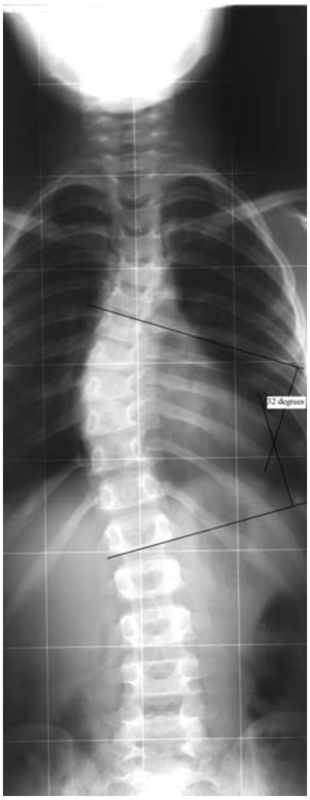
Besides some inter- and intraobserver variability, the Cobb method for scoliosis angle measurement is the most accepted standard technique worldwide. In an AP view, the two neutral vertebrae first have to be determined.

Neutral vertebrae have parallel endplates with—in contrast to the other vertebrae—minimal or no change in shape and are maximally tilted to the horizontal line.

Lines are drawn in extension of the uppermost and lowermost endplates of the neutral vertebra. Because these lines usually intersect outside the X-ray film, two perpendicular help-lines are constructed. At the point of intersection, the complementary angle is measured. This angle is the so-called Cobb-angle or angle of scoliosis (Fig. 1).

When reporting the scoliosis angles, one should mention which measurement method was used and which neutral vertebrae were chosen. In follow-up imaging, the same vertebrae should be chosen for evaluating disease progression.



Scoliosis. Figure 1 **Measurement of the scoliosis angle (Cobb 1948). Anteroposterior radiograph of a 22-year-old man with a single right thoracic curve. Horizontal lines are drawn parallel to the endplates of the neutral vertebrae at the end of the curve. Where perpendicular lines intersect, the angle of scoliosis is measured. In this case the angle of Cobb measures 32°.**

Evaluation of Rotation (Method of Nash and Moe)

For evaluation of the scoliotic rotation of the vertebrae, the method of Nash and Moe (2) is widely used.

There are five grades of rotation. Grade zero rotation means the pedicle outlines are symmetric and equidistant to the lateral borders of the vertebral body. Grades 1–4 illustrate the movement of the pedicle toward and over the midline (Fig. 2).

Determination of Skeletal Maturity (Risser's Sign)

A further goal of the radiographic examination is to determine skeletal maturity. Because curvature of mild scoliosis does not progress after adolescence, the skeletal age is a prognostic factor of the likelihood of curvature progression. Since the iliac crest is usually visible in the total spine study, it can be conveniently used to determine skeletal maturity. The Risser classification (3) of the apophysis of the iliac crest enables the radiologist estimate the expected growth of the vertebral body and therefore estimate the progression tendency of the scoliosis.

Risser Classifies the Progression of Ossification of the Apophysis of the Os ileum into Six Groups

0: Apophysis cannot be seen
1: Apophysis begins to develop laterally and measures up to 25% of the iliac crest.
2: Apophysis covers up to half of the iliac crest
3: Apophysis reaches up to 75% of the iliac crest
4: Complete excursion of the iliac apophysis
5: Complete fusion of the apophysis with the iliac crest

Scoliosis. Figure 2 **The method of Nash and Moe (2) measures the degree of rotation from grade zero (no rotation) to grade 5 (pedicle outline wanders over the midline).**

Cross-Sectional Imaging

Besides conventional imaging measurement, techniques focusing on MRI and CT imaging are being used more and more. They have the drawback that images are acquired with the patient in the prone position, so the influence of the physiological vertical stress of the standing body on the curvature of scoliosis cannot be evaluated.

Multiplanar CT imaging especially enables visualization of complex deformities and a three-dimensional understanding of the scoliotic spine (Fig. 3).

Scoliosis. Figure 3 **Coronal multiplanar reconstruction of a helical computed tomography scan showing a single bended lumbar scoliosis with the concavity on the right side on the basis of a complex spinal deformity, including a hemivertebra L3.**

Nuclear Medicine

The role of nuclear medicine in routine evaluation of scoliosis is limited. An isotope bone scan (^{99m}Tc-methylene diphosphonate) can be helpful when evaluating a child with focal alterations of the bone, such as infection or neoplasia.

Alternative Imaging Methods

To reduce radiation exposure, alternative imaging techniques have been investigated for documentation and to control the course of disease. Light optical methods with the possibility of three-dimensional surface rendering can quantify the cosmetic deformity of the thorax.

Diagnosis

A complete evaluation should include a physical examination and imaging of the total spine. Plain radiography remains the initial imaging method of choice and in certain cases is followed by MRI or CT imaging.

In the radiologic report, the form of the deformity (scoliosis, kyphosis, lordosis, or S-shaped), the side and the degree of scoliosis should be described. The rotational component of scoliosis is described by the Nash and Moe scale, and the skeletal age should be mentioned, for instance using the Risser classification.

Before surgery lateral-bending films are sometimes taken to differentiate structural fixed curves from nonstructural flexible curves.

Because scoliosis is often associated with other congenital deformities, skeletal, cardiac, and urogenital deformaties must be excluded.

Last not least, one must be aware of the radiation exposure caused by scoliosis follow-up. Nash et al estimated that 22 radiographic examinations are performed in the course of scoliosis management (4).

Statistically, an increased risk of developing breast cancer in girls with scoliosis has been reported (5).

Breast cancer screening

Definition

Breast cancer is the most common cancer among women worldwide, with over one million new cases diagnosed in 2000. Although substantial improvements in survival have been recorded in Western countries since the late 1970s, breast cancer still causes the most deaths from cancer among women. Studies have shown that mass screening for breast cancer using mammography as the screening test (mammography screening), with or without clinical breast examination, has the potential to further decrease breast cancer mortality by detecting asymptomatic lesions which can be treated more effectively than symptomatic disease (1). In order to achieve these benefits, however, a number of conditions need to be fulfilled, which are discussed here.

Characteristics

In 2002, an IARC Working Group on the Evaluation of Breast Cancer found sufficient evidence for the efficacy of mammography as the sole screening modality for breast cancer in women aged 50–69 years. The group found only limited or insufficient evidence for other age groups or screening modalities (1).

Target Population

Mammography screening is generally offered to the asymptomatic 50–69-year-old female population in 2-year intervals. If the screening mammogram is normal, no further action will be taken and the woman will be invited to the next round of screening. Unlike diagnostic mammography, mammography screening should not be offered to patients presenting with signs or symptoms of breast cancer. A large proportion of women in a diagnostic breast service will present with benign abnormalities; work-up of benign lesions in a diagnostic service is frequently necessary in order to reassure the patient and avoid unnecessary treatment. The opposite is the case in mammography screening, however. Screening clients are not informed about benign lesions in order to avoid unnecessary anxiety and unnecessary further diagnostic procedures in large numbers of women.

Screening Process

Since the vast majority of women attending screening are disease free, considerable precautions must be taken to ensure that the benefits of screening are maximized while minimizing the potential harm. The physician responsible for the overall performance of the screening service and the attendant staff must constantly strive to optimize the individual components of the entire screening process, as outlined below (2, 3).

Information and Invitation

A significant factor affecting the overall performance of a screening program is the proportion of women in the eligible ►target population who attend. Organized, population-based mammography screening programs have been shown to achieve a high participation rate (over 70% attending in a given round) using invitation letters addressed to each individual woman in the eligible target population. The invitation letter should give a specific appointment (date, time, and place) and a telephone number in case the woman needs to change the appointment. The availability of population registry data can substantially simplify and improve the effectiveness of invitation procedures.

Taking the Screening Mammogram

Screening mammograms (mediolateral oblique and craniocaudal views recommended) should be taken in dedicated units by specially trained staff. The physico-technical quality must be monitored daily by unit staff and by a regional technical quality control office, which fulfills the standards of the European Guidelines (2). In some programs, screening radiographers may be trained to perform additional views on their own initiative. Such a policy can result in lower recall rates, although the overall rate of additional imaging may be higher.

Reading Screening Mammograms

The classification of screening mammograms differs somewhat from diagnostic mammograms, because of the lengthy (2 year) screening interval. In mammography screening, the reader does not have the option of recalling a woman in a shorter (e.g., 6 month) interval because that would generate inordinate anxiety. Thus, the reader must decide whether to recall a woman immediately for further assessment or in 2 years for the next round of screening.

Screening mammograms should also be read in batches of several women. A batch should be of sufficient size to enable the reader to roughly appraise ►sensitivity and ►specificity and to judge whether repeated reading of the entire batch is necessary. Roller viewers should be used and reading should be performed in an undisturbed session with optimal viewing conditions (darkened room). Double reading with arbitration by a third very experienced reader is recommended. The first two readers should be specially trained and experienced in reading screening mammograms. The double readers should strive for optimum sensitivity. The third reader should read any mammograms that one or both double readers find suspicious, with the aim of optimizing specificity.

Assessment of Suspicious Screening Mammograms

All women, the screening mammograms of whom are still deemed suspicious after arbitration, are recalled for assessment that initially consists of additional imaging and clinical breast examination. If suspicion of abnormality persists after additional imaging, biopsy should be recommended. In most cases (>99%) fine-needle aspiration, core cut, or vacuum biopsy can be used.

Preoperative Multidisciplinary Conference

For each case in which suspicion of abnormality persists after imaging, the final decision on the result of screening should be reached in a multidisciplinary preoperative conference in which the assessment team (screening radiologist, pathologist, radiographer, and breast surgeon) consider the correlation between the histopathological assessment of the preoperative biopsy and the other assessment findings. A radiotherapist or radio-oncologist and breast care nurse should also be present so that the entire team can plan the operation/treatment, if breast cancer is diagnosed. The breast care nurse should also be present when a woman is informed of a diagnosis of breast cancer because the woman will have special communication needs, which the breast care nurse is specially trained to deal with.

Postoperative Multidisciplinary Conference

The result of each breast cancer operation and particularly the accuracy of the diagnosis and the appropriateness of the recommendations for management, made at the preoperative conference should be evaluated in a multidisciplinary postoperative conference attended by the same team present at the preoperative conference.

Quality Assurance

At any given time, the vast majority of the target population is free of breast cancer and precursor lesions. Thus, even minimal harm resulting from anxiety or a small proportion of breast cancer cases detected in screening, which may not have become manifest or led to serious complications during a woman's life can shift the delicate balance unfavorably between benefit and harm of screening. It is therefore imperative to continuously strive for optimum quality in mammography screening. Comprehensive guidelines on quality assurance of the mammography screening process have been developed in the Europe against Cancer Programme (2). Staff performing mammography screening should ensure that the minimal standards and procedures recommended in the guidelines are followed.

The European guidelines also emphasize the importance of performing screening in an organized setting as opposed to ►opportunistic screening by referring women for a mammogram in a clinical setting. ►Organized screening programs include an administrative structure responsible for implementation, quality assurance, and evaluation. Accountability for the quality of performance and results is clearer in an organized program and managerial control of the screening process is greater, allowing more rapid response to changes in quality indicators or adverse conditions. Another key quality aspect is population-based implementation of invitation and evaluation. Identifying and inviting all eligible women in the target population is not merely important for maximizing the potential impact of screening. Population-based invitation and a high uptake rate make screening data representative for the local population. Such representative data are essential for internal and external monitoring of screening performance.

Definitions

Scrotal disorders can be subdivided into acute and painful versus chronic and asymptomatic lesions. In acute scrotal pain, the differential diagnosis must be focused on ►testicular torsion, epididymitis, orchitis, torsion of the testicular appendage, or scrotal trauma. Inguinoscrotal hernia or distal ureterolithiasis might be further non-scrotal sources of acute pain.

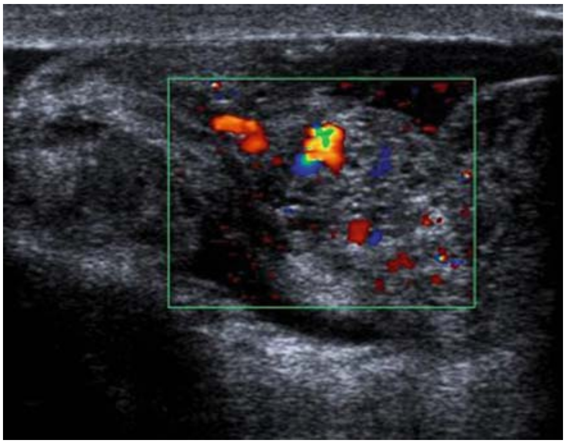
Painless lesions of the scrotal organs present most often as tumor masses, either of the testis (testicular cancer), the epididymis (►spermatocele), the vascular drainage (►varicocele), or the surrounding tissue (►hydrocele).

Pathology

Painful scrotal diseases

Testicular Torsion

Usually there is torsion of the testis within the tunica vaginalis, which covers the anterior surface of the testis and extends over the epididymis and the spermatic cord. Where the covering extends to the cord, the testis is suspended freely within the tunical cavity, within which it may rotate. Torsion of the spermatic cord will strangulate the main vessels and cause ischemic damage to the testis. The main peak of testicular torsion is seen in adolescence. In the neonatal period, testicular torsion presents as torsion including the tunica vaginalis, which is called an extravaginal torsion (Figs 1–3).



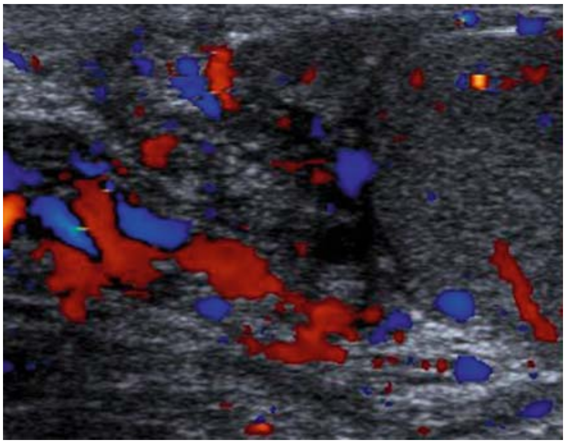
Scrotal Disorders. Figure 1 Testicular torsion. Color Doppler ultrasound reveals lack of vascularization in the twisted spermatic cord.

Scrotal Disorders. Figure 2 Testicular torsion. Intraoperative situs of an intravaginal testicular torsion without infarction.

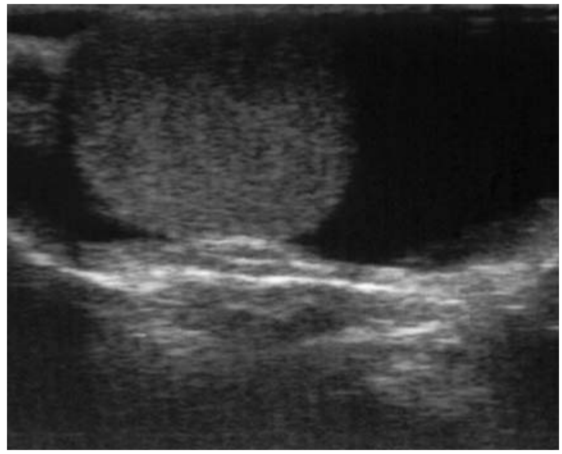
Epididymitis, Orchitis

Epididymitis is usually a bacterial infection, although viral and fungal infections are possible as well. Most common infections in younger patients (<35 years) are sexually transmitted and caused by *Neisseria gonorrhoeae* or *Chlamydia trachomatis*. These patients often suffer from urethritis and concomitant leukocyturia.

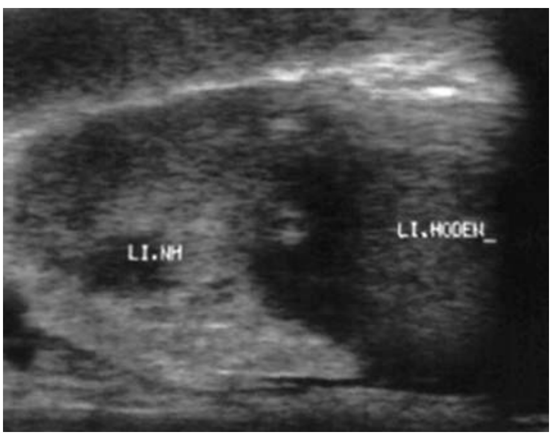
In the elderly patient as well in the very young, coliform bacteria causing urine and bladder infection are most common. Bacteriuria secondary to obstructive urinary disease is very common in these patients.



Scrotal Disorders. Figure 3 **Testicular torsion. Postoperatively, the spermatic cord and the testicle are hypervascularized.**



Scrotal Disorders. Figure 5 **Hydrocele. Peritesticular fluid collection around a normal-sized testicle with homogeneous tissue, revealing a hydrocele.**



Scrotal Disorders. Figure 4 **Epididymitis. Inflamed left epididymis with hypoechogenic areas may indicate abscess formation.**

Orchitis seldom presents without epididymitis. Viral infections such as mumps might cause unilateral isolated infection of testis (Fig. 4).

Painless scrotal diseases

Hydrocele

Hydroceles usually present as painless swelling of the hemiscrotum. In moderate cases, the testis might be palpable next to the hydrocele.

The differential diagnosis includes inguinoscrotal hernia or enlargement of the testis due to cancer. Hydroceles develop most often after or concomitant to inflammatory disease of the epididymis and/or testicles. Due to an inflammatory process, the normal balance of fluid production and reabsorption of the surrounding tissue (tunica vaginalis testis) is disturbed, with consecutive reduction of fluid absorbance and relative fluid overproduction. The produced fluid will collect between the testicle-surrounding tissue and shows specific findings (Fig. 5).

Testicular Cancer

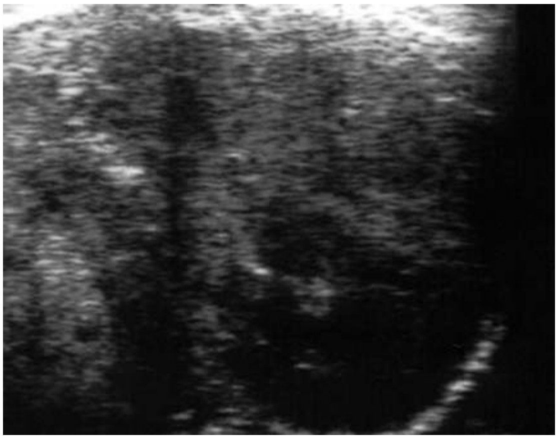
Testicular cancer represents between 1 and 1.5% of male neoplasms and 5% of urological tumors in general. Only 1–2% of the cases are bilateral. The histological type varies, although there is a clear predominance of germ cell tumors (90–95%). Peak incidence occurs in the third decade of life for nonseminoma and in the fourth decade for pure seminoma. Testicular cancer can be classified into germ cell tumors and sex cord stromal tumors. In addition, several different cancers can spread distant metastases into the testis, including lymphoma and cancers of prostatic, penile, and intestinal origin (Fig. 6).

Varicocele

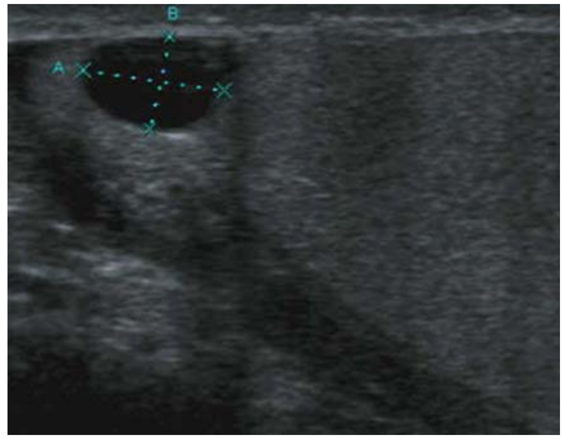
Varicoceles can be found in about 15% of adult men. Incompetent valves of the spermatic vein cause impaired drainage of the blood of the pampiniform plexus of the spermatic cord.

There are idiopathic and primary varicoceles. Primary varicoceles result from compression of blood drainage by a retroperitoneal mass. Idiopathic varicoceles are more common on the left side because the left testicular vein is longer and enters the left renal vein in a right angle. Bilateral or right-sided varicocele must make one suspicious for a primary retroperitoneal cause (Fig. 7).

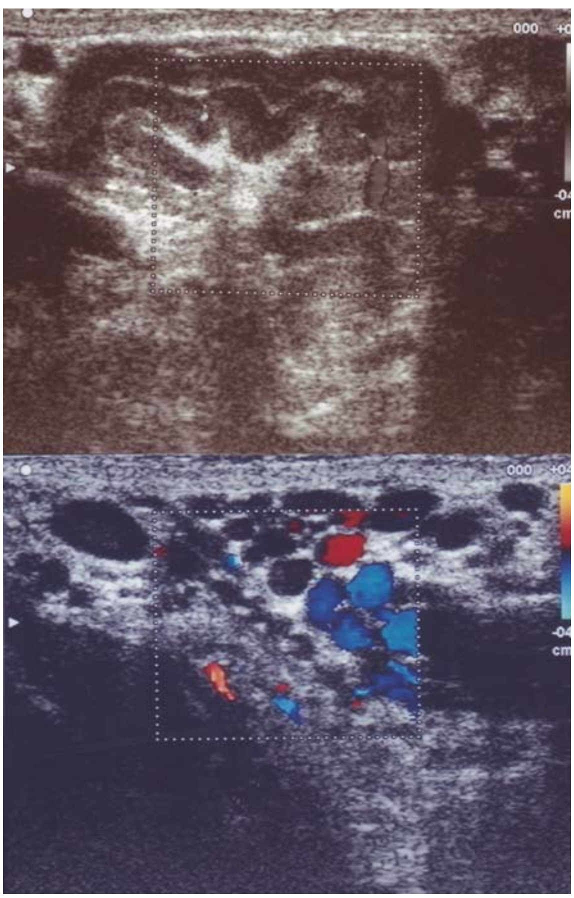
S



Scrotal Disorders. Figure 6 **Testicular cancer. Testicular mass with mixed hypoechogenic and hyperechogenic tissue areas.**



Scrotal Disorders. Figure 8 **Spermatocele. Cystic hypoechogenic area within the upper pole of the epididymis, revealing simple spermatocele.**



Scrotal Disorders. Figure 7 **Varicocele. Venous conglomerates in the spermatic cord (*above*) with increasing diameter under increased abdominal pressure**

Spermatocele

Spermatoceles can appear idiopathically, congenitally because of findings of the Mullerian duct, or secondarily after traumatic lesions of the tubules, which connect the head of the epididymis and the rete testis. The cyst is filled with sediment containing detritus, immobile spermatozoa, and lipids. Spermatoceles are usually unilocular but can also be multilocular (Fig. 8).

Clinical Presentation

Painful Scrotal Disorders

The ►Scrotum, Acute represents a clinical term itself and describes the acute onset of pain in the scrotal region. In testicular torsion as well as in acute epididymitis, even careful examination appears to be very painful and sometimes is not possible. On the affected side, the testis is tender and swollen and rides high in the scrotum, accompanied by a thickened and tender spermatic cord.

In epididymitis, the onset is usually slower than that of testicular torsion, although this might not be differentiated by the history. The epididymis and the spermatic cord are swollen and tender; the testis is often also tender, as a sign of concomitant orchitis. Fever can be present. The history shows urethral discharge and dysuria. Sexual exposure can be months before onset. Laboratory examination can show leukocyturia. It is imperative to promptly differentiate between epididymitis and testicular torsion, and in cases of doubt, to do further investigation to rule out testicular torsion.

Therapy

Once testicular torsion is suspected, immediate surgical exploration and replacement of the testis is crucial for survival of testicular function. Simple epididymitis or orchitis requires anti-inflammatory therapy. Antibiotics, analgesics, and local procedures (cooling, scrotal elevation) will heal most cases. Complications such as abscess are rare but may require surgical therapy.

Painless Scrotal Disorders

Because several pathological scrotal conditions may present as a painless tumor mass in the scrotum, careful clinical examination must distinguish between testicular cancer and benign lesions.

Testicular cancer usually presents as tenderless growth of one testicle with increased consistency. In approximately 20% of the cases, the first symptom is scrotal pain. Gynecomastia appears in 7% of cases and is more common in nonseminomatous tumors. In about 10% of the cases, a testicular tumor can mimic orchidoepididymitis, with consequent delay of correct diagnosis. Increased serum levels for HCG, AFP, and LDH can be found in germ cell tumors.

Hydroceles and spermatoceles usually present as painless swelling of the hemiscrotum. In moderate cases, the testicle might still be palpable next to the hydrocele. In severe cases, the testis can be hidden and not palpable. Spermatoceles are located at the head of the epididymis and in clear distance from the testis and present as small, cystic, usually indolent—sometimes moderately tender—tumor.

Varicoceles provide typical clinical findings as palpation reveals a scrotal mass that feels like a bag of worms. One-third of men undergoing evaluation because of infertility present with varicocele.

Therapy

Suspicion of testicular cancer requires surgical exploration, and if cancer is confirmed, orchiectomy with removal of the spermatic cord up to the inner inguinal anulus will be performed. Depending on histological findings, chemotherapy or radiotherapy might also be necessary.

Asymptomatic hydrocele or spermatocele does not require therapy unless the patient is disturbed by cosmetic reasons or discomfort. Surgical marsupialization or epididymectomy are the therapies of choice. Puncture or sclerotherapy are not good options because of their high recurrence rate and danger of iatrogenic infection.

Varicocele therapy is a controversial issue, with no single approach adopted as best.

Microsurgical ligation of the dilated veins as well as surgical ligation of the spermatic vein show good results. Sclerotherapy can be an alternative minimally invasive approach.

Imaging

Ultrasonography and Color Doppler Sonography

Ultrasonography is the mainstay for imaging scrotal disorders. Gray-scale sonography can show fluid collections in hydroceles or spermatocele lesions as well as solid changes as in testicular cancer. Color Doppler sonography provides the best information on blood flow and can diagnose or rule out torsion against inflammatory diseases such as epididymitis and orchitis. Color Doppler sonography has documented sensitivity for epididymitis of 70% and specificity of 82%. Nevertheless, about 15% of patients with early torsion will present with swelling only in the epididymis. Besides typical clinical findings, sonography as well as color Doppler sonography might help confirm the diagnosis of varicocele.

Magnetic Resonance Tomography

In clinical practice, magnetic resonance imaging (MRI) has a role in specifying unclear sonographic findings. In acute pain, MRI proves accurate results in the differential diagnosis of epididymitis and torsion. Although testicular cancer can be proven only by surgical and pathological examination, MRI can help identify unclear sonographic or clinical findings.

Computed Tomography

Computed tomography (CT) scanning has its main position in staging of malignant processes. Sonography and MRI provide better information on local situations, but CT is a standard imaging tool for evaluating the pelvis, abdomen, and chest.

Nuclear Medicine

In diagnosing scrotal disorders, radionuclide imaging (99m-Tc radioisotope scan) is used rarely when clinical and sonographic findings might be unclear, and in clinical practice it is rarely performed because of its time-consuming nature and logistical problems. Good indications for radionuclide imaging are inflammatory disease and the differential diagnosis of testicular torsion.

Diagnosis

Besides clinical and historical findings, radiological examination will present with more or less specific examination results. As mentioned, sonography remains the mainstay of the diagnostic approach to scrotal disorders. Testicular torsion initially will show no specific changes in gray-scale sonography, but there are inhomogeneous changes of the testicular parenchyma in late-stage torsion due to infarction of the hypoxic tissue. Duplex sonography provides more information on blood flow and will show lack of perfusion compared with the opposite healthy side. Hyperperfusion of the affected testicle can be due to spontaneous reposition of a testicular torsion or—more often—to an inflammatory disorder such as orchitis. An inhomogeneous appearance of the testicular tissue with only moderate or absent pain must provoke suspicion of testicular cancer, which can be diagnosed only by a histological approach. MRI of the testis can give additional information about possible testicular cancer. In MRI, testicular tumors commonly show signal intensity similar to that of normal testis in T1-weighted images. On T2-weighted images, they are mostly hypointense relative to the normal testis, with a homogeneous or heterogeneous signal pattern.

In suspected epididymitis, enlargement of the epididymis with typically reduced echogenicity can be found by gray-scale sonography. There might be increased echo after epididymal hemorrhage. Color duplex sonography shows increased blood flow due to inflammation. In addition, reactive hydrocele might be present in most of the cases.

An echogenic fluid collection surrounding a normal testicle is present in hydrocele. Sometimes septa or a thickened hydrocele wall can be found in a chronic inflammatory process. Well-defined hypoechogenic lesions located at the head of a normal-looking epididymis represent a characteristic finding of spermatocele.

Examination for varicocele should be performed with the patient in supine and standing positions, as described by some authors. The sonographic appearance of varicocele consists of multiple hypoechogenic, serpiginous, tubular structures of varying sizes larger than 2 mm in diameter. The Valsalva maneuver will show increased backflow of venous blood. In the literature, the sensitivity and specificity of varicocele detection is reported to approach 100% with color Doppler sonography.

Second (third) Generation Contrast Media

►Contrast Media, Ultrasound, Low Solubility Gas

Second Harmonic Imaging

Echocardiographic technique based on the nonlinear frequencies generated by ultrasound waves. Second harmonic imaging uses analysis of the received signal with frequency twice as high as that of the transmitted frequency signal.

▶Ischemic Heart Disease, Ultrasound

Second-Generation Contrast Media

A term that is now mostly used for ultrasound contrast media that are not air-based such as SonoVue (Braccotkl, Milan, Italy), Optison (GE Healthcare, UK), or Definity (Bristol Myers Sqibb, New York, USA). These agents are more stable than air-based first-generation agents such as Levovist (Bayer Schering Pharma, Berlin, Germany) and provide strong signal enhancement at a low mechanical index. According to an older definition, second-generation ultrasound contrast media are defined by transpulmonary stability and thus include all commercially available agents with the exception of Echovist (Bayer Schering Pharma, Berlin, Germany).

▶Time Intensity Curves

Secondary Gout

▶Gout

Secondary Hyperparathyroidism

A metabolic disorder such as kidney failure or intestinal malabsorption decreases calcium levels in the blood and leads secondarily to increased PTH levels.

▶Hyperparathyroidism

Secondary Hypertrophic Osteoarthropathy

A syndrome consisting of painful periostitis, arthritis, and bilateral clubbing of the digits on the hands and feet. It is often associated with intrathoracic neoplastic or inflammatory conditions.

▶Hypertrophic

Secondary Trauma, Splenic

A traumatic injury of the spleen that occurs in patients with predisposing pathological splenic processes. For example, subcapsular focal lesions or pathological conditions that cause splenomegaly produce locoregional or diffuse thinning of the capsule, respectively, making the spleen more fragile when trauma occurs.

▶Trauma, Splenic

Secondary Tubo-Ovarian Abscess

Secondary tubo-ovarian abscess may arise by direct or lymphatic spread of infection after pelvic surgery, or as a complication of enteric inflammatory diseases, such as appendicitis, diverticulitis, and Crohn's disease. Tubo-ovarian abscesses in postmenopausal women are rare; however, they are highly associated with pelvic malignancies in this age group.

▶Abscess Tubo-Ovarian

Secretory Calcifications

Characteristic benign calcifications, usually coarse, dense, diffuse, bilateral, and pointing toward the nipple.

Complex partial epilepsy (CPE), focal epilepsy

- Temporal lobe epilepsy (TLE): TLE accounts for approximately 70% of all chronic CPE
- Extra-temporal lobe epilepsy (ETLE): usually the frontal lobe [frontal lobe epilepsy (FLE)]

Definition

Epilepsy is one of the most common neurological diseases. Epileptic seizures may result from events such as fever, hypoglycemia and are then called '*occasional seizures*' (1). When they recur spontaneously without known cause, they constitute '*epilepsy*'. 'Epilepsy' is a chronic condition in which occasional seizures tend to occur repeatedly as a result of either structural brain damage or an intrinsic functional tendency to have seizures.

According to the International League Against Epilepsy (ILAE), an '*epileptic disorder*' is a chronic neurological condition characterized by recurrent epileptic seizures, whereas '*epilepsies*' are those conditions involving chronic recurrent epileptic seizures that can be considered epileptic disorders (►http://www.ilae-epilepsy.org/Visitors/Centre/ctf/glossary.cfm).

A classification of epileptic seizures has been adopted by the ILAE based on the distinction between '*partial seizures*', indicating electrophysiological activation of a small part of a single hemisphere and '*generalized seizures*', indicating involvement of both hemispheres (2). When partial seizures occur without altered consciousness they are termed '*simple partial seizures*' (SPS), otherwise they are termed '*complex partial seizures*' (CPS). Patients mainly suffering from recurrent CPS have '*complex partial epilepsy*' (CPE).

Pathology/Histopathology

Seizures may occur in patients with almost any pathological process: brain malformations, tumors, acquired traumatic lesions, and vascular lesions. Table 1 lists the most important brain disorders that may be treatable with surgical intervention. Mesial temporal sclerosis is a well recognized entity that may result from prolonged febrile seizures or convulsive status epilepticus and accompanying systemic disturbances (hypotension, fever, hypoglycemia, etc.). This entity is often the substrate of temporal lobe epilepsy (TLE).

Malformations of cortical development (MCD) are not specific for epilepsy but are more often seen in epileptic brains.

Tumors that are found in patients with longstanding CPE are usually benign: for example dysembryoplastic neuroepithelial tumor (DNET), ganglioglioma, or glioma.

Imaging

Most patients with epilepsy can initially be treated with standard first-line antiepileptic drugs (AED). About

Seizures, Complex, Partial. Table 1 Disorders causing CPE and that may be treatable by surgery

Genetic and developmental disorders	Acquired disorders
Sturge–Weber–Dimitri syndrome	Rasmussen encephalitis
Neurofibromatosis	*Tumor: primary and metastasis*
Tuberous sclerosis	Infectious lesions: meningitis, abscess, encephalitis
Congenital porencephalic cyst	
Congenital tumor	Subarachnoid hemorrhage
Malformation of Cortical Development (MCD)	Stroke
	Trauma
• focal cortical dysplasia	*Mesial temporal sclerosis (MTS)*
• periventricular heterotopia	
• polymicrogyria	
• DNET	
• ….	

From the listed pathologies in the table, the most important are tumor for recent CPE, and MTS and MCD for chronic CPE.

25–45% of epilepsy patients will become refractory to medical treatment. Some patients who fail to respond to first-line AED therapy will be rendered seizure-free with newer medical treatments introduced in the past decades. For those CPE patients who still remain refractory to medical treatment, surgery can be an effective alternative treatment. The role of neuroimaging becomes very important here for the determination of the actual site of epileptic origin. This includes the identification of lesions that may be amenable for tailored resection, the objectivation of lateralization in TLE by detecting lateralized damage to the hippocampus or temporal neocortical regions, and the detection of often microscopic cortical abnormalities in case of extra-temporal lobe epilepsy (ETLE). The relation also has to be established between the seizure focus and eloquent cortex when resection in such regions is mandatory.

The role of CT in epilepsy is limited to the evaluation of patients who present at emergency wards with acute epileptic seizures with remaining neurological symptoms and the occasional patient with absolute contraindication for MR. All other patients should be examined with MRI.

MRI will detect cortical lesions in patients with CPE in almost 75% in tertiary referral centers for epilepsy surgery.

Hippocampal Sclerosis and TLE

Hippocampal sclerosis (HCS) is the most common pathology found in patients with refractory CPE.

Imaging in these patients focuses on the visualization of the hippocampus and the mesial temporal lobe structures. Tilted-coronal thin-slice high resolution imaging of the temporal lobe is performed with inversion-recovery T1-weighted or fast spin-echo T2-weighted contrast. With experience, neuroradiologist will be able to visually diagnose HCS in 85–90% of histologically proven cases.

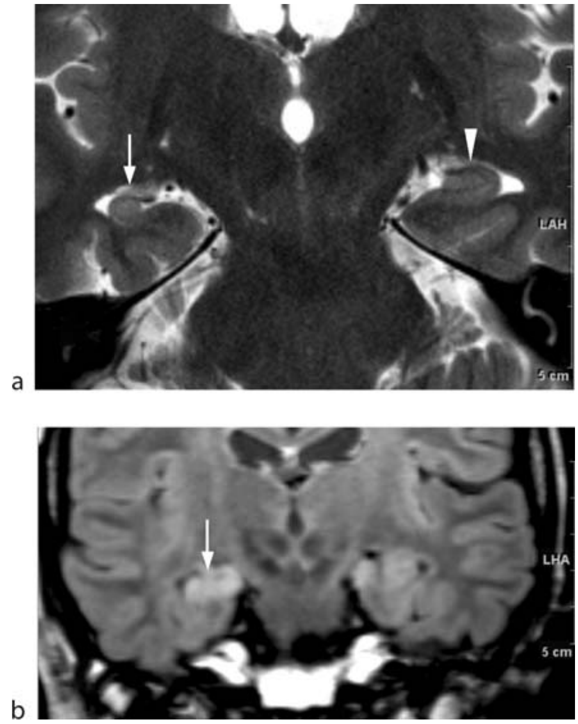
Three important features are characteristic of hippocampal damage: decreased volume, signal changes, and structural changes (Fig. 1) (3). Structural changes are often associated with extensive gliosis. Volume loss and gliotic changes often extend beyond the hippocampus into the adjacent temporal lobe and even in the contralateral temporal lobe. Studies have shown damage to the thalamus, the parahippocampal region and the entorhinal region.

In up to 30% of patients with seizure semiology of TLE and/or EEG findings consistent with TLE, optimal high resolution MRI does not show the classical signs of HCS. A lot of MR research is directed toward these patients. Special MR techniques like DTI and MT have shown abnormalities in the brains of MR-negative TLE patients, but not necessarily in the temporal lobes.

Malformations of Cortical Development

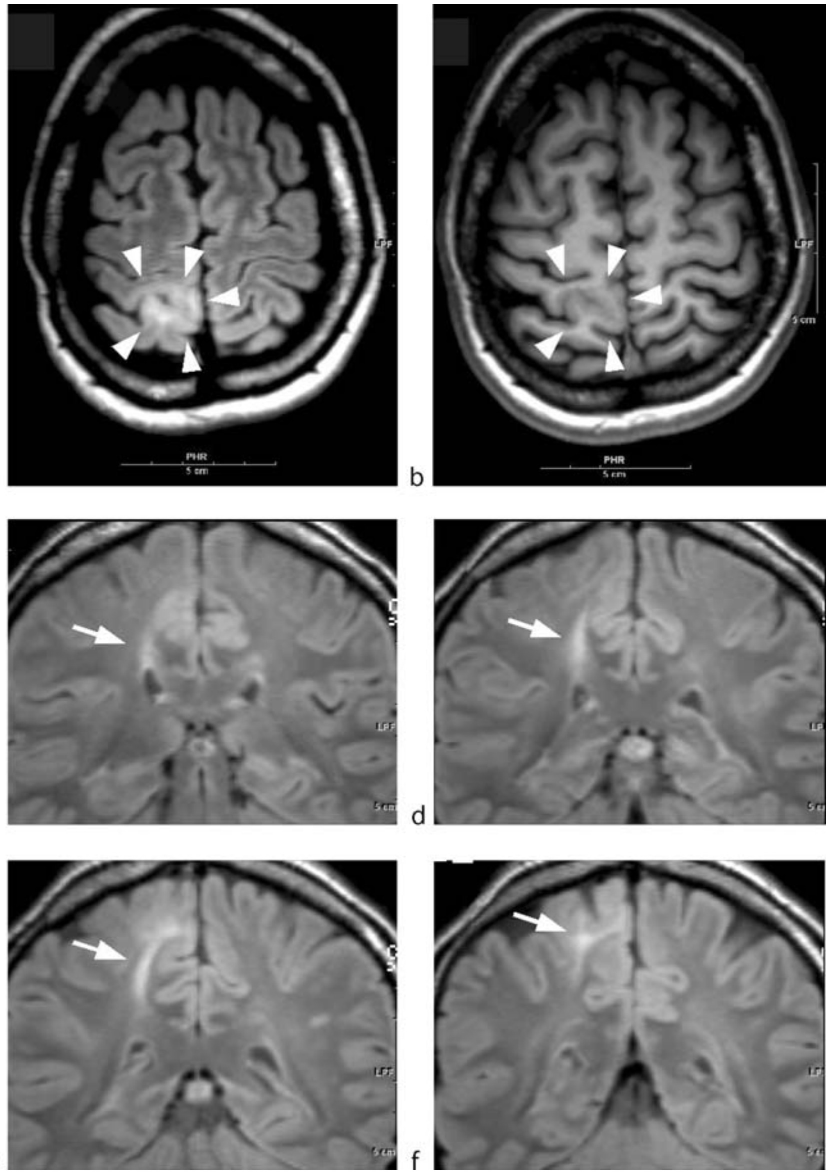
MCD is a blanket term and encompasses many different entities resulting from the disruption of brain formation in utero. These entities differ in their genetic signature, clinical presentation, structural effects and associated pathology and are usually grouped on the basis of three neuro-developmental steps: neuronal proliferation and eventual apoptosis of selected cells, neuronal migration, and cortical organization (4).

MCD is often associated with epilepsy, and is the second most common cause of refractory epilepsy (4): for example focal cortical dysplasias (Fig. 2), periventricular heterotopia and polymicrogyria (Fig. 3). Since many MCDs have been linked to genetic factors, the mere



Seizures, Complex, Partial. Figure 1 Hippocampal sclerosis MRI. Tilted coronal T2-weighted (a) and coronal reconstruction of 3DFLAIR (b) centered on the hippocampal region in a patients with TLE and right sided hippocampal sclerosis. In a, the *arrowhead* point toward the normal left hippocampus in which a clear an normal internal structure can be recognized, and the different divisions of the cornu ammonis and dentate gyrus have normal signal and thickness. On the right side, the hippocampus (*arrow*) is much smaller, the internal structure is mostly effaced (a) and the signal is too high (best seen on b).

S



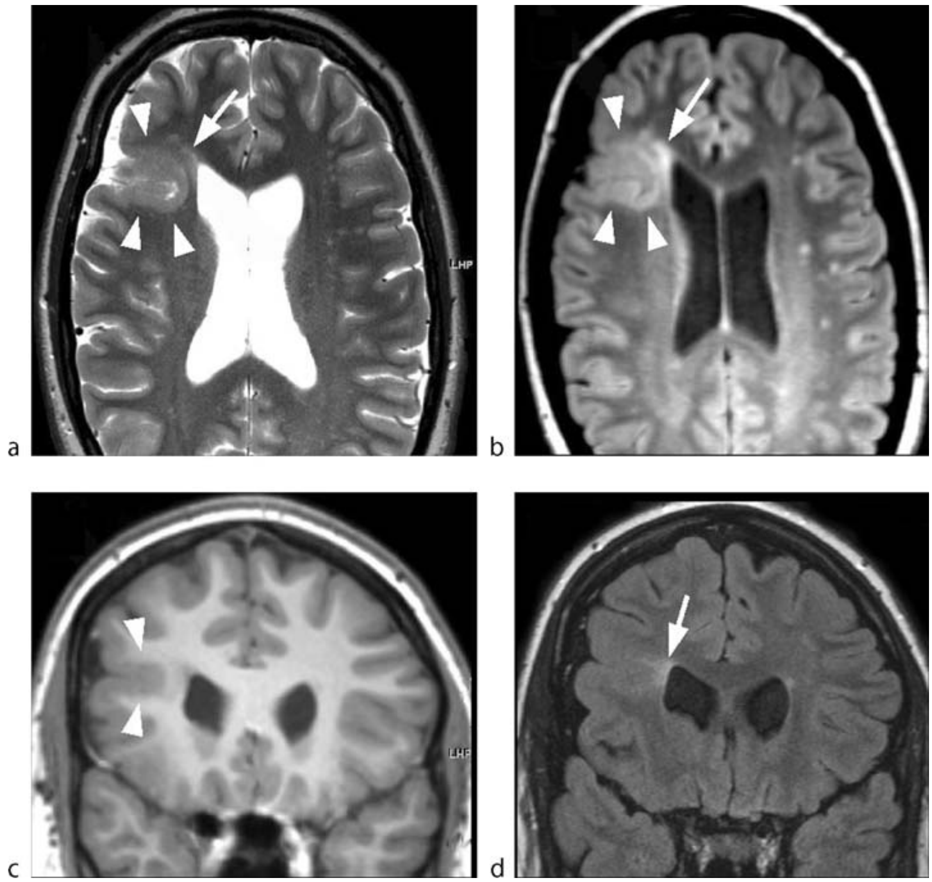
Seizures, Complex, Partial. Figure 2 Focal cortical dysplasia. Focal cortical dysplasia, Taylor type II, in the right medial Rolandic region. The typical disturbance of the architecture of the neocortex can be appreciated on high axial reconstruction of a 3DFLAIR (a) and 3DMPRAGE (b): irregular thickening, altered signal, and effacement of the normal interface between white and gray matter. A spur of signal changes can be seen on consecutive coronal reconstructions of 3DFLAIR (c–f) starting from the edge of the lateral ventricle, presumably deposited during the migration process.

detection of these entities by medical imaging is important for genetic counseling.

Many of these abnormalities can be visualized with high resolution and multicontrast, multiorientation thin-slice or 3D MR imaging (6). Recent work advocates the use of high field imaging because of the higher signal to noise and resolution that can be attained all in view of patient and budget friendly imaging times.

Tumors

The third most common cause of chronic refractory CPE is the presence of low-grade tumors. DNET, ganglioglioma, and gangliocytomas are benign developmental neoplastic lesions. Because these lesions are developmental, epilepsy often develops early in live and quickly becomes refractory to medical treatment. Complete resection is effective for epilepsy relief. MRI is the



Seizures, Complex, Partial. Figure 3 Polymicrogyria. MRI of a patient with frontal lobe epilepsy (FLE): axial T2-weighted (a), axial reconstruction of 3DFLAIR (b), coronal reconstruction of MPRAGE (c) and coronal FLAIR (d). A zone of abnormal folding of thickened cortex can be observed (*arrowheads*) in the right inferior prefrontal region with an underlying area of signal change in the white matter connected with the edge of the lateral ventricle (*arrow*). This abnormality constitutes polymicrogyria.

preferred imaging method to define the location and extend of the lesion. Of course, almost any tumor can cause recent onset CPE.

Sample Optimal Imaging Strategy for CPE

Many centers also use quantitative imaging parameters like hippocampal volume and T2 values in the hippocampus to detect hippocampal damage. Table 2 describes our imaging strategy for patients with chronic CPE. All imaging is performed on a 3 Tesla system. Although we rely heavily on 3D imaging, these sequences can be substituted by 2D sequences, but at least in two directions, axial and tilted coronal. Volume measurements are performed only if no visual abnormality is found in the hippocampi (3). In addition to structural MRI imaging, ^{18}FDG-PET and magnetic resonance spectroscopy (MRS) will be performed in all patients with TLE, and in selected patients with ETLE. fMRI of memory and language is performed presurgically.

S

Complex Partial Epilepsy and Brain Function: Language and Memory

Information on the location of functional areas in the brain of patients with chronic CPE is essential in view of surgery. In patients with HCS, it has been shown that epilepsy surgery in the language dominant hemisphere will often cause language problems. Therefore language lateralization and localization are essential before surgery is attempted. Typically, the presurgical evaluation of TLE patients includes a WADA test or intracarotid amytal procedure to assess language lateralization and memory redundancy. BOLD fMRI and the

Seizures, Complex, Partial. Table 2 The imaging strategy at 3T used at the Ghent University Hospital in Belgium for patients with chronic CPE. Reconstructions of 3D sequences are always performed in 2 mm thick adjacent axial slices along the AC–PC line and coronal slices perpendicular to the hippocampi

Structural Imaging strategy for CPE			
Sagittal MPRAGE	Fast T1W 3D sequence with isotropic voxels of $0.9\times0.9\times0.9$ mm^3	$T_{acq} = 6'$	Anatomical detail, hippocampal volume

DWI along AC–PC line	EPI sequence with diffusion weighted preparation	$T_{acq} = 1'$	
Sagittal MPRAGE after gadolinium injection	Fast T1W 3D sequence with isotropic voxels of $1\times1\times1$ mm^3 (interpolated in slice selection)	$T_{acq} = 3'$	Only if indicated by previous imaging results: tumors, vascular malformations

WADA test are concordant in 90% of CPE patients in defining language lateralization. A single language task is unlikely to show all essential language areas in the brain, and the combination of several language tasks is adopted in many centers to feel more comfortable in lateralization and localization issues of language in CPE. In our epilepsy surgery referral center the combination of a silent word generation task, a reading task, and a self-paced semantic decision task are standard procedure for CPE patients (7).

For surgery in the neocortex, localization of essential language areas is important. fMRI will often show many regions which are not essential to language as predicted from electrocortical stimulation, but a high predictive power of fMRI compared to electrocortical activation has been reported for the presence and absence of critical cortical language zones. fMRI has a high negative predictive value, and regions without activation can probably be safely removed.

Memory testing in epilepsy surgery patients is essential to test adequate postoperative memory function (WADA) and possible neuropsychological rehabilitation (neuropsychological testing). The WADA test cannot reliably detect specific postoperative deficits, but only test whether no devastating postoperative amnesia will be present if a hippocampectomy is performed. Therefor, in our practice we use two fMRI memory paradigms: a complex visual scene encoding task (8) and a less predictable memory paradigm (9).

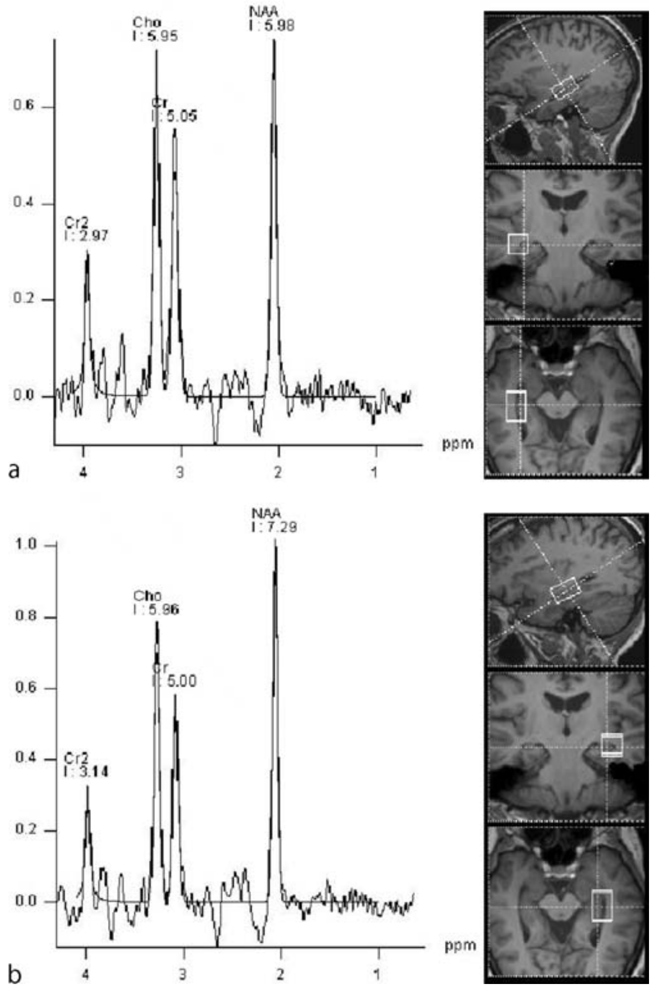
Magnetic Resonance Spectroscopy

Proton MRS has proven to be a sensitive technique to detect metabolic abnormalities and dysfunction in patients with CPE (Fig. 4). With its high sensitivity, metabolite abnormalities can be detected in brain regions distinct from the seizure focus and it remains difficult to disentangle which abnormalities cause seizures and which are their consequences.

Abnormalities detected with 1H-MRS can be used in lateralization issues of TLE and in localization attempts for ETLE, and also in monitoring therapeutic effects of AED. In TLE, NAA is used as a marker for neuronal loss or dysfunction and is often more decreased in the afflicted TL. Although many bilateral abnormal ratios can be found in patients with TLE, the introduction of an adequate asymmetry index (AI) improves the lateralization capabilities of the technique (10).

A recent meta-analysis of the value of MRS in epilepsy shows rather conflicting results for patients with MR-negative patients in an epilepsy surgery program, but a role for MRS could be found for patients with bilateral hippocampal atrophy.

Glutamate and γ-amino-butyric-acid (GABA) can be measured using MRS and many medication related effects on their concentrations have been reported. Intracellular glutamate concentrations are reported elevated in the epileptogenic human hippocampus and neocortex. The high glutamate content may contribute to the epileptic



Seizures, Complex, Partial. Figure 4 Proton MRS in temporal lobe epilepsy. Single voxel proton MRS in the temporal lobe of the patient shown in Figure 2 with right sided HC sclerosis. (a) The spectrum on the right side, (b) the spectrum on the left. The only difference is the amplitude in the NAA peak which is lower on the right side. The NAA/Cho+Cr ratio is 0:54 on the right and 0:67 on the left. Both ratios are too low (less than 0:71), but the asymmetry index is 21, lateralizing the metabolic disturbance to the right side.

state by increasing cellular excitability. The cellular glutamate levels measured by MRS in occipital cortex are increased in patients with refractory CPS.

Introduction

The prognosis of malignant disease is determined by the metastatic potential of the primary tumor. The status of the regional lymph nodes is critical in staging oncologic patients, since lymph node involvement is an unfavorable prognostic factor. Moreover, the detailed histological assessment of the lymph nodes is one of the most significant prognostic indicators and a strong determinant in the choice of therapy.

Minimally invasive surgery combined with lymphatic mapping helps avoiding complete lymph node dissection (ALND) and decrease morbidity. Lymphatic mapping with sentinel node biopsy is a new promising technique to determine lymph node status.

The ▶sentinel lymph node (SLN) is the first lymph node to receive lymphatic fluid from a malignant tumor and is the most likely node to contain tumor cells. Theoretically, if the SLN is free of tumor cells, the remainder of the nodal basin will also be free from metastases.

▶Sentinel lymph node biopsy (SLNB) is an alternative to standard complete ALND that allows complete ALND to be avoided if the sentinel node is metastasis free. It is a minimally invasive technique useful to find out the status of a lymph node basin by removing one or a small number of nodes. SLNB was initially developed to detect lymphatic metastases in patients with penile carcinoma (described by Cabanas in 1977). Now is a widely available technique mostly for patients with melanoma and breast cancer. Moreover, it has a very promising role in other malignancies like gastrointestinal, endocrine, head and neck, and lung tumors.

There are several principal aims for the excision of SLN: (i) Minimally invasive assessment of the nodal status. (ii) Selection of patients with positive SLNs. (iii) Prevention of complete ALND in SLN negative patients. (iv) Detection of alternative lymphatic drainage. (v) Improvement of sensitivity of histopathological detection of lymph node metastases. Since 1 or 2 lymph nodes are removed, a more accurate immunohistochemical evaluation can be done.

Despite the initial enthusiasm, there are controversies in practice and many issues have to be defined. There is no gold standard technique in the performance of the SN procedure yet. Current techniques involve the use of radioactive isotopes and/or the use of dyes. The success of the technique depends on: (i) the accurate preoperative determination of regional lymph node basins at risk and the location of SLN within the basin, (ii) the accurate intraoperative localization and biopsy of the SLN, and (iii) the accurate pathologic evaluation of the removed SLN.

Clinical Applications

The diagnostic utility of SLN technology includes melanoma, breast cancer, colon cancer, and all solid neoplasms that can potentially spread to lymph nodes, like lung cancer, head and neck cancer, gynecological cancer, and urological cancer. However, the clinical significance is not the same in each type of all these solid tumors. For melanoma and breast cancer the SLN concept is an established and of great validity technique, confirmed by many clinical trials.

Techniques in Sentinel Node Detection

Two different techniques are currently available for locating SLNs: (i) radioisotopic and (ii) nonradioisotopic techniques.

Radioisotopic Techniques

The radioisotopic techniques are used for the pre and intraoperative detection of the SLN. They include the lymphoscintigraphy for the preoperative evaluation of SLNs and the use of gamma detection probes for preoperative and intraoperative evaluation.

For the radioisotopic detection of the true SLN several steps must be followed: to choose the most suitable gamma detection probe, the most appropriate tracer, to decide for the best injection technique (site of injection, how many injections, volume of the injectate, how many MBqs) and the imaging protocol (dynamic, early imaging, early and late imaging).

Gamma Detection Probes

A wide range of probes are now available. These detectors must fulfill required characteristics. The high sensitivity (determination of counts per time unit) is very important. Deeply situated sentinel nodes could not be detected without good sensitivity. Other important parameters are the accepted spatial resolution, the energy resolution, and the collimation. Moreover, other factors like visual display clarity, audible feedback, size, and weight must also be taken into account.

Radiopharmaceuticals

The radioisotopic procedure of the SLN detection is based on the injection of a radiopharmaceutical, a specific compound, labeled with a radionuclide to be detected by gamma camera and probe detectors. Labeled colloids seem to be the most appropriate tracer and technetium-99 (^{99m}Tc) is the most often used radiotracer for labeling purposes, because of its relatively short half-life (6 h), the low patient dose, the nonsignificant beta emission, and the good detection energy. The ideal tracer should combine a rapid and predictable transport to the target node and persistent retention in it. Different size averages are used for lymphoscintigraphy (50–90 nm) and sentinel node labeling (100–200 nm). Larger particles may be retained at the injection site and no migration will be noticed. Smaller particles will pass to the capillary instead of the lymphatic system.

How these particles enter the lymphatic capillaries is not completely understood. Lymph nodes are rich in macrophage and colloid particles are phagocytosed by them.

The use of a particular colloid preparation depends on the clinical protocol. Larger particle colloids are more suitable when a patient is to be operated the next day of the imaging and smaller when imaging and operation is to be done on the same day. Moreover, other factors like the number of particles, the charge to the particles with the tracer substance, the rate of degradation by enzymatic activity of proteases are important.

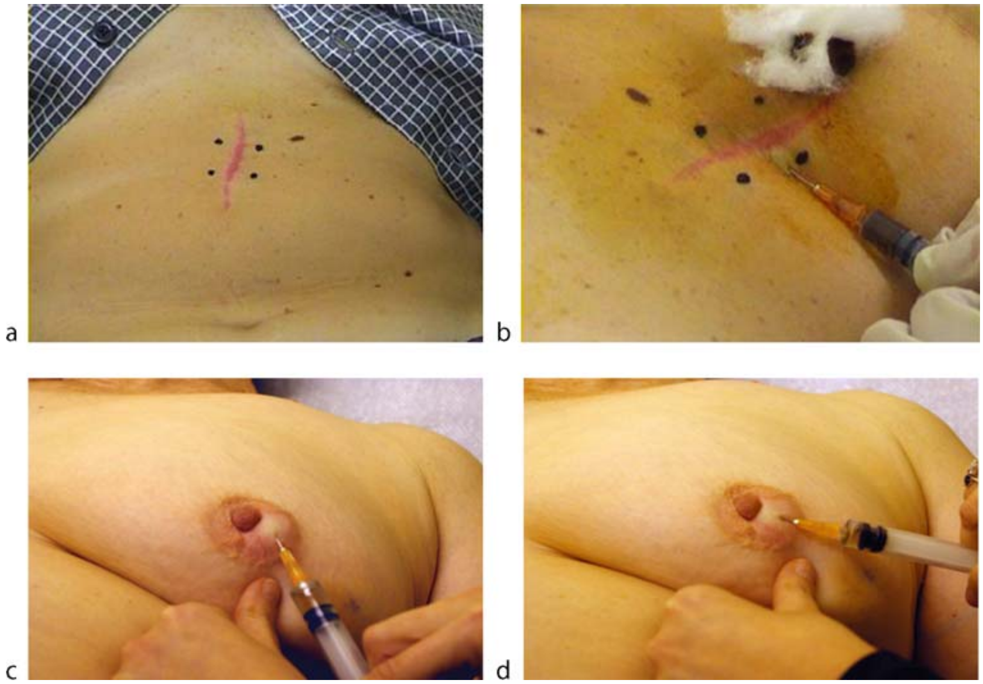
Besides the labeled colloid particles that are routinely used to indicate the localization of SLN independently of the cancer cell infiltration, labeled liposomes are investigated to detect cancer cell infiltrations of lymph nodes.

Injection Techniques

There are different opinions about the injection site, the number of injection sites, the volume of injectate, and the injected dose of the radiotracer.

For malignant melanoma, the subdermal injection site is the most appropriate. The lymphatic tissue is very rich in the peripheral layer of the skin, so a subdermal injection will deliver the tracer to an area rich in lymph vessels. In contrary, subcutaneous tissue has fewer lymphatic vessels.

On the day before or on the same day of the operation up to 1 mCi of radiolabeled colloid is injected subdermally into four equal portions around the primary lesion or the excisional biopsy area, using a 25-G needle. The syringe is held parallel to the skin surface with an angle of 10–20° to the horizontal plane (Fig. 1a, b).



Sentinel Node, Scintigraphy. Figure 1 **(a) Melanoma of the abdomen (b) subdermal injection (c) breast cancer (d) subareolar injection.**

The direction of lymph flow is important in the decision on whether injections should be given in circular or semicircular formation. When the primary lesion is located on the trunk a circular injection is needed because of different possible drainage direction of the lymphatic flow. In contrary, when the lesion is located on the face or the extremities, a semicircular injection is more appropriate because normally there is only one possible drainage direction.

While in melanoma the subdermal injection is a rule, for breast cancer there is an enormous discussion about the injection techniques: single subdermal or intradermal injection, multiple peritumoral and intratumoral. The confusion is mainly generated by the fact that although there is undoubtedly communication between breast and dermal lymphatics, it is debatable whether the lymphatics of the overlying skin drain to the same axillary sentinel node as the underlying glandular breast tissue.

The subdermal injection has several advantages over the intraparenchymal injection such as the ease of injection, the shorter time interval between injection and sentinel node identification, and the increased radiotracer nodal uptake. However, despite its success, subdermal injection failed to identify nonaxillary sentinel nodes when compared to intraparenchymal injection.

The intraparenchymal injection is characterized by a slower removal of the tracer due to the scantier lymphatic supply of the breast parenchyma. The intratumoral injection technique is not widely used.

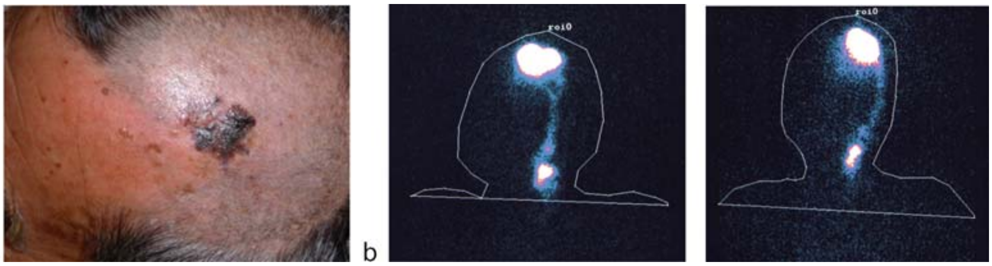
The subareolar or periareolar injection technique has recently been proposed. A local anesthesia is needed. After a few moments to allow the anesthetic to take effect, a dose of 1 mCi diluted with sterile saline to a total volume of 4 mL is injected. The injection must be superficial subdermally toward the nipple. (Fig. 1c, d). Deep breast injections may produce a delay or failure of migration of the radiotracer.

The subareolar or periareolar injection seems to be superior compared to subdermal and intraparenchymal injections. Its superiority is due to the more rapid flow of the tracer to the SN, the more rapid visualization, its simplicity, the quick learning curve, the higher percentage of the injected dose in the SLN and the reduced "shine through" effect.

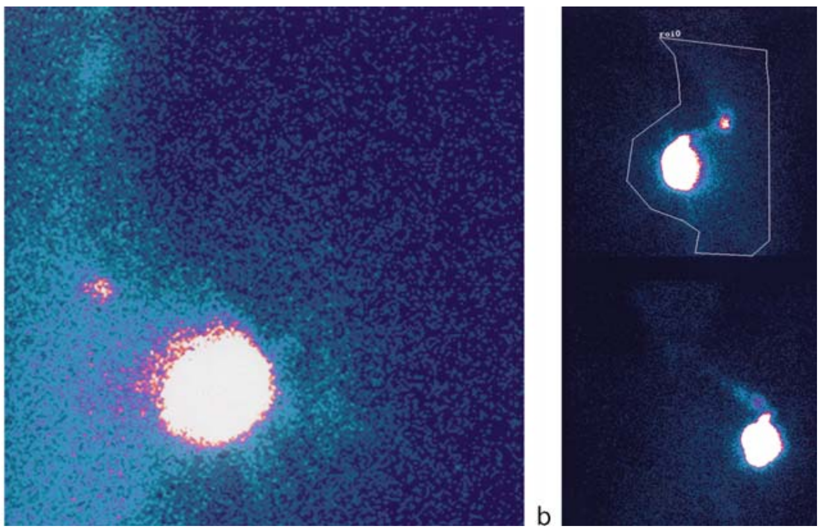
Preoperative–Intraoperative Detection

The sentinel node detection techniques are performed in two steps: (i) the preoperative based on lymphoscintigraphy and on probe detectors and (ii) the intraoperative based on the visual evaluation of the SLN with dyes and on the quantitative evaluation with gamma probe detectors.

The ►preoperative lymphoscintigraphy (PL) is a highly sensitive procedure (Figs 2 and 3). PL is performed routinely in melanoma. For breast cancer, it is not yet clear if it is helpful or not. Some investigators support that PL does not improve the ability to identify axillary SLNs and is not associated with improvement of false negative rate.



Sentinel Node, Scintigraphy. Figure 2 Melanoma of the scalp. The lymphoscintigraphy demonstrates a lymphatic channel that drains into a submandibular lymph node. (a) subdermal injection (b) lateral view, anterior view.



Sentinel Node, Scintigraphy. Figure 3 Ductal carcinoma of the left breast. (a) lateral view which shows the SLN in the axilla (subareolar injection site) (b) illustrates the need for lateral projections compared to the anterior image (upper row: lateral view; lower row: anterior view).

Arguments have been made in favor of PL as a "road map" for the surgeons able to identify all nodal basins at risk from metastatic disease, any transit nodes, and any unsuspected nodal basins. The imaging protocol (dynamic series, early images, early and delay images) depends on the department. However, it comprises: (i) dynamic series, necessary not only to identify the drainage from the lesion to the SLN but also to identify its position. (ii) static images, early and delay, in two projections (anterior, lateral, or obliques), useful to define the lymphatic anatomy (Fig. 2). Additionally, the use of anatomical markers, for example, for the nipple, is helpful.

After the determination of SLN by lymphoscintigraphy, its position is marked on the immediately overlying skin. This mark is subsequently confirmed with a gamma probe.

The combination of the lymphoscintigraphy and the probe detectors is advantageous for the knowledge of the location of SLN before surgery. The overall success of SLN localization is maximized and the false negative results are reduced.

Sentinel Node, Scintigraphy. Table 1 Criteria of successful SLN intraoperative detection.

In vivo	Ex vivo	Incision area	Evaluation
+	+	–	Total excision
+	-	+	Not true SLN excised
+	+	+	Additional SLNs
+	–	–	Technical failure

+ represents high counts, – represents low or no counts compared to background

The intraoperative detection is based on three steps: (i) the *in vivo* evaluation (positioning the probe in the wound and looking for the node with high radioactivity compared to background), (ii) the *ex vivo* detection (counting the radioactivity over the excised node and far away from the body), and (iii) the detection of any remained node with high activity in the wound (Table 1).

Conclusion

The combination of preoperative lymphoscintigraphy and the intraoperative use of the probe and/or dyes is the best available detection method of the SLNs. A good communication between the surgeons and the nuclear medicine physicians is important to improve the accuracy of the SLN procedure.

Shining Corner

Shining corner is the minimal variant of a Romanus lesion without erosion and only minor sclerosis.

▶Spondyloarthropathies, Seronegative

Short Oesophagus

Permanent retraction of the gastro-oesophageal junction into the chest because of chronic oesophagitis and fibrosis.

▶Hernia, Hiatus in Adults

Shoulder Dislocation

The majority of glenohumeral dislocations are anterior. Anterior humeral dislocations are often associated with osseous impaction of the posterolateral humeral head and anteroinferior labral detachment. These lesions are known as Hill-Sachs and Bankart lesions, respectively. Fractures of greater tuberosity are associated with 15% of anterior dislocations. Injuries to the rotator cuff and the articular capsule are also associated with these dislocations. Recurrent dislocations are common in younger patients and those with associated soft tissue and osseous injury. MRI is helpful for characterizing these abnormalities and assists surgical planning. Posterior dislocations usually occur secondary to muscle spasm during seizures. Reverse Hill-Sachs fractures, injury to the posterior labrum, and lesser tuberosity fractures are associated with posterior dislocations.

▶Fractures, Peripheral Skeleton

Shrinking

Lobular invasive carcinoma represented by a decrease in the size of the affected breast.

▶Carcinoma, Lobular, Invasive

Shwachman–Diamond Syndrome (SDS)

Rare autosomal recessive disorder characterized by pancreatic exocrine hypoplasia with pancreatic insufficiency, associated with bone marrow dysfunction and skeletal anomalies (metaphyseal chondrodysplasia).

Sickle cell anemia

Definitions

Sickle cell disease (SCD) is a hemolytic anemia with red blood cells that abnormally sickle. These cells are destroyed at an increased rate leading to a chronic anemia. The sickled cells cause vascular occlusion which often leads to infarction resulting in many clinical and radiologic manifestations of the disease.

Pathology/Histopathology

Hemoglobin (Hb) A consists of four globin chains, two alpha and two beta. In SCD, the beta chain is abnormal with valine substituted for glutamic acid at the sixth position of the B-globin chain locus on chromosome 11. Patients homozygous for the defect have HbSS and are referred as having sickle cell anemia. Those with one normal beta globin chain have sickle trait with a typically benign course unless significantly stressed. Those with one S-globin chain and a second abnormal chain such as Hb sickle thalassemia have a less severe clinical course.

When deoxygenated, the abnormal Hb chains form rigid polymers that cause a sickling shape and reduce the deformability of the red blood cell (RBC) resulting in lysis and occlusion of vessels. HbS adheres to vessel endothelium which can result in intimal hyperplasia. When acutely deoxygenated, an erythrocyte may partially polymerize which reverses when reoxygenated. Polymerization also depends on pH, temperature, and Hb concentration. When polymerization occurs, membrane permeability changes creating a dehydrated RBC. The abnormal Hb becomes more concentrated accelerating the polymerization during the next deoxygenation episode. These cells eventually become irreversibly sickled and cause vasoocclusion even when oxygenated. It has been noted that individuals with abnormal Hbs such as sickle cell trait have fewer parasites and a milder disease course than those with normal Hb. Malaria invades HbS cells as easily as normal cells, however, with lower oxygen tensions, the trophozoites do not grow as well, thus decreasing the severity of malaria.

Clinical Presentation

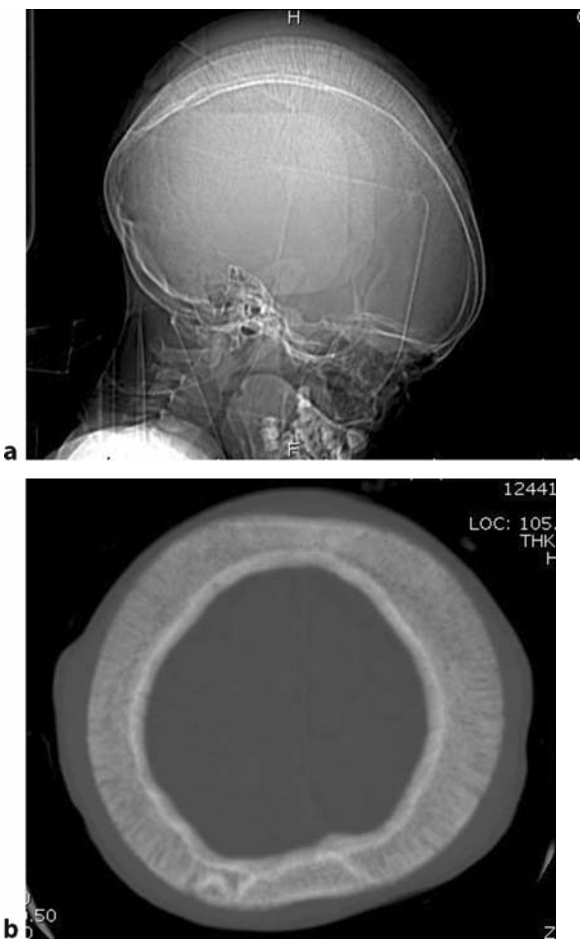
SCD is the most common genetic disorder in black Americans affecting 1 in 375 Americans of African ancestry. SCD is also common in the Middle East, India, Caribbean, and South America. In the neonatal period, higher concentrations of fetal hemoglobin prevent the sickling process. After 6–8 months, HbS percentage increases and clinical manifestations become evident.

As the cells sickle from hypoxic events such as pneumonia, air travel, or dehydration, capillary stasis occurs which leads to hypoxic damage. Crises are associated with fever, nausea, vomiting, abdominal, chest, or bone pain. SCD often results in cardiomegaly and pulmonary hypertension.

Management includes prophylactic oral penicillin to reduce pneumococcal sepsis. Pneumococcal and meningococcal vaccines are given due to poor splenic function

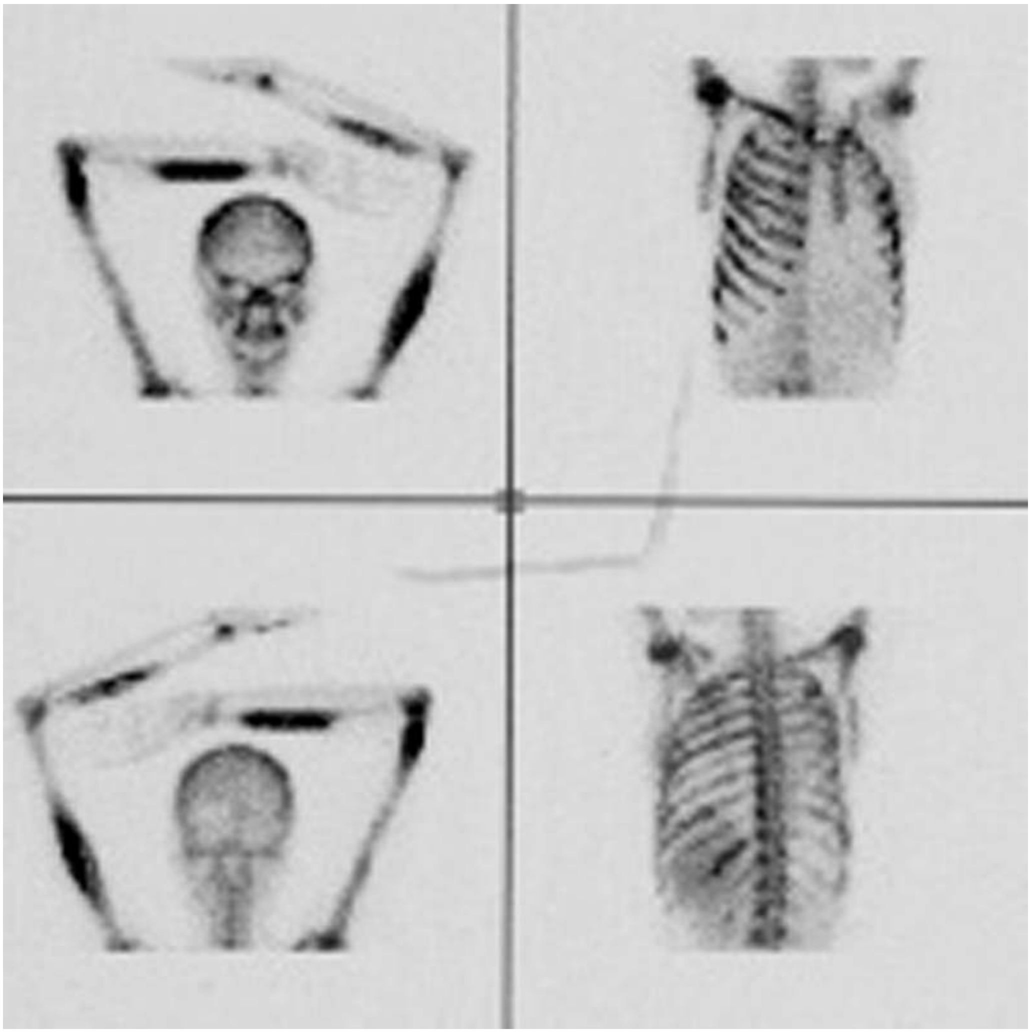
Sickle Cell Disease. Figure 1 Acute chest syndrome. Twelve year old with SCD and acute chest syndrome. There is cardiomegaly with bibasilar infiltrates.

and decreased phagocytosis. Transfusions and combination antibiotic therapy is used for acute infections. Prophylactic chronic transfusions and hydroxyurea are used to decrease the rate of cerebral infarction. The median survival is 40–50 years of age with the highest morbidity in young children. Infection is the most common cause of death in the first decade, followed by sequestration and cerebrovascular infarction. Up to 30% of children have *acute chest syndrome* (ACS) by age 10. Presentation includes chest pain, fever, cough, and dyspnea. ACS may be a sequela of infection or have infection as a complication. Infiltrates not complicated by infection resolve quickly. ACS may progress to severe respiratory distress and death and is the second most common cause of hospitalization in SCD. *Skeletal complications* result from stasis in red marrow and bone. Clinical presentation includes bone pain, fever, and swelling. Complications include avascular necrosis, bone infarcts, and osteomyelitis. Due to diminished phagocytosis and splenic function, children are at high risk for osteomyelitis (particularly *Salmonella*). Infants between 6 and 24 months are at risk of an infarction of the small bones of the hands and feet (“►hand-foot syndrome”). Painful soft tissue swelling of the hands and feet present for several weeks before radiographic changes are evident. *Stroke* is a leading cause of morbidity and mortality in SCD with an incidence of 11% in children. Ischemic infarcts predominate in younger children while hemorrhagic stroke occurs in older



Sickle Cell Disease. Figure 2 Lateral scout film of the skull (a) and axial CT of the parietal skull (b) demonstrate abnormal skull thickening from expansion of the marrow creating a “hair-on-end” appearance.

Sickle Cell Disease. Figure 3 (a) Avascular necrosis. Coronal STIR image of the pelvis demonstrates heterogeneous signal of the femoral epiphysis consistent with evolving bilateral avascular necrosis in 11-year-old with SCD. (b) Lateral radiograph of the lumbar spine demonstrates end plate depression from infarction resulting in a “fish mouth” appearance.



Sickle Cell Disease. Figure 4 Multifocal osteomyelitis. Fourteen year old girl with SCD. A bone scan demonstrates increased uptake in numerous bones including ribs, humeri, and radii.

patients. Both large and small vessel diseases can occur. The proximal middle cerebral artery (MCA) and distal internal carotid artery are at highest risk for stenosis. Children who have had one stroke are at high risk for subsequent strokes. When stenosis becomes irreversible, lenticulostriate collateral develop forming a pattern of moyamoya "puff of smoke."

Imaging

As SCD results in multiple clinical manifestations, imaging becomes a useful tool in the assessment of acute and chronic symptoms. Radiographs are important for evaluating the lungs and bones for infections and infarctions. Ultrasound (US) is useful for biliary, splenic, and renal symptoms. CT can further assess abdominal and chest crisis as well as those children presenting with acute stroke symptoms. Transcranial Doppler (TCD) and magnetic resonance imaging (MRI)/magnetic resonance angiography (MRA) are used as screening tools to assess for stroke risk.

Pulmonary: Chest radiographs should be routinely obtained in patients with SCD and fever. Cardiomegaly invariably is present. With ACS, infiltrates may develop quickly but also resolve quickly if there is no underlying infection (Fig. 1). High-resolution CT may demonstrate reduced peripheral vascularity suggesting microvascular occlusion. Small and large perfusion defects have been shown with scintigraphy. When chest pain develops, there often is a lag time in radiographic changes so close follow-up radiographs are necessary. The most common pneumonias are *Streptococcus pneumoniae*, *Hemophilus influenzae*, and *Staphylococcus aureus*. Four percent of

Sickle Cell Disease. Figure 5 **Renal US of an 8-year-old sickle cell patient demonstrates an enlarged kidney with decreased corticomedullary differentiation and echogenic parenchyma ("pseudonephrocalcinosis").**

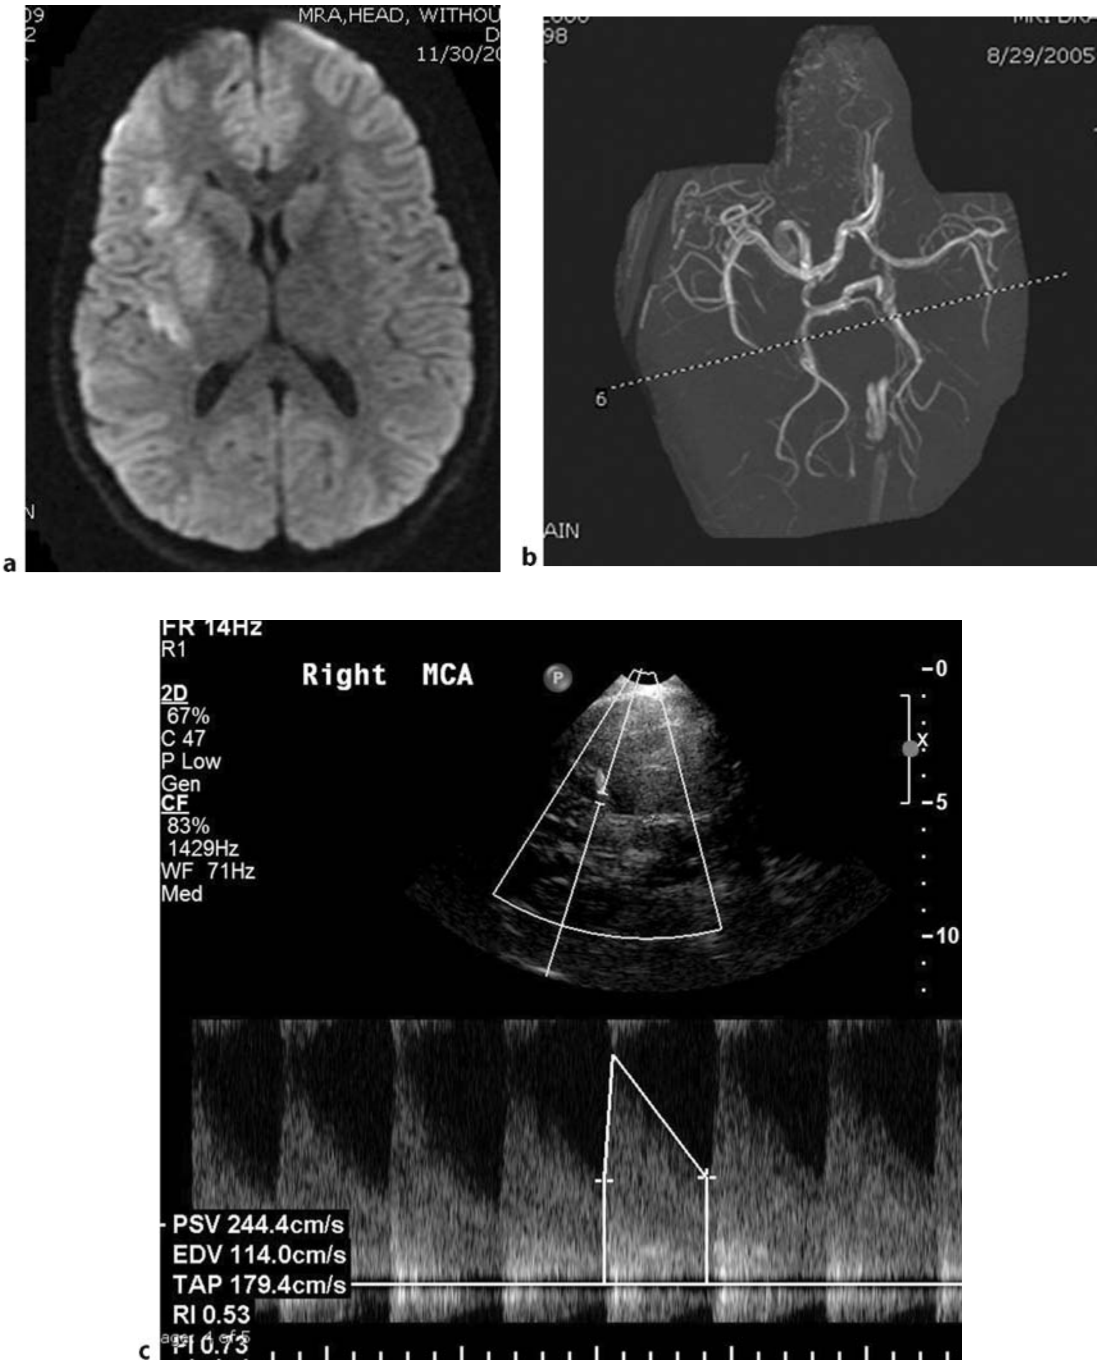
sickle cell patients develop chronic pulmonary disease including fibrosis, pulmonary hypertension, and cor pulmonale. CT findings include septal thickening, a reticular pattern of interstitial disease, bronchiectasis, and cardiomegaly.

Skeletal: Skeletal changes include marrow hyperplasia and bony infarction from vasoocclusive crisis. In SCD, most marrow spaces remain preserved as red marrow even in the epiphysis. MRI demonstrates low marrow signal on T1-weighted. The persistence of red marrow makes detection of infarction and infection difficult by MR. Expansion of the marrow is notable in the skull with widening of the diploic space creating a "hair-on-end" appearance (Fig. 2).

Avascular Necrosis is a common with up to 50% of patients developing osteonecrosis by the age of 35. The epiphyses of the long bones have a limited vascular supply with minimal collaterals. Stasis and occlusion lead to ischemia and infarction most commonly of the hips and shoulders. It may take months for radiographs to demonstrate any changes. Radiographs eventually show sclerosis then fragmentation and collapse. MRI is sensitive for detecting early infarction demonstrating T2-weighted and Short TI Inversion Recovery (STIR) high signal changes (Fig. 3a). Nuclear bone scans can demonstrate early decreased perfusion prior to radiographic changes. Within the spine, infarcts involve the vessels supplying the central vertebral end plates. Central end plate depressions result in a "fish mouth" appearance to the vertebral bodies (Fig. 3b). Compression fractures are common due to marrow hypertrophy and end plate collapse. Bone within bone appearance may be noted after multiple infarctions.

Dactylitis or "hand-foot syndrome," is an infarction of red marrow of the tubular bones of the hands and feet with associated periosteal inflammation. Radiographs demonstrate soft tissue swelling and destructive osteitis of the phalanges though changes are delayed for 1–2 weeks. Periosteal new bone formation can be seen at 7–10 days. Medullary expansion, cortical thinning, and trabecular resorption occurs 2–3 weeks later. Differentiating from osteomyelitis can be difficult but bones tend to reconstitute after several months without residual deformity. Epiphyseal infarction of the hands and feet may produce cone-shaped epiphysis or premature fusion of epiphysis resulting in abnormal shortening of involved bones. Distinguishing between infarction and infection is difficult both clinically and radiographically in patients with SCD. Both may present with pain, swelling, fever, leukocytosis, and elevated sedimentation rate. Infarction is much more common than infection and can be treated with transfusions and hydration. Osteomyelitis requires prompt antibiotic therapy. Radiographs demonstrate osteopenia and periostitis is found in both entities. Later findings of cortical destruction, sinus tracts, and sequestra may develop. CT and/or US can demonstrate subperiosteal fluid collections and sequestra. MRI demonstrates abnormal high signal on T2-weighted and STIR with both infection and infarction Soft tissue edema occurs with both as well. MRI may be useful in differentiating acute

S



Sickle Cell Disease. Figure 6 **(a) Axial diffusion-weighted MR image demonstrates high signal in the right middle cerebral artery territory consistent with an acute infarction. (b) TOF-MRA of an 11-year-old with SCD demonstrates left distal internal carotid artery stenosis. (c) Eight year old with SCD. Screening TCD of the right middle cerebral artery demonstrates elevated mean and peak velocities (in the "conditional range").**

from old areas of infarction by the high intensity signal on long TR-TE images. Tc-99m skeletal scintigraphy can demonstrate hot or cold regions with either infection or infarction (Fig. 4). However, combined bone marrow scintigraphy with Tc-99m sulfur colloid may be useful to differentiate osteomyelitis from osteonecrosis. Indium-111 white blood cell may play a role in difficult cases as well.

Abdominal: The spleen is at high risk for damage as the red pulp becomes congested. As hemorrhages and infarcts develop, the spleen is replaced with fibrous tissue. *Autosplenectomy* eventually occurs leaving the patient at risk for infection. By the age of 6, 90% of children are asplenic. The spleen may become small and calcify. Tc-99m sulfur colloid scans can be used to evaluate residual splenic function.

Splenic sequestration is an acute life threatening event where a sudden accumulation of blood collects in an enlarged spleen resulting in hypovolemia and severe anemia. Splenic sequestration typically occurs below the age of 6 prior to fibrosis developing. The spleen may remain enlarged with clinical signs of hypersplenism.

Gallstones can be found in up to 50% of children with SCD. These stones tend to be pigmented desire from hemolysis and are well seen sonographically. Liver parenchymal disease may occur secondary to infarction. Hepatitis and iron-overload occurs from transfusion therapy. Hemosiderosis can be evaluated using MRI with low signal parenchyma. Chronic renal damage develops by the second decade of life. Renal parenchyma may appear slightly echogenic with poor cortico-medullary differentiation likely related to interstitial fibrosis (Fig. 5). The kidneys enlarge possibly due to glomerular hypertrophy. Of note, patients with sickle cell trait have an increased incidence of renal medullary carcinoma.

Central nervous system: Cerebrovascular infarction is a leading cause of morbidity and mortality in SCD. Children with stroke typically have infarcts in the cortex and deep white matter whereas silent infarcts are limited to the deep white matter. While CT is useful in the assessment of hemorrhagic stroke, MRI has become the method of choice to assess acute and chronic infarction evaluating both large and small vessel diseases. Silent strokes demonstrate small lesions of high signal in the centrum semiovale. Large vessel territories and border zone infarction are noted with large vessel disease (Fig. 6). MRA demonstrates regions of stenosis and collaterals resulting in a moyamoya (Fig. 6). Catheter angiography is rarely needed to assess sickle cell vasculopathy. TCD is a useful screening test in the detection of large vessel disease prior to stroke. While intracranial velocities are already typically higher than the normal population due to anemia, abnormally high velocities are the results of luminal narrowing. TCD has proven to be a safe, reliable, and cost-effective screening method to assess for stroke risk. Via a transtemporal window, mean peak velocities of the MCA, distal internal carotid artery (ICA) and anterior cerebral artery (ACA) can be measured. Those with mean peak velocities greater than 200 cm/sec are considered at high risk to develop stroke (Fig. 6c). Chronic transfusions or bone marrow transplants have been used to decrease stroke risk in children with elevated cerebral blood flow velocities.

Diagnosis

The condition is diagnosed by laboratory, imaging (as described above) used to assess and differentiate the various manifestation.

Single Photon Emission Computed Tomography

S. I. Koukouraki
Department of Nuclear Medicine
University, Iraklion, Crete, Greece
sophiak@her.forthnet.gr

Introduction

There are two main categories of emission imaging: the planar and the tomographic imaging. Emission tomographic studies are divided into single photon emission computed tomography (SPECT) and positron emission tomography (PET).

SPECT uses collimator systems for detection of photons from radionuclides. The conceptual basis is the physical rotation of the camera in small angular steps around the patient, acquiring a usable number of events to form an image. A typical single camera SPECT study requires about 30 min of imaging time.

Despite the recent growth of PET, SPECT is the most appropriate imaging procedure for the everyday management of patients with cardiac diseases, cancer, and neurological diseases. It is a very important complementary tool to planar procedures, increasing the sensitivity especially in small and deeply located lesions.

SPECT is based on the use of conventional gamma cameras and on generator produced radiopharmaceuticals. The development of hybrid scanners SPECT/CT lead to a more accurate diagnosis. In addition, SPECT is substantially less expensive compared to PET and available at every nuclear medicine department.

On the other side, SPECT systems suffer from the limited sensitivity, due to the use of collimators, the difficulties in quantitation due to scatter, the low spatial resolution, the physical problems of attenuation, and statistical limitations. SPECT has a spatial resolution of 8–10 mm dependent on the individual acquisition data. The sensitivity of SPECT is one tenth that of PET. The availability of new SPECT radiopharmaceuticals, the recent advances in technology combined with the well-designed reconstruction software, and the economic aspects of SPECT instrumentation render this mode of emission tomography attractive for clinical studies.

SPECT Radiotracers

SPECT radiotracers are substances labeled with gamma emitting radionuclides. The most commonly used radionuclides are ^{99m}Technetium, ^{123,131} Iodine, and ^{111}Indium. Their long half-life is very important to evaluate the biodistribution changes over the time offering the knowledge of several biological features. Many SPECT tracers used for imaging can also be used for treatment purposes in cancer patients, according to the isotope used with a γ-emitting radionuclide for imaging and β-emitting radionuclide for treating.

SPECT agents:

1 In cardiac imaging: ^{201}Thallium, ^{99m}Tctetrofosmin, ^{99m}Tcsestamibi,^{131}I metaiodobenzylguanetidine (MIBG).
2 In oncology: ^{99m}Tc methylendiphosphonate (MDP), ^{99m}Tcsestamibi, ^{201}Thallium, ^{67}Ga citrate, ^{131}I MIBG, ^{111}In- octreotide, ^{111}In- or ^{99m}Tc- labeled antibodies, ^{99m}Tc-annexin V, labeled antibodies. There are also other agents under investigation like gastrin labeled with ^{111}In, bombesin, labeled with ^{99m}Tc, radioiodinated insulin, and vasoactive intestinal peptide.
3 In brain imaging: ^{99m}Tc-HMPAO, ^{123}I-iodoamphetamine, dopamine transporter agents (DAT).

Thallium chloride-201 (*^{201}Tl*): It is a potassium analog used for the cardiac imaging. The mechanism of uptake is related to blood flow, tumor metabolism, and ATPase activity. Because of its uptake that is related to cellular metabolism, it can also be used in ▶tumor imaging. ^{201}Tl can be used not only for diagnostic purposes but also to monitor and predict the response to treatment. It is also of particular use in patients with radiotherapy able to differentiate fibrotic changes from recurrent disease.

^{99m}Tc-sestamibi and ^{99m}Tc- tetrofosmin: Both agents have active uptake into the cells and are retained to the cytoplasm and mitochondria. The uptake mechanism in malignant cells is not yet well known. Several factors may be responsible: the increased blood flow and capillary permeability, the elevated metabolic activity, the cell membrane and mitochondrial potentials. Even more, for tetrofosmin the Na^+ /K^+ pump and N^+ /H^+ antiport system may also be involved. The efflux mechanism is related to the expression of a membrane protein, *P*-glycoprotein, responsible for the multidrug resistance (MDR1).

^{131}I-MIBG: The mechanism of MIBG uptake by sympathoadrenal tissues is not completely understood. However, the majority of MIBG enters the cytoplasm by an active sodium and energy dependent (uptake-one) mechanism. A smaller fraction enters by passive diffusion. In the cytoplasm, enters the hormone storage vesicles.

^{99m}Tc-MDP: It is absorbed to amorphous bone and on the surface of the hydroxyapatite crystal.

^{67}Ga- citrate: The mechanism of uptake is still unclear. However, it is related to the expression of transferring receptors on the surface of neoplastic cells. In the cell, it concentrates in the cytoplasm and is bound to lysosome like proteins. Its uptake is high in lymphomas. However, the uptake in most solid tumors is around 50%.

^{111}In- octreotide: It is a somatostatin analog with high affinity in SSTRs 2, which are overexpressed in a number of neuroectodermal tumors (neuroendocrine, SCLC, medullary cell carcinoma of the thyroid, etc.).

^{99m}Tc-depreotide: It is a synthetic peptide with high affinity for somatostatin receptors 3, 4, and 5 but lower affinity for 2.

Labeled antibodies: Only two cancer seeking antibodies are now available. Capromab pendetide (ProstaScint) and the Arcitumomab (CEA scan).

Clinical Applications of SPECT Studies

The most important clinical applications of SPECT include the cardiac imaging, the cancer and brain imaging.

SPECT in Cardiac Imaging

Stress myocardial perfusion SPECT imaging provides important diagnostic and prognostic information in patients with coronary artery disease (CAD). It can define the extent and severity of reductions in regional blood flow. It has also an important role to the therapy monitoring.

Diagnosis of CAD

The SPECT perfusion imaging has a high sensitivity and specificity for the diagnosis of CAD. The stress perfusion defect size and extend correlates with the presence and extend of a CAD. It is more sensitive and specific than exercise electrocardiography (ECC). It is also widely used for the assessment of the myocardial viability. New ^{99m}Tc labeled compounds have been developed such as ^{99m}Tc sestamibi and tetrofosmin having the best biological properties. The sensitivity and specificity for ^{99m}Tc labeled agents 90 and 93% compared to 83 and 80% for ^{201}Tl. SPECT perfusion imaging can also be used for patients with acute chest pain on emergency department. It has high-diagnostic accuracy for identifying patients with acute coronary syndrome.

Evaluation of Treatment Response

CAD progression and response to therapy can be monitored with SPECT perfusion imaging. The role of SPECT in the evaluation of patients receiving therapy like nitrates, calcium antagonists, or B-blocker is very important. Studies showed an improvement of perfusion in most patients after 6 months of treatment.

Evaluation After Revascularization

SPECT perfusion imaging has a high ability to locate and evaluate changes in the extent and severity of perfusion abnormalities after revascularization. It accurately identifies the presence of restenosis after a complete revascularization. The overall sensitivity, specificity, and accuracy are up to 89, 75, and 85%, respectively. However, false positive results (i.e., ischemia but no underlying angiographic restenosis) may occur, but because of the improved resolution with technetium agents they may be less common.

A meta-analysis showed a high positive and negative predictive value for restenosis when imaging was delayed 2–4 weeks after the revascularization. Postrevascularization SPECT perfusion imaging can also identify patients who are at risk for a worsening prognosis.

Prognostic Value of SPECT in Patients with CAD

The prognosis in patients with CAD is related to the severity of reversible perfusion abnormality. The number of vascular territories with SPECT perfusion abnormalities is related to MI-free survival. Additionally, the extent and severity of SPECT perfusion abnormalities are highly effective at stratifying patients risk for myocardial infarction (MI) so as to decide for the most appropriate therapy.

SPECT is able to manage patients with cardiac diseases with the same accuracy of PET at a lower cost.

It can also be used as a guide to patient care, to evaluate the disease progression, and the effectiveness of anti-ischemic therapies. Moreover, the use of SPECT/CT offers the contemporaneous evaluation of the morphology of the coronary vessels, the presence of calcified plaques by CT angiography, and the viability and the regional wall motion before and following treatment with SPECT.

SPECT in Cancer Imaging

Diagnosis

SPECT is very useful in the assessment of malignancies and cancer staging. The bone scan is the most useful tool but its low specificity leaves a problem that may be resolved using SPECT. In cases of lymphoma, ^{67}Ga-SPECT images of the thorax improve the sensitivity, being able to distinguish mediastinal and hilar lymph node disease from the physiologic activity in the sternal and the spinal bone marrow. Moreover, SPECT/CT offers additional information for the most accurate staging, the detection of tumor tissue after treatment and the early detection of recurrencies.

SPECT is also very useful in somatostatin receptor imaging and in phaechromocytoma because planar images failed to evaluate accurately abdominal or intrahepatic lesions. Hybrid images can also increase the specificity of SPECT alone.

In breast cancer, SPECT seems to be more sensitive than planar imaging, but until now it has not been largely employed in the diagnosis of breast carcinoma. The sensitivity and specificity of SPECT is 69–95% and 70–91%, respectively. Negative predictive value is high for SPECT (95%), so a negative study excludes breast cancer. SPECT is also more sensitive in evaluating multifocal disease and in palpable lesions.

In the detection of axillary lymph node metastases SPECT has a higher sensitivity (81–94%) and accuracy (83–92%) compared to planar imaging (52–62% and 76–82%). However, the exact number of lymph nodes cannot be determined.

Only few studies are available for the role of SPECT in the recurrent breast cancer. Its sensitivity is similar to that of conventional imaging and higher than that of planar.

In differentiated thyroid cancers, SPECT with cationic lipophilic tracers is more useful than planar because of the better detection of distant metastases in the lung, mediastinum and neck, and could be complementary to 131I-WBS.

SPECT has several advantages over planar in parathyroid imaging, such as higher sensitivity especially in the detection of small and ectopic parathyroid adenomas and in those associated with multinodular goiter. The sensitivity for SPECT is high in adenomas but low in hyperplastic glands.

Assessment of Tumor Response to Therapy

For the assessment of tumor response quantitative SPECT analysis is very important. In cases of lymphoma ^{67}Ga SPECT is superior to CT in differentiating fibrotic/necrotic tissue from residual tumor. A positive ^{67}Ga SPECT study after treatment is associated with poor prognosis. A negative is associated with better prognosis.

SPECT in Neurology

Nowadays is widely used in neurology for the assessment of areas of abnormal perfusion and the pre and postsynaptic neurotransmitter function.

Conclusion

It is essential that SPECT should always be associated to planar imaging in cancer diagnosing since it improves sensitivity and accuracy. It is simple, noninvasive and less expensive.

Sinusitis

Sinusitis is an inflammatory process that involves one or more of the four paired paranasal sinuses. Because of the contiguous anatomical relationships of the sinuses to the nasal mucosa, it is rare to find inflammation of the sinuses without nasal mucosal involvement, and a more appropriate term for the condition is rhinosinusitis.

Definition

Infectious diseases of the small bowel are defined as diseases associated with inflammatory changes of the intestinal layers due to microorganisms. Parasitic infestations or bacterial organisms can occur in countries in Asia and southern Africa. Enteric pathogens are ingested through contaminated food and water and pass through the entire gastrointestinal tract during establishment in the host, with subsequent shedding and spread to new hosts (1). In patients treated by immunosuppressive agents or in small bowel transplant recipients, fungal and viral infections can also involve the gastrointestinal (GI) tract (2–4).

Pathology/Histopathology

The GI mucosa acts as a major interface between the host and its environment. Microbes living in the GI tract of a healthy host constitute its normal flora. Numerous factors regulate its composition. As such, it is continuously exposed to a passing stream of toxins and microbes.

S

Inevitably, some microbial species colonize the gut, causing GI infections. Small bowel infections can result from various causes, including bacterial, fungal, viral, parasitic, and extrinsic inflammatory processes (Table 1).

Mechanisms of bacterial injury can be encountered as bacterial adherence, bacterial translocation, and toxin production. Bacterial pathogenicity in small intestinal injury may vary, such as ingestion of a preformed bacterial enzyme or toxin (*Staphylococcus*), elaboration of an enterotoxin following G colonization (cholera, *Shigella*, *Salmonella*, *Yersinia*), elaboration of a tissue-damaging cytotoxin (*Shigella*), or mucosal invasion (*Shigella*, *Salmonella*) (5).

The major setting in which bacterial overgrowth occurs is called bacterial stasis, stagnant loop, or blind loop syndrome. Proposed mechanisms for the abnormal bacterial proliferation include the following:

- Failure to clear bacteria from the upper GI tract, usually due to achlorhydria
- Continuous seeding of the small bowel with colonic contents as a result of jejunocolic fistulae or reflux following abnormalities of the ileocecal valve
- Motility disturbances

These factors initially cause an overgrowth of coliform bacteria and, eventually, anaerobic bacteria. Neutrophilic mucosal infiltrates represent the hallmark of acute invasive disease. Toxigenic organisms tend to produce less severe morphologic damage than bacteria invading the mucosa (5).

Clinical Presentation

Small bowel infectious diseases frequently manifest as dysenteric syndromes characterized by the presence of fever, abdominal pain, and numerous small-volume stools containing blood, mucus, and polymorphonuclear neutrophils in patients with toxigenic bacterial infections. In contrast, patients with invasive bacterial infections as exemplified by *Shigella*, *Salmonella*, and *Campylobacter* usually have a colonic infection, and diarrhea dominates the clinical presentation. A third type of enteric infection results in enteric fever, often with constipation early in its course, as seen with *Salmonella typhi*. The organisms enter Peyer's patches and regional lymph nodes, and numerous factors predispose to microbial intestinal colonization and contribute to diarrhea, malnutrition, sepsis, and extra-intestinal infections (5). Bacterial overgrowth leads to malabsorption. The clinical presentation of small bowel infections according to microorganism is shown in Table 2.

Imaging

Radiologic imaging modalities used in evaluating small bowel infectious are plain abdominal radiography, barium studies as conventional enteroclysis or follow-through examination, ultrasound (US), computed tomography (CT), and magnetic resonance (MR) enteroclysis.

Plain abdominal radiography: A supine anteroposterior radiogram of the abdomen is essential in the plain film examination of small bowel disorders. The acute abdominal series for patients with possible small bowel obstruction or visceral perforation should consist of supine and erect abdominal radiography. In immobile patients, a left lateral decubitus view of the abdomen should be done (6). Erect or lateral decubitus radiograms demonstrate air-fluid levels in patients with obstruction and free air collection under the diaphragm in patients with perforation. Calcification due to granulomas and lymphadenopathies can be recognized in the right lower region in patients with tuberculosis.

Small bowel follow-through: The conventional small bowel follow-through (SBFT) examination is routine in most radiology departments. But because of its crowded location in the peritoneal cavity, multiple segments of small bowel cannot be adequately delineated (6). Optimal distension of bowel lumen cannot be obtained by this technique, and early mural infiltration and small ulcers and nodules cannot be detected because of superimposition of bowel loops.

Enteroclysis: Intubation is essential in enteroclysis, and intestinal contrast fluid can be administered at the required rate by an enteroclysis catheter. The entire small bowel can be demonstrated in a distended state at the end of the infusion. The evaluation of mucosal detail and early changes of the inner wall is more successful than with SBFT.

Cross-sectional modalities: Extraluminal evaluation of the small intestine can be obtained with cross-sectional modalities. US, CT, and MR imaging (MRI) provide direct visualization of the bowel wall, mesentery, peritoneal cavity, retroperitoneum, and visceral organs. As a result, these imaging modalities are complementary to barium examination of the GI tract. It is essential to obtain intestinal distention. Uniform opacification of the entire small bowel may be accomplished by the steady ingestion of 1,000 mL of contrast over a 45-min period before the CT or MR examination.

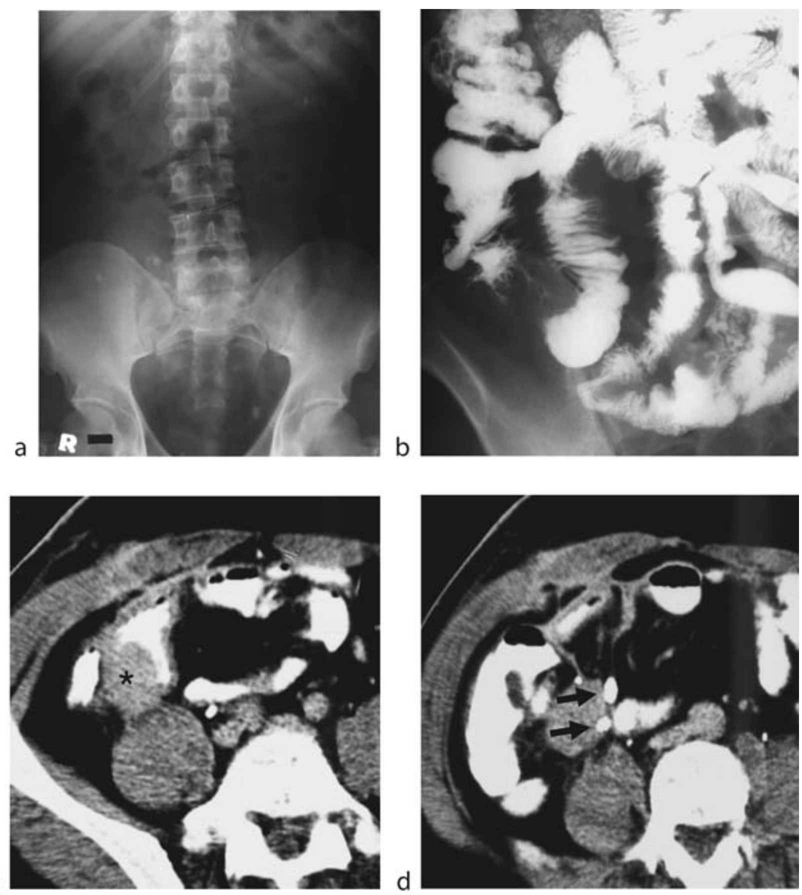
MR enteroclysis: Advantages of this technique are that it provides good information about the intestinal wall and extraluminal soft tissue. During this procedure, polyethylene glycol (PEG) solution is given into the GI lumen *via* intubation. Pre- and postparamagnetic agent injection, fat-saturated T1- and T2-weighted sequences can be obtained. Scanning is done in axial and coronal planes.

Radiological Findings

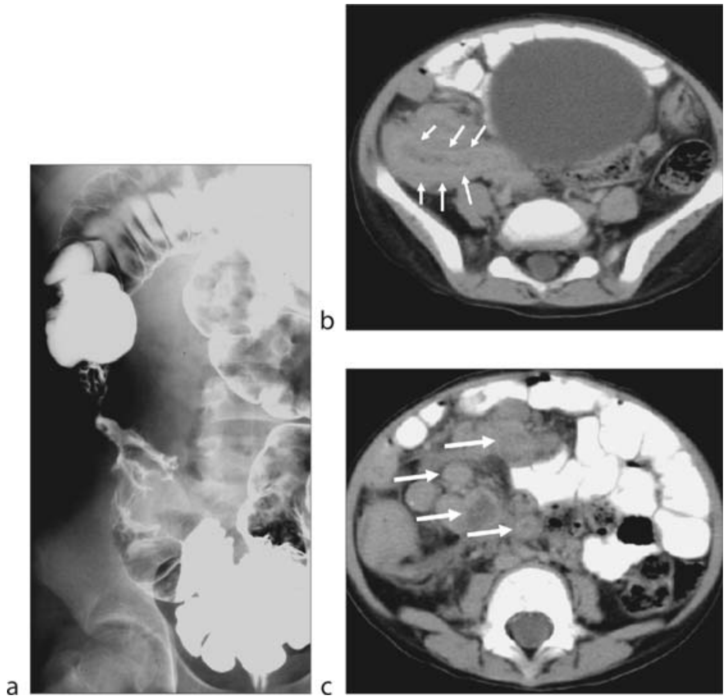
Tuberculosis: Radiographically, calcified mesenteric lymph nodes are helpful in diagnosing tuberculosis. The earliest changes in tuberculous enteritis are altered motility with thickening and nodularity of folds on barium studies. Focal disappearance of folds, the demonstration of polyps, and ulcerations that are usually transaxial are other early findings. Cephalad retraction of the cecum may be associated with straightening of the ileocecal junction (Fig. 1). Predominant mass formation with ulceration involving the terminal ileum is usually a more advanced ulcerative change affecting the cecum or the ileocecal valve area. These changes are usually well demonstrated by CT scans (Fig. 2). MRI is at its best in demonstrating changes in the mesentery and omentum. Complications are infrequent. Obstruction due to strictures, fistulae, or perforation can occur (6). The severity of GI involvement is related to the severity of pulmonary infection. In cases of tuberculous peritonitis, an adynamic ileus may be present with or without ascites. Calcifications may be seen in the adrenal glands, peritoneal surface, lymph nodes, liver, or spleen (Fig. 3).

Yersiniosis: Barium studies can demonstrate changes in the distal 20 cm of the ileum, and these may be seen to extend into the cecum and ascending colon. Thickened nodular folds may be present, often with ulcers that may be aphthoid or larger, and single or multiple. The bowel mostly retains its normal lumen diameter. Thickened folds may later be replaced by fold effacement. Resolution of these changes is expected within 4–5 weeks. Enteritis secondary to a Yersinia abscess has been shown by CT (Fig. 4). CT scans demonstrate an inflammatory mass and mesenteric lymphadenopathy. Radiographic changes mimic those of tuberculosis or Crohn's disease, except that fistula formation and ileal stenosis are unusual (5, 6).

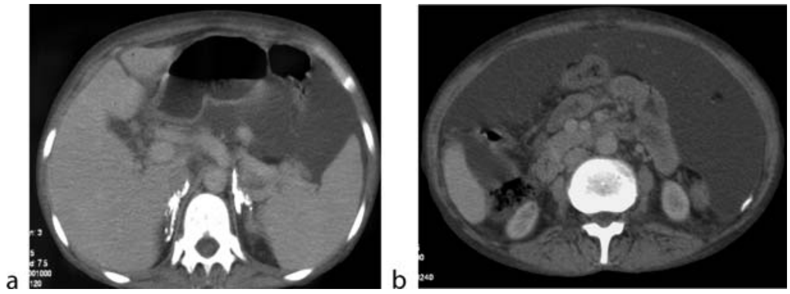
Salmonella: Plain film radiographs may show ileus of the small and large intestine. Barium studies are infrequently indicated. The radiological appearance of the distal ileum is not unlike that of other inflammatory disease. Aphthoid ulcers identified in the early stage of any acute inflammatory disease may also be seen in *Salmonella* infections. CT scans of salmonella enteritis have shown



Small Bowel, Infectious Diseases. Figure 1 Tuberculosis. (a) Plain abdominal film shows nodular calcification in the nearby right lower quadrant. (b) Follow-through small bowel study demonstrates retraction of antimesenteric border, mucosal edema, narrowing, and fissure tracts of terminal ileum. (d, c) Computed tomographic images of right lower quadrant. Wall thickness of ileum (*asterisk*) and calcified granuloma (*arrows*).



Small Bowel, Infectious Diseases. Figure 2 Tuberculosis. (a) Small bowel follow-through study shows narrowing and fibrosis of the distal ileum, ileocecal valve, and ascending colon. (b) Thickened bowel wall of the terminal ileum can be recognized on computed tomography (CT). (c) CT study demonstrates ileocecal and mesenteric lymphadenopathies. These nodes have low-density areas (*arrows*) due to caseation.



Small Bowel, Infectious Diseases. Figure 3 Tuberculosis. (a) Bilateral adrenal calcifications and ascites. (b) Abdominal ascites and focal calcification of the left posterior peritoneal surface.

mild circumferential thickening of the terminal ileum, and a corresponding barium study showed thickened folds.

Campylobacter: On barium study, the distal ileum can be narrowed with irregular nodularity and thickening of the wall. Shallow ulcers may be seen in more severe cases.

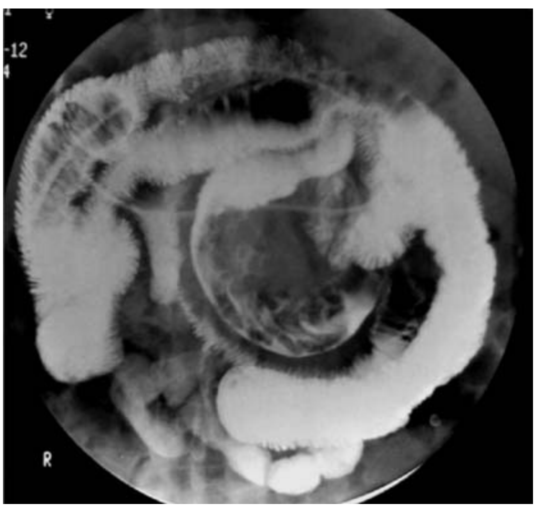
Blastomycosis: The organism is located in the submucosal lymphoid tissue of the gut and then erodes the mucosa. Radiological changes in the small bowel are nonspecific narrowing with mucosal irregularities. Mesenteric nodes are regionally enlarged.

Histoplasmosis: Infection primarily involves the respiratory tract and affects the small bowel or colon by dissemination. Radiography may demonstrate polypoid changes or ulcerations in the small bowel or the ileocecal area, as well as strictures.

Aspergillosis: Disseminated aspergillosis is a rapidly progressive and highly lethal infection that typically affects the immunocompromised patient. GI invasion may occur rarely and result in serious complications such as bowel obstruction and angioinvasion with secondary bowel ischemia, necrosis, and perforation.

Giardiasis: An increase in the fold thickness in the duodenum and proximal jejunum and a state of irritability are seen. CT shows wall thickening in the jejunum as well as mesenteric adenopathy, both reverting to normal after treatment.

Small Bowel, Infectious Diseases. Figure 4 **Yersinia enteritis. Thickened nodular folds and multiple aphthoid ulcers can be seen at the distal ileum. (Courtesy of Prof. Uğur Korman, Istanbul University Cerrahpasa Medical School, Istanbul.)**



Small Bowel, Infectious Diseases. Figure 5 **Ascaris. Middle jejunal segment has tubular filling defect due to infestation with ascarides. (Courtesy of Prof. Uğur Korman, Istanbul University Cerrahpasa Medical School, Istanbul.)**

Ascaris: Ascarides worms can be identified on plain abdominal films. Mature worms within the small bowel are visible because of their soft tissue density against the surrounding intraluminal air. A larger bolus of parasites may create a so-called whirlpool effect and can be associated with ileus-like bowel distension or with obstruction. Edema of the intestinal mucosa may also be evident on plain films. On contrast examination, ascarides cause elongated tubular defects in the barium-filled bowel lumen (Fig. 5). Their linear intestinal tracts may take up barium, to appear as a thin, linear opacity within the soft tissue density of the worm. This linear shadow may persist for some time after barium has been eliminated from the gut. Worms can also be recognized in the colon.

Strongyloidiasis: Mucosal invasion produces only focal edema and spasm. Radiological findings are fold thickening in the duodenum and jejunum and may include effacement of the folds and a pipestem appearance of the jejunum or a diffusely ulcerated, shortened, and narrowed jejunum that will not return to a normal fold pattern after successful treatment. In overwhelming infestation, there may be toxic dilatation with paresis, which is usually permanent.

Diagnosis

Diagnosis can be confirmed by combining bacteriologic and serologic techniques. To establish the diagnosis of infectious diarrhea, the organism must be found in, or cultured from, the stool or intestinal tissues. Alternatively, one should be able to demonstrate a rise in specific serum antibodies to the organism. With the advent of recombinant DNA technology, genes for the heat-labile and heat-stable enterotoxins have been cloned, allowing diagnosis of the toxin-producing bacterial strains.

Diagnostic methods used to identify GI viral infections include viral culture, electron microscopy, immunoelectron microscopy, enzyme-linked immunosorbent assay of stool specimens, use of genetic probes, and, rarely, biopsy. Biopsies show various nonspecific inflammatory changes, including villous shortening, crypt hyperplasia, and infiltration of the lamina propria with mononuclear and polymorphonuclear cells (5).

Postoperative intestinal disease; Postoperative small bowel leak; Postoperative small bowel obstruction

Definitions and Etiology

Any surgery that breaches the peritoneal reflections may result in small bowel complications. The common complications are ►small bowel obstruction (SBO), perforation, leaks, and ischemia.

SBO refers to partial or complete lack of progression of bowel contents due to a mechanical narrowing or occlusion of the lumen. This differs from the paralytic (adynamic) ileus where there is failure of propulsion due to a neuromuscular or metabolic condition, and which occurs in the absence of a mechanical obstruction. The etiology of SBO includes adhesions, internal and external hernia, intussusception, obturation (obstruction by foreign material such as bezoar), anastomotic stenosis, recurrence of cancer or Crohn's disease, marginal ulcers. Of these, the first two are by far the most common.

Ischemia and infarction represent reduction of blood supply to the small bowel, to the point of reversible (ischemia) or irreversible (infarction) tissue injury. Ischemia following abdominal surgery could be caused by vascular occlusion or ►strangulating obstruction.

Strangulating obstruction indicates the impairment of arterial inflow or venous outflow from small bowel due to a twist in the mesentery. Twisting of mesentery may occur in an ►internal hernia or if a dense adhesion obstructs the two ends of a loop of bowel allowing the obstructed segment to become rotate around its fixed ends. Such an obstruction is termed a ►closed loop obstruction (2).

Internal hernia refers to the protrusion of bowel through a defect in its mesentery, but where the abnormally positioned bowel lies within the abdominal cavity. In the past most cases of these were due to congenital defects in peritoneal reflections. Nowadays the majority of cases are seen following surgical anastomosis of small bowel loops that necessitate incision of the mesentery. External hernia occurs when bowel loops protrude *via* a defect in the wall of the abdomen or pelvis.

Pathophysiology

In addition to ingested fluids, salivary, gastric, biliary, and pancreatic secretions, small bowel mucosa produces about 8–10 L of fluid. In normal state only 0.5 to 1 L of this fluid enters the cecum, the rest is absorbed in the small bowel. In SBO the unabsorbed fluid distends the lumen raising intraluminal pressures from the normal 4 cmH_2O to about 10 cmH_2O. In closed loop obstruction pressures of up to 60 cmH_2O may be seen. Bowel distention also occurs due to lack of propulsion of swallowed nitrogen.

Clinical Presentation

The symptoms that suggest postoperative small bowel complications include abdominal pain, vomiting, bloating or distention, early satiety, fever and halitosis, failure to pass flatus, and rarely diarrhea. Clinical signs include abdominal distention, increased or reduce bowel sounds, rigidity, rebound tenderness, unexplained poor oxygen saturation. While these are generally sensitive findings suggestive of postoperative bowel complications, they are nonspecific. Further investigation is usually undertaken except in the very emergent situation where surgery is mandated without expending time on radiological investigations.

Imaging

Plain film radiography is usually undertaken initially. If there are abnormal findings or if radiography is discordant with clinical findings, additional investigations are performed.

CT is the next most commonly performed investigation in the diagnosis of postoperative bowel complications. Unless there are contraindications, such as clearly abnormal renal function, intravenous contrast is used. For borderline abnormal renal function, as is often present in ill postoperative patients, we prefer to use an iso-osmolar iodinated contrast such as iodixanol (Visipaque, GE Healthcare, Chalfont St Giles, UK). Oral contrast is given if the patient is not vomiting and the intestinal tract is not distended and can tolerate it and if emergent surgery is not anticipated. The choice of oral contrast includes positive oral contrast, such as 2% water soluble iodinated contrast, or neutral contrast, such as water or dilute barium. We prefer water since it is better tolerated, shows abnormal mural thickening or enhancement better and

S

does not adversely affect 3 dimensional techniques, such as maximum intensity projections (3). Positive oral contrast on the other hand is useful if a localized leak or abscess is suspected or if the patient has abnormal renal function. It is possible to acquire an isotropic volume acquisition of the abdomen and pelvis in a reasonable breath hold with 16 and higher multislice CT scanners. In isotropic resolution acquisition the size of the voxel is equal in x, y, and z directions. Since the size of x and y dimensions are lesser than 1 mm (field of view of 45–50 cm divided by the CT matrix of 512×512), the z dimension (or the slice width) should be lesser than 1 mm. We routinely use high resolution coronal and sagittal reformats in unraveling the anatomy and pathology of the small bowel.

CT enteroclysis is used to detect low grade of SBO, subtle enteric leaks, and to differentiate with confidence obstruction from ileus. When conventional CT is equivocal, CT enteroclysis is indicated. The technique of CT enteroclysis depends on the clinical question to be answered (1). Ultrasonography and magnetic resonance imaging (MRI) or MR enteroclysis can detect small bowel pathology but are not consistently used in detecting the postoperative small bowel complications.

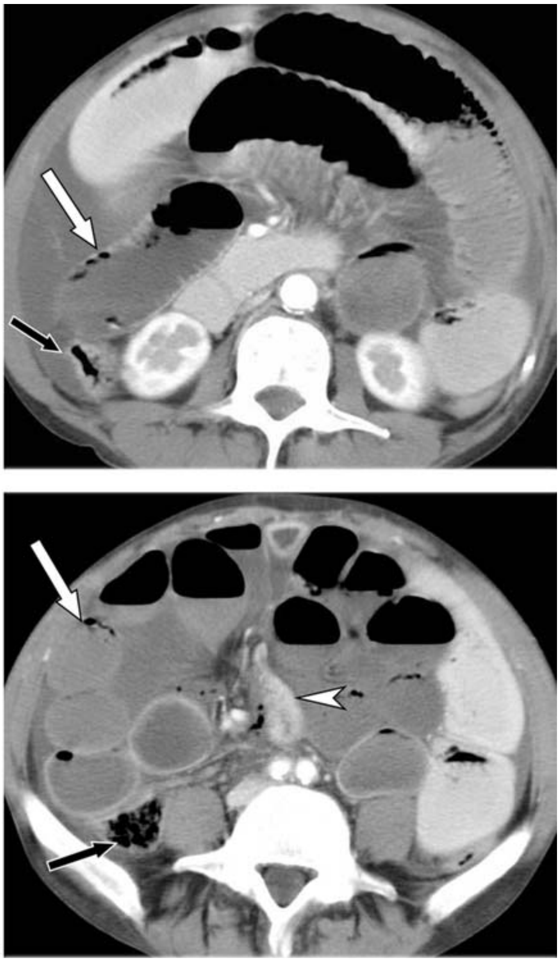
Diagnosis

Postoperative SBO

Plain radiography may show dilated, often fluid filled, loops of small bowel. At least three such loops distended to more than 3 cm are required for a confident diagnosis. Nevertheless plain films have false positive and negative rates of 20–30% and in many instances it is not possible to differentiate between ►paralytic ileus and mechanical SBO.

CT is used to identify the severity, etiology, and site of SBO (Fig. 1). In complete high-grade SBO, orally introduced contrast does not travel beyond the point of obstruction on an abdominal X-ray or repeat CT performed 12 h after initial CT. In partial high-grade SBO there is a caliber change of at least 1 cm at the site of obstruction but there is flow of some oral contrast beyond the point of obstruction. CT has a low sensitivity (50–60%) (2) for low-grade SBO. Adhesions are considered to be the cause if there is an abrupt caliber change, particularly in small bowel close to anterior peritoneum, without identifiable mass at site of obstruction.

Diagnosis of an internal hernia requires identification of distended small bowel loops in a closed loop configuration in an abnormal position, such as between the stomach and omentum (transmesocolonic hernia). In closed loop obstruction, the two ends of the fluid filled heavily distended loop are in close proximity and are often beaked or have a triangular shape. There may be swirling of vessels supplying the involved loop. The bowel proximal to the loop is distended but not to the same degree as the closed loop, while distal small bowel is nondistended (2).



a

b

Small Bowel, Postoperative. Figure 1 (a and b) A 72-year-old man with prior inguinal hernia repair presenting with vomiting and abdominal pain for 3 days. Note multiple distended small bowel loops (white arrows) with nondistended right colon (black arrows). At the site of caliber change (arrowhead) no mass is seen. The appearances are of distal high grade small bowel obstruction due to adhesions, proven on subsequent surgery.

Postoperative external hernia is usually evident clinically. Hernia at incisional site is a common occurrence particularly in the obese. As a rule external hernia and adhesions are more common following open compared to laparoscopic surgery. Internal hernia is said to be more common following laparoscopic surgery, particularly transmesocolonic hernia after roux-en-Y gastric bypass. A rare external hernia that may be seen after laparoscopic surgery is the trochar site hernia. This hernia is usually a Richter type hernia, in which only a part of the wall of a bowel loop herniates. This hernia has a high incidence of infection (2).

In strangulating obstruction, the early features include increased bowel wall thickening or enhancement in venous phase of intravenous contrast, focal ascites, mesenteric vascular blurring or congestion (Fig. 2). Findings of reduced enhancement of affected bowel in arterial phase, hemorrhagic ascites, linear bowel wall pneumatosis, gas in mesenteric, or portal veins herald infarction of bowel (2).

