Masses, Ovarian. Figure 1 Mucinous cystadenoma in a 40-year-old female patient. Transvaginal sonography demonstrates a 9-cm cystic lesion that contains thin septations. Multiple fine echoes are seen within the cyst presenting proteinaceous or mucinous contents. There was no evidence of mural thickening, papillary projections, or solid areas within the lesion.

cystadenomas, mucinous cystadenomas are typically multilocular with different locular contents (1, 3). Rupture of a mucinous cystadenoma can result in pseudomyxoma peritonei.

Fibromas/Fibrothecomas

Fibromas and fibrothecomas are solid ovarian tumors which resemble uterine fibroids on imaging. However, they tend to show mild or delayed contrast enhancement (3). They occur unilaterally (90%), and are typically found in peri- and postmenopausal women.

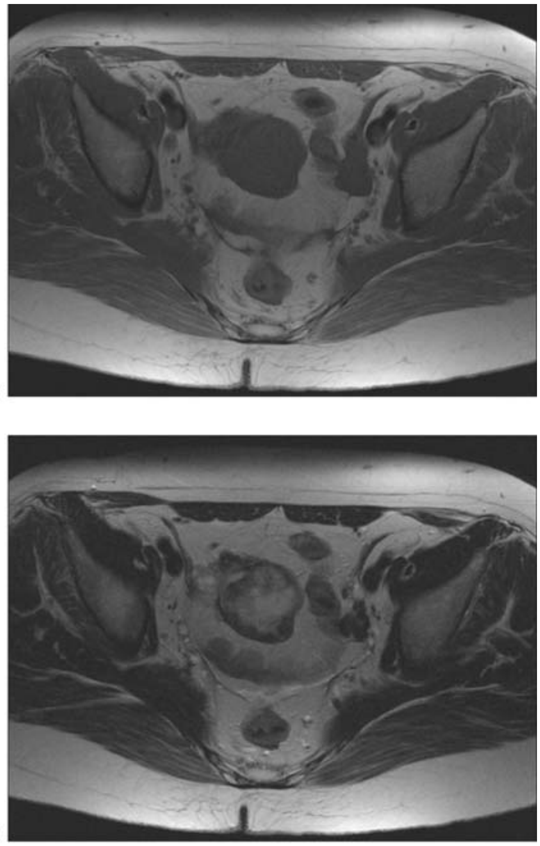
Fibromas are composed of mostly fibroblasts and spindle cells and abundant collagen contents. Fibromas are not hormonally active. Fifteen percent of fibromas are associated with ascites, and in 1% pleural fluid is also found. This triad of an ovarian fibroma, ascites, and pleural effusion constitutes the benign ►Meig's syndrome.

Fibrothecomas consist of thecal cells with abundant and varying amounts of fibrosis, and rarely contain dense calcifications or cystic degenerations (1) (Fig. 2). Sixty percent of thecomas are hormonally active. Women may present with abnormal uterine bleeding. Furthermore, thecomas are associated with endometrial carcinomas in 20% of cases.

Brenner Tumors

Brenner tumors are rare ovarian tumors that occur at a mean age of 50 years. The vast majority is benign, less than 2% demonstrate borderline or malignant transformation. They are typically small, solid, unilateral ovarian tumors, which may show extensive calcifications (1). Sixty percent of Brenner tumors measure less than 2 cm in size. If cystic components are found, Brenner tumors may be associated with cystadenomas or other epithelial neoplasms (collision tumors).

a



b

Masses, Ovarian. Figure 2 Fibrothecoma in a postmenopausal patient. In a 56-year-old woman with history of hysterectomy for benign disease, a solid right adnexal mass is demonstrated, which shows intermediate signal intensity (SI) on T1-weighted imaging (WI) (a) and inhomogeneous peripherally very low SI on T2-WI (b) with areas of high SI. Contrast uptake was very low (not shown). Histopathology revealed fibrothecoma with central areas of degeneration.

Malignant Ovarian Tumors

Malignant tumors of the ovary and borderline tumors comprise 21 and 4%, respectively, of primary ovarian tumors (2). Epithelial ovarian cancer constitutes 85% of ovarian cancers, among which serous epithelial and mucinous ovarian tumor types account for the majority of cancers (2). Unfortunately, there is poor correlation between the gross appearance on pathology and the histologic subtypes of ovarian cancer, and the aggressiveness cannot be determined on the basis of imaging studies. Cancer dissemination most commonly occurs peritoneally and by direct extension. Lymphatic and hematogenous seeding is less commonly found. Large amounts of free fluid in ovarian cancer are highly associated with peritoneal metastases.

Malignant germ cell tumors that represent two-thirds of malignancies in females less than 20 years of age and malignant stromal neoplasm are responsible for 7% of primary ovarian neoplasm each (1).

►Ovarian metastases account for 5–15% of ovarian malignancies.

Ovarian Cancer: see cross-reference Carcinoma Ovarian.

Borderline Tumors

Borderline tumors are epithelial ovarian cancers with low malignant potential. They tend to present as often large, bilateral, cystic ovarian tumors with mural nodules or papillary projections (1). At imaging they cannot be differentiated from invasive ovarian cancer; however, they represent a different entity. Compared to epithelial ovarian cancer, the survival rate stage for stage is much better. In a 7-year follow-up, the survival rate of stage I disease was 99% and for stage II and III disease it was 92%. Borderline tumors account for approximately 4–14% of all ovarian malignancies and are diagnosed at a median age of 40 years.

Dysgerminomas

Dysgerminomas present as multilobulated, well-delineated, solid uni- or bilateral ovarian tumors. Speckled calcifications, central areas with necrosis or hemorrhage, and strongly enhancing fibrovascular septations are other imaging features (1, 3). Seventy-five percent of dysgerminomas occur in early reproductive age, 10% are found in prepubertal girls, and 15–20% are diagnosed during pregnancy or postpartum. The vast majority of patients with dysgerminomas are diagnosed in early stage disease.

Malignant Teratomas

Immature teratomas or malignant teratomas are the second most common germ cell malignancies after dysgerminomas. They are extremely rare malignant tumors which are typically encountered in females between 10 and 20 years of age. In postmenopausal women they are an extremely rare finding and arise from secondary malignant transformation of the dermoid plug in dermoids. Immature teratomas are typically large at the time of diagnosis and present as solid or predominantly solid tumors with cystic elements and areas of fat and calcifications. They may be associated with dermoid cysts, more commonly in the ipsilateral (26%) than in the contralateral ovary. Rarely, they may produce steroids and cause pseudoprecosity in prepubertal girls.

Granulosa Cell Tumors

Granulosa cell tumors are classified as neoplasms of a low-grade malignancy. They typically present as unilateral, often large ovarian tumors that display a broad spectrum from entirely cystic to sponge-like multicystic to completely solid ovarian lesions (3). Granulosa cell tumors account for less than 5% of ovarian malignancies, and are the most common ovarian tumors with estrogen production. Two subgroups of granulosa cell tumors, the juvenile and the adult subtype, can be differentiated. Estrogen effects may induce precocious pseudopuberty or postmenopausal bleeding. Adult granulosa cell tumors

b

Masses, Ovarian. Figure 3 Ovarian metastasis of breast cancer. In a postmenopausal female, transaxial T2-WI (a) and contrast-enhanced T1-WI with fat suppression (b) demonstrate a 4-cm solid lesion of the left adnexal lesion. It can be discriminated by adjacent bowel loops as it is surrounded by small amounts of ascites. SI on T2-WI is intermediate and higher than expected in fibromas, contrast enhancement is slightly inhomogeneous.

M

usually occur after 30 years of age and peak in the perimenopausal age. In this tumor type, late recurrence may be seen several years after the initial therapy for tumor manifestation.

Ovarian Metastases

Ovarian metastases present as bilateral ovarian masses in 75% of cases. They account for approximately 5–15% of malignant ovarian tumors and originate most commonly from colon, stomach, breast, and melanomas as primaries. Ovarian metastases seem more common in premenopausal women due to the higher vascularity of the ovaries in this age, and they may be associated with hormonal activity. Approximately 50% of ovarian metastases consist of Krukenberg tumors which contain mucin-secreting signet ring cells surrounded by ovarian stroma. Krukenberg tumors display characteristic imaging features that include bilateral, oval or kidney-shaped solid ovarian tumors, often with central necrosis (5). Metastatic cancers different from Krukenberg tumors may have a variable often mixed cystic and solid or predominantly cystic or solid appearance (Fig. 3) and tend to resemble ovarian cancer (5).

Mechanical Index

Estimate of the acoustic energy of an ultrasound field used in clinical sonography. The mechanical index (MI) is displayed on the screen of modern US scanners. It is defined as the estimated peak rarefractional pressure in vivo, divided by the square root of the center frequency of the beam. The MI was developed to quantify the likelihood that exposure to diagnostic ultrasound will produce an adverse biological effect by a nonthermal mechanism. It is also used to control the amplitude of the US during contrast-enhanced sonography, since the amplitude used determines the nature and degree of nonlinear bubble behavior (cross reference) and thus the echo response obtained from the microbubble contrast agent.

Meconium Ileus

Veronica Donoghue
Radiology Department, Children's University Hospital, Dublin, Ireland
veronica.donoghue@cuh.ie

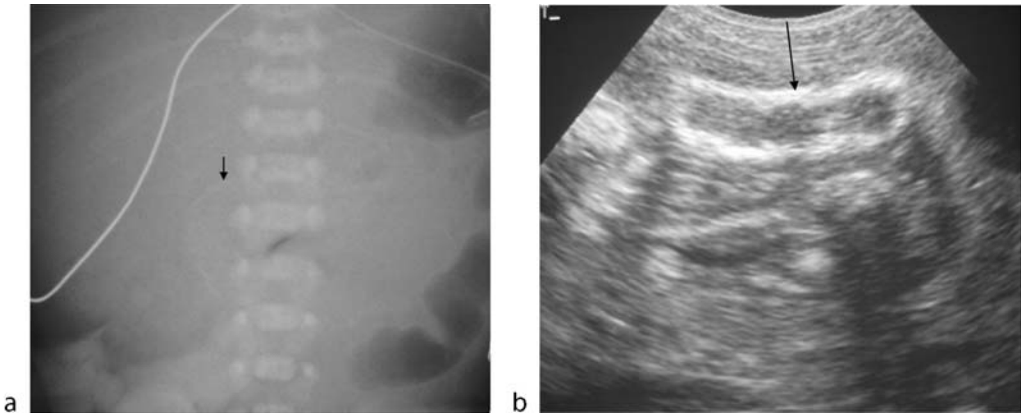
Synonyms

Cystic fibrosis; Microcolon

Definition

Meconium ileus is due to bowel obstruction as a result of impaction of thick tenacious meconium in the distal ileum. It is usually considered an early manifestation of cystic fibrosis. About 10–12% of patients with cystic fibrosis present with meconium ileus. It can rarely occur with other rare pancreatic abnormalities such as pancreatic atresia or stenosis of the pancreatic duct.

M



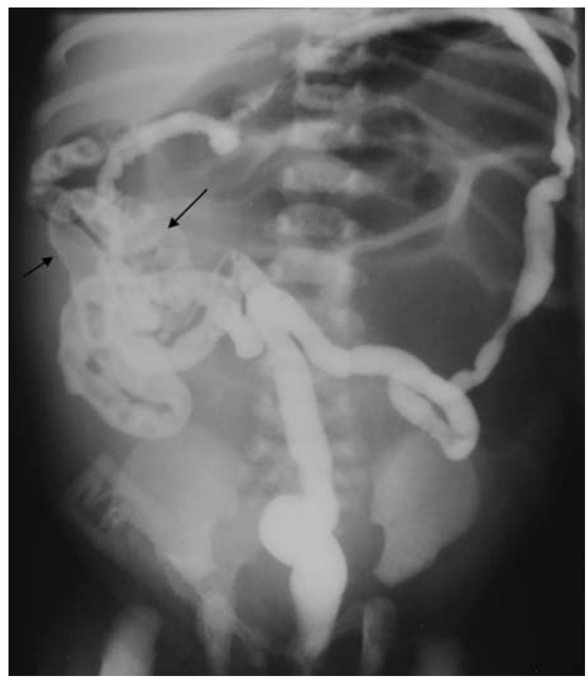
Meconium Ileus. Figure 1 (a) Plain abdominal radiograph with curvilinear calcification (short arrow) secondary to bowel perforation in an infant with meconium ileus. (b) This is also well seen on sonography (long arrow).

Pathology/Histopathology

Analysis of the enzyme activity of disaccharidases such as lactase, sucrase, maltase, and palatinase has shown to be increased in the meconium of infants with cystic fibrosis compared to meconium from normal infants. Normal meconium contains ~50% protein-bound carbohydrate as opposed to ~10% in the meconium from cystic fibrosis specimens.

Clinical Presentation

Clinically, infants with meconium usually present with bilious vomiting, abdominal distension and failure to pass meconium in the first 24 h of life. Pulmonary manifestations of cystic fibrosis are not usually present at birth but may develop shortly after with a bronchiolitis type picture (1).



Meconium Ileus. Figure 2 Contrast enema outlining a microcolon and inspissated meconium in the distal ileum (arrows). There are dilated air filled bowel loops proximal to the obstruction.

Imaging

Abdominal radiographs show multiple dilated air filled bowel loops indicating low intestinal obstruction. In general these infants have fewer air–fluid levels than those with small bowel atresias. This however is a nonspecific finding. A "soap-bubble" appearance maybe seen in the right lower quadrant due to a mixture of air and meconium. Meconium ileus maybe complicated by volvulus, intestinal atresia, and perforation with meconium peritonitis or pseudocyst formation. There maybe evidence of a pneumoperitoneum or ascites. If meconium peritonitis is present there may be associated peritoneal calcification which maybe seen to extend into the scrotum. A localized perforation may form a meconium pseudocyst which may have curvilinear peripheral calcification (Fig. 1a).

Peritoneal calcification may also be well seen on sonography (Fig. 1b). Volvulus is caused by the weight of a meconium filled bowel. A contrast enema clinically demonstrates a microcolon with inspissated meconium identified in the distal ileum and dilated small bowel proximal to the obstruction (2) (Fig. 2).

Older infants may suffer from chronic constipation and intestinal obstruction due to fecal impaction. This is referred to as ▶meconium ileus equivalent. These patients may also present with intussusception. Mucosal thickening of the small and large bowel also occurs in the older patients with cystic fibrosis, probably due to mucous accumulation in the submucosal glands. Other findings in older children include benign pneumatosis intestinalis as a result of chronic constipation, poorly functioning gallbladder, biliary sludge, liver cirrhosis, and portal hypertension. In later childhood a severe colitis can be seen as a result of the pancreatic enzyme replacement therapy used in these infants (1).

▶Meconium plug syndrome is a condition unrelated to meconium ileus and usually presents very early in life with failure to pass meconium and abdominal distension. It is the result of delayed peristaltic activity in an otherwise normal colon. The etiology is uncertain. It is associated with maternal drug ingestion, eclampsia, diabetes, and prematurity. In meconium plug syndrome the colon has a normal caliber. The plug is in the rectosigmoid region but may extend proximally throughout the entire colon. The infant usually passes the plug following a contrast enema or rectal examination.

Diagnosis

The diagnosis of meconium ileus is made by demonstrating a microcolon with the identification of meconium in the distal small bowel causing proximal obstruction in an infant with abdominal distension and failure to pass meconium in the first 24 h of life. Ultrasonography has been shown to be useful in distinguishing infants with meconium ileus from ileal atresia, both of whom have a microcolon. Infants with meconium ileus have multiple loops filled with echogenic thick meconium whereas those with atresia have dilated loops filled with fluid and air.

Interventional Radiological Treatment

Once the diagnosis is established a therapeutic enema should be performed to relieve the obstruction (3). The choice of contrast medium is controversial but we use dilute gastrograffin (diatrizoate meglumine) (2) (see also chapter Gastrointestinal, children, bowel obstruction). It is hyperosmolar and causes fluid shift into the bowel lumen even when diluted. Extreme care must be taken with fluid and electrolyte balance to avoid hypotension and circulatory collapse in the newborn infant. The aim is to introduce contrast medium into the distal small bowel proximal to the obstructing inspissated meconium but care must be taken to avoid over distension of the microcolon. Several attempts maybe made (1–2 per 24 h) provided there is progressive clinical improvement in terms of abdominal distension and passage of meconium. The infants' fluid and electrolyte balance must be closely monitored during and after each procedure.

Overall the therapeutic enema success rate is 50–60% with a perforation rate of 3–10%. In unsuccessful cases surgery often reveals complications. This procedure can also be performed in the older children with meconium ileus equivalent to help relieve bowel obstruction.

Mediastinal Cystic Masses

Koji Takahashi
Department of Radiology, Asahikawa Medical College, Asahikawa, Japan
taka1019@asahikawa-med.ac.jp

Definition

Cystic masses of the mediastinum are encapsulated lesions that contain fluid and are lined with epithelium. Most cystic masses are congenital and include foregut duplication cysts (i.e., bronchial, neurenteric, and esophageal duplication cysts), pericardial cysts, and thymic cysts. Meningoceles, pancreatic pseudocysts, hematoma, abscess, and cystic schwannoma also appear as cystic mediastinal masses.

Pathology

Bronchogenic cysts are considered to result from defective development of the lung bud during the fetal period (1). The cyst wall often contains cartilage, smooth muscle, and mucous glands and is typically lined with respiratory epithelium. Cyst fluid is usually serous but can be hemorrhagic and contain variable amounts of protein or calcium.

Pericardial cysts are outpouchings of the parietal pericardium, which has no communication with the pericardial space, and result from aberrations in the embryogenesis of the coelomic cavity. These cysts are commonly round or spherical in shape, thin walled, unilocular, and contain clear or straw-colored fluid (2). Cyst walls consist of connective tissue and a single layer of mesothelial cells.

Esophageal duplication cysts may result from either abnormal budding of the foregut or a failure of complete vacuolation of the originally solid esophagus (3). The cysts are lined by gastrointestinal tract mucosa and have a double layer of smooth muscle. The cysts are commonly located adjacent to the esophagus.

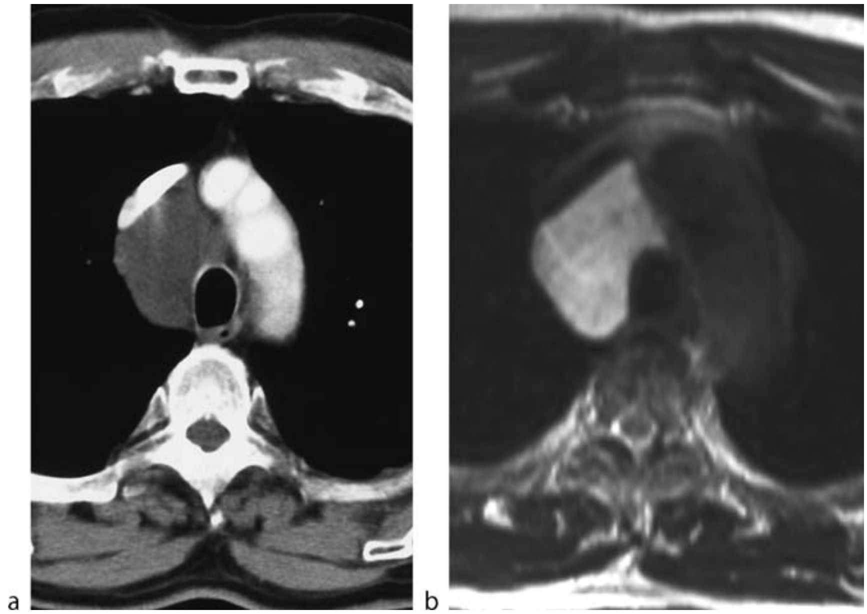
Congenital thymic cysts are quite rare and are derived from a remnant of the thymopharyngeal duct. Multilocular thymic cysts may be the sequela of various inflammatory processes (4, 5).

Clinical Presentation

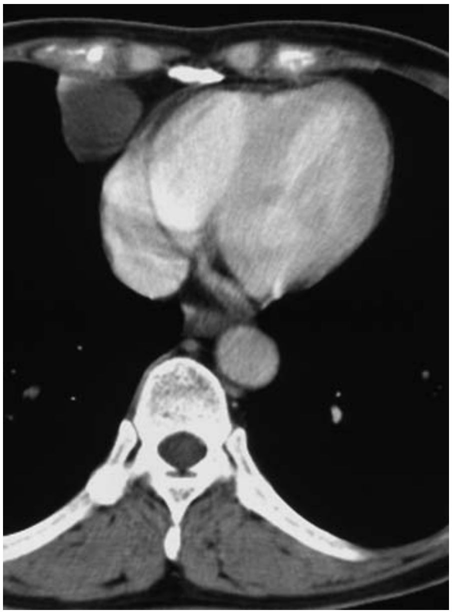
In most clinical situations, mediastinal cystic masses are incidentally detected on imaging. Symptoms might include chest pain, cough, dyspnea, and dysphagia, especially in esophageal duplication cysts. Symptomatic patients are likely to undergo surgery.

Imaging

On the radiographs, focal deformity of mediastinal contours and lines and/or displacement of normal structures must be present so as to identify a mass. On CT, typical features of mediastinal cystic masses include (1) an encapsulated smooth round or oval masses, (2) homogeneous water attenuation, (3) no enhancement of cystic contents with/without minimal enhancement of its wall, and (4) no infiltration of adjacent mediastinal structures. Some mediastinal cysts may reveal high attenuation similar to solid lesions due to a high level of protein and calcium oxalate in the cystic contents. In such situations, magnetic resonance imaging (MRI) can be useful in the differentiation of cystic masses from solid lesions. High signal intensity corresponding to cerebrospinal fluid (CSF) on



Mediastinal Cystic Masses. Figure 1 **Bronchogenic cyst. (a) Contrast-enhanced CT scan shows a thin-walled cystic mass abutting the trachea. (b) On axial T2-weighted MR image, the mass reveals homogeneous high signal intensity consistent with serous fluid.**



Mediastinal Cystic Masses. Figure 2 Pericardial cyst. Axial contrast-enhanced CT scan shows a well-defined cystic mass in the right cardiophrenic angle.

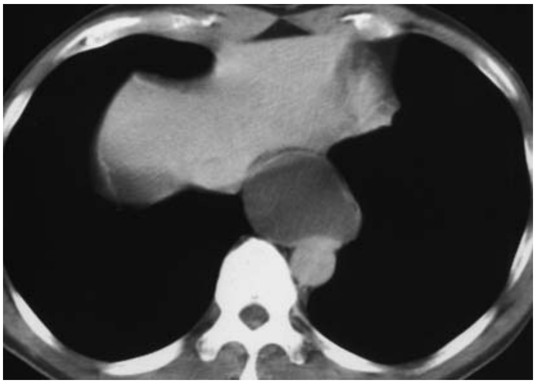
T2-weighted sequences, a fluid–fluid level, and lack of contrast enhancement are highly suggestive of the cystic nature of the lesions.

The majority of bronchogenic cysts are located in the paratracheal or subcarinal region. Rarely, they are seen in the anterior mediastinum or the inferior aspect of the posterior mediastinum. On chest radiographs, bronchogenic cysts usually present as a well-defined mass of homogeneous density in the subcarinal or right paratracheal regions. Computed tomography (CT) is very useful for making a specific diagnosis of bronchogenic cyst. Bronchogenic cysts typically appear as a well-defined, round or elliptical mass with a uniformly thin wall (Fig. 1). Cyst contents reveal homogeneous low attenuation consistent with fluid. In nearly 50% of patients, the cysts have higher attenuation and may be indistinguishable from soft tissue lesions.

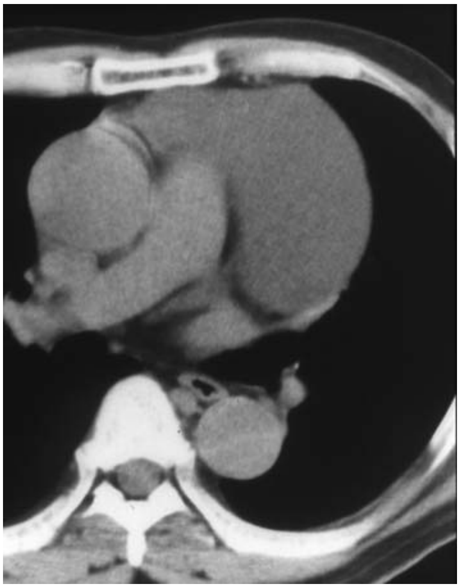
The majority of pericardial cysts are located in the cardiophrenic angles and they are more frequent on the right side. On CT, the cysts characteristically appear as a round or oval lesion of water attenuation abutting the pericardium (Fig. 2). Occasionally, cyst contents show soft tissue attenuation.

The vast majority of esophageal duplication cysts are indistinguishable from other mediastinal congenital cysts. However, the cyst walls may be thicker (Fig. 3) and the lesions may be more tubular in shape and be in more intimate contact with the esophagus.

Thymic cysts appear as smoothly marginated thin-walled mass lesions of water attenuation in the anterior mediastinum (Fig. 4).



Mediastinal Cystic Masses. Figure 3 Esophageal cyst. Axial contrast-enhanced CT scan shows a well-defined cystic mass which abuts and displaces the esophagus. The mass has a relatively thick wall.



Mediastinal Cystic Masses. Figure 4 Thymic cyst. Axial contrast-enhanced CT scan shows a mass of homogeneous fluid attenuation in the anterior mediastinum.

Mediastinal Germ Cell Tumors

Koji Takahashi
Department of Radiology, Asahikawa Medical College, Asahikawa, Japan
taka1019@asahikawa-med.ac.jp

Definition

Germ cell tumors are believed to develop from a germ cell during the process of maturation of a primordial germ cell into a gamete. The mediastinum is the most common site of extragonadal germ cell tumors (1). The vast majority of mediastinal germ cell tumors arise within the anterior mediastinum or in the proximity of the thymus, and only 3% of them arise within the posterior mediastinum (2).

Pathology/Histopathology

Germ cell tumors include teratoma, seminoma, embryonal carcinoma, yolk sac tumor (endodermal sinus tumor), choriocarcinoma, and mixed germ cell tumor. Mature teratoma is the most common histologic type. Seminoma is the most common malignant subtype.

Teratoma

Teratoma usually derives from more than two embryonic layers: ectoderm, endoderm, and mesoderm. Dermoid cyst refers to a tumor composed solely of ectodermal elements. Histologically, teratoma can be divided into mature teratoma, immature teratoma, and teratoma with malignant transformation. Mature teratomas are usually unilocular or multilocular cystic lesions and consist predominantly of ectoderm elements including skin and its appendages followed, in order of frequency, by bronchial tissue, gastrointestinal mucosa, smooth muscle, fat, bone, cartilage, and pancreatic tissue (1). Immature teratomas show various adult tissues derived from three germinal layers but in addition contain immature tissue, most commonly primitive neuroepithelial tissue. Teratomas with malignant transformation contain foci of frankly malignant neoplasms such as angiosarcoma, rhabdomyosarcoma, adenocarcinoma, and squamous cell carcinoma.

Seminoma

Seminoma is a well-demarcated, large, soft, and usually homogeneous mass with small foci of hemorrhage and necrosis (1).

Clinical Presentation

Mediastinum germ cell tumors most commonly occur during the period from the second to the fourth decades of life, and they are much more common in men than women. Most mediastinal germ cell tumors arise within the anterior mediastinum (2). Mature teratomas are often clinically silent. Symptoms might be due to local compression, rupture, or infection and include chest pain, cough, dyspnea, and fever. Most patients with immature teratoma and other malignant germ cell tumors are symptomatic, presenting with fatigue, weight loss, chest pain, cough, or dyspnea.

Teratoma

Mature teratomas are often clinically silent. Symptoms are due to local compression, rupture, or infection. Most patients with immature teratoma and other malignant germ cell tumors are symptomatic, presenting with fatigue, weight loss, chest pain, cough, or dyspnea.

Seminoma

Seminoma occurs almost exclusively in males during the period from the second to the fourth decades of life. Symptoms are usually derived from the presence of invasion to the adjacent mediastinal structures (airways and vessels) and include chest pain, shortness of breath, and superior vena cava syndrome.

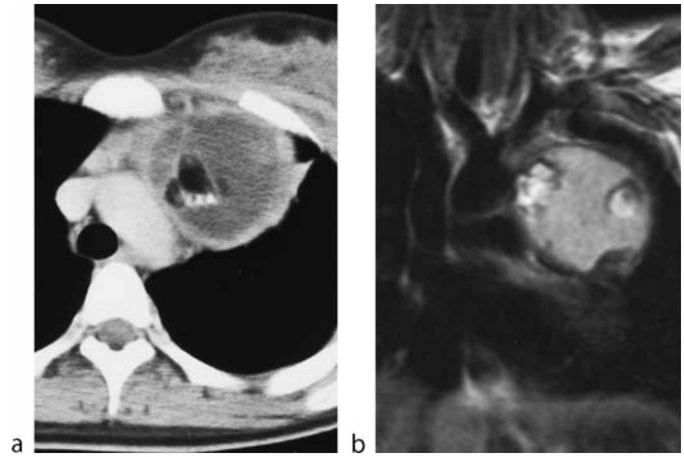
Nonseminomatous Malignant Germ Cell Tumor

Nonseminomatous malignant germ cell tumors are rare, highly malignant tumors that usually occur in young adults and are much more common in men than women. Tumors are usually associated with symptoms including chest pain, cough, fever, and dyspnea and occasional elevation of tumor markers: alpha-fetoprotein from yolk sac tumor and embryonal carcinoma components and the beta fraction of human chorionic gonadotropin from the choriocarcinoma component.

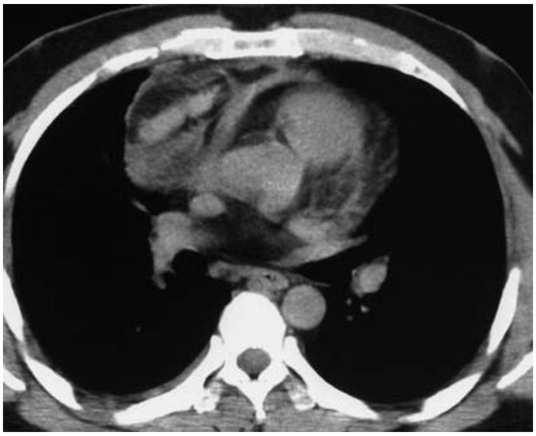
Imaging

Teratoma

The typical radiographic appearance of a mature teratoma is a well-demarcated, occasionally lobulated anterior mediastinal mass. On computed tomography (CT), a mediastinal mature teratoma is a well-defined cystic lesion containing fluid, soft tissue, and fat attenuation. Calcifications of various morphological configurations may also be present within the lesion (Fig. 1) (3). A fat-fluid level is diagnostic of mature teratoma. Rarely, a tooth or a part of bone is seen within the lesions. Mediastinal mature teratomas may be associated with



Mediastinal Germ Cell Tumors. Figure 1 Mature teratoma. (a) Contrast-enhanced computed tomography shows a thick-walled cystic mass in the anterior mediastinum, which consists of areas of water, fat, and calcification. (b) On coronal T1-weighted magnetic resonance image, the mass shows various signal intensities.



Mediastinal Germ Cell Tumors. Figure 2 Ruptured mature teratoma. Axial computed tomography shows a cystic mass consisting of fat, water, and soft tissue in the anterior mediastinum. Pericardial effusion suggests rupture of the tumor into the pericardial space.

complications such as atelectasis or obstructive pneumonitis due to airway compression, pneumonitis due to rupture into the lung, and effusion due to rupture into the pleural space or pericardium (Fig. 2) (4).

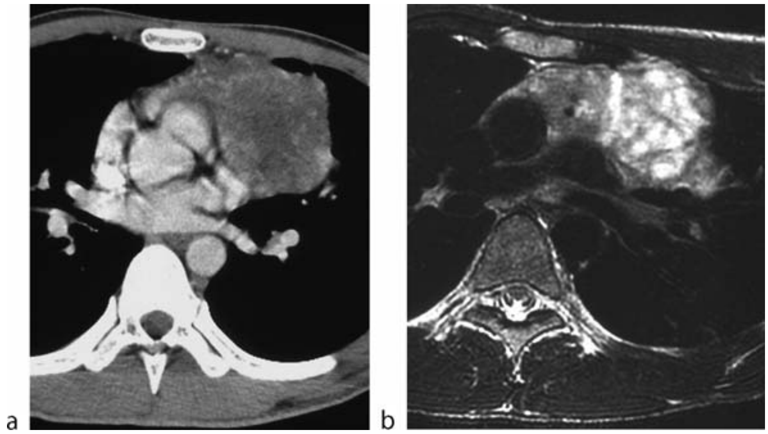
Seminoma

Seminoma appears as a large, well-demarcated anterior mediastinal mass. On CT, seminoma has a homogeneous internal attenuation that shows only slight enhancement. A low-attenuation area due to degenerative change may appear but is usually limited (Fig. 3) (5, 6). Radiological evidence of invasion to the adjacent structures and collections of pleural or pericardial effusion are uncommon.

Mediastinal Germ Cell Tumors. Figure 3 Seminoma. Contrast-enhanced computed tomography shows a lobulated mass in the anterior mediastinum that displaces the superior vena cava and right pulmonary artery. The tumor includes limited areas of cystic change.

Nonseminomatous Malignant Germ Cell Tumor

Nonseminomatous malignant germ cell tumors usually appear as a large anterior mediastinal mass on radiographs. On CT and magnetic resonance imaging (MRI), the tumors consist of irregular soft tissue and multiple areas of low attenuation due to cystic necrosis and hemorrhage (Fig. 4) (5, 6). Obliteration of the adjacent fat planes and invasion to the surrounding structures may occasionally be seen.



Mediastinal Germ Cell Tumors. Figure 4 **Nonseminomatous malignant germ cell tumor. (a) Contrast-enhanced computed tomography shows an irregularly shaped mass in the anterior mediastinum. The tumor reveals fluid attenuation, representing widespread necrosis. (b) Axial T2-weighted magnetic resonance image shows prominent cystic changes within the tumor.**

Mediastinal Malignant Lymphoma

Koji Takahashi
Department of Radiology, Asahikawa Medical College, Asahikawa, Japan
taka1019@asahikawa-med.ac.jp

Definition

Malignant lymphoma accounts for nearly 20% of all mediastinum neoplasms in adults and 50% in children (1). Most often lymphoma involves the mediastinum secondary to generalized disease, while a mediastinal disease can also be a primary lesion. Hodgkin's disease is the most common primary mediastinal lymphoma.

Pathology

Hodgkin's Disease

Hodgkin's disease is the most common lymphoma to manifest in the mediastinum and may involve mediastinal lymph nodes, thymus or both. Nodular sclerosis, which is characterized by orderly bands of interconnecting collagenous connective tissue subdividing abnormal lymphoid tissue into isolated cellular nodules, is by far the most common histologic subtype. The cellular proliferation within the nodules is polymorphic, with small and large lymphocytes, plasma cells, eosinophils, and histiocytes. The distinctive feature is the presence of Reed–Sternberg cells.

Non-Hodgkin's Lymphoma

In non-Hodgkin lymphoma, the two most common forms of primary mediastinal lymphoma are lymphoblastic lymphoma and diffuse large cell lymphoma, while virtually any histologic type of lymphoma may be identified. Most lymphoblastic lymphomas have features of thymic T cells and exhibit a diffuse infiltrative pattern growth. Diffuse large cell lymphoma mostly shows to be of B-cell origin.

Clinical Presentation

Common symptoms of patients with large mediastinal lymphomas include dyspnea, cough, chest pain, malaise, fever, and superior vena cava syndrome

Diffuse large cell lymphoma tends to occur in young to middle-aged adults.

Imaging

Hodgkin's Disease

Mediastinal adenopathies most commonly involve prevascular and paratracheal regions (Fig. 1a). Other sites include subcarinal, hilar, paracardiac, internal mammary, and posterior mediastinal nodes. Most patients are young female adults. On CT, involved nodes usually are well defined and discrete and reveal homogeneous soft-tissue attenuation (Fig. 1b). While involved nodes with cystic and necrotic changes are identified in up to 21% of cases. Thymic involvement is another common manifestation and thymic enlargement is seen in 40% of adult patients.

Non-Hodgkin's lymphoma

Lymphoblastic lymphoma

Bulky disease is easily appreciated on the chest radiograph by mediastinal widening due to mass effect (Fig. 2a). On CT, low-attenuation areas reflecting necrosis are commonly seen after contrast enhancement (Fig. 2b). Pleural and pericardial effusions are also frequent. In extensive disease, tumor may spread to extrathoracic lymph nodes and central nervous system.

Diffuse Large Cell Lymphoma

The most commonly involved lymph nodes in the mediastinum are anterior mediastinum and paratracheal nodes followed by the subcarinal, hilar, internal mammary, pericardial, and posterior mediastinal nodes in decreasing order of frequency. On CT, involved nodes typically show homogeneous soft-tissue attenuation while, less commonly, reveal internal low-attenuation area or rim enhancement (Fig. 3). Pulmonary parenchymal involvement is seen on CT in approximately one third of the patients and commonly appears as nodules, masses, and focal air-space consolidation.

Overall, MRI shows the same morphological features as CT. Advantages of MRI might be detection of chest wall involvement and pleural disease, evaluation of viability of residual mass.

Mediastinitis

Koji Takahashi
Department of Radiology, Asahikawa Medical College, Asahikawa, Japan
taka1019@asahikawa-med.ac.jp

Definition

Mediastinitis can be divided into acute and chronic or fibrosing mediastinitis. Acute mediastinitis usually is bacterial and most commonly results from esophageal perforation. Chronic mediastinitis typically is fungal or tuberculous infection. Other causes of chronic disease include autoimmune disease, drug, radiation therapy, and syphilis.

Pathology

Acute mediastinitis is relatively uncommon bacterial infection and most commonly associated with esophageal perforation. Other causes include esophageal or cardiac surgery, spread of infection from adjacent regions, including retropharyngeal space, bone, and joints, tracheal or bronchial perforation, penetrating trauma, or necrosis of neoplasm (1). Esophageal perforation is usually related to endoscopic procedures. Spontaneous perforation may occur after forceful vomiting (Boerhaave's syndrome). The usual site of tear is adjacent to the gastroesophageal junction.

Fibrosing mediastinitis is a rare disease manifested by chronic inflammation and fibrosis, which focally or diffusely involves the mediastinum. The most common causes of fibrosing mediastinitis are histoplasmosis and tuberculosis, but it can also be related to autoimmune disease, radiation therapy, retroperitoneal fibrosis, methysergide therapy, or may be idiopathic (2). Histoplasmosis infection typically results in focal disease, whereas idiopathic disease is usually diffuse. Chronic mediastinitis leads to obstruction of various mediastinal structures, most commonly the superior vena cava (39%), followed by decreasing in order bronchi (33%), pulmonary artery (18%), and esophagus (9%) (3).

Clinical Presentation

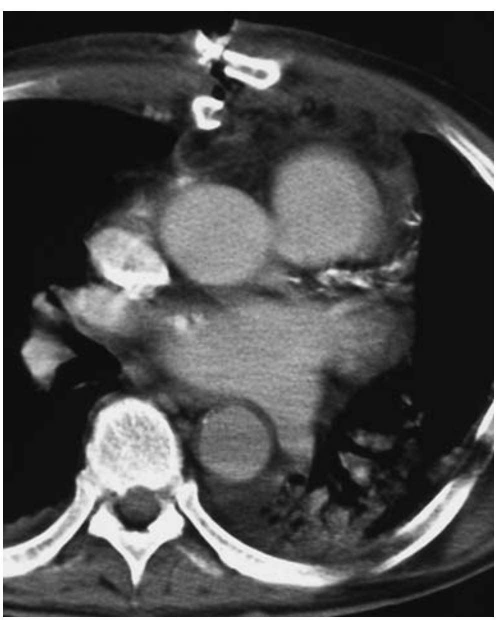
The patients with acute mediastinitis are often very ill and associated with retrosternal pain, chills, and high fever. Acute mediastinitis especially from esophageal perforation has a high mortality rate.

The most common clinical symptoms of chronic mediastinitis are related to the superior vena cava syndrome: headache, cyanosis, and puffiness of the face, neck, and arms.

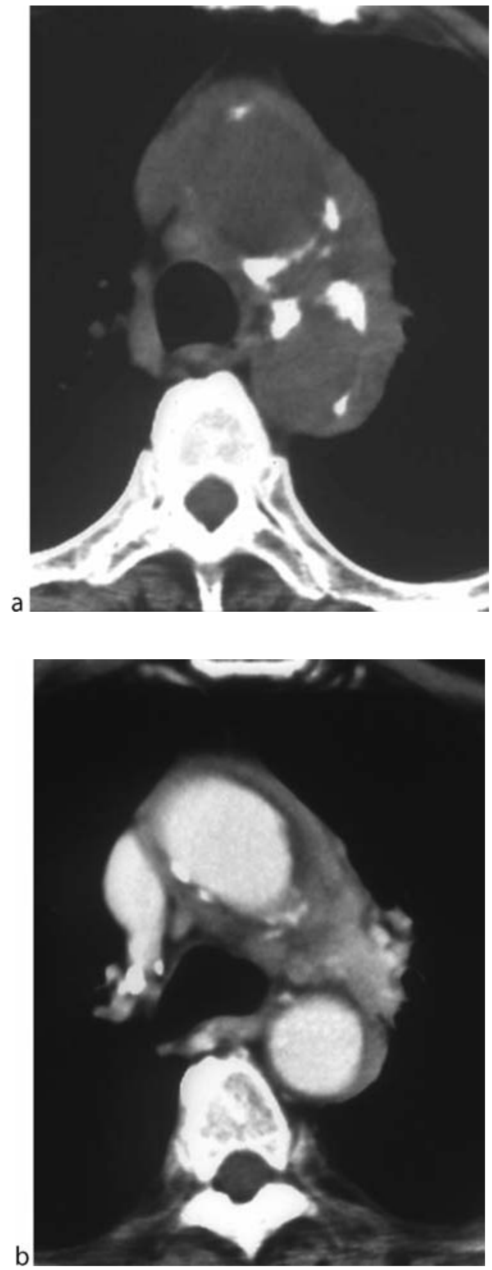
Imaging

The main radiographic features of acute mediastinitis are widening of the mediastinum, pneumomediastinum, pneumothorax, hydropneumothorax, and pleural effusions. Esophagography can be performed safely to confirm the presence and precise location of esophageal perforation. CT findings of acute mediastinitis are mediastinal widening, diffuse or streaky infiltration of mediastinal fat, pleural or pericardial effusion, and air bubbles and fluid collection in the mediastinum (Fig. 1). In cases with abscess formation, which can be single or multiple, localized fluid collections with or without air bubbles or air fluid level are present. In patients after median sternotomy, it is important to consider the normal postoperative appearance of the mediastinum, which can mimic the features of mediastinitis. Air bubbles and fluid collections are normal in the first week or two after sternotomy.

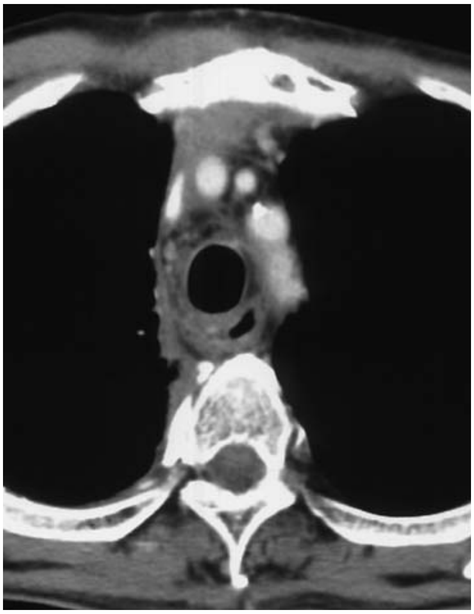
Fibrosing mediastinitis due to histoplasmosis or tuberculosis typically shows adenopathy and/or calcification most commonly in the upper mediastinum. The diffuse form may be manifested by extensive widening of the upper mediastinum, narrowing of the lower trachea or main bronchi. But chest radiographs may be normal in appearance in either focal or diffuse disease. CT is a good diagnostic modality for assessing and diagnosing the extent and site of the disease by soft tissue infiltration and enhancement (Fig. 2). In patients with focal disease by



Mediastinitis. Figure 1 Acute mediastinitis after cardiac surgery. Contrast-enhanced CT scan shows dehiscence of the sternum and multiple irregular strands and small fluid collection in the anterior mediastinum.



Mediastinitis. Figure 2 Idiopathic fibrosing mediastinitis. (a) Axial CT scan shows diffuse soft tissue infiltration in the mediastinum. (b) Contrast-enhanced CT scan shows moderate enhancement of the soft tissue in the mediastinum.



Mediastinitis. Figure 3 Fibrosing mediastinitis due to irradiation. Axial contrast-enhanced CT scan at the level of upper mediastinum shows an area and strands of soft tissue attenuation limited to the mediastinum. The right brachiocephalic vein is narrowed.

histoplasmosis, CT shows the enlarged calcified nodes most commonly in the right paratracheal region, whereas other regions: the left paratracheal, subcarinal, or posterior mediastinal regions may also be involved (4). Calcification is rare in the diffuse form which typically shows diffuse increase in attenuation of the mediastinal fat tissue. CT is useful for assessing involvement of mediastinal structures: narrowing and compression of superior vena cava, airway, pulmonary arteries, and veins (Fig. 3). Although MR imaging and CT are equivalent in assessing the extent of adenopathy or fibrosis, MR allows assessment of vascular involvement without contrast material. On MR imaging, fibrosing mediastinitis shows low intensity on T2-weighted images due to its fibrous content. The major disadvantage of MR is that it cannot confidently identify calcification.

Medullary Carcinoma

►Carcinoma, Other, Invasive, Breast

Medullary Sponge Kidney

R. H. Oyen
Department of Radiology, University Hospitals Gasthuisberg, Leuven, Belgium
raymond.oyen@uz.kuleuven.ac.be

Synonyms

Cacchi-Ricci disease; Cystic dilatation of the renal tubules (1–3); Cystic disease of the renal pyramids; Precalyceal canalicular ectasia; Renal tubular ectasia

Definition

Medullary sponge kidney is characterized by dilated collecting tubules within one or more renal pyramids of one or both kidneys (1–3). Renal size is usually normal. Cysts in other organs are not found. The pathogenesis of medullary sponge kidney is unknown. Medullary sponge kidney has been reported in 0.5% of excretory urograms (2).

Pathology

On cut section there are multiple cyst-like cavities ranging from 1 mm to several millimeters in diameter in one or more pyramids (1, 3). These cysts represent dilatation of the terminal portion of the collecting ducts, the ducts of Bellini. The abnormalities are confined to the papillary portions of the pyramids. Cysts usually communicate proximally with collecting tubules and distally with papillary ducts or the calyx.

Calculi frequently form within the dilated spaces. The most commonly documented change with time is an increase in the number and size of renal calcifications. Less commonly, new cavities develop in previously uninvolved papillae. Interstitial fibrosis and inflammation occur in more advanced forms (1–3).

Clinical Presentation

While medullary sponge kidney has been described in patients of all ages, it is most often encountered in patients in the third and fourth decades of life (1–3). A few cases have suggested a hereditary pattern with abnormalities documented in siblings or several generations. It also has been associated with hemihypertrophy, Ehlers–Danlos syndrome, congenital hypertrophic pyloric stenosis, and hyperparathyroidism (3).

Uncomplicated medullary sponge kidney usually causes neither symptoms nor impaired renal function, although there have been reports of impaired concentration or acidification of urine. Calculi may cause renal colic, hematuria, fever, dysuria, or flank pain.

Imaging

The urographic criterion for the diagnosis of medullary sponge kidney is the demonstration of discrete linear densities in one or more papillae (1–4). Cystic dilatations of the collecting ducts appear as clusters of small rounded spaces in the papillae. The papillae may be enlarged. Precalyceal calculi become surrounded by contrast material.

Advanced stages of medullary sponge kidney cause severe deformity of the papillae with marked distortion of the calyces. Calcifications are numerous and large.

The sonographic findings of medullary sponge kidney are nonspecific and include subtle anechoic spaces and echogenic deposits in the pyramids (1, 2). Increased echogenicity is most evident in the periphery of each pyramid near the septal cortex. When complicated with lithiasis, a typical acoustic shadow is observed.

Unenhanced computed tomography (CT) scans are either normal or demonstrate medullary nephrocalcinosis (precalyceal calculi) (1, 2, 5). Enhanced CT scans and contrast-enhanced magnetic resonance imaging (MRI) during the excretory phase may show accumulation of contrast material in the dilated spaces of the pyramid. MRI is insensitive in detecting calcification.

Differential Diagnosis

The differential diagnosis includes papillary blush, papillary necrosis, tuberculosis, and calyceal diverticulum (2).

Definition

Meningitis is a pathological process involving diffuse inflammation of the membranes (pia-arachnoid mater and cerebrospinal fluid, or dura-arachnoid mater, or both) surrounding the brain and spinal cord. Meningitis is the most common form of central nervous system (CNS) infection. The etiology varies according to the age of the patients and the status of their immune system. In adults, the most common agents for bacterial meningitis include streptococci and *Neisseria meningitidis*. Aseptic meningitis is usually caused by viral pathogens. Meningeal tuberculosis (TB) is the most common presentation, and is most frequently seen in children and adolescents.

Pathology/Histopathology

Bacteria that reach into the subarachnoid space stimulate the production of cytokines and other inflammatory products. The inflammation may extend to the walls of arteries and veins resulting in vasculitis and thrombosis. Accumulation of the exudate may cause the obstruction of the cerebrospinal fluid (CSF) flow and lead to communicating or obstructive hydrocephalus (1).

Clinical Presentation

Meningitis classically manifests as a febrile illness accompanied by meningismus. The patients most commonly present with headache, neck stiffness, fever, and chills.

Imaging

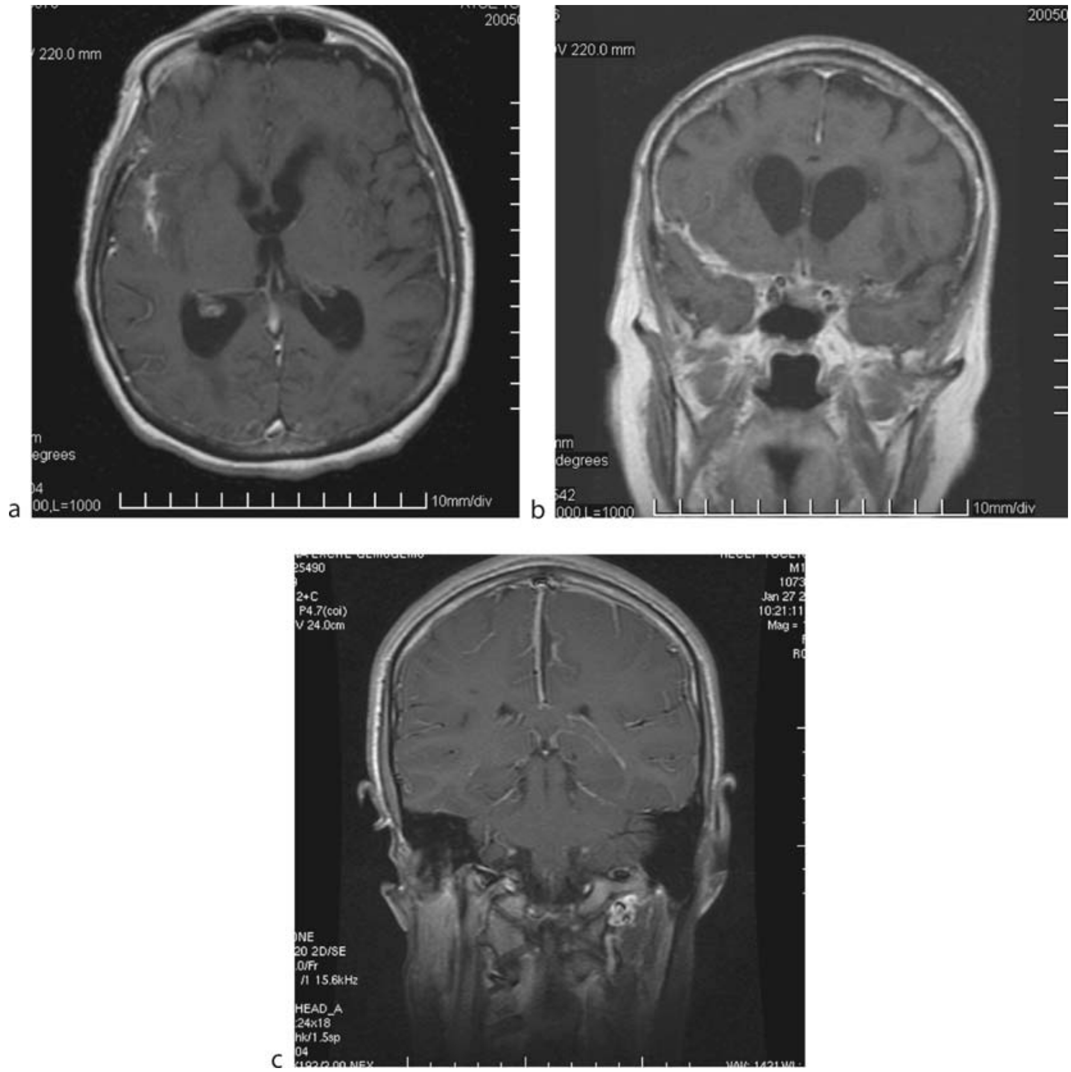
Computed Tomography

The computed tomography (CT) findings are mostly normal in the early phase of meningitis. On noncontrast studies, meningeal inflammation is seen as a subtle "loss of sulci," mild ventricular dilatation, and subarachnoid enlargement. Contrast-enhanced CT may show meningeal enhancement.

Magnetic Resonance Imaging

Unenhanced magnetic resonance (MR) scans of patients with uncomplicated acute bacterial meningitis may be unremarkable. Only 50% of patients with meningitis show subarachnoid space obliteration (1). Postcontrast MR studies can demonstrate leptomeningeal enhancement (Fig. 1). Fluid attenuation inversion recovery (FLAIR) images show the CSF within the subarachnoid space to be of higher signal intensity than expected in meningitis. Magnetization transfer techniques may also help in the visualization of enhancing meninges. On MR spectroscopy, elevation of lactate, large amounts of amino acids, acetoacetate, and reduced glucose with normal NAA, Cr, and Cho levels have been reported.

Imaging findings in patients with viral meningitis are frequently normal. The common triad of imaging findings in TB meningitis is basal meningeal enhancement, hydrocephalus, and infarctions in the supratentorial brain parenchyma and brain stem.



Meningitis. Figure 1 **Meningitis. Axial (a) and coronal (b) postcontrast T1-weighted images show nodular and diffuse pia-subarachnoid type enhancement of meningitis on the right temporal lobe along the sylvian fissure. Coronal (c) postcontrast T1-weighted images from another patient exhibit diffuse pia-subarachnoid type enhancement along the cortical sulci. Thickened and enhanced falx corresponding to dura-subarachnoid type meningitis together with parafalcine subdural effusion are also seen in the same patient.**

Diagnosis

Lumbar puncture with examination of the CSF represents the cornerstone of the diagnosis in suspected cases. Peripheral blood studies are nonspecific. Blood cultures are positive in up to 75% of patients. Polymerase chain reaction for TB can confirm the diagnosis rapidly.

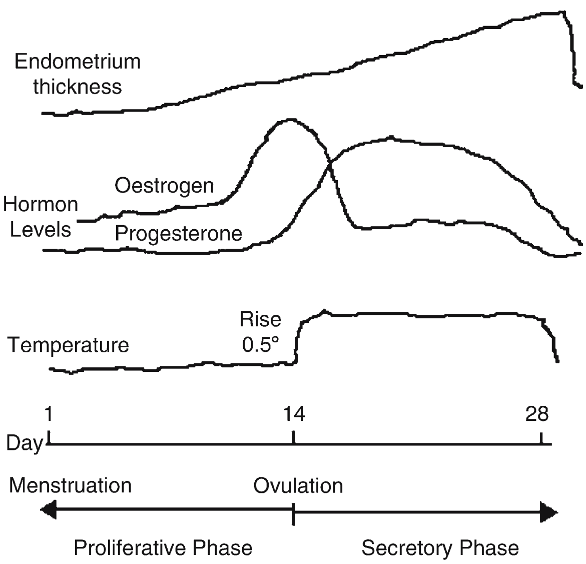
Menstrual Cycle

Martin Unterweger, Rahel A. Kubik
Institute of Radiology, Kantonsspital Badan, Switzerland
Martin.Unterweger@ksb.ch

Definition

The menstrual cycle is defined as a recurring cycle of physiological changes in females that is associated with



Menstrual Cycle. Figure 1 Endometrial thickness, temperature, and hormone levels during the menstrual cycle.

fertility. In women of reproductive age, the time of imaging during the menstrual cycle influences the imaging appearance of the female genital organs, i.e., uterus and ovaries.

The menstrual cycle of hormonal changes is measured from the beginning of the first day of menstruation. The average menstrual cycle is 28 days with a wide individual range. The hormones (estrogen and progesterone) control the menstrual cycle. At the beginning of the menstrual cycle from days 1–4 is the menstruation. Then the pituitary gland releases FSH, which makes the immature follicles to grow in the ovaries. Estrogen level rises, since the developing follicle secretes the hormone in the proliferative phase (days 5–12). During the ovulation, estrogen is at the maximum level and the follicle on the ovary's wall bursts releasing the egg. After ovulation, the secretory phase begins (days 12–28). Both estrogen and progesterone are secreted by the corpus luteum, which is developed from the burst follicle and remains in the ovary. With the disappearance of the corpus luteum, hormone levels fall, which causes the rejection of the endometrium though menstruation (Fig. 1). The principle rule is that morphologic changes during the menstrual cycle of the uterus and ovaries are similar to radiological changes.

Normal Anatomy of the Female Genital Organs and Changes During the Menstrual Cycle

The uterus is divided into three parts: fundus, corpus, and cervix. Normal size of the uterus for women of the reproductive age is 6–9 cm in length and 4–6 cm in transversal dimension. The cervix uteri is smaller and measures normally around 2.5–3.5 cm. Cross sectionally, the uterus has three different layers: (1) Serosa (2) Myometrium (3) Endometrium.

During the menstrual cycle, endometrial thickness varies. The endometrium, as the central portion of the uterus, is thinnest at time of menstruation, being normally thinner than 4 mm. Endometrium gets thicker during the proliferative phase, in the secretory phase endometrium thickness slowly further increases. The thickness of the endometrium varies widely normally the maximal thickness is 3–6 mm in the proliferative phase and 5–13 mm in the secretory phase. In the area of the cervix, the endometrium is normally thinner.

The endometrium stripe does not vary in women with oral contraception. The postmenopausal endometrium is normally thinner than 3 mm, unless the postmenopausal woman takes hormonal replacements therapy. On imaging, a thickened endometrium has a broad differential diagnosis, including endometrial hyperplasia, endometrial polyp, and endometrial carcinoma.

The myometrium also varies slightly in size during the menstrual cycle and becomes thicker in the proliferative and secretory phase. The ovaries vary in size with the female age. Ovarian size in neonates is approximately 3 × 2.5 × 1.5 mm. Mean ovarian volume in premenopausal women is 4.9 cm^3 with an upper limit of 20 cm^3. In postmenopausal women, the mean volume of the ovary is 2.2 cm^3 with an upper limit of 10 cm^3. The ovaries consist of different types of follicles, e.g., primary, secondary, primordial. During the menstrual cycle, the so-called secondary "Graafian" follicle matures. Maturation can be suppressed by hormonal contraception. Without contraception, the Graafian follicle after releasing an egg becomes the corpus luteum. If no pregnancy follows, the corpus luteum changes in the corpus albicans, which normally degenerates completely. Follicles will be seen as functional cysts on the different imaging techniques.

Imaging

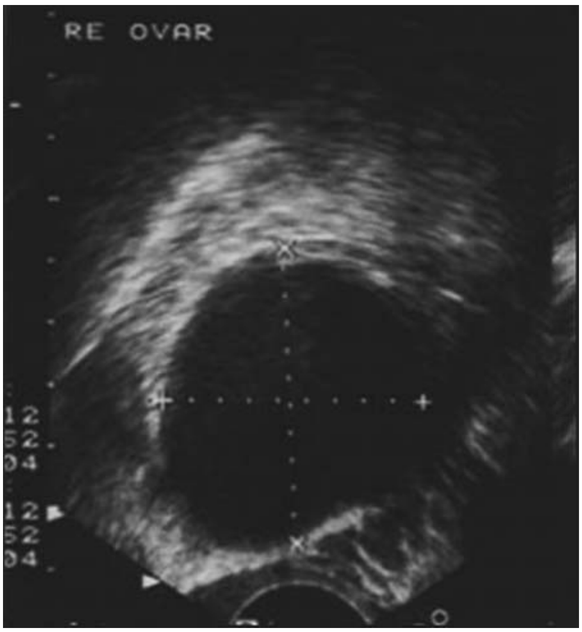
On sonography, the endometrium appears hyperechogenic, while myometrium occurs hypoechogenic. Therefore, the thickness of the endometrium can be measured with sonography. A focal thickening of the endometrium must be recognized as pathologic and needs further examination, because is could also be a sign for an endometrial carcinoma or another pathology as described earlier.

Functional cysts can be sonographically detected as anechogenic well-defined lesions in the ovaries. The greatest number will be found at birth with a significant decrease in number after menopause (Fig. 2).

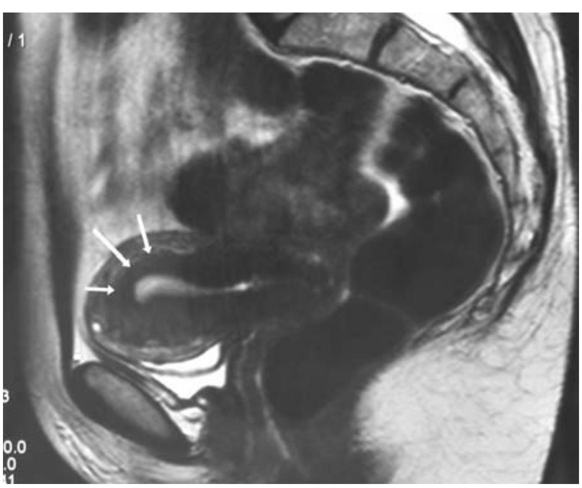
A small amount of free pelvic fluid is physiologic in women at the time of ovulation. On MRI, the uterus is best evaluated on T2-weighted sagittal imaging. Three zones can be recognized: The innermost hyperintense zone is the endometrium, followed by the myometrium that consists of two different signal intensities on MRI. While the inner layer of the myometrium, the "junctional zone" is hypointense, the outer layer of the myometrium is isointense relating to skeletal muscle (Fig. 3). The junctional zone does not correlate to a real anatomic structure, but it is described as the innermost, less water-containing layer of myometrium. Another hypothesis explains the low signal intensity of the junctional zone by the presence of compact smooth muscle bundles and the increase in percentage of nuclear area in comparison to the subserosal myometrium.

At the end of the menstrual cycle, the myometrium appears with a higher signal intensity caused by increased vascularization, so that the contrast to the "junctional zone" and endometrium is more pronounced and the zonal anatomy of the uterus is best differentiated at this time of the menstrual cycle. Therefore, if possible, patients with congenital uterine malformations should be scheduled for MRI toward the end of their menstrual cycle. During menstruation, a common MR finding is an irregular thickening of the junctional zone due to uterine contraction. This is also a finding in diffuse uterine adenomyosis and a pitfall for false positive diagnosis of this entity on MRI.

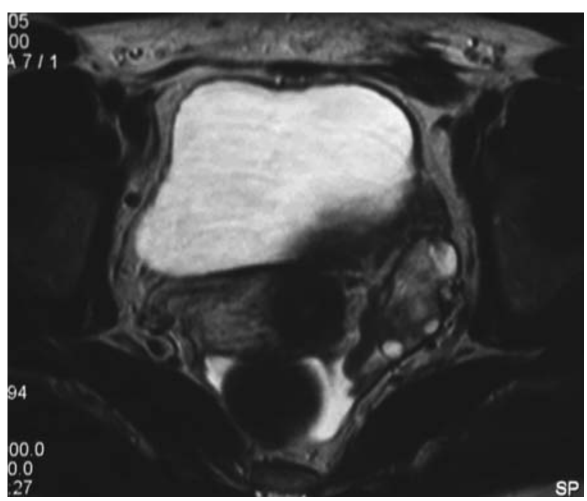
On MRI, the ovaries can be best seen on transversal or coronar T2-weighted images. They are normally iso-intense to the uterus on precontrast T1-weighted images and enhance after contrast media is applied. In the proliferative phase about 10–20 follicles start developing in the ovaries. Functional cysts are normally sharp defined with a high signal intensity on T2-weighted MRI images (Fig. 4). The corpus luteum and albicans (Fig. 5), however, may show an irregular cyst wall and demonstrate variable enhancement. The corpus luteum after releasing the egg could also cause a hemorrhage, which will be seen as high signal intensity on T1-weighted images.



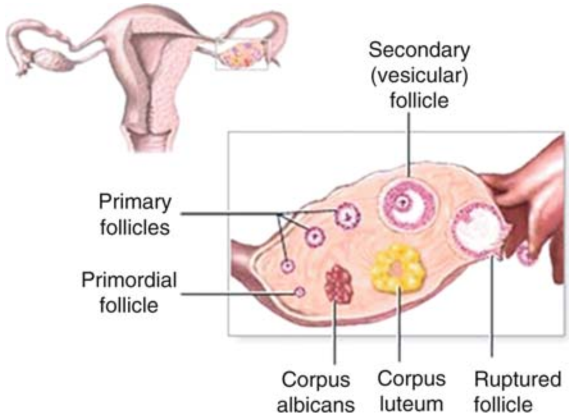
Menstrual Cycle. Figure 2 **Sonography demonstrates a large functional cyst in the right ovary.**



Menstrual Cycle. Figure 3 **Zonal anatomy of the uterus, sagittal T2-weighted MRI: Endometrium, junctional zone of the myometrium (arrows) and the outer myometrium.**



Menstrual Cycle. Figure 4 **Axial T2-weighted MRI of 44-years-old woman with multiple cysts in the left ovary (large arrows). Physiologically a small amount of free fluid (small arrows) is seen in the pouch of Douglas.**



Menstrual Cycle. Figure 5 Different kinds of follicular

As mentioned above, small amount of free pelvic fluid is a physiological finding, seen in many women at ovulation, but can be present during the entire phase of the menstrual cycle. Especially, T2-weighted MRI is very sensitive for free fluid in the pouch of Douglas. Therefore, without any underlying pathology, some amount of fluid in the female pelvis is a physiological finding in most cases and should not be termed ascites (Fig. 4).

Mercury

Mercury (Hg, atomic number 80) is an elemental heavy metal found in both its elemental form and in organic compounds. Elemental mercury is a liquid at room temperature and is highly volatile. Organic mercury is most frequently encountered in contaminated fish. Elemental mercury fumes and organic mercury are highly toxic to the central nervous system. Elemental mercury toxicity was common in the hat-making industry in the early nineteenth century, manifesting as tremors, hallucinations, and psychosis. Chronic organic mercury exposure results in an entity known as Minamata disease, which is characterized by visual field defects, sensory abnormalities, and ataxia.

▶Toxic Disorders, Brain

Mesenchymal Hamartoma, Hepatic

Rare congenital mesenchymal solid/cystic lesion originating from the primitive connective tissue in the portal tracts. It accounts for 22% of the benign liver tumors in children with a marked male predominance. Lesions may be large, usually well demarcated without capsule and formed by a mixture of cysts, bile ducts, vessels, and connective tissue.

▶Hepatic Pediatric Tumors, Benign

Mesenchymal Tumors, Pancreatic

Mesenchymal or soft tissue tumors of the pancreas are nonepithelial tumors arising from the connective, vascular, and neuronal tissue in the pancreas and are classified according to their main histologic component. All these neoplasms are exceedingly rare, representing 1–2% of pancreatic neoplasms and do not differ in structure and imaging findings from those seen in other organs. Benign soft tissue neoplasms that have been reported include benign fibrous histiocytoma, hemangioendothelioma, lymphangioma, lipoma, schwannoma, and neurofibromas (in patients with von Recklinghausen syndrome). Malignant mesenchymal tumors reported in the literature include leiomyosarcoma, fibrosarcoma, malignant fibrous histiocytoma, liposarcoma, rhabdomyosarcoma, hemangiopericytoma, and malignant schwannoma. However, some of these tumors probably represent undifferentiated carcinomas or secondary involvement of the pancreas by primarily retroperitoneal sarcomas. Moreover, sarcomas are often difficult to distinguish from undifferentiated carcinomas also at histology.

▶Carcinoma, Pancreatic

Mesenteric Vascular Occlusion

Metastases, Breast

Geert M. Villeirs
Genitourinary Radiology, Ghent University Hospital, Ghent, Belgium
geert.villeirs@ugent.be

Definition

Breast metastases are relatively rare. The most common primary tumors that can metastasize to the breast are contralateral breast cancers and extramammary tumors such as melanomas, lung cancer (especially oat-cell tumors), ovarian cancer, sarcomas, and gastrointestinal carcinoid tumors. In addition, virtually any primary site has been reported to occasionally metastasize to the breast, for example, thyroid, stomach, colon, rectum, kidney, bladder, cervix, uterus, and so on. In male patients, breast masses can be found to be metastatic from prostate cancer. Hematologic tumors, such as lymphomas, can also affect the breast, but should be regarded as part of a systemic disease and are discussed elsewhere in this volume.

Pathology/Histopathology

Many metastases are found in the subcutaneous fat rather than in the breast parenchyma. If they are large enough, they can be palpated as a solitary nodule. Multiple and bilateral lesions are generally found only later in the

M

course of the disease. The nodules tend to be rounded and well demarcated. Diffuse infiltration may occur in ovarian carcinomas, but it is uncommon in other primary extramammary malignancies. Rarely, metastases may induce an intense inflammatory reaction resembling an inflammatory breast carcinoma.

Microscopically, breast metastases usually reflect the primary cells of origin well, but the diagnosis may be less obvious when the lesion originates from an undifferentiated primary tumor or from a contralateral breast tumor, in which the metastatic cells may closely resemble those of a primary breast tumor. Some clues may help the pathologist to differentiate a metastatic form a primary malignancy. With few exceptions, metastatic lesions are highly cellular and do not present with an intraductal (DCIS) component. Estrogen and progesterone receptors are rarely present in metastatic lesions, except when arising from ovarian or prostatic tumors. Unlike primary breast tumors, metastases are not usually located within an area of proliferative change (with or without atypia). They tend to displace the surrounding normal breast tissue without eliciting a desmoplastic reaction and therefore are fairly well circumscribed with no spiculations.

Clinical Presentation

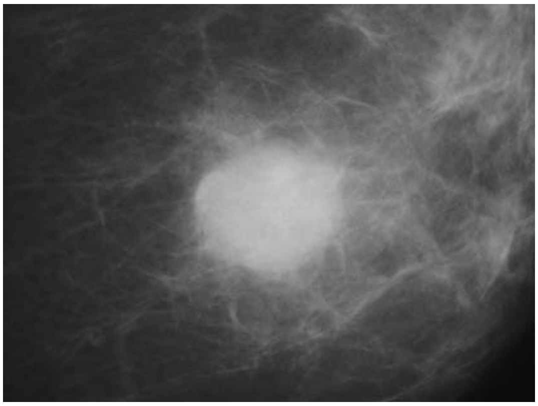
On average, the interval between the treatment of a primary cancer and the development of breast metastases is approximately 2 years. Metastases at sites other than the breast usually have already occurred before a breast metastasis is detected or they occur coincidentally.

Breast metastases may present as solitary or multiple palpable masses. They are usually painless, fairly mobile, smoothly outlined, and rounded. In the absence of a desmoplastic reaction, their palpable size usually closely approximates their mammographic size. In rare cases of diffuse infiltration or inflammatory reaction, skin thickening, peau d'orange, and diffuse swelling of the breast can be observed.

On the basis of clinical examination, however, breast metastases can rarely be distinguished from other breast lesions, although a history of rapid growth and of a known primary malignancy may be suggestive.

Mammography

There are no reliable mammographic criteria that distinguish breast metastases from other breast lesions. Most breast metastases present as solitary round, oval, or lobulated masses with well-defined margins (Fig. 1). Sometimes the margins may be partly indistinct or angular, but spiculation is exceedingly rare. Later in the course of the disease, multiple or bilateral equally sized masses may be observed. In the case of diffuse infiltration or inflammatory reaction, the density of the involved side may increase, along with skin thickening and diffuse trabecular thickening.



Metastases, Breast. Figure 1 Breast metastasis from ovarian cancer, presenting as fairly well-defined lobulated mammographic mass.

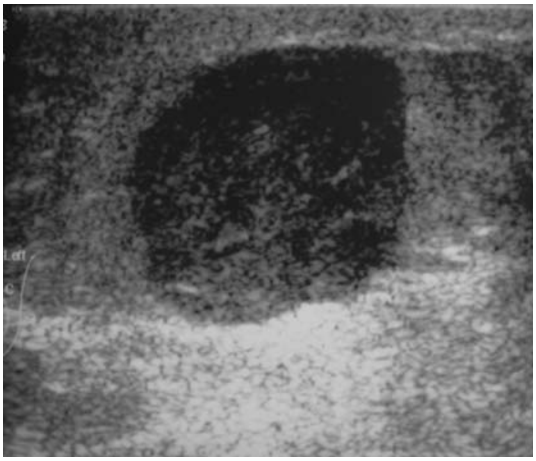
Calcifications are rarely present, except for coarse calcifications involving necrotic areas or calcifications in metastases from ovarian carcinoma or thyroid medullary carcinoma.

Sonography

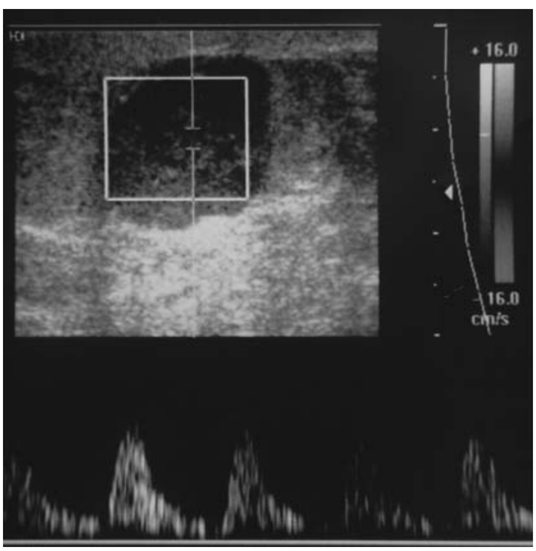
Although sonography can identify a simple cyst as the cause of a palpable or mammographic abnormality, it does not allow a reliable differentiation of breast metastases from other abnormalities. Breast metastases are usually round, oval, or lobulated, and they have a well-circumscribed margin (Fig. 2). Sometimes the margins may be partly indistinct or angular, but spiculation or an echogenic halo due to surrounding desmoplastic reaction is usually absent. The lesions are hypoechoic, with fairly homogeneous internal structure, except when central necrosis occurs. They show normal or enhanced through-transmission, but acoustic shadowing may occur in the presence of intense fibrosis. The compressibility under varying scan pressures depends on the type of the primary tumor, and on Doppler interrogation, many breast metastases appear hypervascular (Fig. 3).

Magnetic Resonance Mammography

There are only few reports on magnetic resonance imaging (MRI) of breast metastases. Most reported cases show a round or oval, well-circumscribed lesion with low signal intensity on T1-weighted images and intermediate to high signal intensity on T2-weighted images. Following



Metastases, Breast. Figure 2 **Sonogram of breast metasis from ovarian cancer, presenting as a well-defined lobulated hypoechoic mass with enhanced through-transmission.**



Metastases, Breast. Figure 3 **Hypervascular appearance of breast metastasis on Doppler-interrogation.**

intravenous contrast administration, most lesions exhibit a fast ring-like enhancement with wash-out pattern, indistinguishable from other breast malignancies.

Percutaneous Biopsy

Since breast metastases cannot reliably be diagnosed clinically, mammographically, sonographically, or on MRI, biopsy is the only way to confirm the presence of a metastasis. Information about a prior tumor and a tissue sample large enough to contain all necessary information for accurate diagnosis are of utmost importance for the pathologist.

Liver metastases

Definition

A malignant tumor of the liver following hepatic migration of tumor cells originating from a primary malignant tumor in another organ.

Epidemiology

The liver is second only to regional lymph nodes as a site of metastatic disease and hepatic metastases represent the most common malignancy of the liver. The true prevalence of liver metastases is unknown; however, between 25 and 50% of patients with known nonhematological malignancies have liver metastases at the time of diagnosis (1, 2).

The liver may be the site of metastasis from virtually any primary malignant neoplasm. The frequency of metastasis to the liver varies considerably with the cell type and the location of the primary tumor, but the most common primary tumor sites are the colon, stomach, pancreas, breast, and lung. Lymphoma may involve the liver as well.

Most metastases to the liver are bloodborne *via* the hepatic artery or portal vein, but lymphatic spread of tumors from the stomach, pancreas, ovary, or uterus may also occur. Particularly, the portal circulation provides direct access to the liver for tumor cells arising from the gastrointestinal tract and accounts for the high frequency of liver metastases from organs drained by the portal vein.

Pathology/Histopathology

The gross features of liver metastases are variable. Lesions are multiple in most cases and depending on the origin of the primary tumor, may be expansive, infiltrative, surface spreading, or miliary (1, 2).

Metastases from colon carcinoma often appear as a few large nodules with central umbilication. Nodules from breast and lung carcinoma are usually medium in size and often show an early central umbilication, whereas a central necrosis is typical for small cell carcinoma, seminoma, sarcoma, and melanoma. Metastatic lesions of miliary type may be observed in breast, prostate, and stomach metastatic cancer. In contrast to the liver parenchyma, hepatic metastases get their blood supply almost exclusively from the hepatic artery.

Most metastases maintain the microscopic features of the primary tumor, including the degree of stroma growth, particularly conspicuous in neoplasms arising from the breast, pancreas, and stomach (1, 2). Other metastases, such as lesions arising from small cell carcinomas and melanomas, do not usually evoke a local reaction and may grow in the sinusoids.

Clinical Presentation

Symptoms due to hepatic metastases may be few and the extent of liver involvement on images may be surprising in the absence of clinical or laboratory signs suggestive of hepatic functional insufficiency. Hepatomegaly is the most common finding, followed by ascites and jaundice. Liver function tests tend to be insensitive and nonspecific (1, 2).

Imaging

The ultrasound (US) appearance of liver metastases is extremely variable, including hypoechoic, isoechoic, hyperechoic, calcified, cystic, and diffuse-infiltrative patterns (1–3).

Depending on tumor vascularity, cellular composition, the degree of tissue invasion, and the presence or absence of necrosis, the echogenicity of the lesions can vary.

