts highlight the arrangement of the atoms, which build a complicated network of interactions. In dark gray is highlighted the backbone of the protein.

traps (metastable states) typical of "frustrated" systems, but folds on a short call. The only feature typical of frustrated systems that survives in the case of proteins is the difficulty of predicting the ground state conformation from the knowledge of its elements (amino acids) and their interaction.

The goal of the physical approach to the protein folding problem is to understand the general principles of the folding mechanism of any protein. This implies that such a mechanism displays some amount of universality. There is indeed evidence that supports this scenario. In fact, aside from displaying a unique state of equilibrium (unique at the length scale of amino acids, i.e., 10^{-10} m) at biological temperatures, most proteins undergo a highly cooperative denaturation when the temperature is increased, similar to first-order phase transition (see **Figure 2**). The average folding time of proteins usually ranges from microseconds to seconds, and the distribution is usually a single- or multi-exponential, typical of a (or of few) Poissonian process. As a rule, proteins are very tolerant to point mutations. Mutations in a large number of sites have little or no effect on the folding properties of the protein, while each protein displays some key sites which, if mutated, lead to a large destabilization of the native state.

Typical cells contain around 20% proteins by weight. Consequently, evolution has provided proteins not only with the ability to fold on their own, but also to avoid aggregation, or to recognize other amino acid chains to perform their biological task. As in the case of oligomers, ordered assemblies of few single chains, which display the same features of unicity, stability, and fast folding of monomeric proteins.

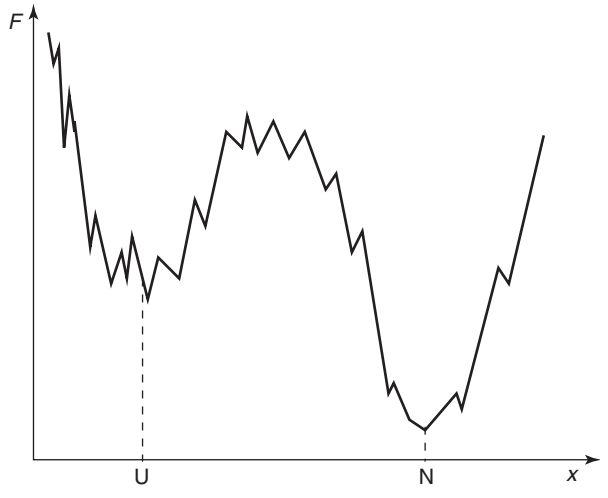

Figure 2 The typical free-energy landscape of a protein, plotted with respect to an arbitrary reaction coordinate *x*. Although the complexity of the interactions leaves some roughness in the landscape, evolution has shaped it in order to display two major wells separated by a barrier. The minimum associated with the native state (N) has essentially zero entropy and is stabilized by its attractive interactions, while the unfolded state (U) is mainly stabilized by its large entropy. As a consequence, when the temperature is increased, the free energy of the unfolded state decreases stabilizing it.

Models for Folding

The simplest (and oldest) interpretation of the folding process consists of summarizing all possible conformations in a few macroscopic states, in the same way as is done to describe chemical reactions. Usually, the thermodynamically relevant states are the unfolded states (U), which contain all the conformations where the protein chain is unstructured; the native state (N), which corresponds by definition to a single conformation; and possibly some intermediate states ($I_1, I_2, \ldots$). The folding reaction is thus viewed as a chain of events $U \rightarrow I_1 \rightarrow I_2 \rightarrow \cdots \rightarrow N$, and the dynamics of the associated probabilities is described by a mean of master equations. The distribution of folding times results in a sum of a number of exponential terms of the type $e^{-t/\tau}$ equal to the number of jumps between states that the system has to do to reach the native state. The typical time τ needed to perform each of such jumps is determined, according to Kramer's theory, by the height of the free-energy barrier ΔF, which separates the two states, and has the form $\tau \propto \exp[\Delta F/kT]$. In the case of small globular proteins, experiments often detect a single timescale for folding, indicating a two-state process between states U and N.

This simple model highlights the cooperativity of the folding process, determined by the presence of a major free-energy barrier, and provides good numerical estimates for the dependence of folding times on temperature and on mutations in protein sequence, but provides little insight into the molecular aspects of folding.

More recently, the focus has moved towards understanding the protein folding mechanism through a detailed description of the associated free energy landscape. A model which pursues this goal (the Go model) describes realistically the geometry of the protein but makes use of a simplified two-body potential function. Starting from the knowledge of the native conformation of the protein, two atoms are defined to be in (native) contact if their distance is smaller than a threshold. To such a conformation is ascribed a (negative) energy, and zero otherwise. This model, used in connection with computer simulations, is aimed at approximating the free energy with a careful entropic part and a simplified energetic part. Studying the folding of a number of small globular proteins with the help of the Go model, it is observed that the

conformations associated with the top of the free-energy barrier separating the unfolded from the native conformation have well-defined structural properties, characterized by some important native contacts.

A different approach focuses attention on the energetic content of the free-energy function and, in particular, on the heterogeneity of the interaction arising from the presence of 20 kinds of different amino acids. It is known that physical systems displaying such a heterogeneity are associated, as a rule, with a rough energy landscape with many competing low-energy states. This picture is incompatible with that of proteins, which must display a unique ground state, well separated from the others, and as few metastable states as possible. The purpose of these models is to understand what makes a protein, characterized by a well-defined amino acid sequence, different from a generic heterogeneous system, whose paradigm is a random sequence of amino acids.

The starting point of energy-based models is the study of the thermodynamics of a random heteropolymer, which is an idealization of the peptide chain only characterized by stochastically independent contact energies. Being the sum of independent stochastic contributions, the total energy of the heteropolymer follows a Gaussian distribution, according to the Central Limit Theorem. Identifying this distribution with the distribution of conformational energies of the heteropolymer, the number of conformational states as a function of energy is

$$n(E) \propto \exp\left[-N_c\left(\frac{(E - N_c\varepsilon_0)^2}{2N_c^2\sigma_\varepsilon^2} - \ln\gamma\right)\right] \qquad [1]$$

where N_c is the number of contacts in the chain (assumed to be constant), ε_0 and σ_ε are the mean and the standard deviation over the 20 types of amino acids of the contact energies, and γ is the number of conformations that the chain can build per contact. Similar to the random energy model used in the field of spin glasses, the random heteropolymer model displays an entropy given by the relation $S(E) = N_c \ln\gamma - (E - N_c\varepsilon_0)^2/(2N_c\sigma^2)$ at energies above the threshold energy $E_c \equiv N_c\varepsilon_0 - N_c\sigma(2\ln\gamma)^{1/2}$. On the other hand, below E_c the probability of finding any state of the heteropolymer is negligible, decreasing exponentially with the number of contacts N_c. Using the replica solution originally set up for spin glasses, it is possible to show that low-energy states are clustered in such a way that different clusters are separated by an energy barrier. This is a picture which can be hardly conciliated with that of proteins displaying a unique equilibrium state.

This simple model emphasizes a property of peptidic chains, that is the "frustration" due to the complicated interaction between 20 amino acids with different physical properties. "Frustration" implies the inability the system has to optimize all interactions at the same time, even in the lowest-energy state. A sequence of amino acids chosen at random is likely to be highly frustrated, and consequently not to display protein-like features. Within such a scenario, it is assumed that evolution selects protein sequences by minimizing the associated frustration. Setting this scenario within the framework of statistical mechanics, one can assume that protein-like sequences are those which display in some conformation an energy much lower than the sequence-independent threshold E_c, this conformation being the native state. In fact, if the native state is well below E_c, it does not have to compete with the other conformations whose energies are controlled by eqn [1]. Consequently, the native state will be unique and stable, more so, the larger the energy gap between the native state and E_c.

From the study of the models described above it emerges that the key ingredients of proteins to fold are their polymeric character and the heterogeneity of interactions. A powerful tool which allows to retain these two ingredients, although relaxing that of providing a detailed description of the protein geometry, is the lattice model. This model is based on two approximations: (1) the internal atomic structure of the amino acids is neglected and each of them is described as pointlike; (2) the amino acids move on the vertices of a cubic lattice of unitary side length. Accordingly, the conformational degrees of freedom are discrete. This is very convenient from a computational point of view and makes conformational entropy easy to handle, provided a contact potential is given. The simplest choice of such a potential has the form

$$U(\{r_i\},\{\sigma(i)\}) = \sum_{ij} \varepsilon_{\sigma(i)\sigma(j)}\Delta(r_i - r_j) \qquad [2]$$

where r_i and $\sigma(i)$ are the position and type of the ith amino acid, $\Delta(r_i - r_j)$ being a contact function assuming the value 1 if the ith and the jth amino acids are in contact and zero otherwise, while $\varepsilon_{\sigma\tau}$ is the element of a 20×20 interaction matrix which measures the interaction energy between amino acids of type σ and τ. A widely used interaction matrix has been determined by Miyazawa and Jernigan from the statistical analysis of the contacts of a large database of proteins, assuming that the frequency with which a given contact appears in the database measures the strength of the contact energy between the corresponding amino acids.

Within the framework of the lattice model, it is possible to obtain a data set of sequences which fold

into a selected native conformation starting from a random sequence displaying the observed composition (experimental ratio of the different types of amino acids), by swapping amino acids in such a way as to minimize the energy of the protein in the native conformation. This is a consequence of the fact that E_c does not depend on the details of the sequence, but only on its length. In other words, swapping amino acids does not change E_c, while the native energy can be decreased until it displays a large gap with respect to E_c.

A key result which emerges from such studies is that the stabilization energy of the protein is not distributed evenly throughout the native conformation, but is concentrated in a few, "hot" sites. This fact has remarkable consequences on the properties of the protein. First, it sheds light on the experimental fact that a protein is essentially insensitive to mutations in most of its sites. In fact, if a site different from the few "hot" sites is mutated, the change in native energy is not enough to fill the gap to the threshold energy E_c (which is not affected by the mutation), and consequently the protein retains its protein-like features. On the other hand, if a "hot" site is mutated, the energy of the resulting sequence in the native conformation can become larger than E_c. Consequently, the native state gets surrounded by a sea of unfolded conformation, losing its uniqueness.

Moreover, lattice model calculations indicate that "hot" sites build, as a rule, local elementary structures (LESs), that is fragments of the chain characterized by strong interactions between the "hot" sites which are close along the chain. Such LESs, which can be viewed as hidden, incipient secondary structures (like beta-sheets and alpha-helices) are very important for the folding dynamics because they bias the chain to the native state, according to a hierarchical scheme. Starting from a random conformation, LESs are formed very fast, because their stabilizing native contacts are close along the chain and, consequently, they do not need to explore a wide conformational space. Due to their large stabilization energy, LESs remain remarkably stable for the whole folding process. The rate-limiting step is then that of the assembly of LESs among themselves to build out their relative native contacts (the so-called "folding nucleus"). Being (quasi-) rigid entities, LESs make the chain effectively shorter. Furthermore, LESs interact among themselves with energies which are much larger than those with which single amino acids do. Consequently, it is unlikely that LESs form metastable structures, different from the native contacts designed by evolution. Once LESs have reached their mutual native positions, the conformational space of the protein is so restricted that the remaining amino acids fold immediately to their native position. Summing up, LESs provide an efficient way to squeeze out entropy from the initial random conformation in its way to the native state, avoiding metastable traps.

The uneven distribution of the stabilization energy and some hints about the events which take place on the folding trajectories of small real proteins can be studied by means of all-atom molecular dynamics simulations, combined with semi-empirical force fields. Results of such simulations, performed by considering specifically water, reveal the existence and allows the identification of "hot" sites. However, the simulation of the complete folding trajectory and the repetition of such simulations to obtain a statistically significant sample of the event is still computationally out of reach.

Aggregation

The term "aggregation" can mean a number of different processes, when applied to proteins. The simplest case is that of dimerization (or oligomerization), where two (or few) amino acid polypeptide chains assemble together into a conformation which displays all properties typical of the native state of monomeric proteins (e.g., uniqueness, stability, etc.). There are essentially three paradigms for this process. The best-understood is that of "exchange-domain" dimers, wherein two identical proteins have been induced by evolution to exchange part of their peptidic chain, giving rise to an interwined, symmetric conformation. The "lock-and-key" scenario is followed by those chains which first fold into monomeric native states and then assemble together, resulting at equilibrium in three populated states: denaturated, intermediate (single chain folded), and oligomeric (dock of single folded chains). On the other hand, "induced fit" oligomers first bind together in an unstructured conformation and subsequently find the native structure. While dimers (or oligomers) following the "exchange-domain" and the lock-and-key mechanism can still be described in terms of a few key sites (hot sites) controlling the whole process as in the case of single domain proteins, the "induced-fit" mechanism seems to be more subtle, implying a delicate balance between the contact energies at the interface and in the volume.

A mechanism similar to the lock-and-key mechanism can be used at larger scales, giving rise to micrometric, ordered structures. It is the case of tubulin, which builds microtubules in the cell, and actin, which builds muscle fibers. Aggregation can involve, under particular conditions, also proteins which usually fold to monomeric native conformations.

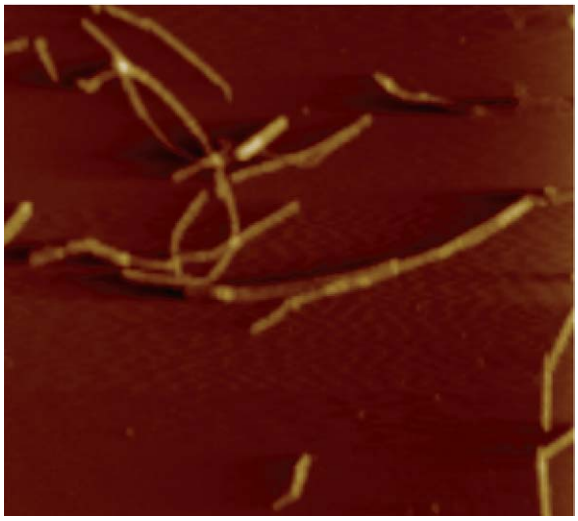

Figure 3 Fibrils made of insulin detected by atomic force microscopy. The length scale of the figure is μm.

A cell contains 17–26% of proteins by weight, and in the cytoplasm there are $\sim 10^6$ peptide chains, separated by an average distance of 3 nm. It is thus likely that evolution has selected sequences not only to fold on their own, but also to avoid the interference of other proteins. Nonetheless, mutations, changes in the chemical environment, or other factors can make proteins aggregate into (usually) biologically inactive, eventually harmful, clumps.

Aggregates can be disordered clumps, kept together by unspecific interactions, or an ordered, elongated structure usually called a fibril (see **Figure 3**). There is strong evidence that a number of diseases are related to the deposit of fibrils in particular areas of the human body (e.g., fibrils of beta-amyloid protein in the brain, in the case of Alzheimer's disease). Solid state NMR experiments have shown that, as a rule, fibrils contain parallel arrangements of specific U-like conformations of parts of the protein.

Aggregation is usually triggered by a nucleation event, and consequently the whole process can be separated into formation of the nucleus, that is, the minimum stable aggregate, and growth. Nucleation is a mechanism which reflects the entire thermodynamics of the solution, affected by the thermodynamic fluctuations of the solvent. For example, it has been shown that nucleation rate of sickle cell hemoglobin is strongly dependent on fluctuations associated with liquid–liquid demixing phase transition. Nucleation can be slowed down by stabilization of nonaggregating metastable states: light-scattering experiments and models based on molecular dynamics simulations indicate that micelle-like structures composed of a few beta-amyloid monomers compete with nuclei and discourage fibril formation. Also, the growth process often involves a nontrivial process which goes beyond mere diffusion. For example, the rate of elongation of beta-amyloid fibrils depends on temperature following an Arrhenius law, indicating that the binding of monomers to the end part of a fibril requires conformational changes.

Protein Folding, Engineering of

S E Jackson, University of Cambridge, Cambridge, UK

Introduction

Proteins are the most diverse of biological macromolecules, both in the structures they adopt and the functions they perform. Proteins are essential in all biological processes, acting as catalysts in the form of enzymes, in structural roles such as collagen and keratin in skin and hair, in the transport of small molecules such as oxygen by the protein hemoglobin, in the immune response in the form of antibodies, and in the regulation of all cellular processes acting

as receptors and mediators of cellular signaling pathways.

Proteins are linear-chain polymers of amino acids, of which there are twenty naturally occurring building blocks. The condensation of the monomeric amino acid units into a polymer produces what is known as the polypeptide chain. Each protein has a specific sequence of amino acids which is encoded by the DNA of the gene for that protein. Proteins vary in length, the shortest are ~40–50 amino acids or residues long, whilst the longest, such as the giant muscle protein titin, can be over 10 000 residues in length. Many proteins, however, are much smaller than this, typically between 200 and 300 amino acid units. This article focuses on how, relatively small proteins, that is to say those that are 100 residues or less in length, fold.

Proteins are produced in cells on ribosomes, the cellular machines for the synthesis of proteins. When it is first made, the polypeptide chain is in a highly flexible and conformationally dynamic state. In this state, the protein is referred to as being "unfolded" or "denatured" and it is not active. The polypeptide chain has to collapse into a specific, compact, and tightly packed folded state, known as the native state, before it can perform its physiological function.

The protein-folding field emerged in the early 1960s with the seminal work of Christian Anfinsen who showed that all the information necessary to specify the final three-dimensional structure of a protein was encoded in its primary amino acid sequence. How, after synthesis, an unfolded polypeptide chain collapses into a specific, compact, and tightly packed folded state, is the protein-folding problem. Up until the late 1980s, most of the work in the field focused on proteins with disulfide bonds or *cis*-prolines, as in these systems stable intermediates were observed which could be characterized experimentally. In these cases, folding is limited not by folding *per se*, but by the formation or rearrangement of disulfide bonds or isomerization of the prolyl peptide bond. Whilst these processes are interesting in themselves, they provide little information on the conformational changes occurring in the protein that result in the formation of a stable native state. In the late 1980s, protein engineering techniques were first employed along with rapid-reaction kinetics to characterize the folding pathways of a number of small proteins. In contrast to earlier studies, in these studies, the rate-limiting steps probed corresponded to folding and not some slower rearrangement or isomerization event. This approach to studying protein folding has now been widely adopted by the experimental protein-folding community and has provided data critical for the development of new protein-folding mechanisms and in benchmarking numerous computational studies. Here, the main features of the protein engineering methods are outlined and the work in this field over the last ten years, which has led to the determination of the energy landscapes for folding at atomic resolution for several small proteins, is summarized.

Protein Engineering

With the advent of recombinant DNA technology in the 1970s and 1980s came the ability to rationally and specifically engineer proteins. Over the past twenty years, these techniques have been considerably further developed and extended to include the use of the polymerase chain reaction (PCR), which now plays a major role in the manipulation of DNA. These methods enable many proteins from a variety of sources (e.g., human, yeast, bacterial, and archaebacterial) to be produced in large quantities in bacteria, generally *Escherichia coli*. This greatly facilitates the process of obtaining sufficient quantities of pure proteins for biophysical analysis. Further, these technologies allow one to engineer proteins with ease by modifying the genes (DNA) that encode for a specific protein. A number of different methods of engineering proteins can be adopted: site-directed mutagenesis can be used to replace one amino acid in a protein with any other at a specific position in the protein thereby producing a mutant protein with a single mutation (the protein with the naturally occurring sequence is known as the "wild type"). Alternatively, multiple mutations can be made either rationally or randomly; the latter is a powerful technique when combined with a selection screen for proteins with a particular property. Proteins can also be changed more radically in a variety of ways, for example, by changing the order in which structural units or motifs are connected, resulting in a mutant protein which has the same overall structure as the wild-type protein but with different connectivities between structural subunits. These mutant proteins are known as circular permutants. These methodologies are now routine and used widely by the protein-folding community. A review of the entire field is beyond the scope of this article. Here, the focus is primarily on the results that have come from single-site-directed mutagenic studies, which have had the biggest impact on the field of protein folding. In particular, the focus is on the methods of analyzing protein-folding pathways using protein-engineering approaches and the models that have resulted from such work.

Characterizing Folding Pathways: ϕ-Value Analysis

In order to understand how proteins fold, the structure and energetics of all states on the folding pathway

need to be characterized. This includes the folded or native state, the unfolded or denatured state, as well as any intermediate states. Whereas, in the early years of protein folding it was thought that stable intermediate states were a prerequisite enabling the protein to fold on physiological timescales by reducing the amount of conformational space that needed to be sampled, in the early 1990s it was shown that a small protein, CI2, could fold very rapidly indeed without populating any such partially structured states. It is now well established that many small proteins fold in this so-called "two-state" fashion. In these cases, and others, one of the most important states to characterize on the folding pathway is the rate-limiting transition state which represents the energetic barrier to folding. Whilst the unfolded and folded states can be characterized directly using X-ray crystallography and multidimensional NMR techniques, the structure and energetics of the transition state can only be inferred from kinetic measurements. Fersht and co-workers have developed a method for analyzing folding transition states which is known as ϕ-value analysis and which uses protein-engineering approaches. The method is outlined below.

A point mutation is made to a protein and the kinetics of folding and unfolding are measured for both the wild-type protein and the mutant. In general, "nondisruptive deletions" are engineered such that the mutation removes a single interaction in the folded state of the protein and does not introduce any new interactions. In these cases, interpretation of ϕ-values is straightforward. The mutations usually destabilize the native state of the protein with respect to the denatured state (**Figure 1**). $\Delta\Delta G_{D-N}$ is the difference in the free energy of unfolding (the energy difference between D, the denatured state, and N, the native state) between the wild type and the mutant, and a positive sign indicates that the mutation is destabilizing. It is straightforward to measure this difference under equilibrium conditions using a suitable probe of the folded state, frequently intrinsic fluorescence of aromatic amino acids or far-UV circular dichroism. In order to quantitate the effect of a mutation on the transition state for folding, then $\Delta\Delta G_{\ddagger-D}$, the energy difference between the transition state ($\ddagger$) and the denatured state, between the wild type and the mutant, also needs to be measured (**Figure 1**). For simple systems, such as CI2 which fold in a two-state manner, this value can be calculated from the unfolding data (by measuring the rate constant of unfolding, k_U, which is determined by the energy barrier for unfolding), or from the folding data using the rate constant for folding, k_F. A ϕ-value is defined as the ratio of $\Delta\Delta G_{\ddagger-D}$ to $\Delta\Delta G_{D-N}$, which is a measure of the extent to which favorable interactions that the side chain of the mutated amino acid makes in the native state are formed in the transition state. Formal definitions of the different parameters are given below. Unfolding data can be used to calculate ϕ-values whether folding is two-state or not, as for small proteins no intermediate states are stable under unfolding conditions

$$\Delta\Delta G_{\ddagger-N} = -RT \ln(k_U/k'_U) \quad [1]$$

where k_U and k'_U are the rate constants of unfolding for the wild type and mutant, respectively. In this case, a ϕ-value is defined as follows:

$$\Phi = 1 - \Delta\Delta G_{\ddagger-N}/\Delta\Delta G_{N-D} \quad [2]$$

For those small proteins that fold with two-state kinetics, ϕ-values can also be calculated from folding rate constants

$$\Delta\Delta G_{\ddagger-D} = -RT \ln(k_F/k'_F) \quad [3]$$

where k_F and k'_F are the rate constants of folding for the wild type and mutant, respectively.

In this case, a ϕ-value is defined as follows:

$$\Phi = \Delta\Delta G_{\ddagger-D}/\Delta\Delta G_{N-D} \quad [4]$$

For two-state systems, ϕ-values calculated from the unfolding and folding data are the same.

Interpretation of ϕ-Values

Briefly, $\phi = 1$ when $\Delta\Delta G_{\ddagger-D} = \Delta\Delta G_{N-D}$, that is, the lost interaction energy upon mutation is the same in the native and transition states (**Figure 1**, case 1). In this case, the mutation affects only the rate of folding and not the rate of unfolding. ϕ-Values of 1 occur when the transition state is highly structured in the region of the mutation. Conversely, $\phi = 0$ when $\Delta\Delta G_{\ddagger-D} = 0$, that is, when the mutation has no effect upon the energy of the transition state relative to the unfolded state (**Figure 1**, case 2). In this case, the mutation affects the rate of unfolding but has no effect on the rate of folding. ϕ-Values of 0 occur when the transition state is completely unstructured in the region of the mutation. Besides the values of 0 and 1, fractional ϕ-values are obtained when $0 < \Delta\Delta G_{\ddagger-D} < \Delta\Delta G_{N-D}$ (**Figure 1**, case 3). In this case, the mutation has an effect on both unfolding and folding rate constants. In general, fractional ϕ-Values are more difficult to interpret; however, in some cases, there is an approximately linear relationship between the ϕ-Value and the extent of formation of nonpolar contacts in the transition state relative to the native state. In these cases, ϕ-values are a good measure of the degree to which interactions of the mutated side

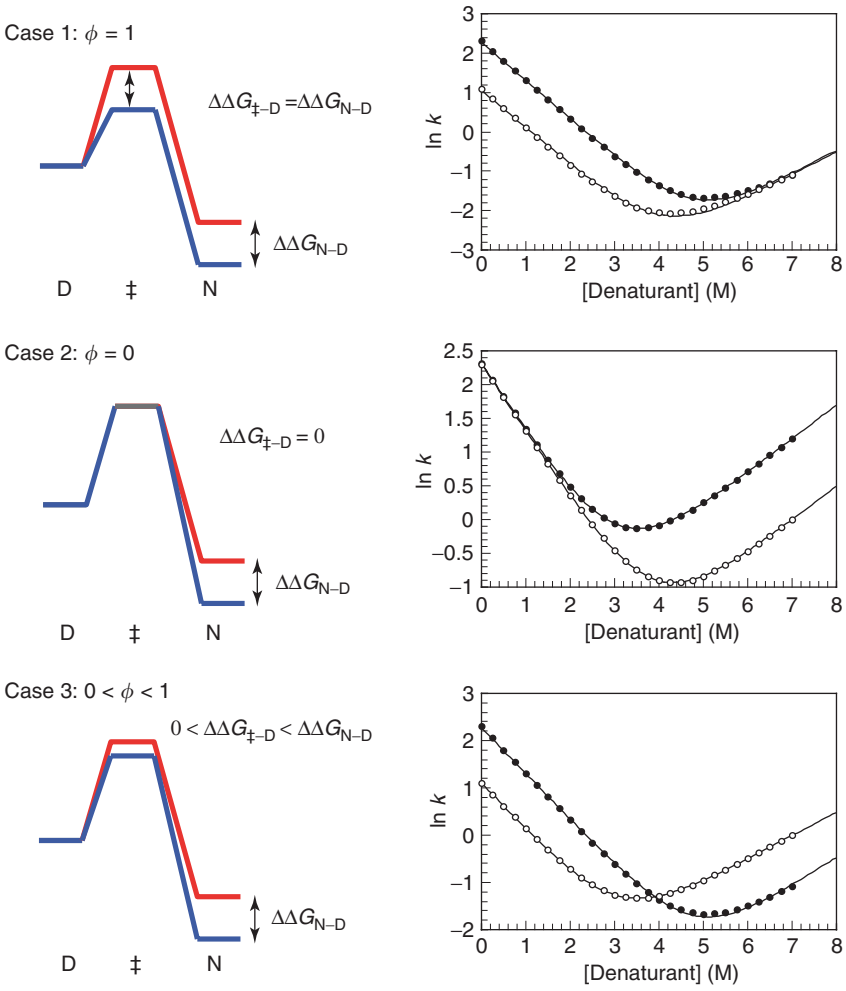

Figure 1 Free-energy diagrams showing the effect of a destabilizing mutation on the energy of the denatured (D), transition (‡), and native (N) state of a protein which folds with simple two-state kinetics. Case 1, when $\Delta\Delta G_{‡-D} = \Delta\Delta G_{N-D}$ then $\phi = 1$. In this case, the mutation affects the folding rate but not the unfolding rate – see the "chevron" plot of the rate constants for folding/unfolding as a function of denaturant concentration (right-hand side of figure). At low concentrations of the denaturant, the folding rate constant is measured and this decreases exponentially with increasing denaturant concentration, whilst at high concentrations of the denaturant, the unfolding rate constant is measured and this increases exponentially with increasing denaturant concentration. Case 2, $\Delta\Delta G_{‡-D} = 0$ then $\phi = 0$. In this case, the mutation affects the unfolding rate but not the folding rate. Case 3, $0 < \Delta\Delta G_{‡-D} < \Delta\Delta G_{N-D}$ then $0 < \phi < 1$. In this case, the mutation affects both unfolding and folding rate constants. chain are made in the transition state. An extensive description of the interpretation of ϕ-values and the assumptions and limitations of this method are not within the scope of this article and are discussed in detail elsewhere; see "Further reading."

In order to illustrate this method, the results of protein engineering and ϕ-value analysis on the small protein FKBP12 from the author's laboratory are discussed briefly below. FKBP12 is a small protein, the structure of which is shown in **Figure 2a**. Extensive protein engineering was performed on FKBP12 and the effect of mutations on the stability and kinetics of folding and unfolding of the protein was measured. Data were analyzed by the method described above and ϕ-values for many residues in the protein obtained. The results of these studies are summarized in **Figures 2b** and **2c**, which show the range of ϕ-values obtained and regions of the protein that have high values (are partially structured in the transition state) and those that have very low values (regions which are largely unstructured in the transition state). As expected, the ϕ-values vary between 0 and 1. In the case of FKBP12, no values of 1 were found, the highest value being 0.6. This is quite typical for small proteins. From **Figure 2**, it can be seen that residues with high values (> 0.5) cluster together and form a folding nucleus (see discussion on nucleation–condensation mechanism). In FKBP12, the

nucleus is formed by residues at the C-terminus of the α-helix and residues in the middle of the central β-strands which form part of the hydrophobic core. There is a gradation of ϕ-values moving away from this nucleus, and edge strands and end of the β-strands and loop regions frequently have values close to zero indicating that these regions are highly flexible and unstructured in the transition state. FKBP12 behaves in many ways like other small proteins including CI2 (see next section).

The resolution with which folding pathways can be determined using this approach has meant that it is now the most popular way of characterizing folding transition states experimentally and ϕ-values have now been measured for a number of proteins. Results from these studies from numerous folding groups fall broadly into one of three categories illustrated by the three examples given below. Together, these studies give a detailed picture of the ways in which proteins fold.

CI2 Protein-Engineering Results: The Nucleation–Condensation Mechanism

As discussed above, the small protein CI2 folds in a simple two-state manner without populating a stable intermediate state. Thus, mechanisms which require a stable intermediate to be present cannot be applied to this protein. Protein-engineering experiments have mapped in detail the structure of, and interactions present in, the transition state. As a result of these studies, the nucleation–condensation mechanism of protein folding was proposed by Fersht and co-workers in the mid-1990s. In this mechanism, the rate-limiting step of folding is the formation of a folding nucleus which can either involve a large part of the protein structure (in this case, the protein is said to have a diffuse nucleus) or comprise just a few elements of secondary structure (in this case, the nucleus is said to be localized). After the nucleus has formed, folding involves the rapid condensation of the rest of the native structure around the nucleus in an energetically downhill process. For CI2, the nucleus is quite diffuse, involving, to some degree, most regions of the protein. However, several residues in the α-helix and in the β-sheet are the most critical in stabilizing the transition state structure. In contrast to earlier proposed mechanisms, in the nucleation–condensation model, secondary and tertiary structures are formed concomitantly, the secondary structure being inherently unstable without the presence of some stabilizing tertiary interactions. NMR spectroscopy and molecular dynamic simulations have both shown that the denatured state of CI2 has little fixed structure and approximates well to a random coil. The complete folding pathway of CI2 is shown in **Figure 3a**.

Barnase: Hierarchical Folding Mechanisms

Barnase was the first protein to be subject to an extensive protein engineering and ϕ-value analysis and its folding pathway illustrates some key differences with CI2. Barnase is a larger protein, 110 residues in length, which, in contrast to CI2, folds with three-state kinetics demonstrating the presence of a kinetically significant, populated, intermediate state on the folding pathway. A close analysis of the native structure of barnase shows that it has two structural

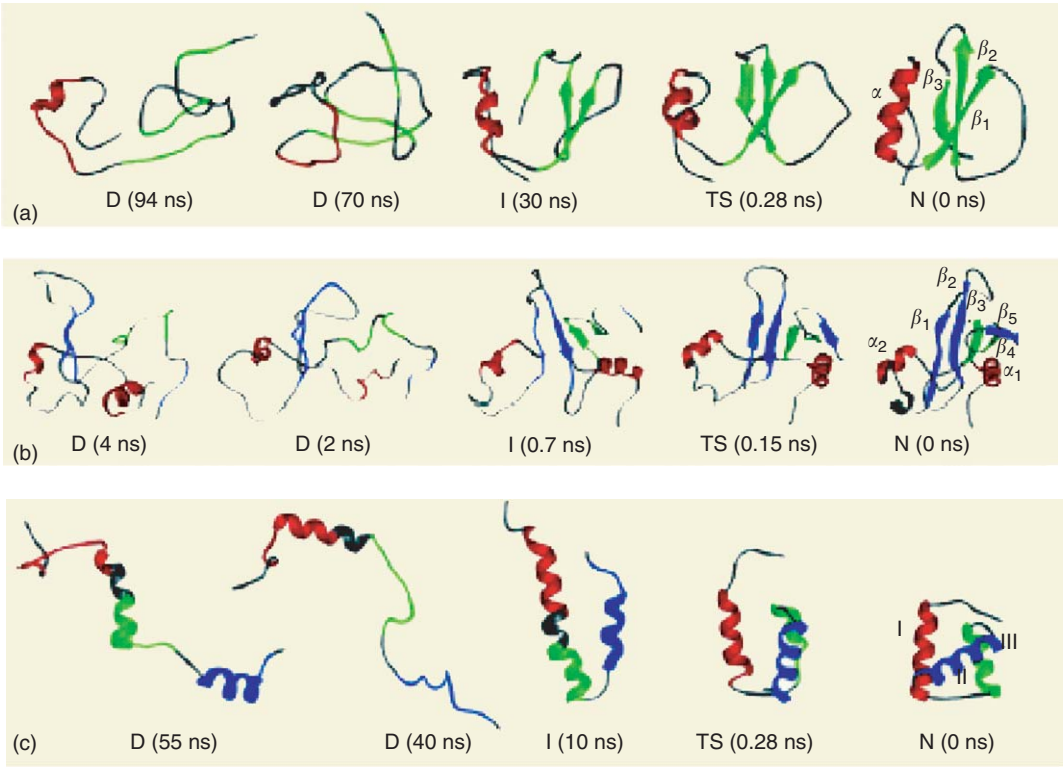

Figure 3 Schematic representations of the folding pathways of (a) CI2, (b) barnase, and (c) engrailed homeodomain. Results from protein-engineering studies and molecular dynamic simulations. (Reprinted with permission from Daggett V and Fersht AR (2003) The present view of the mechanism of protein folding. *Nature Reviews. Molecular Cell Biology* 4: 497–502; © Macmillan Magazines Ltd.)

subdomains. In contrast with CI2, barnase has a significant residual structure in the denatured state as probed by molecular dynamics simulations and NMR spectroscopy, that is, the denatured state is not a random coil and elements of both secondary and tertiary structure are transiently formed in this state. In barnase, the residual structure establishes a loose native-like topology in the denatured state which facilitates folding. From this state, the main hydrophobic core of the protein folds via a nucleation–condensation mechanism similar to CI2. The folding is nucleated by a residual fluctuating native-like helical structure in $\alpha 1$ with a $\beta 3$–$\beta 4$ hairpin. The $\alpha 1$, $\beta 3$, and $\beta 4$ elements of secondary structure form a scaffold or nucleus on which the remaining β-strands pack. This creates the metastable intermediate state observed in the kinetics. Further collapse and consolidation then occurs which brings residues involved in stabilizing the rate-limiting transition state together. During the formation of this nucleus, there is a refinement of packing interactions and consolidation of the interface between the two structural subdomains. Thus, barnase shows more hierarchical folding than CI2, with a gradual build-up of structure along the folding pathway. A schematic representation of the folding pathway of barnase is shown in **Figure 3b**.

Ultrafast Folders: The Engrailed Homeodomain

CI2 and barnase fold on the order of milliseconds to seconds at room temperature. Recently, proteins which fold with much faster rates have been identified and their folding pathways characterized using the techniques described above. The engrailed homeodomain from *Drosophila melanogaster* (En-HD) is a 61-residue, highly helical protein which folds on the microsecond timescale under physiological conditions. When unfolded in high concentrations of chemical denaturant or at very high temperatures, the unfolded state contains rather little residual secondary structure which is highly dynamic and fluctuating. Under more physiological conditions, however, at lower temperatures in the absence of denaturants, the denatured state has considerable residual structure with a high helical content and some long-range tertiary contacts. Combining experimental protein-engineering results with molecular dynamic simulations has provided a detailed picture of how this protein folds, **Figure 3c**. From the physiological denatured state (D), the transition state (‡) is formed by a reorientation of the helices and docking of them to form a partially packed hydrophobic core. In

the final steps, the helices fully dock against each other and water is expelled from the hydrophobic core. En-HD folds by first forming relatively stable elements of secondary structure (in this case α-helices) which then diffuse and collide to form the tertiary structure and the native state. This is much like the framework model proposed by Ptitsyn and coworkers in the early days of protein folding.

A Unifying Mechanism?

Outlined above are the results of detailed experimental and computational studies on the folding pathways of three proteins. These three proteins are excellent examples illustrating the different mechanisms by which proteins can fold. It is useful to include a short history of the field of protein folding here, to show how recent work has established new folding mechanisms and shed light on mechanisms which were proposed in the early days of the field when high-resolution structural information on folding pathways was not yet available. The Holy Grail of folding is, of course, to unite these different mechanisms into a simple single mechanism applicable to all proteins. This unified mechanism is presented later after a brief discussion of individual mechanisms.

Wetlaufer was one of the first to propose a nucleation type of mechanism, that of nucleation growth, back in 1973. Here, an initial nucleus of local secondary structure forms and then the tertiary structure propagates rapidly from this. As this mechanism does not require the formation of stable intermediate states – and at that time all experimental studies were focused on proteins which folded slowly and had discrete intermediates (later some of these intermediates were shown to be misfolded species off the main folding pathway) – the nucleation-growth mechanism was not widely adopted. At that time, experimental studies were limited by suitable experimental techniques and rapid-reaction kinetics had not yet been applied to complex biological problems such as protein folding. In addition, protein engineering was still in its infancy. Other mechanisms were proposed and dominated in the 1970s and 1980s: the framework model in which secondary structure folds first, then diffuses and collides to form the three-dimensional native structure; the hydrophobic collapse model, in which the hydrophobic effect drives the formation of a compact state in which many hydrophobic side chains are excluded from the solvent water, rearrangement then takes place to form the fully folded structure. This model was extended and it was proposed that a secondary structure was formed during the collapse stage to form a "molten-globule"-like intermediate state. These molten-globule states have a native-like secondary structure but a liquid-like core in which side chains retain a high degree of mobility and in which fixed tertiary interactions are not yet formed. In the early 1990s, and as a direct result of protein-engineering studies and ϕ-value analysis by Fersht and coworkers on CI2, a new mechanism – the nucleation–condensation model – was proposed.

The results and models of the folding of CI2, barnase, and En-HD are typical of the range of results obtained for the folding of a number of small proteins. Despite apparent differences in the way in which these three proteins fold, Daggett and Fersht have recently proposed a unified mechanism of folding based on the nucleation–condensation model. In their view of folding, there is a spectrum of pathways available to a protein with the framework mechanism at one end of the spectrum and the hydrophobic collapse model at the other. The nucleation–condensation mechanism lies in the center of this spectrum and the two other models can be viewed as extreme cases. Proteins which have sequences with high intrinsic propensities for forming stable elements of secondary structure, such as the engrailed homeodomain, tend to fold with mechanisms which lie at one end of the spectrum and which approximate to a framework model. Proteins for which the conformational preferences for secondary structure are weak, such as CI2, tend to fold according to a nucleation–condensation mechanism in which secondary structural elements are stabilized by tertiary interactions in the transition state. Larger proteins with more than one structural subdomain, such as barnase, fold in a hierarchical fashion but each subdomain, however, folds with a mechanism which lies somewhere on the spectrum of mechanisms found for smaller proteins. It is interesting that, although the hydrophobic collapse model can be viewed as one extreme of the folding spectrum, there are no examples so far of small proteins which fold in this way. Theoretically, proteins may fold through a molten-globule-like intermediate if hydrophobic interactions are very strong.

Computational Approaches

It is clear from the discussions on CI2, barnase, and En-HD given above that results from computational studies in conjunction with experimental results of ϕ-values from protein-engineering studies have played a critical role in the development of new folding mechanisms and in increasing our knowledge of the complexities of the energy landscape for

folding of small proteins. Although it is beyond the scope of this article, a few words on the main computational techniques used are included here. Many different computational approaches have been employed in the 1990s and applied to the protein-folding problem. These approaches range from rather coarse-grained models in which amino acids in the polypeptide chain are treated as beads on a string, a lattice-based structure is used, and simple pairwise potentials are employed. At the other end of the scale, all-atom molecular dynamic approaches have also been widely applied to the protein-folding problem. The different approaches, limited in different ways, have provided very complementary information on folding mechanisms and the fundamental questions regarding folding. Simple models and lattice-based approaches have provided support for nucleation-based mechanisms of folding, as well as being used to investigate cooperativity in folding. All-atom MD simulations are the most realistic of computational approaches but are restricted by the computational power and time necessary to simulate complex biological systems such as proteins (10 000 plus atoms). With the exception of small structural motifs, such as β-hairpins, for which folding has been simulated using distributed computing techniques, simulations of folding itself are not possible. This problem has been circumvented by simulating unfolding processes using high temperatures to accelerate the unfolding event. In these cases, the potentials used correspond to lower temperatures, the effect of the high temperature merely being to speed up the process but not change the mechanism. Using the principle of microscopic reversibility, the unfolding and folding pathways must be identical under the same conditions. Thus, it has been possible to gain information on folding pathways using these techniques. Rigorous testing of this approach has been performed with multiple simulations of the same protein under different temperatures and conditions. Results of this type of testing have shown the technique to be robust. Further, this type of approach has now been benchmarked extensively against experimental data and shown to be reliable and accurate in predicting experimental results. From these simulations, ensembles of structures corresponding to the denatured, intermediate, and transition states have been identified and characterized for a significant number of small proteins. The data obtained from these simulations is very much complementary to that obtained from ϕ-value analysis, the one generating structures whilst the other provides information on the energetics of the system.

Recently, experimental and computational approaches have been combined and new methods developed by Vendruscolo, Paci and co-workers to probe in further detail the structures of, and interactions in, transition state ensembles. Experimental ϕ-values are used as restraints in simulations, in a manner similar to the use of NOE data in NMR structure determination, and computational approaches used to generate an ensemble of conformations corresponding to the transition state. The advantage over the MD unfolding simulations described above is that a large number of conformations can be generated rapidly. This approach has been successfully applied to the small 98-residue protein acylphophatase to characterize the network of interactions that stabilize the transition state and which are formed when a few key residues (the folding nucleus) form a native-like arrangement.

Protein Folding, Evolution and

R A Goldstein, National Institute for Medical Research, London, UK

Introduction

Many important problems in physics involve the movement of a descriptor over some complicated, often high-dimensional, and sometimes rugged search space. The relationship between evolution and protein folding involves the search over two extremely different interacting spaces; the space of all possible protein sequences and the space of all possible protein conformations. For this and other reasons, physicists have found this area fruitful and challenging.

DNA provides the basic object of evolution for essentially all living systems, from the 580 000 base-pair genome of *Mycoplasma genitalium* to the 3.3×10^9 base-pair genome of humans to the greater-than 10^{11} base-pair genome of some amphibians and plants. Various sections of these genomes, called genes, contain instructions for constructing some biological entity, such as an RNA or a protein. It is the proteins, often combined with other elements (metallic atoms and clusters, RNA, other simple molecular "cofactors," etc.) that fulfill most of the active roles in the organism, from locomotion to metabolism to signaling. Proteins are initially synthesized as a long unbranched heteropolymer consisting of a linear arrangement of various numbers of the 20 amino acids or residues. Before they can fulfill their function, most proteins have to fold into a compact, regular three-dimensional structure.

Folding into a native conformation is a nontrivial task. Consider a moderately sized protein of 200 amino acids, each of which can be in one of three conformations. That means that, ignoring constraints such as excluded volume, the entire protein can have $3^{200} \sim 2.7 \times 10^{95}$ possible conformations. (A concentrated sample of such a protein, with one example of each conformation, would form a ball 10^8 light-years across!) Of all these conformations, some small proportion would be considered correctly folded. While factors such as excluded volume reduce the number of possible conformations, it is clear that finding a protein's folded conformation involves searching for a molecular needle in a cosmological haystack. A number of investigators have demonstrated that such folding is NP-hard.

An additional constraint is that protein folding is highly cooperative, often all-or-nothing. This cooperativity is essential for thermodynamic stability in that there is a large energy penalty for any significant unfolding. If this were not the case, given the number of different ways that some unfolding can occur, the proportion of correctly folded proteins at equilibrium would be negligible. While a few simple schemes have been suggested that allow folding to occur by a simple and gradual reduction in the free energy, these schemes are not consistent with the required and observed cooperativity.

Nevertheless, proteins solve this problem regularly. The fastest proteins fold in microseconds, with folding times of seconds to minutes more common. The difficulty is our problem, not theirs. So how are proteins able to fold so quickly?

There have been two categories of approaches to this problem. The first, more common among biochemists, has been to look for an encoding of the folding pathway. Just as a sheet of origami paper (for beginners) has dotted lines saying "fold here," may be there are patterns in the amino acid sequence that say when certain structural elements should be initiated or terminated. This view of the folding process is supported by the modular nature of proteins. Proteins exist as assemblies of simpler elements: shorter regions of the protein sequence fold into characteristic regular (α-helical and β-sheet) or nonperiodic (turn and loop) "secondary" structures, which are built into three-dimensional "supersecondary" structures containing a small number of these elements, which are in turn assembled into "tertiary" structures. Larger protein structures can be divided into "domains," regions of sequence of 100–300 residues that fold and function as separate entities. Different protein chains sometimes assemble to form "quaternary" complexes. It is argued that the modularity makes it possible for the folding code to be local.

More recently, others (such as physicists) have addressed this issue by considering the free-energy landscape of the proteins, that is, the free energy of the protein sequence as a function of its conformation, and considered how this landscape could be negotiated by a folding protein. Often this has been combined with notions that there is not a single folding pathway, but rather a multiplicity of ways that a protein can go from the large ensemble of unfolded states to the relatively small region corresponding to the folded state. Also, common in this approach is that the "folding code" is distributed in a holographic way throughout the sequence. Theoretical models based on the spin-glass theory by Wolynes and co-workers, in addition to lattice-model simulations by Shakhnovich and co-workers, have suggested that a sufficient criterion for ability to fold is for the protein

to have a native state sufficiently stable, relative to the stability of random conformations. In particular, computational models of lattice proteins that are optimized for rapid folding tend to develop such an "energy gap." More lately, there has been interest in how proteins might develop "funnels" in the free-energy landscape that direct the folding process, and how protein folding might involve the formation of a specific folding nucleus as the rate-limiting step. Again, the challenge is to reduce the search problem while not losing the essential cooperativity.

While protein folding may be NP-hard, this only means that it is impossible to find a polynomial-time general solution. One can ask instead how nature, through the process of evolution, can discover those proteins whose folding is sufficiently easy. This then brings one to the dual search spaces. Consider first the "fitness landscape" of all possible protein sequences. This space is high dimensional, with as many dimensions as the length of the protein, but is also sparse – only 20 points along each dimension. Each sequence in this space has a fitness value associated with it, corresponding to the fitness of the organism with that particular protein sequence. (In reality, the fitness landscape would have as many dimensions as the entire genome, but it is assumed that all of the other dimensions are frozen.) Each point in sequence space is mapped to a corresponding free-energy landscape, encoding the free energy as a function of the conformation of that particular sequence. Some of these free-energy landscapes correspond to fast-folding proteins, not the vast majority. The "foldability" of any particular sequence, that is, the ability of that sequence with its corresponding free-energy landscape to fold, is then a component in the fitness of that sequence in the fitness landscape. As the properties of the free-energy landscape form a contribution to fitness, evolution will result in proteins with free-energy landscapes compatible with acceptable folding rates, a process called "free-energy landscaping."

There is rather universal agreement on certain aspects of evolution. Mutations occur among somatic cells, which affect the fitness of the offspring. Most of the time, this particular mutation will be eliminated from the population. There is a finite chance that, alternatively, the mutated sequence will expand among the population and become the dominant genotype, a process referred to as "fixation." There is also a chance that this mutation will remain in a fraction of the population without eliminating other forms, and this part of the genome will be "polymorphic." Some mutations will be beneficial, others neutral, and others detrimental. While a beneficial mutation has a higher probability of fixation compared with neutral or detrimental mutations, there is a probability of fixation of a detrimental mutation just as there is a probability that a beneficial mutation will be eliminated. These probabilities will depend on the population size, with randomness increasing as the population shrinks. There is a ranging debate about the relative number of beneficial, neutral, and detrimental mutations. While all agree that the vast majority of mutations are detrimental, there are some evolutionists who believe that the mutations that are accepted are generally accepted because they are beneficial, that is, increase the fitness of the organism. Accepted mutations are, then, likely to be "adaptive." Others argue that effectively neutral mutations exceed beneficial mutations to such an extent that most evolution proceeds through "random drift," the accumulation of such neutral mutations.

These neutral mutations can have many important consequences. They allow more freedom in the search over the sequence space, enabling the relatively few adaptive changes to occur. In addition, greater random neutral drift in a population acts in a manner similar to a higher temperature, making "sequence entropy" (i.e., the number of sequences corresponding to a given trait) important in the evolutionary dynamics. Higher mutation rates and smaller population sizes correspond to larger evolutionary temperatures.

One aspect emphasized by neutralists is the dangers of the so-called "Panglossian paradigm," that is, explaining why a characteristic evolved through reference to how it is currently used, in the same way as Candide's Pangloss described how noses were obviously created for supporting spectacles. Evolution is not an optimization procedure, and the caricature embodied by the notion of "survival of the fittest" is not a perspective Darwin would appreciate. In particular, features created for one reason can be used for an alternative task, and characteristics that arise at random may fulfill no role. If random walks through viable regions of sequence space represent a "null model," claiming that an acquired characteristic is adaptive requires demonstrating that it cannot be explained by neutral drift.

There is an interesting timescale separation concerning evolution and folding. Evolution does not occur on the folding timescale, so there is an unchanging sequence that folds. Although there are accessory proteins (such as, the so-called chaperones) that may assist a protein in folding, there is little evidence that these accessory proteins provide any information about the nature of the final folded state. The protein sequence, then, determines the final folded state. In an evolutionary timescale, sequences

change much more quickly than structures, so that two sequences with near-random sequence similarities may fold into near-identical structures. Changes in the sequence inconsistent with this conserved fold will be detrimental and eliminated from the population. Thus, on the evolutionary timescale, it is the folded structure that determines (or at least constrains) the protein sequence.

Certain questions immediately arise. How do proteins evolve to solve the protein-folding problem? What are the properties of the solutions that they find? What are the other consequences of these solutions? The answers to these and similar questions are only now starting to emerge. Many perspectives will likely change quickly as one learns more about proteins, protein folding, and protein evolution.

The Formation of the Universe of Protein Folds

When examining proteins of known structure, it is obvious that not all folds are equally represented. Rather, there are very few extremely likely folds, while the vast majority of folds are rather rare. The observed distribution has been modeled with a few different functional forms, including a power law and a stretched exponential. Four basic explanations have been offered for this uneven distribution. The first is that there are certain structures that are more amenable to structural characterization, and that the distribution is an experimental artifact. The second is that there are certain folds that are compatible with a wider range of functions. The third is that this represents the results of a process of speciation and gene duplication. The fourth explanation is based on ideas of protein "designability," that is, there are certain folds that can be formed by a larger number of sequences compared with other folds. Designability could cause an uneven distribution of folds for one of two reasons. First, initial instances of a given protein would be more likely to result in a highly designable structure. Second, highly designable structures correspond to larger "neutral networks," that is, larger regions of sequence space corresponding to a viable protein. This means that these proteins could have greater freedom to evolve to acquire new characteristics (new specificities, new functionalities) while preserving the folded structure, and would also have an additional evolutionary advantage due to the higher degree of robustness to mutations. It has also been noted that highly designable proteins are more likely to have a large energy gap between the folded and unfolded states, considered in some models to be a sufficient condition for rapid folding. Detangling these different explanations will require a broader analysis of the current distribution, which will be assisted by the various sequencing projects and by current efforts to characterize the broad range of protein structures in a comprehensive manner.

What characterizes highly designable structures? Finkelstein first considered the stability penalty certain substructures would cause, arguing that this would reduce the designability. Calculations for lattice proteins using a simplified amino acid alphabet led Tang and co-workers to note the greater representation of highly symmetric structures. Shakhnovich and co-workers developed analytical models suggesting that designability was strongly influenced by the contacts present in the folded state, especially the total number of contacts as well as the different number and kind of closed loops formed by these contacts. Goldstein and co-workers emphasized the number of contacts unlikely in random structures. Strengthening such contacts, generally between amino acids well separated in the sequence, would stabilize the native state while stabilizing the fewest number of alternative conformations. Micheletti and co-workers provided a different twist with a study of the normal vibrational modes in a protein, demonstrating that protein structures have slow relaxation times relative to random graphs, and that slower relaxation times are correlated with faster folding rates. This is because these slower relaxation times are correlated with larger, low-energy motions that may indicate a smoother free-energy landscape. In this model, the particular protein structures commonly found by evolution may represent better folders in as much as they are compatible with these slower relaxation times.

Have Proteins Evolved for Fast Folding?

There is a current debate over what nature considers important during protein evolution. Have proteins evolved for rapid folding? Is this one of the major sources of selection pressure acting on protein evolution? Or is fast folding a consequence of selective pressure acting on some other characteristic, such as stability? Are other properties of folding under selective pressure?

One approach to gain insight into these questions is to consider how changes in the protein sequence affect folding. In general, the folding rate can be rather insensitive to such changes. In fact, it is often not difficult to find mutations that speed up folding, sometimes significantly. This would seem to indicate that proteins have not evolved under strong selection to fold quickly, as strong selection would likely have yielded faster folding sequences.

Mutational work can also provide information about the folding pathway, an approach pioneered by Alan Fersht. Depending upon the results, Alan Fersht and colleagues were able to identify which amino acids are involved in (presumably native) interactions in the transition state, what has been characterized as the "folding nucleus." This is quantified with a so-called "Φ value"; Φ values close to 1 indicate strong involvement of the amino acid in the transition state, while Φ values closer to 0 indicate lack of involvement. Intermediate Φ values, observed in a large number of proteins, indicate either the partial involvement of that amino acid in the transition state or heterogeneity in the folding process with a distribution of transition states. The presence of such a large number of intermediate values suggests that the folding nucleus is often somewhat diffuse. It is often observed that homologous proteins share the same folding nucleus, as indicated by similar patterns of Φ values. This could mean that there is a tendency for conservation of the folding nuclei. An alternative explanation, indicated by a number of different dynamics simulations, is that the dynamics of the folding of the protein is often relatively insensitive to the actual nature of the interactions that determine the folded state, but depends, instead, mostly on the resultant state. The similarity of the folding nuclei in related proteins may then just represent similarity of the final structure. It is unclear, if the folding pathway is conserved, what the evolutionary advantage of a conserved pathway would be. Baker and co-workers, for instance, demonstrated that it is possible to change the folding pathway through protein engineering, resulting in a more-stable, faster-folding variant.

Φ-value analysis provides an alternative method to investigate whether the folding rate is under active selective pressure. Are residues with larger Φ values, those that are important in the folding nucleus, more conserved? Such a study was performed by Shakhnovich, who observed that residues known to have high-Φ values are, indeed, more highly conserved than the average residue in a protein. This result was subsequently disputed by Baker and colleagues who pointed out a strong experimental bias in the data: namely, not all residues in any protein are characterized experimentally, and the experimentally characterized residues are, on an average, more highly conserved than those that have not been characterized. If one only considers locations with measured Φ values, there is little or no correlation between Φ value and amino acid conservation.

If it is unclear whether folding path or rate is under active selective pressure or not, what is? Artificial mutations are more likely to reduce protein stability, although even this quantity can be rather robust. This suggests that protein stability is under more selective pressure than folding rate. While theoretical calculations link these two quantities, suggesting that a certain stability is sufficient for rapid folding, one might imagine that stability might be important in its own right. All proteins spend some fraction of their time at equilibrium in an unfolded state. Reducing this time might help prevent degradation and aggregation. It is interesting to note, however, that proteins, in general, are marginally stable (stabilities around $-10\,\mathrm{kcal\,mol^{-1}}$, equivalent to only a few hydrogen bonds), that many mutations can be found that enhance protein stability, and that many proteins may actually be largely unfolded under physiological conditions. It has been widely suggested that the observed marginal stability of proteins may represent some adaptation for functionality, although it would also naturally result from neutral evolution.

One interesting approach toward analyzing folding involves the use of circular permutations. The termini of many proteins are near one another. It is possible to create a new protein starting from a random point in the original protein, proceeding to the far termini, continuing across to the beginning of the protein, and then synthesizing the original sequence up until the starting point. The result is a protein with almost the identical final structure (except for the relocation of the termini), but with an extremely different conformational landscape. Interestingly, the reordered proteins do not have appreciably slower folding rates, nor are they less stable, but rather the folding is much less cooperative, with more intermediate Φ values. This suggests that it may be the all-or-nothing nature of the folding that may be under the most selective pressure.

Folding is a difficult problem, but one aspect that may be more directly important is avoiding misfolding. For instance, there may be strong selective pressure on certain amino acids that destabilize alternatively folded states. Often the result of misfolding is the formation of protein aggregates, often connected with pathological conditions such as Alzheimer's, Creutzfeldt–Jakob disease, and type II diabetes. A wide range of proteins can form destructive aggregates under appropriate conditions. The fact that only a relatively small fraction does under physiological conditions suggest that evolution has been quite good at preventing protein misfolding. Evidence of this can be seen in the accepted mutations during evolution. Although amino acids on the outside of the protein generally change faster than internal amino acids, hydrophilicity on the exterior of the protein is sometimes more conserved than hydrophobicity on the protein interior. This would

prevent aggregation as well as discourage folding to alternative states where these amino acids are buried.

Do Proteins Fold into Their Lowest Energy State?

An example of the neutralist approach to protein folding is one of the basic issues in the field; do proteins fold into the state of lowest free energy? This hypothesis, called the "thermodynamic" hypothesis, was proposed by Anfinsen based on the ability of unfolded proteins to refold spontaneously in solution. An alternative perspective was developed by Levinthal. Noting the extremely large number of possible conformations, and the inability of a protein to achieve something resembling thermodynamic equilibrium in any reasonable timescale, led him to doubt the thermodynamic hypothesis. In the absence of any selective pressure, could neutral evolution result in proteins fulfilling the thermodynamic hypothesis? In 1998, Goldstein and co-workers proposed a model for how this could happen. Mutations that destabilize the free-energy minimum corresponding to the folded state might be highly detrimental, and thus eliminated. Conversely, mutations that destabilized other, possibly deeper minima would not have a negative effect on the protein, would be more likely to be advantageous (or at least neutral), and thus have a greater chance for fixation. The result might be the evaporation of these alternative minima over an evolutionary time, resulting in proteins that did fulfill the thermodynamic hypothesis, even in the absence of any selective advantage. The quantitative question concerns the number of expected alternative minima, the probability that they would be explored, and the probability that any minima would be lower in energy than the true native state. A simple calculation indicated that, for reasonable energy parameters, sequences with metastable folded states would be much less likely than proteins fulfilling the thermodynamic hypothesis, and thus neutral evolution would favor this hypothesis. Of course, this argument would fail when there was a specific reason why a metastable folded state would be advantageous, as seems to be the case with serpins, a group of inhibitors that prevent enzymes known as proteases from digesting other proteins, which inactivate themselves by converting from an active metastable structure to a more stable, alternative form.

Evolution and Optimization

One overall problem with a number of these analyses is that evolution is not an optimization process, any more than thermodynamics is an enthalpy-reduction process. (While Baker and co-workers have found that the sequences of proteins can be appreciably constructed by finding the sequence lowest in energy for a given backbone structure, this may be due to information about the protein sequence being embedded in this backbone structure. The reconstructed information sharply degrades as the backbone is allowed to move. These results are also incompatible with the wide range of sequences observed in homologous proteins.) There are stochastic processes underlying mutations and fixation events. Chance can operate either through the memorization of accidental events, as well as through the role of entropic considerations.

In particular, there is selection not for a single point in sequence space, but rather for a distributed somewhat heterogeneous population, what Eigen called a "pseudo-species." As this population samples a region of the fitness landscape, there is a preference for evolution to select flatter regions of the landscape, compared with narrower, higher peaks. This has been called, by Crutchfield and co-workers, the "Survival of the Flattest." Goldstein and co-workers have performed simulations indicating that quantities selected by evolution will be "buffered," that is, these quantities will be surprisingly robust to sequence change. According to this argument, quantities that are seemingly not optimized may be those under strong selective pressure.

Pseudopotential Method

A Filippetti, University of Cagliari, Monserrato, Italy
G B Bachelet, Università di Roma "La Sapienza", Roma, Italy

Introduction

Pseudopotentials were introduced to model the interaction between ions and valence electrons. They effectively eliminate, from the very start, the true electron–nuclear potential and the "inner core" electrons, that is, those electronic states which are tightly bound to the nucleus, do not participate in the formation of chemical bonds, and remain approximately unchanged in atoms, molecules, and solids. This tremendous conceptual simplification also amounts to a very practical and efficient computational scheme, especially when a plane-wave basis set is adopted to expand the electronic wave functions. After 1980, this method, in connection with a density-functional description of the electron–electron interaction, evolved into a reliable prescription for the first-principles computation of electronic, structural, and dynamical properties of molecules and solids. In this context, its present accuracy and predictive power for real materials, as well as relatively complex molecular systems, leads many experimental groups to regard its results as a valuable, independent source of microscopic information.

The physical and chemical basis for this fortunate approximation is twofold. First, in an atom only a few electrons determine the formation of chemical bonds to other atoms, while most of the electrons, tightly bound to their nucleus, are practically frozen; pseudopotentials simultaneously eliminate the unimportant inner electrons and the nuclear potential responsible for their binding. Second, the quantum nature and the Fermi statistics of the electrons are such that the combination of repulsion and attraction due to the inner electrons and to the nucleus results in substantial cancellations, and can be effectively replaced by a relatively smooth ionic pseudopotential, which only acts on the few important electrons.

To fully appreciate contemporary first-principles pseudopotentials, a few key concepts are needed.

Valence and the Periodic Table

Between the end of the eighteenth century and the beginning of the nineteenth century, the pioneering work of Lavoisier, Dalton, Gay–Lussac, Avogadro, and others led to the distinction between compounds and elements, to the discovery that elements combine in fixed and multiple proportions of whole numbers to yield compounds, and, ultimately, to the modern concept of the atom. The formulas of compounds were soon systematized by assigning certain combining powers, the valences, to the elements, as if each atom had a particular number of little hooks on it to attach itself to similar hooks on other atoms. Half a century later, Mendeleev drew up his periodic table of the elements, with eight columns reflecting the remarkable correlations between the atomic valence and weight, first pointed out by Newlands.

What in his table was just a progressive number was in fact the atomic number Z (the number of protons in the nucleus or, equivalently, the number of electrons of the neutral atom) – as shown by Moseley's X-ray experiments, at the beginning of the twentieth century.

The Atomic Shell Structure

In the same years, the advent of quantum mechanics (first the Bohr model and then the Schrödinger equation) allowed a simple and consistent interpretation of the remarkable regularities of the periodic table of the elements.

Atoms are built up of successive orbital shells of electrons, labeled by the principal quantum number n and the angular quantum numbers lm, which are less and less tightly bound to the nucleus. For given nl, each of the $(2l+1)$ equivalent orbitals nlm can host, because of the Pauli principle, a maximum of two electrons. A complete s shell ($l=0$) thus contains $2(2l+1)=2$ electrons, a complete p shell ($l=1$) 6 electrons, and so on. The Pauli principle (i.e., the Fermi statistics obeyed by the electrons) is thus the reason for the progressive filling of orbital shells, as the atomic number grows. Elements of the same group of the periodic table, with different Z and different number of inner, complete core shells, have a common feature: the number of electrons and the electronic configuration of their outermost shell – the valence shell. That is why their chemical properties are so similar; and also why (disregarding transition d- and f-metals) chemical properties go by "octaves" (Newlands) and the groups are eight: it takes eight electrons to completely fill an sp valence shell.

The persistence throughout the periodic table of a recognizable hydrogen-like orbital shell structure explained a lot of experiments in the early days of quantum mechanics, but is not so obvious. Somehow, one-electron quantum numbers and orbitals $\psi_{nlm}(\boldsymbol{r}) = R_{nl}(r)Y_{lm}(\hat{\boldsymbol{r}})$ (where the vector $\boldsymbol{r}$ represents the position of the electron with respect to the nucleus, R are radial functions, and Y spherical harmonics) remain meaningful even for atoms which, unlike hydrogen, have many electrons and not just one. Why? Because, in atoms, to a good approximation, (1) the electron–electron repulsion may be replaced by its average: a mean-field, one-electron potential which screens the strong, attractive $-Z/r$ Coulombic potential of the nucleus, (2) such a mean-field potential is, in turn, well-approximated by its spherical average, so that the atomic states can still be factorized into a radial and an angular part, and thus labeled by the same quantum numbers nlm as the hydrogen atom, (3) since the nucleus is a positive point charge while the negative electronic clouds are more or less delocalized, their spherically-averaged mean-field repulsive potential provides, at finite distance from the nucleus, only a partial screening of the nucleus, and does not completely destroy the order of the energy levels of the bare $-Z/r$ nuclear potential. The validity of the mean-field approximation (1) in atoms is the cornerstone of the remarkable simplicity of their interpretation in terms of one-electron orbitals and quantum numbers, and amounts to the success of the Hartree–Fock variational solution of the true, many-electron quantum problem. Combined with the spherical average (2), it results in a set of hydrogen-like equations (atomic units $\hbar = m_e = e = 1$ (where m_e and e are electron mass and charge, respectively) are used here and in what follows, unless otherwise stated):

$$\hat{h}_{SCF}\psi_{nlm} = \left[-\frac{1}{2}\nabla_{\boldsymbol{r}}^2 - \frac{Z}{r} + \hat{v}_{screen}\right]\psi_{nlm} = \varepsilon_{nl}\psi_{nlm} \quad [1]$$

where $\hat{h}_{SCF}$ is one-electron self-consistent field Hamiltonian and ε_{nl} are its eigenvalues. Equation [1] differs from the true (nonrelativistic) Schrödinger equation appropriate to noninteracting electrons by the presence of a screening potential $\hat{v}_{screen}$, which is a functional of the occupied orbitals $\psi_{nlm}(\boldsymbol{r})$. (The concept of functional generalizes that of function. A function associates a number to each number defined in a certain interval, its domain. A functional associates a number or a function to each function defined in a certain functional space. For example, it can be seen below that for any charge distribution $n(\boldsymbol{r})$, there is a corresponding electrostatic potential $v_H(\boldsymbol{r})$; v_H is then a functional of n: $v_H = v_H[n]$.)

The presence of $\hat{v}_{screen}$ makes the entire effective Hamiltonian $\hat{h}_{SCF}$ depend on its own eigensolutions; this is a nonlinear, but numerically feasible self-consistent-field (SCF) problem. Similar self-consistent equations emerge from the density-functional theory; the reason is quite subtle, but superficially speaking, in comparison to the Hartree–Fock equations, the difference is that the screening potential $\hat{v}_{screen}$ depends on, and acts upon, the orbitals $\psi_{nlm}(\boldsymbol{r})$, in a different way. This difference, however, concerns only part of the screening potential, the so-called exchange-correlation potential, which is not crucial for a qualitative understanding of the atomic shell structure, since the main contribution of the occupied electronic states to $\hat{v}_{screen}$ always comes from the other part, their classical electrostatic (or Hartree) potential

$$v_H(\boldsymbol{r}) = \int \frac{n(\boldsymbol{r}')}{|\boldsymbol{r}' - \boldsymbol{r}'|}\mathrm{d}\,\boldsymbol{r}' \quad [2]$$

where $n(\boldsymbol{r})$ is the electronic charge density, sum of the squares of the occupied orbitals $\psi_{nlm}(\boldsymbol{r})$. In the

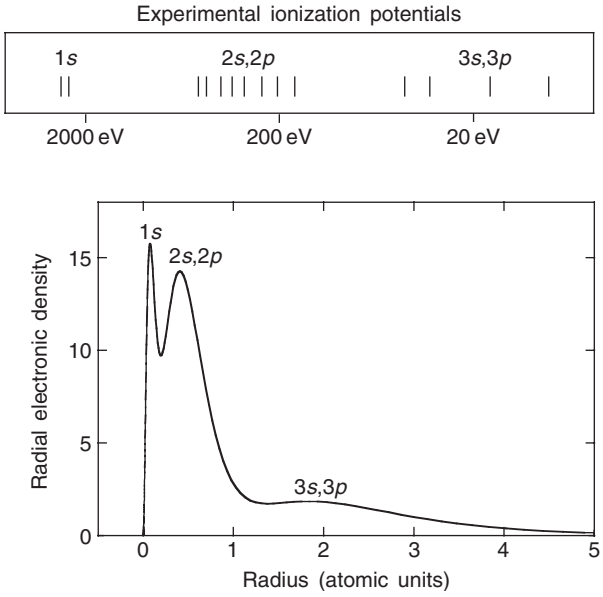

Figure 1 Atomic shell structure: the example of silicon ($Z = 14$). Top: the 14 ionization potentials of silicon, in electron volts (note the logarithmic scale). Bottom: radial electronic density as a function of the distance from the nucleus; both in energy (top) and in space (bottom), the core shells (1*s*, $n = 1$, and 2*s*, 2*p*, $n = 2$) are well separated from each other and from the valence 3*s*, 3*p* shell ($n = 3$).