An unusual SBO following surgery is that of an afferent loop or biliopancreatic limb obstruction. This is a surgically fashioned segment of small bowel, usually used to convey pancreatic and biliary secretions to the proximal jejunum. Obstruction of this loop may be due to adhesions or anastomotic stenosis. The classic finding, best appreciated on coronal reformats, is a blind ending obstructed loop in a C-shaped curve in the right upper quadrant. The obstructed loop may be retroperitoneal if it represents the duodenum or intraperitoneal if it is created from the jejunum.

A rare cause of postoperative bowel obstruction, particularly following gastric resection, is bezoar. This is usually due to indigestible plant food. Preoperative diagnosis may be made by CT showing a low-density luminal mass at the site of obstruction. Unlike feces, bezoar usually is rounded and encapsulated (2).

Small Bowel, Postoperative. Figure 2 A 64-year-old women with Whipple surgery 13 days earlier presents with abdominal pain. Note distended bowel loops with intense wall enhancement (arrowhead). More proximal distended loop does not show wall enhancement. This subtle finding of variable enhancement indicates obstruction to venous outflow and incipient ischemia. Long segment of ischemic bowel, caused by an internal hernia, was found at surgery.

Small Bowel Perforation and Leak

Supine radiographs may show the Rigler sign (clear appearance of the inside and outside walls of the small bowel loops), or gas in the falciform ligament in cases of small bowel perforation. These signs are usually visible only if there is a large amount (more than 1000 mL) of free peritoneal air. Erect or decubitus films may show nondependent air with greater sensitivity.

CT examination is much more accurate for detecting small amounts of free gas. The normal amount of residual free peritoneal gas following surgery varies on many factors including the amount of fat content in the torso. An increase in peritoneal air on serial studies or presence of more than 1 or 2 bubbles of gas after second postoperative week is worrying for bowel perforation.

CT enteroclysis is useful for diagnosing subtle leaks and presence of enterocutaneous or other enteric fistula. Leaks may result in fluid collection that may be diagnosed by CT or sonography.

Nuclear Medicine

Nuclear medicine is currently rarely used to diagnose postoperative small bowel complications. An indium-111 labeled white cell scan may be used to detect on occult source of abdominal infection, but false positive findings include uptake in the site of surgical scar. Some surgeons request HIDA scans if afferent loop obstruction is suspected. Multislice CT cholangiography using a biliary contrast agent is useful in evaluating the biliopancreatic limb.

Interventional Radiology

It is important for the radiologist to differentiate between simple adhesive obstruction and strangulating or closed loop obstruction using criteria described earlier. The latter requires emergent surgery. Adhesive obstructions are usually treated, at least initially, with conservative attempts to deflate small bowel. Nasogastric tubes are often insufficient to remove the daily 8–12 L of secretions produced by small bowel mucosa. Placement of a long nasojejunal tube as close to the site of obstruction helps relieve obstruction and may obviate surgery or at least delay it till the patient is in a positive nitrogen balance and electrolyte abnormalities have been corrected (2). Such a tube could be used subsequently for enteroclysis examination to accurately demonstrate the site and etiology of obstruction.

Given the reluctance to reoperate, postoperative collections from localized small bowel leaks are often treated by CT or ultrasound guided drain insertion. We usually place 8–14 French locking drain catheters. If there is concern that the collection is multiloculated multiple drains are placed.

Small Joints

Small joints are the metacarpophalangeal joint, metatarsophalangeal joint, proximal interphalangeal joint, distal interphalangeal joint, and interphalangeal joint. The term is used to characterize arthritic involvement. Small joints are commonly affected in rheumatoid arthritis, whereas large joints are affected in ankylosing spondylitis.

▶Rheumatoid Arthritis
▶Spondyloarthropathies, Seronegative

Small Left Colon Syndrome

A neonatal condition in which the descending colon is of reduced calibre and usually obstructed by a meconium plug. The colon attains normal calibre after the first normal stool has been passed.

▶Occlusion, Bowel in Childhood

Smart Probes

▶Molecular Probes, Optical Probes

Snapping Hip

Clicking or snapping sensation during movement of the hip. Patients are usually asymptomatic but may present with focal pain secondary to tendinosis or bursitis. Snapping hips may be categorized as extra-articular (lateral or anterior) or intra-articular. The most common type occurs laterally secondary to the gluteus medius muscle or iliotibial band catching on the greater trochanter. This diagnosis is usually made clinically, but MRI may demonstrate thickening of the iliotibial band and fluid within the greater trochanteric bursa. Catching of the iliopsoas tendon on the ileopectineal eminence during flexion is a common anterior cause of an extra-articular snapping hip. Osteophytes, muscular hypertrophy, and tendinosis are common causes of abnormal tracking and catching of the iliopsoas tendon. MR imaging often demonstrates thickening and signal change of the iliopsoas tendon and fluid in the iliopsoas bursa. Loose cartilaginous or osseous bodies within the joint are the most common etiology of intra-articular snapping hip.

Soft Tissue Calcification in Dermatomyositis

Soft tissue Calcification in Dermatomyositis is a common feature especially in children. Four distinct patterns of calcification in childhood dermatomyositis are described:

deep calcareal masses, superficial calcareal masses, deep linear.

▶Connective Tissue Disorders, Musculoskeletal System

Soft Tissue Infections

▶Osteomyelitis, Neonates, Childhood

Soft Tissue Sarcoma

A sarcoma that begins in the muscle, fat, fibrous tissue, blood vessels, or other supporting tissue of the body.

▶Rhabdomyosarcoma

Soft Tissue Swelling

Soft tissue swelling is an important radiologic sign. Its form allows differential diagnostic considerations. For example, the typical appearance of joint or tendon sheath effusion as synovial soft tissue swelling is one of the first signs of an inflammatory process. It belongs to one of the three radiologic key symptoms of arthritis: synovial soft tissue swelling, periarticular demineralization, and cartilage or bone destruction.

▶Rheumatoid Arthritis

Solid Pseudopapillary Tumor, Pancreas

Solid pseudopapillary tumor is a benign or low-grade malignant epithelial tumor also reported as solid-cystic tumor and papillary-cystic tumor. However the term solid pseudopapillary tumor correctly encompasses the two most conspicuous histologic features of these tumors, solid areas mixed to pseudopapillary regions. The tumor is uncommon, accounting for approximately 12% of all exocrine pancreatic tumors. It occurs predominantly in adolescent girls and young women. They present as large, round masses with areas of hemorrhage and necrosis and cystic spaces; they are usually well demarcated from the pancreatic tissue because of the presence of a pseudocapsule of compressed pancreatic and fibrous tissue. The incidence of malignancy is about 15%. The imaging findings reflect the macroscopic appearance of the tumor with evidence of the pseudocapsule and a solid heterogeneous aspect with haemorrhagic, necrotic and cystic areas. At CT calcifications are detected in about 30% of patients, usually at the periphery of the mass. The pseudocapsule may enhance following the administration of contrast medium. At MR, T1 weighted images show high signal areas corresponding to haemorrhage and often a hypointense rim, while the signal intensity on T2 weighted images is usually heterogeneous. The prognosis of the tumor is very good and over 90% of patients are cured with surgery alone. Local invasion and metastases are not contraindications for resection and the prognosis is also good with long-term survival in patients with nonlocalized treated tumors.

▶Cystic Neoplasms, Pancreatic

Somatostatin

Peptide hormone consisting of 14 amino acids that acts as an endocrine and paracrine messenger. The physiological action of somatostatin is reduced secretion of a number of growth hormones.

▶Receptor Studies, Neoplasms

Sonazoid (NC 100100)

Microbubble US contrast agent used with low mechanical index. The bubbles consist of perfluorocarbon and are stabilized by a lipid shell. The agent has a liver-specific late phase. Currently in clinical development in Japan (2006). Manufacturer: General Electric, USA.

Sonography

An imaging technique for diagnosing breast disease, such as cancer. It uses harmless, high-frequency sound waves to form an image (sonogram). The sound waves pass through the breast and bounce back or echo from various tissues to form a picture of the internal structures. It is not invasive and involves no radiation.

▶Lymphadenopathy
▶Ultrasound, Imaging

Sonoporation

Sonoporation comprises the ultrasound-enhanced transfection of cells with genetic material or other substances caused by a reversible enhancement of the cell surface permeability. This effect can be amplified by use of gas-filled microbubbles.

▶Local Drug and Gene Delivery with Microbubbles

SonoVue (BR1)

Microbubble US contrast agent used with low mechanical index. The bubbles consist of sulfurhexaflouride and are stabilized by a phospholipid shell. Commercially available in Europe and many other countries (not in the USA). Manufacturer: Bracco SPA, Italy.

▶Contrast Media, Ultrasound, Hepatic

Sontag Method Bone Age

Bone age estimation obtained by counting eligible growth centers (not the main talus and calcaneus) on left side of body and comparing to the gender-specific charts of Sontag, Snell, and Anderson, with number of centers deviation from the mean also stated.

▶Bone Age

SPACE Trial

Stent-Supported Percutaneous Angioplasty of the Carotid Artery versus Endarterectomy trial.

▶Stent, Carotid Artery

Spared Area

Area not interested by liver fatty infiltration. Liver parenchyma with lower portal supply tends to accumulate less fat. Areas commonly spared by fatty infiltration are the dorsal portion of the IV segment just anterior to the portal vein, the gallbladder bed and the medial portion of the left lobe, along the great interlobar fissure. In these regions, the portal flow is decreased due to anomalous systemic venous drainage into portal venules from structure such as the gallbladder or the stomach. These islands of normal liver tissue are also called ‘skip areas’ and are usually observed at ultrasound as relatively hypoechoic areas.

▶Steatosis, Hepatic

Specific Imaging Techniques, Contrast Media, Ultrasound

Synonyms

Contrast specific imaging techniques; Microbubble imaging techniques; Non-linear imaging techniques

Definition

Contrast specific imaging techniques have been developed to improve the sensitivity and specificity of ultrasound imaging to microbubble contrast agents. Contrast specific imaging approaches are now able to detect small volumes of slow-moving blood deep in the body.

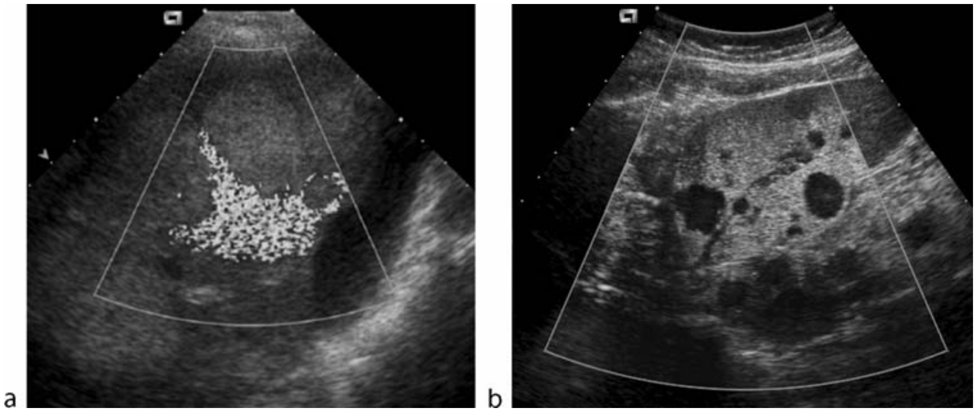
Characteristics

Specific imaging techniques for microbubble contrast media make use of the non-linear acoustic properties of microbubbles to differentiate the bubbles from the surrounding tissues. Originally microbubbles were developed as enhancing agents for Doppler studies to improve the visualization of blood. A primary motivation at this stage was the opacification of the ventricles to allow better delineation of the endocardial border. However, a number of unforeseen circumstances arose, first by boosting the signals in the blood pool to levels similar to the tissue itself in many cases the Doppler processing in the ultrasound systems was no longer able to differentiate between blood flow and moving tissues. Second, the concentrations of microbubble agents required to generate this boost were high enough that attenuation of the signals in the bubble clouds meant that deeper tissues or full ventricle views were unobtainable. Also, standard Doppler modes are designed to use relatively high amplitude pulses due to the weak scattering from red blood cells; these pressures are typically enough to disrupt the microbubbles reducing their effectiveness.

To overcome these limitations a number of microbubble specific imaging approaches have been developed. One of the earliest of these arose from the insight that the microbubbles can be destroyed when using existing Colour Doppler modes (1). The term loss of correlation imaging was coined to describe this approach. The Doppler mode depends on comparing the echoes from a train of pulses, with the Doppler shift or target speed calculated by relative phase changes in the radio frequency echoes; when microbubbles are introduced initially they scatter the signal strongly, but at the high pressures typically used they are destroyed, and then the signal returned by subsequent pulses in the train is dramatically different. The Doppler processing interprets this as a high velocity and as there is no direct correspondence between the initial and later echoes in the train, the direction of the estimated velocity is random, hence the multicoloured mosaic pattern (Fig. 1a). Some modern ultrasound scanners provide microbubble specific Doppler modes (e.g. ADI on the Acuson Sequoia) based on standard colour Doppler approach (Fig. 1b). The main differences being that the directional colour coding has been removed, and the focal region of the image extended to improve the coverage within the image. Furthermore as the actual speed of the microbubbles in not of importance, shorter (higher axial resolution) pulses can be used thus improving the spatial resolution in this mode.

Although able to provide a very sensitive method for detection of microbubbles the main limitation of this approach is the destructive nature. Destroying the microbubbles means that unless time is allowed for the microbubbles to replenish the volume of interest only one image (in any one plane) can be obtained. This precludes real-time imaging. To allow real-time imaging much lower amplitude pulses must be used.

In order to differentiate between tissue echoes and microbubble scattering at low pressures a number of non-destructive bubble specific methods have been developed. All these depend on the non-linear resonant acoustic properties of the microbubbles. The first approach was to directly detect the harmonic signatures of the microbubbles (2). When microbubbles are insonated with ultrasound pulses close to their natural oscillation frequency they will oscillate strongly. The oscillation not only contains strong signals at the natural (or fundamental frequency) but will also contain harmonics (at integer multiples of the fundamental). ▶Harmonic imaging was therefore developed in which the bubbles were insonated with one frequency while the ultrasound detection process was tuned to twice this frequency. Of course, tissues themselves are not truly linear and as



Specific Imaging Techniques, Contrast Media, Ultrasound. Figure 1 (a) Colour Doppler scan of the liver after injection of the microbubble Levovist, showing the characteristic multicoloured mosaic pattern. This colour pattern arises due to a loss of correlation in the Doppler processing caused by the microbubble disruption. (b) This microbubble specific mode (ADI on the Siemens Sequoia) shows improved coverage of the liver. The directional Doppler information is discarded to aid interpretation of the image.

S

ultrasound waves propagate through the tissues a process called non-linear propagation also causes the production of harmonics. However, the non-linear propagation process is quite different to that of the resonant behaviour of microbubbles, primarily in that it requires a propagation distance in which to build up, and that it occurs only at relatively high acoustic pressures.

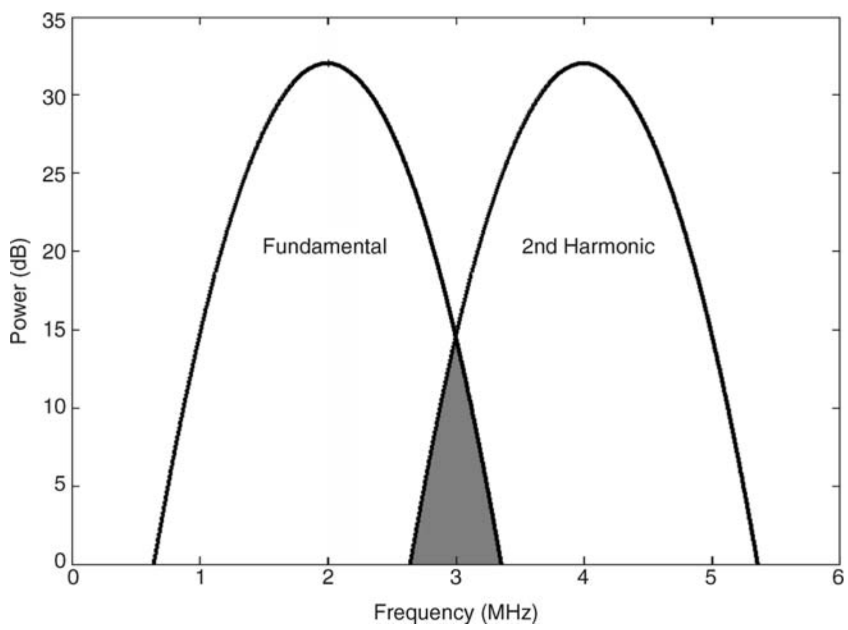
In order to make harmonic imaging work a trade-off between the sensitivity and specificity of the system to the harmonic echoes (the microbubbles) the spatial resolution of the image had to be struck. This compromise arises due to the frequency filtering required to successfully separate the scattered second harmonic signals from the fundamental, and any overlap between the frequency bands must be avoided (3) (Fig. 2).

This can only be achieved by using longer narrowband signals. The harmonic imaging approach has been combined with adaptations of existing Doppler processing to provide harmonic Doppler imaging. This combination has the advantage of reducing the linear tissue clutter in colour and power Doppler images and spectral Doppler traces.

Most recent microbubble specific imaging approaches use modulated pulse sequences to detect the non-linear response of the microbubbles. These pulse sequences contain two or more pulses with alternating phase, amplitude or a combination of the two and are able to avoid the frequency filtering inherent in harmonic imaging. This overcomes the major trade-off between spatial resolution and sensitivity to non-linear signals associated with harmonic imaging.

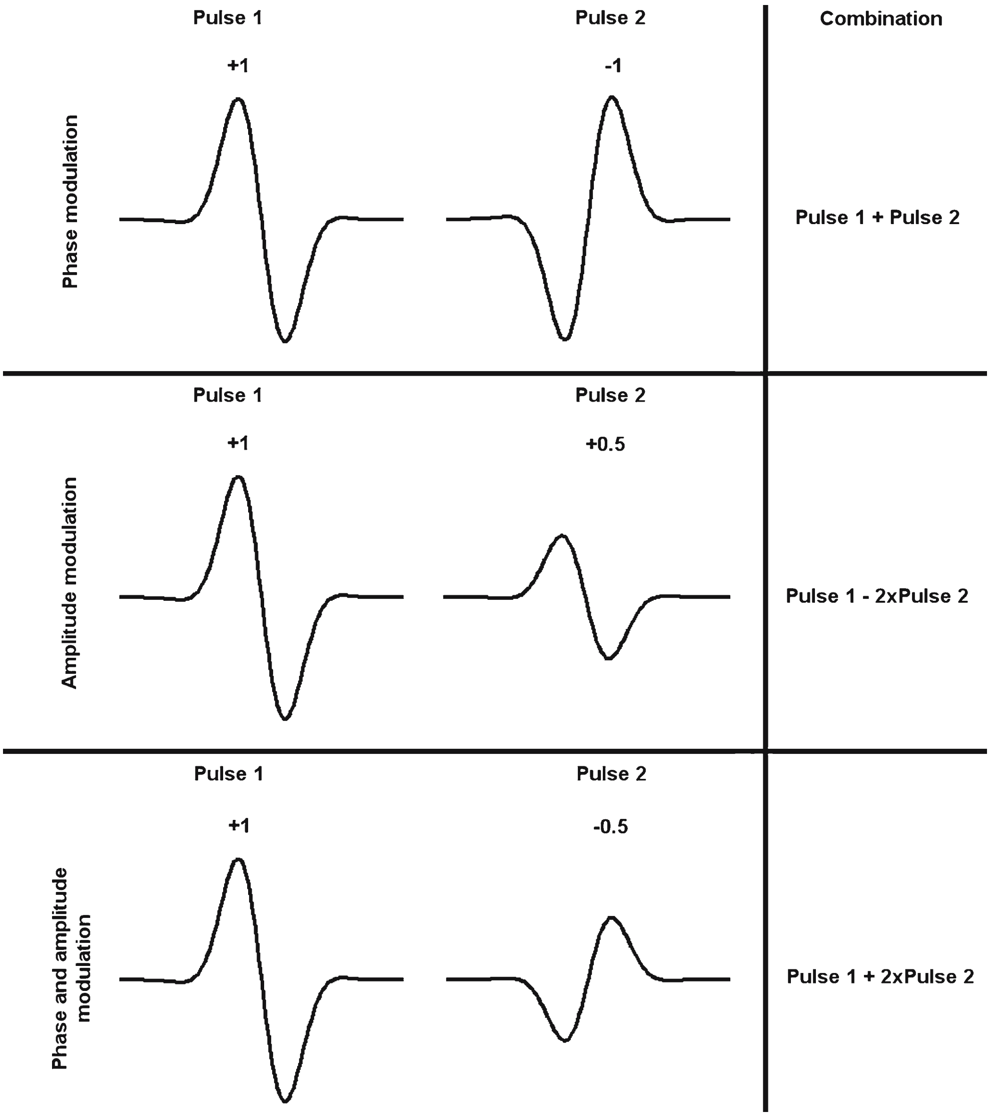
►Phase modulation imaging or pulse inversion imaging involves transmitting pulses with alternating polarity (4). This mode is now widespread and available on many commercial clinical systems. The now standard form of phase modulation imaging is based on alternating the polarity between successive pulses, that is, +1, −1, etc. (see Fig. 3). When these pulses are scattered linearly from tissues, the echoes of subsequent pulses will cancel when combined. The response of the microbubbles to the +1 and −1 pulse is significantly different and when the echoes are combined a residual signal arising from the non-linearity of the bubbles remain. The non-linear signal detected by phase modulation imaging comes from the second harmonic signals in the echoes. Broadband imaging pulses can be used and unlike harmonic imaging this multi-pulse approach does not suffer from the same compromise in specificity and sensitivity to microbubbles against resolution. Successful phase modulation imaging requires precise pulse shaping within the ultrasound equipment to ensure good cancellation of the linear echoes. The specificity of this approach is limited by the generation of harmonic signals during the propagation of the sound through tissues especially at higher MI.

As an alternative to phase modulation an amplitude modulation can be used. In this case consecutive +1,+½

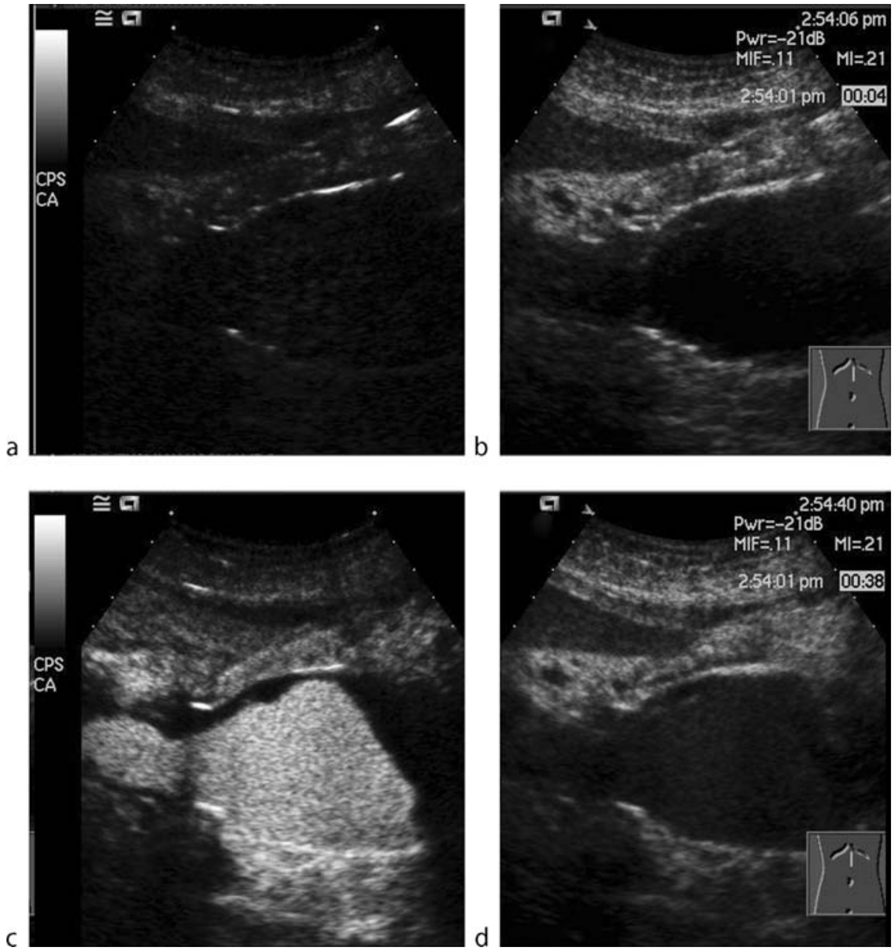


Specific Imaging Techniques, Contrast Media, Ultrasound. Figure 2 **In harmonic imaging to successfully separate the scattered second harmonic microbubble signals from the tissue background overlap (red shaded region) between the fundamental and the second harmonic must be avoided. This can only be achieved by reducing the bandwidth of the ultrasound pulses used, which causes degradation in the spatial resolution of the image.**

(see Fig. 3) pulses are sent, as before, appropriate combination of the echoes will result in a complete cancellation for linear scatterers, whereas non-linear microbubble echoes will show residual signals. These residual signals arise because the microbubbles respond non-linearly to the different amplitude pulses, that is, the double amplitude pulse does not elicit an echo with twice the amplitude, whereas for tissue this would be the case. An advantage of amplitude modulation over phase modulation is that it is able to detect non-linear signals at the fundamental frequency and not just the second harmonic. However, the use of alternating lower power pulses does reduce the sensitivity of this approach. A combination of pulse inversion and amplitude modulation



Specific Imaging Techniques, Contrast Media, Ultrasound. Figure 3 This figure shows (*upper panel*) a simple two pulse phase modulation sequence. When the echoes of pulse 1 and pulse 2 are summed any linear signals will be cancelled. The second harmonic signals in the echoes from microbubbles are preserved by this approach. A simple two-pulse amplitude modulation sequence is also presented (*middle panel*). When the echoes of pulse 1 and pulse 2 are combined by doubling pulse 2 and subtracting the result from pulse 1 any linear signals will be cancelled. Both non-linear signals at the fundamental and 2nd harmonic signals in the echoes from microbubbles are preserved by this approach. In the lower panel a two-pulse sequence with combined phase and amplitude modulation is shown. Linear signals can again be removed by appropriate combination of the echoes. This approach can detect non-linear signals at the fundamental frequency as well as the second harmonic.



Specific Imaging Techniques, Contrast Media, Ultrasound. Figure 4 Pre (a,b) and post (c,d) contrast ultrasound images of the abdomen, showing a longitudinal section through an aneurysmal aorta. The microbubble specific imaging mode (a,c) use both phase and amplitude modulation to detect the non-linear signals (CPS on the Siemens Sequoia). The greyscale images (b,d) are generated from linear echoes in the same sequence. Pre-contrast images show minimal signals in the contrast specific image (a) compared with the standard B-mode image (b). After arrival of the contrast agent strong signals are seen in perfused areas. All scanner settings remain constant in both image pairs.

has been shown to improve the sensitivity to microbubbles over tissues still further (5) (Fig. 4). In each of these cases the pulse sequences can be extended to more than two pulses to improve sensitivity and to enable the use of Doppler processing for motion detection.

As well as overcoming the resolution versus sensitivity trade-off these multi-pulse approaches are highly sensitivity to non-linear signals allowing low amplitude pulses to be used. This means that bubble disruption is reduced and real-time imaging is possible.

These microbubble specific ultrasound imaging approaches have given rise to a number of quantitative tools for making use of the physiological information they can provide. Microbubble contrast agents typically act as blood pool agents and can be used as tracers within the circulation. The most widespread functional approach is flash replenishment imaging (6), in which the microbubbles in the image plane are initially destroyed by a high amplitude ultrasound burst and subsequently a low amplitude real time method is used to monitor the rate at which the image plane refills. Quantitation and modelling of the results allows estimates for the blood volume and tissue perfusion to be made. Techniques measuring the time of arrival of the first pass of the microbubbles in the liver have also shown promise (7).

Specific Microbubbles

▶Targeted Microbubbles

Specific Targeting

▶Targeted Microbubbles

Specificity

The proportion of truly nondiseased persons in the screening population who are identified as nondiseased by the screening test.

▶Screening, Breast Cancer

SPECT

Abbreviation for single photon emission computed tomography—a type of tomographic image acquisition in nuclear medicine. In the course of a SPECT scan, a three-dimensional image is obtained by rotating the detectors of the gamma camera around the patient. For evaluation, slices in any orientation can be reconstructed from this three-dimensional data set. Due to the higher resolution of the method, scans in SPECT generally yield a higher accuracy than conventional planar acquisitions.

▶Pulmonary Function, Nuclear Medicine Methods

Spermatocele

Extratesticular cyst caused by cystic dilatation of tubules of the efferent ductules in the head of the epididymis. It contains sediment including detritus, immobile spermatozoa, and lipids.

▶Scrotal Disorders

Spina Bifida

Strictly speaking, the term “spina bifida” indicates defective fusion of the vertebral neural arch. However, it is widely used as a synonym of spinal dysraphism. Use of the terms “spina bifida aperta” (or “cystica”) and “spina bifida occulta” to refer to OSD and CSD, respectively, is presently discouraged.

Introduction

Diagnostic imaging of the spine and spinal cord is challenging in several ways. In the early days of conventional X-ray imaging, it soon became clear that, although the technique produced good visualization of bony spinal structures and bony pathology, soft tissue resolution of structures within the spine was inadequate. The spinal cord, blood vessels, and emerging nerve roots remained invisible as did the various ligamentous structures connecting the bony elements: intervertebral disk, anterior and posterior longitudinal ligaments, as well as flaval and interspinous ligaments.

Work on contrast techniques to improve cord and root depiction (myelography) commenced in the early decades of the last century. Technically the most challenging technique was probably gas myelography, in which air was injected into the spinal subarachnoid space, producing a faint image of the contours of the spinal cord on tomographic images. Positive contrast media for myelography came next, and the iodized radiopaque oils (Lipiodol, Pantopaque) which were injected into the subarachnoid space made myelography easier and more reliable, as well as being less unpleasant for the patient. These early positive contrast media however had the tendency to disperse into droplets, which degraded the image of the cord and roots, as well as possessing the potential to induce sometimes crippling adhesive arachnoiditis. The introduction of water-soluble iodine contrast media further improved image quality. The first preparation, Abrodil (sodium iodomethyl sulphonyl) caused such severe local irritation that spinal anesthesia was necessary. Later developed contrast media such as Conray (meglumine iothalamate) and Dimer-X (dimer iothalamate) were more patient friendly, and when Amipaque (metrizamide), an iodine solution with decreased osmolality was produced, adhesive arachnoiditis became a problem of the past.

Using the same contrast media, techniques were developed to opacify the nucleus pulposus (discography), the intraspinal epidural space (peridurography or canalography). The introduction of catheterization techniques made it possible to produce diagnostic images of the spinal arteries (spinal angiography) as well as the lumbar and cervical epidural veins (epidural venography).

These contrast techniques require a degree of technical skill from the examiner. Correct needle or catheter placement as well as patient positioning determine success or failure of the examination. The requirement of these technical skills did much to establish neuroradiology as a separate radiological subspecialty, practiced by dedicated radiologists, and not infrequently by neurosurgeons and neurologists.

A technological development of great significance was the development of computed tomography (CT). The improved contrast resolution and sectional imaging capability provided by this technique revolutionized diagnostic imaging. Third and fourth generation CT systems employing high-resolution scanning packages were able to generate diagnostic images of the spinal ligamentous structures, and of ligamentous lesions such as disk herniations. Intradural structures such as the spinal cord and nerve roots could still only be reliably imaged after intrathecal contrast injection: CT-myelograpy. In the same way, CT and intradiskal contrast injection were combined to produce CT-discography.

Magnetic resonance imaging (MRI) in the early days was practically limited to brain scanning. It was only when the next technological challenge had been overcome by the introduction of surface coils that detailed images of spinal structures, including the spinal cord, could be acquired. Technological developments are rapid. The images of the spinal cord and of cord pathology provided by MRI are diagnostically superior to myelographic and CT-myelographic pictures. Intradural nerve roots can be depicted by specialized MR myelographic sequences, without the need for contrast injection. Contrast myelography is rapidly becoming a lost art, and techniques such as peridurography and epidural venography have long since passed from the diagnostic imaging scene. Discography retains a role disputed by some. High-resolution techniques for spinal CT and MR angiography now in development are likely soon to replace catheter spinal angiography.

The replacement of unpleasant, time-consuming, and laborious contrast examinations by rapid and reliable modern imaging techniques is an indisputable boon to patients. In addition, completely new insights into spinal cord morphology and function are promised by novel techniques such as diffusion tensor imaging and BOLD functional MRI.

The greatly improved power of resolution of modern imaging has created a new challenge. The problem is not one of technique or technology, but of interpretation. A case in point is that of patients with low back pain and sciatica. This category at present forms probably the single largest indication for MR imaging. The etiology of these complaints is at present still poorly understood. Nevertheless the wealth of anatomical detail provided by MRI, including features such as degenerative bone marrow changes, fissuring of the annulus fibrosus, and desiccation of the nucleus pulposus has led to arbitrary implication of these and other MRI findings in the production of low back pain. Even a lumbar disk herniation, which has been regarded as a cause of sciatica since the 1930s, can be demonstrated by MRI in up to 30% of healthy volunteers without any complaints of back or leg pain. Careful scrutiny and critical assessment are necessary to differentiate between a disk herniation, which is actually responsible for symptoms, and a chance finding without clinical significance.

Anatomy

The spine is required to meet conflicting demands of stability on the one hand, and mobility on the other. The solution ranges from a complete lack of mobility with maximum stability in the fused vertebral elements of the sacrum at the one end, to the highly mobile but vulnerable structure of the cervical spine at the other. The intervening thoracic spine possesses very limited mobility as it forms part of a rigid thoracic cage while the anatomy of the adjoining lumbar spine permits excursions almost exclusively in the sagittal plane.

The basic building block of the spinal column is the vertebra, which is composed of a vertebral body connected by a pair of pedicles to the posterior neural arch or lamina. Superior and inferior articular processes arising from the junction of the neural arch with the vertebral body form zygapophyseal joints with the articular processes originating from adjacent vertebrae, and these intervertebral joints, also known as facets, are important in regulating spinal motion. In the cervical spine, additional uncinate processes originate from the upper lateral borders of each vertebral body to form uncovertebral joints with the lower lateral borders of the vertebral body above. Transverse and spinous processes provide mechanically efficient attachment points for the various ligaments and muscles important for stability as well as mobility.

Two vertebrae are connected by investing ligaments to form a motion segment. The most important ligamentous spinal structures are the annulus fibrosus forming the outer circumference of the intervertebral disk that connects two vertebral bodies, and the anterior and posterior longitudinal ligaments, which strengthen the connection. The posteriorly located articular processes are connected with their upper and lower counterparts by the facet joint capules, which gradually merge posteriorly with the flaval ligaments connecting each neural arch with the one above and below it. Finally, the spinous processes at the various levels are connected by the interspinous ligaments.

Within the fibrous ring of the annulus fibrosus is located the gelatinous nucleus pulposus, and the combination is responsible for the hydroelastic shock-absorbing properties of the intervertebral disk.

The vertebral canal or vertebral foramen runs the entire length of the spinal column, being bordered anteriorly by the vertebral body and intervertebral disk, and posteriorly by the neural arch and flaval ligaments. Its shape is round or oval in the thoracic, upper lumbar, and upper cervical regions, becoming more triangular in the lower cervical and especially lower lumbar areas, with prominent lateral recesses being formed at the lumbosacral transition. The intervertebral foramina or canals are oriented laterally, being bordered above and below by the superior and inferior pedicle, anteriorly by the vertebral body and intervertebral disk, posteriorly by the facet capsule and articular processes.

The spinal dural sac runs almost the full length of the spinal canal, from its junction with the cranial dura mater to its caudal termination or cul-de-sac at the upper sacral level. The surrounding epidural space contains semifluid epidural fat and epidural veins. Within the dural sac lies the spinal cord, connected cranially with the medulla oblongata, and ending at the tip of the conus medullaris, at the vertebral L1–L2 level. Nerve roots coursing towards the lumbar and sacral foramina form the cauda equina. As a (motor and sensory) pair of nerve roots departs the dural sac to enter the intervertebral foramen, they are accompanied over a short distance by a dural root sleeve or sheath. Spinal cord and cauda equina are covered by pia mater, and are bathed by cerebrospinal fluid (CSF) within the spinal subarachnoid space, which also extends into the root sleeves. Besides the emerging nerve root and dorsal root ganglion, the intervertebral foramen contains fat and foraminal veins.

Sectional Anatomy

In the axial plane, three levels can be identified:

- Pedicular level: The section passes through the upper half of the vertebral body, the pedicles, transverse processes, upper neural arch and spinous process. The borders of the spinal canal are entirely bony at this level
- Infrapedicular level: The section passes through the lower half of the vertebral body and upper half of the intervertebral foramina containing the dorsal root ganglions, additionally the facets with their joint capsules and the flaval ligaments, and the lower half of the spinous process.
- Disk level: The section passes through the intervertebral disk and lower half of the intervertebral foramen, containing mainly fat and veins; also through the lower half of facets, joint capsules and flaval ligaments. The borders of the spinal canal are almost entirely ligamentous at this level.

In the sagittal plane, two sections are distinguished:

- Mid-sagittal section: This section shows the spinal cord and conus medullaris well, also the sagittal dimensions of the spinal canal and the epidural fat.
- Lateral sagittal section: This section provides a good sagittal image of the intervertebral foramen.

The coronal plane is rarely used for spinal imaging. Oblique images are useful for MR myelographic projections.

Functional Anatomy

When the spine moves from flexion or kyphosis to extension or lordosis, this has an effect upon intraspinal dimensions and structures. As lordosis increases, the spinal canal shortens due to the position of the axis of movement being located within the vertebral body, anterior to the canal. The disk bulges backward into the canal and the flaval ligaments also bulge inward, thus narrowing the canal at the disk level. When the spine moves to kyphosis the opposite occurs. These are normal phenomena but in cases with narrowing or stenosis of the canal, these posture-induced changes may be sufficient to cause cauda equina compression with neurogenic claudication in the lumbar spine, or aggravation of spinal cord compression in the cervical region. The presence of semifluid epidural fat permits craniocaudal movement of the dural sac within the spinal canal during flexion–extension movements, and the spongy epidural venous system helps to compensate posture-related intraspinal volume changes, avoiding CSF pressure changes during spinal movements.

Degenerative Disease

Intervertebral Disk

Degenerative changes of the disk commence in late adolescence, with dehydration of the nucleus pulposus and fissure formation in the annulus fibrosus. These changes can be observed by MRI; T2-weighted images demonstrate loss of water signal in the nucleus, and fluid-filled fissures in the annulus. The subchondral bone marrow can also undergo degenerative changes showing different MRI signal patterns: dark on T1- and bright on T2-weighted images (increase in water content); bright on T1- and bright on fast spin-echo T2-weighted images (fatty degeneration); dark on T1- and dark on T2-weighted images (sclerosis). Such changes can also occur in normal aging, and a convincing relationship with backache or sciatic pain has not been established.

With nuclear dehydration goes decrease in disk height, which in turn leads to circumferential bulging of the annulus, also into the spinal canal ("bulging disk"). When a weakened annulus fibrosus ruptures, material from the nucleus pulposus may be displaced into the spinal canal ("herniated disk"; "herniated nucleus pulposus"). Nomenclature is as follows: when the height of the herniated material does not exceed the height of the parent disk, this is called a protrusion. When the herniated mass is higher than the parent disk, it is called an extrusion. Bulging disks usually do not cause nerve root compression, unless there is associated narrowing of the spinal canal. Protruded disks are frequently asymptomatic, extruded disk fragments usually compress the root. Extruded material may migrate some distance to compress a root in the intervertebral foramen or the lateral recess.

A compressed nerve root undergoes inflammatory changes, which in the lumbar region lead to the clinical symptom of sciatica: pain irradiating into the dermatome of the leg supplied by the affected root. Sensory loss in the dermatome may ensue, as well as muscle weakness and decreased tendon reflexes. A large extrusion may cause a cauda equina syndrome with severe neurologic deficit including bladder paralysis. In the cervical spine, root compression by disk herniation causes brachialgia: pain irradiating into a dermatome of the arm.

MRI is presently the best technique available for diagnosing lumbar degenerative disk disease. Soft tissue resolution is better than with CT, this is especially useful for detecting extrusions in areas like the lateral recess. MR myelography with heavy T2 weighting is useful in identifying symptomatic disk lesions causing root compression. In patients with failed back surgery, MRI can detect recurrent herniation. Contrast injection is sometimes useful in these cases to identify postoperative scarring. Even in unoperated patients, extruded and migrated disk material will frequently demonstrate peripheral contrast enhancement. Compressed and irritated nerve roots may also enhance.

In the cervical spine, disk extrusions are generally smaller, and CSF flow artifacts may degrade the image. CT myelography may be necessary. CT is also better able to distinguish between disk extrusion ("soft disk") and bony spurring ("hard disk").

Spinal Narrowing

Developmental spinal stenosis is an uncommon shallowness of the spinal canal seen especially frequently in achondroplasia. Lumbar stenosis leads to neurogenic claudication; irradiating pain and numbness in the legs on walking and standing, relieved by sitting and squatting, caused by chronic posture-dependent cauda equina compression. Much more frequent is degenerative narrowing of the lateral region of the spinal canal due to hypertrophy of the facets and flaval ligaments in spondylarthrosis. This condition can also lead to degenerative anterolisthesis which further narrows the spinal canal. In spondylolisthesis due to spondylolysis the spinal canal is widened rather than narrowed, but nerve root compression may occur in the foramen.

Often the problem is multifactorial: in a patient with already some developmental narrowing and spondylarthrosis in progress, only a small disk protrusion or even a bulging disk can tip the balance and compress the root. In an individual with a roomy spinal canal, a much larger extrusion would be necessary. Increase in the amount of epidural fat (epidural lipomatosis) in adipose individuals or patients with Cushing's disease, can aggravate narrowing.

In the cervical spine, the same combination between developmental and degenerative narrowing can compress the spinal cord. Long tract signs (problems with walking and micturition) occur as the cord is slowly and progressively compressed.

Trauma

Diagnostic imaging in patients with spinal trauma is used to ascertain the mechanism of injury, to image the bony and/or ligamentous injury to the spine and determine the resulting loss of stability, and also to assess spinal cord damage with a view to neurologic prognosis. In the emergency room, conventional films provide a first assessment. Four main force vectors can be distinguished. Hyperflexion of the spine can be combined with compression (resulting in vertebral body fracture) or distraction (resulting in ligamentous injury: hyperflexion sprain or facet luxation with interlocking). Hyperextension of the spine can be combined with compression (resulting in articular process fracture) or distraction (resulting in hyperextension sprain). Fractures of the vertebral body are usually well seen on conventional X-rays, but articular process fractures are often better diagnosed by spiral CT with sagittal reformats. Ligamentous injuries (hyperflexion or hyperextension sprain) are difficult to visualize with X-ray techniques; plain films may show indirect signs of hematoma (widening of the interspinous space in hyperflexion sprain, or the prevertebral soft tissue space in hyperextension sprain) facet interlocking or the "bayonet sign" on the A-P film in unilateral facet luxation.

MRI is able to directly demonstrate soft tissue hematomas indicating ligamentous injury, best on T2-weighted images. Intraspinal lesions such as traumatic disk herniation and epidural hematoma are also well demonstrated. MRI is less reliable for the diagnosis of vertebral body and articular process fractures however.

Combinations of the force vectors mentioned above are quite frequent, also with rotation and lateroflexion

Injuries not yet mentioned are Jefferson fracture of the atlas, odontoid fracture, hangman's fracture of C2 and Chance fracture in the thoracolumbar region.

In any spinal injury, assessment of the loss of stability is of particular importance in order to select appropriate measures to prevent further derangement of the spine, and possible (further) injury to the spinal cord.

Spinal cord injury can manifest itself in various neurologic syndromes, the most severe being a complete transverse cord lesion. Hemitransection of the cord, usually by a penetrating injury, can result in Brown–Sequard syndrome.

MRI can demonstrate compression of the cord, but also spinal cord contusion. The lesion is seen as hypointense on a T1-weighted image, and hyperintense with T2-weighting. T2 hypointensity indicates hemorrhagic contusion, associated with a poor prognosis. Later a posttraumatic syrinx may form.

Nerve root avulsion from the cervical intumescence of the cord can be demonstrated using CT myelography or MR myelography.

Tumors

These can be subdivided as follows:

Secondary and primary vertebral tumors

Secondary metastases are by far the most common spinal tumors, most frequently from carcinoma of the lung, breast, and prostate. Plain films demonstrate metastases only when there is destruction of cortical bone (missing pedicle sign), or collapse of a vertebral body. CT can detect earlier destruction of vertebral spongiosa. Isotope studies are even more sensitive and demonstrate repair activity of affected bone by osteoblasts. Most sensitive of all is MRI, which detects subtle changes in bone marrow composition due to tumor infiltration. Signal from bone marrow fat is decreased in T1-weighted images, and T2-weighted images show increase in tumor water content. This signal pattern is not specific for tumor infiltration, and may also occur in degenerative and infectious disease. Fracture hematoma in vertebrae collapsed due to osteoporosis is indistinguishable by MRI from metastasis. Diffusion-weighted imaging may resolve the problem, as will the finding of normalized bone marrow in healed vertebral fractures elsewhere. Injection of gadolinium contrast media may mask bone marrow metastases on T1-weighted images, and use of the turbo spin-echo sequence can have the same effect in T2-weighted pictures. In both cases, suppression of bone marrow fat signal is useful.

Invasion of the spinal canal is well demonstrated by MRI, sometimes on either side of an intact posterior longitudinal ligament (curtain sign), as is compression of the spinal cord. MRI in these cases is more reliable, more convenient, and less invasive than myelography and CT myelography.

After radiotherapy, T1 bone marrow signal will increase as the red bone marrow is destroyed and fatty marrow now predominates.

The most common benign primary bone tumor is hemangioma, which shows a characteristic high fat signal on MRI, and a spiculated appearance due to thickened trabeculae, best seen on CT.

Other benign tumors are aneurysmal bone cyst, giant cell tumor, osteoid osteoma, osteoblastoma, osteochondroma, and fibroma.

Chordoma is a slow-growing tumor which can produce metastases. Eosinophilic granuloma occurs in children and can result in vertebral collapse.

Malignant bone tumors are osteosarcoma and chondrosarcoma, as well as other sarcomas such as Ewing's.

Bone marrow diseases such as leukemia, lymphoma, and myeloma can affect the spine.

Intramedullary Tumors

The most common of these are astrocytomas, ependymomas, and astrocytomas. Features in common are expansion of the spinal cord, abnormal cord signal pattern with varying degrees of cystic evolution, and contrast enhancement. Syringomyelia may also enlarge the cord. Hemangioblastomas and also glioblastomas can occur in the cord, as can metastases and lymphomas.

Extramedullary Tumors

Seeding of tumor cells *via* the CSF spaces can produce leptomeningeal "drop"metastases. Schwannomas or neurinomas, and neurofibromas originate from the nerve root, but may extend outside the foramen to form a "dumbbell tumor." Meningeomas usually have a broad base of attachment to the dura. Gadolinium injection is helpful in the detection of all these tumors. Lipomas occur most frequently in the filum terminale and are easily seen on T1-weighted images. Teratomas, dermoid, and epidermoid tumors occur infrequently; the latter are often virtually indistinguishable from CSF on CT as well as T1- and T2-weighted MR images.

Infections

Infection of the spine by pathogenic microorganisms may take place by direct contamination (trauma, operation) contiguous spread or hematogenous transport. The disk may be involved (diskitis), the vertebral body (vertebral osteomyelits), or both (spondylodiskitis). Abscess formation may take place in the spine, the epidural space (with spinal cord compression), or the paravertebral region.

Pyogenic Infections

Staphylococcus aureus is the most frequent agent. Severe backache with limited spinal mobility are presenting signs, with clinical and laboratory signs of infection. X-ray studies may show disk space narrowing after a few weeks, and CT erosion of vertebral end-plates. Bone scintigraphy may sometimes show early abnormalities, but is not always reliable. MRI is the best diagnostic technique, with bone marrow lesions showing decreased signal on T1-wieghted images and a bright signal with fat-suppressed T2-weighting. The latter also well demonstrates epidural encroachment. Intravenous gadolinium injection demonstrates enhancement of affected areas, best seen on fat-suppressed T1-weighted images. Abscess formation is well depicted, as is paravertebral spread. After the acute disk infection has subsided, X-ray studies and MRI usually show obliteration of the disk space.

Granulomatous Infections

- Tuberculosis. Generally less severe presentation and course than in pyogenic spondylitis. Several vertebrae are frequently involved. Bone destruction of anterior vertebral bodies may result in gibbus deformity (Pott's disease) with spinal cord compression. Psoas abcesses, sometimes calcified, are seen, epidural spread also occurs. MRI is best for demonstrating bone marrow and disk changes, contrast enhancement, and deformation of spinal canal; CT may show calcifications.
- Brucellosis. More acute presentation than tuberculosis.
- Sarcoidosis and actinomycosis rarely affect the spine.

Other agents

Fungal and parasitic infections may rarely affect the spine.

Transverse myelitis is a condition often associated with viral infection. Swelling of the cord occurs, with increased T1- and T2 relaxation times. Multiple sclerosis can present a similar picture.

Congenital Malformations

The cephalic portion of the spinal cord develops, like the brain, by neurulation: development of a neural plate, neural folds, and neural tube. The caudal portion of the cord, conus medullaris, and filum terminale, arise by a different process: canalization and differentiation. For this reason, different types of malformations are seen in these two cord segments. A third cause of spinal malformations is formed by disorders of notochord development.

Disorders of Neurulation

This category contains a number of dysraphic conditions in which there is a defect in fusion of the midline neural, bony, and mesenchymal structures: spina bifida, either open (aperta) or closed (occulta).

Spina bifida aperta comprises meningocele and meningomyelocele, in which due to lack of fusion of the neural folds a placode of neural tissue is visible on the surface in the midline of the back. The spinal cord is fixed and the conus medullaris is unable to ascend normally to the L1–L2 level (tethered cord). Chiari II malformation is an associated condition featuring a small posterior fossa with protrusion of cerebellar and brain stem structures caudally and cranially.

In occult spinal dysraphism, no placode is visible but cord tethering may be due to conditions such as dorsal dermal sinus or spinal lipoma.

Sometimes there are combinations: lipomyelomeningocele.

A simple dorsal meningocele does not contain neural elements, and is not due to a neurulation disorder.

Disorders of canalization and retrogressive differentiation

Abnormalities of the spinal cord in this condition include dilatation of the terminal ventricle in the conus, tight filum terminale causing cord tethering, fibrolipoma of filum terminale and myelocystocele. The spine may be affected by sacral agenesis or the more complex caudal regression syndrome.

Disorders of notochordal development

Persistence of a patent notochordal canal can result in various vertebral malformations and enteric cysts or diastematomyelia (split cord).

Vascular Disease

Arterial supply to the spine and intraspinal structures is derived from vertebral arteries, the intercostal and lumbar arteries originating from the aorta and the internal iliac arteries. The most important artery to supply the spinal cord is the great radicular artery of Adamkiewicz, which usually originates in the lower thoracic region of the aorta, and is the most important contributor to the anterior spinal artery, which is a usually continuous arterial channel coursing along the entire spinal cord, also receiving minute tributaries from higher and lower levels. Dorsal spinal arteries are smaller and less well defined. Spinal cord drainage takes place *via* intramedullary and radicular veins.

Ischemic Conditions

Interruption of blood supply to the spinal cord can result in transient or permanent neurologic deficit, as in the brain. Anterior spinal supply to the lower cord is most frequently involved, and can lead to transverse cord lesions. These can show up as areas with low signal intensity on T1-weighted images, and signal increase with T2-weighting.

Abnormal arteriovenous connections. There are two main types.

- Spinal cord arteriovenous malformations: Site of shunt is the spinal cord. Generally seen in younger patients, with hemorrhage usually the presenting symptom. Dilated medullary vessels seen on MRI, with dilated arteries and as well as veins visible at spinal DSA.
- Dural arteriovenous fistulas: Older patients presenting with progressive cord deterioration due to increased venous pressure. MRI shows cord swelling with extensive intramedullary high-signal areas, as well as dilated draining veins. Spinal DSA is at present diagnostic gold standard, but MRA and CTA show rapid improvement and potential for replacing invasive catheter techniques.

Treatment of these conditions is endovascular or surgical.

Definition

In the clinical symptomatology, four aspects are important for understanding the clinical pictures of the various disorders of the spinal cord.

The first is the level of the lesion. The more cranial the location of the lesion, the more extensive the neurological deficit caudal to the lesion, with loss of motor, sensory, and autonomic mechanisms.

Secondly, the extent of the lesion in the transverse plane determines the extensiveness of the neurological deficit, which may result in complete or partial transverse cord syndromes.

Thirdly, the extent in the longitudinal plane is important for a lesion comprising several spinal cord segments. This may present as a clinical entity in itself such as in hematomyelia and syringomyelia or it can be associated with transverse lesions of a few segments or all segments of the isolated cord below the primary transverse lesion.

Finally, the nature of the onset of the spinal cord lesion, sudden or gradual, determines the clinical symptomatology of the spinal cord lesion.

Characteristics

The clinical symptomatology in spinal cord disorders depends on the extent of the lesion and/or the neural structures and spinal tracts that are involved and located in the transversal plane of the cord.

The syndromes can be neuroanatomically subdivided into

1. Complete spinal cord transection
2. Spinal cord hemisection
3. Central cord syndrome
4. Anterolateral spinal cord syndromes
5. Long tract syndromes
6. Anterior horn syndromes

A complete spinal cord transection results in a bilateral sensory deficit for all modalities below the level of transection. It is accompanied with spastic tetraparesis of all extremities in cervical lesions or paraparesis of the legs in thoracic lesions, as well as bladder dysfunction. Sometimes, segmental signs such as reflex deficits, muscle weakness, and atrophy are present.

In hemisection of the cord (Brown-Séquard syndrome), the neurological picture is characterized by paresis with segmental muscle atrophy, superficial hyperesthesia, and a deficit of sensation of superficial touch, deep pressure, and vibration, all located at the same side as the spinal cord lesion.

In contrast, a dissociated sensory deficit involving pain and temperature is present on the contralateral side.

In central spinal cord syndromes, unilateral paresis may be present accompanied with bilateral pain and temperature deficit. Because the posterior columns of the spinal cord are spared, sensory qualities such as light touch and vibration are normal.

Anterolateral spinal cord syndromes, mostly of ischemic origin, are characterized by paraparesis, dissociated sensory loss below the level of the lesion, and urinary dysfunction. Because the posterior columns are also spared, sensory qualities such as light touch and vibration are normal.

Some disorders of the long tracts, such as tabes dorsalis, show isolated spastic paraparesis whether or not associated with sensory deficit for deep touch.

Other spinal cord syndromes are related with lesions of the anterior horn gray matter resulting in muscular atrophy. In the case of amyotrophic lateral sclerosis, anterior horn involvement is associated with pyramidal tract signs.

Etiology of Spinal Cord Disorders

A second subdivision of spinal cord disorders is based on the etiology, in which the above-mentioned anatomical subdivision of spinal cord lesions determines the clinical neurological picture.

Congenital Abnormalities of the Spinal Cord

Various congenital spinal cord disorders are due to incomplete closure of the neural tube. Depending on the extent of incomplete neural tube closure, the clinical picture can vary from simple back pain and sciatica to severe neurological deficits. Spinal bifida occulta, meningocele, myelomeningocele, and meningomyelocystocele can be present and associated with hydrocephalus or Arnold–Chiari malformation.

Spina Bifida Occulta

Spina bifida occulta is a benign disorder, which seldom leads to symptoms and/or neurological deficit. The condition is often diagnosed as an incidental finding on routine spinal X-ray studies.

A spinous process and a variable part of the lamina may be lacking. Some patients have low back pain and sciatica, because the spinous process of L_5 irritates the incomplete lamina of S_1.

Spinal Dysraphism

Spinal dysraphism can lead to complex clinical neurological pictures with signs of pyramidal tract involvement, urinary dysfunction, and weakness of the lower extremities. The neurological deficit depends on the spinal level of the disorder.

Deformities of the feet, dermal sinus, lipoma, intraspinal adhesions, and tethered cord may be present.

Diastematomyelia

In diastematomyelia, the spinal cord is cleft in two halves. The neurological picture develops during the growth of the child and is mainly characterized by a paresis of the lower extremities and urinary dysfunction. Deformities of the feet are mostly present.

Tethered Cord

In patients with tethered cord, the symptomatology consists of gradual progressive paresis of the lower extremities and urinary dysfunction. The neurological picture develops during the growth of the child.

Traumatic Disorders of the Spinal Cord

Traumatic disorders of the spinal cord can occur both in infants during labor and birth, and at later ages.

In cases of breech delivery, the spinal cord can be damaged, with traumatic contusion and hematoma. The severity of the clinical picture depends on the extensiveness of the lesion(s) and there may be complete or incomplete transection of the spinal cord.

At adult age, signs of traumatic complete or incomplete transection of the spinal cord can be divided into two phases. In the first 3 weeks of the spinal cord transection, a flaccid paresis with diminished or absent reflexes and no signs of pyramidal tract involvement is present. Both the bladder and bowels are paralyzed.

After this first phase, the clinical picture changes. A spastic paresis develops with signs of pyramidal tract involvement shown in abnormal reflexes and bladder dysfunction. Sensory deficit is seen as anesthesia below a certain segmental level.

Spinal Cord Concussion/Contusion

Different spinal cord lesions can result in different clinical features. In patients with posttraumatic spinal cord concussion, clinical symptoms of complete and incomplete spinal cord transection can occur. However, in contrast to spinal cord contusion, the neurological deficit is reversible and will resolve within a couple of days.

In spinal cord contusion, the neurological deficit is a direct consequence of mechanical compression by dislocated fractured vertebra, bony fragments, herniated intervertebral discs, or vertebral subluxation. Recovery of neurological function is frequently absent or incomplete.

Myelomalacia/Syringomyelia

In some patients with spinal cord injuries, secondary sequelae can develop hours to days after the initial trauma. Due to vascular insufficiency in the anterior spinal artery, an extension of the neurological clinical picture can develop. Late consequences of a spinal cord injury can develop months or years after the initial event in the form of syringomyelia with dissociated sensory loss and trophic disturbance of the muscles.

Epidural Hematoma/Hematomyelia

Mechanical compression of the spinal cord is seen in epidural hematoma and sometimes secondary to epidural abscess. Apart from neurological deficit, pain is a major and first symptom. Pain is also prominent in posttraumatic hematomyelia. A deterioration of the neurological picture in which the initial level of the lesion rises cranially follows the initial incomplete spinal cord transection with Brown-Séquard-like syndromes.

Conus Medullaris/ Cauda Equina Syndrome

Fractures and/or disc herniations in the thoracolumbar junction give rise to lesions in the conus medullaris or cauda equina. In the conus medullaris syndrome, the neurological deficit is mainly restricted to sensory loss of the sacral segments (saddle hypoesthesia) and urinary and sexual dysfunctions. Motor deficit is rare and pyramidal tracts can be involved. Complaints of pain are not prominent.

In contrast, the posttraumatic cauda equina syndrome is often painful. Except for the lack of pyramidal tract involvement, the same clinical picture can be present as in the conus medullaris syndrome.

Spinal Cord Compression by Neoplasm

In contrast to traumatic spinal cord lesions, tumors frequently manifest themselves as a gradually worsening spinal cord syndrome. The onset starts with gait impairment, urinary dysfunction, and sensory loss of the lower extremities, radicular or band-like sensations around the chest or abdomen, and back pain with bilateral sciatica. Extramedullary tumors, such as neurofibroma, and metastasis may present with nerve root pain. The same is true for meningeal carcinomatosis, which is often very painful with polyradicular spread.

Slow-growing tumors like meningioma are often initially silent and become clinically manifest in a late phase when they compress the spinal cord resulting in neurological deficit as a presenting symptom.

Intramedullary tumors are rare and the nature of the neurological deficit is dependent on the location of the tumor. Ependymomas are usually located at the distal end of the spinal cord and can present with back pain and sciatica followed by gradually developing neurological deficit of the lower segments of the spinal cord. In contrast, astrocytoma can affect large parts of the spinal cord.

Spinal Cord Compression of Other Origin

Nonneoplastic compression of the spinal cord can occur in epidural hematoma or in bony structures of the vertebral column.

Epidural hematoma can arise spontaneously and may be associated with the use of anticoagulants or with medical interventions such as lumbar puncture and placement of epidural leads for spinal cord stimulation.

In spondylosis and kyphoscoliosis, bony structures can compress the spinal cord. Hemangioma of the vertebral body can result in nerve root involvement and/or compression of the spinal cord. Local segmental tenderness of a vertebra is frequently present.

Cervical spondylosis can compress the spinal cord, particularly when a congenitally narrow spinal canal is present. Besides directly compressing the cord, posterior osteophytes can interfere with the blood supply of the spinal cord. The neurological picture comprises multisegmental radicular motor deficit with ill-defined sensory loss. In final stages, ataxia due to involvement of the spinocerebellar tracts and spasticity of the lower extremities can develop. Particularly in the elderly, slowly progressive gait disturbances are frequently due to cervical myelopathy in spondylosis.

At the thoracic level, both bony structures and intervertebral discs can compress the spinal cord and present themselves with the same neurological picture as cervical myelopathy. Intervertebral thoracic disc herniations are associated with painful radicular radiation in a thoracic segment.

Infectious Disorders of the Spinal Cord

Antecedental bacterial infections and vertebral osteomyelitis can be followed by the development of subdural and epidural abscesses. Pain and fever are prominent features of the clinical condition. Neurological symptoms such as nerve root compression and pyramidal signs are followed by a rapid onset of paraplegia.

In poliomyelitis, the viral infection affects the central gray matter of the anterior horn. The clinical picture therefore is dominated by marked paresis to paralysis. Sensory loss is absent. In some patients with known poliomyelitis, years after the primary infection a post-polio syndrome may develop, which is characterized by an increase in the existing motor deficit.

Other viral infections can be associated with myelitis and give rise to more or less complete spinal cord transection syndromes. Myelitis is also seen in the context of demyelinating diseases. Particularly in immune-suppressed patients, cutaneous herpes zoster can be followed by myelitis after an interval of 2 weeks.

Transverse Myelitis

Although an infectious disease mostly precedes acute or subacute transverse myelitis by 1–3 weeks, the syndrome may be due to noninfectious inflammatory conditions. Immunopathogenic etiology is likely. In a few instances, transverse myelitis follows vaccination, but in most cases no antecedent event can be traced.

Pain is not a prominent feature and the neurological deficit can vary from urinary retention and lower limb sensory and motor deficit to a complete transverse spinal lesion. The condition can affect patients of all ages and in the majority of the cases is monophasic.

Vascular Disorders of the Spinal Cord

In adulthood, only six to eight anterior and posterior segmental arteries supply the spinal cord. The largest of these, the artery of Adamkiewicz, enters the spinal canal between Th10 and L2 through the intervertebral foramen and communicates with other arteries on the surface of the spinal cord by the single anterior spinal artery and the paired posterior spinal arteries. Through the circular vasocorona, the anterior and posterior spinal arteries are mutually connected.

The extent of the neurological deficit (myelomalacia) in spinal cord ischemia depends on the duration and severity of the vascular insufficiency.

Anterior Spinal Artery Syndrome

Neurological deficit due to anterior spinal artery insufficiency may be preceded by segmental prodromal pain and band-like dysesthesia. Initially there is flaccid paraplegia and a typical dissociated sensory deficit is present, in which the entire body below the level of the lesion is involved. Touch, position sense, and vibration sense (posterior column) are preserved, whereas pain and temperature sensations are disturbed and anal sphincter function may be affected.

Posterior Spinal Artery Syndrome

Neurological deficit due to posterior spinal artery insufficiency consists of severe paraparesis accompanied by deficit of posterior column sensory modalities such as touch, position sense, and vibration sense.

Arteriovenous Malformations of the Spinal Cord and Dural Arteriovenous Fistulae

In arteriovenous (A–V) malformations of the cord, the clinical picture is characterized by a rapid onset of incomplete or complete transverse cord lesion, sometimes preceded by radicular pain. Sometimes, spinal vascular malformations can lead to subarachnoidal hemorrhages.

In the case of dural A–V fistulae, there is no hemorrhagic event and the onset of spinal cord symptoms, due to venous congestion, is more gradual, with the patient's walking progressively declining because of developing paraparesis.

Degenerative Disorders of the Spinal Cord

Anterior Horn Cells Diseases

Many diseases of the anterior horn cells are classified under spinal muscular atrophies (SMA). These often have a hereditary background and are characterized by neurological deficits restricted to the involvement of the anterior horn cells. No sensory abnormalities are present. Paresis and atrophy show a typical pattern, dependent on a specific hereditary etiology.

Spastic Spinal Paralysis

Spastic spinal paralysis is a mainly autosomal-dominant inherited disease of the spinal cord. It starts in childhood with a progressive spastic paresis of the legs. No sensory abnormalities are present. In adulthood, the spastic paraparesis may be accompanied by additional neurological deficits such as atrophy, extrapyramidal signs, ataxia, optic atrophy, and dementia.

Spinocerebellar Ataxia

In some patients, the spinal cord neurological deficits form a part of the clinical neurological picture of a hereditary disease in which both the cerebellum and other central nervous structures are also involved. Classification is made based on inheritance, age of onset, and genetic characterization. The most prominent clinical features are ataxia, gait impairment, dysarthria, and reflex abnormalities. Sensory abnormalities in some syndromes are restricted to posterior column sensory modalities.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS), also known as motor neurone disease, is characterized by a combination of neurological deficits originating from the central as well as the peripheral nervous system.

The initial symptoms are asymmetrical weakness and atrophy of the hand muscles. Complaints of muscle cramps and "restless legs" are frequently present. Bulbar muscle involvement, presenting as dysphagia, as the initial symptom is less frequent. The clinical picture is dominated by weakness, atrophy, and muscle fasciculations in combination with hyperreflexia and other signs of pyramidal tract involvement. The tongue is also involved and shows atrophy and fasciculations, resulting in slurred speech.

Metabolic Disorders of the Spinal Cord

Vitamin B_{12} deficiency can lead to spinal cord involvement. Usually, it is due to inadequate resorption based on lack of intrinsic factor due to gastric mucosal atrophy or total gastrectomy or conditions that affect the small intestine such as sprue.

The neurological deficit is characterized by sensory abnormalities of all modalities, hyporeflexia, and pyramidal tract signs. In the majority of the cases, polyneuropathy is present. Mental abnormalities such as confusional states and dementia may be present but are rare.

Miscellaneous Disorders of the Spinal Cord

Multiple Sclerosis

Multiple sclerosis (MS) is a demyelinating disease that can affect the spinal cord as well as other parts of the central nervous system. The clinical picture frequently has a relapsing and remitting course. The neurological deficits are dependent of the various localizations of the MS lesions. Each MS relapse may give a different neurological deficit to the previous relapse and frequently result in a variable severe residual deficit after remission. The spinal neurological deficit of an MS patient cannot be reduced to a single level or anatomical localization in the central nervous system.

Hydromyelia and Syringomyelia

Hydromyelia is often asymptomatic and gives rise to symptoms when there is an expansion to the spinal cord by the formation of a cavity (syrinx). This syrinx can extend over several segments of the spinal cord. Weakness and atrophy of the arms and hands together with areflexia and segmental deficit of pain and temperature sense form the typical clinical picture. Gnostic sensory modalities such as vibration and position sense are intact. Pain and paresthesia in the arms and hands are frequently the initial symptoms. Due to the progressive character of the disease, the volume increase of the syrinx can lead to involvement of other neural structures of the spinal cord such as the pyramidal tracts and the spinothalamic tracts.

Involvement of the anterolateral descending tracts can lead to autonomic disturbances like trophic skin abnormalities, sweat secretion disturbances, and orthostatic hypotension.

Decompression Myelopathy

In caisson disease, painful dysesthesia and paraparesis or Brown-Séquard syndrome may be present due to air embolism of the spinal arteries.

Radiation-Induced Myelopathy

In radiation therapy of cancer patients, signs of myelopathy can occur with a short latency after the treatment. Generally, such myelopathy has a good prognosis. In contrast, other patients may develop myelopathy months or years after the radiotherapy, which has a poor prognosis.

Definition

The clinical presentation of radiculopathy is characterised by pain radiating into the dermatome of a spinal nerve root. Occasionally, more than one root is involved. Pain may be accompanied by spinal muscle spasm, reflex abnormalities motor and sensory disturbances. Pain may be aggravated by various tests applying tension to the nerve root. Most frequently, these symptoms are caused by disc herniations. Differential diagnosis includes stenosis of the spinal or root canal, infection, multiple sclerosis, autoimmune or metabolic neuropathy and tumours. In this chapter, disc-related compression is emphasised as a cause. For obvious reasons, the spine will be divided in a cervical, thoracic and lumbosacral area.

Pathology

During aging, the spine is subjected to a degenerative cascade deforming the architecture of vertebrae, vertebral articulations and discs. This cascade includes biochemical desiccation changes of nuclear material, physical narrowing of the intervertebral disc space, development of degenerative spondylotic osteophyte formation of the vertebral end plates and in the final stage, eventual loss of the normal intervertebral motion segment. Weakness of the annulus fibrosus causes nuclear material of the disc to protrude or extrude in a posterior direction, sometimes giving rise to nerve root compression near or in the exit foramina of the spinal canal or, when medially located, to devastating compromise of neural structures in the spinal canal: spinal cord or cauda equina. These disc herniations may consist of soft nuclear material, but may also comprise fragments of annulus fibrosus, while in advanced and chronic stages of the degenerative process these benign herniations can evolve to calcified space–occupying lesions. In exceptional cases, in western and more frequently in Asiatic society, calcification of the posterior longitudinal ligament occurs without disc herniation.

Until recently, complaints in radiculopathy were regarded as the sole results of nerve root compressive forces. However, magnetic resonance imaging (MRI) and histopathology studies indicate a biochemical cause of pain generation (1), which is disputed by others. As a rule, disc herniations are not caused by trauma, which is generally the explanation of the layman confronted with the disease. A trauma may aggravate nerve root compression by an already existing disc herniation, giving rise to complaints.

Clinical Presentation

A radiculopathy is presented by a variety of signs and symptoms, depending on the degree of compression, unknown neurogenic changes and site of compression. The cervical, thoracic and lumbar spines are distinct entities.

Cervical Spine

The annual incidence of cervical disc herniations is estimated at 5.5 per 100.000 persons, sometimes higher for the male sex, occurring most frequently between the ages of 45 and 54 years. A significant rise in incidence is attributed to smoking, frequent lifting and diving from a board (2). A patient with a radicular syndrome, caused by a soft cervical disc herniation or a calcified osteophyte, may complain of central–axial neck pain and arm pain (brachialgia). The pain in the arm must however be the predominant symptom, and is typically distributed in a dermatomal fashion according to the root compressed. Such radiculopathy complaints are commonly described as sharp, lancinating pain precipitated or aggravated by postural or Valsalva maneuvers. The pain is intense and occasionally accompanied by reflex disturbance, motor- and/or sensory deficit. Straight raising of the arm can provoke the radicular pain. Another test is extension and lateroflexion of the cervical spine, which compresses the nerve root in the neuroforamen. Sensitivity and specificity of both these tests are however low.

Symptoms vary depending on the anatomic location of the displaced disc material. Laterally, displaced herniated nucleus pulposus material at the lower cervical disc spaces is expressed most often as radiating upper extremity pain as described above. For example, radicular pain in the thumb and index finger with numbness in the same area, decrease of the biceps reflex and biceps muscle weakness is typically caused by a disc herniation at the disc space between the fifth and sixth vertebra with compression of the C6 nerve root whereas pain and numbness in the middle fingers, decrease of triceps reflex and triceps muscle weakness are caused by compression of the C7 root one level lower between the sixth and seventh vertebrae. These two disc levels are the most frequent locations of disc herniations, followed by the adjacent discs and, very seldom, the levels above the third cervical disc. The symptom pattern of laterally displaced soft-herniated material in the upper cervical spine is expressed as neck or axial pain or even suboccipital pain when the second cervical nerve root is involved.

When the disc herniation is not located laterally but in a medial location, or laterally with a large component in the central region, the spinal cord is compromised and signs of myelopathy occur, varying from mild sensory disturbances, to disturbances of gait and micturition to complete tetraplegia.

Most disc herniations in the cervical spine probably resolve naturally in three months. Exact information is missing due to the lack of scientific evidence. Differential diagnosis includes cervical spondylosis which does have the same therapeutic options, and vertebral body dislocations caused by trauma or severe degenerations of the ligamentous structures.

Thoracic Spine

The incidence of radiculopathy of the thoracic spine has never been estimated in an epidemiological study. The main reason is the very low incidence compared to cervical and lumbar pathology and the fact that objectivation of symptoms is difficult. The low incidence appears to be related to the lack of mobility of this part of the spine. Lancinating pain in the area served by a thoracic nerve root may be accompanied by sensory loss in a very small dermatome, overlapped by an adjacent dermatome. Muscle weakness or reflex abnormalities cannot be identified. Furthermore, concussion or fracture of the ribs frequently gives rise to comparable complaints of intercostal neuralgia. Thoracic disc herniations are clinically most often discovered in a late stage when compression of the spinal cord gives rise to gait abnormalities and sensory disturbances.

Lumbar Spine

Sciatica or lumbosacral radicular syndrome (LSRS) is characterised by pain radiating in the dermatome of a lumbar or sacral spinal nerve root. Occasionally, more than one root is involved. Pain may be accompanied by lumbar spinal fixation, reflex abnormalities, motor and/or sensory disturbances. In the vast majority of cases, LSRS is the result of a herniated disc. Measured incidence rates vary. In the United States, an annual incidence of 5 per 1,000 persons is estimated. Most frequently, disc herniations occur between the fourth and fifth lumbar vertebrae, or fifth lumbar and first sacral vertebra. Because of the impact of the condition on daily functioning, indirect costs to society due to loss of production are high.

As described for the cervical spine, pain is sharp and lancinating and aggravated by movement or loading of the lumbar spine. Provoking the irradiating pain by lifting the straight leg in the supine patient is a classic sign of nerve root compression. The dermatome described as painful directs the clinician to the nerve root involved. Radiating pain in the calf, heel and sole and lateral border of foot, accompanied by an Achilles tendon reflex disturbance or weakness of the gastrocnemius muscles, is caused by compression of first sacral nerve root. Radiation to the medial part of the foot and big toe combined with weakness of the dorsiflexors of the foot is caused by compression of the fifth lumbar nerve root. A disturbance of the knee reflex is combined with pain in an area distributed by the fourth lumbar nerve root and quadriceps weakness when this root is involved.

Doubts concerning the validity of these neurologic signs are however present. Studies have shown that disc herniations can cause a variety of dermatomal disturbances not typical for the classical radicular syndrome. The most important cause for this discrepancy is the varying appearance of the lumbar disc herniation. A frequent location of an annulus defect is the mediolateral part of the disc causing a disc to rupture into the subarticular (3) area of the spinal canal and compressing the expected exiting nerve root. In case a median or paramedian defect in the annulus occurs, a more medially located nerve root is involved which exits the spinal canal one level lower than the disc involved. Laterally located disc herniations, inside or outside the foramen, compromise roots which have exited the dural sac one level higher than the disc pathology. Very rarely severe neurological problems can occur as a result of compression of the cauda equina. These are usually caused by large central disc herniations compressing nerve roots in the dural sac.

As stated for cervical radiculopathies, the natural course of sciatica is favourable, resulting in recovery of 70% of patients in the first 6–8 weeks. The clinical syndrome of sciatica may be mimicked by diseases of the nerve roots such as Lyme's polyradiculoneuropathy, which is a very distinct neurological entity with serious deficits in muscle function if not treated.

Imaging

The three parts of the spine have different biomechanical properties, and the indications for imaging and the type of imaging required, may also differ. The general rule is that imaging of the spine is necessary to examine the anatomical relationship between a disc herniation and the nerve root compression, when the natural course has not given rise to recovery of complaints and surgery is contemplated. However, the classical nerve root compression syndrome is not always clearly present in patients with a disc herniation and, MRI studies in volunteers have shown that many asymptomatic individuals harbour disc herniations, with root compression but without any clinical consequences. In contrast, even when clinical signs and symptoms clearly indicating nerve root compression are present, imaging studies of the spine do not show a disc herniation in all cases (4).

The first choice for diagnostic imaging in suspected nerve root pathology is generally considered to be MRI, with computed tomography (CT) considered as second choice. This in spite of the lack of a systematic study clearly demonstrates that MRI is superior in diagnosing a simple disc herniation. In the cervical and especially the thoracic spine, MRI has the drawback that calcification within a disc or disc lesion is not well demonstrated. In these cases, a thin slice CT study can be useful. Plain X-rays are necessary to identify transitional vertebrae before spinal surgery.

Other than delineating the pathology, MRI has not been considered to have great prognostic value so far. However, recent studies have shown that sequestrations of the disc have a more favourable natural history than previously supposed, thus supporting a trend towards a conservative approach in these cases, where in the past surgery was the rule (5). The significance of these findings is currently a subject of investigation in randomized trials.

Diagnosis

Radiological confirmation of disc-related nerve root compression matching the clinical picture completes the diagnosis. If a discrepancy exists between MRI findings and clinical suspicion of nerve root compression, electrophysiological studies can help in diagnosis and treatment selection.

Introduction

The spine is the most frequently imaged part of the human body, even though shortcomings of the various imaging methods are well known. Conventional X-ray images possess a low sensitivity for demonstrating soft tissue pathology, and even bony lesions such as vertebral metastases are only detected at a very late stage. On the other hand, the clinical significance of many presumed pathologic features seen on spinal films is often unclear. This is even more truer for the abundant and frequently confusing detail seen in CT and especially ▶magnetic resonance imaging (MRI) studies.

The high prevalence of a specific backache and lack of understanding of the aetiology of this complaint seems likely to perpetuate reliance in imaging studies which are often performed apparently for the purpose of reassurance.

Conventional X-Ray Imaging and X-Ray Computed Tomography

Plain films of the spine are a quick, simple and inexpensive imaging modality. Spinal curves can be assessed in scoliosis, and the anatomy of individual vertebrae can be defined although superimposition of anatomical structures, as always in 2D projection imaging, is a problem. Plain films are especially suitable for imaging bony anatomy and relationships, but lack of soft tissue resolution is a major drawback. This was first alleviated by injection of contrast media in various soft tissue structures or compartments: the intradural CSF space (myelography), the nucleus pulposus (▶discography), the epidural space (peridurography) or epidural veins (phlebography). The latter two techniques are no longer practised.

At present, plain film spinal imaging is ordered most frequently in patients presenting with low back pain and cervical pain. The diagnostic yield of such studies is generally held to be very limited unless so-called red flags (indicators for specific disease conditions such as neoplasm, disc herniation or infectious disease, for instance) are present. In such cases alternative techniques with higher sensitivity (CT, MRI) are preferable. The so-called degenerative features such as disc space narrowing, spondylosis and spondylarthrosis are frequently seen in symptomatic as well as asymptomatic individuals (Fig. 1). Spondylolysis and spondylolisthesis can be well demonstrated. Plain films are still usually performed as the first examination in spinal trauma, and permit detection and classification of injuries associated with malalignment of vertebrae due to wedging of vertebral body, facet fracture and/or interlocking. More subtle fractures without displacement are easily missed, as well as most of the soft tissue injuries.

Spine and Spinal Cord. Figure 1 ►Plain X-ray film of lumbosacral spine in lateral projection, with degenerative changes: disc space narrowing at L4–5 and especially L5–S1 levels; sclerosis of vertebral endplates; bony spurring or osteophyte formation at ventral corners of vertebral bodies.

►Computed tomography (CT) has revolutionised medical imaging since its introduction in the 1970s. Three improvements were combined: detection of smaller differences in X-ray attenuation by using more sensitive scintillation detectors instead of an X-ray film, acquisition of sectional images by the use of an X-ray tube rotating around the patient in the axial plane and image reconstruction by a computer algorithm permitting selection of window and level settings appropriate for viewing bony and soft tissue structures. This made it possible to appreciate axial spinal anatomic relationships not previously visualised. The improved contrast resolution of CT permits non-invasive imaging of disc herniations and other abnormal and normal soft tissue features. A much better insight was obtained in the morphology and classification of spinal stenosis (Fig. 2a–c). A drawback is the lack of visualisation of intradural details such as the spinal cord and nerve roots; for this CT myelography is necessary. Sensitivity for vertebral pathology such as metastasis and fracture is greater than that of plain films, and rapid spiral CT scanning with multiplanar reformatting is increasingly becoming the first imaging procedure in spinal trauma.

Myelography and Computed Tomographic Myelography

In order to distinguish intradural anatomy and pathology, an iodinated radiologic contrast media can be injected into the spinal subarachnoid space, after which myelographic plain films and/or CT sections are acquired. This provides high-resolution images of the contours of the spinal dural sac and the spinal cord within it, and also of the individual fibres of the cauda equina and the root sleeves (Figs 3a, b). Conventional myelography provides a better longitudinal overview, and CT myelography a more detailed image, especially when the intradural contrast medium has become diluted, as can easily occur.

The main application of this technique is in the detection of intraspinal space occupying lesions. These can be intradural (neoplasm or cyst formation within the cord; extra-medullary meningioma or nerve root tumours), but can also be located outside the dural sac, indenting the dural contours or compressing the root sleeve (disc herniation, vertebral neoplasm or extradural haematoma). Cord atrophy or transection can also be well demonstrated, but spinal cord lesions without mass effect (cord infarct, multiple sclerosis) can only be visualised by MRI.

Discography and Computed Tomographic Discography

Discography

In this examination a needle is placed with the tip within the nucleus pulposus of an intervertebral disc in a patient with low back pain or referred pain, and a contrast medium is injected. Radial fissures of varying extent in the annulus fibrosus can be demonstrated, and also herniation of the nucleus pulposus through the annulus. Such disc protrusions and extrusions can be better demonstrated by CT or MRI, however the present diagnostic role of discography is in pain provocation by the increase in intradiscal pressure produced during the injection. If contrast injection into the affected disc reproduces the familiar pain of the patient, and injections into the adjacent discs do not, then this finding, in combination with radial fissuring extending to the outer one-third of the annulus fibrosus, is considered evidence of a discogenic origin of the pain.

Magnetic Resonance Imaging (Fig. 4)

MRI is a sectional imaging technique like CT, but makes use of a different imaging principle. Instead of image

(a) Normal L4–5 level showing normal disc, facets with covering ligaments, dural sac containing CSF and cauda equina (note that intradural nerve roots cannot be seen). (b) Left herniated disc protruding into spinal canal and compressing dural sac. This case also demonstrates degenerative changes in disc (so-called vacuum phenomenon with air density) and some hypertrophy of facets and flaval ligaments. (c) Developmental stenosis with reduced anteroposterior diameter of bony spinal canal.

contrast being derived from differences in X-ray attenuation due to variations in electron density within various anatomical structures, in MRI the protons of the body are induced to act as radiofrequency (RF) transmitters by being placed inside a magnetic field and subjected to RF energy beamed in from outside the body. This electromagnetic resonance is analogous to the resonance of a tuning fork when exposed to sound of the appropriate frequency. The RF signals from the protons can be manipulated or 'weighted' to selectively amplify signal intensity of various tissues and structures within the body, and are spatially encoded to produce an image. An MR image in which contrast is dependent on differences in longitudinal magnetic relaxation values between various tissues, is called T1 weighted. When differences in transverse magnetic relaxation predominate, the image is called T2 weighted. MR imaging has significant advantages over CT: soft tissue contrast resolution is better and there are no artefacts due to high-density skeletal structures. Subtle changes in shape and composition of the spinal cord can be demonstrated by MRI, and the intradural nerve roots can be imaged without intradural contrast injection (MR myelography). Intravenous injection of MR contrast media improves detection and classification of intramedullary pathology, as well as spinal infectious, neoplastic and post-operative conditions. MR images can be acquired in any desired plane, and are superior to sagittal or coronal reformatted CT images of the spine, especially of the soft tissues.

The largest single indication for spinal MR imaging is presently in degenerative spinal disease, especially disc herniation. After spinal injury MRI is useful in assessing damage to the spinal cord and also in detecting spinal ligamentous lesions which may result in significant instability. Metastases to the spine as well as primary vertebral tumours can be diagnosed accurately as well

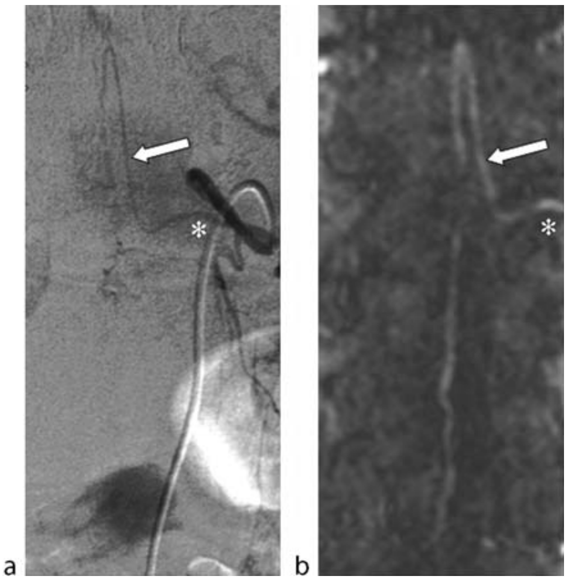
Spine and Spinal Cord. Figure 4 MR imaging of cavernoma in the cervical spinal cord. (a) T1 weighted sagittal image showing high-signal intramedullary mass lesion with thin hypo-intense rim. Note high signal from subcutaneous fat and fatty bone marrow, low signal from CSF. (b) T2* weighted gradient echo image. Note that subcutaneous fat now has intermediate-to-dark signal, CSF and nucleus pulposus have bright water signal. Signal loss at rim of lesion is accentuated in this sequence due to susceptibility effect caused by presence of haemosiderin. Bright signal within lesion is due to presence of methemoglobin.

as tumours of the spinal cord and nerve roots. MRI is used for detecting spinal cord lesions in patients with multiple sclerosis and spinal infectious disease such as spondylodiscitis.

Activation of spinal cord neurons can be achieved by motor tasks and sensory input, and registered in the same way as in the brain (spinal fMRI). Diffusion tensor imaging of the spinal cord (MR tractography) is in development.



Spine and Spinal Cord. Figure 5 Spinal cord angiography. (a) Coronal intra-arterial digital subtraction angiographic (DSA) image of the great anterior radiculomedullary artery, or Adamkiewicz artery. The supplying segmental artery (asterisk) and the Adamkiewicz artery (large white arrow) are shown. (b) Multiplanar reformatted magnetic resonance angiographic (MRA) image in same case presenting good depiction of the supplying segmental artery (asterisk) and the Adamkiewicz artery (large white arrow).

Spinal Cord Angiography (Fig. 5)

Catheter digital subtraction ►angiography (DSA) is at present the reference modality for diagnostic imaging of the spinal cord vasculature. In this examination a catheter is positioned with its tip in the orifice of a segmental artery originating from the aorta, and an iodinated contrast agent is injected. Since all segmental arteries must be selectively examined, a full spinal DSA study can be very time-consuming as well as carrying a risk of ischaemic complications involving the spinal cord. In addition patients are exposed to relatively high radiation doses. DSA does however offer the possibility to combine diagnosis and endovascular therapy.

Magnetic resonance angiography (MRA) has recently emerged as a non-invasive potential alternative imaging modality to intra-arterial DSA. Several flow-weighted MRA techniques are available, but the most promising method employs an intravenous injection of a gadolinium contrast medium combined with a rapid MRI acquisition. Centric ordered K-space filling provides an effective temporal resolution of approximately 10 sec in a 40-sec acquisition. The arrival of the intravenous gadolinium contrast bolus in the spinal arteries is carefully matched to the start of the MRA acquisition sequence. This permits imaging of an arterial phase followed 40 sec later by a mixed arteriovenous image, thus allowing distinction between arteries and veins. After acquisition the 3D datasets are post-processed using maximum intensity projections and multi-planar reformats.

The most common indication to perform spinal cord angiography is the localisation, classification, and follow-up of spinal cord vascular malformations, such as spinal cord arteriovenous malformations and spinal cord arteriovenous fistulas. Another indication is the preoperative localisation of the major anterior radiculomedullary feeder, the Adamkiewicz artery prior to surgical procedures where the spinal cord blood supply may be at risk, e.g. vertebroplasty, thoraco-abdominal aortic aneurysm repair and thoracoscopic discectomy).

S

Definition

Inflammatory diseases of the spine can be divided into rheumatoid arthritis (RA) and the spondylarthropathies (SpAs). SpAs is the term used to describe a group of diseases that share clinical and genetic characteristics that differentiate them from RA. The most common member of this group is ankylosing spondylitis (AS), which is considered the prototype of the SpAs. Other arthropathies included in this group are psoriatic arthritis, reactive arthritis (ReA, formerly Reiter's disease), inflammatory bowel disease-related arthritis, and undifferentiated SpA. Although classification systems are available, categorization of individual patients remains difficult because of the overlap of symptoms and radiological manifestations between the subgroups. Besides manifestations of these diseases in the axial skeleton, peripheral arthritis can occur, predominantly of the lower limbs. In contrast, RA predominantly affects the peripheral joints and, to a lesser degree, the spine, especially in the cervical region.

Pathology/Histopathology

Of all SpAs, the pathogenesis of AS has been studied most. Nonetheless, the pathogenesis of this condition is still poorly understood. Immune-mediated mechanisms involving human leukocyte antigen, inflammatory cellular infiltrates, cytokines, and genetic and environmental factors are said to have a key role. The most recent hypothesis states that a key trigger for the disease is the intracellular proteolysis of (intestinal) bacterial peptides and self-proteins producing peptides that are present on the cell surface. These peptides lead to activation of cross-reactive T-cells, provoking an inflammatory response. Primary sites of inflammation are the fibrocartilage of the enthesis (the insertion of ligament, tendon, or fascia into the bone) and of cartilage at the interface with bone. Clinically, this process becomes apparent as an enthesitis, mainly of the vertebral ligaments, and as a sacroiliitis. Eventually the inflammatory process may lead to ossification and ankylosis of these structures (the "bamboo spine" seen in AS).

SpAs shows a strong association with the class I molecule HLA-B27. In AS, this association is strongest, present in 90% of cases, compared with 7% in the general population.

The primary site of inflammation in RA is synovial tissue. The synovial joints of the peripheral skeleton are especially clinically affected—the small joints of the hand and feet, and much less frequently and less severely, the synovial tissues of the cervical spine.

Clinical Presentation

The most common and characteristic clinical symptom of spinal manifestation of SpA is chronic inflammatory back pain. This type of back pain is most often felt over the sacroiliac region and deep in the gluteal area and is insidious in onset. Remarkably, the pain tends to worsen after prolonged periods of rest and improves on exercise. In some cases, bone tenderness may be the primary complaint. Important extraskeletal clinical manifestations of SpAs are inflammatory bowel disease, acute anterior uveitis, conjunctivitis, dactylitis, psoriasis, carditis, and genital inflammation. These symptoms may occur early in the course of the disease. On physical examination, a loss of spinal mobility, reduced expansion of the chest, and pain in the sacroiliac joints on pressure or movement can be found. Due to muscle spasm, the limited motion can be disproportional to the degree of ankylosis. Except for the HLA-B27 gene, laboratory tests are not diagnostic. Even C-reactive protein (CRP) or erythrocyte sedimentation rate (ESR) is elevated in only 50–70% of the patients with active disease.

Diagnostic for AS is the presence of sacroiliitis, as detected by any imaging modality, in the presence of clinical manifestations. A combination of the presence of inflammatory back pain and at least two other typical features of SpA (such as enthesitis and uveitis) is highly predictive for early AS. However, the diagnosis of AS is difficult before the occurrence of irreversible skeletal damage, and several years may pass between the onset of symptoms and definitive diagnosis. As emerging biological therapies (the antitumor necrosis factor-alpha) may favorably alter the disease process, it has become more important to diagnose the early stages of the disease. With this, the role of imaging in early detection is becoming increasingly important.

In patients with RA, radiological involvement of the spine is a frequent finding (20–70%), but the severity of the disease is rather mild. Spinal involvement is usually limited to the cervical region. The clinical findings here are mainly pain and stiffness of the cervical spine. Symptoms do not seem to be correlated to radiological abnormalities except when neurological deficit is present in severe spinal deformation.

Imaging

Imaging of the sacroiliac joints in SpAs can distinguish inflammatory and structural changes. Inflammatory changes are considered to be reversible whereas structural changes are not. Bone marrow edema at the cartilage/bone interphase, associated with osteitis, is an inflammatory change. Magnetic resonance imaging (MRI) can reliably visualize this edema and therefore is said to be the most sensitive imaging modality to detect early SpA. The earliest structural changes of the sacroiliac joints are blurring of the cortical margins of the subchondral bone, erosions, and sclerosis. Plain radiographs can also visualize these changes, but many years may pass before such changes in the sacroiliac joints become evident on plain radiographs. Computed tomography (CT) is said to detect the lesions earlier and more consistently. With progression of the erosive disease, the joint space may appear wider. Eventually, ankylosis will obliterate the joint. CT, and especially MRI, are not routinely used, but rather are used when the plain radiographs are negative. In AS, the abnormalities are usually symmetrically distributed. Psoriatic arthritis and ReA present involvement of the sacroiliac joints in a bilateral and asymmetrical fashion, and erosions and signs of bony repair appear to be much more extensive than those seen in AS. Ankylosis does not occur until late in the disease process.

RA causes symmetrical uniform narrowing of the sacroiliac joints with very little reparative bone reaction.

Plain radiographs of the spine in SpAs show various types of lesions that may occur at the discovertebral junctions. In AS, osteitis causes destructive "Romanus" lesions at the anterior corners of vertebral bodies, with reactive bone formation creating a squared appearance of the vertebrae and reactive sclerosis producing "shiny corners" to the vertebral bodies. End-plate erosions can progress to destruction of the entire discovertebral junction in advanced cases. Syndesmophytes are formed by ossification of the annulus fibrosus and can bridge the disc space.

As with imaging of the sacroiliac joint, CT and MRI are said to more sensitive, especially in the early SpAs.

In psoriatic arthritis, paravertebral ossifications occur in the thoracolumbar transitional area, usually unilateral or asymmetrical, growing in bulk and eventually merging with the spine. These ossifications (parasyndesmophytes) are bulkier than syndesmophytes. The discovertebral changes and ankylosis that are typically seen in ankylosing spondylitis are infrequent in psoriatic arthritis.

In ReA, as in psoriatic arthritis, plain radiographs show asymmetric paravertebral ossification in the thoracolumbar transition, occasionally with syndesmophytes and ankylosis of the facets resembling ankylosing spondylitis. The disease may also involve the cervical spine.

The most serious complication encountered in AS is spinal fracture. Because of the changed biomechanics of the rigid, fragile spine, minor trauma may lead to fracture. These fractures can have unusual configurations that cause them to go undetected unless carefully searched for. Neurological deficits are relatively common.

In RA, spinal imaging can demonstrate changes that are due to the inflamed synovium. Patients with RA and abnormal cervical spine radiographs have a higher prevalence of rheumatoid factor and advanced erosions on hand radiographs compared with those with normal spine radiographs. The severity of cervical spine changes is related to the duration of disease (>5 years). Spinal involvement occurs late in the course of the disease and frequently goes unobserved because of the extensive involvement of the peripheral joints. The most common abnormality is erosion of the odontoid process (47%), followed by atlanto-axial dislocation and apophyseal joint involvement (24%). Atlanto-axial dislocation is present when the distance between the anterior arch of C1 and the odontoid process of C2 exceeds 2.5 mm and increases when the cervical spine moves from extension (lordosis) to flexion (kyphosis).

CT can be used to demonstrate destructive bony changes and ligamentous calcifications and may also allow evaluation of synovial hypertrophy (pannus formation) in RA.

MRI is best for pointing out soft-tissue changes. Periodontal pannus is the most frequent finding. Pannus is homogeneous on T1-weighted images and shows contrast enhancement and is usually hyperintense on T2-weighted images; in cases of predominantly fibrous tissue, it is hypointense. Odontoid erosions are less frequently observed by MRI. They may show a heterogeneous MRI signal, and sometimes complete destruction.

Spinal cord involvement may occur as a result of severe anterior C1–C2 subluxation, atlanto-axial settling, or compression by retrodental pannus. T2 or T2-weighted images well demonstrate cord deformation and intramedullary signal increase (myelomalacia). MRI studies in cervical flexion and extension are more difficult to perform than dynamic plain X-ray films and do not provide more information.

MRI may also demonstrate spinal canal narrowing, with cord compression occurring in the lower cervical region in RA.

In RA, the thoracic and lumbar spine are infrequently involved. This helps to distinguish RA from ankylosing spondylitis, psoriatic arthritis, and Reiter's syndrome. However, cervical destructive changes with atlanto-axial subluxation may occur in all these conditions.

Definitions

The spinal cord is a small but extremely important element of the central nervous system (►CNS) and is especially well protected by the surrounding cerebrospinal fluid (CSF), the meningeal envelopes, and the bony spine. Although the anatomy is well known for a long time, the radiological approach has remained a sensitive subject and was difficult before the advent of magnetic resonance imaging (MRI). Major progress has been made in this field thanks to MRI (1, 2, 3).

Tumors located within the spinal cord are rare: they account for 4% of all CNS tumors. The vast majority of ►intramedullary tumors are glial tumors: the most frequently encountered neoplasms in adults are ependymoma (40%) and astrocytoma (28%). In children, however, astrocytomas are by far the most frequent tumors (90%) and ependymomas occur only in children affected by neurofibromatosis. Hemangioblastomas represent 14% of all spinal cord tumors.

Less frequent tumors include intramedullary metastasis, lymphoma, epidermoid cyst, lipoma, ganglioglioma, oligodendroglioma, paraganglioma, intramedullary schwannoma, and teratoma (4, 5). Cavernomas represent 8% of intramedullary mass lesions; however, they are not true neoplasms but vascular malformations.

Generally, spinal cord tumors enlarge the spinal cord. Besides a solid nodule, associated cysts may often involve large segments of the cord and should be distinguished from intratumoral cysts.

Histopathology/Anatomy

Only the most commonly found intramedullary tumors are described hereafter.

Astrocytomas are often large lesions with ill-defined limits; a cleavage plane is often not found at surgery. Astrocytomas are hypercellular lesions with no surrounding capsule. At histology, enlarged, irregularly shaped, hyperchromatic nuclei are present. Like in the brain, four different grades are recognized according to the World Health Organization (WHO). Grade I, considered most benign, is pilocytic astrocytoma. Grade II is fibrillary astrocytoma (low grade astrocytoma), which is the most common type in our series (75% of astrocytomas). Anaplastic astrocytoma is grade III, characterized by more hypercellularity and necrotic regions. The most malignant is grade IV, with glioblastoma multiforme showing endothelial proliferation and larger areas of necrosis and hemorrhage. Contrary to the brain, they are rare lesions: 0.2–1.5% of spinal astrocytomas (4).

Ependymomas originate from the ependymal cells surrounding the central canal of the spinal cord. Associated satellite cysts are frequently seen.

Different types of ependymomas are identified: cellular (the classic and most common type), papillary, clear cell, tanycytic, and melanotic (less common type) (4). Perivascular pseudorosettes are required for the diagnosis of ependymoma. The majority of ependymomas are of low grade and are well-circumscribed tumors corresponding to a grade I or II according to WHO classification. Malignant types are rarer. Ependymomas are prone to hemorrhage, especially at the margins of the tumor; this is responsible for the so-called cap sign seen on gradient echo ►T2-weighted images (WI). Calcifications may be found but are rare.

Myxopapillary ependymomas represent a distinct entity: they are typically located at the level of the filum terminale. These tumors are lobulated with a distinct capsule. At histology, tumor cells are heterogeneous, including mucin-producing cells, papillary-type cells mixed with the typical rosettes and pseudorosettes elements. Although usually of low grade, some tumors are more aggressive, type III lesions.

Hemangioblastomas are well-delineated nodular masses with extremely rich vascular components. Histologic examination shows pale stromal cells packed between blood vessels of varying size (4). Commonly, small tumors are associated with huge and extensive cystic components that may involve the entire cord.

Metastasis: Longer survival of cancer patients on the one hand and better imaging techniques on the other hand today allow the detection of a higher number of intramedullary metastases. The most common primary tumors include lung and breast cancer as well as melanoma.

Clinical Presentation

Spinal cord tumors grow very slowly, being mainly low-grade tumors (80%). They occur in younger adult patients: the mean age at diagnosis is 34 years for astrocytomas and 42 years for ependymomas. A slight male predominance (52–55%) is reported. The most frequent and early symptom is pain, and this may be the only one at the onset of the disease. Variations in tumor location will be responsible for variable motor and sensory deficits. Diagnosis is unfortunately made after a long period (mean 2.5 years after the onset of symptoms) as the clinical presentation is not specific. Urinary disturbances and impotence are less frequent and usually appear late in the clinical course of the disease, coincident with paralysis of the legs.

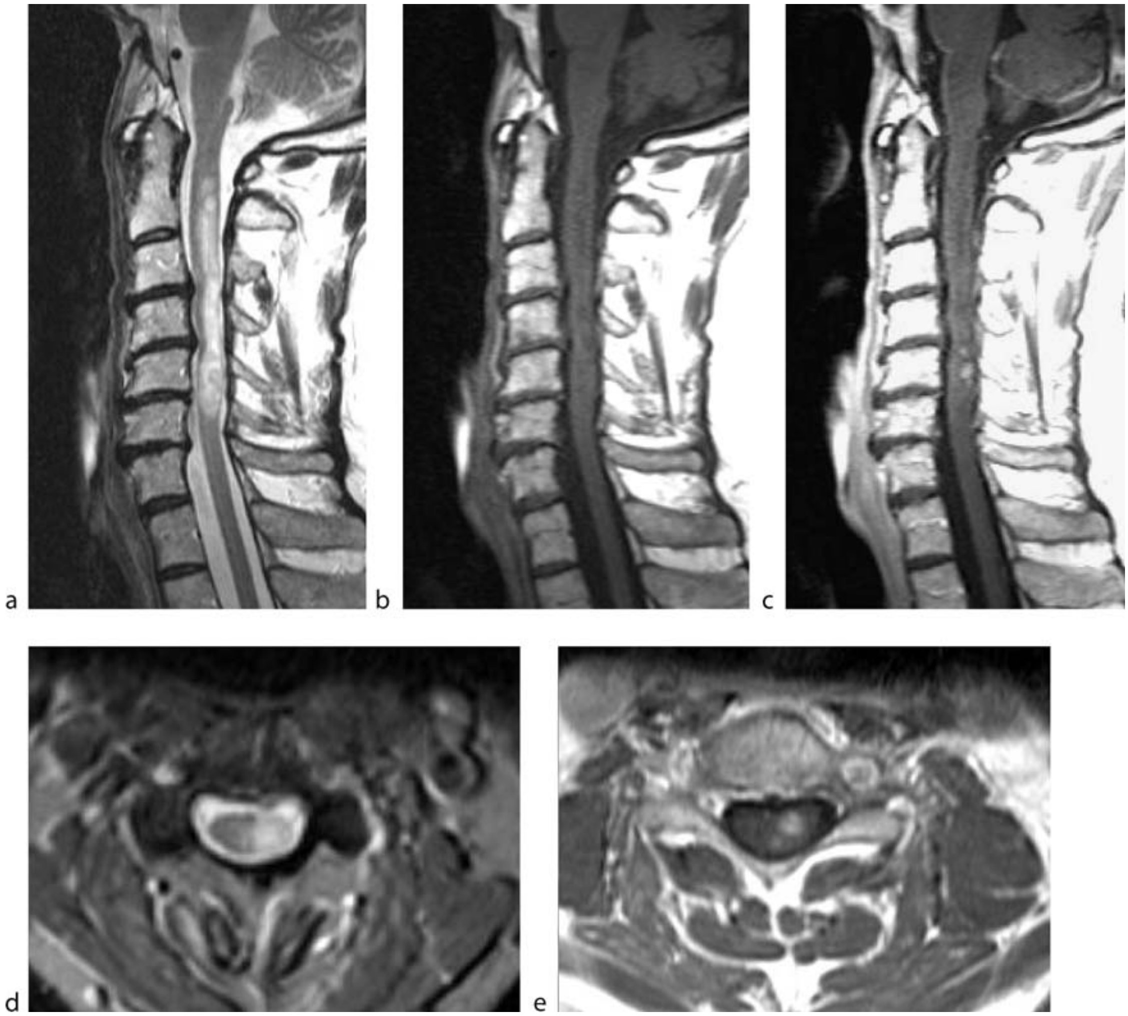
In children as well, pain is the most frequent symptom as reported in 42% of cases. Motor regression is present in 36%, gait abnormality in 27%, torticollis in 27%, and progressive kyphoscoliosis in 24% of cases. Low-grade lesions account for 89% of cases (6).

Acute worsening of the symptoms may occur due to intratumoral hemorrhage. Subarachnoid hemorrhage (SAH) of spinal origin is rare and the most common source is an arteriovenous malformation. Nevertheless, cases of SAH due to bleeding from hemangioblastoma have been reported in the literature. Hydrocephalus may be observed associated with an intradural spinal tumor: this is a rare but classical finding. Finally, it is extremely rare that a spinal cord metastasis presents as the first clinical manifestation of a distant primary cancer. Clinical symptoms are nonspecific, but usually involve root pain.

Imaging

Astrocytomas

According to our experience, astrocytomas are found at the cervical (33%), cervicothoracic (21%), or thoracic (36%) levels, while the remaining 7% are found at the thoracolumbar and lumbar region. The mean size of the solid tumor component involves four vertebral segments. However, especially in the pediatric population, the entire spinal cord may be involved. Cystic components within



Spine, Intramedullary Tumors. Figure 1 Cervical fibrillary astrocytoma (Grade II). (a) Sagittal T2-WI The tumor extends from C2 to C6 and appears heterogeneously hyperintense with ill-delineated borders. (b) Sagittal T1-WI: the cervical spinal cord is moderately enlarged and slightly hypointense. (c) Sagittal Gd-enhanced T1-WI: small areas of patchy enhancement are seen at the level of C5. (d) Axial T2-WI and (e) axial Gd-enhanced T1-WI: tumor infiltration is excentrically located towards the left part of the cervical cord.

the tumor are found in 27% of the cases. Associated satellite cysts and secondary hydromyelia are seen in 50% of astrocytomas. On ►T1-WI, astrocytomas are mostly hypointense (83%), whereas on T2-WI they are predominantly hyperintense. Low-grade astrocytomas usually do not enhance, although moderate enhancement may be observed (Fig.1). Pilocytic astrocytomas, however, do enhance intensely. High-grade astrocytomas and glioblastomas tend to be more heterogeneous with necroticocytic areas and they enhance typically in a patchy mode (60%). Intratumoral hemorrhage is best detected on gradient echo T2-WI. Intratumoral cysts and necrosis are common. Associated huge syringomyelia may occur: the borders of these associated cavities do not enhance after contrast medium injection.

Ependymomas

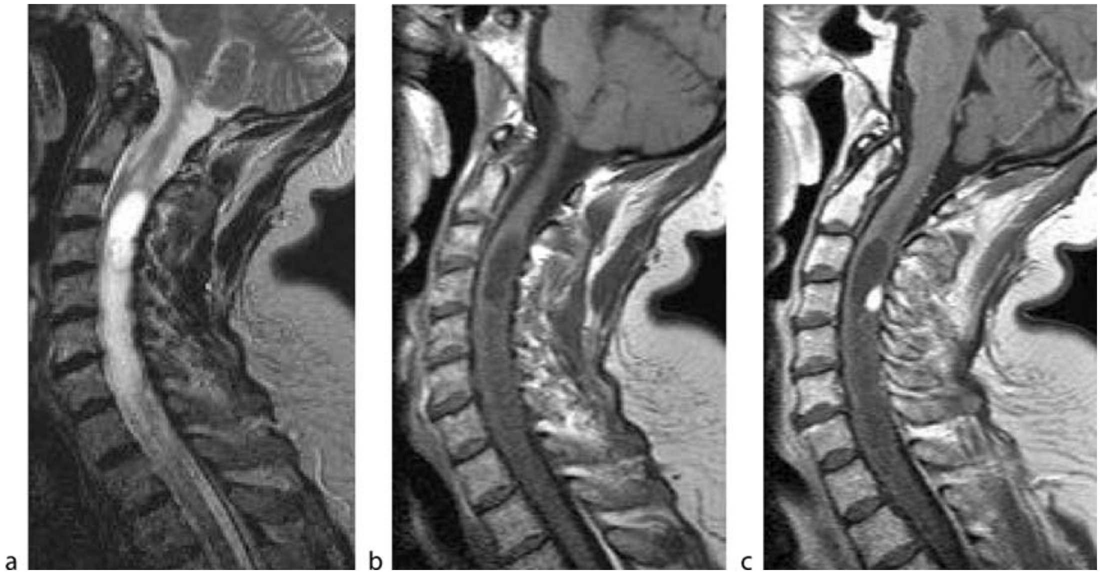
Typically, ependymoma is more frequently found in the cervical spinal cord (50%). Associated large satellite cysts are seen in 60% of the cases. A so-called cap sign is seen in almost one out of four cases (27%) and corresponds to low-signal-intensity areas seen on T2-WI and even better on gradient echo T2-WI, capping the tumor limits on both sides (Fig. 2). These caps are hemosiderin deposits caused by chronic hemorrhage. Ependymomas enhance vividly and homogeneously in 91% of the cases, and usually have well-defined borders. However, no or very limited contrast enhancement may be seen. As ependymomas originate from the cells bordering the ependymal canal they are located more centromedullary compared to astrocytomas. The mean tumor size of ependymomas corresponds to three vertebral bodies (min. 2 to max. 13), while astrocytomas are usually more extensive involving 2 to 19 vertebrae.

Myxopapillary ependymomas of the conus medullaris and filum terminale are often large, well-circumscribed lesions appearing isointense compared to the cord on T1-WI and hyperintense on T2-WI. Strong enhancement is seen after gadolinium injection. Hemorrhage may be observed, explaining the sudden worsening of clinical symptoms with occurrence of acute leg weakness and sphincter disturbances.

Hemangioblastomas

Hemangioblastomas have two different but quite typical presentations: either they are small nodular lesions located in the subpial compartment and surrounded by extensive edema or they are small nodules associated to huge and extensive cystic components (Fig. 3). These tumors are either solitary (80%) or multiple, when associated with von Hippel-Lindau disease. The solid nodule is isointense to hypointense on T1-WI and

Spine, Intramedullary Tumors. Figure 2 Thoracic ependymoma (Grade II). (a) Sagittal T1-WI. (b) Sagittal T2-WI. (c) Gradient echo T2-WI and (d) sagittal Gd-enhanced T1-WI. The solid component of the tumor is located at the level of Th2-Th3. Associated cystic components are found at both tumor extremities. Hemosiderin deposits are best seen on (c). The tumor enhances homogeneously after gadolinium injection.



Spine, Intramedullary Tumors. Figure 3 **Cervical hemangioblastoma. (a) Sagittal T2-WI. (b) Sagittal T1-WI and (c) Sagittal Gd-enhanced T1-WI. The small tumor nodule is best detected after gadolinium injection. The borders of the associated cyst do not enhance. Significant edema is best evaluated on the T2-WI.**

isointense to slightly hyperintense on T2-WI. A rich vascular network in the tumor as well as enlarged feeding arteries and dilated draining veins may best be seen on proton density images and T2-WI. After gadolinium injection, intense and homogeneous contrast uptake is seen exclusively within the nodular part. Contrast administration is especially useful in order to pick up small, multiple nodules when associated to large cystic components whose borders do not enhance.

Metastases

The high sensitivity of MRI enables easy detection of intramedullary metastases; however, no specific MRI characteristics are seen. Usually, spinal cord metastases are small, nodular, well-defined lesions, hypointense on T2-WI, surrounded by mild to extensive edema. The enhancement pattern may be either ring-like or homogeneous and intense.

Melanoma metastasis, on the contrary, has a more specific appearance exhibiting a spontaneously hyperintense aspect on T1-WI linked to the presence of melanin.

Cavernomas

Cavernomas represent in our experience 8% of all intramedullary tumors. On MRI, intramedullary cavernomas are usually easily recognized thanks to a typical "black and white" appearance due to areas of mixed signal intensity on both T1- and T2- or T2*-WI. Contrast enhancement is variable. As cavernomas may be multiple, we recommend cerebral MRI whenever the diagnosis of cavernoma is suspected; indeed, if multiple similar lesions are found in the brain, this should support the final diagnosis of cavernoma of the spinal cord.

Gangliogliomas

Gangliogliomas are rare tumors, representing only 3.8% of all CNS tumors. They are more frequent in children. They mostly involve the upper cervical cord. The diagnosis of ganglioglioma can be strongly suspected in young patients (mean 12 years) whenever a large tumor is found presenting with a tumoral cyst, no edema, mixed signal intensity on T1-WI, and patchy enhancement.

Associated bone erosion and scoliosis have been reported.

Rare Tumors

As mentioned above, rare tumors such as lymphoma, epidermoid cyst, lipoma, oligodendroglioma, paraganglioma, intramedullary schwannoma, and teratoma may be found. These often have nonspecific imaging features except for lipomas, which are typically high-signal-intensity lesions on T1-WI. Melanocytic schwannoma could be suspected preoperatively in our series thanks to the hyperintense appearance of the tumor on T1-WI.

However, in these rare tumors, the ultimate diagnosis will still be ascertained by histopathology after biopsy, which is strongly recommended whenever an intramedullary tumor is suspected both clinically and on the basis of imaging findings.

Synonyms

Infections of the spleen; Splenic abscess; Splenic inflammation

Definition

Infectious diseases of the spleen are related to splenic phagocytic immune functions and are characterized by primary splenic abscess.

Pathology and Histopathology

Splenic abscess is a rare condition that tends to occur in patients with predisposing factors such as preceding pyogenic infection, immunodeficiency, and contiguous disease in the pancreas. Several different mechanisms are presently accepted to explain its etiology. Hematogenous spread from an infective focus elsewhere in the body (endocarditis, intraabdominal sepsis, osteomyelitis, or chest infection) is the most common cause of splenic abscess, but it may also occur as direct spread of infection in contiguous areas, such as pancreatitis, retroperitoneal and subphrenic abscesses, and diverticulitis. Finally, in some cases, splenic abscess represents a delayed infective complication of either traumatic lesions or large *infarctions of the spleen*.

Depending on the causative organisms, pyogenic, fungal, and tubercular splenic abscess may be distinguished (1, 2).

Pyogenic Abscess

The most common organisms obtained from culture of pyogenic abscess are aerobic microbes, in particular the staphylococci, streptococci, *Salmonella*, and *Escherichia coli*. Anaerobic organisms, such as *Pseudomonas*, are less frequently involved (1).

At gross examination, most pyogenic splenic abscesses are solitary and unilocular lesions ranging from a few millimeters to several centimeters in diameter. However, in immunocompromised patients, multiple splenic abscesses usually associated with abscess in other viscera are frequently observed.

At histopathologic analysis, the abscess cavity is filled with purulent material, while the edges are composed of a chronic inflammatory infiltrate and fibrous tissue. The fibrotic edge is often a centimeter or more thick. Depending on the stage, suppuration, liquefaction with presence of debris, and fibrosis are found at microscopic analysis.

Fungal Abscess

Fungal abscesses are most often caused by *Candida albicans*, *Aspergillus*, and *Cryptococcus neoformans* and typically occur in immunocompromised patients, representing a manifestation of disseminated fungal disease. Fungal abscesses are multiple small lesions, typically only a few millimeters in diameter and often also involving the liver and, occasionally, the kidney (1–3).

The typical histological pattern of splenic candidiasis is characterized by microabscesses, with fungi in the center of the lesion and a surrounding area of necrosis and polymorphonuclear infiltrate; in the healing stage there is a fibrotic evolution of the lesions.

Tuberculosis

Tuberculosis of the spleen is rarely seen in isolation and is more frequently seen as part of a multifocal or disseminated disease. The causative organism is *Mycobacterium tuberculosis* or, particularly in immunocompromised hosts, *Mycobacterium avium-intracellulare*. Splenic involvement usually occurs by hematogenous spread of infection in the form of microabscesses in a miliary tuberculosis pattern, which can become calcified, or, rarely, as larger abscesses or granulomas (4).

Clinical Presentation

The clinical presentation is often subtle and diagnosis delayed (1). Fever, left upper abdominal pain, pleuritic chest pain, and malaise are the most common symptoms. The most important findings at physical examination are left upper quadrant tenderness and splenomegaly. Leucocytosis is invariably present in all patients.

Imaging

Pyogenic Abscess

On ultrasound (US), splenic pyogenic abscess shows an anechoic or hypoechoic pattern, with an irregular wall, associated splenomegaly, and variable amounts of internal echogenicity and acoustic transmission due to necrotic debris. Intraabscess gas may be observed and is indicative of infection by gas-producing agents. These features are similar to those for abscess in other abdominal organs and are not pathognomonic for splenic abscess. At color Doppler US evaluation, avascular lesions with no hypervascular rim are usually observed.

Splenic pyogenic abscesses appear as low-density areas on nonenhanced computed tomography (CT) scans and with rim enhancement after intravenous contrast medium administration. A gas or fluid level within the lesion may be observed. Depending on the stage of abscess development, abscesses may be clearly demarcated from the surrounding tissue and have a ringlike, sharply marginated wall.

At magnetic resonance imaging (MR), pyogenic abscesses appear as areas of decreased signal intensity on T1-weighted images and increased signal intensity on T2-weighted images. After contrast administration, the lesion shows peripheral enhancement.

Fungal Abscess

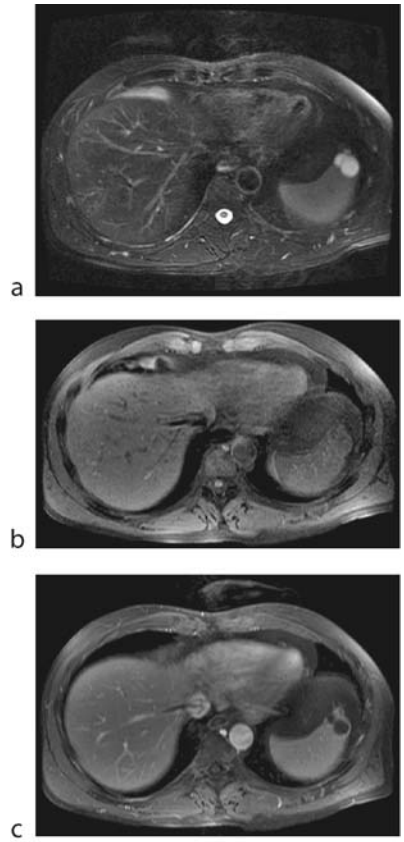
Typically, splenic abscesses are observed in immunosuppressed patients and have a miliary distribution appearing on imaging as multiple small splenic lesions. They are usually associated with hepatic involvement.

Fungal abscesses have variable appearances on US. In most cases they appear as rounded, hypoechoic lesions with a central echogenic area, creating a target or bull's-eye pattern corresponding to fibrotic tissue surrounding a central inflammatory core at histopathologic analysis. The wheel-within-a-wheel appearance is observed when the central hyperechoic portion becomes necrotic and hypoechoic (2).

CT shows multiple small, low-attenuation lesions. The lesions may be missed unless intravenous contrast medium is used. At MR, fungal abscess appears as multiple small lesions that are hypointense on T1-weighted images and hyperintense on T2-weighted images (Fig. 1) (3).

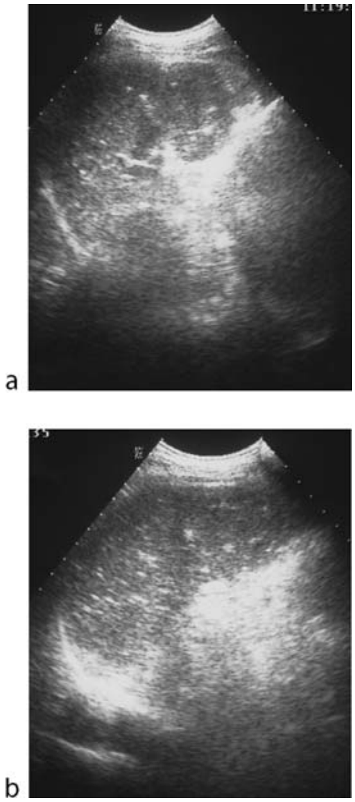
Tuberculosis

Splenic tuberculosis can occur in the form of microabscesses or in the form of larger abscesses or granulomas.



Spleen, Infectious Diseases. Figure 1 At magnetic resonance imaging, the abscesses appear as areas of increased signal intensity on T2-weighted imaging (a) and decreased signal intensity on T1-weighted imaging (b) on a postcontrast T1-weighted image, (c) the lesions show a slight peripheral enhancement.

S



Splenic Abnormalities. Figure 2 Splenic calcifications in an immunodeficient patient with a previous history of tuberculosis and pneumocystis pneumonia. Ultrasound (a, b) clearly demonstrates multiple calcifications in the spleen.

The micronodular pattern is typically observed in the military type of pulmonary tuberculosis and is usually noted as a moderate splenomegaly. On US a typical coarsened echotexture is often seen, while on CT the miliary nodules cannot be detected, and a heterogeneous, moderately enlarged spleen, sometimes with calcifications, is usually the more frequent finding (Fig. 2). However, these radiological features are usually not specific and may be observed in several different benign or malignant conditions of the spleen.

The macronodular form is characterized by the presence of single or multiple larger abscesses or granulomas. Splenic tubercular abscess are often hypoechoic on US and round or ovoid lesions with low attenuation value on CT. Peripheral calcifications and internal septations may be observed. After contrast administration, the rim of the lesion enhances moderately, while no contrast uptake is observed in the low-density center.

On MR a hypointense nodule with a hypointense rim on T1-weighted images and an isointense or hyperintense nodule with a less intense rim on T2-weighted images are usually observed (5).

Nuclear Medicine

Radionuclide scans are sensitive, though less specific, tools for diagnosing splenic abscess and were largely employed before the advent of US and CT. Particularly, 99m-Technetium sulfur-colloid liver and spleen scanning is the scintigraphic technique most commonly used and shows a focal photopenic defect or delayed uptake, while on 67-Gallium citrate scans a focal uptake in the spleen—occasionally with a perisplenic halo—is usually observed (1).

Diagnosis

Early diagnosis and timely treatment reduce the morbidity and mortality associated with splenic abscess. US and/or CT should be used routinely for evaluating patients with fever and abdominal pain. Although both US and CT of the abdomen are of diagnostic value, CT is more accurate and reliable in the diagnosis of splenic abscess. There are several differential diagnoses, including splenic infarct, pseudocysts, hematomas, and tumors. The presence of a gas or fluid level within the spleen, although quite rare, is pathognomonic for pyogenic infection, while multiple small, hypovascular splenic lesions in immunocompromised patients are highly suggestive for fungal abscess (1, 3).

Moreover, the CT and US appearance of splenic abscess is a valuable predictor of the patient's response to treatment, with multiple and gas-containing abscesses indicating a poor prognosis.

Synonyms

Splenic abnormalities; Splenic malformations

Definition

Splenic anomalies include congenital anomalies of shape, location, number, and size of the spleen, due to aberrant embryologic development.

Pathology and Histopathology

Accessory Spleen

The spleen is a mesodermal derivate that first appears as a mesenchymal cell condensation inside the dorsal mesogastrium. One or more additional smaller splenic condensations sometimes develop and give origin to accessory spleens, representing by far the most common congenital abnormality of the spleen. Accessory spleens are small round masses that perfectly resemble the splenic structure. They may be located anywhere in the abdomen, but the most common sites are near the splenic hilum and the tail of the pancreas. Other possible locations are along the splenic vessels, in the gastrosplenic and splenorenal ligaments, in the mesentery, and in the omentum. Any accessory splenic tissue is capable of hypertrophy. When splenectomy is performed for hypersplenism, hypertrophy of an accessory spleen may cause recurrent disease (1, 2).

Shape Abnormalities

Splenic clefts, notches, and lobules may persist in adult life as variations of the normal shape and are quite common findings (1).

Abnormal Location

The spleen may be found in a variety of abnormal locations. In congenital diaphragmatic hernia and eventration of the diaphragm, the spleen may have an intrathoracic location; if the lateral peritoneal recess is particularly deep, the spleen is found posterior to the left kidney. The spleen may rarely be located in the right hypochondrium, usually in patients with situs viscerum inversus (1).

Splenogonadal Fusion and Splenorenal Fusion

Splenogonadal fusion is a rare anomaly. Owing to the close relationship between the developing spleen and the left gonadal-mesonephric structures, an accessory spleen may be found attached to the left ovary or within the scrotum or the left kidney. Splenogonadal fusion can be classified into two types: continuous (direct connection between spleen and gonad) and discontinuous (no anatomic connection between ectopic splenic tissue and the principal spleen). This anomaly predominates in males. It can occur as an isolated condition or can be associated with other abnormalities, such as cryptorchidism and orofacial and limb abnormalities. In splenorenal fusion, normally functioning splenic tissue is abnormally located in close proximity to the kidney, usually on the left side (1, 3).

Wandering Spleen

Absence, laxity, or excessive length of splenic ligaments leads to an abnormal mobility of the organ. This condition is known as "wandering spleen." Torsion of the long vascular pedicle may occur, followed by vascular occlusion and splenic ischemia or even infarction (1, 4).

S

Asplenia and Polysplenia

The absence of the spleen (asplenia) and the presence of multiple small spleens (polysplenia) are rare conditions usually associated with other congenital malformations, especially cardiovascular anomalies. Either polysplenia or asplenia may be seen in association with abdominal situs ambiguous; these conditions have been classically called asplenia and polysplenia syndromes (1, 5).

Splenic Agenesis

Congenital splenic agenesis is quite uncommon and is associated with recurrent bacterial infections (1).

Clinical Presentation

Accessory spleens and splenic shape abnormalities are typically incidental findings at imaging.

Splenogonadal fusion usually manifests as a mobile and painless left scrotal mass in males. Other presentations include cryptorchidism, testicular torsion, and inguinal hernia. Splenogonadal fusion is often asymptomatic in females.

In cases of intrathoracic location of the spleen, patients usually have respiratory symptoms.

The wandering spleen is usually symptomatic in childhood and may present with an abdominal mass and acute, chronic, or intermittent symptoms due to torsion of the pedicle.

In children with *asplenia and polysplenia syndromes,* the clinical manifestations may be related to congenital heart disease, immunodeficiency due to splenic absence, or volvulus due to intestinal malrotation (1).