A hypoechoic appearance, corresponding to hypovascular and uniform neoplastic tissue, is usually observed in metastases originating from melanoma, lymphoma, and breast, lung, and cervical cancer, while hyperechoic metastases can be observed in tumors arising from colon, renal, breast, and islet cell carcinomas. Particularly, metastases from gastrointestinal or pancreatic tumors exhibit a central hyperechoic area surrounded by a hypoechoic halo. This characteristic target pattern is highly suggestive for malignancy and is often secondary. A calcified pattern is commonly due to mucinous adenocarcinomas of the colon or ovary. Cystic metastases, including those from sarcomas and ovarian, pancreatic, and colon cancers, are rare. In rare cases, metastases may cause diffuse parenchymal changes because of the confluence of areas of focal spread, infiltrating tumors, or miliary metastatic deposits, and the liver may appear diffusely heterogeneous. According to this extremely variable, usually nonspecific US appearance of liver metastases, characterization of such lesions with conventional US is not possible in most cases.

Despite Doppler US modalities that allow the addition of information concerning tumor vascularity and enabling improved US characterization of focal liver lesions in some cases, US suffers a relatively poor sensitivity and specificity compared with other imaging techniques, such as spiral computed tomography (CT) and magnetic resonance (MR) imaging. However, with the advent of US contrast agents and new contrast-specific imaging techniques, lesion detection and characterization have significantly improved.

Contrast-enhanced ultrasound (CEUS) provides crucial additional information about the dynamic contrast behavior for lesion characterization, and after US contrast agent injection, metastases show characteristic features. Most metastases are hypovascular and show a typical pattern consisting of absent or peripheral enhancement in the arterial, portal–venous, and delayed phases. Hypervascular lesions (metastases arising from renal cell carcinoma, breast carcinoma, islet cell tumors, carcinoids, melanoma, and sarcoma) exhibit an early, intense, and homogeneous enhancement compared with the surrounding liver during the arterial phase, becoming hypoenhancing in the portal–venous and delayed phases (3). More important, the use of contrast agents substantially improves the ability of US to detect liver metastases. Both portal–venous and delayed-phase imaging markedly increase the contrast between the enhancing normal liver and the nonenhancing metastases, improving the lesion detection rate, especially for very small lesions (<1 cm) and for lesions appearing isoechoic on baseline scan.

Finally, intraoperative ultrasound (IOUS) of the liver can be used in the operative setting before hepatic resection because of its extremely high sensitivity for detecting small hepatic metastases. With a sensitivity of 98% and a specificity of 95%, IOUS is generally considered the gold-standard imaging technique for detecting liver lesions. It is used to evaluate the extent of malignant liver disease and to plan resections by assessing the relationship of a tumor to large vessels.

Spiral CT is the most commonly used imaging modality for both detection and characterization of hepatic metastases. Hepatic metastases usually appear as low attenuating or isoattenuating masses on nonenhanced CT scans. Depending on lesion size, the margins tend to be irregular, and necrosis may be present. Central low attenuation may be the result of necrosis or cystic change. Calcification can be observed within metastases arising from mucinous adenocarcinomas of the colon, pancreas, or ovary. Most metastases, including those arising from the colon, stomach, pancreas, and lung, are usually hypovascular because they receive only minimal arterial and portal venous blood supply due to confluent dense cellularity, fibrosis, or necrosis. On contrast-enhanced spiral CT, a hyperdense rim may be observed during the arterial phase, particularly in colon carcinoma metastases, due to viable tumor in the periphery of the lesion, which appears against a hypodense (necrotic) center. However, the optimal scanning time for detecting hypovascular metastases is the portal–venous phase, when the normal liver parenchyma is maximally enhanced, revealing the relatively hypoattenuating lesions (Fig. 1). In the equilibrium phase, metastases can be isoattenuating. Hypervascular metastases are relatively rare and are often secondary to renal cell carcinoma, breast carcinoma, islet cell tumors, carcinoid tumors, melanoma, and sarcomas. When hypervascular metastases are suspected, a multiphase contrast-enhanced spiral CT evaluation, including at least arterial and portal–venous scans, should be performed. The best phase for detecting hypervascular metastases is the arterial phase. Small hypervascular metastases usually show a strong and homogeneous enhancement with respect to the liver parenchyma, whereas larger lesions appear heterogeneous or show an enhancing peripheral rim surrounding the necrosis. In the portal–venous phase, most hypervascular metastases become isodense and difficult to detect because the tumor still receives some contrast *via* the hepatic artery, and the liver parenchyma also receives contrast *via* the portal vein (1, 2, 4).

Finally, CT arterioportography (►CTAP) currently represents the most sensitive nonsurgical imaging technique for detecting hepatic metastases, with an overall detection rate of 81–94%. However, CTAP is invasive and has a high false-positive rate (5).

Magnetic Resonance (MR) imaging is commonly used as the definitive imaging modality for the detection and characterization of focal liver lesions. The standard MR imaging protocol should always include nonenhanced T1- and T2-weighted and contrast-enhanced pulse sequences by using high-field-strength MR scanners (≥1.0 T) with fast gradients and phased-array surface coils.

Liver metastases usually appear as hypointense lesions on T1-weighted images and as hyperintense lesions on T2-weighted images compared with normal liver parenchyma, according to the higher content of free water molecules. However, depending on the degree of vascularity, necrosis, and hemorrhage, the MR appearance of metastases is variable. The presence of coagulative necrosis, fibrous tissue, or calcification may result in decreasing signal intensity on T2-weighted images, whereas colliquative necrosis, edema, and cystic components lead

Metastases, Hepatic. Figure 1 **Hypovascular metastases on contrast-enhanced multidetector spiral computed tomography (CT), with a characteristic appearance of hepatic metastases arising from colon cancer on dual-phase contrast-enhanced spiral CT. Arterial-phase spiral CT (a) shows a hypodense lesion with slight peripheral enhancement in the right liver, which becomes more evident during the portal–venous phase (b).**

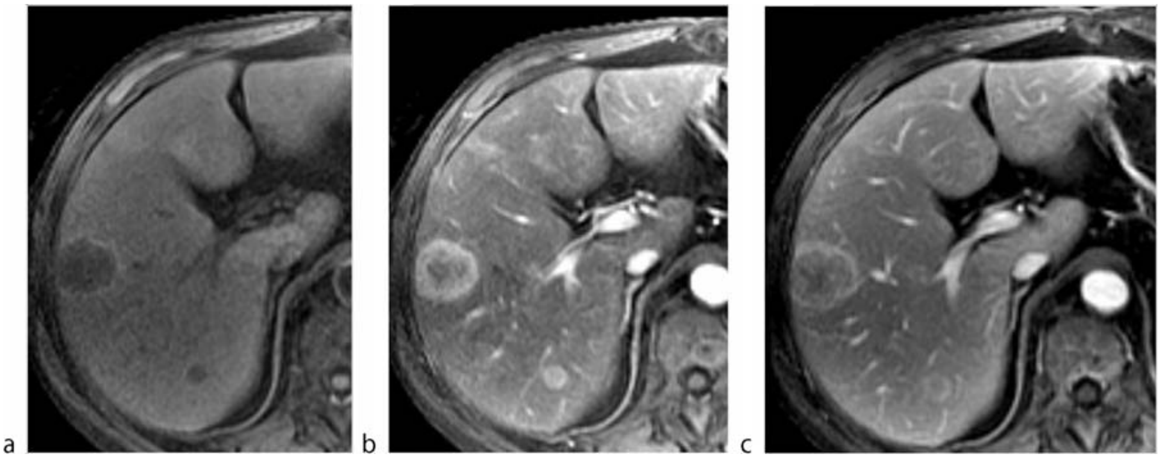
to higher signal intensity. Particularly, on T2-weighted images approximately 20% of all metastases (50% of colorectal metastases) show a peripheral hyperintense halo consisting of central necrosis surrounded by viable tumor (halo pattern), whereas another 5–20% may exhibit a central increase in signal intensity due to colliquative necrosis with an outer ring of lower signal intensity (target pattern).

Another characteristic feature of solid metastases is that they demonstrate a considerable signal intensity drop on heavily T2-weighted images using dual or multiecho T2-weighted pulse sequences. Finally, high signal intensity on T1-weighted images can be observed in rare metastatic lesions containing melanin (metastases from melanoma) or mucin (metastases from mucinous carcinoma of the pancreas or ovary), and in metastases complicated by intralesional hemorrhage (4, 5).

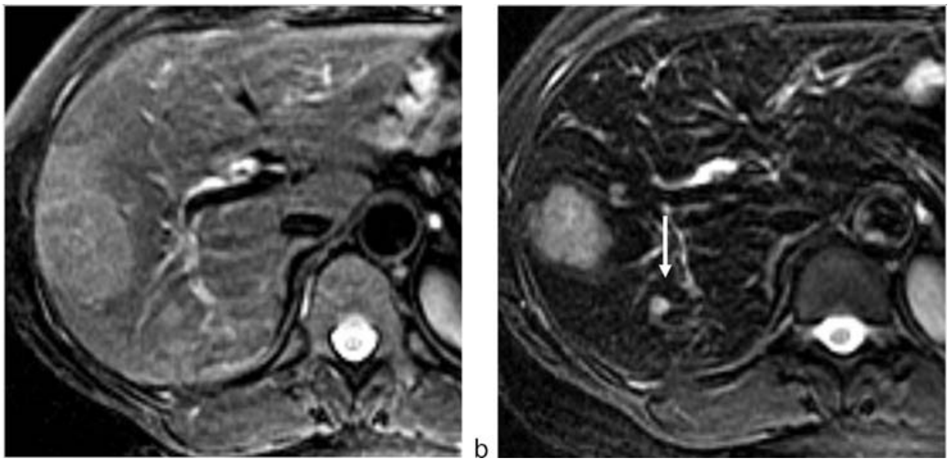
On dynamic gadolinium-enhanced MR imaging, the enhancement pattern of hepatic metastases is identical to that observed on contrast-enhanced spiral CT. Hypovascular metastases appear typically hypointense with respect to the surrounding normal liver tissue after intravenous bolus administration of gadolinium chelates, and higher lesion-to-liver contrast is observed during the portal–venous phase. Hypervascular lesions exhibit intense and homogeneous enhancement in the arterial phase, followed by isointensity or slight hypointensity during the portal and equilibrium phases (1, 2, 4, 5) (Fig. 2).

The availability of MR contrast agents with liver-specific properties further increases the potential for detecting hepatic metastases. After administration of Gd-BOPTA, Gd-EOB-DTPA, or Mn-DPDP, liver metastases appear clearly hypointense against a strongly enhanced normal liver during the delayed T1-weighted ►hepatobiliary phase, with a significant improvement in lesion conspicuity, particularly for metastases <1 cm in diameter. However, metastases from neuroendocrine tumors may rarely show a variable uptake of hepatobiliary contrast agents. Of interest, Gd-BOPTA and Gd-EOB-DTPA have both ►extracellular and hepatobiliary properties, allowing more accurate lesion characterization, which can be especially useful when benign and malignant lesions coexist in the same patient.

Detection and characterization of focal liver lesions can also be improved by administration of ►reticuloendothelial system (RES)-targeted agents consisting of superparamagnetic iron oxide (SPIO) particles or ultrasmall superparamagnetic iron oxide (USPIO) particles. Because of the absence of Kupffer's cells, metastases generally do not show a significant signal drop on T2-weighted images after SPIO injection, appearing as hyperintense nodules against a darkened normal liver (Fig. 3). Improved lesion resolution from suppression of peritumoral edema makes these agents particularly useful in preoperative evaluation of hepatic metastases from primary colorectal cancer. Moreover, SPIO agents are also useful in differentiating metastases from focal liver lesions with phagocytic elements, including focal nodular hyperplasia, adenomas, and well-differentiated hepatocellular carcinomas that result in contrast uptake and show decreased signal intensity on T2-weighted images (2).



Metastases, Hepatic. Figure 2 Hypervascular metastases on dynamic magnetic resonance imaging (MRI), with a characteristic appearance of hepatic metastases arising from carcinoid. Baseline T1-weighted MRI (a) demonstrates two well-defined hypointense nodular lesions in the right hepatic lobe. On gadolinium-enhanced dynamic MRI, both lesions show an early and intense enhancement during the arterial phase (b). The larger lesions appear heterogeneous in the portal-venous phase with an isointense appearance of the peripheral zone, whereas the smaller lesion becomes isointense and difficult to detect (c).



Metastases, Hepatic. Figure 3 **Liver metastases on reticuloendothelial system-targeted enhanced magnetic resonance imaging. Two hyperintense lesions are depicted on baseline T2-weighted image (a). In the liver-specific phase, a third small lesion can be appreciated (b).**

Nuclear Medicine

^{99m}Tc-sulphur colloid scintigraphy, although quite sensitive in lesion detection, is almost nonspecific and is rarely used as an imaging test for liver metastases. However, scintigraphy with a somatostatin receptor analog (such as ^{111}In-octeotride) may be useful for evaluating suspected hepatic metastases arising from carcinoids and other neuroendocrine tumors.

Recently, positron emission tomography (PET) has emerged as an important diagnostic tool in the evaluation of metastatic liver disease. Particularly, fluorine-18-fluorodeoxyglucose PET (^{18}F-FDG-PET) has been shown to be highly sensitive for detecting hepatic metastases arising from different primaries (6).

Diagnosis

The noninvasive diagnosis of liver metastasis at an early stage is almost entirely dependent of imaging. US is usually the first-line imaging investigation for hepatic screening of oncologic patients. Because of its noninvasive character, low cost, and widespread availability, US can be used to help distinguish patients with diffuse disease who are not eligible for curative treatment, patients with no liver metastases, and patients with a limited number of metastases. The patients in the latter group should undergo CEUS, CT, MR imaging, or FDG PET for the selection of appropriate therapeutic approaches (6).

Contrast-enhanced spiral CT offers a comprehensive evaluation, allowing a simultaneous examination of the extrahepatic abdomen and even the pelvis and chest (2, 4, 6). Since the recent advances in hardware and software and the introduction of tissue-specific contrast agents, MR imaging has also gained an important role in the diagnosis of liver metastatic disease. Particularly, the use of hepatobiliary and RES-targeted MR contrast media seem to have significantly improved the detection of hepatic colorectal metastasis, especially in lesions smaller than 1 cm (4, 5).

Interventional Radiology

Surgical treatment is currently considered the best therapeutic option for liver metastatic disease, but only 20% of patients are suitable for surgical resection. Therefore, alternative local or locoregional interventional radiological procedures, including percutaneous tumor thermal ablation (cryoablation and radiofrequency, laser, and microwave ablation) have been largely used in an attempt to obtain large tumor necrosis and improve survival data in patients with unresectable liver metastases (1, 2).

Because the biology and characteristics of metastatic disease may limit the applicability of a local or systemic therapy, the choice of the most appropriate interventional radiological procedures depends mainly on the biology of the primary tumor and, in the case of disease being confined to the liver, by the number and topographic location of the metastases.

Colorectal liver metastasis is the most frequent indication for the use of regional treatment concepts for the liver, but metastases from other primary tumors such as metastases from breast and neuroendocrine tumors (carcinoids) may also benefit from local therapies.

M

Local ablative thermal therapies, particularly radiofrequency thermal and laser ablation, seem to be able to obtain a remarkable local tumor control rate with improved survival results in solitary or fewer than three hepatic lesions that do not exceed 3 cm in their greatest dimension and that arise from colorectal adenocarcinoma. Transcatheter arterial chemoembolization represents a valid therapeutic option in hypervascularized metastases originating from neuroendocrine tumors.

Percutaneous ethanol injection, because of a non-homogeneous distribution of the ethanol within the lesion and poor tumor control has limited use in treating liver metastases.

Metastases, Pancreatic

The prevalence of metastatic involvement of the pancreas is not well known. Although pancreatic metastases are commonly considered infrequent, the occurrence at autopsy ranges from 3 to 12% of patients with advanced malignancy, and they account for 2–5% of pancreatic malignant tumors. A wide variety of primary tumors may metastasize to the pancreas, but the most frequently reported primary are kidney, breast, lung, and thyroid tumors and melanoma. Metastases may occur many years after the initial diagnosis, and treatment of the primary tumor or may be discovered before the primary site is known. Patients may have few or no symptoms referable to the pancreas. Concomitant intra-abdominal metastases to the liver, lymph nodes, and adrenals can be discovered at the time of diagnosis of pancreatic metastases. Metastases do not show any predilection for a specific area of the pancreas. Possible imaging patterns include multifocal lesions or large solitary masses with well-defined margins in the majority of cases, but diffuse infiltration and enlargement of the gland can be observed. Dilatation of the pancreatic duct can occur in up to one-third of cases; obstruction of the biliary tree is less common; and encasement of the major peripancreatic vascular structure is rare. The enhancement pattern is variable and often mimics the enhancement characteristic of the primary tumor. Many lesions, as they grow to a significant size, tend to exhibit heterogeneous enhancement. The suspicion of pancreatic metastases is based mainly on the history of a previously known cancer; however, the metastases may, rarely, be discovered before the primary site is known. The imaging appearance of the secondary lesions usually repeats the appearance of the primary tumor and consequently may suggest the diagnosis, particularly when multiple lesions are demonstrated or other metastatic localizations are present. Solitary hypovascular or hypervascular pancreatic metastases may mimic primary pancreatic ductal carcinomas or lymphomas and islet cell tumors, respectively. In these cases, histological confirmation is always requested.

Definitions

Malignant neoplasms infiltrate the skeleton from the primary site either by direct extension or by lymphatic or hematogenous dissemination. Different imaging techniques, including conventional radiographs (XR), skeletal scintigraphy, computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET), can be used for the detection, diagnosis, monitoring of the treatment, and follow-up of ▶bone metastases.

Pathology/Histopathology

General Mechanisms of Tumor Dissemination

Metastases may reach the skeleton by means of four main mechanisms:

1. *Hematogenous dissemination* (arterial and venous system) is the main mechanism for neoplastic cells to infiltrate the skeleton. Especially in prostate, breast, and colorectal cancer, tumor cells spread through the venous system into the skeleton. For spinal spread, Batson's paravertebral plexus plays a major role, since it is valveless and allows caudal or cranial blood flow depending on abdominal and pelvic pressure. Increased abdominal pressure causes blood to be diverted from the systemic caval system to the valveless vertebral venous system. Retrograde venous blood flow in Batson's plexus may explain the location of 70% of bone metastases in prostate cancer at the pelvis, sacrum, and inferior lumbar spine.
2. *Lymphatic spread* is a relatively infrequent route for the transportation of tumor cells to the bone. After metastatic invasion of lymph nodes, the adjacent skeleton may be secondarily involved with paravertebral soft tissue masses and scalloped erosions of the vertebral bodies. The left side of the vertebral bodies is more frequently affected by direct invasion from local lymph nodes because of the closer location of left-sided lymph nodes to the spine.
3. *Direct invasion* from the primary tumor or by extension from a secondary site (lymph node) is rare and usually associated with a detectable tumoral soft tissue mass.
4. *Intraspinal spread* may occur in patients with intracranial neoplasms and leads to subarachnoid deposit by means of cerebrospinal fluid.

Pathophysiology

The osseous response to tumor cells consists of bone resorption or bone formation, or both (1). Tumor cells arising in bone may produce factors that can stimulate osteoclast formation and bone resorption. Alternatively, tumor cells can also produce factors that stimulate osteoblast recruitment and differentiation, and new bone synthesis. The balance between osteoclastic and osteoblastic remodeling processes determines whether a predominant osteolytic, osteosclerotic, or mixed pattern is identified on radiographs.

Frequency and Distribution of Skeletal Metastasis

Bone metastases are much more common than primary skeletal neoplasms. They may be the first sign of the primary tumor in 20–25% of cases. Solitary bone metastases are frequently seen with renal, thyroid carcinoma, or hepatocellular carcinoma. In 3–4% of cases, the primary tumor remains unknown. In adults, the most common cancers causing bone metastases are breast carcinoma (70% in women), prostate cancer (60% in men), and lung and renal cancers in both genders. In children, bone metastases are much less common and include neuroblastoma, Ewing's sarcoma, osteosarcoma, and malignant tumor of soft tissue.

Axial Skeleton

Two main causes explain the predominant distribution of bone metastases to the axial skeleton and the proximal long bones:

1. Batson's venous plexus distribution, as well as the overall skeletal vascularity, results in a predilection for hematogenous spread to the axial skeleton and the proximal long bones.
2. In adults, bone metastases generally occur in the axial skeletal and the proximal part of long tubular bone corresponding to the distribution of residual red marrow, although they may be found anywhere in the skeletal system.

Axial sites are the following, in decreasing order of frequency: spine (lumbar, thoracic, cervical), pelvis, ribs, sternum, femur, humerus, and skull.

Long Tubular Bones

The long tubular bones, femur and humerus, are involved most frequently in cases of skeletal metastases with metaphyseal, diaphyseal, or epiphyseal location.

Short Tubular or Irregular Bones

Metastatic lesions at the bones of hands, wrists, and feet are infrequent. Imaging findings of acrometastases are an osteolytic appearance with frequent soft tissue mass and rarely periosteal reaction. Bronchogenic, renal, and colonic carcinoma are the main causes of such metastases.

Cortical Metastatic Lesion

Eccentrically located, scalloped erosions of the external surface of the cortex may be observed in cases of bronchogenic carcinoma ("cookie bite metastasis"). They may also arise from kidney cancer, and less frequently from breast, pancreas, larynx, and uterine malignancies.

Clinical Presentation

Bone pain is a common clinical sign that is due to increased medullary pressure and stretching of the periosteal membrane. Metastases that involve joints or periarticular bones may produce symptoms similar to arthritis. Complications of bone metastases include the occurrence of hypercalcemia, pathologic fracture (incidence: [16–60%]), and compression of adjacent neurologic structures such as the spinal cord or cranial nerves. A soft tissue mass and deformity are additional possible manifestations. Infiltration of the bone marrow by metastatic cells results in impaired hematopoiesis and the development of leukoerythroblastic anemia. The associated thrombocytopenia and leukopenia predispose to hemorrhage and infection.

Imaging

Imaging is an essential part of the management of bone metastases. However, no consensus has been reached concerning the optimal imaging modality because the evolution of bone metastases depends of the primary tumor and its aggressivity. When assessing bone tumor response in clinical practice, most oncologists do not use the criteria either developed by the International Union Against Cancer (UICC) (2), the World Health Organization (WHO) (3), or the Response Evaluation Criteria in Solid Tumors (RECIST) group, which consider bone lesions to be nonmeasurable.

Criteria for assessment of bone response are based on plain radiography for the UICC and on plain film or scan for the WHO. Four types of tumor response are defined: (i) complete response: disappearance of all lesions (recalcification of lytic lesion for the UICC; follow-up of at least 4 weeks for the WHO); (ii) partial response: partial decrease in size of measurable lesions (at least 50% and no new or progressive lesions for the UICC; recalcification of lytic lesions or decreased density of osteoblastic lesions for at least 4 weeks for the WHO); (iii) no change: unchanged lesions or limited increase (25%) and decrease (50%) in size of measurable lesions according to the UICC (the WHO requires at least an 8-week interval between the therapy onset and the assessment of stable lesion); and (iv) progressive disease: some or all lesions persist, progress and/or new lesions appear.

Conventional Radiographs

XR remains the most accessible practical method for characterizing symptomatic bone metastases. Bone lesions appear as areas of decreased or absent density (osteolytic), with disrupted or absent trabecular structure, or as sclerotic lesions with rim (osteoblastic).

XR is relatively insensitive in detecting bone metastases. Skeletal metastases become apparent on XR only after a loss of 30–75% of normal bone mineral content. Lesions in trabecular bone (medullary lesions) are more difficult to detect by XR than are lesions in cortical bone because of the limited contrast within trabecular bone. This is even more important in elderly patients with osteopenic bones. Advanced osteolytic lesions of the cancellous bone could be missed in the absence of reactive new bone or cortical involvement. Therefore, XR is less sensitive than bone scintigraphy for detecting and screening initial bone metastases. Combining XR and bone scintigraphy is recommended for diagnosing suspicious or symptomatic lesions.

The response of osteolytic lesions to treatment may be visible as lesion sclerosis on XR, corresponding to active bone formation, and reappearance and normalization of trabecular structure. Sclerosis tends to progress from the periphery of the lesion to its center and may make subtle areas of bone involvement more visible, contributing to a false interpretation of a new sclerotic lesion. Tumor dimensions are not easy to measure on conventional radiographs and cannot reflect only by themselves the response to therapy. For osteoblastic lesions, an increase in density may be visualized in both responding and progressing disease. Combined analyses of findings on radiographs (number, density, size of lesion) and Technetium–99m (^{99m}tc) bone scintigraphy improve the diagnostic accuracy, not only in detecting bone metastases but also in assessing the response to therapy.

Computed Tomography

Computed tomography (CT) offers superior skeletal visualization (sensitivity: [71–100%]) (4). Early detection of metastases in bone marrow is possible with CT before the detection of bone destruction. Metastases in bone marrow appear as an area with higher attenuation than the normal bone marrow. CT is useful for the evaluation of focal abnormalities seen on bone scintigraphy that cannot be confirmed by using radiographs. After therapy, sclerosis of an osteolytic lesion on CT also suggests a response to treatment. Progressive lysis or new areas of lysis within a sclerotic or mixed region represent disease progression. However, considering ionizing radiation exposure, CT is not the most suitable technique for the diagnosis and the follow-up of bone metastases.

MRI—Whole-Body MRI

MRI has evolved as the preeminent imaging technique in detection of changes in bone marrow constituency and in soft tissue. The diagnostic sensitivity of MRI in diagnosing bone metastases ranges from 82% to 100%, and its specificity from 73% to 100%. Use of gadolinium with MRI allows one to distinguish viable tumor from necrotic tissue. Additionally, many studies have shown that MRI depicts early hematogenous dissemination of tumor cells to bone marrow before reactions in adjacent bone are detectable with bone scintigraphy. With the use of new techniques such as contiguous, coronal short T1 inversion recovery (STIR) and T1-weighted sequences, ▶whole-body MRI provides a high sensitivity and specificity equal to or greater than those obtained with PET, and it could become the standard of practice in the future (5).

Diagnosis

Conventional Radiographs

The radiological findings of Skeletal metastases vary according to the patterns of bone response, their number, and their location. The radiographic appearance of skeletal metastases may help to identify the primary tumor (Table 1) and can be classified as purely osteolytic, purely osteosclerotic, or mixed osteolytic–osteosclerotic. Osteolytic lesions may be well circumscribed (geographic bone destruction) or poorly defined (moth eaten or permeative bone destruction). Osteosclerotic lesions may be focal or diffuse in distribution.

A few other radiographic features can help to identify the primary tumor. Their depiction and differential diagnosis are given in Table 2. Destruction of one or both pedicles of a vertebra is a typical radiographic finding of Skeletal metastases (Fig. 1) that is rarely present in multiple myeloma.

Destruction and Collapse of Vertebral Body

Radiological findings suggesting malignant vertebral body collapse (Fig. 2) include involvement of the upper thoracic spine (>T7), fracture of the posterior part of the vertebral body, pedicle destruction or soft tissue mass (asymmetrical paravertebral and >1cm), angular or irregular deformity of the vertebral endplates, convex posterior wall instead of angled posterior wall in benign vertebral collapse, and preservation of discal height. Fracture lines related to osteoporotic fractures are well visualized with CT and MRI. With the axial plane, CT and MRI can also define the risk of spinal cord compression.

MRI

The typical MRI appearance of bone metastatic disease is characterized by low signal intensity on T1-weighted images (equal or lower than muscle and disk). On fat-saturated T2-weighted or STIR sequences, a higher signal intensity than surrounding marrow is found. On nonfat-saturated T2-weighted images, however, metastases may not be well differentiated from the surrounding bone marrow, and the same applies to nonfat-saturated T1-weighted sequences. Fat-saturated contrast-enhanced images, however, clearly show the lesions most of the time. Sclerotic metastases usually show low signal intensity on all sequences. Marrow and soft tissue edema surrounding a metastatic lesion may be extensive or nonexistent. Benign lesions such as Paget's disease and hemangiomas could have similar signal to metastases on

M

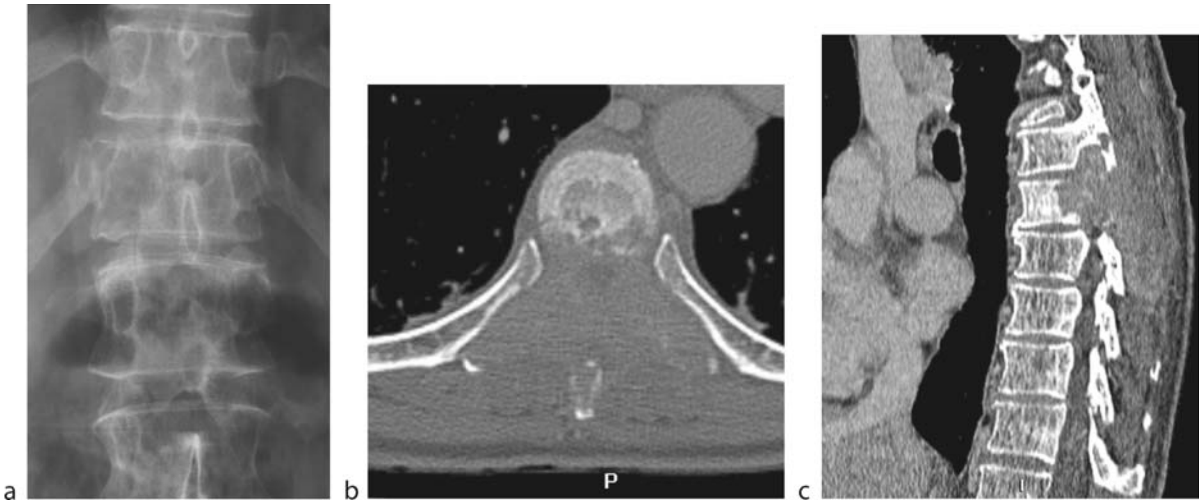
Metastases, Skeletal. Table 1 Radiographic features of various primary tumors

Osteolytic metastases	Osteosclerotic metastases	Mixed metastases
Frequently	Frequently	Frequently
Lung	Prostate	Lung cancer
Breast	Breast	Breast cancer
Thyroid	Malignant carcinoid (bronchial, abdominal)	Uterine cervix
Kidney	Less common cause	Less common cause
Colon	Lymphoma	Ovarian tumor
Less common cause	Medulloblastoma	Testicular tumor
Urinary bladder	Mucinous adenocarcinoma of GI tract	GI tract
Adrenal	TCC of bladder	
Uterine cervix	Medullar thyroid carcinoma	
Testicular tumor	Chest cancer	
GI tract	Neuroblastoma	
Upper respiratory an digestive tract	Osteosarcoma	
Ewing's sarcoma		
Melanoma		
Prostate		

GI: gastrointestinal.

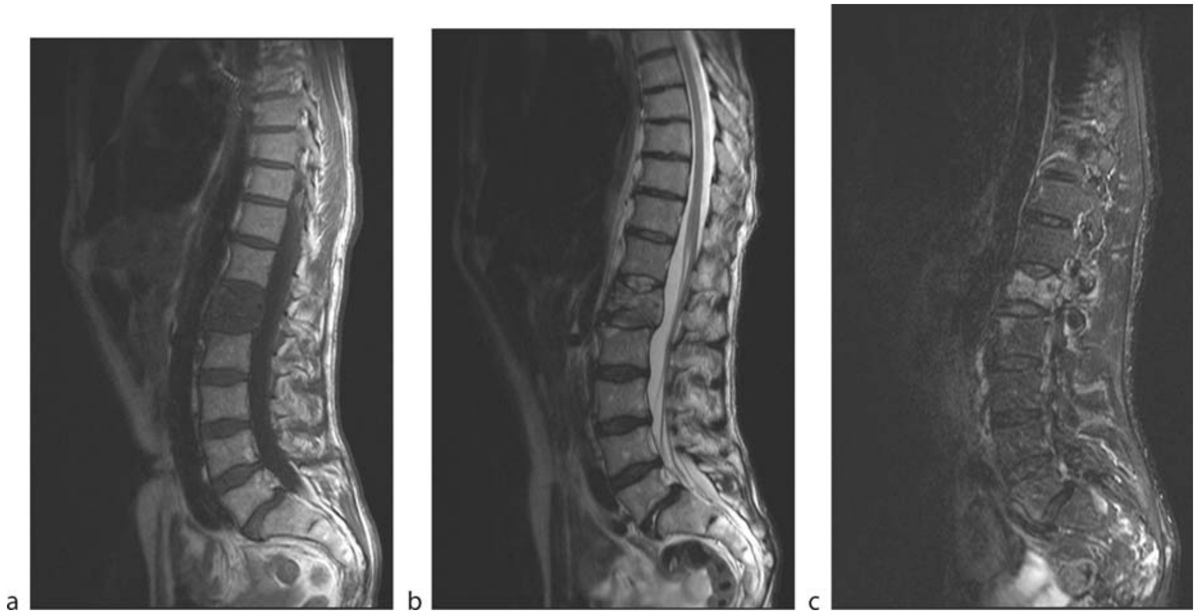
Metastases, Skeletal. Table 2 Radiographic features that are helpful in the differential diagnosis

Feature	Metastases	Differential diagnosis
Sclerosis of vertebral body	Common	Paget's disease (enlargement, coarsened trabecular pattern, "picture frame" appearance)
		Lymphoma, chordoma, mastocytosis
		Hemangioma (accentuated vertebral striation)
		Renal osteodystrophy
		Osteopetrosis (sandwich vertebral body)
Periosteal reaction	Rare	Primary tumors
	Prostate carcinoma	Osteosarcoma
	GI malignancies	Ewing's sarcoma
	Retinoblastoma	
	Neuroblastoma	
Bone expansion	Occasionally	Paget's disease
	Thyroid carcinoma	
	Kidney carcinoma	
	Hepatoma	
Acral location	Rare	Infection
	Lung	Primary tumor (very rare)
	Kidney	
Soft tissue mass	Rare	Infection (swelling rather than mass)
Soft tissue ossification	Rare	Osteosarcoma of soft tissue
	GI carcinomas	Posttraumatic heterotopic ossification
	TCC of bladder	Pseudomalignant osseous tumor of soft tissue
	Breast carcinoma	Ossification after burn and neurologic injuries
	Bronchogenic carcinoma	



Metastases, Skeletal. Figure 1 Metastatic lung adenocarcinoma. Anteroposterior radiograph of the thoracic spine shows a pedicle destruction (a). Axial CT (b) and sagittal reconstruction (c) allow one to establish the destruction of the vertebral bodies and its epidural extension with spinal cord compression and paravertebral soft tissue extension.

T1- and T2-weighted images, and MRI findings should be correlated with other imaging findings to avoid errors. Although most metastatic lesions are focal, metastases may show a diffuse homogeneous or heterogeneous pattern in the marrow. MRI can monitor the response of metastases to therapy by showing metastatic lesion changes in size and signal. A resolving metastatic lesion appears with a rim of high signal intensity of yellow



Metastases, Skeletal. Figure 2 Malignant vertebral collapse is demonstrated by the low signal on T1-weighted images with pedicle involvement and convexity of the posterior wall (a), heterogeneous bright signal on T2-weighted images (b), and destruction of the vertebral body on CT images (c).

marrow surrounding a focal shrinking marrow lesion on T1-weighted images. A focal lesion surrounded by a halo of high signal intensity edema on T2-weighted images indicates an active lesion. Complete fatty replacement of marrow where lesions once existed can occur after treatment. However, the MRI appearance of metastases within the bone marrow may also be quite similar before and after treatment and may not indicate treatment failure, since granulation tissue may substitute tumor and show similar imaging characteristics.

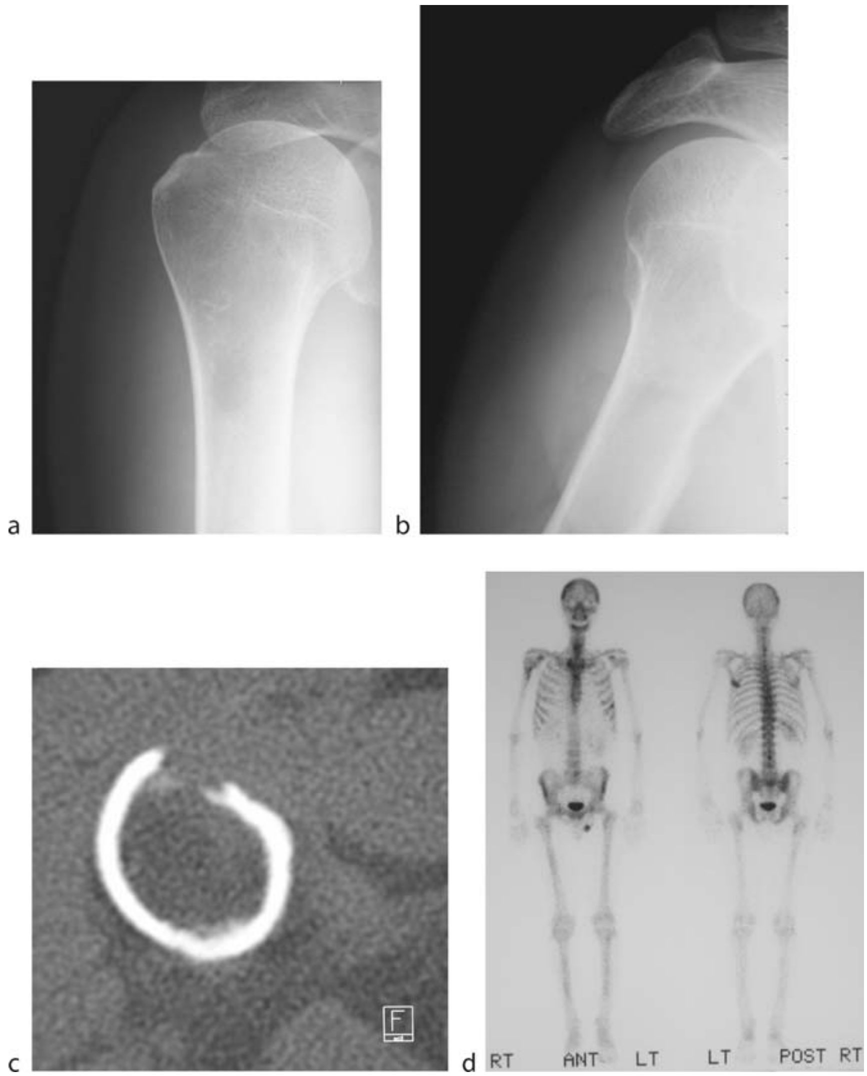
Nuclear Medicine

Bone Scintigraphy

Radioisotope bone scintigraphy is the standard whole-body imaging technique for screening bone metastases (6). The typical finding for bone metastases is a focus or foci of increased accumulation of the tracer in osteoblastic activity areas ("hot spots") modulated by skeletal vascularity (Fig. 3). Many radiopharmaceuticals (radionuclides) have been used including ^{99m}Tc bound to hydroxyethylene diphosphonate, hydroxymethyl enediphosphonate, or dicarboxy propane diphosphonate. Although bone scintigraphy is more sensitive than radiographs, bone scintigraphy has lower specificity (78% to 100%) and higher false-positive rates because it reflects an elevated rate of bone turnover as seen in neoplasia, trauma, arthropathy, or inflammation. In a patient with a known primary malignant tumor, the presence of multiple "hot spots" or a "superscan" on the bone scan is suggestive of metastases; however, osteomalacia, mastocytosis, and myelofibrosis may have a similar pattern. In many cases, further imaging (radiographs, CT, MRI) is required to characterize a solitary region or disseminated foci of radionuclide uptake. There are a number of other limitations to this technique, including difficulty in visualizing the spine because of the overlying hepatic and splenic activity, false-negative findings in cases of very aggressive pure osteolytic metastases, slow bone turnover, or an avascular site ("cold spots"). This may be seen in plasma cell myeloma, leukemia, and highly aggressive anaplastic carcinomas. After radiation therapy, patients could have a false-negative bone scans.

The appropriate intervals between screening bone metastases have not been defined. Three issues should be considered for assessing the response of bone metastases: the lack of specificity, the reduction in isotope uptake in cases of a fast progressive disease, and the flare phenomenon. This phenomenon corresponds to an increase of radionuclide uptake in a lesion during the first 6 months after therapy relating to an increase in regional blood flow or an increase in the bone turnover at the site of metastases or both. This may be indistinguishable from truly progressive disease. A healing bone tumor response usually appears as a decrease in the intensity of the nuclide uptake by metastatic foci. The discovery of new lesions on serial bone scintigraphy is a more reliable sign of tumor progression than an increase in radionuclide uptake at the sites of old lesions.

M



Metastases, Skeletal. Figure 3 **Radiographs (a, b) of the right shoulder show a diaphyseal lucency corresponding to an osteolytic lesion with cortical destruction and anterior soft tissue extension (b) in a 50-year-old patient with hepatocarcinoma. (c) CT scan well depicts the cortical destruction of the proximal humerus and intramedullary involvement. (d) Anterior (*left*) and posterior (*right*) ^{99m}Tc MDP bone scans confirm bone metastasis of the proximal humerus and demonstrate metastases at other locations (left scapula, 8 and 9 left ribs).**

Bone scintigraphy associated with conventional radiographs of areas with abnormal findings on bone scans remains a good technique for bone metastases screening in cases of osteophilic neoplasia (breast (useless if stages I or II), prostate (useless if PSA level <10 ng/mL, Gleason score: 2–5), kidney, thyroid, osteosarcoma, neuroblastoma, and epidermoid carcinoma).

With ameliorated gamma camera design, single-photon emission computed tomography (SPECT) sensitivity and specificity of bone scintigraphy are improved. However, it should be considered that with new technical developments whole-body CT and MRI may be considered as viable alternatives to skeletal scintigraphy.

Positron Emission Tomography

PET was previously considered as a research tool, but there has been substantial increase in its clinical applications in recent years (6). For Skeletal metastases, two radiopharmaceuticals are currently used: 18F-fluoride and 2-deoxy-2-[18F]-fluoro-D-glucose (18FDG). The mechanism of 18F-fluoride uptake is similar to that of ^{99m}Tc-methylene diphosphonate. 18FDG PET is used to measure glucose metabolism in many types of cancer and may distinguish benign from malignant bone lesions. The sensitivity of 18FDG PET dependent on the intensity of primary tumor glucose metabolism ranges from 62% to 100%, and its specificity from 96% to 100%. (Its variable sensitivity is explained by the variable intensity of the glucose metabolism of the primary tumor.) The best results are obtained for pulmonary cancer and lymphomas. The performance of PET in assessing bone metastases is superior to that of bone scintigraphy in breast cancer but lower in prostate cancer.

18FDG PET is more sensitive for detecting osteolytic metastases than osteoblastic lesions. PET can help in identifying bone metastases at early stages of growth before a host reaction of osteoblasts occurs. It depicts, for instance, early malignant bone marrow infiltration due to the increased glucose metabolism in neoplastic cells.

The disadvantages of PET are high cost, limited availability, and false-positive findings observed with inflammatory, infectious diseases, traumas, or benign diseases (Paget's disease).

The fusion of PET and CT technology (PET–CT) increases the potential of an accurate detection of bone metastases. An accurate clinical role for PET in monitoring the response of bone metastases, however, requires further studies.

Interventional Radiological Treatment

Initially limited to preoperative embolization of vascular masses, new endovascular and percutaneous techniques have been developed for bone metastases. Endovascular embolization is used to induce tumor necrosis, reduce tumor size, and relieve tumor pain. Local infusion of antimitotic drugs (intra-arterial chemotherapy) and chemoembolization combining intra-arterial chemotherapy and selective embolization has been developed.

Vertebroplasty is a technique in which polymethylmethacrylate is percutaneously injected into a collapsed vertebral body under imaging guidance. Its primary aim is pain relief, and to a lesser extent reinforcement and stabilization of the malignant collapse of vertebrae. Cementoplasty is a variation of vertebroplasty for osteolytic metastases in bones other than vertebrae.

Radiofrequency (RF) ablation is a percutaneous technique recently used for *in-situ* destruction of bone metastases. RF thermoablation uses long waves of electromagnetic radiation to produce thermal coagulation and necrosis.

Methanol

Methanol (CH_3OH), also known as wood alcohol, is a clear, colorless liquid, found in solvents and antifreeze, which smells and tastes similar to ethanol (CH_3CH_2OH). Methanol and its breakdown products, formaldehyde and formic acid, are toxic to the central nervous system. Ingestion of methanol can result in blindness, obtundation, and death.

MI, Mechanical Index

Estimate of the intensity of the transmitted pulses in diagnostic ultrasound, which is displayed by ultrasound machines. The MI calculations are based on peak rarefactional pressure and center frequency. It provides only a relatively inaccurate approximation of the true acoustic intensity in tissue. The MI is a critical variable in contrast

enhanced ultrasound and can be adapted by changing the acoustic output of the scanner. It determines the type and degree of interaction between the ultrasound pulse and a contrast microbubble.

Microbubble Oscillation

A specific response of ultrasound contrast agent microbubbles during insonation with adequate acoustic pressure (insonation power). If the acoustic pressure is becoming too high, the oscillation of the micro-bubbles is getting so strong that the membrane ruptures and the gas is escaping from the bubble shell within a few milliseconds, resulting in the disappearance of the contrast agent signal.

Synonyms

Bubbles; Contrast microbubbles; Ultrasound contrast agents; Ultrasound contrast media

Definition

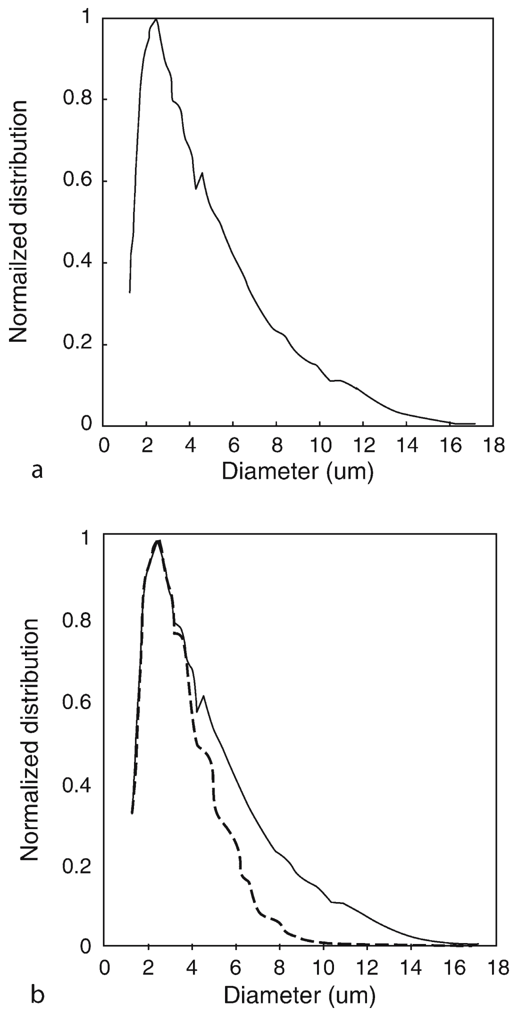
A microbubble is a gas cavity in liquid. The gas can be air, nitrogen, or a high molecular weight gas such as SF_6 or C_3F_8. The liquid is typically water. Microbubbles have a mean size of 3 μm, and in general 95% of the bubbles are smaller than 10 μm. The microbubbles are stabilized by means of encapsulation by a shell that consists of biocompatible material such as protein, lipid, or polymer. In medical ultrasound, microbubbles are used as contrast agents.

Characteristics

The bubbles are smaller than red blood cells and are therefore appropriate for intravenous injection. Unencapsulated free gas bubbles were first used as ultrasound contrast agents as early as 1968 but proved to be unsatisfactory because their size was uncontrolled, inappropriate, and unstable. Once injected, they did not persist long enough in the circulation to permit an adequate ultrasound examination of the left side of the heart.

Because these agents are intended to image the left heart chambers and ultimately to assess the perfusion of the myocardium, they must fulfill certain requirements.

The contrast microbubbles should be administered intravenously, either by bolus or infusion. The microbubbles must be small enough and stable enough to ensure pulmonary passage. In addition, they must be injected in a sufficient concentration to opacify the left heart. Furthermore, the injected microbubbles should remain in the blood pool and be safe and nontoxic. The duration and persistence of the microbubbles should be comparable to that of imaging conditions to enable acquisition of echo images, which is in the order of 1 to a few minutes. To behave as a perfect blood pool, the microbubbles should display the same flow dynamics as the blood itself and ultimately be metabolized from the blood pool. To comply with these requirements, several bubble physical properties must be elaborated carefully. These properties include the size, the gas, and the shell.



Microbubbles. Figure 1 Size distribution of Albunex. (a) Measured distribution. (b) The *solid line* indicates measured size distribution, and the *dashed line* indicates simulated distribution after lung passage.

Below the resonance frequency the scattering of a gas bubble increases with the sixth power of the bubble radius, while this is the second power for frequencies above the resonance frequency. Therefore, larger microbubbles scatter more ultrasound energy than smaller ones. Because ultrasound scattering of a cross-section of a gas bubble, which represents its scattering capabilities, increases with the sixth power of the bubble radius, larger microbubbles scatter more ultrasound energy than smaller ones. Moreover, the mean bubbles size in current commercial available agents is between 3 and 4 μm corresponding to a resonance frequency around 2 MHz. This is equal to the frequency used in precordial diagnostic ultrasound.

Fig. 1a shows a typical size distribution of a commercially available contrast agent, Albunex, which is a first-generation contrast agent. The size distribution was measured with a Coulter Multisizer. The mean diameter of this distribution is 3.8 μm, and less than 4% of the microbubbles are larger than 10 μm, whereas fewer bubbles with a diameter greater than 15 μm are present in the distribution. The size distribution of a contrast agent will however, change when crossing the lungs. Due to the sieving action of the lungs, larger bubbles are eliminated. Fig. 1b demonstrates this effect using simulations. The lung capillaries (1) with a mean diameter between 4.5 and 5.5 μm will filter larger microbubbles, whereas the number of smaller microbubbles remains unaffected.

Mirizzi Syndrome

Mirizzi syndrome is the presence of a large gallstone or multiple small gallstones impacted in the cystic duct or in the gallbladder neck, causing obstruction of the common hepatic duct. There are two types of Mirizzi syndrome: in type I, inflammatory changes of gallbladder wall lead to fusion with the common hepatic duct and its secondary stenosis, whereas in type II, direct pressure necrosis of the duct walls determined by stones leads to cholecystocholedochal fistula formation. Predisposing factors are a low cystic duct insertion and a cystic duct which runs parallel to the common bile duct.

Clinical features of Mirizzi syndrome are those of biliary obstruction and imaging is necessary to make a diagnosis. US is the first examination. CT may also be used as a second-step examination. Imaging findings include impacted stone in the cystic duct or in the gallbladder neck, thickening of the gallbladder wall due to chronic phlogosis, dilatation of the common hepatic duct above the level of the impacted stone, narrowing of the common hepatic duct at the level of impaction, and normal caliber of the common hepatic duct below the impaction. ERCP or PTC may be required to confirm the diagnosis, but MRCP usually represents a valid non-invasive alternative to ERCP and PTC.

Molecular imaging is a shift in the radiological paradigm that has gradually evolved over the past decade and intensified as a separate imaging entity over the past few years. The term encompasses all non-invasive medical imaging aiming at visualizing molecular activity in living tissues. A commonly used definition identifies Molecular Imaging as: "*the visual representation, characterization, and quantification of biological processes at the cellular, subcellular and molecular levels within intact living organisms*".

Molecular imaging has come to practice in recent years due to key advancements in i) developing new or transferring existing molecular and cell biology techniques to reporting technologies for in-vivo imaging, ii) the use of transgenic animal models, iii) the development of advanced reporter probes for high specificity and detection sensitivity and iv) the development or improvement of appropriate imaging technology. In contrast to conventional radiological approaches visualizing anatomy or function, the key principle of molecular imaging follows the paradigm of nuclear medicine in which an appropriate *molecular imaging probe* (for example a radiolabeled probe targeted to a cellular receptor) is non-invasively imaged through the body. However, this key principle has exploded to several different imaging strategies employing several distinct imaging and probe technologies appropriate for imaging an increasing number of complex gene-expression and molecular function patterns. This is a highly interdisciplinary science that can be seen as an addition to standard Radiology, which typically entails only imaging systems and methods and a smaller set of imaging probes. Molecular Imaging can work synergistically with more conventional radiology practices and promises to significantly improve healthcare and drug discovery by identifying disease at an earlier stage and quantifying treatment responses in-vivo and over time.

Molecular imaging has two distinct entities that must work synergistically to achieve successful imaging, that is i) imaging technology, ii) reporting strategies of imaging targets. Those broad areas can be further classified as follows:

Imaging technology

Molecular Imaging is accomplished with different modalities including 1) Scintigraphy and Single Photon Emission Computed Tomography (SPECT), 2) Positron Emission Tomography (PET), 3) Magnetic Resonance Imaging (MRI), 4) Optical Imaging, including Fluorescence Planar Imaging, Bioluminescence Imaging and Fluorescence Molecular Tomography (FMT) and 5) Ultrasound. These approaches are further complemented by X-ray computed tomography (CT) for high resolution anatomical imaging.

An emerging field in radiology is this of ***multi-modality imaging*** where typically two (or more) complementary imaging methods are combined, i.e. one yielding high resolution anatomical information with one yielding high molecular specificity. It is important to note here the recent emergence of hybrid systems that combine CT with SPECT for small animal imaging and novel clinical CT/PET scanners that are gaining ground as they allow for the accurate co-registration of molecular and anatomical contrast.

A secondary classification of molecular imaging systems can group nuclear imaging methods, i.e. imaging techniques that use ionizing radiation and isotopes (i.e. Scintigraphy, SPECT and PET) and techniques using non-ionizing radiation such as optical imaging, MRI and ultrasound. Some more detailed description of these modalities is given in the third section of this hyper-essay.

Reporting strategies

Reporting strategies can be separated in 1) *Direct imaging methods*, i.e. via the use of probes that report on specific molecular process (e.g. a receptor target imaged with a ligand molecular imaging probe) and 2) *Indirect imaging methods* (e.g. expression of an imaging reporter gene indirectly measuring expression of an endogenous gene). Several different approaches have been developed for optimal designs that address these categories as addressed in more detail in the following:

Direct imaging

This strategy uses imaging probes that are generally externally administered. Imaging probes are an essential part of molecular imaging and their development generally considers four distinct issues, i.e.

1. A *reporting mechanism* that reports on the position and accumulation of the probe to the imaging technology selected.
2. A *delivery technology* to ensure favorable probe kinetics in crossing of biological barriers such as

vascular and cellular membranes and synergistic clearance of non-bound or non-delivered probe.
3. *Bio-compatibility* so that responses of the immune system and toxicity are minimized.
4. An *amplification strategy* to maximize contrast and signal to noise ratio's so that highly sensitive detection is achieved.

Imaging probes are divided in two major categories, namely *active probes*, i.e. probes that carry an active reporting component and *activatable probes* i.e. probes that carry an inactive reporting component which is activated through interaction with a molecular target. The latter are also known as *molecular beacons, switches* or *smart probes*. Active probes are generally used to image proteins and receptors via direct interaction with the receptor or other protein (e.g. binding) or preferred accumulation into cells. Activatable probes include molecules that change some physical parameter after interaction with a specific target. They are generally found as optical or MR probes. Several fluorescent probes have been developed to exploit quenching and energy transfer mechanisms to change light emission characteristics that can be detected with high sensitivity. MR probes have also shown capable to change relaxation times after modification from a molecular target.

Another paradigm of direct imaging methods is the use of aptamers for in vitro specific protein-binding studies. Aptamers are DNA or RNA oligonucleotides isolated to bind to various biomolecules with high specificity. Cellular targets can be assessed making this a potentially useful technology for in-vivo imaging. A similar approach using antisense and aptamer oligonucleotide probes has been developed for hybridization to target mRNA thus imaging direct gene expression at the transcriptional level. Radiolabeled antisense nucleotides are called RASON's although fluorochromes or magnetic nano-particles could be used in principle as well. However the low number of target copies coupled with delivery issues and high, non-specific background limits the application of the latter approach to in-vivo imaging applications.

Indirect imaging

This imaging strategy as evolved from corresponding in-vitro reporting assays. Most indirect imaging schemes involve the use of a *reporter-gene* that is used in conjunction with a *reporter probe*. Contrast is generated by the reporter probe after transcription of the reporter gene. Generally, the reporter gene is introduced into the cells of interest via delivery vectors and placed under control of a promoter/enhancer element. The promoter can lead to continuous reporter gene transcription (constitutive promoter) or it can be activated by specific transcription factors (TF) (inducible promoter). When the reporter gene is transcribed it results in translation of mRNA to a gene product, which could be an enzyme, receptor or other protein. This gene product can be a reporter molecule itself (for example a fluorescent protein) or it can lead to trapping of a molecular probe or to increasing the density of appropriate molecular targets that a molecular probe can attach to.

Reporter gene imaging is a generalizable platform that in contrast to the direct imaging method, only one or few well validated reporter-gene and reporter probe pairs can be used to image many different molecular and genetic processes. On the downside is the introduction of foreign proteins and genes which limits applicability to animals and perhaps gene therapy protocols.

Applications of reporter gene imaging include marking of cells for cell-trafficking imaging, monitoring of endogenous gene expression or of externally transfected genes, imaging in gene therapy protocols and imaging of proteins and protein-protein interactions, but this platform is highly versatile to be applied to many other applications as well.

Examples of Molecular Imaging

In the following, some common examples of molecular imaging are given, for different imaging modalities. This is a highly emerging field and the following are given to impart some flavor of the diversity that exists in this field of imaging sciences, and not as an exhaustive list of the technology or the application.

Positron emission tomography (PET)

Positron emission tomography images the bio-distribution of positron emitting radio-nuclides by reconstructing the origin of γ-rays exiting the tissue of investigation. The positron, emitted during the radionuclide decay, travels a short distance in tissue ($\sim$1 mm) until it encounters an electron. The two particles "annihilate" resulting in the emission of two gamma rays of 511 keV each, traveling at opposite directions. Common positron emitting isotopes include ^{15}O, ^{13}N, ^{11}C, and ^{18}F although ^{14}O, ^{64}Cu, $^{6}2Cu$, ^{124}I, ^{76}Br, ^{82}Rb, and ^{68}Ga can be occasionally used as well. Production of isotopes is typically performed in a cyclotron.

Detection of γ-rays is typically achieved through an array of scintillation crystals to convert -ray energy into visible light, suitable light sensors, readout electronics, and image processing units. The coincidence detection of both -rays in PET within nanoseconds of each other defines the line of response in space and thus the direction of flight. In contrast to SPECT, attenuation (quantifiable reduction in events present at the face of the detector due to absorption or scatter through tissues) of the emitted radiation in PET can be corrected precisely because the total length through the body determines the attenuation factor along a coincidence line. By doing so, quantitative information about the tracer distribution can be obtained. The reconstruction software then takes the coincidence events measured at all angular and linear positions to reconstruct an image that depicts the localization and concentration of the positron-emitting radioisotope within a plane of the organ that was scanned.

PET-Advantages: One of the advantages of PET is that drugs or existing molecules involved in a process if interest or known to interact with a specific target can be modified with a radiolabel while minimally perturbing the parent molecule. Therefore many diverse biological and molecular processes can be followed. The sensitivity of PET is relatively high in the range of 10^{-11}–10^{-12} mole/L, and is independent of the location depth of the reporter probe of interest. Typically, several million cells accumulating reporter probe have to be in relative close proximity for a PET scanner to record them as a distinct entity relative to the background. Development of molecular imaging assays with PET is particularly advantageous because of the ability to validate them in cell culture and small animal models prior to using the same reporter probe in established clinical PET centers around the world. The ability to perform translational research from a cell culture setting to preclinical animal models to clinical applications is one of the most unique and powerful features of PET technology.

PET-Disadvantages: Many of the positron-emitting isotopes used have relatively short half-lives (e.g. ^{18}F has $t_{1/2}$ = 110 min), so that the chemical reactions leading to incorporation of the isotope into the parent molecule and subsequent introduction into the subject must take place relatively quickly. Moreover PET cannot distinguish between two or more different isotopes if injected simultaneously. Therefore for studying multiple molecular events, subsequent injection of molecular probes at times allowing for the decay of one isotope prior to administration of the other. This complicates experimental procedures in such studies. Furthermore the spatial resolution of most clinical PET scanners is $\sim(6–8)^3$ mm^3, and $\sim3^3$ mm^3 in brain scanners. Small animal imaging can be currently achieved with resolutions of less than 2^3 mm^3.

Enabling molecular-imaging technologies for PET: The most common reporter gene imaging strategy for PET is the introduction of the wild-type HSV1-*tk* reporter gene or a mutant HSV1-*sr39tk* gene encoding. These genes encode for thymide kinase 1 (TK1) that can phosphorylate radiolabeled probes with higher efficiency than mammalian TK enzymes. This results in reporter probe entrapment and accumulation in tranduced cells yielding contrast in PET images. Reporter gene imaging via up-regulation of membrane receptors is also a common strategy for PET labeling and is exploited as a contrast mechanism.

Optical Imaging

Optical imaging encompasses a series of photonic technologies that may study complex molecular processes in whole animals and human tissues. Optical observations are overwhelmingly used in the bio-medical field through microscopy and histology and through the availability of several optical sensing in-vitro assays for molecular detection. The transfer of several of these technologies to in-vivo applications has been enabled primarily by 1) the development of bio-compatible probes and reporter systems that preferentially fluoresce in the near-infrared and 2) the development of appropriate imaging systems and method that offer low light detection with high sensitivity. Red shifting of the reporter probes is essential for achieving high penetration due to the low light absorption from tissue in the near-infrared. An important emerging technology is the use of tomographic methods that account for photon propagation in tissues in order to provide accurate three-dimensional images of photon propagation in tissues.

Optical Imaging advantages The major advantage of optical methods is the high versatility owing to the existence of a variety of fluorescent probes and reporter gene imaging strategies including expression of fluorescent proteins and bioluminescence. The technology is economic and can be made portable and of small form factors, therefore it is ideally suited for small animal imaging, endoscopy and some large organ applications (i.e. breast). Other advantages include high detection sensitivity, especially in small animals, the use of non-ionizing radiation and the capacity to resolve multiple targets simultaneously using fluorescent reporters emitting at different wavelengths.

Optical Imaging disadvantages Major disadvantages include the compromised resolution and non-linear dependence of photon intensity with the depth, due to the highly photon scattering nature of tissue. This reduces the detection sensitivity at larger tissues and worsens resolution.

Enabling Technologies: A variety of targeted and activatable imaging probes have been developed. In addition fluorescent proteins and bioluminescence approaches have revolutionized modern biology and are increasingly used in molecular imaging applications. Transfection of cells with the firefly luciferase gene (Fluc) encodes Firefly luciferase, an enzyme that oxidizes its substrate Dluciferin to result in light emission (bioluminescence). This chemiluminescent reaction can only take place under physiological conditions within living cells expressing Fluc. Another luciferin–luciferase system used in molecular imaging is based on the sea pansy Renilla luciferase, which uses a different substrate (coelenterazine) that is not ATP-dependent. Other bioluminescence reporter systems have been demonstrated as well. Bioluminescent light emitted from cells can be detected through the animal with highly sensitive, low-noise detection CCD cameras, while offering very low background activity from naturally occurring tissue bioluminescence. In this way a highly versatile molecular activity can be tagged and detected when the reporter gene is expressed. A similar approach, in the fluorescence mode, involves fluorescence proteins (FP's). FPs have become essential reporter molecules for different biomedical applications as they offer a generalized platform for imaging cellular and sub-cellular processes. Mutants of the original green fluorescent protein (GFP) from the jellyfish Aequorea offer bright emission and recent red-shifting of the emission spectrum of different FP offer multi-target visualization capacity and increased detection sensitivity. Finally several active and activatable probes have been developed for targeting cellular receptors, proteins or enzymes. An attractive example is the use of biocompatible probes loaded with many fluorochromes that are dark in their inert state due to close proximity to each other leading to self-quenching. Upon interaction with specific enzymes the fluorochromes loose proximity and can fluoresce, resulting in an on/off light switching mechanism. Fluorescent probes are also appropriate for clinical translation for endoscopic, intra-operative and other application.

Magnetic resonance imaging (MRI)

MRI spatially resolves the relaxations of magnetic dipoles (i.e. atoms with unpaired spins such as hydrogen, phosphorus or carbon) placed in high strength magnetic field and subsequently perturbed from equilibrium using appropriate radio-frequency pulses in the presence of magnetic gradients. MRI can optimally differentiate soft-tissue differences with high detail and offers rich contrast information since dipole relaxation depends on the biophysical environment and interactions between them. Elegant technologies such spin-tagging or diffusion-weighted MRI can be used to further assess functional tissue characteristics such as flow, tissue perfusion and membrane permeability. In addition, the use of appropriate nano-particles that change the MR signal intensity can further improve contrast and in the context of molecular imaging to probe cellular and subcellular activity. More common MRI contrast agents include paramagnetic metal cations such as chelated gadolinium or dysprosium, or super-paramagnetic nano-particles that can be used as compartmental, targeted, or smart probes.

MRI advantages The major advantage of MRI is the high spatial resolution that can be achieved and that anatomical, functional and molecular information can be extracted simultaneously.

MRI disadvantages The major MRI drawback is the reduced sensitivity, which directs the use of relatively large amounts of metal cations.

Enabling molecular-imaging technologies for MRI. Examples of MR molecular imaging includes the Galactopyranoside/Galactosidase System where cell transfection with marker gene LacZ leads to production of b-galactosidase that can cleave a cap of specially engineered MR probes. This process can change the relaxation parameters of the agent resulting in up to 50% decrease in T1. Other examples have shown that transfection with cDNA inset coding for human tyrosinase leads to upregulation of tyrosinase after transcription, which catalyses the hydroxylation of tyrosine to dioxyphenyl alanine (DOPA) which is then oxidized to DOPA-quinone. DOPA-quinone yields melanins through spontaneous cyclization and polymerization, which have high iron-binding capacity. This can significantly increase the MR contrast of transfected cells, similarly to naturally occurring contrast seen in some melanomas on T1-weighted images. Direct targeting of endothelial markers such as the integrin $a_v\beta_3$ has also been demonstrated using paramagnetic liposomes or targeted nanoparticles.

MR Spectral Imaging A special category of magnetic resonance technology is the use of spectroscopic imaging, i.e. localized spectroscopy from spatially resolved voxels within tissue. MR spectra depend on the biochemical composition of each voxel. Therefore localized Magnetic Resonance Spectroscopic imaging is often referred to as a special method of molecular imaging that does not require the use of exogenous reporter probes. Typical molecules targeted by MR spectral imaging are choline, creatine, N-acetyl aspartate (NAA), lactate, myoinositol, glutamine and glutamate, lipids, leucine, and alanine.

Scintigraphy and SPECT

The use of gamma cameras combined with the use of radiolabeled traces has been considered the precursor to molecular imaging as it has evolved today. Injected and targeted γ-emitting isotopes (e.g. ^{99m}Tc, ^{111}In, ^{123}I, ^{131}I) can be detected through tissue using gamma cameras. Planar images can be obtained for two-dimensional observations. A more elegant technique obtains high energy photons at different view angles by rotation around the sample and combines these projections tomographically to obtain three-dimensional images through the body. A characteristic of gamma camera detection is the use of lead collimators, necessary to define the angle of incidence of photons collected. The use of collimators is the main reason of the reduced sensitivity seen in SPECT as compared to PET. In SPECT, collimator design is always a compromise between spatial resolution and sensitivity: reducing the size of the holes or using longer septae improves spatial resolution but reduces sensitivity. Examples of enabling technologies include imaging apoptosis with radio-labeled annexin V, imaging of antisense oligonucleotides and several radiolabeled receptor-binding molecules, antibodies etc.

Ultrasound

Ultrasound imaging is based on interaction of tissue with high frequency pressure waves. Most clinical ultrasound typically uses frequencies at the 2–10 MHz but higher frequency ultrasound is used for intravascular studies or small animal imaging with frequencies reaching 30–50 MHz. As frequency increases resolution increases as well but penetration depth decreases. Ultrasound has also been considered for molecular imaging with the use of targeted ultrasound contrast agents, i.e. targeted micro-bubbles.

Synonyms

Administration of molecular imaging agents

Definition

Manipulations and procedures for the administration of imaging agents (drugs). After the distribution in the body these imaging agents generate signals specific for a given target molecule and could be detected by using biomedical imaging modalities. In the above context the delivery is, as a rule, an invasive procedure designed to penetrate physical barriers existing in the body and is regulated by corresponding institutional or government committees.

A system of measures that increase the probability of a given imaging agent to localize in the compartment of the body that harbor the target molecule. In the latter context the delivery of molecular probes is related to imaging agent (drug) targeting *in vivo*.

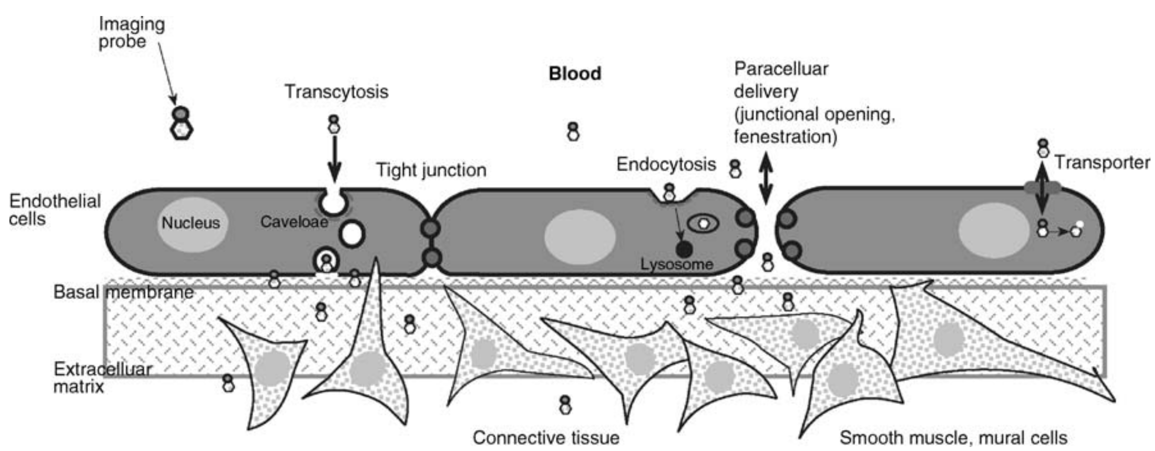
Characteristics

Molecular Probe Administration

Depending on whether molecular probe is exogenous or endogenous, delivery modes may differ. In the case of *exogenous probe* (agent) delivery procedures are used to ensure that sufficiently high concentration of imaging probes will be achieved in the target organ (i.e. blood stream, brain, liver etc.) during the time window required for imaging. The manual, semi- or fully automated devices (injection systems and pumps) are used for this purpose and are similar to those used for delivery of any other contrast agent. *Endogenous probes* (i.e. molecules that are detectable with imaging modalities) are synthesized by the cells of the host due to exogenous gene (or cDNA) expression which includes transcription, translation and posttranslational processing of the corresponding expression product. Expression of these probes is induced by delivery of exogenous genetic material which includes: (i) a compaction of nonviral expression vectors with polycations or packaging DNA or RNA encoding imaging marker genes into virions in cell culture; (ii) transfection or transduction of cells *in vivo*. The latter stage includes delivery of genetic material *in vivo* and is, essentially, a gene therapy procedure. If labeled with radioisotopes or fluorescent proteins, nonviral or viral delivery step could be monitored by using imaging. In above case both delivery and the subsequent gene expression could be imaged *in vivo*.

Molecular Probe Delivery to the Target Tissue (Organ)

The efficacy of molecular probe delivery depends on: (i) chemical and physical characteristics of the probe molecule or nanoparticle, i.e. molecular mass or hydrodynamic radius, electrochemical or surface charge, hydrophobicity and reactivity of chemical groups comprising the probe; (ii) the presence of anatomic or physiological barriers in the body. Transporter-specific small molecules (positron-emitting isotope-labeled for PET) are usually delivered into cells through plasma membrane glucose transporters (for example, Glut-1 glucose transporter in the case of ^{18}F-labeled 2-fluoro-2-deoxy-D-glucose, FDG). Glut-1 and Glut-3 are usually overexpressed in cancer cells thereby enabling imaging of the probe "trapped" inside the cell due to hexokinase activity which mediates phosphorylation of FDG. The role of Glut-1 has been also confirmed in endothelial uptake of FDG. Other PET tracer molecular probes include ^{18}F-α-methyl-tyrosine (FMT), ^{18}F-DOPA for dopaminergic neuronal uptake imaging in Parkinson's disease and others. Unlike non-charged polar FDG molecule, positively charged drugs intended for imaging (or polyplexes for gene delivery) usually bind to α1-acid glycoprotein and lipoproteins whereas negatively charged imaging drugs bind to albumin. In addition, many imaging drugs and probes, especially nanoparticles with multiple hydroxyl groups on the surface bind C3b as a result of C3 complement component activation which could lead to toxicity and anaphylactoid reactions in some species. "Decoration" of nanoparticles and some polymers with plasma proteins increases non-specific uptake in phagocytes thereby promoting a more rapid elimination from circulation. The existing tissue barriers dramatically affect probe delivery. In general, distribution of any drug after systemic administration (usually intravenous) is not uniform due to the local differences in blood supply, binding to blood components, as well as local acidity, and transcellular (membrane) transport. To reach the target molecule (i.e. cell surface receptor or carbohydrate, cytoplasmic protein, mRNA or nuclear target), imaging molecules are required to pass through one or more tissue barriers. The only exception is the class of imaging probes specific for vessel-lining and circulating (hematopoietic) cells. The common tissue and cellular barriers are: (i) endothelial cells and basal membrane (basal lamina, consisting of laminin, fibronectin, tenascin, collagens, and proteoglycans), (ii) connective tissue cells, (iii) parenchymal cell membrane, (iv) nuclear membrane (if delivery of the probe to the cell nucleus is the goal) (Fig. 1). Endothelial cells represent the continuous thin barrier in most normal tissues that controls the exchange of nutrients and cells between the blood and the interstitial compartments. In the liver endothelial cells have multiple pores and fenestrae. Trans-endothelial delivery is usually enabled by targeting to calveolae components which accelerates transcytosis. This is accomplished by using targeting specific plasma membrane proteins present in calveolae. Transcytosis of albumin-bound imaging probes is mediated with specific protein shuttling protein gp 60 (albondin). However, albumins with high degree of amino group modification (for example, albumins highly modified at available amino groups with imaging drugs, i.e. fluorochromes or chelates) are not transported by transcytosis but are endocytosed, stored and degraded in lysosomes. Paracellular delivery from apical to basolateral side of endothelium can be accelerated by selective opening of tight junctions which consist of complexes formed by nectins, claudins, occludins, and junctional adhesion molecules. Tight junctional permeability and drug delivery can be increased by nitric oxide (sodium nitroprusside) or mannitol treatments. The latter is effective in transient opening of the blood–brain barrier. Subsequent steps of delivery could be complicated by the following negatively acting factors: (i) most of the "large" transcytosed imaging probes, including nanoparticles, are accumulated in basal membrane and extracellular matrix components that limit the accessibility of parenchymal cells to these probes; (ii) probes based on high-affinity ligands (antibodies and some library-derived peptides) labeled with imaging molecules or nanoparticles (fluorochromes, isotopes or bound to a MRI agent) are usually bound to superficial layers (cells) of the target organ/tissue and do not permeate into deep layers. This may result in partial imaging artifacts. To allow better permeation through membrane barriers several synthetic peptides (known as "cell penetrating peptides" (CPP) or "protein transduction domains" (PTD) have been tested. Many arginine rich



Molecular Probes, Delivery. Figure 1 Schema showing various mechanisms of drug delivery to and across endothelial barriers (blood–tissue): (i) transcytosis; (ii) endocytosis; (iii) paracellular transport; (iv) transporter-mediated transport.

peptides (including HIV Tat-derived peptide 47–57) were initially shown to assist in translocating large proteins, particles (including superparamagnetic nanoparticles and fluorescent liposomes) into cells *via* energy-independent mechanism suggesting unique translocating mechanisms. The CPP/PTD approach has been used successfully to load isolated cells *ex vivo* with superparamagnetic nanoparticles for tracking stem/progenitor cells administered locally *in vivo* using MRI. Later studies have not confirmed the energy dependent translocation and suggested endocytosis as the major route of CPP/PTD-conjugated imaging probes into the cell interior. However, if Tat or other CPP/PTD peptide-conjugated imaging probes escape endosomes due to rupture or artificial endosomal pH neutralization (e.g. with ammonium chloride treatment), the probe accumulates in the nucleus since cell penetrating peptides often include nuclear translocation sequences (RKRRQRRR sequence in the case of Tat peptide). Amino acids of above sequences interact strongly with proteins of nuclear membrane (importins/karyopherins) and the resultant complex docks and translocates through nuclear pore complex. The lack of any targeting ligands in imaging probes in some cases also can be used for increasing delivery of larger molecules with the diameter of several nm—200 nm in the interstitium. The use of polymer coatings (e.g. covalently bound methoxy polyethylene glycol) enables the probe to escape recognition of the reticuloendothelial system resulting in longer times in circulation. Long circulating probes extravasate slowly due to transcytosis or leakage through the endothelial fenestrations, defects in endothelial lining and specialized endothelium (high endothelial venules in lymph nodes) and accumulate in the interstitium. In pathology (cancer, inflammation) the transfer occurs through abnormally permeable endothelial lining. Interstitial delivery allows molecular imaging of proteinases expressed by fibroblasts by using self-quenched macromolecular optical imaging probes. In the presence of normal lymphatic drainage interstitially accumulated probes are carried with lymph flow to lymph nodes (dextran-coated nanoparticles, some PEGylated particles) where, if recognized by macrophages and dendritic cells, such particles are retained. This effect underlies lymph node specific delivery and imaging. Special mechanisms of probe retention in the target organ include solubility and molecular mass changes in response to enzymatic activity present in the target: the increase in solubility (hydrophilicity) and size would result, for example, in the increase of longitudinal relaxivity which is important for MR imaging.

A Distinction between Therapeutic and Imaging (Diagnostic) Drug Delivery

The combination of size, charge, hydrophobicity and surface chemistry (for nanoparticles) are the main factors that determine the fate of imaging probes in the body. It is critical to underline the difference between therapeutic drugs and imaging probes (drugs). Therapeutic effect of the former usually outweighs poor specificity for any given diseased organ under treatment if toxicity profile of the drug is acceptable. The imaging drug, however, should have a very specific distribution to target organs and relatively low non-specific delivery to other tissues/compartments since low specificity of the imaging probe would result in low target/background imaging ratio and poor imaging contrast.