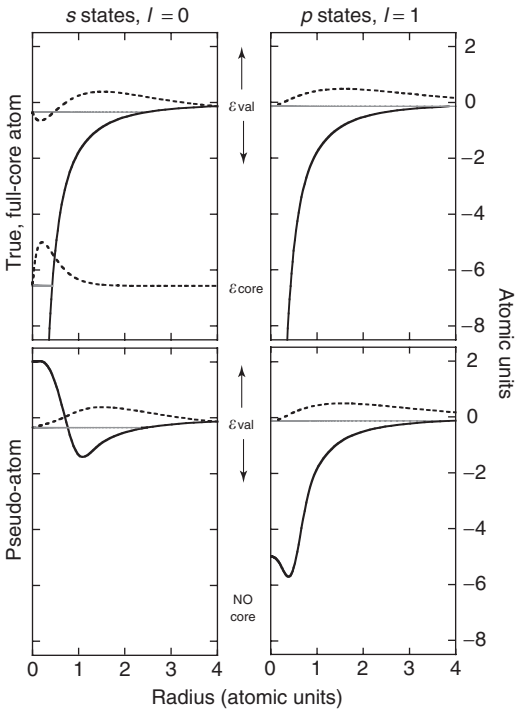

Figure 2 True vs. pseudo-atom, the example of boron ($Z = 5$). In the true neutral atom (top panels) there are five electrons. Two occupy the tightly bound 1*s* core orbital $\psi_{100} = R_{10}Y_{00}$, another two the shallow 2*s* valence orbital $\psi_{200} = R_{20}Y_{00}$ (top left), and the last one the 2*p* valence orbital (e.g., p_z, or $\psi_{210} = R_{21}Y_{10}$: top right). Here, the radial orbitals $\chi_{nl} = r\,R_{nl}$ are dashed lines and their zero is vertically shifted and lined up to the corresponding energy eigenvalue (gray line). The screened nuclear potential (top panels, black solid line) retains much of its original Coulombic shape, and a hydrogen-like shell structure results: the 1*s* orbital corresponds to a deep eigenvalue (ε_{core}, gray thick line) and is localized near the nucleus, while the 2*s* and 2*p* valence orbitals are "fatter" and correspond to a shallower energy (ε_{val}, gray thick line). In a pseudo-atom (bottom panels), the core electrons and the nucleus are simultaneously eliminated and replaced by a pseudopotential (bottom, black solid line); in boron, one is thus left with just three electrons, two in the *s* (left) and one in the *p* (right) pseudo-valence-orbital. These orbitals should ideally have the same energy eigenvalue and wave function amplitude as the true valence orbitals (top, dashes). The amplitude, though, can be the same only outside the core: inside it, the true valence 2*s* orbital (top left) is radially orthogonal to the core 1*s* orbital and changes sign (has one radial node), while, by definition, the pseudo-valence-orbital (bottom left) has no underlying core, and is thus nodeless. Similar considerations apply to energy: the pseudopotential (black solid, bottom panels) may effectively replace the true potential (black solid, top panels) only within some energy window around the valence eigenvalue ε_{val}. But this may be sufficient for an excellent approximation of the atom's behavior in a molecule or a solid, since bands and bonds spread the valence energies only a few atomic units away from the eigenvalue of the isolated atom (see text).

ground state of the neutral, atom they are occupied in order of increasing energy ε_{nl} (decreasing binding energy and localization), each by two electrons (spin, Pauli principle), except for the outermost valence states, some of which may be partially occupied or empty. The repulsive electrostatic potential v_H (eqns [1] and [2]) due to these concentric spherical clouds only partially screens the pointlike $-Z/r$ attractive singularity of the nuclear potential; a hydrogen-like shell structure survives, with the outermost (valence) orbitals usually well separated from the inner-core orbitals (see **Figure 1** and top panels of **Figure 2**).

From Free Electrons to Pseudopotentials

The atomic shell structure, the distinction between core and valence shells, and the fact that the core shells are tightly bound and closer to the nucleus, explain not only the periodic properties of the elements, but also a wealth of other experimental facts, from the energy gaps which separate different groups of atomic ionization potentials in a given atom (see **Figure 1**, upper panel) to the minor role played by the cores in the formation of chemical bonds and in the electrical and thermal properties of solids. Sommerfeld's free-electron model, for example, gave quite a reasonable picture of the conductivity and low-temperature specific heat of simple metals by completely disregarding both the core electrons and the nuclei; the valence electrons were its only ingredient, and, apart from being confined in the crystal, were subject to a completely flat potential. The success of such a crude model rests on more than just

a distinction between core and valence electrons, and is a good starting point for introducing the concept of pseudopotential. It tells that, at least in simple metals such as, say, sodium or potassium, valence electrons roughly behave as if core electrons and strongly attractive nuclei simply did not exist. The successful description of simple metals in terms of quasi-free electrons (an improvement over Sommerfeld's model based on perturbation theory) confirmed that the combined presence of strong and localized objects – core shells plus nuclear potentials – effectively results in a weak periodic perturbation, a lattice of smooth ionic potentials which slightly repel the valence electrons from the immediate vicinity of the nuclei.

If the basic idea of the pseudopotential method goes back to Fermi and in some sense also to Hellmann and Antončik, Phillips and Kleinman were the first, in a seminal paper which appeared on the *Physical Review* in 1959, to show that, inside the core region, the requirement of orthogonality of the valence states to the inner core states, which pushes the outermost maximum of the valence wave functions away from the core region (**Figure 2**, top left), acts like a repulsive potential which tends to cancel the attractive nuclear potential felt by the valence electrons, so that, more often than not, their combined effect may be well approximated by a relatively weak repulsive potential, or pseudopotential (**Figure 2**, bottom left). As soon as their "cancellation theorem" was supplemented by the key observation about the amount of arbitrariness in the choice of pseudopotentials and their general form, independently proposed by Bassani and Celli, and by Cohen and Heine in 1961, a practical prescription for their use became available. These results raised enthusiasm in the scientific community of solid-state theoretical physicists, who started a very fruitful exploitation of the pseudopotential idea, in combination with a basis set of plane waves to represent the valence wave functions. The reason is easily understood. A crystal with lattice vectors $\boldsymbol{R}$ is described by SCF equations analogous to the atomic eqn [1], where a single nucleus is replaced by a periodic array of nuclei, and the eigenstates labeled by the band index n and Brillouin-zone wave vector $\boldsymbol{k}$, satisfy the Bloch condition $\psi_{n\boldsymbol{k}}(\boldsymbol{r}+\boldsymbol{R}) = e^{i\boldsymbol{k}\cdot\boldsymbol{R}}\psi_{n\boldsymbol{k}}(\boldsymbol{r})$. A plane wave $e^{i(\boldsymbol{k}+\boldsymbol{G})\cdot\boldsymbol{r}}$, where $\boldsymbol{G}$ is a reciprocal-lattice vector defined by $e^{i\boldsymbol{G}\cdot\boldsymbol{R}} = 1$, individually satisfies the Bloch condition, and so does any linear combination of plane waves

$$\psi_{n\boldsymbol{k}}(\boldsymbol{r}) = \sum_{\boldsymbol{G}} c_{n\boldsymbol{k}}(\boldsymbol{G}) e^{i(\boldsymbol{k}+\boldsymbol{G})\cdot\boldsymbol{r}} \qquad [3]$$

where $c_{n\boldsymbol{k}}(\boldsymbol{G})$ are one-electron wave functions in the reciprocal space. A basis set of plane waves thus represents a natural choice for solving the crystalline SCF equations. If the sum in eqn [3] includes all the reciprocal-lattice vectors $\boldsymbol{G}$ (a complete set of plane waves), the above expansion becomes an exact transformation, and turns the real-space SCF equations for $\psi_{n\boldsymbol{k}}(\boldsymbol{r})$ into their $\boldsymbol{G}$-space counterpart

$$\sum_{\boldsymbol{G}'} \left[\frac{1}{2}|\boldsymbol{k}+\boldsymbol{G}|^2\delta_{\boldsymbol{G},\boldsymbol{G}'} + \tilde{v}(\boldsymbol{G}-\boldsymbol{G}')\right] c_{n\boldsymbol{k}}(\boldsymbol{G}') = \varepsilon_{n\boldsymbol{k}} c_{n\boldsymbol{k}}(\boldsymbol{G}) \qquad [4]$$

where $\tilde{v}$ are the Fourier components (at wave vectors $\boldsymbol{G}'' = \boldsymbol{G} - \boldsymbol{G}'$) of the spatially periodic potential due to the nuclei plus the screening potential $\hat{v}_{\text{screen}}$ due both to the core and to the valence electrons. In practice, when a numerical solution is being sought, the plane-wave expansion must be truncated so that only a finite number N_{pw} of $\boldsymbol{G}$-vectors, those satisfying $|\boldsymbol{k}+\boldsymbol{G}| < G_{\text{cut}}$, are included in the sum of eqn [3]. Here is where the elimination of cores and the introduction of pseudopotentials become crucial. If the smallest length scale in the electronic wave functions is λ_{min}, one needs at least $G_{\text{cut}} \sim 2\pi/\lambda_{\text{min}}$, and, in the expansion of eqn [3], the number of plane waves $\boldsymbol{k}+\boldsymbol{G}$ included in a sphere of radius G_{cut} is $N_{\text{pw}} \propto G_{\text{cut}}^3$. In the true, full-core atom, λ_{min} is dictated by the 1*s* core state: because of orthogonality, in the core region not only the 1*s*, but also all the higher *s* states, up to the valence shell, will have wiggles of length scale $\lambda_{\text{min}} = \lambda_{1s}$, which is much smaller than typical nearest-neighbor (NN) distances and lattice constants $\lambda_{1s} \ll d_{\text{NN}} < a$. This makes N_{pw} so large, that the $N_{\text{pw}} \times N_{\text{pw}}$ matrix corresponding to eqn [4] becomes practically intractable. (Indeed the computational effort to diagonalize an $N_{\text{pw}} \times N_{\text{pw}}$ matrix scales like N_{pw}^3 for a full diagonalization and approximately like N_{pw}^2 if only the lowest eigenvectors and eigenvalues of the eqn [4] are being sought.) If, instead, core electrons can be effectively eliminated, one is left with a crystal of valence-only, pseudo-atoms where effective ions, screened by their valence electrons alone, replace the true ions made of nuclei and core electrons. Unlike the true valence wave functions, the psuedo-wave-functions are smooth inside the core regions, since, in a pseudo-atom, the spatial wiggles due to the orthogonality to inner-core states disappear (compare the top and bottom panels of **Figure 2**); the minimum electronic length scale λ_{min} is now comparable to typical nearest-neighbor distances. So, with respect to the true crystal, a much smaller number N_{pw} of $\boldsymbol{G}$-vectors is required for an accurate expansion of the crystal wave functions (eqn [3]); the reciprocal-lattice vectors $\boldsymbol{G}'' = \boldsymbol{G} - \boldsymbol{G}'$ to be included in the crystal pseudopotential $\tilde{v} = \tilde{v}^{\text{ps}}(\boldsymbol{G}'')$ of eqn [4] are also few; a numerically affordable $N_{\text{pw}} \times N_{\text{pw}}$ saecular problem results.

Besides rationalizing the perturbative theory of the quasi-free-electron model, pseudopotentials thus

ignited some sort of gold rush in the field of the electronic states of solids: appropriate pseudopotentials for the electron-ion interaction and a basis set of a few plane waves for the expansion of the crystal wave functions were now sufficient, beyond the limits of the perturbation theory, to successfully describe the valence bands (and thus the electrical and optical properties) not only of simple metals, but also of semiconductors and insulators.

Empirical Pseudopotentials

The very argument on orthogonality between valence and core orbitals suggests that pseudopotentials should, in principle, be derived from atomic wave functions.

Luckily, it was clear from the very beginning that, for quite a number of elements, a local (i.e., angular-momentum independent, see later) pseudopotential, given in terms of a few adjustable parameters, could provide an acceptable approximation of the true electron-ion interaction. This was true for many solids, some of which were of paramount technological importance: alkali metals, simple metals such as aluminum, and also elemental and compound semiconductors. Because of this simplification (and also of the difficulties of fully self-consistent calculations in those years), much of the early, successful pseudopotentials were obtained from fits to experimental data and not from atomic wave functions. A very popular empirical procedure was, for example, to (1) directly address a valence-only problem for the crystal: in eqn [4], the core bands are thrown away from the very start; (2) forget about self-consistency, and rather (3) treat as disposable parameters, the (by now few) Fourier components $\tilde{v}^{\mathrm{ps}}(\boldsymbol{G}-\boldsymbol{G}')$ of the total crystal pseudopotential, which replace the true potential $\tilde{v}(\boldsymbol{G}-\boldsymbol{G}')$ in eqn [4], and vary them until the experimental optical absorption spectrum, the effective mass, and/or other measured quantities were optimally reproduced. In less than ten years, these (or similar) empirical pseudopotentials gave a substantial contribution to the basic understanding of many crystalline solids. In particular, they proved the ideal theoretical tool for bulk semiconductors, whose revolutionary impact on technology happened to boom precisely in those years; alternative band-structure approaches, excellent for close-packed solids and transition metals, failed to describe the highly directional covalent bonds of semiconductors.

Model Pseudopotentials

The success on ideal, periodic bulk solids fueled more ambitious tasks of great fundamental and technological interest: the description of electrons at lattice imperfections of solids, such as surfaces, vacancies, interfaces.

These imperfections imply a much lower spatial symmetry than perfect crystals, not only because they break the translational symmetry, but also because, as a consequence of their presence, a number of surrounding atoms may be displaced with respect to their position in the corresponding ideal solid. Periodicity, and thus Bloch's theorem and a plane-wave basis, may still be exploited: one may always treat an arbitrarily complicated, low-symmetry collection of atoms as the (large) unit cell, or supercell, of an artificial crystal. But the early applications to imperfect solids showed that empirical pseudopotentials, tailored to describe perfect crystals, were not transferable to low-symmetry systems: the self-consistent rearrangement of valence electrons around imperfections, with a reliable dependence of their ground-state energy on atomic positions (needed to determine equilibrium atomic displacements), were simply beyond their scope.

New, transferable pseudopotentials were needed for this purpose. In other words, potentials which adequately represent the interaction between ions and valence electrons not just in a given perfect crystal but in many different chemical or solid-state surroundings (isolated atom, molecule, ideal, or imperfect crystal). This brought many theorists back to pseudopotential definitions based on the isolated atom, and to the distinction between a bare ionic pseudopotential $v^{\mathrm{ps,\ bare}}$ which replaces the true ion (nucleus plus core electrons) and never changes, and valence electrons, which are allowed to self-consistently rearrange (i.e., form different bonds in response to different environments). Since by electrostatic arguments, outside the atomic core, such a bare pseudopotential must have a long-range, attractive Coulombic tail $-Z_{\mathrm{v}}/r$ (where r is the distance from the nucleus and Z_{v} is the valence charge, equal to the number of valence electrons in the neutral atom), the simplest bare pseudopotentials were of the form:

$$v^{\mathrm{ps,bare}} = \begin{cases} V_0, & r < r_{\mathrm{c}} \\ -Z_{\mathrm{v}}/r, & r > r_{\mathrm{c}} \end{cases} \qquad [5]$$

The only two parameters appearing in the above model (sometimes reduced to just one, the core radius r_{c}: see **Figure 3** and caption) were determined either from the isolated self-consistent atom or in other semi-empirical ways. Of course fancier models, with more parameters, were also conceived.

To use these bare pseudopotentials in, say, a molecule or a solid, one had then to screen them self-consistently with their valence electrons. For this purpose, the most popular choice within the

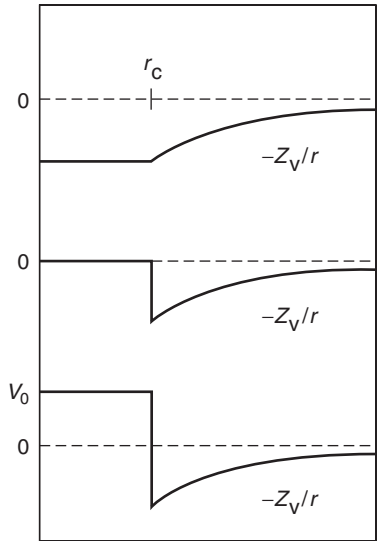

Figure 3 Model bare pseudopotentials. Lower panel: two-parameter pseudopotential. Upper and middle panels: one-parameter pseudopotentials, where the only parameter is the core radius r_c, roughly corresponding to the spatial extent of the outermost core orbitals, or to the outermost radial node of the true valence orbitals (see **Figure 2** and text).

solid-state community was the density-functional theory by Hohenberg, Kohn, and Sham, which, in 1964–65, had opened a historical avenue toward the calculation of structural and electronic properties of atoms, molecules, and extended systems. Here the screening potential (which appears, e.g., in eqn [1]) is $\tilde{v}_{\text{screen}} = v_{\text{H}} + v_{\text{xc}} = v_{\text{screen}}(\boldsymbol{r})$, where v_{H} is the Hartree potential (eqn [2]) and v_{xc} is another functional of the electronic charge density, which includes, in principle, all the exchange and correlation contributions due to the quantum many-body nature of the electronic interacting system. In practice, the functional v_{xc} was given by the (very fortunate) local density approximation, which adopts for v_{xc} an analytic expression derived from the homogeneous electron gas. This approximately yields a cube root law $v_{\text{xc}}(\boldsymbol{r}) \propto n^{1/3}(\boldsymbol{r})$ and thus, unlike the Hartree potential (eqn [2]), v_{xc} has a nonlinear dependence on the charge density: $v_{\text{xc}}[n_1(\boldsymbol{r}) + n_2(\boldsymbol{r})] \neq v_{\text{xc}}[n_1(\boldsymbol{r})] + v_{\text{xc}}[n_2(\boldsymbol{r})]$, a point which will be recalled later on. More accurate approximations of this functional are currently used. The density-functional approach has the additional bonus of a straightforward evaluation of the ground-state energy (yet another functional of the electronic density).

Molecular or solid-state systems were thus described in terms of model ions, sitting at the atomic positions, each represented by a model bare-ion pseudopotential like eqn [5], and valence electrons, self-consistently described with the density-functional theory. This approach gave important insight into the charge rearrangement around, for example, surfaces or defects, but definitely failed to provide reliable ground-state energies, and thus useful predictions on equilibrium atomic geometries. In the case of silicon, for example, it completely missed the experimentally stable diamond structure. Since, in the same decade, parallel applications of the density-functional theory to true, full-core systems (like, e.g., atoms and molecules) gave, instead, very reasonable energies, it appeared very likely that the bug was in the definition of the model pseudopotential. It was shown that model pseudopotentials not only gave poor ground-state energies for crystals, but already failed to faithfully reproduce the valence charge density of an isolated atom outside the core region; an increasing attention was thus paid to the tails of the pseudo-wave-functions in the isolated atom, with the goal of a completely coherent, first-principles definition of the pseudopotential, exclusively based on atomic wave-functions, within a given self-consistent scheme (usually the density-functional theory). The goal appeared very difficult and all the key concepts and approximations involved in the pseudopotential theory were critically revisited: is it at all possible that a smooth, local potential faithfully reproduces the effect of the true, full-core ion in a variety of different physical and chemical situations?

Nonlocal Pseudopotentials

From the original Phillips–Kleinman paper, it was actually clear that the radial orthogonality condition will, in general, produce angular-momentum dependent pseudopotentials. In boron, for example, the pseudo-valence-orbital of *s* symmetry feels an effective repulsive potential (**Figure 2**, bottom left) which is reminiscent of the orthogonality between the true 2*s* valence orbital and the 1*s* core orbital (top left). This is not the case, however, for the 2*p* valence orbitals (top right): for them, no effective repulsion is required in the pseudo-atom, because 2*p* is the lowest possible *p* state and, already in the true boron atom, its orbital has no radial nodes: at variance with the 2*s* states (top left), the 2*p* states (top right) have no underlying *p*-like core to be orthogonal to. In other words, if a pseudo-boron ion must accurately replace a true boron ion (nucleus plus core electrons), then, in the core region, the corresponding pseudopotential must be repulsive for *s* valence electrons but attractive for *p* valence electrons. The same situation holds not only for boron, but also for the entire first row of the periodic table (*sp* elements such as carbon, oxygen, or nitrogen), and, for similar reasons, for the first period of *d*- and *f*-transition elements. But the *sp* angular momentum dependence is not exclusive of

first-row atoms: second-row and heavier elements, which have both *s* and *p* electrons in the core, will have a similar, though less dramatic effect. For example, the silicon ion (not shown) has two *s*-shells but only one *p*-shell in the core, so its *s* valence electrons effectively feel a more repulsive potential than its *p* electrons. Some angular-momentum dependence may, in fact, be required for an accurate description of any element of the periodic table.

Mathematically, such angular-momentum dependent potentials are nonlocal potentials $\hat{v}^{\mathrm{NL}}$, whose action on a wave function ψ may be written, in real space, as

$$(\hat{v}^{\mathrm{NL}}\psi)_{\boldsymbol{r}} = \int \mathrm{d}\boldsymbol{r}' K(\boldsymbol{r}, \boldsymbol{r}')\psi(\boldsymbol{r}') \qquad [6]$$

where the kernel, for an atom sitting in the origin, is

$$K(\boldsymbol{r}, \boldsymbol{r}') = \sum_{lm} Y^*_{lm}(\hat{\boldsymbol{r}}) v_l(\boldsymbol{r}) \frac{\delta(r - r')}{rr'} Y_{lm}(\hat{\boldsymbol{r}}') \qquad [7]$$

and the angular-momentm projector selects the component of $\psi(\boldsymbol{r})$ onto which the corresponding $v_l(r)$ applies. An *s* electron will, for example, feel a radial potential $v_{l=0}$ (**Figure 2**, bottom left, black solid line) and a *p* electron a different potential $v_{l=1}$ (bottom right). This is sometimes called a "semi-local" potential, since it is nonlocal with respect to the direction $\hat{\boldsymbol{r}}$ (the angular coordinates θ, ϕ), but local with respect to the radial coordinate r (the electron's absolute distance from the nucleus). Nonlocal pseudopotentials of this kind attracted interest because, as mentioned, neither the local, empirical pseudopotentials (which had been successful in the basic understanding of bulk metals and semiconductors), nor the local, semi-empirical model potentials described in the previous section, could predict reliable structural properties and ground-state energies. Many groups reconsidered the possible relevance of nonlocal pseudopotentials and went back to the Phillips–Kleinman argument, but even an exact orthogonalization to the core atomic orbitals failed to produce a satisfactory solution of the transferability problem.

Norm-Conserving Pseudopotentials

The breakthrough came from a (by now classical) paper of Hamann, Schlüter, and Chiang, which appeared on *Physical Review Letters* in 1979, closely followed by a very similar, but independent paper of Kerker on the *Journal of Physics C*. They showed how to incorporate, from first-principles, the pseudopotential scheme within the density-functional theory. The key property of a transferable ionic pseudopotential, they said, is to exactly reproduce for each angular momentum, the corresponding valence wave function outside the atomic core. To obtain those exact tails, each valence state of different angular momentum must be subject to a different radial potential, as in eqns [6] and [7].

Why are wave function tails so important? Qualitatively, it is clear that they are the key ingredient for the formation of chemical bonds with neighboring atoms, and thus for accurate charge densities and ground-state energies. By the Gauss theorem, if the tails of the (normalized) pseudo-wave-functions depart from the true tails, then also the electrostatics of the pseudo-atom will inevitably fail to reproduce the true one. But the key observation was the finding that an exact reproduction of the tails ensures transferability: if the tails are right for the isolated atom, then even in a different chemical environment the pseudo-atom will behave like the true one.

Let the original Hamann–Schlüter–Chiang recipe be briefly recalled. First, one chooses a reference electronic configuration (say, the isolated neutral atom) for which the pseudopotential is constructed. For the true atom, the self-consistent radial equations, corresponding to eqn [1] with $\chi_{nl}(r) = r\,R_{nl}(r)$, are

$$\left[-\frac{1}{2}\frac{\mathrm{d}^2}{\mathrm{d}r^2} + \frac{l(l+1)}{2r^2} - \frac{Z}{r} + v_{\mathrm{screen}}\right]\chi_{nl} = \varepsilon_{nl}\chi_{nl} \qquad [8]$$

where $v_{\mathrm{screen}}(r) = v_{\mathrm{H}}[n^{\mathrm{v}} + n^{\mathrm{c}}] + v_{\mathrm{xc}}[n^{\mathrm{v}} + n^{\mathrm{c}}]$, and n^{v}, n^{c} are the charge densities associated to the occupied valence and core orbitals, respectively. One would now want to construct a pseudo-atom which, instead, satisfies

$$\left[-\frac{1}{2}\frac{\mathrm{d}^2}{\mathrm{d}r^2} + \frac{l(l+1)}{2r^2} + v_l^{\mathrm{ps,screened}}\right]\chi_l^{\mathrm{ps}} = \varepsilon_l\chi_l^{\mathrm{ps}} \qquad [9]$$

with ε_l identical to the valence ε_{nl} of eqn [8]. In eqn [9], the principal quantum number n can be dropped since the pseudo-atom has only valence states, and, for each l, there is just one valence radial pseudo-wave-function. The presence of a different radial potential $v_l^{\mathrm{ps,screened}}$ for each l means that this construction allows for a nonlocal potential of the type just discussed. Such a construction starts from the end: one first defines the desired pseudo-wave-functions and then, by inverting the eqn [9], the pseudopotential.

In the first step, for each l, an optimal pseudo-wave-function $\chi_l^{\mathrm{ps}}(r)$ is constructed by exactly matching, at an appropriate core radius r_{c}, the (numerically available) tail of the corresponding true wave function with some smooth, analytical, nodeless radial function defined between $r = 0$ and $r = r_{\mathrm{c}}$, such that the resulting pseudo-wave-function is still correctly normalized to one. For each l, this implies by construction

that the partial norm up to r_c of the true and pseudo-wave-functions is identical,

$$\int_0^{r_c} \mathrm{d}r[\chi_l^{\mathrm{ps}}(r)]^2 = \int_0^{r_c} \mathrm{d}r[\chi_{nl}(r)]^2 \qquad [10]$$

since both radial orbitals are normalized to one. Because of this property, the new generation of first-principles pseudopotentials was called norm-conserving. The norm conservation, eqn [10], not only guarantees the correct electrostatics for the chosen reference atom; its mathematics also ensures, as shown in the original paper, that the scattering properties (hence the bonding properties) of the true and pseudo-atoms closely follow each other over an energy range of $\sim 20\,\mathrm{eV}$ around ε_l; this, as confirmed by a wealth of subsequent applications, amounts to an optimum transferability. Incidentally, the remarkable consequences of eqn [10] shed new light on the links between the pseudopotential method and other electronic-structure methods.

In the second step, once such a good $\chi_l^{\mathrm{ps}}(r)$ has been built, eqn [9] may be inverted to yield the corresponding $v_l^{\mathrm{ps,screened}}$, the screened ionic pseudopotential appropriate to the angular momentum l. This radial function is shown for $l = 0$ (left) and $l = 1$ (right) as a solid black line in the bottom panels of **Figure 2**.

From $v_l^{\mathrm{ps,screened}}$, in the third and final step, the bare ionic potential $v_l^{\mathrm{ps,bare}}$ is extracted with a simple unscreening prescription.

$$v_l^{\mathrm{ps,bare}}(r) = v_l^{\mathrm{ps,screened}}(r) - v_{\mathrm{H}}[n^{\mathrm{ps},v}] - v_{\mathrm{xc}}[n^{\mathrm{ps},v}] \qquad [11]$$

where $n^{\mathrm{ps},v}$ is the pseudo-charge-density of the (just constructed) valence orbitals appearing in eqn [9]. This bare ionic pseudopotential is the actual ingredient of all subsequent calculations; its pseudo-valence-electrons will be allowed to self-consistently rearrange and produce different screening effects in response to different molecular and solid-state environments.

Pseudopotentials That Work

The Hamann–Schlüter–Chiang prescription proved extremely successful for many elements of the periodic table: when these nonlocal pseudo-ions were fed into the scheme based on plane-wave basis functions proposed in the same years by Ihm, Zunger, and Cohen, the structural energies predicted by their self-consistent screening suddenly came out in excellent agreement with experiments. Not only was the diamond structure finally obtained as the lowest-energy crystal structure for silicon, but also its bulk modulus and phonon frequencies, which involve higher derivatives of the energy with respect to the atomic positions, were very accurately reproduced from first-principles, without the need of any adjustable parameter. This suggested a fully reliable theoretical framework, at least for materials where electron correlations are not too strong and the current approximations of the exchange-correlation density functional are satisfactory for the corresponding full-core systems. A second "pseudopotential gold rush" took place, this time aimed at the prediction of unknown equilibrium geometries of surfaces, defects, dislocations, and also at phonon spectra and at the stability of new compounds.

An additional reason for this unprecedented success was a remarkable advantage of plane waves over any set of localized basis functions which – like atomic orbitals, gaussians, muffin-tin orbitals – are attached to atoms and follow their positions. With plane waves, which are independent of the atomic positions in the crystalline unit cell, interatomic forces have a particularly simple expression, related to the Hellmann–Feynman theorem. Forces are thus another almost automatic, accurate byproduct of a density-functional self-consistent calculation based on plane waves and pseudopotentials.

This advantage proved precious in the determination of equilibrium geometries of unknown low-symmetry structures (such as the 2×1 reconstruction of the silicon surface established in those years by Kosal Pandey) or phonon force constants, as shown by Martin and Kunc; but its vital importance became apparent when Car and Parrinello, in 1985, invented a method which combines molecular-dynamics simulations and the density-functional theory. This idea opened to pseudopotentials a completely new field: the real-time microscopic dynamics of the constituent atoms in covalent and metallic systems, or even in the context of chemical reactions.

Other outstanding examples of the combined power of plane waves and pseudopotentials are the linear-response perturbation theory elaborated in 1987 by Baroni, Gianozzi, and Testa, which allows the direct calculation of the full phonon dispersion curves as well as the dielectric and piezoelectric tensors, and the Berry-phase approach to the spontaneous polarization of ferroelectric materials, developed by Vanderbilt and Resta in 1993.

The improved predictive power of contemporary exchange-correlation functionals, which are superior to the original local density approximation, and also some key developments of the original Hamann–Schlüter–Chiang formulation, presented in the appendix, have made the first-principles pseudopotential method a standard working tool for the investigation of real materials and relatively complex molecular systems not only for theorists, but also for

experimentalists, both in the field of solid-state physics and chemistry. The corresponding computer programs, which in 1980 used to be the privilege of a few pioneering groups and would require large-scale computational facilities, are today available in the public domain and may be executed by an undergraduate student on a personal computer.

Appendix: Key Ingredients of Contemporary Pseudopotentials

In the previous section, for the sake of clarity and simplicity, norm-conserving pseudopotentials were presented in their plain, original version. However, the predictive power and computational feasibility reached by contemporary first-principles pseudopotential methods, mentioned at the end of the previous section, would never have been possible without a number of significant improvements and innovations over the original Hamann–Schlüter–Chiang scheme. They are briefly reviewed in this last section.

Nonlinear Core Correction

Shortly after the discovery of norm-conserving pseudopotentials, Louie, Froyen, and Cohen observed that the original unscreening procedure is the simplest, but not always the best one. As a matter of fact, it implicitly assumes that, in the true atom (eqn [8]), the screening potentials depend linearly on the electronic charge density. If it were so, then there would be no error when the screening potential due to the valence charge n^{v} alone, subtracted out at the atomic stage (eqn [11]), is self-consistently added back to the bare pseudopotential in the context of a different molecular or solid-state situation. Unfortunately, such a linear behavior exactly holds for the Hartree potential $v_{\mathrm{H}}[n]$, which, as evident from eqn [2], is a linear functional of the charge density $n(r)$ (i.e., $v_{\mathrm{H}}[n^{\mathrm{v}}+n^{\mathrm{c}}]=v_{\mathrm{H}}[n^{\mathrm{v}}]+v_{\mathrm{H}}[n^{\mathrm{c}}]$), but, as already mentioned, does not hold for the exchange-correlation functional $v_{\mathrm{xc}}[n]$, which is a strongly nonlinear functional of its argument.

Fortunately, core and valence charge densities are often well separated, and thus scarcely overlapping, and this nonlinearity may be safely disregarded: whenever n^{v} rapidly vanishes inside the core and n^{c} rapidly vanishes outside the core, then, apart from a small overlap region, the approximation $v_{\mathrm{xc}}[n^{\mathrm{v}}+n^{\mathrm{c}}]\simeq v_{\mathrm{xc}}[n^{\mathrm{c}}]+v_{\mathrm{xc}}[n^{\mathrm{v}}]$, implicit in the unscreening procedure (eqn [11]), is a good one. This is why the original, simple unscreening procedure works well for many elements of the periodic table – those with well-separated core and valence shells.

But quite a few elements of the periodic table do not share the clearcut core-valence separation (both in real space and in energy) of the examples shown in **Figures 1** and **2**. When the underlying core is shallow, as it happens in most alkali elements, or when two different principal quantum numbers are present in the valence shell (like *d*- or *f*-transition elements), and also in a few other cases, the core-valence overlap may be remarkable, and the nonlinearity of $v_{\mathrm{xc}}[n]$ can seriously hinder the main virtue of norm-conserving pseudopotentials: their transferability. For these atoms, such a desirable virtue is recovered by an alternative unscreening prescription proposed by Louie and co-workers:

$$v_l^{\mathrm{ps,bare}}(r)=v_l^{\mathrm{ps,screened}}(r)-v_{\mathrm{H}}[n^{\mathrm{ps,v}}]-v_{\mathrm{xc}}[n^{\mathrm{ps,v}}+n^{\mathrm{c}}]$$

In this way, the core charge density $n^{\mathrm{c}}(r)$ of the true atom (or an appropriate model thereof) becomes an ingredient of the pseudo-ion, and, although frozen in the reference atomic state, must be carried along with the bare-ion pseudopotential $v_l^{\mathrm{ps,bare}}$ and used in all subsequent molecular or solid-state calculations; this is done by adding it back to the pseudo-valence-charge, of course, within the exchange-correlation potential only. Such a nonlinear core correction restores the nonlinear character of the interaction between a valence electron and the ionic core, and proved to be successful in all the problematic cases mentioned above, for which it immediately became the standard solution.

Relativistic Effects and Separable Pseudopotentials

Two other important developments of modern first-principles pseudopotentials involve one of the fathers of the pseudopotential theory, Leonard Kleinman.

One concerns the possibility of including in the pseudopotential relativistic effects to order α^2, where $\alpha\simeq 1/137$ is the fine-structure constant. Kleinman showed that the Hamann–Schlüter–Chiang construction can be generalized to the relativistic case, and that the resulting pseudopotential can be conveniently used to treat heavy atoms in a nonrelativistic formalism. The reason for this is that relativistic effects on the valence electrons are limited to the core region (only there the valence radial wave functions of the true atom have wiggles, and thus a very high kinetic energy), and can be lumped together with other properties of the core to yield a Schrödinger-like pseudo-atom. This development opened the way to the construction of norm-conserving pseudopotentials for the whole periodic table, from hydrogen to plutonium.

The second development, due to Kleinman and Bylander, amounts to an approximate transformation of the kernel K from its original semilocal form,

given by eqn [7], into a fully nonlocal, but separable kernel $\tilde{K}$ of the form

$$\tilde{K}(\boldsymbol{r},\boldsymbol{r}') = \sum_{lm}\sum_{\beta} Y^*_{lm}(\hat{\boldsymbol{r}})w^*_{\beta l}(r)w_{\beta l}(r')Y_{lm}(\hat{\boldsymbol{r}}') \quad [12]$$

This brings no advantage to the transferability of the pseudopotential, but there is a consistent computational advantage over the original semilocal form. Indeed, the semilocal form requires, to be calculated and stored in $\boldsymbol{G}$-space, an $N_{\mathrm{pw}} \times N_{\mathrm{pw}}$ matrix (if N_{pw} is the number of plane-wave basis functions), whereas a separable pseudopotential can be factorized as a product of two N_{pw} dimensional vectors. For this reason, the Kleinman–Bylander form is now included in all the computer programs dealing with pseudopotentials.

Ultrasoft Pseudopotentials for Hard Atoms

The success of pseudopotentials is largely related to the fact that pseudo-wave-functions can be expanded within a tractable number of plane waves. Not surprisingly, pseudo-atoms with core radii r_{c} imply a plane-wave cutoff $G_{\mathrm{cut}} \sim 2\pi/r_{\mathrm{c}}$ and thus, if the core radius adopted in the pseudopotential construction is too small (compared to typical interatomic distances), then the corresponding pseudopotential is too hard, in the sense that the number of plane waves required to describe its norm-conserving wave functions (eqn [10]) becomes unacceptably large. This happens for the elements with one radially nodeless orbital ($2p$, $3d$, $4f$) in the valence shell. For these valence states, a norm-conserving pseudo-valence-orbital cannot be too different from the original true orbital: near $r = 0$, they both have to go like r^{l+1}; beyond r_{c}, they are identical by construction; between 0 and r_{c}, they are both nodeless and, by eqn [10], they must have the same partial norm. Under these circumstances, it is easy to see that the pseudopotential resulting from the inversion of the Schrödinger eqn [9] will inevitably have strong spatial variations in the small interval between 0 and r_{c}, and thus will be hard, requiring too many plane waves in the corresponding wave functions, as it happens, for example, in the case of the boron p pseudopotential, shown in the bottom right panel of **Figure 2**.

In order to obtain manageable pseudopotentials for these atoms, Vanderbilt proposed a radical departure from the Hamann–Schlüter–Chiang procedure: a more complicated pseudopotential scheme (based on generalized orthonormality conditions) which, by releasing the condition of norm conservation, allowed the generation of a new family of very smooth (ultrasoft), yet reliable and transferable pseudopotentials. In this scheme, the pseudo-wave-functions are allowed to be as soft as possible within the core region, so that the plane-wave cutoff G_{cut} can be reduced dramatically. The scheme works very well even for the worst cases, the hard atoms mentioned above: when applied to the study of compounds involving transition metals and rare-earth atoms as well as nitrides and oxides, the scheme has proved accurate and reliable, and has been adopted and implemented by many groups, in spite of its greater conceptual and numerical complexity.

Pyroelectricity

P Muralt, Swiss Federal Institute of Technology (EPFL), Lausanne, Switzerland

Introduction

Pyroelectricity provides one of the best performing principles for the detection of temperature changes. This occurs in polar matter and results in the appearance of surface charges proportional to a temperature change ΔT. The basic structure is a planar capacitor whose charge Q varies according to $\Delta Q = Ap\Delta T$, where A is the area of the capacitor and p the pyroelectric coefficient. A pyroelectric sensor thus directly generates an electric signal, facilitating the integration into electronic circuits. Pyroelectric crystals, ceramics of ferroelectric materials, as well as polymers have therefore been used since the 1960s in thermal infrared (IR) detectors, joining the earlier thermal IR detection techniques of bolometers and thermopiles. Since the late 1980s, pyroelectrics have also been investigated in the form of thin films and integrated onto micromachined structures. Pyroelectricity thus made its way from a scientific curiosity known since 2500 years to a very useful physical effect that, for instance, enables firemen to see through smoke.

Fundamentals

Pyroelectricity is the electrical response of a polar, dielectric material to a change in temperature. The origin of this effect lies in polar features that are lined up with the same orientation along at least one direction in the material. In polymers, the polar features are polar molecules or groups. One can thus identify microscopic dipoles. In inorganic materials it is often not possible to identify dipoles. It is rather the anisotropy and anharmonicity of chemical bonding that results in the center of gravity of the positive charges moving differently than the center of gravity of the negative charges upon changing the temperature. The case is illustrated schematically in **Figure 1** for a periodic one-dimensional structure. Polarization of periodic structures is a delicate issue and needs careful discussion. The essential point is that the spring constants f_1 and f_2 are different and vary differently with temperature. The macroscopic dipole originating from the way the chain is cut is of no importance because (1) this cut does not change with temperature, (2) each chain is cut in a different way and the net charge is averaged out, and (3) there is anyhow charge compensation with time (leakage). Changing the temperature leads to a relative displacement of the positive ions with respect to the negative ones. In **Figure 1**, the spring constant f_2 hardens more than f_1 upon cooling and the positive ions are shifted toward the negative ones to the right. As a result, the net charges on the electrodes are increased positively on the right, and negatively on the left. These are the pyroelectric charges. An equivalent effect results if negative charges (electrons) from the negative ions move toward the positive ions by a charge transfer process. More insight into such mechanisms of covalent nature in ionic crystals have recently been gained by first-principle calculations.

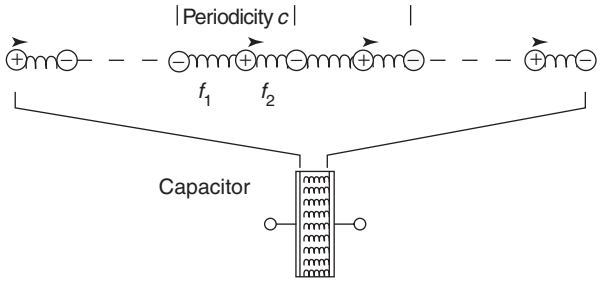

Figure 1 One-dimensional model of a periodic polar material in a capacitor structure.

In crystalline matter, pyroelectricity occurs in all materials with symmetries that allow the existence of a polar direction. No symmetry element may exist in the point group that inverts or rotates this direction by 180°. Such materials are also piezoelectric, i.e., they respond with an electric field to a change of the shape. From the 20 piezoelectric point groups, 10 are polar and allow for pyroelectricity. The pyroelectric effect is anisotropic and depends on the directions of the electroded faces with respect to the crystal axes: $p = (p_x, p_y, p_z)$. The highest pyroelectric coefficients are measured in ferroelectrics. In such substances there is a spontaneous electric polarization P_s that can be inverted by the application of an external electric field, and consequently is a measurable physical quantity. Upon heating up, P_s diminishes and becomes zero at the critical temperature of the ferroelectric–paraelectric phase transition as depicted in **Figure 2** for a second-order phase transition. The symmetry group of the ferroelectric phase is a subgroup of the symmetry group of the paraelectric phase, that is, a number of symmetry elements are lost (certainly the inversion element, if present in the paraelectric phase). The direction of P_s is not uniquely defined. Turning an existing solution by

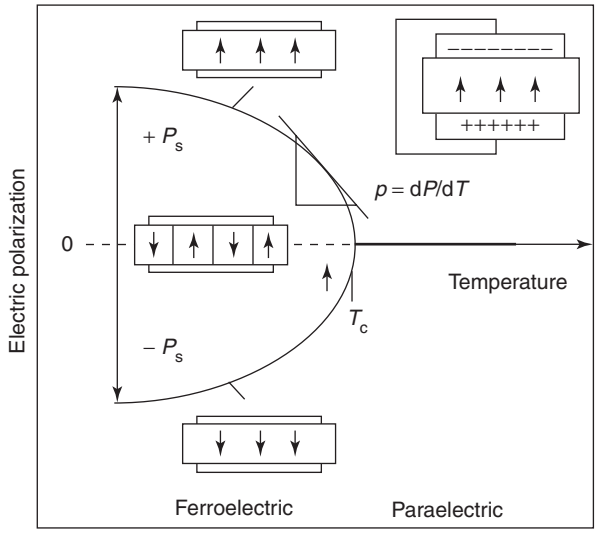

Figure 2 Schematic graph showing the bifurcation (second-order phase transition) of the electrical polarization at the critical temperature from $P = 0$ (paraelectric phase) to the two equally probable solutions $+/-$ P_s for the spontaneous polarization in the ferroelectric phase. The inserted capacitors show extreme cases of 180° domain configurations.

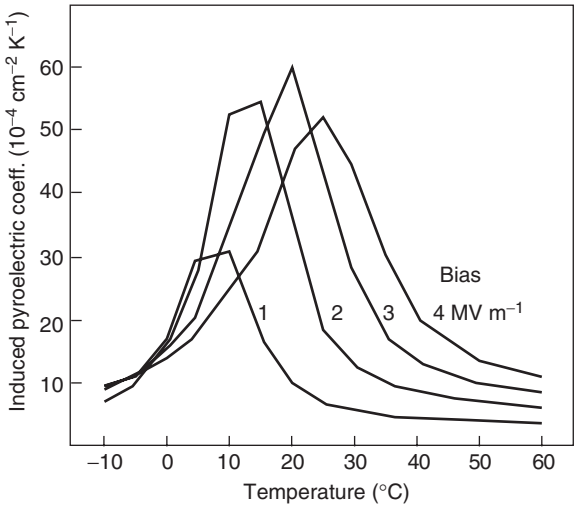

Figure 3 Experimental curves for the induced pyroelectric coefficient in lead scandium tantalate. (Courtesy of R Watton and MA Todd.)

180° (applying the lost inversion, mirror or rotation symmetry) yields always another, equally probable solution. Regions with homogeneous polarization are called domains. For achieving a macroscopic polarization, a poling process in an external electric field – often combined with heating above room temperature – must be applied to eliminate the 180° domains and to also possibly switch ferroelastic domains. The macroscopic orientation obtained after removal of the external field is called remanent polarization P_r.

The charges on the electrodes are given by the electric displacement field D perpendicular to the electrode faces. Giving the index 3 to this direction, the pyroelectric coefficient is equal to $\partial D_3/\partial T$. The electric displacement field in ferroelectrics can be written as $\boldsymbol{D}(\boldsymbol{E}) = \varepsilon_0 \boldsymbol{E} + \boldsymbol{P}(\boldsymbol{E})$, where ε_0 means the permittivity of the vacuum. The polarization part is much larger and the only temperature-dependent term. For the present discussion, one can set D equal to P

$$\Delta D_3 = \frac{\partial P_3(E)}{\partial T}\,\Delta T \cong \frac{\partial P_{r,3}}{\partial T}\,\Delta T + \frac{\partial \varepsilon_{33}}{\partial T}\,E_3 \Delta T \quad [1]$$

The first term is called the true pyroelectric effect and $p = \partial P_{r,3}/\partial T$ is the true pyroelectric coefficient. The second term arises from the first-order correction for $P_r(E)$. Pyroelectricity, arising due to this second term, is called induced pyroelectricity. Accordingly, there are two modes of operations for pyroelectric IR detectors. The first one works without an external electric field at a temperature much below the para-to-ferroelectric phase transition. The polarization P_r has previously been maximized by hot poling at an elevated electric field, assuring a good time stability of p at the application temperature around room temperature. The second mode exploits the peaking of p near the phase transition. A DC electric field needs to be applied to obtain a nonzero average polarization. One speaks of induced pyroelectric currents or sometimes of dielectric bolometer mode, since the field dependence of P can be considered as a dielectric property. The applied field has not only the effect of eliminating 180° domains, it broadens and shifts (first-order transition only) the phase transition to higher temperatures. This leads to a reduction of the signal. There is thus an optimal DC field (a few MV m^{-1}) and temperature (see **Figure 3**) at which the response is peaking. The temperature of such a device needs to be stabilized. The advantage of the first method is the simplicity of operation conditions: no DC field and no temperature stabilization are needed. The second method allows higher sensitivities.

In the following the phenomenological theory of Landau, Ginzburg, and Devonshire (LDG) is used to gain some better insight into the difference of true and induced pyroelectricity and to prepare the ground for discussing materials figure of merits. The free energy density G of the ferroelectric phase is written as

$$\begin{aligned} G(T,P) &= \tfrac{1}{2}\,\beta(T - T_0)P^2 + \tfrac{1}{4}\,\gamma P^4 + \tfrac{1}{6}\,\delta P^6 \\ E &= \beta(T - T_0)P + \gamma P^3 + \delta P^5 \end{aligned} \quad [2]$$

The derivation with respect to P yields the electric field E. The lowest energy at $E = 0$ yields the spontaneous polarization P_s. The inverse permittivity due

to the ferroelectric effect is equal to the second derivative of G with respect to P. A general relation is found for the true pyroelectric coefficient as follows: $p = -\beta\varepsilon P_s$. High pyroelectric coefficients are thus found in materials with high polarization and high coefficient β. The true pyroelectric voltage response, which is proportional to p/ε, follows the spontaneous polarization and is thus optimal at low temperatures, far below the phase transition. In case of a second-order phase transition ($\gamma > 0$), and neglecting the sixth-order term ($\delta = 0$), the spontaneous polarization is readily obtained as $P_s = ((\beta/\gamma)(T_0 - T))^{1/2}$. The true pyroelectric coefficient is derived as $p = (-1/2)(\beta/(\gamma(T_0 - T)))^{1/2}$. The pyroelectric coefficient diverges at the phase-transition temperature T_0. So does the permittivity, for which below the critical temperature T_0, the relation $\varepsilon^{-1} = \partial^2 G/\partial P^2 = 2\beta(T_0 - T)$ is obtained. The pyroelectric coefficient obviously behaves as the square root of the permittivity, that is, $p/\sqrt{\varepsilon} = -\beta\sqrt{2/\gamma} = \text{const.}$ In ideal first-order transitions ($\gamma < 0$, $\delta > 0$), the critical temperature $T_c = T_0 + 3\gamma^2/(16\beta\delta)$ is above T_0 and the polarization jumps form 0 to $\sqrt{-3\gamma/3\delta}$. The permittivity remains finite but jumps as well at T_c. The jump of P_s at T_c gives rise to large pyroelectric currents. Induced pyroelectricity is thus very large in materials with first-order phase transitions. In addition, the field needed for induced pyroelectricity does not simply broaden the transition as in the case of second-order phase transitions, but the discontinuity of P is preserved up to a certain critical field. The critical temperature is shifted to higher temperatures up to a maximal possible value of $T_{max} = T_0 + (9\gamma^2)/(20\beta\delta)$. For illustration, calculated curves are depicted in **Figure 4** for a model substance.

A further type of phase transition that attracts attention for being used in the induced pyroelectric mode is the relaxor-ferroelectric transition. It occurs typically in specifically disordered ferroelectrics, where, for instance, the B-site of the perovskite ABO_3 is a mixture of randomly distributed ions of different valency. In the above-mentioned $PbSc_{0.5}Ta_{0.5}O_3$, Sc^{3+} and Ta^{5+}, ions occupy, in a 1:1 mixture, a site that should have a $4+$ ion. If the two different ions are ordered in a periodic manner, the above discussed ideal first-order phase transition takes place; if they are disordered, the ferroelectric phase is shifted to lower temperatures. Usually, very high low-frequency permittivities are obtained around the phase transition. It is thought that random internal fields prevent a homogeneous, ferroelectric polarization. Instead, local polar regions appear that easily grow in an external field thus providing for the huge dielectric response. There are chances that the absence of domain or phase

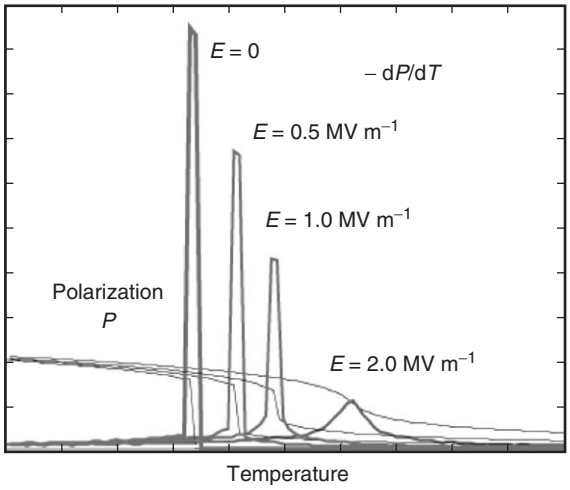

Figure 4 Theoretical behavior of the pyroelectric coefficient as a function of temperature and for various electric fields, as derived from the Landau–Devonshire model. The behavior near the phase transition in the absence of an external field is purely theoretical, since the average polarization decays to zero by thermal fluctuations.

fluctuations in the relaxor phase allow for working points with a larger dP/dT and a lower $\tan\delta$. A modeling of this issue is missing to date.

The pyroelectric charge is usually not directly measured as a charge but as a current I through a capacitor of surface A. Taking the time derivative of eqn [1]

$$I = A\frac{dD_3}{dt} = Ap\frac{dT}{dt} \qquad [3]$$

The current measurement is much less prone to drifts and also faster than charge measurements. In addition, charges are compensated with time either because of leakage currents through the pyroelectric capacitor, or by conduction through air, or along the device surface. For imaging static pictures or temperatures, a chopper is applied that modulates the infrared radiation falling onto the detector with a constant angular frequency $\omega = 2\pi f$. The frequency f amounts to 30–60 Hz for imaging applications.

Several methods have been proposed for the measurement of the pyroelectric effect of bulk or thin-film samples. The most frequently applied techniques are based on the pyroelectric current generated by a temperature ramp of constant rate (i.e., $dT/dt = \text{const.}$), yielding a constant pyroelectric current according to eqn [3]. One speaks of the Byer–Roundy technique when a single ramp is applied. It is important to check heating and cooling curves, because the release of trapped charges (thermally induced currents) might falsify the heating curve. Such trapped charges are injected into the sample during the poling procedure. An improvement of the method is

obtained by cycling the temperature periodically. The temperature is swept up and down with small amplitudes (e.g., 1 K) and with constant rates (e.g., $0.25\,\mathrm{K\,s^{-1}}$) around a given average temperature. The pyroelectric current, being proportional to the slope of the temperature, will switch between two constant values after some stabilization time. The temperature is best controlled on a small chuck equipped with Joule heating and Peltier cooling elements, placed in a chamber protecting from perturbations. For higher modulation frequencies, temperature changes are induced by chopped light absorption (Chynoweth). However, this technique is more qualitative than quantitative as it requires the determination of thermal properties until the temperature change is really known. Sometimes the polarization is measured as a function of temperature. This is rather dangerous, since the polarization must be derived from a hysteresis loop obtained by switching the polarization. First, it is not sure whether the complete polarization is switching, second fatigue could reduce polarization more efficiently than the temperature increase.

The quality of a sensor does not only depend on sensitivity, but also on the signal-to-noise ratio (S/N ratio), or in other words, the noise level. The intrinsic noise type of pyroelectrics is the Johnson noise of the capacitor element. For a capacitor of area A and thickness t, the noise current is obtained as

$$I_\mathrm{n} = \sqrt{\frac{A}{t}\,4kT(\sigma + \omega\varepsilon\,\tan\,\delta)\Delta f} \qquad [4]$$

where σ is the leakage conductivity of the pyroelectric thin film (in bulk detectors, the parallel resistor), ω the angular frequency, $\tan\,\delta$ the loss tangent, Δf the frequency bandwidth, A the surface, and t the thickness of the element. The cross over frequency $\omega_\mathrm{cn} = \sigma/(\varepsilon\,\tan\,\delta)$ between resistor type noise and dielectric noise amounts to typically 0.1–10 Hz. At usual modulation frequencies of 10–60 Hz, the dielectric noise is thus dominating. The intrinsic figure of merit of the dielectric and pyroelectric materials parameters for an optimal S/N ratio can thus be formulated as

$$\mathrm{FM} = \frac{p}{\sqrt{\varepsilon\,\tan\,\delta}} \qquad [5]$$

Various phenomena can contribute to the dielectric loss. At high frequencies (GHz and higher), the dielectric loss increases due to interactions of phonons and AC electric fields. In noncentrosymmetric materials, the dominating phonon mechanism is the quasi-Debye loss mechanism. Thermal fluctuations and relaxation of phonons lead to charge fluctuations in a similar way as dipoles give rise to loss in the Debye theory. In ferroelectrics, domain wall relaxations play a role as well. In the 1–10 GHz range, there is usually a relaxation of 180° domain wall motions. All these mechanisms yield a $\tan\,\delta$ that increases at least linearly with the dielectric constant, that is, $\tan\,\delta \propto \varepsilon^\alpha$, where α is between 1 and 4. It is difficult to make a general theory on loss mechanisms at very low frequencies of a few tens of hertz. In this region, the dielectric loss is governed by defects and ferroelectric domains. Charged or dipolar point defects relax with respect to position or orientation, structural defects may interfere with electric fields by means of the piezoelectric coupling, and defects may delay domain wall motions or give rise to a creeping of domain walls. Many of the low-frequency relaxation mechanisms show again a $\tan\,\delta$ proportional to ε. Near the critical temperature, polarization fluctuation and phonon losses (soft mode) were found to follow a Curie–Weiss law like the dielectric constant, meaning that $\tan\,\delta$ diverges as well at the critical temperature. This has, for instance, been found in 1991 by R Watton and M A Todd where the loss tangent and the dielectric constant increase by about the same factors upon approaching the critical temperature ($PbSc_{0.5}Ta_{0.5}O_3$). The materials figure of merit FM thus behaves rather like $p\varepsilon^{-1}$ than $p\varepsilon^{-1/2}$ especially near critical temperatures.

Evaluating the FM by means of the LDG theory leads to the conclusion that, in case of second-order phase transitions, there is no improvement of the intrinsic S/N ratio when going closer to the phase transition. $p\varepsilon^{-1/2}$ is, in fact, independent of temperature, and taking into account the increasing dielectric losses, the intrinsic signal to noise is expected to decrease with temperature. The case of first-order transitions is more difficult to judge. The permittivity does not diverge at the phase transition, there is only a discontinuity. Lead scandium tantalate showed an increase of FM of nearly a factor 3, hence a clear advantage for induced pyroelectricity in this case. The optimal DC field is, however, not the one at which the pyroelectric current is peaking, that is, inside the hysteretic first-order transition with mixed phase noise, but just somewhat above the critical field at which the jump in polarization is lost.

Operational Principles of Pyroelectric IR Detectors

The main application of pyroelectric materials is detection of IR radiation. The latter is measured indirectly by means of a temperature change ΔT of an absorbing structure as a result of the absorbed radiation power. The thermal properties of the absorbing structure have to be suitably designed for obtaining a

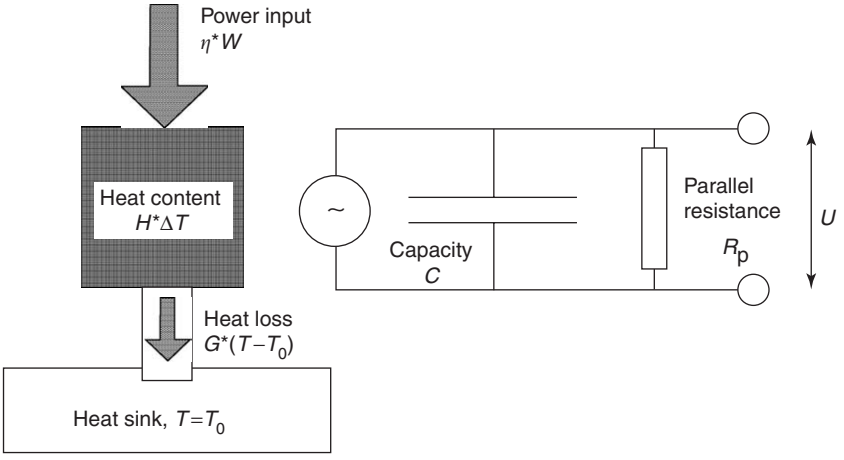

Figure 5 Schematic of thermal and electrical circuit of a pyroelectric element.

maximal temperature increase ΔT at the required response frequency. ΔT is obtained from the balance of the heat flows, as sketched in **Figure 5**. First of all, some fraction η of the IR radiation (power W) falling onto the element is absorbed, that is, transformed into heat. The temperature change at a given heat input $\eta \cdot W \cdot \Delta t$ depends on the heat conductivity G to the surrounding heat reservoir (heat sink) at temperature T_0 and the heat capacity H of the element. It is supposed that the element exhibits a uniform temperature. Thermal wavelength effects are thus neglected. This is justified in thin structures with uniform illumination by the IR radiation. (In $PbTiO_3$ with $c_p = 3.2\,\mathrm{MJ\,m^{-3}\,K^{-1}}$ and $\kappa = 3.8\,\mathrm{W\,m^{-1}\,K^{-1}}$, the thermal wavelength amounts to 600 µm at 1 Hz and 20 µm at 1 kHz.) Considering stationary solutions in the frequency domain for an IR power of $W = W_\omega \cdot e^{i\omega t}$, the temperature modulation is readily obtained as

$$\Delta T_\omega = \frac{\eta W_\omega}{G + i\omega H}, \qquad |\Delta T_\omega| = \frac{\eta W_\omega}{G\sqrt{1+\omega^2\tau_{th}^2}} \quad [6]$$

The thermal time constant $\tau_{th} = H/G$ has been introduced. There are thus two frequency domains separated by the inverse thermal time constant. The current responsivity, that is, the current response per watt of radiation power falling onto the detector element is obtained as

$$\Re_J(\omega) = \frac{J_\omega}{W_\omega} = \frac{p\eta\omega A}{G\sqrt{1+\omega^2\tau_{th}^2}} \quad [7]$$

Alternatively, the voltage across a parallel resistor R_p can be measured. In bulk devices, a value of 10 GΩ is typically applied (R_p should not exceed the gate impedance of the amplifier). In thin-film devices, leakage through the film may yield an R_p in a good value range. At higher frequencies, the dielectric loss tangent $\tan\delta$ also comes into play. The conductance Y of the complete element (thus including the parallel resistance) is obtained as

$$|Y(\omega)| = \frac{1}{R_p}\sqrt{(1+\omega\tau_{el}\tan\delta)^2 + \omega^2\tau_{el}^2} \quad [8]$$

The electrical time constant $\tau_{el} = R_p \cdot C$ has been introduced. The voltage response is proportional to the impedance $Z = Y^{-1}$. Above the angular frequency τ_{el}^{-1}, the impedance decreases as ω^{-1}. The pyroelectric element thus works like a low pass filter, cutting off the high-frequency voltage response. Omitting the small term in $\tan\delta$, the complete voltage responsivity is written as

$$\Re_V(\omega) = |Z(\omega)|\Re_J(\omega) = \frac{p\eta\omega A R_p}{G\sqrt{1+\omega^2\tau_{th}^2}\sqrt{1+\omega^2\tau_{el}^2}} \quad [9]$$

The general trends of the two responsivity functions depends on the relative size of the two time constants. In bulk devices, one generally encounters $\tau_{el} < \tau_{th}$. The inverse situation, that is, $\tau_{el} > \tau_{th}$, is typically thin-film structures. The resultant frequency behavior for thin films is schematically shown in **Figure 6**. In thin-film devices, the parallel resistance is not directly involved in the voltage response. This is very advantageous, as film leakage is not easy to control precisely. The mounting of parallel resistors can be avoided if the leakage is sufficiently large to avoid discharging through the input gate of the voltage amplifier. Observing that $C = \varepsilon A/t_p$, the response can further be developed in the intermediate region as $\Re_V \cong (\eta p t_p)/(\varepsilon G)$ in case of thin films, and $\Re_V \cong (\eta p A R_p)/H$ in the bulk case. The figure of merit given in general, $F_V = p/\varepsilon c_p$, corresponds to a

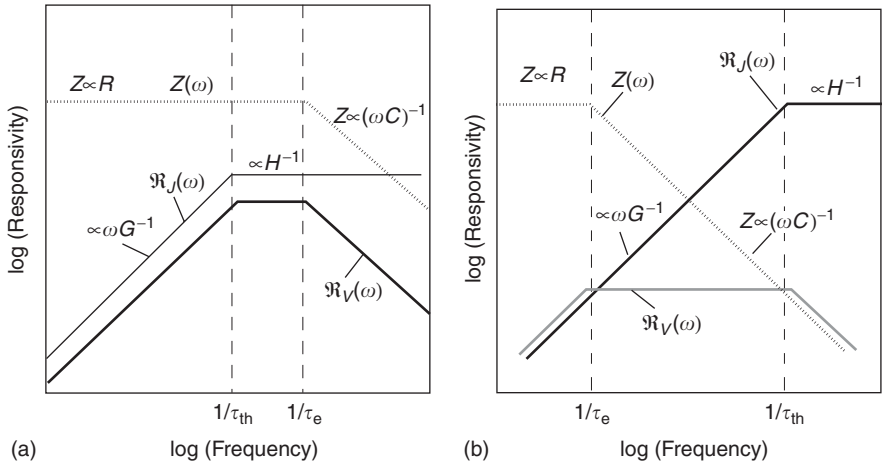

Figure 6 Log–log scheme of current and voltage response, together with the impedance for the typical bulk (a) and thin-film situation (b).

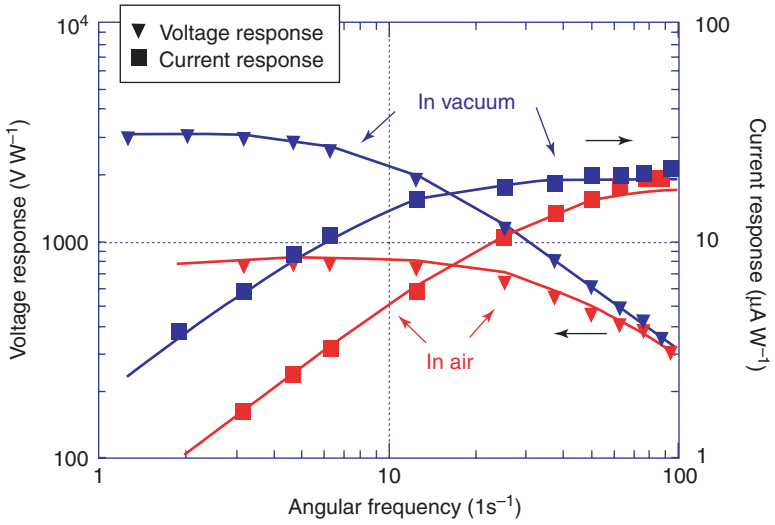

Figure 7 Voltage and current responsivity of a linear array element (1 × 12) measured in air and in vacuum. One element was 0.4 × 0.9 mm large. The curves are calculated according to eqns [7] and [9], the points are measured. (From Kohli M, Wüthrich C, Brooks KG, Willing B, Forster M, *et al.* (1997) Pyroelectric thin film sensor array. *Sensors and Actuators A* 60: 147–153.)

mix of those two situations, and is relevant in any case for the high-frequency case. It includes both the dielectric constant (note that $\varepsilon = \varepsilon_0 \varepsilon_r$) and the specific heat capacity c_p.

A small thickness is favorable to drive the current response up. The impact of the heat conductivity G at intermediate and low frequencies, and its unimportance at high frequencies, is demonstrated in **Figure 7**, which depicts the response of a pyroelectric detector in air and in vacuum, that is, once with air convection (large G), and once without air convection (small G).

The ultimate detection limit of a sensor is given by the intrinsic noise of the detector element. In order to reach this limit with the complete sensor setup, the noise contribution from the amplifier and from external sources of the environment have to be smaller than the intrinsic noise. Using low-noise amplifiers such as J-FET transistors, the theoretical limit of the intrinsic noise can indeed be reached. The thermal noise power $P_{\text{thn}} = \sqrt{4kT^2GB}$ is proportional to the square root of the heat conduction G, and is very small for optimized thin-film devices. The Johnson noise is normally dominating. The contributing noise sources are given by the real part g of the admittance Y. The noise current J_n for a bandwidth B is obtained as

$$J_n = \sqrt{4kTgB} \quad \text{with } g = R_p^{-1} + \omega C \tan\delta \qquad [10]$$

The minimal detectable power is the noise equivalent power defined by $\text{NEP} = J_n/\Re_J$. Very often, the

detectivity D^* is given instead of the NEP:

$$D^* = \frac{A^{1/2}B^{1/2}}{\text{NEP}} = \frac{\Re_I(\omega)A^{1/2}B^{1/2}}{J_n} \qquad [11]$$

The multiplication with $A^{1/2}B^{1/2}$ cancels the surface and bandwidth contribution from the noise. At high frequencies, D^* is independent of the detection area and bandwidth. For this reason, D^* is frequently used as a measure of performance to compare different detectors. The best operating conditions are found near the inverse thermal time constant, where the S/N ratio is peaking. Ideally, τ_{th} should be matched to τ_{el}^* tan δ. The materials figure of merit for the detectivity is generally given as

$$F_D = \frac{p}{c_p\sqrt{\varepsilon \tan \delta}} \qquad [12]$$

Table 1 contains a list of representative materials and their characteristics for pyroelectric applications. It can be noted that thin-film materials show as good characteristics as bulk materials, especially when they are grown epitaxially.