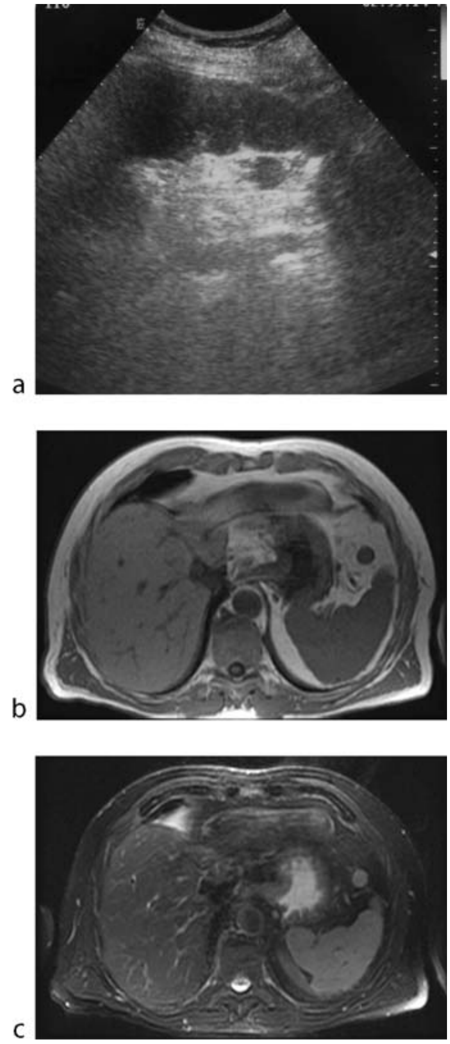
Imaging

Accessory Spleen

Accessory spleens may vary in number and size, usually ranging from a few millimeters to several centimeters in size (Fig. 1). Typically they appear as round or oval masses near the splenic hilum, but they may be found anywhere in the abdomen. Intrapancreatic accessory spleen, typically in the tail, can mimic a neoplastic mass. The demonstration of imaging features identical to those of normal splenic tissue allows the diagnosis (Fig. 2). At ultrasound (US), the mass shows the same echotexture as the splenic parenchyma. At computed tomography (CT), the attenuation values before and after contrast administration are identical to those of the spleen. In particular, depiction of the characteristic inhomogeneous enhancement during the arterial phase is crucial to demonstrate the nature of the mass. On magnetic resonance (MR) images, an accessory spleen has signal intensities identical to the spleen on all sequences both before and after contrast administration; in particular, the use of reticuloendothelial-targeted contrast media can confirm the splenic nature of the mass (1, 2).

Shape Abnormalities

Splenic clefts, notches, and lobules are quite common findings and must be distinguished from traumatic lesions. The demonstration at US and CT of characteristic smooth edges and the absence of extravasation suggest a congenitally cleft spleen (1).

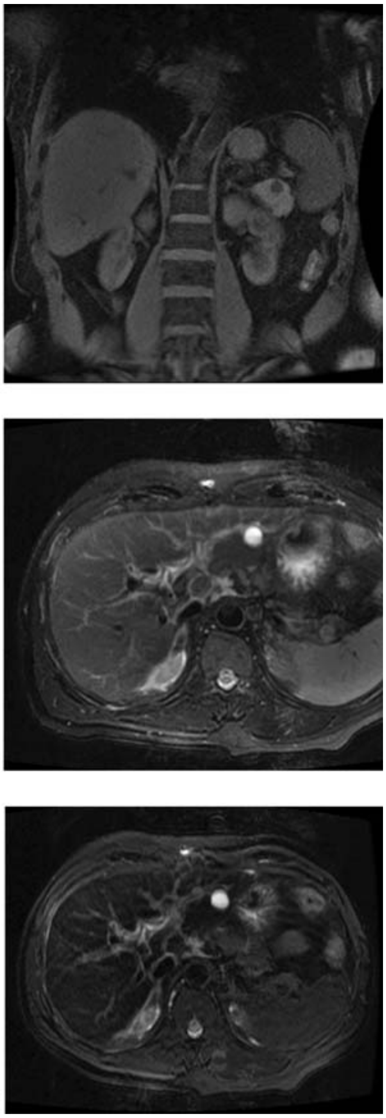


Splenic Anomalies. Figure 1 Accessory spleen. Typically this anomaly appears as a nodule near the splenic hilum. Ultrasound (a) demonstrates a nodule that shows the same echotexture as the splenic parenchyma. On magnetic resonance images, the accessory spleen is hypointense on T1-weighted scan (b) and hyperintense on T2-weighted scan (c) with respect to the liver, showing signal intensities identical to the spleen on all sequences.

Splenogonadal Fusion and Splenorenal Fusion

In the case of left scrotal mass, US is usually the first examination. The splenic tissue appears as a homogeneous, well-encapsulated mass with the same echotexture as the normal spleen. At Doppler US a vascular architecture analogous to that of the spleen can be depicted. If splenogonadal fusion is suspected, a cordlike structure connecting the spleen to the mass should be sought. CT may be helpful to demonstrate associated splenic-renal

a b c



Splenic Anomalies. Figure 2 Intrapancreatic accessory spleen. The accessory spleen appears hypointense on coronal T1-weighted image (a) and hyperintense on axial T2-weighted image (b) with respect to the pancreas. On an axial reticuloendothelial-enhanced T2-weighted image (c) a significant signal intensity decrease is consequently observed at the level of the intrapancreatic accessory spleen, spleen, and liver.

fusion or cryptorchidism and to show the typical enhancement pattern after contrast administration (1, 3).

Wandering Spleen

US and especially CT well demonstrate the absence of the spleen in its expected location and the presence of a homogeneous soft-tissue mass located more inferiorly and medially. Torsion of the pedicle may lead to ischemia or even infarction. The congested or infarcted spleen may have a normal echotexture or show diffuse increased echogenicity corresponding to hemorrhagic phenomena. The spleen's comma-shaped configuration is usually preserved. Splenomegaly with rounded edges of the organ, when present, is strongly suggestive for torsion and has been attributed to congestion. Doppler US demonstrates no flow within the splenic parenchyma. Nonenhanced CT usually shows decreased attenuation of splenic parenchyma, and contrast medium administration may show a partial or total lack of enhancement. A highly specific sign of torsion is a whirl appearance of the splenic vessels and surrounding fat, with alternating bands of high attenuation and low attenuation. This finding is usually noted at the splenic hilum (1). MR can provide useful information about the precise location of the wandering spleen, the viability of the splenic parenchyma (assessed both with nonenhanced and enhanced scans), and the splenic vessel anatomy, thanks to MR angiography (4).

Polysplenia and Asplenia

In polysplenia, numerous small splenic masses can be seen predominantly in the right upper quadrant at US, CT, MR, and scintigraphy. Documenting the absence of the spleen is more difficult than confirming its presence. Scintigraphy is the standard examination (1, 5).

Nuclear Medicine

Technetium-99m sulfur colloid scintigraphy and technetium-99m-labeled heat-damaged red blood cells offer functional images and are therefore highly specific for differentiating spleen from other tissues. Although nuclear medicine offers the most specific imaging techniques for identifying functional ectopic splenic tissue, CT and MR offer superior anatomic resolution (2). Scintigraphic studies are used to confirm the presence of normally functioning splenic tissue in cases of suspected accessory spleens, ectopic spleen, splenogonadal and splenorenal fusion, and polysplenia.

Scintigraphy is also the examination of choice in documenting absence of the spleen. However, absence of uptake of radiotracer can also occur with the so-called functional asplenia, in which the splenic phagocytic function is markedly reduced despite the presence in the body of splenic tissue. Functional asplenia may occur secondary to radiation therapy and chemotherapy, secondary to tumor invasion of the spleen, in sickle cell disease, with splenic anoxia, and after bone marrow transplantation (1).

Diagnosis

Ectopic splenic tissue may mimic neoplasms and lymphadenopathies. Imaging can achieve a definite diagnosis, thus avoiding open biopsy. Ectopic splenic tissue shows imaging features identical to those of the spleen in all imaging modalities. The enhancement pattern, especially the inhomogeneity in the arterial phase, is very specific. MR reticuloendothelial-targeted contrast media can confirm the splenic nature of the mass. 99m-Technetium sulfur colloid scintigraphy and technetium-99m-labeled heat-damaged red blood cells represent the most specific imaging techniques to confirm the presence of functioning splenic tissue (2).

In splenogonadal fusion presenting with scrotal mass, US is usually the first examination to be performed, particularly for identifying a cordlike structure connecting the mass with the normal spleen. However, surgical exploration is generally required to rule out malignancy (3).

Accurate preoperative diagnosis of wandering spleen with or without torsion represents an imaging challenge and can be done with US, CT, and MR. Information concerning splenic perfusion and viability and the performance of Doppler ultrasonography and contrast-enhanced CT and MR studies is important for the surgeon, especially in younger children in whom splenopexy instead of splenectomy is the treatment of choice for uncomplicated wandering spleen.

Spleno-Gonadal Fusion

Spleno-gonadal fusion is a rare anomaly in which an accessory spleen may be found attached to the left ovary or within the scrotum or the left kidney. Spleno-gonadal fusion can be classified into two types: continuous (direct connection between the spleen and gonad) and discontinuous (no anatomic connection between ectopic splenic tissue and the principal spleen). This anomaly predominates in males and may occur as an isolated condition or associated with other abnormalities, such as cryptorchidism, orofacial, and limb abnormalities. Spleno-gonadal fusion typically manifests as a mobile and painless left scrotal mass in males. In females, spleno-gonadal fusion is often asymptomatic and is usually an incidental finding at US or CT. In spleno-gonadal fusion presenting with scrotal mass, US is usually the first examination to be performed. The homogeneity of the echotexture, the regularity of the vascular architecture and the presence of well-defined margins suggest a nonneoplastic nature of the mass. When spleno-gonadal fusion is suspected, a comparison with the US appearance of the spleen and a study directed to the visualization of a cord-like structure connecting the mass with the normal spleen should be performed. A definitive diagnosis cannot be made solely on the basis of US findings. Nuclear medicine imaging can confirm the presence of splenic areas of activity. However, surgical exploration is generally required to rule out malignancy. Nevertheless, orchiectomy can be avoided because splenic tissue can be dissected away from the tunica albuginea.

Spleno-Renal Fusion

In spleno-renal fusion, normally functioning splenic tissue is abnormally located in close proximity of the kidney, usually on the left side. This anomaly presents as a renal mass which shows imaging features identical to those of the normal spleen.

Synonym

Enlargement of the spleen

Definition

Splenomegaly is the enlargement of the spleen. It represents a manifestation of a splenic disorder rather than being a specific entity. In fact, it is the most common pathological finding of splenic disease. Many of the mechanisms of splenic enlargement are exaggerated forms of the spleen's normal function. Although a wide variety of diseases are associated with splenomegaly, the most frequent causes include immune response work hypertrophy, such as in infectious mononucleosis; red blood cell destruction work hypertrophy, such as in ▶hereditary spherocytosis or thalassemia major; congestive causes, such as in splenic vein thrombosis or ▶portal hypertension; myeloproliferative causes, such as in chronic myeloid metaplasia; infiltrative causes, such as in sarcoidosis and some neoplasms; and neoplastic causes, such as in chronic lymphocytic leukemia and the lymphomas. Splenomegaly can also occur as the result of ▶extramedullary hematopoiesis. Miscellaneous causes of splenomegaly include trauma, cysts, hemangiomas, and metastasis.

Pathology and Histopathology

When an enlarged spleen is referred to as hypertrophied, the underlying cause may be hypertrophy or hyperplasia

S

of individual cells. In specific diseases, the splenic architecture is remodeled. For example, in Niemann–Pick disease, sphingomyelin and cholesterol accumulate within large foamy cells. With amyloidosis involving the spleen and resulting in splenomegaly, large hyaline masses are seen as lesions occupying the white pulp space. Two forms exist, including the "sago spleen," in which amyloid deposits are limited to follicles, and the "lardaceous spleen," in which amyloid is deposited in the walls of the splenic sinusoids. In a rare complication of typhoid fever, reactive splenic vasculitis may develop. In inflammatory splenomegaly, the demand for increased antigen clearance from the blood may lead to increased numbers of reticuloendothelial cells in the spleen and may stimulate accelerated antibody production with resultant lymphoid hyperplasia. In infiltrative splenomegaly (Gaucher's disease, amyloidosis), engorgement of macrophages with indigestible materials can be found.

Clinical Presentation

The most common history is mild abdominal pain that is vague in nature. Increased abdominal girth is less common. Early satiety from gastric displacement occurs with massive splenomegaly. Associated symptoms and signs include febrile illness (infectious process); pallor, dyspnea, bruising, and/or petechiae (hemolytic process); symptoms of liver disease (congestive process); and weight loss and constitutional symptoms (neoplastic process).

Examination should include palpation with the patient in the supine and right lateral decubitus positions. Additional signs that identify possible etiologies of splenomegaly include signs of cirrhosis (asterixis, jaundice, telangiectasias, gynecomastia, caput medusae, ascites), heart murmur (endocarditis, congestive failure), jaundice and scleral icterus (spherocytosis, cirrhosis), and petechiae (any cause of thrombocytopenia).

A patient with an enlarged spleen is more likely to have splenic rupture from blunt abdominal or low thoracic trauma, leading to typical symptoms. In particular, in elderly persons the combination of capsular thinning with increased spleen weight and size makes splenic injury more common. These factors account for the increased likelihood of splenectomy for trauma in this subgroup.

Imaging

Ultrasonography

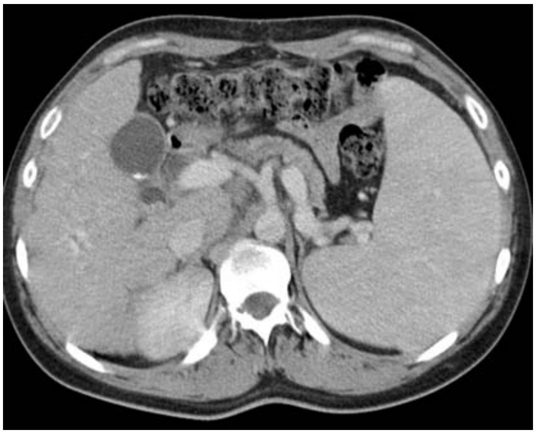
Ultrasound (US) often represents the first imaging modality performed to evaluate the spleen. It allows the clinician to estimate the spleen's size and morphology and, in some cases, to demonstrate splenic lesions or diffuse abnormalities (1). The size of the organ can be evaluated by measuring the length in the longitudinal scan, which allows simultaneous visualization of both the upper and lower poles and the hilum. A craniocaudal measurement of 11–13 cm is frequently used as the upper limit of normal for splenic size. Another possible method to demonstrate splenomegaly is to find an anteroposterior measurement up to two-thirds of the distance between the anterior and posterior abdominal walls. However, because of wide variations in shape, no consistent correlation has been recognized between the spleen's length and its overall volume.

Computed Tomography

Enlargement of the spleen is detectable by a variety of means, including physical examination and US; computed tomography (CT) is rarely necessary to document the presence of splenomegaly. When the spleen is enlarged, the concavity of its visceral surface is often lost as the spleen assumes a more globular shape (Fig. 1). CT can demonstrate findings that suggest the cause of the splenic enlargement (2). Neoplasm, abscess, or cystic lesions can be appreciated; associated abdominal lymph node enlargement can suggest a lymphoma. Cirrhotic patients show characteristic alterations in the size and shape of the liver and in the prominence of the venous structures in the splenic hilum. An increase in the attenuation value of the spleen (as well as the liver) can be found in patients with hemochromatosis.

Magnetic Resonance Imaging

Magnetic resonance imaging (MR) is usually performed for problem solving, such as in the differential diagnosis

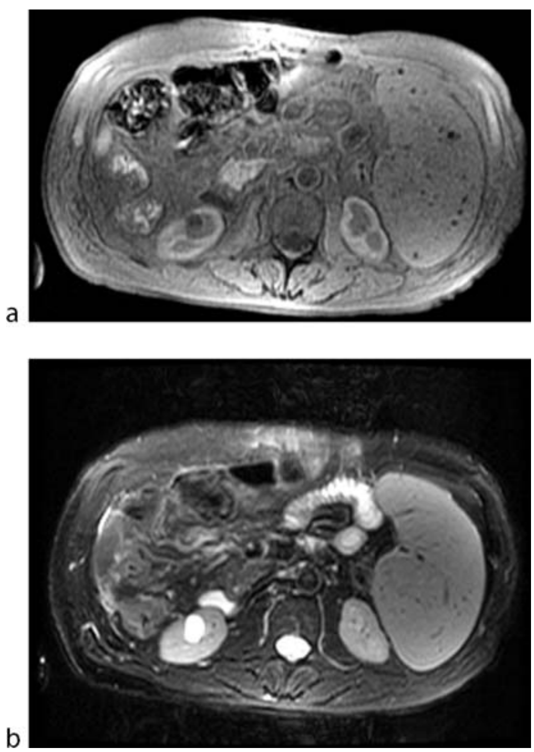


Splenomegaly. Figure 1 Splenomegaly in acquired immunodeficiency syndrome. Computed tomography scan exhibits homogeneous enlargement of the spleen.

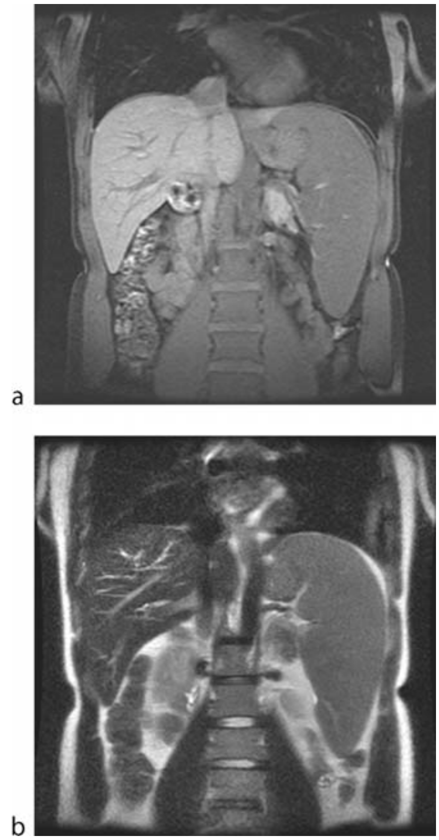
when focal or diffuse disease of the spleen is present (3). For example, lymphoma dynamic sequences after injection of gadolinium-diethylenetriamine pentaacetic acid (DTPA) show large irregularly enhancing regions of high- and low-signal intensity representing diffuse infiltration or focal low-signal intensity mass lesions scattered throughout the spleen. Superparagmagnetic iron oxide (SPIO) particles are selectively taken up by reticuloendothelial system (RES) cells, and not by malignant cells, improving the depiction of malignant lesions of the spleen.

In splenomegaly caused by portal hypertension, arciform high-signal intensity enhancement on images obtained after gadolinium-DTPA injection is characteristic and excludes the presence of malignant disease. Gamna-Gandy bodies are spots of organized hemorrhage caused by portal hypertension and can be detected as multiple low-signal intensity nodules both on T1-weighted and T2-weighted images (Fig. 2) according to paramagnetic effects caused by hemosiderin deposits in the lesions (4).

Patients with splenic enlargement secondary to hematologic disorders generally show no consistent



Splenomegaly. Figure 2 Gamna-Gandy bodies in a patient with splenomegaly who previously underwent liver transplantation. Multiple low-signal intensity nodules are shown both on axial fat-saturated T1-weighted (a) and T2-weighted (b) magnetic resonance sequences.



Splenomegaly. Figure 3 Splenomegaly in a patient with hereditary spherocytosis. Coronal fat-saturated T1-weighted (a) and T2-weighted (b) magnetic resonance images well demonstrate the spleen's increased dimensions.

pattern of signal intensity alteration, and the spleen is often unchanged on MR images (Fig. 3). Patients affected by thalassemia have splenomegaly from extramedullary hematopoiesis and systemic iron overload from blood transfusions, with massive iron deposition in the spleen, which shortens T2.

S

Nuclear Medicine

A spleen scan is a good noninvasive technique for evaluating spleen size; a close correlation exists between spleen length on scan images and spleen weight after splenectomy. Erythrocytes should be labeled with chromium-51, mercury-197, rubidium-81, or 99m-technetium, and the cells altered by treatment with heat, antibody, chemicals, or metal ions so that the spleen sequesters them after infusion. A spleen scan is useful for detecting space-occupying lesions in the splenic substance and for evaluating loss of spleen function.

Diagnosis

Laboratory studies must always be performed to identify possible alterations that may suggest the cause of the splenomegaly. Moreover, splenomegaly produces hypersplenism, which is characterized by anemia, leukopenia, thrombocytopenia, or combinations thereof. Increased splenic platelet pooling is the primary cause of the thrombocytopenia of hypersplenism. In patients with hypersplenism, as much as 90% of the total platelet mass can be found in the spleen. In hypersplenism, the platelet count is usually 50,000–150,000/L. The etiology of the anemia observed in splenomegaly is the result of sequestration and hemodilution. Leukopenia is caused by increased destruction or sequestration of leukocytes. Sequestration may also play a role in the genesis of neutropenia. A complete laboratory study must be done in patients without evident cause of splenomegaly. Imaging studies are useful to assess the splenic enlargement and identify the cause of the splenomegaly.

Splenosis

Splenosis results from the autotransplantation of splenic tissue occurring after splenic trauma or after splenectomy. The incidence of splenosis after traumatic injury of the spleen varies from 27% to 67%. Splenic implants are usually numerous and are spread throughout the peritoneal cavity. In patients with history of thoraco-abdominal trauma with splenic and diaphragmatic injury, splenosis may be intrathoracic. Splenic implants derive their blood supply from the surrounding tissue and do not have a capsule. Splenosis is usually an incidental finding at imaging, and may mimic peritoneal metastases, lymphomegalies and other neoplastic or nonneoplastic masses. Splenic implants appear as round or oval, sharp-marginated nodules resembling the features of splenic parenchyma in the different imaging modalities (US, CT, or MR). The characteristic inhomogeneity in the arterial phase is very typical. MR reticuloendothelial-targeted contrast media can be a useful tool to increase the diagnostic confidence if splenosis is suspected. 99m-Technetium sulfur colloid scintigraphy and 99m-technetium-labeled heat-damaged red blood cells represent the most specific and the most sensitive imaging techniques to confirm the presence of functioning splenic tissue. Splenosis may cause recurrence of hematologic disorders after therapeutic splenectomy.

Definition

Seronegative ►spondyloarthropathy comprises of the following five diseases: ankylosing spondylitis, psoriatic arthritis, reactive arthritis, enteropathic arthritis in Crohn's disease, and ulcerating colitis, as well as undifferentiated spondyloarthropathy. SAPHO syndrome may show overlap and ►SAPHO syndrome. These are systemic autoimmune inflammatory disorders of unknown etiology, promoted by infection and primarily affecting the discovertebral complex, synovial membranes, articular surfaces, insertion of joint capsules, and tendino-osseous junctions. Apart from joint destruction, they are characterized by new bone formation as a highly characteristic feature, with consecutive ankylosis and vertebral column stiffness. There is a hereditary predisposition in patients with HLA B 27 (Table 1).

Source: Dougados M, van der Linden S, Juhlin R et al (1991) The European Spondyloarthropathy Study Group: preliminary criteria for the classification of spondyloarthropathy. Arthritis Rheum 34: 1218–1227.

Pathology/Histopathology

Sacroiliitis begins with hypertrophic synovitis with focal mild intima hyperplasia. Granulation tissue and pannus formation lead to cartilage destruction, reflecting the character of the sacroiliac joints as partly synovial joints. Subchondral inflammation progresses to bony erosion, typically with surrounding reactive bony sclerosis. The bone marrow is filled with inflammatory cells. Later, fibroblast proliferation anticipates fibrous scar and bone formation. Remodeling to mature bone advances toward ankylosis. Reactive sclerosis and bone formation in and following inflammation are typical.

Clinical Presentation

Ankylosing Spondylitis

Ankylosing spondylitis is the prototypical form of the spondyloarthropathies. Because sacroiliitis is the main manifestation, the best diagnostic clue is long-standing low back pain. Typically in inflammatory back pain there is relief not with rest but with exercise. Patients suffer most seriously in the early morning hours, often waking up with low back pain and feeling relief when walking around. Even before bony ankylosis is present, stiffness is a common symptom. Motion restriction of the lumbar spine, neck, hip, and thorax worsens in the course of the disease. Deformity with severe kyphosis may badly handicap patients. Among the extraskeletal manifestations, iritis is most common. Patients often complain about fatigue. Ninety percent show HLA B 27, whereas only 6–9% of the normal population do.

Imaging

The primary imaging tool for inflammatory back pain is plain X-ray of the lumbar spine, despite the fact that early sacroiliac arthritis may not be conspicuous at all. Whenever X-ray imaging is equivocal, further evaluation with computed tomography (CT) or magnetic resonance (MR) imaging should follow. CT is preferred in elderly patients with long-standing symptoms and in cases of known paraarticular sclerosis because bony sclerosis leads to blurring of joint contours in MR imaging, and bony destructions are best viewed by means of a bone technique like CT. MR imaging, on the other hand, is advantageous in young patients due to the lack of radiation and in early cases because of its high sensitivity to inflammatory activity. Diagnosis of lumbar, thoracic, and cervical spine as well as articular involvement is usually confirmed using X-ray imaging, even when MR imaging shows better sensitivity.

Signs and Patterns in Ankylosing Spondylitis

►*Sacroiliacal joint arthritis* is the imperative diagnostic clue of ankylosing spondylitis. A typical X-ray sign is the triad of sclerosis, destruction, and ankylosis (Fig. 1). In early stages, sclerosis may be mild, and when present it is extended, woolly, and more pronounced in the iliac bone. Erosions and bony destructions are primarily seen as indistinct and irregular contours. A pearl-string aspect of confluent erosions is typical but not very common. Most often, destruction and bony bridging go alongside. Bony bridges with blurring and disappearance of the joint space are signs of increasing ankylosis. In the end stage, the sacroiliac joint space may be completely obliterated and disappeared; however, persisting bits of joint space are not uncommon (Table 2).

The differential diagnosis includes degenerative osteoarthritis, which exhibits bandlike subchondral sclerosis or, especially in obese females, multiparae triangular sclerotic areas particularly in the lower aspect of the iliac bone. Variants of the joint form are common and may simulate defects or irregularities. Destruction and pearl-string aspect occur in hyperparathyroidism. Iliacal and sacral bony sclerosis can be signs of insufficiency fractures in severe osteoporosis and should be considered as a differential in patients with low back pain, sacral sclerosis, and generalized osteoporosis.

In MR imaging, periarticular edema, marrow fat accumulation, sclerosis, and blurring of the joint contours are nonspecific findings. Erosion and destruction of the joint contours and ankylosis as well as joint effusion as signs of arthritis are detected in unenhanced images. Contrast material enhancement can be seen in the joint capsule, erosions, subchondral granulation tissue, and areas of edema as well as intra-articularly in pannus formation (Fig. 1).

Spine involvement: The typical feature of spine involvement in ankylosing spondylitis is the ►syndesmophyte, which grows marginally from the vertebral body corner in the exact position of the annulus fibrosus (Fig. 2). Sometimes, in degenerated disks, it is modified, with a more bulging contour. Often it begins consecutively in ►Romanus lesions commonly in the thoracolumbar junction segments. Finally, the disc is completely bridged

Spondyloarthropathies, Seronegative. Table 2 X-ray classification of sacroiliitis

°0	Normal

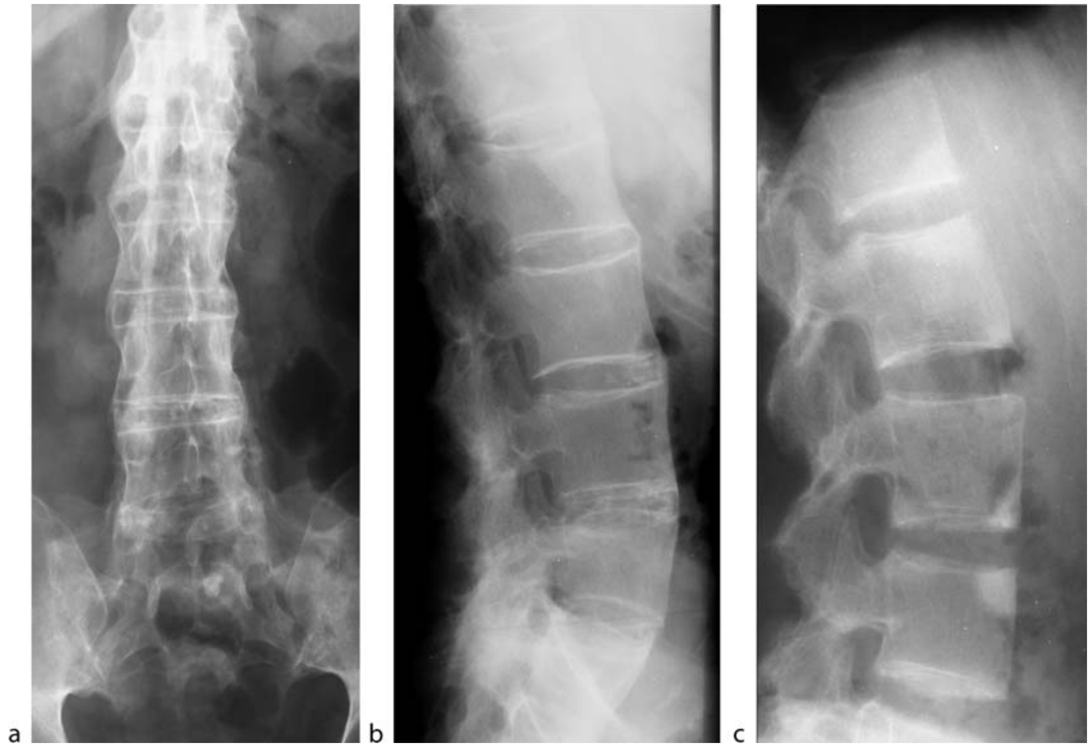
Spondyloarthropathies, Seronegative. Figure 1 Ankylosing spondylitis. (a) X-ray imaging shows paraarticular sclerosis and erosions of the sacroiliacal joint. (b) Computed tomography reveals erosions and iliacal sclerosis as well as bony bridging. (c) Magnetic resonance imaging in another patient allows early diagnosis because of its sensitivity to inflammatory processes. The so-called bone marrow edema is seen mainly in the iliac bone paraarticularly; here on short TR TE images, it is mildly hypointense. (d) Marked hypointensity, however, is a sign of sclerosis. Erosions are visible. Contrast material enhancement is found in the areas of bone marrow edema, in the joint space itself, and in the erosions.



Spondyloarthropathies, Seronegative. Figure 2 **Ankylosing spondylitis. (a) Anteroposterior view of the lumbar spine of a patient with long-standing ankylosing spondylitis shows the typical cane of bamboo with multisegmental syndesmophytic bridging of the disc spaces and the ►Trolley-truck sign referring to the polysegmental bony ankylosis of the ►apophyseal joints. The sacroiliacal joints are completely postarthritically ankylosed, with only mild residual sclerosis. (b) Lateral view of the same patient shows the syndesmophytes growing vertically in the location of the annulus fibrosus and the broad ossification along the apophyseal joints. (c) In another patient, the lateral view reveals multisegmental ►spondylitis marginalis, in the anterior location the so-called Romanus lesions, and in the posterior location the characteristic triangular sclerosis of the vertebral corner. ►Square vertebrae and the faint barrel shape of the vertebrae are other typical features.**

by circular ossification of the annulus fibrosus. When multiple segments are affected, the spine looks like a ►cane of bamboo.

Osteitis of the peridiscal bone (discitis, rheumatic spondylodiscitis) is another typical aspect of inflammation in ankylosing spondylitis. It may be limited to the anterior upper corner and is then called a *Romanus lesion* (Fig. 2c). A Romanus lesion consists of a triangular sclerosis and an erosion of the anterior upper vertebral corner. It usually heals within months or years with syndesmophyte formation. When it is minimal and only sclerosis is present, it is referred to by the term "►*Shinig corner*." Similar lesions exist in the posterior upper corner of the vertebra and are named *spondylitis marginalis*. The inflammation of the central part of the disc results in an aspect resembling spondylitis, with erosions or destructions of the subchondral bone. It is called ►*Andersson lesion type A or inflammatory type*. In comparison to bacterial spondylitis, the destruction remains mild, focal, and unchanged for months or even years. Perivertebral fluid or abscesses are not an aspect of rheumatic disc disease. In the late stage, bony ankylosis is present. ►*Andersson lesion type B* refers to a transdiscal insufficiency fracture. It occurs mostly in the thoracolumbar junction segments of osteoporotic multisegmentally ankylotic vertebral columns with marked kyphosis. Sometimes a minimal trauma is the cause. The prognosis for local control is poor.

Square and *barrel-shaped vertebrae* are the result of inflammatory and osteoproliferative affection of the ventral vertebral aspect. They typically occur in the thoracolumbar vertebral column.

►*Apophyseal joint arthritis* with progression to fibrous or bony ankylosis and consecutive early stiffness is very common in adolescent patients. X-ray images, however, are sometimes not very conspicuous. In late stages, bands of broad ossification over the dorsolateral aspect of the vertebral column are seen. ►*Arthritis of the costotransversal and costovertebral joints* gives rise to persistent thoracolumbar pain and is the reason for respiratory

S

movement restriction. Most often it is occult on X-ray images. MR imaging, however, can show extensive contrast material enhancement in these locations.

Ligament ossification such as of the interspinal and iliolumbar ligaments occurs in late stages of ankylosing spondylitis, some of which are specially named: "►*Dagger sign*" is the polysegmental ossification of the interspinal ligaments. If occurring along with extended bridging ossification of the intervertebral joint capsules, the term "*trolley-truck sign*" is used.

In ankylosing spondylitis, the ►*large joints* are commonly affected: hips, knees, and shoulders. Joint effusion, cartilage destruction with consecutive concentric joint space narrowing, and paraarticular demineralization are the radiologic signs of arthritis. In ankylosing spondylitis, frank bony destructions are rarely found. Inflammatory proliferation at ligament and tendinous insertions is more common. Sometimes, premature degenerative disease is the only sign of postarthritic change.

The ►*small joints* are quite rarely affected in ankylosing spondylitis. Extraarticular inflammatory proliferation is seen in addition to arthritic destruction. In comparison to rheumatoid arthritis, the lower extremities and the DIP joints are more often affected. Postarthritic degenerative osteoarthritis is more common than ankylosis.

Bursitis compromising the underlying bone is most often seen in bursa subachillea, bursa trochanterica, and iliopsoas bursa. It appears as soft tissue swelling in the typical places. Pressure erosions of the bone and inflammatory destructions are both possible. Osteoproliferative changes are common.

In ankylosing spondylitis, an *inflammatory reaction of tendon and ligament insertions* is a leading feature. Common locations are the iliac crest, tubera ischiadica, greater trochanter, plantar fascia (calcaneopathy), and olecranon, but it can appear anywhere. Proliferative changes with indistinct, hairy contours as well as destructions with small grooves or combinations of both are possible features.

►*Synchondritis of the symphysis or manubriosternal junction* exhibits contour defects or broad indistinct defects and surrounding bony sclerosis.

Nuclear Medicine

In bone scanning, inflammatory affection appears as hot spots. Sacroiliacal joints, however, normally show mild tracer accumulation. Asymmetric massive tracer accumulation may be a sign of arthritis, but specificity is very low. Radiologic work-up is mandatory for the differential diagnosis. Bone scanning can show foci of inflammatory affection all over the skeleton, and therefore can direct the following work-up to these foci.

Diagnosis

Since 1966 standardized diagnostic criteria have been employed. The most recent modification of the New York criteria dates from 1984 and provides high specificity and moderate sensitivity. One or more clinical signs and radiological evidence of sacroiliitis must be present for proper diagnosis (Table 3). Early diagnosis, however, may be difficult. MR imaging is one tool to close the diagnostic gap, since sacroiliitis can be found much earlier and with more conspicuity than in X-ray imaging.

Interventional Radiological Treatment

As in rheumatoid arthritis, radiosynovectomy is a promising tool for local control in limited disease of the large joints. CT-guided corticosteroid injection into the sacroiliac joints with satisfactory results is used by several authors.

Clinical Presentation

Psoriatic Arthritis

Psoriatic arthritis occurs in 5–10% of patients suffering from psoriasis. Spondyloarthropathy is found in 25% of patients with psoriatic arthritis and is highly associated with HLA B 27. Inflammatory back pain is the main symptom in sacroiliitis. Lumbar spine involvement is characterized by pain, morning stiffness, and motion restriction. Kyphosis or total vertebral stiffness as seen in ankylosing spondylitis is not a sign of psoriatic spondyloarthropathy.

Imaging

Signs and Patterns in Psoriatic Arthritis

Peripheral arthritis of the small joints is common, but not symmetrical in most patients. Irregular involvement is

Spondyloarthropathies, Seronegative. Table 3 Modified New York criteria (1984) for diagnosing ankylosing spondylitis (≥1 clinical sign and 1 radiological sign)

Clinical signs	Radiological signs
Low back pain and stiffness >3 months, no pain relief with rest but relief with exercise	Bilateral sacroiliitis °2–4
Motion restriction of the lumbar spine sagittally and frontally	Unilateral sacroiliitis °3–4
Respiratory motion restriction (age-related, about <2.5 cm 4. ICR)

more typical. There are, however, additional distribution types, including transverse type (all DIP, all PIP, or all MCP of one hand/foot) and ray type (all joints of one finger/toe). Joint effusion is a sign of articulosynovitis. Excessive swelling of a complete finger or toe is seen in ►*dactylitis*. In contrast to rheumatoid arthritis, there is often no paraarticular demineralization. Characteristic findings in psoriatic arthritis are *osteoproliferations* at the unguicular processes, periarticularly, at ligamentous and capsular insertions, and even near the arthritic destructions (►*proliferosion*) (Fig. 3). Psoriatic arthritis may rapidly progress to mutilation (►*cup-and-saucer deformity*) in one joint and to postarthritic ankylosis in the other joint. A characteristic deformity in advanced disease is the ►*telescope phenomenon*, in which a digit shortens excessively due to destruction not only of the joint itself but also of the adjacent parts of the diaphyses.

Sacroiliacal joint arthritis is the leading sign of psoriatic spondyloarthropathy and mainly occurs together with peripheral or large joint arthritis. In comparison to ankylosing spondylitis, it is often mild and frequently unilateral. Apart from this, the appearance is identical to sacroiliitis in ankylosing spondylitis (sclerosis, destruction, and bony bridging).

Spine involvement is possible with or without sacroiliitis: the typical feature of spine involvement in psoriatic spondyloarthropathy is the *parasyndesmophyte*, which comprises three types. The most common type grows hooked like a bull horn as an intervertebral osteophyte. The other two types refer to ossicles lying paradiscally or paravertebrall (Fig. 3). Romanus lesions, Andersson lesions, and square vertebrae are not signs of psoriatic spondyloarthropathy.

►*Enthesitis* may occur at various places, such as the interspinal ligaments and iliolumbal ligament.

In psoriatic spondyloarthropathy, the *large joints* are commonly affected: hips, knees, and shoulders. Joint effusion, cartilage destruction with consecutive concentric joint space narrowing, and paraarticular demineralization are the radiologic signs of arthritis. In psoriatic arthritis, inflammatory proliferation at ligaments and tendinous insertions are especially pronounced.

Enteropathic Spondarthropathy and Reactive Arthritis

In enteropathic arthritis, sacroiliitis and spinal affection are indistinguishable from ankylosing spondylitis. Arthritis most often affects the lower extremity. Reiter’s disease is the classic and most frequent form of reactive arthritis (conjunctivitis, urethritis, arthritis).

Spondyloarthropathies, Seronegative. Figure 3 Arthritis and spondylathropathy psoriatica. (a) The detailed view of the carpus and radial metacarpus shows peripheral arthritis of the wrist and MCP with cartilage destruction (joint space diminution) and erosions. Proliferations and proliferosions are the typical features in psoriatic arthritis. (b) The lateral view of the lumbar spine reveals ►parasyndesmophytes— here, ossicles and ossifications in a paradiscal and paravertebral location.

S

Spondyloarthropathy

Spondyloarthropathy comprises the following five diseases: ankylosing spondylitis, psoriatic arthritis, reactive arthritis, enteropathic arthritis in Crohn's disease, and ulcerosing colitis, as well as undifferentiated spondyloarthropathies. SAPHO syndrome may overlap. These are rheumatic inflammatory diseases with imperative (ankylosing spondylitis) or facultative spine and sacroiliacal involvement.

▶Spondyloarthropathies, Seronegative

Spondylolysis

A spectrum of abnormalities involving the pars interarticularis and occurs with a prevalence of 6%. Stress fractures are the most common etiology of spondylolysis. These injuries usually occur in childhood, most frequently in Caucasian males. The incidence is increased with certain activities such as gymnastics, diving, and weightlifting. Ninety percent of these injuries occur at the L5 vertebral level with most of the remainder found at L4. The majority of patients are asymptomatic. Some patients present with nonspecific low back pain exacerbated by activity. Frequently, individuals with stress fractures of the pars interarticularis progress to complete fracture and nonunion. The nonunited pars defect is known as a spondylolytic defect. A minority of patients with spondylolysis will progress to spondylolysthesis, anterior translation of the vertebral body secondary to bilateral pars defects.

▶Fractures, Stress

Spondylosis

▶Degenerative Conditions, Spine

Spontaneous Osteonecrosis of the Knee

A cause of sudden knee pain in the elderly patient that usually involves the weight-bearing portion of the medial femoral condyle, but may also involve the lateral femoral condyle or tibial plateau. Its etiology is likely a form of stress injury and a subchondral stress fracture can often be visualized on MR with an adjacent confluent area of bone edema.

▶Fractures, Stress

Spontaneous Rupture, Splenic

A rupture of the spleen in the absence of trauma. Several different pathological conditions of the spleen may produce spontaneous rupture. In particular, all the pathological processes that cause splenomegaly or diffuse alterations in the structure of the spleen (including infectious, neoplastic, hematologic, immunologic, and storage disorders) may be implicated as causal factors. Spontaneous rupture has also been reported in patients receiving anticoagulant or thrombolytic therapy. The clinical presentation varies from sudden hemorrhage causing symptoms of shock to only vague left upper quadrant pain. US examination represents the initial imaging modality for evaluating such patients, whereas in hemodynamically stable individuals, computed tomography should be performed to identify predisposing splenic alterations as well. Possible findings are splenic hematomas or lacerations; if the splenic capsule is damaged, hemoperitoneum may be present.

▶Trauma, Splenic

Sprengel's Shoulder

Congenital elevation of the scapula.

▶Congenital Malformations of the Musculoskeletal System

Sprue

The adult form of celiac disease of childhood. The term "sprue" is often replaced by the term "celiac disease," especially in the English speaking literature.

▶Malabsorption

Squamous Carcinoma, Gallbladder

Represents about 3.3% of gallbladder carcinomas. Typically, this tumor shows squamous epithelial differentiation with keratinization with no tubular structure formation or mucin production. It is characterized by a well-localized growth. Visceral metastases and lymph node involvement are rare with large primary tumors. Various etiological theories have been proposed for the origin of this tumor, including heterotopic squamous epithelium, metaplastic squamous epithelium, or areas of squamous metaplasia inside gallbladder carcinoma.

▶Neoplasms, Gallbladder

Square Vertebrae and Barrel-Shaped Vertebrae

Square vertebrae and barrel-shaped vertebrae show straightening or convex bulging of the ventral aspect of the vertebral body, mainly in the thoracolumbar junction and lumbar segments as a result of rheumatic inflammation. They occur in ankylosing spondylitis and are most conspicuous in the lateral view of lumbar spine X-ray images.

▶Spondyloarthropathies, Seronegative

Staging

The local extent and distant spread of a tumour is classified by using a combination of primary tumour characteristics, nodal status and metastatic disease (TNM). The stage of a tumour will predict the probable prognosis as well as optimising treatment requirements.

▶Neoplasms, Gastroduodenal

Steal Syndrome Vertebral

Elias N. Brountzos
Department of Radiology,
Athens University, Medical School, Greece
ebrountz@cc.uoa.gr

Synonyms

Subclavian steal syndrome

Definition

A vascular disorder associated with significant stenosis (>80%) or obstruction at the prevertebral part of the subclavian artery or at the origin of the innominate artery that results in retrograde flow in the ipsilateral vertebral artery. This is primarily an imaging finding that maybe accompanied by clinical symptoms in one third of the patients (1).

Pathology

The flow reversal in the vertebral artery can be either permanent, the upper extremity being perfused by the ipsilateral vertebral artery (permanent vertebral steal), or induced after exercise or hyperemia of the ipsilateral arm (latent or temporary steal) (Fig. 1). It has been shown that decreased regional cerebral flow is present in patients with vertebral steal. Other types of vascular steal may be encountered: ▶carotid artery steal in the presence of innominate artery occlusive lesion; or in patients with internal mammary artery to coronary artery by pass graft, the presence of a proximal subclavian occlusion may cause ▶coronary artery steal phenomenon (Fig. 2).

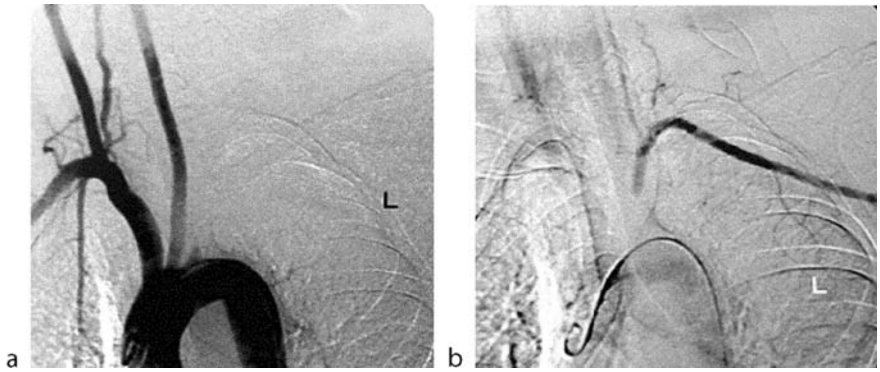
Clinical Presentation

Symptoms of this syndrome include those of upper limb ischemia, usually presenting as claudication, vertebrobasilar insufficiency (visual disturbances, dizziness, drop attack, ataxia, vertigo, syncope), and anterior circulation transient ischemic attacks. Many patients (35%–85%) with subclavian or innominate artery lesion associated vertebral steal syndrome have also concomitant carotid or vertebral artery occlusive disease, so it is not always possible to attribute their cerebral symptoms to the steal syndrome. Patients with prior internal mammary to coronary artery bypass graft and associated subclavian steal may present with angina.

Imaging

Duplex or color Doppler sonography: Flow reversal or absence of flow may be depicted with accuracy using these modalities. Compression of the ipsilateral brachial artery is accompanied with clear change in the direction of the

S



Steal Syndrome Vertebral. Figure 1 (a) arch DSA in the LAO projection in a patient complaining of dizziness during arm exercise, depicts occlusion of the left subclavian artery. (b) arch DSA in the LAO projection of the same patient in a later phase depicts reconstitution of the left subclavian artery from retrograde flow in the left vertebral artery.

Steal Syndrome Vertebral. Figure 2 (a) Selective DSA of the left subclavian artery in a patient presenting with angina 2 years after left internal mammary artery (LIMA) to coronary artery bypass graft depicts severe stenosis at the origin of the subclavian artery. (b) Selective DSA of the LIMA depicts good patency of the graft, with minimal coronary artery atherosclerotic disease. (c) Arch DSA after placement of a 9-mm balloon expandable stent depicts restoration of the flow in the subclavian artery. Ischemic cardiac symptoms of the patient were eliminated.

flow (2). In patients with the temporary type of vertebral steal syndrome, flow reversal is depicted during exercise or hyperemia of the ipsilateral upper extremity. Diagnostic accuracy is 100% (2).

MRA: The cervical vessels are ideal for MRA. Several techniques have been used to demonstrate the flow reversal in the vertebral artery. These include two-dimensional time-of-flight (2-D TOF) with a selective presaturation band applied first above and then below the volume of interest. 2-D phase-contrast MRA demonstrates reversal of flow in the superior to inferior direction. 3-D gadolinium-enhanced MRA is excellent in imaging the vertebral arteries, but cannot be used to detect flow direction. Recently it has been suggested that vertebral steal may be suspected when one observes differences in the time of peak enhancement in the vertebral arteries during a bolus-timing examination performed in the setting of a dynamic 3-D MRA (3).

Conventional angiography: Aortic arch DSA with a pigtail catheter placed in the ascending aorta is the gold standard for the depiction of the flow reversal in the vertebral artery, while the proximal arterial lesion can be evaluated in detail.

Interventional radiological treatment: Percutaneous angioplasty with or without stent placement has evolved as an alternative to the standard surgical management. Only symptomatic patients should be treated. Femoral artery approach is more commonly used; but when dealing with complete occlusions, a brachial artery approach may be necessary to cross the obstruction with the guidewire. Balloon expandable stents are recommended because they can be accurately placed. The reversed flow in the ipsilateral vertebral artery has been shown to provide protection against stroke complication.

Steatosis, Hepatic

Massimo Bazzocchi, Giuseppe Como,
Chiara Franchini
Università dezli Studi di Udine, Udine, Italy
massimo.bazzocchi@med.uniud.it

Synonyms

Fatty change of the liver; Fatty degeneration of the liver; Fatty infiltration of the liver; Fatty liver

Definition

Accumulation of fat in tiny sacs within the hepatocytes.

Pathology and Histopathology

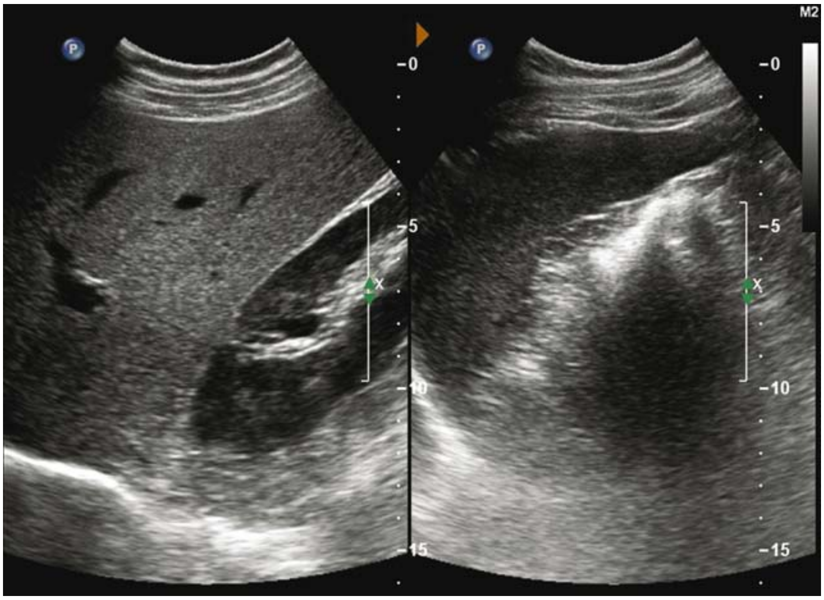
Hepatic steatosis is a common condition which represents a non-specific response to many metabolic disorders and toxic insults. There are many causes of fat accumulation in the liver. Non-alcoholic fatty liver disease (NAFLD) is considered the primary fatty liver disease. The most common risk factors for NAFLD are obesity, diabetes, and elevated cholesterol blood levels. The secondary fatty liver diseases include alcoholic liver disease (ALD), hepatic steatosis occurring in chronic viral hepatitis C (HCV), chronic viral hepatitis B (HBV), chronic autoimmune hepatitis (AIH) and Wilson’s disease. In all of these secondary fatty liver diseases, fat accumulation is associated with other abnormalities and is thought to result from liver cell injury. Another type of secondary fatty liver disease is unrelated to other liver diseases, but is due to metabolic disorders. Such causes include certain drugs, some gastrointestinal surgical interventions, malnutrition, parenteral nutrition and metabolic genetic diseases. Simple fatty liver is a benign condition and it occurs due to the accumulation of fat in the liver cells without flogosis or fibrosis. The fat is composed of triglycerides that accumulate in tiny sacs within the liver cells. Simple fatty liver is rapidly reversible after removing the causing factor. Only a minority of patients with simple fatty liver will develop the so-called ‘steatohepatitis’. In this entity, fatty infiltration of the liver is associated with inflammation. The inflammatory cells can destroy the hepatocytes leading to necrosis (steatonecrosis). Necrosis is followed by fibrotic phenomena, while the last, irreversible stage is cirrhosis. Hepatic steatosis may present with a diffuse, subtotal, segmental or focal distribution. In diffuse fatty infiltration, the liver may be enlarged and have smooth margins. In non-diffuse steatosis, the fat may have an anatomic distribution (segmental steatosis) or a non-anatomic distribution (focal steatosis). The focal distribution of fat is related to local differences in portal perfusion; areas with lower portal supply tend to accumulate less fat. Some areas are commonly spared by fatty infiltration, such as the dorsal portion of the IV segment just anterior to the portal vein, the gallbladder bed and the medial portion of the left lobe, along the great interlobar fissure. In these regions, the portal flow is decreased due to anomalous systemic venous drainage into portal venules from structure such as the gallbladder or the stomach. In other regions of the liver, focal sparing in fatty infiltration may reflect segmental portal vein obstruction (1).

Clinical Presentation

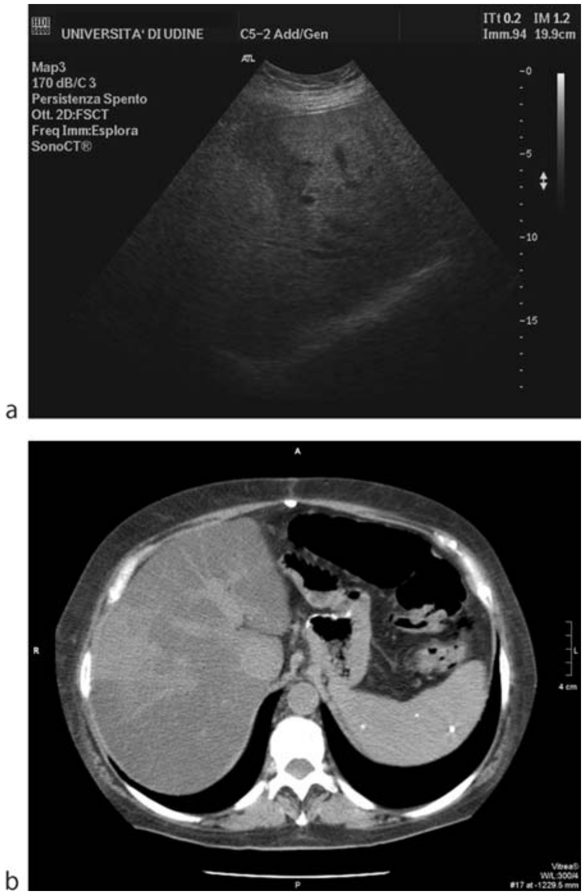
Simple steatosis and steatohepatitis give very slight, aspecific symptoms. Actually, most patients are completely asymptomatic, but they may occasionally have vague right upper-quadrant abdominal pain. The symptoms and signs of liver failure include jaundice, severe weakness, loss of appetite, nausea, vomiting.

Imaging

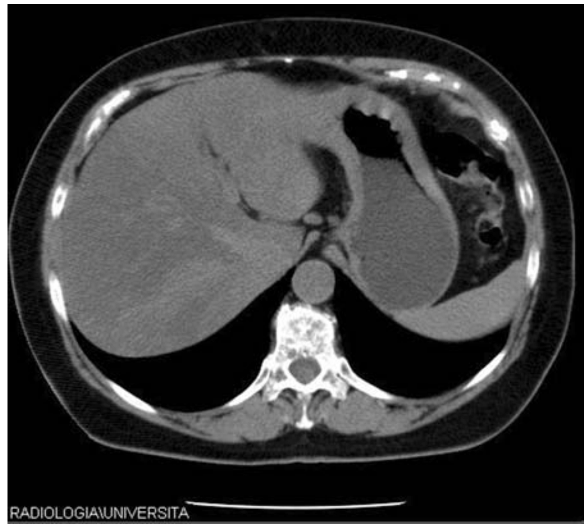
In case of steatosis, the typical finding at ultrasound (US) is the so called '►bright liver', occurring due to a diffuse increase in echogenicity of the hepatic parenchyma, characterised by the presence of numerous, fine, tightly packed echoes of high signal intensity uniformly distributed throughout the liver parenchyma (Fig. 1). The liver may be enlarged with smooth margins. When the hyperechogenicity is particularly strong, a significant attenuation of the signal may be observed. In diffuse forms the increase of echogenicity is homogeneously distributed in the hepatic parenchyma whereas in non-diffuse forms some areas are not interested by the fatty infiltration. These islands of normal liver tissue are called ►'skip areas' or 'spared areas' and appear as relatively hypoechoic areas. Typically, the skip areas are found in the gallbladder fossa, in the IV segment anteriorly to the portal vein or, in individuals with anomalous venous drainage through the gastric veins, in the medial portion of the left lobe, along the great interlobar fissure. In focal steatosis, hyperechoic areas of various sizes with a 'geographic' distribution are depicted in a normally echogenic liver. In rare cases, only the portion of the IV segment just adjacent to the portal vein, is involved by steatosis. This ►focal fatty infiltration appears as a hyperechoic area (2). Focal fat and spared areas can mimic tumour lesions, while heterogeneous fat can sometimes be difficult to distinguish from diffuse malignant diseases. At Doppler US, the finding of normal hepatic vasculature, without any dislocation or interruption, may suggest the diagnosis of steatosis (Fig. 2a). At contrast-enhanced US, skip areas and focal fatty changes become homogeneous and isoechoic with respect to the surrounding parenchyma, having the same vascularisation as the normal liver. The increased echogenicity of the hepatic parenchyma can modify the relative echogenicity of other focal lesions. A quite common finding is the presence of haemangiomas showing a relative hypoechoic appearance over a hyperechoic liver. Furthermore, haemangiomas detected at US before the onset of steatosis may not be visibile or have a reduced detectability in a hyperechoic background. In contrast, hypoechoic lesions, such as metastases, become more clearly depicted, due to the high contrast with the surrounding parenchyma (3). Computed tomography (CT) is less sensitive, but more specific than US in diagnosing hepatic steatosis. On unenhanced CT scans, the hepatic parenchyma has an attenuation value significantly lower than the spleen and the expected normal liver (normal values 45–65 HU), sometimes showing a density close to the water (0–15 HU).



Steatosis, Hepatic. Figure 1 In case of steatosis the typical finding at ultrasound (US) is the so-called 'bright liver', occurring due to a diffuse increase in echogenicity of the hepatic parenchyma, characterised by the presence of numerous, fine, tightly packed echoes of high signal intensity uniformly distributed throughout the liver parenchyma. We can see the hyperechogenicity of the liver if compared to the echogenicity of renal parenchyma (on the *left*) and of spleen parenchyma (on the *right*).

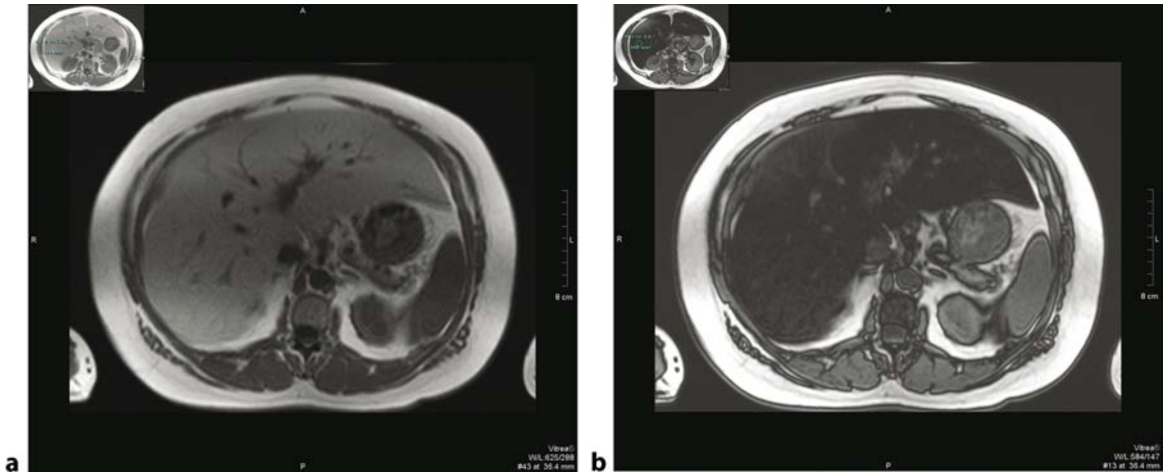


Steatosis, Hepatic. Figure 2 **Segmental or focal forms of steatosis: the hepatic parenchyma appears inhomogeneous with areas of hyperechogenicity and normal echogenicity in the US study (a) and areas of hypodensity and areas of normal density in the CT scan (b). Distinctive features of focal fatty infiltration are non-spherical shape, absence of mass effect, normal vascular architecture, segmental or subsegmental distribution.**



Steatosis, Hepatic. Figure 3 **On unenhanced CT scans, the hepatic parenchyma has an attenuation value significantly lower than the spleen and the expected normal liver (normal values 45–65 HU), sometimes showing a density close to the water (0–15 HU). Peculiar finding in steatosis is the clear evidence of hepatic vessels on unenhanced scans which appear relatively hyperdense compared to the fatty liver (contrast reversal).**

A reduction in density at unenhanced CT scans is also observed in amyloidosis and glycogen storage disease. Another peculiar finding in steatosis is the clear evidence of hepatic vessels on unenhanced scans which appear relatively hyperdense compared to the fatty liver (►contrast reversal) (Fig. 3). In segmental and focal forms, the hepatic parenchyma appears inhomogeneous with areas of hypodensity and areas of normal density. Distinctive features of focal fatty infiltration are non-spherical shape, absence of mass effect, normal vascular architecture, segmental or subsegmental distribution (4) (Fig. 2b). After contrast medium administration, the difference in density between normal and fatty liver does not change. Conventional MR SE sequences have not been proven to be useful in detecting fatty infiltration of the liver on the basis of signal intensity and relaxation times. Actually, hepatocytes with fatty degeneration are usually mixed with normal hepatocytes within the voxel volume, thus preventing substantial changes in signal intensity. Only when the concentration of fatty cells is very high, there is a brightening of fat-containing areas on T1-weighted images, whereas T2-weighted images usually do not show any change in signal intensity. The hyperintensity of the fatty liver on T1-weighted scans creates a marked contrast with hypointense lesions, improving their detection. The low sensitivity of T2-weighted scans in depicting fatty changes can be useful to exclude the presence of a focal liver lesion in case of focal steatosis. Grading fatty infiltration of the liver is not possible using conventional MR because of its insensitivity to fat. MR techniques based on the frequency difference between water and fat can be successfully used for this purpose. These techniques rely on the difference in resonance frequency between water protons and the methyl and methylene protons of fatty acid chains (chemical shift phenomenon). Two populations of protons (water and fat) exist in fatty livers. A specific method for the detection of the two populations of protons has been developed (Dixon's method). It consists in the acquisition of two images in which water and fat protons are 'in-phase' and 'out-of-phase'. In tissues where fat and water protons populations are equally represented, as in fatty liver, a significant signal loss is seen on the out-of-phase scans (Fig. 4a, b). By using this method, areas of focal fatty infiltration may be diagnosed due to the lower signal



Steatosis, Hepatic. Figure 4 MR scan in-phase and out-of-phase of fatty liver: a specific method for the detection of the two entity of fatty infiltration of the liver has been developed (Dixon's method). It consists in the acquisition of two images with two different TE in which water and fat protons are in the first 'in-phase' (a) and in the second 'out-of-phase' (b). In tissues where fat and water proton populations are equally represented, as in fatty liver, a significant signal loss is seen on the out-of-phase scans.

intensity compared to the surrounding liver in the out-of-phase images. In these images focal liver lesions in a fatty liver show a high contrast and their detection is increased (1). Fat-suppressed images may be also used, but they have a lower sensitivity for fatty infiltration compared to the out-of-phase sequences. After administration of hepato-specific MR contrast agents, fatty and normal hepatic parenchyma show similar contrast uptake, becoming isointense. This finding can rule out malignancy in case of focal fatty infiltration and skip areas.

Nuclear Medicine

Tc99m-colloid scintigraphy can differentiate focal liver lesions from focal fatty sparing and focal fatty infiltration: in fatty liver, the colloid uptake by Kupffer cells may vary depending on the degree of steatosis. A ►spared area shows a greater uptake than the surrounding liver whereas a focal fatty infiltration has a variable uptake. Malignant focal liver lesions have no uptake.

Diagnosis

US is the most sensitive imaging technique in the diagnosis of steatosis and it is usually the only examination to be performed in these cases, due to the low clinical relevance of this affection. Anyway its specificity is limited, because it cannot distinguish diffuse infiltration from hepatic fibrosis. Furthermore, in case of focal steatosis or spared areas in atypical locations, US alone may not be able to exclude the presence of a focal liver lesion. The use of Doppler US and US contrast media can be helpful by demonstrating the presence of normal vascular architecture within the focal alterations. CT is highly specific in diagnosing fatty infiltration of the liver, although it is not as sensitive as US. In those cases in which CT findings do not allow to reach a differential diagnosis, particularly in segmental or focal steatosis, MR can give a definite characterisation. In particular, the in-phase and out-of-phase sequences are very useful in assessing fatty infiltration of the liver and the use of hepato-specific MR contrast agents allow to rule out malignancy in case of focal steatosis and spared areas.

Aortic obstruction; Aortic syndrome

Definition

Aortic stenosis usually occurs in the infrarenal segment of the abdominal aorta. If stenotic, it leads to bilateral claudication of both legs including the upper thigh muscles.

Bilateral absence or weakness of femoral pulses is usually found.

Pathology/Histopathology

In more than 90% of cases, the cause for infrarenal aortic obstruction is due to atherosclerotic disease (2). Clinically, simple infrarenal aortic stenoses with no relation to the aortic bifurcation are infrequently found, but a stenosis of both the very distal aortic segment and the common iliac arteries is more frequent. This may be complicated by an acute or subacute thrombosis of the aortic bifurcation known as Leriche's syndrome. A small distal aortic caliber, especially in female patients, may be a predisposing factor. Atherosclerotic stenosis above the orifice of the inferior mesenteric artery is rare (2).

Embolic occlusion of the distal aorta is, on the contrary, exceptional, but may occur in patients with arrhythmias.

Other rare causes of aortic obstruction are fibromuscular dysplasia, Takayasu's disease, and retroperitoneal fibrosis.

The typical age of patients with aortic obstruction is between 40 and 70 years. In aortic occlusions, 55% are located at the level of the aortic bifurcation, 8% involve the complete infrarenal segment, and 37% involve aortic segments alone (2).

Collateral pathways are manifold *via* lumbar, epigastric, and mesenteric arteries.

Clinical Presentation

Clinical symptoms in aortic obstruction are bilateral claudication predominantly with upper thigh symptoms – which may be similar to findings in spinal angina – buttock pain, and erectile dysfunction in males. In occlusions, acute bilateral ischemia may occur if no preexisting stenotic process has promoted earlier development of collateral pathways.

Imaging

Many imaging modalities can be used to make the diagnosis of aortic obstruction. Color-coded duplex sonography, magnetic resonance angiography (MRA), computed tomography (CT), CT angiography (CTA), and intraarterial angiography are useful tools for detecting the location and extent of an aortic obstruction. Due to access limitations, angiography is preferably performed *via* a transbrachial access if the clinical findings suggest an aortic obstruction.

Nuclear Medicine

Nuclear medicine plays no particular role in the diagnosis of aortic stenosis.

Diagnosis

Diagnosis is reliably achieved by angiography, CT, CTA, and MRA. Detection by duplex sonography is sometimes limited due to unfavorable anatomic conditions

Interventional Radiological Treatment

More and more, aortic aneurysmal disease is becoming a field of interest for interventional radiologists and may be combined with atherosclerotic obstructive disease.

Indications for Percutaneous Treatment

Indications for percutaneous versus surgical treatment largely depend on the location, extension, acuteness, and type of obstruction.

Accepted indications for sole balloon angioplasty are:

1. concentric segmental stenosis
2. short-segment aortic bifurcational stenosis

Balloon angioplasty may be followed by stent insertion in the case of insufficient luminal gain after adequate balloon angioplasty or the occurrence of significant dissection after percutaneous transluminal angioplasty (PTA).

Balloon angioplasty is contraindicated if a complete calcified ring is present at the site of obstruction, since aortic rupture has been occasionally reported under these circumstances (3). According to Laplace's law, the aorta is theoretically more easily prone to rupture than smaller-diameter vessels such as the iliac artery. In these cases, primary placement of a stent graft can be considered.

Long-segment diffuse disease of both the aorta and iliac arteries may be considered as a contraindication, while surgical aortobifemoral bypass grafts might be a better choice.

Bifurcational aortic stenosis may also be treated by balloon angioplasty using a simultaneous "kissing balloon" technique in order to dilate the distal aortic segment and both iliac orifices. Stent implantation has been increasingly used to achieve a stable postangioplasty widening by use of kissing stents in the distal aorta and both iliac arteries.

In the case of distal aortic occlusion, few reports exist on remodeling the distal aortic segment or the aortic bifurcation by use of metallic stents (4, 5). In these difficult situations, use of advanced interventional techniques over simple balloon angioplasty is certainly of advantage.

Technical Aspects

There are no major differences between the aortic and the iliac segment concerning techniques of lesion passage or traversal of occluded segments, whether they are located purely in the aortic segment or also involve the iliac segment. This is also true for balloon dilation, which does not differ significantly from angioplasty elsewhere. A large diameter of the aortic lumen, however, is a particular problem.

Kissing balloon technique: Until recently, a major difficulty was the lack of suitable balloons with sufficient diameters of 16–20 mm. Thus, a double or triple balloon technique was recommended to open the aortic stenosis to a sufficiently large diameter. The aortic lumen can be widened to its original diameter with two or three kissing balloons that are inserted by a bifemoral and an additional transbrachial approach and are inflated simultaneously.

A kissing technique is still recommendable for dilatation of bilateral stenosis of the aortic bifurcation and the very distal aortic segment close to the bifurcation that allows remodeling of the aortic bifurcation.

Single balloon technique: Recently, large-diameter balloons, from 16 to 25 mm, have become available (Boston Scientific, Cordis), allowing the use of a single balloon technique by a unifemoral approach. With these balloons, it is strictly necessary to locate the balloon within the aortic lumen not overriding the bifurcation in order to avoid overdilatation and rupture of the proximal iliac segment.

Stent insertion into the infrarenal aortic segment obeys the same rules as elsewhere. Use of a stent of appropriate size, at least 14–16 mm, is necessary to avoid undersizing. The largest stent diameter can be achieved by use of the balloon-expandable Palmaz XXL stent (Johnson and Johnson) that can be mounted on a large balloon and inflated up to 25 mm in diameter.

Single stent technique: In lesions without involvement of the aortic bifurcation, a single stent can be implanted with no specific technical requirements. The type of stent that should be used depends on the experience of the interventionalist. This is particularly true if the lesion is of considerable distance from the bifurcation. Depending on the length of the stent or the location of the lesion, overstenting of the inferior mesenteric artery may be unavoidable.

However, if the lesion ends very close to the bifurcation, placement of a single stent, especially of a balloon-expandable stent, may become difficult without overdilation of an iliac orifice. Under these circumstances, use of a self-expanding stent may be advantageous, while the aortic bifurcation is protected by a cross-over catheter inserted *via* a contralateral approach.

An alternative technique in very distal aortic lesions or bifurcational lesions is use of kissing stents.

Kissing stent technique: In analogy to the kissing balloon method, stents of preferably an identical diameter and length are placed in kissing fashion within the distal aorta with its distal end in the common iliac artery. Very frequently, the stents tend to meet the opposite aortic wall. Thus – instead of being shaped in a kissing fashion – they cross each other forming a mirror-sided artificial iliac orifice.

There are not many reports on this technique and some questions remain open. Especially in stenotic lesions, it is not yet known whether there are potential sequelae from using two open stents that will remain partly nonendothelialized in their aortic portion and may lead to embolic disease or a higher tendency for thrombosis. Whether covered stents are advantageous in these cases is still under discussion. Use of noncovered stents is less problematic in distal aortic occlusive disease.

If a kissing stent technique is applied, it is mandatory that the proximal ends of both stents are exactly parallel to avoid one stent compromising the inflow into the other. For this reason, use of noncompressible stents such as the Palmaz stent or the new Perflex stent (both Johnson and Johnson), which are both balloon-expandable, seems of benefit.

Results

As reported in the literature, aortic PTA has an excellent outcome compared to other PTA sites.

A primary success rate of 95% and a cumulative patency of 98% after 1 year and 80% after 5 years have been reported from different series (6).

Single cases of aortic stenting in stenoses have been reported, usually associated with an excellent outcome. Long reported on two cases of successful stenting in Leriche's syndrome (7), and Dietrich reported on six patients with chronic aortic occlusion who underwent thrombolysis and stenting by use of Palmaz stents (8). The mean patency was about 11 cases with success in all.

Complications

Complications that may occur after aortic dilation are not different from those in other vascular areas; however, they might be of major clinical impact. While severe dissection, recollapse, or residual stenoses are simply treatable by additional stent implantation, aortic rupture has been reported rarely but is potentially life threatening, and therefore patients must undergo immediate surgery. To limit the extent of exsanguination, a large occlusion latex balloon (Boston Scientific) should be positioned just below the renal arteries or covering the site of rupture and left inflated until the patient is prepared for surgical repair. To avoid this complication, CT is recommended before the intervention to exclude complete or nearly complete circular calcification of the aortic wall, which is said to be a risk factor for rupture.

Theoretically, a covered stent graft may be placed across the site of rupture percutaneously; however, this method has only been reported for iliac arterial rupture and may risk occlusion of major collaterals and the inferior mesenteric artery.

Embolization of occlusion material may occur in less than 1% of cases (6).

Subacute complications include thrombosis, which has not been reported for pure aortic dilation or stenting, but is a risk in remodeling techniques of aortic bifurcations. In these cases, the patient may be predisposed to thrombosis by adjacent aortic disease with plaques hanging over the stent orifice, thus causing inflow obstruction or by adjacent outflow problems. If a technical reason has caused stent or post-PTA thrombosis, surgery is a reasonable option. If not, thrombolysis may be tried.

Thanks to their large diameter, reobstruction of aortic stents occurs rarely; however, patients may undergo repeat balloon dilatation as for iliac stents. In kissing stents, obstruction may be caused by neointimal hyperplasia that may be treated with reballooning, atherectomy, or a second stent.

Synonym

Renal artery stenosis (RAS)

Definition

Renal artery stenosis (RAS) is defined by a narrowing of the renal artery trunk or proximal branches by 50% or greater, expressed as a percentage of the diameter of a normal renal artery at the same level. There has been an increase in the incidence of RAS. This is partially due to improved detection imaging techniques such as color Doppler ultrasound (CD-US), computed tomography angiography (CTA), and magnetic resonance angiography (MRA). Another reason is the greater awareness in screening patients with RAS, due to the deleterious clinical consequences in cases of spontaneous evolution and the interesting possibilities of proposed simple endovascular treatment modalities. However, much controversy remains, mostly concerning the benefit-risk ratio of RAS treatment.

Pathology

A variety of pathologic lesions may cause RAS, but the main etiologies are atherosclerosis (75–80%) and fibromuscular dysplasia (15–20%). Atherosclerotic RAS is noted in individuals of either gender who are 50 years of age or older, and it is frequently associated with other atherosclerotic peripheral diseases. The lesion is generally proximal and concerns the first centimeter of the trunk, and is frequently related to atheromatous aortic plaques extending into the proximal part of the renal artery. Fibromuscular dysplasia generally occurs in women in the second to fifth decades of life and is mainly located in the medial and distal thirds of the renal artery trunk. Fibromuscular dysplasia represents about 90% of pediatric RAS. Uncommon causes of RAS are vasculitis (Takayasu's or Buerger's disease, polyarteritis nodosa), neurofibromatosis, radiation-induced RAS, retroperitoneal fibrosis, aortic dissection, renal artery aneurysm or dissection, and external compression. A special situation is represented by RAS of a transplanted kidney, which occurs in 5–10% of cases (1).

An important point to consider is the spontaneous evolution of RAS. The risk of worsening of a fibrodysplastic RAS varies between 10 and 40% according to the pathologic lesion. Concerning the atherosclerotic lesion, progression of RAS to arterial occlusion and atrophy of the kidney is directly correlated to the degree of the stenosis. The viability of the kidney may be totally or partially preserved with collaterals, but its function is likely to be severely impaired and revascularization procedures more difficult to perform. Conversely, the progression of atherosclerotic RAS can be slowed by lifestyle changes and aggressive statin therapy.

Clinical Presentation

Significant RAS can be asymptomatic in about 10–15% of cases. However, high-grade RAS is generally responsible for arterial hypertension and renal insufficiency. ►Renovascular hypertension is the most common cause of secondary hypertension and depends on the renin–angiotensin system. Insufficiently controlled hypertension can lead to heart failure with frequent flush pulmonary edema and/or further deterioration of renal function. RAS can also cause ►ischemic nephropathy in cases of severe bilateral stenosis or in a single kidney.

Because severe RAS may be present in patients with normal blood pressure and no azotemia, and because it is difficulty to assert that symptoms are related to RAS, the main issue is to identify those patients in whom RAS is responsible for their symptoms and who are amenable to revascularization.

Clinical situations suggestive of RAS include:

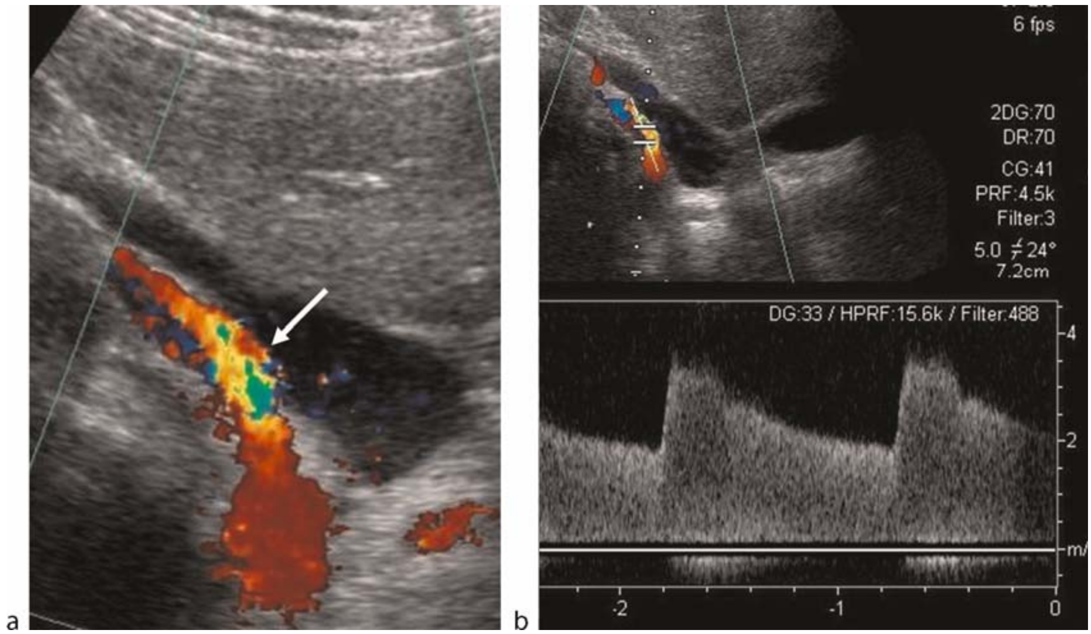
- Onset of hypertension before age 30 years or after 55 years
- Severe hypertension in a child of a female patient between 20 and 50 years
- Hypertension that is malignant, accelerated, or refractory to appropriate treatment
- Unexplained or progressive renal dysfunction
- Development of acute or subacute azotemia after therapy with angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers
- Recurrent pulmonary edema
- Diffuse atherosclerotic vascular disease
- Abdominal bruit
- Unilateral unexplained small kidney.

Imaging

Different modalities are available for imaging RAS.

CD-US has become a leading technique for screening RAS. It allows the following:

- *Direct visualization of the renal arteries and detection of hemodynamically significant stenosis* (Fig. 1). A complete examination of both renal artery trunks can be achieved in 80–90% of cases (2). The main criteria are a peak systolic flow velocity of 180 cm/sec or more and a renal-to-aortic ratio of peak systolic velocity >3.5. The technical limitations and difficulties in detecting accessory renal arteries explain the mixed results, with sensitivity between 50 and 95% for detecting RAS. Other changes are less contributory: turbulent flow in the stenotic area and absence of signal in cases of occlusion.
- *Analysis of waveforms of renal branches downstream from the lesion.* This yields quantitative criteria that improve the global sensitivity of detection.
- *Measurement of the distal resistive index to predict clinical success after revascularization.* Radermacher et al retrospectively found a cut-off point of 0.80 useful for separating patients who failed to show a clinical response to revascularization ($IR \geq 0.80$) compared with patients who did show a favorable response ($IR < 80$) (3). However, these interesting results were not confirmed in others studies and cannot be considered conclusive.



Stenosis, Artery, Renal. Figure 1 **Color Doppler ultrasonography of a high-grade truncal right renal artery stenosis. (a) Presence of an aliasing artifact (*arrow*) at the origin of the right renal artery. (b) Doppler spectrum shows flow acceleration close to 400 cm/sec.**

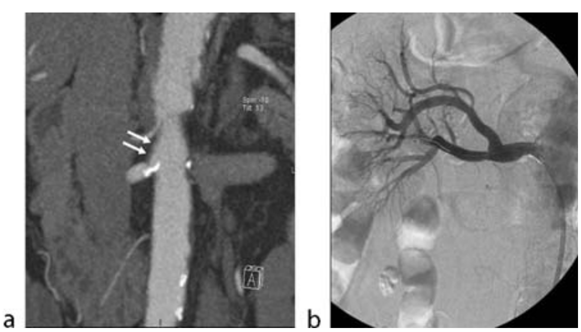
- *Morphologic information about the kidneys*: global or segmental atrophy (a long axis inferior to 7–8 cm is generally considered a contraindication for revascularization), calcifications of the renal artery or aortic wall, aortic aneurysm, or other renal-associated lesions.

CD-US is noninvasive and inexpensive. It can be performed on patients with renal insufficiency and without necessitating discontinuation of their hypertensive medications. It is of great interest for monitoring patients after treatment. Limitations are the technical difficulties associated with excessive bowel gas or body habitus and the lack of generalized expertise in its use.

CTA: With the advent of helical CT and particularly with the multidetector technology, it is now possible to provide angiographic images of renal arteries with excellent spatial resolution (submillimetric). The best reconstruction algorithms are maximum intensity projection (MIP) and volume rendering (Fig. 2a). Sensitivity is about 90–95% and specificity 95% (4). Besides depiction of the lesion, CTA provides important pretherapeutic information, including the exact anatomic type of the stenosis and the presence of aortic associated plaques and calcifications (5).

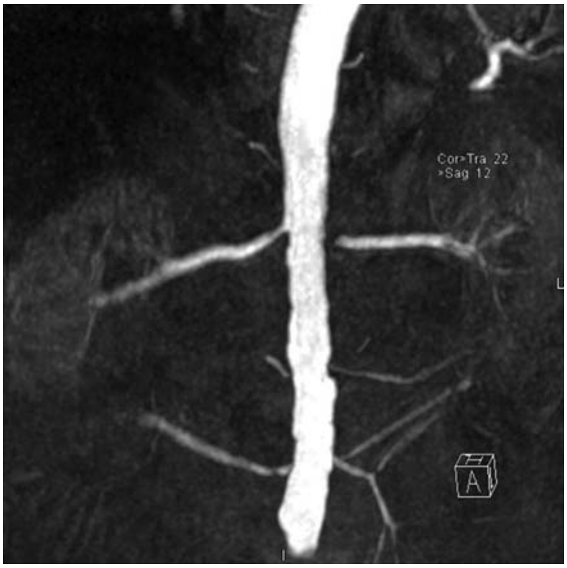
Limitations are the use of ionizing radiation and iodinated contrast media, which is a relative contraindication in patients with renal insufficiency.

MRA: MRA (Fig. 3) has made significant progress in the past few years, particularly with the use of gadolinium-enhanced three-dimensional sequences. Compared to arteriography, sensitivity and specificity are superior, at 95 and 90%, respectively. However, there is a tendency to overestimate the stenosis, and spatial resolution is inferior compared with CTA (2). In addition to three-dimensional morphologic information, it is now possible to provide hemodynamic data about the parenchymal perfusion.



Stenosis, Artery, Renal. Figure 2 **Computed tomography angiography diagnosis and percutaneous transluminal renal angioplasty of renal artery stenosis. (a) Curvilinear reconstruction of the right renal artery ostium shows calcification and aortic atheromatous plaque extending into the renal artery (*arrows*), which is responsible for a significant stenosis. (b) Angiography performed immediately after stenting.**

S



Stenosis, Artery, Renal. Figure 3 Magnetic resonance angiography of bilateral renal artery stenosis in a patient with ischemic nephropathy. The stenosis is estimated at 70% on the right side, whereas the left lesion is overestimated as a pseudo-occlusion.

The main limitations involve cost, patient issues such as claustrophobia, the presence of metallic stents, and evaluation of small branches such as accessory arteries.

Intra-arterial angiography: Intra-arterial angiography currently has no role in screening RAS. Its greatest advantage is its ability to guide intervention and control endovascular correction of the lesions.

Nuclear Medicine

The role of renal scintigraphy is controversial. ACE inhibitors (captopril) decrease the perfusion pressure of the glomerulus with a resultant drop in the GFR. In patients with unilateral RAS, captopril induces significant changes of the scintigraphy compared with the baseline curve. Such changes are not observed in the contralateral normal kidney. In clinical practice, the sensitivity varies between 60 and 80%, and the specificity is 59% (5). Some factors decrease the sensitivity: bilateral RAS (30%), renal insufficiency, and chronic use of ACE inhibitors.

Diagnosis

The roles of RAS imaging are multiple: (i) screening of RAS, (ii) providing precise morphologic information to determine the best therapeutic strategy, (iii) establishing relationships between RAS and symptoms, (iv) guiding endovascular treatment, and (v) monitoring the patient after treatment. Several considerations must lead to a rigorous selection of patients before imaging: (i) the high cost of imaging, (ii) the relatively low prevalence of RAS in the general population, (iii) the frequency of association of RAS, without evident relationships, with essential hypertension, renal failure, or both, (iv) difficulties in predicting a real benefit after revascularization, (v) potential risks of intervention, and (vi) the unpredictability of spontaneous worsening of RAS. Clinical features that must prompt further evaluation of RAS are listed in Table 1.

Screening of RAS must be done by CD-US. Some centers use captopril scintigraphy, but the cost-effectiveness is probably inferior to that of CD-US; operator expertise is increasing, and the probability of failing to detect significant RAS is very small. MRA and CTA are not screening methods except in cases of high clinical suspicion and indeterminate diagnosis after CD-US. CTA or MRA (in cases of renal insufficiency) can also be used in cases of difficult therapeutic decisions for patients at risk (renal insufficiency, complex atherosclerotic lesions).

Endovascular Treatment

Since the first description in 1978 by Gruntzig, ►percutaneous transluminal renal angioplasty (PTRA) has been progressively considered the initial therapeutic approach to RAS whenever possible. Although truncal RAS can be treated very well with angioplasty alone (particularly fibrodysplastic lesions), the introduction of renal artery stenting has considerably improved the anatomic results, and primary stent placement is nowadays the treatment of choice, mainly for the more frequent atheromatous lesions located in the ostial zone and the first centimeter of the artery. With the use of stenting, the global results are comparable to those of surgery but with lower morbidity and mortality.

PTRA is routinely performed *via* a femoral approach, more rarely *via* a brachial approach, using microguidewires (0.018 in.) and microcatheters (3–4 French). Renal arteriography is the first step in endovascular treatment of RAS. It provides useful information for determining the therapeutic strategy, for guiding the procedure, and for evaluating the immediate results. Balloon catheters and stents are generally 12–20 mm in length and 5–6 mm in diameter. Periprocedural treatment consists of intra-arterial heparin, clopidogrel (plavix), and acetylsalicylic acid (aspirin). Postintervention care consists of daily monitoring of renal function and blood pressure before discharge. CD-US is the main tool for patient follow-up for evaluating the renal artery patency. It must be performed at 6 and 12 months and annually thereafter, except in cases of symptom recurrence.

The more recent studies (largely using stents) show a primary success rate between 95 and 100% (6). Midterm recurrences are observed in 15% of cases and are closely related to the quality of the immediate result. Intervention-related mortality is low, at 1%. Major complications occur in less than 5% of cases, and immediate surgery is required in less than 0.5% of patients. Clinical results are not always related to anatomic results and are totally different in atheromatous patients and in cases of fibromuscular dysplasia. In hypertension, a clinical benefit (cure or improvement) is obtained in approximately 50% of all atheromatous stenoses and in 85% of stenoses due to fibromuscular dysplasia. Results are worse in patients with renal insufficiency, many of them being older with extensive atheromatous lesions and probably nephroangiosclerosis. A clinical benefit is obtained in approximately 50% of cases.

Despite the good results for several categories of patients such as those with fibromuscular dysplasia, multiple points of controversy persist, particularly concerning the indications. Due to morbidity of treatment and limited efficacy in some patient categories, a multidisciplinary discussion estimating risks and benefits is mandatory before making therapeutic decisions. Some anatomic parameters such as difficulties of arterial access, the lesion's complexity and severity, diffusion of atherosclerotic lesions, the importance of aortorenal plaques, the presence of calcifications, and kidney size should be taken into account and are often necessary to evaluate before even discussing CTA or MRA. Age, general status, comorbidities, and expected duration of life are other important parameters.

In terms of evidence-based medicine, the universally recognized indications for PTRA are significant and accessible RAS with (i) uncontrolled hypertension with medication, (ii) progressive renal insufficiency with bilateral RAS or RAS of a single kidney, or (iii) acute onset of cardiac insufficiency with recurrent pulmonary edema (6).

In the following situations, the benefit of PTRA has never been clearly demonstrated, and indications must be discussed case by case, as previously described:

- Arterial hypertension well controlled by medical treatment
- Severe asymptomatic RAS
- Renal insufficiency with unilateral significant RAS
- Need for treatment with conversion enzyme inhibitors in patients with RAS
- RAS associated with contralateral lesions necessitating nephrectomy.

Contraindications for endovascular treatment are associated lesions of the abdominal aorta (aneurysms) and complex atheromatous or dysplastic lesions. RAS with a narrowing of less than 50% in diameter should never be treated.

Spinal narrowing; Verbiest syndrome of lumbar spine

Definitions

Spinal stenosis is defined as abnormal general or regional narrowing of the spinal canal. The condition may affect the entire spine as in achondroplasia, but usually sections of the spine are more severely involved than others. Spinal stenosis manifests itself most frequently in the lumbar spine, is encountered less frequently in the cervical region and is occasionally seen limited to the thoracic spinal canal.

According to the reports by Mixter and Barr on lumbar disc herniation as a cause of low back pain with sciatica, the 1930s and 1940s could be described as the "decades of the disc" as far as concepts on causes of low back pain and sciatica were concerned. In the 1950s and 1960s, the realization began to grow that, besides being caused by herniation of the lumbar intervertebral disc, low back complaints irradiating to the legs could also be due to reduced dimensions of the spinal canal or, quite frequently, to a combination of these two conditions.

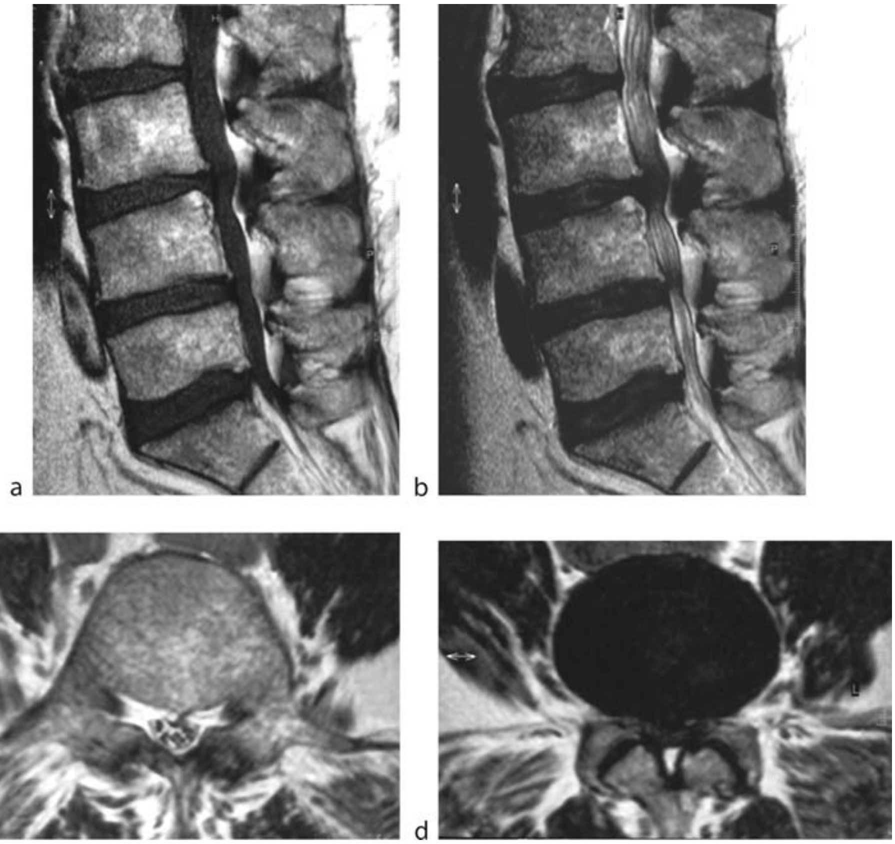
It was also recognized that long-tract spinal cord symptoms originating in the cervical region were caused frequently by spinal cord compression due to narrowing of the cervical spinal canal and not by a disease of the cord itself.

Understanding of etiology, symptomatology, and diagnosis in patients with spinal stenosis is greatly enhanced by insight into the effects of postural changes, such as lordosis and kyphosis upon spinal structures and the contents of the spinal canal.

Etiology, Pathology

The classification of causes of spinal stenosis is extensive (1). Distinction can be made between congenital-developmental and acquired stenosis. The original report by Verbiest (2) described seven patients with what was thought to be developmental narrowness of the lumbar spinal canal, with heavily developed laminae and articular processes compressing the dural sac (Fig. 1). In fact this classic form of stenosis is quite rare, and the most important single cause of spinal narrowing is considered to be degenerative. Epstein focused attention on abnormal narrowing of the lateral recesses of the spinal canal and of the intervertebral foramina as a cause of chronic sciatica (3). The application of computed tomography to spinal imaging in the 1970s and 1980s provided new insights into the various factors causing narrowing of the spinal canal and compression of the dural sac or the emerging nerve root.

Combinations of these factors in spinal stenosis are the rule rather than the exception (4). In the lumbar region the spinal canal may be somewhat narrowed on developmental basis. This need not cause symptoms by itself, but in later life degenerative hypertrophy of the facets and flaval ligaments may further reduce spinal



Stenosis, Spinal. Figure 1 Developmental stenosis of lumbar spine. Sagittal T1-(1a) and T2 weighted (1b) images demonstrate a shallow spinal canal with bony midsagittal diameter of 11 mm. measured at level of L5 lamina. Note L3-4 disc protrusion further reducing available space. Axial T2 weighted cuts at level of lamina (1c) show normal interpedicular diameter and reduced AP diameter, at disc level dorsolateral encroachment by facets is seen (1d). Note that bony AP diameter is smallest at level of lamina, but effective spinal dimensions are smallest at disc level, where CSF block is seen at L3-4 and L4-5.

dimensions, as may degenerative spondylolisthesis due to facet destruction, and/or degenerative disc bulging. Increase in epidural fat in obesity or steroid use can further aggravate the situation. In this way a complex of factors, each in themselves insufficient to cause complaints, can combine to compress the cauda equina and it goes without saying that a small disc herniation or even a bulging disc in such a narrowed spinal canal will cause symptoms much sooner than a similar disc lesion in a patient with a roomy canal (Fig. 2).

In the cervical spine, a developmentally narrow spinal canal will be associated not only with an increased risk of acute cord lesion in trauma, but also with greater risk of chronic progressive myelomalacia as degenerative osteophyte formation causes gradual further narrowing of the spinal canal with compression and wasting of the cord (Fig. 3).

In the thoracic spine, degenerative hypertrophy of the flaval ligaments can occur, with a greater risk of cord compression in a relatively narrow bony spinal canal.

Clinical Presentation

In lumbar spinal stenosis the most common symptoms are tiredness and loss of power in the legs, backache, and bilateral leg pain, occasionally anesthesia, and a feeling of numbness in the sacral dermatomes. Typically, these complaints present and progress when the patient is standing or walking in lordotic posture, and are immediately relieved by sitting or lying down, by squatting or any other posture which reduces lordosis and induces kyphosis. Verbiest named this clinical picture "intermittent neurogenic claudication," and the striking effect of postural changes serves to distinguish it from intermittent vascular claudication which is exercise-dependent and not posture-dependent.

When the patient suffering from neurogenic claudication is lying recumbent there are no complaints, and tests of radicular compression such as straight leg raising are negative.

The clinical picture may not be so clear-cut for neurogenic claudication when only a single exiting nerve root is compressed by narrowing of the lateral recess or the intervertebral foramen, or when there is a concomitant disc herniation. The pain is then more monoradicular in nature, although posture-dependency may be present.

In narrowing of the cervical or thoracic spinal canal it is not the cauda equina which is compressed but the spinal cord. The clinical presentation is that of gradually progressive long-tract neurologic dysfunction, with disturbances of walking and micturition, and muscular weakness with increased tendon reflexes and pathologic extensor plantar responses at neurologic examination. Neck pain radiating to the arms may be present, especially when the cervical foramina are narrowed by osteophyte formation and the exiting nerve roots are compressed.

Clinical signs of cord compression in cervical stenosis are not as strikingly posture-dependent as those of cauda equina compression in lumbar stenosis.

Imaging

Plain X-ray Films

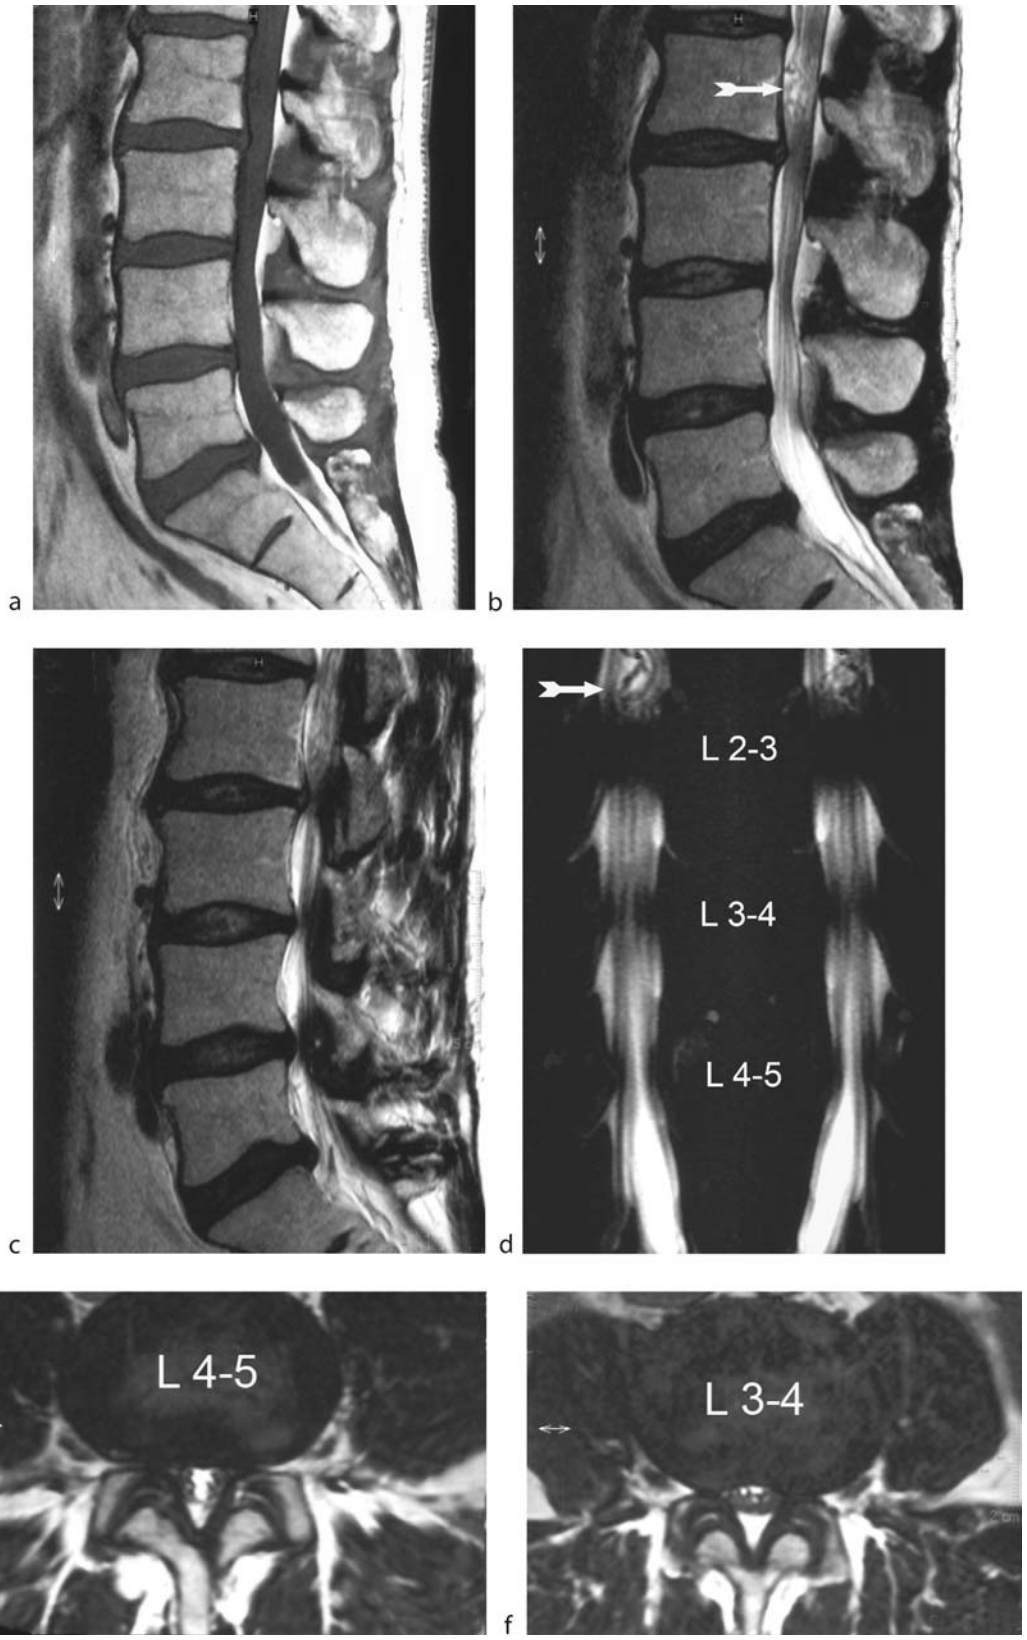
These are of limited value in assessing dimensions of the spinal canal. Verbiest defined absolute lumbar stenosis as a condition in which the bony midsagittal diameter at the upper laminar level is less than 10 mm, while relative stenosis is said to be present when the same diameter is between 10 and 12 mm (mean normal value 17 mm). This diameter cannot be measured on a plain film, however, as it is obscured by overlying bony structures, and the same applies to the dimensions of the lumbar facets and the interfacet diameter which may also be reduced in stenosis. The size of the vertebral body and the interpedicular diameter can be measured accurately, but these are usually normal in patients with spinal stenosis.

Signs of degenerative change such as spondylosis, spondylarthrosis, degenerative anterolisthesis, and foraminal narrowing can be identified on plain films and provide a clue to the possible presence of degenerative narrowing of the spinal canal, but these signs are frequently also present in elderly subjects without symptoms.

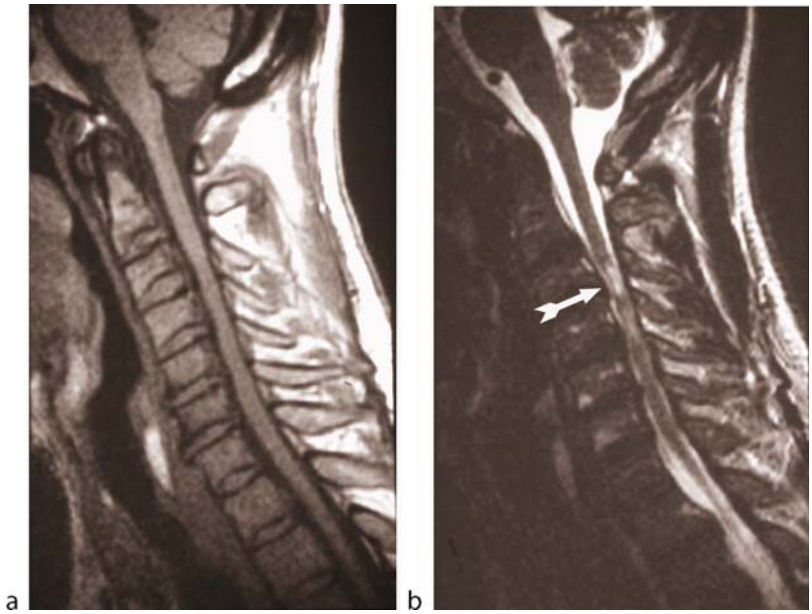
Conventional Myelography

After intradural injection of a radiologic contrast medium, compression of the dural sac by lumbar spinal stenosis is revealed by the presence of a posture-dependent myelographic block present in lumbar retroflexion or lordosis and relieved by anteflexion or kyphosis. This block is invariably present at the level of the intervertebral disc and not at the level of the bony lamina. Posture-related changes in spinal dimensions are a normal phenomenon at the disc level, where the spinal canal is bordered by ligamentous surfaces. In lordosis the annulus fibrosus of the disc bulges backward into the spinal canal and the flaval ligaments dorsolateral to the canal also bulge inwards. In a normal spinal canal this does not produce symptoms, but in a stenotic canal the extra reduction of space induced by lordosis is sufficient to compress the dural sac and cauda equina and cause neurogenic claudication (5).

In the cervical spine, cord compression in symptomatic stenosis is also seen by a myelographic block in lordosis, relieved when lordosis is reduced.



Stenosis, Spinal. Figure 2 **(Continued)**



Stenosis, Spinal. Figure 3 **Cervical stenosis shown on T1-(3a) and T2 weighted (3b) images. Note obliteration of CSF spaces around spinal cord, compression of cord and a high-signal intramedullary lesion in 3b (arrow).**

Computed Tomography

The axial images produced by these techniques greatly improved understanding of various types of spinal stenosis. Accurate measurement of the bony dimensions of the spinal canal was now possible, although limited soft tissue resolution made employment of CT myelography necessary in some cases. As mentioned above, the soft tissues at disc level are instrumental in producing cauda equina compression in spinal stenosis, and soft tissue hypertrophy or bulging may produce symptoms in individuals with bony spinal dimensions well above those defined by Verbiest (5). Undue reliance on bony spinal measurements can therefore prove misleading, and the only soft tissue structure within the canal that can be measured on plain CT is the dural sac. A study comparing myelographic and CT features of nerve root compression in a group of 100 patients with sciatica revealed that a CSF block at myelography in spinal stenosis occurred when the CT cross-sectional area of the dural sac in the lower lumbar region decreased to below 40 mm^2 (6).

In the cervical region the cross-sectional area of the spinal cord can be measured by CT myelography. In normal individuals this value is around 90 mm^2. The cervical cord is surprisingly resilient to chronic compression, and long-tract signs usually do not begin to appear before cord area has been reduced by one third to around 60 mm^2 (7)

CT myelography also provides a detailed image of the cervical nerve root as it departs from the spinal cord and later also from the dural sac within its root sleeve. Nerve root compression by bony foraminal narrowing can best be diagnosed by this technique.

Magnetic Resonance Imaging (MRI)

This is presently the best method for imaging the spine in virtually all conditions. It has been held by some that CT is better suited for the diagnosis of spinal stenosis because of the bright signal of bony structures produced by this technique. In fact, cortical bone outlining the normal and abnormal spinal canal can be easily distinguished in the MR image which has the additional advantage of demonstrating concomitant soft-tissue pathology such as flaval hypertrophy and bulging or protruded disc much more clearly than CT. An important benefit of MRI is the possibility of

S

Stenosis, Spinal. Figure 2 **Combined stenosis. Bony AP diameter is relatively narrow; 12 mm. at level of L4 lamina. T1 weighted sagittal image (2a) also shows some increase in depth of retrodural fat pad. Bulging discs at multiple levels seen on T2 weighted midsagittal (2b) and lateral-sagittal images (2c). At L2-3 this results in a CSF block with elongated and coiled nerve roots above level of block; so-called redundant roots, confirmed by MR myelogram (2d, arrow). At L4-5 there is also some encroachment by hypertrophic facets and flaval ligaments (2e), resulting in kinking of traversing L5 nerve roots, especially at right (2d, arrowhead). At L3-4 there is no disc bulging and no facet hypertrophy (2f), myelogram shows only slight displacement of nerve roots.**

producing heavily T2-weighted myelographic images which make it possible to identify features associated with symptomatic spinal stenosis such as a myelographic CSF block or the presence of redundant nerve roots.

In the cervical region, compression of the spinal cord can be demonstrated directly, and the presence of myelomalacia can be diagnosed by the presence of an intramedullary lesion with increased T2 signal. As mentioned above, an ancillary role is still reserved for CT in the demonstration of osteophytes at the foraminal entrance, potentially compressing the exiting nerve root.

Functional imaging studies in spinal anteflexion and retroflexion are helpful in the diagnosis of spinal stenosis. In the cervical spine such studies can be performed in MRI systems as well as CT scanners. Lumbar functional studies are not possible in most MRI systems presently in use, but the development of open upright MRI systems make loaded functional studies possible and will provide a new dimension in lumbar spinal imaging.

Synonyms

Endovascular treatment of internal carotid artery stenosis; Stenting

Definition

Treatment of a carotid artery stenosis with a stent is an endovascular intervention. It is performed to reduce the risk of stroke.

Characteristics

Introduction

Treatment of carotid artery stenosis is performed to reduce the risk of stroke. A symptomatic stenosis with a grade of over 50% according to ►North American Symptomatic Carotid Endarterectomy Trial criteria (NASCET) (1) or over 70% according to ►European Carotid Surgery Trial criteria (ECST) (2) should be treated. Regarding timing of treatment after brain infarction, in patients with larger infarcts an interval of 2 weeks seems to be safe to avoid reperfusion injury with the risk of secondary hemorrhage. In cases of smaller infarctions, earlier treatment is possible.

Indication

Endovascular treatment with stenting and operative endarterectomy are alternative methods. The largest and most recent randomized study comparing these two methods is the Stent-Supported Percutaneous Angioplasty of the Carotid Artery versus Endarterectomy (SPACE) trial (3). It included 1,200 patients with symptomatic carotid artery stenosis (>50% NASCET, > 70% ECST). The rate of the primary endpoint, death, or ipsilateral ischemic stroke from randomization to 30 days after the procedure was 6.84% with carotid stenting and 6.34% with endarterectomy. These results did not prove equivalence of the two methods statistically, but the difference was not statistically significant (difference of only four events). Long-term results for a period of 2 years will follow.

The use of stenting as therapy for carotid artery stenosis is increasingly widespread, and guidelines are needed for everyday practice. Therapeutic decision should be based on different parameters and should differentiate between three groups of patients:

The first group has a high surgical risk and therefore a clear indication for stenting. This group includes patients with restenosis after endarterectomy, radiogenic stenosis, and stenosis that is surgically not accessible, such as distal extracranial or intracranial carotid artery stenosis or a combined intra-/extracranial stenosis. Stenosis caused by nonarteriosclerotic diseases such as dissection, fibromuscular dysplasia, or Takayasu arteritis should be stented if treatment is necessary (4). Also, patients with high surgical risk due to comorbidity should be treated with local anesthesia with stenting.

Patients in the second group with symptomatic high-grade stenosis can be treated with either method. In this group, the patient's preference for one of the two methods and also the expertise of the different local therapists should be considered.

The third group includes patients with asymptomatic stenosis over 50% (NASCET) who might benefit from surgical treatment. New trials including SPACE II and CAVATAS II will compare the endovascular and operative treatment of asymptomatic stenosis.

Contraindications for Stenting

Contraindications for stenting are allergies to contrast media or to the necessary antiplatelet treatment with aspirin or clopidogrel. Renal insufficiency or hyperthyroidism must be considered. A floating intraluminal thrombus might prevent passage of the stenosis with endovascular tools.

Preparation for the Stenting Procedure

Necessary preinterventional preparation includes clinical neurological assessment of the patient and his or her symptoms and imaging of the stenosis, the supraaortic vessel anatomy, and the brain. Magnetic resonance (MR) or computed tomography (CT) angiography gives an overview of brain-feeding arteries to evaluate the anatomy of the stenosis in relation to surrounding structures and to show, for example, tandem stenosis or occlusion of the contralateral carotid artery. Imaging of the brain with CT or MR gives information about the mechanism of stroke (e.g., embolic or hemodynamic stroke) and should exclude contraindications such as large acute infarction or bleeding. Ultrasound Doppler examination is necessary to estimate the grade of the stenosis.

Antiplatelet medication is mandatory. Different schemes have been described. Patients included in the ►SPACE trial received 100 mg aspirin and 75 mg clopidogrel daily for at least 3 days before and 30 days after stenting. The aspirin was then continued.

The Stenting Procedure

The procedure is performed using local anesthesia *via* a percutaneous transfemoral or transbrachial access with a long sheath or guiding catheter. The sheath or catheter is advanced coaxially over the catheter and guide wire into the common carotid artery. The sheath should be flushed permanently with heparinized saline. After introduction of the sheath heparin can be administered intravenously. The heparin effect can be controlled by bedside measurement of activated clotting time. To prevent bradycardia, atropine can be given subcutaneously at the beginning of the procedure and again intravenously before balloon dilatation of the carotid bulb.

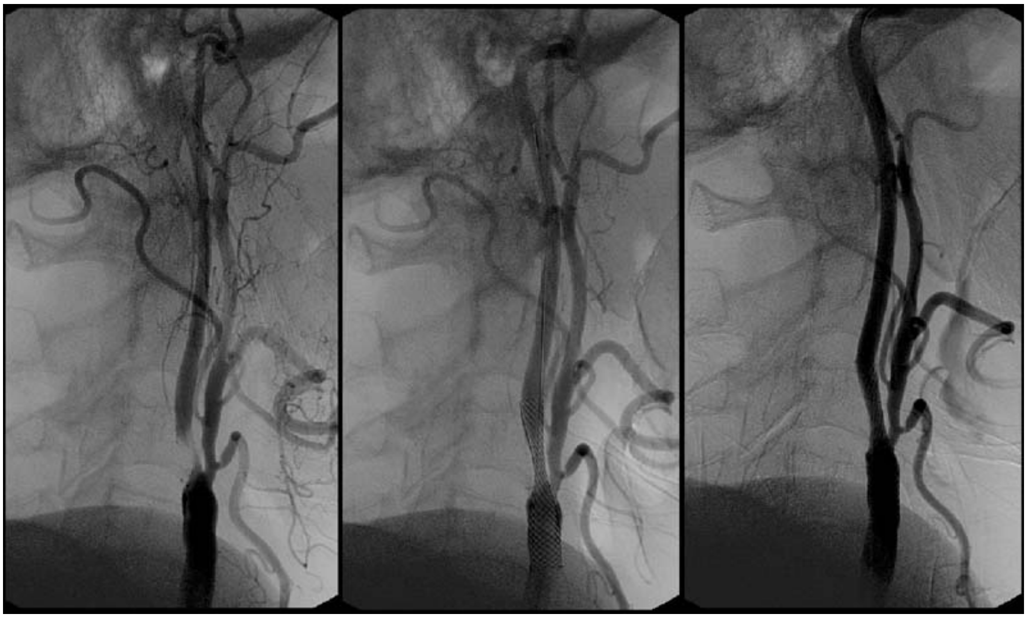
Angiography should include at least two projections showing the stenosis without overlay and two projections of the intracranial vasculature before stenting. For stent placement, fluoroscopy and the road-map technique should be used. The biplane angiography technique is extremely helpful. After stenting, the result should be documented angiographically (Fig. 1).

After the sheath is placed in the common carotid artery, the stenosis is passed with a microguide wire. Balloons and the stent delivery system are commonly monorail systems. Predilation of the stenosis with a 2.5- or 3-mm balloon might be necessary when primary passage with the stent delivery system is not possible. The suitable stent size is then estimated from angiography, depending on the vessel's diameter and the location of the stenosis. After stent placement, secondary balloon dilation is performed. Finally, the sheath is removed.

Protection devices with filters or flow reversal have not yet shown a benefit in controlled studies. They probably reduce the risk of a larger embolism but prolong and complicate the procedure, which might cause other complications.

Possible Complications

Stroke or transient neurological deficit due to periinterventional embolism is probably the most severe complication of stenting. Parts of a thrombus or plaque can be loosened during the passage of the stenosis with the wire, stent delivery system, or balloon. In particular, balloon dilatation of the stent and arterial wall might cause rupture of a plaque followed by embolism. Dissection of the arterial wall in the site of the stenosis and also in adjacent segments can lead to severe stenosis or thromboembolism. After treatment of high-grade stenosis, hyperperfusion in the territory of the internal carotid artery can



Step-off. Figure 1 Three steps of a stenting procedure of a carotid artery stenosis. From left to right: First, the stenosis is shown in a lateral angiographic view without subtraction. Then the stent is delivered, expanding the stenosis with its radial force. Finally, after balloon dilation of the stent, a satisfying result is achieved.

lead to edema or hemorrhage with neurological impairment, headache, seizures, and focal neurological deficits. Potential side effects of contrast media administration include allergic reaction, impairment of renal function, and hyperthyroidism. At the puncture site, a groin hematoma might occur. Restenosis caused by intimal hyperplasia is possible but normally asymptomatic. Intimal hyperplasia typically appears during the first 6 months after stenting. Follow-up with ultrasound over a period of approximately 2 years is necessary to detect severe restenosis, which can be treated with balloon angioplasty or even stenting again.

Future Prospects

Stenting of carotid artery stenosis has the great advantage of avoiding the risks of operative treatment. Incisions, with the risk of cranial nerve palsy or cervical wound hematoma, and longer occlusion of the treated vessel are not necessary. Often, hospitalization of the patients is shorter. Nevertheless, larger trials are needed to show the equivalence of neurological complication rates and long-term results. Improvement of the interventional tools such as stents and protection devices that reduce the rate of thromboembolism, the growing experience of the interventionists, and the refining of the preintervention diagnostic processes (e.g., plaque imaging) will further decrease complication rates and optimize results.

Definitions

Current operations on the stomach and duodenum are performed for the treatment of gastroesophageal reflux, for the complications of peptic ulcer, for the resection of benign and malignant masses, for the complications of chronic pancreatitis, and for the management of obesity (1–3). Indications for surgical management of gastroesophageal reflux and peptic ulcer disease have decreased with the advent of proton pump inhibitors (4). Whereas rates of bariatric surgery have dramatically increased in recent years because morbid obesity is increasing in epidemic proportions (5, 6). Radiologic studies are crucial in the evaluation of patients with symptoms after gastric or duodenal operations. The radiologist may be asked to demonstrate complications in the early postoperative period or to define anatomy and detect disease years later.

Gastroesophageal Reflux

Indications for operative treatment of gastroesophageal reflux include clinical symptoms or esophagitis refractory to medical treatment, and Barrett esophagus (2–4). Standard operations attempt to increase the mechanical component of a competent esophagogastric junction mechanism. The Nissen ▶fundoplication creates an intraabdominal wrap of gastric fundus completely around the lower esophagus. Various other antireflux procedures attempt to restore the abdominal esophagus and ensure that it responds to intraabdominal pressure. Wraps can be noncircumferantial as in the Toupet partial fundoplication.

Peptic Ulcer Disease

Current indications for surgery in patients with peptic ulcer disease include hemorrhage, perforation, obstruction, ulcer intractability, and the inability to exclude malignancy in a gastric ulcer (2, 3). Generally, this can be accomplished with partial gastrectomy, with removal of

S

the ulcer. Combined gastric and duodenal ulcers and prepyloric ulcers are managed according to the principles of surgery for duodenal ulcer.

Duodenal Ulcers

Nowadays, surgery for duodenal ulcers is rare. But physicians who treat postoperative patients must be familiar with procedures that were performed over the past several decades. Antral resection and vagotomy has been used in the treatment of duodenal ulcers to decrease the secretion of hydrochloric acid and to remove ulcer-bearing gastric mucosa. Distal gastric resection with reconstruction by anastomosis of the proximal stomach to the end of the duodenum is known as a Billroth I reconstruction. When anastomosis to the duodenum is not possible, a gastrojejunostomy (Billroth II) is performed. A variable length of jejunum forms the afferent loop and carries duodenal contents toward the stomach. The efferent loop is the jejunum on the side of the gastrojejunostomy that is distal to the duodenum. The gastrojejunostomy may be anterior to the transverse colon (antecolic), or the small bowel may be brought up posteriorly through an opening made in the transverse mesocolon (retrocolic) (3).

An alternate method of reestablishing gastrointestinal continuity after gastric resection is Roux-en-Y gastrojejunostomy. The jejunum is divided just distal to the ligament of Treitz: the proximal end or side of the small bowel is attached to the stomach while the distal end is fashioned into an enterostomy downstream. This procedure diverts duodenal contents away from the gastric anastomosis and prevents bile reflux.

Gastric and Duodenal Masses Resection

Stomach malignancies require formal anatomic resection, with distal or total gastrectomy. Gastrointestinal continuity is restored with loop or Roux-en-Y esophagojejunostomy.

Duodenal malignancies are resected with pancreatoduodenectomy, with reanastomosis of the gastrointestinal tract, bile duct, and pancreatic remnant (1, 3). Pancreatoduodenectomy may involve distal hemigastrectomy, or the stomach and pylorus may be preserved by reconstruction with end-to-side duodenojejunostomy. The bile duct is anastomosed to the jejunum, and the distal pancreas is anastomosed to the jejunum or the posterior wall of the stomach.

Surgery for Obesity

Surgery is an effective alternative to failed medical and dietary therapy for life-threatening obesity. These stapling procedures create a small gastric pouch with a restricted outlet to cause early satiety, decreased caloric intake, and weight loss (5, 6). Currently, most surgeons prefer the gastric bypass approach or the vertical gastroplasty procedure. Bariatric surgeons use gastric silastic rings in both gastroplasty and gastric bypass operations to maintain the function and width of the stoma.

Gastric Bypass (GBP). A small proximal pouch is anastomosed to the jejunum *via* a loop or Roux-en-Y gastrojejunostomy. The stomach is separated from the food path but it is not transected. With a Roux-en-Y type anastomosis, the jejunum is divided, the proximal end or side of the distal bowel is attached to the stomach, and the Roux-en-Y loop is anastomosed to the jejunum downstream. With a loop gastroenterostomy, the standard right-to-left anastomosis is performed.

Vertical Banded Gastroplasty. A small tubular pouch and channel is created on the lesser curvature portion of the stomach.

Pathology/Histopathology

Complications occur when operations on the gastroduodenal tract fail to resect, reconstruct, or redesign the tissues and function of the gastroduodenal tract. There are common complications like anastomotic leaks, abscesses (Fig. 1), strictures, and bowel obstruction that occur during any operation on the alimentary tract. There are other complications that are unique to each operative procedure.

Gastroesophageal Reflux

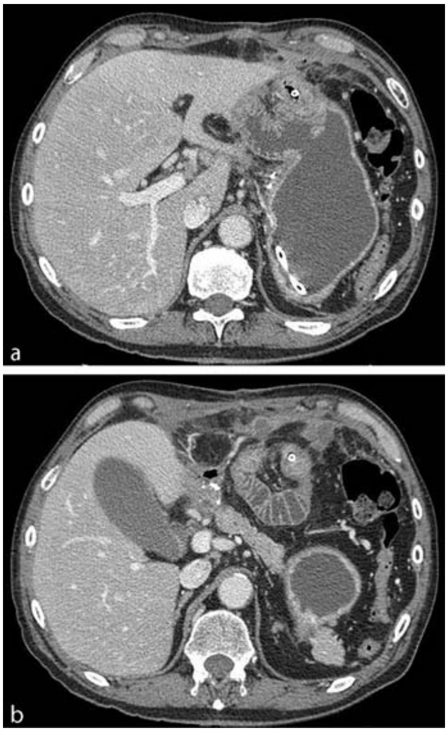
If the fundoplication is too tight dysphagia or so-called gas bloat syndrome may develop, in which patient is unable to belch or to vomit. Long-term complications include fundoplication dehiscence, recurrent hernia, and slip wrap (4).

Peptic Ulcer Disease

After operations for peptic ulcer, the most undesirable gastrointestinal sequelae are consequences of vagotomy, gastric resection, or pyloric ablation (3). Diarrhea, dumping, and bile reflux can cause clinical debility and nutritional deficiency in a small percentage of patients. Early mechanical and anatomic complications are not common but can usually be diagnosed radiologically. Cancer arising in gastric remnants is associated with long-term metabolic effects (2).

Duodenal Ulcers

Antrectomy and total vagotomy increase the risk of undesirable side effects such as dumping, diarrhea, bile reflux, and potential cancer arising in gastric remnants (1, 3).



Stomach and Duodenum in Adults Postoperative. Figure 1 Duodenal stump fistula complicated with intraperitoneal abscesses in a patient with partial distal gastrectomy for gastric adenocarcinoma. On axial enhanced CT with water-contrast agent, the gastro-jejunal anastomosis is clearly depicted (a). Axial enhanced CT at the level of the duodenal stump (b) depicts extradigestive gas in contact with the staples, and intraperitoneal abscesses.

Gastric and Duodenal Masses Resection

Recurrent neoplasm is a potential complication. Diarrhea, dumping, and bile reflux may follow gastric resection. Pancreatic resection may cause a deficiency of digestive enzymes. Metabolic deficiencies (iron or vitamin B12) are accentuated in patients with total gastrectomy.

Surgery for Obesity

Gastric staple line dehiscence is most often caused by repeated overdistention of the gastric pouch with food.

Massive gaseous distention of the excluded stomach may develop occasionally after gastric bypass procedure. It may occur because of edema at the enteroenterostomy, or it may be secondary to small bowel obstruction.

Internal hernias, following Roux-en-Y GBP are much more common than in the general population and are likely to be underdiagnosed (5). The most common type of internal hernia reported after laparoscopic Roux-en-Y GBP is transmesenteric, in which the small bowel herniates through the surgical defect in the transverse mesocolon. The herniated bowel is usually the Roux-en-Y loop itself.

Clinical Presentation

Anastomotic Leaks

The presentation can be acute (peritonitis) or progressive (subphrenic abscess).

Afferent Loop Syndrome

Afferent loop syndrome is caused by increased intraluminal pressure and distension due to accumulation of enteric secretions in an obstructed afferent duodenal stump in a Billroth II gastrojejunostomy (3). Afferent loop syndrome is one of the main causes of duodenal stump blowout in the early postoperative period and is also an etiology for postoperative obstructive jaundice, ascending cholangitis, and pancreatitis due to transmission of high pressures back to the biliopancreatic ductal system. Prolonged stasis and pooling of secretions facilitate bacterial overgrowth in the afferent loop. Bacteria deconjugate bile acids, which can lead to steatorrhea, malnutrition, and vitamin B-12 deficiency. Iron deficiency can occur because of bypassing of the proximal small bowel. Patients with acute afferent loop syndrome typically present with a sudden onset of abdominal pain with nausea and vomiting. If the afferent loop is not decompressed, the patient can develop peritonitis and shock if intestinal perforation or infarction ensues.

Bezoar

Bezoar is reported in patients with impaired digestion and decreased gastric motility. Bezoar may cause vomiting, diarrhea, pain, and gastric ulcers.

Imaging

Before beginning the examination, specific information about the postoperative anatomy should be obtained. If an anastomosis has been fashioned, drug-induced hypotonia, which renders the gastric remnant and small bowel hypotonic, prevents rapid slipping of contrast material into the distal small bowel.