Definition

Optical contrast agents for *in vivo* imaging are ideally fluorochromes with excitation and emission maxima in the near infrared range (NIR; 650–950 nm) since absorption of the photons by water, oxy- and deoxy-hemoglobin are minimal in this spectral range ("diagnostic window"). Cyanine dyes represent one of the most prominent classes of optical contrast agents for *in vivo* imaging (1). More recently, inorganic quantum dots

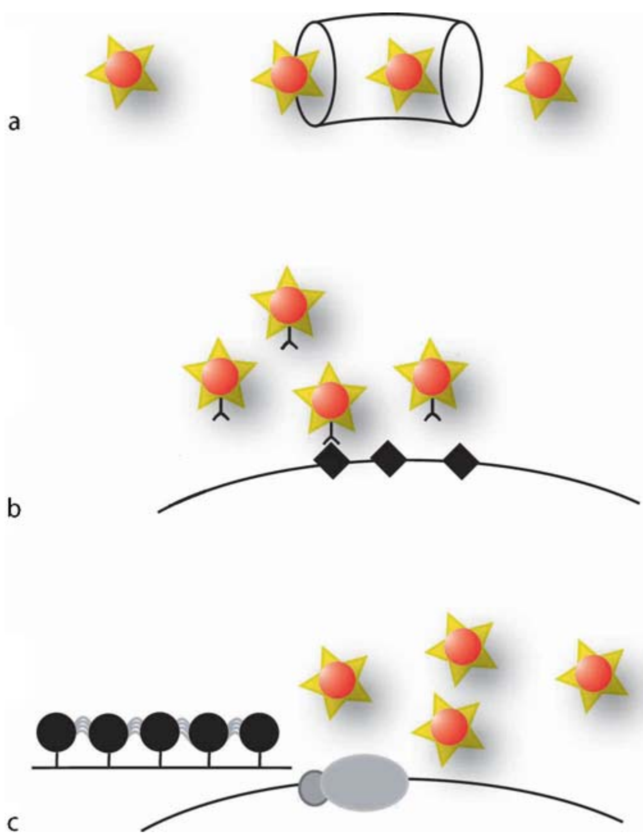
(QDs, fluorescent semiconductor nanocrystals) have been introduced as a novel class of optical contrast agents which can be exactly tuned to a specific wavelength by size variation. The unique property of QDs is a broad absorption band, relatively narrow and symmetrical luminescence band and high resistance to photo degeneration. Biological applications of these novel contrast agents are currently under investigation.

As outlined above, optical probes can be classified as “nonspecific”, “targeted,” and “smart” probes (Fig. 1) (2).

Nonspecific contrast agents such as indocyanine green (ICG) show distribution patterns which depend solely on their pharmacological formulation (i.e., molecular weight, hydrophilicity, lipophilicity, protein binding etc.). These agents can help to measure surrogate parameters for tissue perfusion, vascular permeability or vascular volume. However, true molecular targets cannot be imaged using this approach.

Targeted contrast agents are linked to specific affinity ligands such as peptides, antibody-fragments or small molecules imparting molecular specificity to the probe. In the early phase after injection, high levels of unbound circulating contrast media contribute to the background signal resulting in a slight decrease of the signal-to-noise ratio (SNR). After clearing of the unbound probe, the fluorochromes are ideally retained at the target structure allowing for the detection, for example of cell surface proteins (Fig. 1).

“*Smart*” *contrast agents* can be “activated” upon enzymatic conversion of the probe ideally resulting in an “off” and “on” status. A prominent example was first described by Weissleder and consisted of a large 450 kD carrier molecule coupled to several fluorochromes emitting photons in the NIR; (1). In the native state, mutual energy transfer occurs amongst the fluorochromes, resulting in a quench of the signal. After enzymatic release of the fluorochromes an up to several 100-fold, signal increase can be observed. “Smart” optical probes thus provide a high SNR which is desirable for molecular target identification.



Molecular Probes, Optical Probes. Figure 1 ***Design of different optical contrast agents*. Nonspecific optical contrast agents (a) show simple perfusion and/or permeability properties of the tissue. Targeted probes (b) bind *via* specific ligands to protein structures on the cell surface (e.g., tumor associated receptors). “Smart probes” (c) are activated by an enzymatic conversion from their native (little to no signal) to become brightly fluorescent after enzymatic cleavage (c, *right*; reprinted with permission from Bremer C, Ntziachristos V, Weissleder R (2003) Optical-based molecular imaging: contrast agents and potential medical applications. Eur Radiol 13:231–243).**

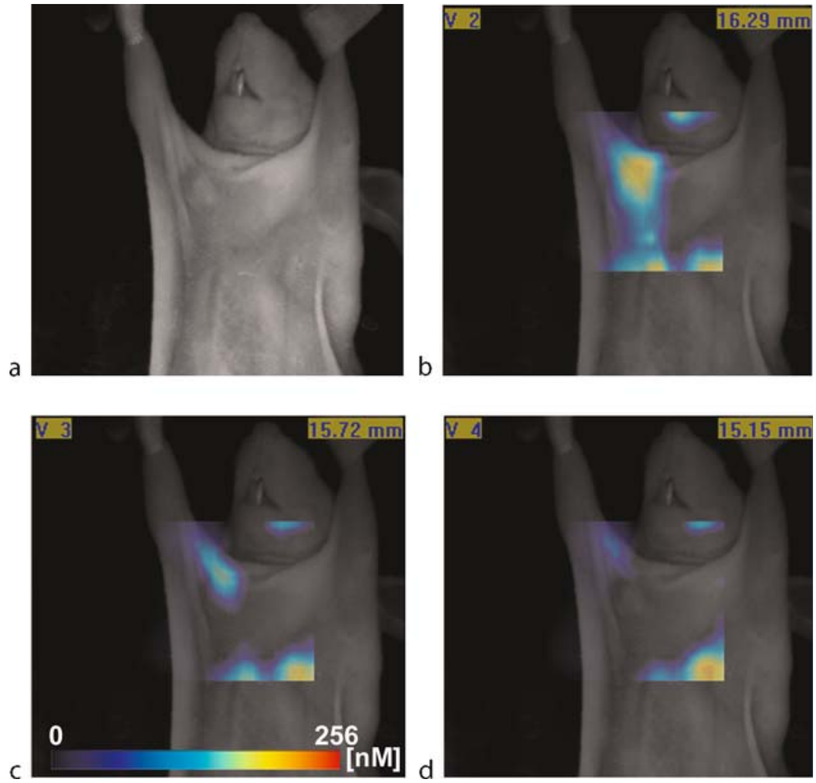
Indications

Nonspecific optical contrast agents are in part clinically available (e.g., ICG, cardio green). ICG is clinically approved and applied for liver function tests, for studying cardiac output, and for ophthalmic angiography. With respect to noninvasive optical imaging, ICG has been successfully applied in an off label use for the detection of breast cancer lesions using diffuse optical tomography (DOT) techniques combined with conventional Gd-enhanced MRI (3).

In experimental investigations, xenograft tumors could be clearly differentiated regarding their levels of angiogenic activity. The underlying contrasting mechanism is thought to be based on vessel permeability leading to an accumulation of fluorescent dyes in the tumor interstitium and is thus comparable to other clinically applied imaging modalities (e.g., contrast enhanced MRI). Currently novel nonspecific fluorochromes are being systematically evaluated in phase I clinical trials for breast cancer lesion detection in combination with DOT.

Targeted optical contrast agents have been designed using different affinity ligands such as peptides, proteins, antibodies or antibody fragments (Figs. 1 and 2).

By conjugation of flourescein and carbocyanine dyes to various peptide motifs, tumor associated cell receptors such as the somatostatin-, bombesin-, vasointestinal peptide- folate and the epidermal growth factor (EGF)-receptor could be selectively targeted in experimental studies. Molecular markers of endothelial proliferation such as the $\alpha v \beta_3$ integrin could be successfully visualized by linking 'RGD' peptide sequences to cyanine dyes. Moreover the conjugation of a cyanine dye to more complex proteins such as annexin-V allowed to fluorescently label apoptotic or necrotic cell types and tissues facilitating an early assessment of treatment response to chemotherapy. Antibody based targeted fluorochromes have been designed to visualize E-selectin expression as an early proinflammatory marker. A bisphononate-NIR dye-conjugate showed distinct binding affinity to hydroxylapatite (HA) allowing for the detection of osteoblastic activity *in vivo*.



Molecular Probes, Optical Probes. Figure 2 ***FMT imaging of $\alpha v \beta_3$-expression using a target-specific optical probe*. Fluorescence-mediated tomography was acquired 24 h after injection of a target-specific optical probe recognizing the integrin $\alpha v \beta_3$, which is a sensitive marker of angiogenesis (a—*white light* image, b–d coronal sections of FMT data superimposed on a; fluorochrome concentration is color encoded). Target affinity was achieved by coupling a cyclic "RGD" peptide to the dye.**

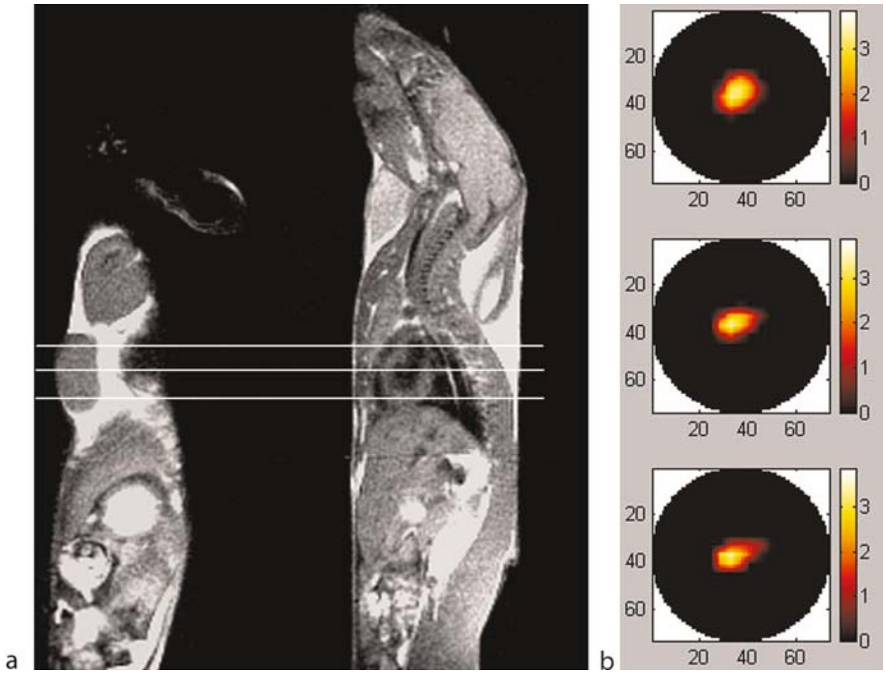
More recently, small non-peptidic molecules (i.e., drug precursors) could be labeled with cyanine dyes through polyethylene glycol (PEG) linkers and still preserve binding affinity of the ligands.

Besides the affinity of the single ligand, steric composition can greatly influence the target affinity of a probe. In this respect, multimeric affinity ligands may substantially increase the ability of the optical probe to bind to the target structure.

Generally speaking, potential clinical indications for the application of targeted optical probes arise from the specific molecular structure which can be displayed by the fluorochrome. Imaging of certain tumor cell receptors (e.g., EGF-receptor) may potentially allow (i) detection of disease at an early stage, (ii) stratification of tumor types for novel molecular targeted therapies and (iii) assessment of treatment effects by targeting cellular apoptosis substantially earlier than is the case with conventional response markers (e.g., tumor size regression).

"Smart" optical contrast agents significantly change their fluorescence emission upon enzymatic conversion (Figs. 1 and 3). These probes therefore show little background fluorescence in their native state while brightly fluoresce after cleavage by the target enzyme. Thus the signal to noise yield is substantially higher compared to the targeted probes.

The first autoquenched fluorescent probe was developed by Weissleder et al consisting of a long circulating carrier molecule conjugated to 12–14 cyanine dyes. The proximity of the dyes in the native molecule results in a signal quench due to fluorescence resonance energy transfer (FRET) while a strong fluorescence signal increase can be detected after probe is cleaved (Fig. 1). The first generation of these protease sensing optical probes is activated by lysosomal cysteine or serine proteases such as cathepsin-B. Meanwhile, probe specificity could be tailored to other enzyme systems by insertion of enzyme-specific peptide stalks between the carrier and the fluorochromes. Thus cathepsin-D, matrix-metalloproteinase-2 (MMP-2) or thrombin and other enzyme systems could be visualized using this approach (1, 4). "Smart" optical probes have been applied to study cancer progression, tumor metastasis, atherosclerosis, myocardial infarction, thrombosis, and inflammation. Since these molecules consist of a large backbone carrier molecule (approximately 400 kD) with several dyes attached to it the overall molecular weight is relatively high. Thus these probes tend to be retained systemically for a long time which is not desirable for diagnostic purposes. More recently, however, smaller activatable optical probes could be designed by attaching NIR fluorescence absorber (e.g., NIRQ820) through a peptide stalk to a NIR dye.



Molecular Probes, Optical Probes. Figure 3 ***Imaging of tumor protease expression by FMT using a "smart" optical probe*. In a transgenic mouse model, spontaneous breast cancer lesions were examined anatomically by MRI (sagittal T1w SE sequence) and optical molecular imaging was performed using a "smart" protease sensing probe (b, axial FMT images). Note the strong tissue fluorescence in the tumor nodule representing the expression of cysteine proteases, a molecular marker that is correlated with tumor aggressiveness (reprinted with permission from Bremer et al Inv Radiol 2005).**

Potential clinical applications of these probes are numerous. Various proteases are known to be key players in oncology, allowing the tumor to invade locally the tissue, form new vascular supply (i.e., perform angiogenesis) and induce distant metastasis. Moreover, proteases such as MMP-2 play a significant role in cardiovascular disease. For instance, it is well established that MMPs contribute to plaque instability in atherosclerotic disease. Other inflammatory diseases are linked to a high degree of protease over expression. Cysteine proteases have, for example, been shown to be upregulated in arthritis and to be a sensitive maker for anti-inflammatory treatment.

Use And Dosage

The potential clinical use of the optical probes presented here is necessarily co-defined by the technical constraints of detecting optical signatures in the tissue. Thus the application of noninvasive optical techniques is limited by the depth penetration of the modalities. However, a variety of clinical issues can be addressed using planar and tomographic imaging techniques. Surface weighted reflection techniques can easily be integrated into endoscopic, laparoscopic, or handheld devices. Combining these sensors with specific (molecular) optical contrast agents would greatly enhance the diagnostic possibilities for endoluminal diagnostics as well as intraoperative imaging. Thus, for example, real time, intraoperative guidance of tumor resection can be envisioned by combining a "tumor selective" optical probe with intraoperative planar imaging devices. Dual labeled probes (i.e., labeled with an MR and optical contrast agents) can be exploited for preoperative tumor localization and for intraoperative guidance by fluorescence reflectance imaging.

Different targets relevant to various aspects of disease have been imaged successfully in an experimental setting including (tumor) cell receptors, endothelial proliferation markers, cancer related or inflammatory proteases and apoptosis associated membrane structures.

Depending on the type of probe applied, optical probes with molecular specificity should significantly enhance the detection and characterization of pathology. Moreover, treatment response should be monitored more sensitively for example by apoptosis-avid agents.

Besides detecting a single reporter molecule multiwavelength, imaging approaches targeting several molecular targets simultaneously can be envisioned using fluorochromes with distinct excitation and emission spectra.

Since optical imaging is a highly sensitive imaging modality, low amounts of fluorochrome suffice for imaging specific molecular structures. The sensitivity of the imaging approach is currently thought to be in the range of (or even higher than) scintigraphic techniques. Based on experimental data generated for targeted and "smart" optical probes, 10–100 nmol/kg bw of the optical probe may provide sufficient optical signal for target detection. This, however, is 3–4 orders of magnitude lower than compared to clinically applied doses of Gd-DTPA for example (5).

Molecular Probes, Ultrasound Probes

M

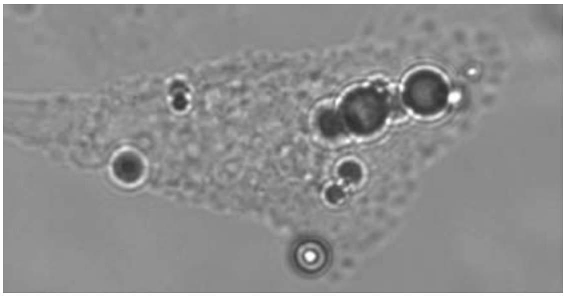
Katherine Ferrara
Department of Biomedical Engineering, Center for Molecular and Genomic Imaging, University of California, Davis, USA

Synonyms

Molecularly-targeted ultrasound contrast agents

Definition

Active and passive targeting mechanisms allow ultrasound contrast agents to accumulate in sites of interest. Active targeting uses ligands attached to the contrast agent shell surrounding each micron or nanometer diameter agent, where these ligands are optimized to adhere to endothelial cell targets (Fig. 1). Passive targeting relies on the size of the contrast agents to restrict their location to the vascular space, or to allow accumulation of the agents in leaky tumors. Agents currently approved for human use as ultrasound contrast agents are microndiameter bubbles,



Molecular Probes, Ultrasound Probes. Figure 1 **Targeted ultrasound contrast agents adherent to an endothelial cell *in vitro*.**

which produce passive targeting of the vascular space. *Ultrasound molecular agents* include molecularly targeted microbubbles, liposomes, and nanoparticles all of which are currently under development (1–4).

Following transmission of a brief ultrasound pulse, targeted ultrasound imaging techniques measure differences in the returned echo amplitude, spectrum, or pulse-to-pulse correlation to detect the presence of localized agents.

Approaches

There are three major types of agents proposed for targeted ultrasound imaging:

- *Microbubble agents* (2, 3) are small gas bubbles (typically a gaseous perfluorocarbon) with a stabilizing shell (albumin, lipid, or polymer) and most frequently used as the basis for molecularly targeted agents.
- *Perfluorocarbon emulsion nanoparticles* (1), with a mean diameter of hundreds of nanometers, are composed of a liquid perfluorocarbon and can include a lipid coating and a diluent for drug delivery.
- *Echogenic liposomal agents* (4) use a formulation involving lyophilization that entraps air in the lipid bilayers when rehydrated.

Requirements

Targeted ultrasound imaging should produce diagnostically significant localization of a receptor or of variations in vascular permeability with a high contrast to noise ratio. Echoes from bound or localized agents should ideally be differentiable both from circulating agents and from tissue. A small number of agents bind at a site of increased receptor density, and this small number can produce a detectable change in the echo. Quantitative estimation of receptor density may be difficult with targeted ultrasound imaging due to the relatively small number of agents, which bind to a large number of active receptors, however, accurate and consistent differentiation of normal and diseased tissue has been shown to be feasible.

Shell Characteristics

Most of the current work with targeted ultrasound contrast agents has involved the attachment of a peptide or antibody to a lipid shell either before or after the creation of the microbubble. Small molecule ligands can be directly attached to the lipids and the ligand–lipid conjugate is then purified. Large proteins (including antibodies) are often attached through covalent or noncovalent chemistry after the contrast agent is formed due to the harsh conditions that accompany microbubble creation. It is more difficult to purify the resulting targeted vehicle following this approach. Chemistries used to attach the ligand to the lipid membrane include:

- Biotin–streptavidin approaches, in which biotin is attached to the lipid or polyethylene glycols (PEG) molecule (2, 3),
- Carboxylic acid–amine approaches, in which a carboxylated lipid derivative is incorporated into the microbubble shell and reacts with an amine on the ligand (2),
- Maleimide–thiol approaches, in which a maleimide–PEG–lipid is incorporated in the monolayer shell and reacts with a thiol-containing targeting ligand (1, 2, 4).

Microbubble Agents

The major advantage to the use of microbubble contrast agents for targeted imaging is that the great difference in material properties between these agents and plasma produce very strong echoes, with properties that can be easily distinguished from the surrounding tissue. Due to the very high contrast-to-noise ratio, an echo from a single microbubble may be detected by a clinical ultrasound instrument.

Possible disadvantages of current targeted microbubbles include the relatively large size and the low circulation time (minutes to tens of minutes). Micron-diameter agents may not be able to bind to the desired site in the presence of high levels of shear stress *in vivo*. The diameter of the agents may be reduced using polymeric shells, which can be stable at an initial diameter of hundreds of nanometers and may circulate for an extended time interval.

Lipid-shelled microbubbles, used in currently published targeted ultrasound imaging research, incorporate a combination of lipids and an emulsifier at a ratio of the order of nine to one. The monolayer shell includes longer chain saturated lipid molecules such as distearoyl phosphatidylcholine, in addition to the emulsifier, typically incorporated as either PEG40-sterate or a PEGylated lipid. Microbubble formation is accomplished through agitation using a sonicator or modified dental amalgamator, and high temperatures typically occur during this process. The resulting microbubbles can then be purified (removing the excess lipid, streptavidin, biotintylated ligand) by centrifugation using a low speed over several minutes.

Both *in vitro* and *in vivo*, the binding efficiency of targeted has not yet been shown to vary greatly with the affinity of the ligands. Probably due to multivalency, the number of agents bound under similar conditions has not been greatly altered by the use of peptide or antibody-based ligands. Some improvement in efficiency has been noted with the presence of excess lipid in loose folds near a microbubble or the use of combined ligand strategies, such as targeting both integrins and selectins.

Detection of Microbubbles

Microbubbles with an initial diameter of the order of a few microns have a resonance frequency in the low megahertz frequency range, the same range of frequencies employed by clinical ultrasound instruments. When excited by an ultrasound wave with a low to moderate intensity (hundreds of kilopascals), their oscillation results in echo components at the transmission frequency and multiples and submultiples of this frequency. The harmonic multiple and submultiple components can usually be easily differentiated from tissue echoes. Alternative multipulse sequences use varied transmission amplitude, phase, and frequency to further improve the contrast to noise ratio, which can be as high as 30 dB. Oscillation of the microbubbles is altered when the agents bind to a receptor, and these small changes in the resulting echo may be used to estimate their density in future studies.

Microbubble contrast agents are destroyed by an ultrasound pulse of sufficient amplitude (amplitude depends upon initial radius and frequency), typically by fragmentation of the bubble into a set of smaller microbubbles where the resulting small gas fragments diffuse more rapidly. Comparison of images before and after microbubbles are fragmented provides a source of contrast to distinguish microbubble and tissue echoes.

Perfluorocarbon Emulsion Nanoparticles

The liquid composition of perfluorocarbon emulsion nanoparticles makes them resistant to pressure and mechanical stress, greatly increasing their circulation time as compared with microbubbles. In addition, with a diameter in the hundreds of nanometers, these particles should bind over a greater range of physiologically relevant shear stress than microbubbles. Peptide or antibody-based targeting ligands can be attached to an outer lipid membrane. An additional diluent may be added to solubilize a drug.

Imaging perfluorocarbon nanoparticles with ultrasound is more challenging than microbubbles, in which nonlinear echo components are not typically produced and therefore tissue and agent echoes have similar spectra. Their echogenicity is not as great as that of a gas-filled agent of similar size, however, the summed echo amplitude of a fixed number of particles increases when they are deposited in a layer.

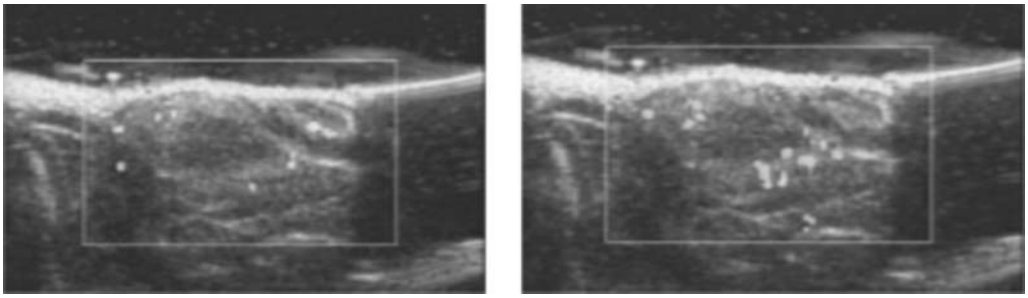
Liposomal Agents

Liposomal agents, like perfluorocarbon emulsion nanoparticles, can circulate for extended periods, providing the opportunity for larger numbers of agents to bind to a site of interest. Echogenicity, on a per agent basis, is expected to be lower than a microbubble based agents, but should increase when the agents bind in a coherent layer. Liposomal agents also allow for the incorporation of hydrophobic or hydrophilic drugs, and can therefore function both as imaging and drug delivery agents.

Applications

Of the many molecular markers that could be used for active targeting, ultrasound research applications have so far been limited to those which are accessible through the vasculature, including inflammation, thrombus, and angiogenesis (Fig. 2). Due to their relatively large size, targeting of microbubbles to capillaries or postcapillary venules has shown the greatest success.

Microbubbles targeted to integrins (incorporating either monoclonal antibodies or RGD-containing disintegrins or peptide) have been shown to be retained in tumors and models of angiogenesis. Perfluorocarbon nanoparticles and liposomal agents have been shown to target atherosclerotic plaques as well as angiogenesis.



Molecular Probes, Ultrasound Probes. Figure 2 Control and targeted ultrasound contrast agents within a model of angiogenesis. A matrigel plug infused with basic fibroblast growth factor to stimulate angiogenesis was implanted within a rat model. Contrast agents were injected and allowed to circulate for 15 min. Overlaid B-mode (10.3 MHz) and power Doppler images (7.2 MHz, PRF 868 Hz) were then acquired. Left image shows the remaining control agents, right image shows targeted agents which were bound to the site (Image courtesy of Paul Dayton and Susanne Stieger, University of California, Davis).

Drug Delivery

Targeted ultrasound particles have the potential to be used for both imaging and drug delivery (3, 5). Several architectures for microbubble-based drug-delivery particles have been described and are under test, including particles with a drug covalently attached to the lipid shell, a thick drug-carrying oil shell encapsulating a microbubble, and a lipid shell carrying nanoparticles or liposomes. With a gas bubble at the center of the particle, low ultrasound pressure levels can be used to deflect the particle using a Bjerknes force and enhance targeting efficiency and the gas particle can be fragmented at the site of interest with a high-pressure pulse.

Nanoparticles and liposomal particles can also be used to carry a drug, as well as to create an image. Perfluorocarbon nanoparticles, have an impedance difference in comparison with plasma, and therefore their biodistribution and properties may be affected by ultrasound.

Molecular Targets

Christoph Bremer
Dept. of Clinical Radiology and Interdisciplinary Center for Clinical Research (IZKF), University of Muenster, Muenster, Germany
bremerc@uni-muenster.de

Definition

Molecular targets are cellular or tissue structures that are intended to be visualized by means of molecular imaging. Different biological structures can potentially serve as imaging targets, ranging from proteins to DNA and RNA.

Characteristics

From sequencing of the human genome, it became clear that the whole human genome consists of approximately 34,000 genes. Therefore, numerous structures could potentially serve as novel tissue-specific markers for *in vivo* imaging. High-throughput analysis tools in genomics and proteomics help to identify new specific target molecules that are upregulated in various disease processes. Profiling-mediated discovery of novel disease-specific markers will spur the development of more specific imaging agents [Feindegen, 2003 #93]. Based on this knowledge, new types of receptor/target ligands (see later) can form the basis for new imaging and therapeutic agents.

Targets for molecular imaging should generally be (i) clinically relevant (i.e., linked to a certain type of disease or be predictive of disease outcome), (ii) abundantly overexpressed compared with healthy tissue, and (iii) easily accessible (e.g., extracellular). Typically, specific proteins (e.g., cell receptors) are chosen as molecular targets since the “natural amplification” mechanism from gene to protein (i.e., one gene translates to several copies of proteins) can be exploited, and—depending on the site of expression—proteins may be more easily accessible.

Targeting interstitially localized or extracellular proteins is the most promising approach to *in vivo* molecular diagnostics, as pharmacological barriers are minimal. Enzymes can be exceptionally interesting targets when combined with enzymatically activatable fluorophores because one target structure (e.g., matrix metalloproteinase, cathepsin) can process several hundreds of reporter probes and thus vastly amplify the signal for molecular imaging.

However, even intracellular structures (e.g., caspases, RNA, DNA) can theoretically be targeted by different imaging approaches. For this purpose, membrane translocation signals can facilitate entry of the probe into the intracellular space. Different approaches have been described to achieve improved transmembrane migration of reporter probes, including the HIV-derived tat-peptide, dendrimers, and polyamine residues.

Molecularly-Targeted Ultrasound Contrast Agents

Morbus Paget

Geert M. Villeirs
Division of Genitourinary Radiology
Ghent University Hospital, Ghent, Belgium
geert.villeirs@ugent.be

Definition

Paget’s disease of the nipple–areolar complex occurs in association with about 1–5% of all breast carcinomas. The presence of malignant cells in the nipple and/or areola causes eczematoid changes that may be the first sign of the underlying malignancy. Carcinomas presenting with only this sign are usually diagnosed early in their course and therefore have a rather favourable prognosis.

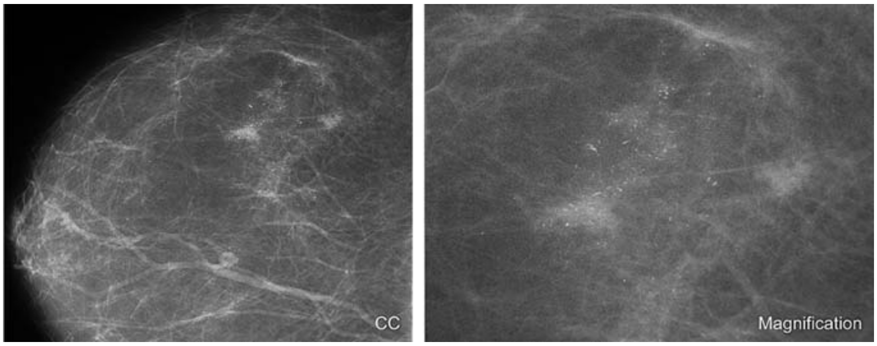
Pathology/Histopathology

Paget’s disease is characterized by permeation of the nipple–areolar epidermis by large malignant cells containing large nuclei and abundant pale cytoplasm. They cause chronic inflammation of the dermis and may be so numerous that they completely destroy the epidermis, causing frank ulceration and erosion of the nipple and/or areola.

The permeating cells originate from a retroareolar carcinoma or from a carcinoma anywhere in the breast, virtually always of ductal type (either *in situ* or a combination of *in situ* and infiltrating carcinoma), and migrate through the ductal system towards the nipple and areola.

Clinical Presentation

The clinical presentation of Paget’s disease is a unilateral itchy erythema of the nipple and/or areola, progressing to eczematous changes with moisture and scaling, and ultimately effacement, ulceration and erosion of the nipple. Bloody nipple discharge may be present.



Morbus Paget. Figure 1 Casting-type calcifications of intraductal carcinoma in a patient with Paget's disease of the nipple.

Mammography

On mammography, the nipple/areolar involvement usually is not apparent, although nipple retraction, skin thickening or calcifications have been reported. When Paget's disease is suspected clinically, the mammogram is rather performed to detect an underlying carcinoma by the presence of a mass or suspicious microcalcifications (Fig. 1).

Sonography

Sonography is of limited use in Paget's disease, except to detect or exclude an underlying carcinoma.

Magnetic Resonance Mammography

In addition to the demonstration of an underlying carcinoma, magnetic resonance mammography may show non-specific enhancement of the thickened nipple–areolar complex.

Percutaneous Biopsy

The clinical diagnosis of Paget's disease can be confirmed by a cytologic smear or excisional biopsy of the eczematous nipple–areolar complex.

Definition

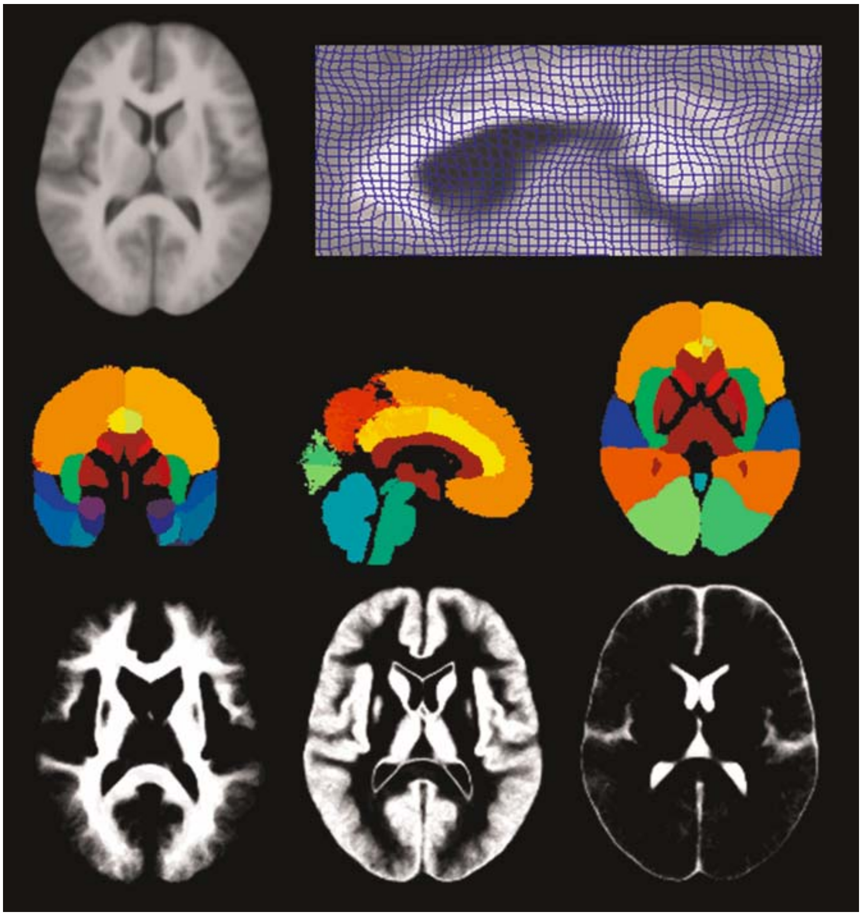
Magnetic resonance (MR) brain morphometry refers to the characterization of morphological, that is, structure- or shape-related features of the brain or its substructures from MR image data, using suitable, computer-aided image analysis methodologies. Current MR imaging technology provides the ability to generate three-dimensional (3D) image volumes of the entire brain with near-isotropic spatial resolution of about 1 × 1 × 1 mm per volume element or voxel. Such 3D image volumes can be sliced and visualized on a computer display along multiple arbitrarily oriented two-dimensional (2D) planes through the brain (MPR or multiplanar reformat), providing a more comprehensive understanding of the 3D anatomy. While visual inspection of the image data is subjective and merely provides a qualitative assessment of morphological characteristics of the brain's anatomy, often objective, quantitative measures, which are obtained by image-based measurements, are of interest. This is typically the case when brain images of different subjects have to be compared in order to detect and characterize subtle morphological differences between them (e.g., a population of normal controls versus patients) or when morphological changes over time have to be assessed in a single individual by comparing images acquired at different time points (e.g., lesion evolution in response to therapy). Morphometric parameters of interest are, for instance, distances between anatomical landmarks, volumes of structures of interest, regional distribution of white and gray matter, location and size of possible lesions, and description of object shape (using suitable mathematical representations) and its deviation from the expected, normal shape.

Characteristics

A prerequisite for the quantification of shape-related parameters of an anatomical structure of interest from image data is that this structure has been defined in the images, that is, its contour (in 2D) or surface (in 3D) has been delineated with sufficient accuracy in order to discriminate this structure from other surrounding structures and background. The process of object delineation in images is termed image segmentation. While in principle the surface of the objects of interest can be delineated manually by an expert in several 2D images displayed on screen, such manual segmentation is tedious and time-consuming and typically subject to significant intra- and interobserver variability. In the field of medical image analysis, more efficient and robust (semi-) automated image processing approaches for segmentation of anatomical objects in medical image data are therefore being investigated.

These methods can be broadly classified as being low-level or model-based. Low-level approaches make use of the intensity information only in the images and they segment the object of interest based on heuristic and often simplistic rules, such as assumed object intensity homogeneity (e.g., thresholding, region growing strategies), object boundary contrast (e.g., edge detection strategies), or combinations thereof. For complex-shaped anatomical objects such as the brain, with significant biological shape variability and possible pathological deviations, in complex image data such as MR images, including noise, intensity inhomogeneity, partial volume effects, and other imaging artifacts, such low-level approaches are usually insufficient to generate accurate delineations of the brain or its substructures and often require tedious, manual postprocessing to correct for segmentation errors. Model-based approaches, on the other hand, incorporate prior knowledge about the appearance of the object of interest in the images, that is, information about the expected intensity and/or shape of the object, as well as contextual information such as its spatial relation to other objects. Model-based approaches apply an optimization strategy to find the parameters of the model that best fit the image data. They are generally more robust than low-level approaches, because the model used imposes constraints on the segmentation result that can compensate for ambiguities in the image data. A typical example of such model-based segmentation is the classification of MR brain image voxels in different tissue classes (usually "white matter," "gray matter," and "cerebrospinal fluid") using a Gaussian mixture model for the image intensity (one or more Gaussian distributions per tissue class), while also incorporating models to correct for MR bias field intensity inhomogeneity and to impose local regularity of the segmented tissue maps (1).

Many applications of MR brain morphometry involve the analysis of multiple MR image volumes for the assessment of morphological differences between different subjects or within a single subject over time. While in principle the morphometric parameters of interest can be obtained from each volume separately and subsequently compared, the analysis is much facilitated if the image volumes are spatially aligned and normalized first, such that corresponding voxels in each image also correspond anatomically. When the images have been segmented in different tissue maps, a voxel-by-voxel statistical analysis can be performed to detect local anatomical differences between different (groups of) subjects (so-called voxel-based morphometry (3)). Image alignment or registration is a fundamental problem in image analysis. Affine registration only compensates for global differences in pose (3D translation and rotation) and size between different images (12 parameters or degrees of freedom), while nonrigid registration also compensates for local shape differences (using a deformation field with many more degrees of freedom, up to three per voxel). Voxel-based nonrigid registration requires a suitable similarity measure to assess the geometric correspondence between different images based on their intensities, as well as an appropriate regularization strategy to ensure that the resulting deformation field is well-behaved and physically realistic (2). The latter is typically achieved by representing the deformation field using smooth basis functions (e.g., B-splines) or by



Morphometry, MR, Brain. Figure 1 **Brain atlas constructed by averaging a set of segmented MR brain images of different subjects after spatial normalization by nonrigid image registration. *Top*: averaged brain image template and typical deformation pattern near the corpus callosum; *middle*: coronal, sagittal, and axial slices with averaged segmentations of different subcortical structures; bottom: averaged tissue maps, showing the expected spatial distribution of white matter, gray matter, and cerebrospinal fluid.**

imposing smoothness penalties or physics-based constraints (e.g., elastic or viscous fluid model). An often-used similarity measure is maximization of mutual information of corresponding voxel intensities. This approach assesses the statistical dependence of the intensities in both images based on their joint histogram, without making assumptions about the nature of the data, which makes the method applicable to multimodal data (e.g., MR/PET or MR-T1/MR-T2 registration) as well.

Spatial normalization by (nonrigid) registration of a set of similar MR brain images of different subjects allows one to average all images voxel by voxel such that a brain image template or atlas is obtained with "average" shape. By also averaging the segmented tissue maps of all subjects, an atlas of the expected spatial distribution of different tissue types (or of other brain structures of interest) can be constructed (Fig. 1). This atlas can then be used for atlas-based segmentation and morphometry of new brain images by (nonrigid) registration of the atlas to the images under study. In addition, shape differences between a set of images of different subjects can be assessed by statistical analysis of the deformation fields that spatially align all images.

Definition

Over the last few years, tremendous advances have been made in the field of magnetic resonance (MR) imaging of the breast. Developments have been made in surface coil technology, resulting in improved spatial resolution, as well as in imaging protocols, resulting in improved temporal resolution. MR mammography (MRM) has a high sensitivity of 88–100% with a relatively low specificity. Therefore, differentiation between benign and malignant lesions is often not possible. In these cases, the patient can be followed up 6 months later or they may undergo MR-guided breast biopsy. MR-guided breast biopsy techniques continue to develop.

Technique

To date, most of the breast MR imaging studies that have been reported in the literature have been performed with high-field-strength MR imaging systems (1–1.5 T). Because of the open architecture and low cost of the lower field strength, open MR systems are widely used to perform contrast-enhanced breast MR imaging at lower field strength. One concern is the signal-to-noise ratio per unit time of sampling data. The need to compromise spatial or temporal resolution is exacerbated at lower field strengths. A second issue is fat suppression, and a third aspect is the difference in contrast characteristics.

Breast Coils

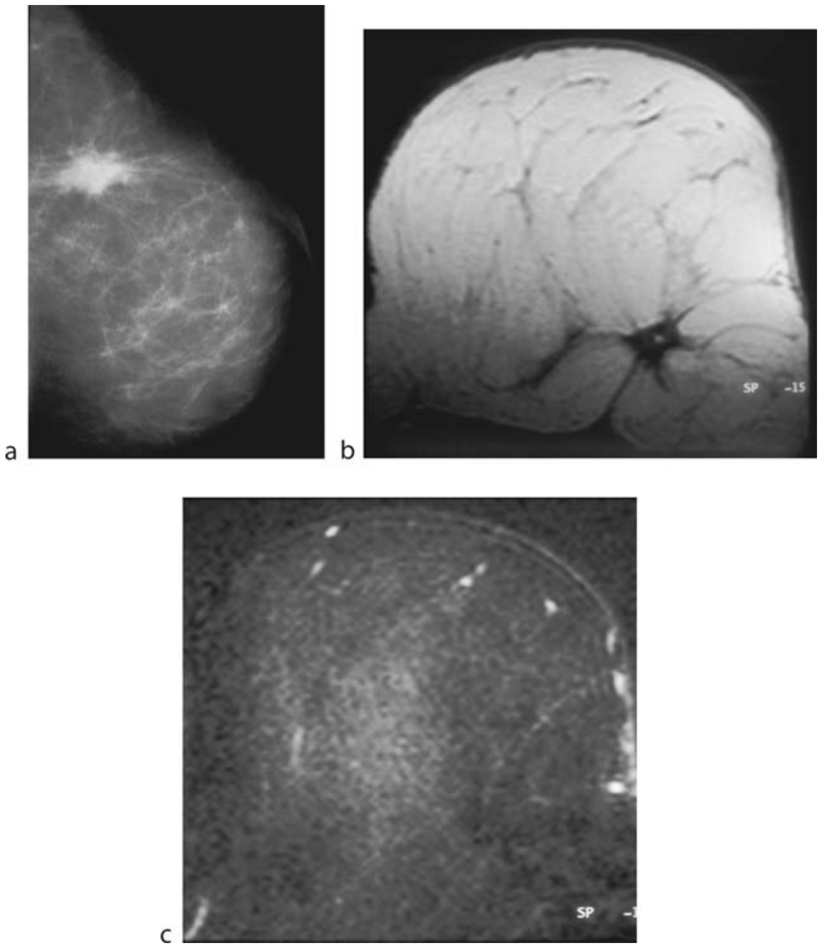
Breast MR imaging is typically performed with the patient in prone position, lying on a platform placed in the MR imager, allowing the breast to extend independently of the patient. Prone patient positioning minimizes the effects of respiratory motion and is preferred to supine imaging, which results in lower image quality.

A dedicated breast surface coil should be used when performing breast MR imaging. These normally include phased-array, bilateral breast coils. The acquisition should be performed in the coronal transverse plane, with a rectangular field of view oriented with the long axis in the medial-to-lateral direction. Imaging of the transverse plane is advantageous, compared with imaging in the coronal plane, because a finding on a transverse MR image can then be correlated with a similarly positioned craniocaudal mammographic view.

Use of paramagnetic contrast agents at a dose of 0.1 mmol per kilogram of body weight is the method of choice. The contrast agent is given as bolus followed by a saline flush.

Imaging Protocols

The protocols for breast MR imaging vary dramatically. Although the hallmark of breast MR imaging is contrast-enhanced imaging, T2-weighted images can be valuable in establishing the diagnosis of a cyst or fibroadenoma. Therefore it is recommended that a fast spin-echo T2-weighted sequence through the breast be acquired



MR Mammography. Figure 1 Patient with previous tumorectomy. Focal mass on postoperative mammography (a). T1-weighted MR mammography showing a mass (b), no enhancement in subtraction image revealing a scar, and no tumor (c).

routinely before administration of contrast material. The T2-weighted sequence should be performed with fat suppression and at a section thickness of approximately 3 mm.

T1-weighted images are acquired before and after intravenous administration of contrast material. Gradient-echo sequences, two- or three-dimensional, are performed, which are much more sensitive to the T1-shortening effects of gadolinium chelates than are spin-echo sequences.

Fat Suppression

Standard presaturation of fat during every repetition time can be used. Fat suppression can also be achieved by means of postprocessing image subtraction. Identical imaging parameters before and after contrast agent administration are required. Subtracted images will yield the difference in signal intensity between the unenhanced and enhanced images, directly proportional to the degree of enhancement.

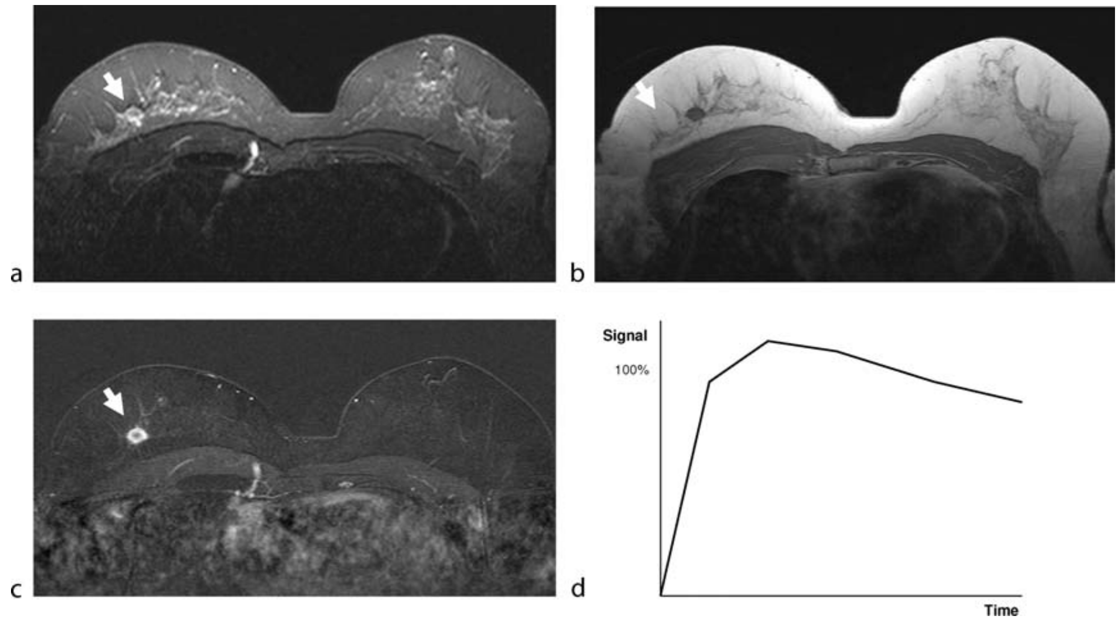
When evaluating breast MR imaging examinations, morphologic and dynamic criteria should be taken into account as classified by the ►MRM-BI-RADS.

MRM-BI-RADS

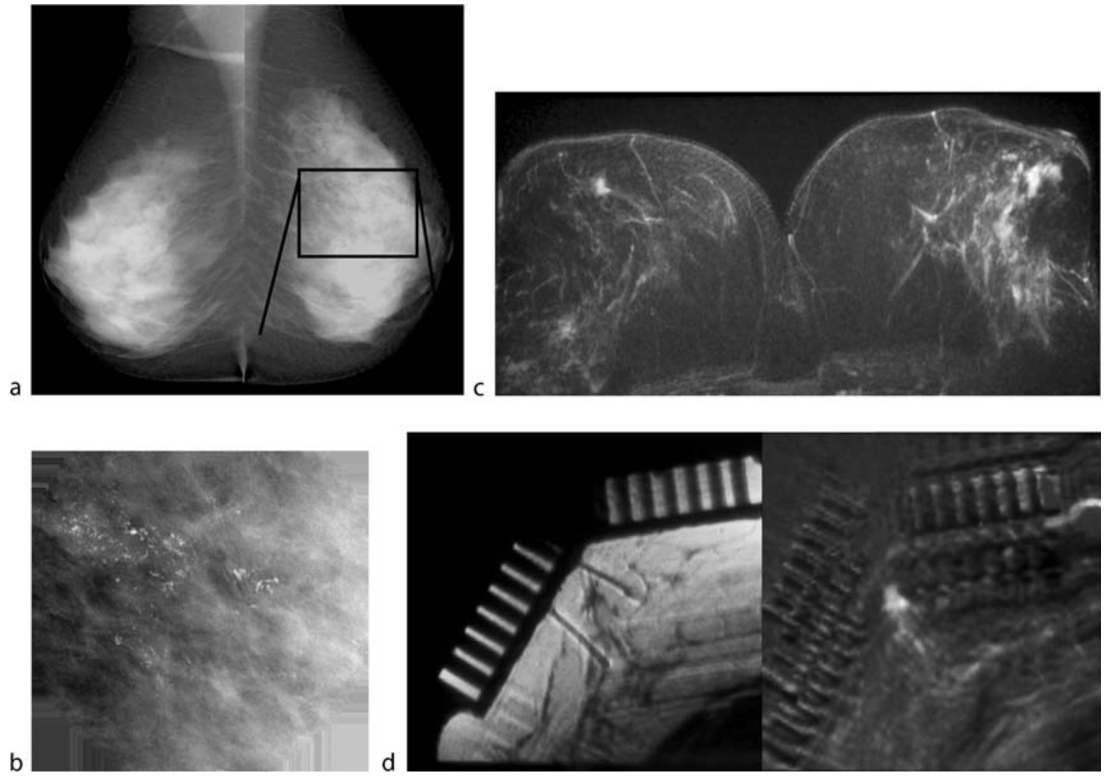
Features in MRM according to the BI-RADS classification are summarized in the chapter on the BI-RADS lexicon.

Indications for MR Mammography

In routine practice, MRM can be used to detect local recurrence in a treated breast and breast cancer in patients with axillary lymph node metastasis and no radiographic or clinical evidence of a primary breast cancer (cancer of unknown origin = CUP syndrome). MRM should be done for the detection of ruptures of silicone implants. MRM is



MR Mammography. Figure 2 Typical example of an invasive tumor in the right breast. T2-weighted image with intermediate signal (a), T1-weighted sequence with hypointensity of the tumor (b), and rim enhancement in the subtraction image of the irregular mass (c). In the signal intensity curve, there is initial enhancement >100% and postinitial wash-out (d).



MR Mammography. Figure 3 Suspicious segmental pleomorphic microcalcification on mammography (a) of the left breast with magnification view (b). Maximum intensity image in MRM with typical diffuse enhancement in left breast directed to the nipple and with a suspicious mass in the right breast (c). Preoperative wire localization of the mass in the right breast on T1-weighted and subtraction image (d). Histology revealed a ductal carcinoma *in situ* in the left side capable of detecting, diagnosing, and staging breast cancer preoperatively. The extent of the cancer can be determined more accurately than with conventional imaging, for example, multifocal or multicentric cancer (examples in Figs. 1–3). At present, screening MRM has not been validated and has only been evaluated in high-risk patients. Because of its high negative predictive value, MRM may be a useful adjunct for further evaluation of a dubious mammographic abnormality, such as architectural distortion. MR imaging is also used to evaluate response to neoadjuvant chemotherapy in locally advanced breast cancers.

Six months are recommended between open breast biopsy and MRM, and 12 months between surgery/radiation (lumpectomy, tumorectomy) and MRM. MRM should be done in the second phase of the menstruation cycle (Figs 1–3).

MR-guided Breast Biopsy and Localization

Different potential solutions for MR-guided breast biopsies and localizations have been used, from single breast coils to dedicated double breast coils.

Except in open magnets, the patient must be removed from the magnet for the radiologist to gain access to the breast in order to perform the localization or biopsy procedure. Because MR imaging is usually performed with the patient prone, the lateral breast is accessible, but access to the medial breast may be more difficult. After contrast medium injection, lesion conspicuity diminishes over time because of the transient nature of contrast enhancement. For MR imaging-guided surgical biopsy, confirmation of lesion retrieval is difficult because the lesion does not enhance *ex vivo*.

Inspissated secretion in segmental bronchial obstruction.

▶Cystic Fibrosis

Mucoviscidosis

▶Cystic Fibrosis

Müllerian Duct Anomalies

MDA are an uncommon but often treatable cause of infertility. Patients with MDA are known to have a higher incidence of infertility, repeated first trimester spontaneous abortions, fetal intrauterine growth retardation, fetal malposition, preterm labor, and retained placenta. The role of imaging is to help detect, diagnose, and distinguish surgically correctable forms of MDA from inoperable forms. In some correctable lesions, the surgical approach is altered based on imaging findings.

▶ Müllerian Duct Anomalies

Multicentricity

One or more tumors are more than 2 cm away from the main tumor, often in different quadrants. Mastectomy is usually performed.

▶Carcinoma, Multiple, Breast

Multicystic Dysplastic Kidney

A congenital type of renal dysplasia, where the kidney is entirely replaced by cysts of varying sizes, with only minimal residual non-functioning dysplastic parenchyma.

▶Cystic Renal Disease, Childhood

Multidetector Computed Tomography

New generation of CT scanners where a 2D array of detector elements replaces the linear array detector elements used in typical conventional and helical CT scanners. The two-dimensional detector array allows acquisition of multiple scans simultaneously and greatly increases the speed of CT image acquisition. With MDCT thin collimation and thus the acquisition of near isotropic imaging of the urinary tract is possible. Isotropic datasets are the basis of high quality multiplanar reformations and 3D reconstructions of the organs including virtual cystoscopic views.

▶Neoplasms, Bladder

Multidetector Row CT

By using multiple rows of CT detectors, scan times can be considerably shortened and smaller slice thicknesses are possible. Improved speed enables the coverage of large volumes of anatomy in a single breath-hold whereas thinner slices produce high-quality axial and multiplanar images.

▶Neoplasms, Gastroduodenal

Multifocality

One or more masses are found in one quadrant, at a maximum of 2 cm away from the main tumor. The therapy of choice is quadrantectomy.

Synonym

Dual modality imaging

Definition

Each imaging modality provides specific types of information regarding the morphology, physiology, metabolism, molecular composition, or molecular pathways within biological tissue, and provides that information on a certain spatial and temporal scale and with a particular sensitivity for detection. No one imaging modality can address all measurements of interest related to a biological system; therefore, it can be advantageous to acquire images of the same subject using different modalities. *Multi-modality imaging* involves the simultaneous or sequential acquisition of imaging data using two or more imaging modalities. A common example would be functional/structural imaging using nuclear medicine techniques (*PET* or *SPECT*) to measure some aspect of biologic or molecular function, combined with X-ray computed tomography (*CT*) or magnetic resonance imaging (*MRI*) to measure structure (1, 2).

Characteristics

Approaches

There are three major approaches to acquiring multi-modality imaging datasets:

- *Software registration* of images acquired on two independent imaging systems. The subject is imaged on two different imaging systems at two different times. Image registration algorithms are used to co-register the imaging data from the two modalities.
- *Combined modality imaging systems* in which two separate imaging instruments are placed in close proximity (usually with a fixed geometric relationship to each other) with a common imaging stage/bed and a common software platform. The subject is moved in rapid succession through the two imaging modalities and the image data are automatically registered because of the known spatial relationship of the two systems.
- *Integrated modality imaging systems* in which the hardware of the two imaging modalities are integrated in such a way that simultaneous acquisition of the same tissue volume with the two imaging modalities is possible, with automatic registration of the datasets.

Requirements

Multimodality imaging should provide diagnostically or scientifically significant information not available from a single imaging modality. To the extent possible, the image quality of each modality employed in multimodality imaging should not be compromised to obtain multi-modality datasets.

Software Approaches

Image registration algorithms have been developed for co-registering image datasets from a wide range of modalities. Approaches include the use of intensity information within the images themselves, the identification of common points within the two image datasets, matching of surface features between two imaging, and the application of external fiducial markers, affixed to the skin or bone, that can be visualized in each modality (3). Two major categories of image registration algorithms have been developed:

- *Rigid-body registration algorithms* are suited to situations in which there is no deformation of the objects to be registered between the two scans, and where the images themselves do not contain any spatial distortions. In this case, the image datasets can be matched by a simple combination of three translations and three rotations. Six parameters completely define the transformation. This approach is well suited for registering images of the human brain using modalities such as *PET*, *SPECT*, *CT*, and *MRI*.
- *Elastic or nonrigid body transformations* are used when there is spatial distortion between the two datasets. This can be caused by relative motion and changes in shape of the internal organs, for example due to differences in the exact body position on the scanner bed for each individual imaging session. Registration becomes far more complicated and can involve both globally and locally elastic parameters. The robustness of the algorithm depends on the degree of deformation that exists between the two datasets, and the

information content of the image characteristics used for co-registration. Elastic transformation algorithms are usually required for registration of images originating from the thorax or abdomen, and have been widely applied to registering *SPECT* or *PET* images with *MRI* or *CT* images.

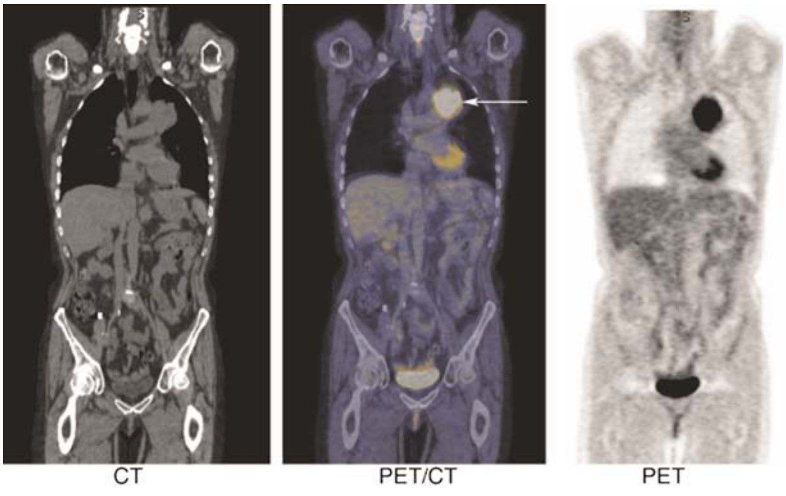
Hardware Approaches

The most common approach to multimodality imaging systems is to combine two independent scanners with a common subject platform/bed, common control and acquisition systems, and a common display system. With careful design, each scanner operates just as well as part of such a multimodality system as it would on its own, and therefore this approach generally involves little to no compromise in image quality or performance. The advantage is that multimodality data are acquired quickly and efficiently, compared with using individual scanners. If images from the two modalities are acquired in rapid succession, then, assuming the subject does not move between the scans, and that the geometric relationship of the two instruments is known, the two image sets are registered to each other without the need for the software registration algorithms described earlier. One common form of multimodality imaging system is the PET/CT scanner. Typically, PET and CT scanners are located back-to-back, with a single patient bed that traverses both imaging systems. The PET and the CT data are acquired in rapid succession. Both SPECT/CT and PET/CT systems are now widely employed in clinical practice (1, 2), primarily for *oncology applications* (Fig. 1). They are also being developed for preclinical imaging in animal models for *molecular imaging* applications (Fig. 2).

A greater challenge is to integrate two imaging systems to enable simultaneous or rapidly interleaved acquisition of the two modalities over the same part of the body. This is important in applications where there is the desire to correlate in time, the signals from two separate modalities. An example of this would be measurements with *fMRI* and *EEG* imaging to study neuronal activation patterns and circuitry, or measurements with *PET* and *MR spectroscopic imaging* to study metabolic pathways. This type of multimodality imaging places stringent requirements on the instrumentation, as they must be able to operate at the same time, and without significant interference. It is therefore not uncommon that in these studies, the image quality of one or both modalities may be compromised compared to the results that would be obtained using each modality on its own. For successful use of such integrated modality systems, the additional information gained by the temporal correlation of the two datasets must outweigh any deterioration in image quality.

Applications

The integration of structural imaging with functional or *molecular imaging* has been by far the largest source of applications for multimodality imaging. The development of multimodality imaging, whether *via* hardware or



Multi-modality Imaging. Figure 1 Multimodality images from a PET/CT scanner showing high accumulation of the metabolic tracer ^{18}F-fluorodeoxyglucose in a lung tumor (*arrow*). (Images courtesy of Hongjie Liang, UC Davis)**

software approaches, has been driven by the need to correlate function (defined in its broadest sense and including metabolism, molecular targets and pathways, immunological homing, gene expression, etc.) with its anatomic localization in the subject. Some examples of specific questions that can be addressed *via* structural–functional multimodality imaging include:

- Correlation of radiotracer uptake in suspicious lesions with CT findings to improve diagnosis and staging of cancer patients (PET/CT and SPECT/CT).
- Studying neuronal circuitry following task-specific activation (MRI/EEG).
- Surgical planning with the goal of preserving vital functions in patients with brain tumors and intractable seizures (combinations of PET, MRI, fMRI, and intraoperative optical imaging).
- Radiotherapy planning using functional imaging to better define target volume (PET/CT).
- Imaging of cell trafficking and engraftment using radiolabeled, magnetically or fluorescently labeled cells (combinations of SPECT, PET, MRI, and optical imaging).
- Imaging location and extent of gene expression in genetically engineered animal models and in monitoring of therapeutic gene delivery (combinations of PET, SPECT, optical imaging, MRI, CT).

Multimodality imaging is being used for all the applications described earlier and has become a widely accepted approach to problems ranging from molecular imaging basic science investigations in small animal models through to advanced diagnostics in the clinic.

In addition to the obvious advantages of correlating structure and function through multimodality imaging, there often are additional benefits in which the two modalities can be used in a synergistic fashion to actually improve image quality or image quantification. For example, in SPECT/CT and PET/CT imaging, the CT scan can be used to correct for tissue attenuation of the photons emitted in the PET or SPECT scans, thus improving quantification of radiotracer uptake. It may also be possible to incorporate anatomical information from MRI or CT into the reconstruction of PET, SPECT, and optical imaging datasets to improve quantification of the distribution of radiotracer or fluorescent probes *in vivo*.

A new class of multimodality applications involves the use of two functional imaging modalities to measure two different biological parameters at the same time. Combinations of modalities that are in the early stages of being explored include PET/optical, PET/ultrasound, ultrasound/optical, and PET/MR spectroscopy. Multimodal contrast agents, imaging probes, and imaging reporter gene systems are also being developed. These will open up new opportunities for studying interactions within biological systems, for example the interaction of a drug with its target and its effect on the function of that target, or the flux through two competing pathways following a targeted intervention on one of the pathways.

Multiphase Bone Scintigraphy

Literally, the bone scintigraphy is the investigation approximately 3 h after intravenous injection of the radiotracer, when a good bone/soft tissue ratio is reached. For certain indications, early phases are added to the investigation using the same radioactivity, which is applied anyway. The radionuclide angiography is performed immediately after injection and reflects arterial perfusion. Early static images acquired a few minutes later display the blood pool.

▶Bone Scintigraphy

Multiple Endocrine Neoplasia (MEN) Syndrome

MEN syndrome is a hereditary disorder that involves many glands. There are three forms: MEN 1, MEN 2a, and MEN 2b. MEN 1 is characterized by development of excessive normal tissue (hyperplasia) or an adenoma (tumor) of the parathyroid, pancreas, pituitary, adrenals (rarely), or thyroid gland (rarely). MEN 2a is characterized by medullary thyroid cancer, unilateral or bilateral pheochromocytoma, and primary parathyroid hyperplasia. MEN 2b is characterized by medullary thyroid cancer and pheochromocytoma, but not hyperparathyroidism.

Definition

Multiple Sclerosis (MS) is an inflammatory demyelinating disease of the central nervous system (CNS) with various degrees of axonal loss. MS most commonly affects young adults between the age of 20 and 40 years and leads to significant neurological disability after 10 to 15 years. The disease favors women over men by a ratio of nearly 2 to 1 and is clinically defined as a predominantly white matter disease distributed in both time and space. There could be a relationship between environmental factors and genetic predisposition. Genetic studies have convincingly shown that multiple genes are involved. The mechanism of these genetic factors and their interactions with the environmental agents in establishing the disease are largely unknown.

In general, the first-degree relatives of probands have a higher risk for developing the disease than the general population. Migrational studies stressed the importance of environmental factors.

There is also a geographic preference for people living in Northern latitudes and Caucasians are considerably more susceptible than Asians or Blacks (1, 2).

Pathology/Histopathology

MS is considered an autoimmune disorder in which autoreactive T-cells drive an inflammatory process leading to myelin oligodendrocyte destruction and axonal loss. The external appearance of the brain is usually normal but slight atrophy with widening of the sulci and enlargement of the ventricles may be seen in some chronic cases.

In sectioning, lesions of varying size become apparent in the white matter of the CNS. The major characteristic of these lesions is focal demyelination.

Different mechanisms are involved in myelin destruction. T-cell, macrophage-mediated myelin damage and precipitation of immunoglobulin with complement fixation are two major phenomenons leading to myelin destruction in MS plaques.

The following four patterns of demyelination have been identified:

Patter I: T-cell/macrophage-mediated demyelination
Patter II: Antibody/complement-mediated demyelination
Patter III: Oligodendrocyte dystrophy with oligodendrocyte apoptosis
Patter IV: Primary oligodendrocyte degeneration with features similar to viral infection or toxic oligodendrocyte damage but not to autoimmunity.

It has been convincingly demonstrated that axonal injury occurs during lesion formation, even in the early stage of MS. Axonal loss is probably the principle determinant of irreversible neurological disability and progressive course (2, 3).

Clinical Presentation

The symptoms of MS vary depending, in part, upon the location of the plaques within the CNS. Weakness in one or more limbs, optic neuritis, paresthesia, and diplopia are the most common presenting symptoms. Other common manifestations include bladder and bowl dysfunction, sexual problems and ataxia. Fatigue is one of the most common complaints reported by the patients and signs of cognitive dysfunction can be detected in about half of the patients using neuropsychological investigations (1).

Four different clinical courses have been described for Multiple Sclerosis:

The first, "relapsing-remitting" MS is characterized by self-limited attacks of neurological dysfunction followed by remission over the next several days or weeks. Most of these patients will evolve into a "secondary progressive" type characterized by a chronic and steady increase of disability. If the patients have a steady neurological decline from the onset, without relapse, they are described as "primary progressive" type of MS.

"Progressive-relapsing" are the patients who have a progressive course from the beginning although they also experience occasional attacks. It should be noted that a small group of patients will remain clinically stable and fully functional for 15 years after the onset of symptoms (benign MS), however, most patients develop moderate to severe disability in this period of time (1, 3).

Imaging

Computer tomography is now rarely used in the diagnosis and follow-up of MS. With CT, it was possible to visualize just some of the MS lesions. In longstanding and severe cases, ventricular dilatation and cortical atrophy can be observed.

MRI has a far better sensitivity for identifying MS plaques and now plays an essential role in initial evaluation of MS patients, predicting prognosis in patients presenting with symptoms highly suggestive of acute inflammatory CNS demyelination and in providing primary outcome measures in phase I and II trials of MS therapeutics.

Three main groups of lesions can be identified with conventional MR imaging. These include acute lesions demonstrating blood-brain-barrier leakage on contrast-enhanced MR images (enhancing lesions), chronic severely damaged areas that are hypointense on T1 images with contrast (chronic black holes), and hyperintense T2 lesions.

MS Lesions in T2-Weighted Images

Focal white matter areas of increased signal intensity in T2 WI images are the characteristic appearance of multiple sclerosis. They are usually round or oval in appearance with a variable size and with the major axis perpendicular to the corpus callosum (Dawson's fingers). They tend to be located in periventricular areas but other common sites are subcortical and infratentorial regions.

Inflammation, demyelination, gliosis, edema, and axonal loss will increase the signal intensity on T2 WI images without any specific pattern. This lack of pathological specificity is one of the possible reasons for poor correlation between T2 WI lesions and disability in MS.

Lesions in the cerebrum are much more likely to be clinically silent compared with those in the brain stem or spinal cord.

The increase in lesion-brain contrast of fluid attenuated inversion recovery (FLAIR) images results in better lesion detection particularly in the subcortical region. Signal suppression from bulk water in CSF also increases depiction of lesions in periventricular area. Flow artifacts and lower sensitivity for posterior fossa are two disadvantages of this technique (Fig. 1).

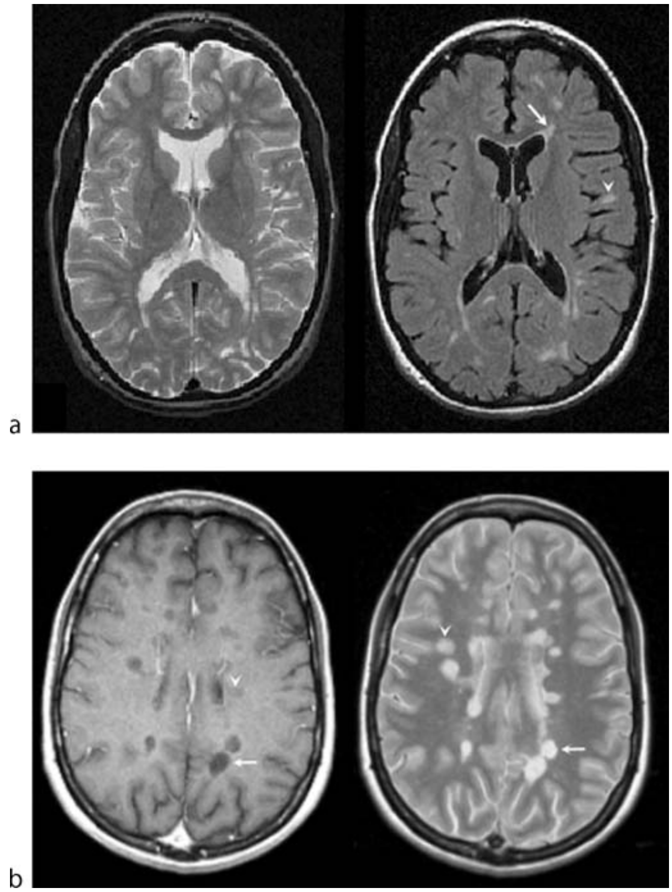
Enhancing Lesions

Enhancing lesions are the lesions that appear hyperintense after the administration of contrast agent in T1 WI images due to impairment of the blood-brain-barrier.

In MS, most new lesions go through a phase of enhancement usually persisting for 2 to 6 weeks and rarely for 3 to 4 months. Once contrast enhancement ends, the hypointense lesions may become isointense or develop into persistent black holes. In fact, less than 40% of gadolinium-enhancing lesions develop into chronic black holes (Fig. 2).

MS Lesions in T1-Weighted Without Contrast

A black hole (BH) is defined as any hypointense region visible on T1 WI sequences correlating with a region of



Multiple Sclerosis. Figure 1 **(a) T2 WI left and FLAIR right sequence of a patient with RRMS, show hyperintense white matter lesions. Note that FLAIR is superior in demonstrating periventricular (*arrow*) and subcortical lesions (*arrow head*). (b) Axial T2 WI (*right side*) demonstrate multiple hyperintense lesions typical for MS (*arrow*) in periventricular and subcortical area (*arrow head*). T1 WI with contrast (*left side*) demonstrate multiple hypointense lesions (*black holes*) with different degrees of hypointensity.**

high signal intensity on T2 WI images. Black holes are considered to be acute when they coincide with a contrast-enhancing lesion (CEL) and to be persistent when no corresponding CEL exists.

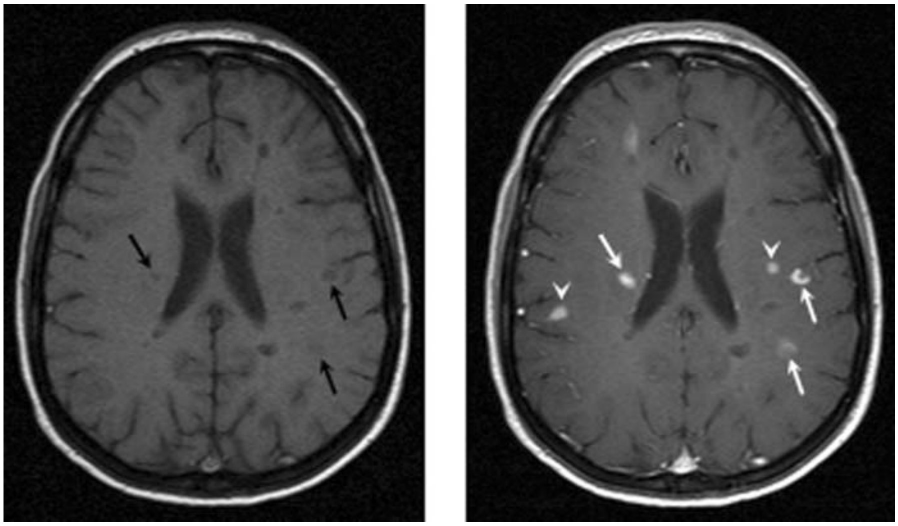
There are several different reports about the correlation of T1 WI black holes and disability. In some studies, T1 lesion load showed a higher correlation with the expanded disability status scale (EDSS) for patients with RRMS or secondary progressive in cross sectional studies.

T1 hypointensity is in principle caused by an expansion of the extracellular space either by an increase in water content or the loss of structural components. In fact the pathological correlates of T1 hypointense lesions are dependent, in part, on the lesion age.

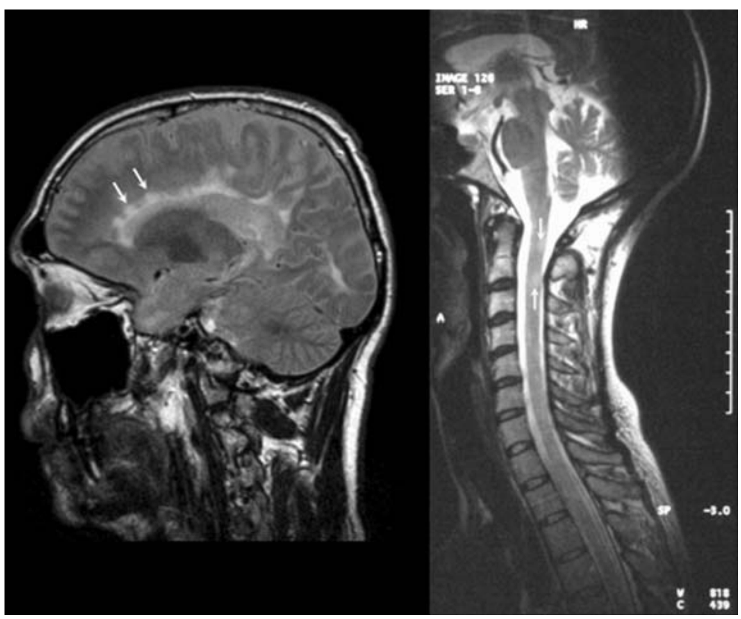
T1 black holes typically begin as contrast-enhanced lesions and evolve differently from patient to patient and also within the same patient. Their intensities are different from black like cerebrospinal fluid to light gray like cerebral cortex. The enhancing lesions that appear hypointense in noncontrast images may become isointense to the normal appearing white matter or develop into chronic black holes. The longevity of persistent BHs may vary after contrast enhancement. Some lesions may be visible for a relatively short period of time, some enlarge or shrink and some others may eventually become permanent.

Volumetric Changes

Brain atrophy is another imaging hallmark of multiple sclerosis. It usually appears as enlarged ventricles and a reduced size of corpus callosum. Atrophy is seen in all stages in a progressive manner, including patients with early MS. The exact mechanism is not clear but demyelination and axonal loss seem to be the main causes. The quantitative measure of atrophy has been studied and sometimes included as an outcome measure in clinical trials.



Multiple Sclerosis. Figure 2 **T1W images with left and without right contrast in a patient with RRMS demonstrate Several enhancing lesions. Some of these lesions have corresponding hypointensity on TWI without contrast (*arrows*).**



Multiple Sclerosis. Figure 3 **Sagittal T2 WI of patient with MS demonstrates typical spinal cord lesions (*right side*) most commonly seen in cervical part (*arrows*). Sagittal T2 WI of another MS patient (*left side*) with multiple hyperintense lesions typical for MS (*arrows*).**

Diagnosis

MS is a clinical diagnosis, dependent on a detailed history, neurologic examination and supportive paraclinical investigations. In fact, the diagnosis is based on the principle of dissemination in time and space of a disease compatible with MS in the absence of better explanations.

The previous diagnostic criteria for MS was codified by Poser for use in clinical trials of MS and included clinically definite MS, laboratory (cerebrospinal fluid) supported definite, probable, and possible MS.

As MRI was relatively new at that time, it was included as paraclinical element to support the diagnosis.

In the new McDonald criteria, the diagnosis of MS also requires evidence of lesions disseminated in time and

Multiple Sclerosis. Table 1 **The 2005 revisions to the McDonald diagnostic criteria for multiple sclerosis**

Clinical presentation	Additional data needed for diagnosing MS
Two or more attacks[a]; objective clinical evidence of two or more lesions	None[b]
Two or more attacks[a]; objective clinical evidence of one lesion	Dissemination in space demonstrated by: MRI[c] *or* Two or more MRI-detected lesions consistent with MS plus positive CSF[d] *or* Await further clinical attack[a] implicating a different site
One attack[a]; objective clinical evidence of two or more lesions	Dissemination in time demonstrated by: MRI[e] *or* Second clinical attack[a]
One attack[a]; objective clinical evidence of one lesion (monosymptomatic presentation; clinically isolated syndrome)	Dissemination in space demonstrated by: MRI[c] *or* Two or more MRI-detected lesions consistent with MS plus positive CSF[d] *and* Dissemination in time demonstrated by: MRI[e] *or* Second clinical attack[a]
Insidious neurological progression suggestive of MS	One year of disease progression (retrospectively or prospectively determined) *and* Two of the following: positive brain MRI (nine T2 lesions or four or more T2 lesions with positive VEP)[f] Positive spinal cord MRI (two focal T2 lesions) Positive CSF[d]

If criteria indicated are fulfilled and there is no better explanation for the clinical presentation, the diagnosis is MS; if suspicious, but criteria are not completely met, the diagnosis is "possible MS"; if another diagnosis arises during the evaluation that better explains the entire clinical presentation, then the diagnosis is "not MS."

[a]An attack is defined as an episode of neurological disturbance for which causative lesions are likely to be inflammatory and demyelinating in nature. There should be subjective report (back up by objective findings) or objective observation that the event lasts for at least 24 h.

[b]No additional tests are required; however, if tests (MRI, CSF) are undertaken and are negative, extreme caution needs to be taken before making a diagnosis of MS. Alternative diagnosis must be considered. There must be no better explanation for clinical picture and some objective evidence to support a diagnosis of MS.

[c]MRI demonstration of space dissemination must fulfill the criteria derived from Barkhof and colleagues and Tintore and coworkers as presented in the text.

[d]Positive CSF determined by oligoclonal bands detected by established methods (isoelectric focusing) different from any such bands in serum, or by an increased IgG index.

[e]MRI demonstration of time dissemination must fulfill the criteria explained in the text.

[f]Abormal VEP of type seen in MS (5).

space but MRI findings have a major impact in this regard.

Dissemination in space can be demonstrated by the Barkhof MRI criteria which requires 3 out of the following 4 elements

- At least one Gd-enhancing lesion or nine T2 hyper-intense lesions
- At least one infratentorial lesion
- At least one juxtacortical lesion
- At least three periventricular lesions.

In this criteria spinal cord imaging can be helpful in fulfilling the criteria for dissemination in space. A spinal cord lesion is equivalent to, and can substitute, for a brain infratentorial lesion, but not for a periventricular or juxtacortical lesion; an enhancing spinal cord lesion is equivalent to an enhancing brain lesion and an enhancing spinal cord lesion can count doubly in fulfilling the criteria (e.g., a single enhancing spinal cord lesion can "count" for an enhancing lesion and an infratentorial lesion and individual spinal cord lesions can contribute together with individual brain lesions to reach the required lesions to satisfy Barkhof criteria.