The detectivity D^* is a useful quantity to characterize an IR detector independent of size and detection bandwidth. However, for thermal imaging applications, D^* alone does not sufficiently characterize the complete device, which also contains an optical part. The quantity of interest is the minimal temperature difference of a blackbody target object with respect to the background temperature one still can detect. It is called the "noise equivalent temperature difference" (NETD). The procedure to evaluate this quantity is as follows: the noise voltage V_n of the detector is measured when the target temperature is in equilibrium with the background temperature. The target temperature is increased by ΔT and the signal voltage $V_s(\Delta T)$ is measured. The NETD is derived as

$$\text{NETD} = \frac{\Delta T}{V_s/V_n} \qquad [13]$$

ΔT is equal to the NETD if the signal is just equal to the noise voltage. Of course, the NETD can be related to the NEP and D^* of the detector, knowing the optical properties of the imaging system. The temperature increase ΔT has to be such that the increase of the power falling onto one pixel of the focal plane array (FPA) equals the NEP. The power increase is proportional to $(dW/dT)\Delta T$ in the wavelength interval $\Delta\lambda$ detected, where W is the power density emitted by the target surface. It is further proportional to the FPA pixel area A_D, and the transmissivity τ of the optics. The reader is referred to special literature on this topic for the derivation of general formulas. The formula given below finds

Table 1 Bulk and polymer pyroelectric materials. The figure of merits F_V, and F_D are given in the text

Material	p (μCm^{-2} K^{-1})	ε_r	tan δ	c_p (10^6 Jm^{-3} K^{-1})	F_V (m^2 C^{-1})	F_D (10^{-5} Pa$^{-1/2}$)	T_c (°C)

frequent use:

$$\mathrm{NETD} = \frac{(4F^2+1)}{A_D \cdot \tau \cdot (\mathrm{d}W/\mathrm{d}T)_{\Delta\lambda}} \cdot \mathrm{NEP} = \frac{(4F^2+1)}{A_D^{1/2} \cdot \tau \cdot (\mathrm{d}W/\mathrm{d}T)_{\Delta\lambda}} \cdot \frac{B^{1/2}}{D^*} \qquad [14]$$

F is the f-number of the optics. Typically, an NETD of less than 100 mK is required for uncooled IR-imaging systems.

State of the Art of Pyroelectric Focal Plane Arrays

Development of pyroelectric focal plane arrays started in the 1980s. A device consisting of a reticulated, 60 μm thick pyroelectric ceramic wafer that was bonded to a CCD readout wafer by means of contact solder bumps, exhibiting a pixel diameter of 70 μm, showed an NETD of 400 mK at 25 Hz. A presently sold commercial product consists of a 14 μm thick reticulated ceramic wafer with a 50 μm pitch. The NETD could be reduced to 75 mK, and the spatial resolution could be increased. The fundamental limits are not yet reached with this camera. However, in the frame of this ceramic wafer technology, a further shrinkage of wafer thickness and pitch will become increasingly difficult. Much more promising are silicon micromachining techniques enabling still smaller and thinner pixels. Thermal cross talk between pixels is reduced very much as well. Unfortunately, there are still processing obstacles preventing integration of high quality pyroelectric thin-film structures directly onto silicon based read-out circuits. The present state of the art arrives at an NTD of 700 mK, allowing, nevertheless, for high quality IR images. In principle, micromachining technology would allow pushing down the NETD to 10–20 mK.

Q

Quantum Cascade Lasers

A Tredicucci, NEST-INFM & Scuola Normale Superiore, Pisa, Italy

Introduction

A semiconductor heterostructure consists of a layered sequence of two or more semiconductor materials with different band gaps. The resulting band-edge discontinuity provides an effective potential profile (with wells and barriers) for the electronic motion. If the layer thicknesses are of the order of the electron wavelength, quantum confinement splits the bulk bands into a number of individual subbands. Inter-subband optical transitions then become possible, for instance involving only electrons belonging to the first conduction band. The transition energy is mainly determined by the width of the quantum well where the electron wave functions are contained.

The idea of constructing a unipolar semiconductor laser operating on inter-subband transitions is due to Kazarinov and Suris and dates back to the 1970s. The concept was immediately appealing because of the artificial nature of the transition, which allows a full control on its properties by design (energy, dipole matrix element, nonradiative scattering rate, etc.). Furthermore, two fundamental aspects are particularly relevant for the implementation in a laser. Both subbands involved originate from the same bulk conduction band and therefore are ideally characterized by the same effective mass. This produces a nearly delta-like joint density of states, maximizing the peak gain dependence on current and temperature. Furthermore, at the end of the photon emission process, the electron is still in the conduction band, and can then be recycled in a subsequent identical active region to emit another photon, for a number of times equal to the number of periods.

Despite many practical proposals and attempts, the first inter-subband laser, emitting in the mid-infrared at 4.3 μm, was realized only in 1994, at Bell Laboratories, thanks also to the development of modern semiconductor growing techniques, like molecular beam epitaxy (MBE). Population inversion was achieved through current injection via resonant tunneling, and the device was named "quantum cascade laser," reflecting the periodic potential profile with the above-mentioned "cascade" of transitions in repeated identical active regions.

In ten years, research on quantum cascade lasers (QCLs) has rapidly developed, and the devices have reached considerable performance levels. They cover the whole mid-infrared range (from 3.4 μm down to 24 μm); single-mode and tuneable emission is routinely achieved using distributed feedback (DFB) resonators; continuous wave output powers as large as 500 mW have recently been demonstrated at room temperature. Lately, far-infrared QCLs with emission frequencies in the THz range (down to 2.1 THz) have also been realized, thereby effectively bridging the gap between quantum photonic sources and classical electronic oscillators.

Physics and Design

A schematic representation of the band profile of the inter-subband laser structures originally proposed by Kazarinov and Suris is shown in **Figure 1**. In an applied external electric field, electrons are injected and traverse a series of identical quantum wells, in the process emitting a photon at every stage. In panel (a) the optical transition is within the same quantum well, between the first excited state and the ground state. Carriers then tunnel into the second excited state of the following quantum well, from where they again relax nonradiatively into the first excited state and undergo the next optical transition. In the concept of panel (b), amplification of light takes place via the tunneling of electrons from the ground state of one quantum well to an excited state of the following quantum well accompanied by the simultaneous emission of a photon.

While these first concepts illustrate well the quantum cascade principle, they turned out to be too simple for practical implementation, as two main issues had still to be properly considered. Carrier dyna mics inside the active region is mainly governed by scattering between electrons and LO phonons. In the

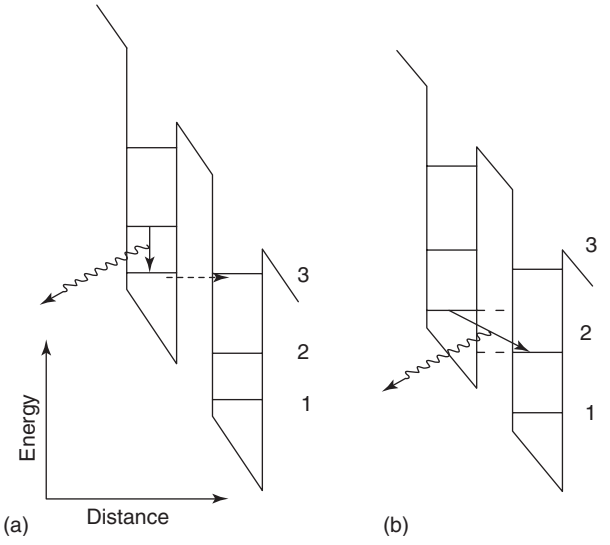

Figure 1 Schematic band-diagram representation of the original proposals by Kazarinov and Suris. (a) Electrons undergo an optical transition between levels 2 and 1 within the same quantum well and then tunnel into level 3 of the next one, from where they nonradiatively relax again into level 2. (b) Electrons undergo a photon-assisted tunnel process from one quantum well to the next, emitting their energy as photons.

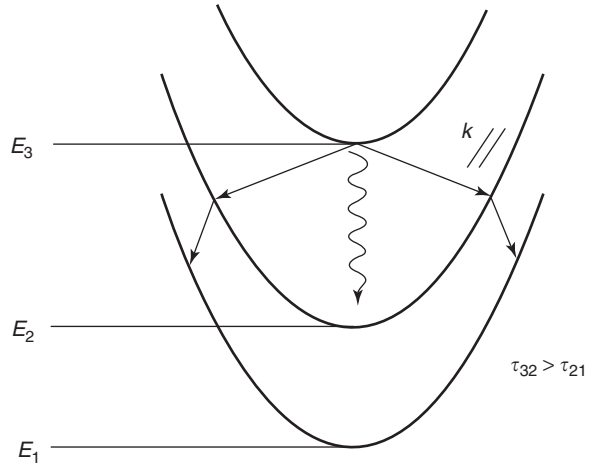

Figure 2 Schematic view of the three subbands labeled 1,2,3 in the active region of a QCL. The optical transition, represented by a wavy arrow, is between bands 3 and 2. The straight arrows indicate possible paths for scattering between electrons and LO phonons. Owing to the larger energy separation between subbands 3 and 2, the corresponding phonon wave vector is larger than in a scattering process between subbands 2 and 1. This resulting difference in the scattering rate is utilized to design population inversion.

polar III–V materials, the Fröhlich interaction is very strong and can lead to scattering rates faster than $1\,\mathrm{ps}^{-1}$. This must be compared with radiative lifetimes that are of the order of microseconds. Initially, it was thought that this would hinder population inversion, or at least make it more difficult, at transition energies above the LO phonon (36 meV in GaAs), rather than below the reststrahlen band, where LO phonon scattering is suppressed. Instead, it turned out that this strong electron–phonon scattering can be exploited to control the level occupation. The basic concept is sketched in **Figure 2**. The scattering rate for phonon emission decays as $1/Q^2$ with the phonon wave vector Q. At mid-infrared wavelengths, where the photon energy exceeds that of the phonon, the wave functions and energies of the states in the active region are engineered so that lasing takes place between subbands 3 and 2 while subbands 2 and 1 are separated by an energy close to that of the LO phonon, that is, the scattering of electrons by LO phonons becomes a quasiresonant process. Owing to the different phonon wave vectors involved in the inter-subband scattering processes between levels 3 and 2 (characteristic time τ_{32}) and 2 and 1 (τ_{21}), the lifetime of level 3, τ_3, computed as $\tau_3 \sim (1/\tau_{32} + 1/\tau_{31})^{-1}$, considerably exceeds that of level 2 $\tau_2 \sim \tau_{21}$. In essence, population inversion is achieved via resonant tunnel injection into subband 3 and using resonant phonon emission to deplete subband 2.

Solving a simple rate equation system,

$$\frac{\partial N_3}{\partial t} = \frac{J}{q_0} - \frac{N_3}{\tau_3} = 0$$

$$\frac{\partial N_2}{\partial t} = \frac{N_3}{\tau_{32}} - \frac{N_2}{\tau_2} = 0 \qquad [1]$$

the population inversion $N_3 - N_2$ can be written as

$$N_3 - N_2 = \left(1 - \frac{\tau_2}{\tau_{32}}\right) N_3 = \left(1 - \frac{\tau_2}{\tau_{32}}\right) \frac{\tau_3 J}{q_0} \qquad [2]$$

It is evident from eqn [2] that a gain in a QCL requires $\tau_{32} > \tau_2$, that is, extraction of carriers from the lower laser level must be more rapid than repopulation by carriers which have been nonradiatively scattered from the upper laser level. Using the last expression, the gain constant (in $\mathrm{m\,A}^{-1}$) of a QCL can then be written as:

$$g = \tau_3 \left(1 - \frac{\tau_2}{\tau_{32}}\right) \frac{4\pi q_0 Z_{32}^2}{\lambda_0 n \varepsilon_0 L_p} \frac{1}{\gamma_{32}} \qquad [3]$$

where Z_{32} is the dipole matrix element between states 3 and 2, λ_0 is the wavelength of the emitted light in vacuum, n the refractive index of the guided optical mode, ε_0 the vacuum permittivity, and L_p the cumulative length of the active region and the injector. γ_{32} (in eV) is the full-width at half maximum

(FWHM) of the inter-subband electroluminescence and phenomenologically replaces the expression for the joint density of states (ideally delta-like).

A second important aspect stems from the fact that a simple periodic sequence of identical quantum wells suffers from an intrinsic instability. Under current injection, the electric field across the entire superlattice will not remain constant, altering the tunneling process and leading to the build-up of charges, in turn affecting the electric field. Carrier transport will therefore differ from one superlattice period to the next, rendering the achievement of gain in such a structure very problematic. In QCLs, as demonstrated by Faist, Capasso, and co-workers in 1994, the problem of an inhomogeneous electric field along the structure can be solved by the introduction of collector/injector regions between the "active" quantum wells that host the optical transition. These regions, called injectors for short, are doped superlattice structures whose states form a miniband that collects electrons from the preceding active region, cools down the carrier distribution, and injects carriers again into the upper laser level of the following active region. The injector regions are doped in order to provide a reservoir of carriers at each stage of the cascade, ensuring electrical neutrality and thereby stabilizing the operation of the laser over a wide range of currents and voltages. A pair of one injector/collector region and one active region forms the building block (often called period or stage) that is repeated many times to give rise, under the appropriate bias, to the cascading potential. An example of a QCL design is shown in **Figure 3**. The moduli squared of the relevant wave functions are shown and the optical transition is indicated by an arrow. The wave functions belonging to the active region are drawn as thick lines. The band structure in the injector is engineered so that the majority of electrons thermalize into the ground state, which is coupled to the active region via the injection barrier. The thickness of this barrier controls the tunneling time from the injector ground state into the upper laser level and is crucial for the operation of QCLs, as its magnitude affects the injection efficiency. The injector not only collects carriers from the two lower states of the active region, but also simultaneously prevents the loss of carriers into the continuum. To this end, the minigap of the injector region is made resonant with the upper laser level. In essence, the injector can also be viewed as a Bragg reflector that possesses a high transparency for electrons with an energy equal to that of levels 2,1 and a stop-band at energies around that of level 3.

The design concept shown in **Figure 3** features an optical transition vertical in real space and a three-well active region. As explained above diagonal transitions (inter-well) are also a possibility. In general,

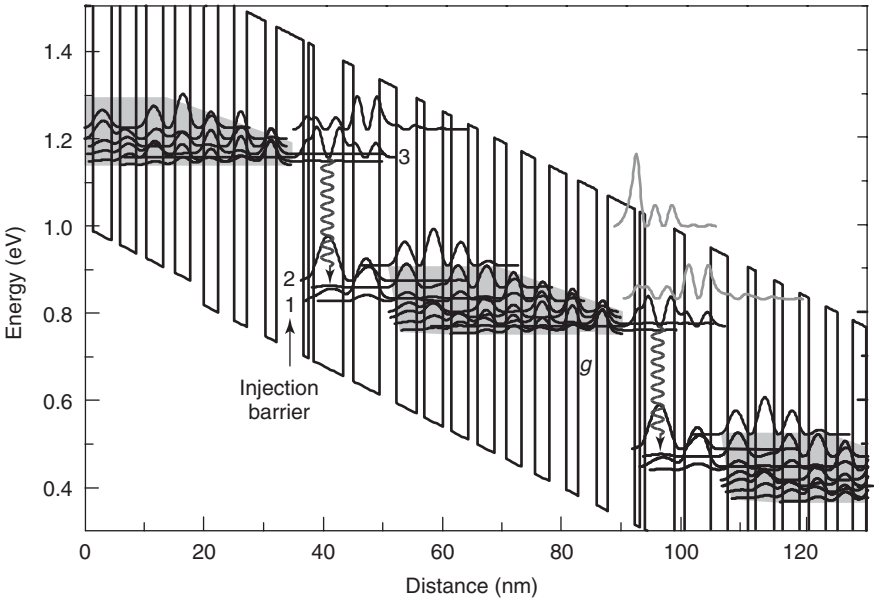

Figure 3 Schematic view of a portion of the conduction band structure of a representative $\lambda \approx 4.6\,\mu m$ QCL. Moduli squared of the most important states in the active region are drawn as thick solid lines labeled 1,2,3, while the injector ground state is labeled *g*. Carrier injection takes place from the ground state *g* into the upper laser state 3 via resonant tunneling through the injection barrier. Electrons subsequently undergo a radiative transition to level 2 (indicated by a wavy arrow), from which they are scattered mainly by LO phonon emission to state 1. Finally, they are extracted from state 1 into the states of the injector and thermalize again into the ground state of the following injector. The miniband comprising the subbands in the injector is shaded in gray. The upper laser state 3 faces a minigap downstream to prevent electrons from escaping into the continuum.

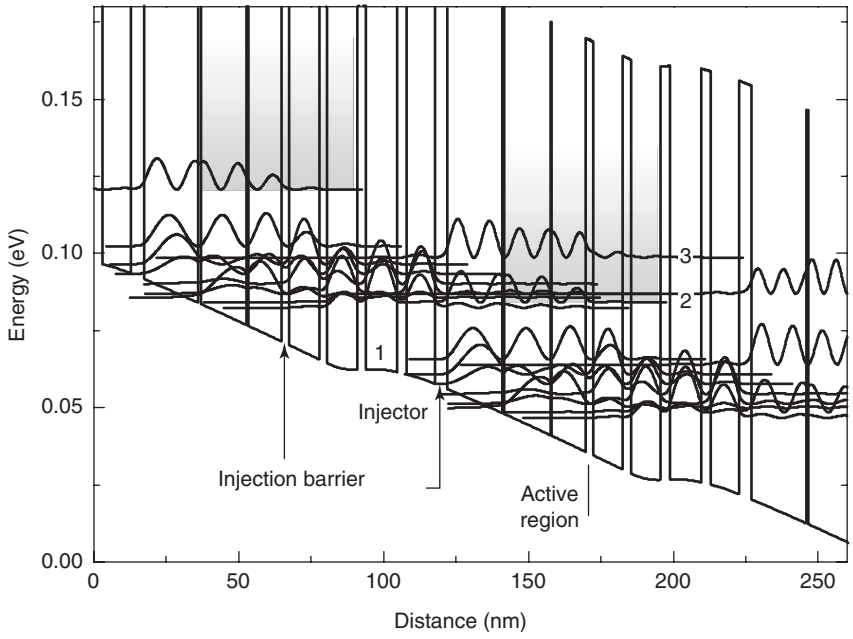

Figure 4 Conduction band energy diagram of a 4.4 THz "chirped" SL QCL under an average electric field of 3.5 kV cm^{-1}. The material is GaAs-based, and the layer thickness (in nm) are, from left to right, starting from the injection barrier 4.3/18.8/0.8/15.8/0.6/11.7/2.5/10.3/2.9/10.2/3.0/10.8/3.3/9.9, where $Al_{0.15}Ga_{0.85}As$ layers are in bold face and the 10.2 nm wide GaAs well is doped 4×10^{16} cm^{-3}. Also shown are the moduli squared of the wave functions; the optical transition occurs between states 2 and 1.

vertical transitions are preferred as they possess larger dipole matrix elements and are characterized by smaller inhomogeneous broadening. On the other hand, diagonal ones can be useful to suppress nonradiative scattering and achieve longer transition lifetimes. While the "three-well-vertical" design is probably the most classic, at least for mid-infrared QCLs, many other ideas have been proposed and successfully implemented, either to enhance performances or to obtain novel functionalities (for instance multi-wavelength or bi-directional emission). A particularly successful concept is the use of superlattice (SL) active regions, which are especially effective in simplifying the achievement of a sizeable population inversion, even in problematic situations like very small transition energies. SLs differ fundamentally from the previously described designs as lasing no longer takes place between individual subbands, but occurs between the first and second SL miniband, across the minigap. In k-space this is at the boundary of the Brillouin zone ($k_z = \pi/d$), leading to very large dipole matrix elements. Furthermore, superlattice active regions readily achieve a population inversion at $k_z = \pi/d$, owing to a favorable lifetime ratio τ_2/τ_{32}. While τ_2 is very short due to the intra-miniband relaxation, nonradiative scattering processes from the bottom of the upper miniband across the minigap now distribute among the many states of the lower miniband. This leads to a long time τ_{32}, albeit the total lifetime τ_3 remains more or less unchanged compared to that in a quantum well structure. In addition, superlattice QCLs are capable of carrying very high current densities without reaching negative differential conductance, leading to high output-power devices.

In a true superlattice, the application of bias along the SL period lifts the degeneracy of the constituent subbands; the states then become more and more localized in their parent quantum well (Wannier–Stark ladders). In order to prevent such break-up, the electric field across the active region must be balanced. In the first SL designs, this was achieved by the re-distribution of the electrons with respect to the donors, which helped in achieving a flat-band condition in almost the entire active region. This technique, however, requires the use of large dopant concentrations. Chirped superlattices instead are now widely used, in which cancellation of the electric field at the design value is obtained by varying the thickness of both wells and barriers leading to a built-in quasifield of equal magnitude and opposite sign. By careful design, truly delocalized miniband states are then recovered. A typical chirped SL design is shown in **Figure 4**, which reports the band structure of the first QCL operating at THz frequencies.

Waveguides and Devices

The resonator is an essential part of every laser. Its general requirements are low propagation losses and

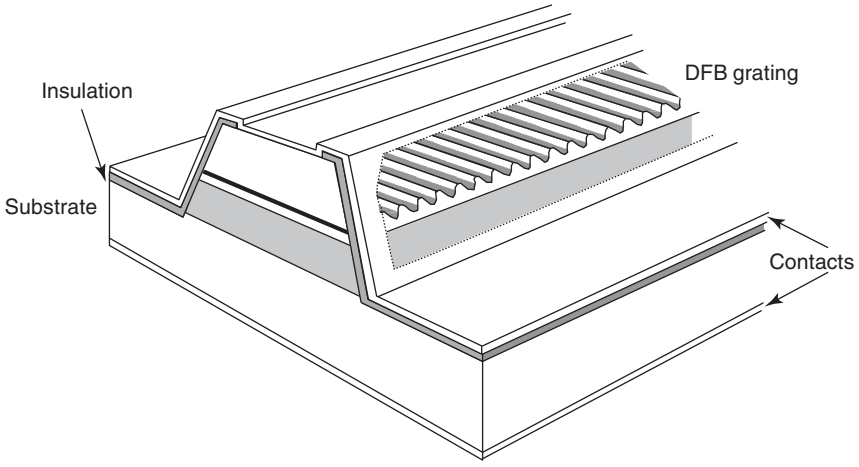

Figure 5 Schematic view of a QCL ridge. It is typically realized through optical contact lithography and wet chemical etching, with a lateral size of the order of a few wavelengths. The core of cascading stages is shaded in gray. An insulation layer (normally SiO_2 or Si_3N_4) is deposited to prevent electrical shorting when the top metallic contact has to extend also away from the ridge (for instance if the ridges are too narrow to allow wire-bonding on their top). Depicted is the case of a mid-IR laser grown on a conducting substrate. For THz QCLs, undoped substrates are preferred for their low absorption; in this case, the "bottom" contact has to be lateral. Front and end facets are obtained by cleaving along a crystal plane but coatings can be applied to alter the reflectivity. Also shown is a buried (in between core and cladding) grating, lithographically etched to provide DFB operation.

a large overlap of the optical mode with the gain medium. In QCLs, the most common resonator is the ridge-waveguide geometry as shown schematically in **Figure 5**. Light propagates along the ridge (taken to be along the x-direction) and is reflected at the back and front facets due to the step in the refractive index. Confinement in the y-direction results from the etching of the ridge. In common interband semiconductor lasers that emit in the visible to mid-infrared spectral range, dielectric waveguides are employed to achieve confinement in the z-direction. In such a waveguide the active core of the laser, in which light is generated, is sandwiched between claddings of lower refractive index leading to a bound optical state peaking in the active core and decaying exponentially into the claddings. Dielectric waveguides are indeed used also for QCLs emitting in the mid-infrared region ranging from $\lambda \sim 3.5\,\mu m$ to about $\lambda \sim 15\,\mu m$. The mode profile along z of a sample waveguide of a QCL emitting at $\lambda \sim 10.6\,\mu m$ is shown in **Figure 6**. Only the fundamental TM mode is plotted as this polarization is implied by the optical selection rules of inter-subband transitions. It is interesting to notice that, at mid-infrared wavelengths, the refractive index of a semiconductor material can be lowered considerably just by increasing the doping concentration, as the plasma frequency of the extrinsic electron gas is raised. This allows a great flexibility in the waveguide design and in the material choice. In particular effective waveguides can be realized using the same material all over the structure, with low doping in the core and large doping in the claddings (typically this is the case for GaAs QCLs).

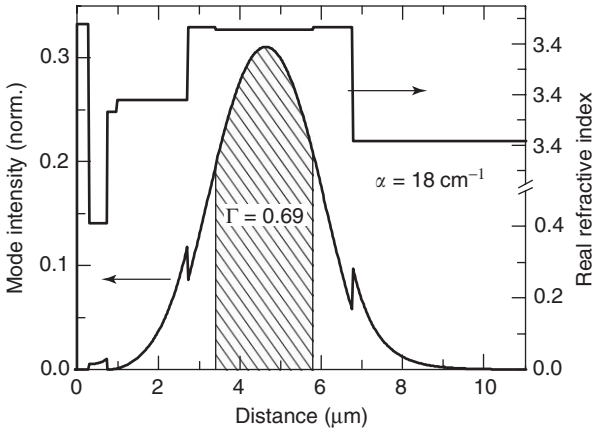

Figure 6 Mode profile of the fundamental mode of a 10.6 μm QCL. The index profile of the dielectric waveguide is shown as well. The confinement factor is calculated to be 0.64. The lower cladding layer is the InP substrate, while the top cladding is made of several AlInAs layers with various doping concentrations, of which the topmost one is highly doped (plasmon-enhanced waveguide) to decouple the mode from the metal–semiconductor interface. Above and below the stack of active regions and injectors, low-doped InGaAs layers are grown to increase the overall refractive index of the core. This results in a greater confinement factor. The discontinuities occur because the mode is TM (transverse magnetic), thus the electric field is discontinuous at the interfaces.

In determining the modal laser gain, the radiation confinement factor Γ on the active core has to be calculated by integrating the intensity over the whole

stack of cascading periods and normalizing it to the total intensity integral:

$$\Gamma = \frac{\int_{\text{core}} |E(z)|^2 \mathrm{d}z}{\int_{-\infty}^{+\infty} |E(z)|^2} \qquad [4]$$

Using eqn [3], the expression for the QCL threshold current density assumes the conventional form:

$$J_{\text{th}} = \frac{\alpha_{\text{w}} + \alpha_{\text{m}}}{g\Gamma} \qquad [5]$$

α_{w} and α_{m} being the waveguide and mirror losses respectively. The former are mainly determined by free carrier absorption in the cladding layers, which have to be doped to allow current injection; the latter are given by the impedance mismatch between the waveguide and vacuum (air) at the cleaved facets acting as front-end and back-end mirrors. In a first approximation, α_{m} can be computed considering a plane wave being reflected at the interface between the waveguide and air:

$$\alpha_{\text{m}} = -\frac{1}{L_{\text{cav}}} \ln\left(\frac{n_{\text{mod}} - 1}{n_{\text{mod}} + 1}\right) \qquad [6]$$

where n_{mod} is the modal refractive index and L_{cav} is the length of the laser cavity (typically few mm).

Although in principle there is no spectral limit for dielectric waveguides, their use at even longer wavelength is hindered by two facts: with increasing emission wavelength free carrier absorption in the cladding layers rises significantly, and, simultaneously, the necessary waveguide thickness, which scales approximately linearly with the emission wavelength, becomes incompatible with MBE growth. Yet, MBE growth is required to achieve the necessary precision and reproducibility of the layer thickness in the active core, although recently MOCVD-grown QCLs have also been reported. These problems were solved in long-wavelength QCLs by the introduction of surface-plasmon waveguides. Surface plasmons are a peculiar solution of Maxwell's equations existing at the interface between materials possessing dielectric constants ε of opposite sign. For an electric field vector perpendicular to the interface (i.e., TM-polarization), a bound state is found that propagates along the interface decaying exponentially in the perpendicular direction. Such a system is realized, for example, at the interface between a metal (negative ε) and a low-doped semiconductor. If a metal with a very large (in absolute value) dielectric constant is chosen, the penetration of the mode into the metal can be made very small and the absorption of light in the metal becomes negligible, reducing the optical losses experienced by the mode. Surface plasmon waveguides become advantageous over dielectric ones above 15 μm wavelength or so and guarantee large confinement factors even with an epitaxial thickness considerably smaller than the wavelength. **Figure 7** shows the computed mode profile in a waveguide using this concept for a $\lambda \sim 24\,\mu\text{m}$ QCL based on the InP material system. The optical confinement reaches a very high value of 88%. Propagation losses are $42\,\text{cm}^{-1}$, and are caused mainly by the doped stack of active regions and the penetration into the doped substrate. A sophisticated version of the surface plasmon waveguide featuring a second layer with negative dielectric constant (realized in a highly doped semiconductor) is customarily employed for THz QCLs.

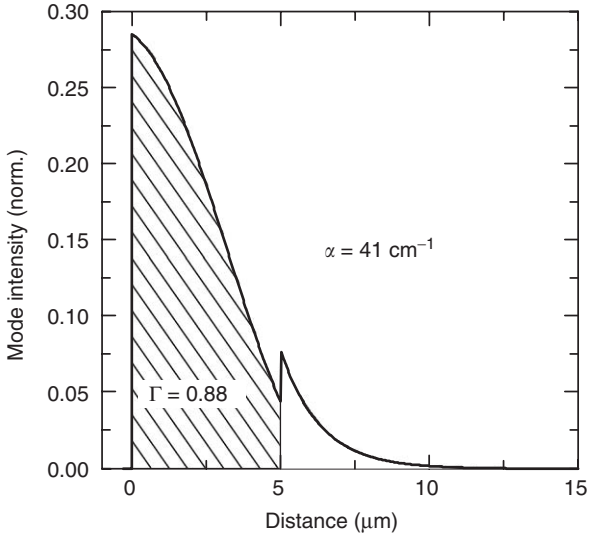

Figure 7 Waveguide of a $\lambda \approx 24\,\mu\text{m}$ QCL employing the surface plasmon to achieve a high confinement factor with a small epilayer thickness. In the present case, this is helped by the additional confinement coming from the low refractive index of the InP substrate, a feature not available in the GaAs material system.

Beyond Fabry–Perot ridge resonators, QCLs have been made with a variety of optical cavities. Suspended microdisks and cylinder lasers based on whispering gallery modes have shown the lowest threshold currents, while deformed stadium-shaped lasers have been realized to study chaotic light propagation. The interest for spectroscopic applications has stimulated the development of single-mode and tunable devices. As for interband laser diodes, this is achieved integrating a diffraction grating in the laser structure (see **Figure 5**), giving rise to distributed-feedback (DFB) resonators. Many different techniques have been developed, relying in turn on gratings patterned on top of the ridge, buried between the ridge and the cladding, two-metal gratings in the top contact, etc. In any case, the presence of

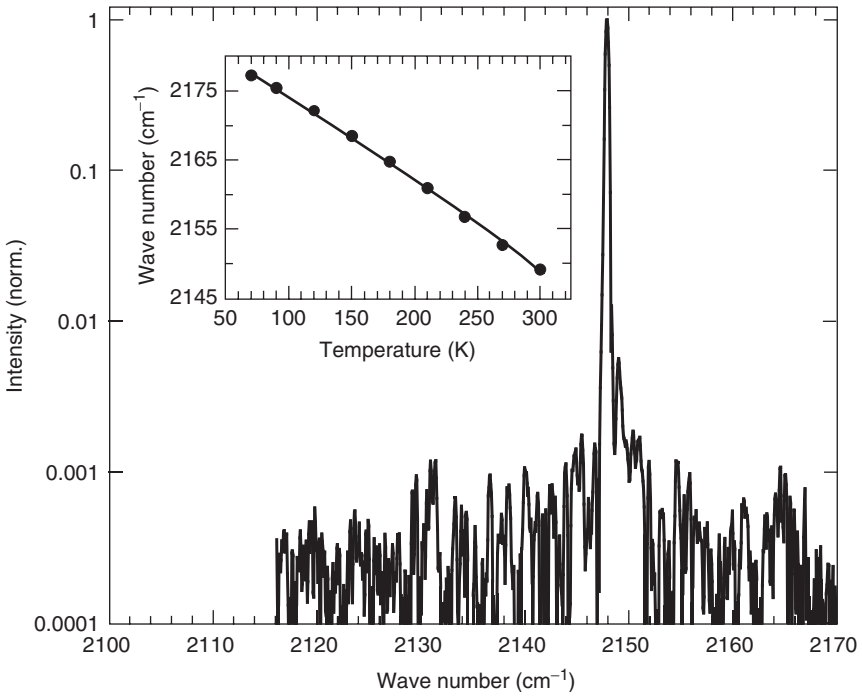

Figure 8 Single-mode laser emission spectrum of a 4.8 μm DFB QCL plotted in logarithmic scale. A side mode suppression ratio of about 30 dB is displayed. In the inset the emission frequency dependence on the laser temperature is displayed; the tuning range is $\sim 30\,\mathrm{cm}^{-1}$ from cryogenic to room temperature. (Courtesy of C Gmachl, Princeton University.)

the grating provides a strongly frequency-selective reflection, which ensures laser oscillation only on the longitudinal mode whose wavelength matches the grating period. Tunability is provided by the change of the material refractive index with temperature (which can be induced also by varying the drive current). High side-mode suppression ratios of more than 30 dB as well as very narrow line widths can be obtained. **Figure** 8 displays an exemplary emission spectrum and tuning characteristics of a 4.8 μm wavelength DFB QCL. Finally, external cavity QCLs have also been recently implemented using an external diffraction grating in Littröw configuration, to allow for a much wider tuning range.

Performance and State of the Art

The first QCLs were realized in the InGaAs/AlInAs material system-grown lattice matched to InP substrate. Later on strain-compensated structures were also introduced to increase the available conduction band offset. Indeed InP-based structures currently still provide the best QC devices for the mid-infrared spectral range. The reasons are to be found in the small electron effective mass, which improves the radiative efficiency, the rather large band offset, the good transport characteristics, the low refractive index substrates, and obviously the very mature fabrication and processing technology. Typical threshold current densities are of the order of a $\mathrm{kA\,cm}^{-2}$, with an exponential dependence on the temperature $\exp(T/T_0)$ characterized by a large T_0 in between 100 K and 200 K. Devices have been realized with a varying number of cascade stages, ranging from a single one to more than one hundred. Obviously the more stages are used in the cascade, the higher output power can be obtained; however, more periods also mean larger applied voltages (the voltage drop per period has to be constant), thereby resulting in higher electric power to be dissipated. In the best lasers, the QC principle, that above the threshold one photon per period is generated per each single electron traversing the structure, has been experimentally verified from the output power slope efficiency:

$$\frac{\partial P}{\partial I} = \frac{1}{2} N_p \frac{\alpha_\mathrm{m}}{\alpha_\mathrm{m} + \alpha_\mathrm{w}} \frac{h\nu}{q_0} \left(1 - \frac{\tau_2}{\tau_{32}}\right) \qquad [7]$$

in which N_P is the number of stages and ν the photon frequency. Peak output powers of about 2 W have been obtained in pulsed operation; at $\lambda \approx 6\,\mu\mathrm{m}$ wavelength, room-temperature continuous wave (CW) operation with about 0.5 W of optical power has been recently demonstrated in a QCL employing a buried heterostructure configuration of the ridge (see data

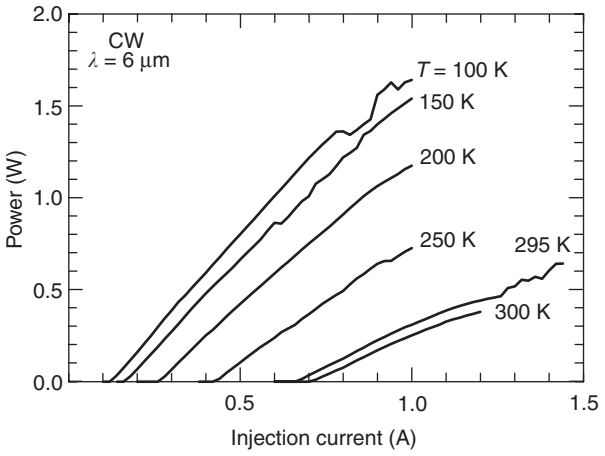

Figure 9 Light–current characteristics as recorded in continuous wave from the front facet of a $\lambda \approx 6\,\mu m$ InGaAs/AlInAs buried heterostructure QCL. A metallic high reflection coating was used on the back-facet. The power represents what collected on a thermopile detector. Data are shown for different substrate temperatures. (Courtesy of M Razeghi, Nortwestern University.)

in **Figure 9**). It actually took eight years before QCLs could be driven in CW at room temperature, owing mainly to the difficult thermal management of a device needing a few watts of electrical power.

In 1998, the first QCLs in the GaAs/AlGaAs material system were developed. While these devices cannot compete with InGaAs/AlInAs ones in the mid-infrared, GaAs QCLs are the only ones presently capable of operating in the THz range, thanks to the highest quality of epitaxial growth and the far-IR transparency of commercially available GaAs substrates. THz QCLs were first fabricated in 2002, after solving the problem of population inversion at transition energies smaller than the LO phonon resonance using SL active regions, and implementing surface-plasmon-based special waveguides. Currently, they cover the region from 2.1 THz to 4.7 THz, with output powers of several tens of mWs, up to a record temperature of 140 K (90 K in CW). Interestingly, THz QCLs display the lowest threshold current densities, down to a couple of $A\,cm^{-2}$ in an external magnetic field.

In an opposite direction, material systems with very large band offsets are being explored to extend the QC concept to the near-IR, possibly toward communication wavelengths. In this respect, an important step has been the very recent development of QCLs in InAs/AlSb heterostructures. The interest stems from the possibility of directly modulating QCLs at very high frequencies, owing to their unipolar nature, and to the ultrafast electron dynamics; such a feature is clearly highly desirable for high-throughput data transmission. Modulation at several GHz has already been proved, limited probably by parasitic capacitance, as well as self-mode-locking on ultrashort pulses.

As far as the spectral emission properties are concerned, DFB QCLs have shown excellent single-mode line widths, and are being implemented in an ever-increasing number of spectroscopic applications, mainly related to trace-gas detection. Direct and modulated absorption, photoacoustic spectroscopy, cavity ring-down, are just a few of the techniques successfully employed. Furthermore, they can be stabilized on molecular absorption lines using servo-feedback systems to bring the frequency noise down to a few Hz, thereby making them appealing also as frequency standards.

The Future

With the commercialization of mid-IR QCLs already a developing reality, open research challenges of immediate technological relevance invest the operation of QCLs in other frequency ranges. Apart from the already mentioned quest for near-IR devices, many elements of the newly developed THz QCLs are presently the object of intense investigation. The improvement of temperature performances, single-mode tunability, and the extension toward 1 THz are the most important goals. In parallel, the application of THz QCLs to imaging systems and security scanners is attracting a lot of attention from the industrial world.

In a similar spirit, nonlinear devices integrated within a QCL cavity are being explored for harmonic and difference frequency generation, with promising perspectives. This research is also stimulating the study of fundamental quantum optics effects using inter-subband transitions.

Basic aspects of the QC concept are also being revisited. The interplay between population inversion and Bloch oscillations is particularly interesting, but the possibility of realizing QCLs in lower dimensionality nanostructures (such as quantum dots or nanowhiskers) is probably the most stimulating idea.

Finally, QCLs offer a perfect laboratory system for developing studies and new devices in various fields of modern optics. Photonic crystals and surface plasmon sub-wavelength components are two examples where QCLs (thanks to their planar TM emission, long wavelength, and insensitivity to surface recombination) could have a deep immediate impact.

Introduction

Miniaturization provides us with an intuitive way of understanding why, in the near future, quantum mechanics will become important for computation. The electronics industry for computers grows hand-in-hand with the decrease in size of integrated circuits. This miniaturization is necessary to increase computational power, that is, the number of floating-point operations per second (flops) a computer can perform. In the 1950s, electronic computers based on vacuum-tube technology were capable of performing $\sim 10^3$ floating-point operations per second, while nowadays (2004) there exist supercomputers whose power is greater than 10 teraflops (10^{13} flops). As remarked, this enormous growth of computational power has been made possible owing to progress in miniaturization, which may be quantified empirically in Moore's law. This law is the result of a remarkable observation made by Gordon Moore in 1965: the number of transistors on a single integrated-circuit chip doubles approximately every 18–24 months. This exponential growth has not yet saturated and Moore's law is still valid. At the present time the limit is $\sim 10^8$ transistors per chip and the typical size of circuit components is ~ 100 nm. Extrapolating Moore's law, it is estimated that around the year 2020, one would reach the atomic size for storing a single bit of information. At that point, quantum effects will become unavoidably dominant.

Quantum physics sets fundamental limitations on the size of the circuit components. The first question under debate is whether it would be more convenient to push the silicon-based transistor to its physical limits or instead to develop alternative devices, such as quantum dots, single-electron transistors, or molecular switches. A common feature of all these devices is that they are at the nanometer length scale, and therefore quantum effects play a crucial role.

So far, the quantum switches that could substitute silicon-based transistors and possibly be connected together to execute classical algorithms based on Boolean logic were discussed. In this perspective, quantum effects are simply unavoidable corrections that must be taken into account, owing to the nanometer size of the switches. A quantum computer represents a radically different challenge: the aim is to build a machine based on quantum logic, that is, it processes the information and performs logic operations in agreement with the laws of quantum mechanics.

Quantum Logic

The elementary unit of quantum information is called a qubit (the quantum counterpart of the classical bit) and a quantum computer may be viewed as a many-qubit system. Physically, a qubit is a two-level system, like the two spin states of a spin-1/2 particle, the vertical and horizontal polarization states of a single photon or the ground and excited states of an atom.

A classical bit is a system that can exist in two distinct states, which are used to represent 0 and 1, that is, a single binary digit. The only possible operations (gates) in such a system are the identity

$(0\to 0,\ 1\to 1)$ and NOT $(0\to 1,\ 1\to 0)$. In contrast, a quantum bit (qubit) is a two-level quantum system, described by a two-dimensional complex Hilbert space. In this space, one may choose a pair of normalized and mutually orthogonal quantum states, called $|0\rangle$ and $|1\rangle$ (say, the eigenstates of the Pauli operator σ_z), to represent the values 0 and 1 of a classical bit. These two states form a computational basis. From the superposition principle, any state of the qubit may be written as

$$|\psi\rangle = \alpha|0\rangle + \beta|1\rangle \qquad [1]$$

where the amplitudes α and β are complex numbers, constrained by the normalization condition $|\alpha|^2 + |\beta|^2 = 1$.

A quantum computer can be seen as a collection of n qubits and therefore its wave function resides in a 2^n-dimensional complex Hilbert space. While the state of an n-bit classical computer is described in binary notation by an integer $k \in [0, 2^n - 1]$,

$$k = k_{n-1}2^{n-1} + \cdots + k_1 2 + k_0 \qquad [2]$$

with $k_0, k_1, \ldots, k_{n-1} \in [0, 1]$ binary digits, the state of an n-qubit quantum computer is

$$\begin{aligned} |\psi\rangle &= \sum_{k=0}^{2^n-1} c_k|k\rangle \\ &= \sum_{k_{n-1},\ldots,k_1,k_0=0}^{1} c_{k_{n-1},\ldots,k_1,k_0}|k_{n-1}\cdots k_1 k_0\rangle \end{aligned} \qquad [3]$$

where $|k_{n-1}\cdots k_1 k_0\rangle \equiv |k_{n-1}\rangle \otimes \cdots \otimes |k_1\rangle \otimes |k_0\rangle$. Notice that the complex numbers c_k are constrained by the normalization condition $\sum_{k=0}^{2^n-1} |c_k|^2 = 1$.

The superposition principle is clearly visible in eqn [3]: while n classical bits can store only a single integer k, the n-qubit quantum register can not only be prepared in the corresponding state $|k\rangle$ of the computational basis, but also in a superposition. It is stressed that the number of states of the computational basis in this superposition can be as large as 2^n, which grows exponentially with the number of qubits. The superposition principle opens up new possibilities for computation. When one performs a computation on a classical computer, different inputs require separate runs. In contrast, a quantum computer can perform a computation for exponentially many inputs on a single run. This huge parallelism is the basis of the power of quantum computation.

The superposition principle is not a uniquely quantum feature. Indeed, classical waves satisfying the superposition principle do exist. For instance, consider the wave equation for a vibrating string with fixed endpoints. Its solutions $|\varphi_k\rangle$ satisfy the superposition principle and one can write the most general state $|\varphi\rangle$ of a vibrating string as a linear superposition of these solutions, which are analogous to eqn [3]: $|\varphi\rangle = \sum_{k=0}^{2^n-1} c_k|\varphi_k\rangle$. It is therefore also important to point out the importance of entanglement for the power of quantum computation, as compared to any classical computation. Entanglement is the most spectacular and counter-intuitive manifestation of quantum mechanics, observed in composite quantum systems: it signifies the existence of nonlocal correlations between measurements performed on well-separated particles. After two classical systems have interacted, they are in well-defined individual states. In contrast, after two quantum particles have interacted, in general, they can no longer be described independently of each other. There will be purely quantum correlations between two such particles, independently of their spatial separation. Examples of two-qubit entangled state are the four states of the so-called Bell basis, $|\phi^{\pm}\rangle = \frac{1}{2}(|00\rangle \pm |11\rangle)$ and $|\psi^{\pm}\rangle = \frac{1}{2}(|01\rangle \pm |10\rangle)$. The measure of the polarization state of one qubit will instantaneously affect the state of the other qubit, whatever their distance is. There is no entanglement in classical physics. Therefore, in order to represent the superposition of 2^n levels by means of classical waves, these levels must belong to the same system. Indeed, classical states of separate systems can never be superposed. Thus, any computation based on classical waves requires a number of levels that grow exponentially with n. If Δ is the typical energy separation between two consecutive levels, the amount of energy required for this computation is given by $\Delta 2^n$. Hence, the amount of physical resources needed for the computation grows exponentially with n. In contrast, due to entanglement, in quantum physics a general superposition of 2^n levels may be represented by means of n qubits. Thus, the amount of physical resources (energy) grows only linearly with n.

To implement a quantum computation, one must be able to control the evolution in time of the many-qubit state describing the quantum computer. As far as the coupling to the environment is neglected, this evolution is unitary and governed by the Schrödinger equation. It is well known that a small set of elementary logic gates allows the implementation of any complex computation on a classical computer. This is very important: it means that, when one changes the problem, one does not need to modify one's computer hardware. Fortunately, the same property remains valid for a quantum computer. It turns out that, in the quantum circuit model, each unitary transformation acting on a many-qubit system can be decomposed into quantum gates acting on a single qubit

and a suitable quantum gate acting on two qubits. Any unitary operation on a single qubit can be constructed using only Hadamard- and phase-shift gates. The Hadamard gate is defined as follows: it turns $|0\rangle$ into $(|0\rangle + |1\rangle)/\sqrt{2}$ and $|1\rangle$ into $(|0\rangle - |1\rangle)/\sqrt{2}$. The phase-shift gate (of phase δ) turns $|0\rangle$ into $|0\rangle$ and $|1\rangle$ into $e^{i\delta}|1\rangle$. A generic unitary transformation acting on a many-qubit state can be transformed into a sequence of Hadamard, phase-shift, and CNOT gates, where CNOT is a two-qubit gate, defined as follows: it turns $|00\rangle$ into $|00\rangle$, $|01\rangle$ into $|01\rangle$, $|10\rangle$ into $|11\rangle$, and $|11\rangle$ into $|10\rangle$. As in the classical XOR gate, the CNOT gate flips the state of the second (target) qubit if the first (control) qubit is in the state $|1\rangle$, and does nothing if the first qubit is in the state $|0\rangle$. Of course, the CNOT gate, in contrast to the classical XOR gate, can also be applied to any superposition of the computational basis states.

The decomposition of generic unitary transformation of an n-qubit system into elementary quantum gates is in general inefficient, that is, it requires a number of gates exponentially large in n (more precisely, $O(n^2 4^n)$ quantum gates). However, there are special unitary transformations that can be computed efficiently in the quantum circuit model, by means of a number of elementary gates polynomial in n. A very important example is given by the quantum Fourier transform, mapping a generic n-qubit state $\sum_{k=0}^{2^n-1} a_k|k\rangle$ into $\sum_{l=0}^{2^n-1} b_l|l\rangle$, where the vector $\{b_0, \ldots, b_{N-1}\}$ is the discrete Fourier transform of the vector $\{a_0, \ldots, a_{N-1}\}$, that is, $b_l = \sum_{k=0}^{N-1} e^{2\pi i k l/2^n} a_k$. It can be shown that this transformation can be efficiently implemented in $O(n^2)$ elementary quantum gates, whereas the best-known classical algorithm to simulate the Fourier transform, the fast Fourier transform, requires $O(n2^n)$ elementary operations. The quantum Fourier transform is an essential subroutine in many quantum algorithms.

Quantum Algorithms

As shown above, the power of quantum computation is due to the inherent quantum parallelism associated with the superposition principle. In simple terms, a quantum computer can process a large number of classical inputs in a single run. For instance, starting from the input state $\sum_{k=0}^{2^n-1} c_k|k\rangle \otimes |0 \ldots 0\rangle$, one may obtain the output state

$$\sum_{k=0}^{2^n-1} c_k|k\rangle \otimes |f(k)\rangle \qquad [4]$$

Therefore, the function $f(k)$ is computed for all k in a single run (note that one needs two quantum registers to compute by means of a reversible unitary transformation $f(x)$). However, it is not an easy task to extract useful information from the output state. The problem is that this information is, in a sense, hidden. Any quantum computation ends up with a projective measurement in the computational basis: the qubit polarization is measured along the z-axis for all the qubits. The output of the measurement process is inherently probabilistic and the probabilities of the different possible outputs are set by the basic postulates of quantum mechanics. Given the state [4], one obtains $|\bar{k}\rangle|f(\bar{k})\rangle$ with probability $|c_{\bar{k}}|^2$, hence, the evaluation of the function $f(k)$ for a single $k = \bar{k}$, exactly as with a classical computer. However, there exist quantum algorithms that exploit quantum interference to efficiently extract useful information.

In 1994, Peter Shor proposed a quantum algorithm that efficiently solves the prime-factorization problem: given a composite odd positive integer N, find its prime factors. This is a central problem in computer science and it is conjectured, though not proven, that for a classical computer it is computationally difficult to find the prime factors. Shor's algorithm instead efficiently solves the integer factorization problem in $O((n^2 \log n \log\log n))$ elementary quantum gates, where $n = \log N$ is the number of bits necessary to code the input N. Therefore, it provides an exponential improvement in speed with respect to any known classical algorithm. Indeed, the best classical algorithm, the number field sieve, requires $\exp(O(n^{1/3}(\log n)^{2/3}))$ operations. The integer factoring problem can be reduced to the problem of finding the period of the function $f(k) = a^k \bmod N$, where N is the number to be factorized and $a < N$ is chosen randomly. The modular exponentiation can be computed efficiently on a quantum computer and one obtains the state $(1/\sqrt{N}) \sum_{k=0}^{2^n-1} |k\rangle|f(k)\rangle$. Notice that there are two quantum registers: the first one stores k, the second $f(k)$. By measuring the second register, one obtains the outcome $f(\bar{k})$. Thus, the quantum computer wave function collapses onto $(1/\sqrt{m}) \sum_{j=0}^{m-1} |\bar{k} + jr\rangle|f(\bar{k})\rangle$, where m is the number of k values such that $f(k) = f(\bar{k})$, and r is the period of $f(k)$, that is, $f(k) = f(k + r)$. To determine the period r, one has to perform the quantum Fourier transform of the first register. It can be seen that the resulting wave function is peaked around integer multiples of N/r. From the measurement of this state, one can extract the period r. It is worth mentioning that there are cryptographic systems, such as RSA, that are used extensively today and that are based on the conjecture that no efficient algorithms exist for solving the prime factorization problem. Hence Shor's algorithm, if implemented on a large-scale quantum computer, would break the RSA cryptosystem.

Other quantum algorithms have been developed. In particular, Grover has shown that quantum computers can also be useful for solving the problem of searching for a marked item in an unstructured database of $N = 2^n$ items. The best one can do with a classical computer is to go through the database until one finds the solution. This requires $O(N)$ operations. In contrast, the same problem can be solved by a quantum computer in $O(\sqrt{N})$ operations. In this case, the gain with respect to classical computation is quadratic.

Quantum Simulation of Physical Systems

The simulation of quantum many-body problems on a classical computer is a difficult task as the size of the Hilbert space grows exponentially with the number of particles. For instance, if one wishes to simulate a chain of n spin-1/2 particles, the size of the Hilbert space is 2^n. Namely, the state of this system is determined by 2^n complex numbers. As observed by Feynman in the 1980s, the growth in memory requirement is only linear on a quantum computer, which is itself a many-body quantum system. For example, to simulate n spin-1/2 particles one only needs n qubits. Therefore, a quantum computer operating with only a few tens of qubits can outperform a classical computer. Of course, this is only true if one can find an efficient quantum algorithm and if one can efficiently extract useful information from the quantum computer. Quite interestingly, a quantum computer can be useful not only for the investigation of the properties of many-body quantum systems, but also for the study of the quantum and classical dynamics of complex single-particle systems.

For a concrete example, consider the quantum mechanical motion of a particle in one dimension (the extension to higher dimensions is straightforward). It is governed by the Schrödinger equation

$$i\hbar \frac{\mathrm{d}}{\mathrm{d}t}\psi(x,t) = H\psi(x,t) \qquad [5]$$

where the Hamiltonian H is given by

$$H = H_0 + V(x) = -\frac{\hbar^2}{2m}\frac{\mathrm{d}^2}{\mathrm{d}x^2} + V(x) \qquad [6]$$

The Hamiltonian $H_0 = -(\hbar^2/2m)\,\mathrm{d}^2/\mathrm{d}x^2$ governs the free motion of the particle, while $V(x)$ is a one-dimensional potential. To solve eqn [5] on a quantum computer with finite resources (a finite number of qubits and a finite sequence of quantum gates), one must first of all discretize the continuous variables x and t. If the motion essentially takes place inside a finite region, say $-d \leqslant x \leqslant d$, decompose this region into 2^n intervals of length $\Delta = 2d/2^n$ and represent these intervals by means of the Hilbert space of an n-qubit quantum register (this means that the discretization step drops exponentially with the number of qubits). Hence, the wave function $|\psi(t)\rangle$ is approximated as follows:

$$|\tilde{\psi}(t)\rangle = \frac{1}{\mathcal{N}}\sum_{i=0}^{2^n-1}\psi(x_i,t)|i\rangle \qquad [7]$$

where $x_i \equiv -d + (i+1/2)\Delta$, $|i\rangle = |i_{n-1}\rangle \otimes \cdots \otimes |i_0\rangle$ is a state of the computational basis of the n-qubit quantum register and $\mathcal{N} \equiv \sqrt{\sum_{i=0}^{2^n-1}|\psi(x_i,t)|^2}$ is a factor that ensures correct normalization of the wave function. It is intuitive that $|\tilde{\psi}\rangle$ provides a good approximation to $|\psi\rangle$ when the discretization step Δ is much smaller than the shortest length scale relevant for the motion of the system. The Schrödinger equation [5] may be integrated by propagating the initial wave function $\psi(x,0)$ for each time-step ε as follows:

$$\psi(x,t+\varepsilon) = \mathrm{e}^{-(\mathrm{i}/\hbar)[H_0+V(x)]\varepsilon}\psi(x,t) \qquad [8]$$

If the time-step ε is small enough, it is possible to write the Trotter decomposition

$$\mathrm{e}^{-(\mathrm{i}/\hbar)[H_0+V(x)]\varepsilon} \approx \mathrm{e}^{-(\mathrm{i}/\hbar)H_0\varepsilon}\mathrm{e}^{-(\mathrm{i}/\hbar)\ V(x)\varepsilon} \qquad [9]$$

which is exact up to terms of order ε^2. The operator on the right-hand side of eqn [9] is still unitary, simpler than that on the left-hand side, and, in many interesting physical problems, can be efficiently implemented on a quantum computer. Advantage is taken of the fact that the Fourier transform can be efficiently performed by a quantum computer. One can then write the first operator in the right-hand side of eqn [9] as

$$\mathrm{e}^{-(\mathrm{i}/\hbar)\ H_0\varepsilon} = F^{-1}\mathrm{e}^{+(\mathrm{i}/\hbar)\ \left(\hbar^2k^2/2m\right)\varepsilon}F \qquad [10]$$

where k is the variable conjugated to x and F the discrete Fourier transform. This represents a transformation from the x-representation to the k-representation, in which this operator is diagonal. Then, using the inverse Fourier transform F^{-1}, one returns to the x-representation, in which the operator $\exp(-\mathrm{i}V(x)\varepsilon/\hbar)$ is diagonal. The wave function $\psi(x,t)$ at time $t = l\varepsilon$ is obtained from the initial wave function $\psi(x,0)$ by applying l times the unitary operator

$$F^{-1}\mathrm{e}^{+(\mathrm{i}/\hbar)\ \left(\hbar^2k^2/2m\right)\varepsilon}F\mathrm{e}^{-(\mathrm{i}/\hbar)\ V(x)\varepsilon} \qquad [11]$$

Therefore, simulation of the Schrödinger equation is now reduced to the implementation of the Fourier transform plus diagonal operators of the form

$$|x\rangle \to \mathrm{e}^{\mathrm{i}cf(x)}|x\rangle \qquad [12]$$

where c is some real constant. Note that an operator of the form [12] appears both in the computation of $\exp(-\mathrm{i}V(x)\varepsilon/\hbar)$ and of $\exp(-\mathrm{i}H_0\varepsilon/\hbar)$, when this latter operator is written in the k-representation. The quantum computation of [12] is possible, using an ancillary quantum register $|y\rangle_a$, by means of the following steps:

$$\begin{aligned} |0\rangle_a \otimes |x\rangle &\to |f(x)\rangle_a \otimes |x\rangle \\ &\to \mathrm{e}^{\mathrm{i}cf(x)}|f(x)\rangle_a \otimes |x\rangle \\ &\to \mathrm{e}^{\mathrm{i}cf(x)}|0\rangle_a \otimes |x\rangle \\ &= |0\rangle_a \otimes \mathrm{e}^{\mathrm{i}cf(x)}|x\rangle \end{aligned} \qquad [13]$$

The first step is a standard function evaluation and may be implemented by means of $O(n2^n)$ elementary quantum gates. Of course, more efficient implementations (polynomial in n) are possible when the function $f(x)$ has some structure, as is the case for the potentials $V(x)$ usually considered in quantum mechanical problems. The second step in eqn [13] is the transformation $|y\rangle_a \to \mathrm{e}^{\mathrm{i}cy}|y\rangle_a$ and can be performed in m single-qubit phase-shift gates, m being the number of qubits in the ancillary register. Indeed, one may write the binary decomposition of an integer $y \in [0, 2^m - 1]$ as $y = \sum_{j=0}^{m-1} y_j 2^j$, with $y_j \in \{0, 1\}$. Therefore,

$$\exp(\mathrm{i}y) = \exp\left(\sum_{j=0}^{m-1} \mathrm{i}cy_j 2^j\right) = \prod_{j=0}^{m-1} \exp(\mathrm{i}cy_j 2^j) \qquad [14]$$

which is the product of m single-qubit gates, each acting nontrivially (differently from identity) only on a single qubit. The jth gate operates the transformation $|y_j\rangle_a \to \exp(\mathrm{i}cy_j 2^j)|y_j\rangle_a$, with $|y_j\rangle_a \in \{|0\rangle, |1\rangle\}$ vectors of the computational basis for the jth ancillary qubit. The third step in eqn [13] is just the reverse of the first and may be implemented by the same array of gates as the first but applied in the reverse order. After this step the ancillary qubits are returned to their standard configuration $|0\rangle_a$ and it is therefore possible to use the same ancillary qubits for every time-step. Note that the number of ancillary qubits m determines the resolution in the computation of the diagonal operator [12]. Indeed, the function $f(x)$ appearing in eqn [12] is discretized and can take 2^m different values.

An interesting physical model, the so-called quantum sawtooth map, that can be simulated efficiently on a quantum computer without ancillary qubits is discussed here. The sawtooth map is a prototype model in the studies of classical and quantum dynamical systems and exhibits a rich variety of physical phenomena, from complete chaos to complete integrability, normal and anomalous diffusion, and quantum dynamical localization. The sawtooth map belongs to the class of periodically driven dynamical systems, governed by the Hamiltonian

$$H(\theta, I; \tau) = \frac{I^2}{2} + V(\theta) \sum_{j=-\infty}^{+\infty} \delta(\tau - jT) \qquad [15]$$

where (I, θ) are conjugate action-angle variables $(0 \leqslant \theta < 2\pi)$. This Hamiltonian is the sum of two terms, $H(\theta, I; \tau) = H_0(I) + U(\theta; \tau)$, where $H_0(I) = I^2/2$ is just the kinetic energy of a free rotator (a particle moving on a circle parameterized by the coordinate θ), while $U(\theta; \tau) = V(\theta) \sum_j \delta(\tau - jT)$ represents a force acting on the particle that is switched on and off instantaneously at time intervals T. Therefore, it is said that the dynamics described by Hamiltonian [15] is kicked. It is easy to integrate the Hamiltonian equations of motion and find that the evolution from time tT^- (prior to tth kick) to time $(t+1)T^-$ (prior to the $(t+1)$th kick) is described by the map

$$I_{t+1} = I_t + F(\theta_t), \quad \theta_{t+1} = \theta_t + TI_{t+1} \qquad [16]$$

where $F(\theta) = -\mathrm{d}V(\theta)/\mathrm{d}\theta$ is the force acting on the particle. In the following, the special case $V(\theta) = -k(\theta - \pi)^2/2$ is considered. This map is called the sawtooth map, since the force $F(\theta) = -\mathrm{d}V(\theta)/\mathrm{d}\theta = k(\theta - \pi)$ has a sawtooth shape, with a discontinuity at $\theta = 0$. By rescaling $I \to J = TI$, the classical dynamics is seen to depend only on the parameter $K = kT$. The classical motion is stable for $-4 \leqslant K \leqslant 0$ and completely chaotic for $K < -4$ and $K > 0$. For any $K > 0$, one has normal diffusion in the action (momentum) variable: $\langle (\Delta J_t)^2 \rangle \approx D(K)t$, where $\Delta J \equiv J - \langle J \rangle$ and $\langle \ldots \rangle$ denotes the average over an ensemble of trajectories. For $K > 1$, $D(K) \approx (\pi^2/3)\ (K^2)$.

The quantum version of the sawtooth map is obtained by means of the usual quantization rules, $\theta \to \theta$ and $I \to I = -i\partial/\partial\theta$ (set $\hbar = 1$). The quantum evolution in one map iteration is described by a unitary operator U acting on the wave function ψ:

$$\psi_{t+1} = U\psi_t = U_T U_k \psi_t,$$

$$U_T = \mathrm{e}^{-\mathrm{i}TI^2/2}, \quad U_k = \mathrm{e}^{\mathrm{i}k(\theta-\pi)^2/2} \qquad [17]$$

The effective Planck constant is given by $\hbar_{\mathrm{eff}} = T$ and the classical limit corresponds to $k \to \infty$ and $T \to 0$ while keeping $K = kT$ constant.

In the following, an exponentially efficient quantum algorithm for simulation of the map [17] is

described. It is based on the forward/backward quantum Fourier transform between momentum and angle bases. Such an approach is convenient since the operator U is the product of the two operators U_k and U_T, which are diagonal in the θ and I representations, respectively. This quantum algorithm requires the following steps for one map iteration:

1. Apply U_k to the wave function $\psi(\theta)$. In order to decompose the operator U_k into one- and two-qubit gates, first of all, θ is written in binary notation:

$$\theta = 2\pi \sum_{j=1}^{n} \alpha_j 2^{-j} \qquad [18]$$

with $\alpha_i \in \{0, 1\}$. Here n is the number of qubits, so that the total number of levels in the quantum sawtooth map is $N = 2^n$. One can insert eqn [18] into the unitary operator U_k, obtaining the decomposition

$$e^{ik(\theta-\pi)^2/2} = \prod_{i,\, j=1}^{n} e^{i2\pi^2 k\left(\alpha_i 2^{-i} - (1/2n)\right)\left(\alpha_j 2^{-j} - (1/2n)\right)} \qquad [19]$$

which is the product of n^2 two-qubit gates, each acting nontrivially only on the four-dimensional sub-space spanned by the qubits i and j.
2. The change from the θ to the I representation is obtained by means of the quantum Fourier transform, which requires and $n(n+1)/2$ elementary quantum gates.
3. In the I representation, the operator U_T has essentially the same form as the operator U_k in the θ representation, and therefore it can be decomposed into n^2 two-qubit gates, similar to eqn [19].
4. Return to the initial θ representation by application of the inverse quantum Fourier transform.

Thus, overall, this quantum algorithm requires $3n^2 + n$ gates per map iteration. This number is to be compared with the $O(n2^n)$ operations required by a classical computer to simulate one map iteration by means of a fast Fourier transform. Thus, the quantum simulation of the quantum sawtooth map dynamics is exponentially faster than any known classical algorithm. Note that the resources required for the quantum computer to simulate the evolution of the sawtooth map are only logarithmic in the system size N.

As an example of the efficiency of this quantum algorithm, **Figure 1** shows the Husimi functions, taken after 1000 map iterations, for $K = -0.1$, $-\pi \leqslant J < \pi$ (torus geometry). The classical limit is obtained exponentially fast by increasing the number of qubits n, with $\hbar_{\text{eff}} = T = 2\pi/2^n$ ($k = K/T, -N/2 \leqslant I < N/2$). For this value of K, the classical limit is characterized by a complex hierarchical structure of the phase space down to smaller and smaller scales and by anomalous diffusion in the variable J. It is noted that $n = 6$ qubits are sufficient to observe the quantum localization of the anomalous diffusive propagation through hierarchical integrable islands. At $n = 9$, one can see the appearance of integrable islands, and at $n = 16$ the quantum Husimi function explores the complex hierarchical structure of the classical phase space.

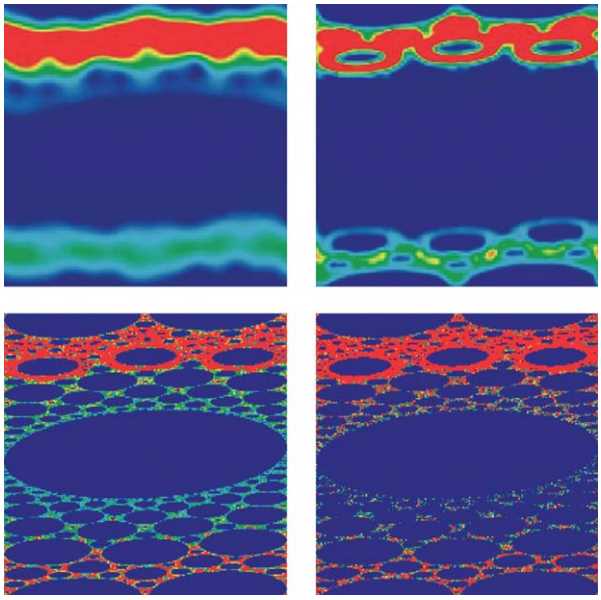

Figure 1 Husimi function for the sawtooth map in action angle variables (J, θ), with $-\pi \leqslant J < \pi$ (vertical axis) and $0 \leqslant \theta < 2\pi$ (horizontal axis), averaged in the interval $950 \leqslant t \leqslant 1000$, for $K = -0.1$, $T = 2\pi/2^n$, $n = 6$ (top left), 9 (top right), 16 (bottom left), and classical density distribution (bottom right). A momentum eigenstate, $|\psi(0)\rangle = |m_0\rangle$, with $m_0 = [0.38 \times 2^n]$ is considered as initial state at time $t = 0$; the classical plot is obtained from an ensemble of 10^8 trajectories, with initial momentum $J_0 = 0.38 \times 2\pi$ and random angles. The color is proportional to the density: blue for zero and red for maximal density.

However, there is an additional aspect to be taken into account. Any quantum algorithm has to address the problem of efficiently extracting useful information from the quantum computer wave function. Indeed, the result of the simulation of a quantum system is the wave function of this system, encoded in the n qubits of the quantum computer. The problem is that, in order to measure all $N = 2^n$ wave function coefficients by means of standard polarization measurements of the n qubits, one has to repeat the quantum simulation a number of times exponential in the number of qubits. This procedure would spoil any quantum algorithm, even in the case, like the present one, in which such algorithm could

compute the wave function with an exponential gain with respect to any classical computation. Nevertheless, there are some important physical questions that can be answered in an efficient way. Two significant examples are discussed.