Conventional Radiographs

The pattern of surgical clips and staples may help determine the anatomy with reliability. Unexpected foreign bodies, extraluminal gas collections, or signs of bowel obstruction should be sought.

Contrast-Enhanced Studies

Water-soluble contrast agents are used when anastomotic leaks, staple line dehiscences, perforations, fistulas, or abscesses are suspected. Barium studies provide an assessment of mucosal detail that cannot be obtained with water-soluble agents. Biphasic techniques that use both high-density barium sulfate suspension and effervescent agents and low-density contrast material with compression and palpation provide an excellent view of mucosal detail and the anastigmatic area (3). Patient cooperation and mobility are crucial for these studies. Protocols for position changes and radiographic sequences cannot be specified because each patient has unique surgical variations.

US, CT, and MRI

US, CT, and MRI are useful to detect fluid collections, abscesses, leaks, or fluid-filled obstructed bowel loops. For CT scanning, water-soluble contrast agents should be used liberally. CT is better suited to detect extradigestive gas.

Nuclear Medicine

Nuclear medicine emptying studies with radiolabeled solids and liquids can be used for patients with suspected postgastrectomy stasis syndromes, afferent loop dysfunction, motility problems of dumping and diarrhea, and postoperative symptoms of an unclear cause (3).

Diagnosis

Anastomotic Leaks

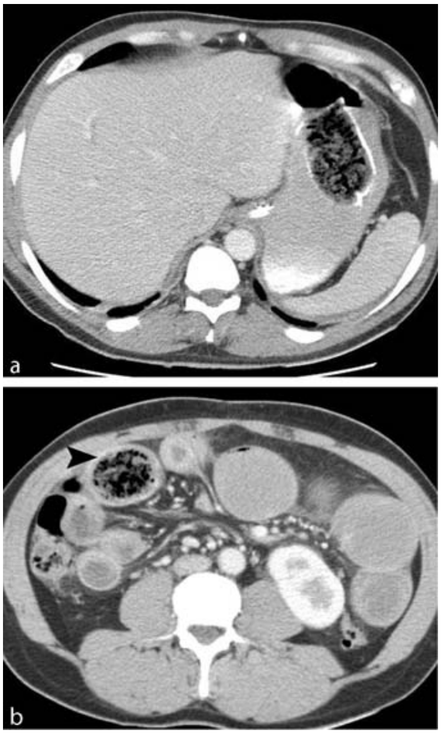
Extravasation of contrast material beyond the bowel lumen can be recognized without difficulty if the normal postoperative appearances are known.

Afferent Loop Syndrome

CT demonstrates the obstructed segment as a U-shaped, fluid-filled tubular structure confined to the subhepatic area or crossing the midline between the abdominal aorta and the superior mesenteric artery. CT is also useful to predict the underlying pathology causing afferent loop syndrome (carcinomatosis, adhesion, or internal hernia).

Bezoar

Conventional radiographs and CT demonstrate an ovoid intraluminal mass with mottled gas pattern within the stomach (2). Small bowel obstruction can follow bezoar migration (Fig. 2).



Stomach and Duodenum in Adults Postoperative. Figure 2 Partial gastrectomy complicated with bowel obstruction after bezoar migration. Axial enhanced CT at the level of the stomach demonstrates an ovoid intraluminal mass with mottled gas pattern (a). Axial enhanced CT also demonstrates small bowel obstruction due to migration of bezoar (arrowhead) (b).

Tumor Recurrence

Local tumor recurrence is usually diagnosed with endoscopy. US, CT, and MRI are useful for loco-regional staging (1, 2).

Long-Term Complications of Fundoplication

Long-term complications are generally evaluated with barium studies (4). A completely dehisced fundoplication often mimics normal findings in a healthy patient who has not undergone surgical intervention. In partial fundoplication dehiscence, there is no significant tapering of the distal esophagus. In slipped fundoplication, the gastroesophageal junction lies above the level of the wrap. In recurrent hernia, the entire wrap lies above the esophagus hiatus.

Interventional Radiological Treatment

CT and fluoroscopic guidance are useful for treatment of the postsurgical complications.

Stone Disease, Urinary

G. Heinz-Peer
Department of Radiology, Medical University, Vienna, Austria
gertraud.heinz-peer@akhwien.at

Epidemiology

Urinary stone disease is a common problem among people from industrialized nations. The incidence is 7 per 1,000 and it is responsible for 7 to 10 of every 1,000 hospital admissions in the USA (1). With increased abdominal imaging more stones are diagnosed as an incidental finding. In most cases, no clear precipitating factor is identified and the natural cumulative recurrence rate is reported to be 14% at 1 year, 35% at 5 years, and 52% at 10 years. In general the overall lifetime risk is accepted as 35–65% with a male preponderance (male: female ratio of 2:1) and the peak age of onset is 20–30 years. Caucasian or Asian origin confers a higher risk (1).

Pathophysiology/Histopathology

The main types of stones encountered are calcium containing, composed mainly of pure calcium oxalate or calcium oxalate mixed with calcium phosphate. The majority of the remainder is so-called struvite or matrix stones composed of magnesium ammonium phosphate. Uric acid and cystine stones account for less than 10% of all calculi. An organic matrix of mucoprotein, consisting 1–5% of the stone by weight, is present in all calculi.

In most cases, a precise etiological factor is not identified but certain predisposing factors are recognized. Incidence is higher in patients with an anatomical abnormality of the urinary tract and this may be related to urinary stasis. Stones form when the concentration of two ions in solution exceeds the saturation point. The condition at which this occurs depends on a number of patient-related factors (1).

Clinical Presentation

Urinary stone disease may present in a number of ways. The classic presentation is with acute severe ipsilateral loin to groin pain, associated with nausea and vomiting. This history combined with renal angle tenderness and microscopic hematuria is highly accurate in making a clinical diagnosis of urinary tract stones with a reported sensitivity and specificity of 84 and 99%, respectively (2). Delayed presentation or diagnosis is often complicated by infection proximal to an obstructing calculus. Matrix calculi are most often infected. Renal impairment at presentation implies a complicating factor, such as underlying renal disease or septicemia. Rarely renal failure may be secondary to bilateral obstructing calculi or an obstructing stone in a single functioning kidney.

Others present with vague symptoms or microscopic or gross hematuria, and in yet others the finding is incidental. Of this last group only one third will become symptomatic. There are no reliable predictive factors to identify those patients who will develop symptoms (2).

Imaging

The purpose of imaging is not only to confirm the presence of urinary stone disease, but also to provide some indication of outcome.

Plain Abdominal Radiograph

KUB has a low sensitivity in the diagnosis of stones, ranging from 45–60% (1). Despite this modest accuracy, the KUB is important in the management of a known radiopaque ureteric calculus especially in planning fluoroscopically guided, ►extracorporeal shockwave lithotripsy (ESWL) or monitoring the progress of stone fragments after ESWL. It is also valuable for assessing stone status in those who are managed conservatively.

Excretory Urography

Over many years, the excretory urography has been the traditional imaging modality of choice for evaluation of patients suspected of having ►urolithiasis. However, small or radiolucent stones may be missed on IVU. Reported sensitivities range from 64–97% for calculus detection (3). The IVU is easy to perform and relatively save and the radiation dose from a standard three film IVU series is 1.5 mSv (1). In case of renal obstruction, additional series are required and the radiation dose may increase up to 10 mSv (4). The radiographic findings are highly accurate in diagnosing renal obstruction and allow excellent evaluation of the topography of the calyceal anatomy. These are most important contributions to management of urinary stone disease (Fig. 1).

Ultrasound

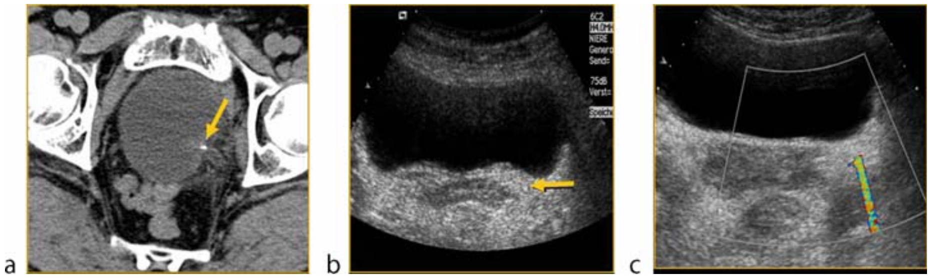
Ultrasound has an important role in the diagnosis and management of urinary tract stones but it has limitations. The sensitivity for calculus detection ranges from 37–64% and for detection of acute obstruction from 74–85% (3). Stones in the pelvicalyceal system can be reliably identified only if they are greater than 5 mm. Furthermore, calculi in the ureter are poorly visualized unless sited within the proximal ureter or at the vesico-ureteric junction (VUJ). However, by using the color Doppler twinkle sign the sensitivity of calculus detection may be improved (Fig. 2). The role of ultrasound in chronic stone disease is also unclear. Pelvicalyceal anatomy cannot be confidently delineated on ultrasound unless the pelvicalyceal system is dilated.

For follow-up of renal stones triaged to conservative therapy, ultrasound is of use. Ultrasound is also recommended in patients in whom radiation exposure is a concern, such as pregnant or pediatric patients (3).

Unenhanced Computed Tomography

The unequivocal advantage of UCT over all other techniques is its diagnostic accuracy. Over 99% of calculi, including those that are radiolucent on the KUB will be seen on UCT. The exceptions are pure matrix stones and stones made of indinavir (and related drugs), a human immunodeficiency virus (HIV) protease inhibitor. UCT has the highest accuracy (approximately 95% compared with around 80% for IVU) in acute ureteric colic (3). As well as

Stone Disease, Urinary. Figure 1 On KUB a 1 cm lower calyceal stone is depicted in this patient with uretero-pelvic junction (UPJ) stenosis as shown by the excretory urography. Since the passage of stones or fragments through this stenosis is unlikely, this particular patient is no candidate for ESWL. On unenhanced CT, the presence of a low or medium graded UPJ stenosis may be missed.



Stone Disease, Urinary. Figure 2(a–c) Patient presenting with a small calculus at the uretero-vesical junction (UVJ) (*arrow*) that is nicely depicted on unenhanced CT (a), and hardly delineated (*arrow*) on grey scale ultrasound (b). The color Doppler twinkle sign improves detection of urinary stones as shown in this patient with a 4 mm calculus at the UVJ (c).

demonstrating the size and site of the calculus, measurement of stone density may be useful, as stones of greater than 1,000 HU appear to respond less well to ESWL (1).

A number of secondary CT signs thought to reflect the pathophysiology of acute urinary tract obstruction have been described (3). It has been suggested that these signs indicate a protection mechanism against renal pressure.

The value of UCT in the management of renal, as distinct from ureteric calculi, is less clearly established. Factors other than stone size that influence the choice of ESWL versus ►percutaneous nephrolithotomy (PCNL) are not easily assessed. Similarly, planning the route for percutaneous entry is imprecise. Multiplanar and volume reconstructions may overcome these limitations (1).

For the diagnosis of ureteral stones, the calculated mean effective radiation dose reported for standard-dose CT ranges from 3.5 to 10 mSv, for low dose CT from 1.5 to 3.5 mSv, respectively.

Multislice CT Urography

CT data acquisition during urographic contrast enhancement for contiguous imaging of the entire upper urinary tract is termed "multislice CT urography" (MSCTU). Multiplanar reconstructions, maximum intensity projections (MIPs), and average intensity projections can be rendered from the volume datasets to view the urogenital tract.

Similar to the excretory urography, MSCTU provides valuable information on the degree of renal obstruction and allows excellent evaluation of the topography of the calyceal anatomy.

The radiation dose reported for MSCTU ranges from 3.9 to 22.6 mSv (4). This great variety may be explained by different examination protocols and to a less extent to scanner- and patient-related factors.

Magnetic Resonance Urography

The current role of MRU in diagnosing urinary tract stones is limited to patients in whom other investigations are contraindicated. MIP reconstructions from three-dimensional datasets can resemble a conventional IVU but the spatial resolution is inferior to alternative techniques. Although the site of obstruction may be demonstrated definitively identification of a stone may be difficult (5) (Fig. 3).

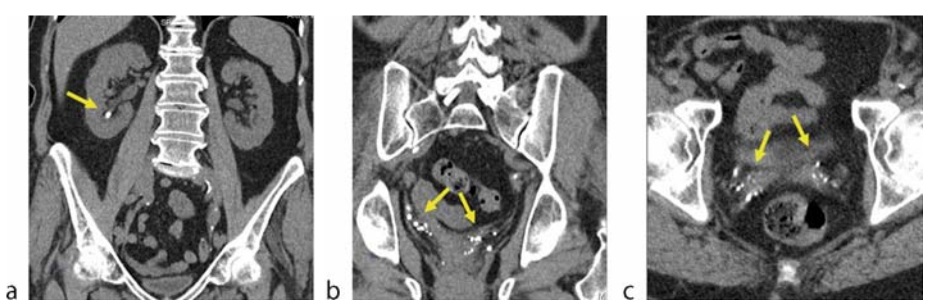
Stone Disease, Urinary. Figure 3 This macroscopic image shows a urinary tract stone of mixed composition (calcium oxalate and calcium phosphate) after stone extraction.

Additional Radiological Investigations

The frequency of *retrograde ureterography/scopy* has been markedly decreased for evaluation of suspected ureteric stones. It is occasionally used in the patient with persistent suspicion of ureteric stone and unclear findings on UCT or IVU (e.g., differentiation of phleboliths and calculi) (1) (Fig. 4).

Nuclear medicine is useful in selected cases. Its principal role is in determining relative renal function to decide whether a minimally invasive therapy is appropriate for a stone-bearing kidney or if the patient should undergo nephrectomy. There is no defined

S



Stone Disease, Urinary. Figure 4(a–c) Patient with right lower urinary calculus (a, *arrow*) and multiple calcifications in the small pelvis. Differentiation of prevesical calculi and phleboliths (*arrows*) may be limited on unenhanced CT as shown in these coronal (b) and axial (c) images.

threshold, but <10% preserved function is probably not worth treating, and nephrectomy is then indicated. The divided renal function is also useful when bilateral renal stones are present as the side with the better function is treated first (1).

Management of Urinary Stone Disease

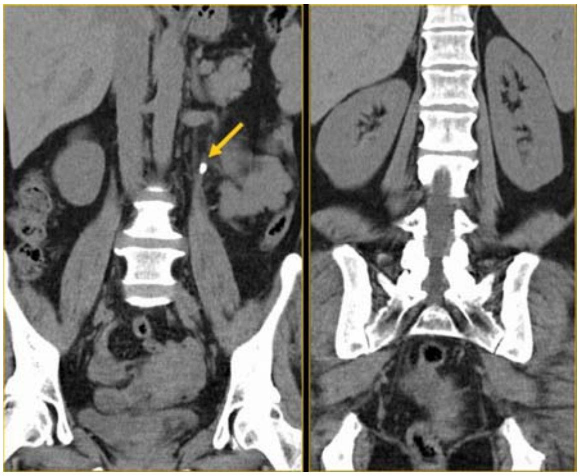
The management of urinary stone disease depends on the clinical presentation, stone location, stone size, and possibly on stone "hardness." With an acute presentation, the presence of complications such as super-added infection or renal impairment may necessitate immediate intervention whilst uncomplicated cases can be managed conservatively with adequate fluids and analgesia. If the stone does not pass spontaneously, definitive stone treatment is required and is often performed as a delayed, elective procedure.

Often, however, it is difficult to determine how closely symptoms are related to a urinary tract calculus. Some studies suggest that even small nonobstructing calculi may be symptom-provoking and patients may benefit from stone removal. In other cases, the stone may be an incidental finding, and it is difficult to justify invasive treatment. Each case must therefore be considered on its merits and the benefits of intervention should be balanced against the risks of the chosen procedure (6).

Conclusion

Modern imaging of urinary stone disease should provide accurate information about the presence, size, and precise location of a renal or ureteric stone, as well as the intracalyceal anatomy. A range of imaging tests are available, but no single test is ideal. The choice may depend on local resources. In the ideal scenario, patients presenting with suspected ureteric colic should undergo UCT. In patients presenting with vague symptoms or abnormalities in dipstick urinalysis, ultrasound combined with a KUB may be the most appropriate first-line examination.

In planning treatment, anatomical information is important and the IVU remains an important imaging method. MDCT-urography also provides detailed anatomical information, however, the radiation dose is higher compared to IVU (Fig. 5). Low dose CT protocols may challenge the radiation dose issue. Recently, high quality multiplanar reconstructions and advances in three-dimensional imaging have improved treatment planning. For follow-up, change in size and location need monitoring that usually can be done by KUB and ultrasound. Since urinary stone disease is often a recurrent disease in young people, the radiation dose should be an issue.



Stone Disease, Urinary. Figure 5 **Coronal reformats of unenhanced MDCT scans are helpful in evaluation of the precise location and size of urinary tract stones as shown in this patient with a left mid-part ureteric calculus (*arrow*).**

Definition

The World Health Organization defined ▶stroke as 'a clinical syndrome typified by rapidly developing signs of focal or global disturbance of cerebral functions, lasting more than 24 h or leading to death, with no apparent causes other than of vascular origin' (World Health Organization 1978).

As a clinical definition, such a presentation in childhood has many potential underlying causes. Modern imaging techniques can distinguish between these potential causes.

The main focus of this essay is on arterial ischemic stroke in childhood. A practical definition of this is, "a clinical stroke syndrome presenting in a child, due to ▶cerebral infarction in an arterial distribution." Please note that this also allows for a diagnosis of arterial ischemic stroke to be made, using medical imaging, in less than 24 h of the onset of disease.

Stroke is one of the top ten causes of childhood death. Many more suffer from long-term disability and are at risk of further strokes in the future. Many children with stroke have another medical condition, such as a cardiac disorder or sickle cell disease, increasing the likelihood of adverse neurodevelopmental effects. Although the numerical burden of disease is smaller than in the elderly, the physical, emotional, and social effects carry long-term implications on the individuals, family, and society as a whole.

Clinical Presentation

The most common clinical presentation of stroke in childhood is an acute hemiparesis. However, the recognition of clinical stroke may be difficult in infants and young children. Focal signs may be absent in neonates and young infants in whom seizures may be the only clinical manifestation. Clinical signs and symptoms may be particularly subtle in children with sickle cell disease, and difficult to distinguish from painful crises or the effects of the treatment of such with opiates. If in doubt, the child should be examined by an experienced pediatrician and advice may be sought from a child neurologist or a tertiary center.

Imaging

Computed tomography (CT) and magnetic resonance imaging (MRI) are the mainstay modalities in the diagnostic imaging of neurological disease. Brain MRI is recommended for the investigation of children presenting with clinical stroke. It should be performed as soon as possible after presentation. If brain MRI is not available within 48 h, then CT of the brain is an acceptable initial alternative (1).

The initial diagnostic imperative is for the confirmation of arterial ischemic stroke as well as for the exclusion of alternative treatable pathologies.

Practical considerations may apply with regard to limited access to suitable imaging facilities for children. It is possible that after initial assessment, transfer to a tertiary center may be required for definitive studies and other investigations.

For the initial diagnosis, an uncontrasted study of the whole brain is all that is generally required. Greater diagnostic confidence is gained using MRI over CT. If using MRI, diffusion imaging is often helpful in confirming the diagnosis.

Diagnosis

The imaging diagnosis of *arterial ischemic stroke* is based on the identification of characteristic radiological signs. There is a hierarchy of radiological signs which when seen together form a diagnostic pattern. The patterns of stroke in children are identical to those observed in young adults, with minor differences to those seen in the elderly.

The most important radiological sign is the identification that the abnormality is confined to or concordant with a recognized arterial territory. As there are relatively few variations in the cerebral arterial territories between individuals, this becomes a very useful indicator for the diagnosis. The margins of these abnormalities are usually well demarcated. Another recognized pattern is that of abnormalities distributed within the arterial border zones, in between the main arterial territories. These watershed regions may vary between individuals and there may be an overlap with other pathologies that affect these regions, therefore the identification of this sign is considered slightly less specific.

Supportive radiological signs are as follows. In the acute phase, the abnormality is typically hypodense on CT. It is recognized that this may take several hours to evolve. An initial early sign is a localized loss of gray-white matter differentiation. On conventional MR, the abnormalities are hyperintense on T2-weighted images and hypointense on T1-weighted images (Fig. 1). Although it is recognized that these may also take some time to evolve, the intensity changes on MR are comparatively much greater than the density changes on CT. This greater contrast resolution gives MR an advantage in both sensitivity and specificity. Furthermore, abnormalities may be detectable using diffusion MR within minutes of the insult, allowing for even earlier detection should the child have access to a scanner in that timescale (Fig. 1). Another characteristic sign that is always present in the acute phase is that of localized brain swelling. The affected areas of brain will demonstrate mass effect, causing localized sulcal effacement.

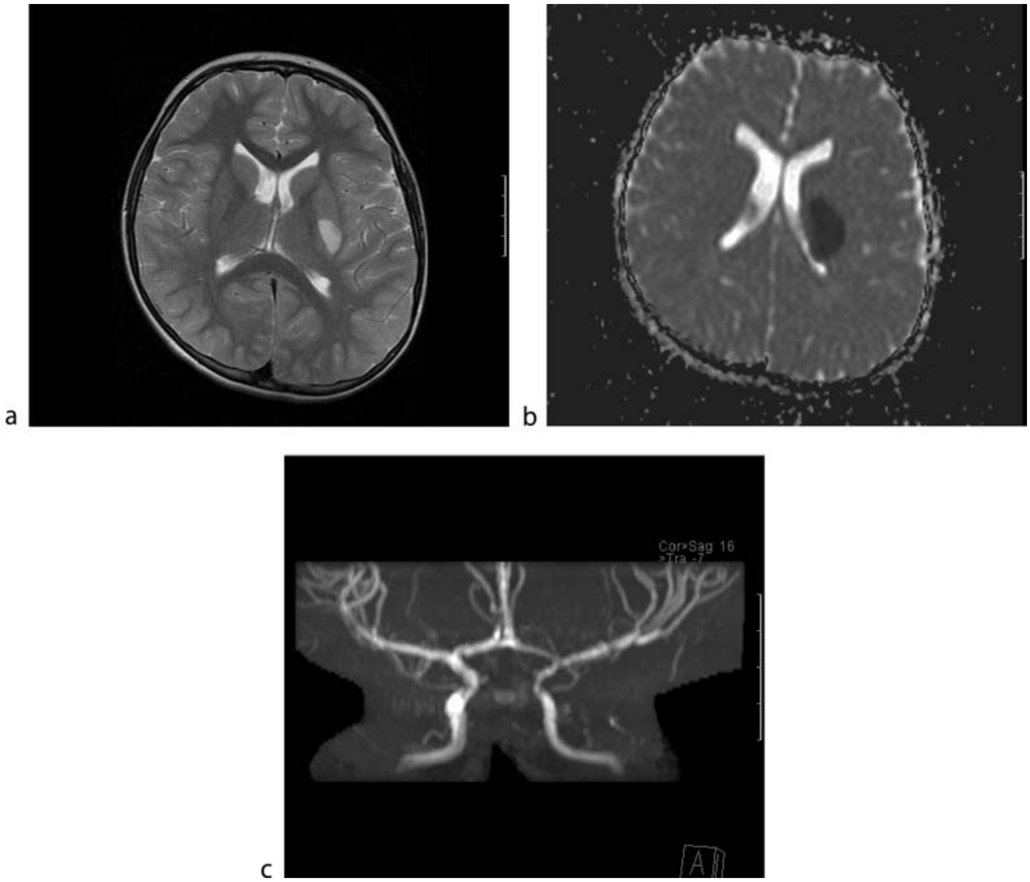
After a few days, the swelling will start to resolve. On CT, the arterial infarct becomes more clearly demarcated. Toward the end of the first week and early part of the second week, most larger infarcts demonstrate a degree of hemorrhagic change. This is accompanied by breakdown in the blood–brain barrier (i.e., manifesting as areas of contrast enhancement), and the distribution of these changes typically follows a gyral or cortical pattern, with relative sparing of the underlying, but also abnormal, white matter. On MR, therefore, the affected cortex starts to become hypointense on T2-weighted images and hyperintense on T1-weighted images. As the hemorrhagic effects clear, the intensity changes will again revert with time.

The chronic phase of an infarct is characterized by focal atrophy. The lesion is typically well demarcated. There may be some residual evidence of mature hemorrhage, but usually no persisting contrast enhancement. This is usually seen after several weeks or a few months and the abnormalities then persist, remaining stable indefinitely.

Other characteristic and supportive radiological signs involve the identification of abnormalities in the feeding arteries and draining veins to and within the infarct. A hyperdense thrombus within the feeding artery is a very important diagnostic sign on CT. A significant stenosis, occlusion, or turbulent flow may be identified on MR angiography. It is not uncommon to identify the presence of acutely thrombosed small veins within a large acute infarct. It is recognized that the pattern of degree and extent of such thromboses and occlusions may vary considerably in the hours, days, and weeks following an infarct.

Imaging allows not only the diagnosis of an arterial ischemic infarct to be made with confidence, but also the exclusion of alternative causes of clinical stroke. These are briefly discussed in the section on differential diagnosis.

At this time, the diagnostic imperative then shifts toward the identification of potentially treatable risk factors for arterial ischemic stroke. In the context of medical imaging, this will involve echocardiography and imaging of the entire intracranial and extracranial ►cerebral vasculature (from at least the aortic arch to the level of the infarct). A variety of angiographic tools are available, but the current evidence base for the choice of modality in the pediatric setting is weak. Catheter angiography remains the gold standard against which alternatives should be compared, but this is an invasive investigation requiring some skill and expertise in the pediatric setting. CT and MR angiography are practical



Stroke, Children. Figure 1 **A 10-year-old boy with an acute presentation of right hemiparesis with facial and bulbar involvement, about 5 months after chicken pox infection. There was a well-demarcated lesion affecting the left putamen, body of caudate nucleus, and intervening capsular white matter (a). The mean apparent diffusion coefficient values within the lesion were $0.28 \pm 0.07 \times 10(-3)$ mm^2/sec (b = 1000 sec/mm^2, 1.5 T), typical of the restricted diffusion seen in arterial ischemic stroke (b). An anteroposterior maximum intensity projection view of the carotid circulation from the MR angiogram of the circle of Willis, showing irregularity and attenuation of flow in the terminal left internal carotid artery and proximal left anterior and middle cerebral arteries (c). The final diagnosis, after confirmation of viral titers in the cerebrospinal fluid, was of varicella vasculopathy. He was treated with aspirin.**

and relatively noninvasive techniques, but they may vary in the quality of implementation when applied to children (Fig. 1). Ultrasound may be a useful adjunct to observe certain segments of the vascular supply.

Table 1 lists a range of pathologies and diseases that are associated with childhood stroke. Most children with stroke have more than one of these risk factors. An important concept is that it is the synergistic effects of these risk factors that result in the development of arterial ischemic stroke. The implication of this concept on imaging strategy is that despite the identification of one or more of these risk factors or conditions, continued and systematic imaging investigations may still be warranted to look for others.

Stroke, Children. Table 1 **More commonly identified causes and risk factors of childhood stroke**

Sickle cell disease
Thrombophilias
Varicella zoster infection (chicken pox vasculopathy)
Trauma and vascular dissection
Congenital cardiac abnormalities, including septal defects
Cerebral vasculitis, either isolated or as part of a systemic vasculitis
Inherited disorders of metabolism and genetic risk factors
Moya-moya disease—primary or secondary
Anemia, hypoxia, polycythemia, dehydration, hyperhomocysteinemia

Imaging is also used for the monitoring of disease. This may include imaging as part of presurgical planning, because some cases benefit from surgical intervention. Various techniques for surgical revascularization are available. Amongst them are external carotid to internal carotid (EC–IC) bypass surgery and varieties of *synangiosis*.

Differential Diagnosis

Some alternative causes of clinical stroke in the pediatric setting that may be identified on the initial scans are as follows. If there is continued uncertainty, repeat scanning after an interval often allows the natural history of these alternatives to evolve.

Venous infarction: these are typically in a venous territory, hemorrhagic, and associated with a greater degree of brain swelling and edema than arterial infarcts. Thrombosis in the veins may be identified and may include the dural venous sinuses.

Metabolic stroke: abnormalities are typically bilateral and relatively symmetrical, or in a distribution that does not confirm to typical arterial territories.

PRES (posterior reversible leukoencephalopathy syndrome): patients are usually identified by being at risk from immunosuppressive therapy. The imaging findings are similar to venous infarcts but without hemorrhagic change.

Acute demyelination: these may present with single or multiple, typically rounded or ovoid lesions that do not conform to a vascular distribution. Some may demonstrate contrast enhancement and a characteristic concentric zonal pattern of signal change.

Definition

Stroke is a clinical syndrome reflecting the sudden dysfunction of specific brain regions caused by focal ischemia, brain hemorrhage, and other conditions like hypoglycemia, focal inflammation, and focal epilepsy (see stroke in adults and children). Because of its high vulnerability, brain tissue may be already irreversibly injured at the onset of ischemic stroke. Under more fortunate circumstances, the impact has impaired brain function only, and the brain's structure is still widely intact. A specific intervention could then rescue brain tissue, restore function, and prevent disability and death. Moreover, endovascular interventions can decrease the risk of stroke in patients with arterial stenosis or malformations.

Interventional neuroradiologists have the training and means to recanalize obstructed brain arteries and veins and to occlude sources of intracranial hemorrhage like aneurysms and other vascular malformations using microcatheters and other devices. They play an important role in preventing and treating acute ischemic and hemorrhagic stroke.

Interventional Radiological Treatment

Ischemic Stroke

Vascular and brain imaging may detect arterial stenotic disease in asymptomatic patients, patients with transient symptoms, and patients with acute stroke syndromes. These patients have an increased risk for disabling stroke that is most prominent in the first days after ischemic brain attack and in patients with impaired cerebral perfusion reserve. In patients with substantial arterial narrowing (50–99%) or occlusion and no permanent neurological deficit, ►*angioplasty* may reduce the risk of disabling stroke by improving hemodynamic conditions. In patients with an acute stroke syndrome, ►*thrombolysis*, thrombus retraction, and/or angioplasty can restore blood flow and enable the recovery of brain function.

Prophylactic Interventions

►*Endovascular therapy* for extracranial and intracranial atherosclerotic disease includes angioplasty with and without ►stent placement in the brachiocephalic and subclavian artery, the internal carotid artery (ICA), the middle cerebral artery (MCA), the vertebral artery (VA), and the basilar artery (BA). *Stent*-supported angioplasty is currently providing a therapeutic alternative to traditional methods of open vascular surgery for revascularization of these vessels and increasing the therapeutic options available for patients who have failed maximal medical therapy. Whereas ►*carotid endarterectomy* (*CEA*) is well established based on good scientific evidence, studies are still missing showing that stent-supported angioplasty of extracranial ICA stenosis has a lower operative risk and can decrease the risk of stroke like CEA

(1). Nevertheless, stent-supported angioplasty of the extracranial ICA is increasingly performed because of its feasibility with a technical success rate of over 90% and low risk in experienced hands. Angioplasty of the atherosclerotic proximal VA bears the problem of elastic recoil that can be overcome with stents. A widely accepted indication is a symptomatic VA stenosis in patients with contralateral VA occlusion or hypoplasia.

The stent-supported angioplasty of other arterial diseases like dissection or vasculitis or of intracranial arteries is still experimental and appears justified in case of severe and symptomatic hemodynamic deficit (Fig. 1). Endovascular treatment of intracranial atherosclerotic stenosis has undergone rapid evolution during the past several years. Large case series show that balloon angioplasty can be performed with relatively low risk (2). The future will show whether the use of balloon mounted or self-expandable stents will improve perioperative and long-term results.

Interventions in Acute Stroke

The beneficial effect of systemic (IV) thrombolysis is limited in patients with combined extracranial and intracranial arterial obstructions, in patients with large vessel occlusion like the distal ICA and BA, and declines over time from stroke onset. Whereas IV thrombolysis is approved for the first 3 h only, the PROACT studies showed that IA thrombolysis of MCA occlusion is beneficial within the first 6 h of stroke onset(3). Endovascular therapy may improve the chances for good clinical outcome of these patients if applied as primary approach or after initiating systemic thrombolysis when interventionalists are not readily available (bridging-concept). Case series show that intra-arterial (IA) thrombolysis with urokinase or recombinant tissue plasminogen activator (tPA) can be as effective as IV thrombolysis in reducing the number of disabling strokes and deaths. In patients with acute symptomatic BA occlusion, most centers prefer IA thrombolysis, although one case series showed that IV thrombolysis might have similar good results(4). A controlled randomized trial comparing both approaches is not available. Endovascular treatment in acute stroke has the distinct advantage that IA thrombolysis can be combined with angioplasty in patients with atherosclerotic obstructions. Moreover, angioplasty and thrombus retrieving devices can be used to quickly recanalize the artery in order to restore blood flow and increase the chance for thrombolytic clot resolution distally in smaller arterial branches. Reports on cerebral hemorrhage after carotid recanalization coined the term "reperfusion hemorrhage" or "reperfusion trauma." It is unclear so far, whether the extent of ischemic brain tissue damage, arterial dysfunction, a sudden increase in perfusion pressure, high arterial blood pressure, anticoagulation, or arterial wall injury by guide wires alone or in combination is the cause of brain hemorrhage.

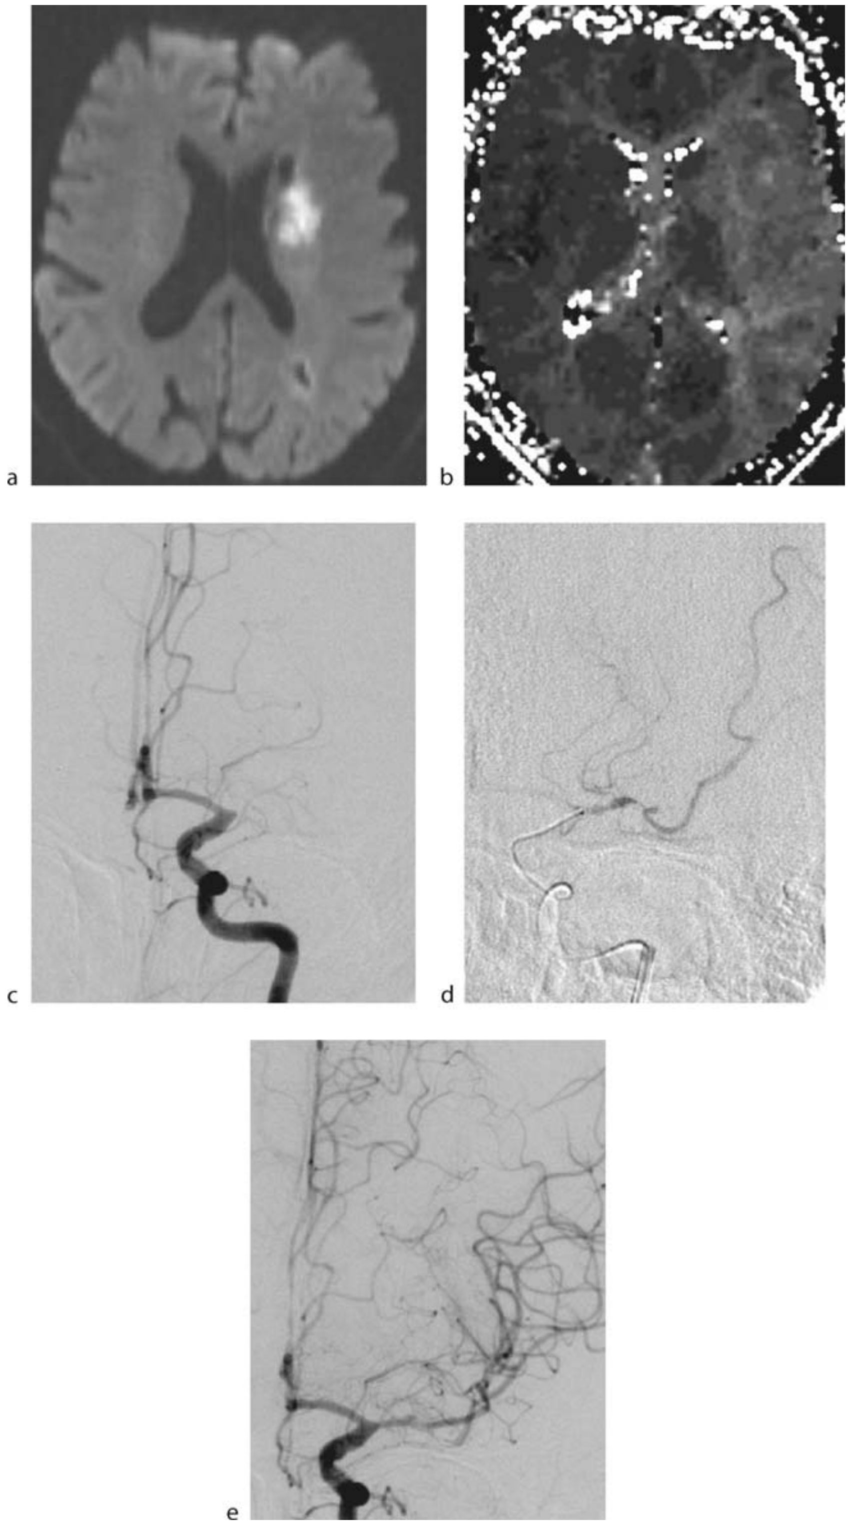
Hemorrhagic Stroke

Spontaneous intracranial hemorrhage has many causes among them arterial *aneurysms* and ▶arterio-venous malformations (AVM) that can be treated with endovascular approach. Ruptured saccular aneurysms account for 10–15% of all strokes.

Subarachnoid Hemorrhage

Occlusion of cerebral aneurysms by clipping or ▶*coiling* is a crucial, but not the only step in treating patients with subarachnoid hemorrhage (SAH). These patients have a 50% risk to rebleed within the first 6 months of SAH. Other risks are the development of hydrocephalus, cerebral edema, and arterial vasoconstrictions with subsequent brain infarction. Patients with SAH need intensive care and must be artificially ventilated in most instances. Early occlusion of ▶aneurysm can prevent recurrent bleeding and enable a treatment with aggressive increase in arterial blood pressure and fluid volume in order to maintain intracranial perfusion pressure.

Until the early1990s, surgical clipping of cerebral aneurysms was the established treatment. The development of microcatheters and detachable coils first enabled the occlusion of aneurysms, which the neurosurgeons could not treat without major morbidity and mortality and is today the treatment modality of first choice in many institutions after a controlled randomized trial has shown improved short- and long-term clinical outcome with endovascular occlusion compared to surgical clipping (5). The advantage of transarterial coiling of aneurysms is its nontraumatic approach with quickly placing a microcatheter in the aneurysm lumen as an immediate step after diagnostic angiography. The aneurysm can thus be occluded within few hours after SAH. Transarterial coiling is feasible, if the aneurysm has a defined neck that prevents protrusion of coils into the parent artery and if no arteries origin from the aneurysm itself. In the latter case, the placement of a surgical clip may avoid arterial occlusion that is not well controlled by coiling. Wide-neck aneurysm can be treated with the aid of stents or temporary balloon occlusion of the parent artery. For wide-neck giant aneurysms (diameter >25 mm) of the ICA, VA, or even MCA or false aneurysms located more distally, occlusion of the parent artery with coils or balloon must be considered. A balloon test occlusion can show whether the permanent occlusion will be tolerated or not. In selected patients, parent vessel occlusion should be combined with bypass surgery. A new approach is the placement of a covered stent over the aneurysm neck.



Stroke, Interventional Radiology. Figure 1 A 70-year-old woman with minor left hemispheric stroke and repeated TIA of her left MCA territory due to tight stenosis of the left M1-segment since 3 months despite antiplatelet therapy. (a) shows old and acute lesions on DWI in the end-supply areas of the left MCA. (b) time-to-peak map demonstrates delayed contrast inflow into the left MCA-territory. (c) DSA of the left ICA shows (ap-view) occlusion of the left MCA-trunk. (d) direct injection of contrast into the left MCA-trunk demonstrates that the obstruction is incomplete. (e) after passing the tight stenosis with a microguide wire, angioplasty with a 2 mm-balloon recanalizes the left MCA. No further TGIA occurred.

These stents are, however, relatively stiff and not well suited to be advanced over the carotid siphon. Arterial vasoconstrictions typically occur 1 week after SAH and jeopardize cerebral tissue. Local arterial infusions of nimodipine and balloon angioplasty can improve blood flow and prevent infarction.

Cerebral Hematoma

Dural and pial *AVMs* are among the causes of nontraumatic cerebral hemorrhages and should be considered in all patients in whom arterial hypertension, coagulation disorder, or amyloid angiopathy is not the obvious reason for the bleeding. Patients with hemorrhage from AVM have an increased risk for a recurrent bleeding and should be treated. It is widely accepted that endovascular treatment is the first choice for dural AVMs. Interventional neuroradiologists treat dural AVMs by occlusion of the fistula with glue or coils after transarterial or transvenous approach. Pial AVMs can be treated with open surgery and resection of the AVM nidus, with radiation of the nidus, or with embolization of the nidus. Because radiation does not immediately decrease the risk of recurrent hemorrhage, it is considered only for patients with small AVMs, which cannot be reached by neurosurgeons or neuroradiologists. A complete embolization of the AVM nidus should be achieved to decrease the risk of another brain hemorrhage. A complete embolization of the AVM nidus can be achieved in 10–20% of the patients only, so that embolization has to be combined with surgery in the majority of patients. Preoperative embolization can, however, diminish the extent of the nidus and thus decrease the risk of surgery in these patients. Embolization with glue has the risk of venous obstruction and subsequent hemorrhage, gluing the microcatheter within the feeding artery, or embolization of nutritive arteries with subsequent ischemia and stroke.

Subchondral Bone Cysts

Subchondral bone cysts are a prominent feature of osteoarthritis, occasionally forming as sequelae of bone injury. Radiographically the lesions are radiolucent, with a surrounding sclerotic margin. Joint-space narrowing and bone sclerosis are accompanying features. These lesions are also found in hemochromatosis.

▶Hemochromatosis, Skeletal

Subchondral Cysts

Subchondral cysts can be found with or without a sclerotic rim. Sclerotic subchondral cysts occur in degenerative osteoarthritis, gout, and SLE. In chronic gout they tend to be large and in a metaphyseal location. In degenerative osteoarthritis the predominant location is eccentric epiphyseal. SLE cysts are tiny and thought to be micronecrotic foci. Arthritic cysts tend not to have the sclerotic rim. Additional signs should be considered to establish the final diagnosis. Small osteolytic lesions have to be differentiated.

▶Connective Tissue Disorders, Musculoskeletal System

Subclavian Steal Syndrome

▶Steal Syndrome, Vertebral

Subcutaneous Rheumatoid Nodules

Subcutaneous rheumatoid nodules can be seen in seropositive rheumatoid arthritis. They are characteristic but not very common and are typically located at bony prominences. There is a typical histologic appearance.

▶Rheumatoid Arthritis

Subependymal Hemorrhage

▶Hemorrhage, Intracranial, Neonates (Neuro View)

Sublingual Gland

The sublingual glands are salivary glands in the mouth. They lie anterior to the submandibular gland under the tongue, beneath the mucous membrane of the floor of the mouth.

▶Inflammation, Chronic, Acute, Salivary Glands

Subluxation

Displacement of the femoral head in the hip that still leaves some surface contact with the acetabulum.

▶Dysplasia, Hip, Developmental

Submandibular Gland

The paired submandibular glands (or submaxillary glands) are salivary glands located beneath the floor of the mouth. In humans, they account for 70% of the salivary volume.

▶Inflammation, Chronic, Acute, Salivary Glands

SUI

▶Stress Urinary Incontinence (SUI)

Sump Syndrome

Uncommon complication of side-to-side choledocho-duodenostomy performed to improve biliary drainage in cases of retained stones or biliary dilatation. The segment of common bile duct between the anastomosis and the ampulla of Vater in cases of malfunction may act as a stagnant reservoir or stump wherein stones, debris, or infected bile accumulate. Bacterial overgrowth inside the stump results in acute cholangitis. Clinically, it presents as recurrent biliary pain or pancreatitis. Imaging findings include debris or stones in the common bile duct that may

appear dilated, dilated pancreatic ducts, and changes due to pancreatitis, cholangitis, or liver abscesses.
▶Cholangitis

Superior Caval Vein Occlusion

▶Thrombosis, Caval Vein, Superior

Superior Vena Cava Syndrome

The obstruction of venous drainage due to tumour infiltration into the superior vena cava. This leads to dilation of collateral veins in the upper part of the chest and neck; oedema and plethora of the face, neck and upper part of the torso, including the breasts; suffusion and oedema of the conjunctiva; breathlessness when supine; and CNS symptoms such as headache, visual distortion and disturbed states of consciousness. Although a dramatic clinical situation, this syndrome requires urgent but not emergency care.
▶Neoplasms Pulmonary

Suppurative Fluid Collection

▶Abscess, Renal

Supramesocolic Peritoneal Cavity

This extends from the diaphragm to the transverse mesocolon and is divided by peritoneal reflections into the following major spaces: right subphrenic, right anterior-posterior subhepatic, left subhepatic, and lesser sac.
▶Peritoneal Collections

Surgical Treatment of Crohn's Disease

Treatment for patients with severe complications or for those not amenable to medical treatment.
▶Crohn's Disease

SVC Obstruction

Narrowing or blockage of the SVC by malignant or benign pathology resulting in characteristic signs and symptoms.

a.wuttge-hannig@gmx.de

Definitions

Swallowing disorders are due to a dyscoordination, a dysfunction or an anatomic alteration in the esophagus or at the cross way of the respiratory and the alimentary tract. The swallowing disorders range from minor nutrition disabilities to the incapacity to ingest food with the consequence of aspiration of food or liquids into the airways. The swallowing disorders may even cause voice disabilities and may be associated with ronchopathy.

S

Pathology/Histopathology

During pharyngeal phase of deglutition in only 0,7 s 24 muscle groups governated by five cranial nerves transport the bolus from the oral cavity to the entrance of the esophageal tube. The speed of bolus transport in the pharynx is about 70 cm/sec. The reduction of the transport velocity in the esophagus is due to the progressive substitution of the striated musculature by smooth musculature. Therefore the speed of the peristaltic wave in the lower esophagus is reduced to 2–4 cm/sec (1).

The swallowing reflex in adults is triggered at the arch of the fauces and the corresponding dorsal pharyngeal wall. In neonates, the trigger occurs physiologically in the valleculae, the substitutive area for adult swallowing. The trigger of the swallowing reflex happens when the critical soil of receptor information from the different types of receptors in the oral cavity, in the valleculae, in the piriform sinuses and even in the laryngeal vestibule is reached (2). Due to surgery, radio- or chemotherapy or in the case of infections and also physiologically in the geriatric age the number of these receptors decreases causing a delayed triggering of the swallowing reflex (3).

The upper esophageal sphincter opens and closes regulated by the swallowing reflex. The sphincter function is modulated not only by influences of the swallowing center in the brainstem and cortico-bulbar afferences but also by humoral transmission due to disorders of the esophageal peristalsis.

The esophagus is innervated by vagal afferences and by an intrinsic autonom system, the Meissner and Auerbach plexus. The propulsion of the bolus is normally performed by a primary peristaltic wave, which is regulated by a single swallowing trigger. Multiple trigger inputs during an ongoing swallowing peristalsis interrupt the first wave; this is the so-called "intradeglutitive swallowing inhibition." The closure of the lower esophageal sphincter is depending from the synergism of its resting tonus and the correct position in the ferrule of the diaphragmatic hiatus. The opening of the lower esophageal sphincter is coordinated by the swallowing reflex. The failure of this function is caused by an alteration of the angle of Hiss, the intrinsic sphincteric resting pressure and the length of the infradiaphragmatic esophageal segment.

The pathology ranges from tumors to neurological and muscular disorders. The functional disorders are mainly due to paraphysiologic alterations in the swallowing act and in the protection of the airways.

The malignant tumors in the oral cavity, the pharynx, and the esophagus are mainly squamous cell carcinoma, distally adenocarcinoma and rarely leiomyosarcoma. Benign lesions are generally not frequent and rage in order of occurrence from leiomyoma, cysts to fibroma.

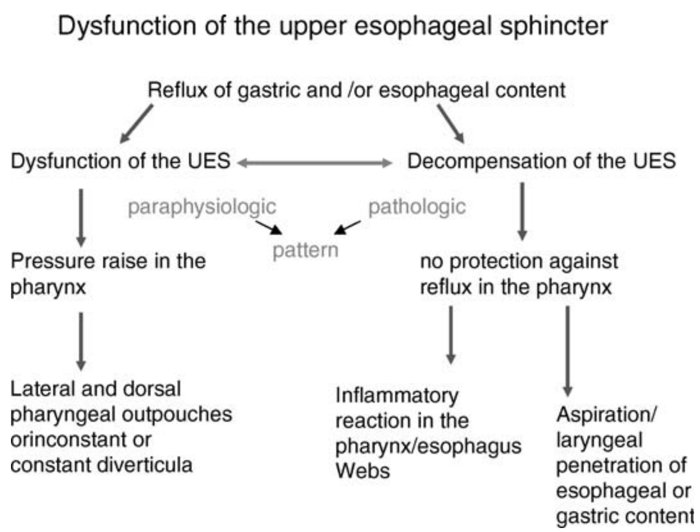
The neurological induced swallowing disorders are referable to stroke, cerebral trauma or posttherapeutic, and tumoral deficiencies. Neuromuscular disorders are caused by neuro-degenerative illnesses as ALS, multiple sclerosis, Parkinson's Disease, Guillaume Barré or by myogen diseases like polymyositis, myastenia gravis, or inclusion bodies myositis.

Functional disorders are frequently caused by a disturbed pharyngo–esophageal interaction like in GERD (Fig. 1) (3).

Clinical Presentation

The symptomatology ranges from hoarseness, globus sensation, heartburn, bolus impaction to dysphagia and odynophagia. According to the definition of Vantrappen Hellemans dysphagia is present when the deglutition of food, but only rarely saliva, causes discomfort. The globus sensation instead describes a discomfort during deglutition of saliva, but not during food ingestion. Odynophagia is painful swallowing.

Neurogenic disorders are often correlated with the aging of population. In nursing homes about 40% of the elderly suffer from a not treated swallowing disorder (4), a so-called silent aspiration. Eight percent of patients



Swallowing Disorders. Figure 1 **Flow sheet of the pharyngo–esophageal interactions.**

surviving a stroke event die in the first year from aspiration pneumonia due to an unobserved swallowing disorder (5).

GERD may induce hoarseness, laryngitis posterior, and reflux induced asthma.

Imaging

For the analysis of pharyngeal swallowing disorders, the imaging frequence needs to be very high. This can be achieved by the video fluoroscopy or the digital spot imaging at a high frame rate more than 20 images/sec. The high-frequence cineradiography at 50 images/sec is now reserved for scientific elaborations, due to the relatively higher radiation dose needed. The frame-by-frame evaluation is of crucial importance for the diagnostic reading process.

In the esophagus the high temporal resolution is not useful. A normal fluoroscopy with spot imaging is sufficient.

Double contrast imaging with $BaSO_4$ is normally applied in every swallowing study. Different preparations with different consistencies adapted to the patients complaints should be carefully chosen. For the mucosal imaging often the application of myorelaxant agent is needed.

Special contrast mediums should be used in patients with suspected or clinical appear ant tracheal aspiration or with suspected fistulas to the bronchial system. An almost iso-osmolar water-soluble iodine contrast medium should be applied, since hyperosmolar solutions lead to a pulmonary edema and/or a vaso-vagal reaction when aspirated.

The modern techniques like CT or MRI have still the huge disadvantage of the obliged prone or supine position. Only in special studies like the analysis of velopharyngeal dysfunctions and its surgical therapy planning dynamic CT or dynamic MRI are used in clinical research (6, 7). Diluted gadolinium-EDTA or plain water can be used in MRI studies.

Nuclear Medicine

First pharyngeal studies for the analysis of neurogenic disorders were performed for the presence of aspiration or nasal penetration (8).

The use of a tracer-marked bolus for the esophageal motility disorder has a long tradition. Quantifications of motility disorders like achalasia, hypomotilities in scleroderma or segmental spasms and the quantification of refluxed material in GERD are possible with a low radiation exposure. The time of observation is not limited in comparison to fluoroscopy (9).

Gastric emptying with radiotracers allows a more physiological assessment of gastric motility, especially in the case of gastroparesis with secondary gastro-esophageal reflux.

Generally, colloids marked with 99mTc in liquid, semisolid, or solid bolus preparations are use for this type of studies.

Diagnosis

Tumoral lesions are visible directly by obstructions or mucosal alterations and indirectly in amotil regions. The extra luminal growth of tumors and the lymph node staging is the domain of the MRI and/or CT.

The functional or motility disorders are best examined by video fluoroscopy or digital spot imaging or by combined methods like radiomanometry.

The description of the functional diagnostic findings can be classified according to the three swallowing phases: the oral, the pharyngeal, and the esophageal phase.

Oral Pathologies

Functional disorders can be divided in neurologic/neuromuscular disorders with or without a tracheal aspiration and gastroenterological disturbances.

In the oral cavity, the bolus preparation and the bolus compression can be disturbed due to dismotility or an atrophy of the tongue or due to a malocclusion of the velum.

Posttherapeutic neurologic or functional disorders can be seen in treated cleft.

Pharyngeal Pathologies

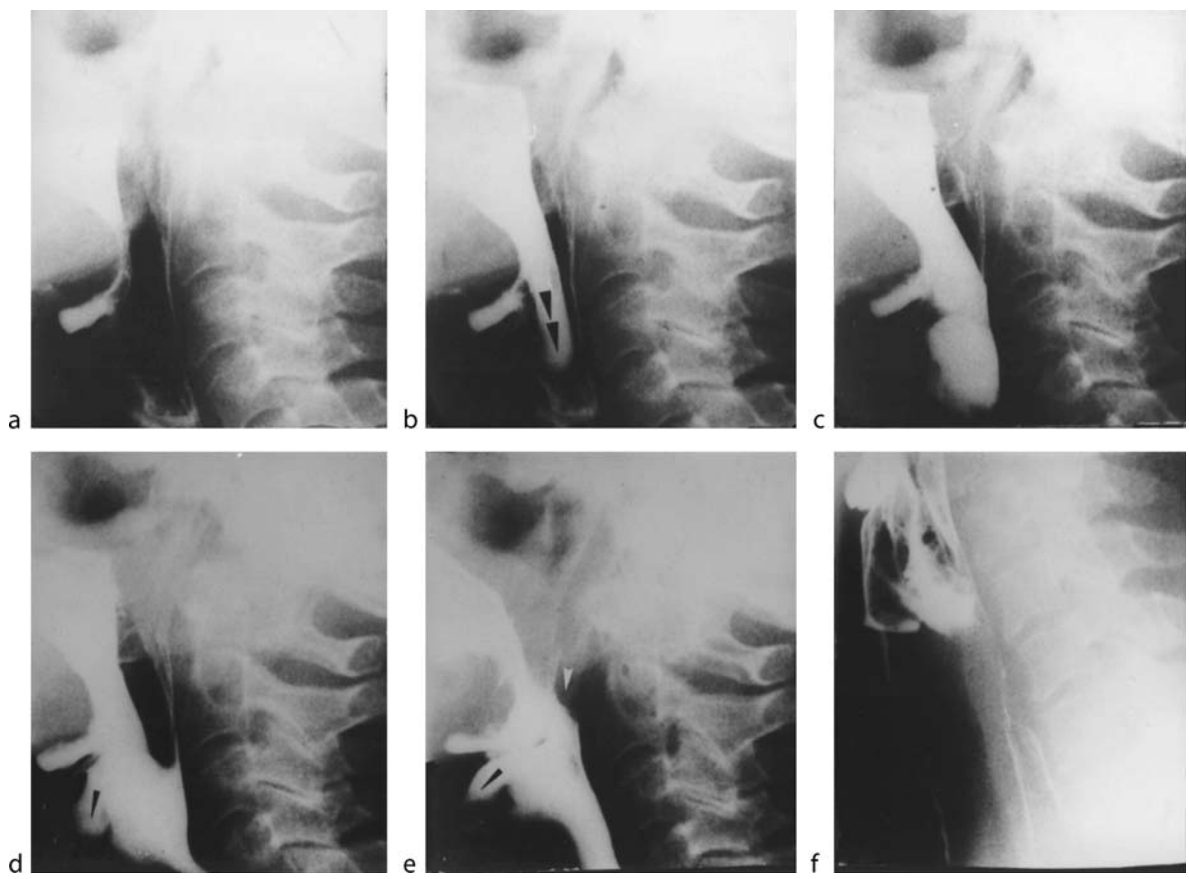
In the pharyngeal phase the predominant finding is a functional alteration of the upper esophageal sphincter caused by GERD or an idiopathic esophageal motility disorder. The delayed and incomplete opening and the premature closure of the upper esophageal sphincter are frequent findings in GERD or neutral mass-reflux (Fig. 2). The pressure elevation in the pharynx leads to diverticula, pouches, and pharyngoceles in patients with a muscular predisposition (3). The entrance of acidity in the pharynx gives origin to web-like scar rings or inflammatory mucosal irritations in the pharynx and in the laryngeal vestibule. Indirectly the delayed opening of the upper esophageal sphincter leads to a closure of the laryngeal vestibule, thus causing a laryngeal penetration of the bolus (10).

The second entity corresponds to the aspiration-related neurogenic or neuromuscular disorders.

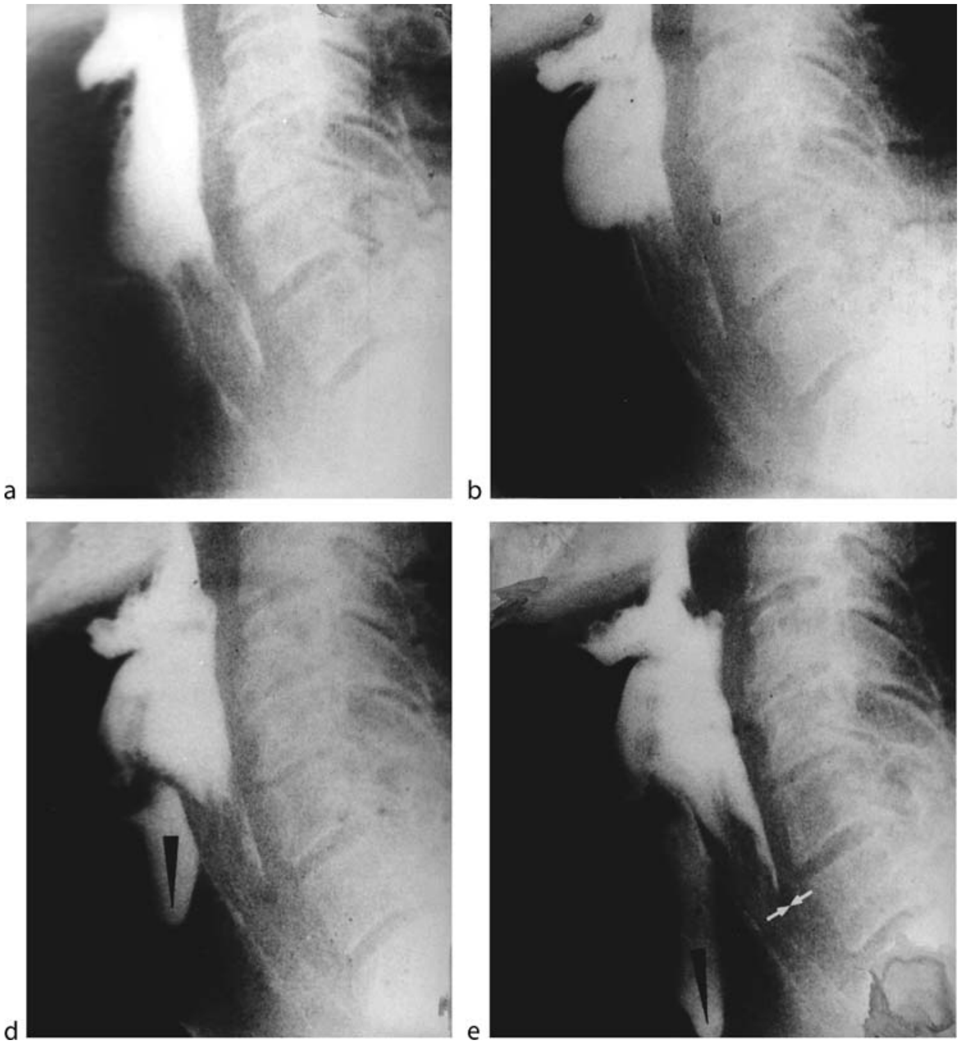
The division in a pre-, intra-, and postdeglutitive form of aspiration (Figs 3–5), this means an aspiration before, during or after the triggering of the swallowing reflex, give useful hints for an adequate conservative rehabilitation or a surgical therapy (11).

Swallowing Disorders. Figure 2 **Dysfunction of the upper esophageal sphincter.**

Dysphagia without aspiration is generally a precursor of aspiration associated dysfunctions. The dyscoordination of the events during a swallowing act is one of the first signs: The so-called cervical achalasia represents the impossible opening or the reduced opening of the upper esophageal sphincter which is due to a loss of interruption of the resting pressure of the sphincter (Fig. 6). The reduced activity in the pharyngeal constriction is often disturbed by myogenic disease like polymyositis, dermatomyositis, muscular amyloidosis, or postradiation or autoimmunologic myofibrosis. The delayed or incomplete opening or a premature closure of the UES might be due to a reduced laryngeal anterior and cranial movement by a deficiency of the extrinsic laryngeal musculature. The lack of a consecutive propulsion in the pharyngeal constrictor muscles, corresponds to the so-called Inclusion Body Myositis. Undefined muscular dyscoordinations might be seen in Parkinson's disease, multiple sclerosis, in the initial stage of amyotrophic lateral sclerosis, and in chorea Huntington (12).



Swallowing Disorders. Figure 3 **Predeglutitive aspiration: Sequence (a–f). Sixty-year-old patient with a media infarct left hemisphere. (a, b) Early leakage of CM in the valleculae and rec. piriformes (*black arrowheads*). (c, d) The CM enters in the hypopharynx and the laryngeal vestibule (*black arrow*) before the triggering of the swallowing reflex (*white arrow*) causing a tracheal aspiration.**



Swallowing Disorders. Figure 4 **Intradeglutitive aspiration. Fifty-six-year-old patient after a stroke, (a, b) pharyngeal retention with a disturbed pharyngeal contraction and a simultaneous spasm the upper esophageal sphincter (radiologically only the diagnosis of a disturbed opening of the upper esophageal sphincter can be observed). The spasm must be evaluated manometrically.**

S

Esophageal Pathologies

The functional disorders can be differentiated in primary or secondary forms.

Primary Forms

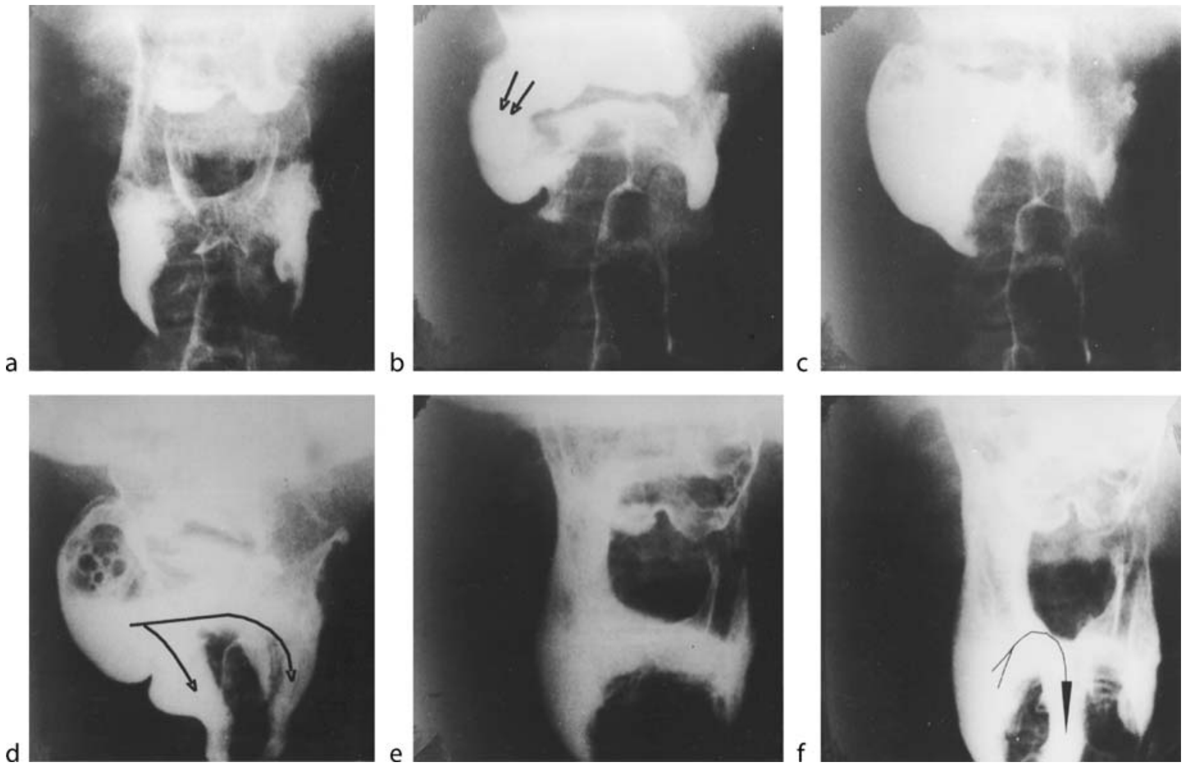
The best defined primary form is the esophageal achalasia, the incomplete or absent reflex induced opening of the lower esophageal sphincter (Fig. 7). A subdivision in three types, the hypomotile, the amotile, and the hypermotile form, is useful for the therapeutic approach.

The diffuse esophageal spasm is the second manometrically defined entity, which can be observed in fluoroscopy as a long segmental contraction or etage-like contractions of the esophageal body (Fig. 8). The symptomatology can be easily be mistaken for a cardiac attack.

The so-called nutcracker-esophagus does not present a typical radiological feature.

Secondary Forms

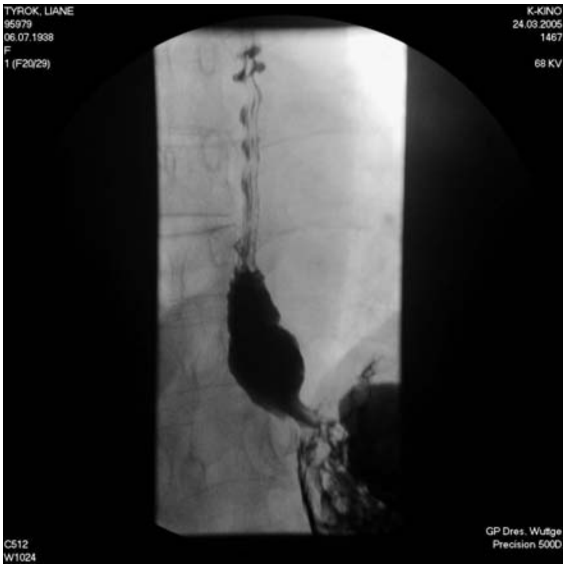
The most frequent is the reflux-associated motility disorder in GERD or large neutral mass refluxes. The lack of a primary peristalsis is the leading symptom. The influence on the pharyngeal phase is explained above. GERD is often associated with a constant or inconstant hiatal hernia (Fig. 9), diagnosed by the classical three-folds sign in prone position. The typical GERD-related mucosal changes are in stage I of esophagitis are the focal granulomatous mucosal alterations and microulcera in the distal esophagus; in stage II superficial ulcerations



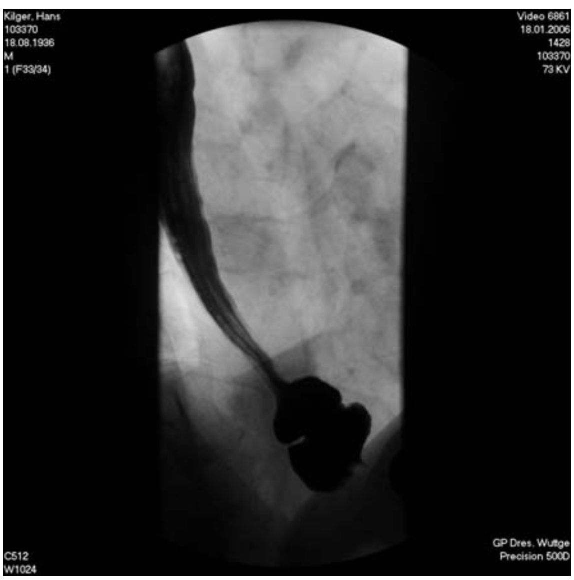
Swallowing Disorders. Figure 5 (a–f) Postdeglutitive aspiration. (a) Already in the resting phase before the swallowing a retention in the right rec. Piriformis can be observed. (b) Beginning of the pharyngeal contraction with extrusion of a pharyngozele of the right side and a CM retention in the right hemipharynx (*black arrow*). (c, d) During the unilateral opening of the upper esophageal sphincter transport of the CM retention from the right hemipharynx to the left side (*black arrow*). (f) Due to the return of the larynx to the resting position for respiration the pharyngeal capacity diminishes. Large aspiration of the CM stored in supraglottic position (*black arrow*).

Swallowing Disorders. Figure 6 Cervical achalasia due to a insufficient sphincter reflex triggered opening. Major retentions in the pharynx can be observed.

Swallowing Disorders. Figure 7 Amotile achalasia with Brachyesophagus.



Swallowing Disorders. Figure 8 **Etagenspasm in the middle and lower third of the esophagus with a hiatal hernia.**



Swallowing Disorders. Figure 9 **Hiatal hernia with a Schatzki's ring and gastroesophageal reflux.**

in the lower third of the esophagus; in stage III larger confluating circular ulcerations, and in stage IV peptic stenosis. The thickened mucosal folds in the esophagus and the so-called feline esophagus with the cat skin like appearance can be observed in stage I (13, 14).

The diagnosis "presbyesophagus" summarizes a lot of primary and secondary esophageal motility disorders frequently found in the elderly population suffering from diabetes or polyneuropathy for example.

The secondary achalasia is mostly caused by a submucosal growth of a carcinoma of the esophago-gastric junction. The differential diagnosis can be oriented by anamnesis and manometric findings, but the final decision remains reserved to biopsy.

Swan-neck Deformity

A typical deformity in late-stage rheumatoid arthritis with hyperextension of the proximal interphalangeal joint and flexion of the distal interphalangeal joint.
▶Rheumatoid Arthritis

Synchondritis of the Symphysis or Manubriosternal Junction

Synchondritis of the symphysis or manubriosternal junction is characterized by adjacent sclerosis and bony destruction. Symphyseal involvement is typically seen in ankylosing spondylitis. Sternal manifestations are seen in ankylosing spondylitis, psoriatic arthritis, and SAPHO syndrome.
▶Spondyloarthropathies, Seronegative

Syndactyly

Fused fingers or toes with or without synostosis.
▶Congenital Malformations of the Musculoskeletal System

Syndesmophyte

An intervertebral osteophyte with special radiologic appearance as a vertebral-based ossification in the exact location and form of the annulus fibrosus. It is seen in ankylosing spondylitis and in lumbar manifestations of reactive arthritis, enteropathic arthritis, and SAPHO syndrome.
▶Spondyloarthropathies, Seronegative

Syndromic Hepatic Ductular Hypoplasia

▶Congenital Malformations, Bile Ducts

Synovial Osteochondromatosis

Multiple ossified or merely cartilaginous fragments in a joint, presumably of traumatic etiology.
▶Transient Synovitis

Synovial Sarcoma

More prevalent sarcoma in younger age groups, often near to joints however not within. May have a variety of appearances from small and well circumscribed to large, solid, infiltrating with areas of hemorrhage and cystic formation. Some 30% have radiographic evidence of soft tissue calcification. Tumor of high malignancy with often slow growth.
▶Neoplasms, Soft Tissues, Malignant

Syringomyelia, Posttraumatic

Post-traumatic intramedullary cavity, often progressive, with a length that could vary from 2 vertebral segments to the whole spinal cord, isointense to CSF in all pulse sequences.
▶Spinal Trauma

Systemic Blood Supply to the Lung

There are normal anastomoses between the pulmonary and systemic (bronchial and ▶non-bronchial arteries) circulations but any abnormal process creating obstruction, compression of pulmonary artery branches or destruction of the pulmonary capillary bed may induce a compensatory development of systemic supply.
▶Hemoptysis

Systemic Mastocytosis

Mastocytosis is characterized by abnormal growth and accumulation of neoplastic mast cells. Bony changes are frequently shown and include osteoblastic changes in conventional radiographs. MRI is more sensitive in depicting bone marrow extension of the disease, but findings are not specific.

▶Myeloproliferative Disorders

Systemic Supply to PAVM

Bronchial arteries or other systemic branches of the aorta or supra-aortic trunks (intercostal, internal mammary or inferior diaphragmatic arteries) may supply PAVM before or after embolization. This systemic supply is a possible source of hemoptysis.

▶Pulmonary Arteriovenous Malformations

Systemic-Bladder Drainage, Pancreatic

In pancreatic transplantation with systemic-bladder drainage technique the arterial graft and the portal vein are anastomosed with the recipient's common or external iliac artery and vein, respectively, whereas the exocrine pancreatic secretions are drained by an anastomosis between the donor's duodenum and the bladder.

▶Transplantation, Pancreatic

Systemic-Enteric Drainage, Pancreatic

In pancreatic transplantation with systemic-enteric drainage the arterial graft and the portal vein are anastomosed with the recipient's common or external iliac artery and vein, respectively, whereas the exocrine pancreatic secretions are drained by an anastomosis between the donor's duodenum and a small bowel loop. In this technique the insulin is released in the systemic circulation, while the exocrine secretions drain physiologically in a bowel loop.

▶Transplantation, Pancreatic

TACE

Transarterial chemoembolization (TACE) involves the periodic injection of a chemotherapeutic agent mixed with an embolic material into selected branches of the hepatic arteries feeding a liver tumor.

▶ Chemoembolization

Talipes Equinovarus (Clubfoot)

Pes adductus, metatarsus, varus, external rotation of the ankle joint and parallel angle between talus and calcaneus.

▶ Congenital Malformations of the Musculoskeletal System

Target Population

The age-eligible population for screening, e.g., all persons offered screening according to the policy of the program.

▶ Screening, Breast Cancer

▶ Targeted Microbubbles

Target-Specific Probe

▶ Molecular Probes, Optical Probes

Target-specific Imaging

Target-specific imaging is the imaging of specific surface molecules or structures using a contrast agent binding to this particular structure. After wash-out of the unattached agent from the vascular system, the bound contrast agent can be detected. Specific accumulation of the contrast agent can be obtained by molecular binding of the agent (e.g., via antibodies) or by intracellular uptake of the agent (e.g., phagocytosis).

Synonyms

Molecular imaging; Specific microbubbles; Specific targeting; Target-specific gas-filled microbubbles; Targeted imaging; Targeted specific ultrasound contrast agents

Definition

Targeted imaging using ultrasound relies on ultrasound contrast agents (USCAs) to localize physiological or pathophysiological molecular or cellular processes. Two mechanisms are described for *in vivo* targeting of USCAs: passive and active. ►*Passive targeting* is a nonspecific accumulation of microbubbles at the target site after their administration and does not require a shell labeling with specific ligands. ►*Active targeting* (specific targeting) requires modification of the bubble shell to allow selective binding to cellular epitopes or other receptors of interest. In general, specific USCAs consist of a stabilized microbubble as signaling moiety and shell-surface-bound ligands (such as antibodies, peptides, polysaccharides, or aptamers) as binding moiety (Fig. 1).

Mode of Action

Passive Targeting

Three main mechanisms (phagocytosis, interaction with cell membranes, and ►lymph flow transport, LFT) are known for passive targeting depending on the size of microbubbles, the chemical properties of the shell, the type of the encapsulated gas, the physiologic system, and the route of administration (Fig. 2, upper part).

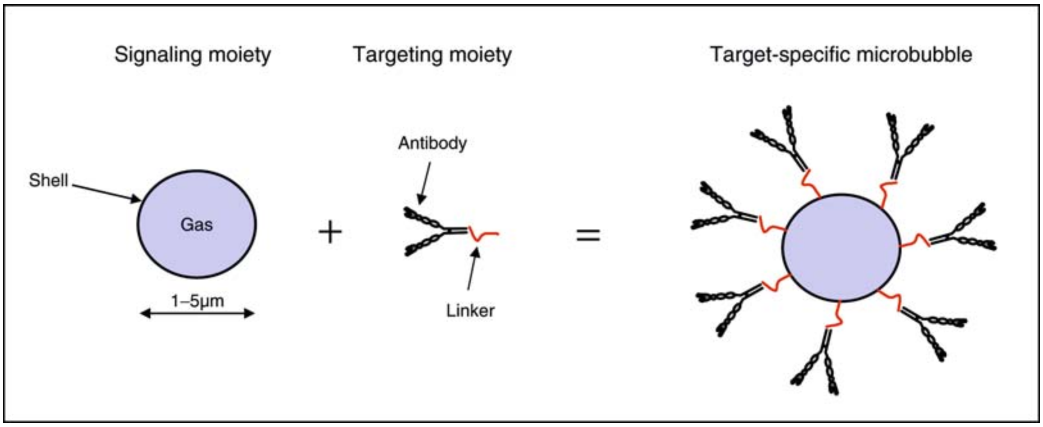
Phagocytosis: Cells of the ►reticuloendothelial system (RES), which clears the body from microorganisms and damaged cells, take up stabilized microbubbles after their intravenous administration leading to their accumulation in organs such as liver, spleen, lung, lymph nodes, and bone marrow. Activated neutrophil leukocytes are able to phagocytose albumin- or lipid-shell microbubbles after their cell-surface adhesion *via* special integrins or complement mediated opsonization.

Interaction with cell membranes: Depending on the shell composition or their surface charge, microbubbles can be adhered to the surface of cells such as activated leukocytes or the ►endothelium. It could be shown that interactions between leukocytes and lipid-microbubbles are mediated by serum complement, which could be accelerated by inclusion of the apoptosis marker phosphatidylserine into the lipid shell. On the other hand, the interactions between leukocytes and albumin microbubbles are mediated largely by leukocyte β_2 integrin. In the presence of a strong negative shell-surface charge, nonspecific adhesion and accumulation of microbubbles on the vascular endothelium has been noted (1, 2).

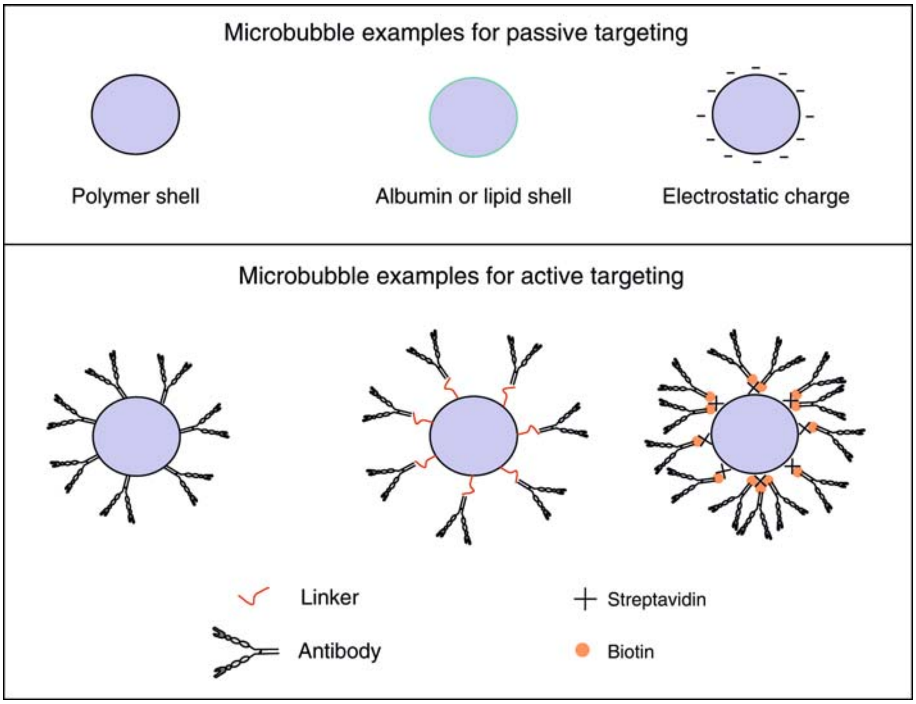
Lymph flow transport: Passive targeting of lymph nodes was demonstrated after interstitial injection of small microbubbles ($\leq$1 μm) consisting of a low-solubility gas or air-microbubbles stabilized with a polymeric hard-shell by using gray scale or color Doppler ultrasound. Interstitial injected microbubbles enter the lymph vessels through gaps between lymphatic endothelial cells or by transcellular endo- or exocytosis and is transported by the lymph flow to the respective regional lymph node.

Active Targeting

Active targeted USCAs have been made specific to cellular epitopes or other receptors by means of coupling of respective ligands with the shell of stabilized microbubbles (Fig. 2, lower part). The attachment of targeting ligands to microbubble shells can be made either before or after the bubble preparation, depending on the composition of the USCA. This can be done either by direct coupling of the ligand to shell-forming molecules or by covalent or noncovalent attachment of ligands to preformed microbubbles. Because of the size of microbubbles (μm-range), they are not able to move through the endothelium and thus do not usually leave the



Targeted Microbubbles. Figure 1 Principle of target-specific microbubbles. The conjugation of a targeting moiety with the signaling moiety results in target-specific microbubbles.



Targeted Microbubbles. Figure 2 **Strategies for passive and active targeted microbubbles. For passive targeting, intrinsic chemical or electrostatical properties of the shell can be used to carry microbubbles to the target. Active-targeted microbubbles can be produced by different coupling strategies depending on the targeting moiety (e.g., antibodies, peptides, polysaccharides, or aptamers).**

vascular system after their intravenous injection. Therefore, selective targeting with microbubbles is generally directed (limited) to specific receptors of physiological or pathological conditions on the surface of the vascular endothelium. However, the endothelium in a human adult has a total mass of about 1,000 g (like the liver mass) and mediates a wide variety of messages from local tissue to the systemic system (e.g., inflammation to immune response). Once a targeted USCAs has been administered, the microbubbles circulate in the blood stream for several minutes and accumulate in the area of interest *via* a ligand–receptor interaction. Free circulating microbubbles will be cleared from the blood by the RES within 10–20 min (depending on the dose). The rapid blood clearance guarantees a strong signal-to-noise ratio for specific accumulated microbubbles at the target site (Fig. 3). The exceptional ultrasound sensitivity of microbubbles allows the detection of signals from single bubbles and their quantification at the target even in high concentrations.

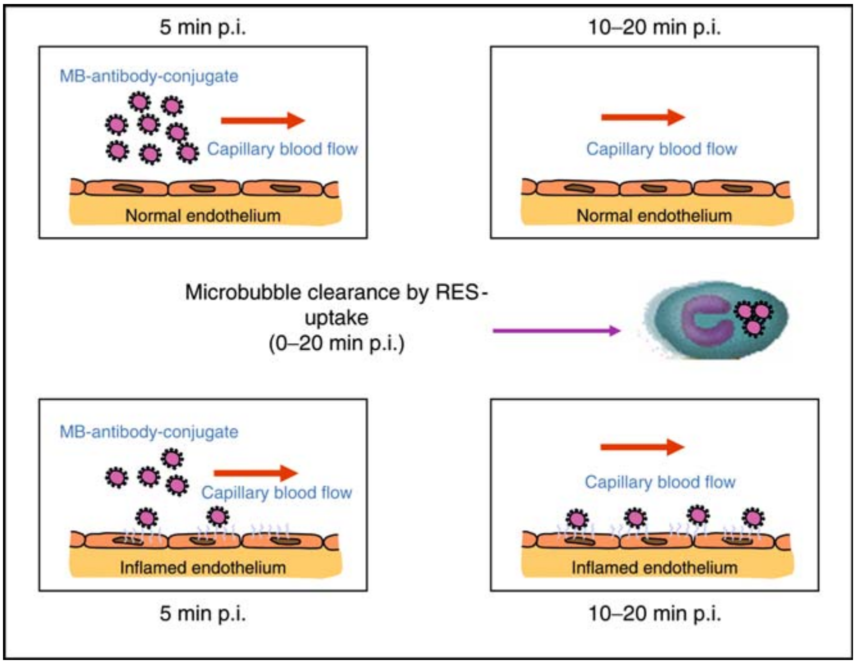
Indication

Passive Targeting

Few of the commercially available USCAs are already suitable for passive targeting in humans. One example is the so-called late phase effect with Levovist® (Schering AG, Berlin, Germany) in the liver and spleen after their intravenous injection. The late phase effect (bubble retention) allows contrast imaging in these organs long after blood-pool enhancement has disappeared and is used for the detection of neoplastic lesions. Another example is the use of Imagent (Alliance Pharmaceuticals, San Diego, California) for passive lymph node targeting after their interstitial administration (3). The nonspecific targeting of activated leukocytes could be shown in preclinical settings with different types of microbubbles, which provides a new approach for ultrasound imaging, the detection of acute inflammation including ischemia-reperfusion injuries. The targeting of myocardial endothelial cells has been achieved in anesthetized dogs with negative-charged microbubbles indicating that those types of agents could provide information on myocardial perfusion and viability (1, 2).

Active Targeting

Although targeted imaging with specific USCAs is currently at an experimental preclinical stage, researchers were able to show the potential of this ►molecular imaging approach in various animal models by targeting several molecular structures. The potential for



Targeted Microbubbles. Figure 3 Mode of action of target-specific microbubbles (principle). The rapid blood clearance of nontargeted MBs by cells of the reticuloendothelial system within 20 min, depending on the dose used, guarantees a strong signal-to-noise ratio for targeted MBs. Moreover, it provides the opportunity of repeated investigations within one session using MBs targeted to the same or other endothelial cell receptors.

the depiction of receptors in healthy tissue (physiological conditions) could be demonstrated in mouse and dog lymph nodes after intravenous injection of L-selectine ligand-specific microbubbles (3). Targeting of microbubbles to molecules which are overexpressed in certain pathological conditions, such as inflammation (P-selectin, ICAM-1, VCAM-1), ischemia-reperfusin injury (P-selectin), thrombosis (GPIIb/IIIa), or angiogenesis (α_V-integrins) was achieved in several experimental animal studies (1, 4, 5). However, each of the broad variety of molecules expressed on the endothelial surface can potentially be targeted with specific microbubbles. Only recently, a new method has been reported allowing the *in vivo* quantification of targeted microbubbles even in high concentrations. It could be shown that this new technique, referred to as sensitive particle acoustic quantification (SPAQ), allows a quantitative molecular imaging which has been demonstrated by counting ICAM-1 and VCAM-1 in an inflammatory model under treatment conditions (5).

Synonyms

Acute cholesteatoma; Chronic otitis media

Definition

Inflammatory diseases of the temporal bone indicate all those inflammatory affections that involve the structures of the external, middle, and inner ear, including the associated complications and the sequelae.

The infections can be of microbial or viral origin and include a series of clinical entities for which several classifications have been proposed. The first distinction must be made between acute and chronic inflammatory, where chronic is defined as an inflammation that does not resolve itself within three months from its appearance.

The inflammatory diseases of the temporal bone are generally classified according to the site of origin: external ear, middle ear and mastoid, inner ear, and petrous apex. The pattern of inflammation is strictly related to regional anatomy.

Pathology/Histopathology

Acute otomastoiditis is an inflammation of bacterial origin. In acute middle ear and mastoid inflammation the mucopurulent fluid is a result of vasodilatation, increasing glandular secretion with mucous production, and polymorphonuclear reaction occurring from the neutrophil cells. Resolution frequently occurs, but, if for some reason, the condition is prolonged, such as inability of the secretions to be drained out of the eustachian tube, the number of glands and goblet cells increases. The areas formerly covered by a cuboidal or flat epithelium change into areas of a less differentiated pseudostratified columnar epithelium. Granulation tissue results from the chronicity of the inflammatory process. Localized areas of the mucosa become hyperplastic with invasion of fibroblasts, capillaries, macrophages, plasma cells, and lymphocytes.

Acute otomastoiditis can cause complications such as coalescence and erosion of the bony septa with osteomyelitis, subperiosteal abscess, labyrinthitis, petrous apicitis (Gradenigo's syndrome), thrombosis of the sigmoid sinus, intracranial empyema, meningitis, or cerebral abscess.

Chronic middle otitis can be distinguished into two main groups according to the integrity of the tympanic membrane: (a) otitis with integrity of the tympanic membrane, which generally represents serous-mucous otitis; (b) otitis with open tympanum, which includes chronic suppurative otitis, chronic noncholesteatomatous otitis with ossicular erosion, and cholesteatomatous otitis.

In serous-mucous chronic otitis the aerial cavities of the middle ear are filled by a transuded serous and serous-mucous fluid that can change into an exudate due to bacterial superimposition.

Chronic noncholesteatomatous otitis is characterized by a tympanic perforation with otorrhea and a range of irreversible modifications that can involve the mucous membrane, the temporal bone, the ossicular chain, the mastoid air cells, and the eustachian tube.

T

Cholesteatoma is the evolution or the complication of chronic middle otitis.

It consists of a cyst-like mass lined with stratified squamous epithelium, usually keratinizing, and filled with desquamating debris often including cholesterol crystals. It behaves as an expansive lesion whose slow growth determines erosion and discharge of bony fragments.

Sequelae or variants of chronic noncholesteatomatous otitis are polypoid otitis, adhesive or fibroadhesive otitis, and tympanosclerosis.

External malignant otitis is the most significant pathological process of the external ear. It is a serious infection, which in 90% of cases is caused by *Pseudomonas aeruginosa*, a bacterial organism that secretes lithic enzymes and toxins that favor the spreading of the inflammatory process into the bone and the adipose spaces of the cranial base, often along the vascular–nervous route.

Acute labyrinthitis is an inflammation of the fluid-filled space of the inner ear and the membranous labyrinth. Abnormal ossification can occur in the chronic phase (ossificans labyrinthitis).

Clinical Presentation

The inflammatory process of the middle ear is generally the consequence of acute or chronic inflammatory affections of the main airway and almost always it also involves the mastoid (otomastoiditis).

Inflammatory disease of the ear is easily assessed clinically: conductive hearing loss, otalgia (earache), and secretion represent the typical clinical signs of the inflammatory process of the external and middle ear. The symptomatology of acute labyrinthitis is characterized by vertigo and sensorineural hearing loss; tinnitus can sometimes be present.

In malignant external otitis, together with general symptoms of inflammation, the local symptomatology consists in strong pain during movements of the temporomandibular joint due to solicitations of the tympanic membrane. The illness usually affects immunocompromised and/or elderly subjects.

Imaging

Acute otomastoiditis does not need evaluation by means of diagnostic imaging, with the exception of rare forms that are accompanied by intracranial complications.

Chronic inflammatory diseases of the middle ear represent the main field of application of radiological imaging.

High-resolution computed tomography (HRCT) of the petrous bone is widely employed in the evaluation of bony structures and it has supplanted conventional radiography. The advent of spiral and multidetector CT (MDCT) has been a further progress in the field. It allows information to be obtained about the bony tissue and the content of the middle ear cavity.

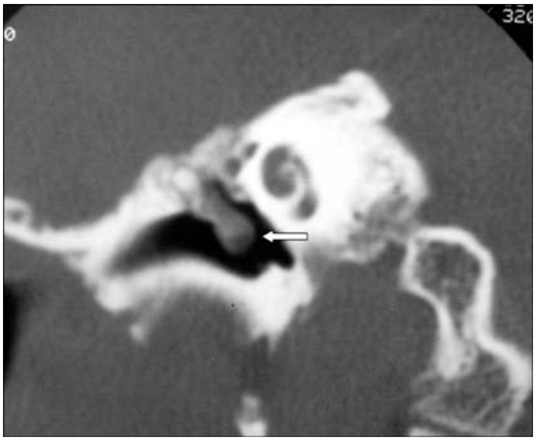
HRCT scan with multiplanar reformation (MPR) today represents the most accurate technique for the diagnosis of external and middle inflammatory diseases.

Magnetic resonance imaging (MRI) has a limited role in this field of pathology, and is generally employed in the above-mentioned intracranial complications of otomastoiditis, in acute external malignant otitis, in acute labyrinthitis, and for postsurgical patients.

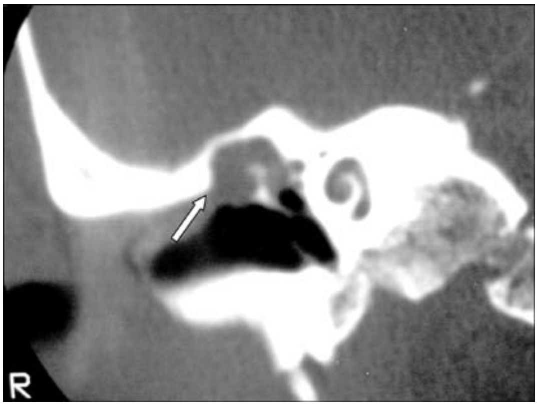
In chronic noncholesteatomatous middle otitis with ossicular erosion, the CT features are characterized by a thickening of the mucosal layer of the middle ear with subtle decalcification and erosion of part of the ossicular chain (Fig. 1).

In cholesteatomatous otitis the main CT features include: a nondependent soft tissue mass in the middle ear cavity with displacement and erosion of the auditory ossicles as well as erosion of the anterior and posterior tegmen tympany and scutum. In some advanced cases, erosion of the lateral wall of the lateral semicircular canal can be found (labyrinthine fistulas). Involvement of the intrapetrous facial nerve can occur. All the information obtained by means of HRCT is pivotal in presurgical planning (Fig. 2).

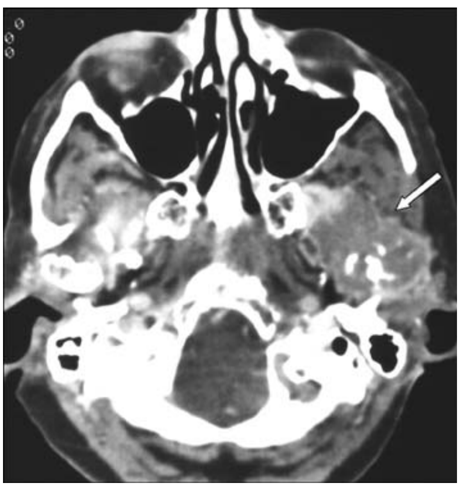
In external malignant otitis, CT represents an emergency examination because of the dramatic and rapid spreading of the disease.



Temporal Bone, Inflammatory Diseases, Acute, Chronic. Figure 1 Chronic noncholesteatomatous middle otitis: coronal CT scan. Partial erosion of the malleus and polypoid hyperplasia of the internal wall of the tympanic membrane (*arrow*).



Temporal Bone, Inflammatory Diseases, Acute, Chronic. Figure 2 Cholesteatoma of the middle ear: the coronal CT scan shows erosion of the scutum (*arrow*) and of the head of malleus.



Temporal Bone, Inflammatory Diseases, Acute, Chronic. Figure 3 External malignant otitis: axial contrast-enhanced CT scan. Inflammatory infiltration of adipose spaces (*arrow*) and bony erosion of the mandibular condyle.

The main CT features are: erosion of the bony wall of the external ear conduct and middle ear and infiltration of neighboring soft tissues. Involvement of the base of the skull and the temporomandibular joint can also be demonstrated. The inflammatory infiltration of the adipose spaces and the subcutaneous planes of the face can be better demonstrated by means of contrast-enhanced CT and/or MRI (Fig. 3).

The diagnosis of acute labyrinthitis is based on MR spin-echo (SE) T1-weighted (T1-W) sequences with contrast medium that shows focal increasing of the labyrinth membrane signal.

In ossificans labyrinthitis the absence of signal of the labyrinthine fluid on T2-W MR images is the main clue for the diagnosis.

Nuclear Medicine

Bone scintigraphy does not have a role in the assessment of acute and chronic diseases of the temporal bone.

Diagnosis

In almost all cases of inflammatory disease of the external and middle ear, the diagnosis is based on the clinical and otoscopy data. Diagnostic imaging is indicated in all those situations in which suitable information is not available for correct therapeutic planning and in local or cranial complications such as labyrinthine fistulas and/or intracranial spreading of the disease.

In cholesteatomatous disease it is well known that microscopic fiberoptic otoscopy allows an accurate evaluation of the tympanic cavity only, and is not able to assess the involvement of the attic, the antrum, and the mastoid.

Interventional Radiological Treatment

Interventional radiology does not have a role in the treatment of acute and chronic diseases of the temporal bone.

Teratocarcinomas

►Neoplasms, Chest, Childhood

Teratoma

A benign germ cell tumor with mature tissues derived from pluripotential cells of all three germinal layers. It is also known as dermoid cyst. Extragonadal teratomas are rare and location in the pancreas is unusual. These tumors are usually large and consist of unilocular or multilocular cysts filled with solid components, including sebaceous material, hair, teeth, calcium and skin. Microscopically the cysts are lined by ciliated or squamous epithelium, while the wall contains dermal appendages (sebaceous glands and hair follicles) and sometimes other tissues (teeth, cartilage, bone). At US examination the lesion has a polymorph appearance because of different prevalence of the three histological structures; in most cases dermoid cysts are complex masses with both liquid and solid components. They contain hyperechoic material (due to hair, teeth and fat) and hypoechoic areas due to fluid material. On CT imaging areas with low density, corresponding to fat, mixed with high density structures can be suggestive of dermoid cyst; a fat-fluid level can be frequently seen. On MR, dermoid cysts present a variable appearance, depending on their fat and fluid content.

Synonym

Germ cell tumor

Definition

Teratoma is a tumor consisting of tissues foreign to the site of origin, originating from all three germ layers.

Teratomas have solid and cystic components.

Overall most teratomas are benign lesions, but malignant degeneration is always possible, increasing with age. Calcification is present in two-thirds of patients.

Incidence

1. Approximately 1 of every 40,000 live births.
2. The tumor has a 4:1 female preponderance ratio.
3. When identified at birth, the neoplasms are more aggressive in boys.

Pathology/Histopathology

Ectodermal, mesodermal, and endodermal tissue.

Clinical Presentation

Teratoma may be found in any part of the body.

►Sacrococcygeal teratoma is the most frequent site (40% of all cases). The majority of cases are apparent at birth. They present as a mass at the level of the buttocks and extent below the gluteal fold.

►Presacral teratoma: pain, constipation, and urinary frequency or signs of urinary tract obstruction. There is weakness of the lower extremities if it invades spine.

Ovarian teratomata are often discovered incidentally. Symptoms may include a mass, abdominal pain, and abnormal vaginal bleeding. Bladder symptoms and gastrointestinal (GI) tract pain are less frequent. Acute symptoms may occur due to torsion.

Testicular teratomata presents as a painless scrotal mass and/or a hydrocele.

Mediastinal teratomata are often asymptomatic. When they become large, tracheal/bronchial compression resulting in chest pain, coughing, and wheezing may occur. Hyperglycemia or precocious puberty due to ectopic production of insulin or sex hormones is possible.

Imaging

The classic imaging appearance shows the presence of all three tissues types: bone, fat, soft tissue.

Conventional: soft tissue mass, scoliosis, mediastinal widening, canal/foramina widening, pedicle erosion, abnormal calcification.

Teratoma, Childhood. Figure 1 Sagittal CT-reconstruction shows a large mass originating from the sacral area containing fat and calcifications with enhancement after contrast injection.

Ultrasound assists in determining the cystic, or partial cystic, part of the tumor and the extent of the tumor.

Computed tomography (CT) often reveals the diagnosis, as it demonstrates fat and/or calcifications, their extent, and any bone destruction. After contrast medium administration, the solid component may show enhancement (Fig. 1).

Magnetic resonance imaging (MRI) is superior in delineating the extent of this tumor.

Occasionally, if there is blood within the cyst, it may show a fluid level.

Nuclear Medicine

Nuclear medicine is used for the evaluation of bone metastasis if the tumor shows malignant degeneration.

Diagnosis

Laboratory: Elevated levels of serum alpha fetoprotein (AFP), and beta human chorionic gonadotropin (HCG).

Biopsy: To differentiate benign from malignant tumor.

Benign teratoma; Cystic teratoma; Dermoid; Dermoid cyst

Definitions

Ovarian teratomas comprise tumors composed of mature or immature tissues of primordial germ cell origin. They can be classified into three main categories: ▶mature teratomas, ▶immature teratomas, and monodermal teratomas (1). The mature cystic teratoma which constitutes 99% of these tumors contains mature elements of ectodermal, mesodermal, and endodermal origin. The mature cystic teratoma also known as dermoid cyst or dermoid is the most common ovarian neoplasm of women younger than 45 years. Although teratomas may occur at any age, they typically affect a younger age group than epithelial tumors, and are the most common ovarian masses in children (2). Approximately 10% of teratomas occur bilaterally. ▶Malignant degeneration of benign teratomas is rare (1–2%), and usually occurs in the sixth to seventh decade of life (2).

Pathology/Histopathology

Sixty percent of cystic teratomas measure 5–10 cm in size (1). Macroscopically, benign teratomas present most often as unilocular tumors surrounded by a firm capsule of varying thickness (1). They contain fatty, sebaceous contents, and hair. The former is liquid at body temperature and semisolid at room temperature (1).

T

Squamous epithelium covers the inner wall of the dermoid. Hair follicles, skin glands, muscles, and fat are located within this wall. Arising from the cyst wall is commonly one or more protuberances, the dermoid plug or Rokitansky nodule, composed of a variety of different tissues. Hair, bone, or teeth and rarely cartilage as well as phalanges may be encountered in this region (1).

Clinical Presentation

The majority of benign teratomas remain clinically asymptomatic. They are often discovered incidentally during clinical examinations or imaging studies. Especially larger teratomas may cause nonspecific symptoms including pelvic pain, abdominal fullness, abdominal swelling, and dysuria. Rarely, abnormal uterine bleeding and hemolytic anemia may be associated with a dermoid (1). Teratomas may become clinically apparent due to complications which include in order of decreasing frequency ►torsion (16%), chemical peritonitis caused by ►rupture, and infection (3).

Mature teratomas tend to grow slowly, with an average diameter of 1.8 mm reported per year (2). Rarely, giant dermoids may be encountered, which grow to a size of up to 40 cm (1).

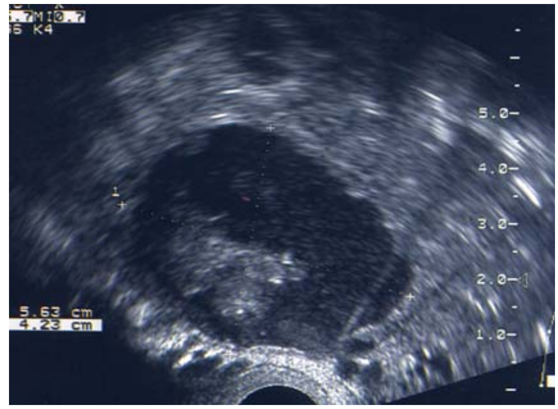
Rapid growth of a dermoid in a postmenopausal woman is a sign of malignant degeneration (2).

Imaging

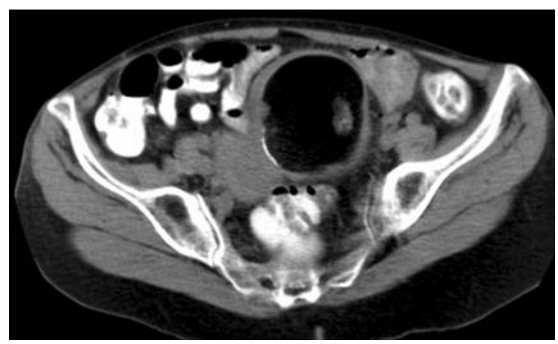
Conventional radiographs are not suited for the diagnosis of teratomas. Rarely, teeth, bone, or wall calcifications may be detected on abdominal plain films.

Sonography is the primary imaging modality for assessing suspected adnexal masses. The combination of transabdominal and endovaginal sonography combined with Doppler findings allows optimal characterization of the morphology and perfusion of adnexal masses. However, at ultrasound teratomas display a broad spectrum of imaging findings. They most commonly present as diffusely or partially echogenic masses with acoustic shadowing due to hair balls, calcifications, teeth, or the Rokitansky protuberance (Fig. 1). Layered lines and dots as well as fat-fluid levels include other findings. However, imaging findings are often noncharacteristic, and the dermoid plug may be misinterpreted as a solid lesion (4) (Fig. 1).

In the case of unclear sonography findings, *computed tomography (CT) and magnetic resonance imaging (MRI)* allow reliable demonstration of intralesional fat, which is the hallmark of benign teratomas.



Teratoma, Ovaries, Mature, Ovalar. Figure 1 Dermoid cyst in a 20-year-old patient: transvaginal sonography shows a well-delineated oval adnexal mass containing multiple homogeneous fine echoes and a solid protruding nodule, the Rokitansky nodule. In this patient the latter did not contain calcifications or teeth, and may be misdiagnosed as a solid element in ovarian cancer. (Courtesy of Dr. R. Gruber, Salzburg)



Teratoma, Ovaries, Mature, Ovalar. Figure 2 Dermoid cyst in CT. Noncontrast CT scan shows a 6.5-cm left adnexal mass that is located adjacent the uterine corpus. Its fatty density values are pathognomonic of a dermoid. The lesion contains areas of higher density representing floating hair and mural calcifications. The homogeneous thickening of the wall was caused by wall edema due to torsion.

In CT, attenuation values indicative of fat (−20 to −140 HU) are the pathognomonic finding (Fig. 2). Bone, teeth, and cyst wall calcifications can also be reliably detected. Contrast-enhanced CT assists in the demonstration of complications of dermoids, for example, torsion or malignant degeneration.

In MRI, detection of fat is also the key for the diagnosis of teratomas. In suspected dermoids, tailored studies consisting of T1-weighted imaging (WI) and T1-WI with frequency-selective fat saturation allow confirmation of dermoids in the majority of cases.

Suppression of the high-signal-intensity sebaceous contents or fat within the lesions is diagnostic (2). Gradient-echo opposed-phase imaging demonstrates a fat–water interface within the lesion. Furthermore, chemical shift artifacts in the frequency-encoding direction may assist in detecting fat and in its differentiation from hemorrhage (2). Contrast-enhanced MRI aids in further characterization in atypical cases and in the assessment of complications of teratomas.

Nuclear Medicine

Nuclear medicine has a very limited role in the assessment of teratomas. It may be useful only in detecting monodermal teratomas, for example, struma ovarii or carcinoids.

Diagnosis

The diagnosis of teratomas is based on the demonstration of sebaceous material or fat within an adnexal mass (Figs 2, 3). The size of teratomas ranges from 0.5 to 40 cm, with the majority measuring less than 10 cm.

As CT or MRT are more sensitive for fat than sonography, they are complementary in indeterminate cases or performed for the assessment of complications caused by dermoids (2).

In CT, demonstration of fat within a cystic adnexal lesion with or without calcifications is the pathognomonic finding of a benign teratoma. A fat–fluid interface may be produced by floating hair. In dermoid cysts, fat is demonstrated in more than 90% of cases, teeth in 31%, and calcifications in the dermoid plug, or more often in the cyst wall, in 56% (5) (Fig. 2).

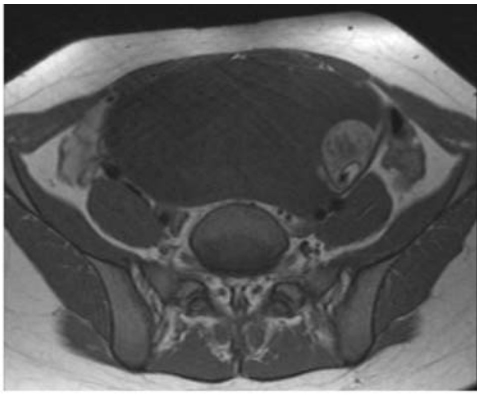
In MRI, the fatty sebaceous contents display typically very high signal intensity (SI) on T1-WI (2). The SI on T2-WI can be variable. As hemorrhagic adnexal masses, endometriomas and hemorrhagic cysts in particular may display similar signal intensities. Loss of signal on T1-WI with fat saturation allows the specific diagnosis of a dermoid.

Approximately 8% of benign teratomas do not show these straightforward findings in CT or MRI (3). In these patients, small foci of fat may be found in the dermoid cyst wall or in the dermoid plug (Fig. 3). When dermoids show no fat they cannot be differentiated from other cystic and solid ovarian tumors, including ovarian cancer.

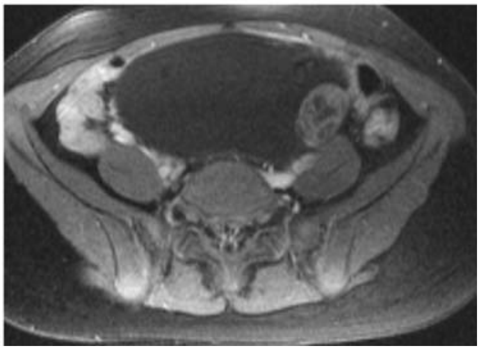
Malignant degeneration in mature cystic teratomas is typically due to carcinomatous or sarcomatous malignant transformation. Its prevalence is less than 1–2%, and it occurs in the sixth to seventh decade of life (2). CT and MRI findings include the presence of a dermoid with fatty contents and a heterogeneous solid component extending transmurally outside the capsule or enhancement of the Rokitansky nodule (3).

In children dermoid cysts may be associated with an ipsi- or contralateral immature teratoma. The latter presents typically as a large, often solid mass that may contain tiny foci of fat or calcifications.

a



b



Teratoma, Ovaries, Mature, Ovalar. Figure 3 Benign teratoma with small amounts of fat. In a 15-year-old girl, transaxial T1-WI (a) and T1-WI with fat saturation (b) show a large predominantly cystic lesion in the upper pelvis. At its left periphery it contains a mural nodule that shows intermediate to high signal intensity on T1-WI. The corresponding T1 fat saturation image shows fat suppression of an ovoid area smaller than 1 cm in diameter. At surgery, a 15-cm cystic dermoid was found, the Rokitansky nodule contained hair and only small areas of fat.

Synonyms

Thrombocytopenia

Definition

Thrombocytopenia is defined as low platelet counts ($<$140.000/µL).

Pathology/Histopathology

Thrombocytopenia may be due to a reduced production (marrow failure, megaloblastosis) or a decreased survival (e.g., immune thrombocytopenic purpura [ITP], thrombotic thrombocytopenic purpura [TTP]) of thrombocytes.

Clinical Presentation

Thrombocytopenia presents with prolonged bleeding from cuts, purpura, and bleeding from the mucous membranes.

Imaging

See "Nuclear medicine."

Nuclear Medicine

The survival time and sequestration site of the patient's own or donor thrombocytes can be determined with the ^{111}In-, ^{51}Cr- (Na_2–$^{51}CrO_4$), or ^{99m}Tc-HMPAO-labeling methods. As a rule, lipophilic ^{111}In-complexes are used (1, 2, 3, 4). The thrombocytes are separated as done with leukocyte labeling.

With a smaller thrombocyte count ($<$30,000 mm^{-3}), donor blood must be used, because the ^{111}In- or ^{51}Cr-uptake of the platelets is relatively low in comparison to the erythrocytes. After infusion of the labeled thrombocytes, blood samples are taken, first hourly and subsequently at intervals of 1–2 days until the half-life is reached. With a greatly reduced life span, blood samples are taken and measurements are performed at shorter time intervals. Simultaneously, the radioactivity from the liver, spleen, and heart (with reference to the blood pool) is measured.

The life span of the thrombocytes is 12 days (norm of the mixed population 3.5–6 days), and approximately one-third of them are found in the spleen.

The differential diagnosis should examine a reduced thrombocyte production as well as an increased thrombocyte sequestration, which may have immunological causes, for example, idiopathic thrombocytopenic purpura (ITP), or may be attributed to consumptive diseases. In particular, indications are the differential diagnosis of increased sequestration or a production disturbance, but also the therapy control of the thrombocytopenia. An increase in the thrombocytes in the spleen, and more seldom in the liver, is to be observed with organ-specific platelet sequestration and can support the indication for splenectomy.

Diagnosis

In addition to platelet counts, antiplatelet autoantibodies (e.g., IgG, ANA) and bone marrow samples should be analyzed.

Thrombosis, Caval Vein, Inferior

Patrick Haage
Department of Diagnostic and Interventional Radiology, HELIOS Klinikum Wuppertal, University Hospital Witten/Herdecke, Wuppertal, Germany
patrick.haage@helios-kliniken.de

Synonyms

Caval vein occlusion; Obstruction of the inferior vena cava

Definition

Acute or chronic thrombotic occlusion of the inferior vena cava

Pathology/Histopathology

Thrombosis of the caval vein is a potentially life-threatening disorder particularly due to its associated risks of pulmonary embolism, renal failure, and phlegmasia cerulea dolens (1). Predisposing factors for acute thrombosis of the pelvic veins and the inferior vena cava (IVC) include abdominal surgery, extrinsic compression by tumor or adenopathy, caval filter-associated thrombosis, trauma, hypercoagulable states, Budd–Chiari syndrome, and extension of peripheral DVT (1).

Clinical Presentation

Chronic venous hypertension resulting in the "postphlebitic syndrome" as a consequence of DVT has been estimated to affect 500,000 individuals in the U. S. alone. Hence, timely diagnosis and treatment are essential measures to provide adequate care for the patient. This postulation is substantiated by the fact that the organization of a venous thrombus proceeds much faster than that of an arterial thrombus, thereby aggravating successful treatment strategies. In addition, early clot clearance lowers the risk for pulmonary embolism and post-thrombotic sequelae.

Imaging

In the last decade, ultrasound (US) has gained more importance in the diagnosis of venous occlusion. If a thrombus is present, the vein is distended and incompressible. The physiologic sharp definition of the venous wall is lost and echogenic material inside the lumen may be noted. Very fresh thrombus may be nearly anechoic and consequently not easily visible (2). Color flow Doppler sonography is supportive in these cases as the thrombus will appear as a color flow void. The most useful criterion for venous thrombosis is failure of the vascular lumen to collapse entirely under moderate pressure. Under regular circumstances, flow is identified as a spontaneous phasic pattern at rest with augmentation on calf compression. When thrombus occludes the vessel lumen, no flow is identified. Venous flow is generally phasic, decreasing in inspiration and increasing in expiration. A proximal obstruction will prevent such respiratory variation resulting in a continuous flow pattern and will also avert venous distension generally seen when performing the Valsalva maneuver.

Color flow Doppler imaging is necessary for the evaluation of pelvic vessels (2), but it is often limited due to the intrinsic difficulty in clearly outlining the pelvic structures. Ultrasonography is the primary diagnostic modality in the pregnant patient and can also serve as a screening test in other patients with suspected thrombosis, proceeding to more invasive testing if the results remain vague.

Venography has long been considered the gold standard for identifying proximal venous occlusion because it allows a complete work-up of the lower limb up to the IVC. Counter to sonography, diagnosis is less restricted by adiposity and bowel gas. It is generally a safe procedure and is often essential in case of failure of sonography and in the absence of CT or MR facilities.

Both CT scanning and MR imaging can accurately provide the diagnosis of pelvic and iliac vein thrombosis. These diagnostic modalities are less dependent on the technical expertise of the investigator than US. CT venography requires the application of IV contrast material and is thus contraindicated in patients with renal failure. Pregnancy is another exclusion criterion for CT imaging. MR venography, not adversely affected by these limitations, provides superior sensitivity and good specificity for the diagnosis of central vein thrombosis compared with contrast venography and in due course could surface as the study of choice for the diagnosis of thrombosis. For pelvic deep venous thrombosis, the sensitivity and specificity are reported to be 100 and 95%, respectively (3). Furthermore, MR venography can demonstrate other causes of symptoms, such as enlarged iliac lymph nodes and pelvic masses. Naturally, MR imaging is restricted in patients with claustrophobia and contraindicated in patients with pacemakers or ferromagnetic clips.

In brief, all current imaging methods for the diagnosis of proximal venous occlusion have their specific disadvantages. Magnetic resonance imaging has the greatest potential for the future because it is noninvasive, does not require contrast agent, carries no exposure to ionizing radiation, and is extremely precise and reproducible. Its accuracy is maintained through comprehensive imaging of the full extent of the occlusion including the calf and pelvis, and sensitivity and specificity below the knee are high; accordingly MR imaging is increasingly employed in the diagnosis of acute venous occlusion not only in pregnancy but also in high-risk patients. It is moreover well suited for diagnosis of recurring thrombosis and asymptomatic disease. Lack of widespread availability of MRI and cost limit its use at present; however, as imagers become more plentiful and scanning speed increases, expenses are decreasing and are becoming comparable to those of other noninvasive tests.

Diagnosis

Since clinical diagnosis is unreliable, imaging modalities need to be integrated in the diagnostic course of action.

Interventional Radiological Treatment

Concerning the therapeutic approach towards ▶thrombosis, anticoagulation alone does not diminish thrombus burden or re-establish valve function. Surgical thrombectomy, although able to adequately remove thrombus, has traditionally been allied with a high rate of recurrence of thrombosis and moderately good clinical results; thus, surgical venous thrombectomy has not been broadly established or regularly employed. Catheter-directed thrombolysis is a potentially attractive alternative for restoration of venous patency and preservation of valve function. In a multicenter registry, marked lysis was observed in 88% of patients with acute iliofemoral occlusion. The 1-year primary patency rate following catheter-directed thrombolysis was 64%. Additional treatment with stent placement was required to treat uncovered stenoses and short residual occlusions that were resistant to lysis in 33%; 94% were performed in the iliac segments. The average urokinase dose was 7.8 million IU and the mean duration of intervention was 53.4 h.

On the other hand, pharmacological treatment of intravascular thrombus is limited by the lengthy time to effect and medication-related severe side effects. Additionally, thrombolytic therapy is costly, labor intensive, and may require several days of intensive care unit hospitalization. Also, this form of therapy entails a significant risk for hemorrhagic and embolic complications and is contraindicated in the postoperative patient. Response may be held up in a large clot burden, resulting in only partial lysis.

Considering these limitations and contraindications of anticoagulation, thrombolysis, and surgical removal, percutaneous interventional techniques have more recently been added to the therapeutic armamentarium for the management of vascular pathologies. In order to perform a safe procedure allowing rapid flow restoration several different types of percutaneous mechanical thrombectomy devices have been developed and tested *in vitro* and *in vivo* (4), which use combinations of mechanical dissolution, fragmentation, and aspiration.

Since then, mechanical thrombectomy devices have proved to be a valuable, fast, and secure treatment tool in venous thrombosis by enabling the recanalization of occlusions in combination with minimal invasiveness and a low bleeding risk, in so doing offering the potential of low (post)procedural morbidity and mortality (Fig. 1) . In cases where thrombolysis is not contraindicated, an adjunctive pharmacological thrombolytic therapy, balloon angioplasty, or endovascular stent deployment, may be of assistance if hemodynamically significant thrombus remains that has not been cleared by the mechanical thrombectomy procedure. Even though only a limited number of patients in a study by Kasirajan received thrombolytic agents, the duration of therapy was significantly shorter than with lysis alone with 20.2 ± 19.4 h (5). After initial thrombus debulking, the consecutive reduction of the thrombus load

led to an increase of the surface area of the thrombus exposed to lytic agent. The risk of hemorrhagic complications can be decreased in light of the decreased quantity of lytic agents required and shortened overall agent exposure.

Placement of an inferior vena cava filter should be considered when there is documented recurrent pulmonary embolism despite adequate anticoagulation or if anticoagulation is contraindicated. It should be kept in mind that the filter does not stop the thrombus growth, and thus additional treatment will be needed.

In conclusion, there are diverse treatment possibilities in proximal vein thrombosis for the interventional radiologist. To obtain instantaneous clot removal with flow restoration and enhanced circulatory hemodynamics within minutes, less hemorrhagic complications, as well as fewer expenditure and in-room time, the primarily mechanical technique shows the most future potential. To prevent procedure-related pulmonary embolism, any mechanical thrombectomy device should only be used in combination with an impermanent cava filter.

Synonyms

Obstruction of the superior vena cava; Superior caval vein occlusion

Definition

Acute or chronic thrombotic occlusion of the superior vena cava.

Pathology/Histopathology

Thrombosis of the superior vena cava is most often caused by intrinsic or extrinsic obstruction attributable to a wide variety of disease entities such as malignancy, extension of central venous thrombosis to the superior vena cava, indwelling catheter induced disease, fibrosing mediastinitis, irradiation, and tuberculosis to name a few.

Clinical Presentation

Symptoms range from congestion and edema of the upper thorax, the face, and the arms to dyspnea, dysphagia, cognitive dysfunction, and pulmonary embolism.

Imaging

Synonyms

Iliac vein obstruction; Iliac vein occlusion

Definition

Acute or chronic thrombotic occlusion of one or both iliac veins.

Pathology/Histopathology

Patients with iliac vein thrombosis are at serious risk for pulmonary embolism and long-term clinical consequences of post-thrombotic syndrome. Approximately 50% of patients with proximal deep vein thrombosis (DVT) have pulmonary perfusion defects characteristic of pulmonary embolism (1).

Iliac vein thrombosis typically results from extension of thrombus from the femoropopliteal system, whereas an isolated acute iliac vein occlusion is rather rare and has been reported mainly as a complication in the postpartum period. Furthermore, thrombosis of the pelvic veins, including the internal iliac veins, can be seen in women with pelvic inflammatory disease and in men with involvement of the prostatic plexus.

Clinical Presentation

The development of symptoms depends on the extent of thrombosis, the existence of proficient collateral veins, and the severity of associated vessel occlusion and inflammation (2). Iliac vein occlusion should be suspected in patients with abdominal pain, a unilateral pelvic mass, uterine infection, painful limb swelling, and fever that fails to respond to appropriate treatment, especially in trauma patients and postoperatively. However, clinical diagnosis of venous thrombosis in symptomatic patients is neither particularly sensitive nor specific (3).

Imaging

Thus, in case of suspected iliac vein thrombosis, an early diagnostic imaging workup is indispensable. Concerning pathology imaging, color flow Doppler imaging is often restricted due to obesity and bowel gas. Venography has long been considered the gold standard for identifying proximal venous occlusion. Nowadays, CT scanning and MR imaging have proven to even more precisely diagnose acute iliac vein occlusion. MRI is the preferred technique because it is noninvasive, does not require contrast agent, carries no exposure to ionizing radiation and is highly accurate and reproducible.

Diagnosis

Since clinical diagnosis is unreliable, imaging techniques need to be incorporated in the diagnostic process.

Interventional Radiological Treatment

Regarding treatment of deep venous thrombosis, it is a well known fact that patients are faced with a significant morbidity rate and manifest post-thrombotic complications, including renal failure, phlegmasia cerulea dolens, and postphlebitic syndrome, when treated conservatively. Post-thrombotic syndrome is observed in 79–86% of cases after 5–10 years of follow-up (4).

There is a clear correlation between early recanalization of the thrombosed vein and subsequent preservation of venous valve competence. This calls for prompt removal of the underlying pathology. From an interventional radiologists point of view, apart from traditional catheter directed thrombolysis, mechanical thrombectomy has also been reported to be a quick and safe treatment modality by enabling the recanalization of thrombotic occlusions in conjunction with minimal invasiveness and a low bleeding risk (Figs. 1 and 2).

krupski@uke.uni-hamburg.de

Synonyms

Portal vein thrombosis; Portomesenteric vein thrombosis

Definition

►Mesenteric vein thrombosis is defined as clot formation within the mesenteric venous system. A high percentage of these growing clots end up as portal vein thromboses.

Pathology/Histopathology

Mesenteric vein thrombosis is a rare disease with an incidence of approximately 2/100,000 (A). In 85% of patients, at least one of the risk factors listed in Table 1 is present at the time of diagnosis. Clot formation can be found in hepatopetal and hepatofugal directions, starting with normal red and white blood cell content within the fresh (red) thrombus and a loose fibrinoid network-caused by thrombokinase liberated from degrading thrombocytes during hemostasis. No tense adherence to the vessel wall is present. When vessel wall alterations such as tumor infiltration or infection cause thrombosis, a mixed type of clot is seen that contains fresh components (red thrombus as described above) located in the growing thrombus head as well as a firmly compacted fibrinoid network and thrombocyte aggregations with only a few red and white blood cells enclosed (white thrombus) and adherent to the vessel wall. In an old or partially recanalized thrombus, the latter appearance will be the predominant histopathologic presentation, with entire adherence to the vessel wall.

Clinical Presentation

The clinical findings in mesenteric and portal vein thrombosis are strictly associated with the development of portal and mesenteric hypertension. Nonspecific symptoms such as upper abdominal pain, nausea, and vomiting are frequently seen and may be associated with the cause of mesenteric vein thrombosis. Early symptoms of enteral

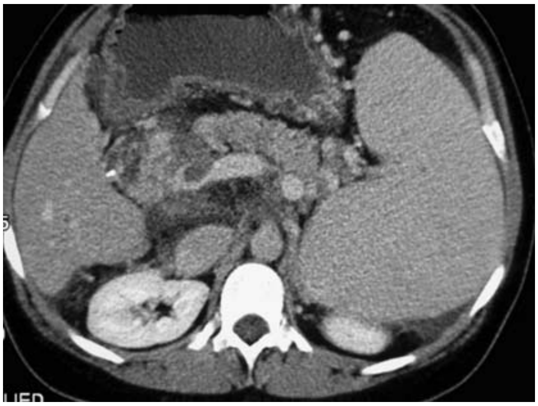
Abdominal trauma

venous congestion may also be seen. Upper gastrointestinal tract bleeding from either esophageal, gastric fundal, or atypical intestinal varices is the most important clinical sign of emerging portal venous hypertension. Variceal bleeding contributes to 5–20% of the mortality rate, resuming three-fourths of the total mortality (7–25%) (1). Other symptoms, including formation of collaterals, ascites, hypertensive gastropathy, splenomegaly, and thrombocytopenia, are postacute phase symptoms representing long-standing vascular occlusions, and they need time to develop. Bloody diarrhea is the leading symptom of enteral venous congestion and is a warning sign of bowel wall necrosis.

Imaging

Color-coded duplex ultrasonography is the first-line method of choice for detecting proximal portomesenteric thromboses. Due to distention of the gut and diffuse air accumulation (paralytic ileus) with emerging ischemia, ultrasound examination of the mesenteric vein can be very difficult or even impossible. Furthermore, because ultrasound is an operator-dependent technique, its reliability in mesenteric vein thrombosis is questionable. Therefore, cross-section imaging—magnetic resonance (MR) imaging and computed tomography (CT)—should be preferred for depicting mesentericoportal thrombosis (superior temporal and contrast resolution as well as extravascular anatomy and complications) (2). In cases without peritonitis, multidetector row CT angiography or three-dimensional contrast MR angiography should be the first imaging step in order to depict thrombosis as early as possible; in cases with peritonitis, helical (particularly multidetector row) CT will assure depiction of both the vascular situation and associated complications (Figs 1–3).



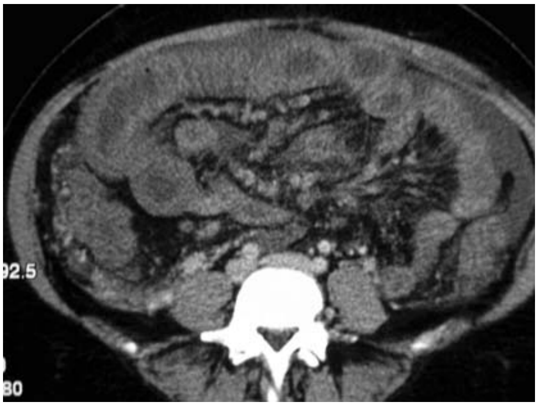
Thrombosis, Venous, Mesenteric. Figure 1 Axial multidetector row computed tomographic image of a 35-year-old woman. The thrombus head is in the confluence area of the main portal vein. Hilar and intrahepatic portal veins are patent as well as the splenic vein.