MRI can also assist in demonstrating dissemination in time. According to revised McDonald criteria any new T2 lesion if it appears at any time compared with a reference scan done at least 30 days after the onset of initial clinical event or detecting a new Gd-enhancing lesion at least 3 months after the onset of the initial clinical event, if not at the site corresponding to the initial event can demonstrate dissemination in time (Fig. 3).

Table 1 shows the 2005 revision to the McDonald diagnostic criteria for MS (1, 5).

Multi-pulse Techniques, Contrast Media, Ultrasound

Multi-pulse techniques are used in microbubble specific imaging for two key purposes. Firstly, a phase and/or amplitude modulated pulse train can be used to preferentially detect the non-linear response of the microbubbles to differing acoustic stimuli against the linear tissue background. Secondly multiple pulses can be used to provide information on the motion of the microbubbles within the circulation, in the same way that multiple pulses are processed for colour or power Doppler imaging.

See under Contrast media, ultrasound, specific imaging techniques, phase modulation, amplitude modulation for further details.

Multislice Computed Tomography

Musculoskeletal Radiology

Thomas M. Link
Department of Radiology, University of California, San Francisco, CA, USA
tmlink@radiology.ucsf.edu

Introduction

Musculoskeletal radiology has emerged as an important subspecialty in radiology and currently gains increasing significance due to sports- and age-related diseases of the musculoskeletal system. A number of imaging modalities are available, the most important being conventional radiography and magnetic resonance imaging (MRI). *Conventional radiography* (CR) is the basic technique to image bones and calcified soft tissue changes; it should be performed before more advanced imaging modalities are applied. CR is very useful to characterize focal and generalized bony disorders but also calcified soft tissue lesions. In the last 20 years, MRI has gained a tremendous importance in the depiction of bone, bone marrow, joints, and soft tissue structures. It is the most sensitive technique to depict (1) bone marrow morphology and pathology, (2) joint disorders including ligamentous and cartilage lesions, and (3) soft tissue pathology. MRI is extremely sensitive but sometimes not very specific in diagnosing specific disease entities. *Computed tomography* (CT) is used less frequently for the assessment of musculoskeletal disease but has a number of important indications such as the assessment of fractures, in particular in the spine and pelvis, and the stability of these fractures. CT may also be very useful in characterizing focal bony and calcified soft tissue pathology, not well-accessible with plain radiographs such as in the pelvis and shoulder. In addition, CT is used for image guided procedures such as bone biopsies and osteoid osteoma ablations. *Ultrasound* is less suited for bone pathology but may be used to depict soft tissues such as tendons and the rotator cuff of the shoulder. With Doppler ultrasound, vascularized lesions may be better characterized.

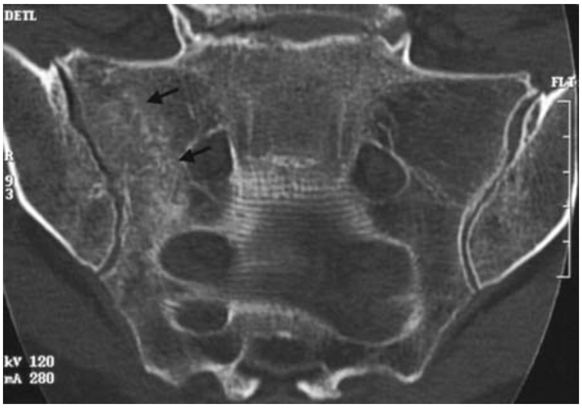
Musculoskeletal radiology can be structured according to disease entities in general or according to anatomy associated pathology. In this hyperessay, we are focusing on the different pathological entities that will subsequently be presented in the individual essays.

Trauma

Fractures usually are diagnosed on conventional radiographs, which should be obtained at least in two different projections. CT is useful in depicting the true extent of fracture, in particular in complex injuries. MRI, the imaging modality of choice for many musculoskeletal injuries, shows occult osseous (such as bone contusions) and osteochondral injury as well as tendon, ligament, and muscle injuries (15).

Among the *peripheral fractures* those of the distal radius are one of the most frequent fracture types (Fig. 1). In the wrist, CT and MRI accurately depict radiographically occult carpal bone fractures especially those of the scaphoid. In the preoperative planning of complex wrist fractures CT is of value, while MRI is very sensitive in the detection of posttraumatic complications such as avascular necrosis. Proximal humerus fractures, frequently seen in older patients, may require surgery if significant segment displacement is present, i.e., more than 45°C of angulation or more than 10 mm separation between fracture fragments according to Neer. True extent of these fractures is frequently underestimated in radiographs and requires CT for further assessment. Joint luxation is seen most frequently in the shoulder; associated lesions include Hill–Sachs defect and Bankart lesions. Fractures of the proximal femur are a frequent

Musculoskeletal Radiology. Figure 1 Dorso-palmar radiograph of the wrist showing a distal radius fracture with intraarticular extension (arrow).



Musculoskeletal Radiology. Figure 2 CT of the sacrum with coronal reformation depicting a right-sided insufficiency fracture of the sacrum (arrow).

complication of osteoporosis and may be divided into femur neck and intertrochanteric fractures. Imaging of tibial plateau fractures in the knee is particularly crucial for good postoperative results, requiring CT and MR imaging. Fractures with a depression of less than 5 mm may be treated operatively. Segond fractures are avulsion injuries of the lateral tibia due to excessive tension on the lateral capsular ligament of the knee. These fractures usually herald extensive damage of the knee such as anterior cruciate ligament fractures. Supination injuries in the ankle are frequently found and may result in fractures of the distal fibula. In the foot, the calcaneus is the most commonly fractured tarsal bone.

In *spine and pelvic fractures*, CT is usually required to assess whether fractures are stable and to plan operative interventions. 2D-reformations of these images and 3D-renderings are required and may be easily obtained with modern Multislice-CT scanners (18).

In children, *growth plate fractures* are particularly important since they may result in growth disturbances, and these are usually categorized according to the Salter–Harris classification.

Stress fractures may be divided into fatigue fractures, which are due to repetitive abnormal stress to a bone with normal elastic resistance and insufficiency fractures that occur when the elastic or mineral resistance of the bone is inadequate to withstand the stresses of normal activity (Fig. 2). The latter fractures are typically found in osteoporosis.

Inflammatory Diseases

Infectious Diseases

Septic osteomyelitis or arthritis may be due to bacteria such as *Staphylococcus aureus* or less frequently due to gram negative, mycobacterial, and fungal organisms. Four principal routes of contamination are observed: (1) hematogenous spread via the bloodstream, (2) spread from a contiguous source of infection such as infected sinus, cutaneous abscesses or dental infections, (3) direct implantation due to trauma, or (4) postoperative infection. Depending on the virulence of the organism osteomyelitis may have a more acute, subacute or chronic course. Conventional radiographs show associated pathology relatively late. At the earliest 3 days after bacterial contamination, subtle changes of the soft tissues may be observed. Typical signs after 1 to 2 weeks are lucent lesions, which may be focal or more diffuse, periosteal changes, and cortical resorption. In less aggressive lesions or a more chronic course of disease, sclerosis may be a more predominant finding (Fig. 3) and lesions may be well-defined. These lesions include Brodie's abscess and Garre's sclerosing osteomyelitis. Early diagnosis in bone infection may be best achieved with MRI, which shows focal lesions and reactive edema (low in signal in T1, high in signal in T2, and contrast enhancement in T1-weighted sequences) very sensitively (14). However, differential diagnosis to neoplastic lesions may be sometimes be difficult.

Rheumatoid Arthritis and Related Diseases

Rheumatoid diseases affecting the joints and spine include rheumatoid arthritis but also seronegative spondyloarthropathies such as psoriatic arthritis, ankylosing spondylitis, and Reiter's disease. Rheumatoid arthritis is a fairly

Musculoskeletal Radiology. Figure 3 Conventional radiographs, T1-weighted and fat saturated T1-weighted contrast-enhanced spinecho MR images of the right clavicula. The radiograph shows sclerosis and increased diameter due to periostitis of the clavicula (black arrows). The MR images depict low signal of the clavicula on the T1-weighted images while the contrast-enhanced images show contrast uptake with high signal in the clavicula (white arrows). These findings are consistent with osteomyelitis.

common disease, most commonly affecting middle-aged women. The joints most commonly involved are the hands and feet (Fig. 4). In radiographs, soft tissue swelling, juxtaarticular osteopenia, and later joint erosions are shown. In the hands, the most frequently affected joints are metacarpo-phalangeal joints as well as the intercarpal, radio-carpal, and ulno-carpal joints. At later stages of disease erosive changes of the upper cervical spine may occur with instability at the level of C0–C2. Ankylosing spondylitis usually affects younger males and has an insidious onset with low back pain. Most commonly the sacroiliac joints are affected first and show erosive and proliferative changes as well as sclerosis. Ankylosis is found in advanced stages. Conventional radiographs usually show these changes at a relatively advanced stage while MRI is more suited to detect early changes (17). Typical changes at the spine are shining corners (Romanus lesions), squaring, syndesmophytes, and discovertebral destructions. Psoriatic arthritis is found in 2–6% of patients with psoriasis (13). Typical features of psoriasis arthritis are erosive and proliferative changes at the joints with less pronounced osteoporosis. In the hands, individual fingers or/and the distal interphalangeal joints are affected typically. Retrocalcaneal bursitis, sacroiliac arthritis, and paravertebral ossifications are other typical changes found in this disease. Reiter's syndrome, enteropathic arthropathies, Behcet's syndrome are rare diseases that may also cause arthritis, sacroiliitis and spine changes.

Other diseases that cause polyarthritis and arthropathies are systemic lupus erythematosus, progressive systemic sclerosis, dermatomyositis and polymyositis, mixed connective tissue disease, rheumatic fever, and vasculitides such as polyarteritis nodosa.

Degenerative Diseases

Degenerative joint disease is found in the aging individual and is nowadays considered as one of the most important joint diseases and a major cause of disability. Osteoarthritis has typical imaging features on radiographs including osteophytes, subchondral sclerosis, and cyst formation (Fig. 5). Enthesophytes at the osseous sites of tendon attachment are also frequent findings in degenerative disease. Sometimes degenerative joint disease shows an erosive pattern, which may be difficult to differentiate from inflammatory, rheumatoid joint disease.

Musculoskeletal Radiology. Figure 4
Conventional dorsoplantar radiograph of the left foot with erosions of the second to fifth metatarsal heads and the first intertarsal joint as well as subluxation in the fifth and third metatarsophalangeal joint consistent with rheumatoid arthritis (black arrows).

Musculoskeletal Radiology. Figure 5
Conventional anteroposterior radiograph of the right knee joint with medial joint space narrowing, subchondral sclerosis, and osteophytes (arrow) consistent with osteoarthritis of the knee.

Degenerative disease of the spine shows a typical pattern on conventional radiographs with a variety of morphologic signs such as osteochondrosis with disc space narrowing and reactive sclerosis, spondylosis deformans, and osteoarthritis of the facet joints. During the course of disease degenerative spondylolisthesis, retrolisthesis, vertebral alignment disorders, spinal stenosis, and segmental instability may occur. Another important entity is posterior disc displacement due to degenerative disk disease (11). This may manifest as anular bulge, discal protrusion (displaced nucleus pulposus extends through some fibers of the annulus fibrosus but is still confined by the intact outmost fibers), discal extrusion (nucleus penetrates all of the fibers of the annulus and lies under the posterior longitudinal ligmanent), and discal sequestration (displaced nucleus penetrates or extends around posterior longitudinal ligament and lies within epidural space or the displaced nucleus migrates a considerable distance in a cranial or caudal direction).

In *diffuse idiopathic skeletal hyperostosis* (*DISH*) abnormal bone formation is found where tendons and ligaments attach to bone, predominantly in the spine. Diagnostic criteria for spinal involvement in DISH are (1) flowing ossification or calcification along the anterolateral aspect of at least 4 contiguous vertebrae, (2) preserved intervertebral disc height and absence of extensive degenerative disc disease, and (3) absence of apophyseal joint ankylosis and sacroiliitis (13).

Crystal-Induced and Related Diseases

Calcium pyrophosphate deposition disease (*CPDD*) is observed in middle-aged and elderly patients and may mimic a variety of other conditions such as rheumatoid arthritis, gout and degenerative joint disease. A variety of names have been used to describe CPPD including pseudogout, chondrocalcinosis, articular and periarticular calcification, and pyrophosphate arthropathy. Radiologic features include (1) calcification of the hyaline cartilage and fibrocartilage such as the menisci (Fig. 6) and the triangular cartilage of the wrist, (2) synovial calcification, (3) capsular calcification as well as (4) tendon, bursa and ligament calcification (1). Calcium hydroxyapatite crystal deposition and CPDD may occur both in the same patient, even the same joint.

Calcium hydroxyapatite crystal deposition disease (*HADD*) results in granular periarticular accumulations of calcium hydroxyapatite most commonly found in the shoulder. These deposits may appear thin, cloud-like and poorly defined but with time they get denser, more homogeneous and more sharply delineated. In these

Musculoskeletal Radiology. Figure 6 **Conventional anteroposterior radiograph of both knee joints with calcification of the menisci, the hyaline cartilage and synovial, and capsular calcifications (arrows) consistent with CPDD.**

patients, acute or chronic symptoms may be found, including pain, tenderness, swelling, and restricted motion of the joint.

Gout (*monosodium urate crystal deposition disease*) may lead to an arthritis that has an asymmetric polyarticular involvement and predominantly affects feet, hands, wrists, elbows, and knees. Radiographic signs of gout are usually found late in the course of the disease and may only show those of degenerative disease or (1) lobulated eccentric soft tissue masses, (2) intraarticular or extraarticular bone erosions with relative preservation of the interosseous joint space, (3) subperiosteal apposition of bone, and (4) intraosseous calcification. Idiopathic gout is far more frequently in males than in females and occurs most frequently during the fifth decade of life.

Neuropathic Joint Disease

Neuroarthropathy may be caused by central or peripheral neuronal lesions, such as syringomyelia, meningomyelocele, trauma, diabetes mellitus, alcoholism, amyloidosis, and administration of corticosteroids. The deprivation of sensory feedback in the joints leads to continuous stress and progressive deterioration. Radiographic signs include (1) joint space narrowing, (2) fragmentation, (3) sclerosis of bone, (4) osteophytosis, and (5) subluxation (Fig. 7) (6).

Musculoskeletal Radiology. Figure 7 **Conventional dorsoplantar radiograph of the left foot with extensive destructions of the metatarsophalangeal joints corresponding with neuropathic joint disease.**

M

Metabolic and Endocrinological Diseases

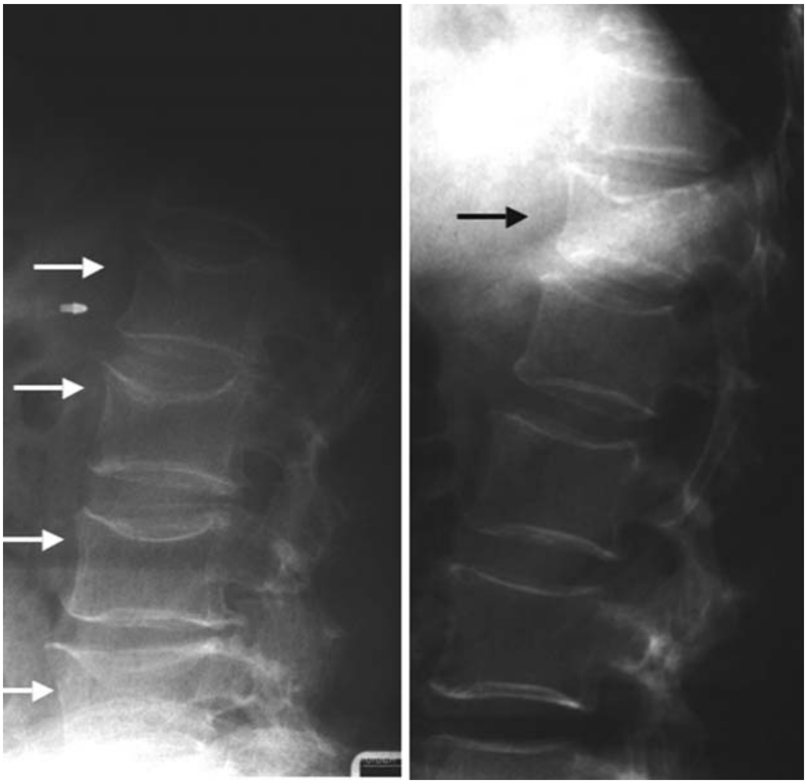
Osteoporosis is the most frequent metabolic disease and is defined as a disease, which is associated with a loss of bone mass and a deterioration of bone structure, both resulting in an increased bone fragility and susceptibility to fracture (Consensus, 1993 #363). Since the bone density, the parameter which can be determined best *in vivo*, has a high precision and correlates well with the biomechanically determined bone strength the WHO defined osteoporosis in postmenopausal females on the basis of the individual's bone mineral density compared to a young normal reference population (WHO, 1994 #362).

As populations age the incidence of osteoporosis and subsequent fractures is increasing. According to the international Osteoporosis Foundation, more than 40% of middle-aged women will suffer one or more osteoporotic fractures during their remaining lifetime. The most important fracture sites are the proximal femur, the spine and the distal radius. Hip fractures are the worst complication of osteoporosis with substantial morbidity and high one-year mortality. Vertebral fractures occur with a higher incidence earlier in life than other types of osteoporotic fractures (Fig. 8). However, it is difficult to determine the exact number of fractures that occur annually as a substantial proportion are clinically undetected.

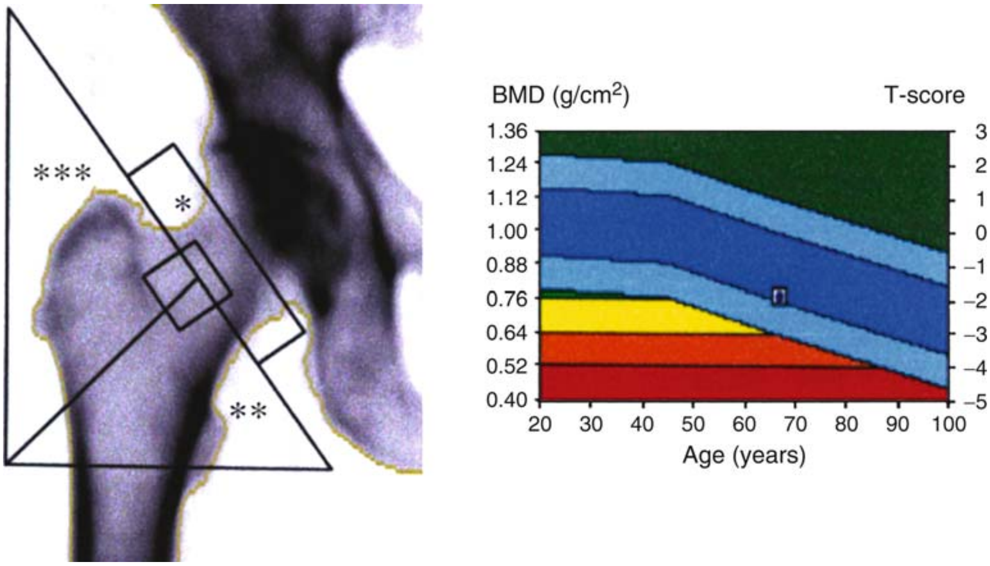
Diagnostic techniques to determine bone mineral density include dual X-ray absorptiometry (DXA) and quantitative CT (QCT) (9). DXA of the spine and the hip (Fig. 9) in an anterior–posterior projection are the most frequently used examinations. The areal bone mineral density values obtained from these examinations are compared to a young normal and to an age-matched population (Fig. 9).

Rickets and osteomalcia are due to abnormalities in vitamin D metabolism and syndromes resulting from renal tubular phosphate loss. Rickets occurs during growth in children and adolescents and results from an interruption of the development and mineralization of the growth plate while osteomalacia is found in adults and results from inadequate or delayed mineralization of osteoid in mature cortical and spongious bone. Typical radiological findings in rickets include widening of the growth plate and disorganization and fraying of the spongy bone in the metaphyseal region, while in osteomalacia osteopenia and a coarsened, unsharp pattern of the trabecular bone is found (13).

Hemochromatosis and Wilson's disease are rare diseases of iron and copper metabolism, which show a similar



Musculoskeletal Radiology. Figure 8 Lateral radiographs of the thoracic and lumbar spine showing multiple osteoporotic compression fractures of the vertebrae (arrows).



Musculoskeletal Radiology. Figure 9 DXA image of the right hip with regions of interest (ROI) including neck (*), intertrochanteric (**), and trochanteric (***) ROI. The right image shows neck BMD value in relation to young normal BMD

pattern as CPDD. In hemochromatosis chondrocalcinosis, joint space narrowing, subchondral cyst formation, and osteophytes are found, most typically located in the metacarpophalangeal joints of the second and third digit.

Alkaptonuria is another rare disorder resulting from an inability to metabolize homogentisic acid, which is oxidized to an ochronotic pigment. This ochronotic pigment is stored in cartilage and connective tissues and leads to discal calcification, disc space narrowing and a severe extraspinal "degenerative" arthropathy.

Hormonal disorders that affect the musculoskeletal system include pituitary disorders (e.g., acromegaly), hyperparathyroidism, thyroid disorders, and Cushing's disease. Acromegaly results from elevated levels of growth hormones resulting in activation of enchondral and periosteal bone formation with soft tissue proliferation. Primary hyperparathyroidism is most commonly due to adenomas and less commonly due to diffuse hyperplasia and carcinoma. Secondary hyperparathyroidism is frequently linked to chronic renal failure and in common with osteomalacia, osteoporosis and soft tissue calcifications are found in *renal osteodystrophy*. Typical radiologic signs in hyperparathyroidism include subperiosteal, subchondral, trabecular, and intracortical bone resorption as well as brown tumors.

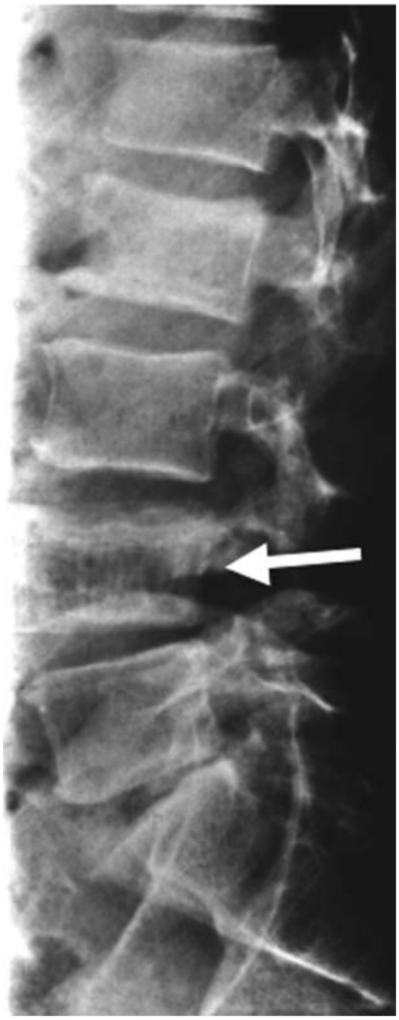
Paget's disease is a relatively frequent disease (up to 3% of the population over the age of 40 years) characterized by excessive abnormal remodeling of bone. Typical radiographic features include an initial osteolytic stage and subsequent osteosclerotic stages with increased radiodensity, an accentuated trabecular pattern and picture frame vertebrae (Fig. 10). Complications include fractures, deformities, articular alterations, and neoplasms (10).

M

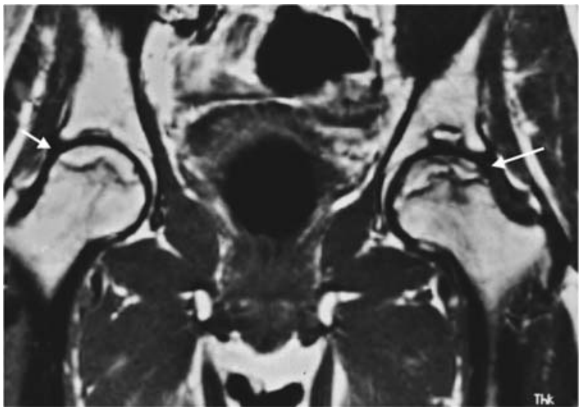
Osteonecroses

Osteonecrosis may be due to a number of disease processes such as trauma, hypercortisolism, hemoglobinopathy, alcoholism, irradiation, and pancreatitis. But it may also occur spontaneously, most commonly in the hip and the knee. In conventional radiographs signs of osteonecrosis are usually found fairly late; these include subchondral lucency, patchy areas of lucency and sclerosis and finally bone collapse with deformity and secondary degenerative changes. MRI can show these changes at a substantially earlier stage before collapse of the bone has occurred (Fig. 11). Infarction in the bone marrow shows shell-like calcifications in radiographs and central fatty necrosis with surrounding granulation tissue that is low in signal in T1-weighted images and high in signal in fat saturated T2-weighted images. The most frequent sites of osteonecrosis are the hip, knee, talus, humeral head, scaphoid, and the vertebrae (Kuemmel's disease). Complications include degenerative changes, intraarticular bodies, cysts, and rarely malignant degeneration.

The entity osteochondroses encompasses (1) *juvenile osteonecroses*, (2) conditions related to trauma and abnormal stress, and (3) variations of the normal pattern of ossification. These are characterized by fragmentation and sclerosis of an epiphyseal or apophyseal center. Diseases characterized by osteonecrosis include Legg–Calve–Perthes



Musculoskeletal Radiology. Figure 10 **Lateral radiographs of the lumbar spine showing an L4 vertebrae that is larger in diameter but lower in height compared to the other vertebrae (arrow). This vertebra also has a frame-like structure, all findings being consistent with Paget's disease.**



Musculoskeletal Radiology. Figure 11
Coronal T1-weighted spinecho image of the pelvis. Avascular necrosis (AVN) of both hips with low signal intensity lines demarcating the necrosis (arrows), but no deformity of the femoral head.

Musculoskeletal Radiology. Figure 12 **Lateral radiograph of the distal femur bone showing ring- and arc-like calcifications consistent with enchondroma. No cortical destruction or scalloping that would suggest malignant transformation.**

disease (femoral head), Koehler's disease (tarsal navicular), Freiberg's infraction (metatarsal head), Panners's disease (capitulum of humerus), Kienboeck's disease (carpal lunate), and Thiemann's disease (phalanges of hand). Blount's disease (proximal tibial epiphysis), Osgood–Schlatter disease (tibial tuberosity), Sinding–Larsen–Johansson disease (patella), and Scheuermann's disease (discovertebral junction) were attributed to a more trauma related etiology.

Bone and Soft Tissue Tumors

Primary bone tumors are frequently found in younger patients, the substantially more common secondary bone tumors (mostly metastases) are found in patients older than 50 years. In bone tumors, an intimate cooperation between radiology and pathology is required to obtain correct diagnoses. The primary imaging technique for bone tumors is CR. Using specific criteria focusing on matrix, periosteal reactions, and tumor border approximately 70–80% of diagnoses can be made with conventional radiographs. In the spine, pelvis, and shoulder region CT may give additional information. In the last years we learned a number of new criteria for assessing MR images of bone tumors, however, up to now the most important role of MRI is to show the tumor extent preoperatively, i.e., to show joint invasion and invasion of the neuromuscular bundle and to monitor tumor size following chemotherapy.

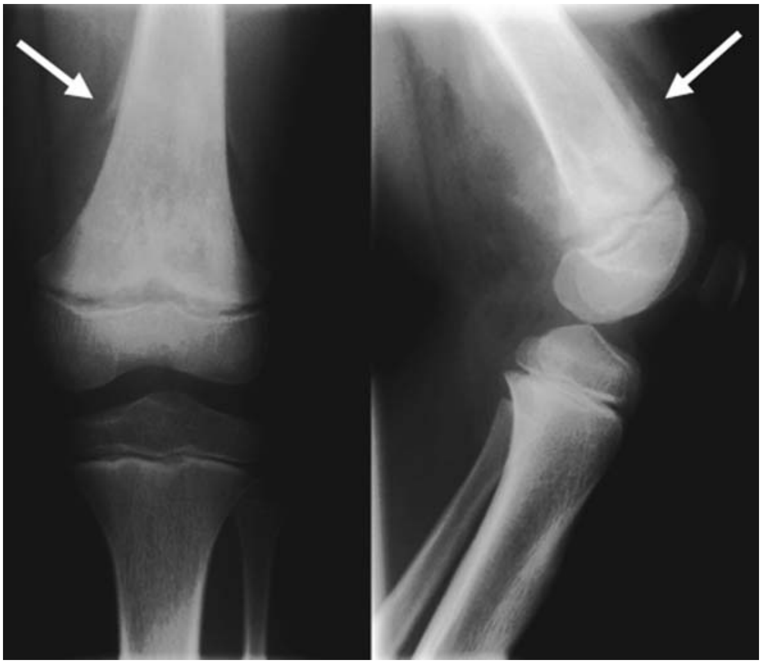
Primary bone tumors can be divided into benign and malignant lesions and also be classified according to the tissue of origin, such as osseous and cartilage-forming tumors.

Osseous tumors include osteoma, osteoidosteoma, osteoblastoma (all benign), and osteosarcoma (Fig. 13) (malignant). Cartilage-forming tumors are enchondroma (Fig. 12), osteochondroma (the most frequent bone tumors), chondroblastoma, chondromyxoid fibroma (all benign), and chondrosarcoma (malignant). Tumors arising from fibrous tissues are nonossifying fibroma, desmoplastic fibroma (benign), and fibrosarcoma (malignant). Other important tumor entities are locally aggressive lesions such as giant cell tumors and chordoma. An important malignant entity are Ewing's sarcomas.

Tumorlike lesions are defined as nonneoplastic bone lesions that may simulate tumors. These include simple bone cysts, aneurysmal bone cysts, eosinophilic granuloma, intraosseous ganglion, and epidermoid cysts as well as fibrous dysplasia (4).

Skeletal metastases can develop due to hematogenous dissemination, direct extension, and lymphatic spread. They can either be osteolytic or osteoplastic. The most common carcinomas that metastasize to the bone arise from the breast, prostate, and lung. Kidney and thyroid carcinoma metastases show a high affinity to the skeleton. Skeletal scintigraphy, whole body MRI and positron emission tomography (PET) are well-suited diagnostic techniques to assess skeletal metastases.

Soft tissue tumors are relatively frequent lesions but commonly the preoperative radiological diagnosis is challenging. Conventional radiographs are of limited usefulness. Calcifications may sometimes be found and the morphology may be helpful in the differential diagnosis. Ultrasound and MRI are the best techniques for soft tissue lesions. Ultrasound is useful to image cystic lesions and with Doppler ultrasound vascularization of a lesion may be characterized. MRI is a sensitive tool to depict soft tissue lesions but a specific tumor diagnosis is only possible in less than 60% of cases (8, 12). Tumors that may be diagnosed with a relatively high confidence are hemangiomas, lipomas, pigmented villonodular synovitis, and cysts.



Musculoskeletal Radiology. Figure 13 Lateral and anteroposterior radiographs of the left knee joint. Complex periostal reactions (arrows), sclerosis, and lytic areas in the distal femur metaphysis consistent with osteosarcoma.

Diseases of the Hematologic and Hematopoetic Systems

Hemoglobinopathies include sickle cell anemia, hereditary spherocytosis, and thalassemia. These diseases are associated with characteristic abnormalities of the skeleton related to marrow hyperplasia and vascular occlusion and encompass fracture, infection, osteonecrosis, and growth disturbances.

Multiple myeloma or plasma cell myeloma is a malignant disease of plasma cells that originates in the bone marrow but may involve other tissues as well. This disease representing 10–15% of malignancies of the hematologic system usually occurs in 40–80-year-old patients and demonstrates typically an increase in the globulin serum protein fraction. Most often multiple osteolytic lesions are noted in the spine, ribs, skull, pelvis, and femur but solitary lesions, i.e., plasmocytoma, may be found for longer periods of time. Diffuse skeletal osteopenia is also a frequent finding, while sclerosis in multiple myeloma is rarely found and more frequently related to complications of the disease or to fracture (13).

Myeloproliferative disorders include leukemia, lymphoma, systemic mastocytosis, and polycythemia vera. Each of these entities has relatively typical musculoskeletal findings ranging from diffuse or focal synovial and osseous infiltration (in leukemia and lymphoma) to sclerotic or lytic osseous lesions (mastocytosis and lymphoma) to osteonecrosis (polycythemia vera).

Bleeding disorders are most frequently related to hemophilia and show a number of relatively typical skeletal abnormalities resulting from hemorrhage in soft tissues or subperiosteal, intraosseous or intraarticular location. Typical findings in the joints include joint effusion, soft tissue swelling, epiphyseal overgrowth, subchondral cysts, osseous erosion, and secondary degenerative changes. MRI is the most accurate imaging modality for assessing hemophilic arthropathy and may have a significant impact on patient management. MRI is anticipated to be useful in documenting early joint changes when treatment may be most effective (7).

Musculoskeletal Radiology. Figure 14 Anteroposterior radiograph of the pelvis showing left-sided hip dysplasia with enlarged acetabular angle, partial uncovering of the femoral head, and coxa valga (arrow).

Congenital Disorders

Congenital dysplasia of the hip is a relatively frequent deformity that affects females more frequently than males

Musculoskeletal Radiology. Figure 15 Lateral radiograph of the proximal femur with areas of well defined sclerosis consistent with melorheostosis.

(Fig. 14) hip dysplasia. Early diagnosis is crucial and variety of radiologic techniques are used (5). *Scoliosis* is the most frequent spinal anomaly and etiology ranges from idiopathic to vertebral dsyplasias and tumors. Other relatively common *congenital* or *heritable anomalies* include foot deformites such as club foot deformity, tarsal coalition, proximal femoral focal deficiencies, Klippel–Feil syndrome, and Madelung's deformity.

Inborn *disorders of the connective tissue* that show typical radiological signs include Marfan's syndrome, Ehlers–Danlos syndrome, osteogenesis imperfecta, homocystinuria, and multiple epiphyseal dysplasias (13).

Skeletal dysplasias are numerous, have a large number of different etiologies, and may show a broad variety of radiological findings (16). The most important dysplasias are (1) Osteochondrodysplasias (e.g., achondrogenesis, spondyloepiphyseal dysplasia, and achondrodysplasia), (2) dysostoses (e.g., Crouzon's syndrome), (3) dysplasias due to chromosomal aberrations (e.g., Trisomy 8, 13, 18, and 21), and (4) dysplasias due to primary metabolic abnormalities (e.g., mucopolysaccharidoses).

Various Diseases

Skeletal disorders that show enostosis and hyperostosis are osteopoikilosis, osteopathia striata, and melorheostosis (Fig. 15) (2, 3). Primary and secondary hypertrophic osteoarthropathy as well as vascular insufficiency show a pattern of periosteal new bone formation. Systemic diseases that may also show skeletal abnormalities include sarcoidosis, neurofibromatosis, and tuberous sclerosis.

Myelocele—Myeloschisis

▶Congenital Malformations, Spine and Spinal Cord

M

Myelofibrosis

Malignant disease due to polyclonal activation of fibroblasts, which secrete collagen and cause fibrosis of the bone marrow. Sclerotic changes may be shown in radiographs. MRI demonstrates relatively characteristic bone marrow changes with low signal intensity infiltration of the bone marrow in both T1- and T2-weighted sequences.

▶Myeloproliferative Disorders

Myelofibrosis, Idiopathic, Chronic

Chronic idiopathic myelofibrosis, one of a group of diseases called chronic myeloproliferative disorders, involves hematopoietic stem cells and is associated with marrow fibrosis. The principal biochemical change in myelofibrosis reflects increased turnover of the hematopoietic cell population. The most common presentation is with symptoms referable to anemia or the characteristic massive splenomegaly.

▶Neoplasms, Splenic, Malignant

Myelolipoma Hepatic

▶Lipomatous Neoplasms, Hepatic

Myelolipoma, Hepatic

Very uncommon mesenchymal tumors composed of adipose tissue associated to hematopoietic tissue elements. The presence of lipoblasts in the adipose tissue components requires great attention in order to avoid an erroneous diagnosis of sarcoma. Diagnostic imaging features reflect its complex structure.

▶Lipomatous Neoplasms, Hepatic

Myelomalacia, Posttraumatic

Diffuse damage of the spinal cord visible in the chronic stage, normally as evolution of cord contusion. Micro and macrocyst are present.

▶Spinal Trauma

Myeloproliferative Disorders

Synonyms and Definitions

Myeloproliferative disorders are a group of diseases that cause an overproduction of blood cells, platelets, white blood cells, and red blood cells in the bone marrow. These disorders include ▶myelofibrosis, polycythemia vera, chronic and ▶acute leukemias, (▶Luekemia, Acute) and primary thrombocythemia. In this review we will also include ▶multiple myeloma and other neoplastic diseases of the bone marrow, but not secondary neoplasias such as metastases of the bone marrow.

Pathology/Histopathology

Myeloproliferative disorders arise from an overproduction of one or more types of cells. The reason for this abnormal increase in cells is largely unknown, but there are a number of associated findings, including the Philadelphia chromosome in chronic myelogenous leukemia (CML) and overexposure to radiation, electrical wiring, or chemicals in a number of myeloproliferative diseases. Characteristically, basophilia and teardrop cells are found in myeloproliferative disorders.

In *myelofibrosis* polyclonal activation of fibroblasts occurs, leading to secretion of collagen and then fibrosis. This results in extramedullary hematopoiesis in the liver and spleen and immature blood cells in the peripheral blood. In *polycythemia vera* an increase in all three cell types is found, which results in pancytosis with normal differential and high hematocrit. In *CML* substantial leukocytosis (>20,000/mL) with too many myelocytes is found, and leukocyte alkaline phosphatase is decreased. *Acute myelogenous leukemia* (AML) is the most frequent leukemia found in adulthood and has a number of different subtypes. Auer rods and discrete tumor masses infiltrating the soft tissues are typical findings. *Acute lymphoblastic leukemia* (ALL) is the most common childhood malignancy; B-cell, T-cell, and null cell ALL are differentiated, with B-cell ALL having a better prognosis. Positive staining for periodic acid Schiff's (PAS) and negative myeloperoxidase staining are typically found in ALL. Idiopathic *thrombocythemia* is a rare malignant disease with megakaryocytes that have a bizarre morphology and platelet counts of more than 1 million/mL.

Multiple myeloma (*MM*) is a clonal B-lymphocyte neoplasm and the most frequent primary malignancy of the bone marrow, accounting for 10% of hematologic malignancies. It is usually systemic, but solitary osseous myeloma is found in approximately 5% of the cases, and frequently these tumors progress to MM. Serum protein electrophoresis reveals monoclonal spikes due to gammopathy, and Bence-Jones proteins are a typical finding in the urine. Lytic lesions found in the bone are due to an osteoclast-activating factor produced by the tumor cells. Amyloidosis and light-chain cast nephropathy are additional characteristic findings. Histologically, sheets of plasma cells are found in the bone marrow.

Mastocytosis, or respectively mast cell disease, is characterized by the abnormal growth and accumulation of mast cells within the bone or other organs. The diagnosis of ▶systemic mastocytosis is most commonly established by a thorough histological and immunohistochemical examination of a bone marrow trephine specimen.

Clinical Presentation

Patients with myeloproliferative disorders frequently have no clinical symptoms when their physicians first make the diagnosis. A sign that is common for myeloproliferative disorders is an enlarged spleen, which can lead to abdominal pain and a feeling of fullness. In addition, since the bone marrow is infiltrated by pathological cells, anemia, decreased functional white blood cells and thus more frequent infections, and decreased thrombocytes and thus higher incidence of bleeding may occur. Other relatively common signs and symptoms include fatigue, general malaise, weight loss, fever and night sweats, nosebleeds, blood in the urine, bruising, dyspnea, and bone or joint pain.

More specific symptoms may be found in individual disease entities, such as intense itching after bathing in warm water, burning pain in the skin and emboli in *polycythemia vera*, substantial anemia in *myelofibrosis*, and substantial increase in spleen size in *CML*. In *MM* typical clinical findings include back pain, hypercalcemic symptoms (weakness, weight loss, altered mental status, constipation), pathological fractures, frequent infections, and findings related to nephropathy. Symptoms in systemic *mastocytosis* are flushing, itching, abdominal cramping, and shock. In addition, musculoskeletal pain, abdominal discomfort, nausea, vomiting, ulcers, diarrhea, and skin lesions may also be found.

Imaging

Conventional Radiographs

Conventional radiographs are not very sensitive in visualizing early disease because a substantial amount of bone (up to 50%) has to be lost before increased lucency is found. Still, skeletal radiography is the primary diagnostic study and also gives substantial information on fracture risk, which may be more difficult to evaluate with magnetic resonance imaging (MRI). Infiltration of the bone marrow can be either diffuse or focal with accompanying osteopenia, but sclerotic changes may be found such as in myelofibrosis, mastocytosis, and, rarely, MM. Pathological fractures may be found at later stages and are a typical finding in MM.

In *MM* the skeletal radiographic survey still has an important role in the Durie–Salmon clinical staging criteria for newly diagnosed MM with the presence of two clearly defined lytic lesions indicating a high tumor burden and stage III disease. The skeletal survey is also used to judge progression of disease. Four distinct forms are found in myeloma: (i) solitary lesions (plasmocytoma), (ii) diffuse skeletal involvement (myelomatosis), (iii) diffuse skeletal osteopenia, and (iv) sclerosing myeloma (1). Plasmocytomas are typically lytic lesions that affect the spine, pelvis, skull, ribs, and proximal extremities. Diffuse myelomatosis is characterized by multiple lytic lesions with discrete margins and uniform size. Diffuse skeletal osteopenia does not show focal lytic lesions and is difficult to differentiate from severe osteoporosis, particularly since this form of disease is frequently associated with multiple vertebral compression fractures. Sclerotic changes in MM are frequently associated with polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes, which is also described as POEMS syndrome (1).

CT

Computed tomography (CT) is more sensitive in depicting focal osteolytic changes than conventional radiography but less sensitive than MRI in visualizing bone marrow pathology. The main roles of CT are to better assess fracture risk and fracture, to guide biopsy, and to better characterize focal pathology in the bone marrow.

In multiple myeloma osteolytic lesions, expansile masses, diffuse osteopenia, fractures, and, rarely, osteosclerosis may be found (1). Multidetector row whole-body CT may be useful to optimize staging of MM as it is faster, better tolerated by patients, and more sensitive than skeletal survey.

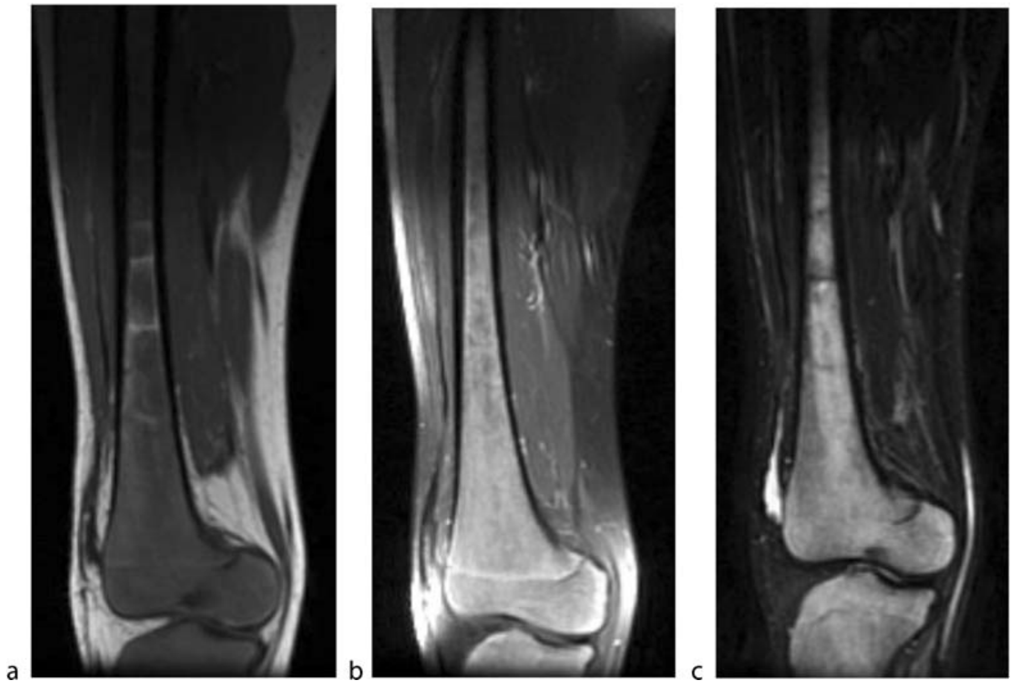
MRI

MRI is very sensitive for detecting bone marrow pathology; however, it should be noted that problems may occur if bone marrow infiltration is diffuse, and differentiation of ►hematopoietic bone marrow and neoplastic infiltration may sometimes be difficult. MR techniques have evolved substantially, and extensive coverage of the skeleton is possible with good image quality and within a reasonable acquisition time. Standard sequences for bone marrow pathology include T1-weighted spin-echo, STIR, and T2-weighted fat-saturated fast spin-echo sequences. Contrast-enhanced sequences may add information, for example to better assess intraspinal pathology or soft tissue extension of lesions, but such applications are controversial.

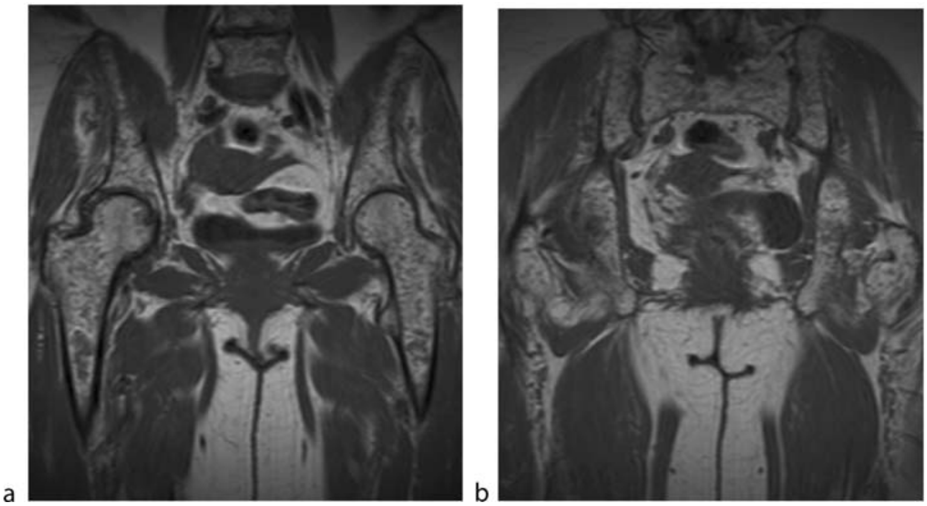
In evaluating MR images, one has to be aware of signal characteristics of normal bone marrow: In young patients, substantial amounts of hematopoietic bone marrow are found, and below the age of 10 years in T1-weighted images the bone marrow may be lower in signal intensity than surrounding muscle or intervertebral disc (2). Above the age of 10 years, lower signal intensity is considered pathological. Conversion from hematopoietic to fatty bone marrow starts in the periphery and the distal part of the long bones. By the age of 20 years, most of the appendicular skeleton contains fatty bone marrow, while the central skeleton including proximal femur and the humerus contains largely hematopoietic bone marrow. In the sixth decade of life, a substantial amount of fatty bone marrow is also found in the axial skeleton. Note also that reconversion of fatty to hematopoietic bone marrow may be observed, associated, for example, with status postchemotherapy, obesity, pulmonary pathology, smoking, and marathon running.

There are four pathological MR patterns in myeloproliferative disorders:

1. A focal pattern with localized areas of abnormal marrow is low in signal in T1-weighted images, bright in fat-saturated T2-weighted images, and showing contrast enhancement; this pattern is found in multiple myeloma and lymphoma but is most typical for metastatic disease from solid primary malignancies.
2. The diffuse pattern shows replacement of the normal marrow with intervertebral discs and muscle appearing in T1-weighted sequences similar or higher in signal than the bone marrow (Fig. 1). The bone marrow is bright in fat-saturated T2-weighted or STIR sequences and shows substantial contrast enhancement (Fig. 1). Depending on the degree of diffuse bone marrow infiltration, however, diagnosis may be difficult, and if less than 20% of the bone marrow is diffusely infiltrated, it is not possible to differentiate malignant infiltration with confidence from hematopoietic bone marrow. The diffuse pattern of disease is found in acute leukemias but may also be found in multiple myeloma and other myeloproliferative diseases.
3. The variegated pattern consists of multiple, innumerable, small foci of disease on a background of normal bone marrow (Fig. 2). These foci are low in signal intensity in T1-weighted images, bright in T2-weighted images, and enhance after contrast administration. If no fat saturation is used, the lesions may be masked by contrast medium in T1-weighted images. The variegated pattern is typically found in MM.
4. Predominantly fibrotic lesions such as myelofibrosis cause diffuse low signal intensity changes both in T1- and T2-weighted images (Fig. 3). Differentiation may be difficult from osteoblastic metastatic disease if no radiographs are available.



Myeloproliferative Disorders. Figure 1 Coronal magnetic resonance images of the distal femur and the knee demonstrating diffuse bone marrow infiltration in a 17-year-old patient with acute lymphatic leukemia. (a) T1-weighted image with low signal intensity in bone marrow, similar to signal intensity of the surrounding muscle. (b) Substantial enhancement of the bone marrow is shown after gadolinium administration. (c) STIR sequence demonstrates bright signal in the bone marrow.



Myeloproliferative Disorders. Figure 2 Coronal T1-weighted images of the pelvis and the proximal femur demonstrating multiple myeloma with variegated pattern of bone marrow infiltration.

Myeloproliferative Disorders. Figure 3 Sagittal magnetic resonance images of the lumbar spine obtained in a patient with myelofibrosis. (a) T1-weighted image with low signal intensity bone marrow, similar in signal intensity to the intervertebral discs. (b) In fat-saturated T2-weighted image, bone marrow also appears low in signal intensity.

Nuclear Medicine

Standard nuclear medicine scans have a limited role in assessing bone marrow pathology.

Standard technetium 99m bone scintigraphy frequently does not show increased uptake in MM because it is primarily an osteolytic neoplasm. Increased uptake may reflect complications of the disease such as pathologic fracture. More favorable results have been found with radiotracers such as gallium 67 and ^{99m}Tc sestamibi.

FDG PET may be a suitable technique to evaluate bone marrow pathology sensitively, and good results have been found for MM in focal, diffuse, and mixed diffuse and focal disease.

Diagnosis

A diagnosis of myeloproliferative disorders is usually not made with radiographic techniques. Usually, blood tests detecting abnormal types or numbers of red or white blood cells with anemia and leukemia, or bone marrow biopsies directly showing histopathology of the bone marrow lead to the diagnosis. However, radiographic techniques can visualize the extent of bone marrow infiltration and can demonstrate complications of the disease. Some myeloproliferative disorders also have fairly typical radiographic findings.

In *myelofibrosis* the predominant radiographic feature is osteosclerosis, which may be found in 30–70% of the patients and is most evident in the bones of the axial skeleton, in particular the spine and pelvis (3). There may be small areas of relative radiolucency, and cortical thickening due to endosteal sclerosis is also found. Rarely, periosteal bone formation, specifically at the distal femur and proximal tibia, may be found. MRI is more sensitive in assessing the extent of the disease; low signal intensity changes both in T1- and T2-weighted images are shown due to replacement of marrow fat by collagen and reticulin fibers. Note, however, that these signal changes may also be found in children with leukemia and Gaucher's disease as well as in iron overload (chronic hemolysis, thalassemia) and AIDS (3). Other findings related to myelofibrosis are hemarthrosis due to impaired coagulation, secondary gout (5–20% of patients), polyarthralgias, and polyarthritis, as well as extramedullary hematopoiesis with tumor like masses that may be found in different locations, including the spinal canal (3).

In *acute leukemias* radiographic findings include metaphyseal banding, periosteal reactions, osteolysis, osteosclerosis, and osteopenia. Advanced disease may present with a higher rate of severe radiographic abnormalities such as geographic destructive osteolysis and periosteal reactions. A diffuse MR pattern (Fig. 1) is typical but not very specific. MRI is sensitive in depicting bone marrow infiltration but has a poor specificity in differentiating active disease from posttreatment changes in AML, yet may better predict response in ALL (4). MRI may also help in differentiating tumor involvement (such as chloromas) from complications of the disease (such as osteomyelitis).

Other myeloproliferative disorders such as *CML, polycythemia vera*, and *thrombocythemia* may have similar imaging findings, which are nonspecific and may have only a limited role in staging the disease or determining prognostic outcome.

MM is one of the most frequent hematological malignancies. Typical findings in MM have been described previously in the text. Conventional radiographs may show diffuse demineralization or variegated or focal patterns. Osteosclerosis is shown rarely. It should be noted that in diffuse infiltration, MRI is only reliable if more than 20% of the bone marrow is infiltrated (5). Compared with the variegated pattern (Fig. 2), diffuse or focal marrow involvement tends to have a higher tumor burden (6). The focal pattern is most frequently seen, while a diffuse pattern is seen in 25% of the patients. After treatment, bone marrow changes may resolve but may also be unchanged, even if patients achieve complete remission. Sometimes changes in the enhancement pattern may be shown, or transformation of a diffuse into variegated or focal pattern may be found (4). Progression of vertebral compression fractures also does not necessarily suggest disease progression but may be due to collapse of the unsupported vertebrae. MRI has an important role in assessing extraosseous masses and neurologic involvement of the disease, such as infiltration of the spinal canal.

Lymphoproliferative disorders are divided into Hodgkin's and non-Hodgkin's lymphomas, and infiltration of the bone marrow is found in 5–15% of patients with Hodgkin's and in 20–40% of patients with non-Hodgkin's disease (4). MRI may show the infiltration more sensitively than bone marrow scintigraphy but may be less accurate than FDG PET in assessing therapy response. On T1-weighted MR images, involvement is usually more diffuse or heterogeneous and less frequently focal. These MR findings are not specific for this disease entity and may be found in other myeloproliferative disease too. A soft tissue mass around an apparent intact cortical bone, however, raises concern for lymphoma, though it may be found in small cell malignancies too.

Systemic mastocytosis is a rare disorder that shows skeletal abnormalities in 70%, with 28% of the patients having pain. Conventional radiographs may show osteoblastic or, less frequently, osteolytic changes, which are nonspecific. MRI is substantially more sensitive in showing bone marrow pathology. Depending on the extension of the cell infiltration, bone marrow involvement may be either nonhomogeneous or homogeneous. In a previous study, nonhomogeneous involvement was more frequent, especially in the pelvis and humerus, while in the spine it was homogeneous in 50% and nonhomogeneous in 50%. There was no correlation between percentage of mast cells in bone marrow biopsy and extent or pattern of bone marrow involvement (7).

Important MRI *differential diagnoses* in myeloproliferative disorders include hematopoietic bone marrow, which sometimes is very difficult to differentiate from neoplastic disease, metastatic disease due to primary carcinomas or sarcomas, and osteoporotic compression fractures in patients with MM. In MR images hematopoietic bone marrow is usually not geographic and is more vague in appearance; it is frequently symmetric and located in the metaphyses, the signal is brighter than that of muscle in T1-weighted sequences. Bone scan is negative while FDb PET may be positive. Metastases are frequently more focal and rarely diffuse. In patients with osteoporotic compression fractures, the bone marrow signal may be normal if fractures are old. In subacute and acute fracture the bone marrow signal may be abnormal but usually extends parallel to the endplate and does not involve the whole vertebra. The posterior border of fractured vertebrae in osteoporosis is usually concave and not convex, and signal abnormalities do not typically extend into the pedicles.

Myocardial Hibernation

Chronic reversible myocardial dysfunction secondary to coronary artery disease.

▶Ischemic Heart Disease, Ultrasound

Myocardial Perfusion Imaging

MPI is an established technique for the diagnosis and prognosis of CAD that provides information about the physiologic significance of CAD.

▶Single Photon Emission Computed Tomography

Myocardial Perfusion Scintigraphy

Myocardial perfusion scintigraphy is a nuclear medicine technique that can be used to visualize and assess myocardial perfusion. This technique is based on detecting photons emitted from radiopharmaceuticals, of which the uptake in the myocardium is proportional to the regional blood flow. It is used to prognostically stratify patients into low-, intermediate-, and high-risk groups for cardiac events.

Myocardial Stunning

Reversible myocardial dysfunction secondary to transient ischemia.

▶Ischemic Heart Disease, Ultrasound

Myofibroblastoma

Benign spindle cell tumour of the mammary stroma composed of myofibroblasts.

▶Breast, Benign Tumours

Myoma

▶Leiomyoma, Uterus

Myometrium

The muscular and thickest layer of the Uterus. It consists mostly smooth muscle. The most inner layer of the myometrium is known as junctional zone.

Myositis

Myositis is one feature of connective tissue diseases such as SLE, Sharp's syndrome, dermato-/polymyositis. Leading clinical symptoms are muscle weakness and exercise-related pain. MR imaging is employed for localization of inflammatory affected muscles if biopsy is required. In the acute stage excessive edema and contrast material enhancement of the affected muscles are seen. Fasciitis in the neighborhood is common. Muscle atrophy with fat interposition and fascial undulation develops.

►Connective Tissue Disorders, Musculoskeletal System

Myositis Ossificans

Heterotopic formation of bone and cartilage in soft tissues, most commonly within muscles. The majority of these lesions occur secondary to trauma. Burns, paralysis, and idiopathic causes are also common. The lesion presents as a soft tissue mass with calcification. Maturation to heterotopic bone with an internal trabecular pattern occurs in the next few months. Regression is common and usually begins between 6 and 12 months. Myositis ossificans may appear very aggressive on MR images. It is better assessed with radiographs and CT, which demonstrate a characteristic peripheral rim of calcification/ossification. It is this feature that helps differentiate it from an osteosarcoma, which is generally characterized by central ossification. Delayed bone scan demonstrates marked uptake in early lesions and decreased uptake in mature lesions. The decreased activity on delayed imaging correlates with lower recurrence rates after surgery.

►Fractures, Peripheral Skeleton
►Neoplasms, Soft Tissue, Benign

Myxoedema

►Congenital malformations, Thyroid and Functional Disorders

Myxoma

Benign soft tissue mass containing gelatinous myxomatous material, often with a small region of visible fat within the wall, when multiple myxoma may be associated with Mazabraud's syndrome.

►Neoplasms, Soft Tissues, Benign

Definition

Renal papillary necrosis is not a pathologic entity but a descriptive term for the disorders causing necrosis of the renal papillae. Renal papillary necrosis develops in a variety of diseases that cause chronic tubulointerstitial nephropathy. The lesion is predominant in the inner medulla. Major underlying causes of renal papillary necrosis are: pyelonephritis, obstructive uropathy, sickle cell disease, tuberculosis, calculi, analgesics, renal vein thrombosis and diabetes mellitus. Other causes include acute tubular necrosis, chronic alcoholism and severe infantile diarrhea. Transplanted kidneys, particularly cadaveric allografts, appear to be susceptible to renal papillary necrosis.

Pathology/Histopathology

The basic lesion in renal papillary necrosis is an impairment of the vascular supply and subsequent focal or diffuse ischemic necrosis of the distal segments of the renal pyramids. In the affected papilla, the sharp demarcation of the lesion and coagulative necrosis seen in the early stages of the disease closely resemble those of infarction.

In diabetes the kidneys are enlarged in earlier stages and become small and scarred in later stages. Acute bacterial infection within the renal pyramids may impair the circulation to the papilla causing vascular sclerosis and secondly induce an infarct like necrosis of the distal segment of the renal pyramid.

Histologically analgesic nephropathy is characterized by chronic tubulointerstitial nephropathy and renal papillary necrosis. In milder cases the disease may be limited to one or several papillae and the kidneys are usually normal sized. In advanced cases however the kidneys eventually become shrunken due to diffuse fibrosis and atrophy.

Calcifications in the renal papillae or cortex and perinephric hematoma can be accompanying features. Even though histologic damage may be present in all papillae, radiological detectable lesions may be spotty or unilateral.

Clinical Presentation

There are no direct signs or symptoms of papillary necrosis. The most common symptoms are nonspecific: uremia, infection and flank pain. In many cases the cause is multifactorial.

Diabetes mellitus is the most common condition associated with renal papillary necrosis, accounting for more than 50% of all cases and renal papillary necrosis has been reported in about 25% of patients with insulin dependent diabetes mellitus. It is often associated with urinary tract infection and impaired renal function but can also be seen in patients without evidence of apparent diabetic nephropathy.

Analgesic nephropathy is caused by excessive intake of analgesics, usually more than 1 kg. It is most common in middle-aged women. Urinary tract infection accompanies in about 50% of patients and pyuria and urinary tract obstruction due to sloughed papillae are also common.

Pyelonephritis can result in papillary necrosis and infection is present in most cases of renal papillary necrosis. However, its exact prevalence as the cause of renal papillary necrosis is difficult to determine because infection may develop secondary to obstruction or diabetes.

In *S*-hemoglobinopathy medullary ischemia caused by sickling is the main cause of the disease. Papillary necrosis can be seen in both homozygous and heterozygous-*S* hemoglobinopathies but is more common in heterozygous-*S* disease. Homozygous-*S* disease is commonly associated with occlusion of small vessels, resulting in lobar infarcts, tubular obliteration and fibrosis but heterozygous-*S* hemoglobinopathies often manifest as papillary necrosis without association with renal failure.

Imaging

Most radiological information is from the time of intravenous urography. The use of contrast medium is mandatory. It must be given either intravenously or retrogradely. No significant difference with regard to diagnosis has been reported between intravenous urography and the now common CT-urography, but the experience is still limited. Ultrasonography may overlook papillary lesions, especially the early stages. Whether the spatial resolution of MR-urography is adequate is unknown. With regard to obstruction the value of all four modalities seems equivalent.

The radiographic appearance of papillary necrosis depends on the degree of disease. The renal size is normal in most patients, although the kidneys may shrink as the disease progresses. The contour remains smooth except in some advanced cases in which a 'wavy' appearance develops owing to the prominence of septal cortex surrounding atrophic areas of centrilobar cortex. In an early stage of the disease, papillary swelling may be the only abnormality. Necrosis of the papilla and disruption of its uroepithelial lining takes several forms. One may find faint streaks of density oriented parallel to the long axis of the papilla, usually extending from the fornix, after intravenous injection of a contrast agent.

Papillary necrosis is readily detectable when there is cavitation of the central portion of the papilla or complete sloughing of the papillary tip. Medullary cavitation is often central but may also be eccentric. The long axis of the cavity parallels the long axis of the papilla. The shape of the cavity varies from long and thin to short and bulbous.

With complete separation, the sloughed tissue is seen as a triangular radiolucent filling defect in the opacified calyx. Margins at the point of separation are initially rough but later become smooth. Necrotic tissue may pass into the renal pelvis and beyond causing obstruction. The remaining calyx has a round or saccular shape and smooth margins.

Calcification in papillary tissue is common in analgesic nephropathy. Nephrocalcinosis may be seen either in papillae that have no other radiological abnormality or in those that have cavitated. In most instances, foci of calcification are round, homogeneous and are arranged in a semilunar arc. Necrotic tissue passing down the pelvocalyceal system and the ureter produces obstruction.

Nuclear Medicine

Renography is useful for the diagnosis of obstruction in particular when the renal function is reduced and the risk of contrast medium induced nephropathy is increased. The papillary necrosis itself is not seen by nuclear medical methods.

Diagnosis

Typical changes of papilla demonstrated by an imaging modality, most typically intravenous urography or CT-urography.

Neonatal Cholestasis

Neonatal cholestasis is a state of improper metabolism of the bilirubin due to hepatic failure or obstruction in the neonatal period. Clinically, jaundice develops within the 24 h of life. Biologically, the rate of rise of serum bilirubin is greater than 5 mg/dL in 24 h, and the direct bilirubin is greater than 1 mg/dL. Also abnormal is the persistence of neonatal jaundice beyond 2 weeks of age. In this condition, the stools become acholic.

Tumorlike lesions of bone

Definition

The term tumorlike lesions of bone summarizes various nonneoplastic conditions which originate from or affect the bone and present as solitary or multiple bone lesions.

Pathology/Histopathology

The most important tumorlike lesions of bone are ▶nonossifying fibroma, ▶fibrous dysplasia, ▶simple bone cyst, ▶aneurysmal bone cyst, and ▶eosinophilic granuloma (Langerhans cell histiocytosis), which are also included in the WHO classification of bone tumors, although many other nonneoplastic alterations of bone can arise in a tumorlike fashion and therefore could be added to this selection. The lesions mentioned above all demonstrate distinct histopathologic features which

N

usually allow for a specific diagnosis. However, a detailed description of the histologic characteristics of every single lesion would go far beyond the scope of this essay.

Clinical Presentation

Nonossifying fibroma, monostotic fibrous dysplasia, ►osteofibrous dysplasia, and simple bone cyst are clinically asymptomatic in the majority of cases and are often detected incidentally on radiographs obtained for some other reason. Particularly larger lesions can give rise to pain, swelling, and stiffness of nearby joints or can lead to pathologic fracture. Aneurysmal bone cysts are mostly painful and, if located in the spine, are often associated with neurologic symptoms due to spinal cord or nerve compression. Patients with eosinophilic granuloma usually experience local pain and swelling not infrequently accompanied by fever, leucocytosis, and an elevated blood sedimentation rate. Neurologic deficiencies in patients with spinal manifestations of Langerhans cell histiocytosis are relatively rare.

For the tumorlike lesions mentioned above Table 1 gives an overview on the typical patient ages, the sex ratios, and the most common sites of involvement within the skeleton and within bone.

Imaging

Nonossifying fibroma (Fig. 1) demonstrates characteristic features on conventional radiographs. The lytic lesions that arise within the cortex have a lobulated contour often associated with a sclerotic border, a shell-like periosteal reaction, and, especially in larger lesions, trabeculations. These abnormalities are virtually diagnostic and usually obviate the need for further imaging or biopsy.

Fibrous dysplasia (Fig. 1) occurs as a monostotic manifestation more often than as a polyostotic disease. Solitary lesions typically present as well-defined intramedullary radiolucencies with “ground glass”-like density and sclerotic margins that might be associated with thickening of the adjacent cortex and variable degrees of bone expansion. In areas of complex anatomy, such as the skull, the spine, and the pelvis, CT can add valuable information with a view to differential diagnosis of fibrous dysplasia as well as the extent of bone involvement. CT images are particularly advantageous in demonstration of well-demarcated borders, osseous expansion, and “ground glass” matrix as typical features (Fig. 2). Compared with CT, MR imaging findings are less specific in differential diagnosis of fibrous dysplasia. However, MR imaging (whole body MR imaging) can demonstrate the full extent of the disease in young patients with polyostotic manifestations without unnecessary radiation exposure.

Osteofibrous dysplasia (ossifying fibroma, Kempson–Campanacci lesion) in the majority of cases affects the anterior cortex of the tibial shaft. Radiographically, it shows similar features as fibrous dysplasia, nonossifying fibroma, or adamantinoma (Fig. 1). Bowing of the tibia of various degrees is apparent in approximately 80% of patients with osteofibrous dysplasia. In most cases, cross-sectional imaging can add only little information to conventional radiography.

Simple bone cyst (solitary bone cyst, unicameral bone cyst) has a relatively typical radiographic appearance particularly if involving a long tubular bone (Fig. 1). Most lesions are centrally located and cause well-defined geographic bone destruction with thinning of the cortex and moderate expansion. Pathologic fracture is not uncommon and can give rise to a “fallen fragment”, an osseous fragment that migrates to the dependent portion of the lesion thereby proving that it has a liquid content. CT and MR imaging both can verify the cystic character of

Neoplasm-Like Lesions, Bone. Table 1 Tumorlike lesions of bone: clinical data and skeletal distribution (LTB = long tubular bones)

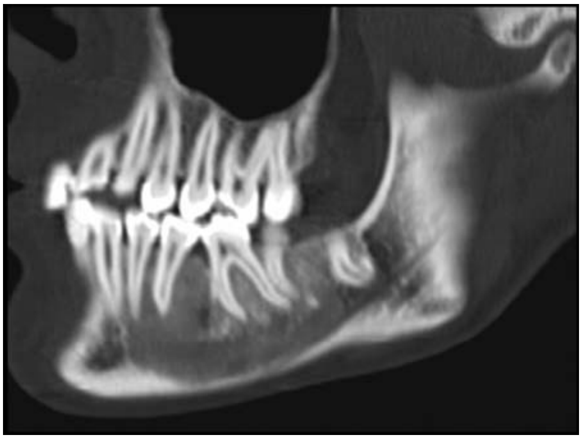
Lesion	Typical age of patients and sex ratio	Typical sites within skeleton	Typical locations within bone
Nonossifying fibroma	2 Decade M:F = 2:1	LTB (femur, tibia) > others	LTB: Meta(dia)physis
Fibrous dysplasia (solitary lesion)	2–4 Decade M:F = 1:1	LTB (femur, tibia), ribs, skull > others	LTB: Metaphysis, diaphysis
Osteofibrous dysplasia	1–2 Decade M:F = 2:1	Tibia, fibula (occasionally)	Diaphysis
Simple bone cyst	1–2 Decade M:F = 3:1	LTB (humerus, femur), calcaneus, pelvis > others	LTB: Metaphysis, diaphysis
Aneurysmal bone cyst	1–2 Decade M:F = 1:1	LTB, spine > others	LTB: Metaphysis spine: posterior elements
Eosinophilic granuloma (LCH)	1 Decade M:F = 3:4	Skull, femur, spine, pelvis, ribs > others	LTB: Diaphysis, metaphysis

Neoplasm-Like Lesions, Bone. Figure 1 Tumorlike lesions of bone: radiographic findings. (a) Nonossifying fibroma of the femur: anteroposterior radiograph shows a lobulated, cortically based lesion with sclerotic margins, trabeculations, and a shell-like periosteal reaction. (b) Monostotic fibrous dysplasia of the femur: anteroposterior radiograph shows a large, well-defined lesion of ground glass density bordered by a thick sclerotic rim and extending from the femoral neck into the proximal diaphysis. (c) Osteofibrous dysplasia of the tibia: lateral radiograph shows a well-defined lucency with sclerotic borders and trabeculations at the typical site of involvement within the anterior cortex of the midshaft of the tibia. Note the slightly increased tibial bowing. (d) Simple bone cyst of the humerus: anteroposterior radiograph demonstrates a centrally located, well-defined lytic lesion with a delicate sclerotic margin and slight expansion of the lateral cortex. (e) Aneurysmal bone cyst of the tibia: anteroposterior radiograph shows an eccentrically located lytic lesion exhibiting well-defined borders, trabeculations, and marked expansion with formation of a thin neocortex. (f) Eosinophilic granuloma (Langerhans cell histiocytosis) of the femur: anteroposterior radiograph reveals a medullary osteolytic lesion within the diaphysis that causes endosteal erosion of the medial cortex and a lamellated periosteal reaction.

N

the lesion and therefore can help to establish the diagnosis in anatomically complex areas such as the pelvis.

Aneurysmal bone cyst (ABC) on radiographs usually appears as an expansile osteolytic lesion regardless of its location within the skeleton. In long tubular bones, the most common features are well-defined margins with or without a sclerotic rim, eccentric location, marked expansion with formation of a thin neocortex, and trabeculations: the so-called "soap bubble appearance" (Fig. 1). However, the lesion might also present with more aggressive findings and therefore can not always confidently be diagnosed with radiography alone. Because MR imaging has the potential to reflect the pathologic anatomy of ABC independent from its location, it represents the most informative additional imaging modality with a view to differential diagnosis (Fig. 3). Primary ABCs are exclusively composed of multiple cystic spaces which contain noncoagulated blood and blood breakdown products which due to sedimentation effects often cause fluid levels particularly on T2-weighted images. Most lesions are surrounded by a rim of low signal intensity and typically demonstrate marked enhancement of cyst walls and internal septations with intravenous contrast administration. The presence of solid components does not generally exclude the diagnosis of primary ABC, but should alert to the most important differential diagnoses, teleangiectatic osteosarcoma, and ABC secondary to



Neoplasm-Like Lesions, Bone. Figure 2 Fibrous dysplasia of the mandible: CT. Sagittal CT reformation image shows a well-demarcated, slightly expansile lesion with ground glass density and some irregular ossifications. Note the distortion of adjacent teeth.

Neoplasm-Like Lesions, Bone. Figure 3 **Aneurysmal bone cyst of the tibia: MR imaging. (a) Sagittal T1-weighted SE, (b) fat-suppressed T2-weighted TSE, and (c) contrast-enhanced fat-suppressed T1-weighted SE images show and internally septated lesion with multiple cystic cavities bordered by a rim of low signal intensity. Note the hyperintense cystic compartments at the bottom of the lesion on T1-weighted image, fluid levels on T2-weighted image, and enhancement of cyst walls and septations with contrast administration. Edema of adjacent bone marrow and soft tissue, as seen in this case, is not an unusual finding in aneurysmal bone cysts.**

another bone lesion, such as giant cell tumor or osteoblastoma.

Eosinophilic granuloma as a solitary lesion represents the most common manifestation of *Langerhans cell histiocytosis* (60–80% of cases). Further osseous lesions are detected in only 10–20% of patients who initially present with a solitary granuloma. The radiographic features of eosinophilic granuloma vary with its skeletal location. Lesions of the skull and those located in flat bones often appear purely osteolytic and sharply delineated. The presence of a radiodense focus within a lytic lesion of the cranium has been described as a "button sequestrum." In long tubular bones, eosinophilic granuloma in most cases arises as a medullary radiolucency with central location and various degrees of endosteal erosion of the cortex (Fig. 1). Active lesions are often accompanied by a simple lamellar or an "onion skin"-like periosteal reaction. Spinal lesions typically cause destruction of vertebral bodies with consecutive collapse and flattening ("vertebra plana"), most often observed in the thoracic and lumbar spine. MR imaging usually shows an intramedullary lesion of low T1- and high T2-weighted signal intensity which is associated with more or less extensive edema of bone marrow, periosteum, and adjacent soft tissues. A rim of low signal intensity at the periphery of the main lesion seen on STIR images has been reported to represent a possible indicator of initial healing. In general, the imaging appearance of eosinophilic granuloma is rather unspecific with subacute osteomyelitis, osteoblastoma, and Ewing's sarcoma representing the main differential diagnoses. Whole body MR imaging is more sensitive than skeletal scintigraphy and radiography in detection of osseous manifestations of Langerhans cell histiocytosis and therefore, should be used as the screening method of choice for documentation of the presence and extent of skeletal involvement.

Nuclear Medicine

Skeletal scintigraphy is not very helpful in the specific diagnosis of solitary tumorlike lesions of bone, but can add information in cases of polyostotic involvement (e.g., in fibrous dysplasia).

Diagnosis

Nonossifying fibroma, fibrous dysplasia and simple bone cyst in most cases can sufficiently be diagnosed by means of radiography and do not require biopsy. The diagnosis of osteofibrous dysplasia should be verified by histology in order to exclude adamantinoma. With a view to their possible differential diagnoses histologic verification is also necessary in ABC and eosinophilic granuloma. The final diagnosis should be established by a combination of radiographic and histologic findings.

Neoplasms, Benign and Malignant, Larynx

Stefano Cirillo
Institute for Cancer Research and Treatment, Turin, Italy
stefano.cirillo@ircc.it

Definitions

Laryngeal neoplasms, either benign or malignant, originate from the mucosa and surrounding cartilaginous or connective structures of any part of the ▶larynx.

The larynx is shaped like a pyramidal frustum joining the upper aerodigestive tract with the trachea. Its upper base faces the tongue and its lower base continues with the trachea. It is primarily an organ of phonation, but also an important regulator of respiration, and it prevents aspiration during swallowing.

The larynx lies in the visceral space of the neck, in front of the esophagus, is lined by prismatic epithelium, and is suspended by muscular and cartilaginous structures (thyroid cartilage, cricoid cartilage, and arytenoids).

The organ is divided into three anatomical regions: supraglottis, glottis, and subglottis.

An important anatomical structure is the prelaryngeal space, the deepest space of the larynx, which is mainly occupied by fat tissue, and extends vertically between the thyroid cartilage and the laryngeal lumen; at the level of the vocal folds this space is named paraglottic. The supraglottic portion of the prelaryngeal space is in communication with the pre-epiglottic space.

Neoplasms can be benign, such as polyps, papillomas, hemangioma, paragangliomas, and chondromas, or malignant, including squamocellular or nonsquamocellular carcinoma.

Pathology/Histopathology

The following rare varieties of benign tumors can arise in the larynx.

Chondroma: Usually 2 cm or less, it arises posteriorly from the cricoid cartilage and projects anteriorly, often causing partial airway obstruction. This benign tumor may evolve into a chondrosarcoma.

Hemangioma: In infants it is a sessile, poorly circumscribed subglottic mass, often associated with obstructive symptoms. In adults, it is uncommon and usually supraglottic.

Paraganglioma: It commonly involves the aryepiglottic fold. It is more frequent (70%) in males and has a malignant behavior in 3–25% of cases.

Papilloma: It is a warty outgrowth of the laryngeal surface epithelium; in children it is usually multiple, most commonly located on true vocal cords, false cords, epiglottis, subglottic area, and rarely within the tracheobronchial tree. Recurrence is common, at times years after excision or destruction, and may be massive and rapidly growing, leading to airway compromise. In adults, mostly male, it is often solitary and recurrences frequently exhibit dysplasia.

Vocal cord polyp: It is more common in heavy smokers or singers, due to inflammation, allergy, or immunologic causes. It almost never evolves into malignancy. It appears as a smooth, round, 1–3-mm growth on the true vocal cords, often on their anterior third.

Nonsquamous cell carcinomas: They are malignant carcinomas including adenoid cystic carcinoma, angiosarcoma, chondrosarcoma, liposarcoma, lymphoma, melanoma, and rhabdomyosarcoma. These nonsquamous tumors typically grow beneath the laryngeal mucosa and are therefore more difficult to diagnose clinically than squa-

N

mous cell carcinomas. Cross-sectional imaging findings are important in defining the disease extent and in directing the clinician to the optimal transmucosal biopsy site.

Squamous cell carcinoma: This malignant carcinoma is the most common laryngeal neoplasm accounting for more than 90% of all malignant lesions; the most frequent histopathological type is the nondifferentiated type, while other varieties such as basaloid, papillary, spindle cell, and verrucous types are very rare.

Squamous cell carcinomas originate in 30% of cases from the supraglottic larynx. Most frequently, in 30–40% of the cases, they arise from the junction between the false cord and the epiglottis.

Epilaryngeal cancers spread to the pharynx (base of the tongue, pyriform sinus, hypopharynx wall); vestibular cancers spread both along the surface and deeply in the pre-epiglottic and paraglottic spaces (Table 1).

The true vocal cords are the most common site of origin of laryngeal carcinomas. The anterior portion of the true vocal cord is the most common location of squamous cell carcinoma. Anteriorly, the tumor may extend to the anterior commissure, where it may involve the contralateral true vocal cord. Advanced lesions arising from the posterior third of the cord may extend posteriorly to involve the cricoarytenoid joint and the interarytenoid region. Tumors may extend inferiorly to involve the subglottic region (Table 2).