Dynamical localization is one of the most interesting phenomena that characterize the quantum behavior of classically chaotic systems: quantum interference effects suppress chaotic diffusion in momentum, leading to exponentially localized wave functions. Dynamical localization can be studied in the sawtooth map model. In this case, map [17] is studied on the cylinder $[I \in (-\infty, +\infty)]$, which is cut-off at a finite number N of levels due to the finite quantum (or classical) computer memory. Similar to other models of quantum chaos, quantum interference in the sawtooth map leads to suppression of classical chaotic diffusion after a break time $t^\star \sim D_I$ where $D_I \approx \langle (\Delta I_t)^2 \rangle / t$ is the classical diffusion coefficient. For $t > t^\star$, while the classical distribution goes on diffusing, the quantum distribution reaches a steady state which decays exponentially over the momentum eigenbasis:

$$W_m \equiv |\langle m|\psi\rangle|^2 \approx \frac{1}{\ell} \exp\left[-\frac{2|m - m_0|}{\ell}\right] \quad [20]$$

where $\ell \sim D_I$ is known as the localization length and m_0 is the initial value of the momentum (the index m singles out the eigenstates of I, that is, $I|m\rangle = m|m\rangle$). Therefore, for $t > t^\star$ only $\sqrt{\langle (\Delta I)^2 \rangle} \sim \ell$ levels are populated. For the sawtooth map, $\ell \approx D_I \approx (\pi^2/3)k^2$. **Figure 2** demonstrates that exponential localization, obtained using the above-described quantum algorithm, can already be clearly seen with $n = 6$ qubits. The exponentially localized distribution, appearing at $t \approx t^\star \approx 10$, is frozen in time, apart from quantum fluctuations. The freezing of the localized distribution can be seen from comparison of the probability distributions taken immediately after $t^\star$ and at a much larger time $t = 300 \approx 25t^\star$.

The localization length can be measured by running the quantum algorithm described above, repeatedly up to time $t > t^\star$. Each run is followed by a standard projective measurement on the computational (momentum) basis. Since the wave function at time t can be written as $|\psi(t)\rangle = \sum_m \hat{\psi}(m,t)|m\rangle$, such a measurement gives outcome $\bar{m}$ with probability $W_{\bar{m}} = |\hat{\psi}(\bar{m},t)|^2$. The results of the measurements are stored in a histogram and then the localization can be extracted from a fit of the exponential decay of this histogram over the momentum basis. The number of runs and measurements required to estimate ℓ depends on the desired accuracy but not on ℓ itself. Let the gain of quantum computation of the

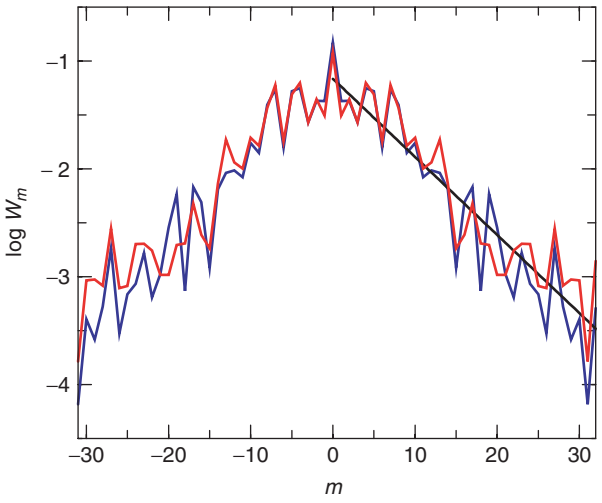

Figure 2 The probability distribution over the momentum basis for the sawtooth map with $n = 6$ qubits, $k = \sqrt{3}$, $K = \sqrt{2}$, and initial momentum $m_0 = 0$; the time average is taken in the intervals $10 \leqslant t \leqslant 20$ (red curve) and $290 \leqslant t \leqslant 300$ (blue curve). The straight line fit, $W_l \propto \exp(-2|m|/\ell)$, gives a localization length $\ell \approx 12$. Note that the logarithm is base ten.

localization length be estimated with respect to classical computation. First of all, recall that it is necessary to make about $t^\star = O(\ell)$ map iterations to obtain the localized distribution. This is true, both for the present quantum algorithm and for classical computation. It is reasonable to use a basis size $N = O(\ell)$ to detect localization (say, N equal to a few times the localization length). In such a situation, a classical computer requires $O(\ell^2 \log \ell)$ operations to extract the localization length, while a quantum computer would require $O(\ell(\log \ell)^2)$ elementary gates. Indeed, both classical and quantum computers need to perform $t \approx t^\star = O(\ell) = O(N)$ map iterations. Therefore, the quantum computer provides a quadratic speed-up in computing the localization length. It is also interesting to notice that, even though the speed-up is only quadratic, the advantage of the quantum computer in memory resources remains exponential. This point becomes crucial in many-dimensional or many-body physical models, in which, using a classical computer, it is very hard, if not impossible, to merely establish if the system is localized or not.

One may ask the following question: why is the speed-up in computing the localization length not exponential, even though a single step of the dynamical evolution can be simulated with exponential speed-up? The ultimate reason is that in the diffusive process that precedes localization, the spread of information is "slow." More precisely, the number N of quantum levels which are significant to describe the system's dynamics grow only as a square root of time. Therefore, in order to use N levels, the

dynamics must be iterated up to a timescale which is $\propto \sqrt{N}$, that is, exponential in the number of qubits.

The quantum computation can provide an exponential gain (with respect to any known classical computation) in problems that require the simulation of dynamics up to a time t which is independent of the number of qubits. In this case, provided that one can extract the relevant information in a number of measurements polynomial in the number of qubits, one should compare $O(t(\log N)^2)$ elementary gates (quantum computation) with $O(tN \log N)$ elementary gates (classical computation). This is the case of dynamical correlation functions of the form

$$C(t) \equiv \langle \psi | A^{\dagger}(t) B(0) | \psi \rangle = \langle \psi | (U^{\dagger})^t A^{\dagger}(0) U^t B(0) | \psi \rangle \qquad [21]$$

where U is the time-evolution operator [17] for the sawtooth map. Similarly, one can efficiently compute the fidelity of quantum motion, which is a quantity of central interest in the study of the stability of quantum motion under perturbations. The fidelity $f(t)$ (also called the Loschmidt echo), measures the accuracy with which a quantum state can be recovered by inverting, at time t, the dynamics with a perturbed Hamiltonian. It is defined as

$$f(t) = \langle \psi | (U_{\varepsilon}^{\dagger})^t U^t | \psi \rangle = \langle \psi | e^{iH_{\varepsilon}t} e^{-iHt} | \psi \rangle \qquad [22]$$

Here the wave vector $|\psi\rangle$ evolves forward in time with Hamiltonian H up to time t and then evolves backward in time with a perturbed Hamiltonian H_{ε}. If the evolution operators U and U_{ε} can be simulated efficiently on a quantum computer, as is the case in many physically interesting situations, then the fidelity of quantum motion can be evaluated with exponential speed-up with respect to known classical computations. The same conclusion is valid for the correlation functions [21].

Quantum Noise

Any practical implementation of a quantum computer will have to face errors, due to the inevitable coupling of quantum processors to the surrounding environment or to device imperfections. The first kind of error is known as decoherence and is a threat to the actual implementation of any quantum computation. More generally, decoherence theory has a fundamental interest beyond quantum information science, since it provides explanations for the emergence of classicality in a world governed by the laws of quantum mechanics. The core of the problem is the superposition principle, according to which any superposition of quantum states is an acceptable quantum state. This entails consequences that are absurd according to classical intuition, like the superposition of "cat alive" and "cat dead" that is considered in the Schrödinger's cat paradox. The interaction with the environment can destroy the coherence between the states appearing in a superposition (for instance, the "cat alive" and "cat dead" states). Therefore, decoherence invalidates the quantum superposition principle, which is at the heart of the power of quantum algorithms.

The presence of device imperfections, although not leading to any decoherence, also hinders the implementation of any quantum computational task. Imperfection effects can be modeled as follows: the quantum computer is seen as a lattice of interacting spins (qubits) where, due to the unavoidable presence of imperfections, the spacing between the up and down states and the couplings between the qubits are both random. The Hamiltonian of this model reads, for a linear array of n qubits, as follows:

$$H_S = \sum_i (\Delta_0 + \delta_i)\sigma_i^z + \sum_{i<j} J_{ij}\sigma_i^x \sigma_j^x \qquad [23]$$

where the σ_i are the Pauli matrices for the qubit i, and Δ_0 is the average level spacing for one qubit. The second sum in eqn [23] runs over nearest-neighbor qubit pairs and δ_i, J_{ij} are randomly and uniformly distributed in the intervals $[-\delta/2, \delta/2]$ and $[-J, J]$, respectively. It is assumed that the phase accumulation given by Δ_0 can be eliminated by standard spin echo techniques, while the other terms give unwanted phase rotations and qubit couplings. In **Figure 3**, the limits to quantum computation due to hardware

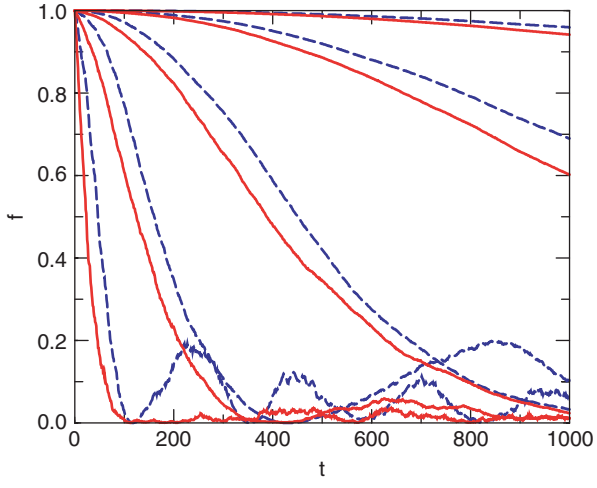

Figure 3 Fidelity as a function of t, for the sawtooth map with parameter values as in **Figure 1**, $n = 9$ qubits, $J = \delta$ (red lines) and $J = 0$ (blue lines). From top to bottom: imperfection strength $\varepsilon = \delta\tau_g = 10^{-5}$, 3×10^{-5}, 10^{-4}, 3×10^{-4}, 10^{-3}. Here τ_g denotes the time interval between consecutive quantum gates.

imperfections in a concrete example are illustrated, the quantum algorithm simulating the sawtooth map. The fidelity of quantum computation, defined by $f(t) = |\langle \psi_\varepsilon(t)|\psi_0(t)\rangle|^2$ is plotted, where $|\psi_\varepsilon(t)\rangle$ is the actual quantum wave function in the presence of imperfections and $|\psi_0(t)\rangle$ is the quantum state for a perfect computation. One can show that the fidelity drops with time according to the law $f(t) \approx \exp(-At^2)$, as expected, for small ε, from perturbation theory. The constant $A \propto n_q(\varepsilon n_g)^2$, with $n_g = 3n^2 + n$ number of quantum gates per map iteration. Therefore, a reliable quantum computation is possible up to a timescale $t_f \propto \varepsilon^{-1} n_g^{-1} n_q^{-1/2}$. A longer quantum computation would necessarily require the implementation of quantum error correcting codes.

Final Remarks

A few significant examples have been discussed showing the capabilities of a quantum computer in the simulation of complex physical systems. A quantum computer with a few tens of qubits, if constructed, would outperform a classical computer in these kinds of problems. Many proposals have been put forward to build a real quantum computer, ranging from atomic physics to solid-state devices. At present, it has been possible to demonstrate several quantum algorithms using NMR quantum processors (with up to seven qubits) and cold ions in a trap, while, in the solid-state arena, two-qubit conditional gate operation has been demonstrated using a pair of coupled superconducting qubits. In these implementations, quantum noise effects allow a reliable quantum computation only up to a few tens of quantum gates, in the best cases. Therefore, decoherence and imperfection effects appear to be the ultimate obstacle to the realization of a large-scale quantum computer.

Quantum Devices of Reduced Dimensionality

M Grundmann, Universität Leipzig, Leipzig, Germany

Introduction

A "quantum device" could be defined as a device whose functionality or principle of operation depends essentially on quantum mechanical effects. However, this definition somehow seems too vague. For example, a chair obtains its holding power from the quantum mechanical overlap of the wave functions of its constituents or a toaster relies on quantum mechanical scattering processes for converting electrical current into heat. Therefore a "quantum device" shall be defined here as a "man-made device that intentionally employs or harnesses quantum mechanical effects for its operation." This article is limited to condensed matter devices, thus completely (but intentionally) bypassing the "natural" use of quantum mechanics in living organisms.

A large number of devices already function based on the control of quantum mechanical interactions or effects. Prominent examples are the LASER (light

amplification by stimulated emission of radiation) and the SQUID (superconducting quantum interference device). A possibly larger number awaits its commercialization or even their invention. This section discusses, in particular, quantum devices with "reduced dimensionality." These shall be understood as devices that rely on structures that confine charge carriers in one, two, or all three dimensions. Such systems are called quantum films or wells, quantum wires, and quantum boxes, respectively. Given the typical de Broglie wavelength of electrons in semiconductors, typical sizes of such structures are in the 1–10 nm range. It is noted that currently (2004) the smallest feature size in mass-market consumer electronics is below 100 nm. The predicted miniaturization will hit the 10 nm mark in the years beyond 2010. Therefore quantum effects seem unavoidable in mainstream microelectronics.

The natural enemies of quantum devices are dephasing events such as scattering of an otherwise coherently evolving state, increasing temperature, either due to higher scattering rate or the modification of thermodynamic distribution functions, and increasing structural size, mostly leading to a transition to classical behavior.

Quantum Mechanical Effects

The quantum effects that are used in quantum devices are sorted by increasing order of complexity and decreasing order of fundamental understanding and employment in devices:

1. single particle effects,
2. Pauli's exclusion principle,
3. quantization of electronic states in confining potentials,
4. tunneling effect,
5. spatial and temporal coherence of the wave function,
6. spin,
7. quantum liquids, and
8. entanglement.

Examples for the use of these effects in condensed matter devices is discussed below. The list, however, may not be exhaustive as eventually any quantum mechanical effect, for example, the quantization of other degrees of freedom or still unexplored effects, may be used in devices.

Quantization in Potential Wells

Quantum devices of reduced dimensionality depend some way or another on the presence of potential wells that limit the motion of charge carriers in c dimensions compared to bulk material. The motion can be limited in one dimension within a quantum film or well (QW), in two dimensions within a quantum wire (QWR), or in all three dimensions within a quantum dot (QD) or box. These structures can be combined to double or multiple structures or even periodic arrays (**Table 1**).

Table 1 Structures with two-, one-, and zero-dimensional confinement

Confinement of motion to c dimensions	*Name*	*Combination of two*	*Periodic structure*
2	Quantum well	Double quantum well	Superlattice
1	Quantum wire	Quantum wire pair	Quantum wire array
0	Quantum dot	Quantum dot molecule	Quantum dot chain

The confining potential can arise from applied spatially modulated electric potentials or the effect of band offsets in heterostructures or a combination of both. The quantization depends on the size, shape, and barrier height of the confining potential. By controlling the barrier height between confinement structures the degree of quantum mechanical coupling can be varied.

The simplest picture arises from the particle in a rectangular box with side lengths L_x, L_y, and L_z and infinite barriers. The quantization energy is given by

$$E = \frac{\pi^2\hbar^2}{2m}\left(\frac{n_x^2}{L_x^2} + \frac{n_y^2}{L_y^2} + \frac{n_z^2}{L_z^2}\right)$$

with m being the effective mass of the particle (here taken as isotropic) and the n_i being the quantum numbers ($n_i \geqslant 1$).

If the confining potential is harmonic, the energy levels are equidistant.

$$E = (d/2 + n)\hbar\omega$$

$d = 3 - c$ shall be the dimension of the confinement potential with c being the number of confined dimensions. For a parabolic confinement potential the generalized Kohn's theorem applies, which states that the resonance energies of many electrons in the dot are the same as for a single electron and that dipole radiation interacts only with the center of mass motion of the electrons.

Since self-assembled nanostructures often involve strained systems, the confining potential depends on

the local strain and the resulting piezoelectric field which may be spatially strongly inhomogeneous.

The finite barrier height limits the number and confinement energy of confined states. In quantum dots, there is a critical minimum size for which at least one state is confined. Quantum dots smaller than the critical size do not exhibit any confined states, as opposed to quantum wells that always have at least one localized and quantized state.

Two-Dimensional Carrier Gases

A particularly important confined electron system is the two-dimensional electron gas (2DEG). Such a gas can develop in a quantum well. However, a single interface between two semiconductors of different bandgaps is sufficient to cause the creation of a 2DEG. If modulation doping, that is spatially inhomogeneous doping, is used, a high carrier concentration can be achieved in the 2DEG without the dopant atoms being located in or close to the 2DEG. In this way, impurity scattering is avoided and a high mobility is achieved. For GaAs/AlGaAs structures the mobility record (2004) stands at 3.1×10^7 Vs cm^{-2} at low temperatures. Thus, 2DEG and its manipulation are the basis for many quantum devices.

In a high electron mobility transistor (HEMT), the transport in a 2DEG is used as channel conductivity in a field effect transistor. HEMTs display high transconductance and low noise figure and are used for many high-frequency applications such as satellite receivers. In order to maximize the carrier confinement, pseudomorphic quantum wells, for example, InGaAs/AlGaAs on GaAs, are used. The highest performance is achieved with InGaAs/InAlAs quantum wells on InP substrate. In order to transfer this technology to (larger and cheaper) GaAs substrates, a metamorphic, dislocated buffer is grown, and such a device is called MHEMT. Similar strategies apply to SiGe/Si HEMTs.

Magnetotransport effects in 2DEGs at low temperature have been studied in detail for a while. In the integral quantum Hall effect (IQHE) the conductivity of the 2DEG exhibits extended plateaus for a range of magnetic fields with a well-defined conductivity value σ_{xy} that takes integer multiples of e^2h^{-1}. This quantum mechanical value is found to be independent from details of the sample (within reasonable spread) such as doping, layer thickness, and growth method. The IQHE can be used for fabrication of a standard for the resistance and the unit "ohm." The precision of the QHE normal is two orders of magnitude better than the realization of the ohm in the SI system. For this purpose, parallel and serial circuits of QHE resistors can also be used and an AC measurement technique can be devised.

It is to be noted that more complicated phenomena, the fractional quantum Hall effect, are observed and discovered in such quantum liquids at even more extreme conditions (very low temperatures and high magnetic fields).

Quantum wells are also very successfully used as active mediums in semiconductor laser diodes. Charge carriers are captured efficiently from the barrier material (high bandgap) into a quantum well or multiple quantum wells (low bandgap). Due to their small thickness a high-density carrier gas is easily achieved and inversion is reached quickly. The finite density of states at the sub-band edges provides a favorable gain spectrum. This leads ultimately to low lasing threshold current of $\sim 40\,\mathrm{A\,cm^{-2}}$. Their combination with high-finesse optical cavities using high-reflectivity dielectric layer packages (Bragg mirrors) leads to vertical surface emitting lasers (VCSEL) and tests the use of quantum electrodynamic (QED) effects (e.g., the modification of spontaneous emission lifetime – Purcell effect).

Quantum Wires

Many device applications have been envisioned for quantum wires. Since they are positioned in terms of reduced dimensionality between quantum wells and quantum dots, for some properties the ultimate solution is quantum dots. Since quantum dots can be fabricated in a self-assembled manner, they have made some of the quantum wire devices obsolete. However, quasi-one-dimensional conduction poses interesting physics (e.g., reduced scattering and Luttinger liquids). Quantum wires can be used as channels in transistors. In order to draw a sufficient current, many wires may have to be used in parallel. Due to the one-dimensional k-space, carrier scattering is reduced and thus a higher mobility should be possible. Recent progress in the self-assembled fabrication of quantum wire nanowhiskers and heterostructures incorporated in them makes them seem attractive for a variety of applications including LEDs, lasers, and sensors.

Quantum Dots

Quantum dots confine carriers in all three spatial dimensions. These are therefore sometimes termed "artificial atoms." The embedding into a solid-state matrix makes them more readily accessible to manipulation with electrodes, currents, fields, etc. than atoms in a trap. However, this comes at the price of stronger (compared to ions in a trap) coupling to external degrees of freedom, such as charge fluctuations and thermal bath.

The primary effect of quantum confinement is to create singular density of states at the quantized levels. The energetic broadening for a single quantum dot is typically small at low temperature (μeV range). With increasing temperature, additional dephasing mechanisms can increase the homogeneous broadening to the 10 meV range. An ensemble of quantum dots exhibits inhomogeneous broadening because the individual nanostructures are not exactly identical with respect to size, shape, and possibly chemical composition.

Devices based on single dots have been envisioned, realized, and investigated for storage of single electrons, emission of single or entangled photons, and quantum information processing.

The storage of single electrons is comparably straightforward. The capture of a single electron causes a second electron to need a larger energy to be on the dot due to Coulomb repulsion. While for typical shallow donors in semiconductors this effect is so strong that only the neutral state (with one electron) is localized, the Coulomb interaction energy in self-assembled quantum dots is typically in the range of 20 meV. At sufficiently low temperature for a given potential landscape, a second electron cannot enter the dot (Coulomb blockade) and the dot charge is fixed to an integer number of electrons, possibly one or zero. The storage of single electrons has been successfully demonstrated at low temperatures. Efforts are underway to maintain the effects up to liquid nitrogen temperature. The dots are typically built into a transistor structure to make a single electron transistor (SET). Here the gate electrode contains the quantum dot close to the channel. Due to electrostatic interaction the source–drain channel only becomes conductive after a sufficient source–drain voltage larger than the voltage related to the Coulomb energy has been applied. Conversely, in a single-electron memory, the conductance of the SET can be used to test whether a single electron is located on the quantum dot or not. By periodically modulating the applied bias voltages in a suitable manner with a frequency f, a single electron can be transferred by tunneling onto and off the dot from source to drain for each cycle. Such a device is called turnstile device and can be used to define a current normal via $I = fe$.

Quantum dots can be used in what is called a "photon gun." In such a device a trigger impulse causes the reliable emission of a single photon. This is a nonclassical form of light which cannot be produced from dimming a conventional source. In classical light the time difference between photons follows Poisson statistics while a photon gun is supposed to create a periodic stream of single photons. With such photons, higher data rates for quantum cryptographic transmissions can be realized. Upon trigger the pulse carriers are injected into the quantum dot. Emission on the single exciton line occurs only once for each trigger with only a small time delay between trigger and emission.

The emission of entangled photons is possible if the cascade relaxation from biexciton to exciton to empty quantum dot is used. If the single exciton state is degenerate with respect to the two in-plane polarization directions, the photons are entangled and can be used for quantum cryptographic information transmission schemes. The polarization degeneracy calls for quantum dots with certain geometrical symmetry as strain, piezoelectric fields, and geometric asymmetries contribute to the lifting of the degeneracy. The two emitted photons have different energies unless the biexciton binding energy is zero. This is generally possible and depends on the size and shape of the quantum dot.

Several schemes have been devised to use quantum dots in quantum computing schemes. The spin degree of freedom seems a good candidate for quantum computational operations due to its long dephasing time of up to several milliseconds. Many of the current experiments involve optical sampling of the quantum information with polarized light and suitable pulses. Eventually electronic means will be more useful to access the quantum dots. This has been accomplished for quantum dots defined with in-plane gates, but only at very low temperatures. Using clever combinations of the Coulomb blockade mechanisms and external bias, the occupation and the spin orientation of a single electron can be tested electronically at low temperatures. Quantum computing schemes based on cellular automata (QCA) have been proposed extensively to realize quantum computational algorithms. QCA rely on arrays of quantum dots that interact to allow for switching of their polarization state.

Quantum dots can be used as active-gain medium in semiconductor diode lasers, which record small transparency current densities due to the fairly small volume for carrier inversion. Till date, reasonable laser performance has been obtained by using only self-assembled quantum dots.

The discrete density of states leads, in an ideal situation, to very large T_0 values (small temperature-dependence of the threshold current) and zero alpha-factor (also termed line width enhancement factor). Realistically, the T_0 values have been found to be large (close to infinity) only up to 150–200 K; for higher temperatures the T_0 values are not particularly advantageous compared to conventional quantum well lasers because of loss of carriers from the

quantum dots due to thermal excitations or the Auger effect. Small α-factors have been realized, also leading to a reduction of current filamentation and a homogeneous optical near field. These properties allow for improved high power lasers.

Typically, lasing is designed to occur on the ground state of the quantum dots since this results in the lowest threshold (below $10\,A\,cm^{-2}$) for laser diodes. Excited states provide higher gain and can be made to contribute to the lasing process simultaneously with the ground state. By intentionally increasing the width of the inhomogeneous broadening, for example, by growing vertically stacked dots with slightly different geometrical properties, the gain spectrum can be made very broad. Such gain medium would allow for wide tunability.

The management of strain and chemical composition allows to create 1300 and 1550 nm emission, important for datacom and telecom applications, respectively, on GaAs substrate. In particular, the use of metamorphic buffers has been successful recently. Quantum dot lasers are found to have a strongly improved radiation hardness compared to quantum well lasers.

Table 2 Quantum devices, the effects they are based on, and applications

Device	*Quantum effect*	*Performance/ Use*
High electron mobility transistor	2D confinement	High-speed, low-noise amplifier, low-threshold laser
Quantum well laser	2D confinement	Low threshold
Quantum dot laser	0D confinement	Low threshold, small α
Quantum Hall effect	Quantum liquid	Resistance standard
Electron turnstile	Tunneling, single electrons	Current standard
Photon gun	Single-particle effect	Quantum cryptography
Quantum cellular automata	0D confinement, coherence	Quantum computing
Quantum dot	Entanglement, coherence	Quantum computing, quantum cryptography
Josephson junction	Coherence of wave function	Voltage standard
SQUID	Coherence of wave function	Sensitive magnetometer

Josephson Junctions

A Josephson junction is made up from two superconductors sandwiching a thin nonsuperconducting layer such that electrons can tunnel through the barrier. The coherence of the wave function in the superconductor leads to DC or AC currents. The DC Josephson current is proportional to the phase difference between the two superconductors. The frequency f of the AC Josephson current is proportional to the voltage V applied across the junction, $f = 2\,eV\,h^{-1}$. This allows for a voltage normal based on a frequency. A Josephson junction standard can realize a voltage with an accuracy of 10^{-10}. For a standard in the volt regime several thousand junctions are put in series. A superconducting loop with two Josephson junctions in either arm is very sensitive (10^{-14} T) to the magnetic flux enclosed (SQUID, superconducting quantum interference device).

Summary

Devices relying on quantum effects have a broad spectrum of applications (**Table 2**). Generally it is difficult to achieve operation at ambient temperatures. Great progress has been made in the field of metrology where quantum devices will become standards that can be easily reproduced, at least in a laboratory environment. Room temperature operation has been achieved, for example, for quantum dot lasers with the preservation of several advantages from the quantum nature of the gain medium.

Quantum Hall Effect

J Weis, Max-Planck-Institut für Festkörperforschung, Stuttgart, Germany

Introduction

The quantum Hall effect (QHE) and its relation to fundamental physical constants was discovered in 1980 by Klaus von Klitzing for which he received a Nobel prize in 1985. The Hall resistance R_H (Hall voltage divided by applied current) measured on a two-dimensional charge carrier system at low temperatures (typically at liquid helium temperature $T = 4.2\,\mathrm{K}$) and high magnetic fields (typically several tesla), which is applied perpendicularly to the plane of the charge carrier system, shows well-defined constant values for wide magnetic field or charge carrier density variations. These plateau values are described by $|R_H| = h/(ie^2)$, where h is the Planck constant, e is the elementary charge, and i an integer value with $i = (1, 2, 3, \ldots)$. Nowadays, this effect is denoted as integer quantum Hall effect (IQHE) since, beginning with the year 1982, plateau values have been found in the Hall resistance of two-dimensional electron systems of higher quality and at lower temperature which are described by $|R_H| = h/(fe^2)$, where f is a fractional number. The fractions $f = \{1/3, 2/3\}$ are the most prominent ones. For the discovery of these unexpected new quantum states in 1982, manifesting themselves in the fractional quantum Hall effect (FQHE), Dan C Tsui, Horst L Störmer, and Robert B Laughlin were honored with the Nobel prize in 1998.

The most important implication of the IQHE is its application in metrology where the effect is used to represent a resistance standard. Due to a small standard uncertainty in reproducing the value of the quantized Hall resistance (few parts of 10^{-9} in the year 2003), its value was fixed in 1990, for the purpose of resistance calibration, to $25812.807\,\Omega$ and is nowadays denoted as the conventional von Klitzing constant R_{K-90}.

It is generally accepted that the von Klitzing constant R_K agrees with h/e^2, and is therefore directly related to the Sommerfeld fine-structure constant $\alpha = (\mu_0\, c/2)(e^2/h) = (\mu_0\, c/2)(R_K)^{-1}$, which is a measure for the strength of the interaction between electromagnetic fields and elementary particles (please note, in the International System of Units (SI), the speed of light c in vacuum and the permeability of vacuum μ_0 are defined as fixed physical constants). The IQHE allows one to determine the fine-structure constant α with high precision, simply based on magnetoresistance measurements on a solid-state device.

The FQHE is a manifestation of correlation effects among the charge carriers interacting in the two-dimensional system, which lead to the formation of new quantum states. With an improvement in the quality and reaching lower temperatures for the charge carrier system, more and more quantum Hall states have been found. Quantum Hall systems are, therefore, used as model systems for studying the formation of correlated many-particle states, developing theory for their description, and identifying, probably, their simpler description in terms of the formation of new quasiparticles, for instance, the so-called "composite fermions."

Hall Effect

An electrical charge moving with constant velocity in a homogeneous magnetic field feels the Lorentz force acting in a direction perpendicular to both the magnetic field and the direction of motion. A current through an electrical conductor (an experimental setup is shown in **Figure 1**) leads to the Hall effect discovered by Edwin Hall in 1879. As can be derived within the Drude model, the free charge carriers in the conductor accumulate due to the Lorentz force on one side and deplete on the opposite side leading to an electrical field (Hall field) in the conductor which in back-action compensates for the Lorentz force so that, under stationary conditions, the charge carriers drift straight through the sample. If only one type of charge carrier is present, the related Hall voltage V_H, that is, the difference in the electrochemical potentials between two contacts at opposite sample edges, where the connection line between these two contacts lies perpendicular to the current direction, is simply described by $V_H = V_y = R_H I_x$

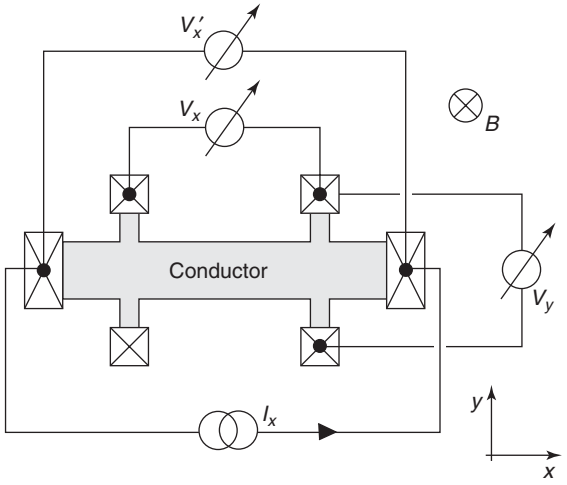

Figure 1 Setup for measuring the Hall resistance $R_{xy} = V_y/I_x$, the (four-terminal) longitudinal resistance $R_{xx} = V_x/I_x$, and the (two-terminal) longitudinal resistance $R'_{xx} = V'_x/I_x$.

with the Hall resistance R_H given by

$$R_H \equiv R_{xy} = B_z/qnd$$

for the orientation of the arrangement shown in **Figure 1**. The Hall resistance is positive or negative depending on the type of charge carriers which are either electrons ($q = -e$) or missing electrons/holes ($q = +e$). Its magnitude increases linearly with the homogeneously applied magnetic flux density B_z and the slope of the increase is given by the concentration n of these carriers and the thickness d of the conducting layer. That is why the Hall effect is used as an important diagnostic tool to determine essential properties of electrical conductors – free charge carrier concentration n and sign of q. Hall devices find various applications as magnetic field sensors.

Two-Dimensional Charge Carrier System

The QHE is observed in two-dimensional charge carrier systems, belonging to the class of so-called low-dimensional charge carrier systems. Generally, the charge carriers in a bulk conductor can be considered as independent charged quasiparticles moving, with an effective mass m^*, freely in the three-dimensional space of the crystal. In the simplest case, such a charge carrier system is treated as the Sommerfeld fermion gas, that is, the wave functions of these quasiparticles are described by plane waves and their eigenenergies by $\varepsilon = |\hbar k|^2/(2m^*)$, where k denotes the wave vector and $\hbar = h/2\pi$. The de Broglie wavelength $\lambda = 2\pi/|k|$ of the charge carriers at their Fermi level in the bulky conductor (= Fermi wavelength λ_F) is given by $\lambda_F = h/\sqrt{(2m^*\varepsilon_F)}$. Confining the charge carriers to spatial dimensions of the length of the Fermi wavelength λ_F, the charge carriers are restricted in their motion. Only certain eigenenergies are possible in the confined direction, and the distance between these eigenenergies increases with narrowing the spatial width of the confinement, until only the lowest eigenenergy is still lying below the Fermi level. Two-dimensional charge systems allow motion only in a plane, one-dimensional charge systems (denoted as quantum wires) only along a line, and in a zero-dimensional system (denoted as quantum dots or "artificial atoms"), the charge carriers are confined in a cage allowing them overall only a discrete set of eigenenergies.

The Fermi wavelength $\lambda_F = h/\sqrt{(2m^*\varepsilon_F)}$ of charge carriers in a bulky conductor is large in the case of a low Fermi energy ε_F, achieved by a low charge carrier concentration n, and in the case of a low effective mass m^*. Therefore, semiconductor and especially III–V compound semiconductor materials (for gallium arsenide (GaAs), $m^* = 0.067\,m_0$, where m_0 is the free electron mass) are preferentially used to define low-dimensional charge carrier systems by confining conduction band electron or valence band holes in one or more directions to a few tens of nanometers or less. The first two-dimensional charge carrier systems were realized in metal-oxide-semiconductor field effect transistors (MOSFETs) in the thin conducting channel at the insulator–semiconductor interface. Silicon-MOSFETs are used as electronic switches of which, nowadays, 100 millions are integrated on a single microprocessor die. The QHE was originally discovered on such an Si-MOSFET device. Two-dimensional charge carrier systems of higher quality are obtained in layers or at interfaces of III–V compound semiconductor heterostructures, which are fabricated by molecular beam epitaxy (MBE) or metal organic chemical vapor deposition (MOCVD). III–V semiconductor heterostructures find various applications as base material for low-noise and high-frequency transistors or as optoelectronic devices such as laser-diodes which belong, nowadays, to key devices in modern communication technology.

The highest quality for two-dimensional electron systems is obtained in GaAs/$Al_xGa_{1-x}As$ heterostructures based on modulation-doping. (The quality of conductors is characterized by the charge carrier mobility μ, which relates, without an applied magnetic field, the drift velocity v_D of the free charge carriers to the applied electric field E by $v_D = \mu E$. As derived from the Drude model, the mobility is obtained from measuring the electrical conductivity σ via $\sigma = q\mu n$. The larger the absolute value of the mobility μ, the larger the distance a charge carrier

can move without being scattered. Due to the spatial separation of dopants and free charge carriers in modulation-doped heterostructures, the scattering of the charge carriers on the ionized dopants is strongly reduced. At temperatures below 1 K, recently, electron mobilities up to $3 \times 10^3\ \mathrm{m^2/(Vs)} = 3000\ \mathrm{1/T}$ have been reported in electron systems at such a heterojunction, allowing free mean paths of several 100 µm. At room temperature, such devices are used as high-electron mobility transistors (HEMT) in communication technology. As shown in **Figure 2**, the donors are located in an $Al_xGa_{1-x}As$ layer, which has a conduction band bottom lying higher than that of bulk GaAs. The band offset is tunable by the ratio x by which gallium atoms are replaced by aluminum atoms on their crystal lattice sites. The electrons separate from their donors and accumulate in the GaAs at the heterojunction, because they are still attracted by the positively charged donor ions. Each electron feels a triangular-shaped confining potential which restricts the electron motion to a free motion parallel to the heterojunction plane. If the electron density and the temperature are low enough, then only the lowest subband with energy $\varepsilon_{z,0}$ is occupied and the possible eigenenergies are described by

$$\varepsilon = |\hbar k_{||}|^2/(2m^*) + \varepsilon_{z,0}$$

where $k_{||}$ denotes the wave vector of the charge carrier in the plane of the 2D system. For the two-dimensional charge system with such a parabolic dispersion relation, the density of states $D_{2D}(\varepsilon)$ is constant

$$D_{2D}(\varepsilon) = g_s m^*/2\pi\hbar^2$$

where the factor $g_s = 2$ takes into account the two possible spin orientations for each plane wave state characterized by the wave vector $k_{||}$.

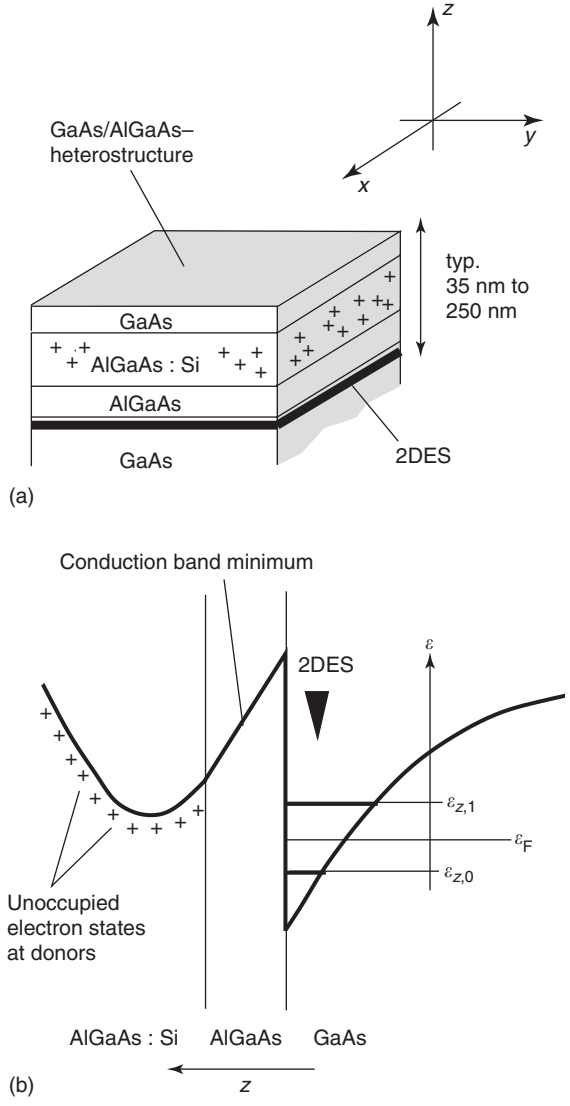

Figure 2 (a) AlGaAs/GaAs heterostructure with a two-dimensional electron system (2DES) at the heterojunction in GaAs. (b) Sketch of the respective profile of the conduction band edge in z direction, and the two lowest subband energies $\varepsilon_{z,0}$ and $\varepsilon_{z,1}$ due to the triangular-shaped confining potential in z direction.

Hall Effect on Two-Dimensional Charge Carrier System – Quantum Hall Effect

In **Figure 3**, Hall resistance curves versus magnetic flux density are shown as they are measured on two-dimensional electron systems of different quality. At low magnetic field, the Hall resistance linearly increases with the magnetic flux density B_z,

$$|R_H| = |R_{xy}| = |V_y/I_x| = |B_z/(-en_s)| \qquad [1]$$

and allows one to determine the respective sheet charge carrier density n_s of the two-dimensional electron system. At higher magnetic field, the Hall effect on the two-dimensional charge system shows, in certain magnetic field ranges, values which are independent of the magnetic field. The values of these plateaus are perfectly described by

$$|R_H| = h/ve^2 \qquad [2]$$

where v is an integer number, $i = \{1, 2, 3, \ldots\}$ or a certain fractional number f which seems to follow $f = p/q$ with $p = \{1, 2, 3, \ldots\}$ and $q = \{3, 5, 7, \ldots\}$, with exceptions like $f = 5/2$. The same plateau values are found by keeping the magnetic flux density B_z constant and varying the sheet electron concentration n_s. Therefore, varying the ratio n_s/B_z in certain ranges allows one to observe Hall resistance plateaus described by eqn [2].

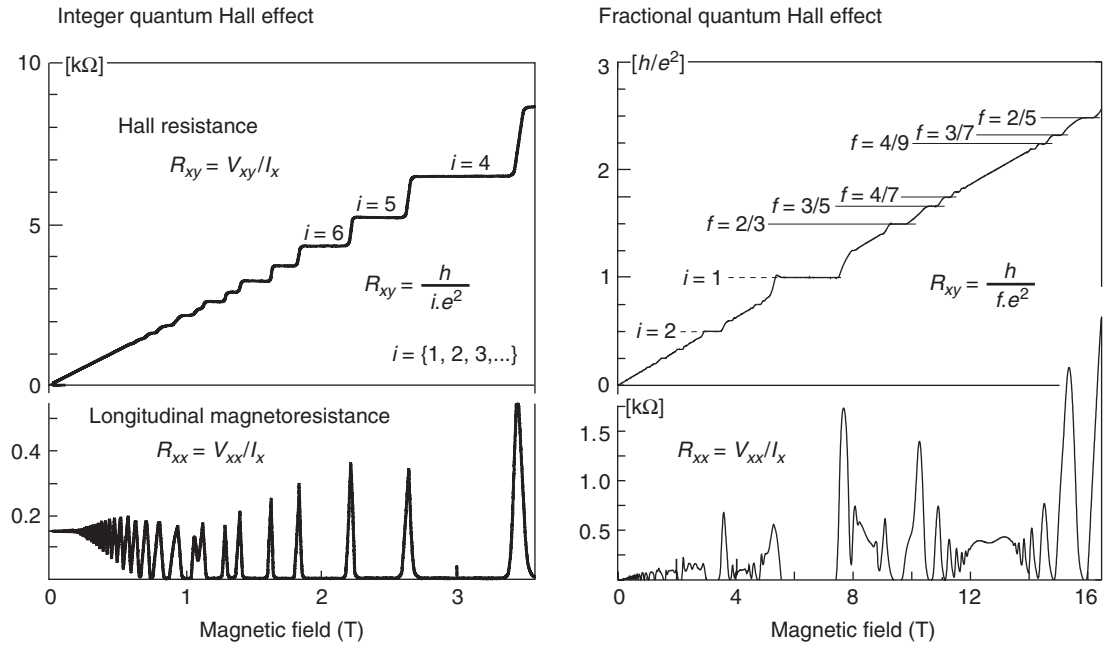

Figure 3 Quantum Hall effect: Hall resistance R_{xy} and longitudinal resistance R_{xx} measured on a 2DES as a function of the applied magnetic field. In certain magnetic field regions, plateaus are observed in R_{xy}, and at the same time R_{xx} vanishes.

Such Hall resistance values are expected due to the comparison between eqns [1] and [2] only for certain well-defined ratios $n_s/B_z = \nu\, e/h$. The meaning of this ratio can be expressed slightly differently: taking a certain area A out of a homogeneous two-dimensional electron system enclosing the integer number $N = n_s A$ of electrons, the magnetic flux penetrating this area is given by $\Phi = AB_z$. The ratio of electron number N and magnetic flux Φ in units of the magnetic flux quantum $\Phi_0 = e/h$ is then

$$\nu = N/(\Phi/\Phi_0) \qquad [3]$$

that is, for each electron, ν^{-1} magnetic flux quanta are present.

Whenever a plateau is found in the Hall resistance, the (four-terminal) longitudinal resistance $R_{xx} = V_x/I_x$ vanishes, that is, $R_{xx} = 0$. The occurrence of the Hall plateau is accompanied by a dissipationless current flowing along the sample. However, this does not mean that there is no dissipation at all. In the plateau regimes, the (two-terminal) resistance $R'_{xx} = V'_x/I_x$ measured between the current biased contacts is about the Hall resistance $|R_H|$, that is, the electrical power $|R_H|\, I_x^2$ is dissipated. The heat is created in two spot-like regions, one located close to each current-biased contact. Along the sample away from the hot spot regions, dissipation is absent, indicated by the absence of a voltage drop along the sample. In the transition regimes between Hall plateaus, dissipation occurs along the whole sample measurable by $R_{xx} \neq 0$.

The Hall plateau values with $i = 2$ and $i = 4$ are reproducible to the standard uncertainty of 10^{-9}, independent of the sheet charge carrier density, the sample geometry, and further properties of the material in which the two-dimensional charge carrier system is embedded. That is why the quantum Hall resistance has been used since 1990 as a resistance standard. Si-MOSFET or GaAs-AlGaAs-HEMT devices are used for this purpose. To trust in the plateau values obtained on a certain sample for metrological application, the flatness of the Hall plateau, the vanishing of the longitudinal resistance $R_{xx} = 0$, and the invariance of the Hall resistance value with changing the temperature are checked. Increasing the quality of the samples, the Hall plateaus get smaller. In consequence, a certain amount of disorder is required to obtain well-defined Hall resistance plateaus and, therefore, accuracy in the quantized Hall resistance value. For metrological application, the sheet density n_s of the two-dimensional electron system in a $GaAs/Al_xGa_{1-x}As$ heterostructure is typically in the range of $3\text{–}6 \times 10^{15}\,m^{-2}$ with a mobility μ of $40\text{–}80\,T^{-1}$, and the measurements are done at the temperature $T = 1.5$ K. For high-precision measurements, it is desirable to have the current level as high as possible. However, the current level is limited for the respective sample, since the QHE breaks down suddenly with increasing the current beyond a certain critical current level. The typical critical sheet

current density I_x/w is ~ 0.5–$1.5\,\mathrm{A\,m^{-1}}$. Also, a significant increase of the working temperature degrades the Hall plateau, and the plateaus finally disappear.

Theoretical Models for the Quantum Hall Effect

A complete microscopic theory, allowing one to derive the Hall plateau values and widths, still does not exist. However, it is commonly accepted that the IQHE can be described within a model of independent electrons whereas for the FQHE, many-particle correlations due to the electron–electron interaction are of importance.

Integer Quantum Hall Effect

In recent years, spatially resolved measurements of the Hall potential profile with low-temperature scanning probe microscopes on two-dimensional electron systems defined in GaAs-AlGaAs-HEMT devices have revealed the following microscopic picture of the IQHE.

The Single-Particle Energy Spectrum – Landau Levels

The magnetic field forces the electrons on cyclotron orbits. Quantum mechanically, the possible eigenenergies cluster in discrete Landau levels described by

$$\varepsilon = \varepsilon_{z,0} + (n + 1/2)\hbar\omega_c + s_z g^* \mu_B B \qquad [4]$$

with the Landau level index $n = \{0, 1, 2, \ldots\}$, and the spin quantum number $s_z = \{-1/2, 1/2\}$. The gaps between the Landau levels are either given by the cyclotron energy $\hbar\omega_c = \hbar eB/m^*$ minus the Zeeman energy $g^*\mu_B B$, or the Zeeman energy (μ_B denotes the Bohr magneton, $\mu_B = e\hbar/(2m_0)$ and g^* the effective Landé factor). The degeneracy $n_L = eB/h$ of each (spin-resolved) Landau level and the cyclotron energy ω_c increases with B. Therefore, with an increasing magnetic field, the electrons are redistributed to lower Landau levels leading to a sawtooth-like variation of the chemical potential $\mu_{ch}(n_s, B)$ for fixed sheet electron density n_s with increasing magnetic field (see **Figure 4**). The ratio of the sheet electron density n_s and Landau level degeneracy n_L is denoted as Landau level filling factor ν_L (or shortly filling factor),

$$\nu_L = n_s/n_L \qquad [5]$$

Whenever the filling factor ν_L takes an integer value, the chemical potential lies energetically between two Landau levels, and in the homogeneous electron system the respective fraction $\nu^{-1} = \{1, 1/2, 1/3, 1/4, \ldots\}$ of a magnetic flux quantum is present for each electron, consistent with eqn [3]. For integer filling factors, the electron system behaves incompressible, that is, the compressibility defined by $\kappa = (\partial\mu_{ch}/\partial n_s)^{-1}$ becomes zero due to the discontinuity in $\mu_{ch}(n_s, B)$ versus n_s.

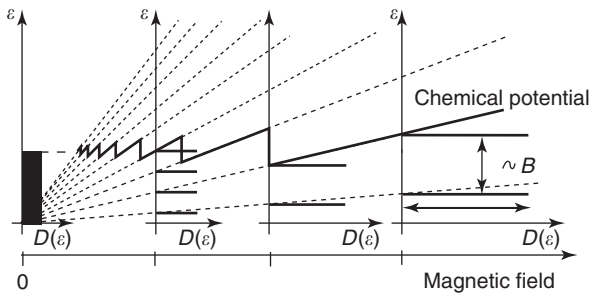

Figure 4 For an infinite homogeneous electron gas, the single-particle eigenenergy spectrum splits up into Landau levels on applying a strong magnetic field (in this sketch, the spin is neglected). The chemical energy varies in a sawtooth-like manner with an increasing magnetic field.

Dissipationless Current Flow

For an infinite two-dimensional electron system with an applied magnetic field in z direction and a homogeneous electric field in y direction, all Landau level states undergo a drift in x direction, so that the local sheet current density j_x in x direction is given by

$$j_x = \nu_L e^2/h E_y \qquad [6]$$

This Hall current is flowing without dissipation since this drift is a property of the eigenfunctions solving the respective Hamiltonian. Actually, for any smooth varying electrical field $E_y(y)$, the eqn [6] remains locally valid. Integrating the sheet current density $j_x(y)$ over a certain width w in y direction, the integral current $I_x = \int_0^w j_x(y)\,dy$ is given by the voltage drop $V_y = \int_0^w E_y(y)\,dy$ over this width,

$$I_x = \nu_L e^2/h V_y \qquad [7]$$

and is therefore independent of the details of the Hall voltage drop along the y direction as long as ν_L is constant on the width w. For integer values of ν_L, that is, whenever the electron system is incompressible, the Hall resistance values (eqn [2]) are obtained. However, this does not allow one to obtain Hall resistance plateaus. Here, theoretical models refer to disorder and inhomogeneities being present in real

two-dimensional electron systems. Especially, the edges of the sample and static potential fluctuations all over the sample lead to variations of the local filling factor within the two-dimensional electron system.

Compressible and Incompressible Regions within a Two-Dimensional Electron System

At the edges of the two-dimensional electron system, within the depletion region, the sheet electron density changes from zero to its bulk value over a typical distance of 1 μm. In thermodynamical equilibrium, the electron density profile can be calculated within a Thomas–Fermi approximation by (1) the constraint that the electrochemical potential μ_{elch} that is, the sum of local chemical potential $\mu_{\mathrm{ch}}(n_{\mathrm{s}}(r))$ plus the electrostatic energy $-e\phi(r)$, is constant within the whole two-dimensional electron system, and (2) by the Poisson equation which relates the local electrostatic potential $\phi(r)$ to the local sheet electron density $n_{\mathrm{s}}(r)$, taking into account the adequate boundary condition for $\phi(r)$, which are due to the respective sample. The problem can self-consistently be solved if (3) the chemical potential $\mu_{\mathrm{ch}}(n_{\mathrm{s}},B)$ of the two-dimensional electron system is known as a function of the sheet electron density n_{s} (see **Figure 5**). Without the applied magnetic field, the density of states is constant and, therefore, the chemical potential increases linearly with n_{s}, and the electron concentration profile increases smoothly at the edge toward the bulk. In contrast, with an applied high magnetic field, the density of states is discrete, the chemical potential increases in a step-like manner with increasing n_{s}, and therefore it is energetically favorable that the electron density profile shows regions of varying and of constant electron density. A strip-like structure is found along the edges, where the strips of constant electron density behave as an incompressible electron system whereas the regions of varying electron density behave compressible. In compressible regions, occupied and unoccupied electronic states exist at the Fermi level, whereas in incompressible regions, the occupied states lie below and the unoccupied states above the Fermi level.

The widths and positions of these strips depend on the imprinted potential profile at the edges and on the quantization energies (cyclotron energy and Zeeman energy) which increase with magnetic field. Therefore, the strips shift with increasing magnetic field away from the edges into the bulk, and the respective innermost incompressible strip covers the whole bulk at integer values of $n_{\mathrm{s}}/n_{\mathrm{L}}$.

Due to potential fluctuations within the bulk region of the real two-dimensional electron system, the local electron density $n_{\mathrm{s}}(r)$ varies – a landscape of compressible and incompressible regions is also formed there which reshapes with varying the mean sheet electron density n_{s} or the magnetic field. Close to integer values of $n_{\mathrm{s}}/n_{\mathrm{L}}$, the bulk is mainly incompressible with compressible droplets embedded.

Current Distribution in Real Samples

With these ingredients (see **Figure 6**), the IQHE is roughly described by the following qualitative picture. With the application of an electrochemical potential difference between the source and drain

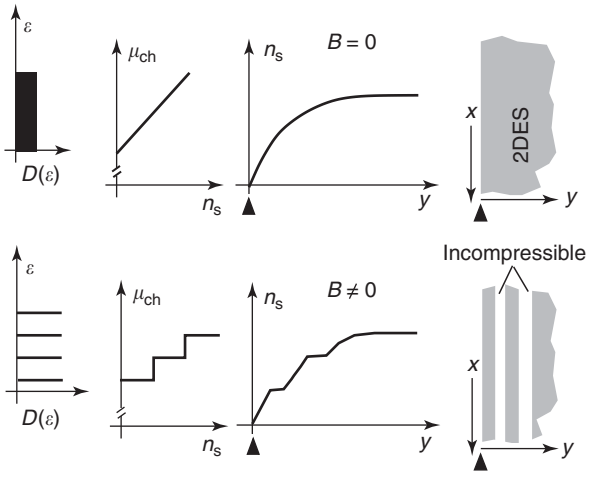

Figure 5 Formation of compressible and incompressible strips within the depletion region along the edges of the 2DES for a strong applied magnetic field.

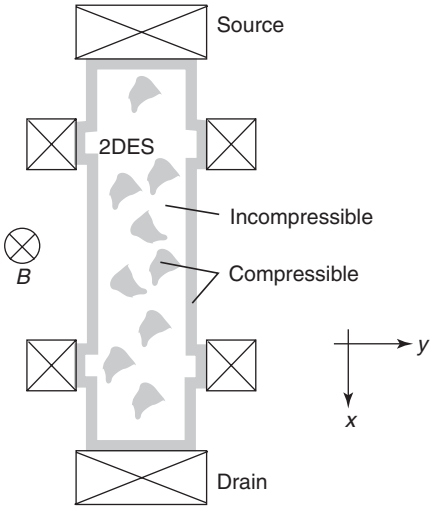

Figure 6 In the (integer) quantum Hall regime, the bulk of the 2DES is incompressible with compressible droplet regions embedded. Along the edges, the electron system has one or more compressible strips.

contact, the electrochemical potential of the source is carried by the compressible strips along one edge, the potential of the drain by the compressible strips along the opposite edge, into the sample. The difference is then present as a Hall voltage driving the Hall current without dissipation along the incompressible regions through the bulk of the sample. Since the Hall voltage drops only over incompressible regions with the same local filling factor, eqn [7] is valid. The inhomogeneities at the edges and within the bulk assure that incompressible regions extend along the whole sample for moderate variations of the magnetic field or for changes of the mean electron density. The Hall plateau values are measured as long as electron scattering from one edge to the opposite edge is suppressed by wide incompressible regions in between.

Localization

Since a certain amount of disorder is required to explain the occurrence of plateaus in the Hall resistance, the QHE has been addressed from the beginning as a localization–delocalization phenomena of electrons in a random disorder potential. The model of an incompressible and compressible landscape within the bulk region, as depicted above, is applicable in the case of a smooth varying disorder potential, and takes the electron–electron interaction self-consistently in an electrostatic manner into account. Other common models investigate the universality of the localization–delocalization phenomenon and the possibility of quantum phase transitions in such a quantum Hall system. The system is then discussed in terms of the density of states in energy where each Landau level is broadened in energy due to the static potential fluctuations. It turns out that states in the tails of the broadened Landau levels correspond to localized states, that is, they are not extended beyond a certain typical length under the respective conditions. Extended states exist only in the energetical center of a broadened Landau level. Localized states cannot contribute to the conductivity, that is, varying the Fermi level in the range of localized states, these states can be filled or emptied without affecting the transport properties – ingredients for the observation of plateaus in the Hall resistance.

Fractional Quantum Hall Effect

With increasing the magnetic field, electrons finally end in the lowest Landau level. Here the electron–electron interaction becomes dominant leading to many-electron correlations, that is, their motions are not independent of each other. For certain fractional filling factors ν, it has been found that the many-electron quantum state behaves incompressible and the respective charge excitations in the electron system are quasiparticles of fractional charge. In a later theoretical description, the electrons and flux quanta present in the system have been combined with new quasiparticles – the so-called composite particles which have either fermionic or bosonic character depending on whether the number of flux quanta attached to an electron is even or odd. This has simplified the picture of the FQHE. Around fractional ν of even denominators, such as $\nu = \{1/2, 3/2, 1/4, 3/4, 5/4, \ldots\}$, composite fermions are formed which do not see any effective magnetic field at the respective filling factor ν. The larger the denominator, the more fragile are these composite fermions. With varying magnetic field, these composite fermions survive and they now feel an effective magnetic field which enforces them to a cyclotron motion. Therefore, within the picture of composite fermions, the series of fractional quantum Hall states which lie symmetrically around $\nu = 1/2$ are interpreted as the IQHE of composite fermions consisting of an electron with two flux quanta attached. (This symmetric structure around $\nu = 1/2$ can be seen in the data of **Figure 3** for FQHE by comparing the low magnetic field region of the IQHE with the regions $\sim$12.6 T, which corresponds to $\nu = 1/2$ in this sample.) At $\nu = 1/2$, the composite fermion does not see any magnetic flux, that is, $(\nu_{\mathrm{CF}})^{-1} = 0$, whereas at $\nu \neq 1/2$, $(\nu_{\mathrm{CF}})^{-1} = |\nu^{-1} - 2|$ flux quanta are present for the composite fermion. An integer filling factor $\nu_{\mathrm{CF}} = \nu/|1 - 2\nu|$ is reached for the fractional filling factors $\nu = \{1/3, 2/5, 3/7, 4/9, 5/11, \ldots\}$ and $\nu = \{1, 2/3, 3/5, 4/7, 5/9, \ldots\}$. The fractional quantum Hall states $\nu = 2/3$ and $\nu = 2/5$ are, therefore, the integer quantum Hall states $i_{\mathrm{CF}} = 2$ of this composite fermion.

The observed exotic fractional quantum Hall state $\nu = 5/2$ is interpreted as a pairing of composite fermions into a novel many-particle ground state. Although the experimental findings support the composite fermion picture, the theoretical foundation for this description is still under debate.

Nomenclature

B	magnetic flux density
c	speed of light in vacuum
e	elementary charge
$-e$	electron charge
E	electrical field
g^*	effective Landé factor
g_s	spin degeneracy
j	current density
$\hbar$	Planck constant
I	current
k	wave vector
m^*	effective mass
m_0	free electron mass
n	charge carrier concentration
n	Landau level index
n_L	Landau level degeneracy
n_s	sheet carrier density
N	electron number
q	charge
r	location vector
R_H	Hall resistance
R_K	von Klitzing constant
R_{K-90}	conventional von Klitzing constant
R_{xx}, R_{xy}	resistance
s_z	spin quantum number
V	voltage
α	Sommerfeld fine-structure constant
$D(\varepsilon)$	energy density of states
ε	single-particle energy
ε_F	Fermi energy
μ	charge carrier mobility
μ_0	permeability of vacuum
μ_B	Bohr magneton
μ_{ch}	chemical potential
μ_{elch}	electrochemical potential
λ	DeBroglie wavelength
λ_F	Fermi wavelength
$\hbar\omega_c$	cyclotron energy
Φ	magnetic flux density
Φ_0	magnetic flux quantum
ν	Landau level filling factor

Quantum Mechanics: Atoms

A Sasso, Università di Napoli "Federico II," Napoli, Italy

Introduction

A quantum mechanical description of the atomic structure began to emerge at the end of the nineteenth century. The period up to mid-1920s produced many fundamental discoveries that laid the foundation of modern physics.

In 1896, the Dutch physicist Zeeman observed that the spectral lines emitted by an excited atomic sample could be separated by a strong magnetic field and he ascribed this phenomenon to the electrons present in atoms. In 1906, J J Thomson proposed an atomic model where the number of electrons Z was equal to the number of positive charges (neutral atoms). According to this model, the electrons were embedded in a positive cloud and their mass was approximately half of the atomic mass.

The scattering experiments of α-rays (particles formed by two protons and two neutrons) through thin layers of matter performed by Geigerr and Marsden represented the arguments used by Rutherford for a new description of atomic structure. Indeed, these experiments suggested that the solid

matter resulted from much more transparent structures than expected from the Thomson model. Since only a small part of the α-particles deviate from their trajectories, the repulsive force should arise from scattering centers occupying a small volume localized within the atom. These scattering centers are called Rutherford atomic nuclei and include almost all the atomic mass. The size is estimated to be 10^{-15} m, hence several orders of magnitude smaller than the atomic size (10^{-10} m). By treating the nucleus as a point of charge Ze and the repulsive interaction of the α-particles (charge $2e$) in terms of the Coulomb force, Rutherford obtained the differential cross section, that is, the probability of finding a particle scattered at an angle θ:

$$\frac{d\sigma}{d\Omega} = \left(\frac{2Ze^2}{4\pi\varepsilon_0}\right)\frac{1}{4\mu^2 v^2 \sin^4 \theta/2} \qquad [1]$$

where v is the relative velocity of the α-particle (mass M_α) and the nucleus (mass M), and m is the reduced mass $\mu = M_\alpha M/(M_\alpha + M)$.

In the Rutherford model, the electrons move in the Coulomb field of the nucleus in orbits similar to the planetary system. Nevertheless, according to the laws of classical physics, an accelerating charged particle, like an electron rotating about its nucleus, radiates electromagnetic waves and hence, loses energy. This would imply that in a time 10^{-10} s, all the energy of the atom is radiated away and the electrons would collapse into the nucleus. This prediction is clearly contrary to the experiment and is one of the most important proofs that the classical laws of motion fail when applied to phenomena on the atomic scale. In addition, the atomic line structure observed in all atomic spectra constitute another important experimental evidence not explainable in terms of the Rutherford model.

A crucial effort to remove these difficulties was done by Bohr in 1913. Bohr was able to put together the concepts of Rutherford's nuclear atoms, Planck's quanta, and Einstein's photons to explain, with high precision, the line positions of the radiation emitted by atomic hydrogen.

Bohr introduced the idea that among all the electrons around the nucleus, only one, the so-called optical electron is responsible for the emission of spectral lines. He still assumed that this electron moves in circular orbits due to the effect of the electrostatic attraction of the nucleus but, instead of the infinite number of orbits allowed by classical mechanics, he postulated that only a certain set of stable orbits, which he called stationary states, are possible and that in these orbits the electron does not radiate electromagnetic energy. Each of these stationary orbits corresponds to definite energies E_a, E_b, E_c, … . The optical electron can emit radiation only when it jumps from an outer orbit toward an inner one. To obtain the frequency of the emitted radiation, Bohr used Einstein's concept of quanta of electromagnetic energy, the photons, which carry an energy $h\nu$ ($h = 6.626 \times 10^{-34}$ J s^{-1} is the Planck constant). The Bohr frequency relation is

$$h\nu = E_{fin} - E_{ini} \qquad [2]$$

where E_{ini} and E_{fin} are the energies corresponding to the initial and final electron energies, respectively. Bohr also postulated the quantization of the angular momentum, L, of the electron moving in its circular orbit, that is,

$$L = m_0 v r = n\frac{h}{2\pi} = n\hbar \qquad [3]$$

where n is a positive integer, $n = 1, 2, 3, \ldots$. Thanks to this idea, Bohr could determine the allowed energies of the electron. If the nuclear mass M is assumed to be much heavier than the electron mass m, then the nucleus can be considered to be at rest and the electrostatic force acting on the electron can be so equated to with the centripetal force:

$$\frac{Ze^2}{4\pi\varepsilon_0 r} = m_0\frac{v^2}{r} \qquad [4]$$

By combining eqns [3] and [4], the possible values of the velocity v and the orbit radius r can be easily found, as well as the total energy of the electron given by the potential energy V and the kinetic energy T:

$$E_n = V + T = -\frac{m_0}{2\hbar^2}\left(\frac{Ze^2}{4\pi\varepsilon_0}\right)^2\frac{1}{n^2}$$
$$n = 1, 2, 3, \ldots \qquad [5]$$

The quantum number n is called the principal quantum number: $n = 1$ corresponds to the ground state, while for $n \to \infty$ the energy is null, $E_\infty = 0$, and this state denotes an electron free from its nucleus (positively ionized atom). Therefore, if one indicates the ionization potential as

$$I_p = \frac{m_0}{2\hbar^2}\left(\frac{Ze^2}{4\pi\varepsilon_0}\right)^2$$

the energy required to bring the electron away from the attraction of its nucleus, then eqn [5] can be written as

$$E_n = I_p\frac{1}{n^2} \qquad [6]$$

For the case of the hydrogen atom ($Z = 1$), the frequency line ν_{ab} corresponding to the transition between two levels labeled with a and b is given by

$$\nu_{ab} = \frac{m_0}{4\pi h^3}\left(\frac{e^2}{4\pi\varepsilon_0}\right)^2\left(\frac{1}{n_a^2} - \frac{1}{n_b^2}\right)$$
$$= R\left(\frac{1}{n_a^2} - \frac{1}{n_b^2}\right) \quad n_b > n_a \qquad [7]$$

where R is called the Rydberg constant ($R = 109\,677.58(8)\ \text{cm}^{-1}$). **Figure 1** shows the main orbits for hydrogen, showing the formation of the different series: transitions involving the states with $n_a = 1$, $n_a = 2$, $n_a = 3$, and $n_a = 4$ give rise to the Lyman, Balmer, Paschen, and Brackett series, respectively.

At the basis of the Bohr's model, there is the correspondence principle according to which for high quantum numbers, the quantum relations asymptotically tend to the classical ones. For instance, the frequency between the levels n and $n+k$ with $n \gg k$ becomes

$$\nu_{n_a, n_a+k} = k\,\frac{2R}{n^3} \qquad [8]$$

that is, the line frequency emitted by the atom corresponds approximately to integer multiples of a fundamental frequency $2R/n^3$, which represents the frequency of a classical oscillator characterized oscillating at the same frequency $2R/n^3$. In terms of classical physics, the orbiting frequency of an electron in an orbit of radius r:

$$\nu = \frac{1}{2\pi}\left(\frac{Ze^2}{m_0 r_n^3}\right)^{1/2} \qquad [9]$$

By combining eqns [8] and [9], the Rydberg constant for an atom with $Z = 1$ can be written in terms of fundamental constants e, m_0, c, and h, that is, $R = 2\pi^2 e^4 m_0 / ch^3$. Taking into account the finite mass M of the nucleus, the Rydberg constants

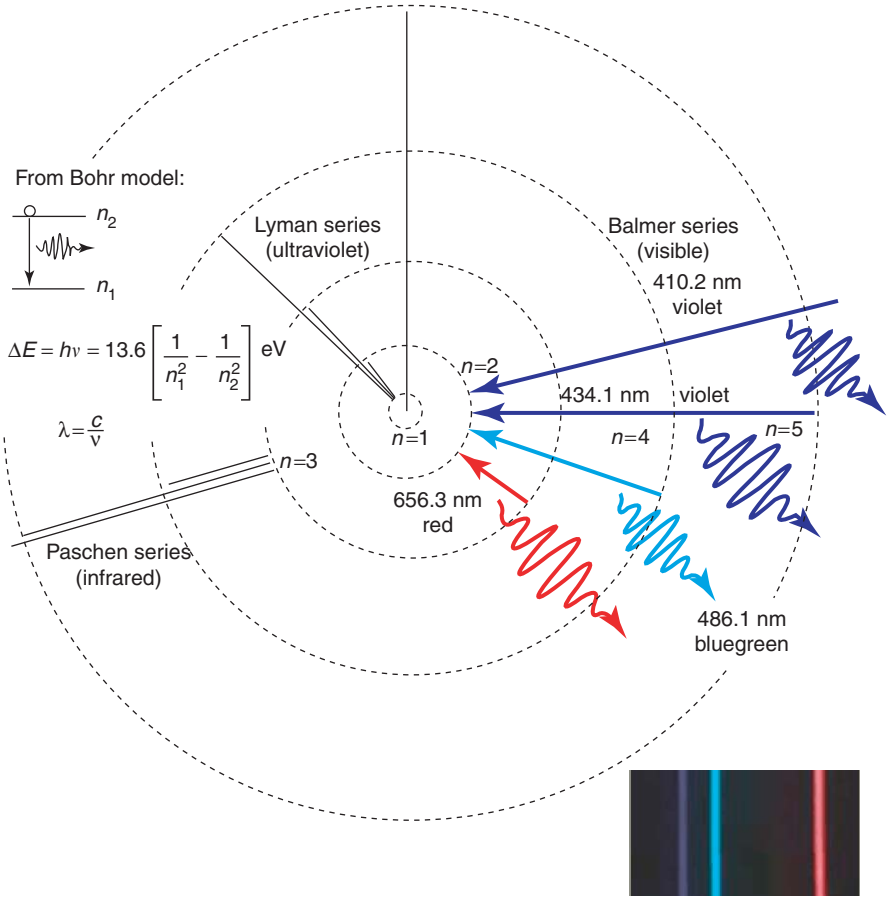

Figure 1 Schematic representation of Bohr model of hydrogen atom. The electron can occupy only quantized orbits corresponding to an energy depending on the principal quantum number n. Emitted radiation at different wavelengths derives from jumps between orbits with different principal quantum numbers n. The first three series (Lyman, Balmer, and Paschen) are shown. In the inset shown in the lower-right corner the first three lines of the Balmer series are also shown (red, visible violet, violet).

become

$$R_M = R_\infty \left(1 - \frac{m}{M}\right) \qquad [10]$$

where R_∞ denotes the Rydberg constant for an infinitely massive atom.