Thrombosis, Venous, Mesenteric. Figure 2 Axial multidetector row computed tomographic image of the same patient as in Fig. 1. No contrast medium is visible in the infrapancreatic mesenteric vein, whereas the mesenteric artery shows marked contrast. This finding is consistent with the diagnosis of complete mesenteric vein thrombosis.

Interventional Radiological Treatment

Although therapeutic approaches to the treatment of mesenteric vein thrombosis as well as portal vein thrombosis are controversial (3), and no evidence-based data yet exist, there is a clear trend for two basic therapeutic strategies, depending on the underlying circumstances:

1. If the mesenteric vein thrombosis is caused by liver cirrhosis with coincident portal venous hypertension, placement of a ►transjugular intrahepatic portosystemic shunt (TIPS) in combination with thrombolysis and/or mechanical thrombectomy has proven to be beneficial (4, 5). The combination of thrombectomy and TIPS is a must in order to create a substantial flow rate in the recanalized mesenteric vein and prevent a rethrombosis. The best results can be expected if mechanical thrombectomy (fragmentation by balloon or basket) is followed by thrombolysis (for hemodynamic reasons, preferably systemic) using rTPA or urokinase (5). High-dose heparin treatment should be given for a few days and then changed to a low-dose regimen (fragmented or low molecular). Capturing of large thrombus fragments with a stent may be necessary. Preexisting mesenteric vein stenosis must be treated by percutaneous transluminal angioplasty (PTA) without stent placement.



Thrombosis, Venous, Mesenteric. Figure 3 Axial multidetector row computed tomographic image of the same patient as in Figs 1 and 2. There is marked ascites in the left paracolic area, along with massive distended bowel walls representing venous congestion due to mesenteric vein thrombosis. Extraluminal or intraperitoneal gas is not yet visible.

2. In patients without portal venous hypertension and liver cirrhosis, systemic anticoagulation is the current therapeutic state-of-the-art, resulting in complete recanalization in 40% of cases and partial recanalization in 55% (4). Interventional radiological treatment, although offering excellent and impressive results on first sight, bears a high complication rate—up to 60% (5), and for surgery, a mortality of 39% has been published (6).

In both groups, follow-up controls by ultrasound or CT and continuation of anticoagulation for at least 12 weeks as well as treatment of the underlying disease are recommended.

patrick.haage@helios-kliniken.de

Synonyms

Ovarian vein obstruction; Ovarian vein occlusion

Definition

Acute or chronic uni- or bilateral thrombotic occlusion of the V. ovarica.

Pathology/Histopathology

Pregnancy and the postpartum period are associated with an elevated risk for deep venous thrombosis, which can be complicated by sometimes fatal pulmonary embolism (1).

A typical location of postpartal thrombosis is the ovarian vein, a however uncommon complication which may lead to dramatic clinical manifestations due to migrated septic pulmonary thrombi (2). Thrombus load may extend into the inferior vena cava, the renal veins and the iliofemoral veins; multiorgan failure, acute ureteral obstruction, spontaneous kidney rupture, and ovarian infarction are further feared complications. The proposed pathogenesis starts from an infectious process expanding from the uterus to the ovarian vein and stasis. A prothrombotic predisposition is discussed as a supportive causative factor.

Incidence is reported to be between 1 of 600 and 1 of 2000 deliveries (1). In nonpregnant or non-postpartal women, ovarian vein thrombosis is extremely unusual.

Clinical Presentation

Main symptoms of ovarian vein thrombosis are non-specific and consist of pain in the flanks, the lower quadrant or the iliac fossa, and associated with fever and leukocytosis. Differential diagnoses include adnexal torsion, endometritis, pyelonephritis, urinary tract infection, thrombosis of the renal veins, and most notably acute appendicitis, whereby discomfort in the appendicitis is situated on the right side. The classical clinical picture is pain in the lower abdomen and elevated temperature not responding to antibiotic treatment. Ninety percent of women are admitted within 1–17 days after delivery (1).

In 80–90% of cases, ovarian vein thrombosis is observed in the right ovarian vein (3), an isolated left ovarian vein thrombosis occurs in 6%, and a bilateral occlusion is noted in 14% (4).

Imaging

The diagnosis of ovarian vein thrombosis can be established by ultrasound, CT, or MR imaging. Color Doppler sonography is the least invasive diagnostic procedure, however may be limited due to bowel gas and obesity, and aggravated by additional intraabdominal pathologies. Spiral CT with intravenous injection of iodinated contrast allows evaluation of the ovarian veins, but entails the application of ionizing radiation.

MR imaging is helpful for investigating the origin of puerperal fever like an abscess or infected hematoma. Contrast-enhanced MR angiography based on T1 shortening is known to offer an excellent visualization of the vascular system. According to Nagayama, coronal source images are useful for evaluating the extent of a thrombus. His workgroup accordingly advocated magnetic resonance angiography (MRA) in postpartum patients with suspected vascular disease (5).

Nevertheless, as a rule of thumb, if ovarian vein thrombosis occurs during pregnancy, administration of contrast material should be avoided. Gadolinium-based contrast material is known to cross the placenta after intravenous administration and appear within the fetal bladder. Its half-life in the fetal circulation and effect on the developing human fetus are unidentified. After delivery and during lactation, traces of gadolinium-based contrast material are excreted into the breast milk after intravenous administration. A minimum of 24-hour postponement of breast-feeding is thus recommended.

Confident diagnosis of venous thrombosis with abandonment of the objectionable contrast agent injection has for years been considered complicated because signal intensities within the vein can be confused with the flow signals of a nonthrombosed ovarian vein. More recent nonenhanced MR venography techniques with TRUE-FISP sequences however can reliably depict thrombosed veins (5).

Kubik-Huch and coauthors compared sonography, CT, and MRI as diagnostic tools in suspected ovarian vein thrombosis and reported sensitivity and specificity values of 55.6% and 41.2%, 77.8% and 62.5%, and 100% and 100% for duplex ultrasonography, contrast-enhanced CT, and MRA, respectively (3).

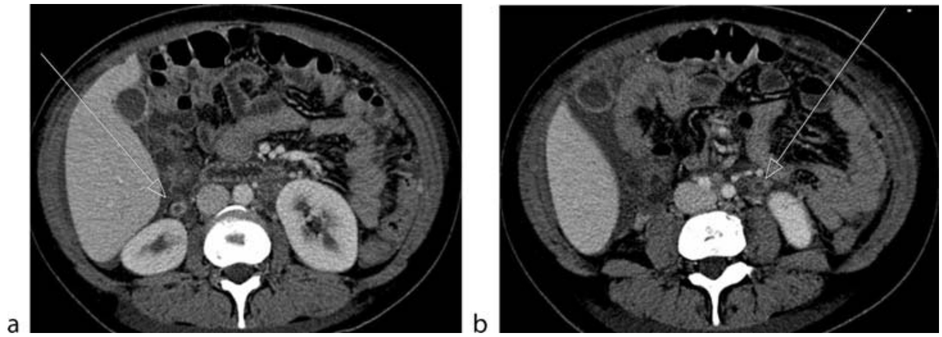
Consequently, nonenhanced MRA can be recommended for the diagnosis of ovarian vein thrombosis; but because of MR-intrinsic contraindications, cost, and speed, contrast-enhanced multislice CT is an acceptable option (Fig. 1). As an initial evaluation modality, in prepartum women and potentially for follow-up, ultrasound can be applied.

Diagnosis

Due to the nonspecificity of symptoms diagnostic imaging is often required.

Interventional Radiological Treatment

In contrast to his/her involvement in the diagnostic workup, the radiologist is only very infrequently involved in the treatment of ovarian vein thrombosis, which is essentially medical. Anticoagulation is normally administered,



Thrombosis, Vein, Ovarian. Figure 1 Contrast enhanced CT of a 26 year old woman 9 days after cesarean section with persistent fever shows extensive bilateral ovarian vein thrombosis (arrows) and infrahepatic ascites.

although there is no uniform conformity regarding the length of anticoagulation treatment. Broad-spectrum antibiotic application should be instantly initiated after acquisition of appropriate cultures.

Although evidence is limited, treatment of women with postpartal deep venous thrombosis not restricted to the ovarian veins by means of timely percutaneous catheter-directed thrombolytic therapy, if necessary combined with thrombectomy, angioplasty, and/or stenting may be an alternative to more invasive surgical procedures and less successful medical treatments (6). In case of extension of the ovarian vein thrombosis into the inferior vena cava, the deployment of a vena cava filter and interventional or surgical caval thrombectomy may be inevitable. The interventional procedures should be combined with the continuous administration of anticoagulants and antibiotics (7).

To conclude, with the introduction of modern imaging techniques the diagnosis of an ovarian vein thrombosis can be made straightforwardly. Even though postpartum ovarian vein thrombosis is a rare clinical entity, early detection of the condition is of vital importance to bring about the adequate treatment and avoid potential serious aftermaths.

Ovarian vein thrombosis should be suspected in any postpartal woman presenting with inexplicable lower abdominal pain, fever, and leukocytosis.

Ultrasound, and owing to circumstances, subsequent MR or CT imaging is advocated for diagnosis to avoid the significant morbidity and mortality rates if the thrombosis and accompanying disease is not adequately treated.

Anticoagulants in combination with broad-spectrum antibiotic are usually sufficient for treatment. In case of widespread thrombosis not only involving the ovarian veins, catheter-directed thrombolysis, mechanical thrombectomy, or stent- and filter-placement may be considered. The decision to treat must then be made on an individual basis.

Thrombosis, Vein, Peripheral

Patrick Haage
Department of Diagnostic and Interventional Radiology, HELIOS Klinikum Wuppertal, University Hospital Witten/Herdecke, Wuppertal, Germany
patrick.haage@helios-kliniken.de

Synonyms

Peripheral vein occlusion; Peripheral venous obstruction

Definition

Acute or chronic thrombotic occlusion of peripheral veins, typically the deep veins of the lower extremity.

Pathology/Histopathology

The risk of suffering from pulmonary embolism (PE) for patients with lower extremity deep venous thrombosis (DVT) is as high as 60%, if left untreated. The development of symptoms depends on the degree of thrombosis, the existence of capable collateral veins, and the severity of allied vessel occlusion and inflammation.

Clinical Presentation

Specific clinical symptoms to attain the proper diagnosis are lacking. Often, deep venous obstructions are clinically unremarkable, particularly when the thrombus does not totally obstruct the vessel or when the thrombosis is well collateralized. If complaints exist, the patient commonly presents with a painful and swollen extremity.

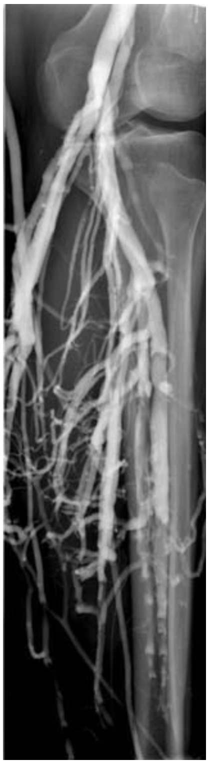
Imaging

Diagnostic imaging modalities and possibilities include ultrasound (US), contrast venography, CT, and MR imaging. More precisely, venography is considered the reference gold standard of diagnosing lower extremity

DVT. Even at present, with a multiplicity of noninvasive tests, venography is important particularly for diagnosing symptomatic calf thromboses that do not extend proximally, recurrent venous occlusion in patients who are again symptomatic, and occlusions in patients who have a high clinical suspicion and a negative or equivocal, noninvasive study (Fig. 1). Typical findings in acute venous thrombosis are a filling defect with surrounding contrast medium "tram-tracking," or sudden vessel cut-off distant from a valve in the case of total vein occlusion. The sensitivity of venography is close to 100%, and the test precisely detects acute venous occlusions of the entire leg including the calf as well as the pelvic veins and the inferior vena cava, which may be overlooked by other diagnostic modalities such as ultrasound (1).

Nonetheless, venography is invasive and has well-known complications such as allergic reactions, nephrotoxicity, and phlebitis, and therefore its application is limited to charily selected patients. In up to 18% of cases venography may be nondiagnostic due to misinterpretations, artifacts, and interobserver disagreement (2). Vessel underfilling and superposition are problems regularly seen in calf-vein phlebography.

Duplex US with manual compression is the most sensitive and specific of the routinely available noninvasive tests when performed by a skilled operator. In many cases, ultrasound has substituted contrast venography. The advantages of US are that it also identifies other distinctive features such as Baker cysts, lymphadenopathy, hematomas, femoral artery aneurysms, superficial thrombophlebitis, and abscesses. Also, it is broadly available and comparatively cheap.



Thrombosis, Vein, Peripheral. Figure 1 Venography of a 28-year-old woman shows acute thrombosis of the peroneal vein, which had not been detected by sonography.

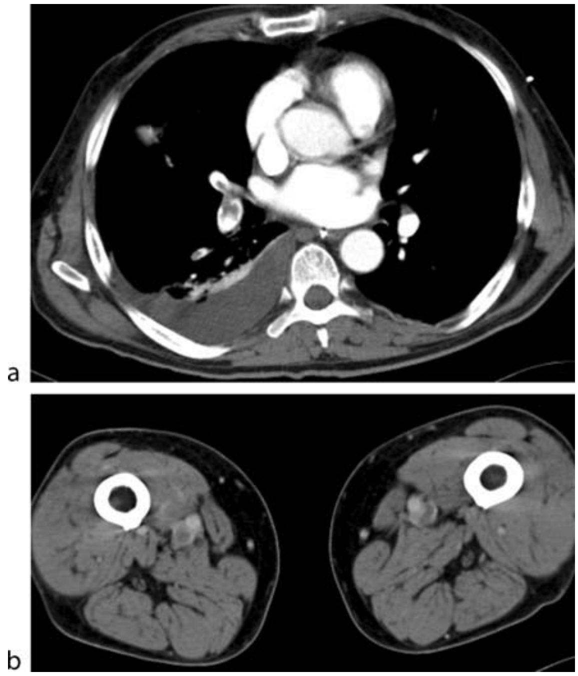
Decisive factors for the diagnosis of DVT by ultrasound comprise failure of the vessel to collapse on manual compression, delineation of thrombus within the usually echo-free lumen, and absent or abnormal venous pulsation on Doppler scanning (3). Failure to compress the common femoral or popliteal vein is usually diagnostic of a first episode of venous occlusion in symptomatic patients with a positive predictive value of about 97%. Full compressibility of both of these regions suggests proximal patency in symptomatic patients with a negative predictive value of about 98% (3).

As a general rule, duplex ultrasound is more precise when the patient has symptoms of acute venous obstruction, and when the occlusion is in the thigh rather than above the groin or below the knee. Venous US has a sensitivity of only 50–75% for isolated distal calf-vein occlusion, and the clinical usefulness of venous US of the distal veins is unclear. A power Doppler study showed a sensitivity of 100%, a specificity of 79%, a positive predictive value of 71%, and a negative predictive value of 100% in detecting an isolated calf-vein thrombosis (4). The peril of calf-vein occlusions is that they can extend to the larger, more proximal veins, thus increasing the threat of PE. Repetition of the ultrasound exam within seven days is therefore indicated in those patients with a primarily normal US exam.

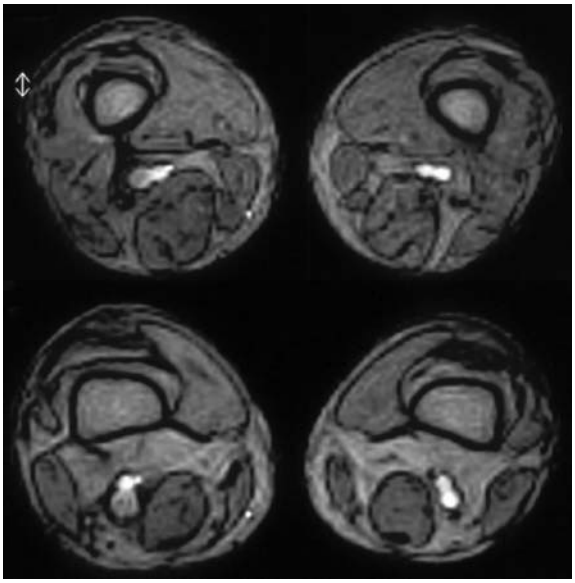
In adipose patients or those with a great amount of lower extremity edema ultrasound can be technically difficult. In asymptomatic patients, the usefulness of US is even more limited. These limitations of sonography and its well-known low sensitivity in recurrent venous occlusion should be recognized in the diagnostic work-up of suspected lower-limb venous occlusion.

In brief, if the pretest probability is high and the results of sonography are nondiagnostic or are discordant with the clinical assessment, venography should be considered.

As an option, spiral CT venography has been proposed as an accurate tool for the evaluation of acute DVT. CT can spot thrombosed veins and is considered superior to conventional venography by identifying intraluminal thrombi, potentially distinguishing fresh thrombi from older ones, and depicting soft tissue changes such as extrinsic compression of the vein. The prevalence of unsuspected venous thrombosis detected by CT in a study was found to be 1.1% (5). In one study, spiral CT venography of the lower extremity



Thrombosis, Vein, Peripheral. Figure 2 **(a) 55-year-old male patient. Right-sided pulmonary embolism at contrast-enhanced spiral-CT and (b) Subsequent demonstration of bilateral deep venous thrombosis of the thigh without additional contrast agent injection.**



Thrombosis, Vein, Peripheral. Figure 3 **Real-time radial plain MR angiography demonstrates a long-segment right-sided superficial femoral vein thrombosis in a 73-year-old male patient with acute renal failure. Thrombus displays low signal intensity in axial orientation.**

showed a sensitivity of 100% and a specificity of 96% (6). The quality of venous opacification with CT venography compared with ascending phlebography was rated superior in all segments; however, the application of CT venography alone is limited due to high costs and concomitant radiation dosage and is presently only applied as an adjunct to pulmonary CT angiography in case of suspected PE. If PE is proven, an indirect CT phlebography can be performed without the need of additional contrast medium application (Fig. 2).

The advantage of MR imaging is that it discriminates an acute thrombosis from chronic thrombosis more accurately than US does (7). Moreover, MR imaging depicts the adjacent tissues and accordingly may point to the cause of the occlusion. Besides, it is less operator dependent than US. It is precise for the diagnosis of DVT of the calf, which can easily be missed by US, and it can be performed in postoperative patients with full-length leg plaster casts. The sensitivity and specificity are reported to be as high as 100% for acute venous occlusion of the thigh and 87–100% and 97% for occlusion of the calf, respectively (8,9). Both legs can be evaluated simultaneously in one session and testing can be easily repeated to monitor thrombus evolution. Due to its high cost and limited access, MR venography is not yet used for the routine diagnosis of lower extremity venous occlusion only; however, it may be useful after other inconclusive tests have been performed or in case of multi-segment thrombosis (Fig. 3).

Diagnosis

Since clinical diagnosis may be erratic, imaging techniques need to be incorporated in the diagnostic process.

Interventional Radiological Treatment

Once the diagnosis of peripheral vein thrombosis has been verified, the next step is its adequate management, since significant spontaneous thrombus disintegration in deep venous thrombosis is very rarely observed. Quite the contrary, the thrombi are likely to grow appositionally and embolize into the pulmonary arterial tree. Chronic venous insufficiency attributable to postthrombotic syndrome is a common end result of DVT. The indications for treatment are reestablishment of unobstructed venous return, impediment of recurrent thrombosis, conservation of venous valve functionality, and prevention of pulmonary embolism.

Systemic anticoagulation with heparin followed by therapy with warfarin sodium can be considered the current standard for peripheral DVT treatment. This treatment, however, does not endorse lysis to decrease the thrombus load, nor does it support the restitution of venous valve function. Consequently, anticoagulation does not guard the limb from subsequent postthrombotic syndrome, which can occur months to years after the acute thrombotic incident. Up to two thirds of patients with acute iliofemoral venous occlusion suffer from edema and pain, and 5% develop ulcers even though adequately anticoagulated.

Thrombolysis is a therapeutic alternative because it has the potential for rapid restitution of venous patency and perpetuation of venous valve function. Thrombolysis may help avoid the dreaded long-term aftermaths of DVT. Thrombolytic agents have been reported to achieve superior results compared to standard anticoagulation therapy for attaining early thrombolysis, even when systemically applied. In a meta-analysis of the results from 13 randomized studies, Comerota and Aldridge (10) pointed out that only 4% of patients treated with heparin had substantial or complete lysis compared with 45% of patients randomly assigned to receive systemic streptokinase therapy.

In spite of these results, broad routine introduction is still delayed. One of the reasons may be that by using systemic administration the drug does not consistently reach and penetrate the thrombosed venous segment in an adequate concentration as to grant most beneficial results.

Injection of the thrombolytic drug straightforwardly into the thrombus may put forward considerable advantages over the systemic route. First hints at the capability of catheter-directed thrombolysis can be derived from the survey by Semba and Dake (11). They noted complete lysis in 72% of their patient collective with sequencing symptom resolve.

Direct delivery of the lytic agent improves its efficiency, because the agents work through plasminogen activation in the thrombus. Lysis rates can be enhanced, the duration of treatment can be decreased, and problems related with the exposure of the patient to systemic thrombolytic therapy may be reduced by delivering higher concentrations of the agent. Semba's results were sustained by the figures from a multicenter venous registry, where marked lysis through catheter-directed thrombolysis was achieved in 83% of patients with femoral–popliteal thrombosis with a 1-year primary patency rate of 47% (12).

Multiple contraindications to the use of thrombolytic agents do limit the value of this treatment; it was reported to be possible in only 7% of patients in one survey. Major bleeding complications were described in 54 (11%) of 473 patients included in the registry (12); of those, 21 (39%) occurred at the venous puncture site, and 7 (13%) resulted from a retroperitoneal hematoma. In an additional 15 (28%) patients, other bleeding complications occurred. No immediate deaths were observed as a result of a major bleeding complication.

Altogether, catheter-directed thrombolysis can be employed to dissolve thrombus safely and effectively from the deep venous system in carefully selected patients with symptomatic venous lower limb occlusion and no contraindications to treatment. The best results can be expected in patients with acute symptoms and no history of preceding thrombosis treated by local thrombolysis. Long-term benefits of this kind of therapy are presently unknown and cannot conclusively be named. Thrombolytic therapy has the aptitude of protecting the patient against chronic venous insufficiency by accomplishing flow and safeguarding valve function.

In cases of isolated calf-vein thrombosis, anticoagulation therapy should be sufficient to avoid chronic venous insufficiency. Mechanical thrombectomy devices at this time cannot be recommended in deep venous thrombosis located in the lower extremity only. In case of recurring pulmonary embolism due to DVT albeit proper therapy, caval filter implantation should be considered.

In conclusion, therapeutic options in DVT consist of anticoagulation and, whenever indicated and possible, thrombolytic recanalizing measures.

Thrombosis, Vein, Renal

PHILIPPE OTAL, FRANCIS JOFFRE
CHU, Toulouse, France
joffre.f@chu-toulouse.fr

Definition

The term "renal vein thrombosis" (RVT) is usually restricted to the cruoric form of occlusion. Direct extension to the renal vein of a renal malignancy does not correspond to the common definition of RVT and is traditionally depicted in the topic "renal tumor."

Pathology/Histopathology

RVT is a common complication of nephrotic syndrome, occurring more frequently in patients with membranous glomerulonephritis, membranoproliferative glomerulonephritis, amyloidosis, lupus, or diabetes. Its incidence varies from 5 to 62% according to the reported series in the literature (1, 2). The mechanism by which the nephrotic syndrome leads to RVT remains unclear. Coagulative disorders, blunt trauma, and open surgery are less common predisposing factors. The thrombosis may be partial or total, unilateral or bilateral, and may extend to the inferior vena cava (IVC). It exposes the patient to the risk of embolic migration, so early diagnosis is essential to assess the need for anticoagulant and fibrinolytic therapy.

Cinical Presentation

RVT is suspected in a patient presenting with oliguria, hematuria, flank pain, and sudden onset of azotemia. Nevertheless, most patients have a chronic presentation with edema and slight decrease in renal function.

Imaging

Intravenous Urography

Since the decline of intravenous urography, this diagnosis is less and less frequently suggested by nonspecific abnormalities such as delayed opacification of enlarged kidneys, poor or absent excretion, and notching of the renal pelvis and ureter.

Doppler Ultrasonography

Doppler ultrasonography is usually the first imaging modality performed in cases of suspected RVT. A search is done for an endoluminal echo, associated with total or partial absence of venous signal (Fig. 1). The peripheral, intraparenchymatous detection of a venous signal does not eliminate the diagnosis because the development of collateral pathways is constant. Thus, renal veins have to be explored in the renal pedicle. A posterolateral or transhepatic approach usually makes this analysis possible on the right side. Exploration of the left renal vein is sometimes limited by the acoustic barriers. Although intrarenal venous signals are normal, parenchymatous arterial waveforms indicate increased resistive indexes (superior to 0.70), especially in the acute phase before the rapid development of collateral pathways leading to the reduction of interstitial edema.

Thrombosis, Vein, Renal. Figure 1 Transverse sonogram of the right renal kidney indicates an echogenic thrombus within the lumen of the right renal vein, extending into the inferior vena cava.

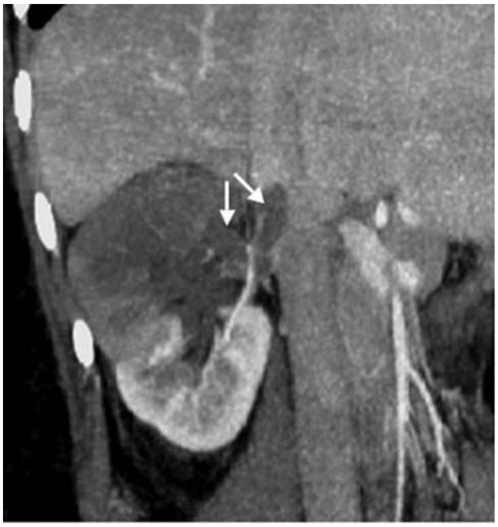
If the examination is negative and considered technically satisfactory, no other imaging modality is recommended. In other cases, complementary computed tomography (CT) or magnetic resonance imaging (MRI) should be considered.

Computed Tomography Angiography

From a technical point of view, a suspected RVT requires standard exploration with nonenhanced and enhanced helical acquisitions. Delayed scans (up to 2 min) are sometimes required to clearly appreciate a possible extension to the IVC.

Thrombus manifests as a spontaneously hyperdense, nonenhancing venous defect (Fig. 2). When the thrombus is occlusive, the vein is commonly dilated, and the hypodensity of the lumen is accentuated by enhancement of the venous wall.

In cases of partial occlusion, indirect parenchymal signs are uncommon. Otherwise, nephromegaly, pale nephrography, delayed medullary enhancement, delayed



Thrombosis, Vein, Renal. Figure 2 **Frontal reformation of an enhanced computed tomography scan showing a filling defect in the upper branch of the right renal vein extending into the inferior vena cava (*arrows*). The upper part of the right kidney is enlarged and low attenuating compared with the lower part.**

excretion, and perirenal edema (fat stranding, perirenal fascia thickening) are common findings. A subcapsular rim sign, even if very common in arterial infarction, has been described in RVT as well.

Owing to its high spatial resolution, CT angiography (CTA) allows clear depiction of perirenal and periureteral collateral veins. It must be noted that the potential for collateral formation is much more significant on the left side because the gonadal, inferior phrenic, and adrenal veins drain into the renal vein on the left side, whereas the right counterparts drain directly into the IVC on the right side (1).

Extension of the thrombus to the IVC or left gonadal vein is clearly depicted on delayed acquisitions with frontal reformations.

An evolutive aspect has to be mentioned: if the thrombosis is not suspected and not treated, or treatment fails, the thrombosed vein tends to shrink and even calcify (Fig. 3).

MRI

MRI is the modality of choice for assessing the extension of neoplastic RVT. Similarly, MRI is probably the best choice to assess renal vein cruoric thrombosis when Doppler ultrasound is not conclusive and when the use of iodinated contrast media is contraindicated by renal insufficiency. The conventional T1- and T2-weighted images are combined with flow-based sequences. Nevertheless, recent imaging systems offer angiographic studies

Thrombosis, Vein, Renal. Figure 3 **Incidental finding during the work-up of renovascular hypertension (occlusion of the right renal artery) of an asymptomatic left renal vein thrombosis: the left renal vein (*arrow*) is shrunken, the left kidney is normal in size, and enhancement owing to large collaterals into the azygous system is present (*arrowhead*).**

requiring a short breath-hold with high three-dimensional resolution and are considered the gold standard in the MR evaluation of renal vessels.

Renal Venography and Arteriography

Venography and arteriography are of limited value in this indication owing to the renal insufficiency. Before the advent of slice imaging, renal venography was considered the definitive study for suspected RVT, allowing direct visualization of the thrombus within the renal vein and IVC. Nevertheless, it is an invasive procedure, with a potential risk of thrombus dislodgment and pulmonary embolism. For this reason, some authors prefer arteriography to venography, demonstrating accentuated opacification of medullary pyramids and venous-filling defects. Thus, the indication for renal venography is limited to selected patients as the initial step before IVC filter placement.

In summary, Doppler ultrasound is recommended as the initial imaging modality because it is noninvasive, cheap, and effective. In cases of incomplete evaluation or technical failure, MRI is the best alternative in patients with compromised renal function. Otherwise, the high spatial resolution of CTA makes it the gold standard for the anatomic depiction of renal vein thrombus and its extension.

Nuclear Medicine

The objectives of the treatment of RVT are to preserve renal function and prevent thromboembolic complications. Besides treating the underlying cause, the management of RVT classically involves anticoagulation followed by oral vitamin K antagonists for at least as long as the nephrotic syndrome persists. Although repeatedly documented in short series, the role of fibrinolytic treatment is not clarified. It seems to provide more rapid resolution than anticoagulation but is associated with a much higher risk of hemorrhagic complications and death. As in other vessels, *in situ* fibrinolysis tends to reduce the risk of systemic complications (3).

Rare cases of surgical thrombectomy have been reported. Nevertheless, percutaneous mechanical thrombectomy provides an attractive alternative option for the treatment of RVT, particularly when anticoagulation fails or is contraindicated (4).

Successful treatment with caval filter in cases of RVT with suprarenal extension has also been reported, but this option is not recommended because it exposes the contralateral kidney to the extension of the clot.

Synonyms

Brachial vein obstruction; Brachial vein occlusion

Definition

Acute or chronic uni- or bilateral thrombotic occlusion of the V. brachialis.

Pathology/Histopathology

With a reported prevalence of 0.15%, symptomatic upper extremity deep venous thrombosis (UEDVT) is a rare condition, which was independently described by Paget and Von Schroetter in the late 19th century. They assumed a correlation to repeated severe effort of the involved extremity, and consequently the condition has been termed spontaneous or effort vein thrombosis. Strenuous arm activity or holding the arm for a prolonged period in a set position is an involved trigger mechanism. An anatomic abnormality, for instance a cervical rib or costoclavicular compression syndrome, is often observed.

The employment of the term primary UEDVT is intentional to differentiate spontaneous or effort thrombosis from the nowadays more frequent secondary type attributable to chronic central venous catheters, pacemaker wires, trauma or intravenous drug use (1). Secondary acute venous upper extremity occlusion is also seen in gene mutations, inherited thrombophilia, malignancy, heart failure, acquired hypercoagulable states and infection (2). Patients with a history of thrombotic lower limb vein occlusion are also more prone to develop UEDVT (3).

Clinical Presentation

Upper extremity occlusions make up only 1–4% of all acute deep venous occlusions (2). The incidence of secondary occlusion appears to be increasing, which could be related to the acceding use of long-term indwelling central venous lines, more liberal use of ultrasound to validate the diagnosis and an increased familiarity with this condition; yet, even in occlusive upper extremity thrombosis, the condition can be asymptomatic.

While pulmonary embolism (PE) is observed in up to 50% of patients with proximal lower extremity DVT, in contrast, upper extremity occlusion has been reported to have a 7–20% rate of PE (1).

Clinical manifestations of UEDVT are non-specific and can simulate lymphedema, local infection or mediastinal malignancy. Scepticism should come up with episodes of paresthesia, tenderness, swelling, functional weakening of the upper extremity, skin discoloration or venous distension.

According to one study, the brachial vein was involved in 36% of diagnosed UEDVT, the axillary vein in 25% and the brachial and cephalic veins in 77%. An isolated brachial vein thrombosis was identified in 3.8% of cases (4).

Imaging

Contrast venography for decades has been the reference standard for the diagnosis of UEDVT, although this procedure has its shortcomings. Venous puncture can be problematic in a swollen extremity, the procedure may cause thrombophlebitis, and there is an albeit low risk of an allergic contrast medium reaction. Recent studies have disclosed that both compression ultrasound and color flow Doppler imaging of the upper extremity venous system are sensitive and specific for the diagnosis of upper extremity occlusion, with reported respective sensitivity values of 96 and 100%, and specificity values of 93 and 93% (3).

Large collateral veins and non-occlusive thrombi may cause false-negative results, and overlying anatomic structures may camouflage vessel segments. Higher sensitivity can be achieved by revelation of normal cardiac pulsatility and respiratory phasicity within these veins.

Computed tomography and MRI may also be valuable in diagnosing acute upper extremity occlusion (Fig. 1). In several studies MRI had a sensitivity and specificity of almost 100% in evaluating the patency of the central chest veins (4, 5). Patients with pacemakers and other implanted devices, which regularly cause UEDVT are thus candidates for imaging, however are not suitable for MR imaging.

Although conventional venography, CT and MRI can all be used to consistently detect upper extremity thrombosis, the excellent results of ultrasound imaging favor its use as the prime imaging modality for the diagnosis of UEDVT, particularly of the upper arm. Because of their common, established and above mentioned limitations, the alternative imaging tools should only be utilized when sonographic findings are unclear.

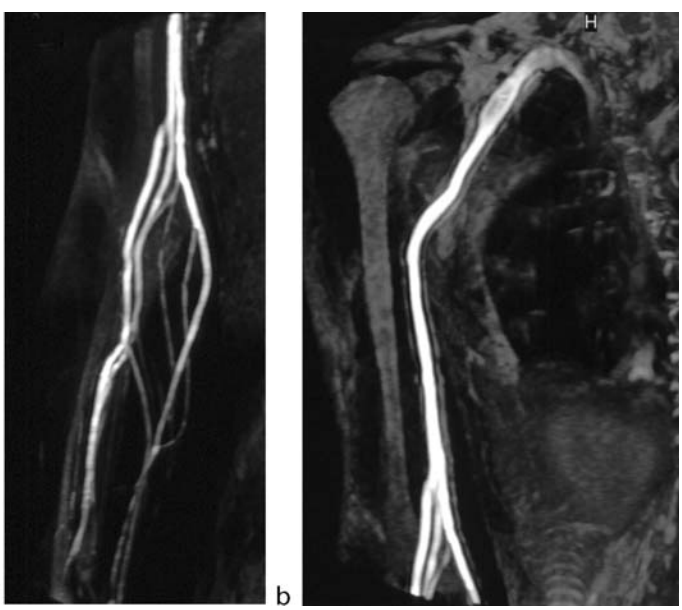
Diagnosis

Since clinical diagnosis is not entirely reliable imaging techniques need to be incorporated in the diagnostic process.

Interventional Radiological Treatment

Prompt treatment is compulsory after the diagnosis has been established to avoid complications of UEDVT such as loss of central venous access, post-thrombotic syndrome and pulmonary embolism. In the acute stage, conventional treatment consisted of elevation of the affected extremity and full-dose anti-coagulation with unfractionated heparin or low molecular weight heparin (3) followed by 6 weeks to 6 months of therapy with oral warfarin sodium. In secondary venous thrombosis, the removal of the underlying cause, such as the central venous catheter, is typically required.

The radiologist is occasionally involved in the treatment of this disease entity. Catheter-directed thrombolysis is known to improve lysis rates by delivering the thrombolytic agent in high concentrations directly to the site of the thrombus. In combination with balloon



a b

Thrombosis, Venous, Brachial. Figure 1 Maximum intensity projection of the lower and upper arm and the central venous vessels after intravenous administration of 5 ml Gadolinium-DTPA *via* the back of the hand shows proper anatomic visualization of thrombus free vessels.

angioplasty, satisfactory results have been achieved (6). Stent deployment should be considered in case a significant residual stenosis or thrombus remains after thrombolysis and PTA (7).

In one study, systemic thrombolysis proved to be effective for nonocclusive thrombi with excellent results in 32 of 36 primary UEDVT patients (8); however, in this patient, collective better results were demonstrated by aggressive thrombolysis and rapid first rib resection to alleviate both the acute and chronic symptoms.

In patients where anti-coagulation and thrombolysis are contraindicated, refractory or complex, and who are prone to pulmonary embolism, the placement of a superior vena cava filter may be discussed. Even though there is pervasive knowledge of inferior vena cava filter placement, only few data regarding placement of superior vena cava (SVC) filters exist. Obtainable results yet show that filters placed in the superior vena cava can be considered a safe and effective method to prevent pulmonary thromboembolism (9). SVC filter placement is indicated in recurrent PE despite full-dose anti-coagulation, or a major complication resulting from anti-coagulation medication.

Due to the variety of underlying causes, a multidisciplinary treatment strategy for UEDVT is often needed. The radiologist should participate in a timely diagnostic work-up and, when indicated, in the primary treatment as well as the prevention of thrombosis sequelae by restituting vessel patency, preserving venous valve function and circumventing pulmonary embolism.

Thymoma

▶Neoplasms, Chest, Childhood

Thymomas and Thymic Carcinomas

Takahashi Koji
Department of Radiology, Asahikawa Medical college, Asahikawa, Japan
taka1019@asahikawa_med.ac.jp

Definition

Thymoma is defined as a benign or low-grade malignant tumor of the thymic epithelium, frequently associated with immature but nonneoplastic T cell lymphocytes (1). Thymoma is the most common primary mediastinal tumor.

Thymic carcinoma is defined as a thymic epithelial tumor with a high degree of anaplasia, obvious cell atypia, and increased proliferative activity and is unassociated with immature T cells (1).

Pathology

Thymomas are divided into an encapsulated noninvasive type and an invasive type that has spread beyond the capsule, initially invading the adjacent mediastinal fat and eventually spreading to the pleura, pericardium, lung, or mediastinal vessels. Most thymomas show lobulated external surface and are either completely or partially encapsulated by fibrous capsule. The capsule connects with fibrous band within the tumor that divides it into multiple lobules. Cystic change, hemorrhage, necrosis are relatively common and sometimes the tumor may be entirely cystic. The neoplastic epithelial cells can vary from polygonal to distinctly spindle in shape, and relative proportions of associated lymphocytes can be minimal or so marked as to completely obscure epithelial cells. The predominantly epithelial thymoma appears to carry the worst prognosis (2). Based on morphologic features of epithelial cells, thymomas are divided into cortical (predominantly and pure subtype), medullary, and mixed forms (1).

Thymic carcinoma possesses traditional features of malignancy, which closely resemble carcinomas seen in other organs. The most common histologic type is squamous cell carcinoma.

The world health organization (WHO) has proposed a consensus classification of thymic epithelial tumors which is based on the morphology of epithelial cells and on the lymphocyte-to-epithelial cell ratio (3). It has been suggested that WHO classification reflects both the clinical and the functional features of thymic epithelial tumors and can be a prognostic factor. The tumors are divided into six subtypes. Type A and B tumors are composed of a homogeneous population of neoplastic epithelial cells with spindle- or ovale-shaped nuclei (A) and dendritic or epithelioid nuclei (B). Type AB tumors combine the morphologic features of types A and B. Type B1 tumors resemble the normal functional thymus and mainly consist of a dense population of lymphocytes, and some epithelial tumor cells with large nuclei of pale chromatin and small nucleoli. Type B2 tumors consist of a nest of epithelial cells, and lymphocytes are less abundant than in type B1. Type B3 tumors predominantly composed of epithelial cells having a round or polygonal shape and exhibiting mild atypia, admixed with a minor component of lymphocytes. Type C tumors exhibit clear-cut cytologic atypia and a set of cytoarchitectural features analogous to those seen in carcinomas of other organs. The classification of type B3 and C tumors corresponds to atypical thymoma and thymic carcinoma, respectively. All tumors are further divided into 3 subgroups: low-risk thymomas (types A, AB, and B1), high-risk thymomas (types B2 and B3), or thymic carcinomas (type C).

Clinical Presentation

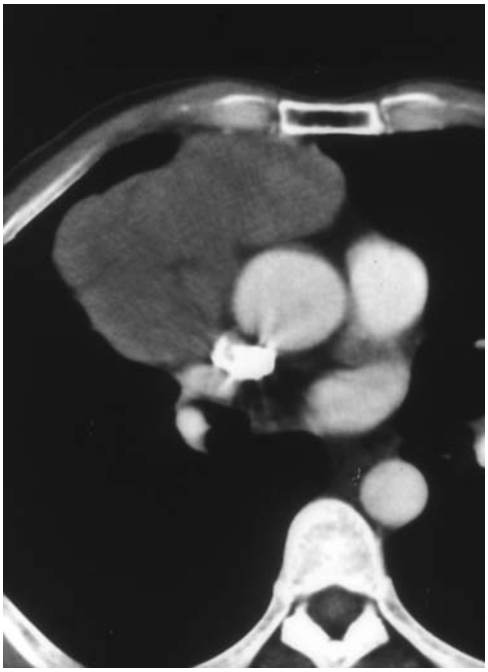
Thymomas usually occur in middle aged adults, the average age at diagnosis being 50 years (2). Thymomas most commonly arise in the upper part of the anterior mediastinum. Patients with encapsulated thymoma are usually asymptomatic. If symptoms occur they consist of chest pain, cough, dyspnea, dysphagia, or hoarseness. Thymomas are occasionally associated with paraneoplastic syndrome such as myasthenia gravis. Approximately 20% of patients with myasthenia gravis have thymoma and up to 40% of patients with thymoma have myasthenia (2).

Thymic carcinomas predominantly occur in adults and are associated with poor prognosis. At the time of diagnosis, most patients are symptomatic and commonly present with chest pain, cough, fever, weight loss, and fatigue. A paraneoplastic syndrome is uncommon in thymic carcinomas.

Imaging

Most thymomas arise in the anterior mediastinum (Fig. 1) near the junction of the heart and great vessels and may project into one or less commonly both sides of the mediastinum. Uncommon location of thymoma includes inferior mediastinum as low as the cardiophrenic angle, middle or posterior mediastinum, the lower and upper neck as high as the submandibular region, or lung parenchyma.

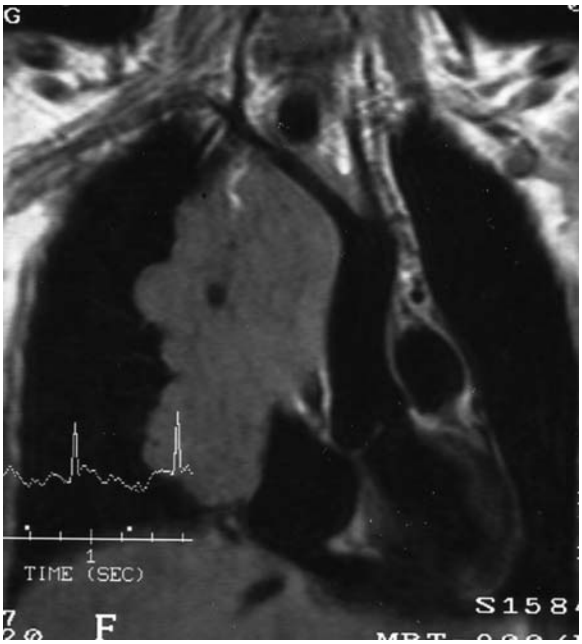
Radiographically, thymomas appear as an oval or round shaped mediastinal mass with smooth or lobulated margins. In the lateral view, the opacity can be identified in the retrosternal space. On CT, thymomas usually present as sharply demarcated round or oval soft tissue masses with mild to moderate contrast enhancement. Less common, focal low attenuation areas are identified within tumors, reflecting hemorrhage, necrosis, or cyst formation. Rarely, a tumor appears entirely cystic (cystic thymoma). Calcifications of punctate, curvilinear, or ringlike in shape are frequently seen in both encapsulated and invasive thymoma. Complete obliteration of the adjacent fat planes highly suggests mediastinal invasion,



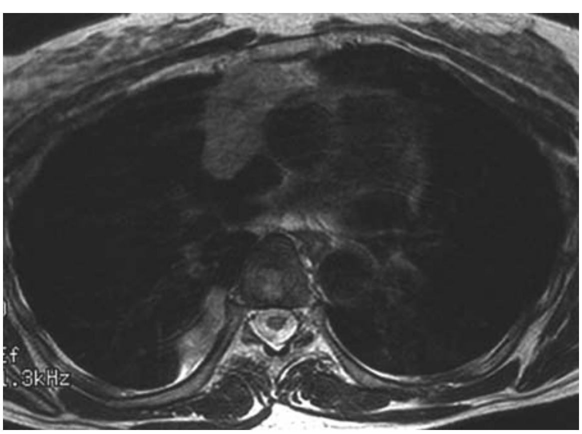
Thymomas and Thymic Carcinomas. Figure 1 Thymoma. Contrast-enhanced CT shows a lobulated mass lesion in the anterior mediastinum. Linear structures of low attenuation within the tumor represent fibrous internal septations.

T

while partial obliteration is indeterminate, and complete preservation of adjacent fat planes usually excludes extensive invasive disease but not minimal capsular invasion (Fig. 2) (4). Transpleural spread either as a sheet of tumor or drop metastasis is a diagnostic finding of invasive thymoma. On MRI internal low intensity septations and signs of mediastinal invasion may be more conspicuous (Fig. 3).



Thymomas and Thymic Carcinomas. Figure 2 Invasive thymoma. Coronal T1-weighted MR image shows a lobulated mass lesion which extends along the branch vessels of the aortic arch.



Thymomas and Thymic Carcinomas. Figure 3 Invasive thymoma. Axial T2-weighted MR image shows an anterior mediastinal mass and associated pleural metastases.

Thymic carcinoma mimics thymoma on imaging (Fig. 4). Thymic carcinomas are commonly associated with mediastinal lymph node and extrathymic metastases, but less commonly associated with pleural implants than invasive thymoma (5).

Nuclear Medicine

Increased uptake of thallium-201 and Tc-99m tetrofosmin has been demonstrated in thymoma and thymic carcinoma (6).

Definition

▶Graves' disease is an ▶autoimmune disease of the ▶thyroid gland, usually presenting with ▶hyperthyroidism.

Pathology/Histopathology

Pathologically the thyroid gland is usually enlarged, with large intraglandular and periglandular vessels.

Histologically diffuse or focal lymphatic infiltrations are visualized. Exophthalmos is regarded as a typical sign of endocrine ophthalmopathy. The orbital muscles show enlargement with myxoid degeneration.

Clinical Presentation

The thyroid gland is usually enlarged on palpation. A murmur may be present during auscultation of the neck.

The clinical picture is variable. In classic disease, typical symptoms are present.

The individual is nervous, with heat intolerance and a tendency to sweat. Tachycardia and weight loss may be present. Tremors, diarrhea, and pigment abnormalities are seen. Other endocrine symptoms such as hypomenorrhea or amenorrhea in women and impotence or gynecomastia in men may be found. Very typical for Graves' disease is an endocrine ophthalmopathy with exophthalmia, and a paralysis of the eye muscles may be

T

found. Pretib ial myxedema is regarded as classic. The combination of thyroid enlargement, endocrine ophthalmopathy, and tachycardia is called the Merseburger triad.

Laboratory Findings

Thyroid-stimulating hormone (TSH) is suppressed. Hyperthyreosis with elevation of T4 and T3 is often found.

TSH-receptor antibodies (TRAK) are regarded as typical for Graves' disease.

Imaging

The thyroid gland is usually enlarged, with an anteroposterior diameter of more than 2 cm in each lobe. The poles of the gland are rounded. The thyroid gland is most often diffusely hypoechogenic (Fig. 1), but normal echogenicity does not rule out Graves' disease. On color Doppler, significant hypervascularization, called thyroid inferno, is found (Fig. 2), and tissue vibrations usually form a mosaic pattern. On pulsed Doppler sonography, the peak systolic velocities are more than 40 cm/sec in the inferior thyroid artery.

No correlation between hypervascularization and thyroid hormone levels has been found.

The gland usually remains hypoechogenic, even in clinical remission. Malignant transformation is rare. Benign nodules are found frequently in Graves' disease, usually presenting as echogenic lesions caused by adenomas.

Enlarged locoregional lymph nodes may be found.

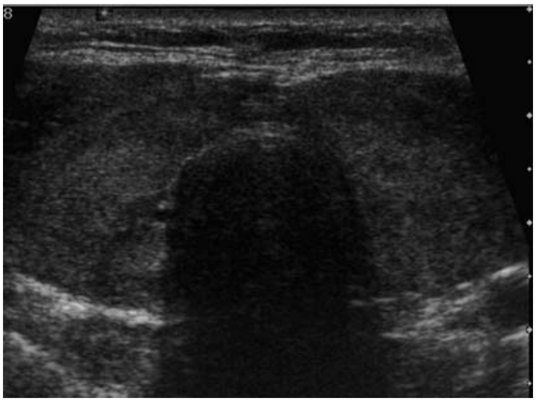
Nuclear Medicine

The thyroid gland is usually scanned after intravenous administration of technetium-99m.

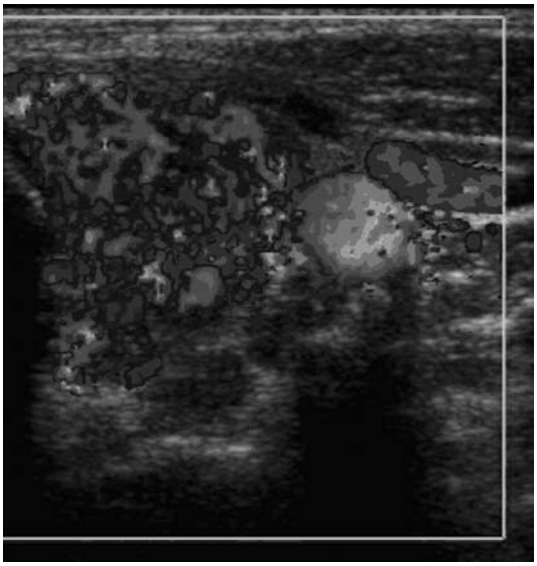
The technetium uptake is elevated, usually more than 4%, and the thyroid gland is homogeneously enlarged (Fig. 3). Uptake in the salivary gland is suppressed. These features are regarded as classic.

Endocrine ophthalmopathy is a typical sign of Graves' disease. The exophthalmos is usually imaged by magnetic resonance imaging (MRI) or computed tomography (CT). A thickening of the orbital muscles is found. Because of myxoid infiltrations and edema, the orbital muscles are bright on T2-weighted images.

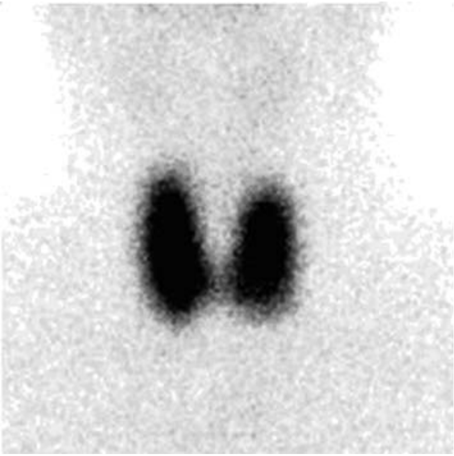
MRI and CT are mainly used to exclude space-occupying retrobulbar lesions in patients with unilateral exophthalmos.



Thyroid Autoimmune Diseases. Figure 1 Graves' disease. Transverse section of the thyroid gland shows diffuse enlargement with diffuse hypoechogenicity.



Thyroid Autoimmune Diseases. Figure 2 Enlargement of the left lobe of the thyroid gland with a mosaic pattern of vascularization, known as thyroid inferno.



Thyroid Autoimmune Diseases. Figure 3 Technetium scan of thyroid gland in Graves' disease. The gland is enlarged, with elevated technetium uptake (more than 4%, often even exceeding 5%).

Acropachydermia may be present, and on plain films of the long bones, bone thickening can be seen.

Diagnosis

The diagnosis of Graves' disease is established by adding the clinical signs, the laboratory findings (hyperthyreosis and TRAK autoantibodies), and the sonographic and scintigraphic picture. Therapy may include: Favistan, near-total resection, and radioiodine therapy.

Hashimoto's Thyroiditis

Definition

►Hashimoto's thyroiditis is an autoimmune; Chronic lymphocytic inflammation of the thyroid gland.

Pathology/Histopathology

In the beginning of the autoimmune inflammation, the gland may be moderately enlarged. In advanced so-called burned-out cases, the volume of the gland shrinks because of fibrosis.

Histologically the thyroid gland is infiltrated by lymphocytes or plasma cells. Fibrous scarring may be found in the later stage of the disease.

Other forms of thyroiditis are subacute thyroiditis (de Quervain's), postpartum thyroiditis, and silent thyroiditis.

Clinical Presentation

The disease has an increased prevalence in middle-aged women.

Patients can be asymptomatic or may present with signs of ►hypothyroidism. Weakness, cold intolerance, swelling of hands and feet, and pretibial myxedema may be seen. The skin may be cold, thickened, and pale or yellow. In rare cases, the patient may initially present with signs of hyperthyreosis (Hashitoxicosis).

Other forms of thyroiditis (de Quervain's thyroiditis, postpartum thyroiditis, silent thyroiditis) usually present without hypothyroidism.

There may be coexistence with other autoimmune diseases.

Laboratory Findings

Autoantibodies are often elevated (MAK, TPO-AK).

TSH is often elevated, and T3 and T4 may be low. In the acute phase, hyperthyroidism may be present.

Imaging

In Hashimoto's thyroiditis, the gland may be enlarged or normal sized, or the volume can decrease depending on the duration of the disease and the amount of scarring. On sonography, the structure of the gland often shows few micronodular hypoechogenic foci, or the gland may be diffusely hypoechogenic. The echogenicity of the thyroid is assessed by comparing it with the surrounding cervical muscles. The gland usually becomes as hypoechogenic as the surrounding muscles.

On color Doppler, the gland usually shows hypervascularization; in advanced fibrous forms, the vascularization diminishes.

Enlarged locoregional lymph nodes may be found.

Nuclear Medicine

The technetium uptake of the thyroid gland usually diminishes (below 0.5%), and the salivary glands are more prominent on scintigraphic imaging. The thyroid structure may be patchy.

Diagnosis

The diagnosis of Hashimoto's thyroiditis is established by adding the clinical signs, the laboratory findings, and the sonographic and scintigraphic picture.

Depending on the grade of hypothyroidism, the condition is treated with thyroid hormone substitution.

Thyroid Gland

The thyroid is a butterfly-shaped endocrine gland located in the lower front part of the neck, with a lobe on either side of the trachea. Its hormones have important roles in regulating metabolism.

►Thyroid Autoimmune Diseases

Thyroid Malformations

Thyroid malformations range from thyroid atresia to thyroglossal duct cysts. Ectopic thyroid tissue may be

located at the base of the tongue in the midline dorsum, but it can be located anywhere along the migration pathway of the thyroid. The most common congenital thyroid anomaly is the persistent thyroglossal duct cyst.

Synonyms

Perfusion curves

Definition

Time intensity curves quantitatively describe the dynamics of the intravascular ultrasound contrast media, and thereby provide a quantitative assessment of tissue vascularization.

Characteristics

Since perfusion is a recognized parameter of tissue viability and functionality, its measurement can be useful in the detection and characterization of various pathological changes such as in ischemia, inflammation, or neoplasia. Thus, ▶*perfusion imaging* is an important part of the growing field of functional imaging, which may become necessary for the characterization of many diseases. Quantification is a prerequisite for many applications in functional imaging, in particular in perfusion imaging. Important indications are the evaluation of tumor or organ perfusion (e.g., brain, heart, or kidney), particularly during follow-up or therapy monitoring.

For quantitative analysis of contrast enhancement in ultrasound examinations, the wash-in and wash-out of the ultrasound contrast medium after injection must be assessed in a region of interest. For this, the transducer is usually kept approximately in the same position. If necessary, the patient must be instructed to stop breathing or to breathe superficially in order to avoid movement during the examination. Video sequences of the dynamic process can be recorded, and postprocessing using commercially available software tools allows for a quick and easy analysis of the obtained image series. An important precondition for quantification of perfusion with contrast-enhanced ultrasound is that the signal intensity of the chosen ultrasound parameter must correlate with the ultrasound contrast agent concentration *in vivo*. High-frequency, raw data of the ultrasound examinations are considered the gold standard in this respect. However, these data are not always provided by the ultrasound scanner. Therefore, the video signals of the ultrasound device are often used, which have also provided accurate measurement of tissue perfusion in several organs.

The detection of microvascularity can be performed in real time with a high spatial resolution using low-mechanical index (MI) ultrasound techniques and ▶*second-generation ultrasound contrast media* such as microbubbles that are stabilized by phospholipids and contain sulfur hexafluoride (SonoVue, Bracco, Milan, Italy). Novel contrast-specific imaging techniques like coherent pulse sequencing (CPS; Siemens-Acuson, Erlangen, Germany) may have advantages in quantification, since they allow the background tissue and the contrast-enhanced signal to be assessed separately.

High-MI imaging destroys the microbubbles in the region of interest during detection. Therefore, ▶*intermittent imaging* must be used when assessing whole tissue vascularization using high-MI techniques such as contrast-enhanced power Doppler ultrasound. At intermittent imaging the repetition rate of the ultrasound pulses (frame rate) is reduced, and the microbubbles can be given enough time to also fill the smallest vessels. Additionally, well-defined variations of the frame rate allow for the assessment of different stages of refilling. Thus, it also can provide the calculation of replenishment kinetics, even though *intermittent imaging* is more complex compared to real-time methods using low-MI techniques.

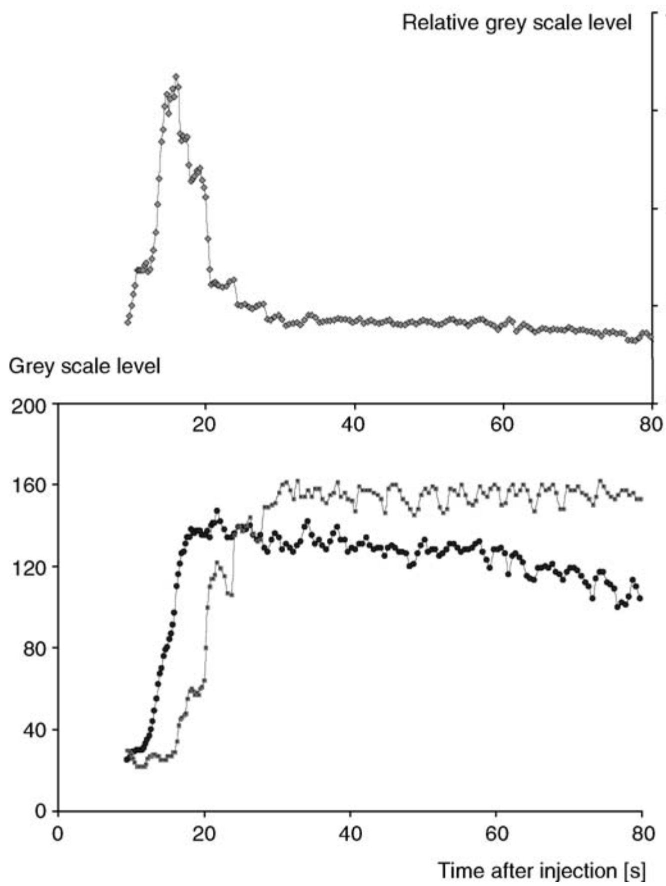
With these contrast-enhanced ultrasound methods, the entire perfusion of an examined region can be detected, that is, the blood flow per tissue unit including the capillary blood flow. Due to the interaction between the microbubbles and the acoustic field (*nonlinear resonance* and *bubble destruction*), each microbubble may be detectable by *contrast-specific imaging technique*s, with a sensitivity that can hardly ever be exceeded. Unlike other contrast agents used in radiology, ultrasound contrast media are confined to the intravascular space. Thus, complex and sometimes inaccurate pharmacokinetic models to describe the contrast agent distribution in tissue are not necessary for quantifying perfusion using contrast-enhanced ultrasound. On the other hand, it is not possible to assess changes of the vessel permeability with intravascular contrast agents, which, however, may be another important functional parameter, for example, in treatment monitoring.

The typical time intensity curve, which describes the ultrasound signal intensity over time in a region of interest after a contrast bolus injection, is also called a perfusion curve. In tissues that are predominant arterially supplied (like in most organs or malignant tumors), the perfusion curve has a typical shape with a rapid increase of contrast enhancement and a slower, exponential-like decrease after reaching a maximum. According to a classic tracer kinetics modeling, the analysis of an input function derived from the arterial enhancement in the feeding vessels is required to allow for the calculation of perfusion. However, in ultrasound, an extraction of the input function and a measurement of the tissue enhancement are difficult to perform simultaneously. Thus, several descriptive parameters are used to characterize such curves, such as the maximum enhancement after contrast bolus injection, the time to peak enhancement, the slope to maximum, or the area under the entire perfusion curve. However, these parameters do not directly characterize the perfusion parameter itself, for example, local blood volume or flow. However, they are quantifiable and relatively easy to obtain, and can be considered as indirect perfusion markers. The maximum of the perfusion curve is considered as a parameter of the overall degree of tissue vascularization. The initial slope and the time to maximum can be used as descriptors of the blood flow characteristics in the region of interest. In several clinical examinations such values have been used to assess tissue vascularization, as in focal liver lesions (1), *renal* examinations, (2), echocardiography, or in transcranial ultrasound studies (3) (Fig. 1).

In addition, time intensity curves can be simply used to obtain ultrasound contrast media arrival times in larger arteries or veins, which provide an accurate transit time analysis of organs such as the liver.

An ultrasound-specific time intensity curve, which allows for the assessment of direct perfusion parameter, is derived from replenishment kinetics of the ultrasound contrast media. This technique uses the potential of ultrasound to destroy microbubble contrast agents if the output power is high enough. After such destructive ultrasound pulses (using a high-MI ultrasound technique, "flash"), it can be assumed that the examined slice is void of microbubbles, and that these will again progress into the slice from outside, where they are still present. The analysis of such replenishment kinetics (ultrasound signal intensity over time after destruction) can provide several direct perfusion parameters. It has been shown that the initial increase of the refilling curve indicates the mean blood flow velocity (m/sec) in the region of interest, and the plateau of signal intensity that will be reached after the complete replenishment is a parameter proportional to the local blood volume (~mL). According to a model of Wei, a parameter proportional to the perfusion (~mL/sec·mg) can be then calculated *via* the product of blood velocity and blood volume (4). This established model assumed a constant velocity of refilling and neglected the fact that the contrast agent will reenter the slice through vessels of varying calibers and directions. Other models have been proposed attempting a more consistent description of the refilling process (5–7). In addition, a method was developed using a single bolus injection instead of the usually required continuous infusion of contrast agent when analyzing replenishment kinetics (8).

Replenishment kinetics requires a more complex ultrasound examination and analysis. It has, nevertheless, been used successfully for the accurate measurement of tissue perfusion in several organs. One important application is the assessment of myocardial microcirculation in echocardiography (9). Furthermore, renal perfusion (7), perfusion of the liver and liver metastases (10), muscle perfusion (11), and changes in tumor perfusion during antiangiogenic treatment have been analyzed (5, 12).



Time Intensity Curves. Figure 1 Time intensity curves from contrast-enhanced ultrasound after injection of 2.4 mL SonoVue (Bracco, Milan, Italy) using a low-MI technique (Acuson Sequoia, Erlangen, Germany) recorded during early enhancement in a liver metastasis of breast cancer (black dots). As reference the time intensity curve of unaffected liver tissue is shown (grey dots). The upper curve (?) describes the ratio of lesion to liver, which can be used for focal liver lesion characterization.

With the increasing development of functional imaging methods, a user-friendly presentation of information derived from such imaging methods has gained interest. The visualization of a (semi)-quantitative parameter value in its spatial distribution is called ►*parametric imaging*. Color-coded maps, which can be superimposed to standard images, are typical examples of parametric imaging. In perfusion imaging such parametric images have entered routine clinical practice in computed tomography and magnetic resonance imaging. In addition, in contrast-enhanced ultrasound, parametric imaging has become feasible for the visualization of perfusion-related information using additional external tools or dedicated software implemented on the ultrasound device. The scope of solutions includes descriptive visualization of microcirculation (e.g., Micro Flow Imaging, Toshiba) and dedicated software tools for quantification of diverse perfusion parameters (e.g., Qontrast, Amid, Rome, Italy).

Definition

Portosystemic shunts are abnormal vascular connections between the hepatic portal and the systemic circulation. Patients with severe liver disease like cirrhosis and Budd–Chiari syndrome suffer from circulation problems. The blood from the lower part of the body normally returns to the heart through blood vessels passing through the liver (hepatic portal vein). If the liver is damaged or the hepatic venous outflow is obstructed, this upward flow of blood becomes difficult leading to portal hypertension. The consequences are that the fluid tends to pool in the legs (edema) and inside the abdomen (ascites), and the blood may flow in unusual pathways, such as through the vessels around the esophagus and stomach. These vessels may become swollen with blood over time, (esophageal and gastral varices) and bleed.

One way to treat this portal hypertension is to form a new connection inside the damaged liver, which allows for better flow of blood back to the heart. This procedure is called an intrahepatic shunt (tube connection inside the liver). It can be done by inserting a metallic endoprosthesis (stent) into place through a vein in the neck (transjugular), down into the liver (Figs. 1, 2). The link between the high-pressure portal vein and low-pressure hepatic vein is an incomplete side-to-side shunt (H-shunt). It does not require surgery to open the abdomen and can be performed in a radiology setting in about 1–3 h, followed by monitoring in the intensive care unit (2). In patients with bleeding, TIPS can be combined with embolotherapy of the varices (3). The rational of embolotherapy is at the same setting *via* the transjugular vein to use long-acting occluding agents embolizing proximal and peripheral collateral veins by combining liquid and mechanical materials in order to prevent collateralization and reperfusion.

Indication and Contraindication

The purpose of TIPS is to achieve portal decompression and therefore prevent rebleeding from varices or stop or reduce the formation of ascites. Since the first TIPS was performed on patients with poor liver function and active variceal hemorrhage in 1988, the indications for

TIPS. Figure 1 Portogram (anteroposterior) after transjugular, intrahepatic punction of a right intrahepatic portal vein shows retrograde filling of the left gastric vein. The portosystemic pressure gradient was 24 cmH20 (cm of water).

TIPS. Figure 2 Portogram (anteroposterior) after the TIPS has been established with implantation of one self-expanding covered stent (Viatorr), and the varices (left gastric vein) have been embolized with natriumamidotrizoat (Ethibloc) in combinastion with coils. The portosystemic pressure gradient was reduced from 24 cmH20 to 9 cmH20.

performing TIPS have increased (2). The recommendations from consensus meeting are discussing accepted indications (+++), potential indications with proven efficacy (++), experimental indications with efficacy not proven by large-scale series (+), indications not accepted (case reports only) (−), and absolute contraindications (−−) for shunting with TIPS.

Accepted indications (+++) are (1) acute variceal bleeding that neither can be successfully controlled with pharmacological agents, nor with mechanical compression or endoscopic techniques, and (2) recurrent variceal bleeding in patients who are refractory or intolerant to conventional medical management, including sclerotherapy and pharmacological therapy.

Potential indications with proven efficacy (++) are (1) refractory ascites (serious tense ascites that does not respond to standard therapy within 4 weeks or where the patient develops secondary effects making treatment impossible), and (2) Budd–Chiari and veno-occlusive syndromes. The rationale for TIPS in BCS is to improve hepatic blood flow and function by creation of an artificial outflow *via* the portal vein bed. The side-to-side shunt allows retrograde arterial perfusion of the sinusoids, thus reducing the hypoxic damage of the hepatocytes and leading to improvement in liver histology.

Absolute contraindications are (1) hepatic insufficiency and chronic, severe encephalopathy; (2) severe right heart cardiac insufficiency; (3) diffuse or multinodular liver cancer, or tumors in the proposed route of the TIPS; (4) advanced cancer; (5) bacterial peritonitis or systemic infection; and (6) unrelieved biliary obstruction.

Results

From a technical point of view, successful placement of TIPS is achieved in more than 95% of patients. Performing TIPS in a patient with BCS can be difficult if the hepatic vein is completely occluded. In meta-analyses of TIPS literature, the incidence of fatal complications (intra-abdominal hemorrhage, laceration of the hepatic artery or portal vein, and right heart failure) was 1.7% (range 0.6–4.3%). Major procedural complications are expected in no more than 3% of cases.

Both randomized and nonrandomized studies have strengthened the evidence that TIPS is more effective than endoscopic therapy in the prevention of variceal bleeding. In randomized trials, the 1-year rebleeding rate ranged between 10 and 27% for TIPS and between 21 and 57% for endoscopic treatment. In a nonrandomized study, the 2-year and 4-year rates of patients free of rebleedings were 61% and 53% in patients treated with TIPS alone, and 84% and 81% in patients treated with TIPS and adjunctive embolotherapy of gastroesophageal collaterals.

All randomized trials but one found TIPS to be more effective than endoscopic therapy in avoiding variceal rebleeding, but average survival of patients treated with TIPS was not higher than survival of patients treated with endoscopic therapy. The incidence of encephalopathy was significantly higher in patients treated with TIPS in four of nine trials.

The main problems with TIPS are their low primary patency-rate (8–48% after 2 years), and an increased risk of encephalopathy of about 29% (7–55%). The preliminary experiences using polytetrafluoroethylene (PTFE)- covered stent-grafts are, with regard to patency, very promising. The actuarial rates of primary patency using covered stents were 86% at year 1 and 80% at year 2.

Several nonrandomized and five randomized studies have evaluated the effect of TIPS on refractory ascites compared to large volume paracentesis (LVP). In the TIPS group, control of ascites was more frequently achieved at 4 months (66 *vs.* 24%) and 12 months (55 *vs.* 19%), whereas encephalopathy was higher (55 *vs.* 38%). Survival at 1 year and 2 years were not different between patients treated with TIPS and LVP.

There have been a number of case reports and three small series on the outcome of patients with Budd–Chiari syndrome who have received TIPS. The largest series reports the technical and clinical success rate of 35 patients (4). The TIPS was successfully implanted in 33 patients (94%). Clinical symptoms (11 patients had a fulminant/acute form; 13 a subacute, and 11 a chronic course of disease) as well as the biochemical test results improved significantly during 4 weeks after treatment. The 1- and 5-year survival rate without transplantation in all patients was 93% and 74%, respectively.

The current recommendations: The decision to create TIPS in a patient with Budd–Chiari syndrome should be based on the severity of disease and only patients with moderate disease appear primarily to be reasonable candidates for a TIPS. Patients with BCS and mild disease can be managed medically, whereas those with more severe disease or acute hepatic failure are best managed by liver transplantation. On the other hand, in the light of not enough available compatible organ for transplantation, transjugular shunt should always be considered as a treatment of fulminant/acute, subacute and chronic severe Budd–Chiari syndrome.

Total Mesorectal Excision (TME)

TME is a standardized surgical technique of sharp dissection of the entire mesorectal compartment, containing rectum, mesorectal fat and mesorectal fascia, used in rectal cancer surgery. In non-locally advanced rectal tumours, this technique results in surgical clearance of the radial margin, and thus in complete resection. This is important, as involved radial margins are accepted as the major cause of local recurrence.

Synonyms

CNS toxicity; Toxic encephalopathy

Definition

Toxic brain disorders are conditions in which injury to brain tissue occurs as a result of an interaction with a chemical compound (a toxin). These disorders encompass a number of disparate conditions, and the list of toxins is extensive. Specific toxins preferentially affect specific brain regions, reflecting a host of factors including regional cerebral blood flow and oxygen demand; neurotransmitter distribution; specific chemical affinity and vulnerability; and brain maturation at the time of intoxication.

Exogenous toxins are introduced into the body *via* several routes including inhalation, ingestion, direct inoculation, and absorption *via* the skin and mucous membranes. Exposures may be accidental or deliberate. Toxins can also be produced endogenously from extrinsic sources such as toxin-producing microbes. Several recognized CNS toxins are listed in Table 1. Some of the more common toxins are discussed in subsequent sections.

Pathology

Inhaled Toxins

Carbon Monoxide (CO)

CO is the leading cause of lethal inhalations in the USA and Europe. It is produced by the burning of fuels such as gasoline, kerosene, wood, coal, and propane. Effects of CO are related to its high affinity for heme-containing molecules (hemoglobin and myoglobin). CO binds hemoglobin ∼250 times more avidly than does oxygen (O_2), causing formation of carboxyhemoglobin (COHb) in favor of oxyhemoglobin (O_2Hb) and decreased blood O_2-carrying capacity. Cellular damage also results from CO's ability to directly bind heme moieties in mitochondrial enzymes involved in oxidative phosphorylation and ATP synthesis, including the cytochrome oxidase system. Finally, brain lipid peroxidation may account for some of CO's neurotoxicity (1).

Toxic Disorders, Brain. Table 1 Exogenous CNS toxins

Inhaled toxins
• ►Carbon monoxide
• ►Toluene
• Nitrous oxide
• ►Mercury (elemental)
• Illicit drugs (heroin pyrolysite)
Ingested or Injected toxins
• ►Lead
• Mercury (organic)
• Manganese
• ►Methanol
• Ethanol
• Cyanide
• Triethyl tin
• Medications (immunosuppressants, chemotherapeutic agents, anticonvulsants, isoniazid)
• Illicit drugs (methamphetamine, cocaine, heroin, MDMA)
• Toxin producing infections (*E. coli*, mycoplasma, diphtheria)

Organic Solvents and Aerosols

Inhalation of organic solvents and aerosols can result in a transient euphoric state. These substances are found in a host of household products (model cement, spray paint, lighter fluid, and paint thinner). Inhaled substances belong to several chemical families, including aliphatic hydrocarbons (gasoline, propane, butane), alkyl halides (refrigerants, aerosol propellants, correction fluid), aromatic hydrocarbons (benzene, toluene, xylene), nitrites (room air fresheners), ethers, and ketones. These compounds are lipophilic and are readily absorbed from blood into lipid rich tissues, including the brain. Long term exposures result in demyelination and gliosis of cerebral and cerebellar white matter (2).

Of the abused inhalants, toluene is the most damaging. Toluene is a component of organic solvents and is found in gasoline, acrylic paints, varnishes, paint thinners, glues, and shoe polishes.

Ingested or Injected Toxins

Heavy Metals (Lead and Mercury)

The leading risk factor is exposure to lead-based paint found in older homes. Children are at highest risk for lead poisoning.

Lead's neurotoxic effects are due, in part, to its ability to substitute for calcium and include apoptosis, excitotoxicity, inhibition of mitochondrial respiration, effects on neurotransmission, and damage to glial cells.

Mercury exposure occurs primarily by inhalation. Less than 0.01% of liquid mercury is absorbed, and skin exposure results in even less absorption. Organic mercury is readily absorbed through the digestive tract. A common source of organic mercury is seafood contaminated with methylmercury used in fungicides.

Methanol

Methanol is found in many commercial solvents and in antifreezes. Intoxication is usually accidental or suicidal, and has occasionally been seen from intentional adulteration of alcoholic beverages. After ingestion there is a latent period of up to 72 h during which methanol is metabolized in the liver into formaldehyde and then to formic acid, resulting in a severe metabolic acidosis. These byproducts are toxic to the CNS.

CNS Disorders Related to Ethanol Abuse

Ethanol is among the most commonly abused drugs. In addition to ethanol's direct toxic effects, there are a number of associated CNS disorders including ►Wernicke–Korsakoff syndrome, ►Marchiafava–Bignami disease, and ►osmotic myelinolysis. In pregnancy, ethanol can be teratogenic, resulting in fetal alcohol syndrome, which affects CNS development. The direct neurotoxic effects of ethanol are poorly understood, but include neuronal damage and myelin degeneration.

Marchiafava–Bignami disease is a rare disorder of chronic alcoholics, first described in drinkers of cheap Italian red wine. The characteristic finding is cystic and laminated necrosis of the corpus callosum, particularly the *genu* and body. Similar findings may be noted in the optic chiasm, anterior commissure, centra semiovalia and brachium pontis. Histologically, there is demyelination with relative axonal preservation.

Osmotic myelinolysis is caused by damage to the blood–brain barrier induced by abnormalities in serum osmolality and electrolytes, particularly hyponatremia. Vigorous sodium correction frequently plays a role in development of osmotic myelinolysis. The pons is most frequently affected (central pontine myelinolysis), but extrapontine sites, including the thalami, basal ganglia, deep cerebral white matter, and lateral geniculate bodies, may be involved.

Clinical Presentation

Inhaled Toxins

Carbon Monoxide (CO)

Acute symptoms of CO toxicity include headache, nausea, vomiting, seizures, and syncope. Severe or prolonged exposures result in coma and death. Physical examination may reveal "cherry red" lips and mucosa. Hyperbaric O_2 is the treatment of choice for acute poisoning and needs to be instituted within 6 h of exposure (1). A delayed encephalopathy can be seen and is characterized by an asymptomatic period of 2–3 weeks after initial recovery, followed by recurrence of symptoms.

Organic Solvents and Aerosols

Chronic abuse of toluene results in cognitive impairment, ataxia, tremor, and cranial neuropathies. An encephalopathy can occur, characterized by euphoria, hallucinations, nystagmus, seizures, and coma (2).

Ingested or Injected Toxins

Heavy Metals (Lead and Mercury)

Symptoms of lead poisoning in children are vague and include decreased appetite, constipation, and abdominal pain. Neurological symptoms include lethargy, irritability, headaches, behavioral changes, and developmental delay. In severe cases, seizures, coma, and death can occur.

CNS effects of chronic mercury poisoning (also known as Minamata disease) include visual field deficits, sensory abnormalities, and ataxia, which are felt to be related to spongiotic changes in the calcarine and postcentral cortex and cerebellar vermis. Other symptoms are neuropathy, choreoathetosis, confusion, and coma. Mercury poisoning is treated with chelation.

Methanol

Patients present with blindness (due to optic nerve necrosis), obtundation or death (3). Treatment includes gastric lavage, administration of sodium bicarbonate to correct acidosis, ethanol administration, and hemodialysis.

CNS Disorders Related to Ethanol Abuse

Acute symptoms in Wernicke encephalopathy include nystagmus, abducens and conjugate gaze palsies, ataxia, and confusion. Korsakoff psychosis is a persistent abnormality of mentation that develops after the initial confusional state of Wernicke encephalopathy begins to resolve with B1 replacement; patients are alert and responsive but have antegrade and retrograde amnesia and confabulation. The term Wernicke–Korsakoff syndrome is applied when components of both Wernicke encephalopathy and Korsakoff psychosis occur (3).

Diagnosis

Inhaled Toxins

Carbon Monoxide (CO)

MRI is more sensitive than CT for detecting brain abnormalities in CO poisoning. Areas of involvement reflect regions of high oxygen demand. The most commonly involved sites are the globi pallidi, which on CT are of low density. MRI demonstrates high T2 signal and, in the acute setting, restricted diffusion in the globi pallidi (Fig. 1). Hemorrhage may be seen. The putamina/caudate nuclei, cerebral white matter, cortex, hippocampi, and cerebellum may also be involved (1). In delayed encephalopathy, MRI reveals confluent, symmetric T2 hyperintensity in the periventricular white matter and centra semiovalia.

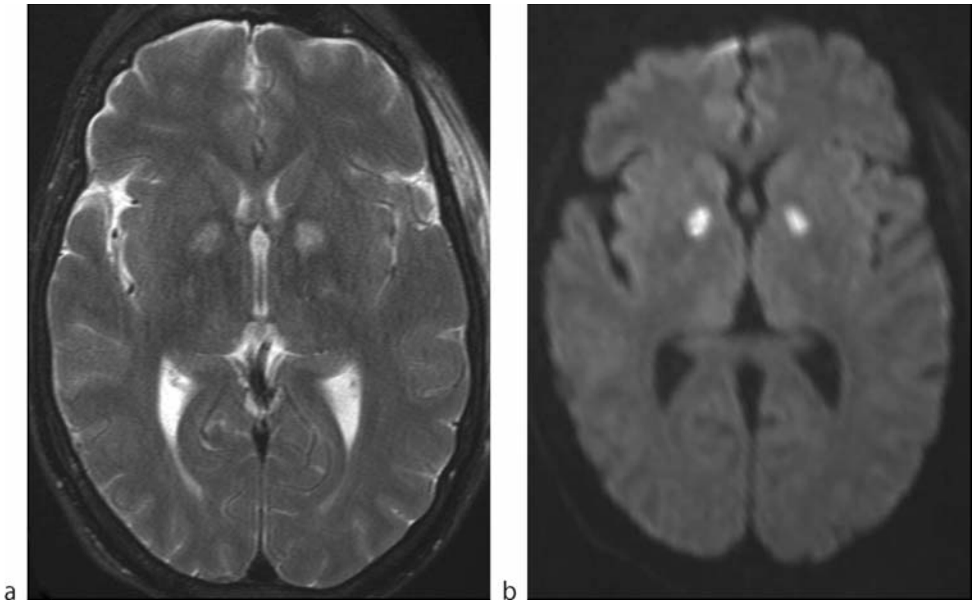
Organic Solvents and Aerosols

MRI in chronic toluene abuse shows diffuse cerebral, cerebellar, hippocampal, and brainstem atrophy, loss of cerebral grey-white matter differentiation, and abnormal high T2 signal in the periventricular white matter and centra semiovalia. Low T2 signal has been reported in the extrapyramidal system, including the thalami, basal ganglia, red nuclei, and substantia nigra. This finding may be due to iron deposition or to partitioning of toluene into cell lipid membranes (2).

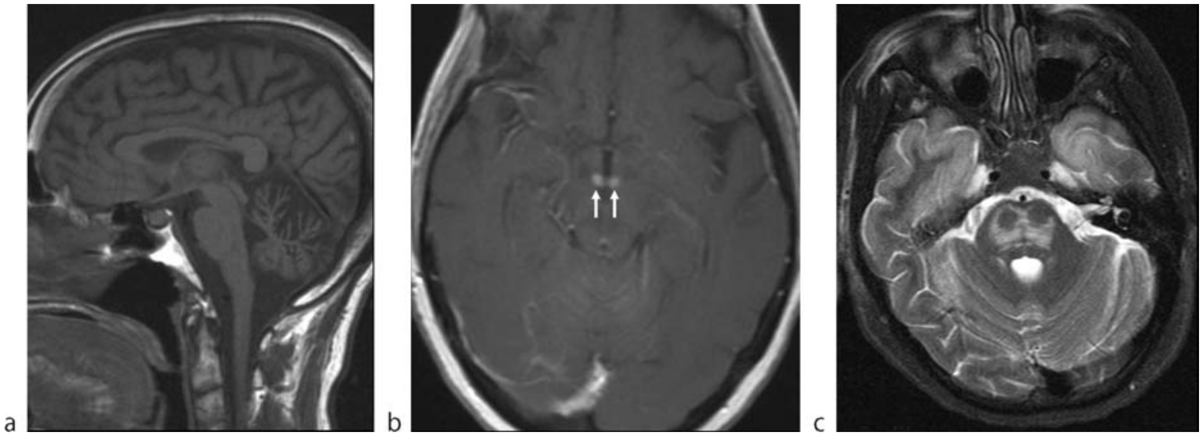
Ingested or Injected Toxins

Heavy Metals (Lead and Mercury)

CT findings include bilateral, symmetric hypodense lesions in the thalami, putamina, claustra, and insulae. MRI shows low T1 signal and high T2 signal areas without



Toxic Disorders, Brain. Figure 1 Acute carbon monoxide poisoning. (a) Axial T2-weighted MR image demonstrates symmetric hyperintensity in the globi pallidi. (b) Corresponding diffusion weighted image ($B = 1{,}000$) demonstrates high signal reflecting restricted diffusion in the globi pallidi.



Toxic Disorders, Brain. Figure 2 Spectrum of ethanol related brain disorders. (a) Midsagittal T1-weighted MR image in a chronic alcoholic demonstrates characteristic atrophy of the superior vermis. (b) Gadolinium enhanced axial T1-weighted image in a patient with Wernicke encephalopathy demonstrates enhancement of the mamillary bodies (*arrows*). (c) Axial T2-weighted image in a patient with osmotic myelinolysis demonstrates diffuse signal abnormality in the pons with sparing of the corticospinal tracts.

enhancement in these areas. In chronic poisoning, extensive cerebral and cerebellar calcifications can occur. Rarely, lead poisoning may manifest as localized cerebellar edema mimicking a mass (4).

MRI in Minamata disease shows atrophy of the calcarine and postcentral cortex and cerebellar vermis (5).

Methanol

Putaminal hemorrhagic necrosis is typical and imaging studies bear this out. On CT, the putamina are swollen and hypodense and may demonstrate hemorrhage. On MRI, they are T2 hyperintense and of high or low T1 signal. Diffuse white matter signal abnormality may also be seen (3).

CNS Disorders Related to Ethanol Abuse

On imaging, cerebral and cerebellar atrophy are noted in chronic ethanol abuse. Atrophy is most marked in the rostral vermis and adjacent cerebellar surfaces (Fig. 2a)

(3). Also observed early are white matter lesions in the periventricular regions thought to be due to myelin degeneration. These lesions manifest as rounded foci of high T2 signal adjacent to the ventricles and appear similar to lesions of multiple sclerosis.

B1 deficiency results in selective damage to the mamillary bodies, dorsomedial thalamic nuclei, pulvinars, walls of the third ventricle, periaqueductal gray matter, colliculi, third cranial nerve nuclei, inferior olives and superior vermis, reflected as high T2 signal within them. Contrast enhancement of the mamillary bodies in Wernicke encephalopathy is pathognomic (Fig. 2b) and hemorrhage may occasionally be seen. Absence of imaging abnormalities does not exclude the diagnosis of Wernicke encephalopathy (3).

In Marchiafava–Bignami disease, the anterior corpus callosum shows low T1 signal and high T2 signal. Signal abnormalities may also be seen in the centra semiovalia.

Osmotic myelinolysis classically reveals high T2 signal in the central pons with sparing of the corticospinal tracts (Fig. 2c) (3).

Toxic Encephalopathy

▶Toxic Disorders, Brain

Toxic Hepatitis

Toxic hepatitis consists in acute liver cell necrosis produced by chemical substances, which have a direct toxic effect on the liver. The most common hepatotoxins implicated in this disease are carbon tetrachloride, phosphorus, chloroform, gold compounds, fungal toxins. These substances are true hepatotoxins because they cause hepatic damage invariably in every individual. The onset is usually within 48 h and it is very similar to acute hepatitis. The symptoms are mainly represented by anorexia, nausea, vomiting, jaundice, and hepatomegaly. Obtaining a history of exposure to hepatotoxic agents is crucial for prognosis because the early removal of the hepatotoxin allows a rapid recovery, while the prognosis is poor if there is a prolonged period of exposure. The final stage of the disease is dominated by delirium, coma, and convulsions and within a few days the patient usually dies of fulminant hepatic failure. Only a few patients recover from acute toxic hepatitis and develop chronic liver disease which may be ultimately followed by postnecrotic cirrhosis.

Tracheo-Oesophageal Fistula

A congenital abnormality in which there is an abnormal fistulous connection between the oesophagus and the trachea; it is most frequently associated with oesophageal atresia but may occur in isolation.

▶GI Tract, Pediatric, Congenital Malformations
▶Oesophageal Disease, Childhood

Tracheobronchial Lesions

Tracheobronchial lesions should be suspected in all patients with penetrating wounds of the neck or chest or with severe chest trauma indicating high kinetic energies. Clinical signs are hemoptysis, pneumothorax, pneumomediastinum, subcutaneous emphysema, or an insufficient expansion of the lungs after drainage of a pneumothorax. More than 80% of tracheobronchial tears are located in the main bronchi lesser than 2.5 cm from the carina and predominantly on the right side. The "fallen lung sign" is indicative for main stem bronchial rupture, but incomplete bronchial rupture may be overlooked and definite diagnosis of airways lesions is usually made by endoscopy.

Screening method of determining risk of stroke in children with sickle cell disease.

▶Sickle Cell Disease

Transducer

A piezoelectric crystal that can convert electrical voltage to a mechanical vibration and vice versa. It can thus be used both for transmitting and receiving acoustic waves.

▶Ultrasound Imaging

Transient Hepatic Attenuation Differences (THAD)

THAD is a CT finding consisting in transient areas of enhancement of liver parenchyma during arterial-phase imaging returning to normal on portal-vein phase. THAD reflects a change in the normal dual blood supply of the liver characterized by a redistribution of the arterial flow to a hepatic segment or lobe, usually due to decreased portal or hepatic venous flow. THAD may be observed in liver cirrhosis, hepatic trauma, hepatic tumors, hereditary hemorrhagic telangiectasia, and after hepatic interventional procedures as a result of arterioportal shunts or focal obstruction of distal parenchymal portal venous flow. Peripheral, triangular, or wedge-shaped areas of arterial enhancement and nondisplaced internal vasculature can suggest the diagnosis.

Transient Synovitis

Alan E. Oestreich
Cincinnati Children's Hospital Medical Center,
Cincinnati, Ohio, USA
Alan.Oestreich@cchmc.org

Synonyms

Sterile effusion in one or more joints; Sterile inflammation of the hip

Definition

Abnormal fluid in the hip (or other joint) not due to infection, nearby tumor, foreign body penetration, juvenile idiopathic arthritis, or other known specific cause. The synovitis is usually self-limited, but occasionally it causes sufficient impairment of blood flow to the femoral head and neck to result in eventual Perthes disease.

A transient effusion without local sequelae in various joints may be a manifestation of such conditions as Lyme disease and some of the recurrent febrile genetic conditions.

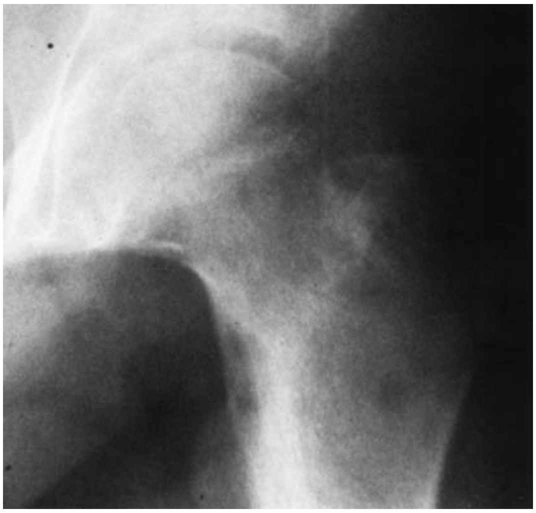
Pathology/Histopathology

By definition, the synovial fluid of transient synovitis contains no microorganisms. The synovium may become thickened, however. As in Lyme disease, ▶tumor necrosis factor receptor-associated periodic syndrome (TRAPS) (1), and osteoid osteoma, increased sterile fluid is present, and some synovial thickening may occur.

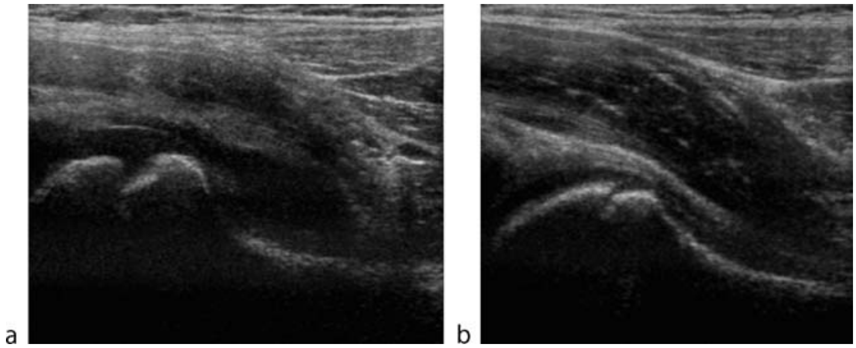
Clinical Presentation

Transient synovitis of the hip is heralded by reluctance to bear weight and perhaps irritability and malaise. In common with septic arthritis and other cases of abnormal hip fluid, the ▶log-roll test is usually positive, yielding pain signs from rolling the upper leg like a log. Septic hip is more likely to have systemic signs of infection such as fever. Hip fluid from femoral neck osteoid osteoma (Fig. 1) tends to be associated with pain at night from the osteoma, which is relieved by pediatric aspirin.

The toddler with a limp is a concern because of the possibility of septic hip arthritis; the discovery of a toddler's fracture of the tibia or fibula or a stress fracture of a tarsal bone or metatarsal is reassuring by revealing a less dangerous cause than pus in the hip. Transient synovitis is also nonthreatening, except when excessive fluid impairs blood flow to the femoral head and neck, raising a danger of Perthes disease as a sequela. Do not forget that neuroblastoma, other abdominal malignancy, or abdominal tuberculosis may cause a limp by involving the psoas muscle. Leukemia and other bone diseases of



Transient Synovitis. Figure 1 Osteoid osteoma near the hip: medial lucent zone in the neck of the left femur with mild surrounding sclerosis in a 12-year-old boy with nocturnal pain. In this example, the osteoid osteoma may be sufficiently distant from the hip capsule not to cause associated synovitis. (From Oestreich AE, Crawford AH (1985) Atlas of Pediatric Orthopedic Radiology. Thieme Verlag, Stuttgart, p 95)



Transient Synovitis. Figure 2 **Ultrasound images of excessive fluid in the hip of a 4-year-old with hip pain. (a) The capsule is bowed away from the anterior surface of the femur by relatively anechoic fluid on the anterior sagittal image. (b) Normal image for comparison.**

the lower extremity are other causes to consider when a limp is present.

Fluid in the hip (and shoulder) is not directly palpable, whereas fluid at other sites, especially the knee, is easily palpated. In general, this distribution reflects plain radiography, in which fluid in the hip and shoulder are not directly detectable, while joint effusion is easily recognizable by interfaces with fat at the knee, ankle, and other sites.

Imaging

One cannot rule out hip fluid on plain radiographs. Generally, fluid collects, even in the supine child, anteriorly, out of the plane seen on plain hip images. Occasionally a large amount of fluid might be noted to displace an obturator fat stripe medially in the pelvis, however, and in a rare infant so much fluid is present that the femoral shaft (and head if ossified) is laterally displaced. The primary imaging modality for hip fluid is ultrasound, with the probe appropriately anterior (Fig. 2). Such images may show synovial thickening as well, but they cannot distinguish pus from sterile fluid or blood. Consult the writings of Simon Robben et al for details on such ultrasound (2). Hip fluid is easily detected on computed tomography (CT) or magnetic resonance imaging as well.

Nuclear Medicine

Transient synovitis is not likely to be hot on bone scan, whereas infection of the hip joint may well be. Effusion secondary to femoral neck osteoid osteoma should reveal the lesion as a localized highly positive uptake. If Perthes disease complicates transient synovitis, lack of uptake will then be present in part of the femoral head. Indeed, during the acute transient synovitis, bone scanning is valuable to document acute loss of vascularity of the femoral head and neck, implying a more urgent need to drain the fluid.

Diagnosis

Fluid in the hip is not recognizable on plain radiographs (unless it is so voluminous as to show displacement of the obturator fat stripe inward, or, in an infant, to displace the femur laterally). The imaging diagnosis of hip fluid is by anterior longitudinal ultrasound in which the anterior capsule is seen to bulge anteriorly as the joint fills with fluid. The distance between that capsule and the bone beneath is increased. Sterile fluid and pus are generally indistinguishable on hip ultrasound. In an older child, one may rarely be surprised to see small bodies within the hip from ►synovial osteochondromatosis—many of these bodies are ossified, so they can be seen on plain images.

Interventional Radiological Treatment

The "interventional" diagnosis of sterile versus infected joint fluid may be done by needle techniques, under ultrasound, CT, or fluoroscopic guidance and documentation. Additionally, osteoid osteomas may be ablated by a variety of techniques under CT guidance, including radiofrequency ablation. Systems have been developed mechanically to guide the instrument more precisely to the nidus.

Transit Time Analysis

HOHMANN JOACHIM
Universitätsspital Basel Institut für Radiologie, Basel, Switzerland
jhohmann@uhbs.ch

Definition

The term transit time analysis is not well defined and therefore it is used in different ways. In general it means the analysis of the time course of an injected contrast agent at one specific or at different locations, e.g., different vessels or organs. The most obvious and most often used definition is the measurement of arrival times of contrast agents and the calculation of time differences of these arrival times at two or more locations. One example is the hepatic transit time (HTT) measurement in patients with liver cirrhosis or with occult liver metastases with ultrasound contrast agents, which will be described in more detail later.

Transit time analysis is strongly coupled with the evaluation of time intensity curves (TICs, Figs. 1 and 2) and there are other definitions of "transit time analysis" which deal not only with the determination of arrival times but, e.g., with the evaluation of the shape of the TICs. One example and yet a standard clinical application, even it is not called transit time analysis by most authors, is the behavior of breast lesions in breast MRI after contrast injection. The rise of the incoming contrast agent and the wash out in a breast lesion is used as a characteristic feature which determines weather this lesion is stated as benign or malignant.

What is the Goal?

The basic idea behind transit time analysis is always the same: to get information about the blood supply or even better to get a value which describes the blood supply in the investigated area. The hypothesis is that different pathologies lead to different and possibly specific and reproducible changes in transit time. Therefore transit time analysis of any kind can be regarded as a functional imaging method in contrast to the more common morphological approach of standard clinical imaging applications. Promising targets are the liver, the kidneys including transplanted kidneys, the spleen, the heart, the breast, and the brain, just to mention the most frequently investigated regions.

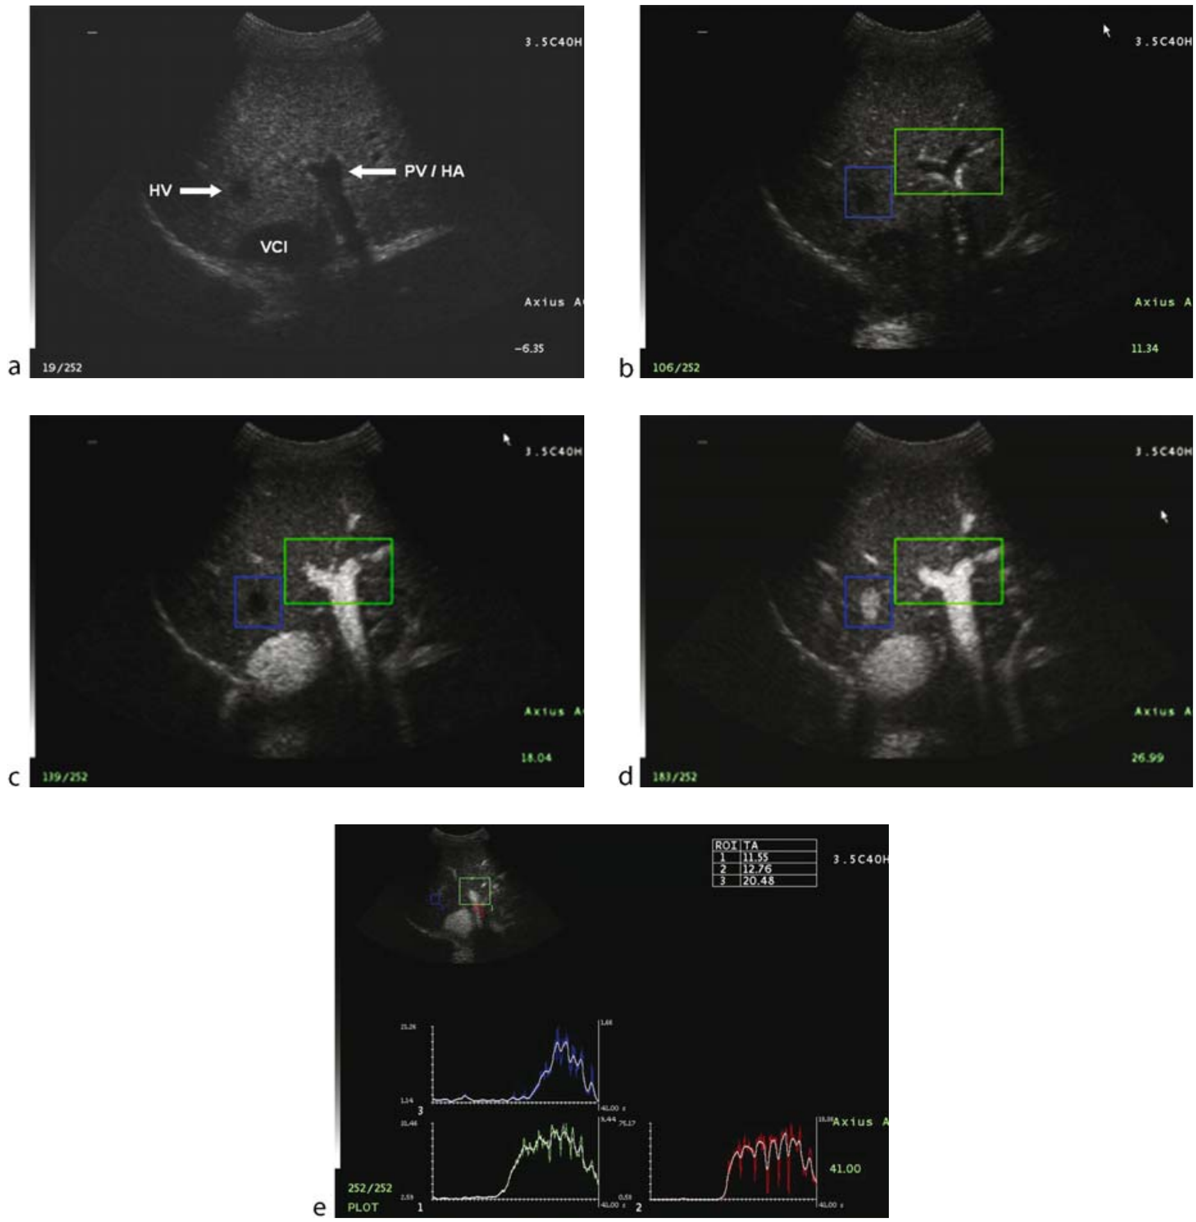
The use of contrast agents for this kind of functional imaging, especially while using ultrasound contrast agents, is a relatively new technique and therefore all the results so far have a more or less experimental or research status and the methods usually are not integrated in clinical routine examinations. Nevertheless there are some situations in which the use of transit time analysis is already helpful in clinical practice, e.g., the mentioned method for breast MRI. Another example is the detection of cardiac right-to-left shunts (RLS) with the ultrasound contrast agent Echovist (Schering, Berlin, Germany), which indeed resembles the most elementary form of transit time analysis in which it is only necessary to detect the contrast agent arrival at all.

The use of ultrasound and ultrasound contrast agents for transit time analysis has some advantages over other imaging modalities especially while using it for HTT analysis. The main advantage is the superior time resolution due to high frame rates of up to 30–60 images/sec. In addition the liver is completely accessible *via* ultrasound examinations in most cases and the spatial resolution is very high (<1 mm).

Methods in Use

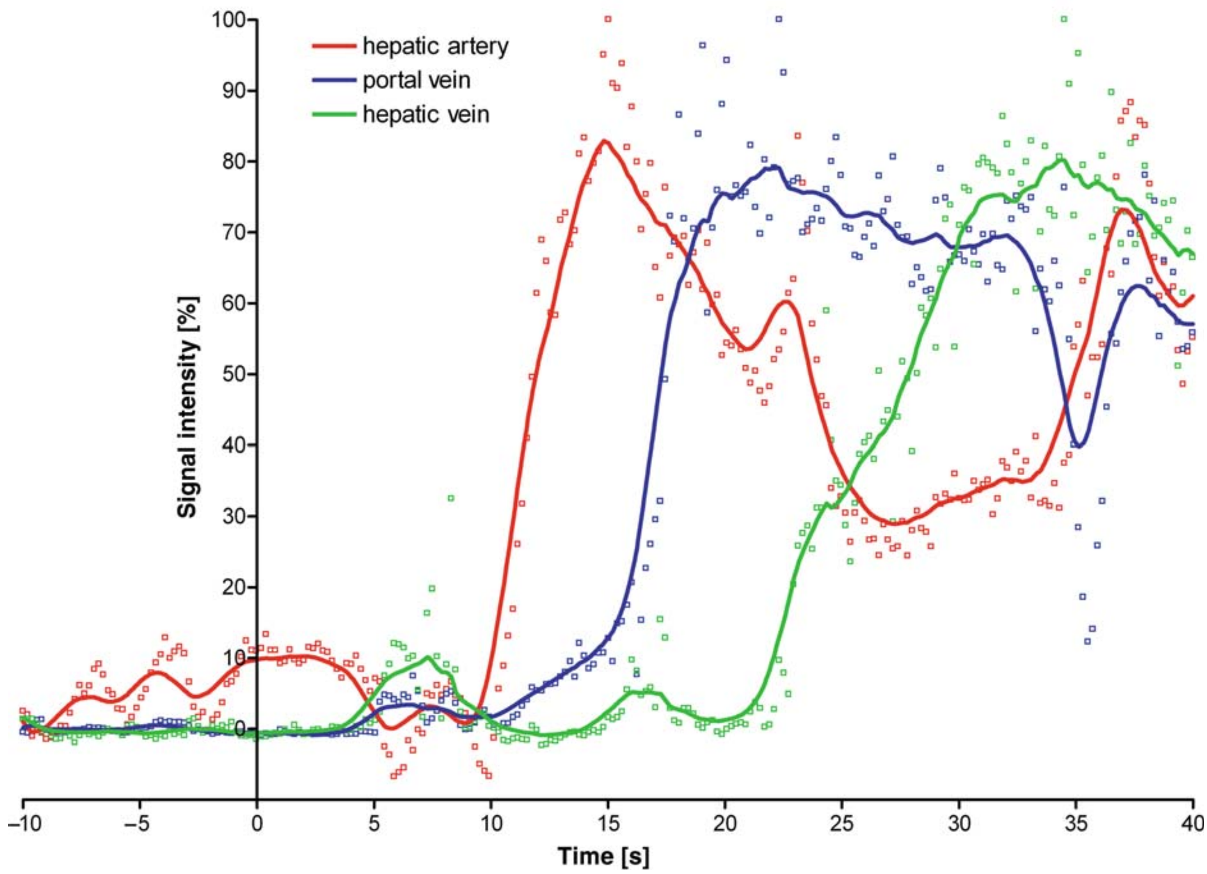
After a bolus injection of the contrast agent and a saline flush the signal intensities are recorded. The contrast agents which are already in use are Levovist (Schering, Berlin, Germany), SonoVue (Bracco, Milano, Italy), and Optison (Amersham, GE Healthcare), which are microbubble agents with different gases and different shells and therefore different pharmacodynamics and different resonance properties. The detection of these ultrasound contrast agents is done *via* special ultrasound techniques which are highly sensitive for the microbubbles. With Levovist-enhanced Doppler signals with a high mechanical index (MI) are in use, while phase inversion imaging with low MI and less bubble destruction is the standard for so-called "second generation" agents like SonoVue and Optison.

The simplest way to measure the arrival time is just to detect the contrast signal in a vessel of interest, e.g., the hepatic vein. In this case the transit time from the point of



Transit Time Analysis. Figure 1 Transit time analysis of the hepatic vessels with contrast-enhanced ultrasound using low mechanical index phase inversion ultrasound on a Siemens Elegra ultrasound machine with SonoVue: (a) While using an appropriate plane in the porta hepatica the portal vein (PV), the hepatic artery (HA, which can not be seen on baseline, but is usually adjacent to the portal vein), and at least one hepatic vein (HV) can be accessed simultaneously. (b) The use of regions of interest (ROI, HA, HV) of the build-in time intensity curve (TIC) software enables the *ad hoc* analysis of the curve and, e.g., the determination of the different arrival times (TA). The export of the data as a spreadsheet is also an option (see Fig. 2). The image shows the hepatic artery *11.34* s p. i. with contrast-enhanced signal and yet well-defined from the portal vein. (c) *18.04* s p. i. also the portal vein and the inferior vena cava (VCI) show a contrast signal. The hepatic vein is still not enhanced. (d) In the later phase at *26.99* s p. i. all vessels show an enhancement. (e) Calculated TIC for the HA (ROI 1), the PV (ROI 2), and the HV (ROI 3). Motion dependent changes of the corresponding ROI are corrected and the curves are also smoothed (white lines) by the software. TA are automatically calculated and shown for each ROI.

T



Transit Time Analysis. Figure 2 Time intensity curve from data which was exported as a spreadsheet and then analysed on a standard personal computer. Data was acquired over a time period of 50 sec with a 10 sec baseline ($t = 0$ sec is the time of injection) and a frame rate of 5/sec ($\delta t = 0.2$ sec), which results in 252 data points. The signal intensities are baseline corrected, normalized, and smoothed. When using the 10% threshold to define the arrival of the contrast agent the following arrival times (TA) are calculated: $TA_{hepatic\ artery} = 10.06$ sec; $TA_{portal\ vein} = 14.21$ sec; $TA_{hepatic\ vein} = 22.07$ sec. Assuming the HTT as the difference of the arrival of the contrast agent in the hepatic vein and the hepatic artery results in an HTT of 12.01 sec.

injection, mainly one cubital vein, to the hepatic vein can be measured. There are some drawbacks to this approach, such as the influence of circulatory impairment, e.g., in heart failure. Another method is the detection of the arrival time of the incoming system of an organ, e.g., the hepatic artery and the portal vein, and the outgoing system, e.g., the hepatic vein, and to calculate the time differences. The second approach makes the measurement more independent and more targeted to the system of interest.

Quantification

The simplest way is just to look at the location(s) of interest and to detect the incoming contrast agent visually. This is called the "visual approach." Another way is a computer-based evaluation. Time intensity signals are recorded and the evaluation of the TICs is done right after the examination. Baseline and maximum values are calculated and a threshold value must be defined. The threshold value is the signal intensity at which the arrival of the given contrast agent seems to be sure. Most transit time analyses define the threshold as the point of signal intensity which is 10% above the baseline signal, while the baseline signal is defined as the signal intensity without a given contrast agent. The major problem is the breathing of the patients. While the time interval for one measurement in the liver is at least 50 sec, it is not possible to do it in apnea. Therefore the regions of interest (ROI) in which the signals are measured shifts due to the breathing motion. Motion correction, automatically or manually, is needed and the TICs have to be smoothed. This may lead to some more or less important errors. In some cases other artifacts can occur, e.g., reflux of the contrast agent from the right atrium into the liver veins, which has to be taken into account and must be eliminated *via* the postprocessing procedures.

Equipment

Very important for the use of transit time analysis as a clinical routine application are the properties of the imaging equipment. Hence the focus of this essay is drawn to ultrasound measurements the focus of the equipment is consequently also drawn to ultrasound machines. First, there is the need of contrast agent specific software which allows special Doppler methods and/or phase inversion methods. Another point is an easy-to-use and fast quantification tool on the ultrasound machine itself. More and more manufacturers have such software packages in their portfolios which allow a realtime quantification of the achieved data. Despite the simple positioning of ROI a correction of the data due to artificial signal variations (see above) and the possibility of a manual correction at different time points are helpful. Nevertheless such tools are also in a more or less experimental status and up to now it seems to be safer to export the given data as a spreadsheet and to perform the evaluation with standard statistical software packages. With the more and more growing need for functional imaging in this specific area this must be changing.

Indication

As stated above, the status of transit time analysis is mainly experimental and therefore almost all indications are already research indications. The focus in ultrasound transit time analysis is drawn especially to the liver and the related HTT changes in patients with liver cirrhosis and occult liver metastases.

Liver Cirrhosis

The research done in the field of liver cirrhosis is dominated by the group of the Hammersmith Hospital, London, UK. It started in the late 90s and showed differences in the hepatic vein transit time (HVTT) due to the grade of liver cirrhosis. They measured the arrival time of an ultrasound contrast agent (Levovist) in the hepatic veins after injection in a cubital vein. Contrast-enhanced Doppler signals were recorded by an additional standard personal computer and arrival times (HVTT) were calculated *via* a MATLAB (The Mathworks, Massachusetts, USA) script. The results are promising and the latest publication showed a linear dependency of the arrival time from the grade of cirrhotic and precirrhotic liver disease in case of a single entity (hepatitis C virus, HCV) related disease (1). Other investigators did not get the same results while using standard Doppler methods without contrast agents. They found a large overlap in the Doppler measurements and findings between various disease stages. Therefore it seems safe to state that using a contrast agent improves the appraisal of the grade of liver cirrhosis and fibrosis. The special pharmacodynamics of Levovist, which has a proven liver-specific phase due to the incorporation of the Levovist particles in Kupffer cells seems to be helpful for the investigation of transit times in the hepatic blood supply. The difficulties with other contrast agents which have a “weaker” (e.g., SonoVue) or not at all a liver-specific phase is that the time differences of the arrival times tend to be shorter and therefore the individual variances seem to have a greater influence on the measurement, which may result in a greater overlap between normal and pathologic liver blood supply.

Occult Liver Metastases

As shown recently by the group of Leen using the standard Doppler methods blood supply properties of the liver seem to change due to the existence of occult liver metastasis. The group of Leen observed such changes in patients suffering from colorectal cancer (2). They found an increase of the arterial blood volume compared with the portal venous blood volume. This ratio was called the Doppler perfusion index (DPI) which was calculated as the ratio of hepatic artery to the sum of hepatic artery flow and portal venous flow. This is similar to the hepatic perfusion index (HPI) which was already investigated in the field of nuclear medicine for a long period. There are different possible underlying mechanisms concerning a humoral factor and/or some more or less mechanical properties. Kruskal et al showed in a remarkable study that the sinusoidal and postsinusoidal flow is significantly reduced prior to the occurrence of visible metastases probably due to an increased rolling and adherence of leukocytes (3). A further reduction was seen while the metastases are growing and an extrinsic compression of sinusoids and portal venules takes place. Unfortunately the promising results of Leen et al could not be reproduced by any other group. This may be due to the difficult examination technique which requires a really experienced examiner. Nevertheless in animal studies by Yarmenitis et al changes similar to the findings of Leen et al were found. Tumor bearing Wistar rats showed an increase of hepatic arterial blood flow and DPI 4 days after subcutaneous inoculation of a Walker 256 tumor (4). At this time only small groups of cells in the connective tissue were found in the *porta hepatica* and the portal triads with no apparent vascular association. Other attempts used contrast-enhanced US techniques which showed comparable results (5). Significant increase of hepatic blood flow was shown in small groups of patients with known liver metastases, mostly of different underlying primary tumors. These results gives rise to the idea that while using contrast agents the method might be more stable and that this examination technique might be easier to perform. Nevertheless there are no studies which included a greater number of patients at risk for liver metastases and a follow up to prove these assumptions like Leen et al did.

It has to point out that the definite answer to the question of the existence of occult liver metastasis in patients with especially colorectal carcinoma, which is the second most common cause of death from cancer in Europe and North America (~15%), is of great clinical importance for the therapy and clinical outcome of such patients. A reliable and reproducible method of detecting such metastases would help to treat these patients on a selective basis and might help to decrease the death rate.

Contraindication*

Contraindications depend on the material of the shell and of the gas phase. For Levovist this means galactosemia and pregnancy. Contraindications for SonoVue are also pregnancy and lactation. In addition SonoVue should not be given in patients with a known acute coronary syndrome, an instable ischemic heart disease, a heart failure (NYHA III/IV), heart rhythm disturbances, shortly after invasive coronary interventions, pulmonary hypertension (p > 90 mmHg), RLS or an acute respiratory distress syndrome (ARDS). Optison should be avoided when patients having severe liver insufficiencies and in patients with known or suspected hypersensitivity to blood, blood products, or albumin.

Pregnancy/lactation*

During pregnancy and lactation, transit time analysis of any kind should be avoided due to the already mentioned experimental and research status of the method.

Use and Dosage*

For transit time analysis, the contrast agent has to be given as a fast bolus with a following saline flush of about 10 mL. The dosage depends on the used agent and is usually 2.4 mL for SonoVue, 2.0 mL for Optison, and about 2.5 g (e.g., 5 mL; 400 mg/mL) for Levovist.

* see also detailed product information

Adverse Reactions*

Ultrasound contrast agents are very safe and adverse reactions are rare. Some mild adverse reactions are known and some very rare serious anaphylactoid adverse reactions in patients with heart failure have been observed with SonoVue.

Interactions*

There are none known interactions so far for intravenous administration.

Complication of kidney graft

Definition

Kidney transplantation is the replacement of a failed kidney with a working kidney from a donor. Kidney transplantation programs are based on organ donation from cadavers and occasionally living donors. The donation rates are low and organ shortage is an essential issue. The standard placement of the transplanted kidney is extraperitoneal, in the right iliac fossa. For an optimal perfusion, the procedure involves two end-to-end anastomoses: the single renal artery from the donor to the recipient iliac artery, and the donor renal vein to the recipient external iliac vein. The best urinary drainage is made *via* a ureteroneocystostomy, which involves reconstruction of the urinary tract by passing the donor ureter through a tunnel carved through the dome of the posterior bladder wall. This tunnel serves as a deterrent to urinary reflux with bladder contraction.

Complications of kidney graft can be classified into two groups:

1. Surgery complications: anastomosis troubles (artery stenosis, vein thrombosis, and ureter stenosis), leak (hematoma, lymphocele, and urinoma), infection (abscess), and prolonged cold ischemia before surgery (tubular necrosis).
2. Immune complications: acute and chronic rejection and immunosuppression with higher risk of infections, neoplasms, and toxicity.

Pathology/Histopathology

Surgery Complications

Acute tubular necrosis depends on the duration of ischemia, with a higher frequency when cold ischemia lasts more than 24–30 h (1). It usually resolves spontaneously in the first 2 weeks after transplantation. Histological findings include dilatation of the tubules, loss of proximal epithelial cell brush border, and epithelial cell necrosis and apoptosis.

Immune Complications

Acute rejection has several grades: tubulointerstitial with tubulitis and interstitial infiltration, vascular with intimal arteritis, severe with transmural arteritis. Chronic rejection is characterized on biopsy by fibrous intimal thickening, interstitial fibrosis, and tubular atrophy (2), and is preceded by episodes of acute rejection. Cyclosporin and tacrolimus can be nephrotoxic, producing vascular constriction or interstitial fibrosis.

Clinical Presentation

Early Complications

Pain is generally caused by urinary tract obstruction, vascular thrombosis, and infection. However, urinoma can be painful without any obstruction. Acute pain is a major symptom in venous thrombosis, whereas arterial thrombosis may be asymptomatic.

Pyrexia is typically related to infections. However, fever can be seen with hematoma, venous thrombosis, and rarely acute rejection.

Acute tubular necrosis and acute rejection are characterized by an asymptomatic renal failure, making differential diagnosis troublesome.

Late Complications

Most late complication findings are limited to asymptomatic graft failure. They include chronic rejection, transplant artery stenosis, and drug toxicity. Transplant artery stenosis can be suspected when arterial hypertension becomes resistant to treatments or when ACE inhibitors induce acute renal failure.

Imaging

Doppler and Ultrasound

Ultrasonography (US) is the noninvasive method of choice for exploring transplant kidneys. It is ideally performed with a low-frequency probe (3–4 MHz) for the main vascular structures, the global morphology, and surrounding tissues of the kidney. A high-frequency probe (7–8 MHz) is useful for an accurate analysis of the intrarenal vessels. The US examination should include: measurements of the graft size and cortex thickness, evaluation of the parenchyma differentiation, and detection of caliceal dilatation or fluid collections.

Color Doppler helps to locate proximal and distal vessels of the transplant. Power Doppler detects perfusion defects in parenchyma. Because of the particular orientation of the vessels parallel to the probe at both poles of the transplant, the apparent perfusion defect should not be interpreted as infarcts.

Pulsed Doppler provides information on the peak systolic velocity in extrarenal arteries and the resistance index (RI) in intrarenal arteries. The superficial situation of the transplant makes the spectral analysis sensitive to the pressure applied by the transducer. Velocity measurements are particularly useful at the level of anastomoses, and care should be exercised in correcting the angle between the vessel and ultrasound directions. Maximal velocities in the main artery should be slower than 120 cm/s. The RI should be between 0.6 and 0.8.

MRI

Magnetic resonance imaging (MRI) is the second choice, when ultrasound findings are not fully convincing.

Contrast-enhanced 3D fast gradient echo sequences used for MR angiography offer multiplanar capabilities, including maximum intensity projection (MIP) and multiplanar reformatting (MPR). T1-weighted sequences are used for the parenchyma study.

Heavily T2-weighted 2D or 3D MR urography sequences before contrast administration help to detect ureteral pathology and peritransplant fluid collections (3)

CT

Computed tomography (CT) is of limited use due to the nephrotoxicity of the iodinated contrast agents.

CT without injection is sometimes sufficient to appreciate peritransplant fluid collections and hematomas. CT is typically used to guide interventional procedures (biopsy, fluid aspiration, drainage, nephrostomy).

Pyeloureterocystography

Pyeloureterocystography (through percutaneous nephrostomy catheter) is usually performed in cases of obstruction or urinoma, to detect ureteral stenosis or urinary leakage. Retrograde cystography is performed when reflux is suspected.

Arteriography

This invasive procedure is reserved as a therapeutic option in the case of arterial stenosis, arteriovenous fistula, or aneurysm.

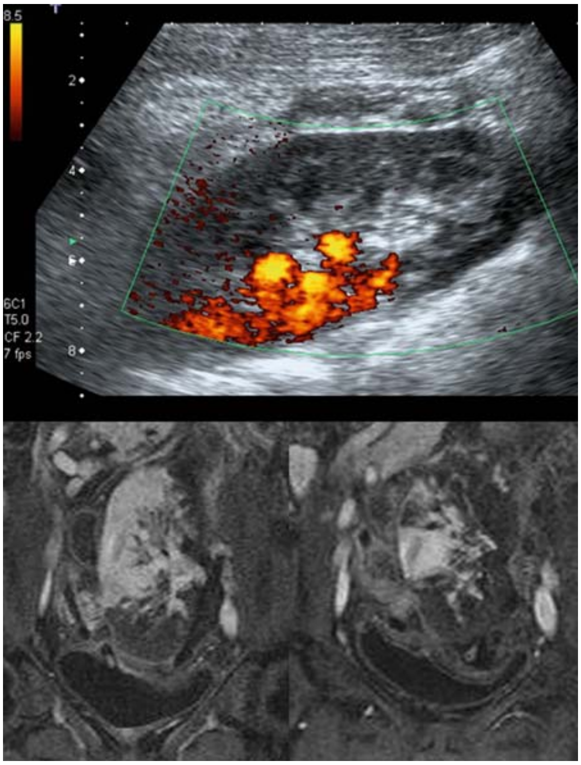
Diagnosis

Early Complications

Vascular

Arterial thrombosis: Color Doppler detects absence of blood flow in the graft. Power Doppler with a high-frequency transducer shows no flow in the cortex. Sometimes, a spectral waveform can still be observed in arteries with absent diastolic flow and reduced amplitude. Thrombus can be observed in the main vein as a consequence of arterial thrombosis. The main differential diagnosis is hyperacute rejection where no flow is detectable. In equivocal cases, the diagnosis may be confirmed by MR angiography (Fig. 1).

Venous thrombosis: It must be evoked in the case of acute pain and abrupt cessation of renal function.



Transplant Kidney, Complications. Figure 1 Renal artery thrombosis with infarction. (a) Power Doppler color shows absence of flow in the lower pole of the graft. (b) Coronal contrast-enhanced–fat-suppressed T1-weighted MR images confirm infarction of the lower pole of the graft, probably due to segmental artery thrombosis.

Diagnostic criteria on US are associated with no detectable venous flow on color Doppler with reversed and prolonged diastolic flow in intrarenal arterial vessels on pulsed Doppler. Reversal diastolic flow alone is nonspecific and can be seen in acute tubular necrosis and severe rejection. Direct visualization of acute thrombus is often difficult. Nonspecific signs also include raft swelling and hypoechogenicity, sometimes associated with infarction when diagnosis is delayed. Thrombectomy should be performed in an emergency.

Pseudoaneurysms: US shows a lesion like a simple or complex cyst, with swirling flow on color Doppler, sometimes with thrombus. The pseudoaneurysm neck can be seen to contain alternating jets of forward and reverse flow.

Acute rejection: Asymptomatic, acute rejection is usually diagnosed at biopsy, but may be suggested by color Doppler in the case of edematous and thickened cortex as well as loss of corticomedullary differentiation associated with an RI higher than 0.9. Reversed diastolic flow has been described in some cases (1); however, it is less marked than in venous thrombosis.

Acute tubular necrosis: The diagnosis is suspected in the case of prolonged ischemia, delayed function recovery, and normal Doppler. However, loss of corticomedullary differentiation and/or increased RI can be seen. The differential diagnosis with acute rejection or drug toxicity is usually made at biopsy.

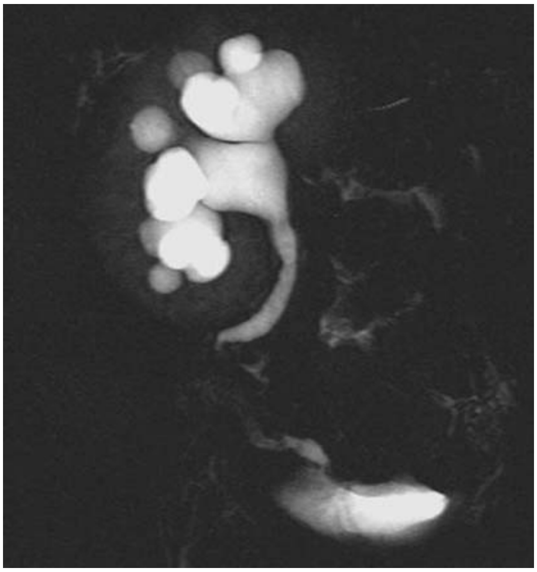
Urinary Tract Obstruction

Dilatation of the collecting system may be obstructive or nonobstructive, and is best seen with US. Mild dilatation is observed commonly very early, due to postoperative edema at the ureteroneocystostomy site.

Obstruction may be due to extrinsic processes (e.g., peritransplant fluid collection) or to ureteral stenosis. MR urography, and pyeloureterocystography in the case of nephrostomy, shows the localization and the degree of stenosis. MR urography is able to demonstrate a parietal thickening of the ureter in cases of ischemic stenosis (Fig. 2).

Collections

Hematomas are extrarenal or subcapsular in location, usually self-limiting, sometimes obstructing when large. The US pattern varies over time: echogenic in the acute phase, hypo- or anechogenic later. High attenuation of acute hematoma on CT decreases over time. The MRI signal is heterogeneous.



Transplant Kidney, Complications. Figure 2 Ureteral stenosis. Coronal T2-weighted MR urography shows extended ureteral stenosis with collecting system dilation.

Urinomas usually develop at the lower pole of the graft, with the extraperitoneal location being more frequent than the intraperitoneal one. Internal septations may be seen, but less often than in lymphocele. Pyelography and CT with opacification by percutaneous nephrostomy are the examinations of choice, showing the fistula and the collection.

Lymphoceles appear as septated fluid collections with low-level echoes, usually inferior and medial in location to the graft.

Perirenal abscess can occur on a preexisting peritransplant fluid collection or most rarely de novo. They appear most often on CT as a heterogeneous collection, occasionally with gas. Diagnosis and treatment require imaging-guided aspiration and drainage.