Neoplasms, Benign and Malignant, Larynx. Table 1
T staging for supraglottic carcinoma

T1	Tumor in one supraglottic subsite with normal cord mobility
T2	Tumor invading the mucosa in more than one supraglottic subsite without laryngeal fixation
T3	Endolaryngeal tumor with fixed vocal cord ± invasion of the postcricoid area or pre-epiglottic tissues
T4a	Tumor invading through to the thyroid cartilage ± other extra laryngeal tissues (resectable), e.g., trachea, cervical soft tissues, strap muscles, thyroid, esophagus
T4b	Tumor invading the prevertebral space, encasing the carotid artery, or invading the mediastinal structures (unresectable)

Neoplasms, Benign and Malignant, Larynx. Table 2
T staging for carcinoma of true vocal cords

T1	Limited to cords with normal mobility
T2	Spreading (supra ± subglottis) with impaired vocal cord mobility
T3	Endolaryngeal tumor with fixed vocal cord ± invasion of the postcricoid area or pre-epiglottic tissues
T4	Limited to larynx with fixed vocal cord

Subglottic carcinomas are rare and account for only 5% of all laryngeal carcinomas. The subglottic region is more commonly involved by the direct extension of a glottic or supraglottic carcinoma than by tumors elsewhere. When present, these lesions are characteristically circumferential and often extend to involve the undersurface of the true vocal cords. They have a tendency to early invasion of the cricoid cartilage and to extension through the cricothyroid membrane (Table 3).

The most important prognostic factors for laryngeal cancers include tumor volume and T stage and N stage. The presence of adenopathy at the time of diagnosis is the most important factor for predicting lymph nodal recurrence (3). The survival rate for ►head and neck squamocellular carcinomas decreases to 50% in patients with homolateral adenopathy, 75% in those with contralateral adenopathy, and even further when capsular rupture of the lymph nodes is present.

The first station of lymph drainage from the supraglottic larynx is at the level of the subdigastric and the middle anterior cervical nodes; the second station is at the level of the lower anterior cervical nodes. The glottic larynx contains only a few nodes, and nodal spread occurs only when the primary tumor extends to the supraglottis or subglottis. The first station of lymph drainage from the subglottic larynx is at the level of the lower anterior cervical nodes, the paratracheal nodes, and the supraclavicular nodes. Glottic and subglottic tumors metastasize to the ipsilateral lymph nodes, but supraglottic tumors often spread to nodes on both sides of the neck.

Clinical Presentation

Laryngeal cancer is the most common cancer of the upper aerodigestive tract (25% of the cases) and represents 4–5% of all neoplasms. The incidence of laryngeal tumors is correlated with smoking, alcohol, and poor oral hygiene.

Laryngeal cancers account for approximately 1.2% of all newly diagnosed cancers; their incidence ranges from

Neoplasms, Benign and Malignant, Larynx. Table 3
T staging for subglottic carcinomas

T1	Tumor limited to the subglottis
T2	Tumor extending to the vocal cords with normal or impaired mobility
T3	Tumor limited to the larynx with fixed vocal cord
T4a	Tumor invading through to the thyroid cartilage ± other extra laryngeal tissues (resectable), e.g., trachea, cervical soft tissues, strap muscles, thyroid, esophagus
T4b	Tumor invading the prevertebral space, encasing the carotid artery, or invading the mediastinal structures (unresectable)

2.5 to 17.1 per 100,000 inhabitants in males, and from 0.1 to 1.3 per 100,000 in females in European countries; the peak incidence occurs at 50–60 years of age (1)(2).

The symptoms of laryngeal tumors largely depend on their size and location. Common symptoms for supraglottic tumors include mild odynophagia, mild dysphagia, and mass sensation. Uncommon symptoms include severe dysphagia and ear pain. For glottic and subglottic tumors, the most common presenting symptom is hoarseness of the voice. Uncommon symptoms include odynophagia, ear pain, thyroid cartilage pain, and airways obstruction. All the above symptoms are, however, not specific for a malignant lesion.

Diagnosis

The physical examination must include a systematic assessment of the patient's general health condition, searching for signs of associated conditions and metastatic disease. The neck and supraclavicular fossa are palpated to search for cervical adenopathy, other masses, and laryngeal crepitus. The oral cavity and oropharynx are examined under direct endoscopic vision. The larynx should also be examined by indirect laryngoscopy after anesthetic spray administration.

If there is a suspicion of cancer, biopsy is usually performed during direct laryngoscopy with the patient under general anesthesia; vital coloring is used to better identify the lesion. The examination should be extended to the whole upper aerodigestive tract and to the esophagus to exclude a second neoplastic lesion.

In cases where cancer is confirmed histologically it is very important that extension be evaluated accurately, in order to plan the most appropriate treatment. Laryngeal tumors arise from the mucosa, thus they are usually visible on the surface, but their submucosal spread may not be accurately evaluated by endoscopic examination alone. Indeed, clinical and endoscopic examinations underestimate tumor extension in 45–50% of cases. Integration between clinical data, endoscopic data, and imaging [computed tomography (CT)/►magnetic resonance imaging (MR)] is necessary for correct staging. Clinical staging is sufficient only for glottic cancer without involvement of the anterior commissure or with preserved vocal cordal motility, or exophytic cancer of the epiglottis and false vocal cord.

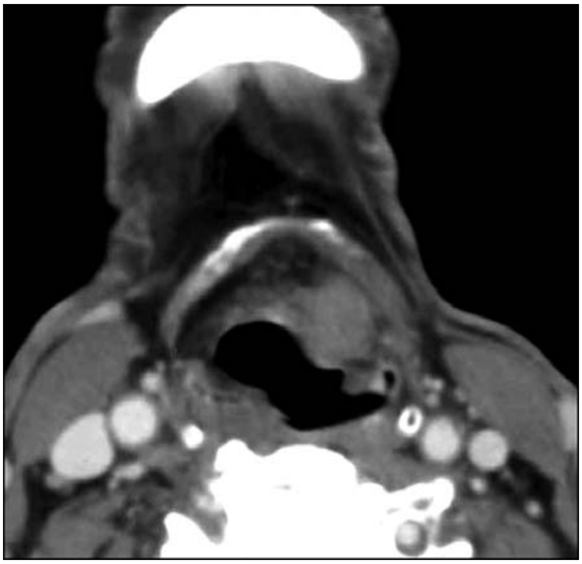
Imaging

The possibility that patients may benefit from conservative surgery or radiotherapy depends on the accuracy of the pretreatment assessment of cancer extension. CT and MRI can both assess the depth of invasion extension, which must be accurately evaluated in the following regions:

a. For supraglottic cancers:
   - Infiltration of the base of the tongue
   - Diffusion to the pre-epiglottic space
   - Diffusion to the superior prelaryngeal space
   - Extension to the pyriform sinus
   - Extension to the glottis plane
   - Involvement of the cartilage
b. For glottic cancers:
   - Diffusion to the paraglottic space
   - Diffusion to the cartilage
   - Involvement of the anterior commissure
   - Vertical diffusion (supraglottic or subglottic)

The imaging criteria used for tumor involvement are abnormal contrast medium enhancement, soft tissue thickening, presence of a bulky mass, infiltration of fatty tissue even without distortion of the surrounding soft tissues, or a combination of these signs. Imaging can underestimate the mucosal extension and overestimate the deep extension in the presence of edema, which may not be differentiated from neoplastic tissue.

►Multidetector CT (MDCT) is the first-choice examination for staging laryngeal neoplasms. The short scanning time of this technique limits the possibility of motion artifacts caused by swallowing and makes it possible to perform scans during functional and dynamic maneuvers, such as phonation or Valsalva, useful for identifying the tumor, and evaluating the degree of extension of the malignant tissue (Figs 1 and 2).



Neoplasms, Benign and Malignant, Larynx. Figure 1 Epiglottic cancer, MDCT – nodular mass in paraglottic superior space.

Neoplasms, Benign and Malignant, Larynx. Figure 2 Dynamic maneuver during laryngeal scans, MDCT: (a) abduction and (b) adduction of vocal folds.

Neoplasms, Benign and Malignant, Larynx. Figure 3 Anterior commissure cancer, MDCT – lesion on (a) axial plane and on (b) sagittal reconstruction.

MDCT allows one to obtain excellent multiplanar reconstructions, with optimal tumor visualization and accurate measurement of its volume and adenopathy diameter (Fig. 3).

With MRI, a high contrast resolution can be obtained between the various anatomical structures, but images are often deteriorated by motion artifact caused by the long acquisition time, especially in patients in advanced stages who have dyspnea, cough, and large respiratory excursions.

If conservative surgery is planned, MRI is a complementary test to MDCT when the latter cannot exclude with certainty infiltration of the base of the tongue and of the cartilage.

False-positive results, however, are inevitable with both imaging modalities, due to inflammation.

MDCT and MRI have the same accuracy in the evaluation of diffusion to the epiglottic space (90–95%) and to the glottis plane. Sensitivity for assessing involvement of the paraglottic space is 93% for MRI and 97% for MDCT, while specificity is lower, being 50–76% for either test due to the difficulty in differentiating edema from neoplastic tissue.

MDCT and MRI may not provide sufficient diagnostic accuracy in evaluating involvement of the pyriform sinus: this may help explain the high rate of hypopharyngeal recurrences.

Involvement of the anterior commissure is considered if a soft tissue with a thickness of more than 1 mm is present (4,5).

Nuclear Medicine Tests

Nuclear medicine tests are useful in the follow-up of patients who underwent surgery or radiotherapy, for whom there is a clinical suspicion of local recurrence. In this setting, FDG-positron emission tomography (PET) provides a high sensitivity (86–100%) and specificity (69–87%) (5).

PET has some limitations due to its low spatial resolution and to the absence of anatomic reference points, which is of particular relevance considering the complexity of the head and neck region. Moreover, uptake is at times present in physiological conditions generating possible false-positive findings. Anatomic limitations can be partially overcome by the combination of CT-PET, which permits simultaneous acquisitions of morphological and metabolic data.

Definitions

A ►*polyp* is any circumscribed protrusion of normal mucosa into the colonic lumen, whether originating from the mucosa or situated submucosally.

According to Morson (1) there are two main groups of polyps projecting into colonic lumen:

- Nonneoplastic polyps (including hyperplastic, inflammatory, juvenile, or hamartomatous lesions).
- Neoplastic (or adenomatous) polyps.

Since most of the colorectal tumors (90–95%) arise from sporadic adenomas (polyps) and most of the remaining are accounted for by several hereditary cancer syndrome, a quick and right diagnosis as well as an appropriate treatment is extremely important in the prevention of colonic cancer.

Pathology/Histopathology

Nonneoplastic polyps include hyperplastic, inflammatory, juvenile, or hamartomatous lesions, which lack dysplastic features.

Hamartomatous polyps are the most common form of polyps in children. They are usually seen in the 4th to 6th year of life in many syndromic forms. The incidence in adulthood is 0.5–3.3% of all endoscopically removed polyps. More than 80% are usually found in the rectum. These polyps can vary in size between 0.3 and 0.5 cm and they are usually pedunculated, even if occasionally can be sessile.

Peutz–Jeghers Syndrome is an autosomally inherited syndrome due to mutations in LKB1 gene, identified in 50–60% of cases. This condition is characterized by hamartomatous polyps of smooth muscle through the GI tract and mucocutaneous pigmentation. Affected individuals have hamartomatous polyps in the small and large bowel and characteristic mucocutaneous brown to black melanin spots most commonly observed in the perioral area. The size of the polyp is 0.3 to 5 cm; they are commonly pedunculated, but occasionally they can be sessile. They cannot be distinguished from adenomas during endoscopy, and should be removed if possible. Risk of gastrointestinal and other malignancies is slightly increased.

Juvenile Polyp Syndrome (JPS) is cystic dilationsof glandular structures in the lamina propria without malignant potential. This syndrome is an uncommon condition that tends to be sporadic although 20–50% has a family history showing autosomal dominant inheritance (2). JPS grows from the lining of the bowel and originates in the tissues supporting that lining. It does not arise from the colonocytes (colonic lining cells) but from the tissues underneath the lining cells. Juvenile polyps are relatively common in children even if by adulthood 50–200 polyps may be present, commonly in the rectosigmoid junction. Juvenile polyposis may or may not be familial. Familial juvenile polyposis has been associated with mutations in two genes: *SMAD4* on chromosome 18 and *PTEN* on chromosome 10. There is a small but significant risk of cancer in patients with juvenile polyposis, mostly due to development of adenomatous tissue in juvenile polyps.

Hyperplastic polyps are lesions characterized by an epithelial dismaturityand hyperplasia caused either by a disturbed maturation process of cell in crypts without a known cause or either by hypertrophy of the crypts due to excessive epithelial cells. These polyps can be seen very

N

frequently in 75% of subjects aged over 40 years and are usually multiple. Most are often tiny lesions ranging in size between 2 and 5 mm. They are the most common colorectal neoplasms (10 times > adenomas). They have no malignant potential and they are often so small that may be missed even on endoscopic examination.

▶*Colorectal adenomas* are benign neoplasms, pedunculated or sessile arising from the epithelial cells of the colorectum, with varying degrees of cellular atypia. Although benign, they are the direct precursors of adenocarcinomas and follow a predictable cancerous temporal course unless interrupted by treatment. There are three histological types:

- tubular adenomas
- villous adenomas
- tubulo-villous adenomas

According to world health organization (WHO) criteria, villous adenomas are composed of greater than 80% villous architecture. Tubular adenomas are encountered most frequently (80–86%). Tubulovillous adenomas are encountered less frequently (8–16%), and villous adenomas are encountered least frequently (5%). It has been shown that the removal of polyps by ▶colonoscopy reduces the risk of getting colon cancer significantly. Malignant potential is determined by the size with 1% risk of adenocarcinoma if lesser than 1 cm in diameter; 10–50% risk if greater than 2 cm as well as by histologic type—greatest malignant potential for villous adenoma; least for tubular. This distribution of adenomatous polyps is paralleled by the distribution of colonic cancer. They may look like a wart when small and when they grow they may appear like a cherry on a stem or fig. There may be single or multiple polyps. The incidence of polyps increases with age, particularly above 40 years of age (M:F = 2:1). The cumulative risk of cancer developing in an unremoved polyp is 2.5% at 5 years, 8% at 10 years, and 24% at 20 years after the diagnosis.

The probability of any singular polyp becoming cancerous is dependent on its gross appearance, histologic features, and size. The risk of cancer is much higher in sessile villous adenomas than in pedunculated tubular adenomas (3). Cancer is found in 40% of villous adenomas, as compared to 15% in tubular adenomas. The good news is that 65% of adenomas are tubular, with villous adenomas accounting for only 10% of adenomatous polyps.

Adenomas are believed to have an abnormal process of cell proliferation and apoptosis. Clinical, autoptical, and epidemiological studies provide evidence of adenoma-to-carcinoma progression. The mean age of adenoma diagnosis is 10 years earlier than with carcinoma, and progression to carcinoma takes a minimum of 4 years.

Molecular genetic studies also describe an adenoma-to-carcinoma sequence through accumulation of lesions in a variety of genes, with activation of oncogenes and inactivation of tumor suppressor genes. The K-ras oncogene is described in 9% of small adenomas, 58% of adenomas larger than 1 cm, and 46% of colorectal carcinomas. Inactivation of tumor suppressor genes on arms 5q, 18q, and 17p is thought to be essential in tumorigenesis. As mutated in 30–60% of persons with sporadic adenomas and adenocarcinomas, the APC gene, on 5q, has an important role in adenoma formation.

Clinical Presentations

They may present with bleeding, prolapse, and rarely intussusception, but most commonly they are asymptomatic. Colonic polypectomy has simplified the management of this condition.

They may, however, cause painless rectal bleeding or bleeding not apparent to the naked eye. Obstruction can occur if they are large.

Usually the colorectal polyps are the ones causing symptoms, such as bleeding, diarrhea, abdominal cramps, and anemia. In such cases surgery is performed, choosing between the same operations offered to patients with familial adenomatous polyposis: colectomy and ileorectal anastomosis, proctocolectomy and pouch, or proctocolectomy and ileostomy.

Imaging

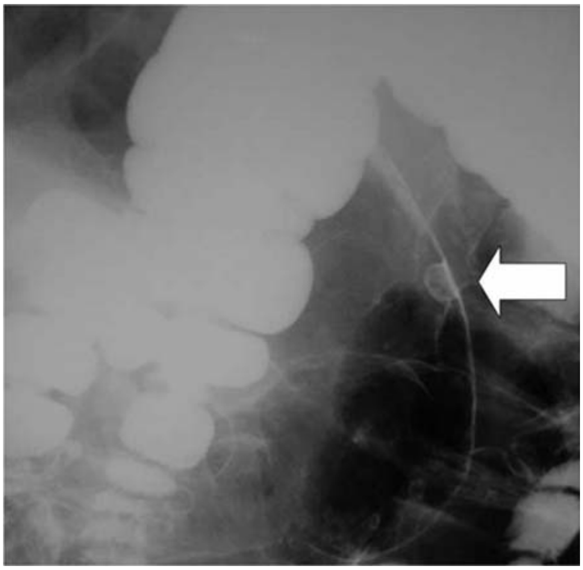
A *double contrast barium enema* (DCBE) is given in order to perform an X-ray examination of the large intestines. Pictures are taken after rectal instillation of barium sulfate (a radiopaque contrast medium) (Fig. 1).

DCBE is generally accepted as less sensitive than colonoscopy for detecting polyps or CRC. Enthusiasm for the double contrast barium enema has declined in recent years in favor of colonoscopy, despite its lower cost and more recently in favor of ▶computed tomographic colonography (CTC).

The reason for this decrease in use as a diagnostic tool lies in the reduced sensitivity of this test in detecting polyps of lesser than 1 cm, in detecting polyps in areas where a single lumen is not detectable (i.e., sigmoid, rectosigmoid, hepatic, and splenic flexures) and patient comfort and compliance issues.

If a polyp is greater than 1 cm, the diagnostic accuracy of this technique has been reported as up to 95%; for polyps smaller than 1 cm well-performed air-contrast barium enema has a sensitivity of 61%.

A false-positive rate of 5–10% is found because of improper cleaning of the bowel. Diverticulosis or redundant bowel can result in a false-negative rate of 10%, especially in the rectosigmoid. The accuracy



Neoplasms, Benign, Large Bowel. Figure 1 Polypoid lesion in a 56 year old female with familial history of adenomatous polyposis. Close-up view of an overhead image from a double-contrast enema examination shows a 1.5 cm well-defined polypoid lesion (arrow) of the colon.

of the procedure also can have an element of operator dependence.

CTC well known even as *Virtual Colonoscopy* (VC) is a novel imaging modality for the evaluation of the colonic mucosa in which thin-section spiral CT provides high resolution two-dimensional (2D) axial images; (Fig. 2a) CT data sets are edited off-line in order to produce multiplanar reconstructions (coronal and sagittal images) as well as three-dimensional (3D) modeling, including endoscopic-like views (Fig. 2b).

Reported diagnostic accuracy for polyps >5 mm exceeds that of barium enema and approaches that of conventional colonoscopy.

CT colonography requires no sedation—a major factor if dealing with old, unstable patients—or screening of asymptomatic subjects who would like to be able to return to work immediately after the procedure. In contrast, colonoscopy is associated with appreciable morbidity and even mortality including significant cardiovascular effects related to sedation.

The success rate of CT colonography approximates 100%, if bowel preparation and distension are optimal, whereas up to 6% of conventional colonoscopy cannot reach the caecum. CT colonography has been investigated as a technique for colon cancer screening. Although it requires a full bowel cleansing similar to that required for conventional colonoscopy, the procedure requires no sedation or analgesia, and is faster to perform than conventional colonoscopy. When a colonoscopy is not

Neoplasms, Benign, Large Bowel. Figure 2 (a) Polypoid lesion in a 65 year old frail and uncooperative patient with rectal bleeding. Axial CT image obtained after colonic distension with air during CT colonography exam shows a 2 cm sessile polyp (arrow) of the descending colon. (b) Endoscopic like view of the same lesion where the polypoid lesion is easily appreciated (axial image obained using Lightspeed VCT 64 detector row, GE, USA; and endoluminal image obtained using VIATRONIX, V3D, USA).

possible CTC is an acceptable alternative. However, since it is only a screening procedure, patients with positive findings require conventional colonoscopy afterward. For this reason CT colonography is generally not being offered in a diagnostic setting (i.e., in symptomatic patients) because these patients have a high probability of having an abnormality that will require a colonoscopy.

CT colonography can detect overt cancers, but these are rare in asymptomatic patients. The major benefit from

CT colonography and other colon cancer screening techniques results from identification and removal of cancer precursors called adenomatous polyps. This assessment reviews evidence on the effectiveness of CT colonography as an alternative to colonoscopy for the purpose of colon cancer screening.

MR Colonography

High performance gradient systems together with fast MRI scanning techniques allow the acquisition of complex 3D data sets within comfortable breath hold.

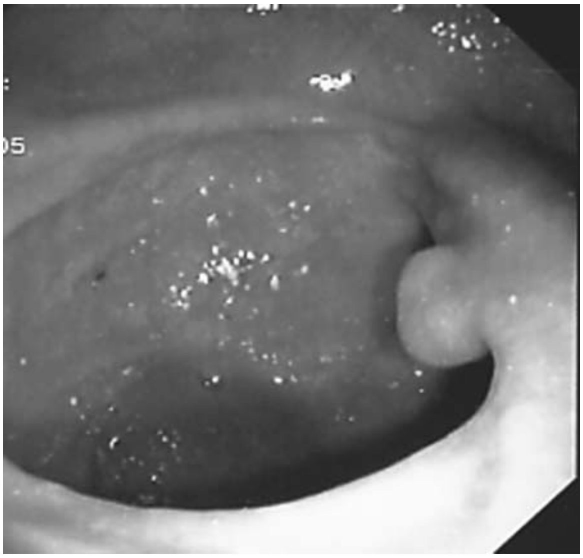
Whereas MR has not been able to provide the necessary spatial and temporal resolution, this technique provides some advantages as optimal soft-tissue contrast and lack of radiation exposure. Fecal tagging to obviate the need for bowel preparation can be used in MR as well as in CTC. Compared to CTC, MR colonography is still under development and promises to reach the accuracy of CTC (4).

Diagnosis

Diagnosis relies on good history and physical examination of patients at risk. Rectal examination can identify cancers up to 8 cm above the dentate line that represent 20% of colorectal cancer.

Fecal occult blood testing (FOBT): is a test that detects the presence of occult (detectable only by chemical means and not visible) blood in the stool. This test has been suggested as a possible adjunct to other screening modalities. Only 20–40% of patients with adenomas have positive test findings, usually resulting from distal and larger polyps. On the other hand, the estimated 30–50% sensitivity is too low to consider FOBT as an effective single screening modality in high risk individuals, particularly since a positive FOBT is unlikely to occur as a result of adenomas before malignant transformation.

Flexible sigmoidoscopy: Flexible sigmoidoscopy can reach as high as the descending colon and can be done by a trained primary care physician. Sigmoidoscopy has been proven to reduce the incidence and mortality of colon cancer through early detection, however, is not an adequate method of screening in hereditary colon cancer as 2/3 of the lesions develop proximal to the splenic flexure. In these cases colonoscopy should be used. Flexible sigmoidoscopy can detect about 65–75% of polyps and 40–65% of colorectal cancers. This test, for an investment of 3–5 min, can with little discomfort reduce the likelihood of your developing colon cancer and if colon cancer is present detecting it at an early, highly curable stage.



Neoplasms, Benign, Large Bowel. Figure 3 Conventional colonoscopy of 53-year old female with familial history of adenomatous polyposis showing a 1 cm lesion of the ascending colon.

Colonoscopy: Colonoscopy remains the gold standard for visualization, biopsy, and removal of colonic polyps (Fig. 3).

The removal of all polyps by colonoscopy has been demonstrated to reduce the risk of colon cancer by 76–90%.

Colonoscopy is the “gold standard” for the detection of colonic neoplasms and the preferred colorectal cancer screening strategy. The incidence rate of colorectal cancer has been shown to be reduced up to 90% in subjects who had polypectomy versus patients in three reference groups, including two cohorts in which colonic polyps were not removed and one general-population registry. It can be completed in more than 95% of examinations with negligible risk. Colonoscopic screening in individuals with average risk has been found to be cost effective, and similar to cervical or breast cancer screening techniques in cost-effectiveness per life-year saved. Medicare has approved the use of screening colonoscopy in average-risk beneficiaries.

The evidence to support colonoscopy is derived from data showing a decreased incidence of colorectal cancer mortality in subjects who have undergone colonoscopic adenoma removal. Additionally, colonoscopic screening has been shown to have favorable cost effectiveness when compared to other screening strategies.

Synonyms

Cholangiocarcinoma, CC; Cholangiocellular carcinoma, CCC; Klatskin tumor

Definition and Classification

Cholangiocellular carcinoma (CCC) is a malignant tumor arising from the bile duct epithelium and comprises 15–25% of all liver and biliary tract malignancies. The tumors may arise at any part and from any component of the bile duct epithelium, ranging from the terminal ductules (canals of Hering) to the ampulla of Vater as well as at the peribiliary glands (intramural and extramural). According to the site of origin, cholangiocarcinoma can be differentiated into intrahepatic/peripheral, hilar (Klatskin tumor), and extrahepatic.

Intrahepatic CCC includes tumors originating from small biliary intrahepatic ductules and is considered as a peripheral, mass-forming tumor.

Hilar CCCs arise from one of the hepatic ducts or the bifurcation of the common hepatic duct and are classified, according to the Bismuth classification, into four different types: type I involves the main hepatic duct below the bifurcation, type II affects the main hepatic duct bifurcation, type III involves segmental ducts beyond the primary hepatic duct bifurcation in one liver lobe (type IIIa: right lobe, type IIIb: left lobe), and type IV involves segmental ducts in both liver lobes.

Finally, CCCs originating from the bile duct below the bifurcation of the right and left hepatic ducts are classified as extrahepatic (1).

Pathology

The gross appearance of intrahepatic CCC is of a gray-white mass with irregular margins. The mass may be solitary or multiple with satellite nodules in its periphery. Size varies, from a few millimeters to more than 15 cm in diameter. The tumor consists typically of a huge amount of whitish fibrous tissue at cut section, especially in large lesions with central necroses. Calcifications and hemorrhages are rare. Finger-like extensions along the portal triads are frequent. Similar to HCC, intrahepatic CCC has the propensity to invade small portal vessels, resulting in portal vein thrombosis. Metastases to regional lymph nodes and pulmonary and peritoneal spreading are common.

Different histological forms of hilar and extrahepatic CCC (such as infiltrative, nodular, and papillary) have been described.

The infiltrative type is the most common (over 70% of cases) and it appears as a sclerotic lesion with abundant fibrous tissue growing along the bile duct wall. It results in a diffuse, firm, gray-white annular thickening of the bile with complete or nearly complete obstruction of the lumen. The extent of the tumor may vary, ranging from few millimeters to several centimeters in length. A dense fibroblastic reaction may compress or encase the adjacent vascular structures.

The nodular form usually consists of a small (1–2 cm in diameter), gray-white nodule causing biliary obstruction. The tumor arises within the mucosa, invades the bile duct wall, and grows outward to form a nodular, exophytic mass.

The papillary CCC is a distinctive pathologic entity characterized by the presence of an intraluminal polypoid or sessile mass of the hepatic bile duct associated with partial biliary obstruction and dilatation. The tumor is usually small and is a low-grade malignancy (2).

Histopathology

Irrespectively of the primary localization of the tumor, whether it is intra- or extrahepatic, more than 90% of CCCs are well to moderately differentiated adenocarcinomas that exhibit glandular or acinar structures with intracytoplasmic mucinous components. Characteristically, the malignant cells are of cuboidal or low columnar type resembling biliary epithelium. In more poorly differentiated tumors, solid cords of cells without biliary ducts may be present. The dense fibrous stroma is characteristic and may dominate the histological architecture. The tumor tends to invade lymphatics, blood vessels, perineural and periductal spaces, and portal tracts, which might be responsible for the secondary atrophy of the dependent hepatic segments particularly in peripheral CCC. Spread along the lumen of large bile ducts can be seen, especially in hilar tumors (2).

N

Clinical Presentation

CCC occurs more frequently in patients in the sixth decade of life. It is associated with primary sclerosing cholangitis, intrahepatic stone disease, choledochal cyst, congenital hepatic fibrosis, clonorchiasis, and exposure to Thorotrast.

Clinical signs and symptoms, including jaundice, itching, clay-colored stools, dark urine, weight loss, and abdominal pain, may vary according to the various sites of origin of the tumor (1, 3).

Jaundice is usually the leading sign in tumors located in the common bile duct or common hepatic duct as a sign of biliary obstruction.

Abdominal pain and weight loss are the most common symptoms in intrahepatic CCC, whereas painless jaundice occurs later and is often a marker of advanced disease.

Extrahepatic cholestasis is reflected in elevated levels of direct bilirubin. Levels of alkaline phosphatase and gamma-glutamyltransferase (GGT) usually rise in conjunction with bilirubin.

There are no specific tumor markers for CCC, although elevation of serum carcinoembryonic antigen (CEA) and CA 19–9 is often found.

Imaging

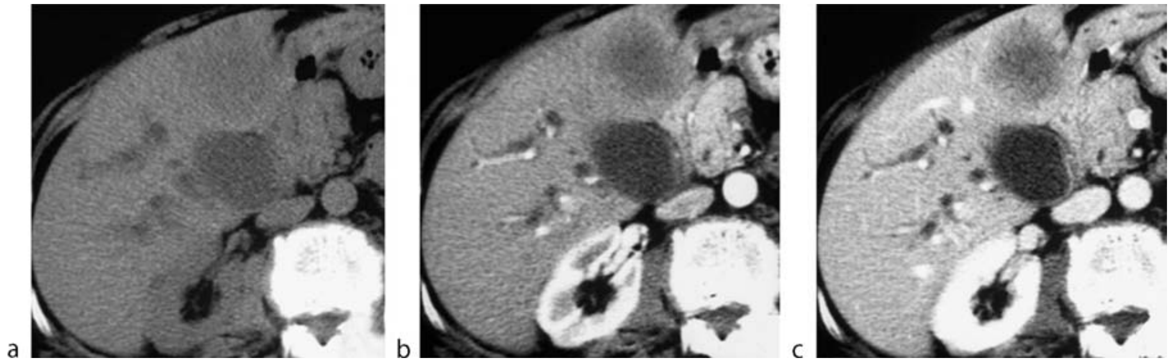
Intrahepatic CCC

The most common appearance of intrahepatic CCC on ultrasound (US) is as an ill-defined, predominantly hypoechoic mass; however, US patterns may vary from homo- or heterogeneous hypo-, iso-, or hyperechogenicity. Hyperechoic foci with acoustic shadowing, suggesting calcifications, and segmental bile duct dilation in the presence of normal extrahepatic ducts may be observed. The presence of satellite nodules is frequent and contributes to a poor prognosis of CCC.

Color Doppler US allows definition of portal vein involvement, without significant usefulness in characterizing the primary tumor mass (3).

On unenhanced computed tomography (CT) scans, intrahepatic CCC usually appears as a large and irregular mass hypodense or isodense relative to the normal hepatic parenchyma. The mass is round or oval, more or less well demarcated, and may demonstrate segmental biliary ductal dilatation peripheral to the tumor. After contrast medium administration, parenchymal CCC usually demonstrates a thin and incomplete rim-like enhancement during both the arterial and portal venous phases (Fig. 1). The central part of the tumor usually does not enhance during these phases, whereas there may be delayed enhancement based on the interstitial transition of extracellular iodinated contrast agents. This pattern of enhancement reflects the hypovascular, desmoplastic composition of most CCCs. Satellite nodules are frequent and variable in size. Additional ancillary CT findings include capsular retraction, intratumoral calcification, invasion of portal or hepatic veins more commonly than in HCC, and dilatation and thickening of peripheral intrahepatic biliary ducts (especially when associated with clonorchiasis). Extrahepatic spread is common and lymph node metastasis with involvement of the celiac and left gastric areas or direct invasion of the omentum is frequently detected (1, 4).

The magnetic resonance (MR) appearance of intrahepatic CCC is that of a noncapsulated tumor, hypointense on T1-weighted images and slightly hyperintense on T2-weighted images. However, the signal intensity of the tumor is variable according to the amount of fibrosis, necrosis, and mucinous components within the tumor.



Neoplasms, Bile Ducts. Figure 1 Peripheral cholangiocellular carcinoma. On unenhanced CT scans (a) the lesion appears as an ill-defined and slightly hypodense mass. After contrast medium administration the lesion shows minimal peripheral enhancement during the arterial (b) and portal venous (c) phases. Peripheral biliary ducts dilatation, distal to the mass, is also evident.

A central hypointensity, corresponding to fibrosis, is usually best appreciated on T2-weighted images. Dilatation of peripheral portions of the intrahepatic biliary ducts may be present and can easily be displayed with standard MR cholangiopancreatography (MRCP) sequences (heavily T2-weighted sequences) which is rarely seen in HCC.

On dynamic contrast-enhanced MR studies, minimal to moderate peripheral enhancement is usually observed followed by moderate progressive, delayed filling. Pooling of contrast within the tumor, reflecting the large amount of fibrous tissue, is typically seen on delayed MR images corresponding to the known CT findings (5).

Neoplasms, Bile Ducts. Figure 2 Hilar cholangiocellular carcinoma. Portal venous phase spiral CT shows a large and hypodense mass with lobulated margins at the hepatic hilum, mainly in segment IV. The contrast enhancement of the tumor is peripheral and irregular. Dilatation of the left hepatic duct and peripheral biliary ducts is present.

Hilar and Extrahepatic CCC

The US appearance of hilar and extrahepatic CCC includes biliary duct dilatation, mass or bile duct wall thickening, and lobar atrophy with crowded, dilated ducts.

Biliary duct dilatation is almost invariably present in hilar and extrahepatic CCC, and can be a useful sign in the differential diagnosis with other hepatic tumors. Typically, ►Klatskin tumors manifest as segmental dilatation and nonunion of the right and left ducts at the porta hepatis.

Although US is accurate for revealing the level of bile duct obstruction, visualization of the tumor mass is difficult and, therefore, characterization of a hilar or extrahepatic cholangiocarcinoma requires meticulous evaluation of the exact localization of the luminal alteration or ductal occlusion. The papillary and nodular forms of cholangiocarcinoma are relatively easy to see on US, appearing as a poorly defined, usually isoechogenic, nodular lesion with associated mural thickening. In contrast, infiltrating CCCs, the most common subtype, are difficult to appreciate on US, appearing only as a focal or diffuse thickening of the bile duct wall.

Lobar atrophy is often extremely subtle on US images. In this case, US scans demonstrate crowded, dilated ducts within the atrophic lobe. The dilated ducts will often almost reach the liver surface, which is pathognomonic. The associated cholangiocarcinoma is often at a hilar localization with a predominant involvement of the duct which drains the dependent segment (3, 4).

Hilar and extrahepatic CCCs usually appear as a focally thickened ductal wall obliterating the lumen on thin-section spiral CT scans. Following intravenous contrast medium administration, enhancement of the lesion is poor to moderate (Fig. 2). The degree of contrast enhancement probably depends on the presence of the fibroid components of the lesion. An enhancing border or pseudocapsule may be visible in well-delineated tumors. In a minority of cases there is early marked contrast uptake in the tumor, but often contrast enhancement is only noted on delayed scans (1, 4).

Lobar hepatic atrophy with marked dilatation and crowding of bile ducts is usually observed on CT scans in patients with hilar CCC in addition to fuzzy invasion of adjacent liver parenchyma and of the hepatoduodenal ligament.

In contrast, satellite nodules are less commonly seen in hilar CCC compared to intrahepatic CCC according to the earlier clinical manifestation of lesions situated at the hilum.

Lymphatic metastases usually involve the portacaval, superior and posterior pancreatoduodenal lymph nodes. Retroperitoneal lymphadenopathy, peritoneal spread, and proximal intestinal obstruction occur in advanced stages.

On MR images, hilar and extrahepatic CCCs appear hypointense to the liver on T1-weighted and moderately hyperintense on T2-weighted images, while on dynamic T1-weighted MR images acquired after gadolinium injection, minimal to moderate incomplete enhancement may be present at the tumor periphery on delayed images. In addition, the combined use of dynamic MR and MRCP depicts the primary tumor in a vast majority of cases and allows evaluation of the overall extent of the biliary tree involvement. The morphology of bile duct stricture detectable on high-resolution MRCP closely reflects the gross morphologic changes along the biliary ductal walls: papillary lesions appear as protuberant, as sessile flat or polypoid-like intraluminal lesions, while diffusely infiltrating tumors may be visualized as a diffuse narrowing of the ductal lumen (5).

Percutaneous transhepatic cholangiography is indicated in any patient who is cholestatic with nondilated bile ducts when there is doubt about the diagnosis and in whom an endoscopic intervention is not possible.

Nuclear Medicine

^{99m} Tc imminodiacetic acid (HIDA) and ^{99m} Tc sulfur scans are the classic nuclear medicine techniques used to display hepatic tumors such as CCCs, but they are of significance only in comparison to contrast-enhanced CT and MRI.

^{99m} Tc HIDA is excreted into the biliary ducts and may reveal the site of biliary obstruction. After injection, the common bile duct and cystic duct are usually visualized within 15 min. However, the ducts might not be visualized, even in healthy patients.

^{99m} Tc sulfur colloid helps in localizing lesions larger than 2 cm. However, the appearances on sulfur colloid and HIDA scans are nonspecific and false-positive findings may occur as a result of the misinterpretation of benign tumors and other malignant tumors.

Positron emission tomography (PET) can be used to assess the metabolism with the administration of positron-emitting radiolabel tracers such as 18F-FDG.

Recent studies have demonstrated the potential role of PET. In particular, 18F-FDG-PET seems to improve the depiction of CCC superimposed on primary sclerosing cholangitis due to the additional inflammatory component and allows the detection of metastatic lymph nodes or peritoneal seeding that other modalities fail to demonstrate.

Diagnosis

Intrahepatic CCC

Intrahepatic CCC classically manifests as a large, well-defined hepatic mass with lobulated margins and peripheral rim enhancement on both contrast-enhanced spiral CT and dynamic MR images. Both modalities are equally effective in the detection and characterization of the tumor, enabling a correct diagnosis and staging of intrahepatic CCCs in a great number of cases (1).

The differential diagnosis includes some bulky hepatic tumors of either primary or secondary origin. Due to a histologically similar appearance in metastatic adenocarcinomas, the differential diagnosis can be difficult for the pathologist. However, absence of a known primary malignancy, a relatively large size, and other ancillary findings such as bile duct dilatation and capsular retraction may support the diagnosis of CCC (4).

The vast majority of HCCs are hypervascularized and therefore easily differentiated from CCCs. Nevertheless, some variants of HCC such as sclerosing, fibrolamellar, and cholangiohepatocellular carcinoma may mimic intrahepatic CCCs. Especially in the latter cases, even biopsy may be unable to resolve the diagnostic dilemma.

Hilar and Extrahepatic CCC

Whenever extrahepatic CCC is suspected, the following aspects should be assessed: biliary dilatation, level of obstruction, presence of mass, focal or diffuse thickening of the bile duct wall, presence of a hepatic tumor, local lymph nodes involvement, and portal vein thrombosis.

US is the primary diagnostic procedure in most cases. US is accurate in revealing the level of bile duct obstruction, but the tumor mass is detected in a few cases only (3–5). In contrast, thin-section contrast-enhanced spiral CT and MR (dynamic MR and MRCP) depict the lesion and allow correct evaluation of the tumor extent in a great number of cases. In addition, dynamic CT and MR provide an accurate evaluation of vascular involvement, of secondary liver atrophy, and of lymphadenopathy of the peripancreatic, periduodenal, periportal, celiac, and mesenteric nodes.

The differential diagnosis of ductal CCC depends on its location. Lesions at the ductal confluence may be mimicked by inflammatory cholangitis (acquired immunodeficiency syndrome, sclerosing cholangitis), oriental cholangitis, benign biliary tumors, HCC, or gallbladder cancer, while ampullary or pancreatic cancer, nonshadowing stones, biliary adenomas or papillomas, blood clots, and benign strictures may simulate lesions of the distal common bile duct. Moreover, metastatic tumoral tissue in the bile ducts or adjacent nodes may mimic CCC at any anatomical level.

Lobar hepatic atrophy with marked dilatation and crowding of bile ducts is highly suggestive of hilar and peripheral CCC, although long-standing biliary obstruction from surgical trauma or focal biliary obstruction can cause similar findings.

Extrahepatic bile duct adenoma is a rare benign lesion of the biliary duct appearing as a polypoid filling defect within the bile duct at direct MRI or MR cholangiography. It is usually located at the common bile duct or at the common hepatic duct and is difficult to differentiate from small nodular extrahepatic or hilar CCC. However, additional findings of hepatoduodenal ligament adenopathy and tumor extension into adjacent structures are helpful diagnostic features supporting a malignant differential diagnosis (4).

Moreover, since intraductal papillary CCC produces single or multiple intraductal masses, the differential diagnosis from a bile duct stone may be difficult. Furthermore, the clinical manifestations of both diseases are similar. On

US a papillary tumor does not cast a shadow like some nonshadowing stones, and on precontrast CT the tumor appears as a high- or low-attenuation soft tissue mass.

Interventional Radiology

Although the prognosis of patients with CCC after surgical resection is poor, complete resection of the tumor is currently considered the best therapeutic option.

Since only 20–40% of patients are suitable for surgical treatment, palliative interventional radiological and gastroenterological procedures, such as percutaneous biliary drainage and stenting, may be employed in an attempt to improve survival and life quality.

Percutaneous transhepatic biliary drainage (PTBD) represents a useful palliative treatment for resolving jaundice. It is indicated as a preoperative or preinterventional decompression procedure, particularly when endoscopic treatment has failed or is not indicated. Preoperative PTBD helps to reduce the incidence of postoperative sepsis, abscess, bleeding, and renal failure. Obviously, urgent PTBD is mandatory in cases of neoplastic biliary obstruction complicated by acute cholangitis (6).

Expandable metallic stents are often used in cases of biliary obstruction caused by an unresectable hilar CCC. Several studies show that the use of metallic stents is able to shorten hospitalization and to improve the quality of survival by lowering significantly the obstruction-related serum bilirubin levels. However, several early (fever, sepsis, bilioma, hemobilia, bile peritonitis, pancreatitis, cholecystitis) or late complications may occur. Late complications such as recurrent symptoms of cholangitis, cholangiohepatic abscess, or jaundice are usually related to stent occlusion by tumor ingrowth, overgrowth, and stent migration. In an attempt to prevent or to delay stent occlusion by tumor ingrowth, covered stents have been used. However, although covered devices impair tumor ingrowth, they cannot prevent neoplastic outgrowth. In addition, the long-term durability of the covered membrane is problematic.

Definition

Carcinoma of the urinary bladder is one of the most common malignant tumors of the urinary tract and represents 2% of all malignancies. It is a disease of later life with a peak incidence during the seventh decade. Bladder cancer is three times more common in men than women and it affects twice as many Whites as Blacks (1). The most well documented risk factor of bladder cancer is cigarette smoking, to which has been attributed up to 45% of urothelial cancers (1). Although difficult to prove with certainty, occupational exposure to β-naphtylamine, paints, oils, gasoline, zinc, chromium, and rubber has been associated with 18–40% of bladder cancer cases. Other risk factors include chronic bladder infection or inflammation, pelvic irradiation, and treatment with cyclophosphamide (1). A genetic propensity to develop bladder cancer has also been observed (1).

Other primary tumors, such as non-Hodgkin's lymphoma and pheochromocytoma are very rare and may arise in the bladder wall. Secondary involvement of the bladder by lymphoma may occur, representing direct spread from grossly involved pelvic lymph nodes. Metastases may also develop within the bladder wall, the extraluminal component being more obvious than the intraluminal mass, providing a clue to the diagnosis in patients with known disseminated disease due to cancers such as malignant melanoma and breast cancer.

Pathology

Most bladder tumors arise from the urothelium. Transitional cell tumors account for 95% of all primary malignant bladder lesions (2). The rest are squamous cell carcinomas, mixed transitional and squamous cell tumors, adenocarcinomas, and undifferentiated lesions

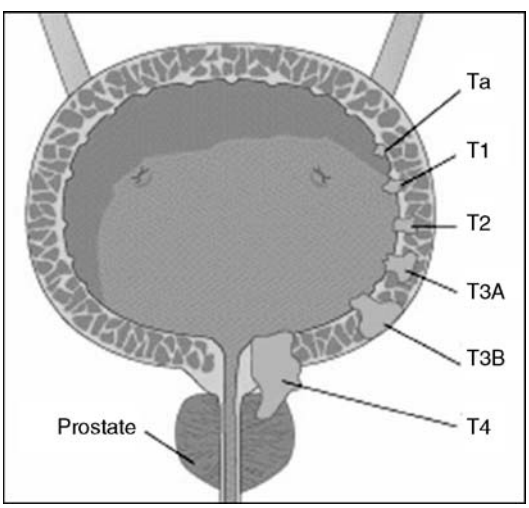
N

(2). Most bladder cancers arise on the lateral walls (47%) or in the region of the trigone (21%). Adenocarcinomas, which account for 3% of all bladder tumors, usually arise in the region of the trigone, but are occasionally seen as exophytic growths arising at the bladder dome and originating from a persistent urachus.

About one-third of cancers are multifocal at the time of diagnosis, and the whole bladder epithelium may undergo malignant change. Recurrences and new tumors are frequent (2). Bladder tumors show a variable pattern of growth and are classified as papillary, infiltrative, papillary and infiltrative, or nonpapillary and noninfiltrative (carcinoma *in situ*). Grade I lesions are well-differentiated tumors and are usually papillary, whereas grade III lesions are poorly differentiated and frequently show an infiltrating pattern of growth. Tumor grade correlates with the natural history of the disease, as those with grade III tumors invading muscle have a significantly worse prognosis than those with grade I or II superficial lesions (1). Approximately one-third of patients present with muscle invasive disease at the time of initial diagnosis (1).

Tumor stage refers to the depth of invasion. The tumor/nodes/metastasis (TNM) staging system is most widely used. Historically, tumors confined to the mucosa (Ta) and lamina propria (T1) have been classified as superficial; muscle invasive tumors are classified as T2-T3. In general, there is a correlation between T-stage and the risk of recurrence, progression, and metastasis.

Once the tumor has penetrated the basement membrane (T1) or muscle (T2-T4), there is an increased likelihood of distant metastases, depending on the depth of penetration (Fig. 1). The tumor may involve adjacent organs (prostate, uterus, vagina, rectum, small intestine) and extend to the pelvic side wall. Transitional cell carcinoma (TCC) of the prostate is present in approximately 40% of men with invasive bladder cancer (1). Coexistent adenocarcinoma of the prostate is present in 40% of men undergoing cystoprostatectomy for invasive TCC (1).



Neoplasms, Bladder. Figure 1 Depth of tumor penetration according to TNM system of staging bladder carcinoma.

Synchronous upper urinary tract urothelial tumors occur in 2–5% of patients (2).

Distant metastasis may occur *via* the lymphatic or vascular systems. The regional lymphatics include the paravesical, obturator, and external iliac lymph nodes. The most common sites of distant metastasis are liver, lung, and bone.

Clinical Presentation

Patients most commonly present with painless ►hematuria, either gross or microscopic. The bleeding may be intermittent, so one should not be lured into a sense of false security by the spontaneous disappearance of bleeding. Irritative voiding symptoms, including frequency, urgency, and dysuria, occur and are often associated with CIS. This constellation of symptoms, however, may also occur with benign entities, such as urinary tract infection, prostatism, and prostatits.

Locally advanced tumors may lead to ureteric obstruction, pelvic side wall muscle invasion, or invasion of adjacent organs. These advanced tumors present with pelvic or abdominal pain and symptoms related to the urinary tract.

Imaging

Excretory Urography

In the past, routine imaging surveillance consisted of periodic excretory urography. In addition, excretory urography was generally performed to examine the upper urinary tract for synchronous tumors, which occur in 2.3% of patients with TCC of the urinary bladder. Excretory urography can also be used to detect other abnormalities such as stones or masses that could account for the patients' hematuria. However, negative findings in excretory urography cannot exclude urothelial cancer.

Computed Tomography

Bladder tumors appear on CT as soft tissue density lesions arising from the bladder wall. The tumor may be sessile or pedunculated, but in some cases the only abnormality seen is thickening of the bladder wall. Tumors enhance following injection of intravenous contrast medium, often to a greater degree than the normal bladder wall.

In the pre-MDCT era, several limitations and difficulties associated with CT staging of bladder cancer have been reported. Review of the literature shows that the accuracy of CT study in the staging of bladder neoplasm has varied between 68 and 85%, and it has been shown that CT has failed in staging early tumors (TIS-T3a). In patients with suspected perivesical spread and more advanced disease, however the usefulness of CT has been reported.

CT has been regarded as inferior to MRI for staging bladder cancer, but as similar in evaluation of extravesical disease.

Multidetector CT offers new possibilities for imaging of the urinary bladder and urinary tract. Using thin collimation, near isotropic imaging of the urinary tract is possible and provides high quality multiplanar reformations and 3D reconstructions of the organ including virtual cystoscopic views.

Since the initial report of Vining et al (3), a growing number of articles on detection of bladder lesions with ►virtual cystoscopy have been published. In general, results of these studies indicated that virtual cystoscopy allows accurate assessment of localization and morphology (pedunculated or sessile) of bladder masses. Additionally, the decrease of post processing time from 6–8 h to a few minutes allows its routine use in the clinical praxis.

Song et al (4) showed that transverse and virtual views are complementary in lesion detection and characterization, and thus should always be used for accurate lesion detection. These authors also recommend that imaging in both positions is necessary for visualization of the entire mucosal surface without obscurity caused by residual urine (4).

Preliminary results of various studies show excellent detection rates, including lesions <5 mm (Fig. 2) and also accurate staging of bladder tumors by combined evaluation of source data and virtual cystoscopy (Figs. 3–5).

At present, virtual cystoscopy based on volumetric data obtained with thin section multislice CT and the use of perspective volume-rendering technique seems to be the most accurate method regarding lesion detection in the urinary bladder.

For virtual ureterorenoscopy i.v. application of contrast media is the only possibility to get sufficient contrast of the excretory system. Negative contrast agents like room air or CO_2 cannot be used in this particular procedure.

Stenzl et al (5) described the usefulness of VE based on CT datasets in imaging of the reconstructed lower urinary tract. 3D reconstruction aided in the interpretation of intraluminal changes, indentations of the pouch wall, voiding problems resulting from a descent of the pouch floor ("pouchocele"), and incisional hernias. Additionally, this series also added to the authors understanding of the postoperative evolution of orthotopic intestinal bladder substitutions (5).

There are still some limitations of virtual cystoscopy. A major limitation is that it is unable to depict flat lesions (carcinoma *in situ*) which appear as subtle mucosal color changes at conventional cystoscopy. In addition, mucosal thickening secondary to fibrosis cannot be distinguished from a neoplasm. Virtual cystoscopy lacks the ability to provide tissue for histologic evaluation.

Magnetic Resonance Imaging

Tumors of the urinary bladder, whether infiltrative, sessile, or pedunculated, can be detected with MR imaging if they exceed 7–8 mm in diameter. Disruption of the muscle layer suggests deep tumor invasion. Immediately after intravenous administration of contrast agent containing gadolinium, tumor, mucosa, and lamina propria show earlier and greater enhancement compared with the muscle layer of the bladder wall or other tissues.

A limitation of MR imaging is the determination of extent of tumor growth in the muscle layer of the bladder wall (differentiation between stages T2 and T3a). However, the use of endorectal surface coils or phased array multicoils in combination with i.v. contrast agents is

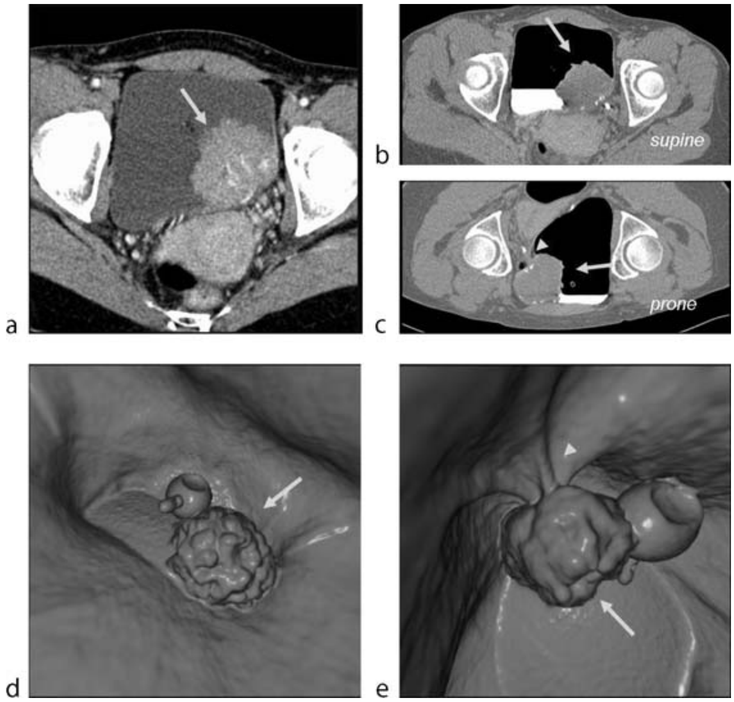
continuing to evolve the role of MR in imaging bladder tumors.

Lämmle et al (6) showed high reliability in the diagnosis of urinary bladder cancer by MR-imaging based virtual cystoscopy. In this study, overall detection rate for bladder tumors was 91%, the detection rate for tumors >1 cm was 100%. Utilizing T2-weighted and Gd-enhanced T1-weighted MR-urography, Beer et al (7) evaluated maximum intensity projection (MIP) and virtual endoscopy in patients with suspected urogenital disease. Results of this study showed that both datasets were equal regarding virtual ureterorenoscopy. For virtual



Neoplasms, Bladder. Figure 5 **Pedunculated bladder carcinoma (*arrow*): Mobility while dual positioning. Stalk (*arrowhead*). No signs of bladder wall infiltration—T1 tumor.**

cystoscopy, T2-weighted datasets were superior to the Gd-enhanced T1-weighted sequences. In addition, 86% of endoluminal diseases were revealed on virtual endoscopy (VE) compared to 15% on MIP images. In renal pelvis evaluation MIP images were superior to VE. Negative contrast agents do not have any role in this setting (7).

Diagnosis

When a clinical diagnosis of bladder tumor is suspected, the initial investigation consists of urine cytology and lower urinary tract endoscopy. The development of flexible cystourethroscopy has allowed diagnostic endoscopy to be performed safely in an office setting with improved patient comfort. It allows thorough endoscopic assessment of the entire urethra, including the prostatic urethra in men, and the entire urinary bladder. Papillary and well-circumscribed bladder tumors are easily recognized. Areas of CIS may appear only as red areas on the mucosa. After endoscopic visualization of a bladder tumor, the histopathologic diagnosis and initial treatment are achieved by transurethral resection (TUR) of the tumor. Complete endoscopic resection of the tumor using a loop diathermy electrode is attempted, unless there is obvious extravesical extension. Areas of abnormal appearing mucosa are biopsied (1).

However, conventional cystoscopy may be limited by diminished visualization of areas such as the mucosa of the bladder neck and within diverticula. In addition, conventional endoscopy proves to be technically very difficult in patients with urinary diversion, and some structures may not even be visualized. Conventional cystoscopy may be invasive, uncomfortable, time consuming, and expensive. In addition, rare complications like iatrogenic injury to the urethra and bladder as well as urinary sepsis may occur. In patients with bacteriuria, acute cystitis, urethritis, prostatitis, obstructive prostatic hypertrophy, and stricture or rupture of the urethra conventional cystoscopy may be contraindicated.

The treatment and prognosis of urinary bladder carcinoma is largely determined by the depth of tumor growth and the extent of tumor metastases (1). Bladder saving treatment is used for superficial tumors (stages Ta-T1), whereas for stage T2-T3b tumors, radical cystectomy is performed. The treatment for stage T4a and T4b tumors and for metastatic disease is usually palliative radiation and chemotherapy, respectively.

The accuracy of the UICC clinical staging which includes deep fractioned TUR is sufficient for superficial tumors. However, the accuracy of clinical staging for stage T2-T4b tumors is poor.

In conclusion, CT- and MR-imaging including virtual endoscopy techniques of the urogenital tract have enormously improved over the past few years. Contributing to this progress is the continuing improvement of MR hard- and software as well as the advent of ▶Multidetector computed tomography (MDCT) and the ability to acquire near isotropic datasets. Commercially available 3D workstations and the rapid evolution of supporting software also fasten the improvement.

Considering the limitations and contraindications of conventional cystoscopy, CT- or MR-imaging including virtual cystoscopy seems to be an alternative in a patient suspected or known to have bladder cancer who is not a candidate for conventional cystoscopy. In addition, these techniques seem to be most appropriate in evaluation of the upper urinary tract. The high accuracy in detection of lesions <5 mm as well as short postprocessing times have tremendously improved the clinical utility of thin section MDCT and virtual cystoscopy and may justify its incorporation into imaging algorithm for evaluation of hematuria. The high degree of accuracy in the depiction of the topographical anatomy of the transposed structures in patients with urinary diversion makes MDCT- and MR-virtual endoscopy unambiguous in this setting.

Benign bone tumors

Definition

Benign bone tumors are true neoplasms that originate from bone.

Pathology/Histopathology

Bone tumors can histologically be classified according to their matrix production and/or predominant cell type. The World Health Organization (WHO) classification of bone tumors includes benign neoplasms categorized as osteogenic tumors (▶osteoid osteoma and ▶osteoblastoma), cartilage tumors (▶osteochondroma, ▶enchondroma, periosteal chondroma, ▶chondroblastoma, and chondromyxoid fibroma), fibrogenic/fibrohistiocytic tumors (desmoplastic fibroma and benign fibrous histiocytoma), vascular tumors (▶hemangioma), lipogenic tumors (▶intraosseous lipoma), and ▶giant cell tumor. Osteoid osteomas, osteochondromas, and enchondromas together account for approximately 20% and giant cell tumors for up to 10% of all primary bone tumors. With the exception of the relatively frequent hemangiomas of the spine, all other benign bone neoplasms are very rare.

A detailed description of the specific histologic features of all lesions mentioned above would go far beyond the scope of this essay.

Clinical Presentation

With the exception of enchondroma, intraosseous lipoma, hemangioma, and giant cell tumor, most benign bone tumors occur in children and young adults. Whereas enchondroma, osteochondroma, lipoma, and hemangioma usually are asymptomatic and therefore are often detected incidentally, osteoid osteoma, osteoblastoma, chondroblastoma, and giant cell tumor cause clinical symptoms in the majority of cases. Pain and swelling are the most common but unspecific complaints. Patients with osteoid osteoma can exhibit more typical clinical features, with pain that becomes more severe at night and promptly responds to analgesics. Pathologic fracture overall represents a rare finding in benign bone tumors, but is relatively frequent in enchondromas of the hand. Osteochondromas can become symptomatic due to compression of adjacent soft tissues, nerves, and vessels.

Table 1 gives an overview on the typical ages of patients, the gender ratios, and the skeletal distribution of the most common benign bone neoplasms.

Neoplasms, Bone, Benign. Table 1 Benign bone tumors: clinical data and skeletal distribution (*LTB* long tubular bones, *STB* short tubular bones)

Tumor	Typical age of patients and gender ratio	Typical sites within skeleton	Typical locations within bone
Osteoid osteoma	1st–3rd decades M:F = 2–4:1	LTB (femur, tibia) > spine > others	LTB: diaphysis > meta-/epiphysis Spine: posterior elements
Osteoblastoma	1st–3rd decades M:F = 2:1	Spine, flat bones, LTB > others	Spine: posterior elements LTB: diaphysis > metaphysis
Enchondroma	3rd–4th decades M:F = 1:1	STB of the hand, LTB (femur, humerus, tibia)	LTB: (dia)metaphyses
Osteochondroma	1st–3rd decades M:F = 2:1	LTB (femur, humerus, tibia) > others	LTB: metaphysis spine: posterior elements
Chondroblastoma	2nd decade M:F = 2–3:1	LTB (humerus, femur, tibia) > others	LTB: epiphysis (epimetaphysis), apophysis
Intraosseous lipoma	3rd–5th decades M:F = 1:1	LTB, calcaneus > others	LTB: metaphysis
Hemangioma	3rd–4th decades M:F = 1:2	Spine, skull > others	Spine: vertebral body
Giant cell tumor	3rd–4th decades M:F = 1:2	LTB > others	LTB: epi/metaphysis spine: vertebral body

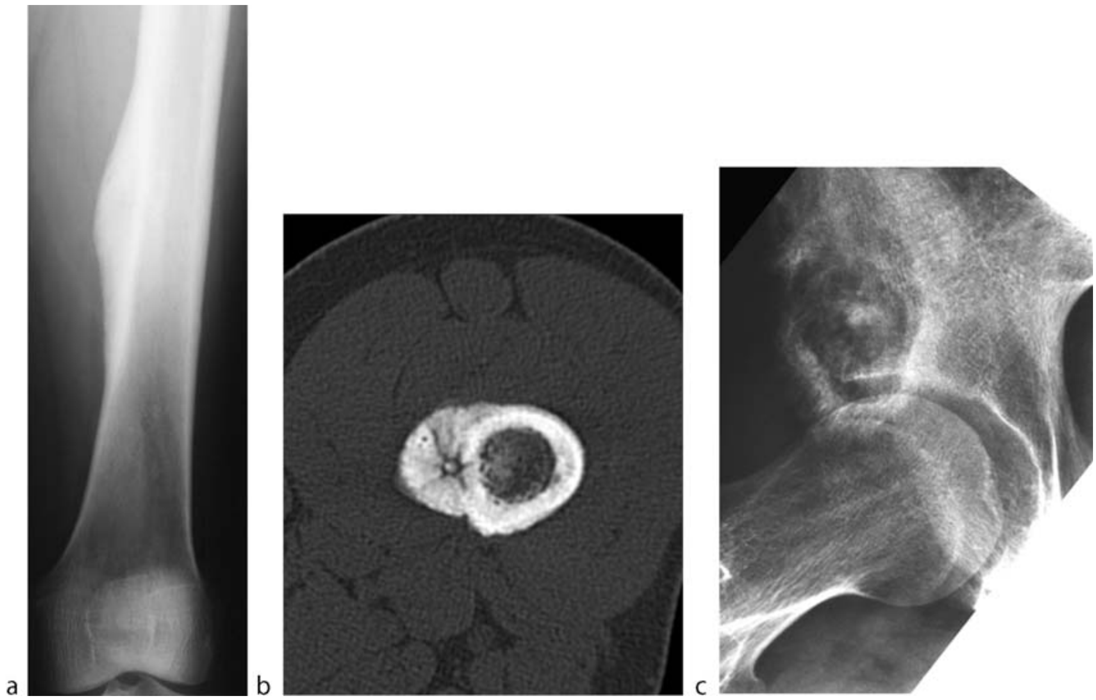
Imaging

Osteoid osteoma (Fig. 1) in cortical locations typically has the radiographic appearance of a round or oval radiolucency of <1.5 cm in diameter (nidus) accompanied by reactive bone sclerosis and a solid periosteal reaction. However, the nidus, which consists of highly vascularized connective tissue with a variable amount of mineralized osteoid, might also be invisible on radiographs. Osteoid osteomas located in the axial skeleton or in small bones and those with a medullary, subperiosteal, or intraarticular localization in long bones are often accompanied by less sclerosis and can present with uncharacteristic or misleading radiographic features. Computed tomography (CT) represents the method of choice in depiction of the nidus and thus in establishing the diagnosis. On magnetic resonance (MR) imaging, the nidus tissue can show various signal intensities depending on its amount of matrix production and mineralization. T2-weighted, STIR, and contrast-enhanced pulse sequences usually show edema of bone marrow and periosteum in the surrounding area of the nidus, which might also extend into adjacent soft tissues. Hypervascularity was demonstrated by angiography in the past, but today can easily be visualized by dynamic CT or MR imaging. The typical arterial enhancement pattern of osteoid osteoma can be used to differentiate the lesion from subacute osteomyelitis.

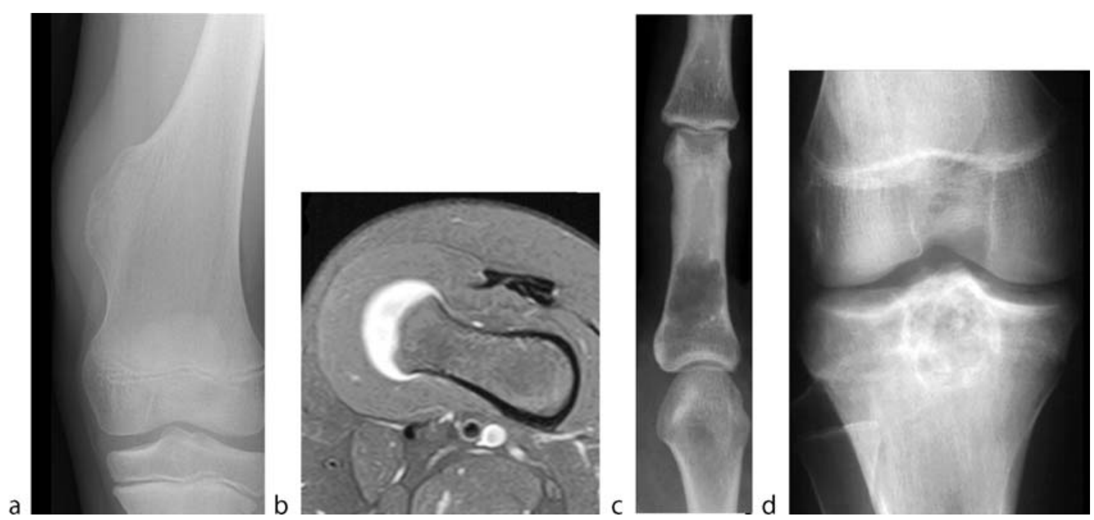
Osteoblastoma (Fig. 1) differs from osteoid osteoma in having a nidus >1.5 cm in diameter and showing a variety of radiographic features. Most lesions originating from the medullary canal or cortex of long tubular bones display a geographic lytic pattern delineated by a sclerotic rim, often in association with expansion of bone and periosteal reactions. However, in most cases the radiographic findings are nondiagnostic. Osteoblastomas of the spine can present as expansile lesions that arise from the posterior elements, most commonly of a thoracic or lumbar vertebra, but they can also be invisible on conventional radiographs. As in osteoid osteoma, CT is therefore the preferred imaging modality for detecting the nidus, assessing the patterns of bone destruction and periosteal reaction, depicting osteogenic matrix mineralizations, and defining tumor extent before surgical resection. MR imaging usually offers more unspecific findings with various signal intensities within the nidus and prominent edema of nearby bone marrow and soft tissues.

Osteochondroma (osteocartilaginous exostosis; Fig. 2) can occur as a solitary lesion or as part of a familial skeletal syndrome with autosomal dominant inheritance, termed hereditary multiple exostoses. Radiographs are usually pathognomonic, as they show one single or multiple sessile or pedunculated osseous excrescenses in continuity with the marrow and cortex of the host bone. The osseous stalk is covered by a cap of hyaline cartilage that might demonstrate calcifications on radiography and that usually ossifies with skeletal maturity.

Malignant transformation into a (low-grade) chondrosarcoma is rare in patients with solitary osteochondroma, but has been reported to occur in 5–25% of patients with multiple lesions. Malignancy should be suspected if the thickness of the cartilage cap exceeds 2 cm



Neoplasms, Bone, Benign. Figure 1 Benign bone neoplasms: osteogenic tumors. (a) and (b) Osteoid osteoma. (a) Anteroposterior radiograph shows circumscribed cortical hyperostosis at the midshaft of the femur. The nidus is hardly visible on radiography. (b) Corresponding computed tomography scan demonstrates centrally mineralized nidus within extensive periosteal new bone formation. Note associated sclerosis of adjacent medullary bone. (c) Osteoblastoma of the ilium. Radiograph shows geographic bone destruction with relatively well-defined margins, incomplete sclerotic rim, and central mineralizations. The cortex is partially destroyed.



Neoplasms, Bone, Benign. Figure 2 Benign bone neoplasms: chondrogenic tumors. (a) and (b) Osteochondroma. (a) Anteroposterior radiograph of the femur shows sessile bony outgrowth arising from the distal metadiaphysis. Note continuity of the cortex and marrow with those of tumor-bearing bone. (b) Corresponding transverse T2-weighted magnetic resonance image with fat suppression demonstrates hyperintense cartilage cap covering the osseous stalk. (c) Enchondroma. Radiograph of the third finger shows centrally located, lobulated lucency with endosteal scalloping of the cortex within the proximal phalanx. (d) Chondroblastoma. Anteroposterior radiograph demonstrates round osteolytic lesion with sclerotic rim and central mineralizations in the proximal epimetaphysis of the tibia.

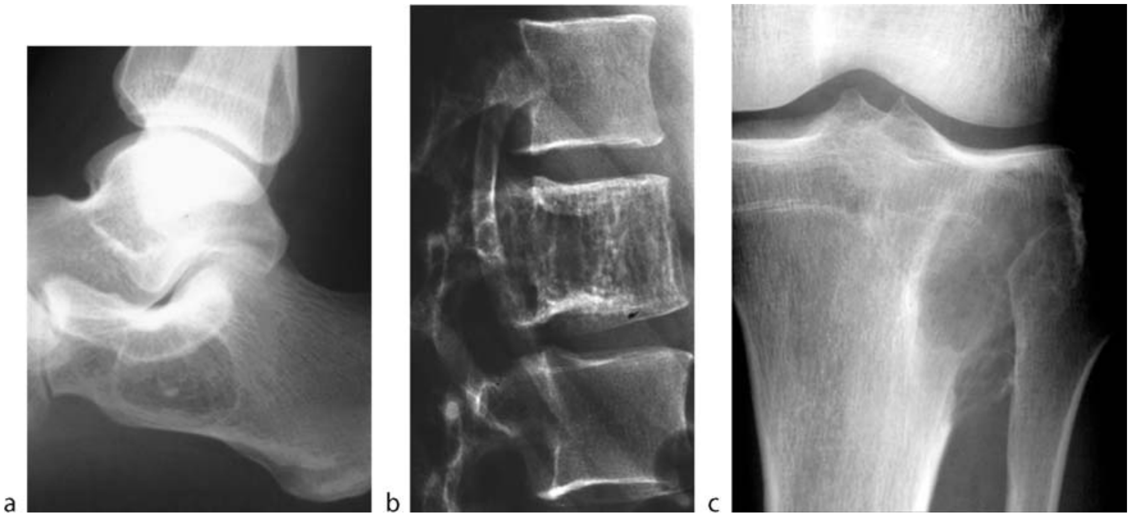
in adults and 3 cm in children. MR imaging with the use of T2-weighted pulse sequences represents the most reliable method to assess cartilage cap thickness, whereas CT shows a tendency for underestimation, and ultrasound can be limited by the anatomic localization and orientation of the osteochondroma.

Enchondroma (Fig. 2) of long tubular bones typically presents as a centrally located oval radiolucency with a sharply delineated and lobulated contour, various degrees of endosteal scalloping, and cartilaginous matrix mineralizations. Punctate, flocculent, or rings-and-arcs-like calicifications/ossifications represent characteristic mineralization patterns that usually allow for the radiographic diagnosis. Lesions located in the short tubular bones of the hand more often appear purely osteolytic, with more pronounced endosteal erosion or even expansion of bone. Epiphyseal or axial location, a lesion size >5–6 cm, periosteal reactions, cortical thickening, deep endosteal erosion (more than two-thirds of cortical thickness) or expansion of a major bone, cortical penetration, and enlargement of a radiolucency over time are findings that should alert to the differential diagnosis of chondrosarcoma. In this regard, CT represents the most valuable imaging method because it is best suited to assess the integrity of the cortex. On MR imaging, enchondromas reveal the typical morphology of a well-differentiated cartilaginous lesion with low signal intensity on T1-weighted images, very high signal intensity on T2-weighted images, and peripheral/septal enhancement following contrast administration ("rings and arcs"). However, compared with CT, MR imaging is less reliable in depicting cortical alterations.

Chondroblastoma (Fig. 2) in typical cases shows the radiographic appearance of a round osteolytic lesion with thin sclerotic borders, which is eccentrically positioned within the epiphysis of the affected bone. Approximately 50% of chondroblastomas show matrix mineralizations that are detectable on conventional radiographs. Solid or lamellated periosteal reactions might be visible at the metaphysis or the diametaphyseal shaft. On MR images, chondroblastomas often show more inhomogeneous signal and a less typical enhancement pattern than other benign cartilaginous lesions. Furthermore, the lesions often cause edema of adjacent bone marrow and reactive synovitis.

Intraosseous lipoma (Fig. 3) usually presents as a nonaggressive radiolucent lesion surrounded by a thin sclerotic margin. Trabeculations and osseous expansion might be evident. Central calcifications or ossifications due to liponecrosis are seen in many cases. Particularly in the proximal femur and the calcaneus, this radiographic appearance is virtually pathognomonic. CT and MR imaging can both be used to verify the lipomatous character of the lesion. Cystic areas, calcifications, and new bone formation are additional findings in lesions with partial or extensive fat necrosis (stages 2 and 3 lipomas).

Hemangiomas (Fig. 3) of the spine usually involve the vertebral body and produce a coarse, vertically oriented trabecular pattern on radiography. On transverse CT or MR images, these thickened trabeculae are seen as



Neoplasms, Bone, Benign. Figure 3 Benign bone neoplasms; miscellaneous lesions. (a) Intraosseous lipoma: lateral radiograph shows the pathognomonic appearance of a calcaneal lipoma with delicate sclerotic margin and central mineralization. (b) Hemangioma: lateral radiograph shows rarefication the of bone structure of the first lumbar vertebra with a vertical trabecular pattern. Note extension into the pedicles. (c) Giant cell tumor: anteroposterior radiograph demonstrates a purely osteolytic lesion with eccentric localization in the proximal epimetaphysis of the tibia. The tumor shows well-defined intraosseous borders and destruction of the cortex with formation of a slightly expanded, incomplete neocortex.

multiple punctate areas within the matrix of the hemangioma, termed polka-dot appearance. At extraspinal sites, hemangiomas show more variable radiographic features, although lytic lesions with slight expansion and a radiating, lattice-like or honeycomb trabecular pattern a highly suggestive of the diagnosis. Particularly in anatomically complex areas, CT can be helpful in identifying these features. The MR imaging appearance of hemangiomas varies with its composition of vascular and nonvascular components. Lesions with a predominantly fatty matrix show high signal intensity on T1-weighted images, intermediate to high signal intensity on T2-weighted images, and a loss of signal on STIR or fat-suppressed T2-weighted images. Predominance of the vascular component results in hypointensity on T1-weighted images, hyperintensity on STIR and T2-weighted images, and marked contrast enhancement.

Giant cell tumor (Fig. 3) typically arises as a purely osteolytic lesion with relatively well-defined margins, which in most cases lack a sclerotic rim. In long tubular bone, the majority of lesions show eccentric location within the epimetaphysel region and variable degrees of cortical violation without a significant periosteal reaction. MR imaging is best suited to demonstrate the true extent of giant cell tumors, particularly with a view to extraosseous growth, which is observed in more than 30% of cases. Many giant cell tumors arise with more or less low signal intensity on T1- as well as T2-weighted MR images, a feature that has been attributed to the presence of hemosiderin deposits and/or high collagen content. Contrast enhancement is usually marked and diffuse, except in cystic areas that might develop following hemorrhage or due to formation of a secondary aneurysmal bone cyst.

Nuclear Medicine

In general, skeletal scintigraphy does not play a major role in the diagnosis of benign bone tumors. Enchondroma, intraosseous lipoma, and hemangioma can represent incidental findings on examinations with bone-seeking agents. The double-density sign is a relatively typical scintigraphic finding in patients with osteoid osteoma. The term describes a hot spot representing the nidus surrounded by an area of less increased uptake, which corresponds with the reactive zone of sclerosis.

Diagnosis

Osteoid osteoma, osteochondroma, enchondroma, intraosseous lipoma, and hemangioma can usually be sufficiently diagnosed by imaging and require histologic verification only in doubtful cases. Osteoblastoma, chondroblastoma, and giant cell tumor should undergo biopsy, and both radiologic and histologic findings have to be considered together to establish the final diagnosis.

Definition

Primary malignant bone neoplasms/tumours arise from the osseous tissues (e.g. ▶osteosarcoma) or the bone marrow tissues (e.g. myeloma). They tend to be locally aggressive causing bone destruction and have the propensity to develop metastases to distant organs—typically the lungs.

Pathology/Histopathology

Bone tumours are classified according to their tissue of origin and then into benign (see Neoplasms, bone, benign) and malignant subtypes (Table 1) (1). The incidence is less than one new case per 100,000 population per year. This compares with an incidence for tuberculosis in the developed world of approximately one per 10,000 population per year. The management and prognosis for a sarcoma depends on the histological grade. The higher the

grade, the increased likelihood after surgery of developing local recurrence and metastatic disease. In general, higher grade lesions show increased cellularity, nuclear enlargement and hyperchromasia, mitotic figures and necrosis. It is important to stress that bone tumour pathology is far from straightforward. Close radiological–histological correlation is important as a small biopsy may not show representative tissue (sampling error) or fail to reveal the highest grade component of the lesion. A multi-disciplinary approach to diagnosis is recommended and both biopsy and pathological assessment is best carried out in specialist centres (2).

Clinical Presentation

Primary bone malignancies, with the exception of chondrosarcoma and myeloma, develop in children, adolescents or young adults. Pain and swelling in an otherwise fit individual are the cardinal signs. Frequently, tumours, particularly around the knee, may be mistaken for athletic injuries. The pain generally increases in severity and is typically non-mechanical in nature. Central lesions developing from the pelvis or shoulder girdle tend to present later than extremity lesions due to the relative size of the normal to neoplastic tissues. Occasionally, the tumour may present with a pathological fracture although this is more commonly seen with benign lytic bone tumours such as the simple bone cyst. Ewing's sarcoma may present with fever, fatigue and a raised serum white cell count suggestive of osteomyelitis.

Imaging

Despite newer imaging techniques, the radiograph is the preliminary and single most important imaging investigation. Early signs of a bone sarcoma and/or osteomyelitis include areas of ill-defined lysis of sclerosis of bone, periosteal new bone formation and soft tissue swelling (Fig. 1). In time, cortical destruction will occur with evidence of a soft tissue mass. The pathological process may be well established even in the presence of a normal radiograph. Up to 50% of trabecular bone must be destroyed before a discrete area of lucency can be seen radiographically. Erosion or destruction of the cortex is more readily seen. Once a bony abnormality has been detected, the next objective of imaging is to attempt to characterize the lesion and, in doing so, indicate an appropriate differential diagnosis. Subsequent imaging is directed at surgical staging if the lesion is considered likely to be a sarcoma (see later).