Although the Bohr model is rather successful, it has several unsatisfactory features: it is not able to treat atoms involving two or more electrons and it assumes circular orbits, which is quite arbitrary. Moreover, the Bohr model cannot be used to calculate the intensities of different spectral lines, that is, the transition probability that an electron jumps (absorbed or emitted photon) from a given level to another one. Some of these objections, such as a more general description in terms of elliptical orbits, were removed by the work of Wilson and Sommerfield (old quantum mechanics theory). Nevertheless, the serious question of the transition rate and other still more intriguing questions could be superseded by the quantum mechanics developed by de Broglie, Schrödinger, Heisenberg, Dirac, and others.

Stern and Gerlach Experiment

A significant improvement of the Bohr model was made by an important experiment performed by Stern and Gerlach in 1922 to measure the magnetic dipole moments of atoms. This moment arises from the fact that, according to the Bohr model of a hydrogenic atom, an electron in a circular orbit with an angular momentum $\boldsymbol{L}$ forms a current loop and produces a magnetic dipole $\boldsymbol{M}$,

$$\boldsymbol{M} = -\frac{e}{2m_0}\boldsymbol{L} = -\mu_B \frac{\boldsymbol{L}}{\hbar} \qquad [11]$$

where $\mu_B = e\hbar/2m_0$ is the Bohr magneton ($\boldsymbol{M} = -(e/2m_0)\boldsymbol{L} = -\mu_B = 9.27 \times 10^{-24}\ \mathrm{J\ T^{-1}}$).

In the Stern experiment, a beam of silver atoms was sent through a spatial region where a magnetic field was created (see **Figure 2**).

The force exerted on the dipole is given by $\boldsymbol{F} = -\nabla(-\boldsymbol{M} \times \boldsymbol{B})$, and for the case where only the magnetic field component B_z presents a gradient along the z-axis, the only force on the atoms in the beam is in the z-direction:

$$F_z = M_z \frac{\partial B_z}{\partial z} \qquad [12]$$

In a classical picture, the direction of $\boldsymbol{M}$ in the atomic beam is random and the possible values of M_z are expected to occur in the interval $-M < M_z < M$. As a consequence, atoms impinging on a collecting screen would be spread over a region symmetrically disposed about the point of no deflection. In their experiment, Stern and Gerlach found two distinct lines, symmetrically arranged around the point of no deflection. This result cannot be explained in terms of the Bohr model, although this model postulated that the orbital angular momentum occurs only in integral units of $\hbar L = l\hbar$, and $L_z = m\hbar$, with $-l < m < +l$. Indeed, the results of Stern and Gerlach for silver do not fit with this model, since the multiplicity $(2l+1)$ is 2, giving $l = 1/2$, a noninteger

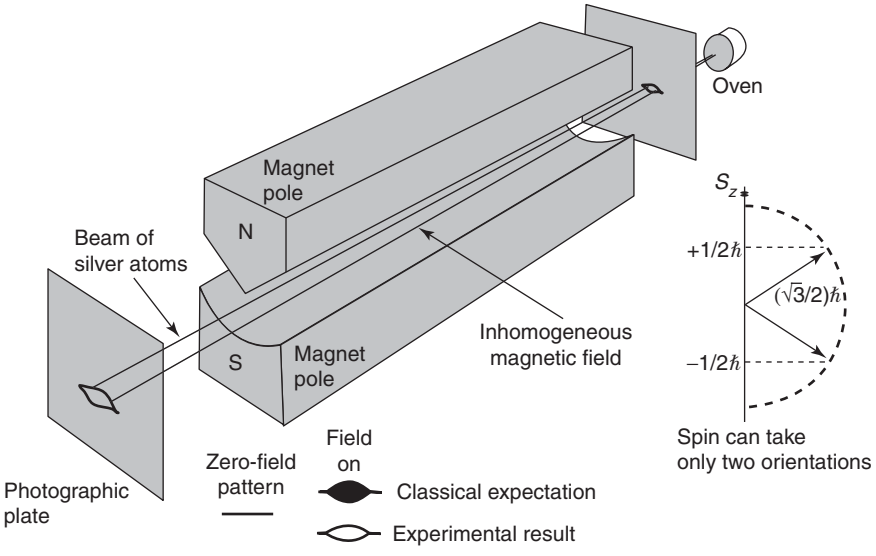

Figure 2 Stern–Gerlach experimental scheme. The silver atomic beam passes through an inhomogeneous magnetic field. One observes the splitting of the beam into two components due to the intrinsic magnetic dipole of the electron (spin).

value. In order to explain the Stern and Gerlach experiment for silver, Gouldsmit and Uhlenbeck suggested, in 1925, that the electron possesses an intrinsic magnetic moment M_s due to an intrinsic angular momentum (spin) in addition to the orbital magnetic dipole moment. Similarly to the orbital magnetic dipole moment, $\boldsymbol{M}_s$ can be written as

$$\boldsymbol{M}_s = -g_s \mu_B \frac{\boldsymbol{S}}{\hbar} \qquad [13]$$

where g_s is the spin gyromagnetic ratio. If a spin quantum number is introduced, similarly to l, the multiplicity of the spin component in a given direction is $(2s+1)$. Therefore, the Stern and Gerlach experiment can be explained if one assumes that the orbital angular momentum of silver is zero, but that its spin angular momentum is $s = 1/2$, so that the possible values of the component of the spin $\boldsymbol{S}$ in the z-direction are $\pm\hbar$.

de Broglie's Hypothesis and the Formulation of Wave Mechanics

As is well known, according to the classical physics, light, described in terms of Maxwell's electromagnetic equations, gives rise to a wide variety of typical wave phenomena, such as interference and diffraction. On the other hand, particles are well described by Newton's law.

In a quantum mechanical picture, the electromagnetic radiation emitted by atoms is quantized, hν being the energy carried by a photon; the energy of electrons in the orbits around the nucleus are also quantized. However, this sharp distinction between waves and matter appears inadequate if compared to experiments where beams of electrons, when impinging on a small aperture, similarly to photons, give rise to diffraction phenomena.

In 1924, de Broglie suggested that just as radiation has particle-like properties, electrons, or other species of particles, show wave-like behavior. With a photon is associated an energy $E = h\nu$ and momentum $p = h\nu/c$, and de Broglie suggested that the frequency and wavelength associated with a particle of energy E moving at a nonrelativistic speed v is

$$\nu = \frac{E}{h} \qquad [14]$$

$$\lambda = \frac{h}{p} = \frac{h}{m_0 v} \qquad [15]$$

This idea directly provides an explanation of the postulate of eqn [3] used in the Bohr model of the hydrogen atom. Indeed, the wavelength of an electron in a stable stationary orbit of radius r is

$$n\lambda = 2\pi r, \quad n = 1, 2, 3, \ldots \qquad [16]$$

and, for eqn [15],

$$L = rp = r\frac{h}{\lambda} = n\hbar \qquad [17]$$

which is identical to eqn [3].

The wave nature of particles is evidenced when their wavelength is comparable with the dimension of the obstacles or slits used in the apparatus. For instance, the de Broglie wavelengths associated with electrons of energy 1, 10, and 100 eV are 12, 3.9, and 1.2 Å, respectively. Davisson and Germer showed that electrons of such energy could be diffracted by crystal lattices whose spacing of atoms is of the order of few angstroms.

Wave Packet and Schrödinger Equation

A next step toward a full quantum mechanics description of an atom requires the introduction of the concept of wave packets and its physical interpretation.

Consider a wave plane of amplitude A_0, frequency $\nu = \omega/2\pi$, and wave number $k = 2\pi/\lambda$ traveling in the x-direction:

$$A(x,t) = A_0 e^{i(kx-\omega t)} \qquad [18]$$

Applying relations [14] and [15],

$$A(x,t) = A_0 e^{(i/\hbar)(px-Et)} \qquad [19]$$

The wave of eqn [19] is an infinitely long wave train. Since this is in contrast with localized "point-mass" particles, one can consider an overlapping of wave planes in the integral form

$$\psi(x,t) = \int_{k_0-\Delta k}^{k_0+\Delta k} a e^{i(kx-\omega t)} dk \qquad [20]$$

where the amplitude of each wave is taken equal to the constant a. To evaluate the integral [20], one can expand ω around the value k_0 using a Taylor series in $(k–k_0)$, that is,

$$\omega = \omega_0 + \frac{\partial \omega}{\partial k}(k - k_0) + \cdots \qquad [21]$$

When expression [21] is inserted in eqn [20], one obtains

$$\psi(x,t) = a\mathrm{e}^{\mathrm{i}(k_0x-\omega_0t)}\int_{-\Delta k}^{\Delta k} a\mathrm{e}^{\mathrm{i}((\partial\omega/\partial k)t-x)\xi}\mathrm{d}\xi$$

$$= a\mathrm{e}^{\mathrm{i}(k_0x-\omega_0t)}2\frac{\sin[((\partial\omega/\partial k)t-x)\Delta k]}{(\partial\omega/\partial k)t-x} \quad [22]$$

Equation [22] represents a wave packet localized in the region around $x = (\partial\omega/\partial k)t$ moving with a group velocity $v_{\text{group}} = \partial\omega/\partial k = \partial E/\partial p$, which is equal to the particle velocity. **Figure 3** shows the real part of eqn [22] at a given instant t: the width of the packet given by the position of the first zero point of eqn [22] (see **Figure 3**) can be easily calculated and it results in $\Delta x = 2\pi/\Delta k$; therefore, the larger the wave vector region, Δk, the narrower the wave packet extension, Δx.

This result represents the Heisenberg uncertainty principle, the uncertainty in the position is connected with the uncertainty in the momentum. Since the momentum and wave vector are connected by eqn [15], $p = \hbar k$, the Heisenberg principle can also be written as

$$\Delta x\Delta p \geqslant \hbar \quad [23]$$

This relation states that it is impossible to measure the position and the velocity of a particle simultaneously and exactly.

A similar discussion applies to another pair of observables, energy and time. In this case, the uncertainties of these quantities are related by

$$\Delta E\Delta t \geqslant \hbar \quad [24]$$

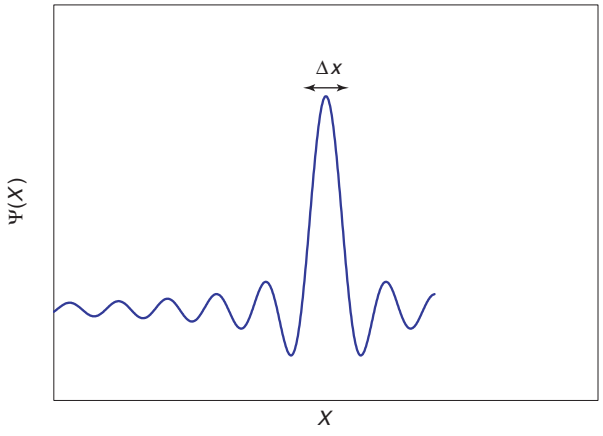

Figure 3 The real part of the wave packet described by eqn [22]. The first node is at $x_0 = \pi/\Delta k$. The rapid oscillations are due to the behavior of the $\sin x/x$ term appearing in eqn [22].

which means that in order to measure the energy with high accuracy, the measurement time has to be large.

The particle picture based on the wave packet is not perfectly equivalent to the wave picture. Indeed, two questions must be solved: the interpretation of $\psi(x,t)$ and the equation to be used for its time evolution. The interpretation given to $\psi(x,t)$ is probabilistic, in the sense that

$$|\psi(x)|^2\mathrm{d}x \quad [25]$$

represents the probability of finding the particle in an interval dx around the position x. In other words, the particle conserves its point-mass nature but it is delocalized within the extension of the wave packet. That implies that $|\psi(x,t)|^2$ is integrated over all space, the particle must be found somewhere. This normalization condition, extended in three dimensions, is written as

$$\int |\psi(x,y,z)|\ \mathrm{d}x\ \mathrm{d}y\ \mathrm{d}z = 1 \quad [26]$$

The equation describing the space–time evolution of the wave function ψ for a free particle is

$$-\frac{\hbar^2}{2m_0}\frac{\mathrm{d}^2}{\mathrm{d}x^2}\psi = \mathrm{i}\hbar\frac{\mathrm{d}}{\mathrm{d}t}\psi \quad [27]$$

This is the basic Schrödinger equation for one-dimensional nonrelativistic force-free particle (particle free from interaction and moving with velocity very small compared to the speed of the light) and its solution automatically fulfils the relation

$$\hbar\omega = \frac{p^2}{2m_0} = \frac{\hbar^2k^2}{2m_0} \quad [28]$$

Equation [27] can be generalized in three dimensions:

$$-\frac{\hbar^2}{2m}\nabla^2\psi = \mathrm{i}\hbar\frac{\partial}{\partial t}\psi \quad [29]$$

and to the case of a particle moving in presence of a potential $V(\boldsymbol{r})$:

$$\left(-\frac{\hbar^2}{2m_0}\nabla^2 + V(\boldsymbol{r})\right)\psi(\boldsymbol{r},t) = \mathrm{i}\hbar\frac{\partial}{\partial t}\psi(\boldsymbol{r},t) \quad [30]$$

The expression $-(\hbar^2/2m_0)\nabla^2$ is called the kinetic energy operator and

$$H = -\frac{\hbar^2}{2m_0}\nabla^2 + V(\boldsymbol{r}) \quad [31]$$

is another operator that represents the total energy (kinetic energy plus potential energy) of the system and it is called the Hamiltonian (in quantum mechanics all physical quantities which are a result of measurement processes (e.g., the momentum p, the angular momentum l, etc.) are associated with some operators).

If the potential V does not depend on time, the time dependence can be separated in the wave function ψ as

$$\psi(\boldsymbol{r}, t) = \mathrm{e}^{-\mathrm{i}(E/\hbar)t}\Phi(\boldsymbol{r}) \qquad [32]$$

and the time-dependent Schrödinger equation [30] becomes

$$\left(-\frac{\hbar^2}{2m_0}\nabla^2 + V(\boldsymbol{r})\right)\Phi(\boldsymbol{r}) = H\Phi(\boldsymbol{r}) = E\Phi(\boldsymbol{r}) \qquad [33]$$

which is normally called the time-independent Schrödinger equation. The functions Φ and the energies E solution of eqn [33] are called eigenfunctions and eigenvalues, respectively.

Quantum Mechanic Description of the Hydrogen Atom

Consider a single electron of mass m_0 in the field of the nucleus of charge Z. In this case, the potential to be used in the Schrödinger equation is given by the Coulomb potential $V(\boldsymbol{r}) = -Ze^2/4\pi\varepsilon_0\boldsymbol{r}$. In a central potential such as this, as in classical mechanics, the angular momentum is conserved. In quantum mechanics, this is equivalent to stating that the energy and angular momentum can be simultaneously measurable or that the corresponding operators, Hamiltonian and angular momentum, commute. Although the individual components of the angular momentum operator $(\hat{l}_x, \hat{l}_y, \hat{l}_z)$ do not commute with each other, one of these components, for example, $\hat{l}_z$, commutes with the square of the total angular momentum operator; thus, $\hat{l}_z$ and $\hat{l}^2$ are simultaneously measurable.

The Schrödinger equation for an electron in a central potential can be more conveniently solved by choosing spherical polar coordinates. The Cartesian coordinates x, y, z are replaced by r, θ, ϕ, where r is the radius, θ the azimuthal angle between the axis z and the vector $\boldsymbol{r}$, and ϕ the angle which the projection of r in the x–y plane forms with the x-axis. If the spatial part of the wave function ψ is separated as

$$\Phi(r, \theta, \phi) = R(r)Y(\theta, \phi) \qquad [34]$$

then the Schrödinger equation [33] becomes

$$Y(\theta,\phi)\left[-\frac{\hbar^2}{2m_0}\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial}{\partial r}\right) + V(r)\right]R(r) + \frac{R(r)}{2m_0r^2}\hat{l}^2Y(\theta,\phi) = ER(r)Y(\theta,\phi) \qquad [35]$$

For simplicity, the expressions for $\hat{l}_z$ and $\hat{l}^2$ are not explicitly given in spherical coordinates. If the fact that $F(\theta, \phi)$ are also eigenfuntions of the operators $\hat{l}_z$ and $\hat{l}^2$ is used, that is,

$$\hat{l}^2Y(\theta,\phi) = \hbar^2\omega Y(\theta,\phi) \qquad [36]$$

$$\hat{l}_zY(\theta,\phi) = \hbar m Y(\theta,\phi) \qquad [37]$$

eqn [35] reduces to the radial equation

$$\left[-\frac{\hbar^2}{2m_0}\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial}{\partial r}\right) + V(r) + \frac{\hbar^2\omega}{2m_0r^2}\right]R(r) = ER(r) \qquad [38]$$

where m appearing in eqn [37] is the magnetic quantum number.

It can be shown that the eigenvalues of $\hat{l}^2$ are $\hbar l(l+1)$ (with $l = 0, 1, 2, \ldots$) instead of the classical expected value of $\hbar l^2$; the eigenvalues of $\hat{l}_z$ are $\hbar m$ (with $-l < m < +l$). The eigenfunctions $Y(\theta, \phi)$ are called the spherical harmonic function and they are labeled by the integer numbers l and m as

$$Y_{l,m}(\theta,\phi) = \mathrm{e}^{\mathrm{i}m\phi}P_l^m(\cos\theta) \qquad [39]$$

$P_l^m(\cos\theta)$ being the Legendre polynomials. The spherical harmonics for $l = 1$ and $l = 2$, both in the spherical and Cartesian coordinates, have the form

$$\begin{aligned}
Y_{1,0} &= \sqrt{\frac{3}{4\pi}}\cos\theta = \sqrt{\frac{3}{4\pi}}\frac{z}{r},\\
Y_{1,\pm1} &= \mp\mathrm{e}^{\pm\mathrm{i}\phi}\sqrt{\frac{3}{8\pi}}\sin\theta = \mp\sqrt{\frac{3}{8\pi}}\frac{x \pm \mathrm{i}y}{r}\\
Y_{2,0} &= \sqrt{\frac{5}{4\pi}}\left(\frac{3}{2}\cos\theta - \frac{1}{2}\right) = \frac{1}{2}\sqrt{\frac{5}{4\pi}}\frac{2z^2 - x^2 - y^2}{r^2}\\
Y_{2,\pm1} &= \mp\frac{1}{2}\mathrm{e}^{\pm\mathrm{i}\phi}\sqrt{\frac{15}{2\pi}}\cos\theta\sin\theta = \mp\frac{1}{2}\sqrt{\frac{15}{2\pi}}\frac{(x \pm \mathrm{i}y)z}{r^2}\\
Y_{2,\pm2} &= \frac{1}{4}\mathrm{e}^{\pm2\mathrm{i}\phi}\sqrt{\frac{15}{2\pi}}\sin^2\theta = \frac{1}{4}\sqrt{\frac{15}{2\pi}}\frac{(x \pm \mathrm{i}y)^2}{r^2}
\end{aligned} \qquad [40]$$

The expression for the radial part $R(r)$ of the eigenfunction $\Phi(r, \theta, \phi)$ is

$$R_{n,l}(r) = N_{n,l} e^{-k_n r} r^l L_{n+1}^{2l+1}(2k_n r) \qquad [41]$$

where n is the principal quantum number, $N_{n,l}$ is a normalization factor, and $L_{n+1}^{2l+1}(2k_n r)$ are the Laguerre polynomials. It can be shown that the orbital angular momentum quantum number l cannot be larger than n–1.

Therefore, one can conclude that the wave functions of the hydrogen atom are labeled by three quantum numbers, n, l, and m, and they may be written in the form

$$\psi_{n,l,m}(r, \theta, \phi, t) = e^{i(E_n/\hbar)t} e^{im\phi} P_l^m(\cos\theta) R_{n,l}(r) \qquad [42]$$

In the Bohr model, the electron moves in circular orbits, similarly as a planetary system; now the electron is described by a charge cloud which is mathematically represented by the wave functions [42] whose square modulus $|\psi_{n,l,m}(r, \theta, \phi)|^2$ represents the probability of finding the electron about a given position. Graphical pictures of some wave functions of the hydrogen atom are depicted in **Figure 4**.

For historical reasons, the following convention is normally assumed to indicate the orbital angular momentum l:

l	0	1	2	3	4	5
orbital	s	p	d	f	g	h

For a single-electron atom, the orbital angular momentum $\boldsymbol{l}$ and the spin angular momentum $\boldsymbol{s}$ couple and precess about their mutual resultant $\boldsymbol{j} = \boldsymbol{l} + \boldsymbol{s}$.

In terms of energies, different wave functions having the same principal quantum number n and different l, m, and s have the same energy. These states are said to be degenerate and, for a given principal quantum number n, the degree of degeneracy is $2n^2$. The physical reason for such a degeneracy lies in the peculiar $1/r^2$ behavior of the Coulomb electric field.

When the spectral lines of the hydrogen spectrum are examined at very high resolution, they are found to be closely spaced doublets. This splitting is called fine structure and was one of the first experimental evidences for electron spin.

The small splitting of the spectral lines is attributed to an interaction between the electron spin s and the orbital angular momentum l, the so-called spin–orbit interaction.

The familiar red H_α line of hydrogen is a single line according to the Bohr theory. The straightforward application of the Schrödinger equation to the hydrogen atom gives the same result. If the wavelength of this line is calculated using the energy expression from the Bohr theory (eqn [7]), the result is 656.11 nm for hydrogen, treating the nucleus as a fixed center. If the reduced mass is used, the wavelengths become 656.47 nm for hydrogen and 656.29 nm for deuterium (see **Figure 5**). The difference between the hydrogen and deuterium lines is $\sim$0.2 nm and the splitting

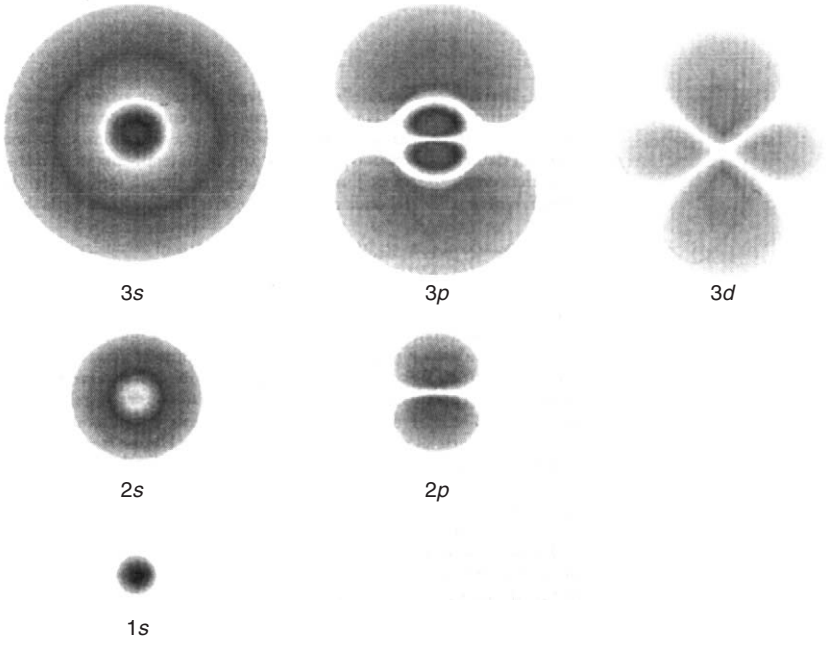

Figure 4 The density electron distribution of different hydrogen states representing the localization probability of $|\psi|^2$.

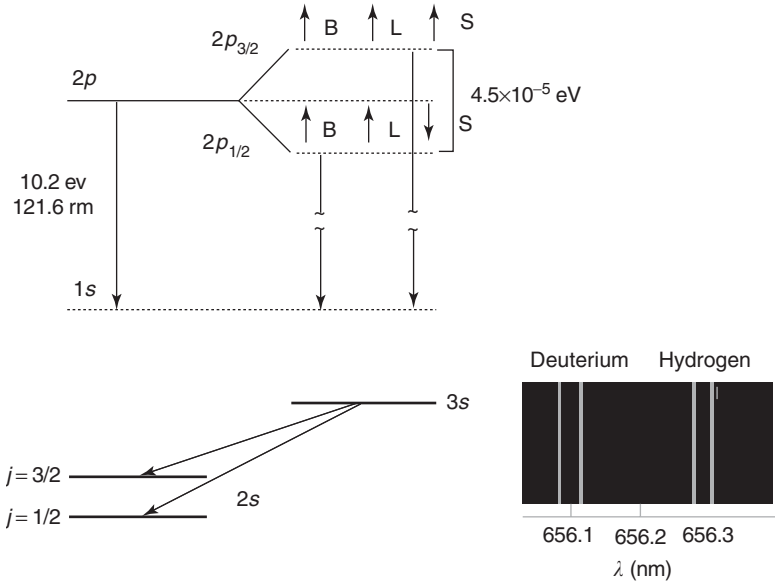

Figure 5 Spin–orbit effect in the 2*p* state of hydrogen atom (upper part). The splitting caused in the 2*p* state is responsible for the doublet observed in the $3s \rightarrow 2p$ transition, in hydrogen or in deuterium (lower part).

of each of them is ~ 0.016 nm, corresponding to an energy difference of $\sim 0.000\,045$ eV. This corresponds to an internal magnetic field on the electron of ~ 0.4 T.

More Complex Atoms: Alkali Atoms and Multi-Electron Atoms

When two or more electrons are bound to a nucleus, their individual electrons can be characterized by the three quantum numbers n, l, and m. This approach is at the basis of the construction of the periodic table of the elements. To do that, one has to take into account the Pauli principle which states that a state labeled by specific values of n, l, and m can be occupied by at most two electrons: one having spin up ($s = +\hbar/2$) and the other one with spin down ($s = -\hbar/2$). As a general rule, the electrons occupy first the levels with lowest energies starting from the ground state which correspond to zero energy. A particular state of occupation of the energy levels is called the electron configuration (or terms) of the atom: for instance for the lowest state of sodium (Na, $Z = 11$), the electronic configuration of the ground state is $1s^2\ 2s^2\ 2p^6\ 3s^1$.

A closed shell occurs when the next electron to be added would occupy the *s* state of the next higher principal quantum number n. Due to symmetry reasons, the angular momentum of closed shells is null and the atoms which reach this condition (noble gases) are particularly stable from a chemical point of view. As a general rule, the electrons in the closed shells are closer to the nucleus than the outer electrons (valence electrons).

Table 1 Ionization energy of alkali atoms

Atomic number Z	*Element*	*Ionization energy* (eV)
1	Hydrogen	13.59
3	Lithium	5.4
11	Sodium	5.14
19	Potassium	4.3
37	Rubidium	4.18
55	Cesium	3.89

Alkali atoms represent atomic systems that are very similar to the hydrogen atom and, for this reason, are also named hydrogenic atoms. Indeed, their electronic configuration corresponds to that of a noble gas plus one electron in the *s* shell. Of course, the similarity with hydrogen atom is only partial, because the inner electrons play some role. For instance, the ionization energies (the energy that has to be furnished to the outer electron to free it from the attractive potential of the nucleus) decrease with the atomic number Z (see **Table 1**).

This behavior can be understood qualitatively by recalling that the electrons in the same subshell have equivalent spatial distributions, so that their screening of one another is rather small.

The valence electron "sees" only partially the nuclear charge $+Ze$ because part of this is screened by the Z–1 inner electrons. This effect can be taken into account by introducing an effective potential $V_{\text{eff}}(r)$ for the valence electron. In this way, the many-body

Table 2 Quantum defects of $\Delta(n,l)$ for the spectra of the sodium (Na) atom

Term	$n=3$	$n=4$	$n=5$	$n=6$
$l=0$	1.373	1.357	1.352	1.349
$l=1$	0.883	0.867	0.862	0.859
$l=2$	0.010	0.011	0.013	0.011
$l=3$		0.000	–0.001	–0.008

problem involving Z interacting electrons in the nuclear potential is strongly simplified and reduced, as for the hydrogen atom, to a two-body problem. The nuclear potential does not vary as $1/r$ and this is the reason why the l degeneracy is removed in alkali atoms. The energy terms $E_{n,l}$ for a given alkali atom X can be written similarly to the hydrogen series but including an effective principal quantum number n_{eff}:

$$E_{n,l} = -R_{\text{X}}hc\frac{1}{n_{\text{eff}}} = -R_{\text{X}}hc\frac{1}{[n-\Delta n(n,l)]^2} \quad [43]$$

where R_{X} is the Rydberg constant for the alkali atom X and $\Delta n(n,l)$ is the so-called quantum defect associated to the quantum numbers n and l. **Table 2** reports the quantum defects (in general, not an integer) of the sodium atom.

Consider now the case when two electrons occupy the outer shell. This is the case of helium atom, or helium-like atoms (Be, Mg, Ca, etc.). Compared with the hydrogenic atoms, the total binding energy contains a term due to the repulsive interaction of the two electrons, that is,

$$V = -\frac{Ze^2}{4\pi\varepsilon_0 r_1} - \frac{Ze^2}{4\pi\varepsilon_0 r_2} + \frac{e^2}{4\pi\varepsilon_0 r_{12}} \quad [44]$$

The repulsive term depends on the n and l quantum numbers since the electronic spatial distribution depends on these quantum numbers. In contrast with the hydrogen atom, the Schrödinger equation with the potential [44] does not have an exact solution. Approximate solutions can be obtained by using perturbative approaches.

Consider the coupling between the individual orbital and spin angular momenta of the two electrons: (l_1, s_1) and (l_2, s_2). These angular momenta are coupled to each other by means of electromagnetic interaction (e.g., the spin–orbit interaction) between the electrons in the atom. They combine according to specific quantum mechanical rules to produce the total angular momentum, J, of the atom. There are two limiting cases in angular momentum coupling: the *LS* (or Russell–Saunders) coupling, and the *j–j* coupling (or the *jj* coupling).

LS Coupling

If the spin–orbit interaction $\boldsymbol{l}_i \cdot \boldsymbol{s}_i$ is smaller than the mutual electrostatic interaction (third term in eqn [44]), the orbital momenta $\boldsymbol{l}_i$ combine vectorially to form the total orbital momentum $\boldsymbol{L}$ while the spin momenta $\boldsymbol{s}_i$ combine to form the total spin $\boldsymbol{S}$. $\boldsymbol{L}$ and $\boldsymbol{S}$ couple to form the total angular momentum $\boldsymbol{J}$. According to the rules of composition of angular momentum, the possible values of L are

$$L = |l_1 + l_2|,\ |l_1 + l_2| - 1, \ldots, |l_1 - l_2|; \quad \text{multiplicity } 2L+1 \quad [45]$$

and each value determines the term characteristic

$$L = 0,\ 1,\ 2,\ 3, \ldots \quad S,\ P,\ D,\ F, \ldots$$

Similarly, the total spin of the two electrons can be arranged such that $S=0$ (antiparallel spins) with multiplicity $2S+1=1$ (the singlet state) or $S=1$ (parallel spins) with multiplicity $2S+1=3$ (the triplet state). This can also be extended to many-electron light atoms:

$$\boldsymbol{L} = \sum_i \boldsymbol{l}_i, \quad \boldsymbol{S} = \sum_i \boldsymbol{s}_i, \quad \boldsymbol{J} = \boldsymbol{L} + \boldsymbol{S} \quad [46]$$

For helium and the alkaline-earth atoms (Be, Mg, Ca, Sr, and Ba) in their ground configuration, the triplet state is not allowed because of the Pauli principle (two equivalent electrons cannot occupy the same state with the same quantum numbers n, l, m, s).

Depending on which values are possible for the corresponding numbers L and S for a certain configuration, a number of electrostatically split terms are obtained. Such terms are designed as ${}^{2S+1}X_J$, where the $2S+1$ denotes the spin multiplicity, X is the total orbital angular momentum (S, P, D, …), and J is the total angular momentum.

Transitions from one state to another are governed by the following selection rules:

$$\begin{aligned} \Delta l &= \pm 1 \quad \text{for the single electron} \\ \Delta L &= 0,\ \pm 1 \quad \text{for the total system} \\ \Delta S &= 0 \quad \text{for the total spin} \end{aligned} \quad [47]$$

jj Coupling

The second limiting case for angular momentum coupling occurs for heavy atoms, because in this case the spin–orbit coupling $\boldsymbol{l}_i \cdot \boldsymbol{s}_i$ for each individual electron is larger than the interactions $\boldsymbol{l}_i \cdot \boldsymbol{l}_j$ and $\boldsymbol{s}_i \cdot \boldsymbol{s}_j$. In the *jj* coupling, the angular momenta couple

according to the vectorial sum:

$$l_1 + s_1 \rightarrow j_1; \qquad l_2 + s_2 \rightarrow j_2 \qquad [48]$$

The individual angular momenta j_i couple to give the total angular momentum $J = \sum_i j_i$. In this type of coupling, the orbital angular momenta L are not defined and there are, therefore, no terms S, P, D, etc.

In real cases, the *jj* coupling is observed only in very heavy elements. In most cases, intermediate forms of coupling exist. One consequence is, for instance, that the selection rules [47] do not apply for these atoms where the intercombination between terms of different multiplicities is not strictly forbidden.

Quantum Mechanics: Critical Phenomena

S Caracciolo, Università degli Studi di Milano, Milan, Italy

Critical Phenomena

Phase transitions are present in a variety of relevant physical systems: from the familiar phenomena of solid–liquid–gas transition to the more intriguing transition to a superconducting state at lower temperature. It is also believed that phase transitions in the early universe from a hotter state with higher degree of symmetry are responsible for the universe as it is known now. The concept of phase transition, and the methods developed in physics to study it, have found fruitful applications very far from the context in which it had been introduced. For example, in computational complexity it is used to characterize the transition for an ensemble of Boolean variables under an increasing number of constraints, which may or may not be satisfied at the same time. It can be used to understand under what conditions a neural network is or is not able to recognize suitable patterns, or to distinguish if the information in a noisy communication channel can or cannot be safely transmitted.

The understanding of phase transitions is one of the most spectacular achievements of statistical mechanics. In the thermodynamical limit, that is, in the presence, formally, of an infinite number of degrees of freedom, the knowledge of the Hamiltonian of the system does not allow one to predict its state: a multiplicity of states are possible! Moreover, the density of a thermodynamic potential, say the free energy, is not necessarily an analytical function of its control parameter, say the temperature, even though it is always a continuous function.

According to the Ehrenfest classification, a phase transition is of order n when, at the transition point,

the thermodynamic potential has a discontinuity at the n-derivative and is continuous in the derivatives of lower order. Nowadays, thanks to the success of ideas related to the application of the renormalization group, it is more customary to make a distinction between critical and noncritical phase transitions, where, in the former case, the correlation length ξ, which is the typical length associated to the fluctuations in the system, diverges at the critical point. Generically, at a critical point, the system, with the disappearance of its typical scale, displays scale invariance. Suppose that the critical point is characterized by a critical value of the temperature T_c, then, the correlation length is expected to diverge with a power law

$$\xi(T) \sim \left| \frac{T - T_c}{T_c} \right|^{-\nu} = |\tau|^{-\nu} \qquad [1]$$

where the power ν is the associated critical exponent and τ is the reduced temperature, a convenient dimensionless parameter. Critical exponents are an example of a universal quantity, that is, something that does not depend on the microscopic details of the system involved, but on more generic features such as dimensionality and the internal symmetries involved. T_c and the size of the critical region, where the universal behavior is observed are, instead, nonuniversal.

Landau introduced the concept of the order parameter. He imagined a local field $\phi(x)$ whose expectation $\langle \phi(x) \rangle = \phi$ (independently from the position because of space homogeneity) vanishes in the disordered phase, but takes a finite value in the ordered phase. The idea behind this concept is that, while the Hamiltonian of the system is invariant under the transformation of a group of symmetry G, the equilibrium states of the system could display a smaller symmetry group H, where H is a subgroup of G. Then, a broken symmetry transformation will send one state into another, and if the order parameter is not left invariant by this broken transformation, it can take a nonvanishing value in the phase with lower symmetry. For example, in a ferromagnet, the Hamiltonian is invariant under the Z_2 inversion symmetry of all the spins, but below the Curie temperature it allows two distinct pure thermodynamical phases with nonvanishing value of the residual magnetization which are sent one into the other by inversion of the spins, as this symmetry is broken.

In classical equilibrium statistical mechanics in the canonical ensemble, relations among various critical exponents can be derived by assuming that, near the critical point, the density of free energy f (more precisely its singular part) expressed as a function of the reduced temperature and the field conjugate to the order parameter h (or to the magnetic field in the case of the ferromagnet) is a homogenous function

$$f(\tau, h) = b^{-d} f(\tau b^{y_\tau}, h b^{y_h}) \qquad [2]$$

where d is the dimensionality of the system, $y_\tau = 1/\nu$ and y_h is another critical exponent. By choosing $b = \xi$, at $h = 0$, because of [1], one gets $f \sim \xi^{-d}$. **Table 1** collects the most common critical exponents. Because of [2], they are not all independent. By applying the definitions, it is easily derived that

$$d\nu = 2 - \alpha, \qquad y_h = \beta\delta/\nu \qquad [3]$$

$$\alpha + 2\beta + \gamma = 2, \qquad 2 - \alpha = \beta(\delta + 1) \qquad [4]$$

called scaling relations. The first one, the Josephson relation, is an example of a hyperscaling law: a scaling relation, which involves directly the dimension d of the system. It has a less secure footing than the other relations. As an example of derivation, consider the specific heat

$$C = \frac{\partial^2}{\partial \tau^2} f(\tau, 0) = b^{-d+2/\nu} f(\tau b^{1/\nu}, 0) \qquad [5]$$

which must behave, for $\tau \to 0$, as $\tau^{-\alpha}$ independently from b, and the first relation follows. Similar

Table 1 Main critical exponents and their mean-field values

	Exponent	*Mean field*	*Definition*	*Conditions*
Specific heat	α	0	$C \propto \lvert\tau\rvert^{-\alpha}$	$\tau \to 0$, $h = 0$
Order parameter	β	1/2	$\phi \propto (-\tau)^{\beta}$	$\tau \to 0^-$, $h = 0$
Susceptibility	γ	1	$\chi \propto \lvert\tau\rvert^{-\gamma}$	$\tau \to 0$, $h = 0$
Eq. state	δ	3	$h \propto \phi \lvert\phi\rvert^{\delta - 1}$	$h \to 0$, $\tau = 0$
Correlation length	ν	1/2	$\xi \propto \lvert\tau\rvert^{-\nu}$	$\tau \to 0$, $h = 0$
Algebraic decay	η	0	$G(r) \propto \lvert r\rvert^{-d+2-\eta}$	$\tau = 0$, $h = 0$

The last two values refer to the properties of the two-point correlation function.

considerations allow one to also derive the relation

$$\gamma = (2 - \eta)\nu \qquad [6]$$

When one also considers dynamics, near the critical point, the typical scale of autocorrelation in time of fluctuations ξ_t also diverges. This phenomenon, known as critical slowing down, is well known to researchers who simulate statistical ensembles by the dynamic Monte Carlo methods, as it makes computer time more and more inefficient in producing statistically independent configurations. The dynamic critical exponent z is defined by

$$\xi_t \sim \xi^z \qquad [7]$$

and, for example, for Brownian diffusion $z = 2$.

Landau Theory

An estimate of the critical exponents can be recovered using the mean-field theory, as shown by Landau. It amounts to imposing analyticity of thermodynamic potentials also at criticality. Consider the thermodynamic potential $g(\phi,\tau)$ at a fixed temperature and an order parameter. In order to fix the ideas, consider a ferromagnet where the order parameter ϕ is the magnetization. Because of analyticity, g can be expanded in ϕ:

$$g(\phi,\tau) \approx g_c(\tau) + r(\tau)\frac{\phi^2}{2} + s(\tau)\frac{\phi^3}{3} + u(\tau)\frac{\phi^4}{4} + \cdots \qquad [8]$$

A linear term in ϕ is not present as, by definition,

$$h = \frac{\partial}{\partial\phi} g(\phi, T) \approx r(\tau)\phi + s(\tau)\phi^2 + u(\tau)\phi^3 + \cdots \qquad [9]$$

that is, one expects a linear response for a small external field. An inversion symmetry would require all odd powers of ϕ in [8] to vanish, so $s(\tau) = 0$. For $u(\tau)$ positive, the series can be truncated to study small effects. For positive $r(\tau)$, there is only a minimum of G, at $\phi = 0$, but for negative $r(\tau)$ there are two of them, among the three values of ϕ corresponding to $h = 0$. Therefore, $r(0) = 0$; thus, at criticality, eqn [9] states that $h \sim \phi^3$, which means that $\delta = 3$. By expanding r in τ, $r(\tau) \sim \tau$. The minima at $h = 0$ for negative τ must have

$$\phi = \pm\sqrt{-\frac{r(\tau)}{u(\tau)}} \sim (-\tau)^{1/2} \qquad [10]$$

thus, $\beta = 2$. For positive τ, $\phi \sim h/r(\tau)$; thus

$$\chi = \frac{\partial\phi}{\partial h} = \frac{1}{r(\tau)} \sim \tau^{-1} \qquad [11]$$

which means $\gamma = 1$. From the scaling relations, $\alpha = 0$ can be obtained. In order to study the correlation functions, fields dependent on position should be introduced to get Gaussian fluctuations which display $\nu = 1/2$ and $\eta = 0$. Josephson hyperscaling relation thus holds for these values only in $d = 4$ dimensions. By taking into account fluctuations of the order parameter by means of a local effective field theory, it can be shown that the Landau theory can hold only in dimension d greater than $d_c = 4$. In lower dimensions, fluctuations are so strong that the effective field theory needs renormalization and the scaling operators acquire anomalous dimensions. The critical behavior is dominated by nontrivial fixed points of the renormalization group flow.

Quantum Critical Phenomena

Relevant fluctuations in finite-temperature transitions are always described according to classical mechanics. The order of magnitude of the classical thermal energy per degree of freedom $k_B T$ can be compared with the zero-point quantum energy per degree of freedom $\hbar\omega_c$, where ω_c is the frequency of the fluctuation. In the critical region, there are modes with enormous autocorrelation time ξ_t, so that the associated frequency is almost vanishing and

$$\hbar\omega_c \ll k_B T_c, \qquad \tau^{z\nu} \ll T_c \qquad [12]$$

which means that at finite T_c transitions, quantum mechanical effects are completely hidden by the thermal fluctuations and the universal properties at criticality are determined by a classical critical point.

However, in some cases, it is possible by changing a parameter at our disposal, say r, to decrease $T_c(r)$ eventually up to zero at some value r_c, that is, $T_c(r_c) = 0$. As an example, at a low enough temperature, $LiHoF_4$ forms an ionic crystal where the only magnetic degrees of freedom are spins of the holmic atoms which choose a preferred axis of orientation in the crystal. In a magnetic field, perpendicular to the preferred axis, this material can be described as a classical Ising model with a ferromagnetic interaction in a transverse field. It has been experimentally found that at a fixed magnetic field, there is a critical phase transition from a paramagnetic phase disordered by thermal fluctuations to a ferromagnetic ordered phase. By increasing the magnetic field, the line of

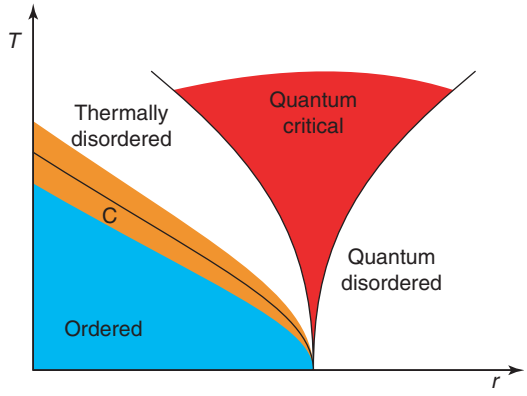

Figure 1 Phase diagram in the plane of the control parameter r and temperature T. Only the curve C is a phase boundary. It ends at the quantum critical point in $(r_c, 0)$. The quantum critical region is bounded by nonuniversal crossover lines.

phase transition reaches $T_c = 0$, at $h_c \sim 50\,\text{kOe}$. At $T = 0$, there are only quantum fluctuations and, therefore, they are only responsible for the (quantum) transition to the disordered phase. For this reason, the endpoint of the line of phase transition at $T = 0$ is called a quantum critical point. In **Figure 1**, the phase boundary curve is denoted by C. At $T = 0$, the line C terminates in the quantum critical point at r_c. In certain cases, such as a one-dimensional magnet or a two-dimensional magnet with a non-Abelian continuous symmetry to be broken, there is no ordered state at nonzero temperature, so that the ordered region below the curve C in **Figure 1** shrinks to the segment to the left of r_c at $T = 0$. Close to the boundary, the region is drawn where classical thermal fluctuations dominate and can be described in terms of a universal classical critical behavior. The disordered region at the right of r_c is a quantum paramagnet where the dominant fluctuations are quantum. The region denoted as quantum critical is dominated by the critical ground state at r_c (where long-range order is the effect of ground-state entanglement) and its thermal fluctuations. Its boundaries occur at

$$T \sim |\tau|^{z\nu} \sim \xi_t^{-1} \qquad [13]$$

(here $\tau = (r - r_c)/r_c$) and do not denote a phase boundary, but only a crossover which discriminates where thermal fluctuations become more important with respect to the quantum ones.

It is important to stress that it is not essential for the experiment that the quantum critical point is not in the physically accessible region, as it is always at $T = 0$. As it always happens around a critical point, fluctuations are well described by an effective field theory.

Phenomenologically, the previous remarks are encoded in a generalization of the scaling ansatz [2], which keeps into account one more relevant parameter

$$f(\tau, T, h) = b^{-(d+z)} f(\tau b^{y_\tau}, T b^z, h b^{y_h}) \qquad [14]$$

In this case, by choosing $b = \xi$, at $h = 0$, one gets the free energy

$$f(\tau, T, 0) = \xi^{-d} \xi_t^{-1} F(T \xi_t) \qquad [15]$$

expressed through a crossover function. It is interesting that, at variance with the classical case, in the effective volume factor, together with ξ^d, there is an explicit contribution from the time direction ξ_t. Indeed, in contrast with what occurs in classical statistical mechanics, where, generally, the contribution from the dynamics (i.e., the kinetic part of the Hamiltonian) is trivially simplified out, in quantum mechanics, because of the Heisemberg uncertainty relations (i.e., noncommutativity of coordinates and momenta), static and dynamic fluctuations cannot be disentangled. This difficulty demands more powerful tools for including quantum effects in statistical descriptions.

Path Integral

There is a formal analogy between the Boltzmann operator in quantum statistical mechanics at temperature $T = 1/(k_B \beta)$ (i.e., $\exp(-\beta \mathscr{H})$) and the time evolution operator in quantum mechanics (i.e., $\exp(-it\mathscr{H}/\hbar)$), after the identification $t = i\beta\hbar$. An analytic continuation to imaginary time, called the Wick rotation, is the starting point for the construction of the Schwinger functions, that is, correlation functions in the Euclidean field theory. A path integral representation is obtained by using the Trotter formula

$$\exp(-\beta \mathscr{H}) = \lim_{N \to \infty} \left[\exp\left(-\frac{\beta}{N} \mathscr{H} \right) \right]^N \qquad [16]$$

that is, one can reduce to consider the time evolution on a small lapse β/N where it is essentially classical, as the quantum effect of noncommutativity of operators is of the order $1/N^2$ and can be neglected in the large-N limit. For example, consider the partition function (which, in the presence of an external source, is the generator of all the correlation functions)

$$Z = \text{Tr} \exp(-\beta \mathscr{H}) \qquad [17]$$

where the trace is over the physical Hilbert space. By introducing a complete basis set for this space at each intermediate time, one has

$$Z = \lim_{N\to\infty} \sum_{\{\phi\}} \prod_{i=0}^{N} \langle \phi_i | \exp(-\Delta t \mathscr{H}) | \phi_{i+1} \rangle$$
$$= \int \mathscr{D}\varphi(x,t) \exp\left(- \int_0^\beta \mathrm{d}t \int \mathrm{d}^d x \mathscr{L}[\varphi(x,t)] \right) \quad [18]$$

where one has to set $\phi_N = \phi_0$ because a trace is being evaluated, and $\Delta t = \beta/N$. When, for example, by means of coherent states, the expectation values are parametrized by auxiliary variables φ, this formula shows that the quantum statistical mechanics in d dimensions can be seen (before the limit $N\to\infty$ is taken) as a classical statistical mechanics of a model in $d+1$ dimensions, which is put in the discrete "time" direction where the index i runs in a box of finite size β. Thus, once more, for finite β, when fluctuations have a correlation length long enough, the effective system dimension is d, but at increasing β there is a crossover to a fully $(d+1)$-dimensional system. Moreover, the path integral representation in [18] shows that, if nontrivial singularities appear in the limit of large N, when time is continuous, it behaves as a spatial dimension, so that the dynamical critical exponent $z=1$. As a consequence, three-dimensional quantum systems, the most interesting quantum systems in solid-state physics, behave at the quantum critical point as four-dimensional classical critical systems. But for $d=4$, the mean-field theory is exact (apart from logarithmic violations) and the critical exponents are those provided in **Table 1**. This conclusion, though often invalid, should also hold when, because of renormalization, $z \geqslant 1$. Indeed, the effective classical description of the soft modes which are massless in the classical theory and are associated with the fluctuation of the order parameter, does not take into account the presence of other modes which can be singular at the quantum critical point because of the vanishing of the temperature. An important example are the particle–hole excitations in an electron fluid that have a mass proportional to the temperature. Indeed, the theory of quantum phase transitions is very rich and shows a complex structure.

Examples

An example of a quantum critical point obtained by changing the magnetic field has already been noted. In other important examples, the control parameter can be the amount of disorder or the strength of the interaction.

Quantum Spin-Glass

$LiHo_xY_{1-x}F_4$ is obtained from $LiHoF_4$ with the replacement of the magnetic ion Ho^{3+} by the nonmagnetic Y^{3+}. By varying the dilution x, and the transverse magnetic field, a divergence in the nonlinear susceptibility, which shows a spin-glass transition, can be moved at zero temperature toward the quantum critical point, even though experimentally the divergence seems to become so weak that it could also be nonexistent, so that the transition could instead be of the first order.

Metal–Insulator Transition

Electrons in a metal form Bloch states which extend throughout the material, and conduction of electricity is allowed from one boundary to the other. But impurities can localize the electron states, that is, wave functions of the electrons have a significant value only over bounded regions, so that electricity can no longer be conducted to the whole sample. The quantum transition from a metal to an insulator, driven by disorder, is called Anderson localization when the interaction among the electrons is neglected. It is known that for $d=2$, in the absence of an external magnetic field, any amount of disorder is enough to produce localization. For $d=3$, when disorder is not too strong, there are both localized and extended states: they are separated in energy by the mobility edge. The difference between the Fermi energy and the mobility edge is the control parameter to the phase transition. By varying the density of electron or the amount of disorder, the transition can be obtained at zero temperature. In the presence of electron interactions, the transition, called the Anderson–Mott transition, is very poorly understood.

Superfluid–Insulator Transition

Disorder can also be responsible for a transition from a superfluid to an insulating state. If there is an attractive interaction between the electrons, superconductivity can arise. In the case of a charged superfluid or superconductor, the transition can be induced by an external magnetic field. Mott transitions can be obtained in Josephson junction arrays where the ratio of the Josephson and Coulomb interaction can be varied.

Quantum Hall Transition

Consider an electron gas confined in an interface between two semiconductors. For $d=2$, free electrons in a magnetic field occupy discrete energy (Landau) levels. By changing the ratio of the density of the

electron to the magnetic field perpendicular to the interface, different phases are obtained. While the resistivity longitudinal to the current flow vanishes, the transverse one, called the Hall resistivity, is quantized. Different states are characterized by the different values of transverse resistivity. Transitions between Hall states are quantum transitions associated with the divergence of the localization length.

Kosterlitz–Thouless Transition

This is a well-known example of a model in classical statistical mechanics which shows a phase transition for $d = 2$, even in the absence of a local order parameter. It is the $O(2)$-vector model, or the XY model, because the spin variables are constrained in a plane. At a high temperature, it is disordered by topological excitations: vortices. However, at temperatures low enough, vortex–antivortex pairs condense and become irrelevant for the Gaussian fixed points. This means that by using mapping between the classical and the quantum models, the quantum $d = 1$ model has a quantum critical point. This transition is relevant for the discussion of the low-dimensional superconductors, and has been used to describe underdoped high-temperature superconducting cuprates.

Deconfinement Transition

Particles or quasiparticles carrying fractionalized quantum numbers interacting through a gauge field, as, for example, quarks in quantum chromodynamics, can undergo a phase transition from a confined phase, where the only excitations at low energy are composite excitations with integer quantum numbers, to a higher-temperature phase, where the effect of the gauge interaction is weak and the fractionalized particles are unbound. The nature of this phase transition is not, in general, fully understood. Different phenomenologies can arise in cases in which the gauge group is discrete, Abelian, or non-Abelian. It could be driven by different topological defects of the gauge fields. In particular, monopoles, instantons, or vortices associated with the center of the gauge group can be effective.

SAT/UNSAT Quantum Transition

There is a quantum version of the classical problems of satisfiability/unsatisfiability in the complexity theory of computation. It refers to the qbits of quantum computation and is governed by a quantum critical point.

Quantum Mechanics: Elementary Particles

G Marchesini, Università di Milano–Bicocca, Milan, Italy

Historical Introduction

By the second decade of the twentieth century quantum mechanics was a "theory": its systematic application to the microscopic world was in general successful both in describing phenomena and in solving fundamental problems.

At that time, the search for a theory to unify quantum mechanics with relativity became an important issue. It was clear that the phenomena in which the two theories were involved were that of fast (relativistic) and small (quantum) bodies, which is the world of "elementary particles." Among the known elementary particles at that time were the photon γ, electron e, proton p, and neutron n. But soon their number increased. The search for the "unified theory" proceeded in two main directions.

On the one hand, a systematic search for elementary particles, conserved (or almost conserved) quantum numbers, and symmetries was initiated. It required a systematic interplay of theoretical, experimental, and technological developments. Soon it became clear that one could classify the interactions in three groups, with increasing strength: weak, electromagnetic, and strong interactions. The well-known electromagnetic interactions are mediated by

photons. Weak interactions are responsible, for instance, for the neutron decay and the weak radiative decay of nuclei. Strong interactions are responsible for nuclear structures.

On the other hand, the search for dynamical formulations also gained momentum around the same time. The first attempt was a relativistic generalization of the Schrödinger equation. Most important among these was the Dirac equation, which successfully predicted antiparticles, fine-structure splitting of the hydrogen spectrum and the electron magnetic moment. This generalization, however, does not account for particle creation and annihilation processes that take place in elementary particle interactions. Instead, it required the formulation of the quantized (relativistic) field theory (QFT). The meaning of "elementary particles" became clear, together with their connection to quantum fields. The first QFT was quantum electrodynamics (QED), the quantization of Maxwell fields with charged currents of quantized (Dirac) electrons. As it will be clear in the following, the formulation of QFT is very constrained, in that it only requires the quantum numbers and symmetries of the fields (particles).

The two directions are thus intrinsically unified. In the following, after the description of quantum numbers and symmetries, the construction of QFT for elementary particles is illustrated.

Quantum Numbers and Symmetries

The characteristic features of elementary particles are listed in "Review of particle physics." The main structures are summarized here. The commonly used units are $\hbar$, c (light velocity) and MeV for masses (or $\mathrm{GeV} = 10^3\,\mathrm{MeV}$). Electric charges of all observed particles are multiples of the electronic charge. Each particle has an antiparticle with the same mass and spin but opposite charge (and quantum numbers in general). They are classified as leptons and hadrons, which undergo weak, electromagnetic, and strong interactions mediated by "gauge bosons" (gravitational interactions are discussed later).

Gauge Bosons

The gauge bosons that mediate the various interactions are: photon γ, weak bosons (charged $\mathrm{W}^{\pm}$ and neutral Z^0), and gluons g. They are responsible for electromagnetic, weak, and strong interactions, respectively. The photon is massless (with two transverse polarizations) and couples to charged particles. The bosons $\mathrm{W}^{\pm}$, Z^0 are massive (with three polarizations). Due to their large masses (almost hundred proton masses), their discovery (1983) was very difficult. Gluons g carry eight "color charges," are neutral and massless; gluons are not produced but are "confined" within hadronic matter.

Leptons

There are three "families" (or doublets) which undergo electromagnetic and weak interactions (they couple to γ and $\mathrm{W}^{\pm}, \mathrm{Z}^0$). The first family is $(\mathrm{e}, \nu_{\mathrm{e}})$: electron (e) is charged and massive, and neutrino (ν_{e}) is neutral and massless. They both have spin 1/2. While the electron has both polarizations, the neutrino is only left-handed, so that parity (reflection into a mirror) is violated in weak interactions. The other two families, (μ, ν_{μ}) and (τ, ν_{τ}), differ only in the masses of charge particles ($m_{\mu} \sim 200 m_{\mathrm{e}}$ and $m_{\tau} \sim 3600 m_{\mathrm{e}}$). There are recent indications that neutrinos are massive (and then oscillate one into the other with characteristic period).

Hadrons

There are few hundred hadrons divided into two groups, according to whether their spin is integer (mesons, such as π^0, $\pi^{\pm}$) or half-integer (baryons, such as n, p). They undergo all three types of interactions (couple to all gauge bosons).

It was a major discovery that all hadrons are described as "made up" of few quanta, quarks, with spin 1/2 and six quantum numbers called flavors ($f = \mathrm{u}, \mathrm{d}, \mathrm{c}, \mathrm{s}, \mathrm{t}, \mathrm{b}$). Their flavors, charges q_f, and masses m_f are

$$f = \begin{pmatrix} \mathrm{u} & \mathrm{c} & \mathrm{t} \\ \mathrm{d} & \mathrm{s} & \mathrm{b} \end{pmatrix}, \qquad q_f = \begin{pmatrix} +2 \\ -1 \end{pmatrix} \frac{e}{3}$$
$$m_f \simeq \begin{pmatrix} 0.003 & 1.2 & 4.3 \\ 0.006 & 0.1 & 178 \end{pmatrix} \mathrm{GeV} \qquad [1]$$

Mesons are made up of quark–antiquark pairs. For instance, the spinless meson π^+ is made up of quark u and antiquark d, so its charge is

$$q_{\pi^+} = \left(\frac{2}{3} + \frac{1}{3}\right) e = e$$

The negatively charged π^-, antiparticle of π^+, is made up of antiquark u and quark d, so its charge is $-e$.

Baryons are made up of three quarks. The proton, for instance, is made up of three quarks u, u, and d, so its charge is

$$q_p = \left(\frac{2}{3} + \frac{2}{3} - \frac{1}{3}\right) e = e$$

The antiproton is made up of three antiquarks u, u, and d, so its charge is $-e$. Flavor quantum numbers are conserved only in electromagnetic and strong interaction but are weakly violated.

Quarks make up hadrons but are not seen; they are "confined" within the hadrons. This fact should be explained in quantum chromodynamics (QCD), the theory for quark and gluon interaction. To construct QCD, one needs to introduce an additional quantum number for the quark, the "color" with three values. The fact that quarks (and gluons) are confined can be formulated by requiring that physical states (hadrons) are "colorless." In mathematical terms, the three color "charges" correspond to the dimension of the smallest matrices for the eight generators of the SU(3) group. Under SU(3) transformations, quarks (and gluons) transform, whereas hadrons are invariant.

The color quantum number is needed to explain the size of total cross sections and decay rates (e.g., $\pi^0 \to 2\gamma$). Moreover, it is needed for the "anomaly cancellation," a requirement for consistency of QFT for elementary particles. Anomaly cancellation should be mentioned here since it provides a strong constraint on the spectroscopy of all elementary particles. The three quark doublets in [1] parallel the three-lepton families:

$$\left\{\begin{pmatrix}\mathrm{u}\\ \mathrm{d}\end{pmatrix}\begin{pmatrix}\mathrm{c}\\ \mathrm{s}\end{pmatrix}\begin{pmatrix}\mathrm{t}\\ \mathrm{b}\end{pmatrix}\right\} \quad \text{and} \quad \left\{\begin{pmatrix}\mathrm{e}\\ \nu_{\mathrm{e}}\end{pmatrix}\begin{pmatrix}\mu\\ \nu_{\mu}\end{pmatrix}\begin{pmatrix}\tau\\ \nu_{\tau}\end{pmatrix}\right\} \qquad [2]$$

Within such a scheme, the charges of leptons and quarks (including color) sum up to zero, so that fundamental conservation laws of weak currents are satisfied. A missing piece in [2] would destroy such conservation laws in the presence of an anomaly. It is interesting to observe that, because of the t-quark large mass, see [1], the t flavor was discovered much later (1994). However, long before its discovery, the theoretical framework was so well established that the general question was not if but when the t flavor would be found.

Quantum Field Theory: Electrodynamics

The construction of QFT started with electromagnetic interactions, QED, which is presented here in a way suited for generalization to other interactions. Two quantum fields are involved, the electron and the photon. The quantum field $\psi(x)$ of the electron (or any other charged fermion) can be decomposed, in perturbation theory, into fermionic operators that create electrons and positrons with momentum $\boldsymbol{k}$ and helicity $(1/2)\lambda$ (here denoted by $b^\dagger_\lambda(\boldsymbol{k})$ and $c^\dagger_\lambda(\boldsymbol{k})$, respectively):

$$\psi(x) = \int \frac{\mathrm{d}^3k}{(2\pi)^3 2E_k} \times \sum_{\lambda=\pm 1} \{\mathrm{e}^{-\mathrm{i}k\cdot x} u_\lambda(\boldsymbol{k}) b_\lambda(\boldsymbol{k}) + \mathrm{e}^{\mathrm{i}k\cdot x} v_\lambda(\boldsymbol{k}) c^\dagger_\lambda(\boldsymbol{k})\} \qquad [3]$$

with $E_k = \sqrt{m^2 + \boldsymbol{k}^2}$ and $x \cdot k = x_\mu k^\mu = tE_k - \boldsymbol{xk}$. The wave functions u_λ and v_λ are solutions of the Dirac equation with positive and negative frequency and, as $\psi(x)$, have four components (spinors) in correspondence with four degrees of freedom: two helicities for the particle and two for the antiparticle. The (free) Dirac action is

$$S_{\mathrm{Dirac}}[\psi] = \int \mathrm{d}^4x \bar{\psi}(x)[\mathrm{i}\partial\!\!\!/ + m]\psi(x) \qquad \partial\!\!\!/ = \partial_\mu \gamma^\mu, \quad \partial_\mu = \frac{\partial}{\partial x^\mu} \qquad [4]$$

with $\mu = 0, 1, 2, 3$, γ^μ being the Dirac matrices and $\bar{\psi} = \psi^\dagger \gamma_0$.

The (free) Maxwell action is given by the well-known expression

$$S_{\mathrm{Maxwell}}[A] = -\frac{1}{4}\int \mathrm{d}^4x F^{\mu\nu}(x) F_{\mu\nu}(x) \qquad F_{\mu\nu}(x) = \partial_\mu A_\nu(x) - \partial_\nu A_\mu(x) \qquad [5]$$

where the (real) vector quantum field has the decomposition

$$A_\mu(x) = \int \frac{\mathrm{d}^3k}{(2\pi)^3 2E_k} \{\mathrm{e}^{-\mathrm{i}kx} a_\mu(\boldsymbol{k}) + \mathrm{e}^{\mathrm{i}kx} a^\dagger_\mu(\boldsymbol{k})\} \qquad [6]$$

with $a^\dagger_\mu(\boldsymbol{k})$ and $a_\mu(\boldsymbol{k})$ the creation and the annihilation operators, respectively. While there are four fields $A_\mu(x)$, the photon has only two polarizations. Related to such a redundancy is the fact that the action [5] is invariant under the "gauge" transformation

$$A_\mu(x) \Rightarrow A_\mu(x) - \frac{1}{e}\,\partial_\mu \Lambda(x) \qquad [7]$$

with $\Lambda(x)$ arbitrary. Therefore, not all of the four fields are independent.

The action of QED, including the photon–electron interaction, can be derived by starting from the free Dirac action plus the gauge invariance. This will be illustrated here since the same procedure will be followed to construct QFT for weak and strong interactions. First, [4] is invariant under the phase

transformation

$$\psi(x) \Rightarrow e^{i\Lambda}\psi(x), \qquad \bar{\psi}(x) \Rightarrow \bar{\psi}(x)e^{-i\Lambda} \qquad [8]$$

where Λ is an arbitrary constant. Then this symmetry is "promoted" by requiring that the action be invariant under [8] with $\Lambda \rightarrow \Lambda(x)$, an arbitrary function of x. The action [4] is not invariant anymore since

$$\bar{\psi}(x)\partial_\mu\psi(x) \Rightarrow \bar{\psi}(x)[\partial_\mu + i\partial_\mu\Lambda(x)]\psi(x) \qquad [9]$$

To enforce the symmetry, one needs to compensate for the $\partial_\mu\Lambda(x)$ term. This is obtained by adding a vector field $A_\mu(x)$ transforming according to [7] and by making the replacement:

$$\begin{gathered}\bar{\psi}(x)\partial_\mu\psi(x) \quad \text{replaced with} \\ \bar{\psi}(x)[\partial_\mu + ieA_\mu(x)]\psi(x)\end{gathered} \qquad [10]$$

in the Dirac action [4]. The result is invariant under the gauge transformation. This shows how powerful requiring gauge symmetry is. From the free Dirac action, one theoretically "discovers" the photon field. Such a strategy will be generalized to "discover" other gauge bosons.

In conclusion, the QED action is

$$\begin{aligned} S_{\text{QED}}[A,\psi] &= S_{\text{Maxwell}}[A] + S_{\text{Dirac}}[\psi] \\ &\quad + ie\int d^4x A_\mu(x) j^\mu(x) \\ j^\mu(x) &= \bar{\psi}(x)\gamma^\mu\psi(x) \end{aligned} \qquad [11]$$

which is a Lorentz invariant, so that unification of relativity and quantum physics is achieved. The interaction does not conserve the particle number. The last term contains three quantum fields (with three creation or annihilation operators), and then a photon could annihilate into an electron–positron pair, an electron can absorb or emit a photon, etc. This feature is unavoidable and is based on the fact that the relativistic action must be constructed only in terms of x-dependent quantum fields, a requirement which is not necessary in nonrelativistic many-body theories. A further important consequence of relativity is that quanta with integer spin must satisfy Bose statistics while quanta with half-integer spin must satisfy Fermi statistics, a consequence of causality of relativistic particle propagators.

The connection between QED action and cross-sections is based on the S-matrix formalism, similar to the nonrelativistic case, apart from nonconservation of particle number. Cross-sections calculation are done (perturbatively) in terms of Feynman rules involving point-like interaction and integration over virtual particle momenta.

The most important surprise of QFT is the presence of infinities arising from integrations over virtual momenta in the ultraviolet (UV) region. The comprehension of this problem (renormalization) has been very laborious from the conceptual and calculational points of view. In QED, all infinities can be completely absorbed into the two parameters (mass and charge) entering the action [11] (and into the normalization of the two fields). Therefore, (m, e) in S_{QED} need to be reinterpreted as UV parameters (m_0, e_0) that absorb all infinities. On the other hand, (m_0, e_0) are determined by two conditions, for instance, giving the physical mass and charge (m, e). In conclusion, all cross sections and distributions involving photons and charged particles can be computed in terms of (m, e), which, however, are not the parameters entering the action but the experimentally measured ones.

The consequences of renormalization is extraordinary from the conceptual point of view: one aims to formulate a fundamental theory, but discovers that QED has to be considered only as an effective theory. Infinities arise from the fact that local fields (defined at point x with infinite resolution) are not adequate for a fundamental description at all distances. At very short distances (much shorter than the present resolution of 10^{-16} cm), nature should be described by different fundamental objects to be discovered (strings?). However, QED remains a predictive theory since the (unknown) fundamental objects can be integrated over the very short distances and the result can be embodied only into quantum fields with UV charge and mass (m_0, e_0).

The features described for infinities in QED are general. A QFT in which all infinities can be absorbed into few UV parameters is said to be renormalizable. It turns out that the criterion is very simple: a QFT is renormalizable if the UV parameters in the action are masses and dimensionless couplings as in QED. Such a criterion allows one to identify the few interaction terms in the action.

In conclusion, quantization and relativity provides remarkably strong constraints: the quantum numbers of fields, their symmetries, and the criterion for renormalizability essentially allow one to uniquely determine the QFT, up to a few UV parameters.