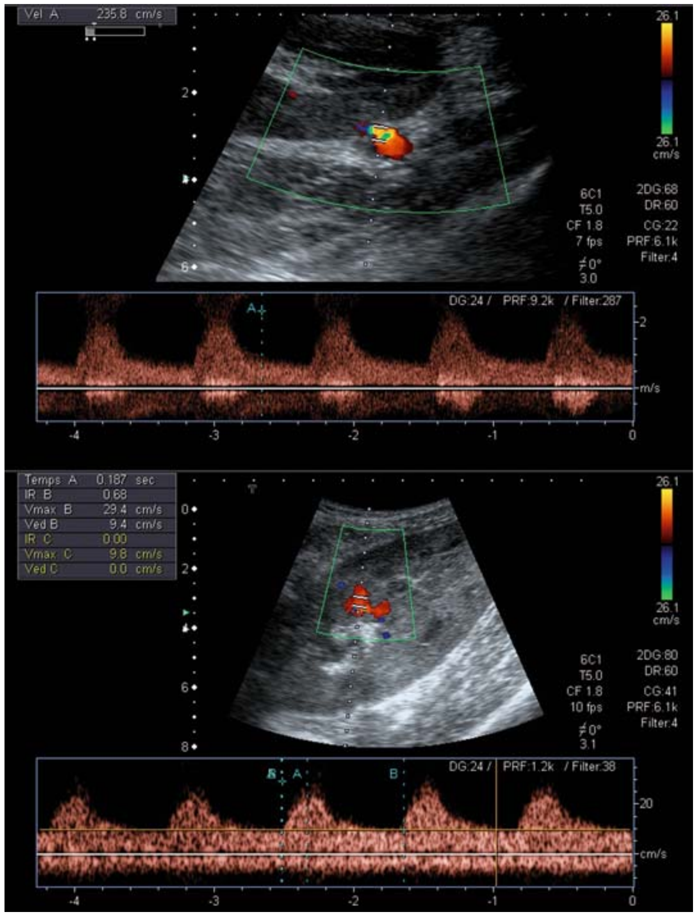
Later Complications

Artery stenosis is often detected with Doppler US, and further confirmed with MR angiography. Color Doppler shows an area of aliasing on a stenotic segment, usually at or close to the surgical anastomosis. Doppler spectrum demonstrates focal elevated peak systolic velocity, greater than 2 m/s. A decreased intrarenal RI is variably present, but adds confidence to the diagnosis (Fig. 3). The diagnosis can be difficult in the case of tortuous renal transplant artery, which may cause increased peak systolic velocity and focal aliasing in color Doppler (2). MR angiography allows a better visualization of the transplant arteries than US, thanks to its multiplanar reformatting. It shows the localization and the severity of the stenosis preoperatively.

Arteriovenous fistula is not linked to surgery but to transplant biopsy which is performed in equivocal cases. This complication can be recognized with color and pulsed Doppler, showing an area of aliasing artifact on color Doppler because of high velocities in the fistula, with low-resistance flow in the supplying artery on pulsed Doppler and arterialization in the draining vein (1).

Chronic rejection can be suggested by US, showing a small graft, thin cortex with increased echogenicity, mild hydronephrosis, and disrupted corticomedullary differentiation. Color Doppler can demonstrate a reduction in the number of intrarenal vessels with increased RI. Impaired renal function, associated with these findings, suggests the diagnosis, which is then confirmed at biopsy.

Infection: Asymptomatic bacteriuria is common. Pyelonephritis is also common and ultrasound is used to exclude obstruction or complications such as abscess. MR or CT parenchymography can show focal parenchymal defects and peritransplant infiltration suggesting the diagnosis.



Transplant Kidney, Complications. Figure 3 **Renal artery stenosis. (a) Pulsed-wave color Doppler US image shows high velocity at the stenotic segment (2.36 m/s) in the region of the anastomosis. Note focal aliasing on Color Doppler at the stenotic segment. (b) Intrarenal spectral Doppler shows low-resistance waveform.**

Neoplasms: Lymphoma and renal cell carcinoma are the two most common graft malignancies. Imaging findings of lymphoma are nonspecific; however, it appears classically as a hypovascular and infiltrative mass, with a predilection for the hilum (4). Renal cell carcinoma appears as a heterogeneous mass, with loss of the graft shape. Nevertheless, percutaneous biopsy has to be performed in all cases of solid mass; renal cell carcinoma requires transplant nephrectomy, lymphoma does not.

Definition

Liver transplantation is a lifesaving therapeutic intervention for patients with severe acute or chronic liver failure for whom no other therapy is available.

Chronic viral hepatitis, alcoholic liver disease, metabolic diseases (alpha-1-antitrypsin deficiency, hemochromatosis, Wilson's disease), cholestatic liver disorders (primary biliary cirrhosis, primary sclerosing cholangitis, biliary atresia), and acute hepatic necrosis represent the most frequent indications for liver transplantation.

Patients with hepatocellular carcinoma (HCC), cholangiocarcinoma, or inoperable neuroendocrine metastases are also potential candidates for liver transplantation. Increasing evidence suggests that with careful patient selection, liver transplantation is the treatment of choice in patients with small HCCs.

On the contrary, liver transplantation is absolutely contraindicated in the presence of acquired immunodeficiency syndrome, extrahepatic malignant tumors, and active intravenous drug use or alcohol abuse (1).

A variety of transplant techniques have been employed. ►Orthotopic liver transplantation (OLT) is the most commonly used procedure and consists in the replacement of the diseased liver by a liver from a cadaveric donor. The standard technique of OLT requires grafting of one arterial anastomosis (hepatic artery), two venous anastomoses (portal vein and inferior caval vein), and a biliary anastomosis (duct-to-duct or hepaticojejunostomy).

Because of the shortage of cadaveric organs, alternative techniques such as ►split-liver donation (in which one donor organ is used for two recipients) and ►living donor liver transplantation (where the donor undergoes partial hepatectomy for donation to a recipient) have been developed.

Characteristics

Pretransplant Imaging

The role of imaging in the pretransplant assessment is to target patients suitable for liver transplantation and to identify anatomic abnormalities or variants that may impact surgical planning.

The pretransplant imaging evaluation includes an accurate exploration of both liver parenchyma and vascular structures (1, 2). Assessment of the arterial and venous hepatic anatomy is of utmost importance in candidates for liver transplantation in order to detect vascular variants or abnormalities and mismatches in donor and recipient vascular size.

Arterial abnormalities require identification before liver transplantation: several arterial anatomic variants may alter the surgical approach and stenotic celiac artery lesions must be alleviated to avoid biliary complications, as hepatic arterial inflow represents the sole blood supply to the posttransplantation bile ducts.

Many patients who are candidates for liver transplantation are cirrhotic and it is very important to have an overview of the portal system of these patients, who are likely to have portal hypertension: the demonstration of portal vein patency and identification of varices are mandatory before liver transplantation. Caval abnormalities must also be excluded.

An evaluation of the liver parenchyma is required for the detection of primary and secondary hepatic malignancies. Additional care is needed in patients affected by HCC and since liver transplantation seems to be the best therapeutic option in patients with single HCC smaller than 5 cm or in patients with less than three HCCs smaller than 3 cm, an accurate radiological staging is utmost important in defining the number and tumor size and in the identification of negative prognostic factors such as vascular invasion, nodal involvement, and extrahepatic metastases.

Ultrasound

Pretransplantation ultrasound (US) evaluation involves Doppler examination of the portal and hepatic veins and real-time B-mode imaging of hepatic parenchyma and bile ducts (1, 2).

US investigation is widely employed for the screening of HCC in cirrhotic patients waiting for liver transplantation. The recent advantages in US technology, including the availability of US contrast agents and the development of nonlinear specific contrast imaging methods, have further improved the sensitivity and specificity of US imaging in the diagnosis of focal liver lesions.

Moreover, Doppler US allows the investigation of flow dynamics through the hepatic veins, the portal vein and its branches, and the intra- and extrahepatic parts of the hepatic artery, representing a sensitive tool for the detection of portal vein thrombosis as well as of arterial abnormalities. It also enables an accurate evaluation of the localization and flow of varices and portosystemic shunt.

Finally, US evaluation offers a complete survey of the abdomen including the demonstration of splenomegaly and ascites.

Computed Tomography

Abdominal spiral computed tomography (CT) is a highly accurate method for the evaluation of the hepatic vessels and liver parenchyma alike.

In particular, three-phase multidetector CT angiography, by means of a double-arterial phase followed by a portal-vein dominant phase, provides a comprehensive depiction of the hepatic arterial and venous anatomy as well as an accurate evaluation of liver parenchyma.

Multidetector row scanners are particularly useful for angiographic applications and several studies show that, in transplantation candidates, multidetector row CT angiography is as accurate as conventional angiography in the evaluation of the hepatic artery anatomy and in the detection of arterial abnormalities such as severe ►celiac artery stenosis and ►splenic or ►*hepatic artery aneurysm* that may lead to liver transplantation (2). CT has the well-known advantage of being safer, more convenient, and more easily tolerated.

Moreover, multiphase enhanced CT provides an accurate evaluation of the liver parenchyma, representing a useful tool in the detection of intrahepatic or extrahepatic malignancies, and in particular it plays a crucial role in the diagnosis and preoperative staging of HCC.

Finally, spiral CT allows a precise evaluation of splenic, superior mesenteric, and portal veins and is useful in the assessment of complications due to portal hypertension such as presence of retroperitoneal, splenorenal, gastroesophageal, or paraumbilical varices and splenomegaly and ascites.

Magnetic Resonance Imaging

Thanks to the recent implementation of new magnetic resonance (MR) technologies, MR imaging of the liver has became a reliable tool for the evaluation of the parenchyma, vascular structures, and biliary anatomy, allowing a complete pretransplantation assessment by using just one imaging modality.

With respect to spiral CT, MR imaging (a) offers the possibility of improved liver parenchyma evaluation in patients with cirrhosis and HCC by the use of hepatocyte- and RES-specific contrast agents, (b) eliminates exposure to ionizing radiation, and (c) uses intravascular–interstitial contrast materials with favorable safety profiles compared with iodinated contrast materials.

Moreover, the availability of MR angiographic techniques allows identification of hepatic artery variants or abnormalities and an accurate evaluation of the portal vein in terms of patency and flow direction.

Finally, using heavily T2-weighted pulse sequences, MR cholangiography offers a high-resolution imaging of the biliary tree, obviating the need for invasive cholangiography in patients affected by cholestatic liver disorders (1, 3).

Invasive Techniques

A variety of invasive imaging techniques such as angiography, cholangiography, and percutaneous or transjugular biopsy have been used in the preoperative evaluation for liver transplantation. However, since the rapid improvements in noninvasive vascular and biliary imaging, particularly in CT or MR angiography and MR cholangiography, the need for pretransplantation catheter angiography and cholangiography has been drastically diminished. Therefore, preoperative angiographic evaluation of arterial and venous liver structures as well as cholangiographic pretransplant examination are rarely necessary and are reserved for a small number of cases in which imaging evaluation is inconclusive (1).

In patients with cirrhosis and HCC, percutaneous biopsy US or CT-guided confirmation should be limited to cases that do not meet current noninvasive diagnostic criteria, in view of the risk of tumor dissemination.

A transjugular approach to reach the liver parenchyma is safe and useful in patients requiring liver biopsy to establish the extent of underlying cirrhosis in nonneoplastic disease.

Posttransplant Imaging

At present, there is a great demand for accurate evaluation of complications occurring after liver transplantation as early diagnosis is critical for graft salvage. Because the clinical presentation of several posttransplantation complications is frequently nonspecific and varies widely, imaging studies are critical for early diagnosis and are required in particular when vascular, biliary, or surgical injuries are suspected (1, 3, 4).

US is the initial imaging technique used for the detection of complications in the early postoperative phase, since it can be performed at the bedside and allows an accurate evaluation of the hepatic parenchyma, vascular anatomy, and bile ducts. In cases where US findings are uncertain or clinical suspicion of a complication persists despite normal US images, spiral CT or MR imaging should be performed. CT and MR, thanks to the recent technical improvements, are both effective methods for a comprehensive assessment of vascular, biliary, parenchymal, and extrahepatic structures in most recipients of liver transplantation, while hepatobiliary scintigraphy (^{99m}Tc-HIDA scintigraphy) is useful in assessing biliary complications.

Finally, invasive imaging methods, such as cholangiography and angiography, can be performed in selected patients to confirm US and CT or MR findings or when the noninvasive imaging evaluation is inconclusive (1).

Arterial Complications

Arterial complications include hepatic artery thrombosis, hepatic artery stenosis, and hepatic artery pseudoaneurysms. Hepatic artery thrombosis is estimated to occur in

6% of patients and is the most frequent cause of graft loss. Graft ischemia causes biliary leaks and strictures as well as hepatic infarction requiring immediate retransplantation. Hepatic artery stenosis is reported in about 5% of cases and generally occurs at the anastomotic site within 3 months of transplantation. If left untreated, it can lead to arterial thrombosis or progress to cause liver ischemia with hepatic insufficiency, biliary strictures, sepsis, and graft loss. Finally, hepatic artery pseudoaneurysm is an uncommon complication of liver transplantation and it represents a rare cause of hematobilia, hemoperitoneum, and gastrointestinal bleeding that may be life threatening. Doppler US is the primary screening technique for detection of these complications. Absence of Doppler flow signal and increase in peak systolic velocity are indicative, respectively, of hepatic artery thrombosis and stenosis (1). However, Doppler US evaluation of arterial abnormalities is associated with a significant frequency of false-negative results and in several cases further investigations are required. In particular, CT and MR angiography are widely used to confirm the Doppler US findings or when the US study is suboptimal (3, 4). However, despite several studies showing that both CT angiography and MR angiography are as accurate as angiography in the evaluation of arterial posttransplantation complications, catheter angiography is often used to achieve the final diagnosis.

Portal and Caval Vein Complications

Portal vein complications following liver transplantation are relatively unusual and occur in 1–3% of cases. The clinical presentation of portal vein stenosis or thrombosis includes symptoms of portal hypertension, liver failure, massive ascites, or edema and it is readily identified on noninvasive studies including US, CT, and MR imaging.

A thrombus in the portal vein is seen on B-mode US imaging as echogenic intraluminal material, and CT or MR angiography provides an excellent visualization of filling defects within the portal vein.

The demonstration of turbulent flow within the portal vein at Doppler US examination allows a presumptive diagnosis of portal vein stenosis requiring CT or MR angiography confirmation (1, 3, 4).

The prevalence of inferior caval vein complications, such as stenosis or thrombosis, is less than 1%.

US and CT examinations may show pleural effusions, ascites, and hepatosplenomegaly and Doppler examination of hepatic veins may demonstrate flow reversal and absence of periodicity in the hepatic venous waveform. A definitive diagnosis, however, is based on cavography and pressure gradient measurement (1).

Biliary Complications

Biliary complications after transplantation include obstruction, stricture, stone formation, and leak. Obstruction occurs more frequently than other complications in both adult and pediatric patients and is most often secondary to an anastomotic stricture that results in dilatation of the donor bile duct.

Bile leak is caused by technical failure at the T-tube site or at the duct–duct anastomosis and by hepatic artery thrombosis at a nonanastomotic site.

Cholangiography is the mainstay for diagnosing liver in biliary complications. US and CT are useful for demonstrating secondary findings such as biloma and bile duct dilatation, but these are not sensitive for the detection of early bile duct abnormalities. MR cholangiography is a noninvasive alternative to cholangiography and represents the most important imaging technique for biliary evaluation in patients who do not have a T-tube in place (1, 3).

Finally, ^{99m}Tc-HIDA scintigraphy is also useful for detecting bile leaks and obstructions in liver transplant recipients. Extravasated bile may appear as diffuse activity within the peritoneal cavity (subhepatic–suprahepatic space, paracolic gutter, or into surgical drains) and the extension of leaks is often better identified on delayed images.

Both in complete extrahepatic biliary obstruction and in severe intrahepatic cholestasis, ^{99m}Tc-HIDA scintigraphy typically shows normal hepatocellular uptake and persistent parenchymal activity without any excretion. When the obstruction is partial and progresses slowly, the scan shows more activity in the dilated portion of the biliary tree proximal to the obstruction with minimal or absent radioactivity in the distal common duct and in the intestinal lumen. On the contrary, the demonstration of bowel activity on the delayed images without biliary visualization is suggestive of intrahepatic cholestasis.

However, in the presence of elevated bilirubin levels, scintigraphy may have limited value and T-tube cholangiography appears more effective for the evaluation of biliary tract complications.

Rejection

Acute rejection is cell mediated and is characterized by lymphocyte infiltration. It is common in the early postoperative period and can be managed with immunosuppression therapies. Since the radiological and scintigraphic findings are nonspecific, including an increased hepatic artery resistance on Doppler US, periportal parenchymal changes on CT, and reduced uptake of the radionuclide on ^{99m}Tc-HIDA scintigraphy, the diagnosis is made on histological grounds.

Chronic rejection is characterized histologically by arteriolar occlusive lesions and obliteration of bile ducts.

It does not respond to immunosuppression therapies and retransplantation is the long-term treatment.

Surgical Complications

There is a risk of abdominal complications associated with major abdominal surgery in liver transplant recipients (1). Fluid collections and hematomas are frequent in the areas of vascular and biliary anastomosis as well as in the lesser sac, surrounding the ligament teres, and in the peri- and subhepatic spaces and they are readily recognized on US and CT examinations. Fluid collections usually resolve over several weeks.

Other rare abdominal complications of liver transplantation include adrenal hemorrhage and acute pancreatitis.

Interventional Treatment

A wide spectrum of image-guided interventional procedures can be performed in the pre- and posttransplant setting. In patients with cirrhosis and HCC, transarterial chemoembolization or radiofrequency thermal ablation can be used as a bridge to liver transplantation to prevent tumor progression while patients are on the waiting list.

Transjugular intrahepatic portosystemic shunt (TIPSS) is very useful for the control of portal hypertension complications including acute variceal bleeding and massive ascites refractory to endoscopic or medical therapy.

Despite the advances in surgical techniques and the improvement of medical treatments, complications following liver transplantation are still a significant cause of graft loss and patient mortality.

Interventional radiological procedures, including percutaneous transluminal angioplasty or stenting, endovascular coil embolization, percutaneous bilioplasty or stenting, and percutaneous drainage are effective therapeutic options for vascular and biliary posttransplant complications obviating the need for further surgical intervention or retransplantation (5).

In particular, percutaneous balloon angioplasty and stenting have been widely employed in the treatment of both arterial and venous stenosis. Hepatic artery stenosis can be treated by percutaneous balloon angioplasty with an 80–100% technical success rate. Restenosis occurs in 30–60% of cases, and stenting has recently been proposed to increase long-term patency. Angioplasties and stenting are also effective in the treatment of venous stenosis by means of a transjugular or a percutaneous intrahepatic approach, with a reported success rate of 60–100%.

Arterial and venous thrombosis may benefit by local infusional fibrinolysis after selective catheterization of the affected vessel. Endovascular coil embolization may be performed for the treatment of unusual vascular complications that occur after liver transplantation, such as bleeding injuries and arteriovenous fistulas.

Interventional radiology is also an effective therapeutic alternative for the treatment of most biliary strictures complicating OLT. Management of biliary strictures is largely influenced by their nature and extension: anastomotic strictures are suitable for a percutaneous approach with a high success rate. On the contrary, percutaneous management of more complex hilar and intrahepatic strictures is less successful, and surgical revision or retransplantation may be necessary for definitive treatment.

Finally, bile leaks and fluid collections can be treated by means of percutaneous drainage.

In conclusion, interventional procedures constitute a minimally invasive and effective approach in the management of complications after liver transplantation, and these are also suitable for critical patients. Successful treatment of posttransplant complications, however, requires careful diagnostic assessment and optimized techniques.

bartolozzi@med.unipi.it
lencioni@med.unipi.it

Definition

The first pancreas transplantation was performed in 1966 by Kelly et al at the University of Minnesota in Minneapolis. To date over 1,000 transplants have been performed at the same university and over 15,000 worldwide, as recorded by the International Pancreas Transplant Registry (IPTR). Despite its invasiveness, pancreas transplantation is currently the only therapy capable of determining a complete recovery in patients with type I diabetes mellitus. Advances in more potent immunosuppressive therapy, improvement in surgical techniques, and postoperative imaging evaluation have allowed pancreas transplantation to become a successful procedure of choice.

Transplantation enables a total restoration of endogenous secretion of insulin as well as regression or stabilization of the degenerative complications of diabetes. In patients presenting chronic renal failure, pancreas transplantation combined with kidney transplantation is the most appropriate therapeutic option. The combined kidney–pancreas transplantation can be performed simultaneously with a kidney from the same cadaveric organ donor (simultaneous pancreas–kidney transplantation or SPK) or from a living donor (simultaneous pancreas-living kidney transplantation or SPLK); in some cases pancreas is transplanted after previous kidney transplant (pancreas after kidney transplantation or PAK). Solitary pancreas transplantation (pancreas transplantation alone or PTA) is reserved for patients without clinically significant nephropathy in the presence of other complications of diabetes (retinopathy, neuropathy, vasculopathy). An alternative new therapy that also may improve diabetes is ►islet transplantation; however that procedure is still experimental and not yet as efficient as pancreas transplantation.

Pancreas transplant results are reported to the Scientific Registry of the United Network for Organ Sharing (UNOS) and the IPTR. Based on this information, the national 1-year patient, kidney, and pancreas survival rates for recipients of an SPK transplant are 95%, 89%, and 85%, respectively. Compared to diabetic recipients of a kidney alone, the addition of a pancreas improves long-term patient and kidney graft survival. Recipients of a pancreas-after-kidney or a pancreas transplant alone have an average 1-year pancreas graft survival rate of about 70–75%.

Characteristics

Surgical Technique

Pancreas transplantation consists of the implantation of the entire gland together with a segment of the duodenum, which is used to drain the exocrine pancreatic secretion. The main technical variants relate to the type of exocrine secretion drainage (duodenocystostomy or duodenoenterostomy) and venous drainage (systemic or portal). The pancreas is removed together with the duodenum, the liver, and the spleen and separated from the liver by detaching the splenic artery from the celiac tripod and the superior mesenteric artery from the aorta and by resecting the gastroduodenal artery, the main bile duct, and the portal vein above the pancreas head. Splenectomy concludes the preparation of the pancreas, with the resection of the superior mesenteric artery, immediately distal to the origin of the inferior pancreaticoduodenal artery and the superior mesenteric vein (distally to the uncinate process of the pancreas). An arterial Y-graft is then fashioned for the simultaneous revascularization of the superior mesenteric and splenic arteries; in most cases an iliac Y-graft is taken from the same donor. When the liver is not transplantable, an aortic patch comprising the origin of the two arteries can be used.

The pancreas is placed intraperitoneally in the right iliac fossa of the recipient. There are currently three possible categories of transplantation: ►systemic-bladder, ►portal-enteric, and ►systemic-enteric drainage. In systemic-bladder drainage the arterial graft and the portal vein are anastomosed with the recipient's common or external iliac artery and vein, respectively, whereas the exocrine pancreatic secretions are drained by an anastomosis between the donor's duodenum and the bladder. Although this technique offers some advantages (especially the usefulness of urine amylase for identifying a change in pancreas function) it results "nonphysiological." All patients develop metabolic acidosis due to urinary loss of bicarbonates, 40% of patients suffer from urological complications, and 1% from pancreatitis due to urinary reflux through the duodenocystostomy. Furthermore, in contrast to the normal situation whereby insulin is released into the portal circulation, the transplanted pancreas secretes hormones into the systemic circulation, such that euglicemia is reached at the price of hyperinsulinaemia. An alternative to this is the recently proposed technique of portal-enteric drainage, in which the portal vein is anastomosed with the recipient's superior mesenteric vein and the exocrine secretions are drained by an anastomosis between the duodenum and a small bowel loop with a diverting Roux-en-Y limb or a side-to-side duodenoenterostomy. Portal venous drainage of the pancreas is more physiological thanks to an immediate delivery of insulin to the recipient liver. This results in diminished circulating insulin levels relative to that in systemic venous-drained pancreas grafts. Moreover, enteric drainage of pancreas grafts is physiological with respect to the delivery of pancreatic enzymes and bicarbonate into the small bowel loops for reabsorption. In the systemic-enteric drainage technique the insulin is released into the common or external iliac vein and the exocrine secretions are drained into a small bowel loop (1–3).

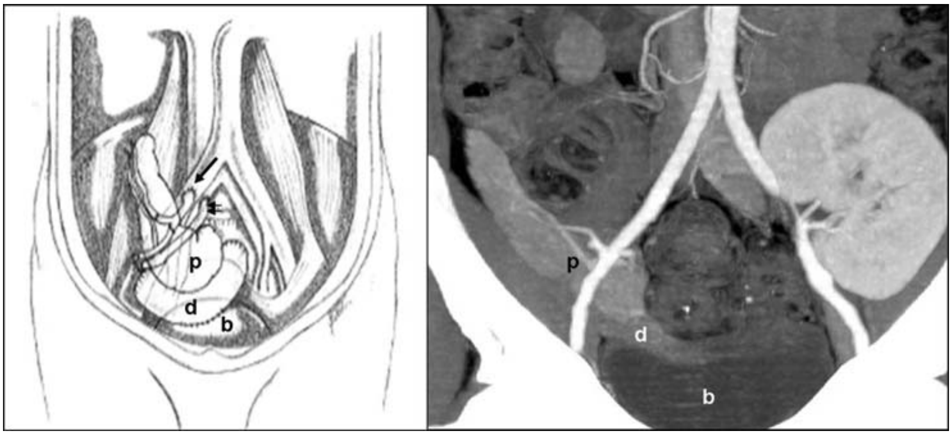
Posttransplantation Imaging

Despite recent advances in surgical techniques and postoperative management, complications are still frequent, thus each patient need a careful clinical and imaging follow-up. Possible complications include graft acute or chronic rejection, pancreatitis, leaks of anastomoses, vascular complications, peripancreatic fluid collections, and systemic complications due to the immunosuppressive therapy (infectious and neoplastic). Clinical surveillance of pancreatic allografts is difficult because of the relative lack of specificity of most physical and laboratory abnormalities, including fever, abdominal pain (due to peritoneal irritation, because of the absence of innervation of the pancreatic graft), graft tenderness, leukocytosis, hyperglicemia and change in insulin requirement, elevated serum amylase, lipase, anodal trypsinogen, and pancreas-specific protein; in bladder exocrine drainage, also reduction in urine amylase levels and positive urine cytology can be found. Therefore imaging evaluation is often necessary to identify possible complications.

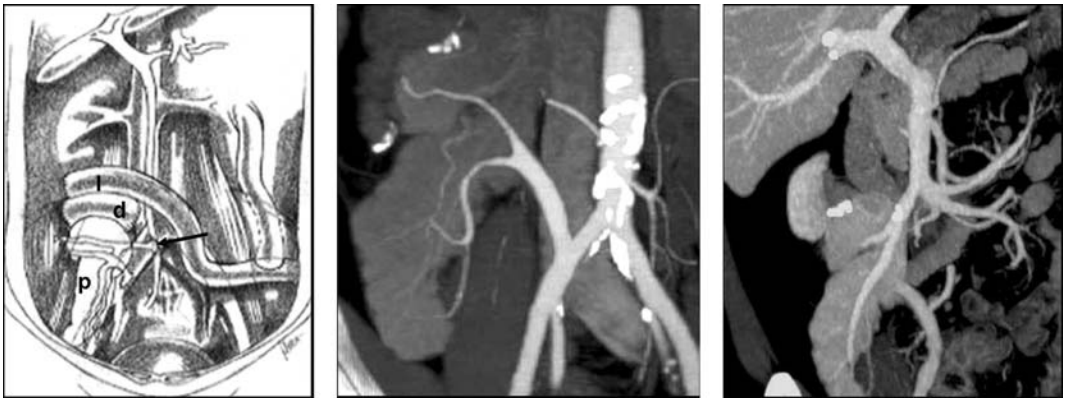
US plays a major role as first-line modality in the postoperative evaluation of the pancreatic graft. Normal transplanted pancreas appears homogeneous, with echogenicity similar to that of muscles and surrounded by more echogenic omental and peritoneal fat; expected dimensions of the normal pancreatic head, body, and tail are no greater than 3 cm, 2.5 cm, and 2.5 cm, respectively. However, US evaluation of the transplanted pancreas often results difficult, because of its intraperitoneal placement, where overlying bowel loops can limit its explorability. Color or power Doppler imaging can aid in locating the pancreas, by showing vascular anastomoses and intraparenchymal major vessels. Furthermore color and power Doppler sonography are able to assess vascularization and spectral analysis of intraparenchymal and peduncular venous and arterial flow can be performed.

CT examination should be performed after intravenous contrast medium administration in transplanted patients without impaired renal function. In particular, thanks to the possibility to perform acquisition in selective arterial and venous phases with thin slices, spiral and multidetector CT allow of precisely defining the postsurgical anatomy of solitary or combined pancreas transplantation, either performed with the systemic-bladder, the portal-enteric or systemic-enteric technique. (Figs 1 and 2). In particular detailed visualization of the anastomoses for exocrine pancreatic drainage and vascular anastomoses can be obtained to understand the surgical technique; selective study in arterial and venous phase associated to MPR, MIP, and VR reconstructions results particularly useful to depict the vascular structures and possible vascular abnormalities. Pancreatic parenchyma can also be assessed to identify focal or diffuse lesions. A further advantage of CT study is the possibility to scan also the entire abdomen and, if necessary, the chest during a single examination, to depict possible distant complications.

MR examination also allows a complete evaluation of the transplanted pancreas, including parenchymal, vascular, and ductal structures, by using both unenhanced conventional sequences and acquisition after gadolinium or tissue-specific contrast medium injection, MR angiographic sequences and MRCP studies (also after secretin injection, to assess the exocrine function). Moreover MR examination can be performed also in patients with impaired renal function (4, 5).



Transplantation, Pancreas. Figure 1 Left image: anatomical representation of the systemic-bladder pancreatic drainage. The duodenum (d) is anastomosed with bladder (b), while the arterial and venous grafts of the pancreas (p) are anastomosed with the common iliac artery (*arrow*) and with the common iliac vein (*double arrow*), respectively. Right image: MIP reformation after CT study. Combined kidney–pancreas transplantation performed by means of the systemic-bladder drainage technique (p: pancreas; d: duodenum; b: bladder).



Transplantation, Pancreas. Figure 2 Left image: anatomical representation of the enteric-portal pancreatic drainage. The duodenum (d) drains the exocrine secretion of the pancreas (p) in a small bowel loop (l), while the venous graft is anastomosed with the superior mesenteric vein (*arrow*). The arterial graft is anastomosed with the common iliac artery. In this case the small bowel loop is inverted according to the Roux technique. Central and right images: MIP reconstructions after CT study of the arterial and venous vessels, respectively.

Graft Acute and Chronic Rejection

Graft rejection represents the most fearful complication of transplantation. Acute rejection is characterized by mononuclear inflammation and usually responds to increased immunosuppression, while chronic rejection consists of luminal narrowing and intimal thickening of the vessels, which leads to fibrosis and hypoperfusion, with consequent poor pancreatic exocrine and endocrine function without improvement with therapy. Therefore early detection of acute rejection is of critical importance to institute an adequate immunosuppressive therapy to prevent further graft loss.

Unfortunately the early sign of both acute and chronic rejection may be subtle and aspecific. Delayed finding include hyperglicemia, because endocrine function may continue with only 25% of endocrine cells functioning. For SPK transplantations, rejection usually involves both grafts. Because renal rejection could easily be diagnosed by monitoring serum creatinine levels, the accepted practice is to use renal rejection to determine pancreas rejection. In PTA transplantation no single biochemical marker is able to demonstrate acute pancreatic graft rejection and to differentiate rejection from other causes of graft dysfunction, such as vascular thrombosis or pancreatitis. US and Doppler findings of chronic rejection include hypoperfusion, and increased parenchymal and vascular resistance with a reduction of systolic and diastolic flow. Ultrasound abnormalities that have been associated with acute rejection include gland enlargement and either focal or diffuse areas of decreased echogenicity, peripancreatic fluid, without pancreatic duct dilatation; however the demonstration of early signs of rejection with ultrasound remains inconstant. Moreover, these findings are also seen in cases of vascular compromise and pancreatitis. Unlike renal transplants for which specific resistive index values have been proved to be accurate predictors of acute rejection, no reliable resistive index measurement has been established for at-risk pancreatic grafts, because the pancreatic graft lacks a capsule, and an edematous pancreatic graft may not possess adequate intraparenchymal pressure to produce a reliable measurement of vascular resistance. Although changes in resistive index are a poor indicator of acute rejection, the absolute value of the resistive index results elevated in cases of chronic rejection.

CT and MR findings also are usually aspecific in case of acute rejection and indistinguishable from that of an acute pancreatitis or a parenchymal injury caused by a vascular thrombosis. At MR the glandular signal intensity results either less than the signal intensity of muscle on T1-weighted images or greater than or equal to the signal intensity of the bladder urine on T2-weighted images. In cases of suspected acute graft rejection often histopathologic diagnosis remains the most effective and reliable method. In chronic rejection the pancreas appears small, with inhomogeneous parenchymal structure or completely calcified, and vascular abnormalities (stenosis or obstructions) can be found. These findings are easily detected by means of US, CT, and MR studies. Transplanted pancreas with rejection enhanced less and inhomogeneously after both gadolinium or Mn-DPDP injection at MR and iodinate contrast medium at CT, because of vascular damage (4–6).

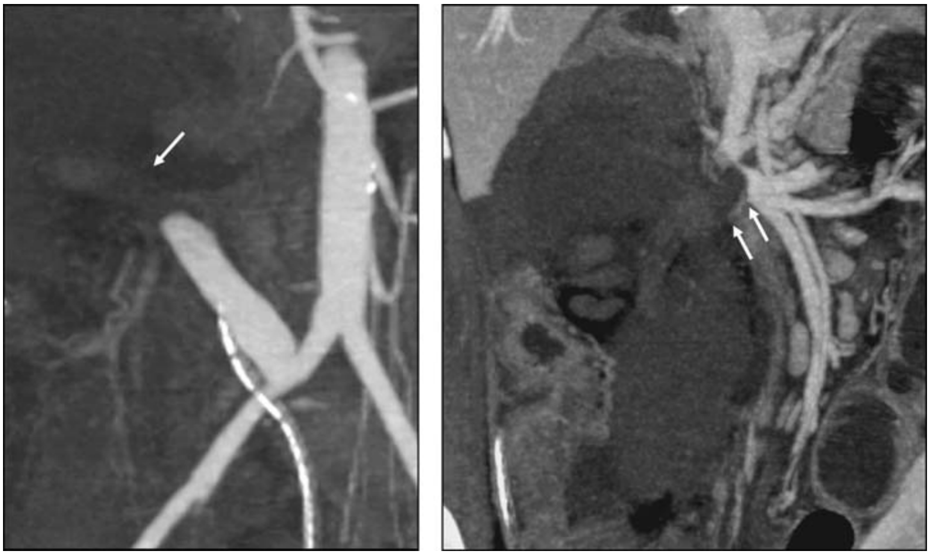
Vascular Complications

Vascular complications of pancreatic grafts are common, with vascular thrombosis second only to acute rejection in abnormalities leading to graft loss. Late thrombosis which occurs more than 1 month after surgery, can results from severe acute rejection, leading to arteritis. Early graft thrombosis has been attributed to a variety of etiologic factors, such as surgical vascular graft lesions, procurement and perfusion injury, poor preservation, reperfusion injury reflecting total cold ischemia time, and, in arterial thrombosis, anastomosis to atherosclerotic vessels. Moreover splenectomy causes low-flow in splenic vessels, predisposing to thrombosis. Partial early venous or arterial thrombosis may be completely asymptomatic, without causing pancreatic dysfunction; partial venous thrombosis can be treated by means of systemic heparin, while partial arterial thrombosis may not require treatment. In case of complete vascular thrombosis prompt treatment is necessary, by means of surgical thrombectomy, Fogarty chateters or transchateter fibrinolysis or heparin, to avoid parenchymal infarction, which require immediate remove of the organ.

Other possible vascular complications include arterial stenoses which are usually secondary to intimal damage in the site of surgical anastomoses or caused by clamping of the artery or by the catheter used for perfusion of the organ. Other arterial lesions that may occur include pseudoaneurysms and arteriovenous fistula secondary to percutaneous biopsy. An arteriovenous fistula between the superior mesenteric artery and superior mesenteric vein occurs occasionally and is related to the surgical technique of stapling the mesenteric vessels together rather than separate dissection and ligature of the vessels. Doppler sonography has been particularly important in detecting vascular complications such as thrombosis, anastomotic strictures, and pseudoaneurysm formation. Thrombosis is demonstrated by the absence of perceptible arterial or venous tracings as well as by direct visualization of intraluminal echogenic material that occludes blood flow. High velocity or turbulence at the arterial or venous anastomoses suggests strictures, and arterial flow within a perianastomotic fluid collection, the presence of swirling blood flow at color flow sonography indicates a complicating pseudoaneurysm. CT also enables the identification and precise characterization of all vascular complications. More specifically, CT study, performed with thin slices, identifes the presence of thrombotic material within the vessels, vascular stenoses or obstructions at level of anastomoses or involving intraparenchymal branches. Compensatory collateral circulation can be identifed in chronic obstructions. Parenchymal ischemic infarction is suggested in the absence of contrast enhancement in the arterial and venous phases (Fig. 3) (4–6).

Pancreatitis

Pancreatitis of the allograft occurs to some degree in all patients postoperatively. Temporary elevation in serum amylase levels for 48–96 h after transplantation is common. These episodes are transient and mild, without significant clinical consequence. In bladder-drained pancreas transplantation pancreatitis can occur because of the reflux of urine through the ampulla and into the pancreatic ducts. If recurrent graft pancreatitis occurs,



Transplantation, Pancreas. Figure 3 MIP reconstructions in the arterial (*left*) and venous (*right*) phases after CT study in a case of parenchymal ischemic infarction. It is possible to observe a complete arterial (*arrow*) and venous (*double arrow*) thrombotic obstruction and the absence of parenchymal enhancement in both arterial and venous phases.

enteric conversion may be indicated. The radiological findings in pancreatitis are nonspecific and similar to the features seen in acute rejection. The patient's serum amylase and lipase levels are usually markedly elevated.

Fluid Collections

Fluid collections are frequently found in transplanted patients, especially during the early period after the transplant. A small amount of fluid around the pancreatic allograft due to leakage at the site of the anastomosis is commonly seen. In some cases infection of fluid collections and sepsis may occur, favored by immunosuppression. In such cases systemic antibiotic therapy and sometimes image-guided percutaneous fine needle aspiration with chemical analysis and bacterial culture are required; fluid collection can be drained, if appropriate, by percutaneous image-guided techniques. Infection of peripancreatic collection may result in necrosis of the transplanted organ and necessitate its surgical removal. In bladder exocrine drainage some fluid collections may originate from leak of the duodenocystostomy, while in enteric-drained pancreas transplantation leak of duodenoenterostomy can occur, leading in both cases to severe infectious peritonitis. This serious complication requires prompt imaging diagnosis to perform operative repair. Sonography is a suitable method for detecting retroperitoneal or intraperitoneal fluid collections; however, the findings are usually nonspecific. Hematomas, abscesses, urinary leaks, ascites, and anastomotic leaks can appear as anechoic, hypoechoic, or complex, debris-filled, irregular collections. On CT, infection of the fluid collection can be suggested if air is demonstrated. The presence of blood can also be recognized if high attenuation is seen on CT or if typical signal intensities are revealed on MR. Cystography is accurate in the detection of collections originating close to the anastomosis between the duodenal stump and the bladder, but in some cases also the CT can demonstrate the site of fistulization. Moreover CT and MR allow a better depiction of the relations of the fluid collections with the surrounding structures (4–6).

Transvaginal Sonography

An imaging technique used to examine the female genital organs, i.e. vagina, uterus, ovaries and fallopian tubes, as well as the urinary bladder. For the transvaginal appraoch, a high resolution probe is inserted into the vagina that causes sound waves to bounce off organs inside the pelvis. These ultrasound waves creates echoes that a re sent to a computer, which creates a picture called a sonogram. Sonography is usually the first imaging techique applied for the diagnosis of a suspected pathology of the female genital organs.

Transverse Diameter

Largest transverse distance on an oblique section of the pelvic inlet.

▶Magnetic Resonance Pelvimetry

TRAM (Transverse Rectus Abdominis Musculocutaneous)

A type of breast reconstruction following mastectomy, made with a transverse rectus abdominis musculocutaneous flap.

▶Recurrent Neoplasms, Breast

Transverse Relaxation Time

This term relates to the T2 time constant, which determines the rate at which excited protons reach equilibrium or go out of phase with each other.

Synonyms

Brachial plexopathy; Brachial plexus injury; Dejerine–Klumpe paralysis; Erb-Duchenne paralysis

Definition

This includes any bone or soft tissue injury which occurs during the delivery process. They occur during difficult deliveries and in particular during breech deliveries.

Clinical Presentation

Overall the clavicle is the most commonly fractured bone during delivery (1). In a study by Joseph and Rosenfeld 80% of *clavicular fractures* are asymptomatic (2). They maybe detected by the presence of a palpable mass over the clavicle some weeks after birth due to callus formation.

Rib fractures are also rare and may also be asymptomatic unless injury is so extensive that there are respiratory difficulties (1).

Long bone fractures usually present with soft tissue swelling and there maybe reduced movement in the affected limb. *Brachial plexus injury* occurs in 0.5–2.6 cases per 1,000 live births and the risk is highest in macrosomic infants delivered by a shoulder or breech presentation. Other risk factors include mid or low forceps delivery and vacuum extraction. The usual mechanism of injury is lateral traction of the neck. The injury ranges from transient neuropraxia secondary to stretching of the extradural plexus in mild cases to severe avulsion of the rootlet from the cervical cord. Injury to the fifth and sixth cervical nerve roots is called ►Erb-Duchenne paralysis and accounts for approximately 90% of obstetric brachial injuries. Clinical signs of Erb-Duchenne paralysis include an adducted, internally rotated upper extremity with variable flexion of the wrist. In the 5% of patients with fourth cervical nerve involvement, respiratory symptoms such as tachypnoea and poor ventilation may occur. Injury of the eight and first thoracic nerve roots or the lower trunk is called ►Dejerine–Klumpe paralysis. Such injury is uncommon in isolation. These infants demonstrate paresis of the intrinsic hand muscles and claw hand. Ipsilateral Horner syndrome may be present (3).

In trauma to the cervical spine and cervical cord the most common predisposing factor is hyperextension of the cervical spine. In addition to brachial plexus injuries these infants may have generalised floppiness, a bell-shaped chest due to hypotonia and respiratory distress because of reduced thoracic movement (1).

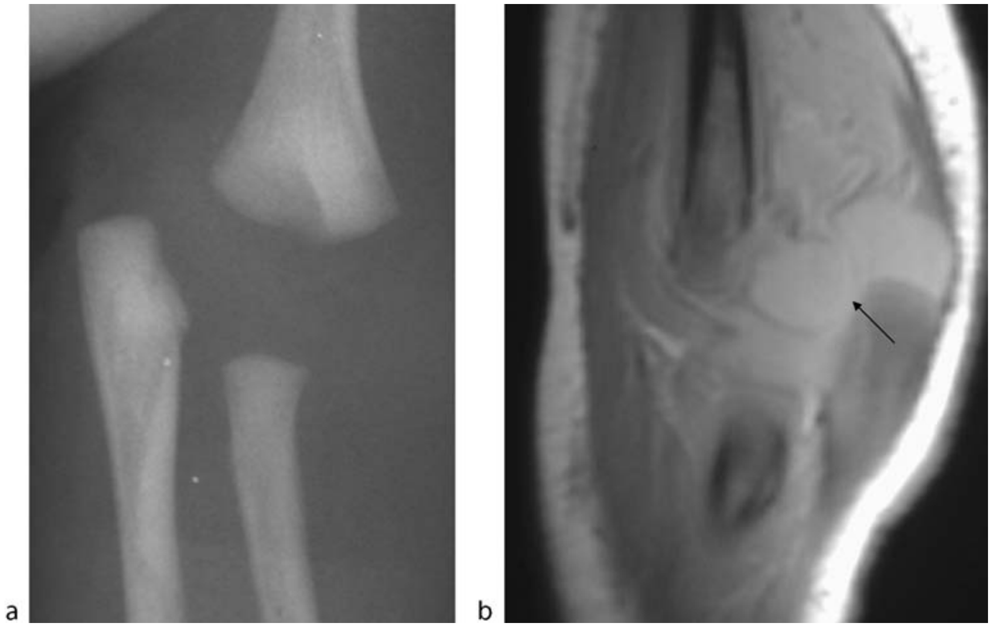
Trauma to the liver and spleen are occasionally encountered. Perinatal hypoxia has been implicated in some cases. This causes congestion and as a result increased susceptibility to rupture. Obstetrical trauma has also been invoked as a cause of adrenal haemorrhage in newborn infants. Iatrogenic fetal injury such as lacerations and digit amputations during caesarean section delivery is rare but serious. Cranial injuries, in particular subdural haematomas, occur more frequently in infants delivered by means of forceps or vacuum. These are discussed elsewhere.

Imaging

Fractures of the clavicle are often in the midclavicular region and are detected by plain radiography. Callus formation is usually seen at 7–10 days after birth. Rib fractures are similarly identified.

Fractures of the long bones can occur at the diaphysis or at the epiphyseal-metaphyseal junction in keeping with a Salter-Harris type I or II injury. Plain radiography may show just soft tissue swelling as there is no epiphyseal ossification. True traumatic joint dislocation is uncommon in the newborn and when there is joint space widening evident the most common cause is separation of the metaphysis from the epiphysis due to an underlying epiphyseal-metaphyseal fracture (1) (Fig. 1a). These injuries maybe well delineated using ultrasonography or magnetic resonance imaging where the displacement of the cartilaginous epiphysis is identified (Fig. 1b). In some infants small metaphyseal fractures are seen. This finding maybe similar to that seen in infants with non-accidental injury. It has been suggested that if a fracture is detected at day 11 of life without callus formation that one should consider it to have occurred after birth as birth injuries usually show callus formation between 7 and 11 days of age (1).

Evaluation of neonates with a brachial plexopathy involves plain radiography to outrule a fracture. In infants with respiratory difficulty, ultrasonography of the diaphragm or chest fluoroscopy can be performed to detect phrenic nerve injury. In more than 80% of these infants spontaneous functional recovery can be expected. Surgical exploration of the brachial plexus has been suggested if biceps function has not begun to return by 3 months of age. The goal of imaging in this group of patients is to demonstrate the level and extent of the

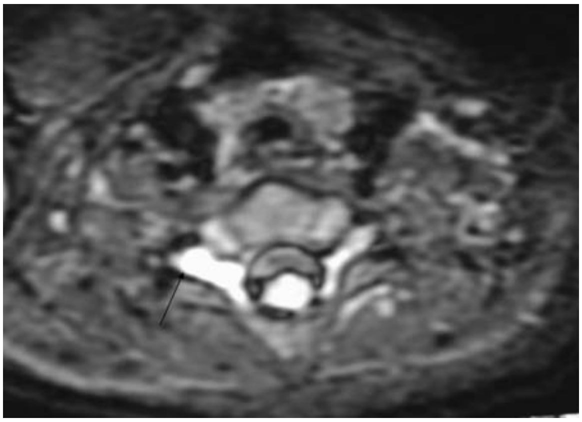


Trauma Birth. Figure 1 **(a) Plain elbow radiograph in newborn following difficult breech extraction. The study suggests traumatic dislocation at the elbow joint. (b) Sagittal proton-density MR image demonstrating a Salter type II injury of the distal humerus with significant posterior displacement of the metaphyseal fragment and epiphysis (arrow).**

injury. Although there is a strong correlation between complete or incomplete root avulsion and the presence of a pseudomeningocoele, pseudomeningocoeles are seen in the absence of root avulsion and root avulsion is seen in the absence of pseudomeningocoeles. CT myelography can be used but more recently MR imaging is used to demonstrate extra-arachnoid pseudomeningocoeles (Fig. 2) though the spatial resolution of MR imaging is still less than that possible with very thin slice CT myelographic images. Individual nerve rootlets are not routinely visualised with MR. MR however may show brachial plexus haemorrhage not seen on myelography. Axial and coronal narrow flip angle gradient-echo sequences are used together with a single three-dimensional gradient-echo sequence performed by means of thin partitions, followed by multiplanar reconstructions (3). We use a short-tau inversion recovery (STIR) sequence in the axial and coronal planes together with a heavily T2 weighted volume sequence.

Focal spinal cord injuries including cord transection and post-traumatic syrinx are best shown on MR imaging (Fig. 3). However, ultrasonography demonstrating increased echogenicity as a result of haematomyelia and oedema maybe useful in the early stages of the disease particularly in those infants who are ventilated and whose condition is complicated by concurrent asphyxia.

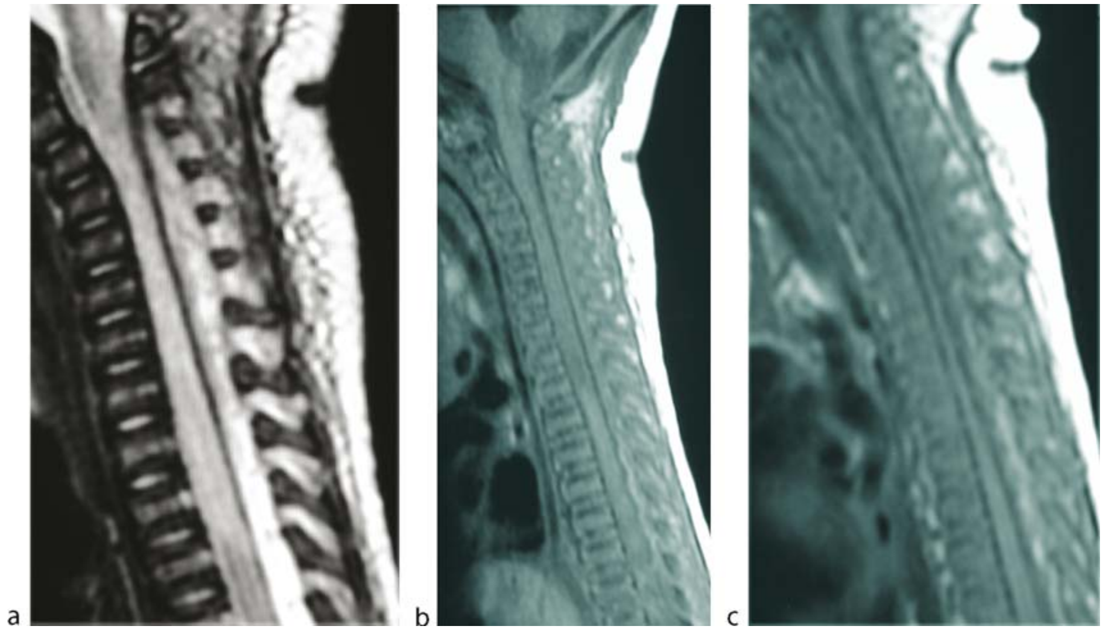
In infants with liver trauma plain radiographs may show liver enlargement. Ultrasonography may reveal parenchymal and subcapsular liver and splenic lesions.



Trauma Birth. Figure 2 **Axial STIR MR Image showing a right pseudomeningocele at T7 level (arrow).**

These abnormalities are usually echogenic in nature initially but as the haemorrhage liquefies they become echo-free. CT however most clearly delineates lacerations, haematomas, subcapsular and perihepatic and perisplenic collections.

Ultrasonography is the modality of choice in detecting adrenal haemorrhage. The abnormality is echogenic in the early stages and becomes echo-poor with time. If this progression does not take place neuroblastoma must be considered. Calcification may develop at the haemorrhage site within a few weeks to months.



Trauma Birth. Figure 3 Sagittal images of cervical and thoracic cord in a newborn following a difficult delivery showing increased T2 (a) and decreased T1 (b) signal in keeping with oedema and swelling due to injury. (c) Follow-up T1 MR image at 3 weeks demonstrating significant cord atrophy.

Diagnosis

A high proportion of clavicular and rib fractures sustained during delivery are asymptomatic and are discovered when there is sufficient callus formation to be palpable clinically some weeks after birth or incidentally on chest radiography performed for other indications.

Long bone epiphyseal-metaphyseal injuries are suspected by the presence of limb immobility and soft tissue swelling detected clinically and on plain radiography. The diagnosis may be confirmed using ultrasonography or MR imaging.

Brachial plexus and spinal cord injuries are suspected clinically and best confirmed using MR imaging. However ultrasonography may be useful in the acute stages of the injuries. Brachial plexus injuries may also be confirmed using CT myelography.

Trauma, Breast

Geert M. Villeirs
Urogenitale Radiologie-Universitair Ziekenhuis Gent, Ghent, Belgium
geert.villeirs@ugent.be

Definition

Traumatic injury to the breast is the result of any physical damage, either accidental (e.g., seat belt injury, stab wound, etc.) or iatrogenic (e.g., breast biopsy, surgery, radiation therapy, etc.), leading to rupture of blood vessels (causing contusion or hematoma) and/or damage to fat cells (causing fat necrosis).

Pathology/Histopathology

In ►contusions, edema and blood diffusely infiltrate the parenchyma and dissect along the fibrous planes of the breast; whereas in ►hematomas, extravasated blood forms a collection of liquid or clotted blood in a traumatic tear or surgical cavity. Both posttraumatic conditions usually resolve spontaneously within a few weeks, but partially resorbed or chronic hematomas may eventually evolve into ►fat necrosis.

Fat necrosis is caused by disruption and fragmentation of fat cells, both by direct trauma or indirectly as a consequence of disruption of the blood supply or pressure necrosis following diffuse or focal extravasation of blood into the parenchyma. Fat debris is then released into the interstitial space and may either elicit a lipophagic granuloma or conglomerate to form a macroscopic pool of oil, known as an oil cyst. However, usually both ends of this spectrum are simultaneously present.

A ►lipophagic granuloma is characterized by a nonsuppurative infiltration of fibroblasts, foamy macrophages, and leukocytes. Fat debris and extravasated erythrocytes are phagocytosed, with formation of foam cells and siderophages. A centripetal fibrous connective tissue response gradually leads to contraction of the area into a hard stellate scar and saponification of fat may give rise to several types of calcifications.

An ►oil cyst is a conglomerate of almost entirely pure neutral fat that becomes surrounded by foam cells and other inflammatory cells. Resorption and scar formation occur along the boundary of this cavity, which gradually becomes encapsulated by a thin, smooth, fibrous wall, in which calcium deposition may occur, leading to the well-known eggshell calcifications of fat necrosis.

Clinical Presentation

In general, the eliciting trauma (either accidental or iatrogenic) is obvious, although "spontaneous" hematomas are not unusual. On the other hand, some abnormalities that the patient relentlessly ascribes to previous trauma prove to be malignant.

At the trauma site, a tender palpable mass with bluish-red discoloration of the skin may be highly indicative of an underlying hematoma, while a diffuse thickening of the breast without mass effect is suggestive of a contusion.

Fat necrosis can remain completely asymptomatic or present as a sometimes painful palpable mass. Differentiating fat necrosis from malignancy may be particularly difficult in the case of a fixed and firm nodule with associated retraction and thickening or dimpling of the overlying skin.

Imaging

Mammography

A contusion may be imperceptible or present as a subtle asymmetric density or diffuse trabecular thickening. Hematomas, on the other hand, are seen as fairly well-defined masses of any shape and of heterogeneous density. In the case of a penetrating wound, air-fluid levels may be observed.

Trauma, Breast. Figure 1 Oil cyst with central lucency and peripheral eggshell calcifications.

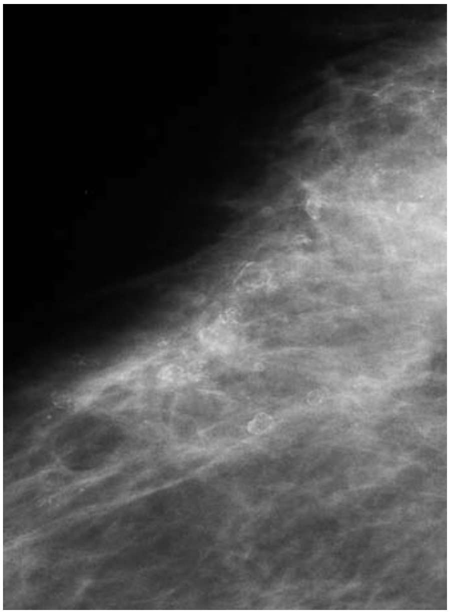
Oil cysts are readily recognizable on mammographs as round or oval sharply demarcated lucent areas, with or without spherical or elliptical wall calcifications (eggshell calcifications) (Fig. 1). These findings should not pose diagnostic problems.

However, fat necrosis presenting mainly as lipophagic granuloma may exhibit a wide range of nonspecific mammographic findings including architectural distortion and ill-defined, spiculated masses with skin thickening and various types of calcifications. The latter can be coarse, round or pleomorphic, or eggshell type with round or bizarre shapes (Fig. 2).

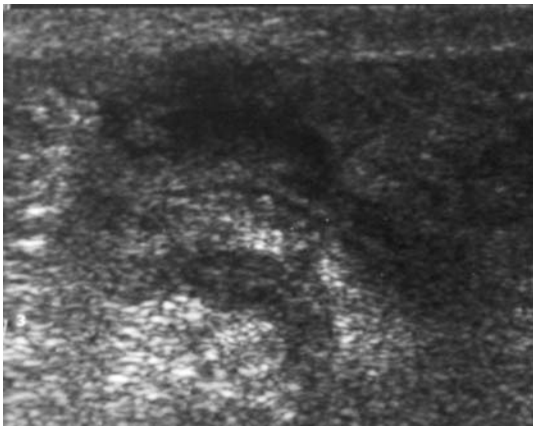
When the mammographic features of fat necrosis or posttraumatic scar resemble those of carcinoma, some clues may help to differentiate them. As opposed to most carcinomas, fat necrosis may appear different on different projections and may contain some fat in its central mass, which can usually be better appreciated on spot compression and/or magnification views. Obviously, an increasing mass on serial posttraumatic mammograms is suggestive of malignancy rather than fat necrosis.

Sonography

A contusion may present as an indistinctly outlined area of hyperechoic edematous fatty tissue intermingled with hypoechoic fluid planes along the trabecular framework



Trauma, Breast. Figure 2 Fat necrosis presenting as architectural distortion with multiple irregular lucent-centered eggshell clacifications.



Trauma, Breast. Figure 3 Sonogram of subacute hematoma with clots and fibrin strands, presenting as a an irregularly outlined mass containing fluid and echogenic elements.

of the breast. Hematomas are initially present as an irregularly outlined anechoic mass containing fresh blood, but as soon as the blood starts forming clots and fibrin strands, echogenic elements appear within the fluid, which becomes more heterogeneous and may fluctuate under varying scan pressures (Fig. 3). Sometimes fluid–debris levels may be seen. As the hematoma ages, it becomes more sharply marginated with a thick echogenic contour (representing older clot) and irregular internal septations, encasing hypoechoic areas of unclotted blood or liquefied clot.

Oil cysts generally do not require sonographic evaluation as their mammographic appearance is so characteristic. They may be present as round or oval sonolucent lesions, with enhanced through-transmission and a thin echogenic capsule. When the latter calcifies, its echogenicity markedly increases, causing gradual retroacoustic shadowing. Usually, oil cysts are found concurrently with some degree of lipophagic granuloma, which presents as an ill-defined heterogeneously hypoechoic area with varying degrees of retroacoustic shadowing. As the entire process starts to contract into a stellate scar with marked retroacoustic shadowing and parenchymal distortion, it may be quite difficult to distinguish fat necrosis from carcinoma. However, as opposed to carcinomas, scars may have a flattened configuration with different diameters on perpendicular scan planes. They may change their appearance with varying scan pressures, and are usually avascular on Doppler interrogation.

Magnetic Resonance Mammography

In early contusions or hematomas, the diffuse infiltration or focal collection of fluid and fresh blood usually shows intermediate to high signal intensity on both T1- and T2-weighted images. Later in the process, the signal intensities may vary depending on fluid resorption and degradation of hemoglobin into ferritin and hemosiderin. The latter causes a significant signal drop on both T1- and T2-weighted images. The fluid or blood collections (both diffuse of focal) do not show enhancement after intravenous administration of gadolinium contrast agent, but the injured or inflamed surrounding tissue may show minimal-to-moderate and usually delayed enhancement.

Because of their fat content, oil cysts show high signal intensity on T1-weighted images. They are usually round or oval, and confined within a smooth low-signal intensity rim with no or minimal enhancement after contrast administration. In contrast to oil cysts, lipophagic granulomas may cause much more diagnostic difficulties, especially in their early course. Fresh granulation tissue is highly vascular, and thus diffuse moderate and delayed, but sometimes fast and strong enhancement can be found throughout the lesion. Therefore, magnetic resonance imaging (MRI) is not useful during the first 6 months after trauma or surgery. After this period, hypovascular scar tissue and fibrosis usually develop, with little or no enhancement, enabling differentiation between old scarring and malignancy.

Diagnosis

Percutaneous Biopsy

There is generally no need to confirm a diagnosis of contusion, hematoma, or oil cyst with biopsy. However, differential diagnostic difficulties may arise in fat necrosis or scar tissue with clinical, mammographic, or sonographic features indistinguishable from malignancy.

Trauma, Genitourinary Tract

Marie-France Bellin
Service de Radiologie, Hôpital Paul-Brousse,
Université Paris-Sud 11, Villejuif, France
marie-france.bellin@pbr.ap-hop-paris.fr

Definition

Trauma of the genitourinary tract includes blunt and penetrating injuries to the kidney, ureter, bladder, and urethra.

Characteristics

The genitourinary tract is involved in approximately 10% of all trauma injuries. Renal damage is a common complication of abdominal trauma, whereas the bladder and urethra are more frequently affected by pelvic injuries.

Renal Damage

Damage to the kidney is the most frequent urologic trauma and occurs in up to 8 to 10% of all blunt and penetrating injuries (1). Blunt injuries account for about 80% of all cases of renal trauma (2), and are mostly due to motor vehicle accidents, less frequently to falls from a height, assaults, bicycle accidents, and horseback riding injuries. Penetrating injuries are mostly due to gunshot or stab wounds and often require surgery. The management of renal trauma is controversial and current trends are for less invasive procedures and a more conservative approach.

The goals of imaging evaluation are to detect and classify renal damage, to assess its extent, to detect or rule out associated injuries, and to help determine which can be managed conservatively and which may require surgery or embolization (1, 3, 4). In addition, imaging modalities are essential for the follow-up and detection of late complications.

Classification of Injury

According to the American Association for the Surgery of Trauma, renal injuries are graded on the basis of their depth and involvement of vessels or the collecting system (5):

1. *Grade* 1 [*82% of the cases* (4)]
   a. Hematuria with normal imaging findings
   b. Contusions
   c. Nonexpanding subcapsular hematomas
2. *Grade* 2
   a. Nonexpanding perirenal hematomas confined to the retroperitoneum
   b. Superficial cortical lacerations <1 cm in depth without collecting system injury
3. *Grade* 3
   a. Renal lacerations >1 cm deep that do not involve the collecting system
4. *Grade* 4
   a. Lacerations extending through the kidney into the collecting system
   b. Injuries involving the main renal artery or vein with contained hemorrhage
   c. Segmental infarctions without associated lacerations
5. *Grade* 5
   a. Shattered or devascularized kidney
   b. Ureteropelvic junction (UPJ) avulsions
   c. Complete laceration or thrombus of the main renal artery or vein.

The increasing grade of renal injury severity generally corresponds to the need for surgery to repair or remove the damaged tissue. However, renal injuries are now often managed conservatively, unless imaging studies show extensive tissue destruction, active hemorrhage, or large rupture of the collecting system.

Symptoms

Most patients with major renal damage present either gross hematuria, hypotension, or flank pain. Microscopic hematuria is a poor indicator of major renal damage. Pertinently, hematuria (or any other symptom) may be absent in patients with renal vascular injuries, UPJ avulsions or ureteral damage.

Imaging Modalities: Advantages and Limitations

CT is the imaging modality of choice for determining the extent of renal and perirenal damage, and for demonstrating the injuries of other organs (2–4). It provides essential anatomic and physiologic information required to make therapeutic decisions. CT should include unenhanced scans to detect hyperdense hematomas, followed by scans obtained during the vascular corticomedullary phase to detect vascular lesions, lacerations and shattered kidney, and scans obtained during the secretory phase to detect urine leakage (6). The use of oral contrast is controversial; slice thickness of 5 mm or less is helpful to avoid distorting volume-averaging artifacts. If bladder injury is clinically suspected, a cystogram or CT cystogram with dilute contrast should be performed to differentiate among intraperitoneal, extraperitoneal, or combined bladder rupture (2).

Angiography is being used less frequently, now that faster CT scanners have become widely available, and their detection of active arterial extravasation and vascular injuries is improved. However, angiography with selective transcatheter embolization is generally reserved for patients with active arterial bleeding detected at CT, traumatic pseudo aneurysms, and/or late hemorrhage that occurs in patients managed without surgery.

Ultrasonography (US) use in trauma patients is controversial (2–3), as it is often limited by pain, ileus, wounds, and so on. US can detect lacerations or modifications in the echotexture of the injured kidney and perirenal fluid. It is less sensitive than CT for detecting solid organ injury, especially of the kidneys, retroperitoneal blood and hollow organ injury. In addition, although US is able to detect free fluid in the abdomen and pelvis, it cannot differentiate among blood, extravasated urine, and other fluids. It is insensitive for determining the source of bleeding. When it is technically feasible, Doppler US can accurately detect vascular complications, by visualizing the pedicles and intrarenal vasculature, and evaluate the extent of renal infarcts. The usefulness of US contrast media has not been established. The major drawback of US is its inability to detect urine leakage, which is a major clinical concern. In most centers, US is reserved for the rapid search for intraperitoneal fluid in the unstable patient and for follow-up.

Intravenous urography (*IVU*) is less sensitive than CT for detecting renal parenchymal injury, urine and contrast-medium extravasation, and associated abdominal or pelvic injuries. With easy access to CT, the role of IVU is now limited to the assessment of hemodynamically unstable patients on the way to surgery or for urologic imaging of patients already in the operating room. In most cases, it includes only a scout radiograph followed by one film immediately after contrast injection and another about 10 min later. Additional late radiographs may be obtained to detect urine leakage or in patients with delayed contrast-medium excretion. Several pathologic conditions can be associated with negative opacification of the collecting system, that is, arterial tear, venous thrombosis, shock and diffuse parenchymal lesions. The ureters should be evaluated and the presence of a contralateral functioning kidney confirmed, should removal of the injured kidney be required.

MRI is rarely used because it is expensive and rarely available as an emergency procedure. However, it is able to detect hematomas, edema, ischemia, and urinomas in stable patients for who use of iodinated contrast media is contraindicated.

Imaging

Renal contusions appear as ill-defined high-density areas on unenhanced images with less enhancement relative to adjacent normal areas.

Subcapsular hematomas indent the renal margin and are seen as rounded areas. Their attenuation values vary as a function of the age of the clot, with acute hematomas being typically hyperdense relative to normal renal parenchyma on unenhanced CT images (Fig. 1).

Minor lacerations appear as areas of linear low attenuation within the renal parenchyma.

Deep lacerations of the renal parenchyma may extend into the collecting system, resulting in urine extravasation on late CT and IVU images (Fig. 2).

Active hemorrhage usually results in intense enhancement during the early phase of the CT examination. It has a linear or flame-like appearance and should be differentiated from a false aneurysm, which tends to appear more rounded and better delineated. In hemodynamically stable patients with active hemorrhage, selective

Trauma, Genitourinary Tract. Figure 2 Urine leakage after a gunshot wound. CT image obtained during the secretory phase demonstrates extravasation of the contrast medium into the left perirenal space and lumbar wall.

angiographic embolization is preferred to surgery to maximize nephron sparing.

Pseudoaneurysms and arteriovenous fistulas can be detected with Doppler US or CT and treated with angiographic embolization (Fig. 3).

Segmental renal infarction may be due to thrombosis, dissection, or laceration of segmental renal arteries. They appear as well-circumscribed, linear or wedge-shaped areas that do not enhance (Fig. 1). In most cases, they are managed medically.

Massive renal infarction may result from a complete or an incomplete tear of the main renal artery with subsequent arterial thrombosis (Fig. 4). Hematuria may be absent. The kidney is not enhanced on CT contrast-medium-enhanced images, except for cortical rim due to intact collateral vessels. Early revascularization may be attempted but is rarely successful.

Main renal vein injury can be detected by US. It may result in massive perirenal hemorrhage or thrombosis with an enlarged kidney and a late and persistent diffuse opacification of the parenchyma on CT and IVU.

UPJ avulsion is most likely due to overstretching of the pelvis and ureter during hyperextension and manifests as massive contrast-medium extravasation along the ureter on late CT images or IVU.

Adrenal Trauma

Adrenal injury has been reported in 28% of the patients with blunt abdominal trauma who were studied at autopsy (7). The mechanism of injury includes direct compression of the gland against the spine or suddenly increased venous pressure owing to transmission from the inferior vena cava. The right adrenal is more commonly involved than the left. In most patients, adrenal hematoma raises no or little clinical concern, unless it is bilateral, in which case the potential for developing adrenal insufficiency must be considered. Adrenal injuries are best depicted by CT (7), which typically shows an enlarged gland with a rounded or swollen-but-normal shape. Initially, the adrenal hematoma appears hyper-

Trauma, Genitourinary Tract. Figure 3 **Posttraumatic renal arteriovenous fistula. (a) Arterial phase CT shows the lesion (*arrow*) with strong enhancement. dense; its density decreases as the blood clot resolves, and a follow-up CT scan may document resolution of the adrenal lesion in 2–4 months. In other cases, it may lead to the formation of a mass and/or pseudocysts seen as incidental findings on CT examinations. Adrenal hematomas are frequently associated with stranding of the periadrenal fat and tracking of the hemorrhage along the crus of the ipsilateral hemidiaphragm.

Ureteral Trauma

Iatrogenic injury is the most common cause, with the ureter being damaged during retrograde pyelography or ureterocystoscopy in most cases. The ureter may also be lacerated or contused during penetrating trauma (especially gunshot wounds) or overstretched during severe hyperextension. Partial disruptions may be treated with percutaneous nephrostomy, with or without ureteral stenting, whereas complete transections usually require surgical repair. The diagnosis of ureteral injury relies on CT or IVU demonstration of extravasation of the excreted contrast medium that accumulates within an urinoma that is generally mixed with blood (2, 6). In patients with suspected proximal ureteral tear, the presence of enhanced urine in the distal ureter indicates only a partial disruption (Fig. 4).

Bladder Trauma

Bladder injuries may be due to blunt or penetrating trauma and are frequently associated with bony pelvic fractures. They are more likely to occur when the bladder is distended than when empty. Extraperitoneal (65% of the cases) bladder injuries are most often due to laceration by a fractured pelvis. Intraperitoneal (35% of the cases) bladder ruptures usually result from blunt trauma with a sudden rise in intraperitoneal pressure causing the bladder dome to burst. Gross hematuria and failure to void are the main symptoms. CT cystography is now considered the imaging technique of choice for detection and assessment of bladder injury. It is performed with 300–500 mL of diluted contrast medium installed retrograde into the urinary bladder. The bladder catheter is then clamped for 10–30 min and CT scans of the abdomen and pelvis are obtained. Intraperitoneal bladder rupture is recognized by contrast-material leakage around bowel loops, into the intraperitoneal recesses of the pelvis, the paracolic gutters, and/or the anterior subhepatic space. Extraperitoneal bladder ruptures create a streaky appearance due to extravasation of opacified urine into perivesical soft tissues.

Urethral Trauma

Urethral injuries occur in 10% of major pelvic fractures and are far more common in men than in women. Posterior urethral injuries may be associated with bladder-base disruptions. Anterior urethral injury may result from iatrogenic or penetrating injury and, less frequently, from blunt trauma. Most patients manifest an inability to void, blood at the urethral meatus, elevation of the prostate during digital rectal examination or perineal hematoma. Patients with suspected urethral trauma should undergo a retrograde urethrogram before insertion of a Foley catheter. It should ideally be performed under fluoroscopic guidance and include oblique radiographs, which may show the precise localization of the tear and subsequent leak of contrast medium. In type 1 injuries, the urethra is narrowed and stretched by a periurethral hematoma; there is no contrast-material leakage. In type 2 injuries, the posterior urethra ruptures proximal to the urogenital diaphragm and extraperitoneal contrast material is seen above the urogenital diaphragm. In type 3 injuries, proximal posterior disruption continues through the urogenital diaphragm, with subsequent contrast-medium leakage into the extraperitoneal space and the perineum.

Definitions

A major craniocerebral trauma should always be examined with computed tomography (CT) using different window/level settings for the intracranial structures and for the bone. Most acute lesions will be clearly visualized, including parenchymal contusions, extracerebral hematomata, cerebral ►edema, and skull fractures. Depending on the impact, additional CT of the skull base, orbits, and/or sinuses may be indicated.

There are two indications for brain magnetic resonance imaging (MRI): a discrepancy between the CT findings and the clinical symptoms, and follow-up to assess the extent of the damage to the brain.

The role of plain X-ray films is limited in craniocerebral trauma and has been replaced by multidetector CT in most centers. The role of CT in minor cranial trauma remains controversial and will depend on clinical factors.

Pathology/Histopathology

One may differentiate primary and secondary brain injuries.

The common primary brain injuries are extracerebral hematoma (in the subdural or epidural space), cerebral contusions, and diffuse axonal injury. Scalp hematomata are usually clinically not significant.

Epidural hematoma is usually associated with the laceration of the middle meningeal artery, a branch of the external carotid artery, or with the laceration of a dural venous sinus. Subdural hematoma follows an acceleration/deceleration trauma with stretching and tearing of bridging cortical veins in the subarachnoid space. Axonal shearing injuries also result from acceleration/deceleration and rotational forces. They occur typically in predictable locations, for example, the corticomedullary junction, the midbrain/pons, and the corpus callosum (posterior truncus and splenium). Cerebral contusions are focal cortical hemorrhages with adjacent edema that often increase up to 48 h after the trauma.

Subarachnoid hemorrhage is a result of a direct injury to the leptomeningeal vessels or of a direct superficial brain injury.

Intraventricular hemorrhage is the result of a disruption of the subependymal veins and is usually associated with other intracranial traumatic lesions. The prognosis is poor.

Secondary brain injuries develop in the hours and days after the trauma. These include herniation of the tonsils, subfalcine herniation and uncal herniation, diffuse cerebral edema, and secondary ischemia. Intracranial hypertension will cause a variable degree of compression and displacement of brain tissue, blood vessels, and/or nerves. Diffuse brain edema is due to increased water content and intravascular blood volume.

The skull should be assessed with CT using appropriate window width/level settings to demonstrate fractures.

Finally, in missile-induced trauma, metallic fragments can be located in the intracranial compartment.

Clinical Presentation

Patients with a Glasgow coma scale less than 9, deteriorating consciousness, or progressive neurological deficit should be examined urgently with CT. Depending on the clinical and CT findings, a neurosurgical intervention may be necessary or follow-up imaging may be obtained within the next 24 h.

In patients with an epidural hematoma, there is often a “lucid interval” between the trauma and the onset of neurological deterioration. Patients with a subdural hematoma usually have low Glasgow coma scales on admission. Occasionally, patients might only develop progressive symptoms days or weeks after a cranial trauma. CT should always be performed urgently in these patients to exclude a subacute subdural hematoma. In elderly patients, there is often no definite history of a major trauma.

Patients with diffuse axonal injury are unconscious upon admission to the emergency department. Cerebral contusions are not necessarily accompanied by unconsciousness and tend to increase in the hours and days after the traumatic event.

The secondary traumatic brain injuries are often clinically even more important than the primary intracranial lesions. They result from increased intracranial pressure and herniations from cerebral structures from one compartment to the other. The patient develops bradycardia and hypertension and, if there is no relief of the intracranial hypertension, a deterioration of the cardiac function and breathing will follow. Transtentorial, subfalcine, and tonsillar herniations are the most common type.

Diffuse cerebral edema is associated with a mortality rate of up to 50%.

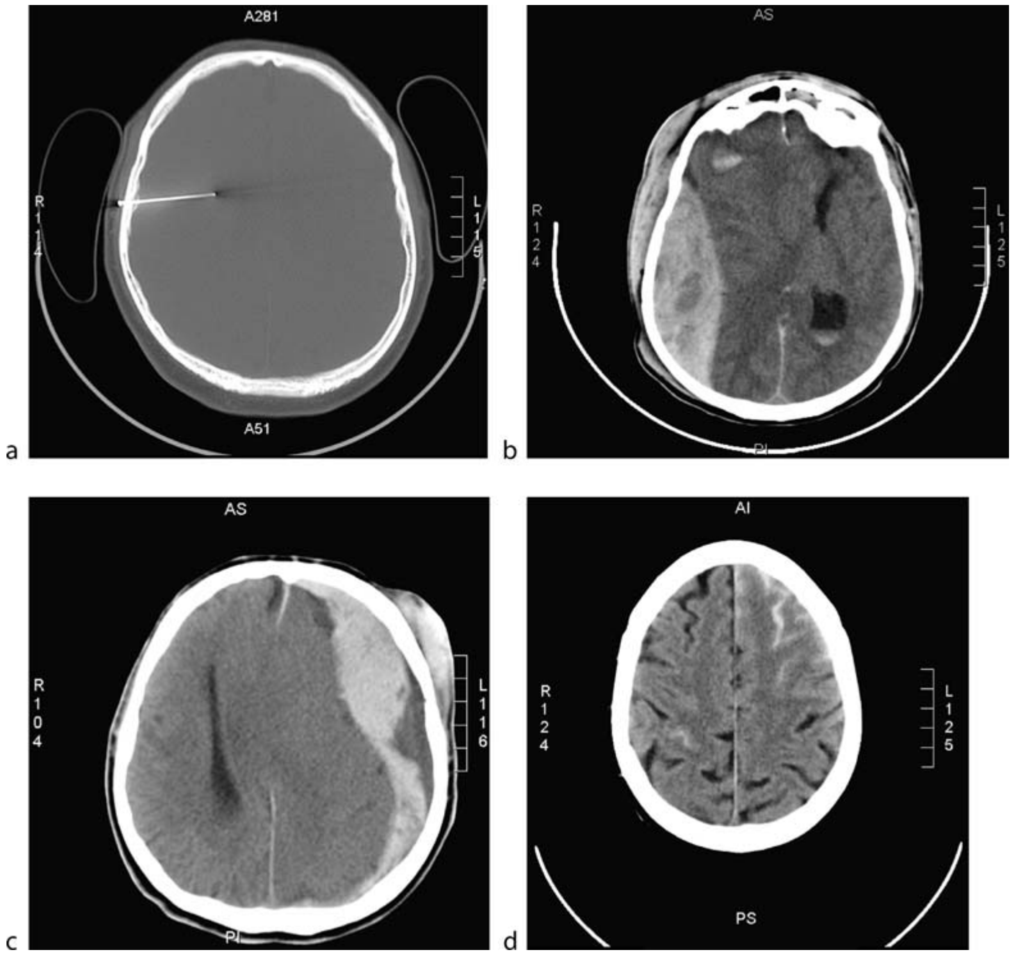
Diagnosis

In the acute stage, CT is the modality of choice. Most acute intracranial lesions can be depicted and, in addition, fractures and the presence of foreign bodies can be demonstrated by using the appropriate bone window width and level settings (Fig. 1).

An acute epidural hematoma appears typically as a biconvex, extracerebral, high-density mass within the epidural space (i.e., the space between the inner table of the skull and the dura). They can displace the brain and cause secondary herniations (Fig. 1). They can cross the falx or the tentorium but not the sutures. Subdural hematomata are located in the subdural space (i.e., the space between the dura and the arachnoid membrane) (Fig. 1). Subdural hematomata can cross the sutures but do not cross the falx or the tentorium. The density of subdural hematomata varies with the clot age. An acute subdural hematoma appears hyperdense and will remain like this for approximately 7 days. In the subacute stage, the hematoma appears isodense compared to brain tissue. A subdural hematoma has a typical crescent shape and may extend over the entire hemisphere.

Posttraumatic subarachnoid and intraventricular hemorrhages can be clearly seen on CT and they also appear hyperdense (Fig. 1).

Diffuse axonal injury may be difficult to detect on CT because these lesions are usually very small, despite the patient’s poor clinical condition. Cerebral contusions are



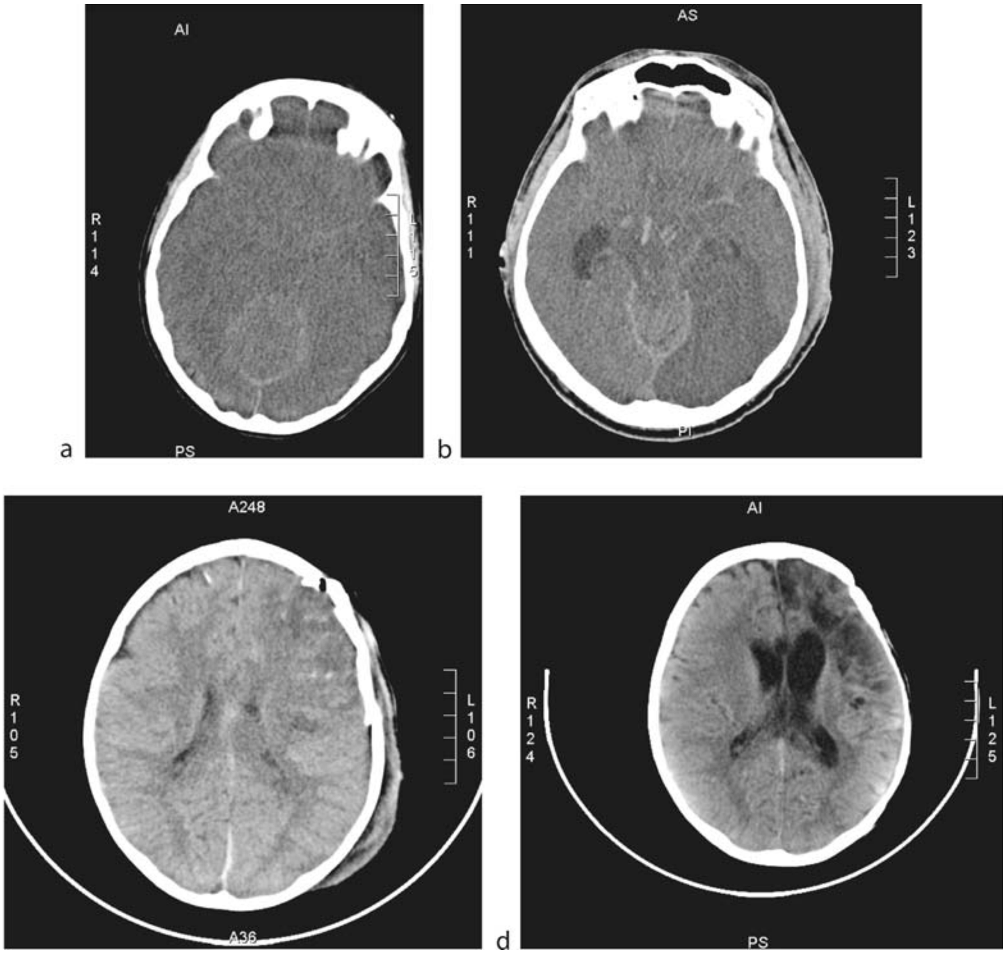
Trauma, Head, Accidental. Figure 1 CT of primary brain injury. Image at bone window setting is acquired to localize the foreign body (a). Epidural hematoma on the right side with displacement of the midline, contusion, and intraventricular blood (b). Subdural hematoma with subfalcine herniation and deviation of the midline (c). Subarachnoid hemorrhage in the left frontal lobe and, to a lesser extent, in the right parietal lobe (d).

seen as ill-defined, low-density lesions containing one or several high-density foci (Fig. 2). Contusions can be subtle in the first hours but can increase in size in the first 24–48 h after the trauma. Brain stem contusions may remain undetected on CT particularly when the hemorrhagic component is subtle.

The two most important secondary traumatic lesions are different types of herniation and diffuse cerebral edema, both of which are the result of the increased intracranial pressure.

The most common herniation is the descending transtentorial herniation. The uncus/parahippocampal gyri are displaced medially with partial or complete effacement of the pentagonal cistern (Fig. 2). One of the consequences is occipital lobe ischemia due to compression of the posterior cerebral artery (Fig. 2). Another well-known complication is Duret hemorrhage in the pons/midbrain. The pathophysiology remains incompletely elucidated and both arterial and venous origins have been suggested. Transtentorial herniation is regularly associated with a tonsillar herniation. The cerebellar tonsils are displaced through the foramen magnum.

Diffuse cerebral edema is an extremely important finding that often warrants immediate neurosurgical intervention. The neuroradiological findings are not always evident. Compression of the ventricles, effacement of the sulci and basal cisterns, and increased density of the falx/tentorium are usually clear. Occasionally, the decreased differentiation between white and gray matter is the first, subtle, sign in the absence of effacement of the sulci (Fig. 2). Diffuse cerebral edema can result in cerebral herniation.



Trauma, Head, Accidental. Figure 2 **CT of secondary brain injury. Transtentorial herniation with obliteration of the pentagonal cistern, effacement of the sulci, and hyperdense appearance of the cerebellum indicating brain edema (a). Transtentorial herniation with secondary infarct in the left occipital lobe (b). Brain contusion in the left frontal lobe after 3 days (c) and visualization of the loss of tissue and brain atrophy after 2 months (d).**

Late follow-up of intracranial trauma will typically result in brain tissue loss and/or residual atrophy (Fig. 2).

MRI plays an increasingly important role in craniocerebral trauma. In the acute stage, its higher sensitivity can be used for improved parenchymal lesion detection (e.g., in the brain stem and corpus callosum). This may concern primary as well as secondary traumatic lesions. The use of diffusion-weighted imaging appears promising in acute trauma (Fig. 3). T2*-weighted gradient echo images are particularly sensitive for the detection of blood degradation products, and diffusion-weighted images can depict acute lesion that remain undetected on CT.

In patients with a severe trauma and little or no evidence of intracranial pathology, MRI is indicated as soon as possible because this technique is more sensitive for the detection of diffuse axonal injury. Frequent locations are the frontal lobe, the temporal lobe, and the corpus callosum (Fig. 3). When the lesions are hemorrhagic, they are best detected on a T2* sequence, which is more sensitive in the detection of blood degradation products (Fig. 3). They may remain visible for several years.

In the chronic stage, MRI may demonstrate diffuse axonal injury that may be responsible for postcommotional syndrome (memory loss, headache, concentration difficulties) and that remain undetected on CT (Fig. 3).

Synonyms

Nonaccidental head injury (NAHI); Shaken baby syndrome (SBS); Shaken-impact syndrome

Definition

Head injury caused by the application of force in excess of that used during normal handling of a child leading to a combination of some or all of:

- Encephalopathy (usually secondary to hypoxic-ischemic brain injury)
- Multifocal subdural hemorrhages
- Retinal hemorrhages.

the so-called "triad."

Not all cases of nonaccidental head injury (NAHI) will show all of these features (retinal hemorrhages are not always present, even in fatal cases of NAHI), just as not all cases where the triad is present are due to NAHI.

Majority medical opinion believes that the major mechanism of injury is likely to involve shaking of the unsupported infant head backwards and forwards leading to acceleration/deceleration and rotational injury to the intracranial contents.

The incidence of subdural hemorrhage due to NAHI appears to be in the region of 20/100,000 infants and children (1).

The minimum degree of force is likely to be such that an independent witness would recognize that it would be likely to lead to harm to the child.

Pathology/Histopathology

Subdural Hemorrhages

Majority medical opinion believes that differential rotation of the brain and the skull leads to stretching and tearing of the veins which cross the (potential) subdural space, which leads to multifocal subdural hemorrhage.

Brain Injury (Generalized)

There does not appear to be correlation between the extent and distribution of subdural hemorrhages and the degree of signs and symptoms exhibited by the child. The degree of symptoms and signs correlates best with the degree of associated brain injury (2), which in most cases is hypoxic-ischemic in nature as seen on neuroimaging (Fig. 1) and at postmortem. The subdural hematomas seen in NAHI tend to be shallow and do not have a significant space-occupying effect.

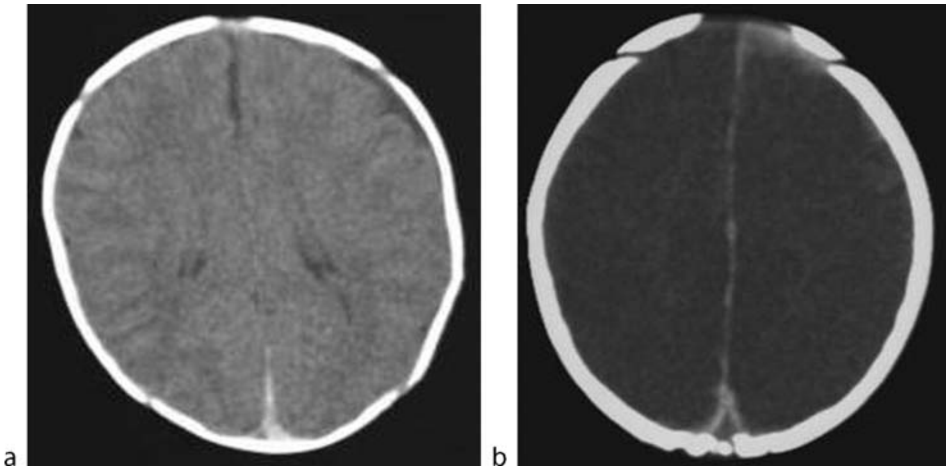
Given this, if an injury occurs of sufficient severity for the child to be admitted to hospital, it is likely that there will have been a change in behavior at the time of the causative event and that the child will not have behaved entirely normally afterwards. The timing of these injuries is therefore better assessed by looking at the clinical features of the case rather than by attempting to estimate the age of the subdural blood on the scans.

Brain Injury (Focal)

Focal traumatic brain lesions such as hematomas and contusion, together with diffuse axonal injury (DAI) are occasionally seen, more often in cases where impact with an external surface has been a major mechanism of injury or in more severe shaking injuries.

Clinical Presentation

The symptoms and signs seen following episodes of NAHI are varied, variable and nonspecific. They range from a relatively small change in behavior such as going quiet to going off feeds, vomiting, reduced levels of consciousness, fits to frank coma. Often radiologists are asked to perform scans because the child has presented



Trauma, Head, Non-accidental. Figure 1 CT scans of two infants admitted following nonaccidental head injury. In (a) there is some high attenuation posterior interhemispheric subdural blood, more on the left than the right. Gray-white differentiation is preserved. This infant presented with relatively few symptoms and recovered rapidly. (b) Shows slightly more extensive acute subdural blood but the acute subdurals are not space occupying. In this infant, the cerebral hemispheres are of abnormally low attenuation and there is loss of gray-white differentiation consistent with extensive hypoxic-ischemic brain injury. The infant presented in a moribund state and died soon after admission.

with an encephalopathic illness and the radiologist may be the first health professional to suggest NAHI as a cause of the encephalopathy. Increasingly, head CT scans are being used as part of the routine investigation of possible nonaccidental injury, even in the absence of neurological symptoms as subdural hematomas can be clinically occult (3, 4).

Imaging

Skull Radiographs

May show fracture(s) and/or soft tissue swelling. It is not possible to assess the age of skull fractures in the same way as for rib/limb fractures; if there is associated soft tissue swelling then a recent injury is more likely.

A full skull series (frontal, lateral, and Townes' views) should be obtained even when a CT head scan has been performed as it is possible to miss quite large fractures on CT if the fracture lies parallel to the scan plane.

The presence of a fracture suggests an impact injury against a hard or unyielding surface. The commonest type of fracture seen in pediatric head trauma (whether accidental or NAHI) is a linear parietal fracture. More complex fractures (diastatic, stellate, depressed, involving more than one bone or a bone other than the occipital) are more likely to be due to, but are not pathognomonic of, NAHI. The complexity of the fracture is more likely to reflect the degree of force causing it rather than the mechanism of injury.

Cerebral Ultrasound

Ultrasound should not be used in isolation in the investigation of NAHI. Convexity subdural hematomas may not be seen on ultrasound and generalized and/or subtle hypoxic-ischemic brain injury may not be appreciated. In experienced hands, subtle focal lesions of DAI may be best seen on ultrasound but such lesions are relatively uncommon in any case.

CT

This is the initial investigation of choice for several reasons. CT scanners tend to be more available than MR scanners; it is easier to scan sick, unstable infants in CT; acute blood is usually easily seen on CT; any abnormalities requiring neurosurgical intervention can be detected early and major focal or generalized brain injury should be reasonably well seen.

Unenhanced scans should be performed initially in the context of the investigation of the undiagnosed encephalopathic child as contrast enhancement may mask the presence of subtle, shallow acute subdural hematomas. A maximum of 5 mm thick sections should be performed throughout the head, especially in the posterior fossa where thicker sections may miss subdural hemorrhage.

The key neuroimaging feature to recognize is the presence and distribution of subdural hemorrhage, the pattern of which is the marker of the mechanism of injury. Subdural hemorrhage or effusion can be seen in a variety of situations in infants and children. A recent UK wide study of subdural hemorrhage and effusion in infants and children under the age of two years (5) showed the following causes from a cohort of 186 cases:

106 = NAHI (57%)
26 = perinatal (14%)
23 = meningitis (12%)
17 = undetermined (9%)
7 = accidental (3.7%)
7 = nontrauma medical (3.7%).

The pattern of hemorrhage seen in association with the naturally occurring medical conditions listed above (as well as others) tends to be rather different to that seen in NAHI and, in any case, there is usually no supportive clinical evidence of such conditions in these cases although, of course, such conditions should be routinely looked for as part of the investigative process. The typical pattern of subdural hemorrhage in the context of NAHI is that of thin, shallow subdurals seen at several separate sites. Because the subdural blood is usually of such small volume, its significance can sometimes be overlooked when seen on scans of infants who are often severely unwell.

Though subdural hemorrhage can be seen following accidental head trauma, when it occurs, it is usually seen at the site of an impact injury and is (usually) seen in association with other evidence of impact injury such as scalp swelling or fracture.

The appearance of blood on CT scans changes with time following an episode of bleeding. Acute blood is by definition brighter than the underlying brain, subacute blood has a similar attenuation and a chronic subdural hematoma is by definition darker than the underlying brain. The time over which this transition occurs is variable and depends on various factors such as the volume of blood present and such factors as whether the patient was anemic at the time of bleeding. Generally a discrete collection of blood may remain bright on CT from soon after an episode of bleeding for up to 7–10 days and blood (if it persists) will become darker that the underlying brain somewhere between 2–3 weeks after an episode of bleeding but these ranges are not absolute.

Low attenuation collections can, however, be seen in the context of acute injuries and it is believed that this happens when the arachnoid is torn at the time of the injury allowing CSF to leak into and collect in the subdural space, diluting any acute blood that is present. Not all low attenuation subdural collections are therefore due to chronic subdural hematomas. If membranes are seen related to the subdural collections on CT or MR then this would be strong supportive evidence of the collections being chronic.

Any assessment of the age of subdural blood on either CT or MR should be restricted to discrete collections of blood and not to hematomas which have been diluted by or mixed with CSF.

Hypoxic-ischemic brain injury may be seen on CT as affected areas of brain will show decreased attenuation usually associated with reduced gray-white differentiation. The pattern of hypoxic-ischemic brain injury may be generalized, focal and occasionally very asymmetrical (e.g., involving only one hemisphere). The absence of any demonstrable hypoxic-ischemic change on CT (or even on standard MR sequences) does not exclude it (but would suggest that any such injury is relatively mild, see later).

MR

MR is usually used as a secondary imaging investigation after initial CT but is an important part of the investigative process both during the acute phase and for follow up (4). It has several advantages over CT mainly related to its greater sensitivity in the detection of small areas of subdural hemorrhage, which are not well seen on CT or detecting subdural blood in sites not as well seen on CT such as in the subtemporal regions. It is also more sensitive for the detection of parenchymal brain injury both in terms of hypoxic-ischemic brain injury and focal traumatic lesions such as parenchymal hemorrhage or contusions and DAI.

To maximize the potential of MR it is important to image in different planes using different sequences and a typical imaging protocol would include sagittal and axial T1W; axial T2W; coronal proton density and T2W, axial T2*. Diffusion weighted imaging is increasingly being used to detect hypoxic-ischemic brain injury not evident on standard scans and MR also gives the opportunity to look at the spinal cord for evidence of injury or to detect extra-axial bleeding related to the spine.

Different blood breakdown products have different magnetic properties and therefore have different appearances on different sequences. As with CT, it may be possible to give a broad indication of the likely age of the subdural blood present if it is a discrete collection and not mixed with CSF.

Trauma Hepatobiliary

Davide Caramella, Marzio Perri,
Paola Vagli, Carlo Bartolozzi
Department of Diagnostic and Interventional
Radiology University of Pisa, Pisa, Italy
caramella@do.med.unipi.it

Synonyms

Abdominal injury; Abdominal trauma; Blunt abdominal injury; Blunt abdominal trauma; Blunt hepatic injury; Hepatic injury; Liver injury; Liver trauma

Definition

Hepatic trauma is a form of abdominal injury involving hepatic structures. Hepatic traumatic lesions include parenchymal (►contusion, ►hematoma, and ►laceration), intrahepatic vascular (arteriovenous fistula, ►arterioportal fistula, ►pseudoaneurysms, avulsion), and biliary injuries (►biloma, biliary leak, biliovascular ►fistula).

Pathology

The liver is the most commonly injured abdominal organ after the spleen. Hepatic injuries are most frequent in abdominal blunt trauma and are usually sustained by rapid deceleration during road traffic accidents. Due to its large size and its location proximal to the ribs, the right lobe is the most involved site. The coronal ligament's insertion in this parenchymal region augments the effect of the acceleration–deceleration mechanism. Associated lesions are usually observed, including ipsilateral costal fractures, laceration or contusion of the inferior right pulmonary lobe, hemothorax, pneumothorax, and renal and/or adrenal lesions (1).

Penetrating injuries (knife wounds or gunshots) represent rare causes of hepatic injury in Western countries.

Interventional radiology procedures, such as percutaneous biopsy or tumor ablation, cholangiography or biliary drainage, and transjugular intrahepatic portosystemic shunt (TIPS) procedures, may also cause traumatic lesions of the liver, including hematomas, bilomas, intrahepatic fistulas, and pseudoaneurysm.

Depending on mechanism, site, and force, different patterns of hepatic traumatic lesions may occur, and several classifications for liver injuries based on anatomic or radiological findings have been proposed. According to the Organ Injury Scale (OIS) described by the American Association for the Surgery of Trauma (Table 1), liver injuries are currently classified into six grades of severity, ranging from small subcapsular hematoma or superficial capsular tear (grade I) to hepatic avulsion (grade VI) (2).

Clinical Presentation

Hepatic traumatic lesions may cause right upper quadrant pain and tenderness. Clinical signs of bleeding (shock, hypotension, and decreased hematocrit level) and of biliary peritonitis (abdominal pain, nausea, and vomiting) are also common. Occasionally, patients who are asymptomatic after the initial injury may develop later complications such as liver abscess or internal hemorrhage, presumably due to unrecognized liver damage. Associated injuries, particularly rib fractures, are often observed.

Elevation of serum liver enzyme levels in a patient with blunt abdominal trauma may be suggestive of liver injuries. Diagnostic peritoneal lavage, although extremely sensitive for the diagnosis of intraperitoneal hemorrhage, is not always able to determine the origin and extension of a traumatic lesion (1, 3).

Despite the recent improvements in resuscitation techniques, anesthesia, and intensive care, the mortality in both blunt and penetrating liver injuries is still high (10–15%).

Imaging

Ultrasound (US) is fast, accurate, portable, and easy to perform, and it represents the screening modality of choice for blunt abdominal trauma (4). US allows rapid and effective evaluation of both abdominal cavity and parenchymal organs. In evaluation of the abdominal cavity, the main focus is detection of free fluid, which represents ►hemoperitoneum and is indicative of intra-abdominal injury. Intraperitoneal hemorrhage collects in the most dependent regions of the abdomen and is generally anechoic, conforming to the anatomic site it occupies. The subhepatic space (Morrison pouch) and the pelvis are the most common sites of fluid accumulation. In massive hemoperitoneum, the intraperitoneal organs float in the surrounding fluid under real-time observation.

In hepatic trauma, US can also demonstrate a number of parenchymal traumatic lesions, such as contusions, acute intraparenchymal hemorrhages, hematomas, lacerations, and bilomas.

Hepatic contusions are initially hypoechoic, becoming transiently hyperechoic and then hypoechoic, whereas acute intraparenchymal hemorrhages may be identified as anechoic regions within the abnormal parenchyma.

Trauma Hepatobiliary. Table 1 Classification of liver injuries according to the Organ Injury Scale (OIS)

Grade[a]	Type	Injury description
Grade I	Hematoma	Subcapsular, <10% surface area
	Laceration	Capsular tear, <1 cm parenchymal depth
Grade II	Hematoma	Subcapsular, 10–50% surface area; intraparenchymal, <10 cm in diameter
	Laceration	1–3 cm parenchymal depth, <10 cm in length
Grade III	Hematoma	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma; intraparenchymal hematoma >10 cm or expanding
	Laceration	>3 cm parenchymal depth
Grade IV	Laceration	Parenchymal disruption involving 25–75% of hepatic lobe or 1–3 Couinaud's segments within a single lobe
Grade V	Laceration	Parenchymal disruption involving >75% of hepatic lobe or >3 Couinaud's segments within a single lobe
	Vascular	Juxtahepatic venous injuries; that is, retrohepatic vena cava/central major hepatic veins
Grade VI	Vascular	Hepatic avulsion

[a]Advance one grade for multiple injuries, up to grade III

Hematomas usually appear as well-defined, round (intraparenchymal hematomas), or curvilinear (subcapsular hematomas) areas of increased echogenicity in the acute phase. In the following phase, internal echoes due to septation and debris may be revealed. In a more chronic stage, hematomas tend to become more hypoechoic relative to the liver parenchyma.

The appearance of hepatic laceration changes with time: it is initially slightly echogenic and becomes hypoechoic or cystic days after the injury.

Bilomas appear as rounded or ellipsoid, anechoic, loculated structures, fairly well defined and in close proximity to the liver and bile ducts.

In massive liver trauma, a widespread hepatic architectural disruption with absence of the normal vascular pattern is observed.

Finally, color and power Doppler US may be useful for evaluating hepatic vascular injuries such as arteriovenous fistulas and pseudoaneurysms.

Computed tomography (CT) is widely used to investigate the acute trauma victim because it allows accurate visualization of both intraperitoneal and retroperitoneal structures, enabling a complete assessment of any lesion associated with blunt abdominal trauma (1, 5).

Although unenhanced CT may allow detection of several hepatic injuries, intravenous contrast medium administration is required in hemodynamically stable trauma patients. On contrast-enhanced CT scans, various patterns of parenchymal injuries may be clearly distinguished and classified, including contusion, hematoma, laceration, and hepatic fracture.

Hepatic contusion appears as a hypodense area due to interstitial bleeding, with irregular margins, and it is usually associated with major hepatic injuries such as lacerations and hematomas.

Hematomas are caused by bleeding into a tissue laceration; in particular, superficial lacerations usually cause a subcapsular hematoma, a very common hepatic traumatic lesion appearing as a biconvex collection imprinting the hepatic parenchyma. In an acute or subacute setting, CT features of hematoma are hyperdense areas on baseline CT scanning not enhanced after contrast medium administration, whereas chronic hematoma is hypoattenuating on the precontrast scan and can display rim enhancement following intravenous contrast medium administration.

Hepatic laceration is a typical lesion appearing as a nonenhancing linear streaking areas on contrast-enhanced CT. These lesions can be single or multiple and tend to involve parenchymal areas contiguous to intrahepatic portal vascular branches and suprahepatic veins. A large range of severity must be distinguished in lacerative lesions of the liver, including small and superficial lesions of the hepatic capsule (capsule tears), lacerations involving the central portal triad (deep lacerations), and major deep laceration extending between two margins of the organ (hepatic fracture). In massive liver trauma, deep and complex lacerations are usually associated with biliary complications, including bilomas, ►hemobilia, and rarely biliary peritonitis.

Hepatic biloma appears as a cystic, loculated structure of low attenuation in or around the liver either on unenhanced or contrast-enhanced CT scans. Hemobilia is due to a posttraumatic communication between a blood vessel (generally, a hepatic artery branch) and a biliary duct, but it also may be caused by a rupture of a pseudoaneurysm into a biliary duct. Bile peritonitis is an uncommon complication of blunt liver trauma. CT findings of bile peritonitis include persistence or increasing amounts of low-attenuating free peritoneal fluid and thickening of the peritoneum that shows evidence of enhancement.

Finally, CT scan is also useful for evaluating injuries involving intrahepatic vessels, particularly hepatic avulsion and hemoperitoneum (1). Hepatic avulsion, consisting of the devascularization of the entire organ, represents the most important traumatic injury of the liver. It results in a complete lack of enhancement after intravenous contrast medium administration at CT scanning. Hemoperitoneum associated with a traumatic lesion of the liver represents an important prognostic factor. Evaluation of intraperitoneal hemorrhage or an expanding parenchymal hematoma is a criterion for grading the severity of trauma. CT may document a minimal quantity of extravasated peritoneal or retroperitoneal blood, also allowing detection of traumatic vascular lesions such as portal or suprahepatic venous branch lacerations, arterial pseudoaneurysm, and arteriovenous fistula.

Other imaging techniques include magnetic resonance (MR), which has a limited role in the evaluation of abdominal trauma patients. However, MR can be used to monitor liver injury, particularly MR cholangiography, and MR angiography offers an accurate depiction of traumatic complications involving biliary and vascular structures.

Another potential use of MR is in patients with renal failure and in those who are allergic to iodinated contrast medium.

Angiography is useful to localize the site of hemorrhage and provides an opportunity for the interventional radiologist to proceed to transcatheter embolization of bleeding sites.

Nuclear Medicine

Biliary scintigraphy with ^{99m}Tc iminodiacetic acid (IDA) provides useful information in cases of suspicious biliary leakage; ^{99m}Tc sulfur colloid or ^{99m}Tc-labeled denatured red blood cell studies are rarely employed in the evaluation of patients with blunt hepatic and splenic trauma.

Diagnosis

The rapid detection of abdominal injury is among the most important goals of trauma care. Before the advent of current diagnostic modalities for abdominal evaluation, many trauma patients died for undetected abdominal lesions, including liver injuries.

Because abdominal physical examination is unreliable in most cases, diagnostic peritoneal lavage has been widely used for evaluating blunt abdominal trauma. However, diagnostic peritoneal lavage has several limitations, including invasiveness and low specificity, and has largely become replaced by US for the early triage of patients with blunt abdominal trauma. Currently, US represents the screening modality of choice for the detection of fluid collections and, if possible, of parenchymal lesions in abdominal trauma patients. US findings suggesting a liver traumatic lesion or peritoneal fluid in hemodynamically stable patients are an indication for CT examination.

In fact, because CT allows definition of the exact location and extension of the liver lesions, demonstration of active hemorrhage, and quantification of the degree of hemoperitoneum, it is considered the mainstay of diagnosis of hepatic injuries in patients who do not undergo immediate laparotomy. Nowadays, initial CT findings help direct patient treatment, particularly by stratifying hemodynamically stable patients into those who require intervention and those who can be treated nonsurgically. Furthermore, repeated CT examinations are useful to monitor the course of healing and detect later vascular or biliary complications that may go clinically undetected (1, 3, 5).

Interventional Radiological Treatment

Several interventional radiological procedures, including therapeutic angiography and image-guided drainage, can be used in the management of abdominal trauma (3).

Transcatheter embolization is largely employed for treating recurrent liver parenchymal bleeding and represents the first therapeutic option in cases of hepatic acquired vascular malformation, including pseudoaneurysms and arterioportal or arteriovenous fistulas.

Bleeding from a major hepatic vein can be controlled by placing an intravenous stent, while percutaneous biliary stenting may be used for treating biliary–vascular fistulas.

Usually, in small bilomas (<3 cm) conservative management is indicated, whereas bilomas >3 cm should systematically be drained under US or CT guidance to avoid pseudoaneurysm development.

CT- and US-guided drainage also provide effective nonoperative options for the management of posttraumatic large hematoma and liver abscess.

Trauma, Pancreatic

The pancreas is involved in 3–12% of abdominal injuries. A mortality rate of 20% has been reported with pancreatic injuries, as these are often associated with trauma to other organs. Usually, penetrating trauma results in the highest frequency of pancreatic injury and is almost always associated with concurrent injury to other intra-abdominal organs. Therefore, the pancreas is prone to injury due to blunt abdominal trauma when it is compressed against the spine, being relatively fixed compared with overlying bowel similarly to other retroperitoneal organs. Injury to the pancreas may cause contusion or rupture and consequently acute pancreatitis and its complications. Although US is excellent for showing fluid collections, CT represents the most suitable diagnostic study in hemodynamically stable patients with trauma. In fact, CT permits to better imaging not only the entire pancreatic gland (thus depicting possible contusion or rupture or inflammatory complications) and other retroperitoneal organs, but it also allows the identification and characterization of other possible traumatic injuries by means of a rapid evaluation of the entire abdomen, chest, and head during the same examination.

Definition

Spinal trauma can take on a variety of forms: road accidents, falls, also gunshot wounds and other penetrating injury. Vertebral trauma may irreversibly damage the spinal cord, and is acute and unexpected, dramatically changing the course of an individual's life. Since spinal cord injuries frequently occur in young and previously healthy individuals, the personal and social cost is extremely high. Severe forces indirectly applied to the vertebral column are the most frequent mechanisms of spinal cord injury. Such a force, generated during sudden flexion, hyperextension, vertebral compression, distraction or rotation of the vertebral column, may result in misalignment of the vertebral column, fracture of vertebral bodies, ligamentous injury, disc herniation and development of epidural haematoma. Consequently, the spinal cord may be compressed and lacerated, or stretched and even transected. Damage to the spinal cord can result in edema and haemorrhage. Spinal trauma can be subdivided into an acute and chronic phase of spinal injury. Since a higher number of patients survive the acute phase than in the past, a higher incidence of chronic lesions will occur [2, 3].

Clinical presentation

Depending on the severity of the injury, symptoms may range from pain, normally at the site of trauma to tetra- or paraparesis when spinal cord is involved or radicular deficits in cases with nerve root avulsion. The American Spinal Injury Association has issued guidelines for a standardized physical examination.

Imaging

This includes plain radiographs, CT and MRI. The first of these is valuable for demonstrating abnormal vertebral alignment in dislocation vertebral compression fractures, and the second for localising osseous fragments relative to the spinal canal, as well as demonstrating articular fractures. Neither can provide evidence of spinal cord injury [1].

MRI has proved to be a significant noninvasive tool in evaluating the spinal cord in the acute stages following injury, and provides a direct image of the nature and extent of cord damage. In addition, MR is very useful in evaluation of chronic sequelae of spinal cord trauma.

To assess traumatic spinal instability the three-column rating is widely used. This states that instability requires disruption of at least two of the three columns. The anterior column is formed by the ventral half of the vertebral body, disc and ventral ligaments; the middle column by the posterior vertebral body, disc and posterior longitudinal ligament, and the posterior column by the posterior bony and ligamentous elements.

Acute Spinal Injury

Bony lesions

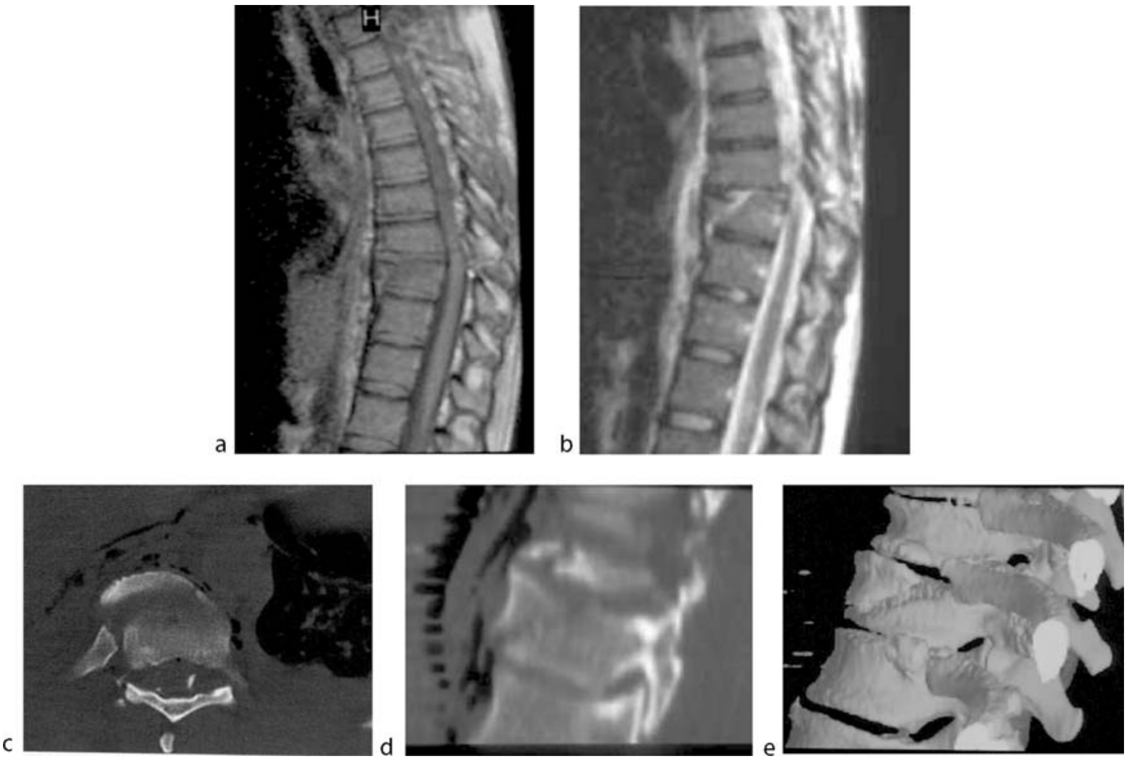
Loss of spinal alignment and vertebral body displacement are readily recognised on plain films: this kind of deformation is also detectable on sagittal CT reconstructions[1] and mid-sagittal MR images (Fig. 1). Degenerative facet changes frequently lead to subluxation which may be misinterpreted as being the result of spinal injury. Undisplaced fractures are difficult to detect on plain films: smaller ones or those involving the posterior elements are usually undetectable. Compression of the anterior vertebral body leads to a wedge-shaped fracture. The posterior vertebral border with the pedicles, arch, articular processes and ligamentous apparatus are usually intact.

In the presence of spinal spondylosis or stenosis, a trivial trauma may cause significant spinal cord injury, even without visible fracture or dislocation.

Fracture lines in the vertebral body are best seen on CT sections, and frequently affect the end-plates, most often the cranial plate, which can then no longer be displayed in one CT section. In compression fractures, sagittal and transverse computerized reconstructions confirm the wedge deformity of the vertebral body, the normal height of the posterior wall and the anatomic contours of the spinal canal.

CT is also useful in the assessment of posterior traumatic lesions of the neural arch and articular processes.

MRI can demonstrate larger vertebral fractures as a discontinuity of the thin black line of cortical bone on T1 W images; sometimes also on T2 W images. The typical wedge-shaped deformity of a vertebral body is well seen on T1 W images. In the acute stage, bone marrow signal intensity may be reduced on T1 W scans; T2 W and STIR images may show inhomogeneous areas of high signal, indicating a higher water and blood content. After a few months, compression fractures show a relatively



Trauma, Spinal. Figure 1 Spinal Trauma; MR SE T1 (a) TSE T2 (b) Tear fracture of vertebral body with posterior displacement. Spinal cord compression is present. This findings are confirmed, with more details by CT (c, d, e).

normal marrow signal intensity and sometimes fatty degeneration in elderly patients. MR is able to demonstrate bone bruising of vertebral bodies, even without other evidence of fracture. This injury produces signal alterations, presumably as the result of microfractures, edema and haemorrhage characterized by hypointensity on T1 W and hyperintensity on T2 W images.

Fracture fragments, especially if retropulsed into the spinal; canal, are also identifiable on MRI, directly on T1 W images if they have a detectable marrow component within them, or indirectly on T2 W images by their impingement on the dural sac. When cortical bone fragments are small, it may be difficult to distinguish them from ligaments, because both structures have the same low signal intensity.

Ligamentous injures

The anterior and posterior longitudinal ligaments, ligamenta flava and interspinous ligaments play an important role in the stability of the spine. Overstretched or ruptured ligaments can be directly visualized on MR images because ligaments normally have low signal intensity. Intermediate or high signal intensity on T2 W images within or around ligaments in their normal location is indicative of edema or hematoma.

Anterior longitudinal ligament disruption may be associated with extensive haemorrhage and oedema in prevertebral soft tissues.

Disc herniation

Spinal trauma can cause intervertebral disc injuries in up to 25% of cases. Marked dislocation of the vertebrae is possible only in association with a severe injury of the involved disk. Traumatic disc herniation may be responsible for cord or root compression. The appearance of a traumatic disk herniation is the same as that of a hernation unrelated to trauma. On T1 W images, disc material of normal intermediate signal intensity is identified anterior or posterior to the vertebral body margins; on T2 W images, the traumatized disc can show abnormal high signal.

Nerve root avulsion

Nerve root avulsion is most often due to a traction injury of the shoulder. There is avulsion of the root sleeve with dural laceration.

Retraction of the nerve stump creates a cavity that is later filled with CSF sometimes extending through the neural foramen, called a root sleeve pocket or pseudomeningocele, demonstrated by CT-myelography or by T2 weighted MR images.

Epidural hematoma

This lesion results from tearing of the epidural venous plexus with extravasation of blood into the epidural space. Since the spinal dura is not firmly adherent to the vertebral canal, large epidural haematomas may extend over multiple levels.

In the acute stage, the hematoma is isointense with spinal cord on T1 W images; on proton density and T2 W images, it is isointense to the adjacent CSF in the subarachnoid space: they may be distinguished by the hypointense dura which separates the two compartments.

Intravenous administration of Gadolinium DTPA does not provide enhancement of the epidural blood collection, but can be useful to outline the haematoma from the adjacent strongly enhancing venous plexus.

Spinal cord lesions

The pathologic appearance of the spinal cord following an injury includes a spectrum of findings, from macroscopically normal through cord swelling, edema, punctuate or coalescent haemorrhages to complete cord transection.

The spinal cord may appear normal in 8 to 34% of patients with traumatic neurological deficits. The short TI inversion recovery (STIR) sequence is the most sensitive to depict intramedullary posttraumatic lesions. Fluid attenuated inversion recovery (FLAIR) images are useful in case of post-traumatic syrinx formation.

Spinal cord swelling is a focal expansion of the cord not associated with intramedullary signal changes, centered at the level of the injury and tapering gradually cranially and caudally. It is better appreciated on T1 W sagittal images. Spinal cord swelling may be difficult to appreciate at the level of compression when traumatic narrowing or pre-existent stenosis of the spinal canal is present; in these cases, the surrounding subarachnoid space is completely effaced.

Cord edema is a focal accumulation of intracellular and interstitial fluid in response to injury. The swollen segment of spinal cord has a normal signal intensity on T1 W and high signal intensity in T2 W images.

A purely edematous intramedullary lesion is associated with less severe clinical deficit than in haematomyelia of the spinal cord, which is associated with the most severe and lasting functional compromise.

The MRI appearance and evolution of haemorrhagic spinal cord lesions resembles those of intracranial bleeds and depend on the time elapsed post-trauma. In the hyperacute phase haemorrhage may be isointense to the cord on T1 W images and iso- or slightly hyperintense on T2 W due to the presence of oxyhemoglobin; in the acute stage, because of the susceptibility effect of deoxyhemoglobin, signal intensity decreases on T2 W images, especially when gradient echo (GRE) technique is employed. In the subacute stage, due to the presence of methemoglobin, haemorrhage may exhibit high signal intensity on both T1 and T2 W images (Fig. 2).

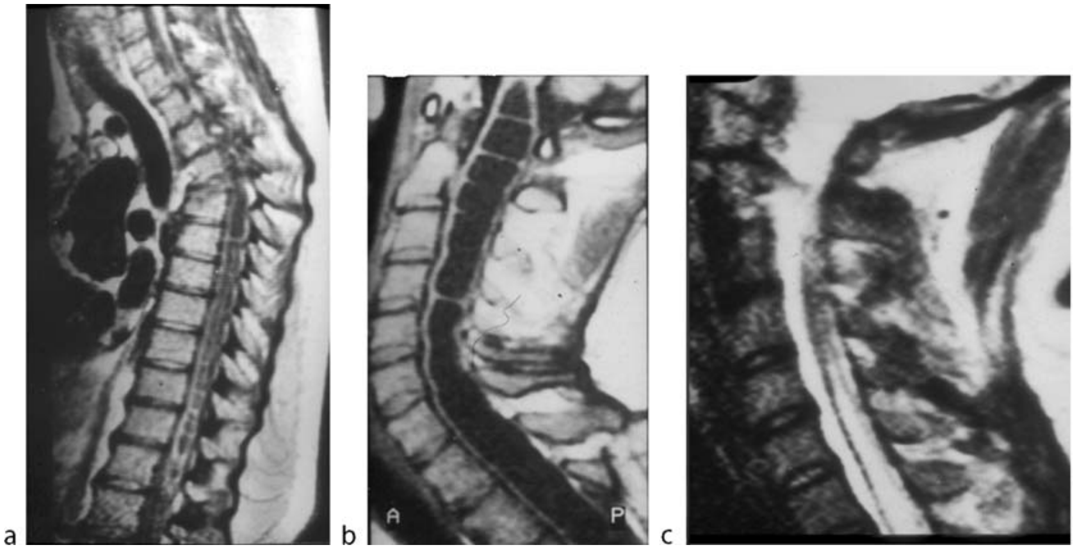
Trauma, Spinal. Figure 2 Spinal Trauma; MR TSE T2 sagittal: vertebral fracture at C5-C6 level; spinal cord compression is visible with a low intensity area inside the cord due to hematomyelia.

The most serious lesion which can occur during spinal trauma is complete cord transection. The discontinuity of the cord is well depicted on T1 W images.

Chronic Injury

Here also, MRI represents the image technique of choice. Initial edema and haemorrhage lead to changes caused by rupture of membranes of the nerve cell bodies, with release of lysosomes and subsequent cytolysis and necrosis. Then the acute exsudate and necrotic tissues are replaced by macrophages. This reparative stage may persist for years, resulting in a pathologic entity defined as posttraumatic myelomalacia and characterized by presence of cysts, gliosis and fibrosis.

On MRI, myelomalacic cavitations produce hyperintensity in the spinal cord on T2 W images; on T1 W



Trauma, Spinal. Figure 3 **Spinal Trauma; Chronic Phase. MR SE T1 sagittal (a) Vertebral collapse at mid-thoracic level one year before. TSE T2 sagittal (c) the cavity is reduced after shunt.**

images they are poorly demonstrated and marginated. They may be found within a normal sized cord or appear as a focal expansion of an otherwise atrophic cord.

On rare occasions, intramedullary cysts may enlarge and coalesce after several years of neurologic stability, leading to a spontaneous deterioration of the neurologic status of a spinal cord injury patient. This deterioration can be catastrophic for the patients with only marginally useful function.

There is no explanation for this delayed progressive myelopathy, classified as post-traumatic syringomyelia, occurs most frequently in cervical lesions, usually progressing rostrally from the original site of the injury. Cyst contents are isointense to cerebro spinal fluid. Cyst enlargement as demonstrated by MRI may aggravate symptoms, making surgical shunt shunting of the cyst necessary.

MRI can also identify other long-standing spinal cord abnormalities such as cord compression due to traumatic fractures and dislocation; focal or diffuse cord atrophy with cord a-p 6mm or less; and subarachnoid adhesions tethering the cord, or cysts which compress the cord.

Synonyms

Splenic traumatic injury; Splenic traumatic lesions; Splenic traumatic rupture

Definitions

Splenic injuries may be classified as subcapsular and ►intraparenchymal hematomas, parenchymal lacerations, ►splenic fractures, or splenic vascular injuries.

Although protected under the bony ribcage, the spleen represents the most frequently injured intraperitoneal organ in cases of blunt thoracoabdominal injury. Preexisting diseases can markedly increase the risks and severity of splenic injury; for example, splenic diseases that produce splenomegaly (such as hematologic, infectious disorders, etc.) are often accompanied by a thinning of the capsule, making the spleen more fragile.

Subcapsular lesions may rupture with apparently insignificant trauma because of a weakened overlying capsule. Penetrating injuries also frequently involve the spleen. The spleen is the most vascular organ of the body; for this reason, splenic injury poses a potentially life-threatening situation.

Clinical Presentation

The clinical presentation of splenic trauma is widely variable, and a significant number of patients do not manifest symptoms. Because the spleen contains no pain sensors, and pain fibers are present only within the splenic capsule, left upper abdominal or flank pain represents the most common clinical manifestation due to local peritoneal irritation or overlying soft tissue or bone injury (e.g., fractures of the lower ribs may be associated). Diffuse abdominal pain may be present in cases of free intraperitoneal blood, leading to diffuse peritoneal irritation.

Clinical findings related to systemic blood loss can manifest and include tachycardia, tachypnea, restlessness, and pallor. Hypotension suggests overt shock and represents a surgical emergency.

Imaging

Although computed tomography (CT) represents the technique of choice for evaluating splenic injuries, ultrasound (US) is effective for initial evaluation of trauma victims with suspected blunt abdominal injuries because it can be performed rapidly in the admission area (1). Thanks to its high sensitivity for detecting free intraperitoneal fluid, US represents the imaging modality of choice for initial screening for free abdominal fluid, and it has widely replaced peritoneal lavage. In hemodynamically unstable patients, the presence of significant hemoperitoneum on US enables selection for immediate exploratory laparotomy. Visualization of fluid in the right upper quadrant suggests the possibility of splenic injury. In some cases, splenic injuries may be identified. Splenic hematomas and ►lacerations may appear hyperechoic if they contain acute hemorrhage; more subacute or chronic parenchymal injuries often result in heterogeneous echogenicity.

In trauma victims who are hemodynamically stable, CT represents the imaging method of choice for detecting visceral injuries and determining their extent. The advent of CT scanning has made conservative management more practical and safer for victims of splenic injury, thanks to the high sensitivity in diagnosis and staging of splenic injuries.

Besides perisplenic hematomas and intraparenchymal clots that may be hyperdense in baseline conditions compared with normal spleen, when performing CT in splenic trauma evaluation, intravenous contrast is essential. In general, areas of intraparenchymal lesions are lower in density than normal spleen; moreover, active arterial extravasation may be identified as high-attenuation foci.

Care must be taken to avoid image acquisition too soon after contrast infusion (before 60 sec), as the inhomogeneous appearance of the splenic parenchyma, due to differential diffusion of contrast between red pulp and white pulp, is difficult to interpret. Another possible pitfall in splenic trauma is diffuse hypodensity due to local hypoperfusion in the hypovolemic state.

CT can accurately demonstrate the presence of hemoperitoneum and determine its extent. In some cases, the only CT finding to suggest a splenic injury is the presence of a perisplenic hematoma or hemoperitoneum in the left paracolic gutter ("sentinel clot sign"). On occasion, this sign is seen only on the precontrast study because the attenuation of hemoperitoneum is highest immediately adjacent to the parenchymal lesion. Another subtle CT feature suggesting splenic injury is thickening of the lateroconal and anterior pararenal fascia, due to parasplenic hemorrhage.

CT is highly accurate in depicting and distinguishing parenchymal traumatic lesions. Splenic parenchymal injuries include subcapsular and intraparenchymal hematomas, parenchymal lacerations and fractures, and vascular injuries involving the splenic pedicle.