Diagnosis

When faced with a radiograph of a potential bone sarcoma it is essential to know the age of the patient and whether there is an evidence of pre-existing bone lesions which might pre-dispose to malignant transformation (Table 2). The next important factor to note is the site of origin in the skeleton and which part of the bone is involved. Most bone tumours, benign and malignant, occur around the knee and as such little diagnostic information can be deduced by noting the affected bone in these cases. There are exceptions. Cartilage tumours of the hands and feet are common and usually benign. Adamantinoma, a low-grade sarcoma, classically involves the diaphysis of the tibia and is extremely rare at any other site. Chordoma characteristically arises from the clivus or sacrum. Both the longitudinal and transverse origin of the tumour should be noted. Malignancy is particularly rare in the epiphysis pre-skeletal fusion. Most osteosarcomas

Giant cell tumour	

are metaphyseal in origin whereas Ewing's sarcoma may be metaphyseal or diaphyseal (Figs 1 and 2). Most of the malignant tumours arising on the surface of bone are the rarer forms of osteosarcoma, for example, parosteal, periosteal and high-grade surface osteosarcoma. Approximately 50% of parosteal osteosarcoma arises on the posterior surface of the distal femoral metaphysis (Fig. 3).

The radiographs of the tumour should then be analyzed to assess the biological activity of the lesion.

Neoplasms, Bone, Malignant. Figure 3 Parosteal osteosarcoma arising at the classic site on the posterior aspect of the distal femur. The tumour osteoid is indicated by the density of the lesion.

Aggressive features such as permeative or motheaten bone destruction and a complex ▶periosteal reaction (Codman angle, hair-on-end/spicculated+/−interrupted) will suggest in a young patient a sarcoma (Figs 1 and 2). Matrix minetralization, if present may help indicate whether the

Neoplasms, Bone, Malignant. Figure 4 Central chondrosarcoma femur. The cartilage matrix is indicated by the stippled/popcorn calcification.

lesion is bone-forming (osteogenic) or cartilage-forming. Tumor osteoid is typified by solid (sharp-edged) or cloud to ivory-like (ill-defined edge) patterns (Fig. 3). Tumour cartilage is variously described as stippled, flocculent, ring-and-arc and popcorn in appearance (Fig. 4). Identifying the pattern of matrix calcification will significantly reduce the differential diagnosis, but matrix *per se* has no influence as to whether the lesion is benign or malignant. It is necessary to combine the analysis of the aggressive features and the matrix mineralization to deduce the likely nature of the sarcoma. In a minority of cases both CT and MRI may contribute to establishing the imaging diagnosis. Both are sensitive to subtle cortical breaching and soft tissue extension that are early signs of a sarcoma. Faint mineralization is also more readily appreciated on CT. Fluid–fluid levels are well demonstrated on both CT and MRI and are seen in a large number of different bone lesions. In the immature skeleton with the appropriate radiographic appearances, fluid–fluid levels are most commonly seen in aneurysmal bone cysts. The most important differential diagnosis in this situation is telangiectatic osteosarcoma, which frequently contains fluid–fluid levels.

Staging, Biopsy and Follow-Up

The surgical staging system most commonly used for bone sarcomas is that adopted by the Musculoskeletal Tumor Society (3). This assigns one of three grades according to the local extent of the tumour (assessed using MRI), presence or absence of metastases (assessed using whole-body bone scintigraphy and chest CT) and the histological grade (assessed on the biopsy and re-evaluated following surgical excision). The MRI scan will accurately identify the extent of the tumour in the bone, confirming or excluding skip metastases, extent in soft tissue and relationship to the adjacent neurovascular bundle and joint (Fig. 5). The sensitivity of chest CT has been improved with the introduction of multi-slice technology. Overstaging is a potential hazard as up to 70% of solitary nodules less than 5mm in diameter at initial presentation in children with solid extra-thoracic tumours are benign (4). Bone scintigraphy, or alternatively whole-body MRI is used to exclude skeletal metastases. Both osteosarcoma and Ewing's sarcoma may present with multi-focal bone lesions. Staging studies are preferably performed before biopsy as they may indicate the optimum site to biopsy and the trauma of the procedure may exaggerate the apparent extent of the lesion. Needle biopsy under fluoroscopic control will usually suffice in most cases. CT-guided biopsy may be helpful when the lesion is small or relatively inaccessible e.g. pelvic or spinal tumours. Most patients with a biopsy-proven bone sarcoma will undergo adjuvant chemotherapy before undergoing definitive surgery. The exception is chondrosarcoma that is not sensitive to chemotherapy or radiotherapy. Staging studies are repeated prior to surgery to assess the effect of chemotherapy. The preferred technique to assess response is MRI. In Ewing's sarcoma, obliteration of the extra-osseous component usually indicates a good response. In osteosarcoma, a dynamic contrast-enhanced sequence is required with a scan temporal resolution of no greater than 3 sec. Comparison of time intensity curves obtained pre- and post-chemotherapy gives a reliable indication of tumour response. As a general rule in bone sarcomas a good response to chemotherapy (as indicated by >90% tumour necrosis) is associated with an improved prognosis. Definitive surgery requires wide excision of the sarcoma and replacement of the affected bone with a prosthesis or an allograft. After surgery, follow-up imaging protocols concentrate on identifying development of local recurrence and distant metastases. This involves chest radiographs at regular intervals (3 monthly for 2 years, 6 monthly for the next 3 years and thereafter annually). If the chest radiograph is suspicious of metastatic disease a chest CT is performed. There is some evidence that resection of one or several pulmonary metastases are associated with prolonged survival. Clearly, multiple bilateral pulmonary metastases are not amenable to surgery. If there is clinical suspicion of local recurrence then an MRI scan should be performed. A gadolinium chelate may have to be administered to help distinguish an enhancing local recurrence from a post-operative seroma.

Definition

These extracerebral tumors are usually benign. The location of a brain tumor affects treatment planning and predicts the tumor's prognosis. ▶Meningiomas are the most common extraaxial neoplasms in the supratentorial compartment. Other extraaxial neoplasms are schwannomas, metastatic lesions, arachnoid cysts, epidermoids, dermoids, and bone neoplasms.

Pathology/Histopathology

Meningiomas are well-circumscribed globular or lobulated ▶dural-based tumors, clearly demarcated from the brain. Histologically, meningothelial, fibrous, and transitional meningiomas are the most commonly found forms. Although psammoma bodies are often found in meningiomas, when abundant, they characterize the tumor as ▶psammomatous meningioma. Less commonly found subtypes are angiomatous, microcystic, and secretory meningiomas. The above-described subtypes are grade I by World Health Organization (WHO) classification. In contrast, the WHO grade II (chordoid, clear cell, and atypical) meningiomas and especially the WHO grade III (papillary, rhabdoid, and anaplastic) meningiomas are more aggressive, with a higher risk for recurrence.

Schwannomas are benign slow-growing tumors that can arise from any nerve containing Schwann cells, including distal portions of the cranial nerves. Macroscopically these are encapsulated, well-circumscribed tumors and are more often globular than fusiform in configuration. Microscopically, two patterns can be distinguished, according to the morphology of the tumor cells and their spatial arrangements: Antoni A, with a compact texture, and Antoni B, with intratumoral cysts.

Metastases on macroscopic examination often appear discolored, rounded, firm, and well demarcated. Certain metastatic tumors such as melanomas tend to bleed, forming frank hematomas. Calcifications appear rarely in metastatic brain tumors. Edema is commonly found in the brain parenchyma adjacent to the tumor. Metastatic lesions to the leptomeninges appear as focal areas of abnormal meningeal thickening on the surface of the brain. Microscopically, metastatic tumors tend to exhibit histologic features similar to those in their primary sites. In poorly differentiated tumors, specific immunohistochemical markers are used to characterize them.

Arachnoid cysts are congenital cysts filled with cerebrospinal fluid (CSF) and are produced by splitting of the arachnoid membrane. *Epidermoids* and *dermoids* are considered by some to represent a continuum of ectodermally derived cystic epithelial congenital lesions. Both types of cysts are lined with stratified squamous epithelium, with dermoids adding mesodermal elements such as hair and sebaceous and sweat glands.

The most common of the *primary bone tumors* of the skull are chordoma, chondrosarcoma, eosinophilic granuloma, and plasma cell myeloma. *Chordoma* is a benign, slow-growing neoplasm arising from notochordal remnants. About one-third of all chordomas occur in the sphenooccipital region. They involve the clivus and extend through the dura into the middle or posterior cranial fossa. *Chondrosarcoma* is a malignant tumor arising from cartilage or embryonal rest of the skull. *Eosinophilic granuloma* belongs to the Langerhans cell histiocytosis. The skull is one of the most common sites of involvement. This tumor is a destructive osseous lesion characterized by a vast number of eosinophils and histiocytes. *Plasma cell myeloma* is a malignant disease of plasma cells that usually originates in the bone marrow of the skull.

Clinical Presentation

The presenting signs and symptoms of the extraaxial brain tumors are related to the tumor's type, location, and size. They are often nonspecific and vague and are primarily related to brain compression and edema from the adjacent neoplasm.

Meningiomas produce signs of increased intracranial pressure (nausea, headache, vomiting) in 50% of patients. Confusion, focal weakness, and seizures are the most common symptoms, while paresis is the most frequently found physical sign. Normal physical examination has been reported in 26% of patients.

In *schwannomas*, the symptoms depend on which cranial nerve is involved. Tinnitus, sensorineural hearing loss, and disequilibrium are the most common symptoms of acoustic schwannomas. In trigeminal schwannomas, pain, paresthesias, and masticatory muscle weakness are the most common symptoms, while paresis is the most common symptom in facial nerve schwannomas.

Metastases during the early stages of the disease are usually asymptomatic. As the tumor enlarges, edema develops, and neurological symptoms appear.

Arachnoid cysts are usually asymptomatic. In *epidermoids* and *dermoids*, the symptomatic onset is generally slow, lasting years or more. Rupture of these lesions can produce aseptic meningitis, which can be lethal.

Primary bone tumors may cause pain, cranial nerve deficits, and compression of the brain stem.

Imaging

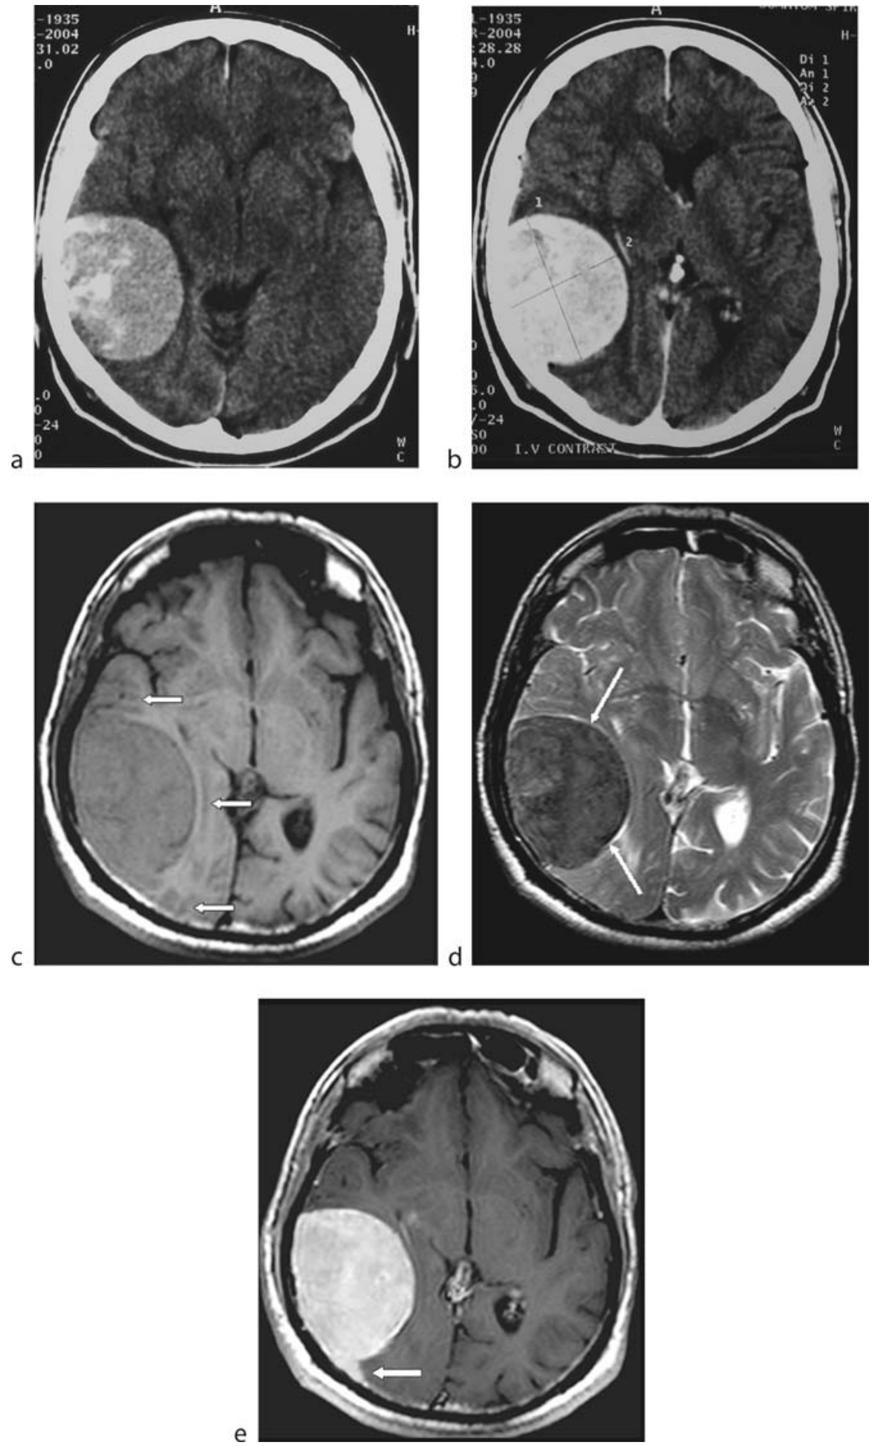
Meningiomas. On plain radiographs, hyperostosis and, rarely, bone erosion may be seen (en plaque).

On noncontrast computed tomography (NCCT), meningioma appears as a unilobular, homogeneous, high-density mass in association with brain parenchyma (Fig. 1a). The hyperdensity on NCCT has been attributed to compact and dense cellularity with a relatively small amount of intercellular water and in part to the presence of calcified psammoma bodies within the tumor. Calcification is seen on CT in 20–27% of meningiomas. It is usually microscopic or punctuated but may be large, conglomerate, peripheral, or central. Among the histological subtypes, transitional and fibroblastic meningiomas most frequently show visible calcium deposits on CT, with an incidence of 39%. After administration of contrast material, approximately 72–80% show intense and homogeneous contrast enhancement (Fig. 1b).

On magnetic resonance imaging (MRI), meningiomas are seen as peripheral unilobular masses with broad-based dural attachments and smooth, well-defined borders. On T1-weighted images, meningiomas are usually isointense or mildly hypointense to normal gray matter (Fig. 1c).

Although the signal intensity on T2-weighted images varies, most tumors are reported to be isointense to mildly hyper- or hypointense compared with gray matter (Fig. 1d).

Nearly all meningiomas enhance rapidly and intensely following contrast administration (Fig. 1e). The wide variation of signal intensity among meningiomas reflects the diversity of their histopathology. Meningiomas hyperintense to the cortex on T2-weighted images are more frequently of syncytial or angiomatous subtype. Tumors



Neoplasms, Brain, Extraaxial. Figure 1 **Right inferior temporoparietal meningioma. (a) Axial noncontrast computed tomography (CT) shows a hyperdense mass with dense calcified foci. (b) Postcontrast CT shows intense and homogeneous enhancement. (c) Axial T1-weighted image shows an isointense mass to the gray matter compressing the adjacent cortical convolutions (*arrows*). (d) Axial T2-weighted image demonstrates a slightly hypointense mass. Note the cerebrospinal fluid cleft between the tumor and the brain parenchyma (*arrows*). (e) The tumor enhances strongly and homogeneously after the administration of contrast medium. Note the enhanced dura (dural tail sign, *arrow*).**

hypointense on T2-weighted images are more frequently of fibroblastic or transitional subtype.

Once a tumor is suspected, the intraaxial or extraaxial location should be confirmed. Useful MRI features confirming the extraaxial location of a tumor are white matter buckling, the dural tail sign, presence of the signal void pseudocapsule, and a CSF cleft.

White matter buckling is the inward bowing of the gray-white junction of the adjacent brain parenchyma (Fig. 1c). The dural tail sign is a linear enhancement along the dura mater on either side of the meningioma on contrast-enhanced MRI and is considered an important finding in the diagnosis of meningioma (Fig. 1e). This sign is not specific to meningioma but is observed in other conditions, including glioma, brain metastasis, acoustic neuroma, lymphoma, adenoid cystic carcinoma, sarcoidosis, and aneurysm. The signal void pseudocapsule consists of a linear signal void representing the dura itself, interposed between the tumor and the brain parenchyma. A CSF cleft represents CSF trapped between the cortex and the meningioma, which demonstrates low-signal intensity on T1-weighted images and high-signal intensity on T2-weighted images (Fig. 1d).

Other MRI features seen in meningiomas are peritumoral edema, cystic changes, lipomatous transformation, intracranial hemorrhage, poorly defined margins, cavernous sinus involvement, and focal or diffuse irregular contour. Venous sinus invasion may be seen in parasagittal meningiomas that are better depicted on MR venous angiography.

On diffusion-weighted imaging, meningiomas may show variable appearance, while the apparent diffusion coefficient was not indicative of malignancy, grade, or histologic subtype. On perfusion MRI, the meningiomas are hyperperfused. In MR spectroscopy, they are characterized by the presence of alanine, low creatine and N-acetyl-aspartate, high choline and glutamine, and the absence or low quantities of lipids.

Angiography shows a vascular tumor, usually supplied from meningeal branches arising from the external carotid artery with dense homogeneous tumor blush in the late arterial and capillary phase.

Schwannomas on CT appear isodense or slightly hypodense, and on MRI they are isointense to hypointense on T1-weighted images and hyperintense on T2-weighted images (Fig. 2). After the administration of contrast medium, they show intense enhancement. Cystic degenerations are common. The main differential diagnosis of acoustic schwannoma is cerebellopontine angle meningioma (Table 1).

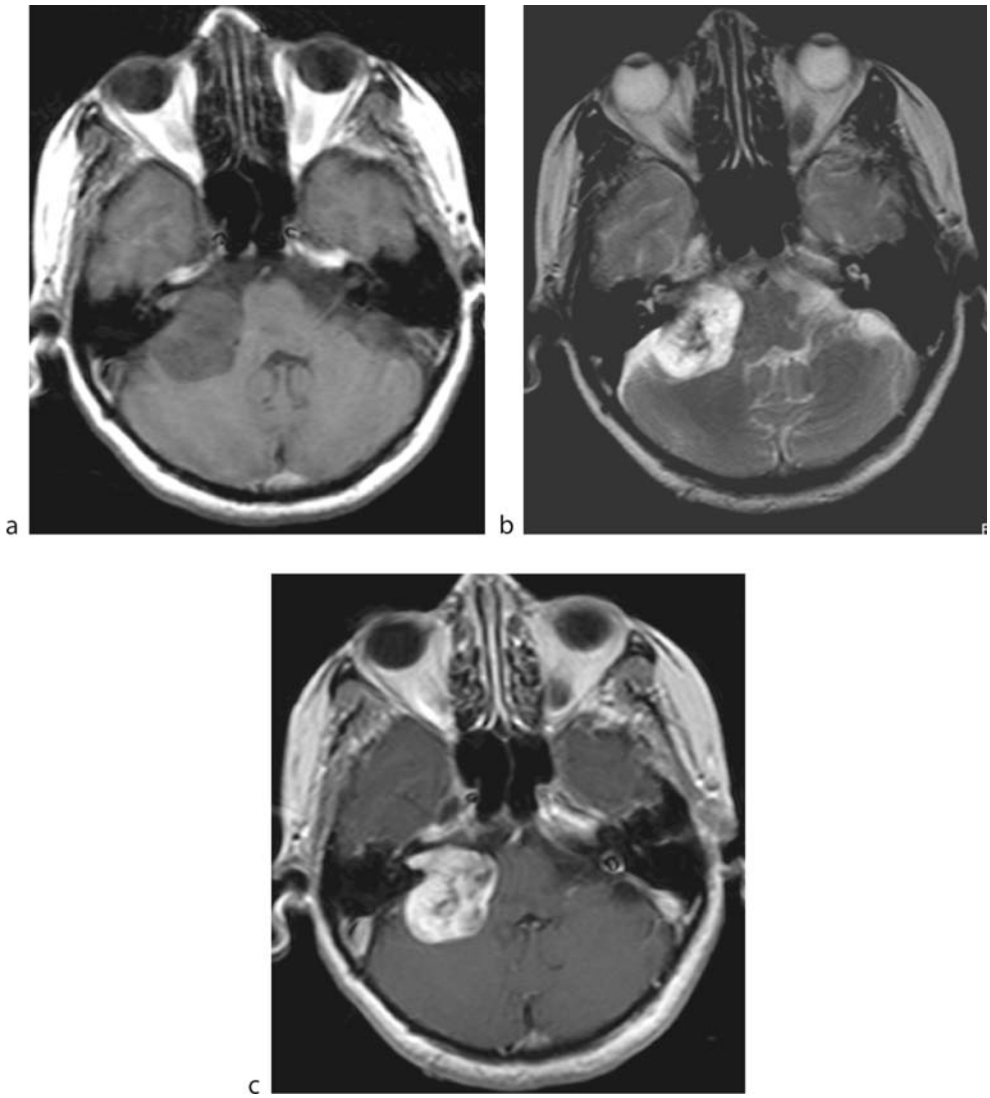
Metastases in the calvarium appear on plain radiographs as osteolytic or osteosclerotic lesions. CT is very sensitive in detecting calvarial metastases. Contrast-enhanced MRI is used to detect subtle intradiploic lesions and to determine extension of the metastatic lesion of the calvarium into the epidural space with involvement of the underlying dura or brain. Dural metastases usually occur as an extension of the tumor to the dura from the adjacent calvarial metastases. Occasionally, dural metastases may occur without associated bony involvement. The most common primary tumors associated with dural metastases are those of breast, lung, and prostate; melanoma; and neuroblastoma. Lymphoma and leukemia are other common tumors. Postcontrast T1-weighted MRI is more sensitive in depicting meningeal involvement (Fig. 3a). Leptomeningeal metastases or meningeal carcinomatosis is usually the result of hematogenous spread from extracranial malignancies. Leptomeningeal metastases present on postcontrast T1-weighted and fluid-attenuated inversion recovery (FLAIR) studies with increased enhancement in the subarachnoid spaces of the cortical sulci, the fissures, and the cisterns (Fig. 3b). A major drawback in the diagnosis of meningeal carcinomatosis by either CT or MRI is that the changes described above lack specificity and may also be seen in inflammatory or infectious pathology.

Arachnoid cysts show density on CT similar to that of CSF. Scalloping of the adjacent calvarium is often present. They are well defined, with no calcification and no enhancement. On MRI, arachnoid cysts show CSF signal intensity on all pulse sequences.

Epidermoids appear on CT as hypodense masses with irregular borders and rare contrast enhancement. Dense lesions have been reported, and calcification is occasionally seen. On MRI, they typically have low signal on T1-weighted images and increased signal on T2-weighted images, following that of CSF on all pulsing sequences. They can demonstrate increased signal on T1-weighted images because of a high lipid content. Epidermoid and arachnoid cysts can also be discriminated on the basis of diffusion-weighted images. Conventional spin echo imaging shows both long T1 and T2 images. On diffusion-weighted images, epidermoid cysts show high signal intensity because of restricted motion of protons by the presence of membranes of densely layered epithelium.

The CT appearance of *dermoids* is similar to that of epidermoids. Their MR appearance depends on the amount of fat present, although they generally have increased signal on both T1- and T2-weighted images. CT and MRI can both allow the diagnosis of rupture.

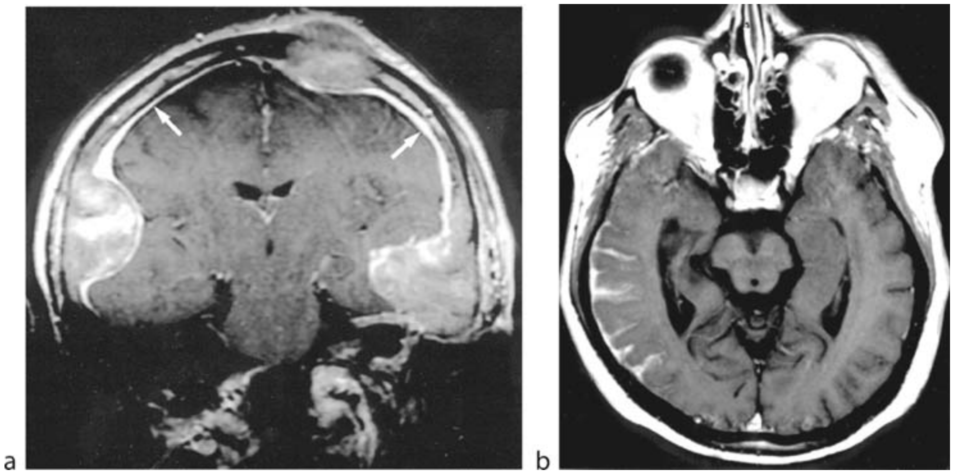
CT of *bone tumors* clearly demonstrates the mass and the bony component of the tumor. MRI better depicts the extent of the lesion and its relationship to adjacent structures.



Neoplasms, Brain, Extraaxial. Figure 2 **Right vestibulocochlear schwannoma. (a) Axial T1-weighted image shows a hypointense mass compressing the adjacent cerebellum. (b) Axial T2-weighted image shows a well-demarcated, heterogeneously hyperintense mass. (c) Postcontrast T1-weighted image shows intense heterogeneous enhancement of the mass extending into the right internal auditory canal.**

Neoplasms, Brain, Extraaxial. Table 1 **Radiological differential diagnosis between schwannoma and meningioma in the cerebellopontine angle (internal auditory canal, *IAC*)**

	Schwannoma	Meningioma
Intracanalicular component	Almost always (95%)	Rare
Centered around the IAC	Yes	No, eccentric
Calcifications	No	Possible
Necrotic/cystic parts	Frequent	Rare
Dural tail sign	Possible	Possible
Secondary arachnoid cyst	Possible in large tumors	No
Influence on the bone	Enlargement of the IAC	Hyperostosis, enostosis, invasion
Supratentorial extension	No	Possible
Contact with facies posterior	Sharp angle	Broad-based contact



Neoplasms, Brain, Extraaxial. Figure 3 Meningeal carcinomatosis. (a) Coronal postcontrast T1-weighted magnetic resonance imaging (MRI) of the brain in a patient with metastatic prostate carcinoma. Three destructive metastatic lesions are seen in the skull. Associated soft tissue tumors are also present extending into the epidural space and compressing the brain parenchyma. The abnormal enhancement of the dura (*arrows*) represents tumor invasion. (b) Postcontrast T1-weighted MRI of the brain in a patient with metastatic breast carcinoma. There is evidence of meningeal carcinomatosis manifested by abnormal enhancement of the leptomeninges over the convexity of the right cerebral hemisphere.

Synonym

Intra-axial brain tumors

Definition

Intra-axial brain tumors are intracranial tumors arising from the neurons, supporting glial cells (astrocytes, oligodendrocytes, ependymal cells), lymphatic tissue, or blood vessels of the brain or from spread of cancers primarily located in other organs (metastases). Intra-axial neoplasms account for more then 75% of all intracranial tumors.

Pathology/Histopathology

The histological classification of brain tumors was defined by the World Health Organization in 1993 and revised in 2000. Primary neuronal tumors (e.g., gangliocytoma, central neurocytoma) are extremely rare. Most primary brain tumors originate from glia and are called gliomas with reference to their cell of origin: astrocytes (astrocytomas), oligodendrocytes (oligodendrogliomas), or ependymal cells (ependymoma). There are also mixed forms, called mixed gliomas or oligoastrocytomas. Additionally, mixed glioneuronal tumors can also be encountered (tumors displaying a neuronal as well as a glial component, for example, gangliogliomas, dysembryoplastic neuroepithelial tumors).

Other varieties of primary brain tumors include: primitive neuroectodermal tumors (PNET, for example, medulloblastoma, medulloepithelioma, neuroblastoma, retinoblastoma, ependymoblastoma), tumors of the pineal parenchyma (e.g., pineocytoma, pineoblastoma), choroid plexus tumors, and others.

From a histological perspective, astrocytomas, oligodendrogliomas, and oligoastrocytomas are benign but are diffusely infiltrating so that neurosurgical removal is not possible. They have a high tendency for anaplastic transformation. Glioblastoma multiforme represents the most aggressive variety of malignant glioma. At the opposite end of the spectrum are the more circumscribed astrocytomas, the pilocytic astrocytomas. The majority are located in the posterior cranial fossa, affect mainly children and young adults, and have a clinically favorable course and prognosis.

Another type of primary intracranial tumor is primary cerebral lymphoma, also known as primary central nervous system lymphoma, which is a type of non-Hodgkin's lymphoma that is much more prevalent in those with severe immunosuppression, for example, AIDS.

Primary brain tumors rarely metastasize, but rather they spread in the spinal canal through the cerebrospinal fluid.

The most frequent types of metastatic brain tumors originate in the lung, skin (malignant melanoma), kidney (hypernephroma), breast (breast carcinoma), and colon (colon carcinoma).

Clinical Presentation

The most frequent general signs and symptoms are seizures, headache, or behavioral changes. Other symptoms relate to the location of the tumor: progressive loss of power or sensation in a limb, imbalance, visual problems, and cranial nerve deficits. Large tumors can cause hydrocephalus with signs of intracranial hypertension.

Imaging

Imaging of brain tumors is done with computed tomography (CT) or magnetic resonance imaging (MRI) before and after intravenous injection of contrast media. Contrast enhancement reflects breakdown of the blood–brain barrier (BBB) rather than an estimation of the vascularity. Advantages of MRI are the absence of ionizing radiation, a higher sensitivity for pathology, easy multiplanar imaging without repositioning of the patient, fewer contrast media reactions, and less toxicity. Moreover, MRI includes more advanced imaging techniques, such as diffusion imaging, diffusion tensor imaging, perfusion imaging, and spectroscopy.

The goals for imaging are: detection (is there a mass lesion?), diagnosis, and differential diagnosis (which kind of tumor is it? is it a tumor, an abscess, a cavernoma, an MS plaque?), grading (is the lesion benign or malignant?), preoperative set-up (extension of the lesion?), and follow-up (is there residual or relapsing tumor? is there radionecrosis?).

Based on published series, some images are almost pathognomonic: pilocytic astrocytoma (a cyst with an enhancing mural nodule), subependymal giant-cell astrocytoma (a calcified strongly enhancing nodular lesion in Monro's foramen in patients with tuberous sclerosis), cystic ganglioglioma (a cystic or nodular enhancing lesion in the temporal lobe in young patients with temporal epilepsy), and central neurocytoma (a tumor in the lateral ventricle with broad base on the septum pellucidum).

Diagnosis

The diagnosis and differential diagnosis of gliomas are challenging with routine imaging. Classically, a benign diffusely infiltrating astrocytoma is homogeneous, with minimal edema and absent contrast enhancement. Anaplastic tumor or anaplastic transformation is characterized by necrosis, edema, hemorrhage, and irregular contrast enhancement. Contrast enhancement is considered essential for diagnosing malignancy or malignant transformation of a previously benign tumor.

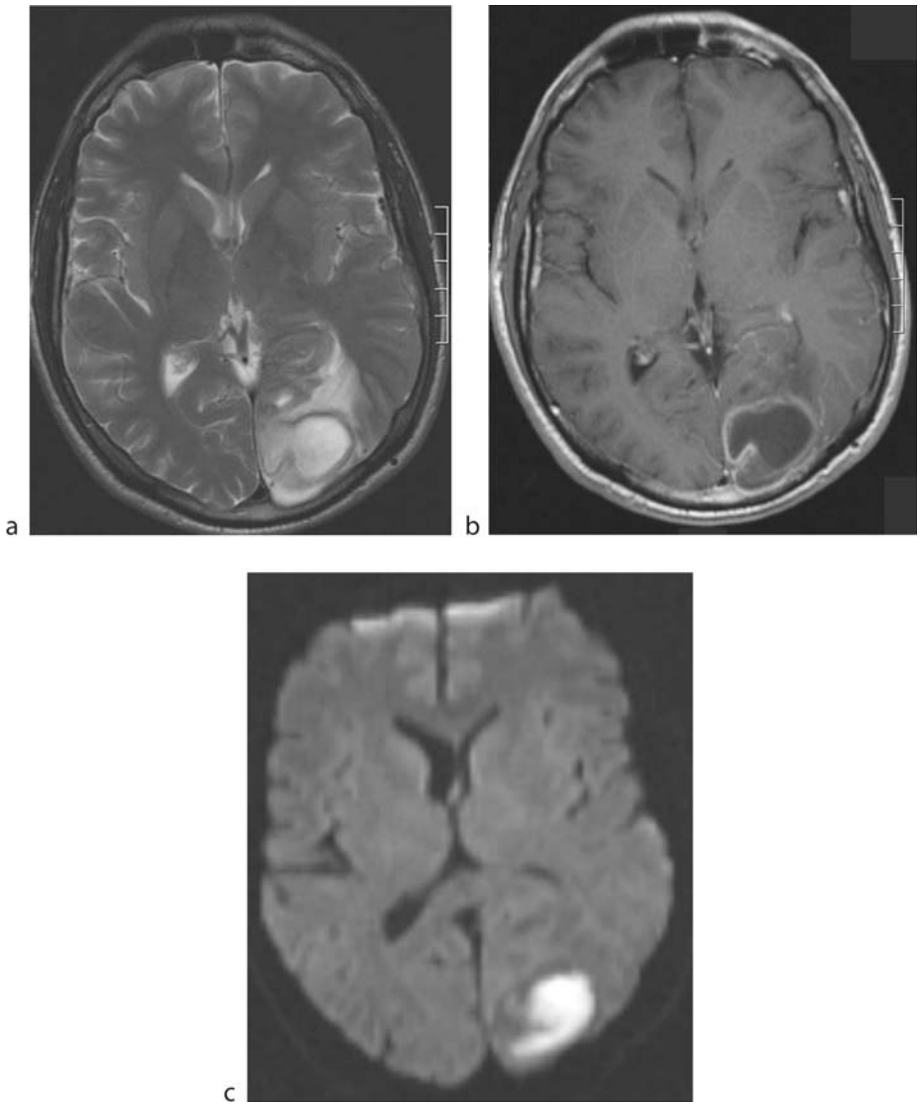
However, a significant amount of nonenhancing lesions appear to be anaplastic gliomas at biopsy, while 50% of enhancing oligodendrogliomas are benign. Malignant cells are found outside the margins of contrast enhancement, and areas of maximal enhancement do not necessarily correspond to areas of maximal malignancy. Finally, enhancement reflects breakdown of the BBB, as in tumors but also in (radio)necrosis.

Further problems concern the differentiation of "ring-enhancing necrotic" lesions (metastasis, glioma, abscess), the differentiation of multifocal lesions (lymphoma, malignant glioma, and metastasis), and the differentiation between radionecrosis and tumor recurrence.

Diffusion-weighted imaging (DWI) can solve some of these problems. Due to hypercellularity, there is low diffusion in cerebral lymphomas leading to a strong hypersignal on DWI allowing one to differentiate them from glioma or metastasis. Pus in the center of the abscess is a viscous fluid that consists of bacteria, inflammatory cells, mucoid proteins, and cellular debris. This again leads to strong hypersignal on DWI, allowing one to differentiate necrotic glioma or metastasis from an abscess (Fig. 1).

Apparent diffusion coefficient (ADC) values, which are a quantitative expression of diffusivity, can help in the grading of malignant gliomas. Lower ADC values are present in the solid portions of anaplastic gliomas (Fig. 2a-c). Nonenhancing brain gliomas with low ADC are anaplastic.

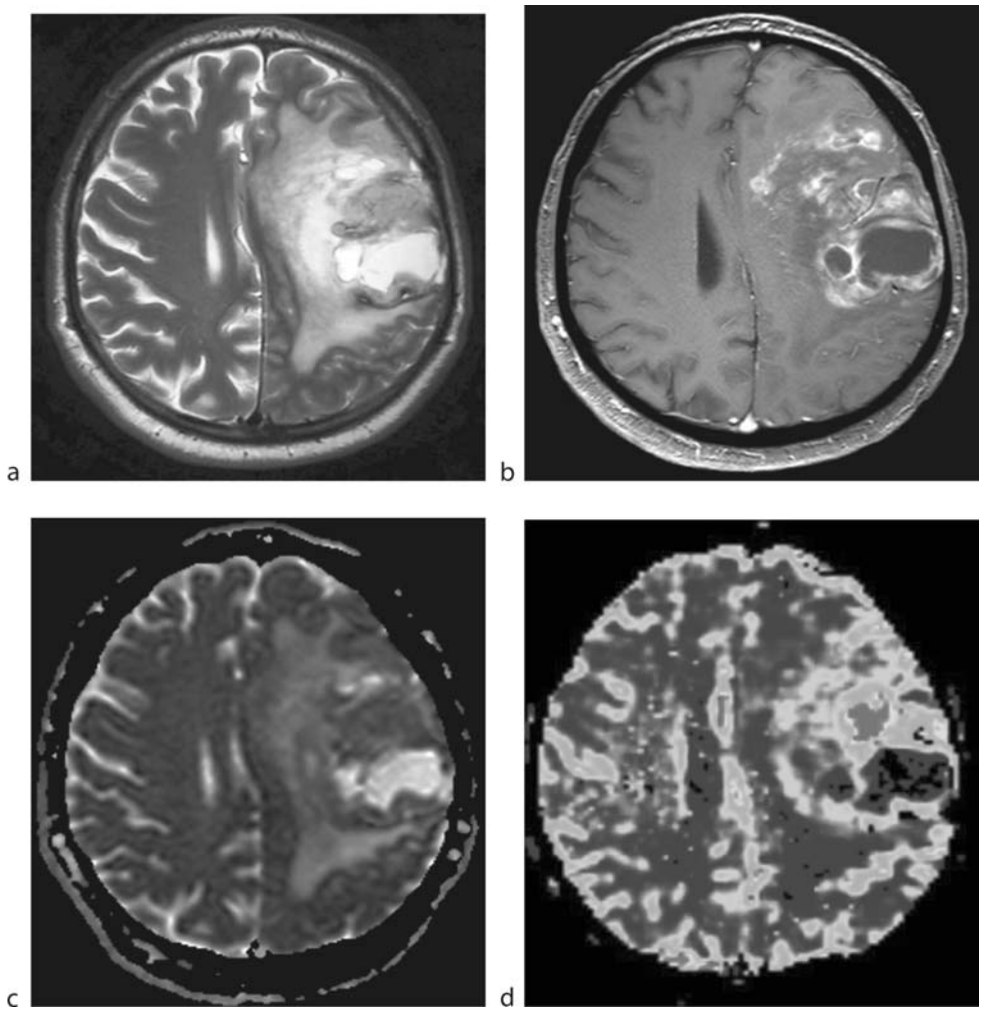
Perfusion-weighted imaging (PWI) is another powerful tool in the differential diagnosis. By measuring the drop of signal on T*-weighted imaging during the first pass of a bolus of contrast agent "passing through" the brain, the relative cerebral blood volume (rCBV) and flow



Neoplasms, Brain, Intraaxial. Figure 1 Brain abscess simulating glioblastoma. (a) Transverse T2-weighted sequence: evidence of rounded hyperintense lesion in the left occipital lobe. Note surrounding edema. (b) Transverse gadolinium-enhanced T1-weighted image at the same level: the ring-like enhancement of the lesion can be seen in glioblastoma, metastasis, abscess, and so on. (c) Transverse diffusion-weighted sequence (b = 1,000): the lesion is strongly hyperintense pointing to diffusion restriction. This is due to the presence of pus and cellular debris in the center of the lesion.

through the tumor can be measured. Since tumor aggressiveness is correlated with endothelial neovascularization ("angiogenesis"), a high correlation exists between tumor grade and rCBV as measured with PWI (Fig. 2d). In this way, malignancy is detected in nonenhancing lesions, the optimal site for biopsy can be determined based on higher angiogenesis rather than the breakdown of the BBB, and less vascular lymphoma is differentiated from hypervascular malignant glioma. Finally, by definition, avascular radionecrosis is differentiated from glioma recurrence.

Metabolic information can be obtained from tumoral tissues with MR spectroscopy. The widely used "single-voxel proton MR spectroscopy" examines NAA (*N*-acetylaspartate), tCr (total creatine), and tCho (total choline) in particular. Typically, there is an increase in tCho (cellular proliferation), a decrease in NAA (replacement of normal neurons by tumor cells), and in some lesions decreased tCr (energy metabolism). With better techniques (shorter echo time), other components such as myoinositol, glutamate, glutamine, and lipids can be studied. This allows further differentiation between

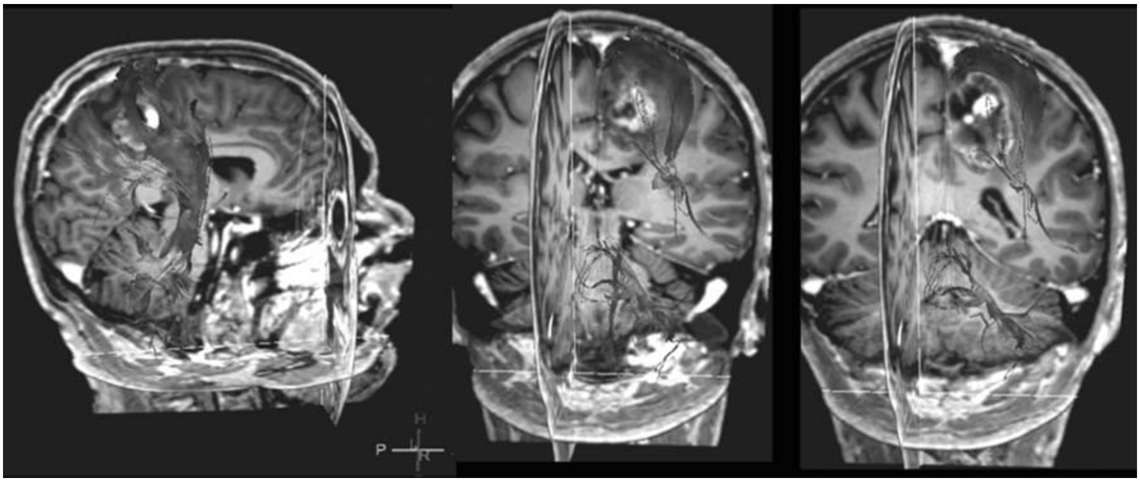


Neoplasms, Brain, Intraaxial. Figure 2 Glioblastoma multiforme. (a) Transverse T2-weighted sequence: evidence of huge lesion in the left hemisphere. The aspect of the lesion is very inhomogeneous. The anterior hypointense nodule corresponds to the "core" of the tumor. The more posterior hyperintense part represents a necrotic part. The lesion is surrounded by edema. (b) Transverse gadolinium-enhanced T1-weighted image at the same level: the lesion shows inhomogeneous enhancement with patch areas of enhancement in the anterior part and more ring-like enhancement in the posterior part. (c) Transverse ADC map at the same level: the ADC values in the "core" of the tumor are low, due to high cellularity. The surrounding edema has higher ADC values. Perfusion rCBV map of the lesion: the center of the lesion has high rCBV, pointing to extensive neoangiogenesis typical of a malignant tumor. Please note that the site of maximal neoangiogenesis does not correspond to the areas of maximal enhancement.

low- and high-grade glioma, oligodendroglioma and astrocytoma, schwannoma, hemangioblastoma, and meningioma. Diagnosis of radionecrosis is easy.

Functional MRI shows the "brain at work." Performance of a specific task in the magnet, such as finger tapping, the (inarticulate) pronunciation of words, or watching visual stimuli, "lights up" the motor cortex, the speech areas of Broca and Wernicke, and the visual cortex, respectively. This allows localization of these functional areas. It has also been demonstrated that a tumor can only be safely removed without a risk of functional deficit if the distance to an eloquent zone is less than 2 cm. If the distance is smaller than 1 cm, the risk of a severe functional deficit is 50%. A disadvantage of the method is that the test relies on the capacity of patients to perform certain tasks that can be hampered by the patient's symptoms, for example, paralysis. Nevertheless, it has been shown that on the basis of data obtained from functional MRI, the removal of a brain tumor is safer and more complete.

With diffusion-tensor imaging (DTI) it is possible, based on the anisotropic diffusion in white matter tracts, to actually visualize the different white matter tracts and



Neoplasms, Brain, Intraaxial. Figure 3 **Diffusion-tensor imaging (DTI) in brain metastasis fused with the contrast-enhanced T1-weighted images. The enhancing metastasis of an esophageal cancer is located in the right pre- and postcentral gyri. Functional MRI confirmed the location of the lesion within the primary motor cortex strip. DTI fiber-tractography of the right corticospinal tract (colored areas) reveals that it runs laterally and cranially along the lesion. The DTI suggests that it is feasible to remove the metastasis using a medial wall approach, which would spare fibers of the corticospinal tract. The lesion was totally removed with this medial approach. Postoperatively, neurological (motor) status was unchanged.**

to determine their relationship with the tumor. Since this technique is independent of the patient's functional capacity, it allows even better determination of the operability than functional MRI (Fig. 3).

Definition

Tumors of the central nervous system (CNS) account for 20.3% of all tumor diseases in children in Germany up to the age of 15 years at the time of diagnosis. The incidence is 2.8 per 100,000. About 42% of CNS tumors in children are localized in the posterior fossa, comprising about 15% of tumors in the brain stem. The most frequent pathologies are cerebellar and pontine astrocytomas, ►medulloblastomas (infratentorial primitive neuroectodermal tumors, or PNET), ►ependymomas, and—increasingly often diagnosed—atypical teratoid rhabdoid tumors (ATRTs). Hemangioblastomas, choroid plexus tumors of the 4th ventricle subependymomas, cerebellar liponeurocytomas, and dysplastic cerebellar gangliocytomas (Lhermitte–Duclos disease) are tumors found in adolescence and adulthood.

Pathology/Histopathology

Astrocytomas belong to the tumors of glial origin. The most frequent ►pilocytic astrocytoma corresponds to a grade I tumor. Diffuse astrocytomas vary in the degree of malignancy from grade II to grade IV (glioblastoma multiforme). While mitotic activity, necrosis, and vascular proliferation are absent in grade II, grade III is characterized by a marked increase in mitoses, and grade IV shows necrosis and vascular proliferations (1).

Medulloblastomas are highly cellular grade IV tumors of embryonal origin. The classic type (about 75%) arises in the vermis. The desmoplastic subtype shows a nodular pattern involving the hemispheres and has a better prognosis than the classic type. A more benign variant is the medulloblastoma with extensive nodularity, while large cell medulloblastomas behave more aggressively than the classic type.

Ependymomas can be divided into grades II and III (anaplastic) variants. While grade II tumors show moderate cellularity, cell density and the number of mitoses increase in grade III. Key histological features are perivascular pseudorosettes and ependymal rosettes, which are absent in grade III tumors. The high grades show microvascular proliferation and pseudopalisading necrosis.

ATRTs are highly malignant embryonal tumors that occur most often in very young children. Data on their localization differ, but the most recent clinical studies show a slight predominance in the supratentorial compartment. Until recently, the tumors have been misdiagnosed as PNET. The histological hallmark is the presence of rhabdoid cells together with variable components of PNET, mesenchymal, and epithelial cells.

Clinical Presentation

Tumors arising from the cerebellum may lead to specific cerebellar symptoms such as ataxia or neck pain, especially during inclination of the head. If the 4th ventricle or parts of the cerebrospinal fluid (CSF) pathways are compressed, the resulting hydrocephalus leads to signs of increased intracranial pressure, including headache, vomiting, and visual disturbances. Tumors within the pons or medulla oblongata may result in cranial nerve disturbances, hemisyndromes, or signs of increased intracranial pressure. Periaqueductal tumors lead to the signs of long-standing increased intracranial pressure because of hydrocephalus. Multiple nerve palsies and crossed spastic paresis are typical signs of pontine tumors. Whereas low-grade astrocytomas may have long-standing and astonishing mild or even missing clinical symptoms, the duration of symptoms in high-grade tumors rarely exceeds some weeks.

Imaging

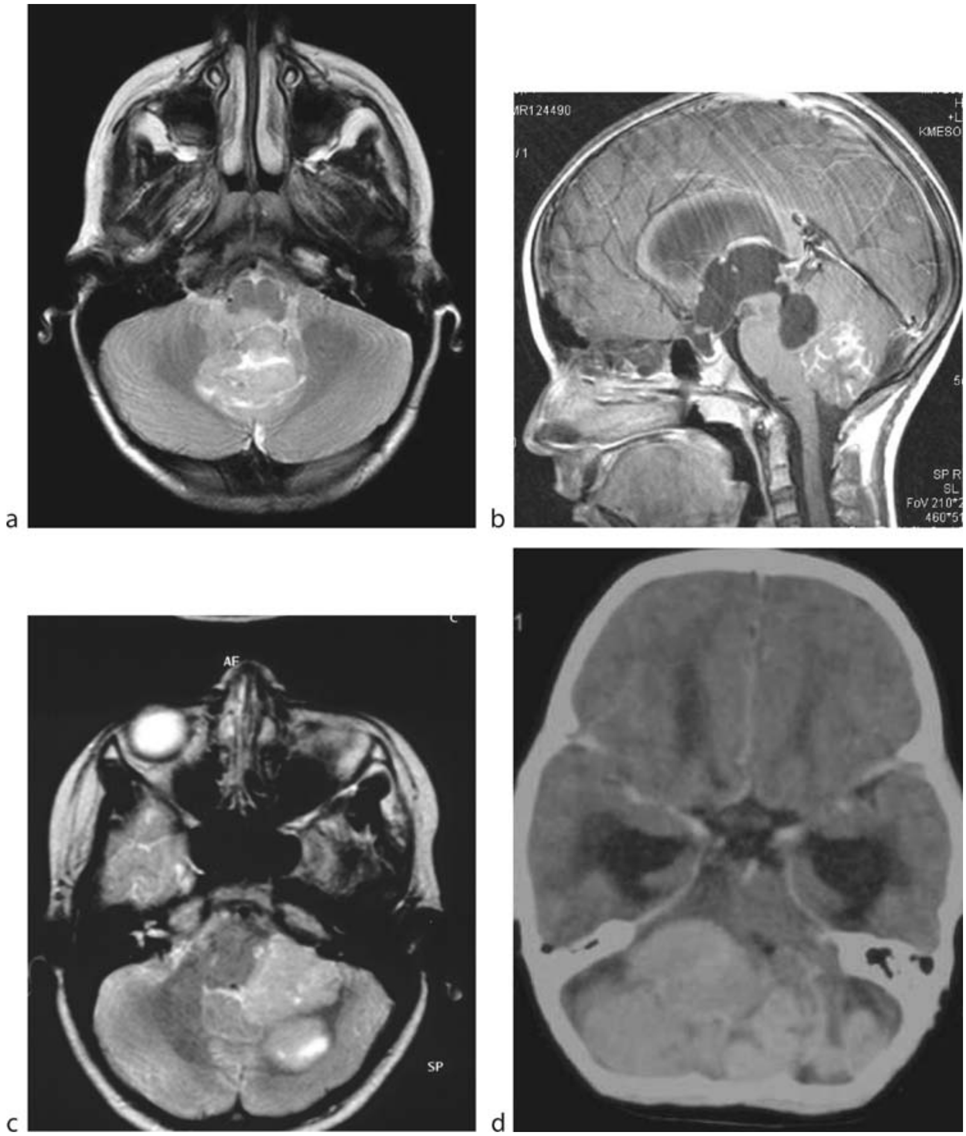
Magnetic resonance imaging (MRI) is the imaging modality of choice. However, computed tomography (CT) still seems to be the most frequent type of examination for the initial diagnosis of brain tumors, even in children. Some specific features that might be of important differential diagnostic impact, including calcifications and an estimation of a tumor's cellular density, are better identified by CT (2). MR spectroscopy (MRS) is useful for estimating cellular proliferation or tumor composition, such as the demonstration of tumor necrosis. A possible advantage of MRS is the monitoring of tumor response to treatment or the differentiation between a recurrence and a treatment-related necrosis. The differential diagnosis between the tumors of the cerebellum is, to some extent, possible by their localization, growth patterns, and CT density or signal intensities on MRI (3). Tumors in the brain stem can be differentiated concerning their histology mainly by their localization (2).

Medulloblastoma

Two different types of medulloblastomas show different behavior on imaging. The most frequent, classic type expresses markers of primitive periventricular precursor cells, which are found in the vermis of the cerebellum. The desmoplastic type of medulloblastoma expresses markers of the outer granular cells of the cerebellar cortex and is found in roughly 25% of patients. According to these histogenetic differences, classic medulloblastomas usually arise in the vermis of the cerebellum and then extend into the 4th ventricle. Desmoplastic medulloblastomas are most often found in the surface of the cerebellar hemispheres, often invading the overlying dural structures. Medulloblastomas are highly cellular tumors with rather low signal intensity on T2-weighted MRI compared with cortex. But due to the coexistence of necrotic areas or bleeding residue, the low T2 signal is sometimes hard to depict. More accurate is a high density on CT, leading most often to hyperdense and, rarely, isodense CT values in the solid parts of the tumor. CT density can be used in the differentiation from cerebellar pilocytic astrocytomas, which can be found in the same location. Medulloblastomas already show a high rate of leptomeningeal dissemination at the time of diagnosis. Because meningeal dissemination is one of the most important prognostic factors, staging consisting of CSF examination and complete cranial and spinal MRI are essential for adequate treatment. Enhancement can be uniform and strong but is more often patchy and mild, partial, or completely missing (2–4). This leads to considerable problems in defining ►residual tumor after surgical resection (5). The residual tumor definition should be performed within 72 h after surgery because nonspecific postoperative cerebral enhancement begins after this time (Fig. 1).

Ependymoma

Ependymomas (grades II and III) arise from the ependymal layer of the 4th ventricle; therefore, they do not show such a strict relationship to a definite structure around the ventricle. Usually they arise from the lower part of the 4th ventricle, but they may also be isolated in the cerebellopontine angle. They are so-called plastic tumors and grow out of the openings of the 4th ventricle surrounding the cranial and spinal nerves and vessels (4). Meningeal dissemination is rare at the time of initial diagnosis. More often, a local recurrence or the progression of a residual tumor is observed. MRI signal intensities and CT density are similar to those of medulloblastomas (Fig. 2).



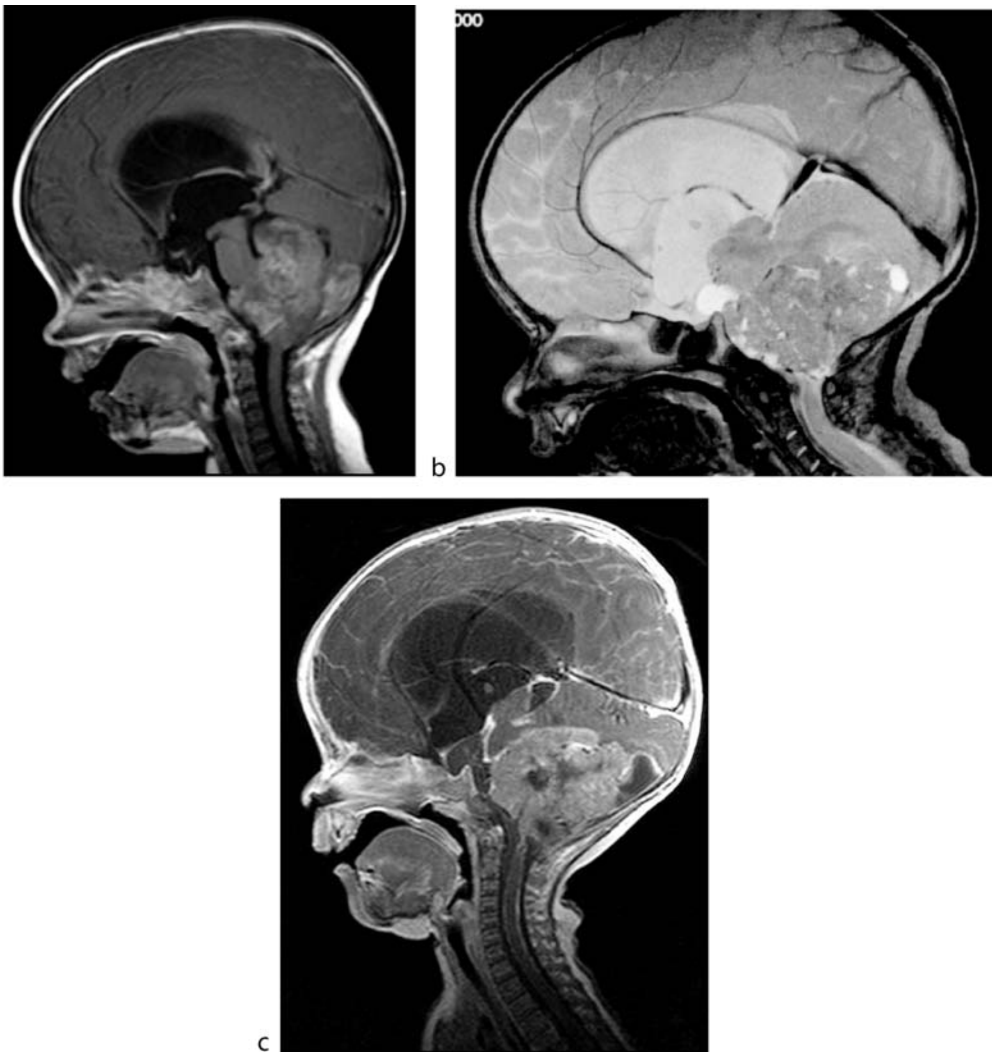
Neoplasms, Brain, Posterior Fossa, Pediatric. Figure 1 Medulloblastoma. (a) On T2-weighted axial magnetic resonance imaging (MRI), the typical relationship of a classical medulloblastoma to the vermis cerebelli is clearly visible. Signal intensity near isointensity to the gray matter gives an impression of cell density within the tumor. An infiltration of the lower parts of the floor of the 4th ventricle on the right-hand side cannot be excluded. (b) Sagittal T1-weighted enhanced MRI of the same patient shows some enhancement and also the origin of the tumor from the lower part of the vermis. (c) The typical localization of a desmoplastic medulloblastoma within the left hemisphere is seen on the axial T2-weighted image. (d) Typical medulloblastoma with extensive nodularity on postcontrast computed tomography. This type of tumor has a better prognosis.

Atypical Teratoid Rhabdoid Tumors

The highly malignant ATRTs primarily affect very young children. The supratentorial (mostly frontal) localization is more frequent than the infratentorial. Quite often, huge tumors, often not differentiable from medulloblastomas, involve both compartments. In about 40% of cases, a seemingly typical pattern of enhancement with a bandlike peripheral character can be seen. Meningeal dissemination and tumor bleeding are quite frequent.

Cerebellar Astrocytoma

Low-grade astrocytomas are the most frequent tumors in children. The most common location is within the cerebellum. The histologically benign tumor usually enhances and can be solid or at least partly cystic. Cyst walls containing tumor usually enhance and can be differentiated from cystic hemangioblastomas without enhancement of the cyst walls. Cellular density is low; therefore, T2 signal is usually very high, and CT density is



a b c

Neoplasms, Brain, Posterior Fossa, Pediatric. Figure 2 Ependymoma and atypical teratoid rhabdoid tumor (ATRT). (a) The typical growth pattern of an ependymoma arising from the lower parts of the 4th ventricle, growing within the cisterns, and surrounding the brain stem is demonstrated on sagittal postcontrast T1-weighted magnetic resonance imaging (MRI). (b) A very low signal on T2-weighted sagittal MRI correlates with very high cellularity in this baby with an infratentorial ATRT. (c) Besides the large moderately enhancing ATRT seen on postcontrast T1-weighted sagittal MRI in another very young child, meningeal dissemination is best seen within the cervical spinal canal.

either hypodense or isodense in the solid tumor parts. Calcification is possible in all sorts of infratentorial tumors and does not enable differential diagnosis. Up to about 7% of low-grade astrocytomas are complicated by asymptomatic meningeal dissemination.

Quadrigeminal Plate Tumors

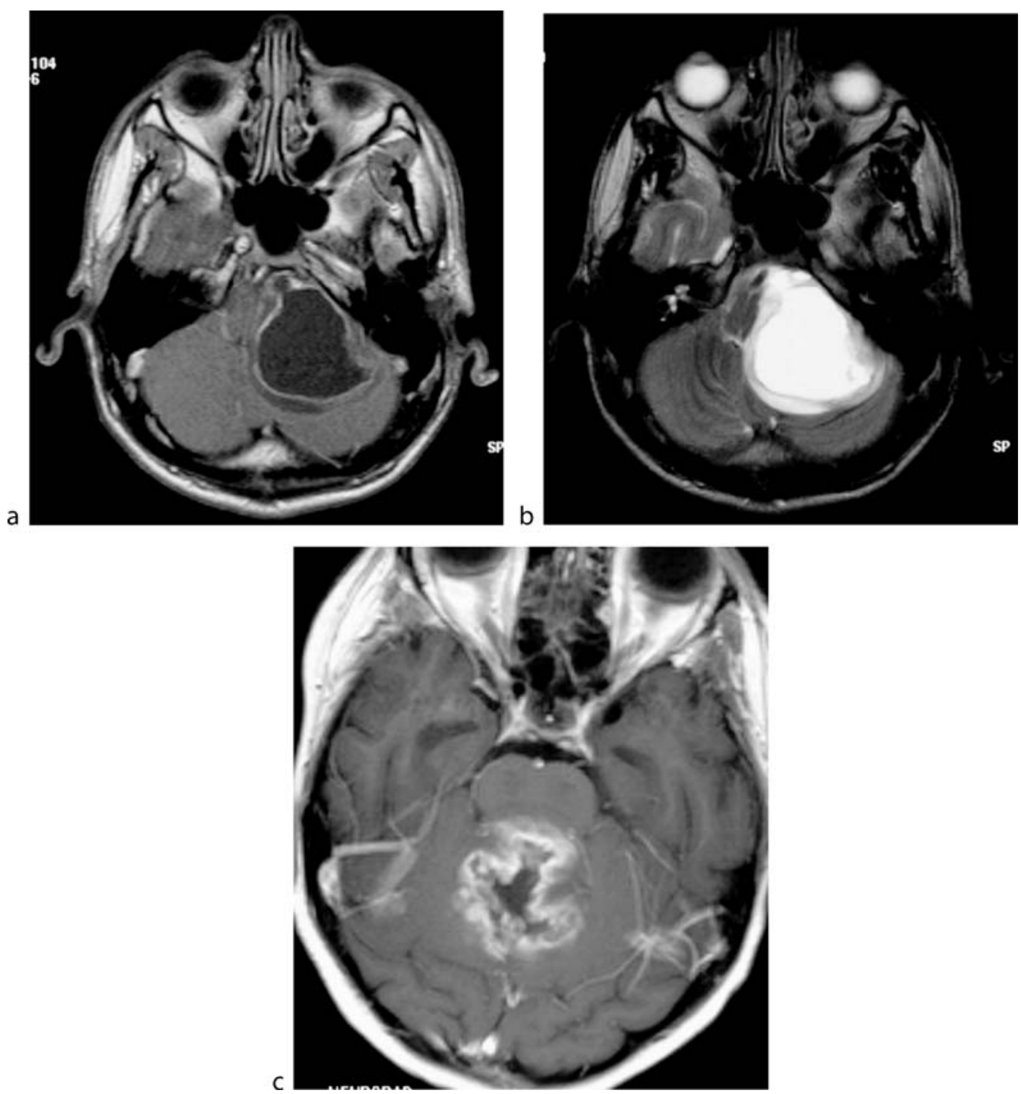
Quadrigeminal plate tumors are of astrocytic origin in most cases. The typical tectal glioma leads to a long-standing hydrocephalus on the basis of compression of the aqueduct. Tumors are small without enhancement and usually do not require specific treatment after CSF diversion. Follow-up is mandatory because some tumors may develop atypical characteristics such as contrast enhancement or growth into the thalami and may eventually require treatment.

Pontine Tumors

Diffuse and focal tumors must be differentiated. Focal tumors may have a benign course, show prominent exophytic components, and represent pilocytic astrocytomas. Diffuse tumors in children older than 2 years are associated with an extremely bad prognosis. Biopsy may reveal grade II–IV astrocytoma with no predictive value for treatment or prognosis; therefore, biopsy or even resection is usually followed by the risk of further neurological damage. The differentiation between focal and diffuse tumors is most reliable on the basis of an estimation of the percentage of cross-sectional area of the pons infiltrated by tumor, with a cut-off point of 50%. The tumor margins in so-called diffuse pontine gliomas are very often sharp, so we do not believe this is a reliable criterion. Enhancement may be seen but is often absent in the beginning. Meningeal dissemination is rare but possible. Typical features are splitting of the pontine fibers by tumor infiltration and encasement of the basilar artery. Hydrocephalus is usually not present despite sometimes large tumor masses in the posterior fossa (Fig. 3).

Tumors of the Medulla Oblongata

Diffuse tumors of the medulla oblongata may behave similarly to diffuse pontine gliomas, but histological verification should be attempted because the differential diagnosis cannot be made with similar accuracy on the basis of MRI. Many tumors in the medulla oblongata lead to a pronounced and typical exophytic growth of its dorsal part and are therefore called dorsal exophytic



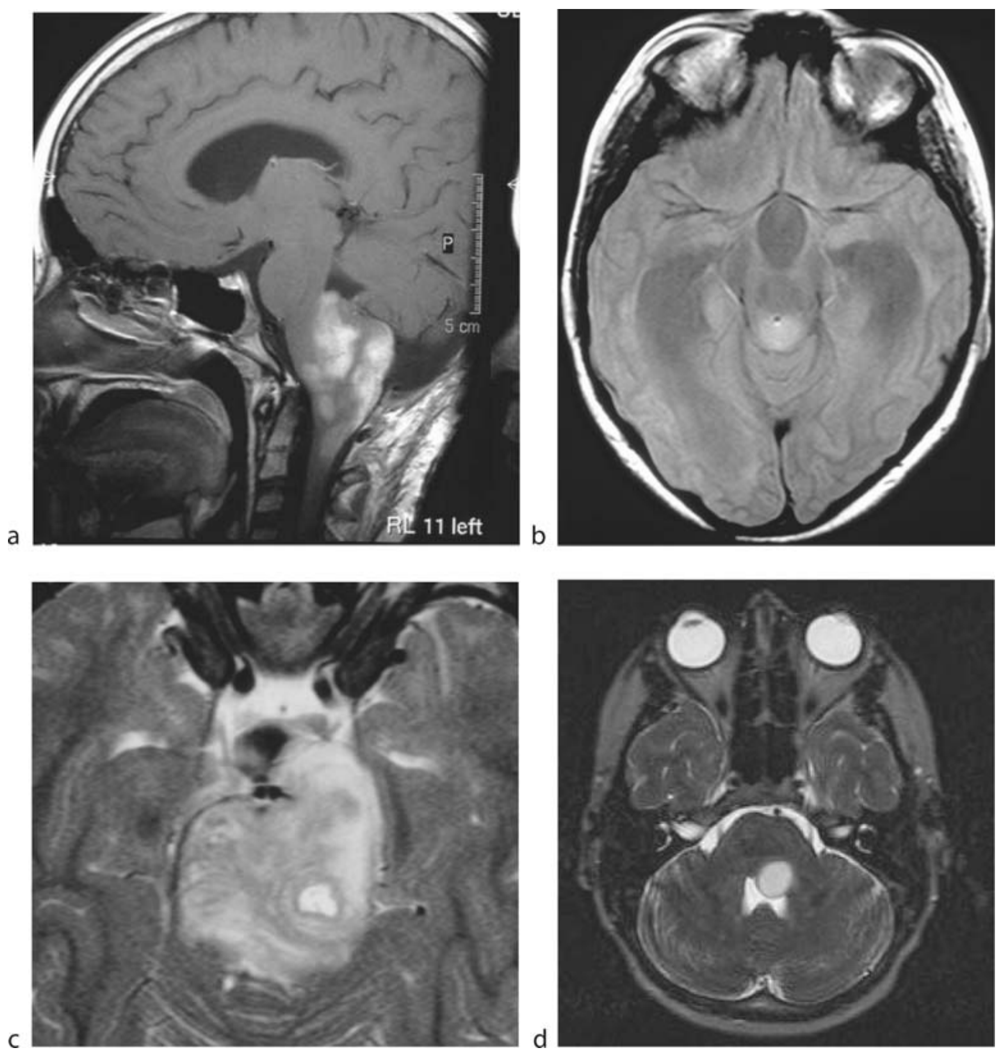
Neoplasms, Brain, Posterior Fossa, Pediatric. Figure 3 Pilocytic astrocytoma. (a) Pilocytic astrocytoma in the left cerebellar hemisphere with a typical large cyst. (b) The same tumor on T2-weighted magnetic resonance imaging (MRI) shows a very high signal not only within the cyst but also within the solid margin. (c) On postcontrast T1-weighted MRI, the differentiation between a pilocytic astrocytoma seemingly arising from the vermis cannot be reliably differentiated from a classical medulloblastoma.

tumors of the medulla oblongata. Histologically, these tumors are most often of astrocytic origin, either grade I or II. Rarely, gangliogliomas are found in this location. As in all low-grade tumors, neurosurgical resection or debulking should be attempted as often as possible before any other form of treatment. Histological diagnosis of the tumor *via* biopsy before an attempt at resection is usually not necessary. Independent of the tumor grade, enhancement may be present. CT density of the solid part shows hypodensity or isodensity, and calcifications do not allow further differentiation (Fig. 4).

Diagnosis

Although CT and MRI features of tumors of the posterior fossa are sometimes very characteristic only in cases of diffuse pontine glioma or typical tectal glioma, histological verification by biopsy or resection is dispensable. Cytological examination of the CSF in cases of meningeal dissemination can clarify tumor histology.

Imaging should always aim not only at the diagnosis of the tumor itself but also at the staging of disease dissemination. Therefore, imaging must include a spinal



Neoplasms, Brain, Posterior Fossa, Pediatric. Figure 4 Brain stem tumors. (a) The dorsal exophytic part is typical in this low-grade tumor restricted to the medulla oblongata and the upper cervical cord. Histology demonstrated a pilocytic astrocytoma. (b) A fairly sharply delineated small tumor on proton density-weighted magnetic resonance imaging (MRI) within the tectal plate has led to a long-standing hydrocephalus occlusus. In this typical tectal plate glioma, only third ventriculostomy was necessary. (c) Diffuse infiltration of the pontine fibers and encasement of the basilar artery are typical features of a ▶diffuse intrinsic pontine glioma. (d) Focal tumor of the left dorsal pons. Despite the unequivocal enhancement on T1-weighted MRI (not shown), histology revealed a grade II astrocytoma.

staging MRI in tumors with a known propensity for meningeal dissemination.

The correct identification of residual tumor after resection on the basis of early postoperative MRI or CT (within 72 h) facilitates subsequent treatment decisions and is therefore absolutely necessary as the basis of further evaluations (5).

Cerebral tumors in childhood; Intrinsic brain tumor

Definition

Neuroepithelial tumors are primary neoplasms of embryonic neural tube origin. Gliomas originate from astrocytes, oligodendrocytes, or ependymal cells.

Central nervous system (CNS) tumors are the second most common tumor in children after leukemia. Low-grade tumors are more frequent in children than in adults. In children, 25% of CNS tumors are located supratentorially, 17% are suprasellar, and 35% are infratentorial. During the first 2 years of life, cerebral tumors are more common in girls than in boys. At older ages, boys are affected twice as frequently as girls. The peak incidence of brain tumors in children is below the age of 5 years.

Different tumors present at different ages. In children younger than 1 year of age, two-thirds of the CNS tumors are located supratentorially. Astrocytomas are most frequent (40–50%), followed by primitive neuroectodermal tumors (PNETs; 20%), and 20% are of various other histologies. Astrocytomas, choroid plexus papillomas, teratomas, and embryonal tumors typically occur in the first 2 years. Ependymomas and medulloblastomas usually present before age 4 years. The peak age for pilocytic astrocytomas is between 5 and 9 years.

Astrocytomas are the most frequent pediatric brain tumors in general and may arise at any location within the CNS, including the spinal cord. Prognosis depends on the tumor grade, tumor site, and invasion of the functional center. Outcome is usually excellent, with a 5-year survival of 85–95%.

Meningiomas and metastases are rare in children. Children may develop CNS neoplasms after treatment of non-CNS malignancies.

Pathology/Histopathology

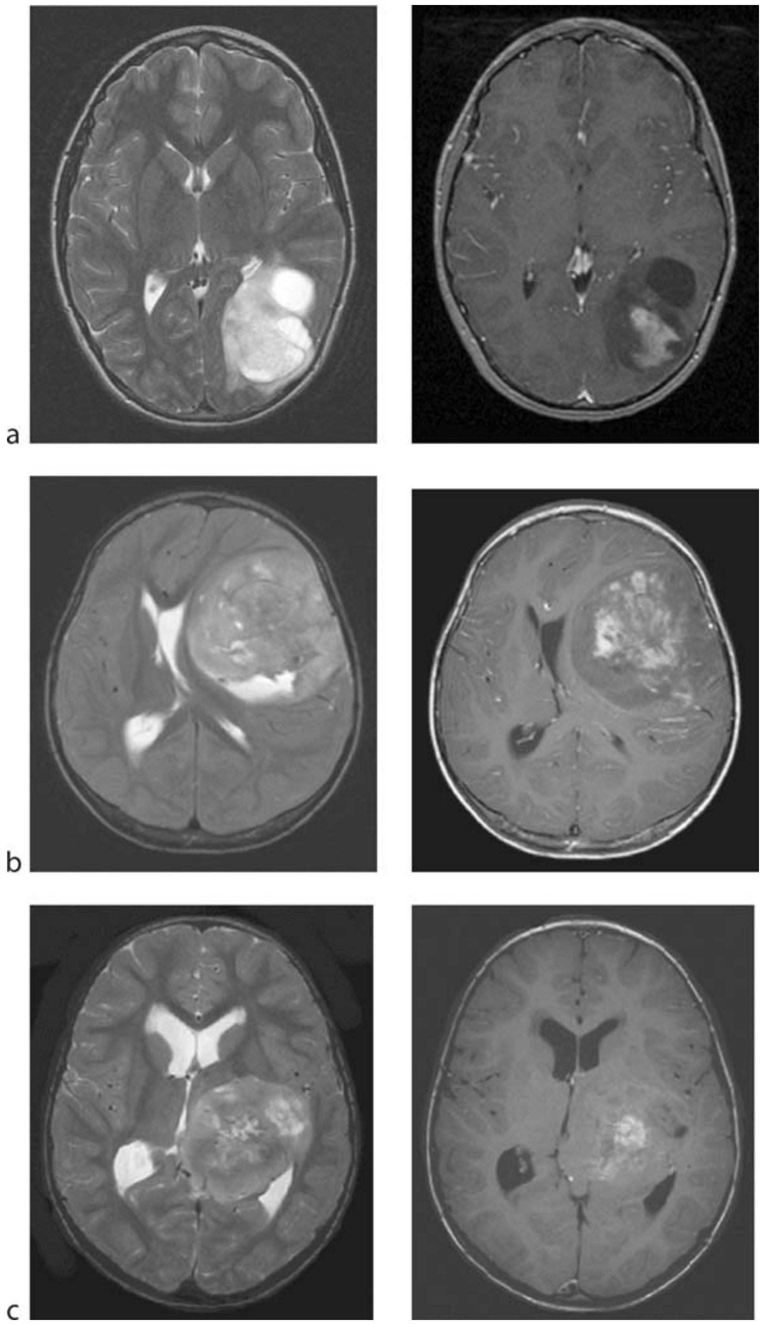
Brain tumors are classified according to the dominant cell type within the tumor and are graded according to the World Health Organization (WHO) classification. Grades I and II are considered *low grade* and grades III and IV are considered *high grade*.

N

Neuroepithelial Tumors

Astrocytomas are the most common neoplasm in children. Fifty percent are located supratentorially.

1. *Pilocytic astrocytomas* (WHO grade I) are the most frequent astrocytomas in children (Fig. 1a). They may present in the cerebellum, hypothalamus, thalamus, anterior visual pathway, or cerebral hemispheres. A solid tumor nodule is frequently seen in combination with cysts of various sizes. Microscopically, loose spongy areas are intermixed with compact cellular regions. Spontaneous evolution into higher-grade malignancy may occur.
2. *Fibrillary astrocytomas* (WHO grade II) are the second most common astrocytomas in children. Occasionally they are seen in the cerebellum, but they are more frequent in the brain stem, spinal cord, and cerebral hemispheres. Microscopically there is moderately increased cellularity. Histologically, well-differentiated fibrillary or gemistocytic astrocytes are seen within a loosely structured and commonly microcystic matrix. Progression to higher-grade malignancy over time is frequent.



Neoplasms, Brain, Supratentorial, Pediatric. Figure 1 (a) Axial T2 fast spin echo (FSE) and contrast-enhanced T1 spin echo (SE) magnetic resonance image of a pilocytic astrocytoma; partially solid, partially cystic tumor of the left hemisphere in a 12-year-old boy (*left*). After contrast administration, the axial T1-weighted image shows partial enhancement of the solid component. The left lateral ventricle is compressed. (b) Axial T2 FSE and contrast-enhanced T1 SE magnetic resonance image of a primitive neuroectodermal tumor; left-sided insular mass in a 2-year-old child. The tumor reaches the cortex. There is significant midline shift with compression of the left lateral ventricle. The tumor reveals an irregular enhancement of solid components. An eccentric necrosis is seen along the dorsal border (*right*). (c) Axial T2 FSE and contrast-enhanced T1 SE magnetic resonance image of an ependymoma; heterogeneous tumor in the left cerebral hemisphere in a 3-year-old girl with epicenter adjacent to the posterior horn of the lateral ventricle. No significant edema is seen. Compression of the foramen of Monroe and the Sylvian aqueduct results in an obstructive hydrocephalus. The tumor shows sparse contrast enhancement on T1-weighted images (*right*).

3. High-grade astrocytomas, including *anaplastic astrocytoma* (WHO grade III) and *glioblastoma multiforme* (GBM; WHO grade IV), are usually located within the cerebral hemispheres and brain stem. These tumors are predominantly seen in adults.
4. *Subependymal giant cell astrocytomas* (WHO grade I) are seen in tuberous sclerosis and are typically located at the foramina of Monroe. Microscopically, large multinucleated cells are seen mixed with abundant hyalinized blood vessels.

Neuronal and Mixed Neuronal/Glial Tumors

1. *Gangliogliomas* may occur at any age but are more frequent in children. They typically present in the temporal lobes. Microscopically, clusters of large neurons are mixed with astrocytes and perivascular lymphocytes.
2. *Dysembryoplastic neuroepithelial tumor* (DNET) is a benign cortical tumor with a multilobulated "bubbly" appearance. DNETs are commonly temporal located. The overlying skull may be scalloped. Microscopically, DNETs contain glial cells and neurons. At the junction to normal brain, areas of cortical dysplasia may be apparent.
3. *PNETs* are embryonal tumors and represent the second most common CNS neoplasm in childhood (20%; Fig. 1b). Microscopically they consist of undifferentiated small round cells with divergent patterns of differentiation along astrocytic, neuronal, ependymal, or melanocytic lines. The histogenesis of this tumor type is still discussed in the literature.
4. *Atypical teratoid rhabdoid tumor* is an embryonal tumor that is equally frequent supratentorial and infratentorial and may involve the pineal gland. This tumor occurs in children younger than 2 years. Microscopically it consists of areas of varying differentiation, such as neuroglial, epithelial, or mesenchymal cells and the characteristic rhabdoid cells. The latter is a medium-sized cell with a prominent nucleolus in an eccentric nucleus and granular cytoplasm. Immunocytochemically there exists a broad phenotype with positivity for multiple antisera.
5. *Ependymomas* are the fifth most frequent CNS tumor in childhood (Fig. 1c). Of these, 65% are located infratentorially, 25% supratentorially, and 10% in the spinal cord. Cerebral hemispheric tumors occur near the ventricles and grow either into the hemispheric parenchyma or into the ventricles. Cysts and calcifications are frequent. Microscopically, ependymomas present glial and epithelial properties. In most cases they have characteristic perivascular pseudorosettes around blood vessels, and 25% show anaplasia with a high mitotic rate, pleomorphism, and necrosis.