Quantum Chromodynamics: Strong Interactions

The fundamental fields in QCD are the quarks (which make up the hadrons). To construct the action one proceeds as in QED and starts from the free Dirac action. The quarks are described by the fermion field

$\psi_{af}(x)$, given in [3] with flavor $f = 1, \ldots, 6$ and color $a = 1, 2, 3$ quantum numbers. The Dirac action is

$$S_{\text{Dirac}}[\Psi] = \int \mathrm{d}^4x \sum_f \bar{\Psi}_f(x) \cdot [\mathrm{i}\partial\!\!\!/ + m_f]\Psi_f(x)$$
$$\bar{\Psi}_f \cdot \Psi_f = \sum_a \bar{\psi}_{af}\psi_{af} \qquad [12]$$

with $\Psi_f(x)$ the triplet field

$$\Psi_f(x) = \begin{pmatrix} \psi_{1f}(x) \\ \psi_{2f}(x) \\ \psi_{3f}(x) \end{pmatrix}$$
$$\bar{\Psi}_f(x) = (\bar{\psi}_{1f}(x)\bar{\psi}_{2f}(x)\bar{\psi}_{3f}(x)) \qquad [13]$$

To search for the interaction and the gluon, one focuses on the field transformations. One observes that [12] is invariant under the SU(3) transformation (cf. (8))

$$\Psi_f(x) \Rightarrow U\Psi_f(x), \qquad \bar{\Psi}_f(x) \Rightarrow \bar{\Psi}_f(x)U^{-1}$$
$$U = \mathrm{e}^{\mathrm{i}u}, \qquad u = \sum_{\alpha=1}^{8} \lambda^\alpha \theta^\alpha \qquad [14]$$

with λ^α the eight (Hermitean and traceless) 3×3 matrices of SU(3) and θ^α eight real arbitrary parameters.

To find the gluon, the gauge vector boson analogous to the photon field A_μ, one promotes [14] into a local symmetry with $U(x)$ an arbitrary x-dependent SU(3) matrix. In this case, [12] is not invariant since (cf. (9))

$$\bar{\Psi}(x) \cdot \partial_\mu \Psi_f(x)$$
$$\Rightarrow \bar{\Psi}(x) \cdot [\partial_\mu + U^{-1}(x)\partial_\mu U(x)]\Psi_f(x) \qquad [15]$$

To obtain an invariant action, one needs to compensate for the $U^{-1}(x)\partial_\mu U(x)$ terms by introducing eight vector gluon fields $G^\alpha_\mu(x)$ and make in [12] the replacement (cf. (10)):

$$\bar{\Psi}(x) \cdot \partial_\mu \Psi_f(x)$$

replaced with

$$\bar{\Psi}(x) \cdot [\partial_\mu + \mathrm{i}g_{\mathrm{s}} G_\mu(x)]\Psi_f(x)$$
$$G_\mu = \sum_{\alpha=1}^{8} \lambda^\alpha G^\alpha_\mu(x) \qquad [16]$$

with g_{s} the color coupling (analogous to e) and G_μ a 3×3 traceless matrix quantum field which undergoes the gauge transformation (cf. [7])

$$G_\mu(x) \Rightarrow U(x)\left[G_\mu + \frac{\mathrm{i}}{g_{\mathrm{s}}} U^{-1}(x)\partial_\mu U(x)\right] \qquad [17]$$

The replacement [16] in [12] leads to the action

$$S_{\text{QCD}}[\psi, G] = S_{\text{Dirac}}[\psi] + S_{\text{gluons}}[G]$$
$$+ \mathrm{i}g_{\mathrm{s}} \int \mathrm{d}^4x \sum_{\alpha=1}^{8} G^\alpha_\mu(x) j^{\alpha\mu}(x) \qquad [18]$$

with the eight color currents

$$j^{\alpha\mu} = \sum_f \bar{\Psi}_f(x) \cdot \lambda^\alpha \gamma^\mu \Psi_f(x) \qquad [19]$$

The pure gluon term $S_{\text{gluons}}[G]$ is constructed as in QED by requiring invariance under [17]. One finds that it contains gluon self-interaction terms (three- and four-gluon interaction vertices) corresponding to the fact that the gluon field is a matrix in color indices, that is, the gluon has "color charge" and can interact with itself. S_{QCD} contains only the quark masses and the dimensionless gauge coupling g_{s} and is, therefore, renormalizable.

The most challenging question is that while fields are quarks and gluons, only hadrons are seen at large distances. Therefore, the main question is how the QCD action explains that colorless hadrons are made up of color quanta (color confinement). There is no answer yet to this question. Numerical studies of QCD, formulated in terms of Feynman path integrals, seem to reproduce hadron spectra and indicate that color is confined.

Perturbative methods can be used at short distances. Here the effective strength of QCD interaction (the color coupling g_{s}) is small, due to radiative correction (asymptotic freedom). This unexpected phenomenon (in QED, the effective charge increases by going to short distance) is due to gluon self-interaction and radiative corrections, from nonphysical polarization of virtual gluons. Predictions obtained for short-distance distributions are in general well confirmed by experimental data.

Electroweak Theory and Standard Model

One of the most beautiful discoveries in particle physics is the unified theory of electromagnetic and weak interactions, a basic element of the standard model.

Weak phenomena (the prototype is neutron decay) are characterized by very short distances, in contrast to electromagnetic phenomena with an infinite range

of action. This is because the photon is massless (infinite range), while the weak bosons $W^{\pm}$, Z^0 are very massive, so that, at low energy one can assume point-like weak interactions (Fermi theory). It is then surprising that these two completely different interactions could be unified into the electroweak (EW) theory.

To illustrate the EW theory, consider the first lepton family (e, ν_e) and neglect neutrino mass. The important phenomenological observation is that the neutrino is only left-handed and is described by

$$\psi_{\nu L}(x) = P_L \cdot \psi_\nu(x) = \nu_L(x) \qquad [20]$$

with ψ_ν the fermion field given by [3] and $P_L = (1-\gamma_5)/2$ the chiral operator which, for massless fermions, projects on left-handed helicity ($\lambda = -1$). The electron, instead, is present in nature with both helicities. Using the left (P_L) and right (P_R) chiral projectors, one can write the electron quantum field ($P_L + P_R = 1$)

$$\psi_e(x) = P_L \cdot \psi_e(x) + P_R \cdot \psi_e(x) = e_L(x) + e_R(x) \quad [21]$$

(ν_L, e_L, e_R are projected neutrino and electron quantum fields). The (free) Dirac action written in terms of left and right field is

$$S_{\text{Dirac}}[\psi] = i \int d^4x \{\bar{\nu}_L(x) \partial\!\!\!/ \nu_L(x) + \bar{e}_L(x) \partial\!\!\!/ e_L(x) + \bar{e}_R(x) \partial\!\!\!/ e_R(x)\} \qquad [22]$$

The electron mass term $m_e(\bar{e}_R e_L + \bar{e}_L e_R)$, which mixes the left and right electron fields, will be taken into account later.

To construct the theory, one proceeds as in QED and QCD and identifies the symmetry transformations. The Dirac action [22] is invariant under the $SU(2) \times U(1)$ transformation (the transformation of a doublet and a phase rotation)

$$\begin{pmatrix} \nu_L(x) \\ e_L(x) \end{pmatrix} \Rightarrow V \begin{pmatrix} \nu_L(x) \\ e_L(x) \end{pmatrix}$$
$$V = e^{i\nu}, \quad \nu = \sum_{i=1}^{3} \sigma_i \theta_i$$
$$\begin{pmatrix} \nu_L(x) \\ e_L(x) \end{pmatrix} \Rightarrow e^{i\Lambda Y_L} \begin{pmatrix} \nu_L(x) \\ e_L(x) \end{pmatrix} \qquad [23]$$
$$e_R(x) \Rightarrow e^{i\Lambda Y_R} e_R(x)$$

with V an SU(2) matrix, σ_i the Pauli matrices, and (θ_i, Λ) arbitrary real constants. The proportionality constants turn out to be the hypercharges ($Y_L = -1$ and $Y_R = -2$), a generalization of electric charges.

The next step is the search for the gauge vector bosons, $\gamma, W^{\pm}, Z^0$, mediating the interactions. This is done by promoting [23] into local symmetries requiring $\theta_i(x)$ and $\Lambda(x)$ to be four arbitrary x-dependent functions. If one proceeds as in the case of QED and QCD, one obtains four massless gauge vector boson fields.

To set up EW action, one has to take into account that $W^{\pm}, Z^0$ are massive, while γ remains massless, that the electron has a mass and charge, while the neutrino is massless and neutral. The simplest way to obtain all these features is to introduce two complex scalar fields $\phi_1(x)$ and $\phi_2(x)$ and write the (unique) action which is invariant under the $SU(2) \times U(1)$ transformation [23], together with

$$\begin{pmatrix} \phi_1(x) \\ \phi_2(x) \end{pmatrix} \Rightarrow V \begin{pmatrix} \phi_1(x) \\ \phi_2(x) \end{pmatrix}$$
$$\begin{pmatrix} \phi_1(x) \\ \phi_2(x) \end{pmatrix} \Rightarrow e^{i\Lambda(Y_L - Y_R)} \begin{pmatrix} \phi_1(x) \\ \phi_2(x) \end{pmatrix} \qquad [24]$$

Moreover, one has to require that the scalar fields undergo a symmetry breaking and acquire a vacuum expectation value v in one of the four real components, in particular, in physical gauge,

$$\begin{pmatrix} \phi_1(x) \\ \phi_2(x) \end{pmatrix} \to \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ v + \chi(x) \end{pmatrix} \qquad [25]$$

with $\chi(x)$ a real scalar field. The other three real scalar fields disappear from the EW action and become the longitudinal polarization of the three massive gauge bosons. The particle of $\chi(x)$ field, called Higgs meson, is spinless and neutral, and then couples only to weak bosons. Its mass is not constrained. This particle has not been observed yet and its discovery is very important, since it gives the most clear signal of spontaneous symmetry breaking at the basis of the EW theory.

Spontaneous symmetry breaking in the EW theory is similar (non-Abelian version) to the one used in the standard Bardeen–Cooper–Schrieffer theory of superconductivity, in which one requires that the single complex scalar field (Cooper pair) acquires a ground-state expectation value. This gives a finite range (inverse effective mass) for the electromagnetic field in the superconducting material.

The EW theory for the electron family contains few UV parameters: four dimensionless couplings (two associated with SU(2) and $U(1)$, the coupling of lepton family with the scalar doublet and the scalar doublet self-interaction) and the vacuum expectation value v which has dimension of mass. EW action is then renormalizable.

To complete the EW theory, one has to add the other two lepton families and the quark doublets in (2). For the leptons, one simply replicates the previous construction (with a new parameter for each lepton family, the coupling with the scalar doublet). Taking into account quarks is more subtle, since all fermions in the doublets are massive (quark family mixing). As mentioned before, only by adding together lepton and quarks families, as in [2], and the color charge for quarks, one finds a consistent theory (anomaly cancellation).

Finally, to construct the standard model, the unified theory of all interactions among the elementary particles, one has to merge EW and QCD action. The resulting theory has the symmetry $SU(3) \times SU(2) \times U(1)$, where SU(3) is the color symmetry of QCD. The standard model has been successfully tested, especially by precise measurements at LEP, the electron–positron collider at CERN. At the moment, the fact that neutrino has a mass is the only experimental indication that the theory needs to be modified.

Beyond the Standard Model

Although the standard model is theoretically very constrained and has been successfully tested, there are various reasons to expect that it is incomplete, besides the neutrino mass problem. Schematically, the reasons are: (1) spontaneous symmetry breaking, needed to provide mass to weak bosons and fermions, could be more complex than the one used here. The point will be clarified by the discovery of the Higgs meson; (2) the number of UV parameters in the action is finite but large; (3) the mass scales for various particles is not naturally explained; (4) a simple merging of EW and QCD into the standard model without constraints is not satisfactory, one would expect that they are unified at a deeper level, for instance, by a symmetry unifying SU(3) color with EW symmetry $SU(2) \times U(1)$; (5) to obtain a complete theory, one should take into account gravitational forces as described by general relativity but its quantization leads unavoidably to QFT which is nonrenormalizable (with infinite number of parameters in the action). Finally, as discussed before, the theory is formulated as QFT, which should be considered as an effective theory involving UV parameters to account for infinities. Intensive experimental and theoretical activity is focused on the study of the above questions.

From the experimental point of view, one faces challenging technological problems due to the extreme conditions: one needs to deal with very high energy (e.g., for the Higgs meson search) or with the very small cross sections involved in neutrino physics. In the last few decades, large developments in the astrophysical and cosmological measurements are producing important information for elementary particle physics.

There have been many attempts to search for a theory which solves the above problems. Super-symmetry, in which bosons and fermions are unified, is by now an important element in this search. It is so elegant, and unifies so many aspects and seems to partially explain particle mass scales that one cannot resist but think it represents natural facts. However, up to now, there are no experimental indications of boson–fermion unification.

Infinities in QFT suggest that, at very short distances, fields are not adequate for a physical description. The string theory is a candidate for a fundamental theory. It generalizes QFT: it unifies quantum and relativistic aspects for extended objects (strings) instead of point-like objects as in QFT. The surprise is that the resulting theory is not only highly constrained and mathematically beautiful, but it also requires unification with gravitation, the only force not yet considered at quantum level. Many attempts are ongoing in this direction. The important difficulty, coming as a prize for unification with general relativity, is that the scale at which one starts to resolve strings is $\sim 10^{-33}$ cm, the Planck scale. Essentially no experimental data will be available at such a short distance. Nevertheless, string theories continuously produce theoretical ideas on the construction of the fundamental theory which will supersede QFT. Recent examples are QFT in spaces with extra dimensions (more than three space and one time coordinates) which, in physical dimensions, involve extended objects. They partially solve some of the above problems and have a unifying aspect; however, they can be considered only as first attempts (their actions are not renormalizable).

Quantum Mechanics: Foundations

A J Leggett, University of Illinois at Urbana-Champaign, Urbana, IL, USA

Introduction

When one thinks about fundamental tests of the principles of quantum mechanics, the area of condensed matter physics is not the first that springs to mind. At least at first sight, such tests would seem to require the use of physical systems which are very well characterized, well isolated from their environments, and (for certain kinds of tests) propagate at or close to the speed of light. None of these conditions is at all well satisfied by a typical condensed matter system. Nevertheless, there are certain kinds of fundamental tests for which such systems are indispensable and others for which they permit substantial extensions of the results obtained on more "microscopic" systems, and this is the subject of this article. The issues of "quantum statistics" discussed are: one aspect of nonlocality in quantum mechanics, and the universal validity of the quantum description.

Quantum Statistics

It is a well-known consequence of the basic principles of the quantum field theory that "elementary" particles can be partitioned into two and only two classes, based on their possessing integral or half-odd-integral spin in units of $\hbar$; these are called bosons and fermions respectively (cf. below for the names). A very fundamental consequence of the indistinguishability in principle of elementary particles, coupled with considerations peculiar to the relativistic quantum field theory, is the spin-statistics theorem: the wave function of any quantum-mechanical system containing more than one particle must be unchanged under the exchange of any two identical bosons, and must change sign under the exchange of any two identical fermions. (A conventional, if somewhat imprecise, phrasing of this principle is that particles of integral (half-odd-integral) spin obey Bose (Fermi) "statistics.") The spin-statistics theorem has been well confirmed at the level of particle physics, for example, in the selection rules on decay processes, and in the case of fermions one of its consequences, the Pauli exclusion principle which forbids more than one fermion from occupying any single-particle state, has well-known effects for the structure of both atoms and nuclei. The spin-statistics theorem applies not only to "elementary" particles but also to complexes built up from the latter, provided that (1) the "internal" structure of the composites is identical, and (2) they remain undissociated in the regime of interest. This follows because if S is the total spin of the complex, the parity of $2S$ is just that of the total number of fermions contained in it, and this is also the parity of the wave function under the simultaneous exchange of all the fermions between two such complexes. Thus, for example, the ^{4}He atom (2 electrons, 2 protons, 2 neutrons, $S = 0$) behaves as a boson, while the ^{3}He atom (2 electrons, 2 protons, 1 neutron, $S = 1/2$) behaves as a fermion. The same conclusion obviously applies to the even and odd isotopic species of any chemical element. Does this difference in "statistics" have any effect in the microscopic limit?

Actually, it is an experimental fact that the properties of most substances do not depend qualitatively on their isotopic composition. The reason is that for the effects of the statistics to be appreciable, two conditions must hold simultaneously. The first is that the behavior predicted by a quantum-mechanical calculation should differ appreciably from that obtained in the classical approximation (if this is not true, then the whole concept of a wave function becomes unnecessary, so its symmetry clearly cannot affect any physical property); this requires that the thermal de Broglie wavelength of the particles in question should be greater than, or at least comparable to, the average interparticle spacing. The second condition is that the particles in question can exchange places fairly readily; if this is not so, it is easy to show that the symmetry of the wave function under interchange can have no substantial consequences. Now for almost all elements and compounds, at temperatures low enough for the first condition to be satisfied the system is already solid, so that the second condition is violated (in a solid the atoms change places, if at all, only very rarely). In fact, by the traditional definition the only

"condensed matter" systems where the two conditions are simultaneously satisfied are the above two stable isotopes of helium, both of which are unique in the remaining liquid under their own vapor pressure down to the lowest temperatures investigated.

The effect of the "statistics" on the behavior of liquid helium is indeed spectacular. The two isotopes, ^{4}He and ^{3}He, are essentially identical in their electronic structure and interatomic interactions, and the difference in nuclear mass does not seem to have any major qualitative effect; indeed, in the solid phase the properties of the two species are very similar (with the exception, of course, of those associated explicitly with the nuclear spin degree of freedom, which is peculiar to ^{3}He). Despite this, the properties in the liquid phase are completely different: in the case of liquid ^{4}He, the liquid enters, below the so-called λ-temperature of $\sim$2.17 K, a "superfluid" phase which displays a variety of exotic properties (persistent currents, nonclassical rotational inertia, film creep, fountain effect, etc.). By contrast, liquid ^{3}He behaves, right down to temperatures below 3 mK, in a way qualitatively similar to that of any other liquid, and in particular, shows none of the above exotic effects. (Below 2.6 mK, liquid ^{3}He does indeed become superfluid, but as shall be seen below, the character of the superfluid phase(s) is/are rather different from that occurring in ^{4}He.)

The origin of this spectacular difference in the behavior of the two isotopes (or at least of much of it) may be understood, at least qualitatively, by asking how they would behave in the complete absence of interactions between the atoms. If N identical noninteracting atoms (of either species) are considered to be moving in a volume V, the relevant single-particle energy eigenstates are plane waves of the form

$$\psi_k(\boldsymbol{r}) = V^{-1/2} \exp(\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}) \qquad [1]$$

If the system is considered to be in thermal equilibrium at temperature T and the standard principles of statistical mechanics are applied subject to the constraints imposed on the many-particle wave function by the spin-statistics theorem, one finds that the distribution $n_k(T)$ of atoms between the single-particle plane-wave states [1] is given by the formula

$$n_k(T) = (\exp((\varepsilon_k - \mu)/k_\mathrm{B}T) \pm 1)^{-1},\ \varepsilon_k \equiv \hbar^2 k^2/2m \qquad [2]$$

where the plus sign applies for fermions and the minus sign for bosons. In these formulas, the quantity $\mu(T)$ is the chemical potential, and its value is fixed, for either sign, by the self-consistency condition

$$\sum_k n_k(T : \mu(T)) = N \qquad [3]$$

The consequences of the sign difference are profound: for fermions, in the limit $T \to 0$, the N lowest-energy single-particle states are each occupied by a single atom, in accordance with the Pauli exclusion principle; one can say that they fill up a "Fermi sea" or "Fermi sphere" in momentum space, with a radius k_F given (for spin 1/2) by the formula $k_\mathrm{F} = (3\pi^2 n)^{1/3}$, where $n \equiv N/V$. At nonzero but low temperatures, particles can be excited to states which lie $\lesssim k_\mathrm{B}T$ in energy above the top of the Fermi sea, leaving "holes" in a similar range in the sea. Although such a "free Fermi gas" model is of course not a realistic picture of real liquid ^{3}He, it turns out that the modifications necessary to take account of the interatomic interactions do not change the situation qualitatively (this is the essential content of Landau's "Fermi-liquid" theory), and that the behavior of the resulting system is overall not very different from that of a classical liquid; in particular, it is predicted to show none of the exotic effects seen in liquid ^{4}He.

In the case of a system of noninteracting bosons, which is described by eqn [2] with the minus sign, the behavior is again not qualitatively very different from that of a normal liquid so long as the chemical potential μ has a finite negative value (which is the case at sufficiently high temperatures). As the temperature falls, however, the value of $\mu(T)$ increases, and for a system moving in free space there exists a nonzero temperature T_c (whose value depends on the density n) below which such a nonzero negative value of μ is incompatible with the self-consistency relation [3]. For $T < T_\mathrm{c}$, the chemical potential tends to zero, and a finite fraction of all the atoms (i.e., a macroscopically large number N_0) occupies the lowest-energy single-particle state, namely that with $\boldsymbol{k} = 0$. This is the phenomenon known as Bose–Einstein condensation (BEC). For a gas of atoms with the mass and density of ^{4}He, the onset temperature T_c of BEC is $\sim$3.3 K, not far from the temperature (2.17 K) of the onset of superfluidity in liquid ^{4}He. It is the almost universal belief that below this latter temperature, BEC indeed occurs in liquid ^{4}He, and that this is the origin of the complex of exotic properties observed in that system.

To illustrate how BEC can give rise to this kind of exotic behavior, the focus is, for definiteness, on the property of "nonclassical rotational inertia." Consider a free gas of N identical atoms (of any species) in a toroidal (annular) container of radius R and thickness $d \ll R$, which rotates at an angular velocity $\omega < \omega_\mathrm{c}/2$, where $\omega_\mathrm{c} \equiv \hbar/mR^2$. What is the angular

momentum of the system in thermal equilibrium? Classical intuition suggests that the system would like to rotate so that its mean velocity exactly matches that of the container, and that its angular momentum will then be simply $NmR^2\omega$. It is easy to show that a system which is well described by classical (Newtonian) mechanics will indeed behave in just this way. For a quantum-mechanical system, it turns out that the effect of the rotation is to change the "effective"energy of a single-particle state with angular momentum l from its original energy $l^2\hbar^2/2mR^2$ to $l^2\hbar^2/2mR^2 - \hbar\omega l$. For a system of any species which is not Bose-condensed, the distribution given by formula [2] is a smooth function of energy, and provided only that the thermal energy k_BT is $\gg\hbar^2/mR^2$ (a condition very well satisfied in any currently realistic experiment), the classical result for the total angular momentum is obtained. However, for a boson system below T_c, a macroscopic fraction of all the atoms must occupy the single lowest-(effective)-energy single-particle state; for $\omega < (1/2)\omega_c$, this is a state with $l = 0$, so a fraction of the atoms stays at rest in the laboratory frame and the observed angular momentum is less than the classical value. Again, this simple model is not a realistic description of liquid ^{4}He (and in fact, cannot account for all the exotic behavior of the latter), but a model which takes adequate account of the interatomic interactions while still assuming the existence of BEC, and has been very successful in explaining all the main phenomena of superfluidity in that system.

Finally, it is generally believed that below 2.6 mK the fermions in liquid ^{3}He form "Cooper pairs" – a sort of giant "diatomic molecules." (A similar phenomenon occurs for the electrons in metals below the transition temperature for superconductivity, but the Cooper pairs in ^{3}He have a more sophisticated structure). Since such pairs of fermions have integral spin, they are in effect bosons and can (and do) undergo Bose condensation. One, therefore, expects the system to show exotic properties such as those displayed by ^{4}He below the λ-temperature, and indeed such are found.

Thus, the two isotopes of liquid helium manifest, in a dramatic way, the consequences of a fundamental principle, the indistinguishability, in principle, of elementary particles.

Aharonov–Bohm Effect

In the classical electromagnetic theory, all electromagnetic effects on charged particles can be obtained from a knowledge of the electric and magnetic fields "seen" by the particle, that is, the fields at the position of the latter; the electromagnetic vector potential $\boldsymbol{A}(\boldsymbol{r}, t)$ is introduced purely as an auxiliary function to simplify some of the calculations. However, in quantum mechanics the situation is different. Consider an experimental arrangement in which a solenoid, regarded here as of infinite length, carries a finite steady current (see **Figure 1**). The magnetic field produced by the current is entirely confined to the interior of the solenoid; outside it is zero. Now consider a beam of electrons which is split so as to pass on either side of the solenoid, and detected on a screen behind it (**Figure 1**). According to a quantum-mechanical calculation, the position of the interference fringes observed on the screen should depend on the current in the solenoid, being periodic in the flux through the latter with period h/e. This is despite the fact that there are no electric or magnetic fields at any point on the trajectories of the electrons! This strange behavior, usually known as the Aharonov–Bohm effect, can be interpreted as showing either that the electrons can "feel" fields even at points they never travel to, or that the vector potential has a "physical reality" not envisaged in the classical electromagnetic theory.

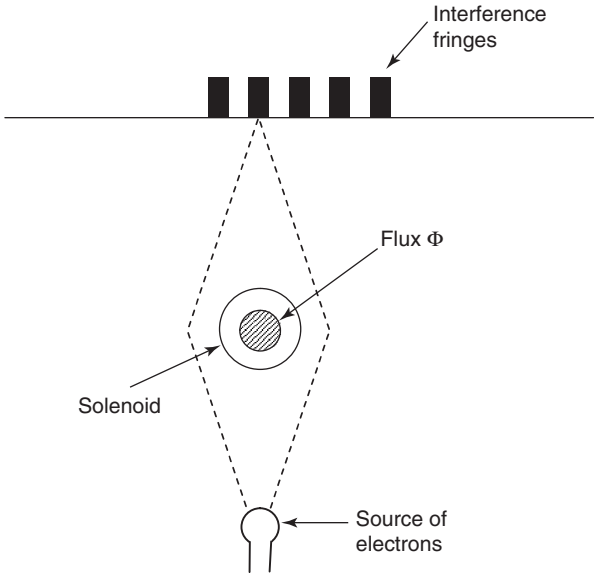

Figure 1 The Aharonov–Bohm effect. The magnetic field of the solenoid is confined to its interior, so there are no fields at any point on the paths taken by the electrons.

While the most loophole-free tests of the Aharonov–Bohm effect have been done with electron beams in free space, the use of condensed-matter systems permits one to display the effects of this "nonlocality" on a macroscopic scale. This is possible in a superconductor, since, to produce the superconducting state, the electrons must form Cooper pairs (as in the superfluid phase of liquid ^{3}He, see above), and these pairs then effectively form bosons

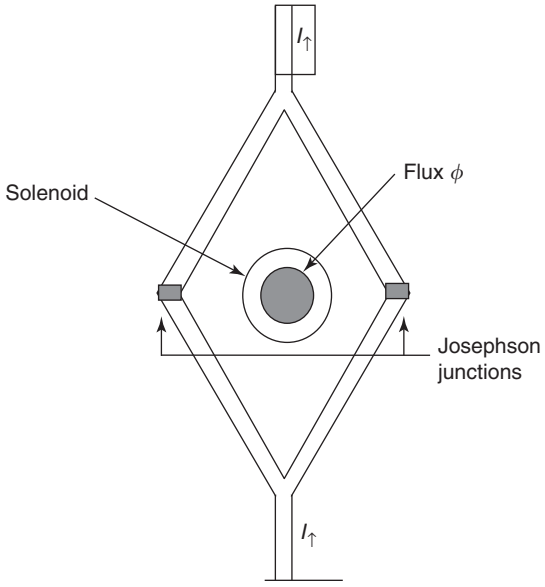

Figure 2 The Aharonov–Bohm effect in a superconducting circuit. The solenoid produces no field anywhere in the metal.

and undergo a sort of BEC (again just as in ^{3}He). Suppose now one forms the completely superconducting device shown in **Figure 2**; in the present context it is enough to know that each junction by itself can carry, without dissipation, a certain maximum ("critical") current I_c, which is assumed for simplicity to be the same for the two junctions. Thus, if one of the arms were blocked the critical current of the device would simply be I_c, while if both are open and there is no current in the solenoid S, the currents in the two arms just add and the critical current of the device is $2I_c$. If however, one imposes a current through the solenoid and thus generates a total flux ϕ through the device, it turns out that the critical current of the latter should be modulated by a factor $|\cos(\pi\phi/\phi_0)|$; thus it is periodic in the (superconducting) "flux quantum" $\phi_0 \equiv h/2e$. (The reason the period is $h/2e$ rather than h/e as in the electron beam case is that the Cooper pairs have charge $2e$, not e). As in the electron-beam case, this is despite the fact that the electrons which carry this current never experience any electric or magnetic fields. This prediction is well verified experimentally, showing that the Aharonov–Bohm effect has not merely atomic-level but also macroscopic manifestations.

Limits on the Validity of Quantum Mechanics

The quantum measurement paradox (or, as it is sometimes known after its most famous instantiation, the "Schrödinger's Cat" paradox) may be stated succinctly as follows: at the microscopic level, if one considers a standard example such as the Young's slits experiment with attenuated beams of single electrons, the fact that the probability amplitude (wave function) which in quantum mechanics describes the ensemble in question, has a finite value at each of the two slits of the intermediate screen cannot, at least without extreme contortions, be interpreted as implying that each individual electron of the ensemble passed through a definite slit (so that the only significance of the amplitude is that its square is a measure of the probability of a given electron passing through the slit in question). The evidence for the above statement is the phenomenon of interference at the final screen. Now, if one believes (as most physicists do) that quantum mechanics is, in principle, the complete truth about the physical universe, it can be applied not just to single electrons and atoms, but to arbitrarily complex objects composed of them, and in this process the formalism itself is in no way modified. This means that it is perfectly possible to devise thought-experiments (such as Schrödinger's original example involving the cat) such that the unambiguous description given by quantum mechanics of the final state of the universe (or more precisely the relevant "ensemble of universes") is a linear superposition of amplitudes corresponding to macroscopically distinct outcomes (e.g., living or dead cat). Thus, unless the interpretation of the quantum formalism is changed significantly between the microscopic and macroscopic levels, one is forced to conclude that it is not true that, for example, each individual cat was either alive or dead before inspection. Yet it is (or at least appears to be!) a fact of our direct experience that inspection reveals each cat to be in one state or the other!

In literature it is often claimed that the apparent paradox can be resolved by appealing to the phenomenon known as "decoherence": when an object is sufficiently macroscopic, and/or interacts with a sufficiently complex environment, then one effect of this interaction is, in effect, to "scramble" the relative phases of the amplitudes representing the two macroscopically distinct states, so that the reduced density matrix of the system becomes equivalent to that of a classical "mixture" of the two states (which *inter alia* gives no possibility of interference), and can thus (it is claimed) be interpreted as simply saying that one or other of the two states is definitely realized for each cat, but one does not know which, and thus have to give a probabilistic description. While the occurrence and ubiquity of the decoherence phenomenon at the macroscopic level is not in serious dispute, the validity of the last, crucial step in the argument (which is equivalent to a major change in the interpretation of the quantum formalism between

the micro- and macro-levels) is controversial in the extreme, so that it is by no means universally agreed in the physics community that the measurement paradox is "solved."

The premise underlying the above discussion is that since the pristine quantum formalism describes, apparently perfectly, the behavior of individual atoms and molecules, it must likewise describe perfectly, at least in principle, the behavior of arbitrarily complex objects composed of them. Given the situation just described concerning the measurement paradox, it would appear to make sense to ask if one is sure that this premise is actually true, or could it perhaps be that by the time one gets from the level of atoms to that of cats, some new physics comes into play which, *inter alia*, has the effect of reducing any superposition of macroscopically distinct states, not to a mixture as the "decoherence" argument would have it, but to a definite one of its branches for any given system of the ensemble. The class of theories which have these properties are termed "macrorealistic"; a number of such theories have appeared in literature, the most fully developed probably being that associated with the names of Ghirardi, Rimini, Weber, and Pearle. The question is whether one could actually devise an experimental test of the class of macrorealistic theories against quantum mechanics.

It is fairly obvious that to the extent that a superposition of macroscopically distinct states is *ipso facto* automatically subject to a degree of decoherence sufficient to reduce the density matrix to that of a classical mixture, it will be impossible to implement such a test, because the experimental predictions of the "mixture" description are, by definition, equivalent to those of a theory in which a definite outcome is realized for each system, that is, a macrorealistic theory. The experimental challenge is thus to find a system, where the superposition is both of "macroscopically distinct" states and at the same time sufficiently resistant to decoherence. Of course, the possibility of doing so rests on the definition of "macroscopically distinct," and this point has had considerable discussion in literature; for present purposes, it is adequate to define two states as having this property relative to one another if there is at least one extensive physical quantity whose expectation value in the two states is different by some large number (say 10^4–10^9, see below) in the "natural" (atomic) units. Below, for convenience, this number is denoted by the symbol Λ.

Suppose, for the sake of argument, that one has found such a system; then one can try to engineer a situation where, if quantum mechanics is indeed the whole story, at some stage the correct description of the relevant ensemble is indeed a linear superposition of two (or more) macroscopically distinct states. At that point one can, in principle, (1) test whether the predictions of quantum mechanics in fact correspond to experiment, and (2) test whether predictions made on the basis of a macrorealistic theory correspond to experiment. While it can be shown that there exist experimental situations in which a positive answer to (1) automatically implies a negative answer to (2) (i.e., confirmation of the quantum-mechanical predictions automatically refutes the whole class of macrorealistic theories), such experiments have not yet been realized, and the experiments to be described have been of type (1) only. In such tests, the interpretation of the raw data is always done in explicitly quantum-mechanical terms, and the question being asked is whether the experimentally realized state is, as predicted by theory, a superposition or rather a mixture of macroscopically distinct states.

Condensed matter experiments, which were consciously designed to test the validity of quantum mechanics at the macroscopic level were started as early as 1980. The first generation of these experiments looked for, and saw, the essentially quantum-mechanical phenomenon of tunneling out of a metastable well (often referred to, in this context, as "macroscopic quantum tunneling" or MQT). A second generation of experiments has looked more directly for the effects of superposition, by testing for NH_3-type oscillations or a related phenomenon. The system of choice is usually a bulk superconducting ring interrupted by a single Josephson junction ("RF SQUID"), or some variant thereof, and the two states in question are states in which the current circulates clockwise or counterclockwise respectively; depending on the details of the geometry, the value of Λ can range from 10^4 to 10^9. If such a system is subjected to an external flux ϕ_{ext}, the energy eigenstates are (in the absence of decoherence) linear superpositions of the above two states; for the special case $\phi_{\text{ext}} = \phi_0/2 = h/4e$, the ground state has even parity and the excited state odd parity, and the level splitting is twice the matrix element t for tunneling between the clockwise- and anticlockwise-circulating states. More generally, as a function of flux the level splitting has the form

$$\Delta E = 2\sqrt{t^2 + \text{const.}\ (\phi - \phi_0/2)^2} \qquad [4]$$

as shown by the solid line in **Figure 3**. By contrast, if the true density matrix of the system is a mixture then the splitting should be linear in the flux, as indicated by the broken line. In the experiments (which used a spectroscopic technique to measure the splitting), it was unambiguously the solid line which was found.

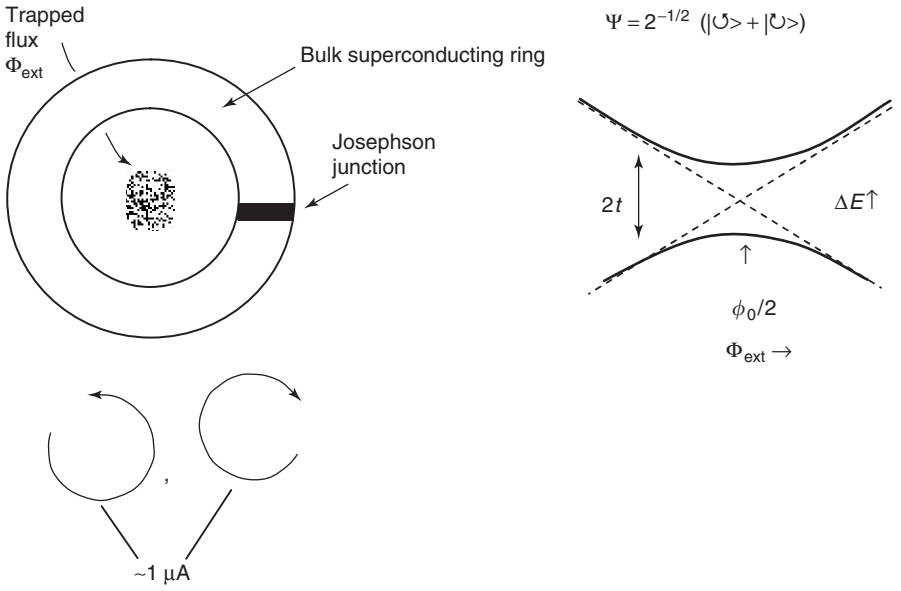

Figure 3 The predicted dependence of the energies of the two lowest states of an RF SQUID ring on the externally applied flux, under the assumption of a coherent superposition (solid lines) or a mixture (broken lines).

In one set of experiments, the value of Λ was $\sim 10^9$, which is probably a record at the time of writing. Note however that these experiments, while verifying that the behavior at this level is consistent with the predictions of quantum mechanics, have not explicitly excluded theories of the macrorealistic class.

In the last two years, experiments on similar systems have detected the NH_3-type oscillations between the clockwise and counter-clockwise-circulating states directly (although the Λ-values in these experiments have been somewhat less spectacular, $\sim 10^5$–10^6). This observation opens the way to eventual tests of type (2), in which (assuming the result is consistent with the predictions of quantum mechanics) one will be able to definitively exclude the viability of any theory of the macrorealistic class at the level of SQUID rings. Whether such a theory may become viable at a level closer to direct human experience is, of course, a matter for experiments, most likely of a different and perhaps currently unforeseeable type, in the (probably distant) future.

Quantum Mechanics: Methods

G M Prosperi, University of Milan, Milan, Italy

Introduction

In principle, any problem in quantum mechanics can be reduced to the solution of the corresponding Schrödinger equation

$$H\psi(t) = i\hbar\frac{\partial\psi(t)}{\partial t} \qquad [1]$$

where obviously H is the Hamiltonian operator and $\psi(t)$ the state vector. As is well known, if H is time independent, this is equivalent to the solution of the

stationary equation

$$Hu_n = W_n u_n \qquad [2]$$

W_n and u_n being the eigenvalues and the eigenstates of H, respectively.

In practice, only in very special cases one can solve eqns [1] or [2] analytically. This essentially happens for a system of free particles, for the single particle or two particles with very few types of potential, for free fields and for certain simplified many-body or field theory models. In the majority of the realistic cases, it is necessary to revert to approximate methods or to make use of numerical simulations.

Leaving apart numerical procedures, methods of very general application are those based on expansions on small parameters, variational methods, semiclassical methods such as the Wentzel–Kramer–Brilouin (WKB) method or those based on the Feynman path integral formalism. Many other methods can be reduced to these.

Various types of small-parameter expansions are used: weak and strong coupling expansions in quantum mechanics and in field theories, $1/c$ expansions in evaluating relativistic corrections to nonrelativistic results, small density, low- and high-temperature expansions in quantum statistical mechanics, and so on.

The many variants of the perturbation theory are typical, in that they are based on the idea of decreasing order of terms in the perturbation expansion. Consider the Hamiltonian of a system split into two parts,

$$H = H_0 + \lambda H_1 \qquad [3]$$

λ being a small parameter, and assume that one is able to solve the eigenvalue equation for H_0,

$$H_0 u_n^{(0)} = W_n^{(0)} u_n^{(0)} \qquad [4]$$

The general idea is to solve eqn [1] or [2] by an expansion in λ. However, in the field theory and in certain versions of the many-body theory, it is often more convenient to work in the Heisenberg picture and use similar techniques for studying the ground-state expectation values of products of appropriate observables.

In bound-state problems, such as those typically considered in atomic and molecular physics (or in nuclear physics or in quark models), the Hamiltonian H_0 already includes a part of the interaction which is more tractable and λH_1 denotes an additional "perturbation." In the scattering theory or in theories involving second-quantization techniques, H_0 often includes only the free part of the Hamiltonian and λH_1, the interaction. In the latter case, λ is usually a coupling constant.

In any case, the perturbation idea is based on the convergence of some expansion (or at least on a good asymptotic approach to a quantity of interest), and sometimes it can completely break down. Then it becomes necessary to turn to other methods.

This article is restricted to the most elementary types of time-dependent and time-independent perturbation theories, to the Green function technique, to variational methods, and to the main ideas on WKB and path integral formalism. Some simple illustrative examples of application are also given.

Time-Independent Perturbation Theory

This is a recursive method for solving the eigenvalue equation [2] for a Hamiltonian of the form [3]. It consists in setting

$$\begin{aligned} u_n &= u_n^{(0)} + \lambda u_n^{(1)} + \lambda^2 u_n^{(2)} + \cdots \\ W_n &= W_n^{(0)} + \lambda W_n^{(1)} + \lambda^2 W_n^{(2)} + \cdots \end{aligned} \qquad [5]$$

in the eigenvalue equation for [3], and in equating equal-power terms in λ on the left- and right-hand sides of the equation. In this way, one can obtain an infinite set of equations; a zero-, a first-, a second-order equation, and so on. These are equivalent in principle to the original equation and should be solved recursively. The zero-order equation coincides with eqn [4], and the successive equations can be written as

$$\begin{aligned} &H_0 u_n^{(1)} + H_1 u_n^{(0)} = W_n^{(0)} u_n^{(1)} + W_n^{(1)} u_n^{(0)} \\ &H_0 u_n^{(2)} + H_1 u_n^{(1)} = W_n^{(0)} u_n^{(2)} + W_n^{(1)} u_n^{(1)} + W_n^{(2)} u_n^{(0)} \\ &\vdots \end{aligned} \qquad [6]$$

where each equation depends on the quantities determined by the solutions of the preceding ones.

The simplest situation occurs when the spectrum of H_0 is not degenerate, that is, when a single eigenfunction $u_n^{(0)}$ (unique up to a factor) corresponds to each unperturbed eigenvalue $W_n^{(0)}$. Then, since the $u_n^{(0)}$ must make an orthonormal basis (up to normalization) set, one can put in the first-order equation

$$u_n^{(1)} = \sum_s a_{ns}^{(1)} u_s^{(0)} \qquad [7]$$

and, after projecting over the vector $u_k^{(0)}$, one obtains

$$\begin{aligned} &a_{nk}^{(1)}((W_k^{(0)} - W_n^{(0)}) + \langle u_k^{(0)} | H_1 | u_n^{(0)} \rangle) \\ &\quad = W_n^{(1)} \delta_{kn} \end{aligned} \qquad [8]$$

where the Dirac notation $\langle \phi|\psi \rangle$ has been used for the scalar product and the relation $\langle u_r^{(0)}|u_s^{(0)} \rangle = \delta_{rs}$.

From [8], one has, for $k = n$,

$$W_n^{(1)} = \langle u_n^{(0)}|H_1|u_n^{(0)} \rangle \qquad [9]$$

that is, the first-order correction to $W_n^{(0)}$ is simply given by the expectation value of H_1 over $u_n^{(0)}$.

For $k \neq n$, one has instead

$$a_{nk}^{(1)} = \frac{\langle u_k^{(0)}|H_1|u_n^{(0)} \rangle}{W_n^{(0)} - W_k^{(0)}} \qquad [10]$$

Equation [8] does not determine $a_{nn}^{(1)}$; however, up to the first order, the normalization condition $\langle u_n|u_n \rangle = 1$ gives $a_{nn}^{(1)} + a_{nn}^{(1)*} = 0$. So, $a_{nn}^{(1)}$ must be purely imaginary and can be taken equal to 0; indeed, to set $a_{nn}^{(1)} = i\eta_n \neq 0$ would be equivalent to multiplying $u_n^{(0)}$ in the preceding equations by the inessential phase factor $1 + i\eta_n \simeq e^{i\eta_n}$.

After introducing into the second-order equation the expression for $W_n^{(1)}$ and $u_n^{(1)}$ obtained above, one can proceed in a similar way for the second-order equation and obtain

$$W_n^{(2)} = \sum_{s \neq n} \frac{|\langle u_n^{(0)}|H_1|u_s^{(0)} \rangle|^2}{W_n^{(0)} - W_s^{(0)}} \qquad [11]$$

and a complicated expression for $a_{nk}^{(2)}$.

In principle, the procedure could be repeated indefinitely until sufficiently small corrections are obtained and, if the resulting expansions [5] converge, eqn [2] would be solved to the required approximation. In fact, eqn [11] itself would require the evaluation of an infinite number of terms, and only in very special cases, the method is of practical application beyond the first order.

If the spectrum of H_0 is degenerate, the unperturbed eigenvectors $\{u_n^{(0)}\}$ are no longer uniquely determined. For each unperturbed eigenvalue $W_n^{(0)}$, one has an eigenspace which may have more than one dimension. Then, a basis $u_{n1}^{(0)}$, $u_{n2}^{(0)}$, ... in each of these subspaces can be chosen and the submatrices $\langle u_{ni}^{(0)}|H_0 + \lambda H_1|u_{ni'}^{(0)} \rangle$ can be considered. The eigenvalues and the eigenstates obtained by diagonalizing this type of matrices must be considered as the new first-order eigenvalues and zero-order eigenstates, and from these one can proceed as above. Actually, the treatment can be simplified by restricting to appropriate invariant subspaces if common constants of motion with respect to H_0 and H_1 exist.

The calculation of the first relativistic correction to the spectrum of the hydrogen atom may be considered as a typical example of application of the above theory. In this case, one can set

$$H_0 = \frac{1}{2m_e} \boldsymbol{p}^2 - \frac{e^2}{4\pi r} \qquad [12]$$

where in the usual Schrödinger representation, $\boldsymbol{p}^2 = -\hbar^2\nabla^2 \equiv -\hbar^2(\partial^2/\partial x^2 + \partial^2/\partial y^2 + \partial^2/\partial z^2)$. The Hamiltonian first relativistic correction, $O(1/c^2)$, can be obtained from the Dirac equation and has the form

$$H_1 = -\frac{1}{6m_e^3c^2} \boldsymbol{p}^4 + \frac{e^2}{4\pi m_e^2 c^2 r^3} \boldsymbol{S}\cdot\boldsymbol{L} + \frac{\hbar^2}{8m_e^2c^2} e^2\delta^3(\boldsymbol{x}) \qquad [13]$$

where $\boldsymbol{S}$ and $\boldsymbol{L}$ denote the spin and the orbital momentum of the electron.

The nonrelativistic energy levels and eigenstates of H_0 can be written in the form

$$W_n^{(0)} = -w_0\frac{1}{n^2} \quad \text{and} \qquad u_{nlmm_s} = R_{nl}(r)Y_{lm}(\theta,\phi)v_{m_s} \qquad [14]$$

n, l, m, m_s being the ordinary total, azimuthal, magnetic, and spin quantum numbers respectively, $w_0 = m_e e^4/8\pi^2\hbar^2 = 13.6$ eV the hydrogen ground state energy, $Y_{lm}(\theta,\phi)$ the spherical harmonics, $R_{nl}(r)$ the radial parts of the eigenfunctions, usually expressed in terms of Laguerre functions, v_{m_s} ($m_s = \pm 1/2$) ordinary two-component spinors. The spectrum of H_0 is obviously degenerate in this case (the eigenvalue depending on the quantum number n alone). However, both H_0 and H_1 commute with $\boldsymbol{L}^2$, $\boldsymbol{J}^2$, and J_z ($\boldsymbol{J} = \boldsymbol{L} + \boldsymbol{S}$ being the total angular momentum). One can replace then the original u_{nlmm_s}, as given in [14], with the system of the eigenstates $|n; l, j, m_j\rangle$ common to H_0, $\boldsymbol{L}^2$, $\boldsymbol{J}^2$, and J_z, that can be obtained from the preceding ones by linear combination with the appropriate Clebsh–Gordan coefficients. The subspaces spanned by these new unperturbed states for fixed l, j, and m_j are invariant under the action of H_1, and H_0 is no longer degenerate in them. In conclusion, one can use the ordinary formula

$$W_{n,l,j}^{(1)} = \langle n; l; j, m_j|H_1|n; l; j, m_j \rangle \qquad [15]$$

The quantity [15] does not depend on m_j for symmetry reasons and can be calculated with some manipulations. Adding [15] to [14] one obtains, finally, the well-known expression

$$W_{n,j} = -w_0\left[\frac{1}{n^2} + \frac{\alpha^2}{n^3}\left(\frac{1}{j+1/2} - \frac{3}{4n}\right)\right] \qquad [16]$$

which in fact depends only on n and j. In this case, in the end the small parameter is the so-called fine structure constant $\alpha = e^2/4\pi\hbar c = 1/137.036$.

In a similar way, one can evaluate spin–orbit, spin–spin and tensorial splittings, relativistic corrections, two-particle exchange effects, etc., in various bound-state problems in atomic physics, molecular physics, nuclear physics, quark model, etc.

With appropriate modifications, the method can be applied even to continuous spectrum and to scattering problems. However, in the latter connection the following time-dependent theory is more important.

Time-Dependent Perturbation Theory

In this case, it is convenient to work in the so-called Dirac or interaction picture. This consists in giving observables a time dependence of the form

$$O_{\mathrm{I}}(t) = \mathrm{e}^{(\mathrm{i}/\hbar)H_0 t} O \mathrm{e}^{-(\mathrm{i}/\hbar)H_0 t} \qquad [17]$$

and, correspondingly, in redefining the state vector as

$$\psi_{\mathrm{I}}(t) = \mathrm{e}^{(\mathrm{i}/\hbar)H_0 t}\psi(t) \qquad [18]$$

In eqns [17] and [18], O denotes the ordinary time-independent operator in Schrödinger picture and $\psi(t)$ a solution of [1].

As can easily be checked, $\psi_{\mathrm{I}}(t)$ satisfies the equation

$$\mathrm{i}\hbar\frac{\partial}{\partial t}\psi_{\mathrm{I}}(t) = \mathrm{i}\lambda H_{1\mathrm{I}}(t) \qquad [19]$$

Introducing the state evolution operator in interaction picture by $\psi_{\mathrm{I}}(t) = U(t, t_0)\psi_{\mathrm{I}}(t_0)$, such an equation can be rewritten in an integral form as

$$\begin{aligned} U(t, t_0) &= 1 - \frac{\mathrm{i}\lambda}{\hbar}\int_{t_0}^{t} \mathrm{d}t' H_{1\mathrm{I}}(t') U(t', t_0) \\ &= 1 + \sum_{n=1}^{\infty}\left(-\frac{\mathrm{i}\lambda}{\hbar}\right)^n \int_{t_0}^{t}\mathrm{d}t_1 \int_{t_0}^{t_1}\mathrm{d}t_2 \cdots \\ &\quad \times \int_{t_0}^{t_{n-1}} \mathrm{d}t_n H_{1\mathrm{I}}(t_1) H_{1\mathrm{I}}(t_2)\cdots H_{1\mathrm{I}}(t_n) \end{aligned} \qquad [20]$$

where the obvious relation $U(t_0, t_0) = 1$ has been used, and the second line is obtained by repeated iteration of the first one.

The quantity

$$P_{r\to s}(t - t_0) = |\langle u_s^{(0)}|U(t, t_0)|u_r^{(0)}\rangle| \qquad [21]$$

gives the transition probability of the system from an initial unperturbed state $u_r^{(0)}$ to the final state $u_s^{(0)}$ during the time $t - t_0$. Approximate expressions for $P_{r\to s}(t - t_0)$ can be obtained by truncating the expansion in [20] to some definite order.

In principle, in [19] and [20] the quantity H_1 can be supposed to be either explicitly time dependent or time independent (i.e., time dependent or time independent in the Schrödinger picture). If H_1 does not depend explicitly on time, one has, up to the first-order,

$$\begin{aligned} &\langle u_s^{(0)}|U(t, t_0)|u_r^{(0)}\rangle \\ &\quad = \delta_{rs} - \frac{\mathrm{i}\lambda}{\hbar}\int_{t_0}^{\mathrm{t}} \mathrm{d}t' \langle u_s^{(0)}|H_{1\mathrm{I}}(t')|u_r^{(0)}\rangle \\ &\quad = \delta_{rs} - \mathrm{i}\frac{2\lambda}{W_s^{(0)} - W_r^{(0)}} \\ &\qquad \times \sin\left[\frac{1}{2\hbar}(W_s^{(0)} - W_r^{(0)})(t - t_0)\right] \\ &\qquad \times \mathrm{e}^{(\mathrm{i}/2\hbar)(W_s^{(0)} - W_r^{(0)})(t - t_0)} \langle u_s^{(0)}|H_1|u_r^{(0)}\rangle \end{aligned} \qquad [22]$$

and, correspondingly, for $s \neq r$

$$\begin{aligned} P_{r\to s}(t - t_0) = &\frac{4\lambda^2}{(W_s^{(0)} - W_r^{(0)})^2} \\ &\times \sin^2\left[\frac{1}{2\hbar}(W_s^{(0)} - W_r^{(0)})(t - t_0)\right] \\ &\times |\langle u_s^{(0)}|H_1|u_r^{(0)}\rangle|^2 \end{aligned} \qquad [23]$$

If the unperturbed energy levels are sufficiently dense to be treated as a continuous distribution, one can use in [23] the asymptotic formula $(\sin^2\omega\tau)/\omega^2 \to \tau\pi\delta(\omega)$ valid for large τ. The replacement is legitimate as soon as $t - t_0$ is large with respect to an appropriate relaxation time δt which will be defined, and so small that $P_{r\to s}(t - t_0) \ll 1$ (so that first-order approximation can be applied). The time δt is given by $\delta t = \hbar/\delta W$, δW specifying the order of magnitude of $W_s^{(0)} - W_r^{(0)}$ for which $\langle u_s^{(0)}|H_1|u_r^{(0)}\rangle$ remains significantly different from 0; it can be interpreted as the duration of the transition. During the considered interval of time (if it exists), $P_{r\to s}$ remains proportional to $t - t_0$ and it is possible to define the transition probability per unit time,

$$\Gamma_{r\to s} = \frac{2\pi}{\hbar}|\langle u_s^{(0)}|H_1|u_r^{(0)}\rangle|^2 \delta(W_s^{(0)} - W_r^{(0)}) \qquad [24]$$

Equation [24] is called Fermi's golden rule and has a large number of applications that range from emission and absorption of radiation by matter, to β decay, weak decay of particles, and elastic and inelastic scattering.

The scattering of a particle by a fixed potential is discussed now. The Hamiltonian may be written as

$$H = \frac{p^2}{2m} + V(r) \qquad [25]$$

Set $H_0 = p^2/2m$, $\lambda H_1 = V(r)$ and denote by $|\boldsymbol{p}\rangle$ the eigenstates of the linear momentum of the particle ($\langle \boldsymbol{p}'|\boldsymbol{p}\rangle = \delta^3(\boldsymbol{p}-\boldsymbol{p}')$, $H_0|\boldsymbol{p}\rangle = W_p|\boldsymbol{p}\rangle$, $W_p = p^2/2m$).

It can be shown that for a short-range potential, the quantity $U(t, t_0)$ has a limit for $t \to +\infty$ and $t_0 \to -\infty$ in the strong sense of the operator theory. Taking into account the second asymptotic relation $(\sin \omega\tau)/\omega \to \pi\delta(\omega)$ (for large τ) and generalizing eqn [22], one can write

$$\langle \boldsymbol{p}'|U(\infty, -\infty)|\boldsymbol{p}\rangle = \delta^3(\boldsymbol{p}'-\boldsymbol{p}) - 2\pi\hbar i\delta(W_{p'} - W_p)T(\boldsymbol{p}', \boldsymbol{p}) \qquad [26]$$

which is the S-matrix for the problem. It is to be noted now that in [23] and [24], the final state $u_s^{(0)}$ can be indifferently supposed to be normalized according to the continuum or the discrete spectrum rules, but the initial state $u_r^{(0)}$ must necessarily be a proper vector normalized to 1. It is then convenient to consider the momentum eigenstates $|\boldsymbol{p}\rangle$ referring to the infinite space (represented by $(1/(2\pi\hbar)^{3/2})e^{i\boldsymbol{p}\cdot\boldsymbol{x}}$ in the usual Schrödinger representation) as the limit case of states $|\boldsymbol{p}\rangle_L$ referring to a finite box of side L (represented by $(1/L^{3/2})e^{i\boldsymbol{p}\cdot\boldsymbol{x}}$, with $\boldsymbol{p}$ assuming only approate discrete values). Then, since $|\boldsymbol{p}\rangle_L = (2\pi\hbar/L)^{3/2}|\boldsymbol{p}\rangle$, one has

$$d\Gamma(\boldsymbol{p}') = d^3\boldsymbol{p}'\frac{(2\pi\hbar)^4}{L^3}\delta(W_{p'} - W_p)|T(\boldsymbol{p}', \boldsymbol{p})|^2 \qquad [27]$$

where $[\delta(W_{p'} - W_p)]^2 = ((t-t_0)/2\pi\hbar)\delta(W_{p'} - W_p)$ has also been used, which follows from a comparison between the two mentioned asymptotic relations for the δ function. Dividing [27] by the flux $\Phi = (1/L^3)(p/m)$, the differential cross section finally obtained is

$$d\sigma(\boldsymbol{p}') = d^3\boldsymbol{p}'(2\pi\hbar)^4\frac{m}{p}\delta(W_{p'} - W_p)|T(\boldsymbol{p}', \boldsymbol{p})|^2 \qquad [28]$$

This is supposed to be an exact equation. However, up to the first order, $T(\boldsymbol{p}', \boldsymbol{p}) = (1/\hbar)\langle \boldsymbol{p}'|V(r)|\boldsymbol{p}\rangle$, and one has the famous Born approximation.

The method can be easily extended to inelastic scattering, such as the collision of an electron with an atom, a proton with a nucleus, and so on.

Green Functions

If $V(r)$ in [25] is time independent, one can write

$$U(t', t) = e^{(i/\hbar)H_0t'}e^{-(i/\hbar)H(t'-t)}e^{-(i/\hbar)H_0t} \qquad [29]$$

From this equation, one immediately has

$$e^{-(i/\hbar)H\tau}U(0, t) = e^{-(i/\hbar)H\tau}e^{(i/\hbar)Ht}e^{-(i/\hbar)H_0t} = U(0, t-\tau)e^{-(i/\hbar)H_0\tau} \qquad [30]$$

and taking the limits $t \to -\infty$ or $t \to +\infty$

$$e^{-(i/\hbar)H\tau}U(0, \mp\infty) = U(0, \mp\infty)e^{-(i/\hbar)H_0\tau} \qquad [31]$$

Then, setting $|\boldsymbol{p}, \pm\rangle = U(0, \mp\infty)|\boldsymbol{p}\rangle$, one finds

$$H|\boldsymbol{p}, \pm\rangle = U(0, \mp\infty)H_0|\boldsymbol{p}\rangle = W_p|\boldsymbol{p}, \pm\rangle \qquad [32]$$

that is, the states $|\boldsymbol{p}, \pm\rangle$ are eigenstates of H corresponding to the same eigenvalue $W_p = p^2/2m$ as $|\boldsymbol{p}\rangle$ of H_0. Furthermore, setting $\tau = t$ in [30], considering again the limits $t \to \mp\infty$ and applying the expression to $|\boldsymbol{p}\rangle$, one obtains

$$\begin{aligned} e^{-(i/\hbar)Ht}|\boldsymbol{p}, +\rangle &\to e^{-(i/\hbar)H_0t}|\boldsymbol{p}\rangle \quad \text{for} \to -\infty \\ e^{-(i/\hbar)Ht}|\boldsymbol{p}, -\rangle &\to e^{-(i/\hbar)H_0t}|\boldsymbol{p}\rangle \quad \text{for} \to +\infty \end{aligned} \qquad [33]$$

which shows that $|\boldsymbol{p}, +\rangle$ and $|\boldsymbol{p}, -\rangle$ correspond to an ingoing and outgoing particle, respectively, both with momentum $\boldsymbol{p}$. Notice that, keeping in mind the relations $U(t_2, t_1)U(t_1, t_0) = U(t_2, t_0)$ and $U^\dagger(t, t_0) = U(t_0, t)$, the S-matrix can be written in terms of such states in the alternative form,

$$\langle \boldsymbol{p}', -|\boldsymbol{p}, +\rangle = \langle \boldsymbol{p}'|U(\infty, 0)U(0, -\infty)|\boldsymbol{p}\rangle = \langle \boldsymbol{p}'|U(\infty, -\infty)|\boldsymbol{p}\rangle \qquad [34]$$

which is more frequently used in the relativistic theory. It can be shown that the set of all $|\boldsymbol{p}, +\rangle$ (the set of all $|\boldsymbol{p}, -\rangle$) together with the possible bound states makes a complete basis.

An observable in the Heisenberg picture is denoted as $O(t) = e^{(i/\hbar)Ht}Oe^{-(i/\hbar)Ht}$ and the same observable is denoted in the interaction picture with $O_0(t) = e^{(i/\hbar)H_0t}Oe^{-(i/\hbar)H_0t}$, which is obviously the Heisenberg picture for the free case. Taking into account

eqn [20], one has

$$\begin{aligned}
&\langle \boldsymbol{p}', -|O(t)|\boldsymbol{p}, +\rangle \\
&\quad = \langle \boldsymbol{p}'|U(\infty, t)O_0(t)U(t, -\infty)|\boldsymbol{p}\rangle \\
&\quad = \sum_{n=0}^{\infty}\left(-\frac{\mathrm{i}\lambda}{\hbar}\right)^n \sum_{s=0}^{n}\int_t^{\infty}\mathrm{d}t_1\cdots\int_t^{t_{s-1}}\mathrm{d}t_s\int_{-\infty}^{t}\mathrm{d}t_{s+1}\cdots \\
&\qquad \times\int_{-\infty}^{t}\mathrm{d}t_n\langle \boldsymbol{p}'|H_{1\mathrm{I}}(t_1)\cdots H_{1\mathrm{I}}(t_s)O_0(t)H_{1\mathrm{I}}(t_{s+1})\cdots \\
&\qquad \times H_{1\mathrm{I}}(t_n)|\boldsymbol{p}\rangle
\end{aligned} \tag{35}$$

The above equation can be easily generalized to the products of r operators in the following way:

$$\begin{aligned}
&\langle \boldsymbol{p}', -|T[O(t_1)O(t_2)\cdots O(t_r)]|\boldsymbol{p}, +\rangle \\
&\quad = \sum_{n=0}^{\infty}\left(-\frac{\mathrm{i}\lambda}{\hbar}\right)^n \int_{-\infty}^{\infty}\mathrm{d}\tau_1\int_{-\infty}^{\infty}\mathrm{d}\tau_2\cdots \\
&\qquad \times\int_{-\infty}^{\infty}\mathrm{d}\tau_n\langle \boldsymbol{p}'|T[O(t_1)O(t_2)\cdots O(t_r) \\
&\qquad \times H_{1\mathrm{I}}(\tau_1)H_{1\mathrm{I}}(\tau_2)\cdots H_{1\mathrm{I}}(\tau_r)]|\boldsymbol{p}\rangle
\end{aligned} \tag{36}$$

where $T[A(t_1)B(t_2)\cdots]$ denotes the time-ordered product (i.e., the product of the operators ordered according to decreasing times).

The above developments can be repeated with minor modifications for a system of N particles or in the second-quantization formalism. The single-particle states have only to be replaced with N-particle states $|\boldsymbol{p}_1, \boldsymbol{p}_2, \ldots \boldsymbol{p}_N\rangle$ and $|\boldsymbol{p}_1, \boldsymbol{p}_2, \ldots \boldsymbol{p}_N; \pm\rangle$. Some subtleties occur in the relativistic field theory, where the operator $U(t', t)$ converges for $t' \to +\infty$ and $t \to -\infty$ only in the weak sense.

In the second-quantization formalism and relativistic field theory, the ground-state or vacuum-correlation functions have a special interest. One can write (up to a phase factor)

$$\begin{aligned}
&\langle \Psi_0|T[O(t_1)O(t_2)\cdots O(t_r)]|\Psi_0\rangle \\
&\quad = \sum_{n=0}^{\infty}\left(-\frac{\mathrm{i}\lambda}{\hbar}\right)^n \int_{-\infty}^{\infty}\mathrm{d}\tau_1\int_{-\infty}^{\infty}\mathrm{d}\tau_2\cdots\int_{-\infty}^{\infty}\mathrm{d}\tau_n \\
&\qquad \times\langle \Phi_0|T[O(t_1)O(t_2)\cdots O(t_r) \\
&\qquad \times H_{1\mathrm{I}}(\tau_1)H_{1\mathrm{I}}(\tau_2)\cdots H_{1\mathrm{I}}(\tau_n)]|\Phi_0\rangle
\end{aligned} \tag{37}$$

where Φ_0 denotes the unperturbed ground state, and $\Psi_0 = U(0, \mp\infty)\Phi_0$ (the $\mp$ expressions are identical up to a phase factor) the actual ground state (vacuum state), the energy of which can be conventionally assumed to be 0.

The vacuum correlation functions contain, in principle, all the information about the system. They are also called Green functions and are used in many contexts. In particular, they can be related to the S-matrix and therefore to the scattering theory; they are the basis for a correct introduction of the idea of a quasiparticle and for establishing gap equations in the many-body system; they are a useful tool in the renormalization theory and for the treatment of the bound-state problem in field theory.

It is to be noted in the last connection that, using the completeness relation for the eigenstates of H $\left(\sum_n |u_n\rangle\langle u_n| = 1\right)$, one can write

$$\begin{aligned}
G(t) &= \langle \Psi_0|T[O(t)O(0)]|\Psi_0\rangle \\
&= \theta(t)\sum_n \langle \Psi_0|\mathrm{e}^{(\mathrm{i}/\hbar)Ht}O\mathrm{e}^{-(\mathrm{i}/\hbar)Ht}|u_n\rangle\langle u_n|O|\Psi_0\rangle \\
&\quad + \theta(-t)\sum_n \langle \Psi_0|O|u_n\rangle \\
&\quad \times \langle u_n|\mathrm{e}^{(\mathrm{i}/\hbar)Ht}O\mathrm{e}^{-(\mathrm{i}/\hbar)Ht}|\Psi_0\rangle \\
&= \sum_n \langle \Psi_0|O|u_n\rangle \\
&\quad \times \langle u_n|O|\Psi_0\rangle(\theta(t)\mathrm{e}^{-(\mathrm{i}/\hbar)W_n t} \\
&\quad + \theta(-t)\mathrm{e}^{-(\mathrm{i}/\hbar)W_n t})
\end{aligned} \tag{38}$$

where $\theta(t)$ is the step function: ($\theta(t) = 1$ for $t > 0$ and $\theta(t) = 0$ for $t < 0$). Then, for the Fourier transform, one obtains

$$\begin{aligned}
\hat{G}(\omega) &= \int_{-\infty}^{\infty}\mathrm{d}t\mathrm{e}^{(\mathrm{i}/\hbar)\omega t}G(t) \\
&= \mathrm{i}\hbar\sum_n \langle \Psi_0|O|u_n\rangle\frac{2W_n}{\omega^2 - W_n^2}\langle u_n|O|\Psi_0\rangle
\end{aligned} \tag{39}$$

Therefore, $\hat{G}(\omega)$ has poles at the discrete energy eigenvalues (bound states) in the complex ω plane and cuts on the continuum part of the spectrum. A similar argument can be repeated in the relativistic field theory; in this case, however, the relevant Green function is of the form $G(x) = \langle \Psi_0|T[\phi(x)\phi(0)]|\Psi_0\rangle$, $\phi(x)$ being the appropriate field. The Fourier transform, $\hat{G}(p) = \int d^4x\, \mathrm{e}^{(\mathrm{i}/\hbar)px}G(x)$ is on the space–time coordinates and the single-particle masses correspond to poles on the squared four-momentum $p^2 = p_0^2 - \boldsymbol{p}^2$.

Obviously, poles of this type are not present in the single terms of the perturbative expansion [37], if H_1 is identified with the entire interaction and, in particular, in the one-particle case, with the entire potential $V(r)$. This indicates a lack of convergence in the expansion for $\hat{G}(\omega)$ for ω close to the poles and a breakdown of the perturbative approach.