►Subcapsular hematoma characteristically appears as a peripheral collection of fluid with a lenticular shape that flattens or compresses the lateral margin of the spleen. If the splenic capsule is intact, no free perisplenic blood may be observed at all.

Intraparenchymal hematoma appears as a round or irregular area with attenuation values of 50–70 UH. The attenuation value of the clotted blood within the hematoma gradually decreases, becoming a hypodense area within normally perfused splenic parenchyma.

Parenchymal lacerations are linear low-density lesions with a branching appearance.

They typically involve the lateral surface of the spleen, whereas splenic fractures are deep lacerations that traverse the splenic parenchyma and extend to the splenic hilum. In severe cases, the spleen is shattered into small fragments.

Vascular injuries involving the splenic pedicle or parenchymal arteries can be identified.

CT enables detection of intrasplenic pseudoaneurysms, arteriovenous fistulas, and active contrast extravasations. Pseudoaneurysms are caused by intimal trauma and disruption of elastic fibers, leading to intimal lesion and weakening of the arterial wall.

The presence of splenosis is a possible complication of splenic trauma, easily detectable during a follow-up examination.

Various CT-based grading systems to help determine patient outcome and management have been proposed. For example, Resciniti grading analyzes the extent of splenic parenchymal injury, capsular lesions, and hemoperitoneum by using a quantitative CT severity score. However, its effective value in clinical decision making and therapeutic planning remains controversial.

The role of magnetic resonance (MR) in evaluating splenic trauma is actually limited because several technical restrictions often render MR examination impractical in victims of multiple trauma. However, MR can be useful in the follow-up of some splenic traumatic lesions, such as hematomas, which demonstrate a time course of changes in signal intensity due to the paramagnetic properties of degradation products of hemoglobin. Subacute hematomas usually present high signal intensity on both T1- and T2-weighted images because of the presence of methemoglobin. In case of areas of devascularization within the splenic parenchyma, low signal can be appreciated, compared with the high signal intensity of normal splenic tissue after gadolinium injection.

Angiography is not employed as a diagnostic tool but is reserved for treatment in patients with active bleeding. Angiography is sensitive in detecting the site of active (1, 2) arterial bleeding, and transcatheter embolization represents an alternative to surgery for conservative treatment and preservation of the immunologic function of the spleen (1–3).

Nuclear Medicine

Nuclear medicine imaging is not helpful in evaluating splenic trauma and is nowadays widely substituted by tomographic imaging techniques, in particular CT.

Diagnosis

In patients with blunt abdominal trauma, physical examination is not sufficient to diagnose an abdominal visceral injury. Laboratory studies are also not very helpful in diagnosing splenic injury, but blood cell count and hemoglobin level are important in the initial evaluation and follow-up of trauma victims. Before the advent of tomographic imaging techniques (US and CT), diagnostic procedures such as diagnostic peritoneal lavage were the only diagnostic methods. Nowadays, diagnostic imaging in the hemodynamically stable patient has become indispensable, not only for diagnosis but also for adequate management. In particular, CT allows the identification and characterization of traumatic splenic injuries and the rapid evaluation of the entire abdomen, chest, and head to identify other possible lesions during the same examination.

Rupture of the spleen after an asymptomatic period, defined as delayed rupture, represents a possible feared complication. Delayed rupture of a subcapsular hematoma may occur as a result of hyperosmolarity in the course of clot lysis; delayed bleeding may also originate from the free rupture of a perisplenic hematoma into the peritoneal cavity. In some cases, delayed hemorrhage is due to a splenic capsular disruption with either intermittent or very slow continuous bleeding. Therefore, delayed splenic rupture represents an injury in evolution, and patients with abdominal trauma must be submitted to careful clinical surveillance and imaging follow-up.

The diagnosis of splenic rupture is not particularly challenging; however, many processes can affect the spleen and sometimes simulate laceration or intrasplenic hematoma, such as splenic infarction and splenic focal lesion. Congenital clefts of the spleen should not be mistaken for parenchymal lacerations; these are generally seen along the medial margin of the spleen, often at the superior margin. Care must be taken to distinguish splenic traumatic lesions from a ►spontaneous rupture due to predisposing pathological splenic processes, which must be identified.

Traumatic Diaphragmatic Tear

Most frequently due to penetrating chest trauma. Large lesions allow for herniation of the abdominal organs into the thoracic cavity. Typical clinical complications are intestinal obstruction and respiratory failure. Small lesions are often overlooked on initial chest X-rays because they are masked by pleural effusion or atelectasis and may lead to secondary herniations. Signs are an abnormal course of the nasogastric tube, intrathoracic location of abdominal organs, obliteration, elevation, or distortion of the diaphragm, pleural effusion, contralateral shift of the mediastinum, and fractures of the lower ribs. CT shows the discontinuity of the hemidiaphragm in 70% of the patients and/or herniation. Dynamic MRI is well suited to show diaphragmatic integrity and function.

Definition

Pulmonary tuberculosis (TB) is a common lung infection caused by *M. tuberculosis*. Classically, pulmonary TB is divided in two forms: primary and postprimary. These groups not only represent clinically different processes, but also different radiological presentations. AIDS patients are frequently infected by TB and respond differently than patients with normal immunity.

Atypical mycobacterial infections (atypical TB) are steadily increasing, whereas the incidence of tuberculosis in the Western World has declined. Because of the similarities, pulmonary disease caused by nontuberculous mycobacteria (NTMB) is included in this chapter.

Pathology/Histopathology

In primary TB, the initial response relies in macrophages and lymphocytes, resulting in an indolent inflammatory reaction. Delayed hypersensitivity develops 4–10 weeks after the initial infection; its hallmark is caseous necrosis. In reactivation TB, hypersensitivity accelerates the changes and caseous necrosis occurs at an early stage. Same changes occur in AIDS, conditioned by the immune status of the patient. The gross and microscopic changes of NTMB are usually undistinguishable from TB.

Clinical Presentation

Worldwide, primary TB occurs mainly in the pediatric age group. In areas where the disease is not prevalent, the primary form may represent up to a quarter of adult TB cases. It presents few clinical symptoms and the patients are usually asymptomatic.

Postprimary TB is considered a reactivation of a previous tuberculous lesion. Often, this reactivation is related to periods of immunodepression, malnutrition, or debilitation. Symptoms are often unspecific. Patients may have a mild cough with hemoptysis and low-grade fever.

Altered immunity such as in AIDS patients favors the infection and alters the natural course of the disease. TB is usually disseminated and up to 60% of patients have extrapulmonary disease.

The most common clinical presentation of NTMB is similar to that of tuberculosis and indistinguishable from that disease.

Imaging

Imaging findings are based mainly on two techniques: conventional chest radiograph (CXR) and CT. CXR is good for initial suspicion and for monitoring treatment. CT helps to discover new findings or to clarify findings of CXR.

Primary TB

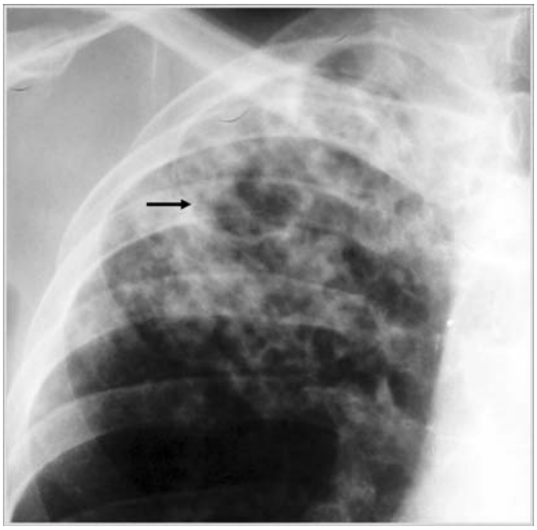
Mediastinal lymphadenopathy is often the only radiological finding. Pulmonary consolidation may be an associated feature. CXR is often normal, but sometimes it shows hilar enlargement with or without a faint infiltrate. CT is more sensitive than CXR for the detection of lung lesions and enlarged lymph nodes.

Miliary TB may occur in both primary and postprimary TB and is commonly seen in the elderly, children under 2 years of age and in immunocompromised patients. It is due to hematogenous spread and consists of multiple diffuse nodules, typically 1–3 mm in size. CXR may be normal in early stages. CT allows accurate early diagnosis, by depicting the randomly distributed micronodular pattern.

Pleural TB is considered a complication of primary TB and is common in adolescents and young adults. Nevertheless, it sometimes occurs in postprimary TB. CXR shows unilateral pleural effusion. Tuberculous effusions are very rich in proteins and often show fibrin strands and septa on ultrasound. CT rarely detects this finding. Tuberculous pleuritis usually resolves spontaneously, but treatment is necessary to prevent the development of fibrothorax. Despite proper treatment, around one third of patients develop some degree of pleural thickening. Empyema is a rare complication.

Postprimary TB

In the lung, postprimary TB manifests as patchy, poorly defined segmental consolidation, mainly located in the apical and posterior segments of the upper lobes, and less frequently in the superior or inferior segments of the lower lobes. Cavitation is the hallmark of this form and appears in around half of patients (Fig. 1). In tuberculous lobar pneumonia evolution is more indolent than bacterial pneumonias



Tuberculosis, Lung. Figure 1 Active postprimary TB. There is air-space disease in the RUL with a central cavity (*arrow*).

Disseminated nodular opacities associated with the cavitation or alone are common parenchymal features of bronchogenous spread. It is seen in CT as the "tree-in-bud" pattern, consisting of multiple peripheral branching linear structures representing bronchogenic dissemination of the disease with caseation necrosis in the respiratory and terminal bronchioles. They have a lobar or segmental distribution and are considered a reliable marker of the activity of the process.

Involvement of the tracheobronchial tree is frequent in the postprimary form. If airway involvement is not recognized and appropriate antituberculous therapy is not instituted promptly, cicatricial bronchial stenosis is almost inevitable, with resultant atelectasis, obstructive pneumonitis, and bronchiectasis. The prevalence of tuberculous bronchial stenosis varies from 40% in the preantibiotic era to 10% in patients in more recent years (1).

Complications and Late Sequelae

Tuberculomas are seen as well-defined nodules located mainly in the upper lobes. They may appear after primary TB or reactivation TB. Calcification occurs in about 20–30% of cases. CT provides better visualization of the calcifications and characteristics of the nodules. In rare cases, they have areas of decreased attenuation corresponding to caseum (2).

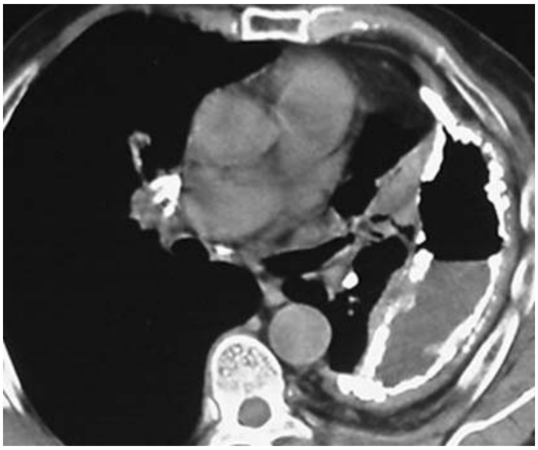
Postprimary TB may heal with parenchymal scarring, nodules, and calcification. Fibrotic mass-like lesions may form and become indistinguishable from superimposed carcinoma. Apical pleural thickening ("apical cap") may be seen on X-rays. CT demonstrates that this is mainly a thickened layer of extrapleural fat.

A complication of cavitary scarring is colonization with *Aspergillus* and development of a fungus ball. Massive hemoptysis is the cause of death in 5–14% of patients. At CT, the immature ►aspergilloma is seen as a network with irregular air pockets within the cavity. This network coalesces to form a mature fungus ball, classically seen as a round mass, which moves within the cavity depending on the patient's position.

Fragments of calcified necrotic material from lymph nodes can erode through a bronchial wall and come to lie within the airway lumen (►broncholithiasis), often causing obstruction and atelectasis. Finding calcium near an area of pulmonary collapse should arouse suspicion of a broncholith. The location of calcium within or adjacent to the bronchus is easily confirmed with CT (Fig. 2).

Bronchial involvement in pulmonary tuberculosis is not rare and bronchial perforation of tuberculous origin is common in children. Bronchoesophageal perforation secondary to tuberculosis and leading to fistulous tract formation (bronchoesophageal fistula) is significantly

Tuberculosis, Lung. Figure 2 Broncholithiasis. The arrow points to a broncholith, which occludes the anterior segment of the RUL bronchus.



Tuberculosis, Lung. Figure 3 Bronchopleural fistula. Note the air–fluid level within the calcified pleural layers.

rare. The diagnosis is usually made with a barium esophagogram, which shows the fistulous communication between the esophagus and the bronchi.

Rasmussen aneurysm is a pseudoaneurysm of a peripheral pulmonary artery that forms in a tuberculous cavity. It may cause severe hemoptysis and necessitate embolization. CT is specially suited for their demonstration.

Calcified mediastinal lymph nodes are usually found in healed TB. An excessive fibrotic reaction may cause fibrosing mediastinitis with compression and sometimes occlusion of mediastinal structures. CT is useful for suggesting or corroborating the diagnosis, and for showing the effect on the mediastinal cardiovascular structures and tracheobronchial tree.

A complication of TB pleuritis is the development of fibrothorax, with or without calcification of the pleural layers. Fibrothorax appears to be the most common source of late bronchopleural fistula. Radiographically, it most often appears as a new pleural air–fluid level (Fig. 3), sometimes with a tension pneumothorax. Knowing whether active infection is present is crucial in selecting appropriate medical treatment.

Tuberculous ►empyema necessitatis is an uncommon complication of fibrothorax in which the inflammatory mass spontaneously bores its way from the pleural cavity into the soft tissues of the thoracic wall, forming a subcutaneous abscess that sometimes opens to the skin. The usual clinical presentation is a mass in the thoracic wall, accompanied or not by a cutaneous fistula. CT and MRI are of great value in making the diagnosis by showing a pleural collection associated with an abscess in the chest wall.

TB in the Immunocompromised Host, Especially AIDS

Radiographic manifestations depend upon the immune status of the patient. In AIDS, patients with CD4 lymphocyte count greater than 200 cells/mm^3 usually have radiographic findings similar to postprimary TB, whereas patients with lower counts have atypical findings: diffuse and lower lobe opacities, mediastinal adenopathy, and military pattern. Some of these patients may have normal CXR. Patients infected with NTMB may have apparent radiographic worsening when treated with antiretroviral (3).

Atypical Mycobacteria Infection

NTMB infection is similar to that of tuberculosis and, in a specific patient, is indistinguishable from that disease. Two specific appearances are described:

The first group is typified by elderly white men who have underlying chronic lung disease, such as chronic obstructive pulmonary disease or pulmonary fibrosis. The chest radiograph shows changes that are indistinguishable from postprimary TB. Cavitation is common. Lymphadenopathy and pleural effusion are unusual.

The second group includes middle-aged or elderly white women without underlying lung disease. Characteristic CT findings are scattered bronchiectasis and multiple centrilobular nodules of varying size, usually less than 1 cm. These nodules are thought to represent NTMB granulomas. The most common location for bronchiectasis is the middle lobe and lingula. There is no dominant apical distribution in contrast to postprimary TB (4).

Nuclear Medicine

Isotopic studies are not generally used in tuberculous infection. It is important to know that active pulmonary tuberculomas commonly cause increased FDG uptake in PET studies and should not be confused with malignant nodules (5).

Diagnosis

A definitive diagnosis of TB is established by isolation of tubercle bacilli in culture. Sputum is the diagnostic specimen of choice. Bronchoalveolar lavage and transbronchial biopsy may be used in patients that do not produce sputum.

Gastric contents in children may also be examined.

Diagnosis of NTMB is more difficult and includes culture confirmation from sputum or tissue whenever possible and/or radiographic or clinical improvements (or both) while the patient is receiving three to five antimycobacterial drugs.

Interventional Radiological Treatment

In incoercible hemoptysis, embolization of bronchial arteries can be an alternative to surgical treatment.

Percutaneous injection of amphotericin B has been proposed in inoperable active pulmonary aspergilloma.

Tuberculosis, Parenchymal

E. Turgut Tali, Serap Gultekin
Gazi Üniversìtesì, Turkey
turgut.tali@gazi.edu.tr

Definition

Parenchymal tuberculosis (TB) can manifest as TB granuloma (tuberculoma; most common form), focal areas of cerebritis, cerebral abscess, or rarely as TB encephalopathy and may be isolated or associated with basal meningitis.

Pathology/Histopathology

These lesions originate as a conglomerate of microgranulomata in an area of TB cerebritis that join to form a mature noncaseating tuberculoma. In most cases, subsequent solid center caseous necrosis will develop which may eventually liquefy. Outside the capsule, there is parenchymal edema and astrocytic proliferation (1, 2).

Clinical Presentation

The clinical manifestations are nonspecific. The common presenting symptoms and signs are headache, intracranial hypertension, seizures, focal neurological signs, and fever.

Imaging

Tuberculomas are located at the corticomedullary junctions. In children, most tuberculomas are infratentorial, in adults they are supratentorial and frequently affect the frontal and parietal lobes (1, 2). The radiological presentation depends on the content of the lesion. One or more lesions with different characteristics and stages may be seen in the same patient.

Computed Tomography

The lesions are usually of reduced density or isodense with brain before contrast medium administration. In contrast to metastasis, there is little edema.

Magnetic Resonance Imaging

Noncaseating tuberculomas are usually hyperintense on T2-weighted imaging and they do enhance. Solid caseating tuberculomas display a shortening of T2 signal that may be due to the presence of free oxygen radicals in macrophages (3). They show central heterogeneous enhancement with a capsule presenting a ring-enhancing pattern. Tuberculomas with central liquefaction demonstrate a central hypointense signal on T1-weighted imaging and hyperintense signal on T2-weighted imaging. An intense rim enhancement is seen on postcontrast T1-weighted images. Magnetic resonance spectroscopy (MRS) may show prominent lipid peaks due to high lipid content in the caseous material. Presence of serine has been accepted as a distinct feature in tuberculomas.

In contrast to the solid caseating tuberculoma, the TB abscess is formed by semi-liquid material which is rich in bacilli (2). Tuberculous encephalopathy shows extensive damage to the white matter and seems to be due to a type IV hypersensitivity mechanism including cell-mediated immunity to tuberculoprotein. Neuroimaging studies show uni- or bilateral cerebral edema, perivascular demyelination, or hemorrhagic leukoencephalopathy (1, 2).

Diagnosis

The cerebrospinal fluid (CSF) findings on lumbar puncture are increased protein, low glucose levels, and pleocytosis. Isolation of microorganisms from CSF is positive in less than 40% of initial lumbar punctures. Polymerase chain reaction for TB may help confirm the diagnosis earlier.

Tuberculosis, Urinary Tract

F Z Gueddari, F Imani
Service de Radiologie Centrale, CHN, Rabat, Morocco
fzgueddari@hotmail.com

Definition

Tuberculosis remains a significant lethal contagious disease. In developed countries, the urogenital system is the second most frequent location after the lung, representing 5% of the tuberculosis bacteria.

The female-to-male ratio is 3:1. The average age of patients at diagnosis is 43 years, with renal infection rarely occurring before 20 years of age. Approximately 50% of the patients have a simultaneous active pulmonary infection or have a medical history of lung tuberculosis.

Pathology/Histopathology

Usually, the urinary system focus appears 5–20 years after the infection, a period during which the initial focus, generally pulmonary, has seeded the kidneys silently *via* the blood circulation, constituting cortical lesions that are cured or encysted by sclerosis (1–3).

Tuberculous granulations will evolve toward caseation and the opening in the excretory system. From there, the Koch bacillus will follow the course of the urine with a possible colonization of all the segments of the upper and lower excretory tract.

The characteristic element of this progression is the absence of lesion continuity and the absence of parallelism between the renal lesions and the underlying lesions. More rarely, the renal attack is part of the visceral dissemination of the tuberculous miliaries. It is exceptional during an evolutive pulmonary tuberculosis, as well as in a tertiary phase.

Histologically, lesions come in the shape of typical tuberculous follicles grouped in granulations or in nonspecific nodules. On the other hand, the macroscopic aspect depends on two opposed processes, one of destruction and caseation, creating cavities, the other of defense by fibrosis and sclerosis limiting the extension of the lesions and inducing signs of obstruction which evolve on their own account and which give the urogenital localization all its particularity, compared to other localizations.

Clinical Presentation

Renal tuberculosis may remain dormant for many years after the kidneys have become seeded during the primary tuberculous infection. Patients usually become symptomatic, with extension of the disease to the renal pelvic area and ureters causing hydronephrosis. Specific symptoms may be lacking until the hydronephrotic kidneys become secondarily infected. Frequency and urgency of urination and dysuria may ensue, with development of tuberculous cystitis. However, long before patients become symptomatic, sterile pyuria, albuminuria, and hematuria are present, although cultures for pyogens yield negative results (1, 3, 4).

Diagnosis is usually made using imaging, cystoscopy, and culture of acid-fast bacilli from early-morning urine specimens. Needle aspiration biopsy is a last resort when urine cultures are negative.

Imaging

Plain radiographs can show the size and the shape of the kidneys as well as calcifications at the level of the genitourinary system. Renal calcifications are found in more than 50% of cases, consisting of stones in the excretory tracts, calcifications in the caseous debris, or in the cicatricial lesions of the kidneys. The calcifications suggestive of tuberculosis are either fine and in clods, or joining and bulky in the kidney cement. They can also outline the walls of the pyelic cavities or the ureter in which they are encrusted, giving an image of ureteral rails or of a small porcelain basin.

Intravenous urography (*IVU*)(1, 4): It demonstrates the extension and the severity of the lesions, allowing one to evaluate the efficiency of treatment and to detect any complications.

Renal Parenchymatous Lesions

Tuberculomas rarely result in a renal tumoral syndrome. The calyceal ulceration results in a loss of the concavity of the calyx, the picture of which is fuzzy and irregular.

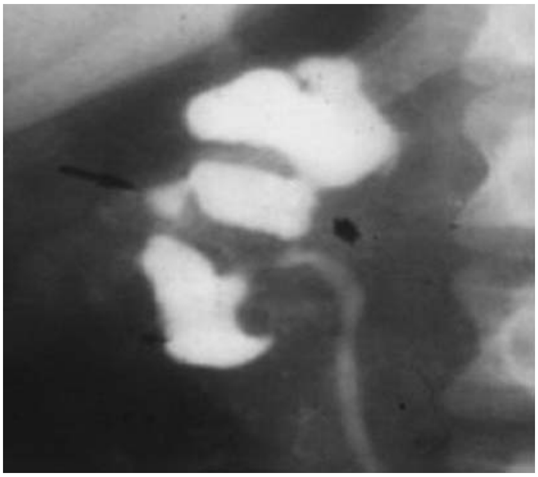
The evolution is toward an incompletely opacified calyx, or a phantom calyx. The tubercular cavities show cavities of variable aspect. Their filling is slower than that of the healthy excretory tract. They are joined to the pyelocalyceal cavities by a thin opening, typically short, irregular, and sinuous (Fig. 1).

Clear pockets on nephrographs are images of a spherical gap of avascular structure, bordered by a fine wall. They correspond either to cavities that no longer communicate with the excretory tract or to hydrocalyces.

Parenchymatous atrophy may be localized (notch, segmentary atrophy) or diffuse (small disharmonious kidney). Usually, these scars are associated with a calcification of the parenchyma, at the level of parenchymatous destruction zones or in a blocked cavity.

Lesions of the Upper Urinary Tract

In the initial stages, IVU can be normal in 10% of cases or can show fuzzy walls, thin ulcerations, and hypotonia with loss of peristalsis.



Tuberculosis, Urinary Tract. Figure 1 Urinary tract tuberculosis. Intravenous urograph of the right kidney shows a shortened, strictured, and tubular renal pelvis with dilated cavities, and presence of hydrocalyx.

In the advanced stages, the lesions of the upper urinary tract are tight and retractile stenoses, shortening the tuberculous segment and leading to a dilatation higher up. In the calyces, we can observe a calyceal amputation with an attraction of the renal pelvis toward the amputated calyx. The stenosis of the renal pelvis can reduce it to a short and thin conduit (Fig. 1).

Ureteral stenoses can be solitary or multiple, taking on a moniliform aspect.

In the terminal stages, a final fibrosis and a consecutive obstructive uropathy are responsible for real "autonephrectomy" with a mute kidney. The kidney can be small, normal, or hypertrophied according to the degree of atrophy and hydronephrosis. In this case, the study of the kidney is best carried out by ultrasound and tomodensitometry.

Lesions of the Bladder

A normal aspect corresponds to the first contaminations, making cystoscopic exploration necessary with eventual biopsies. An image with a double contour is a result of a significant thickening of the bladder's wall. The bladder can be deformed and asymmetrical with ureteral reflux.

Wall ulcerations can simulate a carcinoma. A small tubercular bladder corresponds to a significant retraction of the bladder, which becomes irregular with reduced capacity and with parietal calcifications.

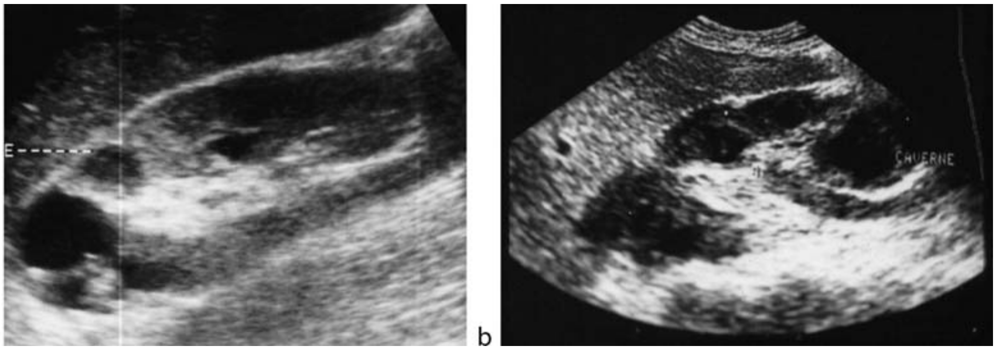
Ultrasound

Ultrasound is used particularly for the identification of hydronephrosis or pyonephrosis in the case of an alteration of the renal function. However, its sensitivity is limited in the detection of small calcifications as well as for cavities communicating with the excretory tract. Its main disadvantage is that early papillary anomalies or tiny urothelial anomalies are not highlighted. It allows two forms to be described (1, 3):

Infiltrative form: The kidney is the seat of one or several parenchymatous masses or caverns sometimes deforming its contours. The cavern usually produces a transonic image of variable margins. It can also be presented in the form of a parenchymatous, hypo- or isoechogenic nodular image (Fig. 2a). These lesions correspond to tubercular abscesses.

One can also find heterogeneous hyperechoic caverns, probably due to their fibrous evolution. A hyperechoic cavern with a subsequent cone of shadow testifies to a calcified cavern.

Renal calcifications are visible, but it is difficult to recognize fine and homogeneous calcifications, in mounds, specific to tuberculosis, whose regrouping is often evocative on plain radiographs. In the case of



a b

Tuberculosis, Urinary Tract. Figure 2 (a) Urinary tract tuberculosis. Ultrasound image shows multiple cortical lesions of different aspects: echogenic mass probably corresponding to a tuberculoma, transonic mass corresponding to a parenchymocalyceal tuberculous cavernous lesion. (b) Urinary tract tuberculosis. Ultrasound image showing hyperechoic sinus, strictured renal pelvis, and cavernous cortical lesion suggesting renal tuberculosis.

cement kidney, the renal surface considerably attenuates the ultrasounds and renders the analysis of the structures impossible. Ureteral calcifications are seldom seen on ultrasound.

Obstructive form: The dilation of the pyelocalyceal cavities is a dominant element. Their contents can be transonic in the case of hydronephrosis, hypoechoic and inhomogeneous in the case of pyonephrosis. Sometimes there is a liquid–liquid level with mobile fragments. The dilation of only one part of the cavities, by located stenosis, generally with presence of debris, is very suggestive of tuberculosis.

On the other hand, ureteral dilation is not always detectable. The use of high-frequency probes makes it possible to detect other sonographic signs such as the thickening of the dilated calyceal wall, having a double-rail aspect, or a fine transonic sluice connecting a cavern to a pathological calyx.

Other sonographic forms: A sonographically normal kidney, associated with a mute kidney on the IVU, is pathognomonic of tuberculosis and corresponds to a diffuse infiltration of the parenchyma. We can also observe a pyelocalyceal cavity dilation with a spoke-wheel appearance, with an invisible sclerosed renal pelvis, and a hyperechoic sinus, evocative of tubercular kidney (Fig. 2b).

CT Scan

It is generally prescribed as a second option to evaluate the formations responsible for a mass syndrome in the excretory system, to explore mute kidneys, and to evaluate the perirenal and pararenal space. It is also more sensitive than IVU for the detection of functional anomalies and allows a better evaluation of the morphological anomalies (1, 2).

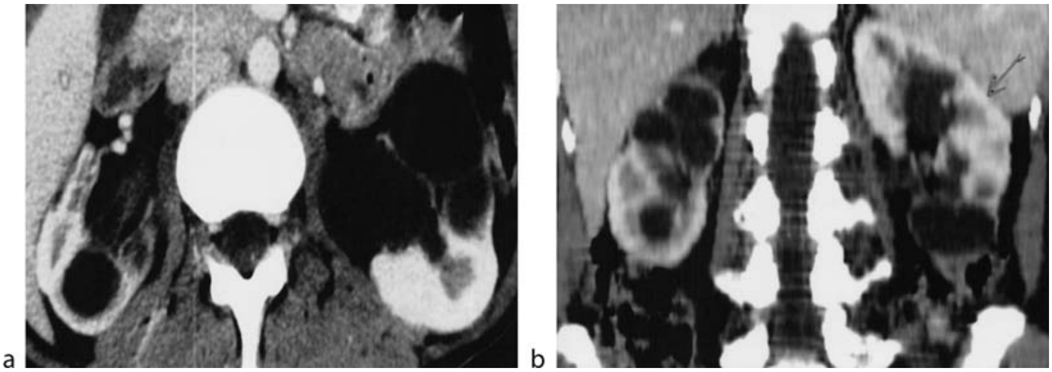
In the initial forms, computed tomography (CT) scan is generally normal, but it can sometimes show a small renal pelvis and the thickening of its walls. In the more advanced stages, the morphological modifications shown on CT scan include the focal scars responsible for cortical notches, hydronephrosis or generalized pyonephrosis, calyceal dilation without renal pelvis dilation, the degree of renal destruction, focal hypodensities, and the presence of calcifications.

If the calyces are full of liquid, the densities vary from 0 to 10 H. Debris and casein measure between 10 and 30 H, calcifications between 50 and 120 H, and calculi nearly 120 H. Hypodense zones of the tubercular abscesses corresponding to caseous necrosis are presented as a solid mass, with variable enhancement after contrast medium injection (Fig. 3a, b).

Thirty-five percent of patients present dilation of the pyelocalyceal cavities, cortical notches, calcifications, and hypodense zones; 40% present at least three of these signs. Calcifications are clearly seen on CT scan (detected in more than 50% of cases), and are more easily classified, including calculi, the calcification of a part or the entire kidney, and the homogeneous calcification of cement kidney.

CT scan is also very useful in the determination of the renal and perirenal extension by highlighting pseudotumoral infiltrative images. It will also depict extrarenal infections, particularly in the adrenal glands. In the final stages, evaluation of the mute kidneys is possible (cement kidney, hydronephrosis, or pyonephrosis). CT scan can sometimes incidentally detect very advanced forms of tuberculosis.

Ureteral lesions: They appear in nearly 50% of genitourinary tuberculosis cases and lead to the formation of stenoses and dilation. CT scan is more sensitive than IVU and ultrasound for the detection of ureteral dilations. The thickening of the ureteral wall as well as the periureteral fibrosis are easily identified on CT scan. Stenoses are frequently multiple, usually touching the



Tuberculosis, Urinary Tract. Figure 3 (a) Urinary tract tuberculosis. Postcontrast CT in a man with renal tuberculosis shows cortical bilateral excluded cavities, and a tissular enhancement of the left posterior localization corresponding to a young tuberculoma. (b) Urinary tract tuberculosis. Coronal CT reconstruction shows multiple cystic lesions communicating with the excretory system corresponding to parenchymocalyceal tuberculous cavernous lesions, and a localized tissular enhancement of the left kidney corresponding to a young tuberculoma.

distal third of the ureter. CT scan is also sensitive in the detection of ureteral calcifications.

Bladder lesions: CT scan is seldom required for the exploration of a tubercular bladder; it is generally carried out for the assessment of abdominal or urogenital tuberculosis. The organic aspects are especially represented by a small bladder with irregular thickened wall. Lesions of the upper urinary tract are often present.

Magnetic Resonance Imaging

Thanks to the development of good imaging, fast new sequences, with diuretic and contrast medium injection, Magnetic Resonance Imaging (MRI) allows a fast exploration in one session of the three components of the upper urinary tract, called nephro-angio-uro-MRI (NAU-MRI). The level of a ureteral obstacle is easily determined without the need to carry out delayed scans, as well as the severity of the obstruction by visualizing perirenal and periureteral edema (1, 5).

MRI is good at depicting tuberculous cavities, sinuses tracts, and fistulous communications (Fig. 4a, b). However, small areas of calcification are difficult to detect on MRI scans, although they are pivotal to the diagnosis of tuberculosis.

This technique could be valuable for patients with renal insufficiency and pregnant women, constituting a diagnostic technique and allowing nontraumatic and nonradioactive monitoring. In the same way, its excellent visualization of the ureters should make it possible to reduce significantly the indications of invasive techniques such as retrograde pyelography.

Other Techniques

Retrograde ureteropyelography is seldom used and its indications are limited to the nonfunctional kidneys. It shows hydronephrosis, pyonephrosis, or ureterohydronephrosis with one or more ureteral stenosis (1/3 of the cases). In the remaining cases, it finds extensive lesions of the excretory system. It should be noted that catheterization failure occurs in less than 5% of cases, by stenosis of the ureter (1–3).

Retrograde cystography can highlight a vesicoureteral reflux or allow the study of the urethra if the IVU is insufficient (voiding scan).

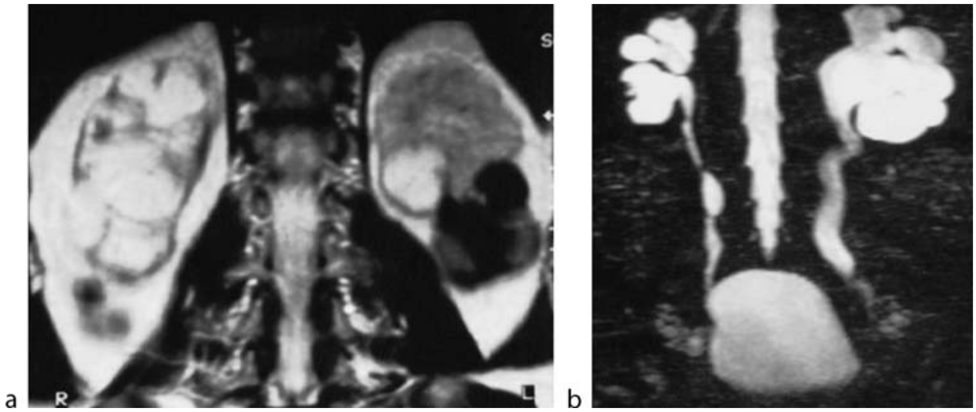
Arteriography is carried out only when a partial nephrectomy is considered. It can be normal if the lesions are tiny.

Nuclear Medicine

Isotope renography is the most sensitive imaging modality available for the assessment of renal function. The role of radionuclides in imaging patients with renal tuberculosis is confined to assessment of relative renal function by renography when surgery or nephrectomy is contemplated. However, radionuclide imaging usually cannot differentiate the various causes of depressed renal function.

Diagnosis

Findings in all imaging modalities used for the diagnosis of GUT are essentially nonspecific because the diagnosis is based on the presence of calcification, cavities, and strictures, which are associated with a long list of differential diagnoses: genitourinary calcification may occur in patients with schistosomiasis and diabetes mellitus. Brucellosis also may mimic tuberculosis. A congenital megalycalyx and focal papillary necrosis may mimic renal tuberculosis radiologically.



Tuberculosis, Urinary Tract. Figure 4 (a) Urinary tract tuberculosis. MRI T2 coronal plane image shows cortical heavy calcification of the inferior left renal pole, and a parietal cavernous calcification in the superior right renal pole, with intense hyposignal. Note the multiple cavernous lesions, with liquid signal on T2-weighted imaging. (b) Urinary tract tuberculosis: URO-MRI showing pyelocalyceal lesions, strictured renal pelvis, and multiple ureteral stenoses on the right side, ureterohydronephrosis with stenosed lower ureter.

However, a fairly confident diagnosis can be made in most instances with clinical correlation. In summary, imaging changes are observed late in the disease (all imaging findings may be normal in patients with early GUT); in many instances there is a significant group of differential diagnoses, and therefore the diagnosis is determined by culture not imaging.

Synonyms

Acute tubular necrosis; Acute tubular nephropathy; ATN

Definitions

Acute tubular necrosis (ATN) is the predominant cause of acute renal failure (ARF) among hospitalized patients (1). This pathological condition is characterized by varying degrees of tubule cell damage and by cell death usually resulting from prolonged renal ischemia or from nephrotoxins. The process is potentially reversible, but patients frequently die before renal recovery as a result of comorbid illness and ATN itself. Despite technological advances in dialysis, the mortality rate in patients with ATN who require dialysis remains between 50 and 80%.

Pathology/Histopathology

Ischemic ATN is caused by hypotension and hypovolemic shock following trauma, infections, burns, or hemorrhage. There is a rapid fall in blood pressure, which causes hypoperfusion of the peritubular capillaries with consequent tubular necrosis. Injury of tubular cells is most prominent in the straight portion of the proximal tubules and in the thick ascending limb of the loop of Henle, especially as it dips into the relatively hypoxic medulla. The reduction in ▶glomerular filtration rate (GFR) that occurs from ischemic injury is a result not only of reduced filtration due to hypoperfusion but also of casts and debris obstructing the tubular lumen, causing back-leakage of filtrate through the damaged epithelium. In addition, ischemia leads to decreased production of vasodilators by the tubular epithelial cells, leading to further vasoconstriction and hypoperfusion.

Toxic ATN is caused by agents with specific nephrotoxic activity such as poisons, organic solvents, drugs, and heavy metals causing damage to the epithelial cells. Damage by nephrotoxic substances is usually limited to the proximal tubules. These substances cause the cells to detach from the basement membrane. Necrotic cells fall into the tubular lumen obliterating it and causing acute renal failure. Since the basement membrane is intact, regeneration of the tubular epithelium is possible. Glomeruli are not affected.

Clinical Presentation

ATN typically does not produce specific signs or symptoms. The patient presents with ARF. Tubular dysfunction usually leads to an increase in urinary sodium concentration and fractional excretion of sodium and to impairment in urinary concentrating capacity characterized by a decrease in urine osmolality and urine–plasma creatinine ratio (2). However, the utility of these urinary measures may be limited in patients with advanced chronic renal failure and recent medical treatment with diuretics. If ATN is a result of impaired renal perfusion, oliguria and anuria are very common.

Imaging

Urography is not indicated for evaluation of patients with ATN, but it has been used in the past to rule out obstruction. The nephrograms of most patients with ATN become dense immediately following contrast material injection and remain so for a prolonged time. In about 25% of patients, the nephrogram becomes increasingly dense during the contrast material-enhanced study. Despite the presence of a large amount of contrast material in the kidney, opacification of the pyelocalyceal system is markedly reduced.

Ultrasound (US) is the imaging modality of choice in patients with ARF. Generally, gray scale US is used to exclude renal obstruction. Evaluation of renal size has a role in clinical practice, since the finding of large, smooth kidneys should indicate that ARF is probably due to primary acute renal disease and that the process is potentially reversible, while detection of kidneys of reduced size suggests a complicated underlying chronic nephropathy and a worse prognosis. No specific findings are found in patients with ATN. The kidneys may appear normal or enlarged, with a variety of pathologic changes that can also be observed in patients with other renal pathologies. Renal echogenicity and parenchymal thickness are usually normal; about 11% of patients with ATN have hyperechoic kidneys (Fig. 1) with increased corticomedullary differentiation.

State-of-the-art color Doppler and power Doppler US equipment allow an excellent evaluation of normal renal vasculature. In patients with ATN a significant but

a b

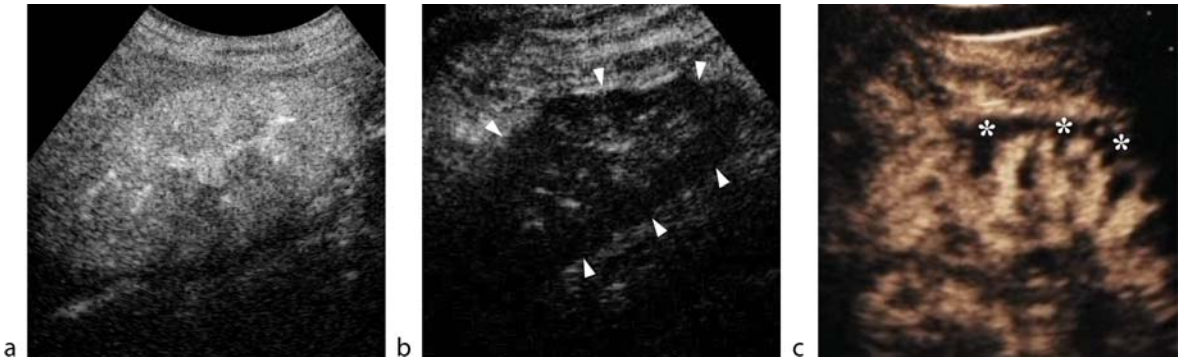
Tubular Necrosis, Kidney, Acute. Figure 2 **Acute tubular necrosis. Same kidney. RI at the onset of ARF (a) is elevated (RI = 0.79). During recovery from ARF (b) RI values returned to normal values of 0.57.**

nonspecific reduction of renal perfusion is usually appreciable, which can also be observed in patients with other renal pathologies. Duplex Doppler evaluation of renal hemodynamics provides functional information which is useful when differentiating among different causes of ARF that are morphologically indistinguishable. In a series of 91 patients with ARF, only 11% presented morphologic alterations of the renal parenchyma, whereas 69% presented elevated renal resistive index (RI) (3). In particular, duplex Doppler US proved valuable in the differential diagnosis between prerenal ARF and ATN (3–5). Most patients with prerenal ARF have normal parenchymal flow, whereas patients with ATN reveal markedly abnormal Doppler flow profiles with increased pulsatility or loss of the diastolic flow (Fig. 2a). An RI threshold value of 0.75 is reported as optimal in attempting a differential diagnosis between renal and prerenal ARF (3). The course of ATN may be monitored with duplex Doppler US by serial scanning. Follow-up studies during recovery from ARF (Fig. 2b) show improvement of the Doppler flow before recovery of function occurs (5). However, in common clinical practice, ARF is often caused by drug abuse or dehydration in elderly patients with hypertensive nephrosclerosis. The differential diagnosis between ATN and prerenal causes of ARF not complicated with ATN can be difficult in these patients since the RI is usually elevated due to the preexisting renal parenchymal disease (6). Duplex Doppler US is unable to distinguish the various causes of ATN. Similar changes in Doppler waveforms may be seen from a variety of causes including septicemia, hypovolemia, rhabdomyolysis, nephrotoxic drug intake, and multiple organ failure.

Recently, US contrast media have been introduced in clinical practice which can improve the diagnostic capabilities of US in the assessment of patients with ARF (6). In particular, measuring the arteriovenous transit time after bolus injection of microbubbles has been shown useful, in transplanted kidneys, to discriminate between acute tubular necrosis and acute rejection (6). In patients with ischemic ARF, contrast-enhanced US



Tubular Necrosis, Kidney, Acute. Figure 3 Patients with ARF from different causes. Contrast enhanced US after bolus injection of 2.4 mL Sono Vue (Bracco, Milan, Italy). (a) Acute tubular necrosis. Renal perfusion is relatively preserved. (b) Acute renal infection. The renal parenchyma (arrowheads) does not enhance. (c) Acute cortical necrosis. allow the differential diagnosis between ATN (Fig. 3a), in which the renal cortex enhances, acute renal infarction (Fig. 3b), in which the renal parenchyma does not enhance, and acute cortical necrosis (Fig. 3c), in which only the renal cortex does not enhance (6).

Computed tomography (CT) is not suited to patients with ATN because no clinically useful information is obtained and iodinated contrast agents are nephrotoxic. The differential diagnosis between ACN and other causes of ARF, such as ATN, can be made with contrast-enhanced CT, since ACN typically presents with an enhancing renal medulla, nonenhancing renal cortex, and a thin rim of enhancing subcapsular tissue. However, due to the nephrotoxicity of iodinated contrast media in the context of ARF, magnetic resonance imaging (MRI) and contrast-enhanced US should be preferred when this differential diagnosis is required.

MRI should be preferred to contrast-enhanced CT for assessment of renal perfusion in patients with ARF because no significant nephrotoxicity is reported in the literature for paramagnetic contrast agents. As occurs with contrast-enhanced CT, the differential diagnosis between ACN and other causes of ARF, such as ATN, can be obtained.

Nuclear Medicine

Renal scintigraphy can be a useful imaging study in selected clinical circumstances, especially when severe renal insufficiency contraindicates the administration of iodinated contrast material. Tc-99m mercaptoacetyltriglycine (MAG3) is more useful in cases of renal insufficiency than Tc-99m diethylenetriamine pentaacetic acid (DTPA) and is able to evaluate both renal flow and function. In patients with renal transplantation, scintigraphy may play a role in the assessment of both perfusion and function of the graft. This technique helps differentiating ATN from graft rejection, especially in the immediate postoperative period. In patients with ATN, Tc-99m-MAG3 scintigraphy characteristically shows relatively preserved renal perfusion and poor tubular function; in those with early rejection, perfusion is decreased and function is preserved relatively early, followed by reduction of both perfusion and function. In practice, however, a considerable overlap of the findings exists and the differential diagnosis is usually difficult. As a consequence, biopsy is still considered the gold standard for diagnosing rejection.

Since the rejection process is accompanied by the infiltration of lymphocytes, uptake of Tc-99m-mononuclear leukocytes is higher in this pathologic condition, improving the differential diagnosis between rejection and ATN in renal grafts.

Diagnosis

The diagnostic approach to ATN must rely on a synthesis of data from the patient's history, physical examination, laboratory studies, and imaging. A relevant role is given to serum markers such as creatinine and ►blood urea nitrogen (BUN).

The diagnosis is often supported by a positive history of risk factors; however, the physician must rule out other reasons for ARF, such as prerenal, postrenal, and renal ARF. Distinguishing ATN from prerenal ARF can be extremely difficult. Recognition of the characteristic urinary sediment of ATN, including renal tubular epithelial cells, granular casts, and muddy brown granular casts, helps to confirm the diagnosis; moreover, ATN does not rapidly improve following the administration of

T

large-volume intravenous fluid, as usually occurs in patients with noncomplicated prerenal ARF.

In general, renal biopsy is not necessary in the evaluation and therapy of patients with ATN. In fact, kidney biopsy, besides carrying a risk of complications, provides only a partial analysis of the renal tissue and may not be useful in assessing the prognosis.

Tumoral Calcinosis

The primary type is a relatively rare disorder most commonly seen in people of African descent. The etiology is uncertain, but manifestations are often apparent by the second decade of life, affecting the hips most frequently, then buttocks, elbows and smaller joints. The histologic appearance is characterized by densely loculated masses of calcific debris and fluid enclosed by fibrous tissue. Lesions grow quite slowly and rarely cause pain unless there is nerve involvement. Surgical removal is the treatment of choice. Incomplete resection leads to recurrence.

The term “tumoral calcinosis” has also been used to describe similar lesions seen in conjunction with systemic disorders, such as chronic renal failure and scleroderma (secondary tumoral calcinosis).

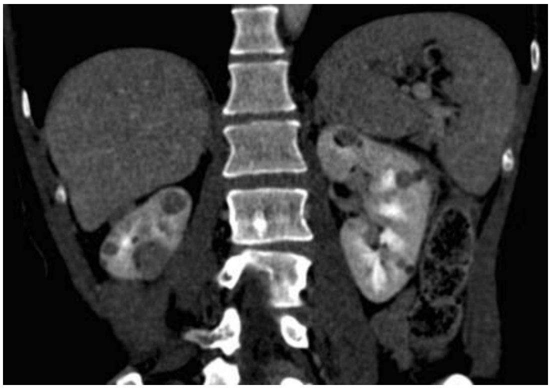
Angiomyolipoma

Epidemiology and Clinical Features

Angiomyolipoma is the most common benign renal lesion. It occurs as isolated, sporadic entities in 80% of the cases, most commonly manifesting in middle-age women. The other 20% of AML develop in association with tuberous sclerosis (1). The two forms vary to some degree in their imaging features but are histologically indistinguishable. The penetrance of such lesions in the tuberous sclerosis complex can be up to 80%. AMLs that occur in association with tuberous sclerosis manifest at a younger age (31.5 years vs. 53.6 years), are likely to be larger, multiple, bilateral, and are prone to grow and need surgical treatment (Fig. 1) (2). In patients without tuberous sclerosis, the tumors usually are solitary. The female predilection seen in sporadic AMLs does not occur in patients with tuberous sclerosis.

Patients with AMLs may present abdominal and flank pain, nausea, vomiting, and fever. Common findings described include a palpable mass, abdominal tenderness, hematuria, anemia, shock, hypertension, urinary tract infection, and renal failure. These signs and symptoms are usually a result of mass effect and hemorrhage. The main predictor of hemorrhage has been reported to be size tumor. Occasionally, AMLs can extend into the inferior vena cava or adjacent nodes, mimicking a malignancy; however, death due to metastatic AMLs is exceedingly unusual.



Tumors, Renal Mesenchymal. Figure 1 Angiomyolipoma. Multiple fatty-density renal lesions are seen in this patient with tuberous sclerosis.

Histologic Characteristics

AMLs are composed of varying amounts of mature adipose tissue, smooth muscle, and thick-walled blood vessels. Historically, AMLs have been classified as hamartomas. Although calcification and necrosis are rare, hemorrhage is frequent, despite the fact that the tumor blood vessels have a thicker wall than normal vessels. In 17–20% of patients with spontaneous perinephric hemorrhage, AML is the cause of bleeding. Malignant transformation does not occur except in rare cases.

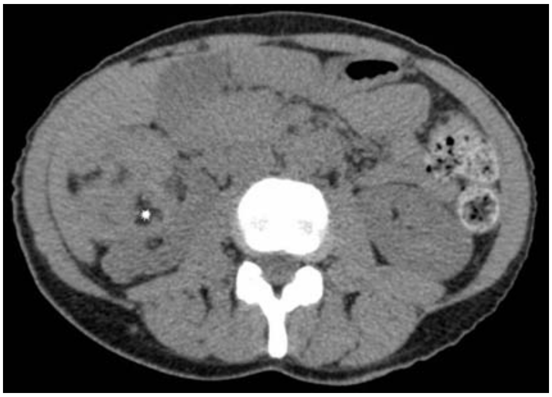
Radiologic Features

Plain radiographs may demonstrate a relatively lucent mass if there is a large fatty component to the tumor.

Urography may demonstrate a renal mass. However, the urogram often is unrevealing, because the tumors frequently have an exophytic growth pattern.

At US, AML demonstrates marked increased echogenicity. If there has been hemorrhage, sonolucent areas may be seen. Occasionally, other renal tumors may demonstrate the type of dense, increased echogenicity reported with AML. In addition to benign lesions such as oncocytoma, cavernous hemangioma, and renal infarction, malignancies such as renal cell carcinoma, liposarcoma, and lymphoma may be indistinguishable from AML at US (3). If there is relatively little fat,

T



Tumors, Renal Mesenchymal. Figure 2 Angiomyolipoma. Nonenhanced CT scan show a large tumor of fat attenuation (*).

Tumors, Renal Mesenchymal. Figure 3 Angiomyolipoma. A renal lesion without detectable fat (*arrow*), homogenous with attenuation higher than normal parenchyma.

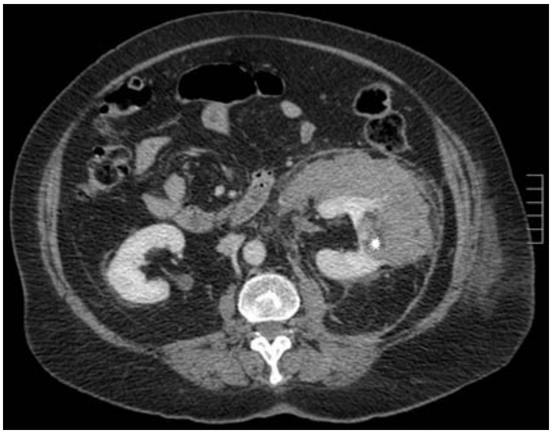
the ultrasonographic pattern will be indistinguishable from other renal masses.

The most reliable imaging modality for AMLs is CT. Single or multiple well-circumscribed noncalcified renal cortical tumors containing tissue with fat attenuation of less than −20 HU are characteristics findings of AML at nonenhanced CT (Fig. 2). CT examination of a fatty renal mass must be performed carefully to avoid volume averaging adjacent perinephric fat and a false low-density reading. An unenhanced CT examination with thin sections combined with a pixel analysis is the most sensitive test to confirm a small amount of fat. Although demonstration of intratumoral fat attenuation is almost pathognomonic for this lesion, there are other rare benign and malignant processes that should be considered: perirenal fat entrapment, lipid necrosis, or osseous metaplasia, all of which may occur in renal cell carcinoma. Other rare renal lesions that can contain fat are liposarcoma, myolipoma, lipoma, oncocytoma, and Wilms' tumor. It may not be possible to distinguish these types of masses from each other.

The degrees of soft tissue attenuation of AMLs may vary, depending on the relative proportion of vascular or smooth muscle composition, and on the presence of hemorrhage. Therefore, the absence of intratumoral fat does not preclude the diagnosis of AML (Fig. 3). This unusual manifestation so called AML with minimal fat accounts for approximately 4.5% of all AMLs (4). High-tumor attenuation on unenhanced scans and homogeneous and prolonged enhancement has been presented as a unique finding in AML with minimal fat but these findings are not specific enough to make a confident diagnosis (5). AML rarely contain calcification and, therefore, a diagnosis of AML should not be made if a lesion contains fat and calcium. In such a case, a renal cell carcinoma must be considered likely. Most AMLs and renal cancers show dramatic enhancement after contrast material administration, so this is not a point of differentiation.

On MRI, the fatty portion of an AML is hyperintense to the renal parenchyma on T1-weighted images; however, other renal masses, including hemorrhagic-proteinaceous cyst and renal cell carcinomas that contain hemorrhage, may have similar signal characteristics. Therefore, to establish the presence of macroscopic fat within a renal mass, obtaining frequency-selective fat-suppressed T1-weighted images and comparing them with nonfat suppressed T1-weighted images is necessary. However, by evaluating the location of the India ink artifact on opposed-phase chemical shift MRI, characterizing AMLs without the use of frequency-selective fat-suppressed T1-weighted images is possible (6). When clearly imaged, MRI should have the same accuracy as CT in diagnosing an angiomyolipoma. However, MRI probably is not as sensitive as CT in detecting fat in small tumors.

AngioCT or arteriography may demonstrate tortuous, almost aneurysmally dilated vessels. Clusters of saccular micro- and macroaneurysms have been reported to be the most characteristic finding of AML at angiography, with other suggestive features including a dense well-organized early arterial network, a late whorled appearance, sharp margination, and no appreciable arterious-venous shunting (7). Vascular encasement found in malignant tumors is not present in AMLs. AngioCT may now be helpful in defining the vascular supply to tumors in which local resection is planned.



Tumors, Renal Mesenchymal. Figure 4 Angiomyolipoma. Transverse CT shows a tumor contains fat (*). High attenuation material suggestive of hematoma is visible in the tumor and the perirenal space.

Treatment

Small lesions discovered incidentally in asymptomatic patients do not usually prompt surgery for diagnosis or cure.

The need for intervention, should be predicated on the presence of rapid growth or the development of symptoms related to retroperitoneal hemorrhage (Fig. 4) and mass effect (8). Tumor diameter greater than 4 cm has also been used as a criterion for prophylactic treatment, since many studies show a higher frequency of hemorrhagic complications with larger tumors. However, depending on the size and location of the lesion, total nephrectomy may not be required. Treatment with selective arterial embolization or radio-frequency ablation of the lesion may also be used, especially in patients with tuberous sclerosis, who may have limited nephronic reserve.

Lipoma

Renal lipoma is a very rare tumor exclusively composed of mature adipose tissue. The presentation on imagery is not different from AML with predominant adipose tissue.

Hemangioma

Epidemiology and Clinical Features

Renal hemangioma is a rare benign neoplasm, with 90% occurring in the medulla (papilla) and the renal sinus (9). Most lesions are solitary, unilateral, and less than a centimeter in size. In children, the occurrence of renal hemangioma is well documented in congenital syndromes like Sturge–Weber and Klippel–Trenaunay.

In adults, hemangioma is usually solitary and unilateral with no predilection for side or sex.

Histologic Characteristics

Hemangiomas may be of the capillary or cavernous type. The most common location of these lesions is in the mucosa or submucosa of the pelvis and the medullary pyramids (91%) rather than the cortex. Consequently, it follows that its cardinal manifestation is hematuria.

Radiologic Features

Renal hemangiomas are hyperechoic at US. At CT and MR imaging, they may demonstrate intense arterial phase contrast enhancement that persists into the venous phase. At MR, hemangiomas may appear homogeneously hypointense on T1-weighted images and hyperintense on T2-weighted images (10).

Preoperative diagnosis of renal hemangioma is extremely difficult, and the lesion is often mistaken for more common renal pelvic malignancies such as transitional cell carcinoma and renal adenocarcinoma.

Leiomyoma

Epidemiology and Clinical Features

Adult renal leiomyomas are rare, benign spindle cell tumors that are found in approximately 5% of autopsy specimens (11).

Among those tumors found at autopsy, the average size is less than 5 mm. Clinically apparent leiomyomas are substantially larger but are far less common. As with AML, these lesions are more likely to be seen in middle-aged and older women (median age, 42 years), have no metastatic potential, are currently discovered as incidental findings, and occur with increased frequency in patients with tuberous sclerosis.

Histologic and Pathologic Characteristics

Leiomyoma of the kidney consists predominantly of smooth muscle cells without pleomorphism or nuclear atypia. Generally, leiomyomas are well-circumscribed, peripheral lesions. Most of them are considered to be hamartomatous.

Radiologic Features

Although cyst formation may occasionally be seen, leiomyomas typically appear as well-circumscribed, solid lesions (12). There may be a cleavage plane between the leiomyoma and the cortex and the lesion may be extremely exophytic or attached to the cortex by only a small stalk (13). Irregular calcification may be seen in a minority of cases.

Differential Diagnosis

Leiomyoma lacks features that allow it to be distinguished from leiomyosarcoma, a rare malignant smooth muscle tumor.

Treatment

The radiologic findings cannot differentiate leiomyoma from renal adenocarcinoma. The suspicion of a leiomyoma will prompt surgical exploration for diagnosis. However, identification of a well-circumscribed, peripheral renal mass, especially if it is small (less than 4 or 5 cm) in a middle-aged woman, should allow one to suggest the diagnosis of a leiomyoma. Although this will not obviate surgical exploration, it may allow the surgeon to prepare for a renal-sparing operation in selected cases. The prognosis after resection of these lesions is excellent (3).

Characteristics

Oncocytoma

Epidemiology and Clinical Features

Renal oncocytomas are benign tumors originating from the intercalated cells of the collecting duct. They have a male predilection and a mean age of presentation in the seventh decade. Renal oncocytomas occur with an overall incidence of 3 to 7% among all renal tumors. Although most tumors are unifocal, 2 to 12% are multifocal and 4 to 12% are bilateral (1). Most are diagnosed incidentally, but symptomatic patients usually present with gross hematuria, flank pain, or a palpable mass. The preoperative distinction between benign oncocytoma and renal cell carcinoma (RCC) is important because a correct diagnosis could allow patients to avoid aggressive surgical procedures. Oncocytomas are biologically benign. Among patients who have had an oncocytoma resected, there has been no demonstrated evidence of metastases or diminished longevity; very few cases of recurrence after enucleation of a tumor have been reported (2).

Associations between a subset of patients with multifocal renal oncocytomas and hereditary syndromes have been described, including familial renal oncocytoma and Birt–Hogg–Dube syndrome. This autosomal dominant syndrome is characterized by various dermatologic disorders and the development of renal tumors (renal cancers, particularly chromophobe 34%, oncocytoma 5%, hybrid chromophobe-oncocytomas 50%, clear cell carcinoma 9% and papillary renal cancer 2%) (3).

Histologic Characteristics

An oncocyte is a large transformed epithelial cell that has a finely granular eosinophilic cytoplasm. Oncocytes increase in number with age and are found in a variety of organs, including salivary gland, thyroid, pancreas, and kidney. In the kidney, oncocytomas arise from the distal tubule or collecting ducts.

The gross appearance of an oncocytoma is a well-defined tan to brown tumor. A "pseudocapsule" is often seen where the tumor compresses the adjacent renal parenchyma. Although hemorrhage is typically absent, focal areas can be detected in some tumors. Gross calcification is exceedingly rare. Most cases of oncocytoma are confined within the renal parenchyma, and gross evidence of capsular or vascular invasion is rare. One distinctive feature of oncocytomas is the presence of a prominent central scar in an otherwise homogeneous tumor, seen in 33 to 80% of cases (4). The average size of oncocytomas with central scars is slightly less than that of tumors without scars, indicating a limited correlation between tumor size and the presence of central scars.

Although there are occasional reported cases of involvement of regional lymph nodes and tumor extension into the vein, the vast majority of oncocytomas are well differentiated and benign.

Despite the well-characterized cytologic features of renal oncocytomas and the obvious benefits of the preoperative diagnosis of a benign tumor, the role of tumor biopsy for definitive diagnosis has been studied only retrospectively on samples taken from surgical specimens and remains questionable. Moreover, the overall sensitivity of renal biopsy ranges from 40 to 90% (5) and many tumors that are read as "nondiagnostic" on biopsy are often found to be malignant after complete surgical extirpation and thorough histologic examination. Until the techniques and interpretations of biopsies become more consistent, its use for the preoperative diagnosis of renal oncocytomas will remain limited.

Radiologic Feature

Oncocytomas are usually homogeneous at US, but some are heterogeneous; they may be hyperechoic, hypoechoic, or isoechoic with respect to the normal renal parenchyma. If a central stellate "scar" is seen, it can be hyperechoic, hypoechoic, or anechoic. RCCs are often more heterogeneous than oncocytomas and are more likely to display the ultrasound findings of gross calcification.

Angiography is potentially useful for the diagnosis of oncocytoma. The characteristics attributable to oncocytomas include the "spoke-wheel" appearance resulting from vessels radiating toward the center of the lesion, a homogeneous capillary blush during the nephrogram phase, and an enhanced rim around the perimeter of the lesion. However, the features are not consistently found and the presence of the "spoke-wheel," thought to be the most distinguishing quality on angiography is seen in 4 to 76% of the tumors (6). Angiography demonstrates a vascular renal tumor with a dense tumor blush. A "spoke-wheel" pattern of vessels penetrating into the center of the tumor is common. Although this vascular configuration often is described in an oncocytoma, it is not pathognomonic because it also can be seen in renal adenocarcinoma.

CT usually reveals a solid, homogeneous lesion that can demonstrate a centrally located stellate area of low attenuation, indicative of a central scar (Fig. 1). This central scar is not pathognomonic for an oncocytoma because it can be seen in renal adenocarcinoma. Most studies have shown that oncocytomas are usually isodense or slightly hypodense to normal renal parenchyma on unenhanced CT. A few have been described which are hyperdense. Tumors homogeneity has been observed in 50 to 100% of tumors (7). The examination of comparable RCC lesions showed that 22% also appear homogeneous on CT. The central stellate scar, if present, is less dense than surrounding tissue, both before and after intravascular contrast administration. The remainder of the tissue of the tumor enhances but to a lesser degree than normal renal parenchyma, enhancement is usually homogeneous. Occasionally, a thin enhancing rim and a lucent capsule-like margin has been described (8). Rare manifestations include small cystic regions, gross calcification, and an irregular margin invasion of surrounding fat. However, neither venous tumor thrombi nor hilar nodal metastases have been encountered.

MRI of oncocytomas reveals spherical masses that are relatively homogeneous. On T1-weighted spin-echo images, the solid portions of the tumor may be isointense or hypointense when compared with normal renal parenchyma. However, 27% of the cases did not

Tumors, Renal Parenchymal. Figure 1 Oncocytoma. Contrast-enhanced CT scan show a solid tumor (*arrow*) with an area of low attenuation indicative of a central scar.

demonstrate this finding and were actually isointense relative to the renal cortex (9). On T2-weighted images, the tumor may be heterogeneous, although homogeneous isointense, hypointense, and hyperintense appearances have been found. When present, the central stellate "scar" has been described as being of diminished intensity on both T1-weighted and T2-weighted images. This can be differentiated from the necrosis common to RCC, which appears as areas of decreased signal intensity on T1-weighted imaging and as areas of increased signal intensity on T2-weighted imaging. Unfortunately, a direct comparison of various renal tumors using magnetic resonance imaging indicated that a distinction between tumor types was not possible.

Treatment

Because an oncocytoma cannot be reliably diagnosed radiographically, treatment is surgical. If typical radiographic features of an oncocytoma, such as central stellate scar and a spoke-wheel, vascular pattern are present, an oncocytoma may be suggested. However, neither appearance is pathognomonic, surgery is required. The excellent prognosis associated with this tumor seems to indicate that minimally extensive and invasive ablative techniques such as partial nephrectomy, cryotherapy, or radiofrequency may be adequate for the removal of the tumor while sparing unaffected renal parenchyma (1). However, the coexistence of RCC and oncocytoma is not uncommon and is seen in 10 to 32% of patients with oncocytoma. These findings seem to suggest that nephron-sparing surgery should be attempted only after thorough intraoperative inspection by open or laparoscopic techniques for the presence of additional lesions.

Papillary Adenoma

Papillary adenomas are tumors with papillary or tubular architecture of low nuclear grade and 5 mm in diameter or smaller.

These benign tumors often are confused with and may be difficult to distinguish from renal adenocarcinoma. Both renal adenomas and adenocarcinomas develop in the proximal convoluted tubule and cannot be distinguished by histologic or histochemical means. They both occur in the same age groups, and both show a marked male predominance. Many authors believe that an adenoma is a small renal carcinoma that has not yet metastasized.

Because most of these renal adenomas are detected at autopsy, they have little clinical significance. However, when they are detected in a surgery, the nomenclature used to describe these cortical glandular tumors implies prognostic significance. It may be best to describe these tumors as renal adenocarcinomas, but with a low likelihood of metastasis. Search for evidence of metastasis and arranging appropriate follow-up may be beneficial.

Metanephric Adenoma

Metanephric adenoma is an uncommon benign renal tumor that has been reported previously in the pathology literature as embryonal adenoma. Unlike renal adenoma, which is by definition <5 mm in diameter, metanephric adenoma can grow to a larger size. Grossly, small tumors (<5 cm) are characteristically homogeneous and solid; however, larger tumors may be extensively necrotic and simulate the gross appearance of RCC. Histologically, the tumor is composed of numerous small tubular structures, some of which have distinctive papillary infoldings.

At ultrasound the adenomas are hyperechoic. On unenhanced CT scans, adenomas are usually hyperdense compared with the renal parenchyma, and enhanced less than adjacent renal parenchyma. Because RCC may have an identical CT and US appearance, the diagnosis of benign metanephric adenoma cannot be made on imaging studies, and adult patients should undergo surgery.

Juxtaglomerular Tumor

Epidemiology and Clinical Features

These very rare tumors have been found in patients ranging from 7 to 58 years of age, and are almost twice as common in women than in men. The mean age of detection is 24 years. The clinical presentation includes marked and sustained hypertension. Laboratory testing may reveal evidence of secondary aldosteronism with hypokalemia and elevated levels of aldosterone.

They are benign neoplasms and neither malignant transformation nor local recurrence after surgery has been reported.

Histologic Characteristics

Juxtaglomerular tumors are renin-producing tumors of the juxtaglomerular apparatus of the kidney.

Radiologic Features

CT is the most sensitive method of detecting a juxtaglomerular tumor. Because the attenuation of the tumor is similar to that of normal renal parenchyma, contrast-enhanced images are often needed to detect the mass, which enhances less than the renal cortex (10).

MR imaging may be performed either to examine the renal arteries or to detect a renal mass. A juxtaglomerular tumor has been reported to have peripheral enhancement on T1-weighted images following intravenous administration of gadopentetate dimeglumine. Delayed images demonstrated reversal of the enhancement pattern, with washout of contrast material at the periphery and filling in of the central portion of the tumor (11).

In patients with a juxtaglomerular tumor, elevated renin levels may be detected in the main renal vein. However, this procedure may be unrewarding if selective samples are not obtained from different segments of the kidney. If the tumor lies in a peripheral location, the venous drainage may be to capsular vessels and even segmental renal vein sampling can be unrewarding.

Treatment

The treatment of juxtaglomerular tumors is surgical excision.

Nephroblastomatosis

Epidemiology and Clinical Features

Nephroblastomatosis is a group of pathologic entities characterized by persistent nephrogenic blastema. Although nephroblastomatosis is not malignant, it is associated with a high incidence of Wilms' tumor. They are found incidentally in 1% of infants. They are associated with Beckwith–Wiedemann syndrome and hemihypertrophy, Perlman syndrome, and trisomy 18.

Histologic Characteristics

Nephrogenic rests are classified histologically as dormant, sclerosing, hyperplastic, or neoplastic. Dormant and sclerosing rests are usually microscopic and are not considered to have malignant potential. Hyperplastic and neoplastic rests are grossly visible as small tan nodules surrounded by normal parenchyma.

Radiologic Features

The radiographic features are dependent on the size and distribution of the embryologic remnants. The lesions in the multifocal form usually are microscopic nodules and are difficult to image. In the diffuse form, the kidneys are enlarged and the collecting system may be deformed by parenchymal nodules.

The lesions often are hypoechoic, but also may be isoechoic or hyperechoic. Their subcapsular location suggests nephroblastomatosis and helps to distinguish this condition from polycystic renal disease or lymphoma.

At CT, macroscopic nephrogenic rests appear as low attenuation peripheral nodules with poor enhancement relative to that of adjacent normal renal parenchyma. At MR imaging, the nodules demonstrate low signal intensity foci on both T1- and T2-weighted images (12).

Typical angiographic features include a normal caliber main renal artery. Peripheral nodules are hypovascular and do not blush with contrast, and the kidney has a scalloped appearance.

Treatment

Patients with nephroblastomatosis are at increased risk of developing Wilms' tumor. Many are treated with antineoplastic drug, which often decrease the renal size. However, such patients remain at risk and should be followed to detect the subsequent development of a Wilms' tumor.

Mesoblastic Nephroma

Epidemiology and Clinical Features

Mesoblastic nephroma is the most common solid renal neoplasm in the first 3 months of life (12). There is no sexual predilection. The most common clinical presentation is a palpable abdominal mass, with hematuria occurring less frequently.

Histologic Characteristics

Gross pathologic examination reveals a solid, unencapsulated tumor that commonly occurs near the renal hilum. Hemorrhage and necrosis are infrequent. At histologic analysis, mesoblastic nephromas are composed of interlacing sheets of fibromatous cells.

The tumor is large averaging over 6 cm in diameter and often replaces almost the entire renal parenchyma. Although the tumor may penetrate the capsule and may involve the perinephric space, it rarely extends into the renal vein or renal pelvis. Cases with a low grade of malignancy have been reported and may be confused with Wilms' tumor.

Radiologic Features

At imaging, mesoblastic nephroma appears as a unicentric, relatively homogeneous, solid mass that typically involves the renal sinus. Mesoblastic nephroma is homogeneously hypoechoic at US, low attenuation at CT, and homogeneously hypointense on both T1- and T2-weighted MR images. Infrequently, areas of necrosis and hemorrhage are seen (13).

Angiography may occasionally be needed for preoperative evaluation. Most mesoblastic nephromas are moderately vascular and demonstrate tumor vascularity.

Treatment

Mesoblastic nephroma exhibits benign behavior, and nephrectomy usually suffices as treatment.

In some patients, extensive tumor necrosis extrarenal infiltration and mesenchymal immaturity suggest more aggressive behavior of the tumor. In these patients, who usually present beyond 3 months of age adjunctive chemotherapy or radiation may be given.

Tumors, Spine

A. M. De Schepper
Leiden University Medical Centre, Leiden, The Netherlands
arthurdeschepper@hotmail.com,
A.M.de_Schepper@lumc.nl

Characteristics

Because of the unique anatomy and morphology of the osseous spine, enveloping major neural structures (cord and radicular nerves), and because of its guarantee to the static equilibrium of the human body, primary tumors of the spine, malignant as well as benign, may cause severe clinical symptoms and complaints such as local or radicular pain, neurological symptoms due to spinal cord and/or radicular nerve compression (Horner's syndrome, sciatic pain), up to transverse cord lesions, spinal instability, and scoliosis. In this regard, clinical symptoms may be the first alarming signs pointing to the possible presence of a tumor of the osseous spine.

There have been improvements in minimally and maximally invasive therapy by radiofrequency or laser ablation (osteoid osteoma), percutaneous injection of corticosteroids [aneurysmal bone cyst (ABC)], vertebroplasty (aggressive hemangioma), arterial embolization [giant cell tumor (GCT)], corporectomy, and even vertebrectomy (malignant tumors) as well as in adjuvant radio- and/or chemotherapy. However, early detection and tissue-specific diagnosis are required to achieve a long-term cure and improved outcome.

Initial imaging consists of plain radiography, whose value is hampered by the complex anatomy and morphology of the vertebrae, causing superimposition of different elements and possibly obscuring pathological processes. Cross-sectional imaging [computer tomography (CT) scan and magnetic resonance imaging (MRI)] is the modality of choice in staging and further characterization, because it couples morphological information to tissue-specific information by using Hounsfield units, signal intensities, and enhancement behavior (static as well as dynamic) after administration of contrast agents (iodinated or gadolinium chelates). MRI is the best modality for presurgical planning, showing the extent of involvement in the bone marrow, soft tissue, and spinal canal, and for evaluating treatment effect and follow-up.

In most handbooks one will find a descriptive or encyclopedic approach to tumoral pathology. We prefer a more pragmatic or analytical approach using a combination of a series of individual parameters, which is briefly discussed in the next few sections.

Clinical Information

The presence of clinical symptoms is related to the type of tumor (benign lesions are merely asymptomatic), its location, and its extension. In this regard, osteoid osteoma, aggressive hemangioma, and malignancies are mostly symptomatic.

History of night pain should alert one to search carefully for osteoid osteoma, whereas recent-onset painful scoliosis is suggestive of osteoid osteoma or eosinophilic granuloma. Tumors that are mostly asymptomatic, such as nonaggressive vertebral hemangiomas, may occasionally become symptomatic due to associated pathology such as disc herniation.

The age of the patient is important in the assessment of these lesions. In a young patient, osteoid osteoma, ABC, and Ewing's sarcoma predominates, whereas GCT is normally seen in the middle-aged and chordoma in the elderly.

Prevalence

Some tumors such as chondroblastoma, intraosseous liposarcoma, malignant nerve sheath tumor or malignant melanoma, and monostotic fibrous dysplasia are rarely found in the osseous spine. In children the most common benign tumors are eosinophilic granuloma, osteoid osteoma, osteoblastoma, and ABC, whereas Ewing's sarcoma is the most common malignant tumor.

Solitary Versus Multiple Lesions

It is important to determine whether a lesion is solitary or multiple. Multiple lesions are most commonly due to metastases from breast and lung cancer in women and prostate and lung cancer in men.

The most common cause of multiple primary lesions is lymphoproliferative disorder such as multiple myeloma and lymphoma.

The presence of multiple lesions may be noted on plain radiograph but is more likely to be seen on bone scintigraphy or MRI including whole-body MRI. However, both plain radiographs and MRI may be normal in 20% of cases of multiple myeloma.

Another condition that can rarely present as multiple lesions is eosinophilic granuloma (EG), which needs to be considered in children. Fibrous dysplasia occasionally involves the spine at multiple sites. One-third of spinal hemangiomas may involve multiple levels.

Solitary lesions are less frequent than multiple ones, consisting of only 4–9% of all ►tumors of the osseous spine.

Topography: Location

The location of the tumors in the spine is useful in determining the nature of the lesion. In general, most tumors are located at the thoracic and lumbar spine. The cervical spine is the predilection site for osteoblastoma and osteochondroma. It is also commonly involved in eosinophilic granuloma, particularly the C2 vertebra in adults. The thoracic spine is the preferred site in more than 50% of cases of hemangioma, enostosis (particularly T1–T7), and chondrosarcoma. ABC also occurs at the thoracic spine, but most commonly involves the lumbosacral spine.

Enostosis and osteoid osteomas have strong affinity for the lumbar spine. Chordoma, GCT, and plasmacytoma have a penchant for the sacrum. Indeed, GCT comprises 71% of benign sacral tumors. Ewing's sarcoma is a rare cause of sacral spine tumor.

Site within the Vertebra

The body of the vertebra is mainly involved in benign conditions such as hemangioma, bone islands, and GCT, with the size of the hemangioma varying from a small lesion to complete involvement of the vertebral body. However, about 10% may involve the posterior elements. The vertebral body is also favored by chordoma and Ewing's sarcoma. Benign conditions commonly involving the posterior elements are osteoid osteoma, ABC, and osteochondroma.

Morphology

Border of the Lesion, Pattern of Bone Destruction, and Periosteal Reaction

A well-defined border (geographic) is seen with benign conditions such as hemangioma, enostosis, osteoid osteoma, osteoblastoma, and ABC.

A permeative appearance with a broad zone of transition indicating aggressive biologic activity is seen in Ewing's sarcoma.

Periosteal reaction is rarely seen in vertebral lesions and is difficult to assess. If present, the possibility of an osteosarcoma should be considered.

Matrix

Well-defined borders (geographic) are seen with benign conditions such as hemangioma, enostosis, osteoid osteoma, osteoblastoma, and ABC.

A permeative appearance with a broad zone of transition indicating aggressive biologic activity is seen in Ewing's sarcoma.

Periosteal reaction is rarely seen in vertebral lesions and is difficult to assess. If present, the possibility of an osteosarcoma should be considered.

Expansion

Expansile lesions are seen in ABC, osteoblastoma, and occasionally in aggressive hemangioma. Malignant lesions such as chordoma, Ewing's sarcoma, and chondrosarcoma also demonstrate expansion along with soft tissue extension. This feature may also be seen in relatively benign conditions such as osteoblastoma and GCT.

Soft Tissue Extension

Some of the primary spinal tumors have a proclivity for soft tissue extension. This is not only seen with malignant conditions such as Ewing's sarcoma or chordoma, but also in benign lesions like osteoblastoma. Occasionally, hemangiomas may be associated with an extensive soft tissue component and are then referred to as aggressive hemangiomas. These lesions tend to be symptomatic.

Density (Hounsfield Units) on CT, Signal Intensities on MRI, Degree and Pattern of Enhancement after Contrast Agent Administration

The density of the lesion may be helpful in characterizing it. Fatty lesions such as lipoma have low density on CT (−50/−100 HU). Density allows for differentiation with air (−800/−1000 HU), which is occasionally seen in the vertebral body and originates from degenerative disc disease.

Enostosis appears very dense, with a density similar to cortical bone, lying within the cancellous vertebral body.

Most pathological lesions tend to have low signal intensity on T1-weighted (T1-WI) and high signal intensity on T2-weighted (T2-WI) sequences. This reflects the high relaxing value of water on long TE sequences. Hemangioma and EG tend to have increased signal intensity on T1-WI indicating the presence of fat. Low signal intensity on T2-WI is seen in GCT due to high collagen content, hemosiderin, and increased cellularity of the lesion. Bone islands demonstrate low signal intensity on all MR sequences, as they are basically cortical bone.

Contrast enhancement following administration of gadolinium chelates can help characterize the tumor. A typical ring and arc pattern of enhancement is characteristic of chondroid tumor.

Morphological Pattern

There are some morphological patterns seen in the spine on various imaging modalities, which have a very specific differential diagnosis.

Vertebra plana is mostly seen in EG. *Honeycombing* or *corduroy* pattern seen on plain radiographs and *polka dot* appearance on axial CT sections are characteristic of hemangioma.

A lucent center (*nidus*) with variable central mineralization surrounded by extensive reactive sclerosis is seen in osteoid osteoma on plain films, CT, and MRI.

Marked sclerosis with expansion of the whole vertebral body, which is referred to as *ivory vertebra*, is seen in lymphoma or Paget's disease.

Fluid–fluid levels are characteristically seen in ABC due to sedimentation of blood degradation products. However, this is not specific and may be seen in osteoblastoma and (teleangiectatic)osteosarcoma too, as well as in secondary cases of ABC that may occur in conditions such as osteoblastoma, GCT, and fibrous dysplasia. A feature that may distinguish primary ABC from other causes is the presence of solid tissue in the latter. This is not usually seen in primary ABC unless there has been a pathological fracture.

Mini-brain appearance is seen in plasmacytoma mimicking the MR appearance of brain.

Dumbbell or mushroom shape may be seen in chordoma together with preservation of disc space.

The patterns mentioned are useful in characterizing the lesions, but they need to be cautiously interpreted taking into account the rest of the features.

The "*spider pattern*" is an interesting example that we have seen on CT. This pattern is noted in plasmacytoma but also in angiomatosis.

Tumors, Spine, Intradural, Extramedullary

Niloufar Sadeghi
Department of Radiology, Erasme Hospital, Brussels, Belgium
nsadeghi@ulb.ac.be

Definitions

Spinal intra-dural extra-medullary tumours (►SIET) arise inside the dura and outside the spinal cord. Nerve sheath tumours and ►meningiomas account for 80% to 90% of all SIET (1). More recently, due to intensified therapy of systemic malignancies and prolonged patient survival as well as increased sensitivity of imaging techniques the incidence of detected leptomeningeal metastases has significantly increased.

MR imaging is the method of choice in the diagnosis of SIET and allows direct demonstration of both the mass and associated intraspinal alterations. The mass usually displaces the spinal cord and enlarges the ipsilateral subarachnoid space.

Conventional myelography or CT-myelography were previously performed and demonstrated indirect signs such as intra-dural contrast filling defect with the displacement of the spinal cord or a myelographic block caused by the mass.

Histopathology/Anatomy

Benign Tumours

Nerve Sheath Tumors: Nerve sheath tumours are the most common SIET, accounting for 25% to 30% of all cases (1, 2). Nerve sheath tumours arise from dorsal sensory roots, although occasional examples on motor nerve roots have been recorded. They are often located in the anterolateral part of the spinal canal; their distribution throughout the spine is fairly uniform with a slight lumbar predominance. Two main types of nerve sheath tumours are found in the spine: schwannoma and neurofibroma. ►Schwannomas are encapsulated, well-circumscribed round or oval tumours that often show cystic degeneration and haemorrhage. The tumour arises eccentrically from the parent nerve. ►Neurofibromas are unencapsulated, fusiform and less well-delineated lesions. Necrosis and cystic degeneration are rare in neurofibromas and the parent nerve typically runs through the lesion with nerve fibres dispersed throughout the tumour. A third type of neurogenic spinal tumour, ganglioneuroma, is relatively rare.

Between 35% and 45% of patients with nerve root tumours have Recklinghausen's disease, or ►neurofibromatosis (NF) type I, in which multiple lesions are common. Multiple spinal schwannomas characteristically occur in patients with NF type 2. Spinal neurofibromas less commonly occur in NF type I, and when they do occur they are often associated with plexiform peripheral neurofibromas. Malignant transformation of neurofibromas to neurofibrosarcomas in NF type I patients is estimated to range from 4% to 11%, whereas schwannomas essentially lack potential for malignant degeneration.

In 70% to 75% of the cases nerve sheath tumours are intra-dural, in 15% extra-dural and in 15% there are combined intra- and extra-dural 'dumbbell' masses. Less than 1% is intra-medullary (2, 3).

Occasionally an intra-dural tumour extends through the intervertebral foramen to expand into a greater mass on the peripheral nerve. The extra-vertebral tumour is often the significant clinical feature and may be found in the neck, posterior mediastinum, behind the peritoneum or in the pelvis, depending on the level of origin of the mass (3).

Meningiomas: After nerve sheath tumours, meningiomas are the most frequent SIET, accounting for 25% of all spinal tumours. Twelve percent of all meningiomas are located within the spinal canal. Aggressive tumours and hemangiopericytomas are rare. The peak incidence is in the fifth and sixth decades with predominance in women (80%). Ninety percent of spinal meningiomas are intra-dural and 5% are either 'dumbbell' or extra-dural lesions. The thoracic spine is the most common site (80%), followed by cervical spine (15%). These tumours are usually located in the posterior aspect of the spinal canal and as in the cranium, the tumour is usually firmly fixed to the dura (2).

Paragangliomas: Paraganglioma is a tumour of paraganglia, the accessory organs of the peripheral nervous system. Spinal paragangliomas are rare tumours that are found in the cauda equina and filum terminale. Males are affected slightly more than female, and the average age at diagnosis is around 50 years (2, 3).

Epidermoid Tumours: Epidermoid tumours are uncommon (0.5% to 1.0% of all spinal tumours). They can be congenital or acquired, as a late complication of lumbar puncture by deposition of a fragment of epidermis within the dural sac. Congenital epidermoids are mainly located at the conus or cauda equina level and are often associated with vertebral abnormalities (spina bifida, hemivertebrae). Acquired cysts are found in the lower lumbar region and lack osseous abnormalities (2).

Dermoid Tumours: Dermoid tumours are congenital midline cystic tumours and account for 20% of intra-dural tumours seen during the first year of life. Half of them are intra-medullary and others are extramedullary intra-dural masses. Most lesions are located in the lumbar spine.

Neurenteric Cysts (*spinal enterogenous cysts*): These are uncommon congenital intra-dural cysts usually located in the thoracic spine anterior to the spinal cord.

Arachnoid Cysts: These are rarely intra-dural. The thoracic spine is the most common site, with a posterior midline situation.

Lipomas: These tumours account for about 1% of all tumours of the spinal canal and are distributed equally between the sexes. Most intraspinal lipomas are subpial, in the thoracic region. Associated congenital abnormalities, such as spina bifida or other forms of dysraphism are found in about a third of the cases.

Teratomas: These are very rare in the spine, and may occur in isolation or in association with congenital spinal anomalies.

Malignant Tumours

Metastases: The most common malignant SIET are leptomeningeal metastases. Ependymoma, posterior fossa medulloblastoma, glioblastoma, germinoma and pineoblastoma are the most common central nervous system (►CNS) primary tumours that metastasise to the spinal subarachnoid space. Non-CNS sources are carcinoma of the lung or breast, melanoma and haemopoietic neoplasms (lymphoma and leukaemia). Age of patients at diagnosis

T

depend on the type of the primary neoplasm. The lumbosacral subarachnoid space is the most frequent site. Multiple lesions are common and vary from diffuse infiltration of the arachnoid membrane or thickening of lumbar nerve roots to nodular deposits scattered throughout the subarachnoid space ('drop' metastases) (2, 3).

Clinical Presentation

Clinical presentation is often non-specific and related to the location and the volume of the lesion. Pain and radiculopathy are the most frequent presenting symptom, followed by paresthesia and limb weakness. Myelopathic symptoms may result from cord compression. Infrequently, subarachnoid haemorrhage occurs in cauda equina nerve root tumours. Both schwannomas and neurofibromas usually become symptomatic in the middle decades with a slight female predominance for schwannomas. Schwannomas never become malignant, whereas sarcomatous transformation occurs in 4% to 11% of patients with neurofibromatosis.

Most spinal meningiomas are benign, slowly compressing the cord and causing progressive motor (90%) or sensory (60%) deficits. Sphincter dysfunction and pain occur later in about 50% of cases.

Imaging

Nerve Sheath Tumours: Since neurofibromas and schwannomas cannot be reliably distinguished by ►CT or MR, the two lesions are collectively referred to as 'nerve sheath tumours'. On plain films, scalloping of vertebral bodies, pedicle erosion and enlarged neural foramen may be found. Kyphoscoliosis and so called 'ribbon ribs' are seen with neurofibromatosis. On non-enhanced CT, bone erosions are identified, calcification and haemorrhage are rare. Seventy-five percent of nerve root tumours are isointense to spinal cord on T1-WI and 25% are hypointense. More than 95% are hyperintense on T2-WI. Approximatively 40% of spinal schwannomas have a cystic component. These cysts may resemble cerebrospinal fluid (►CSF) or may be hyperintense on both T1- and T2-weighted images due to protein content or haemorrhagic products. Virtually all nerve sheath tumours enhance after contrast administration (Fig. 1). Contrast medium improves the detection of small lesions. The major differential diagnosis is meningioma (2–4).

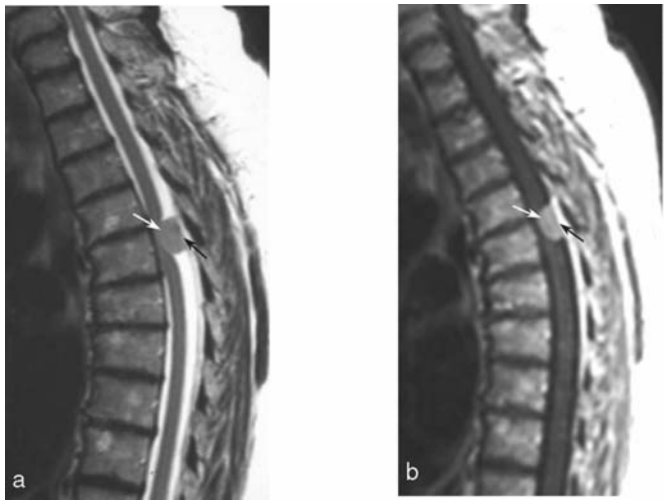
Meningiomas: Calcification is only visible in 1% to 5% of cases. Bone erosion is uncommon. On MR images most meningiomas are isointense to CSF on both T1- and T2-weighted images, with homogeneous enhancement following contrast administration, often demonstrating the characteristic thickening of their dural implantation, dural tail sign (Fig. 2) (2–4).

Paragangliomas: These are well-encapsulated masses, isointense with cord on T1- and iso- to hyperintense on T2-weighted images. Haemorrhage is common. Paragangliomas are highly vascular tumours and enhance strongly following contrast administration.

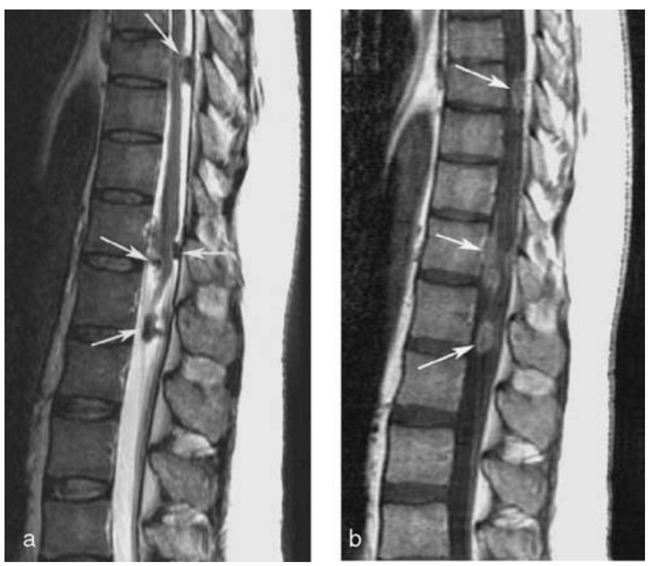
Epidermoid Tumours: Signal intensity is typically iso- or slightly hyperintense compared to CSF on all sequences.

Dermoid Tumours: These usually represent the appearance of fat. In case of rupture, multi-focal high signal areas are found on T1-weighted images.

Tumors, Spine, Intradural, Extramedullary. Figure 1 Cystic schwannoma: Sagittal T1-weighted (a), sagittal T2-weighted (b) and sagittal T1-weighted with contrast (c) images of the lumbar spine show a well-defined mass appearing isointense on T1, isointense on T2 and enhances after contrast injection, corresponding to a schwannoma (black arrows). Note the inferior part of the mass which is cystic and display the same signal intensity as the CSF on both T1- and T2- weighted images (white arrows).



Tumors, Spine, Intradural, Extramedullary. Figure 2 **Meningioma: Sagittal T2-weighted (a) and sagittal T1-weighted images after contrast (b) of the thoracic spine show a meningioma which appears isointense to the cord on T2, and enhances homogeneously after contrast (white arrows). Note the dural attachment of the mass (black arrows) and the mass effect on the spinal cord which is displaced anteriorly.**



Tumors, Spine, Intradural, Extramedullary. Figure 3 **Metastases from lung carcinoma. Sagittal T2-weighted (a) and sagittal T1-weighted with contrast (b) images of the lumbar region show multiple small nodular lesions in the ►intra-dural extra-medullary space which appear hypointense on T2, and enhance after contrast injection. The cord and the cauda equina are compressed and displaced by the lesions (arrows).**

T

Neurenteric Cysts: The MR image shows well-delineated areas iso- or hyper-intense compared to CSF on T1-weighted images.

Arachnoid Cysts: Signal intensity on MR images is like CSF. Unless the cord appears displaced and flattened; ►MRI may fail to demonstrate the cyst.

Metastases: These lesions appear as thickened roots or nodular lesions which are isointense with spinal cord in most cases. Non-contrast MRI may underestimate lesions. Following contrast administration even small nodular metastases usually enhance strongly and permit better depiction of the lesions (Fig. 3). Intravenous contrast injection may also demonstrate diffuse meningeal infiltration.

TUNEL Assay

Abbreviation for terminal transferase dUTP nick end labeling. This assay relies on the formation of nicks in DNA that can be identified by terminal transferase, an enzyme that catalyzes the addition of dUTPs that are secondarily labeled with a marker.

▶Apoptosis

TVS

▶Transvaginal Sonography

Tympanosclerosis

Tympanosclerosis is the thickening and calcification of the tympanic membrane. The process starts as hyaline degeneration, which is then followed by calcification.

▶Temporal Bone, Inflammatory Diseases, Acute, Chronic

Tyrosinemia

Genetic error of metabolism associated with severe liver disease in infancy due to the absence of an enzyme (fumarylacetato hydrolase) resulting in accumulation of toxic metabolic products and progressive liver and kidney failure. In the acute form, symptoms appear in the first month of life. Infants may show liver and spleen enlargement, hemorrhagic diathesis, and jaundice. The chronic form is characterized by a gradual onset and more severe liver damage with liver and spleen enlargement, ascites, jaundice. This form leads to micro–macronodular cirrhosis in early childhood and may induce hepatocellular carcinoma (HCC), often requiring liver transplantation. Diagnosis is based on blood and urine tests. Abdominal US and CT demonstrate liver enlargement, signs of cirrhosis on follow up and development of HCC.

Synonyms

Gastric ulcer; Duodenal ulcer

Definition

Peptic ulcer is defined as a loss of mucous surface, causing gradual disintegration and necrosis of the tissues (1). Partial or complete loss of the mucosa only, without penetration into the submucosa, is generally called erosion. Peptic ulcers affect about 10% of the adults in Western countries and may be located in the stomach or the duodenum (which is four times more common).

Peptic ulcers may be acute (completely respond to medical therapy) or chronic. They are clinically important not only because of symptoms (mainly pain) but also because of complications such as bleeding and perforation. A peptic ulcer is a benign condition that, in cases of gastric ulcers, rarely transform to malignancy. Gastric ulcers are usually larger than duodenal ulcers and affect an older population (2).

Pathology/Histopathology

Both duodenal and gastric ulcers are essentially gastric ulcers because they occur in the gastric mucosa of the stomach or in gastric metaplasia of the duodenal mucosa (3). Peptic ulceration in the stomach or duodenum is considered the outcome of an imbalance between the aggressive acid/peptic factors and the mucosal defense factors. The large majority of peptic ulcers are strongly related to *Helicobacter pylori* infestation and/or nonsteroidal anti-inflammatory drug use. *H. pylori* predisposes to ulceration both by acid hypersecretion and by compromising mucosal defense mechanisms. Gastric ulcers result from weakened mucosal resistance in patients who have normal or even decreased acid secretion. Aspirin and other nonsteroidal anti-inflammatory drugs inhibit the synthesis of prostaglandins that contribute to the integrity of the gastric mucosal barrier. Chronic gastritis, duodenogastric reflux of bile, and delayed gastric emptying also play a role in the pathogenesis of gastric ulcers. Infection by *H. pylori* results in chronic gastritis that is strongly associated with mucosal ulceration. Patients with duodenal ulcers usually have antral gastritis and peptic acid hypersecretion. Gastric metaplasia develops in the duodenal cap, allowing *H. pylori* colonization, which leads to duodenitis and finally to ulcer.

A combination of other hereditary and environmental factors also plays a role in the development of peptic ulcers. Hereditary parameters include family history of ulcers, O-blood type, and some genetic syndromes. The list of etiologic agents includes stress, smoking, alcohol, coffee, and cocaine.

Clinical Presentation

Postprandial epigastric pain during the night is the typical and major symptom. Pain emerges 2–4 h after meals (relatively later in duodenal ulcers) and may waken the patient. Other symptoms consist of right upper quadrant, back, or chest pain; bloating; belching; nausea and vomiting; anorexia; and weight loss. Differential diagnosis may include reflux esophagitis, gastritis, duodenitis, cholecystitis, pancreatitis, gastroenteritis, irritable bowel syndrome, ischemic bowel disease, Crohn's disease, and gastric or pancreatic carcinoma. Complications include free or defined perforation (peritonitis and constant pain that radiates to the back are the relevant symptoms), gastric outlet obstruction, and gastrointestinal bleeding (more likely to occur in gastric ulcers). It is of interest that 25–50% of patients with peptic ulcers are asymptomatic and bleeding or perforation may be the presenting clinical condition. Conversely, symptoms can be typical for peptic ulcer, but both radiological and endoscopic examinations may reveal no pathology (2).

Imaging

Gastric Ulcers

Despite excellent diagnostic results, the number of barium studies performed to diagnose peptic ulcer disease has dramatically decreased during the last 10–20 years in favor of endoscopy, although the latter is more expensive and less safe. Nowadays, radiological assessment is required in those who are unable or unwilling to tolerate an endoscopy.

A ►biphasic study using ►double-contrast examination is recommended. Intravenous administration of 0.1 mL of glucagon is helpful to facilitate gastric hypotonia. Ulcers on the lesser or greater curvature are better depicted in profile views, whereas those on the anterior or posterior wall are better seen en face. The latter are more difficult to evaluate. Supine and oblique views are ideal for revealing ulcers located on the posterior wall or greater curvature. Flow technique (slow rotation of the patient from side to side) is helpful to identify shallow ulcers on the posterior wall or near the gastric cardia because it may lead the barium to the dependent surface of the stomach. Ulcers on the lesser curvature are better evaluated in the upright compression views. These views are also ideal for assessing features of benign ulcers (depth of penetration, Hampton's line). Prone, right anterior oblique views with 15–45° of cephalic tube angulation may reveal lesser curvature ulcers in patients with a high transverse stomach. Prone compression views or views in prone Trendelenburg position are recommended for anterior gastric wall ulcers.

Duodenal Ulcers

The most difficult ulcers to demonstrate are those located on the anterior wall. Prone compression views are required for this purpose. A biphasic examination that also includes upright compression views and double-contrast views of the duodenal bulb is considered complete (2).

Diagnosis

Gastric Ulcers

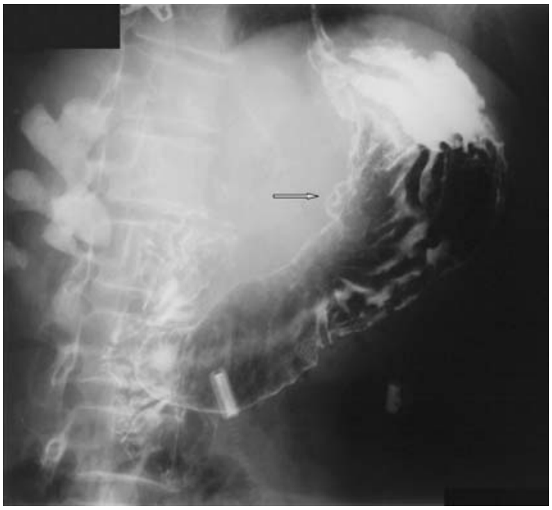
Radiologic features of gastric ulcers include the size, shape, and depth of the ulcer crater; radiating folds; Hampton's line; and the ulcer mound or collar. Gastric ulcers are usually less than 1 cm in size when diagnosed. When they are greater than 2 cm (►giant ulcers), they are more prone to bleeding or perforation. It has also been noted that malignancy is more common in giant ulcers than in their small counterparts (3).

Gastric ulcers are commonly round or ovoid collections of barium, but they can also be linear (which probably represent a healing process), rod-shaped, rectangular, serpiginous, or flame-shaped. When seen en face, an ulcer on the dependent wall of the stomach fills with barium, whereas an ulcer on the nondependent wall will appear as a ring. Most of them (about 80%) are located in the lesser curvature or the posterior wall of the stomach. Multiplicity occurs in about 20–30% of patients, tends to affect the gastric antrum and body, is strongly correlated with ingestion of nonsteroidal anti-inflammatory drugs, and does not favor benign disease (3).

Computed tomography (CT) has no clinical usefulness in detecting uncomplicated peptic ulcers because only the superficial layers of the gastric wall are affected. Deep ulcers or penetrating or perforated ulcers can be depicted. Inflammatory changes in adjacent soft tissues in addition to gastric wall thickening denote an ulcerous penetration. CT is the ideal method for diagnosing peptic ulcer perforation (4).

Ulcers on the lesser curvature typically appear as smooth protrusions beyond the normal contour of the stomach (Fig. 1). Some may have a “collar button” or “mushroom” appearance or are associated with ▶Hampton’s line. Hampton’s line is a radiolucent line that separates barium in the ulcer crater from barium in the gastric lumen, created by the undermining of mucosa with minimal edema. When this radiolucent line becomes wider because of edema, it gives rise to the ulcer collar or the ulcer mound. These findings are considered pathognomonic of benign ulcers. Inflammation of the surrounding mucosa is responsible for enlarged areae gastricae, while retraction of the adjacent gastric wall leads to the development of radiating folds (2).

Ulcers on the greater curvature (3–11% of the total) are not always easy to differentiate from malignancies because they are associated with a mass effect and irregular folds around the ulcer. They may appear to have an intraluminal location, with an inner margin concave toward the lumen, and their crater may be incompletely filled because of overhanging edematous tissue (quarter moon or crescent sign). Although there is a history of aspirin ingestion in most of these ulcers, implying benign gastric ulcers, endoscopy may be required because of suspicious findings. These ulcers have a tendency to penetrate into the gastrocolic ligament, leading to the development of gastrocolic fistulas (2).



Ulcer Peptic. Figure 1 **A smooth, round ulcer (*arrow*) is seen on the lesser curvature, projecting beyond the normal contour of the stomach. Radiating folds and enlarged areae gastricae are seen in the adjacent mucosa because of associated inflammation and edema.**

Posterior (dependent) wall ulcers, if shallow, produce a ring shadow on double-contrast studies. The ulcer crater will be filled with barium when the flow technique is used. Radiating folds may be very large, leading to distortion in the region of the ulcer. Severe narrowing and deformity of the distal stomach due to edema and spasm may make evaluating these ulcers very difficult (2).

Anterior (nondependent) wall ulcers (1–7% of the total) may also appear as ring shadows. Prone compression views are recommended for better diagnostic results.

Pyloric channel ulcers are usually less than 1 cm in size and should fill with barium on prone or upright compression views. Although marked edema and spasm of the pyloric region may make radiological evaluation of the area very difficult, irregularity, angulation, or distortion of the pylorus should raise the possibility of an ulcer in symptomatic patients. The constant shape and size of pyloric channel ulcers enables their differentiation from pseudodiverticula caused by ulcer scarring or a surgical pyloroplasty. Adult hypertrophic pyloric stenosis also leads to a narrowed, elongated pyloric channel with superior or inferior outpouchings, but this can be differentiated from ulcer deformity on the basis of the patient’s history (2).

The incidence of *recurrent and marginal (stomal) ulcers* has decreased along with the decrease in elective operations for ▶peptic ulcer disease. It is suggested that these kinds of ulcers may be seen more frequently in the future because of the increase in obesity operations (especially roux-en-Y gastric bypass) (3).

The healing process may be followed by barium studies, which must be performed 6–8 weeks after the start of conservative medical treatment. Findings with ulcer healing include a decrease in size, a change in shape of a linear ulcer, and splitting of the ulcer crater. Complete healing is compatible with a benign gastric ulcer. Nodular or irregular scarring and clubbing or amputation of radiating folds raise the suspicion of malignancy. The healing process may result in a scar that is radiographically seen as a central pit or depression, radiating folds, and/or retraction of the adjacent gastric wall. Scars on the lesser curvature may be very subtle, whereas scars on the greater curvature may appear as impressing radiating folds. Not all ulcer scars are easy to differentiate from ulcer craters. Gradually sloping margins, normal areae gastricae within the central portion of the scar, and unchanged features on follow-up studies favor the diagnosis of a scar. Healing of antral ulcers is unique because it may lead to a variety of appearances, such as a prominent transverse fold (which mimics an antral web or diaphragm), antral narrowing and deformity (identical to linitis plastica), or a widened and eccentric pylorus. Scar formation on lesser curvature ulcers may produce a deep incisura on the greater curvature that forms the hourglass stomach deformity.

Differentiating Benign from Malignant Ulcers

Benign gastric ulcers appear en face as round or ovoid ulcer craters surrounded by a smooth mound of edema or regular, symmetric mucosal folds that radiate to the edge of the crater. In profile views, benign gastric ulcers protrude outside the expected line of the stomach. Adjacent areae gastricae may be enlarged, extending to the edge of the ulcer crater without evidence of nodularity, mass effect, or tumor infiltration (2). In patients with gastric ulcers that are classified as benign or probably benign on the radiological study, it is unnecessary to perform endoscopy.

Malignant gastric ulcers are usually located on the fundus or proximal half of the greater curvature and appear en face as irregular ulcer craters (more wide than deep) eccentrically located in an irregular mass with distortion or obliteration of the normal areae gastricae surrounding the ulcer and a tumor rim (Carman's meniscus sign). Radiating folds tend to be nodular and irregular and do not reach the orifice of the ulcer crater; their tips may be fused, clubbed, or amputated. In profile views, a malignant ulcer at the apex of a protruding tumor mass will lie within the outline of the stomach. Adjacent mucosa may be nodular, and radiating folds can be thickened and lobulated (2). Although most ulcers with an equivocal appearance are proven to be benign, it is prudent to suggest the possibility of malignancy to these patients and to recommend endoscopic evaluation.

Differential diagnosis of gastric ulcers is easy and is based both on imaging findings and clinical history/presentation. Rarely, gastric ulcer must be differentiated from gastritis or gastric metastases and lymphoma. In the former, there is a marked thickening of the gastric folds and enlargement of the areae gastricae without an ulcer crater. In the latter, we may identify a necrotic cavitated lesion with a bull's eye or target lesion appearance (in cases of metastatic melanoma or Kaposi's sarcoma). Infiltration of the stomach by lymphoma may be seen as mucosal nodularity identical to enlarged areae gastricae.

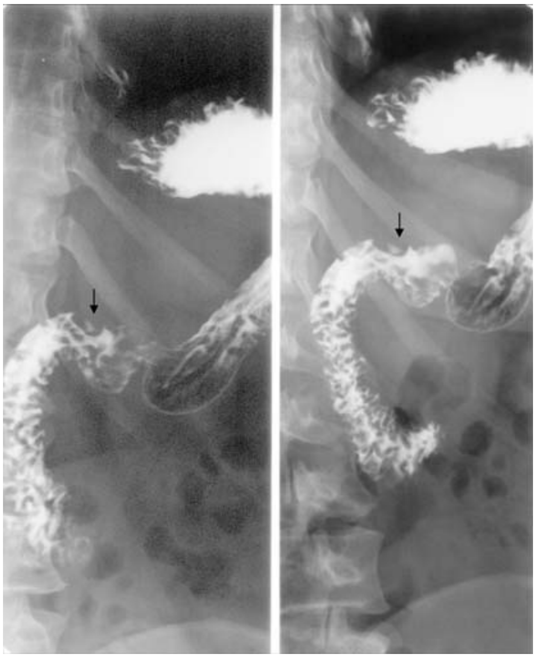
Duodenal Ulcers

The vast majority of duodenal ulcers are less than 1 cm in size, have a round or ovoid shape, and are located in the duodenal bulb. They are virtually always benign, and in 15% of patients they are multiple. About 15% are linear or located in the postbulbar duodenum. Any duodenal ulcer presenting distal to the papilla of Vater should raise the suspicion of Zollinger–Ellison syndrome.

Bulbar ulcers appear as discrete niches surrounded by a smooth, radiolucent mound of edematous mucosa (Fig. 2). Radiating folds that converge centrally at the edge of the crater can be very striking, helping to localize the ulcer. Duodenal ulcers are often associated with bulbar deformity that may obscure small ulcers.

Postbulbar ulcers are usually located on the medial wall of the descending duodenum just above the papilla of Vater. A shallow, flattened niche may be seen, associated with eccentric local spasm or with a ring stricture (1).

An ulcer larger than 2 cm in size is defined as a *giant ulcer*. These ulcers are clinically important because of their higher tendency for perforation, bleeding, and obstruction. Conservative treatment is adequate. They can replace the entire bulb and be mistaken for a normal or scarred bulb. Fluoroscopy may help differentiate between a deformed bulb and a giant ulcer because the former changes appearance whereas the latter has a constant size and shape. It is also possible to recognize these ulcers on



Ulcer Peptic. Figure 2 An ulcer niche in the duodenal bulb (*arrows*) surrounded by a smooth, radiolucent mound of edematous mucosa (Hampton's line, a pathognomonic feature of benign ulcers).

ultrasound studies as a cystic lesion anterolateral to the pancreatic head.

The *differential diagnosis* of duodenal ulcer includes inflammatory conditions (duodenitis, Crohn's disease, tuberculosis), duodenal stricture (due to pancreatitis or gallstone erosion), duodenal carcinoma, duodenal diverticulum, extrinsic invasion, and duodenal hematoma.

Healing Process

Conservative treatment usually leads to rapid healing. The result of the healing process is a linear barium collection and an ulcer scar manifested by radiating folds or bulbar deformity. It can be difficult to differentiate small healing ulcers from ulcer scars. Follow-up studies must be reserved for patients with persistent symptoms or complications. Bulbar deformity may lead to the classic cloverleaf appearance because of asymmetric scarring and retraction of the duodenal bulb (Fig. 3).

Complications

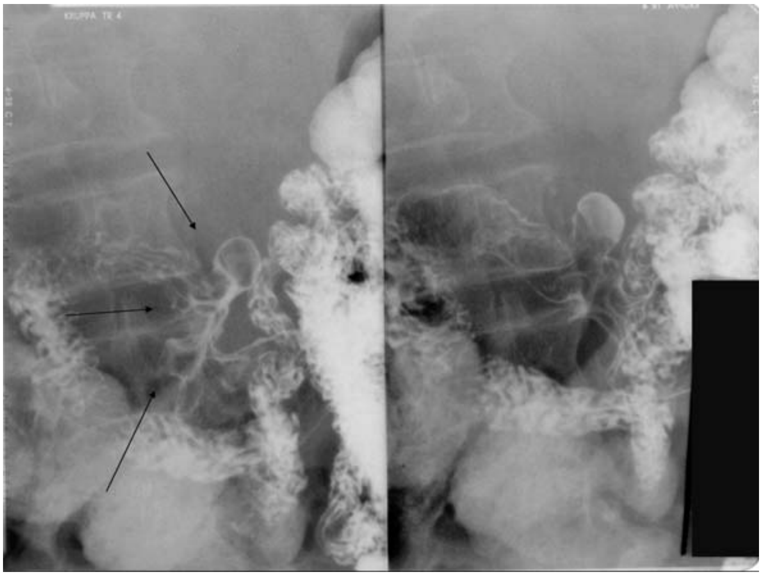
The most important and life-threatening complications of peptic ulcers include upper gastrointestinal tract bleeding, obstruction, and perforation. Early treatment is essential, and imaging plays a major role in diagnosing these complications.

Upper gastrointestinal bleeding may be manifested by sudden hematemesis, melena, or rectal bleeding or by chronic guaiac-positive stools or iron deficiency anemia. Endoscopy is superior to barium studies for depicting the bleeding site. Barium studies may show a filling defect in the barium-filled ulcer crater, which represents a blood clot. Differential diagnosis of this sign also includes granulation tissue or debris.

Ulcers that can lead to *obstruction* due to both edema and spasm or scarring and fibrosis are located in the distal antrum, pyloric channel, and postbulbar part of the duodenum. Abdominal radiographs may imply obstruction by demonstrating a dilated stomach with retained food and debris. In this case, a barium study using high-density barium must be performed after decompressing the stomach with a nasogastric tube. The major differential diagnosis of gastric outlet obstruction includes scirrhous carcinoma, and endoscopy with biopsy may be required. Duodenal obstruction may be the result not only of ulcer but also of other inflammatory conditions, hematomas, duplication cysts, or pancreatic pathology.

Ulcers on the anterior wall of the stomach or duodenum may *perforate* directly to the peritoneal cavity, whereas ulcers on the posterior wall of the stomach or duodenum usually result in a walled-off or "confined" perforation. Free intraabdominal air on plain radiographs is the major radiological sign but is seen in only 50–70% of patients because the volume of escaped gas can be small and the site of perforation may quickly become sealed off (4). Confined perforations are usually seen as an abscess in the lesser sac or the anterior perirenal space. CT is the ideal method to diagnose both free and confined perforations. It is fast, easy to perform, and sensitive, with no need for patient preparation and cooperation. Free air is seen in almost all the cases of perforations due to peptic ulcer. Common sites of pneumoperitoneum include the anterior surface of the liver and the perigastric/duodenal region (4).

Penetrating ulcers occasionally produce gastroduodenal, gastrocolic, duodenocolic, choledochoduodenal,



Ulcer Peptic. Figure 3 Bulbar deformity due to marked scarring has the classic cloverleaf appearance.

duodenorenal, and gastropericardial fistulas. Gastroduodenal fistulas lead to the typical "double-channel pylorus" sign on barium studies. Gastrocolic fistulas used to result from stomach or transverse colon carcinomas but now are mainly caused by aspirin-induced ulcers on the greater curvature of the stomach. The clinical triad of diarrhea, feculent vomiting, and foul-smelling eructations is typical. Endoscopy is contraindicated due to the risk of perforation. Barium studies and barium enema examination may reveal pathology. A barium enema study is also superior to barium studies of the upper gastrointestinal tract for revealing duodenocolic fistulas. Peptic ulcers cause only 5% of choledochoduodenal fistulas. Barium studies may be diagnostic, but because the inflammatory process may seal off the fistula, the diagnosis may sometimes be missed. Gastropericardial fistulas can be a fatal complication of peptic ulcer in the intrathoracic portion of the stomach (hiatal hernia or after esophagogastrectomy). Sudden pneumopericardium on chest radiographs is the major finding (2).

Ultrasonography

Imaging of tissue using acoustic waves at frequencies higher than the human audible range.

▶Ultrasound Imaging

Ultrasound (US)

Ultrasound emitted from a transducer (piezo-electric crystal) travels at constant velocity into tissues, and is reflected differently from different tissue interfaces back to the transducer that acts also as a receiver. Echoes are electronically converted to the image on the monitor. Outlining the kidneys and other abdominal organs, US can distinguish solid from cystic lesions, and detect tumors by assessing their shape, volume, and structure. Stones cause almost complete reflection of US waves; are therefore echogenic with a characteristic dorsal acoustic shadowing. Urinary stones are detected directly inside the collecting system, better dilated than not. US guided PNS insertion is recommended, and drainage assured in patients with persisting obstruction, uncontrollable pain or infection.

▶Colic, Acute, Renal

Ultrasound Appearance of Hepatic Hematoma Changes with Time

It is usually hyperechoic in the acute phase, whereas it appears inhomogeneously hypoechoic, with internal echoes due to septation and debris, in a more chronic stage.

In an acute or subacute setting, computed tomography (CT) features of hematoma are hyperdense areas on baseline CT scan not enhanced after contrast medium administration, whereas chronic hematoma is hypoattenuating on the precontrast scan and can display rim enhancement following intravenous contrast medium administration.

The magnetic resonance characteristics of hepatic hematoma depend mainly on the age of the hemorrhagic lesion. Acute hematoma shows an intermediate signal intensity on T1-weighted images and a low signal intensity on T2-weighted images due to the high-intracellular concentration of deoxyhemoglobin in red blood cells, whereas subacute hepatic hematoma, because of the presence of extracellular methemoglobin, appears as a heterogeneous mass with pathognomonic high signal intensity on T1-weighted images and intermediate signal intensity on T2-weighted images.

Ultrasound Contrast Media

Thomas Albrecht
Klinik und Hochschulambulanz für Radiologie und Nuklearmedizin, Charité-Campus Benjamin Franklin, Berlin, Germany
thomas.albrecht@charite.de

Ultrasound contrast media (USCM) or echo enhancers consist of minute gas-containing microbubbles that have a high reflectivity when exposed to an ultrasound field. These highly reflective microbubbles produce intense echoes on the ultrasound (US) image.

The first microbubbles used for medical imaging (mainly for *echocardiography*) were created by agitating saline solutions. When injected intravenously, small air bubbles included in the fluid produce signal enhancement in the draining veins and right heart. These bubbles are, however, unable to withstand pulmonary passage, so there is no signal enhancement in the left heart under normal conditions. They can be used for detection of right-to-left shunts by demonstration of microbubbles within the left heart. Due to their lack of transpulmonary stability, such agitated fluids can neither be used for echocardiography of the left heart nor for extracardiac US.

Since the mid-1990s, transpulmonary microbubble USCM have become available. Transpulmonary stability is achieved by the addition of a *shell* surrounding and thus stabilizing the microbubble. The different USCM that are *currently commercially available or in clinical development* consist of various gases and shell materials. They can be divided into two major categories: *high-solubility gas* (*air*) and *low-solubility gas* (*perfluor gas*) agents. The much lower solubility of perfluor gases in plasma leads to a higher stability of these agents with stronger and longer-lasting signal enhancement.

USCM are blood pool agents that do not diffuse into the extracellular fluid compartment. They distribute evenly throughout the entire blood pool and can be used for echocardiography of the left heart as well as for extracardiac ultrasound of vessels and almost every organ. The average diameter of the microbubbles of all dedicated USCM ranges between approximately 2 and 7µ; they are thus smaller than red cells and there is therefore no risk of capillary embolization.

Because USCA are blood pool agents, in contrast to conventional agents for CT or MRI, they distribute evenly throughout the whole blood pool and can be used for imaging for several minutes following intravenous injection. In addition to the blood pool phase, some USCM have a *liver-specific delayed phase* that begins a few minutes after injection and lasts from minutes to hours or even longer. The gas is gradually eliminated from the blood by exhalation *via* the lungs, and the shells are metabolized. All licensed USCA have a very favorable *safety* profile, with few *adverse reactions* reported. They are not nephrotoxic, and allergoid reactions are very rare and considerably less frequent than with iodinated x-ray contrast agents.

Nonlinear Properties of Microbubbles and Contrast-Specific Imaging Techniques

USCA were originally developed to enhance signals from flowing blood in technically difficult spectral or color *Doppler studies*. Due to rapid improvements in equipment technology and particularly in Doppler sensitivity, this application has become rare in most vascular territories, it still has niche role in some patients with unfavorable acoustic access and in *transcranial Doppler*.

Outside the heart the agents do not provide sufficient signal enhancement on conventional B-mode imaging. To achieve clinically useful and Doppler-independent extracardiac enhancement, *contrast-specific imaging techniques* are required. Several such techniques have been developed in recent years. They all exploit the so-called *nonlinear acoustic properties* of microbubbles.

When exposed to an US field, microbubbles show a complex acoustic behavior, and this behavior determines the properties of the signal that is returned from the microbubble to the transducer. It is crucially dependent on the amplitude or energy of the transmitted pulse (transducer output). In clinical imaging, the *mechanical index* (MI) is used as a measure of transducer output, and the MI is an important variable in contrast-enhanced US that needs to be controlled carefully by the operator. With increasing amplitude, the microbubble response ranges from linear scattering and *linear resonance* to *nonliner resonance* and *bubble destruction*.

Contrast-specific imaging techniques utilize the nonlinear bubble response for highly sensitive and specific display of contrast agents. Various techniques are used to achieve this. These are mainly *multipulse techniques* that use either *phase modulation (inversion), amplitude modulation*, or a combination of the two.

High and Low MI Imaging with USCM

Air-based microbubbles are relatively instable when exposed to an US field and show only weak *resonance*. Imaging with air-based microbubbles requires *microbubble destruction* for adequate enhancement. Therefore, *intermittent imaging* with low frame rates to allow refilling of the microbubbles into the microvasculature is necessary. Alternatively, it is possible to use a fast *sweep technique* with offline review of the digitally stored cine loops.

Low-solubility gas USCM are characterized by the combination of improved stability with favorable resonance behavior at low acoustic pressure. This allows minimally disruptive contrast-specific imaging at low MI and enables effective investigations over several minutes with the visualization of the *dynamic enhancement* pattern in real time.

Functional Perfusion Studies with USCM

USCA can be used as tracers for dynamic studies of perfusion. Arteriovenous *transit time analysis* of organs such as the liver, kidney, and brain can be assessed based on *time-intensity curves* measured in artery and vein. Another approach for hemodynamic studies, such as the myocardium, the kidney, or tumors, is the *destruction-reperfusion technique*. For this technique a steady state of microbubble concentration is required, which is achieved by continuous infusion of USCA. During the steady state, microbubbles in the imaging plane are destroyed by short insonnation at high MI. After switching back to low MI, the signal recovery curve is used to calculate perfusion and fractional vascular volume.

Targeted Microbubbles for Imaging and Drug Delivery

By attaching certain ligands and antibodies to the shell of a microbubble, the bubble will specifically bind to certain types of (tumor) cells or to thrombus, for example. This can be used for specific imaging of defined organs or diseases or for local drug delivery. If a targeted microbubble is filled with a certain pharmaceutical or gene, it can be destroyed by high MI US after binding to the target, and the drug is released at the site or even into the target cell. The use of targeted microbubbles as specific contrast media or drug carriers or even as vectors for gene therapy is currently in an experimental preclinical stage.

Clinical use of USCM

Common applications of USCM in clinical practice are echocardiography, transcranial Doppler studies, imaging of focal liver lesions (1), renal imaging for reflux in children as well as for focal renal lesions, imaging of focal splenic lesions, and assessment of soft tissue organs in blunt abdominal trauma. Apart from these common indications, USCM can in principle be used in every organ or vascular territory accessible to US by analogy with the use of contrast media in other imaging modalities.

Definition

Sounds with a frequency above 20 kHz are called ultrasonic because they occur at frequencies inaudible to the human ear. When emitted at short bursts, propagating through media such as water with low reflection coefficient and reflected by obstacles along their propagation path, detecting the reflection, or *echo*, of the ultrasonic wave can help localize the obstacle (1). This principle has been used by sonar (SOund NAvigation and Ranging) and inherently used by marine mammals, such as dolphins and whales, to help them localize prey, obstacles, and predators. In fact, the frequencies used for "imaging" vary significantly depending on the application: from underwater sonar (up to 300 kHz), diagnostic ultrasound, therapeutic ultrasound, and industrial nondestructive testing (0.8–20 MHz) to acoustic microscopy (12 MHz to above 1 GHz).

Imaging

Scattering and Attenuation

Tissues are constituted of cells and groups of cells that serve as complex boundaries to the propagating wave. As the wave propagates through all these complex structures, reflected and transmitted waves are generated at each one of these interfaces depending on the local density, compressibility, and absorption of the tissue. The groups of cells are called "scatterers" because they scatter acoustic energy. The backscattered field, or what is "scattered back" to the ▶transducer, is used to generate the ultrasound image. In fact, the backscattered echoes are usually coherent. Fig. 1a shows an ultrasound image of an 8-week-old fetus in the womb. This grainy appearance is called "speckle," a term borrowed from the laser literature. Speckle is produced by the constructive and destructive interference of the scattered signals from structures smaller than the wavelength—hence, the appearance of bright and dark echoes, respectively. Thus, speckle does not necessarily relate to a particular structure in the tissue.

Transducers

A pressure wave is generated using an ultrasound transducer, which is typically a piezoelectric material. "Piezoelectric" denotes the particular property of certain crystal polymers of transmitting a pressure ("piezo" means "to press" in Greek) wave generated when an electric potential is applied across the material. Most importantly, since this piezoelectric effect is reciprocal (i.e., a piezoelectric crystal will convert an impinging pressure wave to an electric potential), the same transducer can also be used as a receiver. Such crystalline or semicrystalline polymers include polyvinylidene fluoride (PVDF), quartz, barium titanate, and lead zirconium titanate (PZT).

Ultrasonic imaging has recently also expanded to three-dimensional (3D) imaging in clinical applications, especially in cardiology and obstetrics (Fig. 1). This is due to advances in transducer design, namely the 2D arrays, in which beams are generated in all three planes (Fig. 1b), but 3D images (Fig. 2c) can also be achieved by sweeping a linear or phased array out of plane.

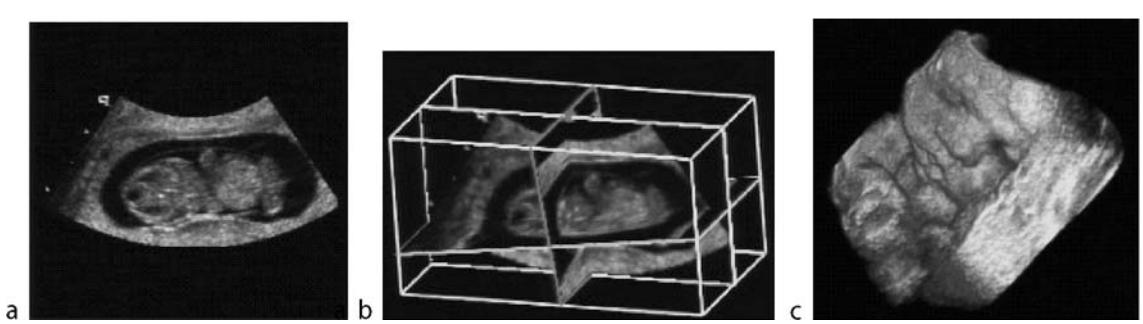
Modes of Imaging

A-Mode

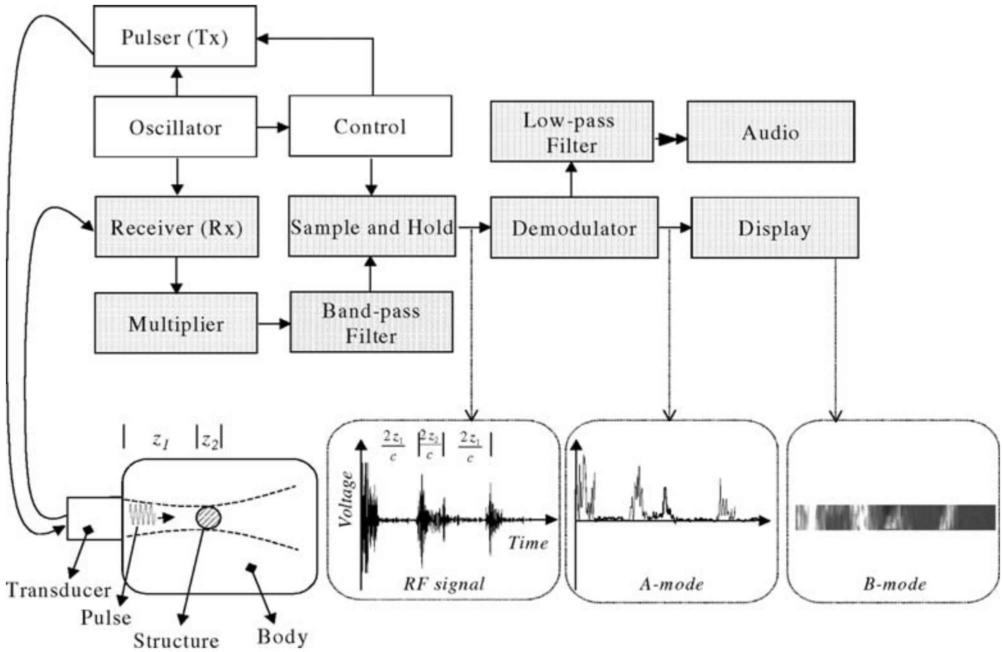
Fig. 2 shows a block diagram of the different steps that are used to acquire, process, and display the received signal from the tissue.