Suprasellar Tumors

Seventy-five percent of suprasellar tumors are craniopharyngiomas, 15% are germ cell tumors, and 10–15% are of various histology. Craniopharyngiomas comprise up to 10% of all CNS tumors in children and represent the fourth most common intracranial neoplasm. Germinomas are the most frequent germ cell tumor. Optic nerve gliomas are pilocytic astrocytomas (WHO grade I) and present predominantly in the first decade of life (75%). Up to one-third of these tumors are associated with neurofibromatosis type 1.

Intraventricular Tumors

Ependymoma and choroid plexus papilloma/carcinoma are the most common frequent intraventricular tumors. Papillomas may produce excessive amounts of cerebrospinal fluid, resulting in a hydrocephalus. They occur in infancy or early childhood and are predominantly located in the lateral ventricles. Macroscopically, papillomas are soft, cauliflower-like, grayish-pink vascular masses. Choroid plexus carcinomas show a high degree of mitosis and cell atypia. Immunocytochemistry and electron microscopy help distinguish these tumors from other malignancies, including ependymomas.

Differential Diagnosis

A careful analysis of the clinical history, neurological symptoms, and laboratory and imaging findings allows differentiation of lesions. Differentiation between an abscess and a necrotic GBM remains difficult. Advanced imaging techniques, including diffusion-weighted imaging, are helpful.

Clinical Presentation

Clinical presentation depends on many factors, including the age of the child, the location and extent of the lesion, the rate of tumor progression, and complicating factors such as vasogenic edema, intralesional hemorrhage, or necrosis. Histology and tumor grade determine prognosis.

In neonates the open fontanelles prevent a significant increase in the intracranial pressure. This may delay diagnosis. Consequently, tumors are frequently large on initial diagnosis. As soon as the fontanelles are closed, the symptoms of raised intracranial pressure in children are similar to those in adults and include headache, vomiting, and altered consciousness. Depending on the tumor's location, various neurological symptoms may occur, including focal neurological deficits and seizures.

Neoplasms, Brain, Supratentorial, Pediatric. Table 1 **Computed tomographic (CT) and magnetic resonance (MR) features of supratentorial childhood tumors (*CECT,* contract-enhanced computed tomography; *GM* gray matter; *CSF* cerebrospinal fluid; *WM* white matter)**

Supratentorial tumors	Imaging characteristics	CT	MR imaging		MR + CT with contrast
			T1-weighted	**T2-weighted**	**T1-weighted + CECT**
Astrocytoma:	Well-circumscribed cystic +/− solid mass	Solid parts: hypodense to isodense	Solid: isointense/ hypointense to GM	Solid: hyperintense to GM	95% enhance:
Pilocytic	Cysts with mural nodule	Cysts: hypodense	Cysts: isointense to CSF	Cysts: hyperintense to CSF	−10% solid + homogeneous
	Little or no surrounding edema	Ca^{2+}: 20%			−40% solid with necrosis + heterogeneous enhancement
	Hemorrhage rare				−50% nonenhancing cyst + enhancing nodule
					Cyst wall sometimes enhances
Fibrillary	Ill-defined	Hypodense to iso-dense	Infiltration of adjacent brain	Homogeneous	Usually no enhancement unless focal differentiation
	Homogeneous	Ca^{2+}: 20%	Homogeneous	Hyperintense	
	Rarely cysts +hemorrhage		Hypointense		
Anaplastic	Ill-defined	Hypodense	Isointense to hypointense	Heterogeneous Hyperintense	Usually no enhancement unless focal differentiation, then focal heterogeneous
	Hemorrhage	Ca^{2+}	Infiltration of WM + possibly GM		
	Rarely cysts				
Glioblastoma multiforme	Irregular margins	Isodense or hypo-dense	WM mass	Heterogeneous Hyperintense	95% irregular rim enhancement around central necrosis
	Mass + surrounding edema	Ca^{2+} rare		Hypointense blood products	*or*
	Central necrosis				Solid or patchy enhancement
	Hemorrhage				
Subependymal giant cell tumor	Well-circumscribed, often lobulated	Heterogeneous	Hypointense to isointense to GM	Ca^{2+}: hypointense	Heterogeneous enhancing mass near foramen of Monroe
	Intraventricular mass in tuberous sclerosis	Hypodense to iso-dense	Ca^{2+}: hyperintense to hypointense		
	Near foramen of Monroe	Variable Ca^{2+}			
	Hydrocephalus				

Ganglioglioma	Cortically based circumscribed cyst + mural nodule or solid tumor	Variable density, mostly hypodense	Solid: hypointense to isointense	Hyperintense mass	50% enhance: solid, rim, or nodular
	Remodeling of bone	Ca^{2+}: 35–50%		Possibly heterogeneous	Heterogeneous
					Rarely, meningeal enhancement
Primitive neuroectodermal tumor	Large complex mass + surrounding edema	Hypodense to isodense	Hypointense to isointense to GM	Solid: isointense to hyperintense to GM	Heterogeneous enhancement
	Homogeneous or heterogeneous mass	Ca^{2+}: 50–70%		Hyperintense Surrounding edema	CSF seeding
	Often hemorrhage + necrosis				
Atypical teratoid rhabdoid tumor	Heterogeneous	Hypodense to isodense	Isointense	Hyperintense cysts	Heterogeneous enhancement
	50%: infratentorial	Cysts + Ca^{2+} common	Hyperintense Hemorrhage	Hypointense blood products	Meningeal spread + CSF seeding
	40%: hemispheric or suprasellar		Hyperintense cysts to CSF		
	10–20%: disseminated hydrocephalus				
Ependymoma	Intra-/periventricular large soft mass growing out of foramina	Variable density	Heterogeneous	Heterogeneous	Variable heterogeneous mild to moderate enhancement
	Small cysts + hemorrhage	Ca^{2+}: 50%	Isointense to hypointense	Isointense to hyperintense	
				Hyperintense cysts	
				Hypointense blood products	
Choroid plexus tumor (papilloma or carcinoma)	Lobulated cauliflower-like intraventricular mass	75%: isodense to hyperdense	Isointense to hypointense	Isointense to hypointense	Strong homogeneous enhancement
	50%: lateral ventricle, left >> right	Ca^{2+}: 25%:	CSF entrapment	Flow voids in tumor	Occasional cysts +small necrotic foci
	10%:3rd ventricle			Ca^{2+}: hypointense	CSF seeding
Germinoma	80–90%: midline infiltrating mass near 3rd ventricle	Hyperdense to GM	Isointense to hypointense to GM	Isointense to hyperintense to GM	Strong homogenous enhancement
	Well-circumscribed	Large mass:		Hyperintense: cysts + necrosis	CSF seeding
	May engulf pineal gland	cysts + necrosis + hemorrhage		Hypointense blood products	
	Hydrocephalus				

Nuchal rigidity, back pain, and radicular symptoms may indicate intracranial or intraspinal cerebrospinal fluid dissemination.

Imaging

Various imaging techniques can be used to examine the cranial vault, including transfontanellar ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI), and digital subtraction angiography (DSA; Table 1).

US is primarily used in neonates. Sagittal and coronal images can be acquired at the bedside without the use of ionizing radiation. Midline shifts and obvious tumors may be diagnosed, but a detailed study of the neuroanatomy is limited. CT is a first-line imaging tool in children who have acute onset of neurological symptoms. MRI's high spatial resolution, multiplanar imaging capability, ability to generate different tissue contrasts, use of contrast media, functional techniques—including diffusion-weighted imaging, perfusion-weighted imaging, and MR spectroscopy—and the lack of ionizing radiation make it ideally suited to image the child with a brain tumor (Fig. 1a, c). Because of the long acquisition times, the examination is often performed under general anesthesia, especially in young children. DSA is rarely indicated. Advanced functional MRI techniques have replaced most scintigraphy indications.

It goes without saying that currently no imaging modality is capable of making a histological diagnosis. But by combining the anatomical and functional imaging information with the child's age, the neurological symptoms, and the tumor's location and progress over time, the histology of the lesion may be speculated with varying degrees of certainty.

Diagnosis

Diagnosis relies on an accurate neurological examination. The radiologist should guide the neurologist in choosing the appropriate imaging modality and should localize the tumor with regard to the different anatomical and functional regions within the CNS. In addition, displacement, encasement, or infiltration of important, potentially threatened fiber tracts or vessels should be studied. By combining the age, location, and biological behavior of the tumor, the radiologist should be able to make the most likely diagnosis. In addition, he or she should differentiate the lesion from nonneoplastic lesions that can mimic tumors. Furthermore, before surgery, tumor seeding within the cerebrospinal canal or ventricular system should be ruled out. Postoperative imaging should be performed as soon as possible, preferably within 24 h of surgery, because this allows discrimination between residual tumor and postoperative blood–brain barrier disruption.

Definition

The ►*thymus* is a gland situated in the ►anterior mediastinum. It is the source of T lymphocytes and plays an important role in cell-mediated immune responses (see Pediatric Imaging Case Review Ward, Robert J. Blackman, Hans. 2005. Elsevier health sciences).

Bronchial adenocarcinomas are rare neoplasms of the tracheal bronchial tree commonly referred to as adenomas, which are low-grade malignant lesions that can metastasize. Benign ►bronchial adenomas are extremely rare. More then half of these lesions are bronchial cancerous tumors that arise from ►Kulchitsky's cells of the respiratory epithelium, part of the amine precursor uptake and decarboxylation (►APUD) system. Mucoepidermoid carcinomas account for 80% of bronchial adenomas.

Chest wall ►*Ewing's sarcoma* and *primitive neuroectodermal tumors* are biologically related lesions. The peak incidence is between 10 and 15 years of life, and they are more common in males.

►*Germ cell tumors* include teratomas, teratocarcinomas, germinomas, and embryonal cell carcinomas, among others.

Histiocytosis is a group of disorders characterized by granulomatous lesions in various organs. It occurs in all ages and there is no difference between boys and girls.

The etiology of *inflammatory pseudotumor of the lung* is multifactorial and probably a repair phenomenon. It is the most common mass lesion of the lung in children, comprising approximately 50% of benign lung lesions in childhood. They can occur at any age; the youngest case reported is of a 12-month-old patient. Sometimes these lesions are difficult to differentiate from embryonic *pulmoblastoma* (pulmonary blastoma), which may have a malignant and semimalignant course.

Lymphoma: In the first years of life, these lymphatic tumors are known as non-Hodgkin's lymphoma (NHL). In the teenage years, these tumors predominantly represent Hodgkin's lymphoma/disease (HD) and are almost always associated with lymphadenopathy (supradiaphragmatic). In the younger age group, the cells can be difficult to distinguish from acute lymphoblastic leukemia and are therefore known as "leukemia lymphoma complex." Of all mediastinal tumors, approximately 20% consist of malignant lymphomas of the mediastinum. Together with germ cell tumors they account for 80–85% of anterior mediastinal masses. There is a male preponderance in the pediatric population.

Neuroblastoma is a neurogenic tumor originating from the paravertebral sympathetic chain. *Ganglioneuromas* usually occur in older children and adolescents; neuroblastoma and ganglioneuroblastoma occur in the first decade of life. Thoracic neuroblastoma comprises about 15% of all cases of neuroblastoma. There is less dissemination than in the abdominal variant, with about 20% of cases presenting with metastatic disease.

Additionally, there are other entities such as metastasis or the rare pulmonary or pleural sarcoma.

Pathology/Histology

The thymus consists of lymphoid tissue containing dense accumulations of lymphocytes. It is surrounded by a thin, connective tissue capsula.

Bronchial adenocarcinomas are histologically similar to salivary gland tumors. They can be of high- or low-grade malignancy. Rarely, they metastasize to regional lymph nodes and their clinical history is usually one of respiratory infections, low bar consolidation, and a central or nodal mass.

Ewing's sarcoma of the chest and *primitive neuroectodermal tumors* are histologically different entities, but they both consist of malignant, small, round cells.

Germ cell tumors can be malignant (10%) and can be associated with elevated levels of human chorionic gonadotropin or alpha-fetoprotein. Most often they are located in the anterior mediastinum. Germ cell tumors are asymptomatic in more than half of patients and they seldom occur before the second decade of life. *Teratomas* are the most common type, with varying degrees of differentiation. The immature types can be potentially malignant. If located in the thymus, it may be seen as an anterior mediastinal mass, sometimes with calcifications.

Histiocytosis is characterized by granulomatous lesions with infiltration of large histiocytes and monocytes in varying degrees. ►Langerhans' cells are seen in the cytoplasm of histiocytes.

Inflammatory pseudotumor is a benign tumor typically characterized by localized proliferation of mononuclear inflammatory cells, plasma cells, lymphocytes, and eosinophils.

Pulmoblastoma is a mostly benign embryologic tumor that rarely turns malignant.

Lymphoma varies with age and cell type. Histology determines the diagnosis of NHL, HD, and leukemia lymphoma complex.

Neuroblastoma is derived from primitive ganglion cells. These may partially differentiate into cells having the appearance of immature neurons.

Presentation

Thymoma can be seen in childhood in combination with myasthenia gravis.

Children with *bronchial adenocarcinoma* present with wheezing, hemoptysis, or lobar collapse. Very seldom are they asymptomatic. Adenoid cystic carcinoma or cylindroma, a slow-growing lesion, may also present with respiratory symptoms and persistent atelectasis.

The child with *Ewing's sarcoma* of the chest or *primitive neuroectodermal tumors* presents in most cases with chest pain and/or a palpable mass and, often, pleural effusion.

Patients with *germ cell tumors* may present with chest pain, hemoptysis, and possibly even a ruptured tumor. A minority of the patients is asymptomatic.

If *histiocytosis* is located in the thymus, it may be seen as an anterior mediastinal mass, sometimes with calcifications. If the disease is located in the lungs, the child presents with coughing and/or dyspnea.

Inflammatory pseudotumor: It is unclear whether there is a relationship with malignancy. In children without a known underlying malignancy, an ▶inflammatory pseudotumor is more likely than a malignant lesion. There is seldom a history of trauma or preceding infection, although some of these lesions begin as a radiologically designated "pneumonia."

Pulmoblastoma has a similar presentation.

In *lymphoma*, clinical presentation varies with the extent of disease, particularly in its systemic manifestations. It can be silent or present with fatigue, swollen nodes, and malaise.

The presentation of *neuroblastoma* depends on its anatomic site of origin. In the posterior mediastinum, neurogenic tumors make up the majority of the differential diagnosis in the abdomen. Fifty percent of children with intraspinal extension of a neuroblastoma are symptomatic when they present.

Imaging

The normal *thymus* is seen in infancy as a low radio-opaque structure that usually allows the pulmonary vessels to be seen through it. The so-called sail sign is due to a prominent thymus with straight borders. On conventional thorax images, the thymus becomes less noticeable after the age of 4 years; however, it is still easily seen on computed tomography (CT) and magnetic resonance (MR) images until after puberty (Fig. 1a and b). Under the age of 10 years, the thymus has an intermediate signal on T1-weighted images and is hyperintense on T2-weighted MR images. *Ectopic thymus* is in most cases positioned in the neck. Cervical thymus may contain cysts and cross-sectional imaging may be necessary, with a preference for MRI. It may show a mass effect on surrounding organs, contrary to the normal thymus. *Thymolipoma* is seen in children and young adults and is mostly discovered as an incidental finding. On CT and MR images, it is seen as a fatty mass containing solid, thymic tissue elements. The solid tissue elements enhance after administration of intravenous contrast medium. There is no invasion of adjacent structures.

On CT images, *bronchial adenocarcinomas* are generally ovoid, soft tissue masses. Calcification is seen in about 50% of cases.

Ewing's sarcoma of the chest or *primitive neuroectodermal tumor* is, on CT, a solid heterogeneous mass with, especially in larger lesions, necrotic centers. In most cases there are no calcifications in the tumor (Fig. 2). There may be cortical rib destruction. On T2-weighted MR images the tumor is hyperintense and in most cases these lesions are of intermediate signal on T1-weighted images. Contrast enhancement is variable. Ultrasound (US) is sometimes superior to CT and MRI in delineating the diaphragm.

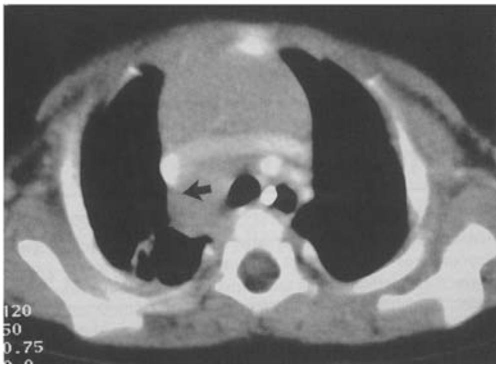
b



Neoplasms, Chest, Childhood. Figure 1 **(a) Chest radiograph showing the thymus as a density that looks like a right, upper lobe consolidation. (b) CT of the thorax showing a normal homogeneous thymus with extension posterior to the superior vena cava (*arrow*).**

Neoplasms, Chest, Childhood. Figure 2 **Ewing's sarcoma, extraosseous, situated in the posterior mediastinum. Large, solid lesion with a few low-attenuation lesions.**

Most of the *germ cell tumors* can be diagnosed on CT (Fig. 3). Attenuation values are indicative of the germ cell layers and MR signal intensity may mirror this. They are usually well demarcated and have thick walls.

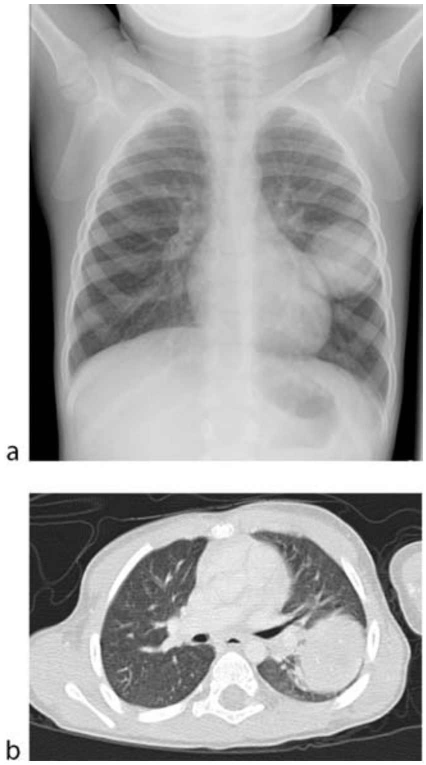
Histiocytosis (Fig. 4): On a conventional thorax image, interstitial and nodular changes can be seen. Upper lobe

Neoplasms, Chest, Childhood. Figure 3 Germinoma: a large lesion situated in the anterior mediastinum in a newborn child containing the three germ layers: fat (A), soft tissue (B), and bone (C).

Neoplasms, Chest, Childhood. Figure 4 CT of histiocytosis of the lung. Bilateral increased interstitial markings with small nodules.

involvement is at least equal to lower lobe involvement. CT scanning in an early stage of the disease may show a ground glass appearance, resulting in the typical honeycomb lung in the later phase. If the thymus is also involved, the organ is enlarged and shows cysts and calcifications on CT images. Mediastinal and hilar lymphadenopathy can also be present. The thoracic bone structures should also be evaluated for bony lesions on CT scanning. There is no role for MRI.

Inflammatory pseudotumor/pulmoblastoma: A majority of the lesions occur in the lower lobe; they are approximately 3–4 cm in diameter and can about the pleura (Fig. 5a). CT is the major modality used in the evaluation of these lesions, and these masses are usually well circumscribed. If they reach the lung surface, they can



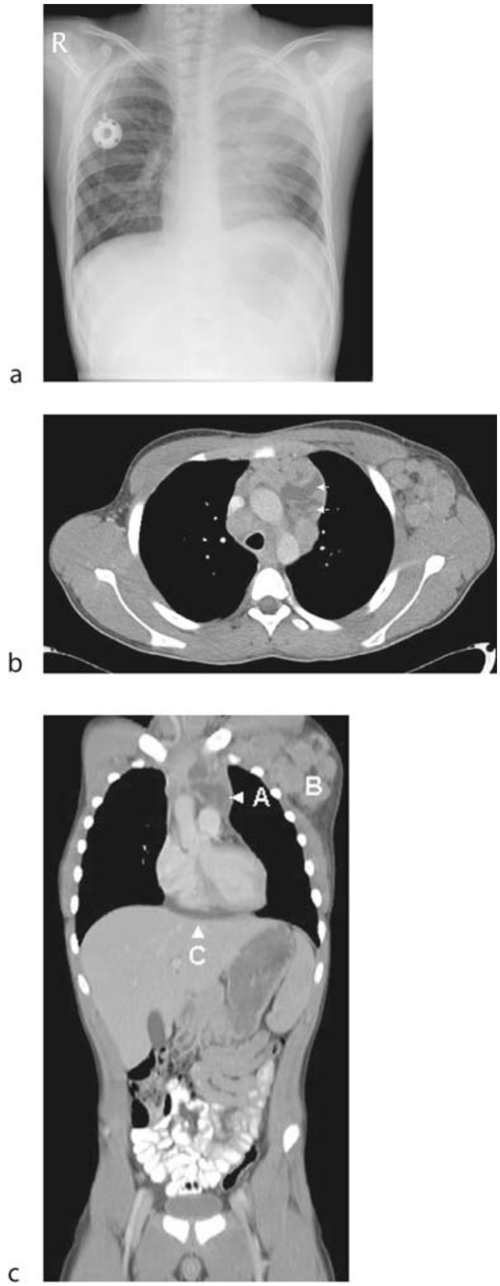
Neoplasms, Chest, Childhood. Figure 5 (a) Chest radiograph of inflammatory pseudotumor with round mass in left lower lobe of the lung. (b) CT of the same inflammatory pseudotumor.

be visualized with US (Fig. 5b). They can resemble a coin lesion, possibly with calcification, an endobronchial mass, and a spicular mass with necrosis. There is varied enhancement following intravenous administration of contrast medium. Lymphadenopathy and plural effusion are rare. MRI is of no additional value.

Lymphoma

NHL: Typically, an anterior mediastinal mass is noted on chest radiographs (Fig. 6a). Pleural effusions are frequently noted. In addition, there may also be pericardial effusion. Airway compression may be noted, which might be important when subsequent CT imaging is contemplated. CT can be omitted as there is seldom any additional staging information. On the other hand, staging in the abdomen, and sometimes in the neck region, make CT the most efficient modality.

HD: In contrast to NHL, HD is usually nodal (Fig. 6b). It is rare before 5 years of age and is characterized by the so-called Reed-Sternberg cell. The nodular sclerosing type accounts for 70% of all cases, with 20% having mixed cellularity. Painless adenopathy is the usual presentation; 30% of cases have hilar adenopathy. CT will demonstrate



Neoplasms, Chest, Childhood. Figure 6 **(a) NHL: chest radiograph of lesion situated in the anterior mediastinum, no effusion, normal ribs. (b) CT of Hodgkin's lymphoma in the anterior mediastinum with necrotic areas (*arrows*). Large lymph nodes in left axillary tail. (c) Coronal thorax and abdomen image of a patient with Hodgkin's lymphoma showing the mediastinal tumor (A), left axillary involvement (B), and pericardial effusion (C).**

abnormalities in about 50% of patients with a normal chest radiograph. Pleural effusions as well as pericardial effusions occur frequently (Fig. 6c). Calcification is seldom present before treatment has been initiated.

Neoplasms, Chest, Childhood. Figure 7 **CT image of neuroblastoma. *Arrow* indicates calcification.**

Neuroblastoma: Usually the chest radiograph shows a mass, possibly with calcifications, that may erode the posterior rib and vertebral body. This is then often verified by US; however, cross-sectional imaging is needed to detect nodal enlargement and intraspinal extension. Approximately 80% contain calcification on CT images (Fig. 7). Assessment of the enlargement of intervertebral neural foramina is best shown with MRI. To exclude or identify metastatic disease, sonography, nuclear medicine bone scan, or MIBG scintigraphy should also be performed.

Interventional Radiology

There is no place for interventional radiologic treatment in these conditions; sometimes imaging my help by offering a safe, image-guided biopsy option or may enable uncomplicated drainage of secondary collections (usually using US, CT, or rarely fluoroscopy).

Synonyms

Benign and malignant tumors of the gallbladder; Gallbladder cancer; Gallbladder neoplasms

Definition

Gallbladder tumors are defined as primary tumors, both benign and malignant, arising from the gallbladder wall.

Pathology/Histopathology

Adenoma, Gallbladder

In the majority of cases, benign tumors originating from the epithelium of the gallbladder are associated with cholelithiasis. The overall incidence is low (0.5% of cholecystectomy specimens), with a female predominance.

Adenomas of the gallbladder are less common with respect to other benign lesions such as cholesterol polyps and adenomyoma. An increased prevalence of adenomas of the gallbladder and the biliary tract can be associated with both adenomatous polyposis and Peutz-Jeghers syndrome.

Histologically, adenomas are subdivided into tubular (the most frequent variant), papillary, and tubulopapillary types. On gross specimen, the tumors appear as polypoid structures projecting into the gallbladder lumen, with a broad base or pedunculated with a well-defined stalk. Tubular adenomas present a typically lobular contour, whereas papillary types may have a cauliflower-like appearance. The lesion size is variable usually <2 cm in diameter. In about 10% of cases there are multiple adenomas. Malignant progression is reported rarely (1).

Carcinoma, Gallbladder

Although uncommon, carcinoma of the gallbladder represents the most frequent malignant tumor of the biliary tree and the sixth most common malignancy of the gastrointestinal tract, accounting for 3% of all gastrointestinal tumors. The reported incidence in patients undergoing cholecystectomy is about 1%, whereas in autopsy studies it ranges from 0.5 to 24%. Peak incidence is in the seventh decade of life with a female predominance (3:1). An increased incidence is reported in Native Americans.

Even if a multifactorial etiology is considered in most cases, gallbladder carcinoma seems to be related to longstanding (more than 15 years) cholecystolithiasis. More than 80% of patients have cholesterol gallstones. Theoretically, malignant transformation may be related to a peculiar bile composition causing gallstone formation, associated chronic inflammation, and repetitive epithelial repair, followed by dysplasia. In animal studies, chronic inflammation has been confirmed as the most important pathogenetic factor. This theory may also explain the higher incidence in women.

Also, porcelain gallbladder, an advanced stage of chronic cholecystitis, is closely associated with gallbladder cancer. The presence of an anomalous pancreaticobiliary junction as well as congenital cystic disorders of the biliary tree have been suspected as other predisposing factors, as well as a genetic mutation on gene p53 and K-ras. Previous infection by *Salmonella typhi* and exposure to some environmental carcinogens (methylcholantrene) have been reported as potential risk factors. Although lacking proof, an association with lifestyle factors such as cigarette smoke, coffee, alcohol abuse, and obesity has been suggested. An increased risk of developing carcinomas of the extrahepatic biliary tract in patients with chronic inflammatory bowel disease (ulcerative colitis, Crohn's disease) and primary sclerosing cholangitis has also been reported, indicating an association with an autoimmune distortion. In rare cases, an adenoma–carcinoma sequence has been histologically documented.

Histologically, this malignant tumor arises from the gallbladder epithelium. The most common primary form is ►adenocarcinoma (►Adenocarcinoma, Gallbladder) (90% of cases) originating from the columnar cells with a pattern similar to other bile duct carcinomas. Several subtypes with slightly different biological behavior can be

N

differentiated: papillary, nodular, and tubular tumors with or without mucin production. The papillary type seems to be more often localized and less infiltrative, whereas the nodular type shows early spread to regional lymph nodes and, *via* venous drainage, the liver bed.

Less frequent epithelial tumors include ►squamous cell carcinoma (Squamous Carcinoma, Gallbladder), ►adenosquamous carcinoma (►Adenosquamous Carcinoma, Gallbladder) (►adenoacanthoma (►Adenocanthoma, Gallbladder)), ►small cell carcinoma (►Small Cell Carcinoma, Gallbladder) (oat cell), and anaplastic carcinoma. While well-differentiated tumors with metaplasia are typically less invasive, undifferentiated tumors are associated with a poorer prognosis.

In most cases (60%) the tumors involve the fundus of the gallbladder; location in the body and neck occurs in 30 and 10% of cases, respectively. Macroscopically the tumors are usually diffusely infiltrating, whereas an intraluminal polypoid growth is less common.

At the time of diagnosis, an extensive tumoral involvement of the gallbladder can be observed with metastatic lymph nodes in half the cases. Early metastatic involvement includes hepatoduodenal and pancreaticoduodenal lymph nodes; right celiac and retroperitoneal lymph nodes may be involved as well. Local spread through the gallbladder wall leads to direct invasion of the liver bed, extrahepatic biliary ducts, duodenum, and, less commonly, the colon. Spread to the organ wall may determine intraperitoneal seeding with implants on the liver surface, bowel, and pelvis. Hematogenous metastases are most commonly seen in the liver.

Staging of the tumoral extent is a prerequisite for establishing appropriate treatment and the patient's prognosis. Tumoral staging is performed according to the TNM classification. Another classification commonly used and more strictly related to the clinical presentation is the Nevin–Moran staging system (Table 1).

Other exceedingly rare malignant tumors of the gallbladder include malignant mesenchymal tumors (embryonal rhabdomyosarcoma, leiomyosarcoma, and malignant fibrous histiocytoma), ►carcinosarcoma, carcinoid, lymphoma, and melanoma (2, 3).

Neoplasms, Gallbladder. Table 1 Nevin–Moran staging system for gallbladder carcinoma

Stage	Tumor location
I	Intramucosal tumor
II	Mucosa and muscolaris involved
III	All three layers involved
IV	All three layers and cystic duct lymph nodes involved
V	Liver or distant metastases

Clinical Presentation

Adenoma, Gallbladder

Gallbladder adenomas are usually asymptomatic lesions that are occasionally discovered. Chronic or intermittent right upper quadrant pain may occur in patients with large adenomas or adenomas obstructing the cystic duct.

Carcinoma, Gallbladder

Due to its natural history, the clinical presentation of gallbladder carcinoma is more common in advanced stages of disease. Clinical symptoms are not specific. Patients may present at early stages with symptoms attributable to gallstones or cholecystitis, such as abdominal pain, nausea, and vomiting. Constitutional symptoms, including fatigue, weight loss, anorexia, hepatomegaly, and ascites, occur late and are considered poor prognostic signs. Jaundice and Courvoisier gallbladder (i.e., painful hydrops) occur in cases of invasion of the extrahepatic biliary tree and are not specific. Clinical signs may include a palpable mass in the right upper quadrant, supraclavicular lymphadenopathy, and rectal shelf in cases of pelvic spreading. Duodenal or colonic obstruction and cholecystoenteric fistulae are signs highly indicative of very advanced stages.

Laboratory tests may reflect the presence of extrahepatic cholestasis (increased levels of conjugated bilirubin, alkaline phosphatase, and gamma glutamyl transpeptidase). Tumor markers such as CA19-9, CA125, and carcinoembryonic antigen can be elevated but are not specific.

Patients with gallbladder carcinoma have an overall mean survival of 6 months, and the 5-year survival rate is about 5%. Surgery is the therapy of choice; however, because most gallbladder carcinomas are quite advanced when detected, surgical treatment is often not amenable. Only one-fourth of patients are eligible for curative resection (tumors incidentally diagnosed at cholecystectomy). Radiation therapy with or without concurrent chemotherapy is the therapeutic approach for surgically nontreatable patients (3).

Imaging

Adenoma, Gallbladder

Ultrasound (US) displays gallbladder adenomas as nonmobile structures protruding into the gallbladder lumen, with smooth margins. A lobulated or cauliflower appearance is infrequent. In cases of pedunculated adenomas, visualization of the stalk with the patient in lateral decubitus is helpful. The thickness of the adjacent gallbladder wall is usually normal (<3 mm). Adenomas present moderately hyperechoic without acoustic shadowing and may be heterogeneous or hypoechoic with increasing size. On contrast-enhanced computed tomography (CT), gallbladder adenomas appear as intraluminal soft-tissue masses that are isodense or hypodense in comparison with hepatic parenchyma. In CT the differentiation of noncalcified gallstones can be crucial, whereas in magnetic resonance cholangiopancreatography (MRCP), small, nonmobile, filling defects inside the gallbladder lumen can be the only finding (1).

Carcinoma, Gallbladder

The role of conventional radiology is very limited and reveals suspicious signs only incidentally. A systematic work-up by conventional imaging is not appropriate anymore. Plain abdominal films may demonstrate calcifications of the gallbladder wall (porcelain gallbladder) or calcified gallstones. Punctate calcifications of the primary tumor or metastases may be seen with mucinous tumors. Biliary gas resulting from a cholecystoenteric fistula is uncommon. In further advanced tumors, barium studies can show invasion or displacement of the duodenum or transverse colon.

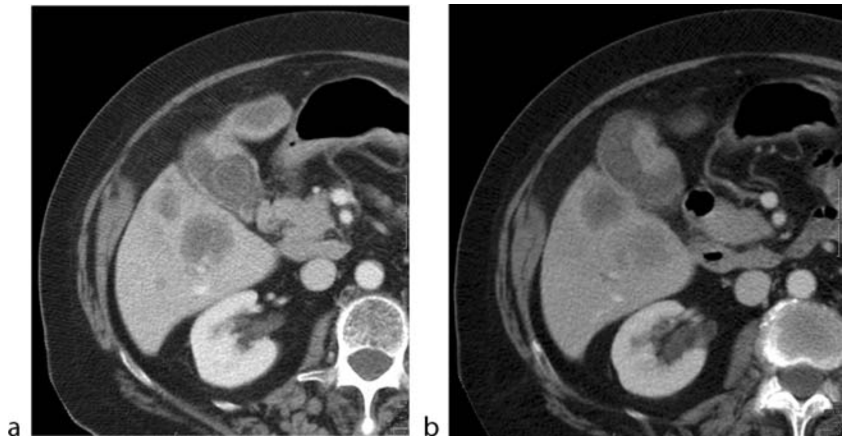
US is used mostly as a diagnostic modality. Features on US range from a relatively normal or distended gallbladder with only an intraluminal polyp or focal wall thickening, to the presence of a large, ill-defined mass associated with invasion into the surrounding structures. In contrast to the fine-lined normal gallbladder wall, neoplastic mural thickening appears heterogeneous. Advanced gallbladder carcinoma typically presents as a large, single or multinodulated, hyperechoic, inhomogeneous mass associated with strong echoes and acoustic shadowing due to gallstones or tumoral calcifications. The presence of an extraluminal complex mass extending to the liver that is indistinguishable from the surrounding parenchyma, with multiple hypoechoic areas due to necrosis, is a sign of advanced disease. US can also show signs of tumoral spread such as hilar lymphadenopathy and bile duct dilatation but is inferior to CT or magnetic resonance (MR) imaging for further staging in terms of intraperitoneal disease and distant metastases.

In CT, gallbladder carcinoma is determined by a focal or diffuse wall thickening up to an isoattenuating or hypoattenuating soft-tissue mass filling and/or replacing the gallbladder in more advanced cases. Fuzzy borders and heterogeneous enhancement (due to the combination of both necrotic and viable tissues) of the mass is common. While a bright enhancement is often present in cases of isolate tumoral wall thickening, the less common polypoid tumors may show well-defined round borders and may be isoattenuating or hypoattenuating after contrast medium administration (Fig. 1)(3, 4).

Metastatic lymphadenopathy may be seen as well-defined nodular masses in the hepatoduodenal ligament or the presence of an infiltrating, soft-tissue enhancing mass, obscuring portal vein margins. Other frequent sites of lymphatic spread, well depicted by CT, are the peripancreatic lymph nodes. Associated biliary dilatation due to obstruction at the level of the hepatic hilum or soft-tissue invasion into the liver bed is usually well visualized. Peritoneal and distant hematogenous metastases (mostly in the liver and less frequently in lungs, skeleton, pancreas, and brain) may be detected.

MR does not represent a primary imaging modality for gallbladder cancer but may be helpful to distinguish benign from malignant mural thickening. MR findings in gallbladder carcinoma resemble those known from CT.

N



Neoplasms, Gallbladder. Figure 1 (a, b) Gallbladder carcinoma, polypoid form. Computed tomography scans at two different levels show a focal thickening extending beyond the gallbladder wall and protruding into the lumen, with lobulated contours, and isoattenuating with respect to the adjacent wall. Metastatic spread to the liver parenchyma and intraluminal stones are also displayed.

Gallbladder carcinoma is associated with prolonged T1 and T2 relaxation times, appearing hyperintense and poorly marginated on T2-weighted images, and isointense to hypointense on T1-weighted images. Ill-defined early enhancement is the typical aspect of gallbladder carcinoma at dynamic gadolinium-enhanced MR imaging (5).

MRCP may complete the study of the biliary tree, showing filling defects in the gallbladder lumen or also in the biliary tree and providing an excellent, noninvasive overview of potential biliary obstruction.

Direct cholangiography (percutaneous transhepatic cholangiography, or PTC) or endoscopic retrograde cholangiopancreatography (ERCP) may be indicated if cytology is desired or an intervention (such as drainage or stent placement) in cases of jaundice is recommended.

Angiography is of no additional value in the diagnosis of gallbladder carcinoma whenever tumoral neovascularization, arterial, and/or venous encasement/invasion can be displayed by angiography.

Nuclear Medicine

Carcinoma, Gallbladder

FDG-positron emission tomography (PET) and biliary scintigraphy with ^{99m}Tc iminodiacetic acid analogs are not specific and are not indicated in gallbladder carcinoma. Whether CT–PET will gain some importance in this disease is not yet defined.

Diagnosis

Adenoma, Gallbladder

Differentiation of gallbladder malignancies is crucial, especially in case of lesions >1 cm and/or associated with focal gallbladder thickening. Adenomas usually tend to be more homogeneous than malignant lesions.

Carcinoma, Gallbladder

Despite advances in diagnostic imaging, early-stage carcinoma is usually diagnosed only incidentally. Many benign conditions may resemble imaging features of gallbladder carcinoma. Gallbladder wall thickening may be appreciated in cholecystitis (acute and chronic), heart failure, hypoalbuminemia, and liver cirrhosis. The presence of a diffuse mural thickening instead of a focal involvement (more typical of gallbladder carcinoma) associated with specific clinical features may help differentiate benign from malignant processes. Pronounced wall thickening (>1 cm) when associated with irregularity and lymphadenopathy should suggest malignancy. However, adenomyomatosis can cause focal gallbladder thickening and mimic carcinoma. The presence of hyperechoic areas creating "comet-tail" reverberation artifacts in the Rokitansky-Ashoff sinuses may lead to diagnosis. Polypoid lesions are difficult to distinguish from polypoid carcinoma. Larger polyps with cauliflower appearance suggest malignancy, whereas polyps <5 mm are unlikely to be malignant. Polyps ranging between 5 and 10 mm must be followed up.

Metastases of melanoma may also cause polypoid gallbladder lesions. Tumefactive sludge may mimic an intraluminal mass; nevertheless, a tumor can usually be excluded in cases of dislodgement of the sludge and the absence of vascularization on Doppler US. Xanthogranulomatous cholecystitis—an inflammatory process with mural thickening and involvement of the surrounding tissue, including lymph nodes—may cause difficulties in differentiation from gallbladder carcinoma. In ambiguous cases MR may be helpful for differentiating focal or diffuse mural thickening from gallbladder carcinoma, adenomyomatosis, and chronic cholecystitis (3).

Consultant Radiologists, Leeds General Infirmary, Leeds, UK
keith.harris@leedsth.nhs.uk
Alan.Chalmers@leedsth.nhs.uk

Imaging of gastroduodenal neoplasms relies on the complimentary roles of computed tomography (CT) and ►endoscopic ultrasound (EUS). Multidetector row technology has established CT as the primary technique for the overall evaluation and ►staging of gastroduodenal tumours (1). For the specific detail of local staging, EUS is the most accurate tool currently available.

Stomach

Benign Tumours

Approximately 85–90% of all gastric neoplasms are benign.

Polyps

Gastric polyps can be demonstrated by a good quality double contrast barium meal. Most of them that are less than 1 cm diameter, arise in the gastric fundus and body, are hyperplastic and have no premalignant potential. Adenomas account for up to 10% of gastric polyps. Dysplastic adenomas have a malignant potential; the risk of malignancy increasing with increasing polyp size (>2 cm). Any sizable or unusual polyp must be evaluated with endoscopy and biopsy.

Submucosal Tumours

Benign submucosal tumours include lipomas, haemangiomas, neural tumours and small ►gastrointestinal stromal tumours (GISTs). These tumours may be demonstrated by contrast radiology and have no discriminating features. A fatty mass on CT will represent a lipoma but otherwise evaluation of submucosal lesions requires EUS to establish the exact layer of origin within the bowel wall. By assessing position and morphology, EUS can indicate the probable aetiology (2) as well as categorising lesions as highly likely to be benign and safe to ignore, indeterminate and worthy of follow-up, or of concern and requiring biopsy or resection.

Malignant Tumours

Gastric Cancer

Gastric cancer (3) is the second commonest cancer worldwide with adenocarcinoma, accounting for more than 90% of all of malignant tumours of the stomach. Gastric cancer presents with a wide range of symptoms including dyspepsia, anorexia and weight loss. Diagnosis is usually made by upper gastrointestinal endoscopy and biopsy. On barium, certain features suggest malignancy such as thickened irregular folds and shallow eccentric ulceration but it is essential that any suspicion is confirmed with endoscopy and biopsy. Prognosis is related to tumour stage and accuracy is essential to plan the most appropriate management, predict prognosis, and reduce unnecessary surgical interventions.

Tumour staging is based upon the widely accepted tumour-node-metastasis (TNM) classification:

Primary tumour (T)

T1: Tumour invades lamina propria or submucosa
T2: Tumour invades the muscularis propria or the subserosa
  T2a: Tumour invades muscularis propria
  T2b: Tumour invades subserosa
T3: Tumour penetrates the serosa (visceral peritoneum) without invading adjacent structures
T4: Tumour invades adjacent structures (e.g. spleen, pancreas, transverse colon, etc.)

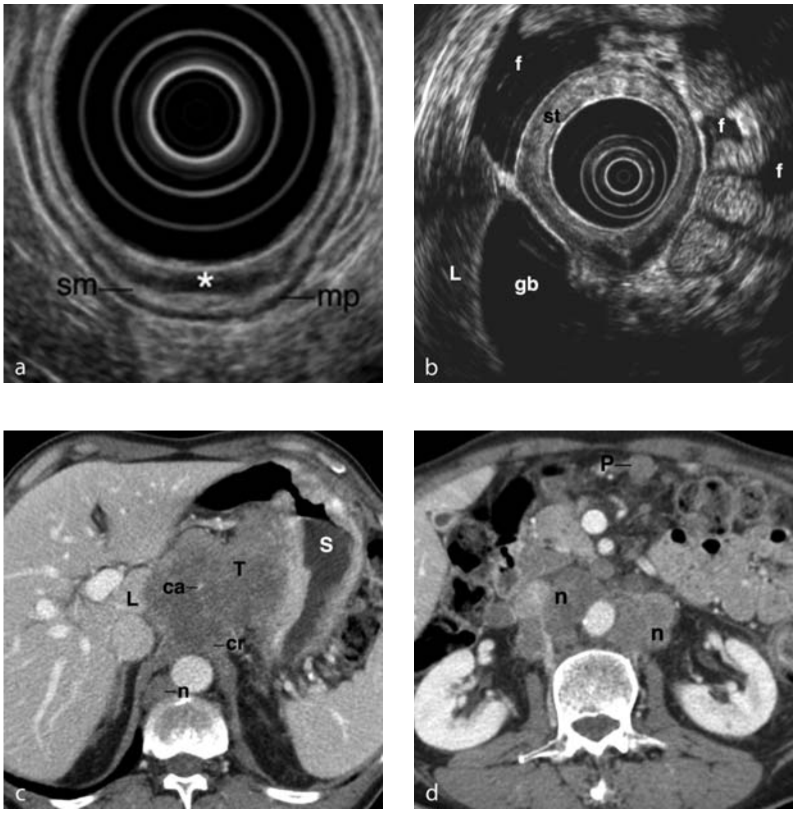
CT has clear advantages when evaluating spread of disease outside the stomach but despite optimised multidetector techniques is inferior to EUS when assessing the layers of the gastric wall. EUS is the only imaging technique that can reliably discriminate the component layers allowing accurate prediction of T stage (Fig. 1a–d). The omental reflections around the stomach are not clearly seen with EUS, making it impossible to determine whether tumour has penetrated through the muscularis propria into the greater or lesser omenta to breach the visceral peritoneum, i.e. T2b or T3.

Multiplanar and 3D techniques are considered a routine component of any multidetector CT assessment of gastroduodenal pathology and its potential spread. Coronal reformats are particularly suited for the study of gastric pathologies, both from improved staging accuracy and the improved overview afforded to the surgeons and medical oncologists. 3D-rendering techniques (virtual gastroscopy) have been advocated for gastric fold assessment. Direct invasion into adjacent structures (T4) can be difficult to establish on both CT and EUS. CT relies upon tumour contact with the contiguous organ and loss of intervening fat plane. EUS can exclude direct invasion if free movement is shown between tumour and adjacent organ.

Regional lymph nodes (N)

N0: No regional lymph node metastasis
N1: Metastasis in 1 to 6 regional lymph nodes
N2: Metastasis in 7 to 15 regional lymph nodes
N3: Metastasis in more than 15 regional lymph nodes

The regional lymph nodes are the perigastric nodes along the lesser and greater curvatures, and the nodes located along the left gastric, common hepatic, splenic and coeliac arteries. Involvement of other intra-abdominal lymph nodes, such as the hepatoduodenal, retropancreatic, mesenteric, and para-aortic, is classified as distant metastasis (M1). The CT assessment of nodal involvement relies almost entirely on size with upper limits of normal chosen to achieve a best compromise between sensitivity and specificity. Currently >6 mm maximum diameter short axis is advocated for regional nodes, rising to >8 mm for non-regional nodes. Certain morphological features such as nodal enhancement or a rounded margin suggest infiltration whereas clusters of smaller nodes should raise concern. Reported CT accuracy rates are no better than 50–70%. Lymph nodes are well seen on EUS and several morphological features correlate well with malignant



Neoplasms, Gastroduodenal. Figure 1 Gastric cancer. 1a: EUS image of a T1 gastric cancer (*) demonstrating preservation of a normal layer of submucosa (sm) deep to the tumour, mp = muscularis propria. 1b: EUS demonstrating small volume ascites (f), thick-walled stomach (st) due to tumour infiltration, L = liver, gb = gallbladder. 1c: CT of an advanced gastric cancer (T) extending from the posterior wall of stomach (S) to liver (L) and abut the diaphragmatic crura (cr). Encasement of the coeliac axis (ca) and a retrocrural node (n) also noted. 1d: Same patient as 1c demonstrating further non-regional lymphadenopathy (n) and peritoneal tumour deposits (P).

infiltration. Hypoechoic nodes greater than 1 cm with well-defined rounded margins are likely to be malignant.

Distant metastasis (M)

M0: No distant metastasis
M1: Distant metastasis

CT provides an excellent whole body survey for the common sites of metastatic disease namely lung, liver, adrenals, ovaries, peritoneum and bone. EUS can detect low volume ascites, which may be the first indication of peritoneal spread. Magnetic resonance imaging (MRI) and positron emission tomography (PET) are not part of routine staging but have roles to play in problem-solving equivocal CT or EUS findings. PET may be helpful in detecting distant metastases and reports suggest that PET is more sensitive than CT for the detection of peritoneal disease. However, some gastric tumours such as mucinous or signet ring types typically take up fluorodeoxyglucose (FDG) poorly. For recurrent disease, PET may be useful when CT is negative or equivocal.

Lymphoma

The commonest site of extranodal non-Hodgkin's lymphoma is the stomach (approximately 25%) but lymphoma only accounts for 2–8% of all gastric malignancies. Morphology ranges from ulcers, nodules and polyps to fold enlargement and diffuse infiltration. The CT appearances of lymphoma and carcinoma can be similar. Lymphoma is often advanced at presentation with an average tumour size of 10 cm. Mural thickening is characteristically more marked and lymph nodes are larger. Mucosa-associated lymphoid tissue (MALT) lymphoma is most frequently found in the gastrointestinal tract, particularly the stomach. Gastric MALT lymphoma may regress completely after *Helicobacter pylori* eradication and EUS has been shown to be more sensitive than endoscopy and CT for staging and predicting tumour response. EUS can differentiate superficial from infiltrative variants which are of prognostic significance and can confirm remission or persistence of the disease during follow-up (4). Continuing gastric wall thickening, even with negative histology, requires repeated biopsies as persistent disease is likely.

Metastases

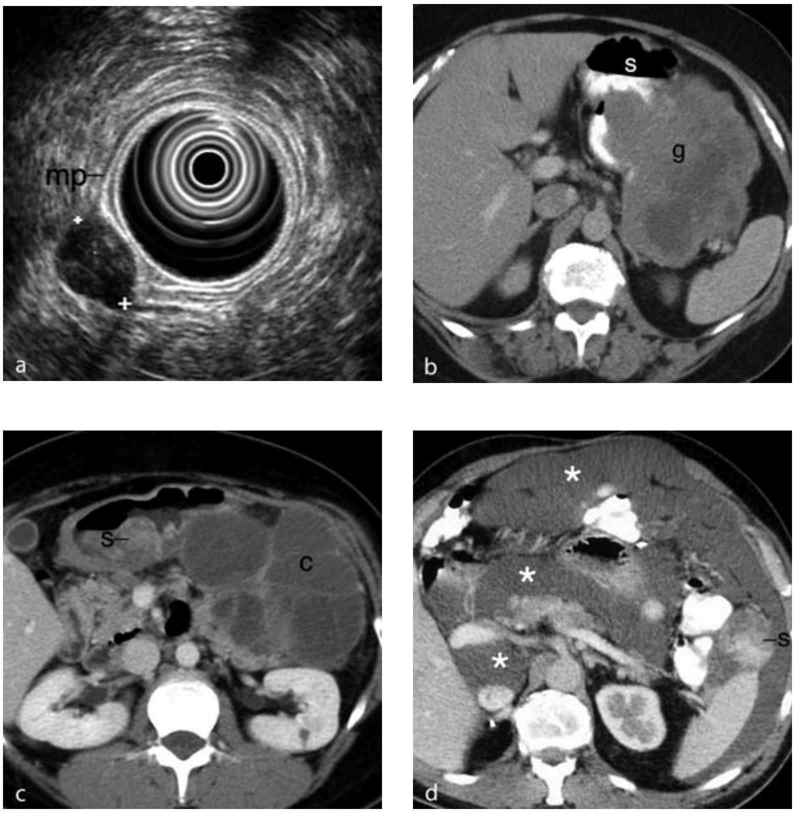
Metastases to the stomach are uncommon being found at post-mortem in only 2% of patients dying from malignancy. They may present as focal lesions (e.g. melanoma, lung, Kaposi's sarcoma), or as diffuse linitis type infiltration (e.g. breast). Direct or transperitoneal spread from other abdomino–pelvic tumours can occur.

Gastrointestinal Stromal Tumours

Most GISTs arise in the stomach (60–70%). About 10–30% of all GISTs are malignant and the risk of malignancy increases with size (>5 cm). Liver and the peritoneal cavity are the commonest sites for metastatic disease but lymph node and bony metastases are rare. Gastrointestinal bleeding is the commonest symptom but most small gastric GISTs are asymptomatic and detected incidentally. Barium studies show features of a submucosal mass—a smooth well-defined filling defect with either intact mucosa or central umbilication. Smaller GISTs are typically intramural and EUS will show them usually arising from the fourth hypoechoic layer, the muscularis propria (Fig. 2a). The vast majority have very low malignant potential but EUS can predict malignant change by identifying irregular margins, cystic spaces, and malignant-looking lymph nodes (5).

With increasing size, a more exophytic morphology is seen and patients typically present with abdominal pain or a palpable mass. The CT features of larger GISTs are variable and range from uniformly solid to marked heterogeneity with solid and frankly cystic change mimicking lymphoma or sarcoma (Fig. 2b and 2c). GISTs can appear aggressive with involvement of multiple adjacent organs but in contrast to adenocarcinoma, they tend to abut and displace rather than infiltrate. Peritoneal spread can be extensive.

After imatinib, both the primary mass and the peritoneal changes can display a rapid reduction in size and density with cystic changes mimicking a pseudomyxoma appearance (Fig. 2d). As most GISTs and their metastases take up ^{18}FDG, a preoperative PET study is highly sensitive in demonstrating metastatic disease not visible on other imaging. PET can also be used to assess response to non-surgical treatment.



Neoplasms, Gastroduodenal. Figure 2 Gastrointestinal stromal tumours (GIST). 2a: EUS of a small gastric GIST (12 mm between +) arising within the muscularis propria (mp). 2b: CT demonstrating a large GIST (g) arising from the posterior wall of the stomach (S). 2c: CT of a gastric GIST with both solid (S) and cystic components (C). 2d: GIST following imatinib therapy. Low density peritoneal tumour mimicking pseudomyoma peritonei (*) along with a persisting solid component (S).

Carcinoid
Approximately 30% of gastrointestinal carcinoid tumours arise in stomach. The lesions can be small and submucosal, large and ulcerated, focal or multicentric. Benign and malignant variants occur. Small carcinoid tumours are best demonstrated by EUS or on CT during the arterial phase of contrast enhancement.

Duodenum

Tumours arising in the duodenum include carcinoma, GIST, neuroendocrine pathologies such as carcinoid and glucagonoma, schwannomas and paragangliomas. They account for 20% of all small bowel neoplasms.

Benign Tumour

Adenoma
Duodenal polyps are less common than gastric and are usually hyperplastic or adenomatous. Adenomas are the commonest symptomatic small bowel tumour, most frequently encountered in the duodenum, and present with bleeding, obstruction, or intussusception. If multiple polyps are seen, a polyposis syndrome should be considered when 60–70% of symptomatic lesions will be malignant.

Brunner's Gland Hamartomas
These are rare tumours of the duodenum, usually benign with only rare incidences of malignancy. Smaller lesions present as incidental findings during barium examination or endoscopy whereas larger lesions present with bleeding or obstruction. EUS may help characterise the lesion but histology is crucial and endoscopic snare excision or surgery is required depending on the size.

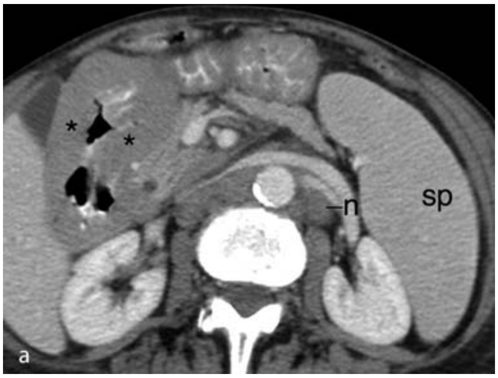
Lipoma
Can be polypoidal or submucosal.

Haemangioma
These are frequently symptomatic with bleeding a common presentation. Imaging features include calcified intraluminal phleboliths and the demonstration of feeding vessels.

Carcinoid
The majority of duodenal carcinoids are located in the proximal duodenum, can be single or multiple, intraluminal and polypoidal, or intramural. In contrast to jejunal and ileal carcinoids, duodenal carcinoid rarely produces symptoms of carcinoid syndrome. The majority are gastrin cell tumours with one-third of these leading to Zollinger–Ellison syndrome.

Malignant Tumour
The majority of small bowel carcinomas arise in the duodenum or proximal jejunum. They are often advanced at presentation and symptoms include anaemia due to chronic bleeding or vomiting due to obstruction. Duodenal carcinomas are rare but show an increased incidence in patients with familial adenomatous polyposis and long-standing coeliac disease. Early tumours can be polypoidal and may be detected by barium or endoscopy. More advanced tumours show shouldered irregular stricturing. Biopsy of any suspicious lesion is essential to detect malignant change and CT is required for tumour staging.

Lymphoma
Secondary involvement of the small bowel is more common than primary disease with approximately 40% of gastric lymphoma showing duodenal extension.



Neoplasms, Gastroduodenal. Figure 3 Duodenal tumours. 3a: CT of a patient with duodenal lymphoma—note the gross wall thickening (*), splenomegaly (sp) and para-aortic lymphadenopathy (n). 3b: CT demonstrating a duodenal stricture (*) due to metastases from a squamous cell lung cancer, d = duodenum.

Imaging may demonstrate nodular wall thickening of various degrees or an eccentric mass (Fig. 3a).

Secondary Spread to Duodenum

Metastases to small bowel are found more frequently than primary neoplasms with lung and melanoma among the commoner primaries (Fig. 3b). The duodenum may be directly invaded by tumours originating in pancreas, gall bladder, bile ducts or colon, or from other tumours of the retroperitoneum such as sarcomas. High resolution curved planar reformats provided by ►multidetector row CT can provide useful diagnostic information with respect to adjacent organ involvement.

Ampullary tumours are discussed elsewhere.

Synonym

Nephroblastoma

Definition

Malignant tumor of the kidney usually arises from ►nephroblasts. It is the most common genitourinary malignancy in children (95%).

Predisposing anomalies may consist of ►aniridia, ►hemihypertrophy, ►Beckwith–Wiedemann syndrome, and Drash syndrome as well as congenital genitourinary anomalies (horseshoe kidney).

Incidence

1. The peak incidence is between 1 and 3 years of age.
2. The female:male ratio is equal.
3. It is rare in the neonatal period.
4. The incidence of bilateral tumor is up to 10%.

Pathology/Histopathology

The classical triphasic Wilms' tumor consists of blastemic, stromal, and epithelial elements.

Tumors with favorable histology do not contain any anaplastic changes. In the National Wilms' Tumor Study Group 5 (NWTS 5), the tumor stage is determined operatively in five stages.

The 4-year survival rate is 94% for those patients whose most advanced lesion is stage I or stage II, and 76% for those whose most advanced lesion is stage III.

In Europe, the staging system is based on the radiologic findings.

N

Clinical Presentation

1. Abdominal mass, occasionally with pain
2. Hematuria
3. Nonspecific sign such as fever, or hypertension

Imaging

Ultrasonography (US) reveals an intrarenal mass of heterogeneous echogenicity and may contain cystic components, either portions of obstructed and entrapped pyelocaliceal systems or hemorrhagic and necrotic tumor (Fig. 1). Extensions into the inferior vena cava and right atrium are characteristic routes of tumor growth and can be well visualized with sonography, computed tomography (CT), and magnetic resonance imaging (MRI). The tumor typically forms a pseudocapsule, but may invade the renal capsule spreading into the retroperitoneal space, or may grow directly into mesentery and omentum.

On CT, Wilms' tumor is generally spherical and intrarenal and contains small amounts of fat or fine calcifications. Calcifications are seen in about 9% of Wilms' tumor.

After contrast medium injection, the tumor shows heterogeneous enhancement and less enhancement than the

Stage	Description
I (43% of patients)	Tumor is limited to the kidney and is completely resected
II (23% of patients)	The tumor is completely resected, but there is regional extension of the tumor (penetration of the renal sinus capsule, or extensive invasion of the soft tissue of the renal sinus). The blood vessels within the nephrectomy specimen outside the renal parenchyma, including those of the renal sinus, contain tumor
III (23% of patients)	Residual nonhematogenous tumor is present after surgery, and is confined to the abdomen

(*continued*)

renal parenchyma. Low attenuation representing necrosis, cystic degeneration, or hemorrhage is seen (Fig. 2).

On MRI, the tumor is intense on T1-weighted images (WI) and hyperintense on T2-WI. After contrast administration, Wilms' tumor is hypointense in relation to normal renal parenchyma and may define the borders more clearly.

Nuclear Medicine

Depicts bone metastasis.

Diagnosis

Most often, Wilms' tumor presents as an abdominal mass, and sometimes there is hematuria.

Imaging findings can differentiate Wilms' tumor from neuroblastoma.

Rarely, Wilms' tumor will invade surrounding tissues and even more rarely extend into the spinal canal, this being much more frequent with neuroblastoma. Clear cell sarcoma and rhabdoid tumor of the kidney are more aggressive than Wilms' tumor, but they cannot be differentiated on imaging.

A definite diagnosis of Wilms' tumor is based on histopathology.

Differential Diagnosis

1. Neuroblastoma: The imaging hallmark is distortion of the renal parenchyma in Wilms' tumor and renal displacement by neuroblastoma.

Neoplasms, Kidney, Childhood. Figure 1 Wilms' tumor: US shows intrarenal mass with pelviocaliceal distortion.

Neoplasms, Kidney, Childhood. Figure 2 CT shows a mass originating from the right kidney with distortion of the parenchyma.

2. Clear cell sarcoma of the kidney: This tumor is not a Wilms' tumor variant, but it is an important primary renal tumor associated with a significantly higher rate of relapse and death than Wilms' tumor of favorable histology findings.
3. Rhabdoid tumor of the kidney: This tumor tends to metastasize not only to the lungs, but also to the brain (10–15%). There is a distinct clinical presentation with fever, hematuria, and young age (mean 11 months) (see Table 1, Neuroblastoma).

Definitions

►Colorectal cancer (CRC) is the second leading cause of cancer related deaths in the United States and the most common cancer of gastrointestinal tract with approximately 150,000 new cases every year (1).

It is the second most lethal cancer in men after bronchial carcinoma and in women after breast cancer, with a slight female predominance in colon cancer and male predominance in rectal cancer. Despite these statistics, mortality from colon cancer has decreased over the past 30 years, possibly because of earlier diagnosis through screening and better treatment modalities.

When detected at an early stage, this type of cancer has great potential for cure, with a 5-year survival rate of 90% when the cancer is localized versus a survival rate of less than 10% when it has metastasized. Unfortunately, while incidence rates have stabilized since the mid-1990s, only 38% of colorectal carcinomas are localized at initial diagnosis, whereas almost 20% of newly diagnosed cases have distant metastases (2).

Most of colorectal tumors (90–95%) arise from sporadic adenomatous polyps and most of the remaining are accounted for by several hereditary cancer syndromes.

Prognosis is closely related to the stage at presentation and this underlies the importance of early detection. The strongest risk factor for colon cancer is age (Table 1). Incidence rates rise from 10 per 100,000 at age 40–45 to 300 per 100,000 at age 75–80. The cumulative life time risk for the disease is 1 in 20.

Pathology and Histopathology

The most common colon cancer cell type is adenocarcinoma which accounts for 95% of cases. Other rarer types include lymphoma and squamous cell carcinoma.

Adenocarcinoma is a malignant epithelial tumor, originating from glandular epithelium of the colorectal mucosa. This tumor invades the wall, infiltrating the muscularis mucosae, the submucosa, and the muscularis propria. Tumor cells describe irregular tubular structures, harboring pluristratification, multiple lumens, reduced stroma ("back to back" aspect). Sometimes, tumor cells are discohesive and secrete mucus which invades the interstitium producing large pools of mucus/colloid (optically "empty" spaces)—mucinous (colloid) adenocarcinoma, poorly differentiated. If the mucus remains inside the tumor cell, it pushes the nucleus at the periphery "signet-ring cell". Depending on glandular architecture, cellular pleomorphism and mucosecretion of the predominant pattern, adenocarcinoma may present three degrees of differentiation: well, moderate, and poorly differentiate. Histologically, most colon carcinomas arise from the mucosal lining and are adenocarcinomas.

Neoplasm, Large Bowel, Malignant. Table 1 **Risk factors for colorectal cancer**

Personal history of adenomas or colorectal cancer
First-degree relative age <60 years with adenoma or colorectal cancer, or two first-degree relatives of any age with colorectal cancer
Inherited colorectal cancer syndromes
Hereditary nonpolyposis colorectal cancer
Familial adenomatous polyposis
Ulcerative colitis and Crohn's colitis

The mucinous adenocarcinoma subtype occurs in about 10% of patients. It is found more frequently in men and is generally more aggressive. Thus, these patients will more often present with an advanced stage of cancer. Flat lesions, defined as masses with a height no more than one-half their width, are potentially problematic because their morphologic characteristics can result in a false-negative diagnosis at conventional ►colonoscopy as well as other imaging modalities. Lymph node involvement is not possible until the muscularis mucosa has been invaded; at first, regional lymph nodes are involved; later the more centrally located nodes.

Lymph node metastases may affect the paracolic, paraortic, iliac, and even inguinal nodes (in case of rectal cancer).

Clinical Presentation

CRC can have a subacute or acute presentation that is strictly related to the location of the primary lesion. Morphologically, colorectal carcinomas initially arise *in situ*, then slowly progress into a sessile mass. Their subsequent appearance and clinical behavior depend on where they originate.

Left colon lesions more often cause abdominal pain, changing in bowel habits, melena or hematochezia and tend to be diagnosed earlier because they cause obstruction, and are susceptible to ulceration due to vascular encroachment.

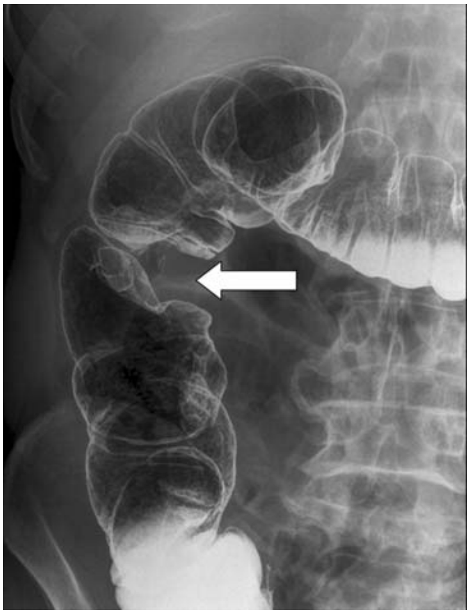
N

In the right colon, neoplastic lesions occasionally cause hematochezia, but more often bleeding is occult, causing anemia with correlated symptoms such as tiredness, malaise, and pallor. Right-sided lesions are generally diagnosed later because of the relatively larger caliber of the right colon, and they tend to grow into polypoid fungating masses with a propensity for necrosis. Approximately 50% of patients can present an unexplained weight loss, even if this symptom is almost never the sole manifestation of CRC.

Acute presentation with large bowel obstruction with impossibility to pass for air or fecal material, abdominal pain, and distention accounts for less than 10% of patients.

Rarely colon cancer presents itself as perforation with focal or diffuse peritonitis. Metastatic disease may present acutely with jaundice, pruritus, ascites, and hepatomegaly due to spreading of the tumor.

It is also possible that there will be no symptoms at all. This is the reason why periodical screening for the disease is recommended.



Neoplasm, Large Bowel, Malignant. Figure 1 Adenocarcinoma of the colon with typical "apple core" appearance in 75 year old male with rectal bleeding and anemia. DCBE shows a constant annular lesion (arrow) in the ascending colon, close to hepatic flexture, proved to be a carcinoma as expected.

Imaging

Plain Film: In patients with obstructing symptoms diagnosis, the abdominal plain film can demonstrate some dilations of the colon proximal to the obstructing colonic carcinoma. Free intraabdominal air can be seen in case of perforation.

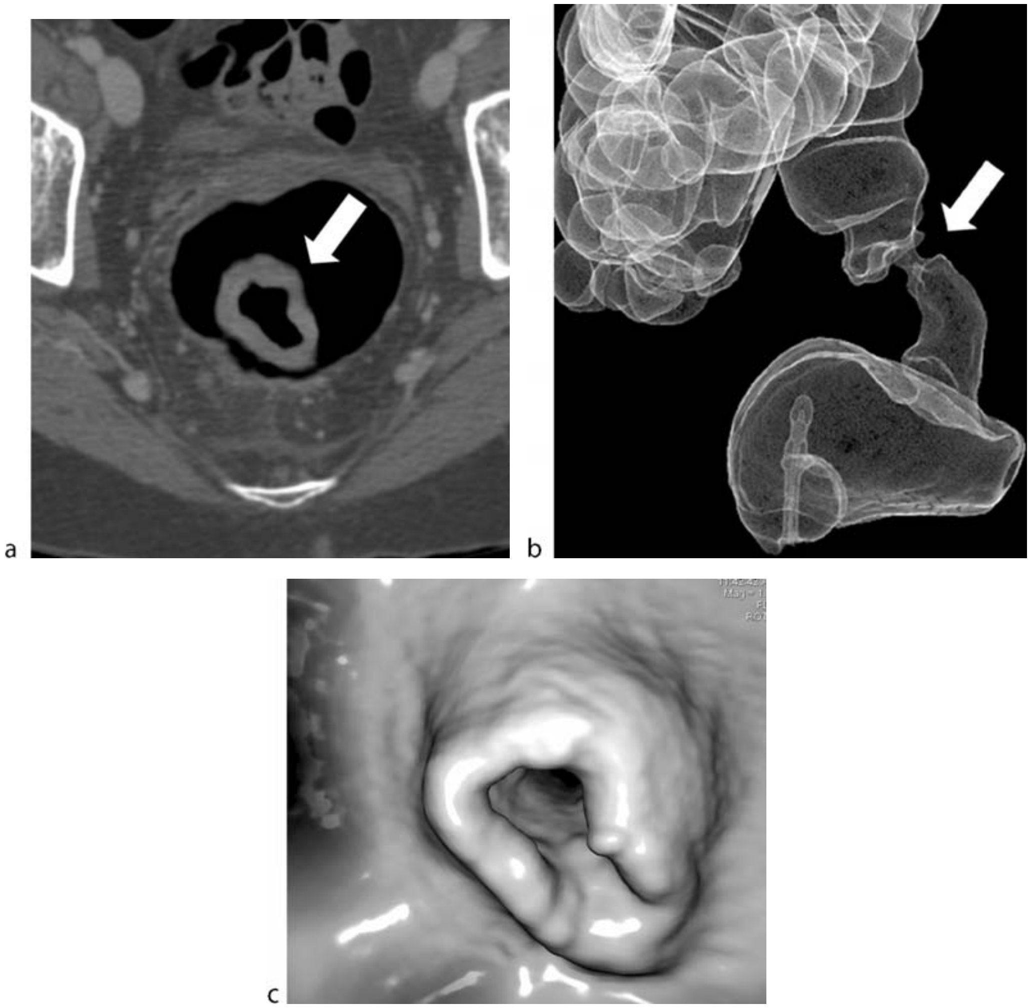
Double Contrast Barium Enema (*DCBE*) is generally accepted as less sensitive than colonoscopy and CT Colonography for detecting CRC (Fig. 1). DCBE has the advantage of imaging the entire colon. However, recent evidence suggests it is inaccurate for the detection of polyps and early cancers and suboptimal for colorectal cancer screening or surveillance. In a prospective study comparing the use of DCBE and colonoscopy, the miss rate of barium enema for polyps larger than 1 cm was 52% (3). If DCBE is the only option for screening or surveillance, it should be coupled with flexible sigmoidoscopy. The use of flexible sigmoidoscopy allows visualization of the rectosigmoid, which may not be well seen on barium enema because of the overlapping loops of bowel. Lesions detected on DCBE warrant colonoscopic evaluation.

Computed Tomography (*CT*): Colorectal carcinomas are clinically staged by using the modified Astler-Coller-Dukes staging system or the TNM staging system established by the American Joint Committee on Cancer. Accurate staging is necessary for determining patient prognosis and therapeutic management. In contrast to most other tumors, the staging for colorectal tumors depends more on the depth of invasion than on the size of the primary mass. However, conventional CT has not been accurate in determining the depth of invasion or in evaluating tumor foci in nonenlarged lymph nodes. Therefore, routine preoperative assessment for local disease is generally not performed. In patients suspected to have distant metastases or adjacent organ invasion, conventional CT has been shown to be accurate in determining the appropriate surgical procedure and neoadjuvant therapy.

►*Computed Tomographic Colonography (CTC) or Virtual Colonoscopy* (*VC*) is a noninvasive, rapidly evolving technique that has been shown in some studies to be comparable with conventional colonoscopy for the screening of colorectal cancer.

The role of CT colonography in staging has yet to be defined. A recent study reported that multidetector CT colonography with contrast media has an 83% accuracy for identifying tumor wall invasion by colorectal carcinoma and an 80% accuracy for identifying regional lymph node involvement with a combined transverse and multiplanar reformation image evaluation (4) (Fig. 2).

In addition, a preoperative CT colonography examination is increasingly being performed after incomplete colonoscopy to assess for Synchronous lesion. In all these cases as well as in the follow-up of those patients who underwent surgical hemicolectomy, the use of intravenous contrast agent is required. Concerning the use of VC as screening tool, current uses of VC generally do not



Neoplasm, Large Bowel, Malignant. Figure 2 **Stenosing carcinoma of the rectum in a 47 year old female with malaise and rectal bleeding; (a) Axial 2D slice shows annular thickening (arrow) of the colonic rectal wall; (b) Virtual double contrast enema view demonstrates typical "apple-core" lesion (arrow), and (c) Endoluminal view of the stricture, with annular, irregular lesion, and eccentric stenotic lumen (images obtained using Lightspeed VCT 64 detector row, GE and ADW 4.3, GE, USA).**

include the screening of asymptomatic persons, as also suggested by the American Cancer Society and the American Gastroenterological Association both of which decided that it should not yet be used for colorectal cancer screening, because data on true screening populations are missing. A practical approach is to consider VC as a currently credible alternative screening method and as a reasonable alternative to the other colorectal cancer screening tests when a patient is unable or unwilling to undergo conventional colonoscopy (Fig. 3).

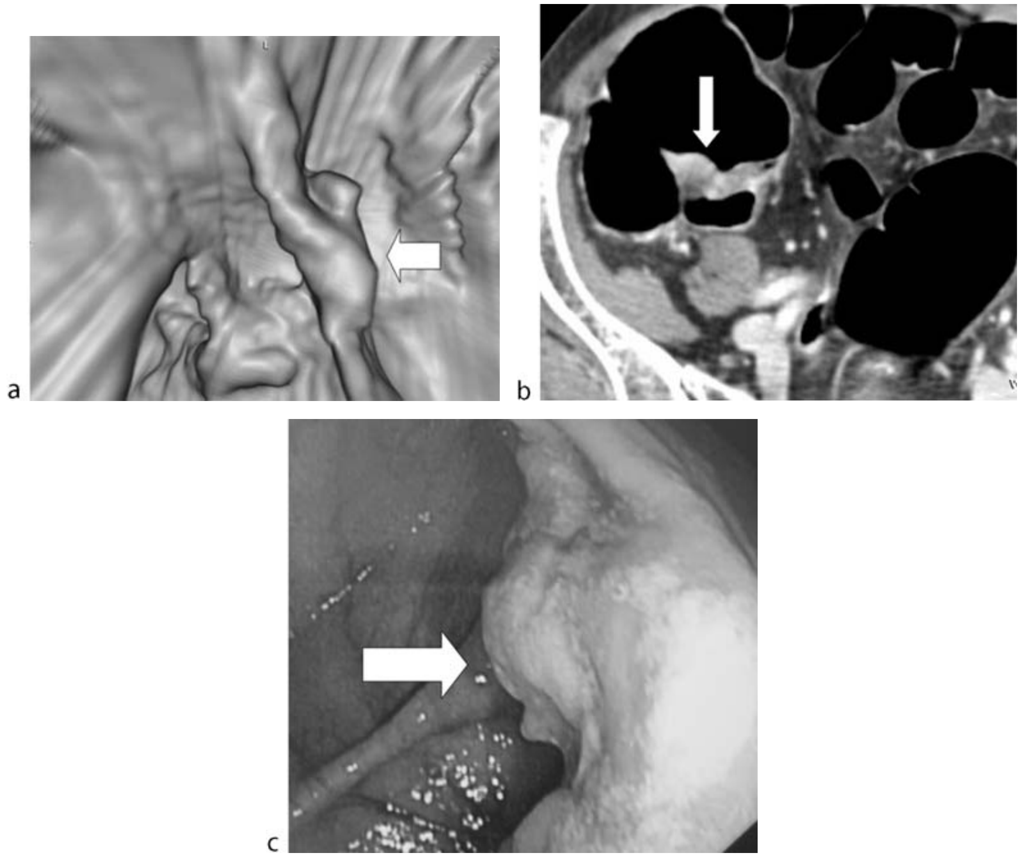
At present, *magnetic resonance imaging* (*MRI*) is the best imaging modality for completely fulfilling the clinical requirements for preoperative staging of rectal cancer, where CT has limitations in differentiating the different layers of the rectal wall, demonstrating mesorectal fascia and depicting tumor invasion in surrounding pelvic structures.

Diagnosis

The diagnosis of colorectal polyps and cancer is most often made during a colonic evaluation performed for gastrointestinal symptoms, colorectal cancer screening, or as part of endoscopic surveillance.

Once the diagnosis is suspected based on history, physical examination, or screening tests, every attempt should be made to obtain biopsy of the primary lesion and rule out synchronous cancer (3–5%).

Fecal Occult Blood Test (*FOBT*): This test has been suggested as possible adjunct to other screening modalities. Randomized trials have found that the use of annual FOBTs have decreased the mortality from colorectal cancer by up to 33%, but the estimated 30–50% sensitivity is considered too low as an effective single



Neoplasm, Large Bowel, Malignant. Figure 3 **A 72 year old women with adenocarcinoma of ileocecal valve who underwent incomplete colonoscopy due to severe diverticular disease; (a) Three-dimensional threshold-rendered endoluminal CT colonograph of ascending colon shows an ileocecal valve characterized by irregular surface (arrow); (b) Axial CT scan using abdominal window at same level as (a) reveals a vegetating sessile lesions with a large base of implant (arrow) that enhanced following intravenous administration of contrast agent, and (c) Endoscopic examination reveals an engorged mass on ileocecal valve (arrow) representing an adenocarcinoma of ileocecal valve (axial image obtained using Lightspeed VCT 64 detector row, GE, USA; amd endoluminal image obtained using Vitrea 3.7 Vital Images, USA).**

screening modality in high-risk population. The reductions in mortality are associated with a shift to detection of earlier-stage cancer. In addition, one study found the incidence of colorectal cancer was reduced by 20% in an annually screened group. This is likely due to polypectomy in patients whose positive FOBT was evaluated by colonoscopy. Since large polyps and cancers intermittently bleed, the peroxidase activity of hemoglobin in the stool can be detected by a color change when it catalyzes the oxidation of guaiac by a peroxide reagent. A special diet (e.g., a meat-free, high-residue diet without vegetables having peroxidase activity, such as turnips and horseradish) is recommended for at least 24 h before three separate stool specimens are collected at least 1 day apart. Unrehydrated test sensitivity is low at approximately 80%, with a specificity of up to 98%. Any positive FOBT should be evaluated by colonoscopy.