Actually, in some cases in field theories and in many-body theories, it is possible to isolate leading contributions in each term in [37] and to sum them up again, circumventing the difficulty. For instance, in a self-interacting scalar field theory, the various contributions to a two-point Green function can be

represented by Feynman graphs with vertices, internal lines, one incoming and one outgoing line (the single lines being associated with unperturbed two-point functions). Each graph can be divided into various irreducible segments (again beginning and ending with single lines but such that they cannot further be split in parts by cutting single lines). If $\mathrm{i}\Pi(p)$ is the sum of the Fourier transforms of the irreducible contributions of any order, the expansion can be reorganized in the following way:

$$\begin{aligned}\hat{G}(p) &= \frac{\mathrm{i}}{p^2-m^2} + \frac{\mathrm{i}}{p^2-m^2}\,\mathrm{i}\Pi(p)\frac{\mathrm{i}}{p^2-m^2} \\ &\quad + \frac{\mathrm{i}}{p^2-m^2}\,\mathrm{i}\Pi(p)\frac{\mathrm{i}}{p^2-m^2} \\ &\quad \times \mathrm{i}\Pi(p)\frac{\mathrm{i}}{p^2-m^2} + \cdots \\ &= \frac{\mathrm{i}}{p^2-m^2} + \frac{\mathrm{i}}{p^2-m^2}\,\mathrm{i}\Pi(p)\hat{G}(p) \end{aligned} \qquad [40]$$

The resulting equation can be solved explicitly

$$\hat{G}(p) = \frac{\mathrm{i}}{p^2-m^2+\Pi(p)} \qquad [41]$$

and the physical mass of the particle is given by the root of the denominator in p^2, m being simply a parameter with the dimension of a mass occurring in the Lagrangian or the Hamiltonian with no immediate meaning. By similar procedures one can obtain gap equations in many-body theories, Bethe–Salpeter equations for bound states in field theory, etc. Naturally, there exist even more essentially nonperturbative effects that cannot be obtained simply by resummation techniques.

Variational Method

This method uses primarily the property of the ground state to be the minimum of the so-called numerical range of H, that is, the set described by $\langle\phi|H|\phi\rangle$ for any vector ϕ such that $\langle\phi|\phi\rangle = 1$. In fact, setting

$$\phi = \sum_n c_n u_n, \quad \text{with } \sum_n |c_n|^2 = 1 \qquad [42]$$

it is clear that one has

$$\langle\phi|H|\phi\rangle = \sum_n |c_n|^2 W_n \geqslant W_0 \qquad [43]$$

W_0 being the ground-state energy.

Then, if a normalized state vector is considered, depending on a certain number of parameters $\phi(\alpha_1, \alpha_2, \ldots)$, it is clear that the minimum of the quantity

$$\langle\phi(\alpha_1,\alpha_2,\ \ldots)|H|\phi(\alpha_1,\alpha_2,\ \ldots)\rangle \qquad [44]$$

provides an upper bound to W_0, which can, however, be very close to the actual value. The vector $\phi(\alpha_1, \alpha_2, \cdots)$ is called a test function. The more appropriate the choice of such a test function, the better the estimate. In the case of a hydrogen atom (eqn [12]) setting $\phi(\alpha) = \sqrt{\alpha^3/\pi}\mathrm{e}^{-\alpha r}$, one obtains the exact expression for W_0 and the corresponding eigenfunction. This obviously is due to the specific form of the test function that includes the exact eigenfunction for a $\alpha = m_\mathrm{e}e^2/(4\pi\hbar^2)$ (the reciprocal of the Bohr radius). In general, using the variational method, the accuracy in the determination of the eigenvalue is much better than in the determination of the eigenfunction.

As a less trivial example, the determination of the ground state of the helium atom may be considered. Neglecting spin-dependent forces, the Hamiltonian is

$$\begin{aligned} H &= H_0 + \frac{e^2}{4\pi r_{12}} \\ &= \frac{\boldsymbol{p}_1^2}{2m_\mathrm{e}} + \frac{\boldsymbol{p}_2^2}{2m_\mathrm{e}} - \frac{2e^2}{4\pi r_1} - \frac{2e^2}{4\pi r_2} + \frac{e^2}{4\pi r_{12}} \end{aligned} \qquad [45]$$

where r_1, r_2, and r_{12} are the distances of the two electrons from the nucleus and the distance between the two electrons, respectively. The ground state of H_0 (i.e., of H when the interaction between the two electrons is neglected), satisfying the Pauli principle requirements, can be written in the form

$$\begin{aligned}\phi_0 &= u_{1S}(\boldsymbol{r}_1)u_{1S}(\boldsymbol{r}_2)\frac{1}{\sqrt{2}} \\ &\quad \times (v_{1,\frac{1}{2}}v_{2,-\frac{1}{2}} - v_{1,-\frac{1}{2}}v_{2,\frac{1}{2}}) \end{aligned} \qquad [46]$$

where $u_{1S}(\boldsymbol{r}) = (1/\sqrt{\pi})(2/a_0)^{3/2}\mathrm{e}^{-(2r/a_0)}$ and $a_0 = 4\pi\hbar^2/(m_\mathrm{e}e^2)$. The experimental value of W_0 is $-78.99\,\mathrm{eV}$ (i.e., 78.99 is the energy necessary to strip both electrons from the atom). If the interaction between the electrons is treated as a perturbation, one finds, applying eqn [9],

$$\left\langle \phi_0 \middle| \frac{e^2}{4\pi r_{12}} \middle| \phi_0 \right\rangle = \frac{5}{2}\,w_0 \qquad [47]$$

($w_0 = 13.6$, defined as in [14] and so $W_0 = -2\times 4w_0 + \frac{5}{2}w_0 = -\frac{11}{16}w_0 = -74.8\mathrm{eV}$. However, if one replaces in [46] the function $u_{1S}(\boldsymbol{r})$ with $u_{1S}^{\mathrm{test}}(\boldsymbol{r}) = \pi)(Z/a_0)^{3/2}\mathrm{e}^{-Zr/a_0}$, one obtains by simply rescaling

$$\langle\phi^{\mathrm{test}}|H|\phi^{\mathrm{test}}\rangle = (2Z^2 - 8Z + \tfrac{5}{4}\,Z)w_0 \qquad [48]$$

This expression is reduced to the preceding one for $Z = 2$; however, it attains its minimum for $Z = 27/16$ and using such a value, it gives $W_0 = -5.70\,w_0 = -77.5\,\text{eV}$ in much better agreement with the data. It is to be noted that Z can be interpreted as a kind of effective nuclear charge acting on each electron, due to the partial screen produced by the other electron.

In case there exist other constants of motion, such as the angular momentum or components of the angular momentum, the test function should be chosen as a common eigenfunction. Then, the same method can be used to determine the ground state of H inside every invariant subspace specified by the values of such quantities. In this way, the lowest triplet S state, singlet and triplet P states can be determined for the same helium atom by variants of the test function.

The method can be successfully applied in a similar way to a large variety of problems. In particular, it can be applied to the evaluation of the binding potential among nuclei in molecules in the Born–Openheimer approximation. This consists in treating the nuclei as fixed, and in studying the electron ground-state energy as a function of the nuclei positions. This problem can be exactly solved (in a sense) only in the very special case of the ionized hydrogen molecule, but in many cases the variational method offers a simple and at least a qualitative understanding of the properties of the molecule.

Up to now, the attention has been restricted to the case of the ground state of a system, or the ground state inside an invariant subspace of states, that is, to the actual minima of the functional $W[\phi] = \langle \phi|H|\phi \rangle$ under the constraint $\langle \phi|\phi \rangle = 1$. However, it is worth mentioning that the same functional is stationary at every eigenstate of H and vice versa, under the same constraint. Using the Lagrange multiplier theorem, the condition for $W[\phi]$ to be stationary can in fact be written as

$$\begin{aligned}\delta(W[\phi] - \lambda\langle \phi|\phi \rangle) &= \langle \delta\phi|H|\phi \rangle + \langle \phi|H|\delta\phi \rangle \\ &\quad - \lambda(\langle \delta\phi|\phi \rangle + \langle \phi|\delta\phi \rangle) \\ &= 0\end{aligned} \qquad [49]$$

Combining this equation with the one obtained by replacing $\delta\phi$ with $-\mathrm{i}\delta\phi$, one immediately obtains $\langle \delta\phi|(H - \lambda)|\phi \rangle = 0$ and then, due to the arbitrariness of $\delta\phi$,

$$H\phi = \lambda\phi \qquad [50]$$

which proves the statement.

In applying the above result to the determination of the excited states, one should choose test functions orthogonal to those corresponding to lower eigenvalues and, since approximations are involved, it is clear that this cannot be done with the same confidence as for the ground state. However, such generalization is important for theoretical developments and to justify more elaborate methods, such as, for instance, the famous Hartree–Fock method.

The Hamiltonian for a many-electron atom is

$$H = \sum_{i=1}^{Z}\left(\frac{p_i^2}{2m_\mathrm{e}} - \frac{Ze^2}{r_i}\right) + \sum_{i<j}\frac{e^2}{r_{ij}} \qquad [51]$$

which generalizes eqn [45]. One can expect that for large Z, a qualitative understanding of the spectrum can be achieved by replacing the complicated interaction acting on each electron according to [51] with an average central potential $V(r)$ and by simply writing $H = \sum_{i=1}^{Z}[(p_i^2/2m_\mathrm{e}) - V(r_i)]$. This suggests that the test function to be chosen is (once again consistent with the exclusion principle)

$$u^{\text{test}}_{a_1,a_2,\ldots a_z}(1, 2, \ldots, Z) = \det[u_{a_i}(j)] \qquad [52]$$

in which 1, 2, …,Z denote briefly the coordinates and the spin indices for the various electrons, and $u_{a_i} = R_{n_i,l_i}(r_i)Y_{l_i,m_i}(\theta_i, \phi_i)v_{m_{si}}$, the one-particle eigenfunctions corresponding to the quantum numbers $a_i = (n_i, l_i, m_i, m_{si})$ for the hypothetical potential $V(r)$. Leaving actually the radial functions $R_{nl}(r)$ undetermined and treating them as variational parameters, one obtains the Hartree–Fock equations (strictly speaking the simple form [52] applies only to complete shells, to one electron plus a complete shell, to a complete shell minus one electron).

Semiclassical Methods

Among the semiclassical methods, the WKB method is a classic one. However, in its simplest form this method applies only to problems that are or can be reduced to one-dimensional (as in the case of a particle in a central potential $V(r)$) and has today little more than historical interest.

It consists in setting $u(x) = \mathrm{e}^{(\mathrm{i}/\hbar)S(x)}$ in the eigenvalue equation

$$\frac{\hbar^2}{2m}\frac{d^2u(x)}{\mathrm{d}x^2} + V(x)u(x) = Wu(x) \qquad [53]$$

and in solving the resulting equation

$$\left(\frac{\mathrm{d}S}{\mathrm{d}x}\right)^2 - \mathrm{i}\hbar\frac{\mathrm{d}^2S}{\mathrm{d}x^2} = 2m(W - V(x)) \qquad [54]$$

by an expansion in $\hbar$,

$$S = S_0 - i\hbar S_1 + (-i\hbar)^2 S_2 + \cdots \qquad [55]$$

Keeping only the first two terms in the expansion, one obtains the two independent solutions of the original equation

$$u_{\pm}(x) = \frac{C_{\pm}}{[p(x)]^{1/2}} \exp\left(\pm\frac{i}{\hbar}\right) \int_0^x dx' p(x') \qquad [56]$$

where $p(x) = \sqrt{2m[W - V(x)]}$ and $C_{\pm}$ are arbitrary constants. In a region in which $V(x) < W$ (classically accessible region), $p(x)$ is the classical momentum of the particle in point x, and $u_{\pm}(x)$ are oscillating functions. When asking for a real solution, the latter can be also summarized as

$$u(x) = \frac{A}{[p(x)]^{1/2}} \sin\left[\frac{1}{\hbar}\int_0^x dx' p(x') + \alpha\right] \qquad [57]$$

A and α being arbitrary constants. On the contrary, in a region in which $V(x) > W$ (classically inaccessible region), [56] becomes

$$\bar{u}_{\pm}(x) = \frac{C'_{\pm}}{[\bar{p}(x)]^{1/2}} \exp\left(\pm\frac{1}{\hbar}\int_0^x dx' \bar{p}(x')\right) \qquad [58]$$

with $(\bar{p}(x) = \sqrt{2m[V(x) - W]})$. These have a stable behavior and vanish or diverge for $x \to \pm\infty$, if the region extends to such limits.

By considering the order of magnitude of S_2, one can see that the above approximations are good as long as $V(x)$ does not change appreciably for a variation of x of the order of $\hbar/p(x)$ or $\hbar/\bar{p}(x)$. Such conditions cannot hold, obviously, in the vicinity of an inversion point x_0, that is, a point for which $V(x_0) = W$ and $p(x)$ and $\bar{p}(x)$ vanish. However, using a linear approximation for $V(x)$ in the neighborhood of such a point, an appropriate rule can be given to connect solutions of the types [57] and [58] through it.

The above rule is not explicitly reported here. However, the two most interesting situations that can occur are only mentioned. Assuming that $V(x)$ vanishes for $x \to \pm\infty$, let the potential have a negative minimum $-V_0$ from where it rises regularly to 0 in both directions (potential well). The other case considered here involves a positive maximum from where similarly it decreases uniformly (potential barrier). In both cases, if W has an intermediate value between $-V_0$ and 0 or between 0 and V_0, there exist two inversion points x_1 and x_2. In the first situation, the classically nonaccessible region is the external part of the interval (x_1, x_2), and the condition for which an internal solution of the form [57] is connected simultaneously with a $\bar{u}_+(x)$ (vanishing for $x \to -\infty$) through x_1 and with a $\bar{u}_-(x)$ (vanishing for $x \to +\infty$) through x_2, respectively, is

$$2\int_{x_1}^{x_2} dx\, p(x) = \left(n + \frac{1}{2}\right)h \quad (n = 0, 1, \ldots) \qquad [59]$$

which allows only discrete values for W, for $W < 0$, and provides a justification of the famous Sommerfeld conditions of the old quantum mechanics.

In the second situation, the classically inaccessible region is the interval (x_1, x_2) itself. The energy spectrum is purely continuous and the wave functions are different from 0 in the entire x-axis. Then, there is a finite probability that the particle, initially on the left of x_1, goes through the barrier and is found on the right of x_2 after some time (tunnel effect). Such a probability is expressed by the transmission coefficient

$$\tau = \exp\left(-\frac{2}{\hbar}\int_{x_1}^{x_2} dx\, \bar{p}(x)\right) \qquad [60]$$

Equation [60] has been largely used in discussing nuclear reactions and particularly in the theory of α radioactivity.

Finally, methods related in some way to the preceding one, but of much more general application, are those based on the path integral formalism.

One may consider, for simplicity, a particle in one dimension with its position and momentum operators denoted by Q and P, and with $|q\rangle$ and $|p\rangle$ their respective eigenstates. Let $Q(t) = e^{(i/\hbar)Ht} Q e^{(-i/\hbar)Ht}$, and $|q, t\rangle = e^{(i/\hbar)Ht}|q\rangle$ be the corresponding operators and eigenvectors in the Heisenberg picture, with $H = P^2/2m + V(Q)$. For an infinitesimal ε, one has

$$\begin{aligned}
&\langle q', t+\varepsilon | q, t\rangle \\
&\quad = \left\langle q' \middle| \left(1 + \frac{i}{\hbar} H\varepsilon\right) \middle| q \right\rangle \\
&\quad = \delta(q' - q) + \frac{i}{\hbar}\varepsilon\left[\int dp \langle q'|p\rangle \frac{p^2}{2m} \langle p|q\rangle \right. \\
&\qquad \left. + \delta(q' - q) V\left(\frac{q+q'}{2}\right)\right] \\
&\quad = \int \frac{dp}{2\pi\hbar} \exp\left\{\left(\frac{i}{\hbar}\right)\varepsilon\left[p(q'-q) + \frac{p^2}{2m} + V\left(\frac{q+q'}{2}\right)\right]\right\}
\end{aligned} \qquad [61]$$

where $\langle q|p\rangle = (1/2\pi\hbar)e^{(i/\hbar)pq}$ and $\delta(q - q') = (1/2\pi\hbar)\int dp e^{(i/\hbar)p(q'-q)}$ have been used. Then, for a finite time interval (t, t'), by dividing this into a small subinterval (t_{n-1}, t_n) with $t_n = t_{n-1} + \varepsilon$, one

can write

$$\begin{aligned}
&\langle q', t'|q, t\rangle \\
&\quad = \int \mathrm{d}q_1 \mathrm{d}q_2 \ldots \mathrm{d}q_{N-1} \langle q', t'|q_{N-1}, t_{N-1}\rangle \cdots \\
&\qquad \times \langle q_2, t_2|q_1, t_1\rangle \langle q_1, t_1|q, t\rangle \\
&\quad = \int \mathrm{d}p_1 \mathrm{d}q_1 \ldots \mathrm{d}p_{N-1} \mathrm{d}q_{N-1} dp_N \\
&\qquad \times \exp\left\langle \frac{\mathrm{i}}{\hbar} \sum_{n=1}^{N} \left\{ p_n(q_n - q_{n-1}) \right.\right. \\
&\qquad \left.\left. -\varepsilon\left[\frac{p_n^2}{2m} + V\left(\frac{q_n + q_{n-1}}{2}\right)\right]\right\}\right\rangle
\end{aligned} \tag{62}$$

where $q_N = q'$. In the limit $\varepsilon \to 0$, eqn [62] can be interpreted as an integral over the infinite paths connecting q with q' and written in short

$$\begin{aligned}
&\langle q', t'|q, t\rangle \\
&\quad = \int_{q(t)=q}^{q(t')=q'} \mathscr{D}p \mathscr{D}q \exp\left\{\frac{\mathrm{i}}{\hbar} \int_t^{t'} \mathrm{d}\tau \left[p(\tau)\dot{q}(\tau) \right.\right. \\
&\qquad \left.\left. -\frac{p^2(\tau)}{2m} + V(q(\tau))\right]\right\}
\end{aligned} \tag{63}$$

If one sets formally

$$\begin{aligned}
\mathscr{D}q &= \lim_{\varepsilon \to 0}\left(\frac{m}{2\pi\hbar \mathrm{i}\varepsilon}\right)^{N/2} \mathrm{d}q_1 \mathrm{d}q_2 \cdots \mathrm{d}q_{N-1} \\
\mathscr{D}p &= \lim_{\varepsilon \to 0}\left(\frac{\mathrm{i}\varepsilon}{2\pi\hbar m}\right)^{N/2} \mathrm{d}p_1 \mathrm{d}p_2 \cdots \mathrm{d}p_N
\end{aligned} \tag{64}$$

one can also explicitly integrate the momenta and write

$$\begin{aligned}
&\langle q', t'|q, t\rangle \\
&\quad = \int_{q(t)=q}^{q(t')=q'} \mathscr{D}q \exp\left\{\frac{\mathrm{i}}{\hbar} \int_t^{t'} \mathrm{d}\tau \left[\frac{1}{2}m\dot{q}^2(\tau) - V(q(\tau))\right]\right\}
\end{aligned} \tag{65}$$

It is to be noted that eqn [63] is in terms of paths in the phase space, eqn [65] in terms of paths in the configuration space. It is also to be noted that the quantity $S(q', t'; q, t) = \int_t^{t'} \mathrm{d}\tau [\frac{1}{2}m\dot{q}^2(\tau) - V(q(\tau))] = \int_t^{t'} \mathrm{d}\tau\, L[q(\tau), \dot{q}(\tau)]$ occurring in [65] and the corresponding one occurring in [63] are the classical actions for the particular paths in the configuration and the phase space, respectively.

To evaluate $\langle q', t'|q, t\rangle$ is obviously equivalent to solving the Schrödinger equation [1]. Since the classical action is stationary over the classical solution of the equation of motion joining q and q', the quantum theory can be viewed as the result of quantum fluctuations around the classical solution.

One could now consider the Green functions in this formalism. In analogy with what has been done in the section "Green functions," one can start from the expression

$$\begin{aligned}
&\langle q', t'|Q(t_1)Q(t_2)\cdots Q(t_r)|q, t\rangle \\
&\quad = \int \mathrm{d}q_1 \mathrm{d}q_2 \cdots \mathrm{d}q_r \langle q, t|q_1, t_1\rangle q_1 \\
&\qquad \times \langle q_1, t_1|q_2, t_2\rangle q_2 \cdots \langle q_{r-1}, t_{r-1}|q_r, t_r\rangle \\
&\qquad \times q_r \langle q_r, t_r|q, t\rangle
\end{aligned} \tag{66}$$

Assuming $t_1 > t_2 > \cdots t_r$, this can be rewritten as

$$\begin{aligned}
&\langle q', t'|T[Q(t_1)Q(t_2)\cdots Q(t_r)]|q, t\rangle \\
&\quad = \int_{q(t)=q}^{q(t')=q'} \mathscr{D}q \exp\left[\frac{\mathrm{i}}{\hbar}\int_t^{t'} \mathrm{d}\tau L(q, \dot{q})\right] \\
&\qquad \times q(t_1)q(t_2)\cdots q(t_r)
\end{aligned} \tag{67}$$

or in the corresponding form in terms of phase space paths (see [63]). Obviously, written with the explicit insertion of the time-ordering prescription T, eqn [67] remains valid for any possible ordering of t_1, t_2,…, t_r.

If the times t and t' have a small negative phase $\mathrm{e}^{-\mathrm{i}\delta}$, one can perform the limits $t \to -\infty$ and $t' + \infty$ and obtain

$$\begin{aligned}
&\langle q', t'|q, t\rangle \\
&\quad = \sum_n \langle q'|u_n\rangle \mathrm{e}^{-(\mathrm{i}/\hbar+\delta)W_n(t'-t)} \langle u_n|q\rangle \\
&\qquad \to \langle q'|\Psi_0\rangle \mathrm{e}^{-(\mathrm{i}/\hbar+\delta)W_0(t'-t)} \langle \Psi_0|q\rangle
\end{aligned} \tag{68}$$

Ψ_0 being again the ground state of the system. Similarly, one also has

$$\begin{aligned}
&\left\langle q', t'|T\left[Q(t_1\mathrm{e}^{-\mathrm{i}\delta})Q(t_2\mathrm{e}^{-\mathrm{i}\delta})\cdots Q(t_r\mathrm{e}^{-\mathrm{i}\delta})\right]|q, t\right\rangle \\
&\quad \to \langle q'|\Psi_0\rangle \mathrm{e}^{-(\mathrm{i}/\hbar+\delta)W_0(t'-t)} \langle \Psi_0|q\rangle \langle \Psi_0| \\
&\qquad \times T\left[Q(t_1\mathrm{e}^{-\mathrm{i}\delta})Q(t_2\mathrm{e}^{-\mathrm{i}\delta})\cdots Q(t_r\mathrm{e}^{-\mathrm{i}\delta})\right]|\Psi_0\rangle
\end{aligned} \tag{69}$$

Combining the last two equations with [65] and [67], one obtains finally (suppressing phase δ)

$$\begin{aligned}
&\langle \Psi_0|T[Q(t_1)Q(t_2)\cdots Q(t_r)]|\Psi_0\rangle \\
&\quad = \frac{\int \mathscr{D}q \exp\left[\frac{\mathrm{i}}{\hbar}\int_{-\infty}^{\infty} \mathrm{d}\tau L(q, \dot{q})\right] q(t_1)q(t_2)\cdots q(t_r)}{\int \mathscr{D}q \exp\left[\frac{i}{\hbar}\int_{-\infty}^{\infty} \mathrm{d}\tau L(q, \dot{q})\right]}
\end{aligned} \tag{70}$$

where any specification of boundary conditions has been suppressed, since in the limit the right-hand expression is independent of it.

The preceding equation can be immediately extended with obvious modifications to more complicated systems, and in particular to bosonic fields and even to fermionic ones, if in the latter case one makes use of the Grassmann variable formalism. In field theory, obviously, the Lagrangian $L(q(\tau), \dot{q}(\tau))$ must be replaced by a Lagrangian density $\mathscr{L}[\phi(x)\partial^{\mu}\phi(x)]$, variables $t_1, t_2, \ldots \tau, \tau_1, \ldots$ with space–time point specifications $x_1, x_2, \ldots, \xi, \xi_1, \ldots,$ etc. The method turns out to be particularly convenient in treating gauge field theories, such as quantum electrodynamics (QED) or non-Abelian theories, as the electroweak theory and quantum chromodynamics (QCD).

Equation [70] can be used in various ways. Writing $L(q, \dot{q}) = L_0 + \lambda L_1$ enables one to establish the perturbative expansion

$$\begin{aligned}
&\langle \Psi_0 | T[Q(t_1)Q(t_2)\cdots Q(t_r)] | \Psi_0 \rangle \\
&= \left\{ \sum_{s=0}^{\infty} \left(\frac{\mathrm{i}}{\hbar}\lambda\right)^s \frac{1}{s!} \int_{-\infty}^{\infty} \mathrm{d}\tau_1 \int_{-\infty}^{\infty} \mathrm{d}\tau_2 \cdots \right. \\
&\quad \times \int_{-\infty}^{\infty} \mathrm{d}\tau_s \int \mathscr{D}q \exp\left[\frac{\mathrm{i}}{\hbar} \int_{-\infty}^{\infty} \mathrm{d}\tau\, L_0(q(\tau), \dot{q}(\tau))\right] \\
&\quad \times q(t_1)q(t_2)\cdots q(t_r) L_1(q(\tau_1), \dot{q}(\tau_1)) \\
&\quad \left. \times L_1(q(\tau_2), \dot{q}(\tau_2)) \cdots L_1(q(\tau_s), \dot{q}(\tau_s)) \right\} \\
&\quad \times \left\{ \sum_{s=0}^{\infty} \left(\frac{\mathrm{i}}{\hbar}\lambda\right)^s \frac{1}{s!} \int_{-\infty}^{\infty} \mathrm{d}\tau_1 \int_{-\infty}^{\infty} \mathrm{d}\tau_2 \cdots \int_{-\infty}^{\infty} \mathrm{d}\tau_s \int \mathscr{D}q \right. \\
&\quad \times \exp\left[\frac{\mathrm{i}}{\hbar} \int_{-\infty}^{\infty} \mathrm{d}\tau\, L_0(q(\tau), \dot{q}(\tau))\right] \\
&\quad \left. \times L_1(q(\tau_1), \dot{q}(\tau_1)) L_1(q(\tau_2), \dot{q}(\tau_2)) \cdots L_1(q(\tau_s), \dot{q}(\tau_s)) \right\}^{-1}
\end{aligned} \tag{71}$$

In the one-dimensional example considered above, L_0 can be the kinetic energy and $L_1 = -V(q)$, or better L_0 a harmonic oscillator Lagrangian and L_1 some anharmonic term. In field theory, $\mathscr{L}_0(x)$ is typically assumed to be the kinetic part of $\mathscr{L}(x)$, and $\mathscr{L}_1(x)$ the interaction. In any case, if L_1 does not depend on time derivatives of the basic variables, one has $L_1 = -H_1$ and eqn [71] has the same content as eqn [36]. If L_1 depends on time derivatives, $L_1 \neq H_1$ and [71] and [36] are formally different. However, it can be shown that the modifications, implied in the last case, in the definition of the conjugate momenta cancel the modifications in the definition of H_1 (normal dependent terms). Then, even in this case, eqn [36] can be recast in the simpler form corresponding to [71].

In fact, eqn [70] can be used for nonperturbative developments. In particular, one can fix a small but finite value for the lattice spacing ε introduced above, specify the path $q(\tau)$ in terms of a finite number of variables as in [62], and interpret the measure $\mathscr{D}q$ as in [64], without performing the actual limit. In this way, a theory with a discrete time or a discrete space–time is obtained (lattice theory), which has to be understood as an approximation to the continuous theory. To such a procedure, often there are not many alternatives in field theories for an understanding of essentially nonperturbative effects, such as color confinement in QCD. The resulting expression can be treated analytically in some cases. More frequently, it can be used for direct numerical evaluations.

Actually, to make integrals well defined, it is convenient to work in the corresponding Euclidean theory that is obtained from [62] by performing the analytic continuation to an imaginary time, $\tau \to -\mathrm{i}\tau$, $t_1 \to -\mathrm{i}t_1, \ldots$ (corresponding to $\delta = \pi/2$ in [69]). This amounts to writing

$$\begin{aligned}
&\langle \Psi_0 | T[Q_{\mathrm{E}}(t_1)Q_{\mathrm{E}}(t_2)\cdots Q_{\mathrm{E}}(t_r)] | \Psi_0 \rangle \\
&= \frac{\int \mathscr{D}q \exp\left[-\frac{1}{\hbar}\int_{-\infty}^{\infty} \mathrm{d}\tau L_{\mathrm{E}}(q, \dot{q})\right] q(t_1)q(t_2)\cdots q(t_r)}{\int \mathscr{D}q \exp\left[-\frac{1}{\hbar}\int_{-\infty}^{\infty} \mathrm{d}\tau L(q, \dot{q})\right]}
\end{aligned} \tag{72}$$

where one has set $Q_{\mathrm{E}}(t) = Q(-\mathrm{i}t) = \mathrm{e}^{(1/\hbar)Ht} Q \mathrm{e}^{-(1/\hbar)Ht}$ and $L_{\mathrm{E}}(q, \dot{q}) = -L(q, \mathrm{i}\dot{q})$. For example, in the one-dimensional example, one has $L_{\mathrm{E}} = \frac{1}{2}m\dot{q}^2 + V(q)$, which turns out to be formally identical to the Hamiltonian.

An alternative approach to consider the infinite time limit in [65] is to set $q' = q$ and integrate with respect to such a variable. One has then in the Euclidean formalism

$$\begin{aligned}
&\mathrm{Tr}\{T[Q_{\mathrm{E}}(t_1)Q_{\mathrm{E}}(t_2)\cdots Q_{\mathrm{E}}(t_r)]\} \\
&= \int_{\text{periodic}} \mathscr{D}q \exp\left[-\frac{1}{\hbar}\int_{-\infty}^{\infty} \mathrm{d}\tau L_{\mathrm{E}}(q, \dot{q})\right] \\
&\quad \times q(t_1)q(t_2)\cdots q(t_r)
\end{aligned} \tag{73}$$

where the integration is over paths satisfying periodic boundary conditions, $q(t') = q(t)$. In the limit of large time, this equation has essentially the same content of [72] and is often more convenient for numerical applications. On the contrary, for finite $t' - t$ one can set $t' - t = \hbar\beta$ thinking of β as $1/kT$, T being the absolute temperature and k the Boltzmann constant. In this form, for $r = 0$, the right-hand side of [73] becomes identical to the partition function $Z(\beta) = \mathrm{Tr}\,\mathrm{e}^{-\beta H}$, and for $r \neq 0$ to the corresponding correlation functions.

This establishes a connection with statistical mechanics, and [73] becomes the basis for important developments, both analytical and numerical, in this field.

Quantum Mechanics: Molecules

V Schettino and M Mugnai, Università di Firenze, Florence, Italy

Introduction

A molecule is an ensemble of atoms held together by electrostatic forces or, in the language of chemistry, by chemical bonds. Stable molecules are considered as examples in the following; but from the quantum mechanical point of view unstable and short-lived molecules, which are amenable to direct experimental observation with available time-resolved techniques, can also be treated on the same footing. The quantum mechanics of molecules is a complicated many-body problem whose complete treatment should include the degrees of freedom of the electrons and the nuclei. In favorable cases, the problem can be simplified by exploiting the molecular symmetry that can allow some qualitative or semiquantitative understanding as well. Actually, an exact numerical solution of the Schrödinger equation can be found only for the hydrogen molecular ion H_2^+, which, at least for linear molecules, can serve as a reference, very much like the hydrogen atom for many-electron atoms. In the most general case, the quantum mechanical treatment of polyatomic molecules can only be carried to obtain approximate solutions for the molecular energy and eigenfunctions. However, the dissociation energy of a chemical bond is in the range of a few electronvolts. Therefore, to reach an accuracy of significance, in many chemical and molecular problems the solution of the Schrödinger equation of the molecule must be carried to a reasonably high level of approximation. The quantum mechanical treatment of polyatomic molecules is generally carried out in the so-called molecular orbital method or, alternatively, in the valence band approach. These methods are presented in the following and compared with the alternative approach of the density-functional theory (DFT). As an example, the molecular orbital results of biatomic molecules are described qualitatively. The application of group theory and symmetry considerations to polyatomics are also discussed. The nuclear Schrödinger equation and its separation into the translational, rotational, and vibrational terms are also presented and the connection with various spectroscopic techniques are discussed.

The Born–Oppenheimer Approximation

One is generally compelled to consider the quantum mechanics of a molecule in the framework of the Born–Oppenheimer approximation. Taking advantage of the fact that the electron mass is several orders of magnitude smaller than that of the nuclei, the total wave function is written as a product of an electronic wave function Ψ_e, which depends on the electron coordinates q_i and parametrically on the nuclear coordinates q_α, and a

nuclear part Ψ_n:

$$\Psi(q_i q_\alpha) = \Psi_e \Psi_n = \Psi_e(q_i \bar{q}_\alpha)\Psi_n(q_\alpha) \qquad [1]$$

The Schrödinger equation is then separated into an electronic equation with the Hamiltonian

$$H_e = T_e + T_{en} + T_{ee} + T_{nn} \qquad [2]$$

including, in order, the electronic kinetic energy, the electron–nucleus interaction, the interelectron repulsion and the nucleus–nucleus repulsion (the last term can be considered as a constant at any given nuclear configuration). An equation for the nuclear motion with a Hamiltonian, where the total electron energy U_t contributes to the potential, is given by

$$H_n \psi_n = (T_n + U_t)\psi_n = E_n \psi_n \qquad [3]$$

where T_n is the kinetic energy of the nuclei and U_t is the total electron energy corresponding to the Hamiltonian [2]. In essence, the problem is similar to one of solving the electronic problem at fixed nuclear configurations and searching for the minimum corresponding to the equilibrium structure (see **Figure 1**). An approximate solution of the electronic wave equation is generally attempted by the variational method.

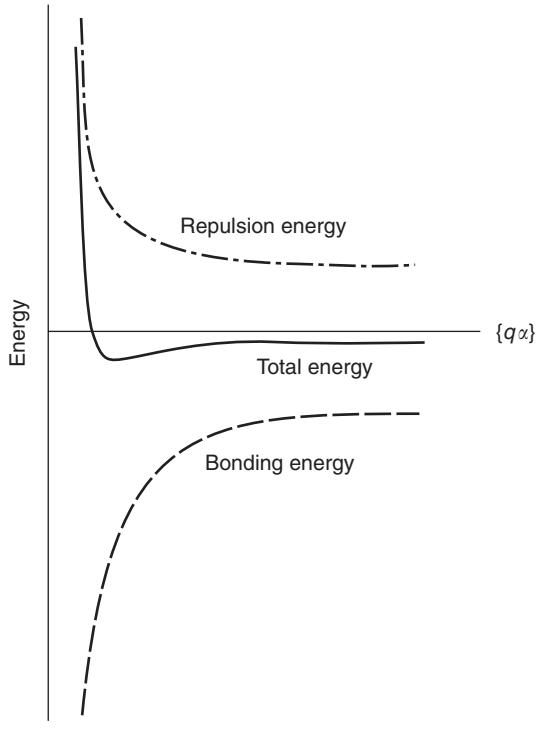

Figure 1 Variation of the bonding and repulsion energy as a function of the intermolecular coordinates q_α.

The Molecular Orbital Method

In the molecular orbital method, the multi-electron wave function $\Psi_e(q_i \bar{q}_\alpha)$ is expressed as an antisymmetrized product of single electron spin orbitals, written as a Slater determinant. The electronic wave function Ψ_e corresponds to a given electron configuration where the electrons are allocated in molecular orbitals according to the Pauli principle. For a $2n$-electron molecule, the ground-state configuration is shown in **Figure 2a** and the corresponding Slater determinant is given by

$$\Psi_e(q_i \bar{q}_\alpha) = N|\varphi_1(1)\alpha(1)\varphi_1(2)\beta(2) \cdots \varphi_n(2n-1)\alpha(2n-1)\varphi_n(2n)\beta(2n)| \qquad [4]$$

where α and β denote the spin eigenfunction.

The general purpose of the method is to reduce the multi-electron wave equation into an effective one-electron equation for the molecular orbitals. Separating the one- and two-particle moieties of the electronic Hamiltonian, one obtains the variational integral in the form

$$E = \langle \Psi_e | H | \Psi_e \rangle = E_1 + E_2 = 2\sum_i H_{ii} + \sum_{ij}(2J_{ij} - K_{ij}) \qquad [5]$$

which exposes the contributions to the energy from the single electron in the molecular orbital φ_i in the nuclear field H_{ii} and the electron–electron repulsion including the Coulomb contribution J_{ij} that represents the electronic repulsion of electron 1 in orbital i, electron 2 in orbital j, and the exchange contribution K_{ij} arising from the antisymmetric character of the multi-electronic wave function. Applying the variational principle to the above integral and defining appropriate Coulomb $\hat{J}$ and exchange $\hat{K}$ operators, the minimization procedure (preserving

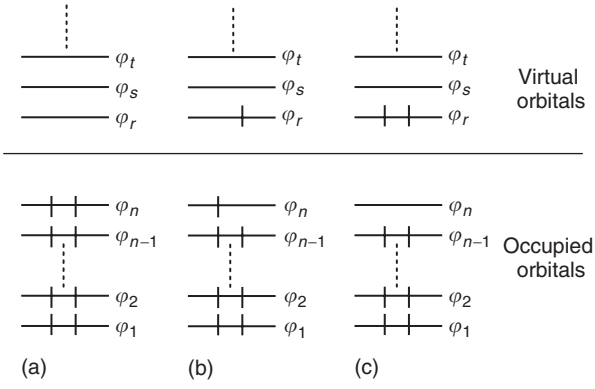

Figure 2 Electronic state configuration of a $2n$-electron molecule. (a) Ground-state configuration; (b) a singly excited configuration; and (c) a doubly excited configuration.

the orthonormalization of the basis functions) leads to the pseudo-eigenvalue-equation

$$\hat{F}\varphi_i(1) = \left(H_1^c + \sum_j (2\hat{J}_j(1) - \hat{K}_j(1))\right)\varphi_i(1) = \sum_j \varepsilon_{ij}\varphi_j(1) \quad [6]$$

called the Fock equation. The Fock operator $\hat{F}$ is an effective one-electron Hamiltonian including an averaged electron–electron repulsion. Since the operator $\hat{F}$ depends on the solutions, the molecular orbitals can be determined by an iterative procedure starting from an initially guessed form. From a practical point of view, the starting form of the molecular orbitals is chosen as a linear combination of the atomic orbitals φ_μ of the atoms that constitute the molecule

$$\phi_i = \sum_\mu c_{\mu i}\varphi_\mu \quad [7]$$

This reconduces the approach into the framework of the linear variational method. The integrodifferential Fock equation [6] is transformed into a set of linear algebraic equations in the c coefficients (Roothan equations). The problem is conveniently expressed in matrix notation. Defining the overlap matrix

$$S_{\mu v} = \langle \varphi_\mu | \varphi_v \rangle \quad [8]$$

the electron density matrix

$$P_{\mu v} = \left(\sum_i 2c_{\mu i}^* c_{vi}\right) \quad [9]$$

and the Fock matrix F (the matrix of the operator [6]), the Roothan equations can be written in the form

$$FC = CSE \quad [10]$$

which is evidently amenable to an iterative solution. The selected basis set of the atomic orbitals can be transformed into an orthonormal basis set to have the Roothan equations in the form of an eigenvalue problem.

The atomic orbitals of the basis set contain an angular part expressed as spherical harmonics and a radial part in the form of Slater orbitals expressing an exponential decay with distance. The latter, however, are not computationally convenient for the calculation of the two-electron integrals. The radial part is normally expressed as a combination of Gaussian functions. In general, the results of the Hartree–Fock approach to the electronic molecular wave function and properties will depend on the ex-tension of the basis set used for the expansion of the molecular orbitals. The fit of the predicted properties to experiments rapidly improves enlarging the basis set and the calculated values converge to the so-called Hartree–Fock limit. This, however, does not match the experiment within the limit of chemical accuracy. Expressing the multi-electron wave function as a single Slater determinant of the occupied molecular orbitals is not a correct approximation. The multi-electron wave function should be expressed as a combination of the Slater determinants corresponding to configurations of the ground state and of the singly, doubly and multiply excited states, as shown in **Figure 2b** and **2c** (configuration interaction). The difference between the Hartree–Fock and the experimental energy is called correlation energy

$$E_{corr} = E_{HF} - E_{exp} \quad [11]$$

A full configuration interaction for the obtainment of the correlation energy of a molecule is in most cases an unfeasible computational task, and an estimate of the major contribution to the correlation energy can be afforded by perturbation methods where the Hartree–Fock Hamiltonian is assumed as the unperturbed part of the Hamiltonian. However, even at a perturbation or multiperturbation level the calculation of the correlation energy is computationally too demanding for medium- or large-size molecules.

Density-Functional Theory and the Kohn–Sham Equations

The computational demand for post Hartree–Fock (correlated) calculations does not allow the application of accurate quantum mechanical methods to systems of practical interest, such as biological molecules, macromolecules, solutions, and condensed phases. A way around this problem has been furnished by the DFT based on the Hohemberg–Kohn theorems. The first theorem states that, for a multi-electron system in the ground state, the expectation value of any physical observable O is a unique functional of the electron density ρ, unique in the sense that it will not depend on the external potential (which, in the case of interest, is the nuclear potential)

$$\langle \Psi_0 | \hat{O} | \Psi_0 \rangle = F_{HK}[\rho] \quad [12]$$

The electron density thus determines the kinetic and potential energy of the system and the total energy. One can write the total electronic energy E_v as the sum of the kinetic T, electron–electron E_{ee} and

the electron–nuclei E_{en} energy

$$E_v[\rho] = T[\rho] + E_{ee}[\rho] + E_{en}[\rho] = \int \rho(r)V(r)\,dr + F_{HK}[\rho] \quad [13]$$

where

$$F_{HK}[\rho] = T[\rho] + E_{ee}[\rho] \quad [14]$$

and $V(r)$ is the nuclear potential in the present case. The electron–electron repulsion term E_{ee} now includes the classical term and all the exchange and correlation terms. If the functional F were known, by application of the variational principle, guaranteed by the second Hohemberg–Kohn theorem, one could determine the electron density of the system. Unfortunately, this knowledge is not available. However, the Hohemberg–Kohn theorems are the foundation of a theory allowing the search of solutions of increasing accuracy.

From a practical point of view, one can resort to the Kohn–Sham scheme where it is assumed that there is an auxiliary system of noninteracting electrons subject to a local potential V_s with Hamiltonian

$$H_s = T_s + V_s \quad [15]$$

and energy

$$E_s = T_s + \int dr\, V_s\rho_s(r) \quad [16]$$

with the property of having the same electron density ρ_0 as the real system. In the Kohn–Sham approach, one considers a one-particle Schrödinger equation

$$H_{KS}\psi_i = \left(-\tfrac{1}{2}\nabla^2 + V_s\right)\psi_i = \varepsilon_i\psi_i \quad [17]$$

and the Kohn–Sham occupied orbitals give the exact electron density. The total energy of the system of interacting particles subjected to an external potential V is given by

$$E_v[\rho_0] = T_s[\rho_0] + \int dr\, V(r)\rho_0(r) - \frac{1}{2}\int dr\, dr' \frac{\rho_0(r)\rho_0(r')}{|r-r'|} + E_{xc}[\rho_0] \quad [18]$$

and the crucial quantity is the exchange correlation functional E_{xc}. As a useful approximation (LDA, the local-density approximation), the exchange correlation functional can be calculated using the homogeneous electron gas expression $\varepsilon_{xc}(n)$ substituting the constant density n with the local density $\rho(r)$ of the inhomogeneous system

$$E_{xc} = \int dr\, \rho(r)\varepsilon_{xc}[\rho(r)] \quad [19]$$

Several improvements are possible to the LDA approximation. Since the exchange correlation functional depends on the electron density, an iterative procedure can be used. A starting electron density is obtained as a superposition of the atomic electron densities for a given nuclear configuration. The main advantage of the DFT approach in quantum mechanical calculations of molecules is the drastic reduction of computational time while all exchange and correlation terms are included. This allows one to perform calculations on more complicated systems such as large molecules or macromolecules or biological systems, liquids, solids, and solutions. One of the major successes of the DFT in molecular systems has been achieved by extending the approach to molecular dynamics simulation with an on-the-fly calculation of intermolecular forces. This has allowed a reasonably realistic representation of complex systems including chemical reactions. Attempts to extend the application of the DFT to excited states are ongoing.

The Valence Bond Theory

The molecular orbitals method discussed above describes the molecule as an arrangement of nuclei in some equilibrium configuration and generating a field, in which the interacting electrons move. Therefore, in principle the structure of the atoms forming the molecule is not relevant, even though for practical purposes the molecular orbitals are expressed as a linear combination of atomic orbitals. The approach of the valence bond theory is quite different and closer to the chemical point of view that the molecule is made by interacting atoms. The valence bond theory accounts for the formation of a chemical bond as a result of the interaction of two atoms when the interatomic distance becomes reasonably short. Actually, the first quantum mechanical description of the chemical bond in the hydrogen molecule was reported by Heitler and London in 1927 according to the valence bond approach. Considering two hydrogen atoms H_A and H_B in their ground state with the unpaired electron in the respective 1*s* orbitals (φ_A and φ_B), at large separation the total wave function of the couple will be

$$\Psi_I = \varphi_A(1)\varphi_B(2) \quad [20]$$

When the two atoms are close enough such that the atomic electron clouds overlap, the above wave

function is not appropriate since the two electrons are identical particles and Ψ_I distinguishes between the two by assigning electron 1 to atom A and electron 2 to atom B. The wave function

$$\Psi_{II} = \varphi_A(2)\varphi_B(1) \qquad [21]$$

gives an equivalent description of the system and the idea of the valence bond theory is that the wave function of the system (the hydrogen molecule in the present case) is a linear combination of the two,

$$\Psi = a\Psi_I + b\Psi_{II} \qquad [22]$$

The coefficients can in general be determined variationally but, in the case of the hydrogen molecule, the symmetry requires that $a = \pm b$ and their values can be found by the normalization condition. The Ψ_+ state has energy lower than the separated atoms and corresponds to the ground state. The correct antisymmetric character of the wave function can be ensured by multiplying the orbital part by an antisymmetric spin term. Alternatively, introducing the spin directly, the Ψ_I and Ψ_{II} components can be expressed in the form of Slater determinants.

Along the same lines, the valence bond theory can be applied to more complicated molecules by considering the formation of the individual bonds by spin-coupling unpaired electrons of the atoms that form the molecule. Each possible coupling scheme of the electrons corresponds to a Slater determinant and the total wave function is a linear combination of the determinants corresponding to independent coupling schemes.

At the lowest level of approximation, the valence bond treatment of the hydrogen molecule gives better results than the molecular orbital method with the molecular orbitals expanded in the minimal basis set (the 1*s* orbitals of the two atoms in the case of the H_2 molecule). However, it can be seen that when the configuration interaction is applied to the molecular orbital method and the ionic formulas with the two electrons in turn on the same atom are included in the valence bond theory, the two methods converge to the same result.

The Molecular Orbital Description of Biatomic Molecules

It is useful to consider the results of the molecular orbital methods for the homonuclear diatomic molecules of the second row of the periodic table (Li_2, Be_2, B_2, C_2, N_2, O_2, F_2, and Ne_2), since the same concepts can be easily extended to more general cases. In the simplest approximation, the molecular orbitals are expanded in the minimal basis set, that is, in the 1*s*, 2*s*, $2p_x$, $2p_y$, and $2p_z$ orbitals of the two atoms. In principle, the molecular orbitals will be linear combinations of all the atomic orbitals of the basis set. In practice, the different overlap of the atomic orbitals and symmetry restrictions make it possible to approximately represent the molecular orbitals as linear combinations of the corresponding atomic orbitals two-by-two, as shown in **Figure 3**.

This gives an approximate ordering of the energy of the molecular orbitals. The structure of the molecule is then obtained by allocating the electrons in the molecular orbitals according to the Pauli exclusion principle.

Biatomic (and linear) molecules have axial symmetry and, therefore, the Hamiltonian commutes with the *z*-component L_z of the angular momentum (*z* is intended as the molecular axis). The molecular orbitals will then be eigenfunctions of the L_z operator as well and they can be classified according to the M_z quantum number as σ ($M_z = 0$), π ($M_z = 1$), δ ($M_z = 2$) orbitals, etc. In addition, the molecular orbitals can be also classified in terms of the atomic orbitals that are formed when the atoms separate at infinite interatomic distance (separated-atoms approximation). The molecular orbitals in **Figure 3** are labeled according to these rules. In addition, the *g* and *u* labels indicate the symmetric and antisymmetric character of the orbital with respect to the inversion center, respectively. Finally, the asterisk labels the molecular orbitals that are antisymmetric for a reflection in a plane perpendicular to the molecular axis. As can be seen from **Figure 3**, the latter are antibonding orbitals, that is, their energy is higher than the energy of the atomic orbitals from which they are formed as linear combinations.

As an example, the ground-state configurations of the nitrogen and oxygen molecules are

$$N_2: \quad (\sigma_g 1s)^2(\sigma_u^* 1s)^2(\sigma_g 2s)^2(\sigma_u^* 2s)^2(\sigma_g 2p_z)^2(\pi_u 2p_x)^2 (\pi_u 2p_y)^2$$

$$O_2: \quad (\sigma_g 1s)^2(\sigma_u^* 1s)^2(\sigma_g 2s)^2(\sigma_u^* 2s)^2(\sigma_g 2p_z)^2(\pi_u 2p_x)^2 (\pi_u 2p_y)^2(\pi_g^* 2p_y)(\pi_g^* 2p_y)$$

and the ground-state wave function can be consequently written as a Slater determinant. In particular, it can be seen that the molecular orbital approach simply explains the paramagnetic character of the oxygen molecule arising from the presence of two unpaired electrons in the degenerate π_g orbitals.

The ordering of the molecular orbitals can change significantly along the second row of the periodic table. A qualitative idea of these changes can be obtained by considering not only the above separated-atoms

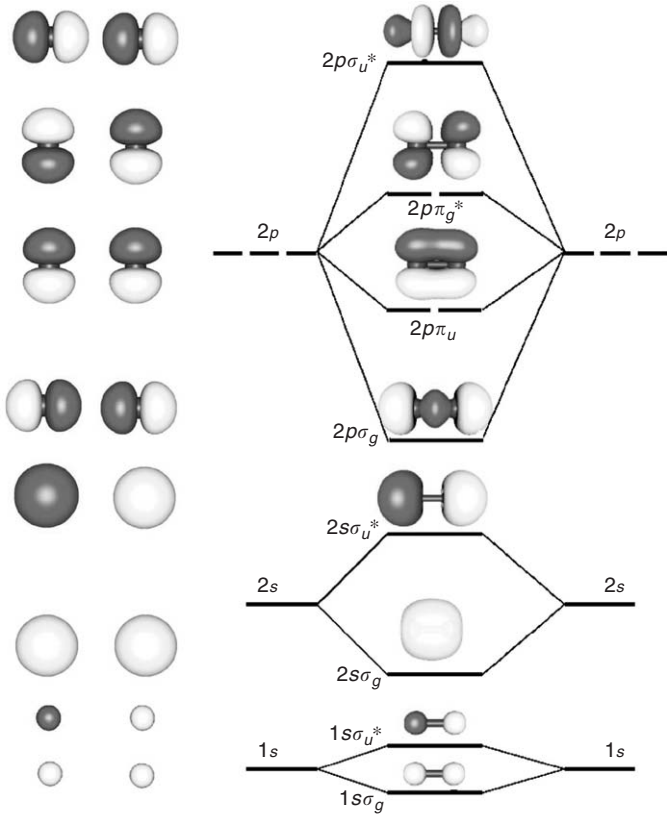

Figure 3 Schematic representation of the molecular orbitals of second row diatomic states obtained as a linear combination of the relevant atomic orbitals.

limit but also the united-atom approximation correlating the molecular orbitals with the atomic orbitals resulting at zero interatomic separation. A correlation diagram can then be obtained (shown in **Figure 4**) between the united- and separated-atoms limits that gives an idea of the changes in the molecular orbitals energy as a function of the interatomic separation. The diagram is constructed by considering that the orbital symmetry is conserved at all interatomic distances.

As discussed earlier, an accurate fit of the molecular energy and structure cannot be obtained by representing the molecular wave function as a single Slater determinant and with the expansion in the minimal basis set. For accurate prediction of molecular properties, it is necessary to use an extended basis set and to take account of the correlation energy as discussed earlier. The same qualitative description can be given for a heteronuclear diatomic molecule. In this case, however, the distinction into *g* and *u* type molecular orbitals is obviously lost and, in addition, the coefficients of the linear combinations of atomic orbitals are different for the two atoms. This will result in the presence of a nonzero electric dipole moment in heteronuclear diatomics.

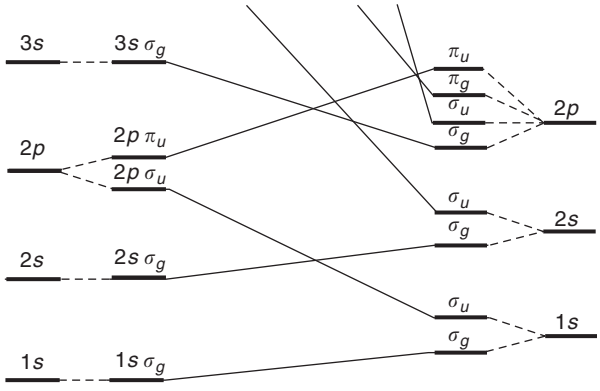

Figure 4 Molecular orbital theory. Correlation of molecular orbital energy of first and second row diatomic states between the united atom (left) and separated atom limits (right).

Quantum Mechanics and Symmetry of Molecules

The symmetry group of a molecule (point group) can be defined as the collection of symmetry operations that commute with the Hamiltonian. These are unitary transformations of two types: proper rotations (rotations of an angle $(2\pi/n)k$ around a C_n symmetry

Table 1 The irreducible representation of the symmetry group of the H_2O molecule (*yz* is the plane of the molecule)

C_{2v}	E	C_2^z	σ_{yz}	σ_{xz}
A_1	1	1	1	1
A_2	1	1	−1	−1
B_1	1	−1	1	−1
B_2	1	−1	−1	1

axis, with $k = 0, 1, \ldots, n-1$) and improper rotations (rotations around an axis followed by a reflection through a plane perpendicular to the axis). The latter include, as particular cases, the inversion through a center and the reflection through a plane. There are compatibility relations among the symmetry operations of a point group and it turns out that most molecules belong to one of the 32 crystallographic point groups. Since all the symmetry operations of a molecule commute with the Hamiltonian operator, the molecular wave functions must also be eigenfunctions of the symmetry operators. As a consequence, the molecular orbitals and the total electronic wave function form the basis for the irreducible representations of the molecular symmetry group. As an example, the water molecule belongs to the C_{2v} symmetry group, a group of order 4, including as operations the identity E, a rotation C_2, and two reflection operations σ_1 and σ_2. The molecular orbitals will necessarily behave as one of the irreducible representations of the C_{2v} group that are labeled as A_1, B_1, A_2, and B_2 (see **Table 1** and **Figure 5**).

Expanding the molecular orbitals as a linear combination of the minimal basis set (including the 1*s* orbitals of the hydrogens and the 1*s*, 2*s*, $2p_x$, $2p_y$, and $2p_z$ orbitals of the oxygen atom), one obtains seven molecular orbitals. The characters of the completely reduced representation of the molecular orbitals are the same as the characters of the reducible representation of the atomic orbitals. By analyzing the reducible representation of the atomic orbitals, one obtains the symmetry of the molecular orbitals; in the present example,

$$\Gamma = 4A_1 + 2B_1 + B_2$$

Using the appropriate projection operators, the atomic orbitals can be linearly combined into symmetry-adapted functions according to the above reduced representation. With this choice, the Fock matrix entering in the Roothan equations is block-diagonalized into three blocks of dimensions 4, 2, and 1. The resulting approximate form of the molecular orbitals of water is shown in **Figure 5**. The electronic ground state of the water molecule

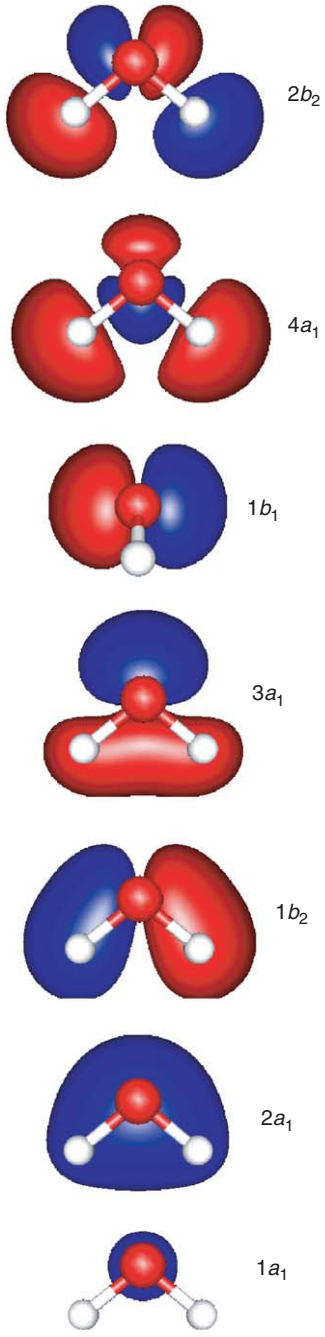

Figure 5 Schematic representation of the molecular orbitals of the H_2O molecules classified by their symmetry character and in order of increasing energy.

corresponds to the configuration

$$(1a_1)^2(2a_1)^2(1b_2)^2(3a_1)^2(1b_1)^2$$

and its symmetry is given by the direct product of the representations of the occupied molecular orbitals. In the present case of a closed-shell molecule (with

double occupancy of the orbitals), the total wave function turns out to be totally symmetric with spin multiplicity equal to 1 (a singlet state $^1A_1$).

The Nuclear Schrödinger Equation

The solution of the Schrödinger equation for the nuclear motion (with the Hamiltonian defined in [3]) can be obtained by first decoupling the translational, rotational, and vibrational degrees of freedom. For this purpose, one can define a laboratory X, Y, Z and a molecule-fixed x, y, z Cartesian reference system. The position of each nucleus α, with mass m_α, is then specified by giving the three Cartesian coordinates of the origin of the molecule-fixed system, three Eulerian angles describing the orientation of the molecular axes relative to the laboratory axes and, for an n-atomic molecule, the $3n$ coordinates in the molecular reference frame x_α, y_α, z_α. Among the latter, there are two vectorial relations specifying the position of the origin of the molecule-fixed system, placed at the center of mass,

$$\sum_\alpha m_\alpha \boldsymbol{r}_\alpha = 0 \qquad [23]$$

and the orientation of the molecule-fixed system

$$\sum_\alpha m_\alpha \boldsymbol{a}_\alpha x^* \boldsymbol{r}_\alpha = 0 \qquad [24]$$

where $\boldsymbol{a}_\alpha$ denotes the equilibrium position of atom α. With this choice of the reference system, it can easily be shown that the translational degrees of freedom are completely decoupled from the rotational and vibrational degrees of freedom. Therefore, the translational motion of the molecule can be conveniently treated with the particle-in-a-box model. However, there is still a Coriolis coupling between the rotational and vibrational motions. Considering that the vibrational velocities are much higher than the rotational velocities, the Coriolis coupling can be considered to be small for vibrational motion but can be substantial for the rotational motion. In condensed phases, where the molecules cannot rotate freely, the rotational–vibrational coupling is eliminated.

The Vibrations of Molecules

The potential governing the vibrational motion of a molecule can in principle be obtained from an *ab initio* calculation of the electronic energy. In practice, the potential is expanded around the equilibrium configuration and in the harmonic approximation it is in the quadratic form

$$V = \frac{1}{2}\sum_{ij} f_{ij}\rho_i\rho_j \qquad [25]$$

where ρ is a $3n$-dimensional vector of the Cartesian displacements, from the equilibrium. To fully decouple the problem, it is appropriate to transform to a set of $3n$ normal coordinates Q_k, linear combinations of the Cartesian displacements that simultaneously diagonalize the kinetic and potential energy,

$$H = T + V = \frac{1}{2}\sum_k P_k^2 + \frac{1}{2}\sum_k \lambda_k Q_k^2 \qquad [26]$$

where P_k is the conjugate momentum and $\omega_k = \sqrt{\lambda_k}$ is the classical normal frequency of vibration. Because of the relations [23] and [24], six (five in the case of linear molecules) of the normal coordinates describe overall translations and rotations of the molecule and the corresponding frequencies are zero. Neglecting the zero-frequency normal coordinates and writing the vibrational wave function as a product of functions of the individual remaining normal coordinates,

$$\psi_v(Q_1Q_2\ldots) = \psi(Q_1)\psi(Q_2)\cdots\psi(Q_{3n-6}) \qquad [27]$$

The vibrational Schrödinger equation

$$\left(\sum_k -\frac{\hbar^2}{2}\nabla_k^2 + \sum_k \lambda_k Q_k^2\right)\psi_v(Q_1Q_2\ldots) = E_v\psi_v(Q_1Q_2\ldots) \qquad [28]$$

can be separated into $3n-6$ (or $3n-5$) harmonic oscillator equations,

$$-\frac{\hbar^2}{2}\nabla_k^2\psi(Q_k) + \lambda_k Q_k^2\psi(Q_k) = E_k\psi(Q_k) \qquad [29]$$

Therefore, the vibrational eigenfunction is the product of $3n-6$ harmonic oscillators functions

$$\psi_v = \prod_k \psi_{n_k}(Q_k) = C\exp\left(-\frac{1}{2}\sum_k \gamma_k Q_k^2\right)\prod_k H_{n_k}(\gamma_k^{1/2}Q_k) \qquad [30]$$

where C is a normalizing factor, $\gamma_k = \omega_k/\hbar$, and H_{n_k} is the Hermite polynomial of degree n_k. A vibrational state is specified by $3n-6$ quantum numbers $(n_1n_2\ldots n_k\ldots n_{3n-6})$. The vibrational energy

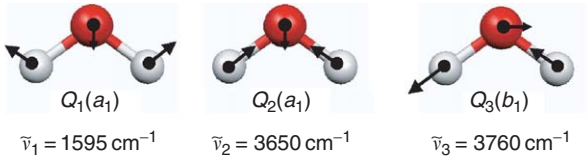

Figure 6 Normal modes of vibration of the water molecule.

is given by

$$E_v = \sum_k \hbar\omega_k (n_k + \tfrac{1}{2}) \qquad [31]$$

In **Figure 6** the vibrational normal modes (or the normal coordinates) of the water molecule are represented.

The normal coordinates form a basis for a completely reduced representation of the molecular point group. The characters of this reduced representation can be obtained from the equivalent representation of the Cartesian displacements since the normal and Cartesian coordinates are related by a linear transformation. By eliminating the zero-frequency normal coordinates, one obtains for the water molecule that the normal coordinates (or the wave functions with quantum numbers (1 0 0), (0 1 0), and (0 0 1)) classify in the irreducible representations of the symmetry group

$$\Gamma = 2A_1 + B_1$$

as seen from **Figure 6**. Qualitative information on the form of the normal coordinates can be obtained by using symmetry arguments and internal coordinates (stretching and bending of bonds and torsional coordinates) instead of Cartesian coordinates.

Symmetry arguments can also be used to obtain the selection rules for transitions between two vibrational eigenstates i and f. In the infrared absorption spectroscopy, the relevant operator is the electric dipole moment P and the transition probability is proportional to

$$|\langle \psi_f | P | \psi_i \rangle|^2 \qquad [32]$$

Symmetry considerations require that the transition probability is nonzero when the direct product of the irreducible representations of the terms appearing in the matrix element $\Gamma_f \otimes \Gamma_P \otimes \Gamma_i$ contains the totally symmetric representation. The spectrum is dominated by the fundamental transitions from the ground state (totally symmetric) to states where a single quantum number is equal to 1. These have nonzero transition probability if the corresponding normal coordinate belongs to the same irreducible representation as one of the components of the electric moment. Nonlinearities in the expansion of the electric moment and anharmonic terms of the potential make multiple transitions weakly active in the infrared spectrum. Vibrational transitions can also be observed directly in the Raman spectrum. In this case, the relevant operator is the molecular polarizability and the selection rules are consequently different.

Rotation of Molecules

The rotation of a diatomic molecule can, to a first approximation, be described by the rigid rotator model and the rotational Hamiltonian can be written as

$$H_r = \frac{1}{2I} L^2 \qquad [33]$$

where I is the inertia moment and L is the angular momentum operator. The rotational eigenfunctions are, therefore, the spherical harmonics and the rotational energy levels are given by

$$E_J = B_0 J(J+1) \qquad [34]$$

where $B_0 = \hbar^2/2I$ is the rotational constant and J is the rotational quantum number ($J = 0, 1, 2\ldots$). The rotational levels and eigenfunctions have $2J+1$ degeneracy in consideration of the possible orientation of the angular momentum. The rotational constant refers to the vibrational (and electronic) ground state. The inertia moment and the rotational constant change in vibrational excited states. The rotational constant also changes, which in turn changes the rotational level because of centrifugal distortion effects, and in each vibrational state n the energy levels of the rotating molecule should be written as

$$E_r = B_n J(J+1) - D_n J^2 (J+1)^2 \qquad [35]$$

where the centrifugal distortion constant D_n is much smaller than the rotational constant and can be related to the vibrational force constants. As a consequence of the second term in [35] in the pure rotational spectrum (selection rule $\Delta J = \pm 1$), the lines are not exactly equidistant.

The rotational problem of polyatomic molecules is considerably more complicated. The structure of the spectrum is determined by the relative values of the principal inertia moments. In the case of symmetric-top molecules, for which

$$I_{xx} = I_{yy} = I_\perp, \qquad I_{zz} = I_{||} \qquad [36]$$

the rotational Hamiltonian has the form

$$H_r = \frac{1}{2I_\perp} L^2 + \left(\frac{1}{2I_{||}} - \frac{1}{2I_\perp} \right) L_z^2 \qquad [37]$$

and the eigenvalues are

$$E_{JK} = \frac{\hbar^2}{2I_\perp} J(J+1) + \hbar^2 \left(\frac{1}{2I_{||}} - \frac{1}{2I_\perp} \right) K^2, \quad K = J, J-1, \ldots \qquad [38]$$

and the selection rule is

$$\Delta J = \pm 1, \qquad \Delta K = 0 \qquad [39]$$

Quantum Mechanics: Nuclei

R A Broglia, University of Milan, Milan, Italy

Introduction

The atom is the smallest unit into which matter that has the characteristic properties of a chemical element can be divided. Most of the atom is empty space. The rest consists of a cloud of negatively charged electrons whirling around a small, very dense, positively charged nucleus made of protons and neutrons which contains essentially all the mass of the atom. The electric forces bind the electrons to the nucleus giving rise to a miniature planetary-like system. The strong and Coulomb forces acting among nucleons lead to a self-bound system. Inside it, nucleons move essentially independent of each other. Bouncing in their trajectories elastically off the nuclear surface, they describe closed orbits which resemble, at a length scale five orders of magnitude smaller, those of the electrons in the atom.

The Atomic Nucleus

Nucleons, like electrons are fermions, that is, they have a half-integer spin $(1/2, 3/2, \ldots)$, and, according to quantum mechanics, obey the Pauli exclusion principle which allows only one particle to occupy each quantal state. Consequently, for the ground state of the system, the available orbitals of the mean field are filled from the bottom upwards to the Fermi energy. Under normal conditions, atomic nuclei are in their ground state, that is, at zero temperature. This is because nuclei on earth, leaving aside those that arrive in the form of cosmic rays, are isolated. In fact, for two nuclei to interact, they need to have large kinetic energies, of the order of tens of MeV ($1\,\text{MeV} = 10^6\,\text{eV}$), so as to be able to overcome the Coulomb repulsion in a collision and reach within the range of the nuclear attraction. Energies of such magnitude contrast with the energies available at room temperature ($\approx 25 \times 10^{-3}$ eV). This is the reason why one needs large machines, so called atomic smashers, to make two atomic nuclei interact. In these machines, an atom containing a heavy atomic nucleus is stripped of most of its electrons becoming a heavy ion, which is subsequently accelerated and collimated. The resulting beam, aimed at a target of other heavy atomic nuclei, eventually leads to a heavy ion reaction (**Figure 1**).