Transducer frequency

A pulse of a given duration, frequency, and bandwidth is first transmitted. A tradeoff between penetration (or low attenuation) and resolution exists. Therefore, the chosen frequency will depend on the application. Usually for deeper organs, such as the heart, uterus, and liver, the frequencies are restricted in the range of 2–5 MHz, whereas for more superficial structures, such as the thyroid, breast, and testis, and for use in infants, a wider range of 4–15 MHz is applied. Finally, for ocular applications, a range of 10–20



Ultrasound Imaging. Figure 1 (a) B-mode ultrasound scan of an 8-week fetus (coronal slice); (b) orthogonal slices obtained with a 2D array; (c) 3D ultrasound image.



Ultrasound Imaging. Figure 2 **Block diagram of a pulse-echo system and the resulting signal or image at three different steps.**

MHz is determined by the low attenuation, low depth, and higher resolution required.

The pulse (Fig. 2) is usually a few cycles long (usually 3–4 cycles) to ensure high resolution, and it is generated by the transmitter through a voltage step sinusoidal function at a voltage amplitude of (100–500 V) and a frequency equal to that of the resonance frequency of the transducer elements. For static structures, a single pulse or multiple pulses (usually used for averaging off line) could be used at an arbitrary frequency. However, for moving structures such as blood, liver, and heart, a fundamental limit on the maximum pulse repetition frequency (PRF) is set by the maximum depth of the structure, or PRF (kHz) $= c/2D_{\max}$ (2). Typically, the PRF is in the range of 1–3 kHz.

RF amplifier

The received signal needs to be initially amplified to guarantee a good signal-to-noise ratio. At the same time, the input of the amplifier should be devoid of high voltage pulse to protect the circuitry and maintain its low noise and high gain. A typical dynamic range expected at the output is of the order of 70–80 dB.

Time-gain compensation

Attenuation is unavoidable and increases with depth as the wave travels through the medium. To avoid artificial darkening of deeper structures as a result, a voltage-controlled attenuator is usually employed, in which a control voltage is used to manually adjust the system gain accordingly after reception of an initial scan. A logarithmic voltage ramp is usually applied that compensates for a mean attenuation level with depth. The dynamic range becomes further reduced to 40–50 dB.

Compression amplifier

The signals will ultimately be displayed as a gray scale on a cathode ray tube (CRT), where the dynamic range is typically only 20–30 dB. For this purpose, an amplifier with a logarithmic response is used.

Demodulation or envelope detection

Because the image is a gray-scale picture, the amplitude of the signal is displayed. For this, the envelope of the RF signal needs to be calculated. This is usually achieved by using Hilbert transforms. The resulting signal is called a detected A-scan, A-line, or *A-mode scan* ("A" for amplitude). An example is shown in Fig. 2.

B-Mode

When the received A-scans are spatially combined after acquisition using either a mechanically moved transducer or the previously mentioned arrays and used to brightness-modulate the display in a 2D format, the brightness or B-mode ('B' for brightness) is created, which has a true image format and is by far the most widely used diagnostic ultrasound mode. By default, sonogram or echogram refers to B-mode. Fig. 1a shows an example of a B-mode image. One of the biggest advantages of ultrasound scanning is real-time capability, and this is achieved due to the shallow depth of scanning in human applications and the high speed of sound. The frame rate is usually of the order of 30–100 Hz (whereas in the M-mode version it can be as fast as the PRF itself; see later). The frame rate is limited by the number of A-mode scans acquired, N_A, and the maximum depth, that is, frame ratemax $PRF_F = c/2D_{max}/N_A$.

M-Mode

Another way of displaying the A-scans is as a function of time, especially in cases in which tissue motion needs to be monitored and analyzed. In this case, only one A-scan from a particular tissue structure is displayed in brightness mode but is followed in time depending on the PRF used and called motion-, or M-mode scan. A depth-time display is then generated. A typical application of the M-mode display is used in the examination of heart-valve leaflet motion and in ▶Doppler displays.

Doppler Mode

The Doppler effect is defined as the frequency shift that results from a nonzero scatterer velocity. Several techniques have been developed to maximize performance; they include an adjustable gate depth according to the PRF used and a sharp cut-off smoothing filter with an adjustable cut-off frequency, also dependent on the PRF. These shortcomings can also be avoided by combining the B-scan mode with the Doppler sonogram mode, otherwise known as *duplex mode,* or the *triplex mode,* which is the duplex mode with an additional color Doppler map superimposed on the B-mode image.

Undifferentiated Embryonal Sarcoma

Mesenchymal tumor, known in the past as "malignant mesenchymoma," is the fourth most common hepatic malignancy in infants, typically occurring in older children (6–10 years) and young adults. It is composed of spindle and stellate sarcomatous cells, closely packed in whirls, or scattered loosely in a myxoid substance. The lesions are usually large, hypovascular and can be either solid or cystic. Cystic areas result from hemorrhage and necrosis. Metastases involve the lungs and skeleton.

Ureteropelvic junction obstruction

Definition

Ureteropelvic junction (UPJ) obstruction is defined as an obstruction of the flow of urine from the renal pelvis to the proximal ureter. This results in high pressure in the renal pelvis, ►hydronephrosis, diminished renal function, and progressive renal damage. In its extreme form, UPJ obstruction may lead to complete loss of renal cortex.

UPJ syndrome can be primary or secondary. Primary UPJ obstructions are diagnosed in the antenatal or postnatal phases. They are related to congenital stricture of the ureter. The etiology of these strictures is unclear. However, it has been postulated that in utero ischemia leads to the formation of focal lesions of the ureter and fibrous scarring of the ureteral musculature. This condition occurs in approximately one in 1,500 children and can be associated with other kidney, bladder, or intestinal tract pathologies. The male-to-female ratio is 3:1 and the left side is affected more commonly than the right side. The development of ultrasound (US) and its widespread use for in utero screening have allowed the diagnosis of primary UPJ obstructions long before birth and their management in the first weeks of life.

When it is diagnosed later in childhood or in adulthood, the condition is called secondary UPJ obstruction, which can be related to congenital or acquired lesions. Congenital abnormalities are either similar in their physiopathology to that previously described for primary UPJ obstruction or correspond to a UPJ compression caused by an accessory crossing vessel. The delayed presentation of congenital UPJ stricture in a child or an adult is believed to result from progressive worsening of the ureteral scarring caused by intermittent inflammation or from the increase in urine production due to growth. UPJ compression caused by an anomalous accessory vessel crossing the lower pole of the kidney represents approximately 25% of all secondary UPJ obstructions.

Acquired conditions responsible for secondary UPJ obstructions are stones, ureteral tumors, compression from extrinsic processes (tumors, cysts, retroperitoneal fibrosis, or other inflammatory lesions, etc.), and periureteral scars caused by prior surgery.

Clinical Presentation

Immediately after birth, primary UPJ obstruction can be revealed by an abdominal mass or a urinary tract infection presenting with fever and hematuria.

In older children or adults, symptoms of secondary UPJ are back or flank pain which may be permanent or intermittent, urinary tract infection with hematuria, abdominal mass, or elevated blood pressure.

Imaging

Primary UPJ Obstruction

Careful antenatal US examination is effective in detecting urinary tract abnormalities such as hydronephrosis. Fetal hydronephrosis is defined as an anteroposterior (AP) pelvic diameter of 4 mm or more before 33 weeks and 8 mm or more after 33 weeks of gestation (1). Although hydronephrosis is diagnosed with an incidence of 1% of all antenatal ultrasonographic studies, only one in 500 infants will be found to have a significant urologic condition in the first days of life. Most of these renal pelvis dilatations are therefore related to nonobstructive conditions.

When hydronephrosis is diagnosed prenatally, prophylactic antibiotherapy is started at birth pending further investigations. Postnatal US is recommended in the first days of life but should only be performed at 7–10 days. In fact, earlier examinations may yield false-negative results due to a relative dehydration state of neonates. An additional voiding cystourethrogram (VCUG) should be discussed to rule out vesicoureteral reflux. UPJ obstruction is suspected when postnatal US demonstrates a pure pelvocalyceal dilatation (without ureteral dilatation) associated to an absence of reflux on VCUG. Important features to evaluate on postnatal US are renal length, the AP diameter of renal pelvis, cortical thickness, and renal cortex echogenicity.

When postnatal US findings are consistent with the diagnosis of UPJ obstruction, diuretic renal scan (DRS) is performed to assess renal function. The radiopharmaceutical agents used are DTPA, MAG3, or DMSA and are all bound to Tc-99m. DRS is usually performed for infants above 1 month of age.

Management of UPJ obstruction is currently based on the conclusions made after US and DRS (2):

1. Neonates with a hydronephrosis less than 12 mm require US at the ages of 3 months and 1 year.
2. Neonates with a 13–19 mm hydronephrosis and good renal function on DRS should undergo follow-up US and DRS at 3 months and 1, 2, 5 and 10 years of age.
3. Neonates with 20–50 mm hydronephrosis but normal renal function require further long-term studies (at 3 months, 6 months, 1 year, and yearly thereafter) to identify those who will benefit from surgical treatment. Surgery is indicated in cases of worsening hydronephrosis or degradation of the renal function alteration.
4. Neonates with a dilatation of more than 50 mm or altered renal function should undergo surgery by 3 months of age.

Secondary UPJ Obstruction

US remains the best method for diagnosing hydronephrosis in children or adults with flank pain, hematuria, or urinary tract infection. Hydronephrosis refers to both renal pelvis and calyceal dilatation. On the other hand, an isolated renal pelvis dilatation without calyceal dilatation suggests the diagnosis of extrarenal pelvis, which is an anatomical variant of the upper urinary tract.

Diagnosis of secondary UPJ obstruction should be suspected when hydronephrosis is not associated with ureteral dilatation on US and can be confirmed by intravenous urography (IVU), computed tomography (CT), or magnetic resonance imaging (MRI).

1. In IVU (Fig. 1), UPJ obstruction is responsible for delayed nephrogram, delayed excretion of contrast media in the renal collecting system, and for pelvocalyceal dilatation without ureteral dilatation. In cases of mild UPJ stricture, additional intravenous injection of furosemide is often necessary so as to increase the diuresis to demonstrate the dilatation of the renal collecting system. IVU may also demonstrate UPJ abnormalities such as intraluminal radiopaque stones or radiolucent filling defects suggesting the diagnoses of radiolucent stone or transitional cell carcinoma (TCC).
2. Helical CT (Fig. 2) has many advantages over IVU because it is more sensitive in diagnosing intraluminal UPJ pathologies such as stone or TCC, or extrinsic

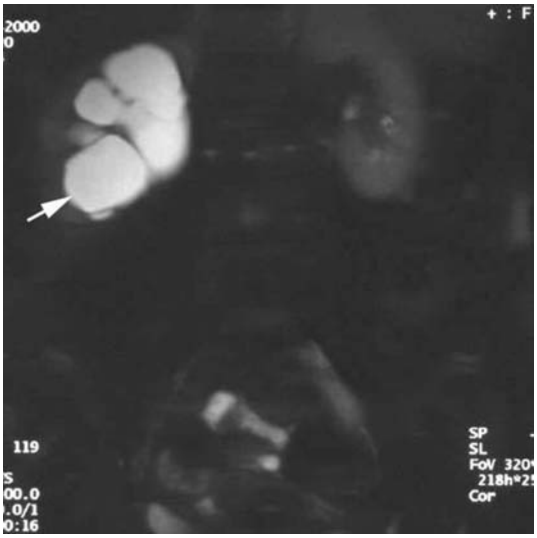
Ureteropelvic Junction Syndrome. Figure 1 **Right UPJ syndrome in a 25-year-old male patient. IVU, AP view (Fig. 1A), and PA view (Fig. 1B) performed at 10 min and 30 min after intravenous injection of contrast media. At 10 min (Fig. 1A), there was a delayed excretion of contrast media in the right upper excretory system (arrow). At 30 min (Fig. 1B), a right pelvocalyceal dilatation (arrow) without ureteral dilatation (arrowhead) was clearly demonstrated. This dilatation was related to a right UPJ obstruction.**

U

Ureteropelvic Junction Syndrome. Figure 2 Right UPJ syndrome in a 40-year-old male patient. Multislice CT with helical acquisition of 3 mm slices, 30 min after intravenous injection of contrast media. MPR reconstruction in the sagittal plane. Enlargement of right upper excretory system (arrow). Narrowing of the right UPJ without endoureteral mass or extrinsic lesion (arrowhead).

lesions such as retroperitoneal fibrosis or a tumor responsible for UPJ obstruction. Moreover, CT angiography (CTA) is a reliable method for the depiction of crossing arteries responsible for secondary UPJ obstruction. These accessory renal vessels are most commonly located anterior to the UPJ (3). Currently, CTA with a multislice technique is as accurate as digital subtraction angiography (DSA) in demonstrating an UPJ ►crossing artery, is less expensive, less invasive, and can be easily performed on an outpatient.

3. MRI (Fig. 3), including MR urography (MRU) (RARE or HASTE sequence) and additional MR sequences with gadolinium injection, is a reliable alternative to CT especially in patients in whom injection of iodinated contrast media is contraindicated (renal insufficiency, risk of adverse reaction, etc.) and in pregnant women (4). MRU is accurate in demonstrating a dilatation of the renal collecting system and in specifying the degree and the level of obstruction. With an “all-in-one approach,” MRU completed by an MR angiography (MRA) sequence may be useful for demonstrating an accessory renal artery crossing the UPJ. Moreover, additional conventional MR sequences allow one to study the thickness of renal cortex, visualize the retroperitoneal soft tissues, and specify the nature of the pathology responsible for the pelvocalyceal dilatation and the UPJ filling defect on MRU. For example, these conventional sequences may demonstrate lesions such as TCC or retroperitoneal tumor. However, it seems clear that MRI is not able to substitute CT in the diagnosis of urolithiasis responsible for UPJ obstruction.



Ureteropelvic Junction Syndrome. Figure 3 Right UPJ syndrome in a 30-year-old female patient. MR urography with frontal T2-weighted RARE sequence. Severe pelvocalyceal enlargement (arrow) without visualization of the right ureter. This dilatation of the right upper excretory system was related to a right UPJ syndrome.

Interventional Radiological Treatment

UPJ obstruction can be treated by open pyeloplasty or by several minimally invasive procedures such as a retrograde endourologic balloon incision or an antegrade endopyelotomy. Open pyeloplasty has been accepted as the surgical treatment of choice for primary UPJ obstruction in children, with a success rate of more than 90% in most reports. However, to many authors, success rates of ►endourologic surgery are comparable to those of open surgery but with lower morbidity. Therefore, secondary UPJ obstructions are currently treated in adults mostly by endoscopic procedures.

Nephrectomy is performed in rare cases with complete destruction of the renal parenchyma.

Temporary percutaneous nephrostomy may be indicated in cases of severe urinary tract infection or before surgery when a major loss of renal cortex is diagnosed and a nephrectomy or a surgical repair is discussed.

Synonym

Urethral stricture

Definitions

The male urethra is subdivided into prostatic, membranous, bulbar, and penile portions. The prostatic portion begins at the bladder neck and passes through the prostate gland up to the prostate apex. The membranous urethra passes through the urogenital diaphragm. The bulbar urethral portion is surrounded by the bulb of the corpus spongiosum and extends from the perineal area to the suspensory ligament, which anchors the penis to the symphysis pubis. The penile or pendulous portion of the urethra stretches from the suspensory ligament to the external urethral meatus. Before its emergence at the meatus, there is an ampullar dilatation called the *Fossa* navicularis.

The female urethra is about 4 cm long and extends from the bladder neck to the vestibule, where it forms the external meatus between the *Labia* minora.

Urethral stenosis is a pathology that mainly affects the male urethra, due to its anatomical conformation and length, but distal strictures can also occur in female patients.

Pathology/Histopathology

Narrowing of the urethra can be congenital or acquired. Malformations are due to complete or segmental stenosis, atresia, duplication, and congenital dilatation. Acquired stenosis, or urethral strictures, are much more common and can be caused by primitive lesions of the urethra or by lesions secondary to compression from an enlarged prostate. In general, most nonprostatic urethral strictures are the result of infection, trauma, or iatrogenic maneuvers. Neoplastic urethral stenosis is very uncommon, with a female-to-male ratio of 4:1.

Inflammatory strictures can be classified as gonococcal and nongonococcal. Gonococcal urethritis has become less common despite the fact that gonococcus remains the most common sexually transmitted disease. Chlamydia trachomatis is the most common cause of nongonococcal urethritis. Urethral trauma can be divided into external trauma, either contusive or penetrative, and internal or endourethral trauma. External traumas are frequent events and can occur in the penile urethra as a result of road or work accidents, sporting activities, or sex.

Iatrogenic stenoses may result from radiation therapy, catheterization, and endoscopic prostatic resection; recurrent strictures occur frequently after ►urethral dilatation, ►internal urethrotomy, and ►urethroplasty. Stenosis usually occurs in the bulbomembranous region and, less commonly, at the penoscrotal junction. In clinical practice, urethral stenoses can occur following suprapubic or endoscopic prostatectomy. Traumatic meatitis and/or meatal ischemia following damage to the frenular artery at circumcision are suggested as possible causes of meatal stenosis in men.

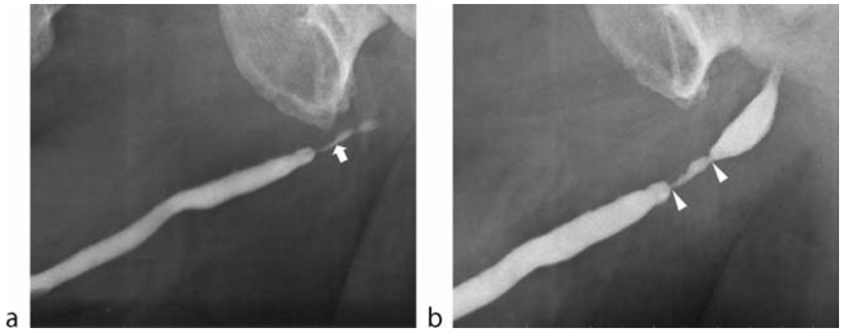
Clinical Presentation

Urethral stricture causes bladder outflow obstruction; if untreated and progressive, it may cause urinary retention, reflux, urinary tract infections, hydronephrosis, and renal failure. The most common clinical presentation includes obstructive voiding symptoms, which are characterized by decreased force of urinary stream, increased urinary frequency or urgency, urinary terminal dribbling, and bleeding at the end of urination.

Imaging

Retrograde urethrography is usually considered the best initial study for imaging the anterior urethral stricture in men (1). It consists of taking radiograms as an iodate contrast agent is introduced through the external urethral meatus (Fig. 1). After the gland and urethral meatus are

U



Urethra, Stenosis. Figure 1 Urethral stenosis studied with retrograde urethrography. (a) Iodinated contrast material is injected under fluoroscopic guidance through a Foley catheter placed into the *Fossa* navicularis so that the anterior urethra is filled up to the stenosis (*arrow*). (b) Slow, gentle pressure is needed to distend the stenotic tract of the urethra and fully delineate the length of the stenosis (*arrowheads*).

cleaned with antiseptic material, a small Foley catheter is placed in the distal urethra, and the balloon is slowly distended into the *F.* navicularis. Lubrication is not recommended because it may prevent the balloon from remaining in place for optimal occlusion (1). Distension of the urethra occurs slowly, through direct injection of the iodate solution in the catheter (1, 2) or by allowing the iodate solution to drip down through a bottle located at a height of 40–50 cm (3). Real-time fluoroscopic observation allows targeted radiograms and images to better identify the urethral disease.

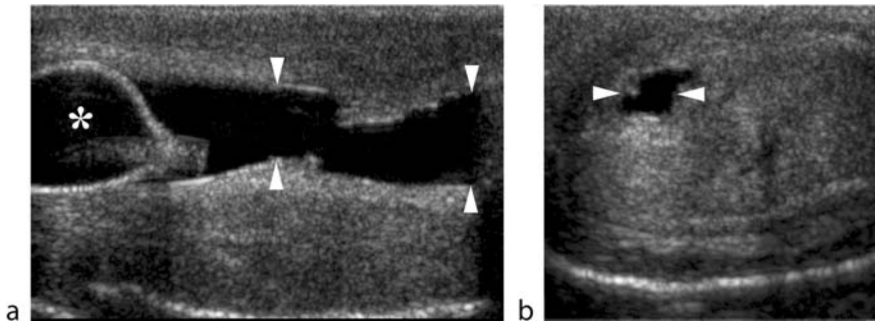
Voiding cystourethrography is currently the most commonly used imaging method in evaluation of the female urethra and male posterior urethra (1). Voiding urethrography is usually performed after the bladder is filled with contrast material *via* a transurethral or suprapubic catheter, or it represents the final part of urography (3). The exam is best carried out with the patient in an upright position and with video monitoring. Radiographs of the bladder and urethra are obtained during voiding under fluoroscopic observation. This method provides an accurate picture of urination and localization of any functional and organic alteration. Although the anterior urethra is not fully distended to the degree seen at retrograde urethrography, voiding cystourethrography allows evaluation of distal urethral stenosis (Fig. 2) when it is not possible to introduce the Foley catheter and retrograde urethrography cannot be performed.

Sonourethrography: The penile and bulbar male urethra can be accurately studied using high-frequency linear probes that are able to examine the penile and perineal tract. Using the traditional technique (Fig. 3), normal saline solution is introduced repeatedly through a small Foley catheter to distend the urethra and create a good contrast with adjacent tissue (2, 3). In patients with long, severe strictures, sonographic contrast medium can be injected intraurethrally to help delineate the abnormal lumen from the surrounding tissues and associated abnormalities, such as secondary lumen, fistulae, reflux into Cowper's glands, and abscess (4).

Urethra, Stenosis. Figure 2 Distal urethral stenosis (*arrowhead*) studied with voiding cystourethrography. Note marked urethral dilatation and elongation proximal to the stenosis.

An intraluminal lubricant or anesthetic jelly can be used instead of saline solution to distend the urethra. Sonourethrography with jelly is particularly useful in distal urethral stenosis and in stenosis of the meatus when it is not possible to introduce a Foley catheter. The use of jelly, however, has the disadvantage that urethral distension is less marked.

Endocavitary ultrasound: The posterior tract of the male urethra can be investigated during voiding using linear high-frequency endorectal probes (3). The main



Urethra, Stenosis. Figure 3 **Urethral stenosis studied with sonourethrography. Sagittal (a) and axial (b) views of the urethra after saline infusion through a small Foley catheter (*) placed into the *Fossa* navicularis show a complex urethral stenosis (*arrowheads*) with wall thickening.**

drawback of this technique is the difficulty patients have in urinating in a lateral position with the probe positioned in the rectum. The female urethra can be successfully studied with transvaginal ultrasonography. Some centers prefer transrectal sonography in female patients to avoid compression or distortion of the urethra.

Computed tomography (*CT*) has a limited role in evaluation of the urethra. Certain urethral abnormalities such as calculi or diverticula may be incidentally discovered at CT performed for other indications. CT is useful in patients with pelvic trauma (5) and associated urethral injuries and for staging of urethral carcinoma. CT virtual cystoscopy and voiding urethrography can be indicated in patients with complex urethral strictures and malformations.

Magnetic resonance imaging (*MRI*) is not widely used to evaluate the urethra. However, because of its multiplanar capability and excellent tissue contrast, it provides excellent anatomical detail of both the urethra and periurethral tissues (6). Distension of the urethra is obtained with saline solution after a small Foley catheter is placed in the *F.* navicularis. Imaging is performed using a surface coil that employs a small field of view with multiplanar T1- and T2-weighted sequences. Contrast medium is injected to evaluate tumors and the degree of activity in inflammatory lesions.

Nuclear Medicine

Radionuclide studies have no role in diagnosis of congenital or acquired narrowing of the urethra because of the poor anatomic detail, but they can depict the presence of ►vesicoureteral reflux and can be used to assess renal function.

Diagnosis

Urethral strictures may be assessed by direct urethroscopy, urethrography, or sonourethrography. Retrograde urethrography is the standard imaging technique to evaluate anterior urethral stricture (2–4). Radiographic evaluation helps define the location, length, number, and degree of strictures. More than one projection may be necessary to visualize the stricture and to correctly estimate the stricture length. In posterior urethral strictures following blunt trauma, simultaneous antegrade cystourethrography, and retrograde urethrography are often required to determine the length of the urethral defect.

Sonourethrography may be chosen instead of radiographic techniques because it does not involve ionizing radiation. This may be particularly important in patients needing repeated investigation. This technique can be more accurate than retrograde urethrography for estimating the length of urethral strictures (2). In addiction to evaluation of the urethral lumen, sonourethrography gives information about the depth and density of periurethral changes not provided by radiographic methods (2, 3). Periurethral fibrosis manifests at ultrasound as thickened, irregular, nondistensible tissue encroaching into the otherwise anechoic urethral lumen.

CT virtual cystoscopy and CT voiding urethrography have been recently introduced to evaluate patients with urethral disease; however, large studies are needed to determine the clinical value of these new techniques (5).

MRI is indicated to evaluate spongiosal fibrosis in patients with postinflammatory strictures (6). Moreover, MRI is considered to be the best imaging modality for assessing posttraumatic pelvic anatomy in patients with urethral injury. In neoplastic strictures, MRI has a role in staging the size, location, and local extension of the primary pathology.

Urethral Dilatation

Procedure performed to open a urethral stricture by passing a dilating instrument into the urethra. This can be done under local or general anesthetic.

▶Urethra, Stenosis

Urethral Stricture

▶Urethra, Stenosis

Urethritis

Inflammation of the urethra.

▶Neoplasms, Urethra

Urethrography

Progressive opacification of the urethra with iodinated contrast medium performed under fluoroscopic guidance. It usually includes a series of radiographs with coronal and oblique images.

▶Neoplasms, Urethra

Urethroplasty

Surgical procedures used to correct urethral stricture following repeated recurrence after urethrotomy. A variety of techniques may be used: excision and primary reanastomosis (particularly for short strictures in the bulbar urethra); excision and substitution with free tissue grafts or vascularized flaps; staged procedures in which nonviable tissue is excised first, followed by retubularization of the urethra (used particularly for long strictures and ones that have been unsuccessfully repaired previously).

▶Urethra, Stenosis

Urinary Casts

Casts are cylindrical structures composed mainly of a mucoprotein (the Tamm-Horsfall mucoprotein), which is secreted by epithelial cells lining the loops of Henle, the distal tubules, and the collecting ducts. The factors responsible for the precipitation of this mucoprotein are not fully understood, but may relate to the concentration and pH of urine in these areas. Casts may form in the presence or absence of cells in the tubular lumen. If cells (epithelial cells, WBC) are present as a cast forms, they may adhere to, and subsequently be surrounded by, the fibrillar protein network. The appearance of a cast observed in urine sediment depends largely on the length of time it remains in situ in the tubules before being shed into the urine. A cast recognizable as "cellular," for example, is shed shortly after it is formed. A waxy cast, in contrast, is retained longer in the tubular system before being released. Casts are quantified for reporting as the number seen per low-power field (10x objective) and classified according to type. In the urine of normal individuals there are few casts or none at all.

▶Tubular Necrosis, Kidney, Acute

Urinary Incontinence

Involuntary urinary loss during all usual situations or activities.

▶Incontinence, Urinary

Urinary Obstruction, Acute

Sudden blockade of the urinary collecting system caused mostly by calculi. Stretching of the collecting system is responsible for the pain in renal colic. Immediately after onset of complete obstruction, autoregulatory mechanisms due to vasoactive factors and hormones try to overcome obstruction. First, an increased blood flow preserves the glomerular filtration rate, while hyperperistalsis and antidiuretic hormone blockade increase the volume of hypotonic urine. If passage is not attained in the next hours, and to preserve renal function, blood flow is reduced by preglomerular arteriolar vasoconstriction, which together with a decrease in hydrostatic pressure gradually leads to reduction of pain.

▶Colic, Acute, Renal

Urinary Stones

Calculi in the urinary tract (renal, ureteric, bladder) are often idiopathic, but can be secondary to stasis, and infection, or in association with several hereditary metabolic disorders like renal tubular acidosis, cystinuria, xanthinuria, hydroxyadeninuria, and others. Intermittent urine supersaturation is necessary for crystals to form and grow. Stasis as in PUJ obstruction, sponge kidneys, and other anatomic abnormalities are prerequisite for stone formation. The majority are composed of calcium, magnesium ammonium phosphate, or urate. Ninety percent are radiopaque.

Urodynamic Studies

Registration of pressure inside the bladder and during micturition

▶Bladder, Neurogenic

Urodynamic Tests

Several techniques to measure functional parameters associated with urination. Urodynamics require positioning of catheters into the urethra and bladder and into the vagina to register pressure curves. Urodynamic parameters are urine speed, bladder volume, residual bladder volume, leak point pressure, bladder pressure, and electromyography curves during voiding.

▶Pelvic Floor Dysfunction, Genitourinary

Urogenital Sinus (UGS)

In the foetus, the UGS forms when the cloaca is divided by the urorectal septum into the UG sinus anteriorly and the rectum posteriorly. The UGS subsequently contributes to the formation of the urethra in males, and the urethra, vestibule and lower vagina in females. A persistent UGS in females refers to a situation where the vagina and urethra join to form a single channel proximally to the vestibule, resulting in a single vestibular opening.

Female Pelvis

Introduction

Advances in imaging and minimally invasive interventions in women with pelvic disorders have occurred at an unprecedented rate in recent years. For the initial evaluation of any suspected pathologic condition, transabdominal or transvaginal ultrasound remain the imaging modalities of choice. Technical advances in cross-sectional imaging, however, have opened up many diagnostic applications in female pelvic pathology. Thus, computed tomography (CT) and magnetic resonance imaging (MRI) nowadays play an increasing role in the diagnosis

U

of a variety of diseases of the female pelvis including preoperative tumor staging and follow up of oncologic patients. Due to its wide availability, CT is usually employed in an emergency situation, e.g., for the assessment of an *acute abdomen*. Compared to CT, MRI provides a better soft tissue contrast and is thus better suited for evaluating the genital organs. Furthermore, it does not employ ionizing radiation and has no teratogenic effects. It is thus well suited for imaging women of reproductive age and especially also during pregnancy, e.g., in MR pelvimetry and more recently as an adjunct to sonography for *fetal imaging*.

Imaging Techniques and Normal Anatomy of the Female Pelvis

Transvaginal ultrasound using a 5.0–7.5-MHz probe is usually performed by the gynecologist as part of the gynecologic examination. Transabdominal ultrasound allows one to assess not only the genital organs, but also the entire abdomen, for example, the kidneys to exclude hydronephrosis. The patient should be investigated with full bladder to better visualize the uterus using a 2.5–5.0-MHz transducer. On ultrasound, the myometrium is of homogeneous intermediate echogenicity. Endometrial thickness varies with the *physiological changes during the menstrual cycle*, measuring up to 14 mm in premenopausal women. On MRI, the normal anatomy of the uterus is best seen on T2-weighted imaging. Three different zones can be distinguished, i.e., the hyperintense endometrium, the junctional zone of low signal intensity, and the myometrium. Normal ovaries measure between 1.5 and 3 cm during reproductive age, with their size decreasing after menopause. They can be depicted by MRI in over 80% of cases in women in their reproductive phase due to the presence of T2-weighted hyperintense follicular cysts.

Hysterosalpingography and *sonohysterography* are imaging techniques that are performed for selected indications only, i.e., in patients with a history of *infertility*.

Congenital Anomalies of the Female Genital Organs

According to the American Fertility Society classification, several classes of *congenital anomalies of the uterus* (synonym: *müllerian duct anomalies*) can be distinguished, e.g., unicornuate, bicornuate uterus, or uterus didelphys.

Clinical manifestations include subfertility or *infertility*, pregnancy wastage, and menstrual disorders. Furthermore, müllerian duct anomalies are commonly associated with anomalies of the urinary tract, e.g., renal agenesis.

Whereas transvaginal ultrasound and hysterosalpingography are the primary imaging modalities, MRI is currently used as a problem-solving tool in inconclusive cases, e.g., in the differentiation between septate and bicornuate uterus.

Benign Disorders of the Vulva, Vagina, Cervix Uteri, and Uterine Corpus

Bartholin's cysts are caused by retained secretions within the vulvovaginal glands, mostly as a result of chronic inflammation or trauma. They are located in the posterolateral parts of the lower vagina and vulva, whereas *nabothian cysts* are retention cysts of the cervical glands and clefts.

Common benign uterine masses are *leiomyomas* (synonyms: fibroids; fibromyoma). The lesions must be differentiated from adenomyosis.

Endometrial hyperplasia and endometrial polyps are benign entities that must be distinguished from endometrial carcinoma.

Inflammatory changes, i.e., endometritis or endomyometritis, are rare indications for cross-sectional imaging.

Malignant Disorders of the Vulva, Vagina, Cervix Uteri, and Uterine Corpus

Endometrial carcinoma is a common gynecologic tumor in postmenopausal women. Most patients present with abnormal uterine bleeding. MRI is the imaging modality of choice for preoperative staging of endometrial carcinoma proven by fractional abrasion. It is especially useful in those patients in whom the extent of tumor growth may alter the surgical approach or in patients in whom concomitant lesions, e.g., the presence of leiomyoma, make the clinical assessment difficult.

Most uterine tumors are adenocarcinomas; other histologic subtypes such as *leiomyosarcoma* or endometrial stromal tumors are rare.

Gestational trophoblastic disease encompasses a spectrum of tumors ranging from benign hydatidiform mole to choriocarcinoma. Diagnosis will be established based on clinical symptoms confirmed by human chorionic gonadotropin (HCG) measurements. Thus, the role of imaging is very limited in this patient population.

Early detection of *cervical carcinoma* due to gynecologic examination and Papanicolaou smear has led to a significant reduction in mortality. At histology, a squamous cell carcinoma is found in over 90% of cases. Transvaginal ultrasound and MRI are used for staging of disease.

Vaginal metastases are more common than primary *vaginal carcinoma* and are usually the result of metastatic spread from *carcinomas of the vulva*, endometrium, or cervix.

Benign, Nonneoplastic Ovarian Masses

Physiologic *follicular cysts* are the most common benign ovarian masses. Other nonneoplastic adnexal lesions include *endometrioma*, *adnexal torsion*, and *tubo-ovarian abscess*. *Paraovarian cysts* (synonym: Gartner's duct cysts) are remnants of the Wolffian body and are found in the mesosalpinx in the hilum of the ovary.

Ovarian vein thrombosis (synonyms: septic puerperal ovarian vein thrombosis; SPOVT) is a complication in the puerperal period. The clinically suspected diagnosis can be confirmed by duplex sonography, contrast-enhanced CT, or MR angiography.

Ectopic pregnancy occurs in most cases in the fallopian tubes. Ultrasound is the imaging modality of choice. Laparoscopy of laparotomy will be performed for therapeutic reasons.

Benign and Malignant Neoplastic Ovarian Masses

Differentiation between benign and malignant ovarian lesions is based on various imaging criteria. Ovarian epithelial tumors account for approximately 65% of ovarian neoplasm. Of these tumors, 60% are benign (e.g., cystadenoma), whereas 5% are present with a borderline histology. The other 35% are malignant *ovarian carcinoma*. Preoperative cross-sectional imaging may help in preoperative planning in patients with suspected ovarian carcinoma. Whereas MRI is superior to CT and US in lesion characterization and in demonstrating the origin of a pelvic mass (e.g., distinguishing a subserosal uterine leiomyoma from an ovarian mass), CT, being widely available and more cost-efficient, is usually preferred for preoperative staging.

Evidence of intralesional fat, independent of the size of the lesion, is indicative of a benign *mature teratoma* (synonym: dermoid cyst). These tumors are very common ovarian neoplasms and belong to the group of germ cell tumors.

Imaging the Obstetric Patients

There is no clinical or experimental evidence of teratogenic or other adverse fetal effects from performing MRI in pregnancy. Thus, this technique has become an important adjunct to ultrasound for imaging of pregnant women for maternal reasons, *MR pelvimetry* in cases of suspected cephalopelvic disproportion, and more recently also for *fetal imaging*.

Pelvic Floor

Stress urinary incontinence is a significant problem in older women.

Its predominance in parous women prompted the etiologic hypothesis of trauma to pelvic-floor support structures during childbirth. More recently, MRI has gained an increasing role in assessing *pelvic floor* pathology. The advantages of this method are high soft-tissue contrast for visualizing the pelvic floor morphology and nonexposure of the patient to ionizing radiation.

Male Pelvis

Introduction

Ultrasound is the primary imaging modality for the evaluation of suspected pathology of the male pelvis, e.g., assessment of a *scrotal mass* or diagnosis of suspected prostatic disease. Transrectal ultrasound is usually performed directly by the urologist and nowadays is often considered an extension of the physical examination. In many cases, it supplies sufficient information to establish the diagnosis. Cross-sectional imaging is indicated in cases in which sonographic findings are equivocal or a discrepancy between clinical and ultrasound findings exists. Furthermore, CT and MRI are important tools for staging of malignant disease, e.g., in *testicular cancer*.

Benign Lesions of the Prostate and Seminal Vesicles

Diagnosis of congenital *prostate cysts*, i.e., utricular and müllerian duct cysts, has increased in parallel with the use of transrectal sonography and MRI in prostate lesion diagnosis. Since there is an association of utricular cysts with malformations of the genitourinary tract, e.g., renal agenesis, hypospadias, pseudohermaphrodism, and cryptorchidism, they are usually detected in childhood. Both types of cysts can cause symptoms such as dysuria, urinary tract infections, prostatitis, and infertility; smaller cysts, however, are mostly incidental findings.

Benign prostatic hyperplasia (BPH) impairs micturition in about half of all men over 50 years of age. Whereas BPH is not an indication for cross-sectional imaging, it is a frequent incidental finding in patients investigated for other reasons, e.g., local staging of *prostate carcinoma*.

Chronic *prostatitis* is more common than the acute form and often clinically silent. Acute prostatitis is caused by direct extension from the urethra or urinary bladder in most cases, often a result of surgical manipulation of these structures. It might be complicated by *prostatic abscess* formation.

Prostate Cancer

Prostate cancer is the leading cancer in males. It is usually suspected by digital rectal examination and elevated PSA levels, and will subsequently be confirmed by transrectal ultrasound-guided biopsy.

High-resolution MRI using an *endorectal coil* can be an important adjunct to ultrasound for the local tumor staging of prostate cancer in selected patients, i.e., for the detection of extracapsular tumor extension, *seminal vesicle* invasion, as well as bone marrow metastasis, which are contraindications for radical prostatectomy.

Scrotal and Penile Disorders

Benign Lesions of the Scrotum and Testis, Benign Penile Disorders

Although the *scrotum* is a superficial structure, its clinical examination frequently fails to provide a specific diagnosis because the clinical history and physical findings are similar under many conditions. Ultrasound confirms the presumptive clinical diagnosis and provides relevant additional information. A color-coded duplex sonography or power Doppler examination is indicated in any situation in which additional information on perfusion is needed to establish the diagnosis, particularly in *testicular torsion*, inflammation (*epididymitis, orchitis*), *scrotal trauma*, and varicocele. Other imaging modalities should be used only as problem-solving approaches.

The most common *benign masses in the scrotum* are *spermatoceles* of the epididymis. Benign neoplasms of the testis account for only approximately 5% of all testicular neoplasms. *Hydroceles* are common fluid accumulations located between the two layers of the tunica vaginalis testis. They may be idiopathic in origin or develop in association with inflammation (epididymitis or orchitis), secondary to trauma or testicular torsion, and in the presence of a testicular tumor.

Catheter angiography, Doppler ultrasound, and more recently MRI are used for imaging *penile vasculature* when arteriogenic *impotence* secondary to aortoiliac occlusive or small-vessel disease or as a result of pelvic trauma is suspected.

Ultrasound or MRI may be used to evaluate benign entities, e.g., periurethral abscess, Peyronie's disease, or Cowper duct syringocele that manifest as palpable penile masses, the nature of which may not be apparent at clinical evaluation, as well as for the evaluation of *penile trauma*.

Malignant Lesions of the Penis, Scrotum, and Testis

Whereas malignant tumors of the epididymis and the spermatic cord are extremely rare, *testicular cancer* constitutes approximately 1% of all malignancies in men, being the most frequent cancer in young males. The tumor typically presents as a lump or painless swelling of the testis. Ultrasound and sometimes MRI are employed to establish the diagnosis, whereas CT will usually be performed for lymph node staging.

Most primary *penile malignancies* are squamous cell carcinomas. Carcinoma of the male urethra and primary sarcoma may also occur in the penis. Metastases to the penis are rare. They usually arise from other primary malignancies of the genitourinary tract, e.g., the urinary bladder, and may manifest with malignant priapism.

Urothelial Neoplasms, Kidney and Ureter

Samuel Merran, Annick Vieillefond, Olivier Helenon
Neckert, Paris, France
olivier.helenon@nck.ap-hop-paris.fr

Definition

Tumors arising from the renal pelvis and ureter are usually of urothelial origin, with transitional cell carcinoma (TCC) being the most common tumor. Urothelial tumors are most frequently malignant, and their prognosis is variable, depending on their degree of differentiation and their extension through the wall of the renal pelvis or ureter. Papillomas are the most common benign tumor. Much rarer are tumors of connective tissue origin.

Peak incidence of urothelial upper tract tumors is in the sixth and seventh decades. Patients with urothelial upper tract tumors have a 30 to 75% incidence of prior or later bladder cancer, so that bladder evaluation is essential. Microscopic or gross hematuria occurs in 60 to 75% of patients at presentation. Fifteen percent of the cases are detected incidentally on imaging studies. Advanced stages account for less than 10% of the cases and patients present with a palpable flank mass, anorexia, or weight loss.

Characteristics

Urothelial tumors of the renal pelvis represent approximately 7% of primary renal neoplasms (1) and approximately 5% of the urinary tract tumors (2).

The urothelial neoplasms are dominated by the TCC. Ninety percent of the tumors that arise from the urinary epithelium are TCCs. The other epithelial tumors are rare: epidermoid carcinoma (related to bilharzias) and adenocarcinoma.

These tumors share the same epidemiologic features associated with TCC of the urinary bladder: history of exposure to chemical (aromatic amine) in the dye and in the paint, rubber, petroleum industry, tobacco use, high amount of coffee consumption, and chronic inflammation or infection. Patients with a history of analgesic abuse are also at risk for TCC. Urinary bladder location of TCC is much more frequent than in the other parts of the urinary tract. Location to the renal cavities (pelvis and calices) is second in frequency. Synchronous or asynchronous multiple tumors locations occur in 10 to 20% of cases (Fig. 1). This known multifocality requires thorough examination of the entire urinary tract in high-risk patients, such as patients with bladder cancer or known chemical exposure (2).

Imaging

CT and CT Urography

Traditionally intravenous urography (IVU) has been the screening examination of choice for detection of upper urinary tract neoplasms in patients with hematuria or for high-risk patients. However, 40% of upper urinary tract tumors are missed by IVU (1). With the advent of multidetector CT enabling the rapid acquisition of thin-section images through the entire urinary tract, CT urography (CTU) has superseded IVU as the examination of choice to detect upper urinary tract tumors. The techniques and protocol we use for CTU are summarized in Table 1.

On imaging TCC of the renal cavities (calices or renal pelvis) manifests as a focal soft tissue mass or wall thickening (3–5). On noncontrast scans, the mean density is around 30 HU (Fig. 2) and are differentiated from

U

blood clot (50–75 HU) (Fig. 3) and calculi (>100 HU) (Fig. 4). TCC appears rarely calcified (microcalcifications) on nonenhanced scans (Fig. 5).

On early phase postcontrast study the enhancement of TCC is mild to moderate (Fig. 6). In infiltrative cases of TCC the wall thickening of the renal pelvis also enhances on arterial phase scans (Fig. 7).

In the excretory phase of CTU [sometime performed on a prone position to fill the renal cavities with contrast in case of obstruction (Fig. 8),] TCC appears as a filling defect within the high-density contrast excreted into the collecting system (Fig. 9). Sometimes TCC can appear as a focal or diffuse wall thickening (Fig. 10). Fifteen percent of TCCs are more aggressive, infiltrating lesions that show mural thickening and at a more advanced stage an invasion of the renal sinus fat (Fig. 11) or even the renal parenchyma (Fig. 12).

CT plays a role in staging urothelial tumors. CT cannot accurately distinguish T1 tumor (limited to uroepithelium and lamina propria) from T2 tumors (extending into muscularispropria but not beyond, but CT is accurate to distinguish early stages T1 and T2 from T3 (invading renal sinus fat or renal parenchyma) and T4

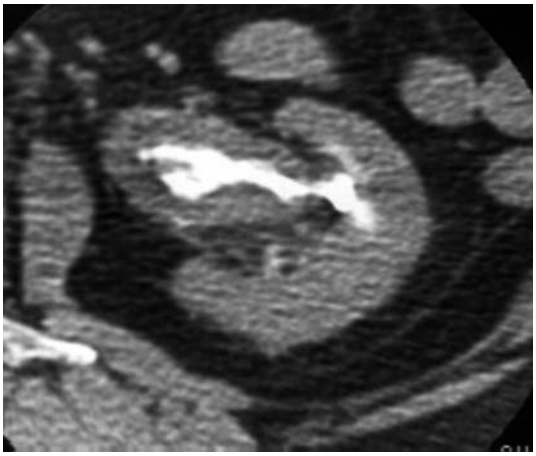
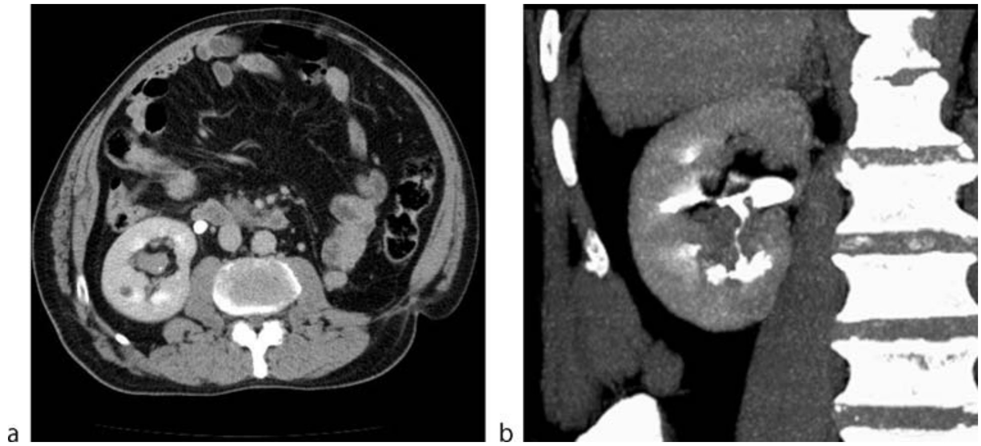
Because of the beginning obstruction of the left kidney the contrast media excreted do not surround the soft tissue mass visible in the renal pelvis on a, b, and c. On the propone position acquisition, the mass is clearly delineated by the high-density contrast media.



Urothelial Neoplasms, Kidney and Ureter. Figure 10 Postcontrast CT: wall thickening of the left renal pelvis wall in an infiltrative TCC.

U

(invading adjacent organs or extending into perinephric fat through the renal parenchyma. This distinction is important because there is a significant difference in survival between stage II and III tumors (5). Advanced stage tumor is suspected when the normally low-density renal sinus fat increases in attenuation or when—the fat plane between the tumor and the renal parenchyma is lost. In some cases CT may show a direct invasion of tumor into the renal parenchyma which can appear as an infiltrative renal mass (6) (Fig. 12). Usually, uroepithelial



Urothelial Neoplasms, Kidney and Ureter. Figure 11 (a) Axial slice through the lower pole of the right kidney: a soft tissue mass occupies the fat of the renal sinus. (b) Coronal reconstruction shows a thickening of the excretory cavity of the lower pole and an infiltration of the renal sinus fat.

Urothelial Neoplasms, Kidney and Ureter. Figure 12 Hypodense renal mass corresponding to direct invasion of tumor into the renal parenchyma which can appear as an infiltrative renal mass.

neoplasms are more to expand the kidney centrically while preserving the renal contour (6, 7). TCCs can invade the renal vein and the inferior vena cava, and less frequently renal cell carcinomas. CT also allows high-quality imaging of lymph nodes, liver, bones, and lungs, which are the most common sites of metastatic spread of urothelial neoplasms (5, 6).

A recent 3D CT based reconstruction allows “navigation” within the renal cavities. This virtual endoscopic technique is based on segmentation of the contrast-filled cavities and shows in 3D the lumen and filling defects (Fig. 13). Axial slices are mandatory to distinguish between tumors, blood clots, and calculi.

Ureteral location of urothelial neoplasms has the same appearance as tumors of the renal pelvis and calices: either a filling defect within the ureteral lumen (Fig. 14a) or a thickening of the ureteral wall (Fig. 14b).

MRI and MRI Urography

MRI is a good alternative to CT in the radiological exploration of urothelial neoplasms. Consequently, this technique is indicated for assessing patients with a known intolerance of iodinated contrast medium and patients with moderately reduced excretory function. Moreover, excretory MR urography can also be performed to examine children and young adults because it does not require the use of ionizing radiation (7).

MR protocols and sequences are summarized in Table 2. For MR urography, we use both nonenhanced T2 weighted sequence (HASTE): (half-Fourier acquisition single-shot turbospin echo) and single-shot turbospin echo, and gadolinium enhanced sequences using high resolution images and maximum intensity projection (MIP) reconstruction.

TCC of the renal pelvis appears as soft tissue masses within the lumen, usually hypointense T2 in the hyperintense fluid-filled renal cavities (Figs 15 and 16). Enhancement is present after injection (Figs 15 and 16). Lesions of the ureters are usually more difficult to point out; the spatial resolution of the MRI is much lower compared to the CT spatial resolution.

Cross sectional imaging, specifically multidetector CT and CTU, is essential in detection and follow-up of urothelial carcinomas.

US

▶Ultrasound

USPIO

Ultra-small superparamagnetic iron oxide (USPIO) particles are iron oxide nanoparticles stabilized with low molecular weight dextran with a mean diameter of 30 nm. These relatively small particles have a much larger half-life in blood than the conventional superparamagnetic iron oxide particles, with a mean diameter of 150 nm. Because of their long half-life in blood, USPIOs can be taken up by macrophages in the whole body.

▶Glomerulonephritis

Uterine Fibroid

▶Leiomyoma, Uterus

Uterus

The uterus is the major female reproductive organ. The uterus is divided into three parts; fundus, corpus and cervix. It is located within the female pelvis, between the urinary bladder and rectum. It is held in place by ligaments and consists mostly of smooth muscle (= myometrium). The innermost layer of the myometrium is known as junctional zone. The lining of the uterus is called the endometrium (see zonal anatomy).

VA(C)TERL Syndrome

VATER or VACTERL association combines Vertebral anomalies, Anorectal atresia, Cardiac failure, Tracheoesophageal fistula, Esophageal atresia, Renal dysplasia, and Limb malformation. Currarino triad: The Currarino triad represents a combination of malformations consisting of imperforate anus, sacral dysplasia, and an anterior sacral mass (e.g., teratoma, anterior meningomyelocele). As a general rule, associated malformations occur more frequently in the high ARM or intermediate AMR groups than in group low ARM group.

►Anorectal Malformation

Vaccum-Assisted Biopsy

Percutaneous puncture technique used to remove cylinders of tissue from suspicious lesions for histological study. The procedure combines cutting and aspiration systems. For breast lesions, 8-, 11-, and 14-gauge needles are used. Many specimens can be removed with only an insertion of the needle.

►Breast Conserving Therapy

Valve Mechanism

A valve mechanism is due to partial airway obstruction of an inhaled foreign body and is characterised by air-trapping, mediastinal shifting and paradoxical movement of the hemidiaphragm on inspiratory–expiratory films or under fluoroscopy.

Varices, Oesophagus

Simon A Jackson, John Shirley
Imaging Directorate, Derriford Hospital, Plymouth, UK
simon.jackson@phnt.swest.nhs.uk
john.shirley@phnt.swest.nhs.uk

Definition

Oesophageal varices are defined as pathologically dilated veins lying within the wall of the oesophagus, which normally project into the oesophageal lumen. Dilated veins lying adjacent to, but outside the wall of the oesophagus, are termed ►paraoesophageal varices. Both types of varix are usually found simultaneously in patients with pathology causing increased pressure and venous flow through the normal collateral oesophageal vessels. Rarely varices are diagnosed in patients without related pathology and these are termed idiopathic varices.

The radiological appearances of oesophageal varices were first described in 1928 using a basic contrast imaging technique. Today, imaging modalities including endoscopy, cross sectional imaging and interventional techniques are used to more accurately define the presence and distribution of both symptomatic and asymptomatic varices.

Pathology/Histopathology

A variety of pathologies can cause increased flow through the oesophageal veins. Depending on the direction of blood flow within the native oesophageal collateral vessels, oesophageal varices are termed uphill or ►downhill varices.

Uphill Varices

Uphill varices are found in patients with portal hypertension, which most commonly develops secondary to underlying cirrhosis. Hepatitis B/C and alcohol related liver disease remain the most common aetiologies of cirrhosis worldwide. Currently the worldwide incidence of hepatitis C is increasing. The varices are the result of changes to the normal direction of collateral vessel flow. In particular, increased portal pressure leads to reversal of normal venous flow through the main left gastric (coronary) vein. Anatomically this vein drains the collateral vessels of the distal oesophagus inferiorly into the splenic or portal vein. This reversal of flow (uphill) leads to dilatation and formation of lower oesophageal varices, which in turn anastomose and drain into the central venous circulation *via* tributaries of the azygos and hemiazygos venous systems within the thorax.

Downhill Varices

Pathology obstructing the superior vena cava (SVC) commonly results in reversal of flow within the veins of the upper body. This in turn leads to increased flow through the oesophageal and para oesophageal veins as venous flow bypasses the obstruction before returning to the systemic circulation. The direction of blood flow through these collaterals is thus caudad leading to the term downhill varices.

The position of the varices however is variable and depends on the level and site of SVC obstruction. In particular, pathology obstructing the SVC above the level of the azygos vein, results in the downhill flow of venous blood from the head and upper extremities *via* the oesophageal veins into the azygos vein. The azygous vein in turn drains into the SVC below the level of obstruction. Associated oesophageal varices therefore develop within the upper or mid oesophageal segments.

If the level of ►SVC obstruction occurs below the site of entry of the azygos vein, venous flow develops *via* the oesophageal collaterals inferiorly into the coronary vein and thence to portal circulation and inferior vena cava. Associated oesophageal varices thus extend throughout the length of the oesophagus.

The most frequent cause of SVC obstruction is secondary to malignancy within the lungs or mediastinum. Due to the relatively short patient survival time, downhill varices are normally confined to the upper and mid oesophageal segments even in patients with obstruction of the SVC below the azygos vein termination. SVC obstruction, secondary to benign pathologies including radiation fibrosis is well described as well as iatrogenic SVC obstruction secondary to central venous line placement.

Clinical Presentation

The vast majority of patients presenting with uphill varices demonstrate the varied clinical sequelae of portal hypertension secondary to cirrhosis. The underlying architectural disturbance of the liver results in an increased hepatic portal venous pressure (greater than 10–12 mm Hg) and when taken in combination with the associated hyperdynamic portal circulation, the risk of complications and in particular variceal haemorrhage increases. At diagnosis, varices are present in approximately 40% of patients with compensated liver disease increasing to 60% of patients who present with decompensation. Overall 60–70% of all upper GI bleeding episodes in patients with portal hypertension are secondary to rupture of oesophageal varices. The six-week mortality after variceal bleeding is approximately 30% with uncontrolled bleeding occurring either during the initial presentation episode or soon after contributing to approximately 60% of deaths. The early re-bleeding rate remains the most important forecasting indicator of six-week mortality. In addition, 63% of patients re-bleed within 1–2 years with a corresponding mortality rate of 33%.

In contrast, the majority of patients presenting with haemorrhage from downhill varices exhibit symptoms related to SVC obstruction. These can be characterised by facial, neck and arm soft tissue swelling/oedema with dilated veins over the chest wall.

Imaging

Oesophageal varices may be imaged by a variety of imaging modalities.

Conventional Radiographs

Plain films are limited in their sensitivity and thus are not performed for the assessment of varices. However in some cases dilatation of the paraoesophageal veins, may result in a posterior mediastinal mass as well as obliteration of the normal descending aortic outline (1). A mediastinal mass is commonly identified in patients with downhill varices associated with dilatation of either the azygous or hemiazygous veins.

Oesophageal varices are not visualised on plain radiographs because of their location within the wall of the oesophagus.

Contrast Studies

The barium examination is no longer routinely used for the diagnosis of oesophageal varices due to the technique's relative lack of sensitivity. However, in similarity to all forms of contrast examination, the diagnosis of pathology relies on the meticulous performance of an optimal technique. This includes the use of a high-density barium suspension with ingestion of a limited volume of barium during each swallow to minimise the risk of luminal over distension causing compression of the mucosal surface and varices. Mucosal relief views help to increase the sensitivity of the study. In addition, patient positioning is important with an oblique position and slight Trendelenburg table tilt increasing distension of the varices.

Morphologically the vessels appear as tortuous or serpiginous longitudinal filling defects which project above the adjacent mucosal surface into the oesophageal lumen (Fig. 1). Varices may also appear as thickened folds of lower density when compared to the adjacent oesophageal wall during a double contrast examination, due to the collection of contrast in the mucosal grooves adjacent to the vessels. Importantly varices collapse and distend with varied respiration and thus may transiently disappear during an examination. Thus, the use of a Valsalva manoeuvre improves venous distension and thus variceal conspicuity.

The rare varicoid carcinoma of the oesophagus may mimic varices on a contrast study, however is distinguished due to the absence of morphological changes during the respiratory cycle or patient position.

Computed Tomography

Developments in multidetector contrast enhanced CT have resulted in the widespread use of this technique for the evaluation of the portal venous system and diagnosis of oesophageal varices. In addition, multi-planar reconstruction techniques also improve the depiction of the sequelae of portal hypertension (2). Varices appear as multiple tubular or serpentine vessels, which surround and involve the oesophageal wall (Fig. 2). Both uphill and downhill varices demonstrate homogeneous enhancement on portal venous phase imaging and whilst downhill varices demonstrate similar morphology to their uphill counterparts they usually differ in location. In addition, other collateral pathways may be visualised within the thorax secondary to associated SVC obstruction. These pathways include distension of the azygous, thoraco epigastric, mediastinal and internal mammary veins.

Magnetic Resonance Imaging

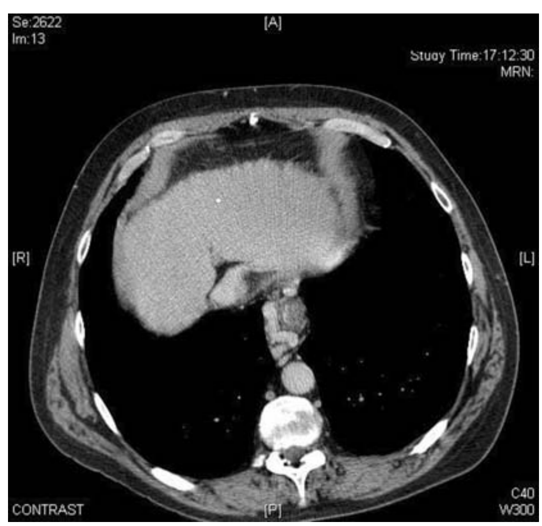
The multi-planar and contrast tissue resolution of magnetic resonance imaging (MRI) allows excellent visualisation of oesophageal varices and their related aetiologies. Flowing blood within the varices appears as a signal void on conventional T1W and T2W sequences. However, unenhanced sequences when used in combination with gadolinium enhanced MR angiography allow improved depiction of vessels with a sensitivity of 81% (3). After intravenous contrast injection and as demonstrated on computed tomography (CT), varices appear as serpiginous contrast enhanced vessels best assessed on dynamic portal venous phase sequences.

Ultrasound

Whilst transabdominal ultrasound and in particular the use of duplex Doppler ultrasound is routinely used for the evaluation of portal vein patency and liver pathology, the technique can also delineate lower oesophageal varices (4).

Endoscopic ultrasound (EUS) however provides excellent visualisation of the oesophageal wall and adjacent structures, thus allowing the accurate characterisation of

Varices, Oesophagus. Figure 1 Mucosal relief barium swallow images demonstrating uphill varices involving the lower third of the oesophagus.



Varices, Oesophagus. Figure 2 Contrast enhanced CT image demonstrating lower oesophageal varices in a patient with portal hypertension.

both oesophageal and paraoesophageal varices. Vessels are defined as hypo or anechoic well-circumscribed structures with a serpiginous appearance on grey-scale imaging. Colour flow and duplex ultrasound allows quantification of the velocity and direction of blood flow within the varices. In addition, therapeutic EUS has been used to guide sclero-therapy and assess post sclero-therapy variceal recurrence.

Angiography

Historically, angiography was used as the primary imaging technique for the depiction of oesophageal varices. However, the use of alternative non-invasive imaging modalities including endoscopy and cross sectional techniques has led to the routine use of angiography as a primary therapeutic rather than diagnostic procedure (5).

Angiography may however be performed using a variety of approaches to evaluate the portal venous system and associated collateral pathways. These included the use of wedged hepatic venography obtained after placement of a catheter within the hepatic vein *via* either an internal jugular or common femoral vein approach. This technique is routinely performed during a transjugular intrahepatic portosystemic stent shunts (TIPSS) procedure (see Chapter TIPSS). Alternatively varices may be visualised either by direct portography obtained after percutaneous trans-hepatic puncture of a portal vein branch or by indirect arterial portography performed after placement of a catheter within either the superior mesenteric or splenic arteries.

Nuclear Medicine

Nuclear medicine has a limited role in the diagnosis and assessment of oesophageal varices. Radiolabelled RBC imaging may however confirm variceal haemorrhage as a cause for upper GI bleeding and SPECT has been performed for the evaluation of variceal recurrence after endoscopic sclerotherapy (Fig. 3).

Varices, Oesophagus. Figure 3 Selective venogram following cannulation of the coronary vein demonstrating extensive uphill oesophageal varices in a patient with recurrent variceal haemorrhage.

Diagnosis

Upper GI endoscopy is used as the primary modality for the diagnosis and assessment of oesophageal variceal severity and bleeding risk. Varices are graded using a variety of criteria including size, colour, location and stigmata of bleeding. In addition, endoscopy is routinely used for the therapeutic management of varices. Paraoesophageal varices which lie outside the oesophageal wall are however not visualised during endoscopy. Cross sectional imaging techniques and in particular CT and MRI are both sensitive and specific for the diagnosis of moderate or large oesophageal varices including vessels lying adjacent to the oesophageal wall. In addition, these modalities allow evaluation of co-existing pathology within the thorax and abdomen. EUS when available allows accurate variceal assessment although is currently not routinely performed worldwide. The cross sectional imaging modalities, however, are not as sensitive as endoscopy for the diagnosis of small varices and the evaluation of bleeding risk. Angiography is no longer used routinely for the initial diagnosis, although it does play an important role in the subsequent management of varices. The use of contrast techniques in the diagnosis of oesophageal varices has diminished due to the widespread use of the other more sensitive imaging techniques.

Interventional Radiological Treatment

Following an initial haemorrhage the primary treatment for the majority of oesophageal varices remains a combination of endoscopy and medication. Interventional radiology however plays an important role in patients with recurrent variceal bleeding. Techniques including the embolisation of varices as well as the use of TIPSS. This latter technique is covered in more detail in Chapter TIPSS.

Vascular Anomalies

Two major categories are distinguished in the setting of vascular birthmarks: vascular tumors and vascular malformations. Vascular tumors include hemangiomas, Kaposiform hemangioendothelioma, and tufted angioma. Vascular malformations comprise high-flow malformations and slow-flow malformations. High-flow malformations may be arterial or arteriovenous. Slow-flow malformations include venous malformations, capillary and lymphatic malformations.

robert.hurst@uphs.upenn.edu

Definitions

Vascular disease of the spine and spinal cord comprises an important but uncommon group of conditions affecting this portion of the central nervous system (CNS). Spinal vascular malformations and cord ischemia represent the two most important manifestations of spinal vascular disease.

The optimal diagnosis and management of patients with spinal vascular disease requires consideration of these conditions in the appropriate clinical setting followed by imaging evaluation. Recent developments in noninvasive neuroimaging currently provide considerable information regarding all types of spinal vascular pathology. Nevertheless, digital subtraction spinal angiography retains an important role in both the diagnostic evaluation and neurointerventional treatment of those spinal vascular malformations characterized by arteriovenous shunting.

Pathology/Histopathology

Spinal Vascular Malformations

Spinal vascular malformations are a heterogeneous group of nonneoplastic vascular abnormalities that comprise from 5% to 15% of spinal mass lesions. Classification of spinal vascular malformations is based on angioarchitecture and hemodynamics. Lesions characterized by arteriovenous shunting include four major groups, designated Types I through IV.

Type I: ▶Spinal dural arteriovenous fistulas (SDAVF). These are the most common. SDAVF's (Type I) acquired lesions, not congenital malformations, which probably result from thrombosis of the extradural venous plexus. SDAVF develop within the dural covering of the spinal cord, usually at a nerve root sleeve. SDAVF receive arterial supply from a dural branch of a radicular artery with no arterial supply originating directly from the spinal arteries. The fistula drains into the pial veins of the cord, increasing pressure and dilating the pial venous system. The resulting venous hypertensive myelopathy impairs cord perfusion with hypoxia, edema, and disruption of the blood CNS barrier. Extensive and progressive cord dysfunction results, with poor correlation between the site of the SDAVF and the clinical level of neurological deficit.

Pathologic changes in the spinal cord involve both vascular structures and cord parenchyma. Hyalinization of vessels, arterialization of veins, vascular calcification, and thrombosis are common findings. Parenchymal changes include necrosis, myelin loss, gliosis, hemosiderin deposition, and Rosenthal fibers. Venous hypertensive myelopathy, likely from SDAVF, is believed to represent the underlying pathology in "subacute necrotizing myelopathy" or "Foix-Alajouanine Syndrome".

Types II and III: ▶Spinal cord arteriovenous malformations (SCAVM) were subdivided into two subtypes depending on whether they are confined to the spinal cord (Type II) or extend into the adjacent bone and soft tissue structures (Type III). SCAVM are congenital lesions characterized by arteriovenous shunting through a nidus on or within the substance of the spinal cord, whose arterial supply arises from vessels, which directly supply the cord. Dilated draining veins are present within the spinal subarachnoid space. SCAVM's most frequently affect the cervicothoracic region (5).

Type IV: ▶Spinal cord arteriovenous fistulas (SCAVF), a relatively rare type of lesion (1). (Fig. 1). SCAVF are uncommon congenital vascular malformations which usually present in the second through fourth decade (6). The lack of intervening nidus, intradural location, and supply from spinal arteries, differentiate SCAVF from both SDAVF and SCAVM.

In addition, ▶cavernous malformations (CM) without arteriovenous shunting may also affect the spinal cord. (Table 1). CM of the spine are pathologically identical to intracranial cavernous malformations, and consist of multiple cystic or sinusoidal vascular channels with very slow or stagnant blood flow. They are, well demarcated from surrounding tissue by a complete rim of hemosiderin stained gliosis and inflammatory cells. CM varies in size from several millimeters to over a centimeter in diameter (7).

Spinal cord ischemia is an uncommon cause of myelopathy with well under 1% of all strokes involving the spinal cord (8).

Clinical

In SDAVF, males are afflicted in 80–90% of cases with a usual presentation after the 6th decade. SDAVF usually occur between the T5 and L3 spinal levels.

Chronic progressive myelopathy, with ascending motor and sensory deficits affecting the lower extremities, characterizes the course of SDAVF (2). Back pain is inconstantly present. Prior to diagnosis bowel, bladder, and sexual dysfunction develops in the majority of patients. Consideration of SDAVF in the differential diagnosis and awareness of imaging findings are the most important factors in early diagnosis.

Hematomyelia or subarachnoid hemorrhage are common in SCAVM and may arise from arterial aneurysms, the nidus, or draining veins. Men and women are equally affected by SCAVM, which usually presents in the second or third decade.

Patients may present with progressive lower extremity deficits or acute hemorrhage in SCAVF.

Patients with CM most often present in the fourth decade, usually with discrete episodes of neurological dysfunction followed by variable recovery.

▶Spinal cord infarction usually involves the anterior spinal artery distribution and is most often characterized clinically by acute flaccid paralysis with decreased or absent pain and temperature sensation below the level of the lesion and sparing of posterior column function. Several clinical situations have been associated with spinal cord infarction, most commonly aortic dissection, and surgical repair of thoracoabdominal aortic aneurysms.

Imaging

In SDAVF, MRI shows abnormal cord signal intensity on T1- and T2-weighted images, often with abnormal enhancement and diffuse cord enlargement. The conus is uniformly involved although abnormal signal frequently extends into thoracic levels. Flow voids of the dilated pial veins on the cord surface are a more specific finding, and may often be made more conspicuous by enhancement (3).

Recent data support the use of contrast enhanced MRA to confirm the presence of SDAVF and identify the level of the fistula prior to angiography. Spinal angiography remains necessary to confirm the diagnosis and location of SDAVF as well as to plan or perform therapy (4).The spinal angiogram requires selective evaluation of lumbar and intercostal arteries to identify the location of the shunt. Early filling of the pial veins of the cord through the tiny shunt is the most important angiographic feature to confirm the presence SDAVF.

In SCAVM, flow voids representing feeding arteries, nidus, and draining veins are well seen in MRI (Fig. 1b). The extent of flow voids suggests whether at Type II or Type III lesion is present. Evidence of subacute or chronic intramedullary hemorrhage is frequently present as well as nonhemorrhagic intramedullary signal abnormality indicating gliosis, edema, or infarction. Although MRA sequences may detect high flow, specific feeding and draining vessels can be, rarely and reliably identified.

Spinal angiography is mandatory to define the angioarchitecture of the suspected SCAVM sufficiently to plan and carry out the treatment.

In SCAVF, flow voids indicate the enlarged feeding and draining vessels to the fistula on MRI, often with cord displacement or distortion as a result of mass effect. Intrinsic cord signal abnormality is frequent, often with enhancement and evidence of hemorrhage. Spinal angiography is necessary to determine the location of the fistula, its feeding arteries, and draining veins.

In CM, the central portion of the lesion is heterogeneous on both T1- and T2-weighted MR images. A rim

CM-Cavernous Malformation.

of low signal intensity representing iron storage products completely surrounds the lesion. The findings are characteristic and often permit specific diagnosis. The surrounding parenchyma may have abnormal signal intensity as a result of gliosis, edema, or syrinx. Following acute hemorrhage, the MRI appearance may be less specific and other differential considerations may require consideration. With typical MRI features, angiographic evaluation is unnecessary.

MRI findings in spinal cord ischemia are similar regardless of the etiology of the infarction (9). Cord signal abnormality and subtle enlargement in the acute stage are best seen in proton density and T2-weighted images. Signal abnormality may involve only the gray matter but often extends throughout the entire cross section of the cord. Enhancement may occur, especially involving the gray matter. In the chronic stages, cord atrophy may be present.

Interventional Treatment

Endovascular occlusion of SDAVF should be considered at the time of the diagnostic angiogram. Surgical treatment with coagulation or resection of the site of the nidus and surrounding dura also represents viable therapy for many patients.

Hepatic vascular pathologies; Primary circulatory liver disorders

Definition

Vascular disorders of the liver are several different pathological conditions including ►portal vein thrombosis, ►Budd–Chiari syndrome, ►veno-occlusive disease (VOD), ►peliosis hepatis, ►arterio-venous malformation, and ►congestive cardiac cirrhosis.

Pathology and Histopathology

Portal Vein Thrombosis

Etiological factors of portal vein thrombosis are slow flow secondary to cirrhosis, direct invasion by cancer, inflammatory changes in pancreatitis, sclerosing cholangitis, and abdominal infections, coagulation disorders, and surgical interventions. In chronic occlusion, the portal vein is retracted and dilatated, periportal collateral veins (►portal cavernoma) may be observed, while the chronic occlusion of a branch of the portal vein is usually accompanied by segmental atrophy and compensatory hypertrophy of other segments (1).

Budd–Chiari syndrome

The Budd–Chiari syndrome is a hepatic venous obstruction at any level from the small hepatic veins to the junction of the inferior vena cava and the right atrium. Outflow obstruction caused by hepatic VOD and cardiac disorders is excluded from this definition (2). Distinction is made between primary and secondary forms. The primary type is caused by endoluminal venous lesion (thrombosis, webs, endophlebitis) and is usually associated with underlying thrombogenic conditions. The secondary type includes obstruction originating from a lesion outside the venous system (tumor, abscess, cysts) and compressing or infiltrating the hepatic venous system. Venous compression can be complicated by thrombosis. Both in the primary and secondary forms, obstruction of the hepatic venous outflow tract results in increased hepatic sinusoidal pressure and portal hypertension. Hepatomegaly is usually seen. However, in later stage of Budd–Chiari syndrome peripheral atrophy associated with caudate and central hypertrophy is usually observed. Centrilobular necrosis is histological observed. In chronic cases the affected areas become fibrosed and shrink in size (2, 3).

Veno-Occlusive Disease

Hepatic VOD is a common complication of bone marrow transplantation (BMT). It is characterized by obstruction of small and medium-size intrahepatic veins due to vasculitis. It differs from Budd–Chiari syndrome in that the major hepatic veins and inferior vena cava primarily remain patent. It is usually associated with the use of chemotherapeutic agents or radiation and secondary to progressive inflammation with deposition of coagulation factors, red cells, and hemosiderin-laden macrophages within terminal hepatic venules resulting in a nonthrombotic venule occlusion (4). Histologic features consist of centrilobular sinusoidal fibrosis followed by necrosis of the zone 3 hepatocytes.

Peliosis Hepatis

Hepatic peliosis is a rare benign pathological entity characterized by focal, multifocal, segmental, or diffuse dilatation of liver sinusoids. At gross examination multiple cyst-like, blood-filled cavities within hepatic parenchyma are observed (1). Although several theories, including outflow obstruction of the blood flow at the sinusoidal level, hepatocellular necrosis, or direct lesions of the sinusoidal barrier, have been postulated to explain its etiology, the pathogenesis of peliosis hepatis is still unclear.

Clinical Presentation

Portal Vein Thrombosis

In most cases, portal vein thrombosis occurs slowly and silently. Biochemical tests of the liver are normal or only mildly elevated. Ascites and encephalopathy are uncommon. Splenomegaly and esophageus varices are the most common clinical findings and gastrointestinal hemorrhage for portal hypertension is usually the first manifestation of portal vein thrombosis. Rarely, thrombosis extends from the portal vein to the mesenteric arcades, leading to bowel ischemia and infarction.

Budd–Chiari Syndrome

Since the extent and rapidity of the hepatic vein occlusion and of the development of venous collateral circulation is highly variable, fulminant, acute, subacute, or chronic clinical presentation may be observed (3). The acute and fulminant forms are associated with an acute thrombosis of the main hepatic veins and the etiologic factors are related to hypercoagulability of blood. Patients rapidly develop hepatomegaly, intractable ascites, jaundice, and abdominal pain leading to liver failure and hepatic encephalopathy. The subacute and chronic types are most common and have an insidious onset; since the development of venous collateral vessels, ascites, and hepatic necrosis may be minimal and splenomegaly or esophagogastric varices may represent the only clinical findings. The degree of aminotransferase, alkaline phosphatase and

V

bilirubin levels elevation is variable, depending on the rapidity of the onset. Patients with Budd–Chiari syndrome who have deteriorating liver function and complications usually need to undergo liver transplantation.

Veno-Occlusive Disease

VOD occurs in over half of BMT patients. Risk factor include preexisting liver disease or liver function test abnormalities and underlying infection or antibiotic use during conditioning chemotherapy. Jaundice, weight gain, and ascites occurring within the first 3 weeks after BMT represent the typical clinical manifestations. At laboratory exams, elevated transaminases and hyperbilirubinemia (direct bilirubin >2) are observed (1, 4). In severe cases, multiorgan failure with pulmonary infiltrates, pleural effusions, congestive heart failure (CHF), and renal failure may occur.

Peliosis Hepatis

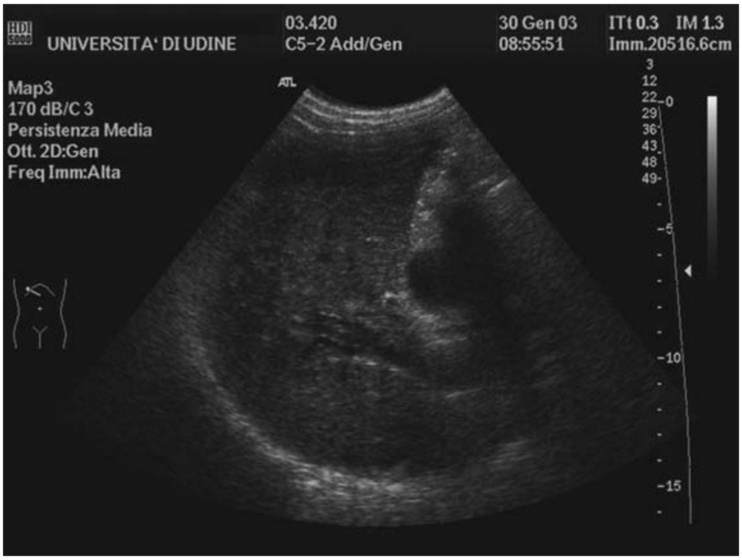
Peliosis hepatis commonly occurs in patients treated with anabolic steroids, corticosteroids, or oral contraceptives. The disease is associated with chronic wasting diseases such as tuberculosis, hematological malignancies, diabetes, acquired immunodeficiency syndrome (AIDS), posttransplant immunodeficiency, and exposure to toxic agents (1, 5). Hepatic peliosis is usually asymptomatic and focal liver lesions are discovered incidentally. However, in rare cases, the lesions may be revealed by major complications such as liver failure, portal hypertension, or hemorrhage.

Imaging

Portal Vein Thrombosis

Ultrasound (US) features are echogenic thrombus within the lumen of the vein, demonstration of portal vein collateral circulation, enlargement of the thrombosed segment of the vein, and the cavernomatous transformation of the portal vein (Fig. 1). Color Doppler US is a useful tool for detection of portal vein thrombosis (Fig. 2). It is also useful for differential diagnosis between nonneoplastic and neoplastic thrombosis in presence of hepatocellular carcinoma. The demonstration of arterial flow within the thrombus is specific for malignancy.

Nonenhanced computed tomography (CT) may show focal high density in enlarged portal system in acute thrombosis while chronic venous thrombosis appears as linear areas of calcification within the thrombus. A filling defect in the vessel lumen during the portal venous phase represents the typical finding of portal vein thrombosis on contrast-enhanced CT (Fig. 2). In a patient with hepatocellular carcinoma enhancement of the thrombus during the arterial phase is suggestive for neoplastic thrombosis. Typically, a regional parenchymal hyperdensity due to a compensatory increase in arterial blood flow to the segments poorly perfused by the portal vein is observed during the arterial phase while the locally decreased portal vein perfusion results in a hypodense appearance on the portal-venous phase. On magnetic resonance (MR), acute thrombosis manifests as absent flow signal void within a normal or dilated vein, generally associated with edge enhancement of the thrombosed



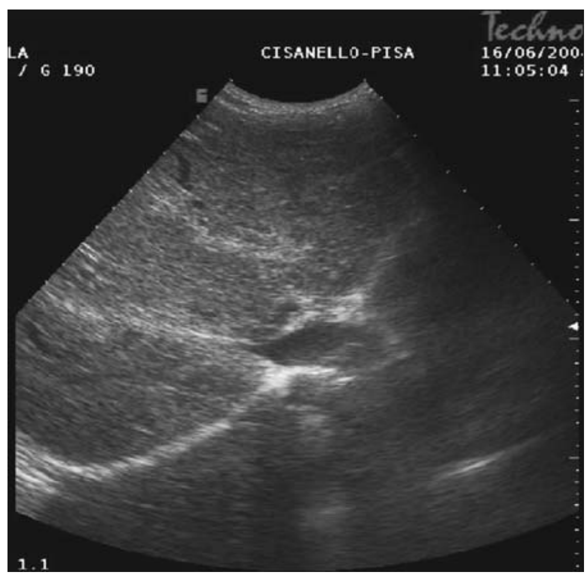
Vascular Disease, Spine. Figure 1 US scan of hilum hepatis: for chronic occlusion, the portal vein is retracted and we can see dilated periportal collateral veins (portal cavernoma).

Vascular Disease, Spine. Figure 2 **A filling defect in the vessel lumen during the portal venous phase represents the typical finding of portal vein thrombosis on contrast-enhanced CT. We can see axial scan and coronal MPR reconstruction. At US scan features are echogenic thrombus within the lumen of the vein with enlargement of the thrombosed segment.**

vein because of blood flowing around the thrombus, or inflammatory response of the venous wall. The clot is isointense or hyperintense on T1-weighted images, and hyperintense on T2 (1). Moreover, using angiographic sequences (contrast-enhanced 3D MR portography), MR provides detailed information not only about the location and length of portal vein obstruction but also about portal collateral pathways.

Budd–Chiari Syndrome

Doppler US is the modality of choice for diagnosis of Budd–Chiari syndrome, with a sensitivity of more than 85% (3). A spectrum of hepatic venous abnormalities (hepatic veins tortuosity, thrombosis, flow reversal, and monophasic flow waveform) may be observed and the association with intrahepatic or subcapsular portosystemic shunts and venous collaterals is suggestive for the diagnosis (2). US may demonstrate the occlusion of the hepatic veins due to thrombus or tumor as well as the narrowing of the inferior caval vein due to a web, appearing as an echogenic structure without acoustic shadowing (Fig. 3). Finally, US may demonstrate hepatomegaly, ascites, and parenchymal changes such as necrotic or fibrotic areas. CT scan and MR imaging allow a most extensive and accurate evaluation of the parenchymal changes. A heterogeneous enhancement of the liver parenchyma, hypertrophy of the caudate lobe, direct findings of hepatic venous occlusion and extrahepatic findings such as ascites, splenomegaly, and portosystemic collateral vessels represent the most common features of Budd–Chiari syndrome on both CT and MR contrast-enhanced imaging. Moreover, MR, by the use of angiographic sequences, allows also an extremely accurate evaluation of the vascular abnormalities and is a highly sensitive tool for the diagnosis of hepatic veins thrombosis (3).



Vascular Disease, Spine. Figure 3 **US scan demonstrates the occlusion of the hepatic veins that appear as echogenic structures.**

Veno-Occlusive Disease

The diagnostic imaging study of choice is US with Doppler modalities. Nonspecific US findings have been described, including ascites, gallbladder wall thickening, and hepatosplenomegaly. Moreover, the absence of obstruction of hepatic veins or inferior cava at Doppler US or MR imaging enables differential diagnosis between Budd–Chiari syndrome and VOD (4).

Peliosis Hepatis

Imaging findings are variable depending on differing pathological patterns and on often concomitant liver steatosis. On US, numerous poorly defined foci of varying hypoechogenicity may be observed; however, these findings are nonspecific and may simulate hepatic metastasis, cirrhosis, hemangiomatosis, or adenomatosis.

The CT and MR findings may differ according to the size of the lesions, the extent of communication with the sinusoids, the presence or absence of thrombi within the cavities, and the presence or absence of hemorrhage (5). However, multiple small hepatic lesions with variable enhancement represent the most common findings, while larger and even solitary lesions are uncommon. The lesions appear usually as irregular, hypodense regions on unenhanced CT scan and, occasionally, hyperdense spots for focal hemorrhage may be observed. After contrast medium administration, a slight peripheral enhancement is usually seen. A typical finding of hepatic peliosis is the lack of mass effect on hepatic vessels.

On MR, the multiple hepatic foci in peliosis hepatis show a high signal on T2-weighted images and a variable signal on T1-weighted images, presumably reflecting various stages of subacute hemorrhage. A late and slow but intense enhancement is observed on contrast-enhanced MR imaging.

Diagnosis

Portal Vein Thrombosis

Portal vein thrombosis is usually asymptomatic and diagnosis is mainly done by imaging. Doppler US is the first imaging modality used. In patients who are candidates for surgery, that is, for portosystemic shunt procedures, a more accurate imaging evaluation covering the whole portal venous system is required. Traditionally, assessment of the portal venous system has been achieved with intraarterial splenoportal and mesentericoportal angiography, but, recently, the value of MR angiography as another noninvasive procedure for the assessment of the portal venous system has been increasingly recognized.

Budd–Chiari

The diagnosis of Budd–Chiari syndrome is established only upon demonstration of an obstructed hepatic venous outflow tract. Doppler US has a sensitivity of more than 85% and should be the first line of investigation, while the association of Doppler US and MR allow the diagnosis in almost all cases and an optimal delineation of the venous obstruction is usually obtained (2).

In a minority of patients, mostly individuals with cirrhosis, liver biopsy may be required to firmly establish the diagnosis and to rule out other processes such as VOD and cirrhosis of other etiologies.

Direct venography is no longer considered necessary. However, since it allows a precise delineation of outflow obstruction and pressure measurements, venography should be performed when percutaneous or surgical shunting is considered.

Venous-Occlusive Disease

Diagnosis can usually be made based on clinical criteria. Direct bilirubin 2 mg/dL, hepatomegaly and weight gain due to fluid accumulation occurring within 20 days of transplantation are the typical clinical findings. The diagnosis can only be made when hyperacute graft-versus-host disease, sepsis, cardiac failure, and tumor infiltration have been ruled out. US can exclude tumor infiltration and biliary tract disease and confirm hepatomegaly and ascites while color Doppler US, MR imaging, and angiography can accurately determine the level of involvement enabling the differentiation between Budd–Chiari syndrome and VOD (4). Finally, transvenous liver biopsy is required in patients with thrombocytopenia posttransplantation to differentiate VOD from acute graft-versus-host disease.

Peliosis Hepatis

Imaging findings are often not sufficiently specific and histology is the only certain way of making the diagnosis. However, the risk of performing a needle biopsy in peliosis hepatis is unclear and severe hemorrhage and even fatal outcome following needle biopsy have been reported.

Angiodysplasia; Arteriovenous malformation; Vascular ectasia

Definition

Vascular disorders of the gastrointestinal tract include occlusive, aneurysmal diseases, and congenital malformations of the arterial or venous mesenteric vessels. These disorders are rare and difficult to diagnose and therefore account for many malpractice claims. Symptoms can be divided into two groups: ischemic and hemorrhagic.

Ischemic diseases can lead to chronic or acute intestinal ischemia. The small bowel and the right colon are the parts of the digestive system most sensitive to ischemia. Etiologies of acute mesenteric ischemia can be divided into arterial occlusive diseases, venous thrombosis, and nonocclusive arterial diseases (1). Arterial occlusions are related either to embolism in the superior mesenteric artery, mainly from a cardiac origin, or to thrombosis of the superior mesenteric artery. Venous thrombosis of the superior mesenteric veins is either primary, due to coagulation disorders, or related to various abdominal diseases favoring venous thrombosis, such as cirrhosis and intraperitoneal infectious diseases. Nonocclusive mesenteric ischemia means that there is an insufficient oxygen supply to the digestive wall despite patent mesenteric vessels. As a result of systemic hypoperfusion (cerebral and/or cardiac), mesenteric vasospasm occurs to preserve cardiac and cerebral blood flow. Therefore, this condition is encountered in severely ill patients with advanced cardiac insufficiency and is favored by the use of vasoconstrictive agents.

Chronic mesenteric ischemia occurs due to occlusion or stenosis of at least two of the three digestive arterial trunks, including the superior mesenteric artery (celiac trunk, superior, and inferior mesenteric artery). The main cause is atheroma (2).

Gastrointestinal bleeding can be caused by many pathologies, including cancers and inflammatory diseases, but some vascular diseases such as ►angiodysplasia can cause recurrent bleeding in elderly patients (3). Angiodysplasias are acquired capillary vascular malformations encountered mainly in the cecum (78%), jejunum (10%), ileum (5%), and stomach (4%) in elderly patients.

Pathology/Histopathology

Acute mesenteric ischemia can lead to various degree of ischemia of the bowel wall, from transient mucosal ischemia to irreversible bowel wall necrosis. Arterial etiologies first induce digestive mucosal ischemia, which extends progressively to the muscularis mucosa and to the serosa. In the early phase, the intestine is pale and spastic; in later phases, the loops are dilated, with a gray appearance and edematous infiltration of the mesocolon. In the late phase, the loop is atonic and dilated, with focal hemorrhage in the bowel wall and focal areas of necrosis. Thirty minutes of ischemia are sufficient to produce necrosis. Venous etiologies are characterized by early mesenteric edema and bowel wall hemorrhage. Thrombosis of distal venous branches is mandatory for producing ischemia.

In chronic mesenteric ischemia, histopathology of the digestive wall is usually normal. Analysis of the main digestive trunks shows various degrees of occlusion of the main trunks. Occlusion of the celiac trunk is usually proximal, favored by compression from a median arcuate ligament, and is found in 15–24% of patients. Occlusion of the superior mesenteric artery is usually found in the first 5 cm after its origin.

Angiodysplasia is found in the submucosa and is characterized by one or multiple dilated submucosal veins and a cluster of capillaries and small arteries.

Clinical Presentation

Acute mesenteric ischemia has various clinical presentations. The most common symptom is a sudden pain localized in the periumbilical region of the right iliac fossa. This pain is usually severe and induces agitation. It occurs in older patients (mean age 70 years) with multiple cardiac and vascular comorbidities. Cardiac disease, myocardial infarction, and cerebrovascular disorders, and congestive heart failure are found in 91%, 27%, 23%, and 45% cases of mesenteric embolism, respectively. The association of sudden abdominal pain with multiple cardiovascular events in the previous

V

history is highly suggestive of acute mesenteric ischemia. If the diagnosed is delayed, peritonism as well as shock can be encountered. Patient survival is inversely correlated with diagnostic delay.

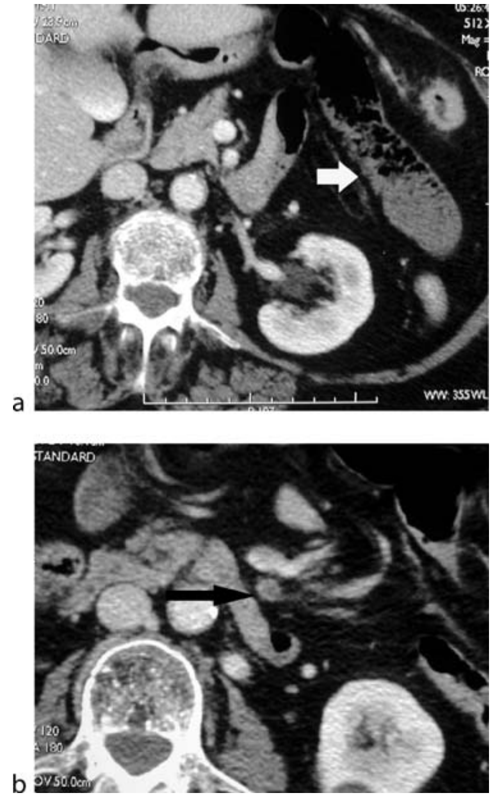
Clinical symptoms of chronic mesenteric ischemia include so-called ▶intestinal angina. Patients with intestinal angina complain of periumbilical abdominal pain that starts approximately 30 min after eating and lasts for 1–2 h. The patient may recognize the relationship between eating and abdominal pain, resulting in a fear of eating and subsequent weight loss. Some patients, however, will present with anorexia and weight loss without complaints of abdominal pain. Symptoms may be less specific, such as diarrhea or vomiting, resulting in delayed diagnosis.

Angiodysplasia is usually silent, but bleeding may occur in up to 10% of cases. Depending on the lesion's localization and the volume of blood loss, symptoms may range from hematemesis to melena as well as hematochezia or only symptoms of chronic anemia.

Imaging

For the diagnosis of acute mesenteric ischemia, the most critical issue is to save time and not delay treatment. Plain X-ray films are usually done at the onset of acute abdominal pain. Although useful for eliminating other causes of abdominal pain such as nephrolithiasis or bowel perforation, they are insufficient for diagnosing acute mesenteric ischemia. Ultrasound (US) and Doppler of mesenteric vessels are nonspecific and very difficult to perform in this situation and should not be done. Computed tomography (CT) and, more recently, multidetector CT of the abdomen are now recommended (4). They allow visualization both of bowel wall ischemia (wall thickening with submucosal edema) and necrosis (lack of enhancement of the bowel wall after injection of contrast media, pneumatosis; Fig. 1a) and of its vascular etiology, with an embolus visible as a filling defect in the lumen of the superior mesenteric artery (Fig. 1b) or a thrombosis of the superior mesenteric artery or vein. If CT does not provide sufficient information for treatment, angiography can be performed to visualize mesenteric vessels.

Imaging of chronic mesenteric ischemia relies mainly on Doppler US. In thin patients, this technique is able to depict stenoses of the superior mesenteric artery, celiac axis, and inferior mesenteric artery with excellent sensitivity. The diagnosis of hemodynamically significant stenosis is based on velocity measurements at the origin of these trunks. A velocity of over 275 cm/sec in the superior mesenteric artery and 200 cm/sec in the celiac axis is specific. The relationship between the stenoses and the pain usually remains unresolved until correction of the stenoses, either by intravascular methods or surgical bypass techniques. Angio-CT and magnetic resonance angiography have also been advocated, but their performance does not seem superior to Doppler US.



Vascular Disorders, the Gastrointestinal Tract. Figure 1 A 67-year-old woman who presented with sudden acute abdominal pain. (a) Computed tomography slice after injection of contrast media shows a dilated jejunal loop without enhancement of the bowel wall (*white arrow*), suggesting bowel wall ischemia. (b) Zoom view of the mesenteric vessel shows occlusion of the superior mesenteric artery by an embolus (*bold arrow*).

Diagnosis of angiodysplasia is usually done by endoscopy, but during bleeding episodes, lesions can be obscured by the intestinal contents and blood clots. Mesenteric angiography is the method of choice, showing a nidus typically located on the antimesenteric border of the right colon that is associated with early filling of a large adjacent drainage vein. The feeding artery is inconsistently enlarged. Bleeding becomes visible as a pooling area of contrast persistent on late images when bleeding exceeds 0.5 mL/min. CT has recently been proposed to demonstrate these lesions. On the arterial phase after injection, the filling defect as well as the large draining vein can be visible. The performance of CT in detecting angiodysplasia is unknown.

Nuclear Medicine

Nuclear medicine has no role in diagnosing acute or chronic mesenteric ischemia, but it has been proposed for diagnosing chronic bleeding of unknown origin. Technetium-99m-labeled red blood cell scintigraphy has proved to be efficient in localizing the bleeding site if a pooling is visible in the first 2 h after injection when bleeding exceeds 0.1 mL/min. This technique allows the bleeding site to be localized but does not give information about the bleeding etiology. There is no specific sign on technetium-99m-labeled red blood cell scintigraphy for angiodysplasia.

Diagnosis

The diagnosis of acute mesenteric ischemia should be suspected when an acute onset of abdominal pain is associated with a previous history of a cardiovascular disorder in an elderly patient. Diagnosis is usually done by CT because both bowel wall ischemia and the cause of the ischemia are visible. Nowadays, mesenteric angiography is reserved for equivocal cases and/or associated treatment. When signs of peritonism are concomitant, laparoscopy, or laparotomy can be proposed directly without preoperative imaging.

The diagnosis of chronic mesenteric ischemia relies on the association of typical symptoms associated with weight loss and Doppler signs of mesenteric vessel stenoses or occlusions. Because symptoms are aspecific (abdominal pain and weight loss are encountered in many abdominal cancers) and stenoses of two mesenteric vessels can be completely asymptomatic due to collateral vessel recruitment, the final diagnosis can be made only after having treated the stenoses if symptoms disappears afterward.

The diagnostic strategy of lower gastrointestinal bleeding is based on the results of endoscopy. Gastroscopy and colposcopy are typically always performed. Angiodysplasia usually presents at endoscopy as an intense red stellate flat lesion. If the bleeding site is not localized and bleeding persists, mesenteric angiography can be proposed to detect the lesion and embolize the feeding artery.

Interventional Radiological Treatment

Endovascular treatment of acute mesenteric ischemia is the treatment of choice if type B aortic dissection is the etiology. In other situations, endovascular methods should be discussed on a case-to-case basis. The use of thrombolytic medication is not without risk if necrosis of the bowel wall is already present.

Endovascular treatment of chronic mesenteric ischemia has now become widely accepted when the lesions are stenoses and not occlusions. Stent placement allows similar symptom relief as well as a long-term symptom-free survival rate.

Vascular Imaging and Vascular Interventional Radiology

Dierk Vorwerk
Department of Diagnostic and Interventional Radiology, Klinikum Ingolstadt, Ingolstadt, Germany
dierk.vorwerk@klinikum-ingolstadt.de

Imaging of vascular structures was a very early goal of radiologists before researchers were able to introduce fast imaging facilities, fluoroscopy, nontoxic contrast media, and suitable selective catheter techniques into radiology, which were all necessary for the depiction of arteries and veins.

After definition of these invaluable tools, conventional angiography became one of the early revolutionizing techniques that was added to plain-film radiography, and until the development of computer tomography (CT), it was one of the most important tools for the specific diagnosis of cerebral and abdominal problems.

In the meantime, diagnostic angiography—albeit refined by digital subtraction techniques—has been widely replaced by cross-sectional imaging in the diagnosis of organ-related diseases and will be more and more replaced by CT angiography, magnetic resonance (MR) angiography, and duplex ultrasound for many purely arterial or venous problems.

There are, however, some special diagnostic problems that still require selective angiography for detailed diagnosis, such as cerebral vascular dysplasias or searching for sources of bleeding.

Selective arteriography is still the guiding tool for intravascular interventional radiology, and to date there is no alternative available for this purpose.

Anatomically, vascular imaging includes arteries, veins, arteriovenous connections such as hemodialysis fistulas and grafts, large visceral veins, and pulmonary veins and arteries.

Classical imaging modalities for vascular imaging are nonsubtracted and subtracted angiography and phlebography preferably with direct contrast medium injection. Intravenous digital subtraction angiography (DSA) is no longer accepted as a sufficient diagnostic tool, with very few exceptions. Further imaging tools are duplex sonography with its modifications such as color-coded and power duplex, CT angiography, and MR angiography.

In arteries, pathological patterns include acute disease with arterial rupture, perforation, embolic or thrombotic occlusion, and formation of pseudoaneurysms. Chronic arterial disease shows chronic occlusions, atherosclerotic stenoses, and chronic aneurysms as well as inflammatory disease.

In veins, acute and subacute thrombosis, rarely stenoses, collateral pathways, and inborn variations and changes are found.

In hemodialysis fistulas and grafts, stenoses and thrombotic occlusions as well as aneurysm formation are relevant findings.

The choice of the primary imaging tool depends on the location of the disease. In intracranial cerebral arteries, MR angiography or CT angiography are the modalities of choice, and selective angiography is used for specialized indications or in connection with an interventional procedure. The same is true for the intracranial venous structures. Extracranial cerebral arteries are diagnosed with duplex sonography, MR or CT angiography, and selective angiography, particularly in preparation for interventions.

In the thorax, imaging of the large arteries and veins is a domain for CT and MR angiography. Small vessels such as bronchial arteries require selective angiography.

In the abdomen, visceral arteries and veins are usually well depicted by CT angiography, duplex sonography, and MR angiography; in arteries, however, selective arteriography is used to verify the diagnosis or to intervene.

For peripheral arteries, DSA is a very reliable diagnostic tool, depicting location of lesions as well as their morphology, but it is being replaced by MR angiography. Duplex sonography as a sole diagnostic tool is also frequently used, but lacks demonstrability and is time consuming. For peripheral arterial interventions, angiography is the working modality. In peripheral veins, duplex sonography is the modality of choice and phlebography is preserved for nondiagnostic cases.

Vascular interventional radiology involves all vascular areas and vascular systems. The guiding tool is still contrast-enhanced X-ray fluoroscopy, and no other tool is yet available that gives a comparable timely resolution and precision.

Treatment options include reopening of stenosed and occluded arteries and veins with different tools such as balloon angioplasty, stent implantation, and mechanical and chemical thrombolysis as well as temporary or permanent occlusion of vessels by embolization with particles, fluids, or coils or with chemoembolization. Exclusion of aneurysms is performed by stent graft implantation or coil embolization. Access for percutaneous arterial interventions is transfemoral, transbrachial, transpopliteal, or rarely by direct puncture. For venous interventions, a transfemoral, transbrachial, or transparenchymal access may be used. In hemodialysis problems, direct puncture is preferred.

Interventional vascular procedures in arteries have been accepted by the medical community as a valuable treatment option in many regions and as the treatment of choice particularly in the iliac arterial region. Embolization procedures are frequently used as life-saving interventions in cases of acute bleeding.

Vascular Origin Malignant Tumors

Group of tumors with lower to higher grade malignancy including hemangioendothelioma, hemangiopericytoma, angiosarcoma, Kaposi sarcoma.

▶Neoplasms, Soft Tissues, Malignant

Vasculitis

Vasculitis is an inflammation of blood vessels caused by autoimmune disorders, infections, exposure to radiation or toxins and other conditions.

▶Oral Cavity, Inflammatory Diseases

VB

Vacuum biopsy or vacuum assisted biopsy is a form of biopsy where several large specimens (usually 11 or 8G) can be taken from the breast under stereotactic or sonographic guidance.

▶Carcinoma, Ductal, *In Situ*, Breast

VCUG

▶ Voiding Cystourethrography

VE

▶ Virtual Endoscopy

Vector

A vector is a vehicle or carrier used to deliver genetic material into the body for gene therapy.
▶ Local Drug and Gene Delivery with Microbubbles

VEGF

Vascular epithelial growth factor.
▶ Carcinoma, Ductal, *In Situ*, Breast

Veno-occlusive Disease

Hepatic veno-occlusive disease (VOD) refers to the obstruction of small and medium-size intrahepatic veins. It is a common complication following bone marrow transplantation and it is usually associated with the use of chemotherapeutic agents or radiation. Diagnosis can usually be made based on clinical criteria. Commonly used clinical criteria for the diagnosis are direct bilirubin ≥ 2 mg/dL, hepatomegaly, and >2% weight gain due to fluid accumulation; the diagnosis requires 2 of 3 criteria, occurring within 20 days of transplantation. US can exclude tumor infiltration and biliary tract disease and can confirm hepatomegaly and ascites. Transvenous liver biopsy is required in patients with thrombocytopenia posttransplantation to differentiate VOD from acute graft-versus-host disease.
▶ Vascular Disorders, Hepatic

Venous Stasis

Venous dysfunction causes swelling of the lower extremities with dermatitis and ulceration. In advanced stages of the disease, periostitis may occur at tibia, fibula, femur, metatarsal bones, and phalanges. The periosteal appositions have an undulated osseous contour and cortical thickening appears as the appositions are not well separated from the original cortex.
▶ Hypertrophic, Osteoarthropathy

Venous Stenosis

Focal narrowing of a segment of the efferent vein or of the arteriovenous anastomosis mostly owing to intimal hyperplasia; other causes of stenoses are focal fibrosis of the venous wall secondary to chronically high pressure in the venous circulation or to repeated traumatic needle punctures during hemodialysis. Finally, a central venous stenosis is nearly always the result of neointimal thickening and formation of a fibrous sheath as a result of a previously placed indwelling dialysis catheter or central line. If this stenosis becomes significant or eventually critical, the dialysis session will become insufficient and intervention is mandatory to rescue the fistula.
▶ Fistula, Hemodialysis

Venous Thromboembolic Disease

Ventral Induction Anomalies

▶ Congenital Malformations, Cerebrum

Verbiest Syndrome of Lumbar Spine

▶ Stenosis, Spinal

Vertebral Body Degeneration

According to Modic there are three types of vertebral body degeneration changes, which can be well assessed on MR images. Type 1 lesions (aseptic spondylodiscitis) exhibit decreased signal on T1-weighted images due to increase in bone marrow water content, and increased water signal on T2-weighted images. Type 2 changes (fatty degeneration) have increased fat signal on T1-weighted images and intermediate signal on T2-weighted images (high fat signal with turbo spin-echo T2 weighted images). Type 3 (osteosclerosis) have low signal on both T1 and T2-weighted images as well as high density on plain films and CT. All three types of lesions are located adjacent to the endplates of the vertebral bodies.

Other common manifestations of vertebral body degeneration are osteophytes, which can protrude into the spinal canal and intervertebral foramina and are easily detected with plain films, CT or MRI.

▶Degenerative Conditions, Spine

Vertebral Steal Latent or Temporary

Reversed flow in the vertebral artery, which is induced after exercise or hyperemia of the ipsilateral arm.

▶Steal Syndrome Vertebral

Vertebral Steal Permanent

Flow reversal in the vertebral artery that does not depend on the patient's state of activity or other parameters.

▶Steal Syndrome, Vertebral

Vesicoureteral Reflux

Pathological condition in which, during voiding, some urine goes back up into the ureters and possibly up to the kidneys. Reflux exposes the kidneys to infection. The injury to the kidney may result in renal scarring. Untreated reflux on both sides can, in the most severe instances, result in kidney failure requiring dialysis or kidney transplantation.

▶Contrast Media, Ultrasound, Applications in Vesicoureteral Reflux
▶Reflux, Vesicoureteral, Adults
▶Reflux, Vesicoureteral, Childhood
▶Urethra, Stenosis

Vesicoureteric or vesicoureteral reflux

▶Reflux, Vesicoureteral, Childhood

Vibration-Induced White Finger

Symptoms similar to that of Raynaud's syndrome (blanching of the fingers, coolness, paresthesias) but occurring in patients who use vibratory tools.

▶Ischemia, Brachial

Virtual Cystoscopy

Technique of virtual endoscopy applied to urinary bladder.

▶Neoplasms, Bladder

Virtual Endoscopy

New method of diagnosis using computer processing of 3D image datasets (such as CT or MRI scans) to provide simulated visualization of patient specific organs similar or equivalent to those produced by standard endoscopic procedures.

▶Neoplasms, Bladder

Vitamin Deficiency

Dorothy Bulas
Division of Diagnostic Imaging and Radiology, Children's National Medical Center, The George Washington University School of Medicine and Health Sciences

Synonyms

Rickets—vitamin D Deficiency; Scurvy—vitamin C Deficiency

Definitions

There are several vitamin deficiencies that can result in skeletal changes.

The most common deficiencies that will be described include deficiencies in vitamin D and C.

Vitamin D deficiency results in under mineralization of the boney matrix-osteomalacia. *Rickets*, "to bend," is the result of decreased mineralization of the growing physis resulting in delayed skeletal development and growth. Rickets is found in infants and children prior to growth plate fusion, while osteomalacia can occur at any age.

Vitamin C (ascorbic acid) deficiency results in *scurvy*. In the 1700s, a British naval surgeon established that oranges and lemons would cure scurvy. By the 1900s, infant scurvy was eradicated when heated formulas (boiling destroys vitamin C) was supplemented with fresh fruits or vegetables.

Pathology/Histopathology

Rickets is caused by a deficiency or abnormal metabolism of vitamin D or abnormal excretion of phosphate leading to bony deformities and hypocalcemia (Table 1). The physis is a region of chondrocyte hypertrophy, proliferation and vascular invasion which then converts into primary bone spongiosa. Vascular invasion requires mineralization of the physeal cartilage. If calcium or phosphorus is deficient, the growth plate thickens, the chondrocytes become disorganized, and osteoid accumulates. The metaphysis widens, compensating for decreased bone strength. Vitamin D requires activation to regulate absorption and renal retention of calcium and phosphorus, and modulates osteoblastic function. In humans, vitamin D can be exogenous or endogenous. Vitamin D is synthesized endogenously in the skin following sunlight exposure. Dietary vitamin D from plants is known as ergocalciferol—vitamin D_2 and that from animal is known as cholecalciferol—vitamin D_3. Both vitamins D_2 and D_3 must be further metabolized. Activation occurs by hydroxylation at two sites of the vitamin D molecule. Hydroxylation at the 25th site occurs in the liver (25-OHD). Hydroxylation at the first site takes place in the kidneys and is regulated by 25-hydroxy D-1 alpha hydroxylase. 1,25-Dihydroxycholecalciferol is the active form of vitamin D (1,25-(OH)2D). This process is regulated by parathyroid hormone (PTH) which inhibits 25-hydroxy D-1 alpha hydroxylase. If PTH is suppressed, 25-hydroxy vitamin D can be converted to a less potent 24,25-dihydroxy vitamin D.

Vitamin Deficiency. Table 1 **Causes of rickets**

Deficient intake: Dietary, lack of sunlight
Poor absorption: Malabsorption, antacids, anticonvulsants, renal insufficiency, hepatic insufficiency, cystic fibrosis
Increased excretion: Renal tubular acidosis, renal tubular damage
Medication: Anticonvulsants, fluoride, diphosphonate
Chronic renal failure
Hereditary: X-linked hypophosphatemic rickets, type I and II pseudovitamin D deficiency

Very low birth weight infants can develop metabolic bone disease of prematurity. The need for calcium and phosphorus is at its peak in the third trimester. If the dietary calcium is low, renal alpha1 hydroxylase is activated and 1,25 hydroxy vitamin D is made, increasing gastrointestinal uptake of calcium and inhibiting PTH release. There is a net decrease in bone mass unless adequate amounts of calcium and phosphorus are supplemented. This is particularly true if breast milk is the primary source of nutrition as it contains less than half of the needed calcium and phosphorus for growing premature infants.

Scurvy is caused by a deficiency of vitamin C. Vitamin C is required for the formation of hydroxyproline, crucial for collagen formation which makes up 90% of mature boney matrix. Lack of collagen severely affects bone formation in childhood, resulting in scurvy and osteoporosis in adults. Defective collagen synthesis also leads to poor dentine formation, hemorrhage of gums, and diffuse bleeding. The pathophysiological changes in scurvy are the results of depression of normal cellular activity. Osteoblastic activity is suppressed with failure to form osteoid, yet resorption continues with resultant osteoporosis. At the physis, cartilage proliferation is decreased yet mineralization is unimpaired, thus the zone of provisional calcification appears wide and dense. Changes around the epiphyseal ossification center result in a thin ring of increased density. Vascular invasion in the zone of provisional calcification with suppressed osteoblastic activity results in decreased density in the zone of primary and secondary spongiosa. The zone of provisional calcification extends beyond the margins of the metaphysis resulting in periosteal elevation and marginal spur formation. Increased capillary fragility results in subperiosteal hemorrhage elevating the periosteum. These changes are most marked in most active endochondral bone growth. Intraarticular hemorrhage is rare as periosteal attachment to the growth plate is strong.

Clinical Presentation

Rickets: With the introduction of dietary supplements, the incidence of rickets has decreased significantly. Cases still occur, particularly in breastfed infants with limited sunlight exposure who are not supplemented with vitamins. The recommended vitamin D intake is 200 IU for infants, yet breast milk contains less than 60 IU/L. Mothers with vitamin D deficiency can result in decreased transfer to the fetus. Muslim women wearing veils are at high risk of vitamin D deficiency secondary to under-exposure to sunlight. Blacks are more affected than whites possibly due to decreased penetration of ultraviolet light. Premature infants are at highest risk with an incidence of 5–20% particularly when triphosphopyridine nucleotide total parental nutrition (TPN)-dependent.

Rickets occurs in children whose growth plates have not yet closed. Children present with genu varum or anterior tibial bowing. Late teeth eruption, scoliosis, thickened wrist, and ankles may be noted. Ligaments are lax and muscle tone decreased. Rarely, hypocalcaemic seizures may be a presenting symptom. Vitamin D resistant rickets is found in children older than 30 months of age. These children are short and bow-egged. Ectopic calcification can be featured.

Scurvy is quite rare now due to vitamin C supplementation. Patients who are elderly or alcoholic with diets lacking in fresh fruits and vegetables are most vulnerable. It rarely occurs in children less than 6 months of age. Initial symptoms include poor weight gain, anorexia, diarrhea, and tachypnea. More specific symptoms include bleeding gums, pseudoparalysis, with subperiosteal bleeding causing severe pain. Petechial hemorrhage, hematuria, and corkscrew hair can develop. Sudden death due to cardiac failure has been reported. Prognosis is excellent if diagnosed and treated appropriately.

Imaging

Radiographs are most useful in diagnosing rickets and scurvy. CT/MRI/nuclear studies have limited roles. Dual X-ray absorptiometry (DXA) may document severity of osteomalacia.

In *rickets*, skeletal changes are due to lack of calcification of osteoid. The first radiographic changes appear in rapidly growing distal ends of the radius and ulna. There is a loss of ossification at the zone of provisional calcification. The metaphyseal margin becomes indistinct then frayed with widening of the growth plate (Fig. 1). Weight bearing and stress on uncalcified bone result in splaying and cupping of the metaphysis. The subperiosteal layer becomes indistinct. The bone density is reduced with course trabeculation. The epiphysis may develop hazy cortical margins. The enlarged ends of the ribs can be palpable at the costochondral junction clinically, called "the rachitic rosary." The sternum becomes prominent and a pectus carinatum may develop (Fig. 2). The skull becomes demineralized. Basilar invagination, indistinct sutures, delayed tooth eruption, and premature craniostenosis can occur. Green stick fracture of the cortex may develop with

Vitamin Deficiency. Figure 1 Rickets. AP radiograph of the wrist of a 9-month-old demonstrates cupping and fraying of the metaphysis of the distal radius and ulna. There is periosteal elevation along the metacarpals with an indistinct cortex.

Vitamin Deficiency. Figure 2 Rickets. AP view of the chest demonstrates indistinct humeral metaphyseal margin with loss of ossification at the zone of provisional calcification. The costochondral junctions are widened ("rachitic rosary").

bowing of the long bones. Vertebra becomes biconcave with resultant scoliosis (Table 2).

Following treatment, there is ossification of the provisional zone of calcification. The radiolucent metaphyseal bands become more prominent as the zone of provisional calcification becomes denser. Distortion of the spongiosa may occur and remain visible for years. Calvarial thickening develops with frontal and parietal bossing and premature suture closure. During healing, there is extensive periosteal new bone formation along the cornices of the diaphyses. Angulation deformities secondary to pathological fractures can result in genu valga or varum. Cortical thickening may persist though remodeling of bowing deformities eventually occurs.

In *scurvy*, radiologic changes occur at the physis of bones with rapid growth. The knee, wrist, proximal humerus, and sternal ends of the ribs are typical sites of involvement (Table 3).

In the early phase, the cortex becomes thin and the trabecular structure of the medulla atrophies and develops a ground-glass appearance. The zone of provisional calcification becomes dense and wide referred to as the ▶white line of Frankle. The epiphysis demonstrates a ground glass appearance with a sharp sclerotic rim called the ▶Wimberger's ring. As scurvy becomes advanced, a zone of rarefaction occurs at the metaphysis below the white line of Frankle. This transverse band of radiolucency beneath the zone of calcification is called the *Trummerfeld zone of lucency* (Fig. 3). The zone involves the lateral aspects of the white line, resulting in triangular defects called the *corner sign of park*. This region has multiple microscopic fractures and can collapse with impaction of the calcified cartilage onto the shaft. The lateral aspect of the calcified cartilage can project resulting in a spur called *Pelkan's spur*. Subperiosteal hemorrhages are frequent and are most commonly noted

Vitamin Deficiency. Figure 3 Scurvy. AP view of the knee demonstrates a thin cortex with ground-glass trabecula. The zone of provisional calcification is sclerotic. The epiphysis has a sharp sclerotic rim called the Wimberger's ring. Extensive subperiosteal hemorrhages have calcified, resulting in significantly elevated periosteum.

in larger tubular bones of the femur, tibia, and humerus. Rarely, subperiosteal hematomas develop on the flat bones of the orbit causing proptosis. Subperiosteal hemorrhages do not extend to the epiphysis.

Following treatment, the cortex becomes thicker. The metaphyseal transverse band of decreased density normalizes. The thick provisional zone of calcification becomes a thin transverse line. The raised periosteum layers the periphery of the hematoma with subperiosteal bone. Cortical thickening, central and epiphyseal rarefaction may persist for years.

Multiple vitamin deficiencies can modify the radiologic appearance of growing bone (Fig. 4). When scurvy and rickets are both present, scurvy findings are predominant because of diminished osteoblastic activity. Scurvy could potentially be mistaken for nonaccidental trauma when corner fractures and subperiosteal elevation is noted. Response to treatment with vitamin C can establish the diagnosis.

V

Diagnosis

Rickets: The diagnosis of vitamin D deficiency is made on clinical, radiographic, and laboratory values. In the early

Vitamin Deficiency. Figure 4 **Metabolic bone disease of prematurity. AP view of the knee (a) and the pelvis (b) of a 3-month-old very low birth weight infant on total.**

stages, histological changes are developing and blood serum levels become abnormal several weeks prior to radiographic changes. Radiologic findings are first noted in the most rapidly growing physis. The rarefaction and irregular fraying of the zone of provisional calcification are virtually diagnostic but the underlying cause needs to be evaluated via biochemical and clinical assessment. Dietary history, medication history, and measurement of creatinine and liver enzymes may help pinpoint the cause. Alkaline phosphatase is usually increased and is an excellent marker of disease activity. Serum 25-OH vitamin D is low.

Scurvy: Radiologic findings of scurvy are diagnostic with laboratory tests not significantly helpful. Low alkaline phosphatase levels are noted due to decreased osteoid production. Anemia may be present. Serum ascorbic acid levels <1 mg/dL are considered abnormally low.

Voiding Cystourethrography

A radiological examination for assessment of the urinary bladder and potential VUR that also enables visualization of the ureter and the pelvocaliceal system. It uses radiopaque contrast material that is instilled into the bladder *via* puncture or catheterization to fluoroscopically examine the bladder and—during voiding—the urethra.

▶Contrast Media, Ultrasound, Applications in Vesicoureteral Reflux
▶Reflux, Vesicoureteral, Childhood

Voiding Urosonography

Contrast-enhanced sonographic examination of the urinary tract for exclusion or detection of vesicoureteral reflux after administering intravesically US contrast medium.

▶Contrast Media, Ultrasound, Applications in Vesicoureteral Reflux

Volume of Distribution

The steady-state ratio of the activity in tissue to activity in blood/plasma.

▶Perfusion, Neoplasms

Volumetric CT

The volumetric CT is a particular tomographic appliance that uses the Cone Beam technique.

▶Caries and Periodontal Diseases

Volvulus

The twisting of a loop of bowel on its mesentery and vascular pedicle. Most importantly occurring in the mid gut of neonates and infants and resulting in bowel obstruction, ischemia, and eventually infarction. Volvulus may also occur in the sigmoid colon.

▶GI Tract, Pediatric, Specific Problems

Von Hippel–Lindau Syndrome

An autosomal dominant disorder, caused by a defective tumor suppressor gene, VHL, at chromosome 3 and characterized by the occurrence of various tumors in different organs. The presence of more than one hemangioblastoma in the central nervous system is the most characteristic feature of this phakomatosis.

▶Neurocutaneous Syndromes

Von Meyemburg Complexes

Bile duct hamartomas are small clusters of slightly dilated bile ducts surrounded by a fibrous tissue. They do not communicate with the biliary tree. At pathologic analysis, they appear as grayish-white nodular lesions 0.1–1.5 cm in diameter scattered throughout the liver parenchyma. Bile duct hamartomas are rather common and usually represent an incidental finding at imaging examinations. At ultrasound biliary hamartomas may present as either hypoechoic or anechoic small nodules; in rare cases they have a hyperechoic appearance. CT shows hypodense small hepatic nodules. At MR the lesions are hypointense on T1-weighted images and markedly hyperintense on T2-weighted images.

Von Meyemburg complexes: Biliary hamartoma.

▶Cystic-Like Lesions, Hepatic

Vulnerable Populations

Participants with limited or compromised decisional capacity (e.g., children or adults with cognitive impairment), recruited from employer–employee relationships, or without health care.

▶Incidental Neuroradiological Findings

Vulvar cancer

VUR

▶Vesicoureteral Reflux

VUS

▶Voiding Urosonography

Wall Displacement

▶Compression, Extrinsic, Esophagus
▶Compression, Extrinsic, Stomach and Duodenum

Wandering Spleen

In this condition, the spleen has an abnormal mobility due to the absence, laxity, or excessive length of the ligaments. The most important complication is represented by torsion of the vascular pedicle, followed by vascular occlusion and splenic infarction. The wandering spleen usually is symptomatic in the childhood and may present as an abdominal mass and acute, chronic, or intermittent symptoms due to torsion of the pedicle. Accurate preoperative diagnosis of wandering spleen with or without torsion represents an imaging challenge and can be made with US, CT, and MR. Perfusion and viability of the splenic parenchyma can be assessed by contrast-enhanced CT and MR, Doppler ultrasonography, and scintigraphy. Information concerning splenic perfusion and viability is important for the surgeon, especially in younger children where splenopexy instead of splenectomy is the treatment of choice in uncomplicated wandering spleen.
▶Congenital Abnomalies, Splenic

Watson-Alagille Syndrome

▶Congenital Malformations, Bile Ducts

Wernicke–Korsakoff Syndrome

Wernicke–Korsakoff syndrome is a condition caused by severe vitamin B1 (thiamine) deficiency, characterized by nystagmus, abducens and conjugate gaze palsies, ataxia and confusion (Wernicke encephalopathy); and memory problems and confabulation (Korsakoff psychosis). Symptoms of Korsakoff psychosis persist after thiamine replacement. MR may demonstrate signal abnormalities in the mamillary bodies, dorsomedial thalamic nuclei, pulvinars, walls of the third ventricle, periaqueductal gray matter, colliculi, third cranial nerve nuclei, inferior olives and superior vermis.
▶Toxic Disorders, Brain

Westermark Sign

Regional hyperlucency of lung reflecting focal oligemia due to vasoconstriction distal to an embolus
▶Chest, Thromboembolic Disease

White Line of Frankle

Also known as the scurvy line; this is a dense band of provisional zone of calcification found with scurvy.
▶Vitamin Deficiency

White Matter Hyperintensities

Areas of high-signal intensity on dual-echo and FLAIR scans of the brain, also called leukoaraiosis. WMHs are a relatively common finding in elderly people and can give rise to various MRI abnormalities, including punctate hyperintensities, periventricular caps and halos, and confluent lesions.
▶Aging Brain

White Matter Lesions

Subcortical white matter lesions complicate moderate or severe BGT. More widespread WM lesions are unusual following an acute isolated event. Other aetiologies should be sought. They result in WM atrophy and subsequent poor head growth, a secondary microcephaly. Children are at increased risk of cognitive impairment.

▶Hypoxic, Ischaemic Brain Injury

White Out of the Lung

When the lung does not include sufficient air to enable unhindered passage of the roentgen beam for a chest radiogram, the lungs appeal white on the film. A typical condition in neonates with severe IRDS or as a treatment effect during ECMO, when the lung is put at rest and not fully ventilated.

▶ECMO (neonated, pediatric) Imaging

Whole-Body MRI

Technique of total body screening in selected patients with a high risk of distant bone metastases usually includes the following MRI sequences: T2-weighted turbo-spin-echo in the transverse plane on the cranium, coronal STIR and T1-weighted with the use of automatic table movement performed successively on the cervical spine, thorax, abdomen, pelvis, and lower limb.

▶Metastases, Skeletal

Wilson Disease

Wilson disease, or hepatolenticular degeneration, is a rare autosomal recessive metabolic disorder, characterized by copper accumulation in the liver, basal ganglia, and cornea. Hepatic involvement finally results in cirrhosis. Wilson disease is invariably fatal if left untreated. Imaging findings are quite aspecific, being indistinguishable from those of cirrhosis of other causes. At CT, hepatic attenuation values are usually within normal limits. Concomitant fatty infiltration may hide the increase in density due to copper deposition. Although copper has a paramagnetic effect, substantial changes in liver signal intensity are not observed in patients with Wilson disease. In fact, copper has a slight paramagnetic effect; furthermore, copper concentration within the liver is relatively low.

▶Diffuse Infiltrative Diseases, Hepatic

Wimberger's Ring

Small epiphysis surrounded by a sclerotic rim found with scurvy.

▶Vitamin Deficiency

Wiskott–Aldrich Syndrome

Condition with variable expression, but commonly includes IgM deficiency, causing severe thrombocytopenia. In its complete form, it also includes small platelets, atopy, immunodeficiency, and an increased risk of autoimmune disease and hematologic malignancy.

▶Neoplasms, Splenic, Benign

WMHs

▶White Matter Hyperintensities

Wolman's Disease

Congenital inborn error of metabolism resulting from acid lipase deficiency leading to an accumulation of lipids in the adrenal glands, liver, spleen, and lymph nodes.

▶Congenital Malformations, Adrenals

WOMAC Osteoarthritis Index

This is a validated index applied for the clinical evaluation of OA severity assessing pain, disability and joint stiffness by use of a questionnaire.

▶Degenerative Joint Disease, Peripheral Joints

Work-related Lung Disorders

▶ Pneumoconiosis

Wormian Bones

Intrasutural bones of the calvarium; a large number of them is seen in several diseases, including osteogenesis imperfecta, Menkes disease, and pyknodysostosis, each of which has easily fractured bones, plus other conditions without easy fracturability.

▶ Battered Child Syndrome

WORMS-Score

This whole-organ magnetic resonance imaging score incorporates 14 features for the evaluation of MR images of the knee providing a whole organ assessment of the knee. In addition to the KOSS-Score (→ keywords), cruciate and collateral ligaments are evaluated and the presence of intra-articular loose bodies is taken into account.

▶ Degenerative Joint Disease, Peripheral Joints

Xanthogranulomatous Pyelonephritis

Chronic infection related to a long evolution of obstruction, causing renal parenchyma destruction and its replacement by lipid-laden macrophages.

►Pyelonephritis, Chronic

XX or XY Sex Reversal

►Ambiguous Genitalia

Zenker's Diverticulum

A posterior diverticulum just above the cricopharyngeus that occurs in some patients with long standing gastro-oesophageal reflux disease.

▶Hernia, Hiatus in Adults

Zig-Zag Deformity

A typical deformity in late-stage rheumatoid arthritis and a combination of carpal ulnar drift and ulnar deviation of the metacarpophalangeal joint.

▶Rheumatoid Arthritis

Zone of Provisional Calcification

The final layer, considerably less than 1 mm thick, of the enchondral growth plate both at the metaphyseal interface with physis and around secondary growth centers and their equivalents.

▶Demineralisation, Bone, Childhood

Zone of Transition

Point at which, in obstruction, bowel calibre changes from dilated to collapsed.

▶Occlusion and Subocclusion, Small bowel in adults

ZPC

▶Zone of Provisional Calcification