In the event where the two nuclei fuse, the energy and angular momentum of relative motion become mostly excitation energy and angular momentum of the composite system. Typical values of these quantities are set (**Figure 2**), in relation to temperatures and rotational frequencies observed in other

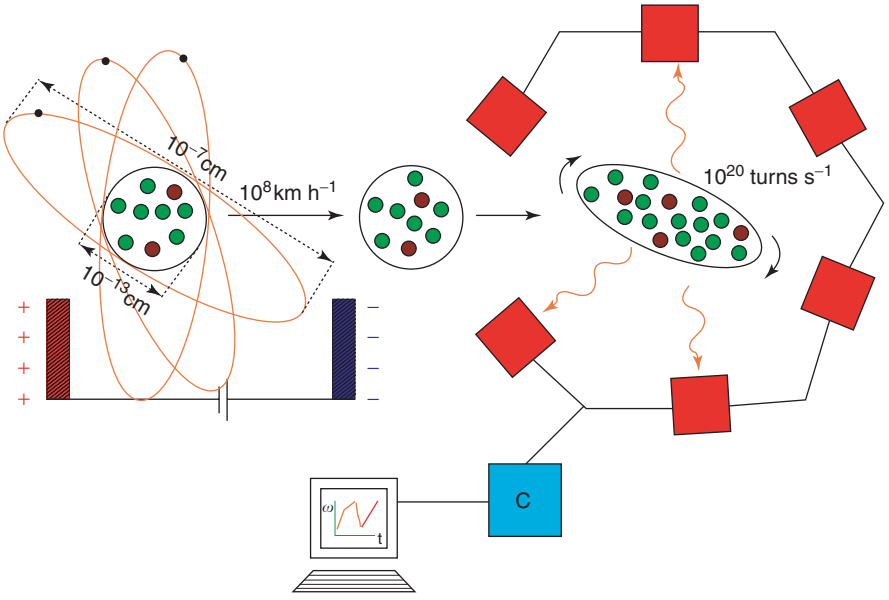

Figure 1 Schematic representation of a heavy ion accelerator used to induce nuclear reactions. A neutral atom (left part of the figure), formed of a nucleus made of protons (red dots) and neutrons (green dots), is stripped off the electrons (small black dots) moving around it. The system becomes positively charged and the resulting heavy ion is accelerated to velocities $\sim$100 millions of kilometers per hour in an electric field and smashed against the atomic nuclei of a target (middle). Out of the violent encounter between the two atomic nuclei, a number of processes can take place: Coulomb excitation, particle transfer, etc. In some cases the two nuclei fuse, leading to a highly excited, rapidly rotating compound nucleus (right) which, in the process of cooling down, emits nucleons, alpha particles and γ-rays (wavy arrows). These γ-rays (photons) can be detected by use of a so-called 4π-array, that is a set of detectors (red squares) covering a consistent fraction of the solid angle. Once the signal is collected, it is analyzed making use of specifically developed computer programs (software labeled C) and the results are eventually displayed on a screen.

physical systems. The thermalization of such a system depends, naturally, on the specific heat of the system, a quantity which is directly related to the density of levels around the Fermi energy.

Single-Particle Motion

To study the single-particle motion in nuclei, the best probe one can use are transfer reactions. For example, aiming a beam of deuterons (the isotope $^{2}_{1}\mathrm{H}_{1}(\equiv d)$ of hydrogen containing one proton and one neutron) on a target nucleus, one can learn about the properties of the single-particle neutron levels lying above the Fermi energy, by studying the spectrum and angular distribution of the emerging protons, resulting from the stripping of a neutron from the projectile (**Figure 3**). The main outcome of these studies, in particular of those carried out on the closed-shell nucleus ^{208}Pb, shows that the mean-field theory is able, in most cases, to correctly predict the sequence of single-particle levels.

Collective Motion

Nuclear vibrations are excited by bombarding nuclei with high-energy photons, nucleons, electrons, etc. The vibrations are detected by observing how photons are absorbed by the nucleus, or how protons are scattered inelastically from the nuclear surface, etc. These experiments reveal that the nucleus displays both elastic and plastic behavior. In fact, the so-called giant dipole resonance corresponding to a back- and -forth sloshing of protons against neutrons, excited in photoabsorption experiments has an energy centroid which scales with the inverse of the radius of the nucleus (a dependence observed for all nuclear resonances), that is, with the nuclear momentum, a behavior typical of elastic vibrations. Once excited into a giant dipole resonance, the nucleus vibrates at an extremely high frequency, of the order of 5×10^{21} Hz (which corresponds to a vibrational energy of $\sim$20 MeV). To make more vivid the qualification of "extremely" used above, it is useful to remember that the nominal range of human hearing extends from about 20×10^{4} to 2×10^{4} Hz, while that of human vision ranges from 4×10^{14} to 8×10^{14} Hz. In order to excite giant resonances with suitable cross sections, use has to be made of fields that change quickly with time, with frequencies of the order of those associated with single-particle motion ($1/\omega \equiv 10^{23}$ Hz).

The lowest excited states of even–even nuclei display, with very few exceptions, quadrupole and

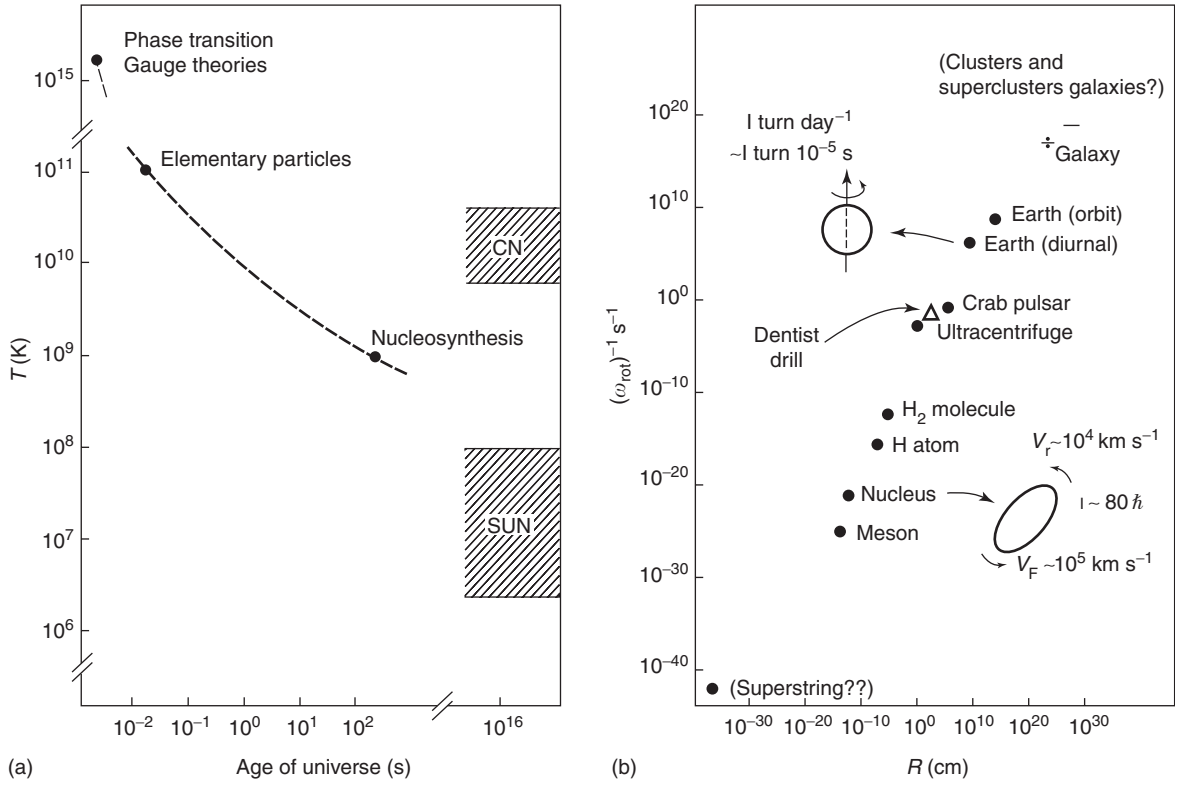

Figure 2 Temperatures and rotational frequencies typical of reactions where two heavy ions fuse and eventually, after a time of the order of a few times 10^{-21}s equilibrate all their degrees of freedom, forming a single compound nucleus. (a) The scale of temperature has been set in connection with the temperature ascribed to the Universe at different times after the Big Bang through the first 3 min to our times. (b) The inverse of the rotational period (in seconds) of a variety of rotating objects observed (or thought to exist, like superstrings which are the mathematical connotation of an elementary particle) in the Universe from the largest to the smallest, are quoted as a function of their radius. Both the inverse frequencies and the radii span 60 orders of magnitude, the relation between the two quantities being almost linear.

octupole character, that is, they correspond to surface collective vibrations of multipolarity 2 and 3. The associated energies, 1–3 MeV, show a dependence with mass number inversely proportional to the area of the nuclear surface, typical of the vibrations of a liquid drop. They reflect the plastic properties of atomic nuclei. In fact, away from closed shells, the energy of the lowest $2+$ state can become particularly low in energy (**Figure 4**). In these nuclei (^{152}Sm,^{154}Sm, or e.g.,^{238}U), the $2+$ state is the lowest member of the so-called ground-state rotational band of a spheroidal nucleus rotating around an axis perpendicular to the symmetry axis (**Figure 5**). These states are excited with large cross sections by Coulomb and by nuclear fields which change slowly in time ($1/\omega \equiv 10^{20}$ Hz), as compared with typical frequencies associated with single-particle motion.

Further evidence of the plastic behavior of the nucleus is provided by nucleon fission. This process can be viewed as the division, similar to that of a cell, of a liquid drop into two smaller droplets as a result of deformation (**Figure 6**). All these phenomena are essentially controlled by the nuclear surface.

Pairing

The theory describing the coupling of the nucleons to vibrations and to static deformations of the nuclear surface provides a unified description of liquid drop and of independent-particle behavior.

The rotational motion is one of the simplest and, at the same time, most profound examples of periodic motion (think only of the earth's rotation around itself and around the Sun, and of the succession between day and night and between summer and winter). A detailed study of the rotational frequency and of the variations of the rotational period as a function of time can provide important information on the physical properties of the system under study and on the forces acting inside it.

Strongly rotating nuclei (**Figure 2**) can be produced in the laboratory either via a Coulomb excitation (**Figure 5**) or in fusion processes (**Figure 1**). Because

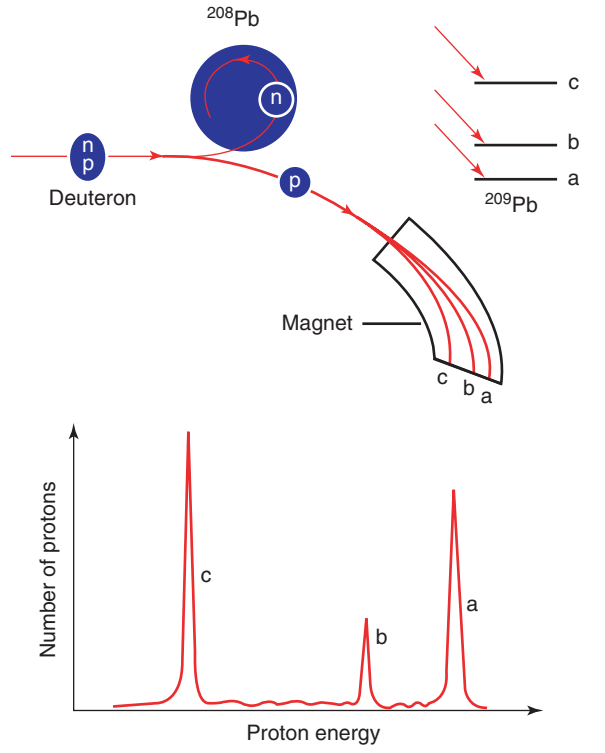

Figure 3 Nuclear reaction in which a neutron is transferred from the projectile (deuteron) to the nucleus ^{208}Pb. The energy of the outgoing proton reflects both the Q-value of the reaction and the energy of the final state of the system.

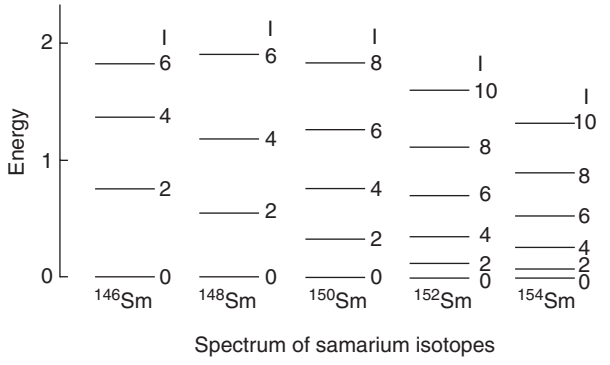

Figure 4 Sequence of positive parity states of the isotopes of ^{62}Sm. The energy scale is in MeV.

the system is charged, the rotating nucleus emits "light," that is gamma-rays which provide detailed information on the properties of the system. A surprising result emerging from such measurements is that at low rotational frequencies, the moment of inertia of the system is considerably smaller, about half of the expected (rigid) moment of inertia, while at higher rotational frequencies the moment of inertia coincides more or less with the rigid moment of inertia of the system. The explanation of this behavior is connected with the fact that the nucleus, which in connection with the present discussion can be viewed as a spheroidal container, is filled at low rotational frequencies with a nonviscous (superfluid) liquid. Spinning the container, only the matter at the poles, that is, the matter directly pushed by the walls (surface) of the container, is set up into motion, the central core remaining at rest (**Figure 7**). On the other hand, at high rotational frequencies the nucleus displays a phase transition, into a system of nucleons moving independently of each other in well-defined orbits (normal system). Each of these orbits are solidly anchored to the mean field (surface) of the nucleus. Consequently, each nucleon inside the nucleus reacts to a change in the rotational frequency with its full mass. The collective motion of the system thus coincides with that of a rigid body of the same mass, dimension, and deformation of the nucleus under study.

These phenomena are closely connected with the variety of effects belonging to the field of low-temperature physics, which go under the name of "superconductivity" when they occur in an electric charged system such as electrons in a metal, and "superfluidity" when they occur in a neutral system such as an insulating liquid. The behavior of a superconducting metal is qualitatively different from that of a normal metal, in that it conducts electricity with zero resistance (hence the name). Similarly, a liquid that is superfluid can flow through tiny capillaries without apparent friction, and can even climb up over the rim of a vessel containing it and thereby gradually empty the vessel.

Bose–Einstein Condensation

To sketch the general picture, let the focus be on the common isotope of helium (^{4}He). Such an atom has zero total spin, and therefore, according to quantum mechanics should obey Bose–Einstein statistics. Consequently, when a large number of such particles are placed in a restricted volume and are cooled down below a certain temperature (which for helium turns out to be ~ 3 K), a phenomenon called "Bose–Einstein condensation" (BEC) takes place: namely, a finite fraction of all the atoms begins to occupy a single quantum-mechanical state, the fraction increasing as the temperature decreases. Thus, in the same way that fermions are extremely individualistic, each of them occupying a different (quantal) state, bosons are extremely gregarious and love to be in the same (quantal) state of the system. The atoms in this special situation become locked together in their motion, like soldiers in a well-drilled army, and can no longer behave independently. Thus, for example, if the liquid flows through a narrow capillary, the processes of

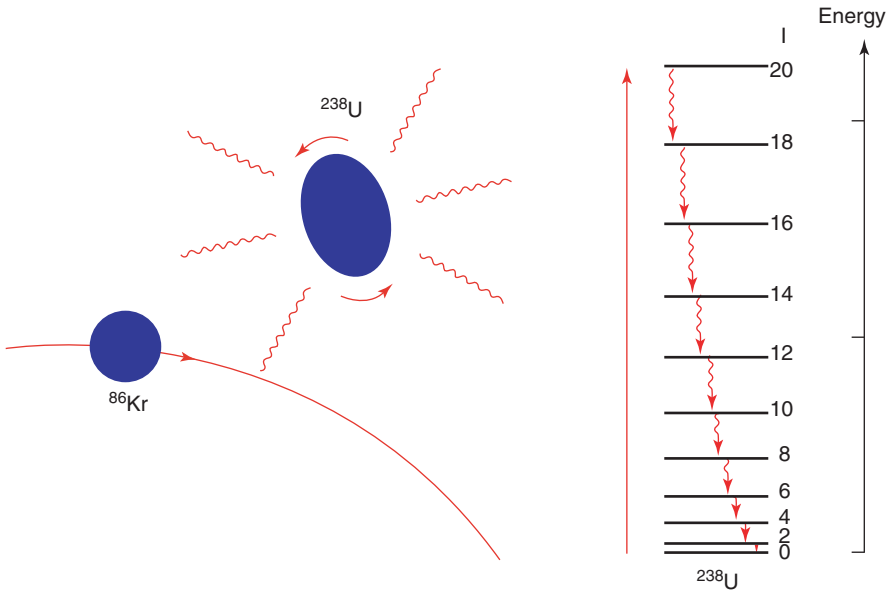

Figure 5 Excitation of the rotational motion of a (target) nucleus of ^{238}U by a ^{86}Kr projectile through the Coulomb field (Coulomb excitation). The system cools down by emitting a number of γ-rays (red wavy arrowed lines) each carrying angular momentum 2 (in keeping with the quadrupole deformation of the nucleus ^{238}U) and different energy, connecting the members of the ground-state rotational band of the system.

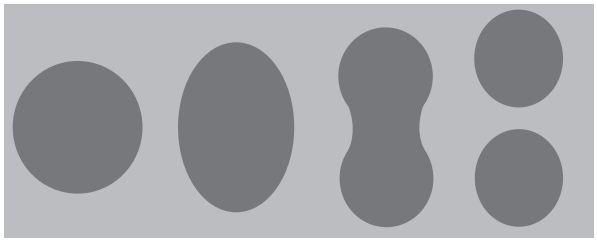

Figure 6 A schematic sequence of events in the process of spontaneous nuclear fission.

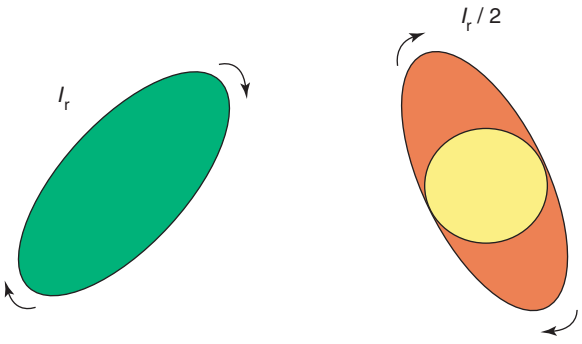

Figure 7 Schematic representation of the reaction to rotation of a deformed nucleus. In the left part of the figure, it is assumed that the system can be described in terms of the motion of independent nucleons (fermions). The associated moment of inertia is equal to the rigid moment of inertia I_r. In the right part of the figure, it is assumed that the system is filled with a superfluid fluid (made out of pairs of fermions) displaying no friction. The associated moment of inertia of this system is $\approx I_r/2$. Consequently, under rotation the central core (yellow) remains essentially at rest, the matter associated with poles (orange) being involved in the rotation.

scattering of individual atoms by roughness in the walls, which would produce so strong a viscous drag on any normal liquid as to effectively prevent it from flowing at all, is now quite ineffective, since all atoms (bosons) or none must scatter.

A similar picture applies to superconductivity in metals. However, in this case the "particles" that undergo BEC (and are therefore required to be bosons) are not individual electrons, which have spin 1/2 and are fermions. The "particles" are pairs of electrons (Cooper pairs) which form in the metal, and carry mass and charge which are double that of a single electron aside from total spin zero. Cooper pairs condense when the metal is cooled down (e.g., below 7 K in the case of lead) and occupy a single quantal state. A similar phenomenon takes place in the nuclear case, where pairs of nucleons moving in time-reversal states form Cooper pairs with total angular momentum zero (**Figure 8**). Because the nucleus in its ground state or in the states belonging to the so-called yrast band (that is the states of lowest energy for a given angular momentum, where all the energy of excitation is tied up in the collective, ordered rotational motion of the system as a whole) is at zero temperature, these Cooper pairs condense, giving rise to a superfluid nonviscous liquid.

The variation of the rotational frequency of deformed nuclei displays sharp discontinuities (**Figure 9**).

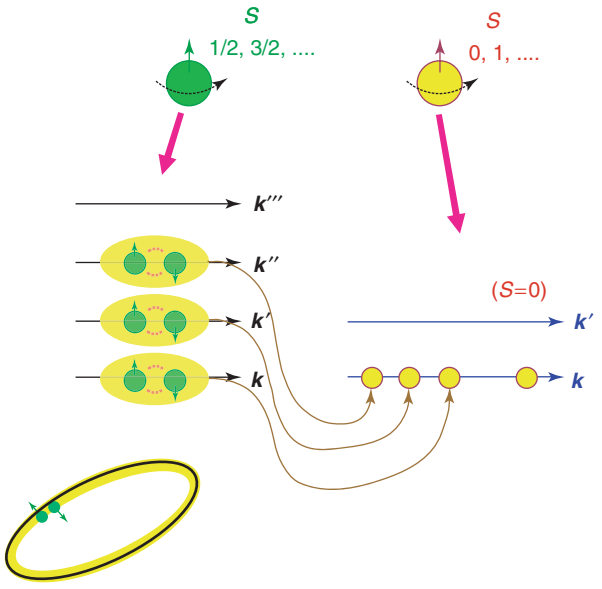

Figure 8 Particles displaying half-integer values of the spin are called fermions, fulfill Fermi–Dirac statistics, and according to the exclusion principles cannot occupy the same quantal state labeled in the figure by the quantum number ***k*** and by the intrinsic spin which can be in one of two states, namely spin up and spin down, associated with the two projections ($\pm 1/2$) of a spin $s = 1/2$ as that of the nucleon or of an electron, and explicitly shown in the figure in terms of an arrow pointing up or down respectively. Particles of integer spin are called bosons and fulfill Bose–Einstein statistics. They can all occupy the same quantal state. Coupling two fermions to integer spin, e.g., $S = 0$, one can form a boson (Cooper pair). If the temperature of the system is lower than the binding energy of the Cooper pair, a condensation phenomenon can also take place in this case. In nuclei, the interaction responsible for the formation of Cooper pairs can be viewed as a surface phenomenon effect (cf. also **Figure 11**).

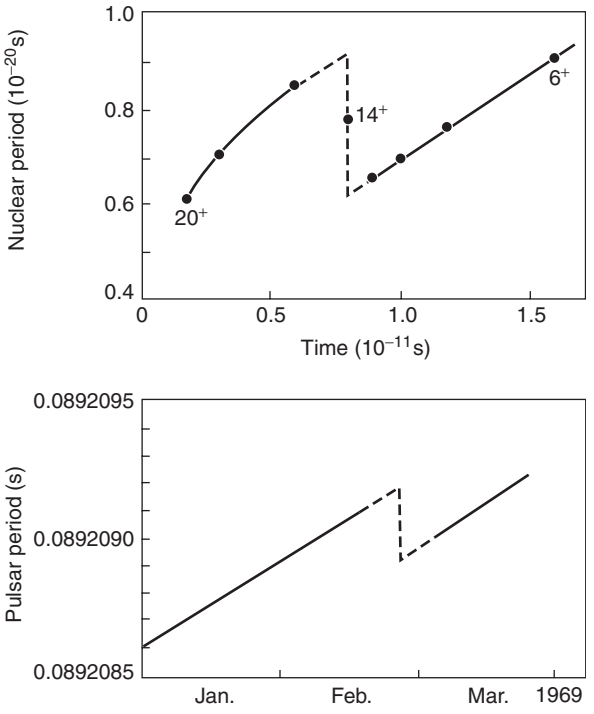

Figure 9 Plot of the rotational period vs. time for the nucleus ^{158}Er (top) and the pulsar Vela (bottom).

This phenomenon reflects the fact that rotation has an opposite effect on the motion of the two members of each Cooper pair (**Figure 10**). After a compound nucleus with high angular momentum and excitation energy has been formed in a fusion process, it cools down by evaporating particles. When the excited nucleus comes close to or eventually reaches the yrast line, it continues to slow down by emitting gamma rays each carrying two units of angular momentum. At the beginning of this process, the rotational frequency is so high that the associated energy is larger than the binding energy of each pair. Consequently, no Cooper pair is present in the system, and the nucleus behaves as a normal system displaying a rigid moment of inertia. As the nucleus continues to decrease its rotational frequency, it will eventually arrive at a (critical) frequency below which pair formation can take place, and the system can make a transition to the superfluid phase. Consequently, the moment of inertia of the system decreases by a factor of ~ 2. The rotational frequency thus increases sharply. This is because the product of the moment of inertia and the rotational frequency is equal to the total angular momentum of the system, a quantity which is conserved. Thus, the observed decrease of the rotational period is intimately related with the normal superfluid-phase transition taking place as a function of the rotational frequency. This transition is associated with a violent variation of the moment of inertia of the system, that is, to a nuclear-quake.

In the case of low-temperature superconductivity, the attraction among electrons is generated by the exchange of lattice phonons between them (and the energy needed to break the pair is of the order of a few milli (10^{-3}) electronvolts). In the nuclear case, roughly 50% of the pairing effects is due to a phenomenon similar to this one, namely the exchange of collective surface vibrations between nucleons. The other 50% is due to the strong force acting between nucleons and arising from the exchange of mesons (the carriers of the strong force) between nucleons (cf. **Figure 11**). The effect which this force has on nucleons moving in states connected by the operation of time reversal (**Figure 10**), can be measured in the scattering process between nucleons and expressed in terms of the $^1S_0$ phase shift (cf. **Figure 11** and corresponding caption). It is found that the exchange of mesons leads to a pairing force which is attractive at low relative momenta, that is, in situations similar to

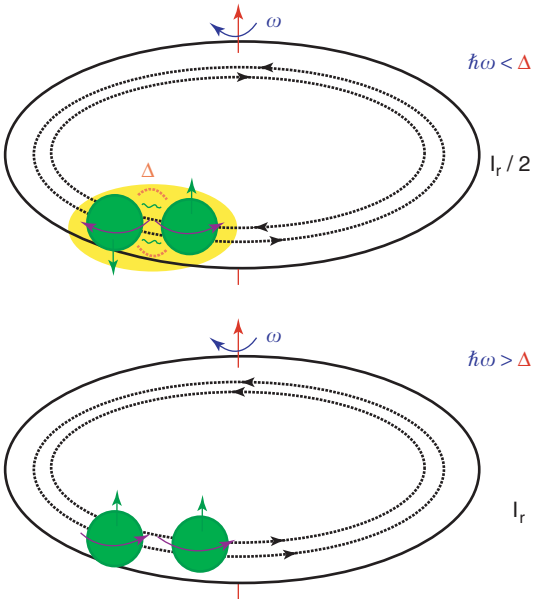

Figure 10 Pair of nucleons moving in states of time-reversal (clockwise and anticlockwise, spin up and spin down) and forming a Cooper pair in a deformed nucleus which rotates as a whole with frequency ω. The binding energy of the pair is measured by the quantity Δ, known as the pairing gap, the interaction among the nucleons being represented by red dotted curves and green wavy lines (see also **Figure 11**). For rotational frequencies such that the rotational energy $\hbar\omega$ is smaller than the pairing gap (top), the system behaves as a condensate of Cooper pairs (bosons), with the moment of inertia being one-half the rigid moment of inertia (cf. **Figure 9**). For rotational frequencies such that $\hbar\omega$ is larger than Δ, the nucleon moving clockwise in its trajectory is so much retarded in its revolution period with respect to the partner nucleon, that it cannot correlate efficiently any more with it and "align" its motion (and spin) with the rotational motion, becoming again a pair of fermions and not participating any more in the condensate (cf. **Figure 9**).

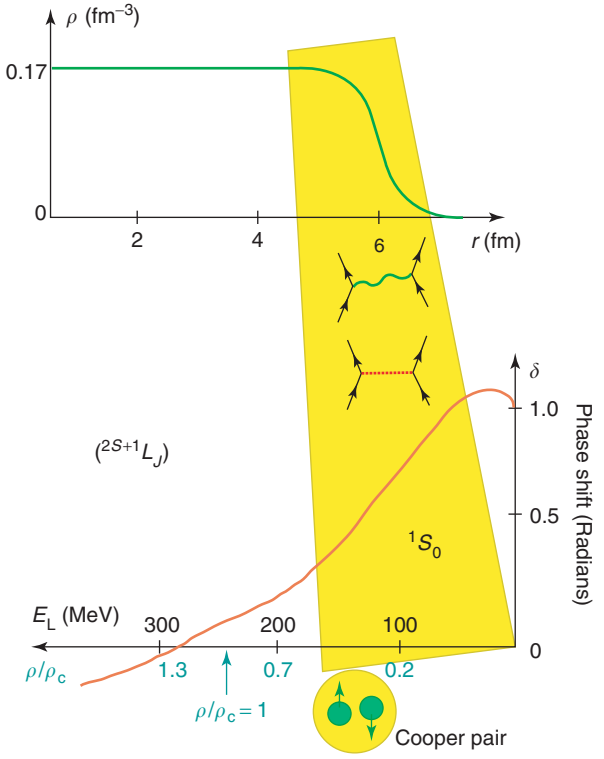

Figure 11 (top) Nuclear density ρ in units of fm^{-3} (where $\text{fm} \equiv 10^{-13}$ cm), plotted as a function of the distance r (in units of fm) from the center of the nucleus. Saturation density corresponds to $\approx 0.17\ \text{fm}^{-3}$, equivalent to $2.8 \times 10^{14}\ \text{gm cm}^{-3}$. Because of the short range of the nuclear force, the so-called strong force, the nuclear density changes from 90% of saturation density to 10% within 0.65 fm, the so-called nuclear diffusivity. (bottom) Phase parameter associated with the elastic scattering of two nucleons moving in states of time reversal, the so-called $^1S_0$ phase shift, in keeping with the fact that the system is in a singlet state of spin zero. The solution of the Schrödinger equation describing the elastic scattering of a nucleon from a scattering center (in this case another nucleon) is, at large distances from the scattering center, a superposition of the incoming wave and of the outgoing, scattering wave. The interaction of the incoming particle with the target particle changes only the amplitude of the outgoing wave. This amplitude can be written in terms of a real phase shift–or scattering phase–δ. Positive quantities of δ implies an attractive interaction, negative a repulsive one. For low relative velocities (kinetic energies E_L), i.e., around the nuclear surface where the density is low, the $^1S_0$ phase shift arising from the exchange of mesons (like, e.g., pions, represented by a horizontal dotted line) between nucleons (represented by upward pointing arrowed lines) is attractive. This mechanism provides about half of the clue to nucleons moving in time-reversal states to form Cooper pairs. These pairs behave like bosons and eventually condense in a single quantal state leading to nuclear superfluidity. Cooper pair formation is further assisted by the exchange of collective surface vibrations (wavy curve in the scattering process) between the members of the pair.

that experienced by pairs of nucleons moving on the surface of the nucleus.

The role that the exchange of nuclear surface vibrations has on Cooper pair formation is larger for small rather than for large nuclei. This is because the surface to volume ratio, and thus the curvature of the system as well as the spill-out of nucleons is larger for the light nuclei. Consequently, in these systems the collectivity of surface vibrations is larger than in the heavier systems. These effects become exacerbated in the case of very light exotic nuclei. Effects similar to these open the possibility of creating real high T_c superconductors when applied to the case of fullerene-based materials.

The central role played by the surface in the condensation process leading to nuclear superfluidity, where nucleons move without friction, is demonstrated by the fact that BEC essentially happens only at the surface of the nucleus. In other words, nucleons behave in the nuclear surface like a superfluid, while inside the nucleus they display normal properties, including friction. The pairing gap, the energy which provides a quantitative measure of the binding energy of the Cooper pairs and thus of the superfluidity of the

system, is large ($\equiv 1$ MeV) at the nuclear surface, becoming small (zero) inside the nucleus.

Exotic Forms of Nuclear Matter

Surface-controlled pairing is also believed to be responsible for the existence of exotic forms of nuclear matter at very low densities. These so-called halo nuclei, which lie at the limits of stability of the chart of nuclides (cf. **Figure 12**), are composed of essentially all surface and display a very large spill-out of nucleons.

Halo Nuclei

These nuclei exist at the neutron drip line in the chart of nuclides (see below and **Figure 13b**), and their study constitutes one of the most important subjects lying at the forefront of nuclear research.

When neutrons are progressively added to a normal nucleus, the Pauli principle forces them into

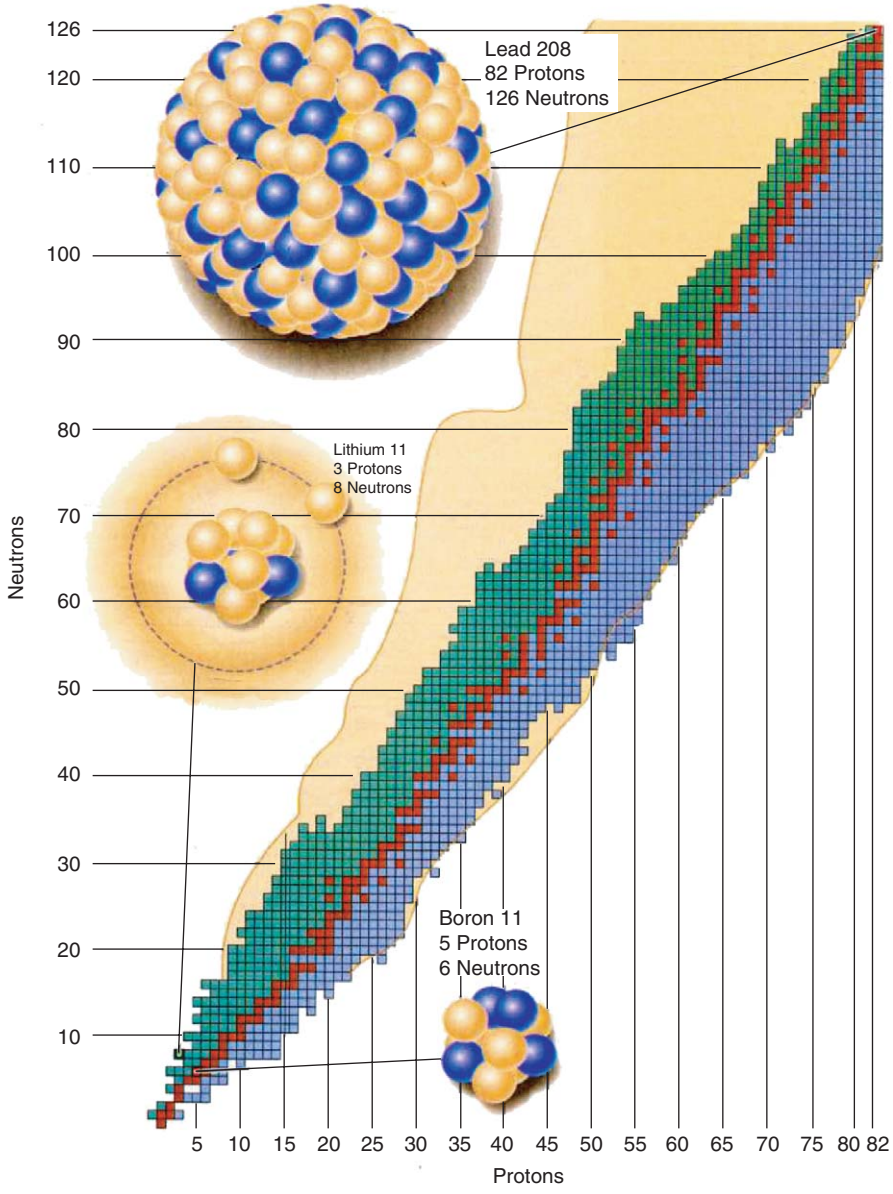

Figure 12 Nuclei are represented here by squares, positioned horizontally according to the number of protons and vertically according to the number of neutrons they contain. Stable nuclei are shown as red squares. Green squares indicate bound but unstable nuclei that have excess neutrons. Blue squares mark bound, proton-rich nuclei. The outer borders of these regions are called drip lines, along which large halo nuclei may be found. The extended halo of lithium 11, comprising two neutrons, makes this nucleus nearly twice as large as boron 11, a stable nucleus containing the same number of nucleons. ^{11}Li is half the size of a lead nucleus, ^{208}Pb, that holds 197 more particles.

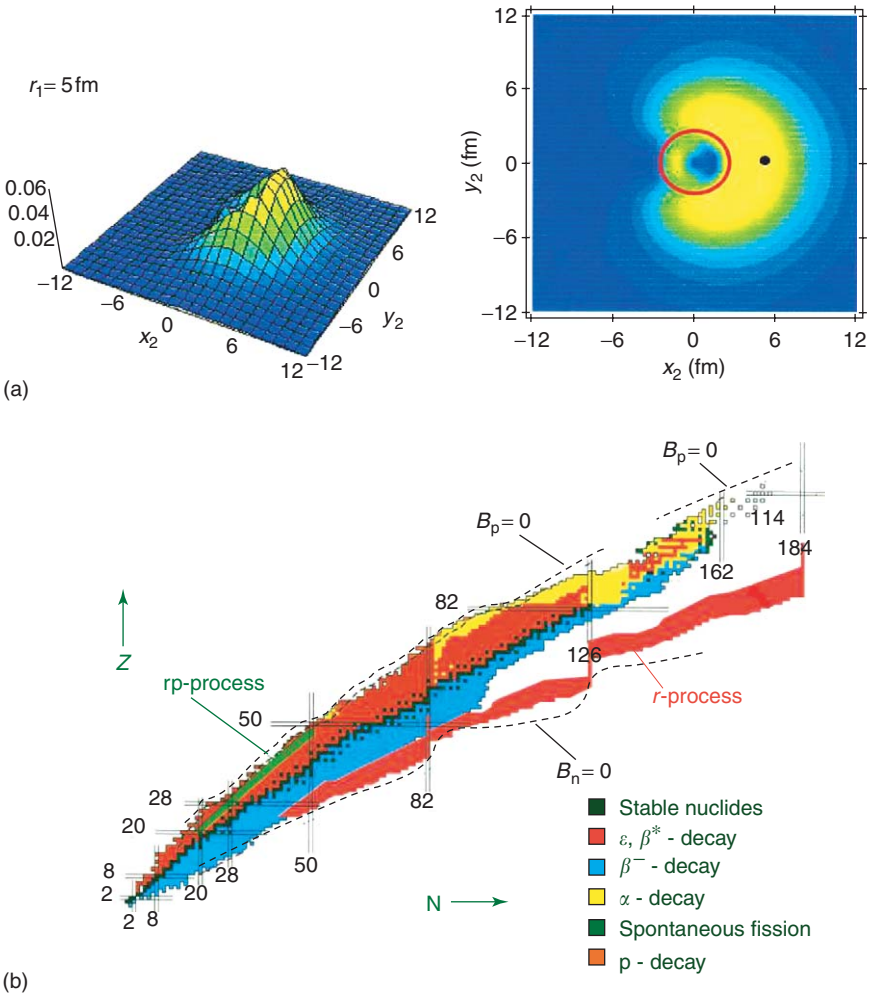

Figure 13 (a) Spatial structure of the Cooper pair which describes the two halo neutrons of ^{11}Li. Fixing one of the two neutrons at a distance of 5 fm from the origin of the nucleus (black dot) on the *x*-axis, the probability of finding the other neutron is displayed. The numbers appearing on the *z*-axis of the 3D plot displayed to the left side are in units of fm^{-2}. The projection on the *x*–*y* plane is shown on the right panel, where the core ^{9}Li is shown as a red circle. (b) Map of the nuclear landscape, as in **Figure 12**, where particular characteristics which makes it easier to appreciate the new area of research associated with exotic nuclei are emphasized. The nuclei existing naturally on Earth are marked by black squares. The magic numbers associated with increased stability (closed shells), are the convenient "landmarks" in the map and are indicated by double lines. Also shown are estimates of the borderline of stability, the so-called drip lines, where the proton and neutron binding energies B_p and B_n become zero. Two paths which astrophysicists identify as important in the creation of elements in the Universe are also displayed: the r-process and the rp-process which traverse regions yet unexplored. A third path, the s-process path, runs along the stable nuclei.

states of higher momentum. When the core becomes neutron-saturated, the nucleus expels most of the wave function of the last neutrons outside to form a halo, which because of its larger size can have lower momentum. In most cases neutrons essentially drip off from the nucleus, defining the lines of stability for neutron number in the chart of nuclides (neutron drip line, cf. **Figure 13b**, dashed lines marked $B_n = 0$). In some few, selected cases, the system becomes a halo nucleus. In halo nuclei, some of the constituent neutrons venture beyond the drop's surface and form a misty cloud or halo (similar effects are found for nuclei close to the proton drip line, cf. **Figure 13b** dashed lines marked $B_p = 0$). Not surprisingly, these extended nuclei behave very differently from ordinary ("normal") nuclei lying along the stability valley in the chart of nuclides. In particular, they are larger than normal nuclei of the same mass number. For example, ^{11}Li is twice as large as ^{11}B, a stable nucleus containing the same number of nucleons and half the size of the lead nucleus ^{208}Pb, which holds 197 more particles (**Figure 12**). In the case of ^{11}Li, the last two neutrons are very weakly bound. Consequently, these neutrons need very little energy to move away from the nucleus. There, they can remain in their "stratospheric" orbits, spreading out and forming a tenuous

halo. If one neutron is taken away from ^{11}Li, a second neutron will come out immediately, leaving behind the core of the system, the ordinary nucleus ^{9}Li. This result indicates that pairing may play an important role in the stability of ^{11}Li. In fact, the properties of the exotic nucleus ^{11}Li can be understood, even quantitatively, in terms of the simplest scenario imaginable: the formation of a single di-neutron Cooper pair which is held together to the ^{9}Li core essentially by the exchange of surface vibrations among the halo nucleons (**Figure 13a**). The importance of these vibrations is due to the high polarizability displayed by ^{11}Li.

It is to be noted that of all the atomic nuclei which are thought to be possible, only about half of them have been observed in the laboratory, and a small

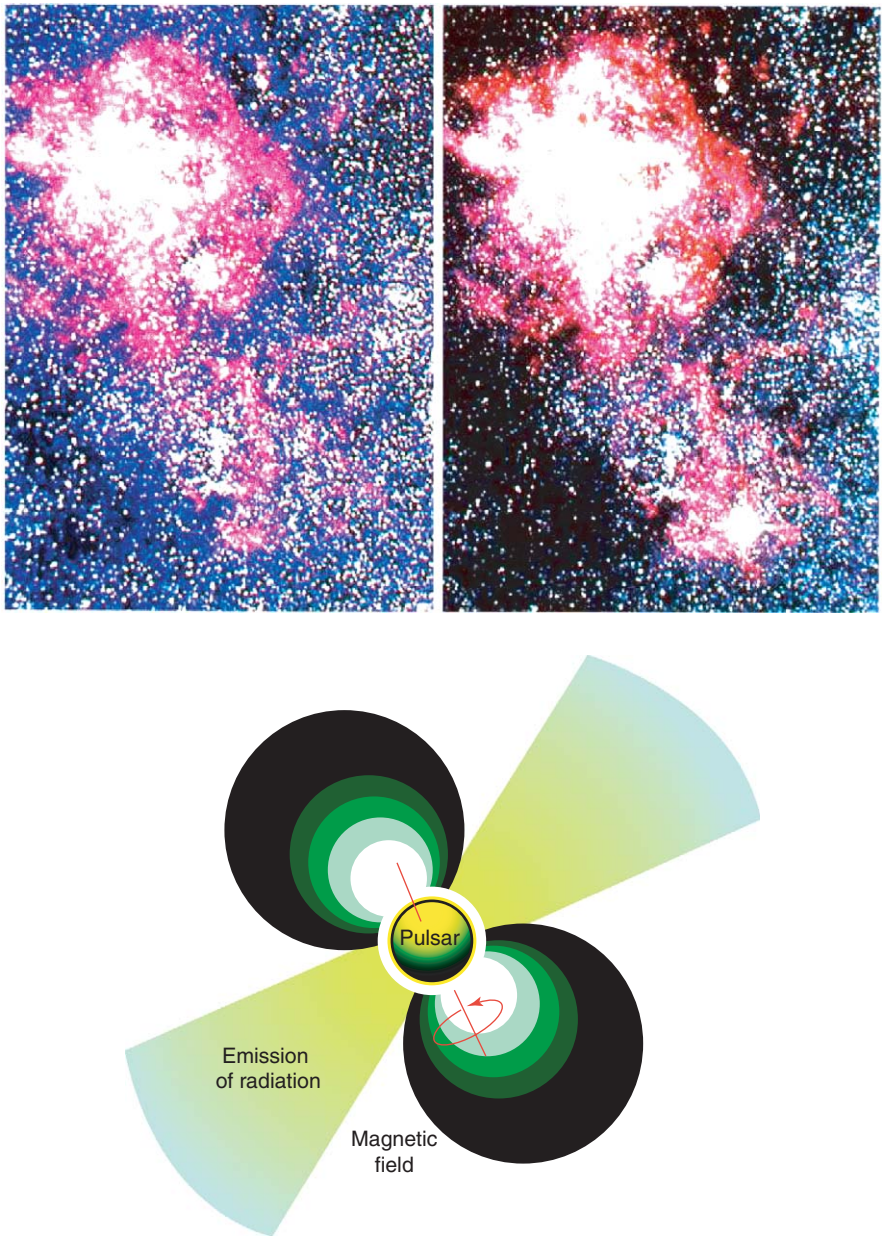

Figure 14 On 23 February 1987, the great Magellean cloud was the scene of a Supernova explosion. Supernova 1987A, as it was christened, was so bright that one could see it from the southern hemisphere and during a period of about six months with the naked eye. (top) A photo of the Magellean cloud before (left) and after (right) the date indicated above. A bright spot on the lower part of the figure is clearly visible. (bottom) Neutron stars have an intense magnetic field which accelerates electrons and protons, inducing those particles to emit beams of radiation. These beams arrive to the earth with a frequency determined by the rotation of the star giving rise to a pulsating signal like light emitted by a lighthouse. Hence, the name pulsar.

fraction exists naturally on earth (cf. **Figure 13b**). Of particular importance in this research is the mechanism for the creation of elements in the Universe. Unstable nuclei are involved in explosive burning in astrophysical environments. Prominent among these processes are explosive hydrogen burning (the rp-process) on the surface of accreting white dwarfs (novae) or neutron stars (X-ray bursts), as well as rapid neutron capture (the r-process) in very neutron-rich conditions of Supernova explosions (cf. **Figure 14**). The r- and rp-process paths shown in **Figure 13b**, traverse regions of unstable nuclei of the chart of nuclides which are as yet unexplored. A third path, the s-process path, runs along the stable nuclei.

Neutron Stars

The nuclear surface controls not only the properties of individual nuclei, but also the properties of "materials" whose building blocks are atomic nuclei. These femtometer materials display properties reflecting not only the ubiquitous role played by the interweaving of nucleons and surface vibrations, but also the marked dependence of the strong force with density. A textbook example is provided by neutron stars (pulsars). These remnants of fierce Supernova explosions are gigantic, rapidly rotating nuclei thirty kilometers across, held together by the gravitational force (**Figures 14** and **15**). Neutron stars display, in the process of cooling down through radiation and particle emission, marked glitches (starquakes) (**Figure 9**), which are likely to be connected with nuclear superfluidity. In fact, neutron stars usually rotate with such precision that they are known as the best time keepers in the universe. But ever so often their rotation rate increases. It is thought that these glitches are related to superfluidity inside the star, in particular superfluidity in the inner crust of the star, where nuclei forming a crystalline lattice are immersed in a sea of free, superfluid neutrons.

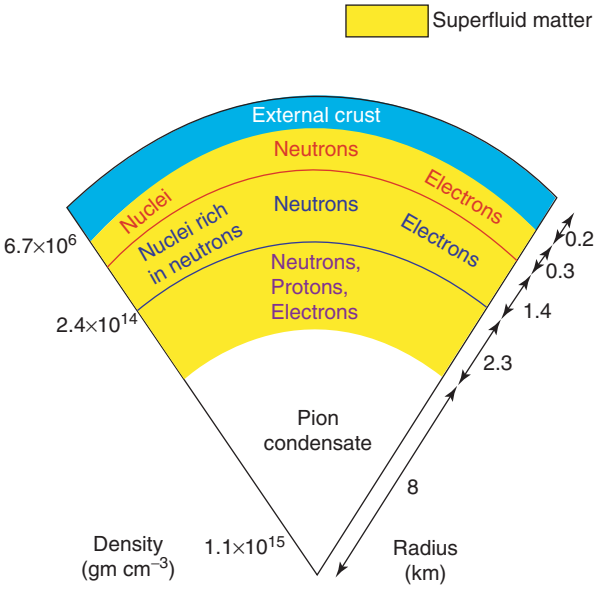

Figure 15 Cross section of a neutron star calculated making use of a so-called stiff equation of state for neutron matter densities larger than or equal to nuclear saturation density.

Introduction

The atomic structure of condensed matter has for a long time been described by the ideal crystal model: a unit cell, which repeats periodically toward infinity, and is decorated by a motif (atomic positions). The atomic structure is completely determined by the decoration of the unit cell. Only particular symmetries are compatible with periodicity, leading to the 14 Bravais lattices and 230 different space groups. For instance only two-, three-, four-, and sixfold rotation axes are allowed, the fivefold rotational symmetry being incompatible with periodicity.

Extremely powerful tools have been developed for solving periodic atomic structures by means of the

analysis of the intensity distribution in the X-ray or neutron diffraction pattern and complex structures such as proteins, which contain several thousands of atoms in the unit cell, are now almost routinely determined. Indeed, if an X-ray (or neutron or electron) beam is sent on a periodic crystal, it is diffracted in specific directions and forms a diffraction pattern. The diffraction pattern of a crystal is best understood in the so-called reciprocal space in which it forms a periodic lattice. The position of reciprocal lattice vectors or Bragg peaks is given by the Bragg law which relates the lattice plane d-spacing, the reciprocal lattice vectors, and the incoming radiation wavelength. The reciprocal lattice has the same point group symmetry as the crystal under study, that is, if a crystal has a threefold rotation, the reciprocal space also has threefold symmetry. The intensity distribution of the Bragg peaks depends on the atomic decoration of the unit cell, being the square of the Fourier transform of the structure. All structural information is contained in this intensity distribution, but cannot be used directly because the phase of the Fourier transform is unknown. Direct methods allow one to overcome this "phase problem" and give a starting model which is further refined against the observed Bragg peak intensity distribution.

The power of the periodic description of condensed matter is also that it allows describing their physical properties by means of the Bloch theorem, for instance. Real materials are in most cases considered as a perturbation of the ideal crystal in which defects are introduced (vacancies, dislocations, chemical disorder, etc.).

At the other extreme, if too much disorder is present, the material is described by the glass model in which only short-range order exists: it is characterized by a diffraction pattern in which Bragg reflections no longer exist, and presents a smooth variation as a function of the scattering angle.

In 1984, Shechtman *et al.* published the electron diffraction pattern of a rapidly cooled AlMn alloy which displayed Bragg reflections and fivefold symmetry axes. This was a break in the crystal description of matter, since two properties, believed to be incompatible, were present: long-range order, as evidenced by the Bragg peaks, and fivefold symmetry. An example of the Laue diffraction pattern of a high-quality Al–Pd–Mn icosahedral quasicrystal is shown in **Figure 1**: Bragg peaks are sharp and the fivefold symmetry, characteristic of the icosahedron, is clearly visible. The discovery of Shechtman was named quasicrystal and is a new kind of long-range ordered matter. Although it gave rise to a controversy in the crystallographic community, it appears now as the new paradigm for long-range ordered structure.

Nonperiodic long-range order had already been observed before the discovery of the quasicrystal, in incommensurately modulated structures but could, in general, be described as a perturbation on a periodic underlying structure. Aperiodic crystals encompass long-range ordered, nonperiodic structure such as incommensurately modulated structures, composite structures (where two incommensurate lattices are in interaction), and quasicrystals. Tools for structure determination are common to all aperiodic crystals and make use of the so-called high-dimensional crystallography.

Quasicrystal Synthesis

The first quasicrystalline samples were obtained by rapid quench from the melt and were metastable. As a consequence, only small single grains ($< 1\,\mu m$) could be synthesized and the only tool to pinpoint the quasicrystalline character was electron diffraction. Since then a large number of quasicrystalline phases have been discovered, all made of metallic alloys (AlMn, AlPdMn, ZnMgY, AlNiCo, etc.). Some of them are stable at room temperature and can be obtained by slow cooling from the melt, or usual growth process such as Bridgman or Czochralski, leading to mm- or even cm-sized single-grain quasicrystals. Their composition range is, in general, very limited, almost as a line compound. The stabilizing mechanism of the quasicrystal is far from being understood, but size effects and Hume–Rothery electronic stabilization are believed to play a crucial role.

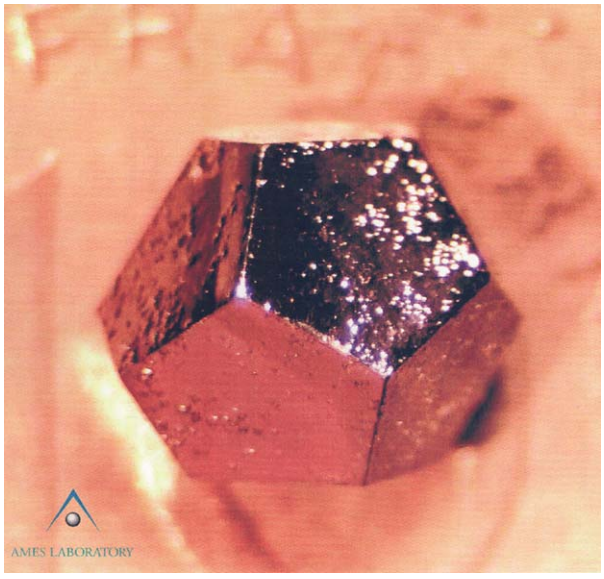

Figure 2 Single grain of the ZnMgY phase obtained by slow cooling from the melt. (Courtesy of P Canfield and I Fisner, Ames Laboratory, USA.)

Figure 2 displays an example of a single grain of the ZnMgY icosahedral phase obtained by slow cooling from the melt which shows a macroscopic icosahedral symmetry. Besides the icosahedral symmetry, quasicrystals have been obtained in systems which are a periodic stacking of quasiperiodic planes with 8-fold, 12-fold, and 10-fold symmetry. However, most of the structural studies have been carried out so far in a few icosahedral and decagonal phases, where the quasicrystalline long-range order is well defined.

High-Dimensional Crystallography

The structural analysis of quasicrystals is now best achieved using the high-dimensional description. As an illustration of this procedure, a simple 1D example is considered: the Fibonacci chain. It is made of two tiles whose length is in the ratio $\tau/1$ τ being the golden mean (1.618…). The Fibonacci chain can be built up by a substitution rule L→LS and S→L, where L and S are for the long and short segment. The resulting 1D structure is quasiperiodic and has the form LSLLSLSLLSLLS… . A compact description of this structure is achieved in a 2D periodic space. A square lattice in a 2D space is taken up to start with. The latter is decomposed in two orthogonal subspaces: the physical space, also called parallel space (E_{par}), and a complementary space called perpendicular space (E_{per}, **Figure 3**). The slope of the physical space with respect to the lattice is irrational and is equal to $1/\tau$. The square lattice is

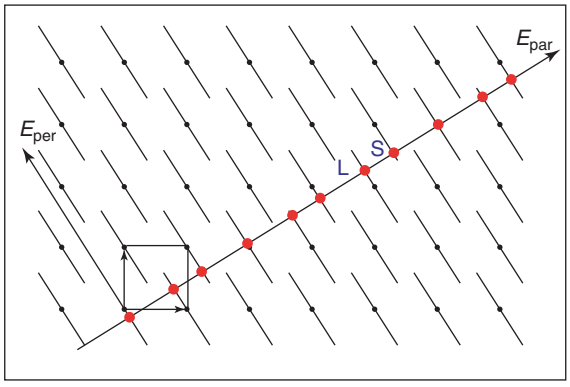

Figure 3 Illustration of the 2D description of a 1D quasicrystal, here the Fibonacci chain (see text).

decorated with segment lines, elongated along the perpendicular direction, and whose length is equal to the projection of the square onto the perpendicular space. The 1D quasicrystal is obtained as a section of the decorated periodic lattice by E_{par}: each time the E_{par} line intercepts a segment line, an atomic position is generated. The final result is the Fibonacci chain. The advantage of the high-dimensional description is that, since periodicity is recovered, usual crystallographic tools such as Patterson analysis or structure factor calculations are easily carried out. Moreover, all the information on the structure (local environment, interatomic distances, etc.) is now contained in a very compact form as the decorated square lattice. More complex structures can be generated: for instance, the segment line can be given a longer length; this will generate additional positions in the 1D quasicrystal. It is also possible to add other segment lines in the square unit cell, which could mimic another atomic species.

This procedure generalizes to the case of a 3D quasicrystal such as icosahedral phases. In this case, the higher-dimensional space is 6D and the lattice hyper-cubic. Segment lines are now 3D objects called occupation domains or atomic surfaces. The problem of structure determination is that of finding the location and the detailed shape of the occupation domains. Although it might seem a simple task, it is a complex problem, for which satisfactory solutions have been proposed only recently. Indeed, specifying the shape of a 3D occupation domain requires an infinite number of parameters, and guidelines have to be found for the modeling.

Return to the 1D case and look for the diffraction pattern of the Fibonacci chain. The diffraction pattern can be computed from the 2D decorated lattice, remembering that the section operation becomes a projection by Fourier transform. For a square lattice, the diffraction pattern can be indexed by 2-integer

indices, and each reciprocal lattice vector has a component in the parallel space and one in the "perpendicular" space. Since the structure is nonperiodic, there is a dense set of Bragg reflections, but only a finite number of them are larger than a given threshold. In the case of the icosahedral phase, 6-integer indices are necessary for indexing the diffraction pattern: they correspond to the six directions pointing toward the vertices of an icosahedron.

The route from diffraction data to the atomic structure is, in some sense, similar to what is achieved in standard crystallography: the point group and space group of the quasicrystal is determined from the diffraction spectrum (see **Figure 1**). Then, the Patterson analysis allows one, in general, to specify approximately the position and shape of the atomic surfaces; from this, a model is proposed which is then compared to available diffraction data. Before presenting experimental results along these lines, the study of the structural quality of quasicrystals is briefly outlined.

Structural Quality of Quasicrystal

As for any materials, quasicrystals contain defects (vacancies, dislocations, strain, etc.), which results in either a Bragg peak broadening or diffuse scattering. Because of the quasiperiodic arrangement, the effect of defects on the diffraction depends on both the parallel and the perpendicular component of the reciprocal lattice vector. In the theory of QC, a distortion or a fluctuation associated with the perpendicular component has been named "phason" (this notion will be referred to later), and leads to changes in the diffraction pattern associated with the perpendicular component of the scattering wave vector (Q_{per}). For instance, one can imagine that the slope of the parallel space in **Figure 3** is changing: if the slope becomes rational, this will lead to a periodic structure. Such a change is equivalent to a shear strain in the perpendicular direction and has been named "phason strain." A distribution of phason strain will result in a broadening of the Bragg reflection (which are no longer delta peaks), in very much the same way that a distribution of elastic strain in a periodic crystal leads to a Bragg peak broadening. In the early days of quasicrystal studies, most of the obtained quasicrystals displayed distorted diffraction patterns, or Bragg peak broadening, the notion of long-range quasiperiodic order even being questioned. Quasicrystals, obtained most recently, display a high quasiperiodic long-range order, with Bragg peaks which are almost resolution limited. In some cases, the structural quality is such that dynamical X-ray diffraction has been evidenced. **Figure 4** shows 2D images of Bragg peaks

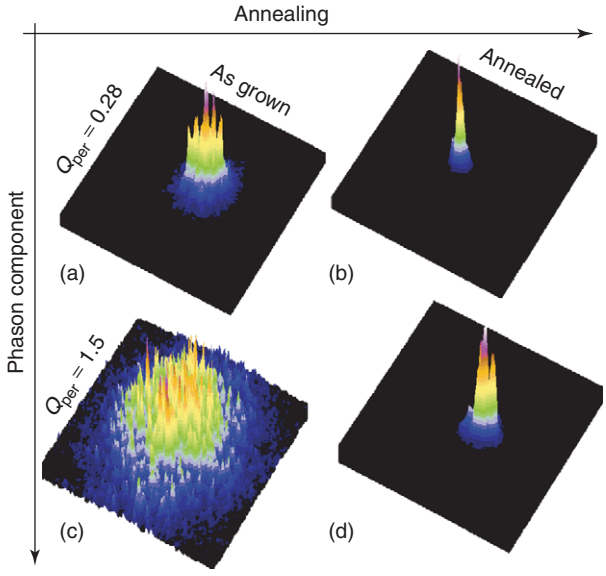

Figure 4 2D images of the Bragg reflections obtained in the i-AlPdMn phase for an as-grown single-grain quasicrystal (left) and the same sample after annealing (right). Whereas Bragg reflections are broadened (with a broadening proportional to Q_{per}) in the as-cast sample, they are almost resolution limited in the annealed sample.

obtained in a high-resolution setting. The left part shows Bragg peaks in an i-AlPdMn sample obtained by the Czokralski method, whereas the right part corresponds to the same Bragg reflections, once the single quasicrystal has been annealed. As it is evident, Bragg reflections are almost resolution limited with a coherent length which is of the order 10 μm. Of course, quasicrystals still contain some defects and are not as "perfect" as silicon for instance, but their quality is comparable to the best metallic alloys, and the notion of long-range quasiperiodic order is strongly supported by experimental results.

From Diffraction Data to a First-Order Model

As an example of structure determination, results obtained in the i-AlPdMn phase, which is stable at room temperature and can be obtained as cm-sized single grains are presented. This is a ternary alloy, with a composition of $Al_{68.9}Pd_{22.1}Mn_9$ with a very narrow composition range. The icosahedral symmetry of this phase is illustrated in **Figure 1** which displays a fivefold symmetry Laue pattern. In order to facilitate the analysis, both X-ray and neutrons diffraction data have been collected. Indeed, scattering power is very different for X-ray and neutrons, Pd atoms being mostly "visible" with X-rays, whereas Mn atoms are more "visible" with neutrons: the use

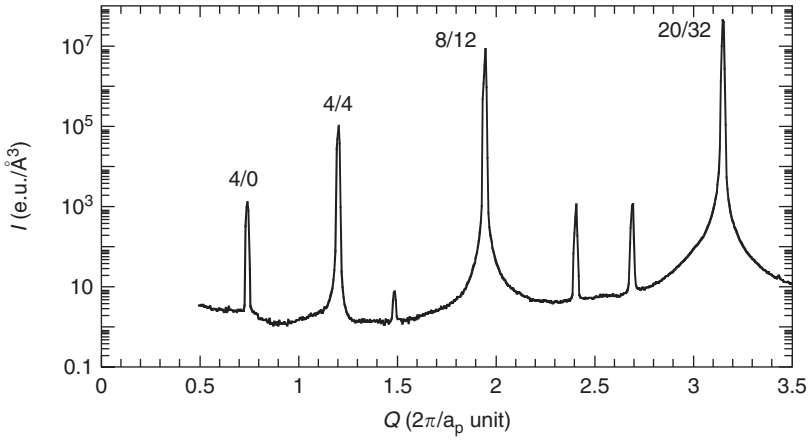

Figure 5 X-ray diffraction pattern taken along a twofold axis in the i-AlPdMn phase. The 2-number indices is a short-hand notation for the 6-indices scheme. Note that the position of the indexed Bragg reflections scales with τ, the golden mean.

of the combined set of data leads to a precise structural information. Indexing of the diffraction pattern allowed determining that the reciprocal lattice is body-centered icosahedral, with systematic absences which are similar to the cubic b.c.c. lattice, that is, 6D indices are all even or all odd. A systematic scan along a twofold direction is shown in **Figure 5**: note that the intensity scale is logarithmic, and that very weak reflections can be measured. The position of all reflections is in perfect agreement with the 6D indexing scheme, and data have been collected using a standard neutron and X-ray diffractometer. Once integrated intensities are collected, the first step is to compute the so-called 6D Patterson function. It is obtained by Fourier transform of the intensities, and represents the autocorrelation function of the 6D structure. In principle, a direct interpretation of this function is difficult, but in several cases, it has been possible to derive the position and the rough size of the atomic surfaces. For instance, in the i-AlPdMn phase, it could be demonstrated that there are only three atomic surfaces, located on the nodes and "body center" sites of the 6D cube. A section of this 6D cube is shown in **Figure 6**, with the position of the three different atomic surfaces. In **Figure 6a**, the section of the 6D periodic structure is such that it contains a fivefold axis both in the physical space and in the complementary perpendicular space. The section also shows the 6D periodicity, and is built up by a linear combination of two 6D lattice vectors with indices [100000] and [011111]. The segment lines, elongated in the perpendicular direction, are just traces of the 3D atomic surfaces. As can be seen in this figure, only three different positions in the 6D cube are occupied, labeled n1, n2, and bc1, the other positions being imposed by the face-centered icosahedral symmetry of the 6D structure (because a body-centered icosahedral reciprocal lattice corresponds to a face-centered icosahedral direct lattice). Moreover, some information on the chemical content of each atomic surface is also obtained by the

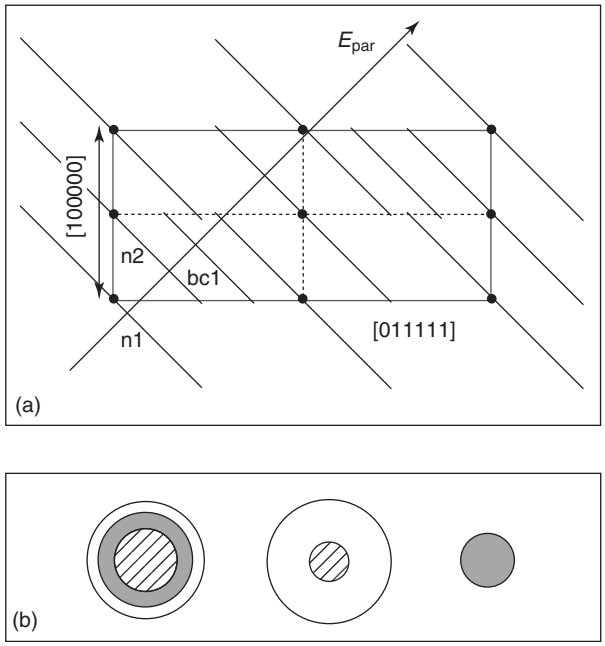

Figure 6 Sketch of the spherical model of the i-AlPdMn icosahedral phase. (a) Section of the 6D space, with a fivefold axis both in the parallel and perpendicular space. The segment lines are traces of the atomic surface. The unit cell is shown as a black rectangle. It is a doubling of a smaller unit cell shown as dashed line, due to a superstructure chemical ordering. There are two different atomic surfaces on the nodes (shown as black and gray lines, and labeled n1 and n2) and a third one on the body-center site (bc1). (b) Decomposition of the different atomic surfaces in the perpendicular space n1, n2, and bc1 (from left to right). There are spherical shells with different atomic composition; the shading stands for the different chemical species: hatched Mn, grey Pd, and white Al.

analysis of the Patterson function. In particular, it can be shown that the n1 atomic surface contains Mn, Pd, and Al atoms, whereas the n2 atomic surface only contains Mn and Al atoms. In a first crude approximation, atomic surfaces are modeled by spheres and spherical shells as illustrated in **Figure 6b**. The chemical content of each atomic surface is modeled by successive shells, with, for instance, a first Mn sphere, enclosed in a Pd shell, and finally an Al external shell for the n1 atomic surface. Although the model presented in the **Figure 6** is simplistic, it already allows reproducing the strongest Bragg peak intensities, and is thus a good first-order model. This model is not only a theoretical view of the 6D structure but it allows one to predict some of the main ingredients of the resulting 3D structure. In particular, it is possible to determine which kind of local environments are to be found in the 3D structure. For example, there are groups of atoms packed along successive shells of icosahedral symmetry, referred to as clusters in the following. Four different types of clusters are found and are packed quasiperiodically. It can also be shown that the structure can be viewed as a quasiperiodic packing of dense atomic planes. This is described again in a later section.

Modeling the Atomic Structure of Quasicrystals

Although the previous first-order model gave some information on the resulting atomic structure, it is obviously necessary to go beyond this model if any detailed information has to be predicted. This is particularly important for the theoretical study of physical properties of quasicrystals. It has to be pointed out that the comparison with diffraction data remains a powerful test, especially for weak Bragg reflections which are very sensitive to the details of the atomic structure (details of the atomic surface shape, for instance).

Modeling of the atomic structure of quasicrystals requires, in principle, an infinite number of parameters since it is an infinite structure. Although the high-dimensional description simplifies the quasicrystal picture, the number of parameters remains much larger than the one which can be refined using the diffraction data. This is why a certain number of constraints or hypotheses have been proposed to restrict models within a reasonable number of parameters.

The first one corresponds to the usual density and chemical composition constraint. The model should also be designed to avoid short distances. Although these two constraints are simple, they are already difficult to fulfill. However, they are not sufficient to restrict the modeling fully and two main routes have been followed to go further: a decoration of tiling, such as a Penrose tiling, or a modeling directly in the high-dimensional space. In both cases, a very fruitful approach has been the comparison with crystalline "approximant": these are periodic crystalline phases which share the same local environment as the crystalline phase. In the high-dimensional picture, a crystalline approximant can be obtained by changing the slope of the cut space which becomes rational. Depending on the symmetry of the periodic approximant, there is a relation between the unit cell of the 6D periodic structure and the cell parameter of the crystalline approximant. Thus, it has been very surprising that such a relationship was observed experimentally. The crystalline approximant serves then as a template for the quasicrystal: for instance, the atomic clusters which are identified in the crystal are used as "building" blocks in the quasicrystal. In the Penrose tiling decoration scheme, the difficulty is then to find the appropriate tile dimension and the cluster connectivity. Moreover, clusters only define a backbone of the structure and it is necessary to fill the "gaps" between clusters. In the high-dimensional scheme, the cluster density can, for instance, be maximized. Other constraints have been proposed on the shape of the atomic surfaces, for instance. The most fruitful approach so far has been one which combines both approaches: using both the knowledge of the local structure obtained from the analysis of a crystalline approximant and a sophisticated 6D modeling, it is possible to achieve a refinement which is similar to what is done in 3D crystallography.