Sigmoidoscopy: Results of several case–control studies show a reduction in deaths from colorectal cancer in subjects who undergo sigmoidoscopic examinations. The reported reduction in mortality varies between 59% and 80%. The most well-known study compared the use of rigid sigmoidoscopic screening in 261 patients who died from cancer of the distal colon or rectum to 868 control subjects. Screening reduced the rectosigmoid cancer mortality rate by 60%, and the protective effect of sigmoidoscopy was noted to last for up to 10 years. This reduction in mortality may have resulted from earlier detection of cancer and removal of premalignant polyps. Sigmoidoscopic screening allows the lower third of the colorectal mucosa to be visualized directly and diagnostic biopsy to be performed at the time of examination. Both the sensitivity and the specificity are high for detection of polyps and cancer in the segment of the bowel examined.

Unfortunately, however, nearly 50% of polyps and cancers are beyond the limits of detection of the longest (e.g., 60 cm) flexible sigmoidoscope.

Opinions vary regarding the need for colonoscopy for patients in whom a single, small adenoma (<1 cm) is found on flexible sigmoidoscopy. Many studies have shown that the prevalence of advanced proximal neoplasms in patients with distal adenomas is up to 9%. Therefore, the use of colonoscopy to detect proximal neoplasia in patients with distal adenomas is strongly recommended. Additionally, colonoscopic screening has been shown to have favorable cost effectiveness when compared to other screening strategies.

Colonoscopy: Colonoscopy is the "gold standard" for the detection of colonic neoplasms and the preferred colorectal cancer screening strategy. The incidence rate of colorectal cancer has been shown to be reduced up to 90% in subjects who had polypectomy versus patients in three reference groups, including two cohorts in which colonic polyps were not removed and one general-population registry. It can be completed in more than 95% of examinations with negligible risk. Colonoscopic screening in individuals with average risk has been found to be cost effective, and similar to cervical or breast cancer screening techniques in cost-effectiveness per life-year saved.

Synonyms

Malignant lesions of the nasopharynx; Neoplasms of the nasopharynx; Neoplasms of the rhinopharynx; Tumors of the nasopharynx

Definition

Neoplasms of the nasopharynx include all the malignant lesions originating from the nasopharyngeal mucosa.

Pathology/Histopathology

The mucosa covering the walls of the nasopharynx is composed of squamous pseudostratified epithelium associated with a submucosal lymphoid stroma and seromucinous glands. It is the reason why a wide variety of malignant neoplasms can originate in the nasopharynx.

The most frequent malignant lesion arising in the nasopharynx is squamous cell carcinoma, which accounts for about 70% of cases. Lymphomas account for approximately 20%. The remaining 10% of malignant tumors include neoplasms stemming from seromucinous minor salivary glands (adenoid cystic carcinoma, mucoepidermoid carcinoma, adenocarcinoma, malignant mixed tumors, acinic cell carcinoma).

Squamous cell carcinoma of the nasopharynx is a worldwide diffuse tumor and one of the most common malignancies in adults in China, where it is characterized by an epidemic incidence. The etiology is related to environmental, genetic, and infectious factors. There is, in fact, a very close correlation between such tumors and the Epstein–Barr virus, the DNA of which can be found in the tumoral cells.

The World Health Organization's histopathological classification of nasopharyngeal carcinoma includes three types: (i) squamous cell carcinoma (type 1), (ii) nonkeratinizing carcinoma (type 2), and (iii) undifferentiated carcinoma (type 3).

The latter is very similar to a large cell lymphoma and includes some subtypes of malignancies such as lymphoepithelioma, spindle cell carcinoma, clear cell carcinoma, and anaplastic carcinoma.

Hodgkin's and non-Hodgkin's lymphoma originating in the rhinopharynx as an isolated primary site of involvement is considered a rare event. More common is the involvement of the nasopharynx in the presence of systemic and advanced disease.

Hodgkin's lymphoma is more frequent in young adults, and the diagnosis is suggested by the presence of Reed-Stemberg cells in the biopsied material. In contrast, non-Hodgkin's lymphoma is more often found in older patients and is frequently related to immunodeficiency states. The histopathologic classification of non-Hodgkin's lymphoma is actually based on evaluation of immunologic markers, which allows differentiation of the disease into T-cell, B-cell, and histiocytic lymphomas.

Localization in the nasopharynx of tumors derived by seromucinous glands is a rare event because the minor salivary glands are represented more in different areas of the head and neck, such as the soft palate, oral cavity, and nasal fossa. Such tumors are typically characterized by submucosal spreading, perineural diffusion, and low propensity to give nodal metastasis.

Finally, plasma cell tumors of the nasopharynx are mainly represented by extramedullary plasmocytoma, which accounts for 20% of all plasma cell neoplasms.

Clinical Presentation

The clinical presentation of malignant tumors of the nasopharynx is closely related to their localization, size, and pattern of spreading. In most cases, the neoplasm is represented by a mass centered in the posterolateral recess of the nasopharynx because of its origin in the Rosenmuller fossa. Nodal metastasis can be found in 75–90% of cases of squamous cell carcinoma at presentation.

Patterns of spread include:

1. Anterior diffusion toward the nasal and pterygopalatine fossa (PFF).
2. Antero-inferior diffusion with involvement of the soft palate and oropharynx.
3. Lateral diffusion with involvement of the parapharyngeal and masticator spaces.
4. Posterior spreading with infiltration of the prevertebral muscles.
5. Superior diffusion toward the base of the skull, which can be involved by direct bony invasion and/or by perivascular diffusion (along the internal carotid artery or middle meningeal artery) and perineural diffusion (along the mandibular nerve). Invasion of the base of the skull can lead to intracranial progression of the disease with involvement of the cavernous sinus.

On the basis of the above features, patients with nasopharyngeal tumors can be described in the following manner:

1. Asymptomatic patients with neck masses due to metastatic lymphadenopathy.
2. Patients with serous otitis media due to Eustachian tube obstruction; in many cases, symptoms of a chronic otitis are the only signs of the presence of a nasopharyngeal malignancy.
3. Patients with neurological symptoms due to involvement of the posterior cranial nerves (IX, X, XI, XII) in the case of posterolateral tumoral spread. Conversely, lateral (toward the parapharyngeal and masticator spaces) and superior (toward the base of the skull and cavernous sinus) diffusion of the tumor can determine the involvement of the trigeminal and/or the oculomotor nerves (III, IV, V, VI). Obviously, the neurological symptoms are peculiar to more advanced disease.

Ancillary and nonspecific symptoms include nasal obstruction, epistaxis, headaches, sore throat, proptosis, and trismus.

Finally, nasopharyngeal carcinoma, compared with other malignancies of the head and neck, is characterized by a higher frequency of distant metastasis (5–41%). The most common sites are the bones (20%), liver (9%), and lungs (13%).

Imaging

Conventional radiographs are no longer performed for diagnosing nasopharyngeal neoplasms. Computed tomography (CT) and magnetic resonance imaging (MRI) have been proved to be valuable in the modern diagnosis of tumors in this deep anatomical region. Both techniques have dramatically improved the accuracy in defining the tumor extent as well as the presence of regional nodal metastasis.

Due to the better soft-tissue contrast resolution, MRI is more suitable for delineating neoplastic lesions from surrounding normal structures compared with CT; moreover, MRI is more sensitive than CT in detecting subtle skull base involvement as well as perineural tumor spread.

Because a CT examination can be performed within a few seconds with modern techniques, CT remains the most commonly used technique for detecting and staging nasopharyngeal carcinoma, as access to MRI is still limited. However, MRI is the recommended modality in the assessment of recurrence.

Liver ultrasound and chest X-ray are generally routinely performed as part of the overall staging procedure, whereas bone scans are reserved for clinical suspicion of osseous metastasis.

General features of nasopharyngeal tumors are similar on CT and MRI. In typical cases, a huge, poorly marginated soft-tissue mass, centered in the lateral pharyngeal recess with occupation of the nasopharyngeal lumen, is seen, with a variable degree of deep extension and infiltration (Fig. 1). On MRI, most tumors appear isointense to muscles on nonenhanced T1-weighted images and moderate to strong hyperintense on T2-weighted images. On contrast-enhanced imaging, the tumor shows mild inhomogeneous uptake, which reflects the degree of vascularization as well as the intratumoral necrosis (Fig. 2).

The most common direction of tumoral spreading is lateral, where the soft-tissue tumoral mass obliterates and/or infiltrates the fat of the parapharyngeal space with displacement of the pterygoid muscles; further lateral spread involves the masticatory and infratemporal spaces with infiltration of the muscles of mastication. In such cases, the presence of fluid within the middle ear and mastoid cells due to serous otomastoiditis is often demonstrated (Fig. 3).

Neoplasms, Nasopharynx. Figure 1 Axial contrast-enhanced computed tomography scan. A huge mass (m) centered on the right lateral wall and Rosenmuller fossa is shown. Note also the involvement of the ipsilateral parapharyngeal space and posterior infiltration of the prevertebral muscles.

In anterior spreading, the tumor can reach the nasal fossa inferiorly and the pterygoid plate superiorly with secondary involvement of the PFF. The obliteration of the fat content of this fundamental anatomical landmark is the hallmark of involvement. From the PFF the tumors often show a tendency to spread along the maxillary nerve (perineural diffusion or spreading) to reach the cavernous sinus, Meckel's cave, the trigeminal nerve, or the skin in the infraorbitary region.

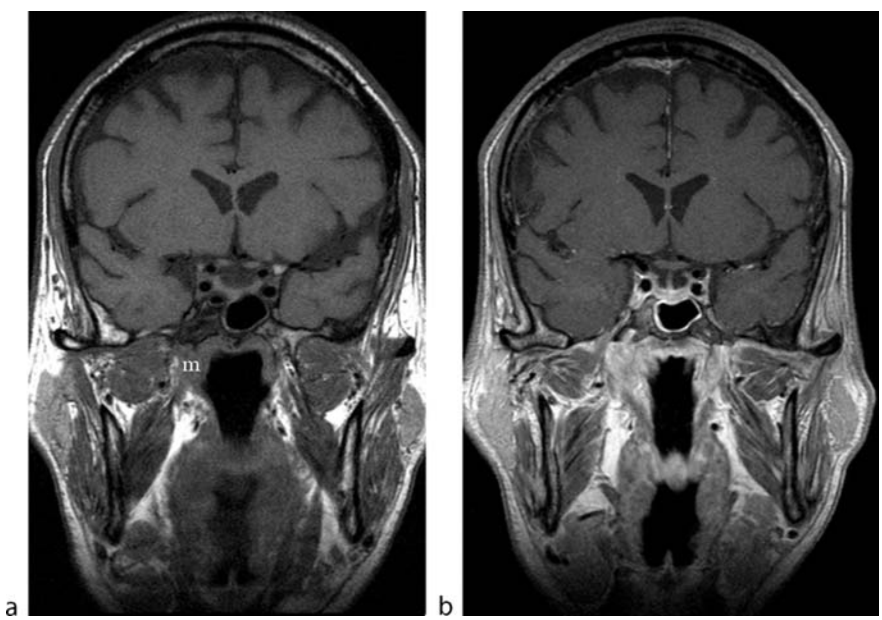
Enlargement or remodeling of bony walls of the cranial nerves are the CT features suggesting perineural spreading, whereas direct enlargement of the nerves is well appreciable with MRI.

Inferior spread can occasionally occur, with a subtle submucosal soft tissue causing oropharyngeal wall thickening.

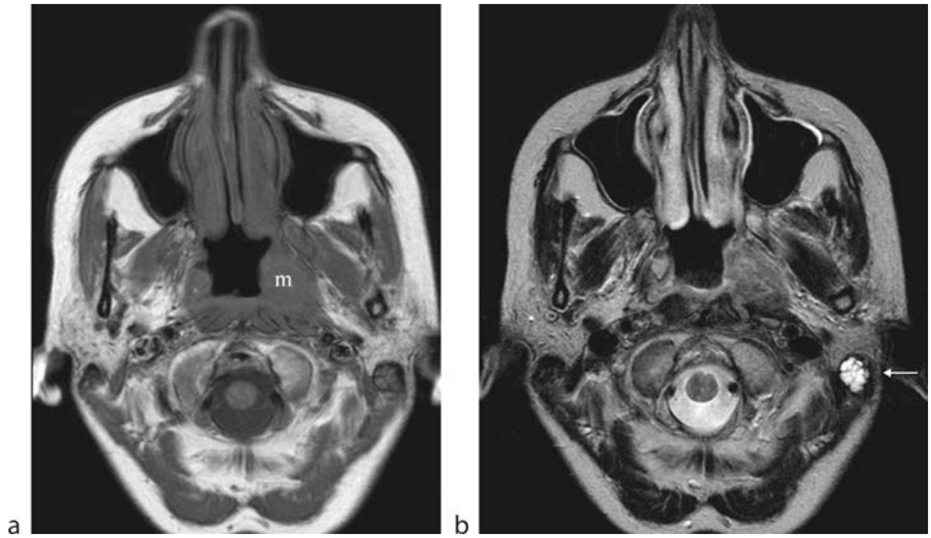
Posterior spread is characterized by obliteration of the retropharyngeal space and infiltration of the prevertebral muscles; posterosuperior neoplastic extension may involve the jugular foramen and the adjacent hypoglossal canal.

Finally, but not infrequently, carcinoma of the nasopharynx can spread superiorly involving the skull base. Subtle erosion with a mottled appearance of the clivus or the basisphenoid is the key finding in CT imaging; on MRI, infiltration with replacement of high signal intensity of bone marrow on T1-weighted images is very suggestive of skull base neoplastic involvement.

N



Neoplasms, Nasopharynx. Figure 2 (a) On coronal T1-weighted magnetic resonance image, a soft-tissue mass (m) abutting right superior-lateral wall of the nasopharynx is well demonstrated. The lesion effaces the upper part of the parapharyngeal space. (b) Coronal contrast-enhanced T1-weighted image shows mild enhancement of pathological tissue.



Neoplasms, Nasopharynx. Figure 3 **(a) Axial T1-weighted magnetic resonance image shows a mass (m) involving the left wall of the nasopharynx with infiltration of the elevator and tensor veli palatine muscles and partial obliteration of the fat in the anterior parapharyngeal space. (b) T2-weighted image shows fluid into the mastoid cells (*arrow*) due to a serous otomastoiditis.**

The third cranial branch of the trigeminal nerve (mandibular nerve) is a common preformed route of intracranial diffusion of nasopharyngeal neoplasms.

Cervical nodal metastases are better studied with CT, which is also useful in depicting nodal necrosis and extracapsular spread.

Nevertheless, MRI is also well suited in clinical practice.

Nuclear Medicine

Nuclear medicine techniques are not routinely employed in nasopharyngeal neoplasms, but they can provide relevant information in certain cases.

18-fluoro-2-deoxyglucose positron emission tomography (18-FDG PET) is the newest and leading nuclear medicine procedure, giving information about the degree of glucose metabolism in different tissues. A certain level of increased uptake of FDG is considered to indicate malignancy. However, routine use of PET in pretherapeutic staging of nasopharyngeal carcinoma cannot be recommended. Sometimes an 18-FDG PET scan can be considered in nasopharyngeal cancer to search for occult distant metastases.

Nevertheless, the major role of this nuclear medicine technique is its high value in detecting residual or recurrent neoplastic tissue following radiotherapy.

The advent of CT–PET and MRI–PET can provide even more information by coregistering tracer uptake with anatomic information. CT–PET scanning is recently being evaluated for the identification of the most active tumor regions, which will allow biological radiotherapy planning using intensity-modulated radiotherapy techniques.

Diagnosis

The diagnosis of nasopharyngeal neoplasms is based on histopathology obtained by biopsy during rhinoscopy. Staging and full extension of tumors are of the utmost importance for therapeutic decisions and the patient's prognosis.

CT and MRI are nowadays the fundamental modalities used to obtain all of this information, whereas 18-FDG PET, CT–PET, and MRI–PET should be used in selective cases, especially for detecting tumoral recurrence after chemotherapy and radiotherapy.

Definition

Neoplasms of the nose and paranasal sinuses include all the malignant and benign tumors stemming from mucosa that covers the rhinosinusal apparatus.

Although tumors of the nose and paranasal sinuses are uncommon, accounting for only 0.3% of all cancers and 4% of all head and neck malignancies, the disease is occasionally confined to sinuses (1). The tumor behaves like a benign infectious disease in the beginning, with the actual diagnosis only being made in the advanced stage thereby explaining the overall poor prognosis of malignancies in this region.

Pathology/Histopathology

The most commonly encountered sinonasal malignancy (SNM) is squamous cell carcinoma (80%), with 25–60% of these carcinomas originating from the maxillary antrum, followed by the nasal cavity (30%), ethmoids (10%), and sphenoid and frontal sinuses (2%). An increased risk is observed in those exposed to nickel, chromium pigment, bantu snuff, thorotrast, mustard gas, polycyclic hydrocarbons, and cigarette smoke, as well as in wooden furniture, isopropyl alcohol, and radium production workers (2, 3). Cervical lymph node involvement which occurs in 25–35% of SNMs is associated with a poor prognosis.

Adenoid cystic carcinoma and adenocarcinomas are next in frequency (10%) (2). Adenoid cystic carcinoma is the most common minor salivary gland tumor, accounting for one-third of these malignancies, and more than 80% originate from the maxillary sinus and nasal cavity (3). Perineural invasion with secondary invasion of the orbit and intracranial compartments is common. Approximately one-half of the patients have distant metastasis to the lungs, brain, and bones (3).

Adenocarcinomas are more commonly found in the upper nasal cavity and ethmoid sinuses. The prognosis depends on the differentiation of the tumor and is comparable with that of adenoid cystic carcinoma (2, 3).

Less than 4% of melanomas arise from the sinonasal cavity. It is believed that nasal melanomas originate from melanocytes that migrated from the neural crest to the mucosa of the sinonasal cavity during embryological development. Prognosis is poor with a mean survival of 2 years. The cervical nodal metastasis rate is 40% and local recurrence is seen in two-thirds of patients. Nasal melanomas have a better prognosis than those originating in the paranasal sinuses (3).

Olfactory neuroblastomas (esthesioneuroblastomas) are rare neoplasms of the cribriform region and arise from the olfactory nerves. When intracranial extension is present, craniofacial resection is necessary. Subarachnoid seeding occurs because of direct extension of the tumor or after surgery (3).

A variety of benign neoplasms such as osteoma, chondroma, schwannoma, neurofibroma, ossifying fibroma, cementoma, and odontogenic tumors can arise from the sinonasal cavity. Some are classified as intermediate neoplasms, such as inverted papilloma, meningioma, hemangioma, and hemangiopericytoma.

Juvenile fibroangioma can be considered as a rare, benign, highly vascularized tumor of the nasosinusal region because of its particular growth. It occurs exclusively in young male patients.

Finally, one should recall that malignant transformation occurs in about one of eight patients with multiple neurofibromatosis (von Recklinghausen's disease) and in 10% of inverted papilloma patients. Recurrence is likely due to the locally aggressive behavior of hemangiopericytoma (3).

Clinical Presentation

The clinical presentation of sinonasal tumors depends on the site of origin, size, vascularization, and pathway of tumor diffusion.

The main symptoms can be summarized as follows: nasal obstruction, epistaxis and nasal discharge, exophthalmos due to orbital involvement, and cranial nerve impairment due to involvement of the skull base with secondary perineural extension.

Over the last 30 years, the morbidity and mortality rates of ACB surgeries for sinonasal tumors have improved significantly with the availability of new imaging technologies such as computed tomography (CT) and magnetic resonance imaging (MRI), intraoperative navigation systems together with a multidisciplinary team approach, and a variety of craniofacial resection techniques (2). Parallel to technical developments, a variety of ACB reconstruction methods such as microvascular free-flap reconstructions and oto- and homografts are widely used, and thus postoperative complication rates have decreased.

Diagnosis

The diagnosis is based on endoscopy, biopsy, and radiological imaging, namely, CT and MRI.

To distinguish the clinical and radiological appearance of neoplasms in the paranasal sinuses and nasal cavity from coexistent inflammatory changes that usually occur with such tumors, it is necessary to be familiar with the normal anatomy or anatomical variations and the drainage pattern of sinus secretions.

Basically, the paranasal sinuses are composed of four pairs of sinuses: frontal, maxillary, ethmoidal, and sphenoid sinuses. The most prognostically significant structures are above and behind the maxillary antrum. Superiorly the orbit, ethmoid sinuses, and the ACB and the posterior border approach the pterygoid plates, the pterygoid space, and the infratemporal fossa (4). The sphenoid sinus is in the center of the head and is related to very complex structures: the optic nerve and pituitary gland are superior to it and the internal carotid artery and cavernous sinuses sit laterally. Thus, the complete resection of a malignancy involving the sphenoid is occasionally possible (2).

The pattern of spread of SNMs is mostly *via* direct invasion or perineural extension as in cases of adenoid cystic carcinoma. Detailed knowledge about the anatomical boundaries of the paranasal sinuses is essential to map the extent of the disease and to plan the surgical resection and reconstruction preoperatively (2).

The American Joint Committee on Cancer (AJCC, 2002) staging criteria of primary tumors (T) for SNMs are shown in Table 1.

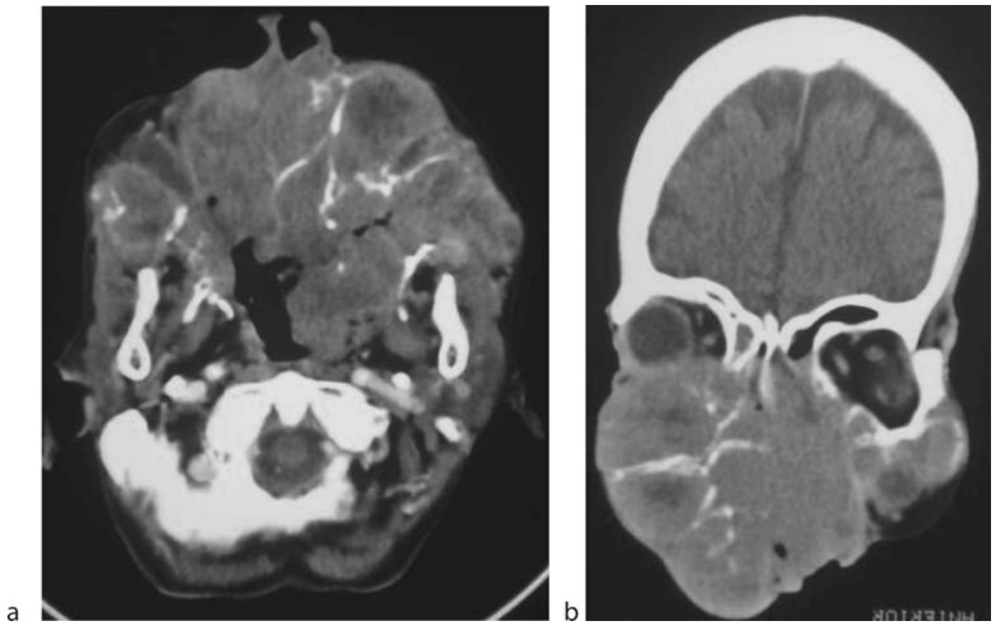
Imaging

It is often difficult for the radiologist to hone down on a particular histological diagnosis because of the marked overlap of the imaging appearance of different tumors on CT and MR images (4) (Figs. 1–3).

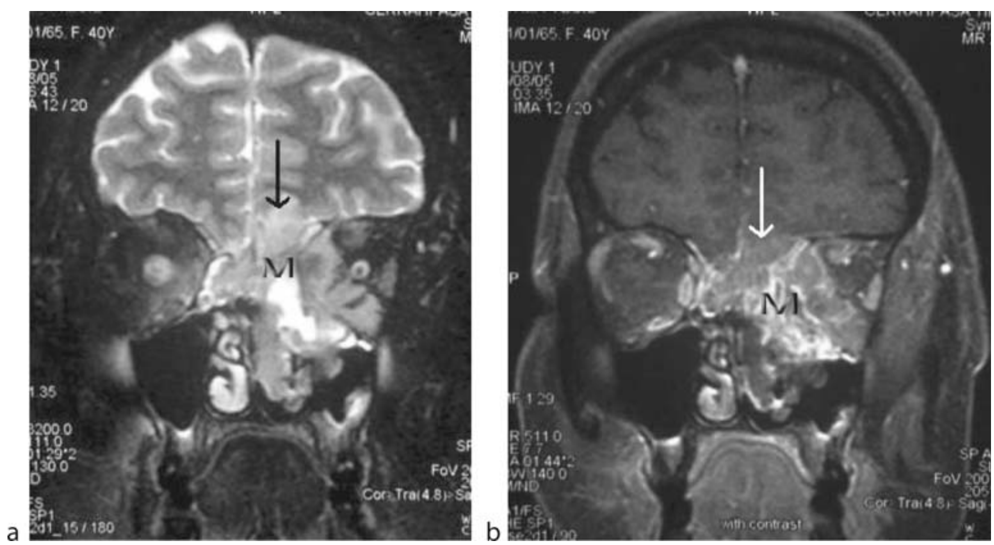
CT and MR are complementary and together can provide adequate information of both bony and soft

Neoplasms, Nose and Paranasal Sinus. Table 1 Staging of the paranasal sinus carcinoma

Maxillary sinus
Primary tumor (T)
• TX: Primary tumor cannot be assessed
• T0: No evidence of primary tumor
• Tis: Carcinoma *in situ*
• T1: Tumor limited to maxillary sinus mucosa with no erosion or destruction of bone
• T2: Tumor causing bone erosion or destruction including extension into the hard palate and/or the middle of the nasal meatus, except extension to the posterior wall of maxillary sinus and pterygoid plates
• T3: Tumor invades any of the following: bone of the posterior wall of maxillary sinus, subcutaneous tissues, floor or medial wall of orbit, pterygoid fossa, ethmoid sinuses
• T4a: Tumor invades anterior orbital contents, skin of cheek, pterygoid plates, infratemporal fossa, cribriform plate, sphenoid or frontal sinuses
• T4b: Tumor invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than maxillary division of trigeminal nerve (V_2), nasopharynx, or clivus
Nasal cavity and ethmoid sinus
Primary tumor (T)
• TX: Primary tumor cannot be assessed
• T0: No evidence of primary tumor
• Tis: Carcinoma *in situ*
• T1: Tumor restricted to any one subsite, with or without bony invasion
• T2: Tumor invading two subsites in a single region or extending to involve an adjacent region within the nasoethmoidal complex, with or without bony invasion
• T3: Tumor extends to invade the medial wall or floor of the orbit, maxillary sinus, palate, or cribriform plate
• T4a: Tumor invades any of the following: anterior orbital contents, skin of nose or cheek, minimal extension to anterior cranial fossa, pterygoid plates, sphenoid or frontal sinuses
• T4b: Tumor invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than (V_2), nasopharynx, or clivus.



Neoplasms, Nose and Paranasal Sinus. **Figure 1** Axial (a) and coronal (b) CT scan show a giant squamous cell carcinoma of the nasal cavity and paranasal sinuses. Note the extensive destruction of the bones and invasion into the paranasal soft tissues.



Neoplasms, Nose and Paranasal Sinus. **Figure 2** Olfactory neuroblastoma, a rare neoplasm arising from the olfactory epithelium and found in the upper nasal cavity. (a) T2-weighted coronal MR scan, showing a large mass (M) in the left nasal cavity and left ethmoid air cells. (b) Corresponding enhanced fat-suppressed coronal T1-weighted MR image shows enhancement of the tissue consistent with the tumor. Note tumor extension into the orbit and cribriform plate/skull base (*arrow*).

tissue involvement. In the appropriate clinical setting, the CT and MR appearance of the nasal tumors will allow the radiologist to provide the differential diagnosis.

Extension of the neoplasm outside of the sinonasal cavity to the adjacent anatomic locations has significant impact on the patient's operability, the type of resection, the surgical approach, the necessity for radiation therapy, the placement of radiation portals, and the prognosis (3).

The role of the radiologist is to provide accurate information about the tumor location and mapping, and to detect critical areas of involvement, which may alter surgical approach and treatment planning.

Neoplasms, Nose and Paranasal Sinus. Figure 3 **Angiosarcoma of the nasal cavity. (a) T2-weighted coronal MR image reveals centrally located tumoral mass occupying the nasal cavity. (b) Coronal postcontrast T1-weighted MR image shows extension of the tumor centered at the cribriform plate into the anterior cranial fossa (*arrow*). The lesion enhances diffusely. Note the postobstructive inflammatory fluid retention in the maxillary sinuses.**

CT is helpful in evaluating soft tissue details and its relationship to bone and air-containing space of the sinuses (5).

A benign soft tissue mass may cause a gradual pressure atrophy and erosion of the adjacent bone, which can easily be seen on CT images (Fig. 1).

The hallmark of malignancies involving the sinonasal cavity is the presence of osseous destruction (4). CT is an excellent modality for detecting bone erosion or destruction.

Skull base invasion is more commonly seen in malignant lesions such as carcinomas, lymphomas, and sarcomas. The pattern of osseous destruction of benign and malignant lesions is similar at the skull base, because osseous remodeling in this location is unusual (3) (Figs. 2 and 3).

Osseous destruction with the involvement of orbital fat suggests orbital invasion. Presence of nodularity at the interface between the tumor and periorbita, assessment of the extraocular muscles (enlargement, displacement, and signal abnormalities), and evaluation of the integrity of the osseous structures including the orbital walls adjacent to the tumor are further criteria for orbital invasion. However, none of these criteria is very accurate (3, 5).

It may be difficult to differentiate the neoplasm from postobstructive inflammatory changes on CT images. MR imaging provides excellent delineation of tumor from surrounding soft tissue, inflammatory tissue, and retained secretions within the sinuses (5).

SNMs tend to have lower T2 signal with respect to fluid collections within the paranasal sinuses on MR imaging (Fig. 3). Tumors tend to have more homogeneous contrast enhancement as opposed to rim enhancement seen with the inflammatory mucosa, which is seen better on contrast-enhanced MR imaging.

Carcinomas of the nasal cavity and paranasal sinuses share similar gross and microscopic pathological characteristics. They are highly cellular tumors with little free water and, as such, are represented by a homogeneous MR appearance, with low to intermediate signal intensity on T1- and T2-weighted images (5) (Fig. 3).

In postoperative patients, differentiating the residue and the recurrent tumor from the granulation tissue is also a problem. In this regard CT has limited utility because these tissues frequently have overlapping densities, making their distinction difficult. MR imaging can be more sensitive and specific in this distinction (3).

In conclusion, paranasal sinus neoplasms are difficult to diagnose in early stages of the disease. A high index of clinical suspicion leading to more detailed studies is therefore necessary. Use of different imaging technologies is essential and crucial for planning a treatment strategy.

Nuclear Medicine

Nuclear medicine plays a fundamental role in the evaluation of recurrent disease or in the evaluation of nodal metastasis from SNMs by means of PET-FDG.

Interventional Radiological Treatment

Embolization of juvenile angiofibroma is the only application of radiological interventional procedures.

Benign and malignant odontogenic tumors

Definitions

Odontogenic lesions arise from the cells and tissues that are part of the tooth-forming apparatus.

They can be found in the mandible, maxilla, and gingiva. Odontogenic lesions include odontogenic cysts and tumors (1). Odontogenic cysts are epithelial-lined structures derived from odontogenic epithelium containing fluid or semisolid material (2). They can be classified as inflammatory or developmental cysts (1). Odontogenic tumors may arise from epithelial or mesodermal elements, or both, involved in odontogenesis (3). They are in the majority of cases benign although some malignant odontogenic tumors have been reported. Odontogenic carcinoma is a carcinoma arising within the jawbone without a lesion of the mucosa (1). It can be subcategorized in: malignant ameloblastoma, when it represents a malignant transformation of a benign ameloblastoma; primary intraosseous carcinoma; carcinoma arising in preexisting odontogenic cyst.

Pathology/Histopathology

Cysts

The most common odontogenic cyst is *periapical (radicular) cyst*, an inflammatory cyst that results from a periapical granuloma. It arises by ▶Malassez epithelial rests stimulation by chronic apical periodontitis due to periapical diffusion of a pulp infection in carious teeth. The cyst wall, lined by stratified nonkeratinizing squamous epithelium, may show inflammatory changes.

Dentigerous (*follicular*) *cyst*, the second most common odontogenic cyst, forms within the normal dental follicle. It is lined by stratified squamous nonkeratinizing epithelium and is usually larger than the normal dental follicle. It surrounds the crown of an unerupted tooth, most frequently mandibular or maxillary third molars or maxillary canines and may become quite large leading the risk for pathologic jaw fracture. Tumoral lesions like ameloblastoma, mucoepidermoid carcinoma, and squamous cell carcinoma may occasionally develop within the cyst wall.

The third most common odontogenic cyst is *odontogenic keratocyst* (*primordial cyst*). It is lined by stratified keratinizing squamous epithelium and is often filled by degenerating keratin, appearing as a foul-smelling cheese-like material. This cyst is aggressive, can be difficult to remove and frequently recurs. It more often grows in the mandible and may be in conjunction with an impacted tooth. Multiple odontogenic keratocysts may develop as part of the genetic disorder known as "▶basal cell nevus syndrome."

Uncommon odontogenic cysts are represented by: calcifying odontogenic cyst (Gorlin cyst), a developmental lesion with both cyst and solid neoplasm features (1) also identified with the term "odontogenic ghost cell tumor," because of the presence of a characteristic cell with eosinophilic cytoplasm an no nucleus in the cyst wall; lateral periodontal cyst, a developmental cyst arising from epithelial remnants in the periodontal ligament that grows along the lateral aspect of the tooth, most commonly in the mandibular premolar area.

Residual cyst is a term of convenience used to identify a retained cyst (most frequently a periapical cyst) from a

N

tooth that have been removed. It should be differentiated by primordial cyst that develops instead of a tooth, since it derives from cystic degeneration of a dental follicle which formed without ever-completing odontogenesis.

Benign Neoplasms

Ameloblastoma (18% of odontogenic tumors) is a slow-growing, cystic, epithelial tumor thought to arise from ►ameloblasts. It has not a capsule, is locally aggressive and infiltrative and tends to recur after surgical excision. It has a wide spectrum of histological varieties including follicular, plexiform, acanthomatous, keratinizing, granular cell, basal cell, clear cell types, and a desmoplastic variant (3). It is located more commonly in the mandible, preferentially in the molar regions. About 1% of ameloblastomas are malignant.

Other epithelial tumors include adenomatoid odontogenic tumor (adenoameloblastoma), an uncommon well-circumscribed tumor with ductlike structures and calcifications that usually occurs around the crows of anterior teeth of young patients and is usually associated with impacted tooth; *calcifying epithelial odontogenic tumor (Pindborg tumor)*, a locally aggressive tumor composed of polyhedral epithelial cells in a fibrous stroma, often accompanied by spherical calcifications and hyaline deposits that usually occurs in posterior mandible in association with impacted tooth; squamous odontogenic tumor, a rare, potentially aggressive tumor made by islands of stratified epithelium containing microcysts and calcifications in a dense fibrous background.

Tumors deriving from connective tissue include odontogenic myxoma (3–6% of odontogenic tumors), a noncapsulated tumor consisting of a mucoid ground substance with scattered rounded and angular cells, characterized by rapid and locally aggressive growing with propensity to invade local soft tissues; cementoblastoma, a rare, well-circumscribed neoplasm of functional cementoblasts, usually observed in patients younger than 25 years, growing in association with the apical cemental layer of a molar or premolar tooth with the mandibular first molar being most frequently involved; and odontogenic fibroma.

Tumors derived from mixed epithelial and connective tissue include odontoma, the most common odontogenic tumor, commonly found on unerupted teeth, made up of various components of teeth (enamel, dentin, cementum, and pulp) arranged in a disorderly pattern and bearing no morphologic similarity to normal or rudimentary teeth (complex odontoma) or approaching normal tooth structure (compound odontoma), and located more frequently in the premolar and molar regions of the mandible and in the incisor-canine region of the maxilla, respectively; ameloblastic fibroma, a circumscribed lesion usually located over unerupted molars in young patients; ameloblastic fibro-odontoma, a mixture of soft tissue components of ameloblastic fibroma and the hard tissue elements of complex odontoma, always associated with developing teeth; ameloblastic odontoma, a very rare tumor containing an ameloblastomatous component and odontoma-like elements.

Malignant Neoplasms

Odontogenic malignancies are rare and most commonly located in the mandible. Malignant ameloblastoma is “a neoplasm in which the pattern of an ameloblastoma and cytological features of malignancy are shown by the primary growth in the jaws and/or by any metastatic growth” (1). Primary intraosseous carcinoma may develop from epithelial components that participate in the development of the teeth or from epithelial cells that become enclosed within the deeper structures of the jaw during embryonic development. Carcinomatous transformation of the epithelium in odontogenic cysts is a rare event although it has been reported in dentigerous cysts, radicular cysts, residual cysts, and keratocysts.

Other rare malignant epithelial lesions are clear cell odontogenic carcinoma and malignant odontogenic ghost cell tumor (odontogenic ghost cell carcinoma), a histologically malignant solid tumor related to calcifying odontogenic cyst.

Odontogenic sarcomas include ameloblastic fibrosarcoma, ameloblastic fibrodentinosarcoma and ameloblastic fibroodontosarcoma, odontogenic carcinosarcoma (1).

Clinical Presentation

Odontogenic lesions are frequently asymptomatic. When clinically evident, swelling is the most common presenting symptom. Lesions, that usually grow slowly, may reach a considerable size determining facial deformities or pathologic fractures. Pain is infrequent and often associated with cementoblastoma or secondary cysts infection. Lesions may determine displacement of teeth or may prevent or delay their eruption.

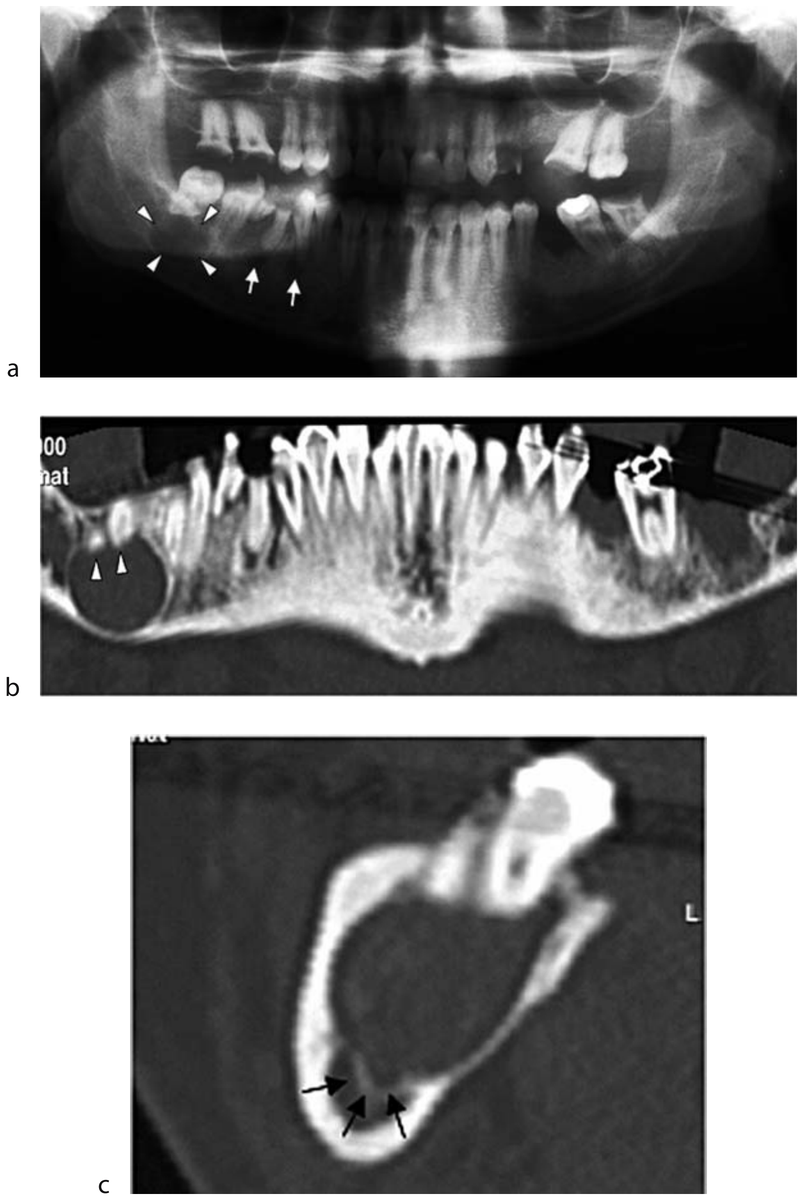
Imaging

Plain X-rays and ►pantomography are the main imaging tools in investigating odontogenic lesions. Radiographic approach is highly effective in detecting odontogenic lesions and permits evaluation of lesion size and margins, location, radiological pattern (radiolucent, mixed radiolucent–radiopaque, or radiopaque lesion), and relationships between lesion and tooth (periapical, pericoronal, no relationship with tooth). Small lesions (less than 2 cm) can be evaluated by radiography alone, whereas larger lesions may require further radiological examinations (4).

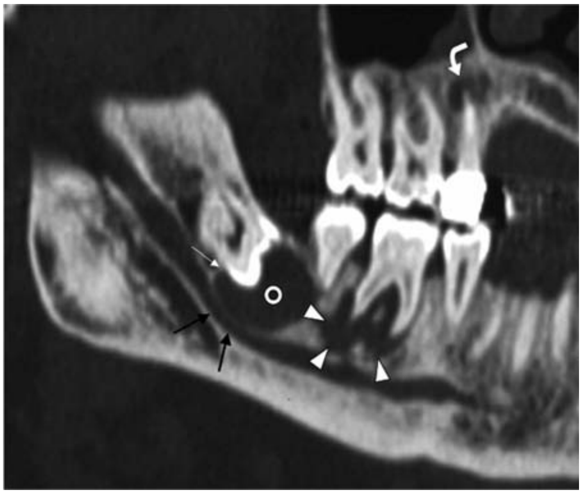
Computed tomography permits an excellent assessment of the topography and extent of the lesions and better demonstrates the degree of bone resorption, ►osteosclerosis, cortical bone swelling, destruction, and calcification. CT dentascan also provides cross-sectional as well as panoramic sectional imaging.

Magnetic resonance imaging is effective in differentiating between tumors and cysts, in evaluating the appearance of fluid in cystic lesions and the infiltration of malignant tumors in the jawbone (especially permeative extension) and surrounding soft tissues (4).

Cysts appear as well-demarcated radiolucencies (Figs. 1 and 2), calcifying odontogenic cyst often contains scattered calcifications. Cysts show different relationships with tooth: radicular and lateral periodontal cysts have



Neoplasms, Odontogenic. Figure 1 Radicular cysts. Pantomogram (a) reveals a radiolucent, well-defined lesion (arrowheads) around the apices of the mandibular third molar tooth associated with defect of the upper cortical margin of the mandibular canal. Similar smaller lesions can be seen around the apices of the mandibular first molar tooth and the second premolar tooth (arrows). Panoramic reformat (b) and cross-section oblique view (c) from spiral CT better show the relationships between the larger cyst, the slightly resorped tooth roots (arrowheads) and the mandibular canal (arrows).



Neoplasms, Odontogenic. Figure 2 Panoramic reformat from multidetector spiral CT demonstrates an expansive, well-defined, unilocular area of osteolysis (circle) in the mandible incorporating the crown of the unerupted third molar tooth. The lesion wall converges to the cementoenamel junction (white arrow) strongly suggesting the diagnosis of dentigerous cyst. The lesion determines remodeling of the mandibular canal (black arrows). Also note well-circumscribed radiolucency arising from the apex of the upper second premolar tooth (curved arrow) compatible with periapical granuloma. Irregular periapical radiolucencies (arrowheads) and widening of the periodontal lucency separating the roots of the mandibular first molar tooth from the lamina dura, due to periapical abscesses, are also appreciable.

Neoplasms, Odontogenic. Figure 3 MIP reconstruction from multidetector spiral CT shows a huge multilocular lesion in the body of the mandible determining swelling and bone resorption. The lesion was a recurrent ameloblastoma.

a periapical location; dentigerous cyst, odontogenic keratocyst and calcifying odontogenic cyst are usually pericoronal; primordial and residual cysts are associated with missing tooth. Larger lesions may expand the cortex, extent into the maxillary sinuses or nasal cavity and displace teeth. Periapical cyst and calcifying odontogenic cyst may determine tooth root resorption. Radiographically, radicular cysts cannot be differentiated from periapical granulomas, which are usually less than 1.6 cm in diameter (4). On MR imaging, cysts show high signal intensity on T2-weighted images and regular walls with slight to strong enhancement. Odontogenic keratocyst characteristically presents with inhomogeneous cyst content (5).

Ameloblastoma appears as a unilocular or multilocular radiolucency (Fig. 3), commonly with a pericoronal location or without any contact with tooth. In multilocular lesions, loculi can vary in size and shape and may confer a honeycombed or bubble-like appearance to the lesion. Ameloblastoma can reach a considerable size causing bony expansion or extensive destruction of the mandible or maxilla and loss of the lamina dura, erosion of the tooth apex and displacement of the teeth. It sometimes break the cortex extending into the adjacent soft tissues. Ameloblastoma can be differentiated from a cyst by demonstrating enhancing irregularly thick walls and septa or papillary projections on contrast-enhanced T1-weighted images at MR imaging (5). Unusual radiographic findings (mixed radiolucent–radiopaque appearance with poorly defined margins) can be related to the desmoplastic variant.

Odontogenic fibroma, ameloblastic fibroma, squamous odontogenic tumor, and odontogenic myxoma also appear as radiolucencies. The last two show tendency to cause extensive destruction of bone and to extend into the adjacent soft tissues.

A mixed radiolucent–radiopaque appearance is usually associated with adenomatoid odontogenic tumor, calcifying epithelial odontogenic tumor and ameloblastic fibro-odontoma. The formers appear as a radiolucent lesion with many calcifications, usually associated with the crown of an impacted tooth; the latter usually presents as a solitary mass or several small radiopaque masses with lucent well-defined margins that may resemble miniature teeth.

Odontoma, at first appearing as a radiolucent area, undergoes progressive calcification during its development that initially results in small, speckled calcific densities and eventually forms a radiopaque mass surrounded by a lucent ring due to fibrous capsule. The tumor is situated between the roots of teeth and is frequently associated with unerupted teeth. The teeth contained in a compound odontoma are dwarfed and usually distorted, with simple roots.

Benign cementoblastoma appears as a radiopaque mass surrounded by a radiolucent zone of uniform width associated with the tooth root, sometimes expanding the cortical bone.

Malignant lesions usually present as a radiolucent lesion with ill-defined, irregular, or moth-eaten margins showing inhomogeneous enhancement on gadolinium-enhanced T1-weighted images (4).

Nuclear Medicine

Bone scintigraphy has a limited role in the assessment of odontogenic lesions. It could be of support in evaluating whether a soft-tissue mass is a recurrence or fibrous healing and in evaluating patients with suspected ►osteomyelitis.

Diagnosis

Diagnosis of odontogenic lesions is mainly based on imaging, although an exact definition of the lesion is often impossible because of considerable overlapping of the imaging features. Furthermore, many nonodontogenic jaw lesions (dysplastic and inflammatory lesions, non-odontogenic cysts, and tumors) have similar appearance.

Final diagnosis is obtained histopathologically, after biopsy or surgical treatment.

Synonyms

Oesophageal cancer; Oesophageal malignancy; Oesophageal tumour

Definition

Oesophageal neoplasms may be benign or malignant. While benign oesophageal neoplasms are rare, oesophageal cancer (OC) is increasingly common and responsible for 1–1.5% of all cancers in the western world and 4–10% of all gastrointestinal tract malignancies. Despite advances in imaging and treatment 5-year survival is lesser than 10%. OC is predominantly of two types—squamous cell carcinoma (SCC) and adenocarcinoma (AC).

Worldwide SCC accounts for 70% of OC and has a very wide variation in geographical incidence. It is endemic in northern China, parts of South Africa, Northern Iran and Northwest France. In non-endemic areas, smoking and alcohol are risk factors with heavy use causing a 44-fold increase. Other risk factors include achalasia, caustic injury, human papilloma virus, head and neck tumours, Plummer–Vinson syndrome, sprue and tylosis.

The incidence of AC of the oesophagus and gastro-oesophageal junction (GOJ) has rapidly increased over the last 20 years, and is now the commonest OC in white men in the USA. The single most important risk factor is ►Barrett's oesophagus. Prospective studies indicate the annual incidence of malignant transformation in Barrett's oesophagus is 1–2%. Overall risk of adenocarcinoma is 125 times greater than in the general population (1).

Less common forms of OC include mucoepidermoid carcinoma, spindle cell carcinoma, small cell carcinoma, leiomyosarcoma and lymphoma.

Pathology/Histopathology

Squamous Cell Carcinoma

About 20% of SCC involves the upper third (<24 cm from the incisors or above the aortic arch), 50% mid-oesophagus (25–32 cm) to the level of the pulmonary vein and 30% the lower oesophagus. They may be fungating (60%), ulcerated (25%) or infiltrative (15%).

Adenocarcinoma

About 90% occur in the distal oesophagus. About 20–50% of all AC arise from Barrett's oesophagus and dysplasia predicts malignant transformation. Low grade dysplasia has variable progression or regression, whereas 33% of patients with high grade dysplasia will have unsuspected foci of AC and oesophagectomy is usually indicated. AC is macroscopically similar to SCC.

SCC and AC may spread directly, *via* lymphatics or through the haematogenous route. Direct extension occurs into aorta, heart, lungs, airway, thoracic duct, azygous vein and diaphragm. Sub-mucosal extension may be a feature. The oesophageal wall lacks serosa, allowing easier spread to the adventitia and adjacent structures. AC commonly (35–60%) directly invades the GOJ and proximal stomach, and the degree of involvement influences surgical planning. Complex lymphatic drainage of the oesophagus can lead to skip metastases in the absence of segmental lymph node involvement e.g. gastric and hepato-duodenal ligaments drain the lower third of the oesophagus but may be involved in 44% of middle third and up to 10% of upper third tumours.

Haematogenous metastases are more common with locally advanced disease. Lungs and liver are the most likely sites but metastases may be seen in the adrenals, kidneys, pancreas, peritoneum and bone.

Clinical Presentation

Dysphagia occurs in 90% and weight loss in 70%. These alarm symptoms should prompt urgent investigation. Unfortunately, when they are present the disease is often advanced with a poor prognosis. Other symptoms include retro-sternal pain and regurgitation, which may lead to aspiration. Tumour friability may cause bleeding with haematemesis or anaemia. Anorexia and satiety may occur if the tumour involves the stomach. Other symptoms include odynophagia and pneumonia secondary to tracheo-oesophageal fistula.

Imaging

Imaging has a role in the diagnosis, staging and follow-up of OC. Barium studies are still used for diagnosis but this has generally been superseded by endoscopy and biopsy. Computed tomography (CT) has a role following neo-adjuvant chemotherapy +/-radiotherapy to exclude disease progression prior to surgery, and in the detection of recurrence. However, the greatest modern impact of imaging is in pre-treatment staging.

Staging

Pre-operative ▶TNM classification provided by imaging governs treatment strategy and predicts prognosis.

The primary tumour is classified from Tis to T4 depending on the degree of oesophageal wall involvement.

Tis-carcinoma *in situ*

T1—invades lamina propria or sub-mucosa
T2—invades muscularis propria (MP)
T3—through the muscularis propria into adventitia
T4—adjacent structures
N1—regional lymph node metastases
M1—distant metastases
Lower thoracic oesophagus—M1a coeliac nodes, M1b other distant metastases
Upper thoracic oesophagus—M1a cervical nodes, M1b other
Mid-thoracic oesophagus—M1b non-regional lymph nodes or other

GOJ tumours have no separate TNM classification, which is unfortunate. However, the Siewert I, II and III classification describes whether the tumour arises above, at or below the GOJ, and can assist surgical planning.

A reasonable staging strategy is to exclude metastatic disease with CT, and then assess local disease extent with Endoscopic Ultrasound (EUS). ▶FDG-PET is increasingly used as it becomes more widely available.

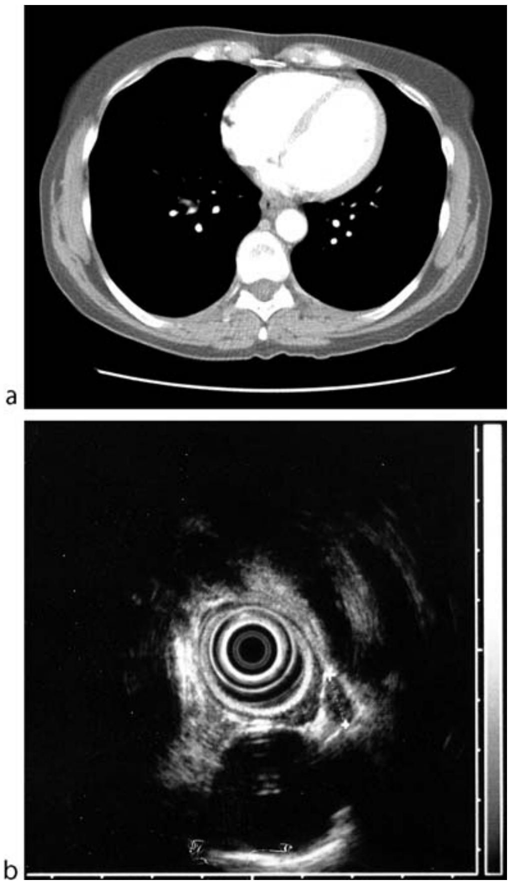
Computed Tomography

Following gastric distension with water (if not limited by dysphagia) post-contrast CT of the chest and abdomen is performed and reviewed with reformatted images as required. T1 OC may not be visible, and as the oesophageal wall layers cannot be seen clearly with CT the distinction between T2 and T3 tumours can be difficult. It is reasonable to assume 100% circumferential tumours are T3 or greater. CT has reported sensitivity of 58%, and specificity of 80% for estimating T staging with better accuracy with advancing T stage (2).

Aortic invasion is found in only 3% at autopsy and is probably less frequent at initial staging. Loss of fat planes is a poor predictor as they are often absent. Aortic invasion is unlikely if the mass involves the aortic circumference by <45 degrees, intermediate between 45 and 90 degrees and highly suggestive if >90 degrees, particularly when the small triangle of fat between oesophagus, aorta and spine is obliterated. However, distinguishing between primary tumour and lymph nodes can be difficult (Fig. 1a and b).

The likelihood of airway invasion increases with respiratory symptoms, tumour length and EUS T stage. The posterior wall of the normal cervical trachea often has a concave appearance as opposed to the convex lower trachea. Disruption of this appearance or asymmetry/nodularity suggests tracheobronchial invasion. However, overall accuracy for diagnosis of tracheobronchial invasion on bronchoscopy, bronchoscopic ultrasonography, EUS and CT are reported as 78%, 91%, 85% and 58%, respectively (3). CT is poor in the assessment of pleural and pericardial invasion but thickening adjacent to the tumour, local effusions, and inward deformity are suggestive. Diaphragmatic invasion can also be difficult to assess, particularly if there is a hiatus hernia. However this is of limited significance, as it would not preclude resection.

There is a 60–80% prevalence of lymph node disease at diagnosis. If lymph nodes are enlarged, metastases are suspected (5 mm supra-clavicular; >6 mm retrocrural;



Neoplasms Oesophagus. Figure 1 (a) Post-contrast CT through the lower oesophageal SCC. Abnormal soft tissue contiguous with the oesophagus abuts almost 25% of the aortic circumference raising the possibility of T4 disease. (b) EUS at 7.5 MHz at the same level as Fig. 1a illustrates the CT appearance is due to a lymph node (between calipers). T2 N1 disease was confirmed at resection.

>8 mm gastrohepatic ligament; >10 mm in the remainder). Reported N staging sensitivity is 79%, and specificity is 84% (2).

Distant metastases from oesophageal cancer at presentation are seen in the liver in 35% and lungs in 20%. Ascites, pleural effusions or nodules in the omentum or pleura are suspicious for metastases and should be further investigated, e.g. laparoscopy. Indeed in AC, laparoscopy when performed routinely identifies metastases in up to 10%. Non-regional lymph nodes are considered to be M1 disease, particularly coeliac and cervical nodes.

EUS

EUS performed at 5–12 MHz depicts the gastrointestinal wall as a five-layered structure of alternating hyper and hypoechoic bands, which correlates well with histology. The fourth (hypoechoic) layer represents the MP. By defining the relationship of the primary tumour to the MP, a pre-operative T stage can be established. EUS is almost unique in providing this detailed pre-operative information (Figs 2 and 3).

Lymph node metastases are defined by EUS using the following criteria: hypoechoic structure, sharp borders, round contour and size greater than 10 mm. Reactive nodes may have an echogenic centre representing the fatty hilum and this feature is usually considered a benign characteristic. However, we have described central echogenic areas, presumed to be due to necrosis, as an additional sign of malignant lymphadenopathy. The site and number of malignant looking lymph nodes seen preoperatively is closely related to prognosis. However, even when the EUS features described earlier are present, accuracy for predicting malignant invasion may be only 80%. It is therefore important to establish if a distant lymph node is malignant as its presence may deny a patient potentially curative surgery. We therefore perform EUS guided biopsy of lymph nodes considered to be M1.

Comparative studies with CT consistently demonstrate superior T and N staging accuracy with EUS. In a systematic review by Harris et al., the T & N staging accuracy of EUS approaches 90% and 80%, respectively (4). While helical CT has had little impact on the role of EUS in this disease, we have reported a complementary role for the locoregional staging of OC in the setting of a multidisciplinary team (2).

EUS has its greatest impact with advanced, nonresectable tumours by preventing open and closed thoracotomy. In patients with T4 disease on pre-operative EUS, surgery has no impact on survival compared to nonsurgical groups. Patients who have unnecessary surgery have been shown to have poor quality of life.

Transcutaneous Ultrasound

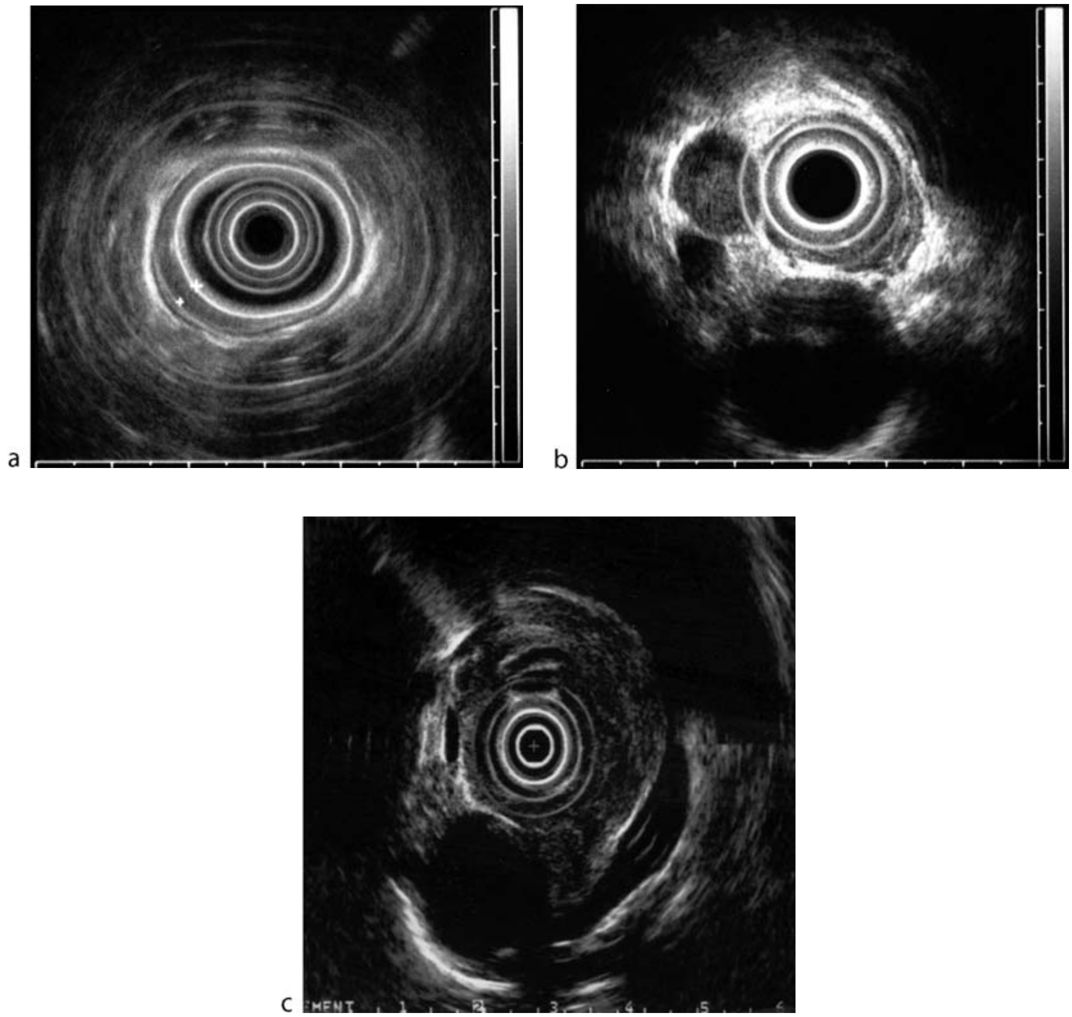
Some centres, particularly in the Far East, use neck US to exclude lymph node metastases in SCC. US may help characterise liver lesions, and guide biopsy.

Magnetic Resonance Imaging

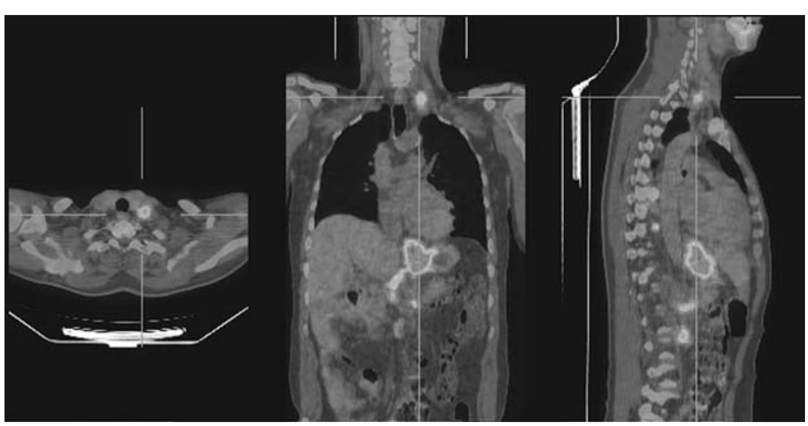
Magnetic resonance imaging (MRI) has a limited role in the assessment of oesophageal neoplasms. Endoluminal MRI offers no advantage over EUS. MRI is occasionally used to clarify the nature of liver lesions.

Nuclear Medicine

The preceding staging strategy assumes FDG-PET is unavailable, but it is increasingly used for staging



Neoplasms Oesophagus. Figure 2 EUS of various stages of OC in three different patients. (a) EUS of the distal oesophagus (12 MHz) with mucosal thickening (between calipers). The hyperechoic sub-mucosa and hypoechoic MP deep to this are intact. AC confined to the mucosa was confirmed on resection. (b) The MP is absent between 5 and 8 o'clock but the tumour is separate from aorta at 6 o'clock. Malignant looking lymph node at 9 o'clock. T3 N1 confirmed at resection. (c) EUS of T4 OC invading the aortic wall at 6 o'clock. Treated with a stent.



Neoplasms Oesophagus. Figure 3 PET CT demonstrating ^{18}FDG uptake in a junctional oesophageal tumour and a supra-clavicular node rendering this patient inoperable.

oesophageal cancer. In the detection of hepatic metastases in gastrointestinal tumours in general, FDG-PET is more sensitive (90%) than CT (72%) or MRI (76%). In a meta-analysis of the staging performance of FDG-PET in oesophageal cancer only, sensitivity and specificity was 67% and 97% for M1 disease and 51% and 84% for N1 disease (5). There is therefore an argument for performing FDG-PET first to exclude M1 disease, but this is limited by cost and availability. While ^{18}FDG accumulates in over 92% of primary tumours, only limited T stage information is obtained.

If surgery is to be denied on the basis of M1a disease on FDG-PET, then ideally histological confirmation should be obtained as false positives do occur.

Diagnosis

Histological diagnosis of oesophageal cancer is made by endoscopic mucosal biopsies.

Interventional Radiological Treatment

Self expanding, metal mesh oesophageal stents are used to palliate dysphagia in patients with inoperable oesophageal cancer. Other indications include recurrence, tracheo-oesophageal fistulae, anastamotic leaks and perforation. Placement can be performed with endoscopic or fluoroscopic control or in combination. Recent technical advances include anti-reflux, anti-migration and retrievable devices. Most patients (75–90%) resume a near normal diet after stent placement, but further intervention is required in up to 60%. Survival may be increased by the use of concurrent chemoradiotherapy or endoluminal brachytherapy, although this may lead to more stent-related complications.

Neoplasms, Oral Cavity

Sabrina Kösling
Martin-Luther-Universität Halle-Wittenberg,
Klinik für Diagnostische Radiologie, Halle, Germany
sabrina.koesling@medizin.uni-halle.de

Definition

Neoplasms are characterised by an abnormal growth of tissue, which occur within structures of the oral cavity. Malignant neoplasms show a greater degree of anaplasia and have the properties of invasion and metastasis. Neoplasms of the oral cavity are soft tissue tumours arising from the mucosal surfaces or deeper structures.

Typical benign tumours of the oral cavity are papillomas and fibromas. Other benign soft tissue neoplasms as fibromatosis, lipoma, leiomyoma, rhabdomyoma or neurogenic tumours (granular cell tumour, schwannoma, neurofibroma) are less frequent at this site.

Haemangiomas and lymphangiomas as congenital vascular lesions are presented in another chapter. Cysts and dermoids are developmental cystic degenerations and not true neoplasms. The known salivary gland neoplasms may arise from minor salivary glands in the oral cavity. They are discussed in the salivary gland chapter.

Compared to other lesions, malignant lesions are found seldom (7%) in the oral cavity; 90% of them are squamous cell carcinomas (1). Adenocarcinomas may occur; melanomas and sarcomas are exceedingly rare.

Pathology/Histopathology

Papillomas are characterised by a growth of keratinised or non-keratinised squamous epithelium with normal maturation pattern. They contain fibrovascular connective tissue and chronic inflammatory cells. In fibromas—hyperplasias of fibrous connective tissue—there is a proliferation of fibroblasts and collagen fibres. Several patterns that reflect progressive stages of fibroblastic differentiation are identified microscopically in fibromatosis. Dense or moderately dense, rather vascular, bland collagenic connective tissue with scattered chronic inflammatory cells can be observed. In lipomas, superficial or deeper adipose tissue proliferates; in leiomyomas smooth muscle—in the oral cavity usually of the blood vessels—and in rhabdomyomas skeletal muscle. The submucosal granular cell tumours are composed of diffuse sheets of large cells of either nerve or muscle origin with a cytoplasm of densely packed eosinophilic granules. In schwannomas (synonym:

neurilemoma) there is a fibroblastic proliferation of the nerve sheath cells (Schwann's cell). Neurofibromas consist of diffuse proliferations of perineural fibroblasts that are orientated in either a random or nodular pattern (2).

Squamous cell carcinomas develop from the stratified squamous epithelium of the mucosa. Histologically, they show large polygonal or fusiform cells with atypical nuclei and increased mitotic activity. They may contain keratinised and inflammatory cells. Depending on the differentiation four degree (G1–G4) are distinguished: high, moderate, poor, undifferentiated or anaplastic. Adenocarcinomas (G1–G4) are epithelial tumours with glandular components, which may produce mucus. Carcinomas of the oral cavity are classified according to the ▶TNM criteria of ▶UICC (Tables 1 and 2).

At first presentation about 60% of the patients with carcinomas of the oral cavity have nodal metastases, even if the tumours are small. The first order drainage of oral cavity carcinomas is the submental and submandibular lymph node group for anterior processes, and the jugulodigastric node for posterior lesions. From there the drainage of both regions goes mostly down into the deep cervical and spinal accessory chain. Especially carcinomas of the tongue are predisposed to bilateral affection.

Melanomas are malignant neoplasms deriving from cells that are capable of forming melanin, which may occur in the mucosa of the oral cavity. The usually high malignant sarcomas are formed by the proliferation of mesodermal cells.

Clinical Presentation

Neoplasms are usually painless. Benign tumours, but also adenoid cystic carcinomas grow slowly—malignant more rapidly. Due to slow growing, benign tumours are often asymptomatic and will be detected incidentally. A criterion of benignancy is that the lesion is movable against the undersurface. Depending on the localisation and size, neoplasms can cause dysphagia, dyspnoea and difficulties in speaking; if the tumour is injured bleedings might occur. Malignant epithelial tumours are often accompanied by foetor ex ore.

Some tumours have a characteristic optical appearance. Papillomas are white or pink, sessile or pedunculated exophytic nodules of cauliflower-like appearance; they may occur anywhere on the oral mucosa. The firm and often exophytic fibromas, located on the buccal mucosa, tongue, lips or gingiva, are usually smaller than 2 cm. Lipomas are soft on palpation and of yellow colour. A nodular, possibly exophytic, ulcerous, hard, easily bleeding mass, which is more or less fixed and sometimes painful on palpation, is suspicious to be a carcinoma; otalgia may occur due to connection of the lingual to the facial nerve. Often enlarged lymph nodes can be palpated. Clinical signs of infiltration are a fixed tongue and trismus. Mesenchymal and neurogenic neoplasms lie submucosally without typical clinical signs.

Imaging

Conventional radiographs are performed in tumour diagnostics of the dental apparatus. They do not play a role in tumour imaging of the oral cavity. CT and MRI have been proved to be valuable in the modern diagnostics of neoplasms in this region. Ultrasound is of secondary importance (4).

Neoplasms, Oral Cavity. Table 1 T-categories of oral cavity tumours (UICC)

T0: No evidence of tumour
TIS: Carcinoma *in situ*
T1: Tumour ≤20 mm
T2: Tumour >20 mm, ≤40 mm
T3: Tumour >40 mm
T4a: Infiltration through cortical bone, in external tongue muscles, maxillary sinus or skin
T4b: Infiltration of the masticator space, pterygoid process or skull base, or encasement of internal carotid artery

Neoplasms, Oral Cavity. Table 2 N-Categories of oral cavity tumours (UICC)

NX: Regional lymph nodes are not assessable
N0: No regional lymph node metastases
N1: Metastasis(es) in solitary ipsilateral lymph node—≤30 mm
N2a: Metastasis(es) in solitary ipsilateral lymph node—>30 mm, but ≤60 mm
N2b: Metastasis(es) in multiple ipsilateral lymph nodes—none of them >60 mm in its largest dimension
N2c: Metastasis(es) in bilateral or contralateral lymph nodes—none of them >60 mm in its largest dimension
N3: Metastasis(es) in lymph nodes >60 mm in its largest dimension

Computed Tomography and Magnetic Resonance Imaging

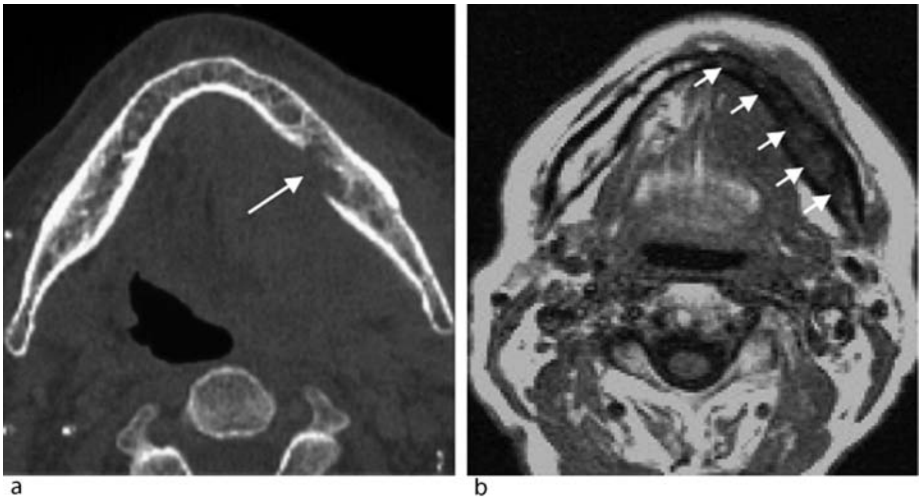
Neoplasms of the oral cavity are detected by clinical investigation. Imaging is performed to depict the full extension in larger benign tumours and especially in malignancies, first of all in carcinomas. Very small tumours with mucosal spread can be undetectable on CT and MRI. Due to the better soft tissue contrast, MRI is more suited in the delineation of tumourous lesions from surrounding structures compared to CT. Beam-hardening artefacts caused by dense bones and teeth, or by dental fillings may seriously disturb the visibility of tumours on CT. On the other side, a CT examination is performed within a few seconds with modern technique whereas a complete MRI study lasts about 30 min. In the case of less co-operative patients CT should be preferred.

The general signs of tumours on CT are similar to those on MRI. Tumours show a space-occupying growth, larger ones an obliteration of fat planes. An infiltration of muscle and bone are hints for a malignancy. Cortical erosion is seen better on CT (Fig. 1a), the extent of medullary invasion better on MRI (Fig. 1b). Many tumours show a ►contrast enhancement, which is different to surrounding structures. Larger tumours have sometimes inhomogeneities. On MRI, most tumours appear isointense to muscles on unenhanced T1-weighted images, and moderate to strong hyperintense on T2-weighted images. Except of lipomas and cystic lesions, there are no characteristic densities or signal intensities for a single neoplasm on CT or MRI (Fig. 2).

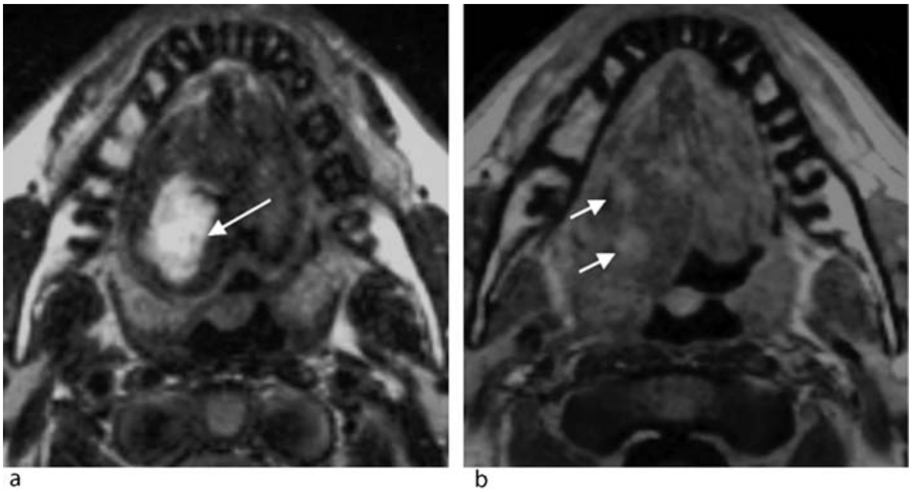
In general, cancer has several modes of spread. Firstly, most tumours grow superficially within the mucosa. Mucosal spread is best evaluated by inspection. Before invasion of muscles and bones tumour spreads within spaces, along the muscular fasciae and the periosteum. Cancer may show a ►perineural spread and lymph node metastases. Both have a negative impact on prognosis.

The deep spread of a neoplasm cannot be exactly assessed by clinical examination; this is where imaging plays a role. In dependence of the primary site (floor of the mouth, tongue, oral mucosa with different sub-sites, upper and lower gingiva, hard palate), carcinomas show preferential ways of extension with increasing growth, which can be best visualised by MRI: Tongue carcinomas grow first along the intrinsic muscles deeper into the tongue, along extrinsic lingual muscles into the sublingual and submandibular space; they can reach the base of the tongue and the muscles of the floor of the mouth. Cancers in the floor of the mouth (Fig. 3) spread along the muscles, periosteum of the mandible, within the lingual septum and submandibular space; the tongue and tongue base may be involved; relative early the mandible is invaded; the Warton‘s duct can be occluded resulting in an adenitis of the sub-mandibular gland. Carcinomas of the oral mucosa and gingiva spread first into the buccal space; later they may invade the masticator space; a retromolar localisation is endangered for a perineural spread along the inferior alveolar nerve. Cancers of the hard palate break early through into the maxillary sinus, a perineural spread along the palatine nerves to the pterygopalatine ganglion may occur.

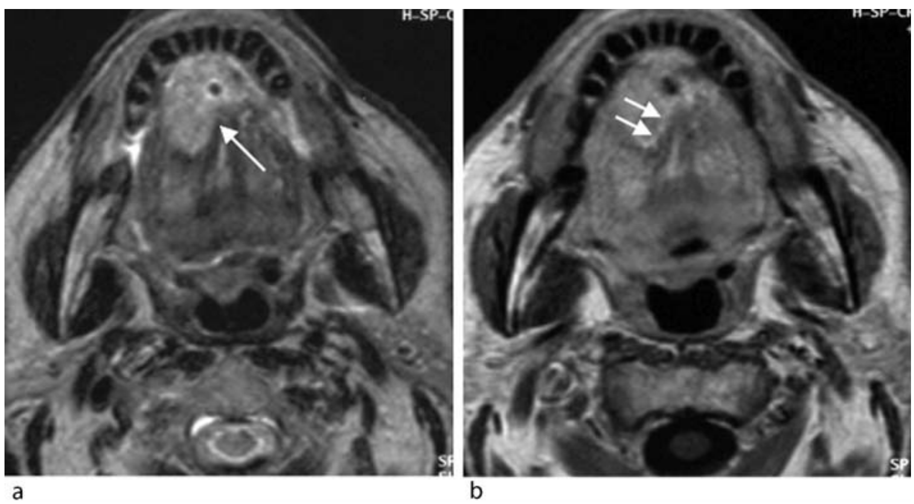
In lymph node judgment, morphological criteria—size larger than 10 mm, central necrosis, indistinct nodal margin as a sign of extra-capsular spread—are used for



Neoplasms, Oral Cavity. Figure 1 T4-stage squamous cell carcinoma of the floor of the mouth in two different patients. (a) Axial high-resolution CT in bone window shows a cortical defect in the mandible (arrow). The extent within the bone marrow is not quite clear. (b) Axial T1-weighted image demonstrates a wide medullary invasion of the mandible (arrows).



Neoplasms, Oral Cavity. Figure 2 Axial MRI of a patient in whom clinicians found an unclear mass in the tongue. (a) On T2-weighted image the lesion can be demonstrated best (arrow) and estimated in size. It is relatively sharp demarked. (b) On contrast-enhanced T1-weighted image, the tumour showed a described enhancement (arrows) and is less well demarcated. The imaging diagnosis was 'probably benign neoplasm'. Histology revealed a regressively changed fibroma.



Neoplasms, Oral Cavity. Figure 3 Bioptically proven squamous cell carcinoma of the floor of the mouth. (a) Axial T2-weighted images visualise a hyperintense mass in the anterior part of the oral cavity, which crosses the midline (arrow). (b) On axial contrast-enhanced T1-weighted image, there is a blurred margin of the tumour (arrows), which is suspicious of infiltration of the genioglossal muscle as T4 criteria. The patient underwent radiochemotherapy.

the distinction between normal and metastatic lymph nodes in CT and MRI, but the number of false-negative and false-positive findings is still high with this approach. If enlarged lymph nodes are related to the primary disease and the corresponding lymph node drainage, the results can be improved. The major problem of both methods is the high false-negative number in normal sized lymph nodes with micro-metastases. Despite of technical improvements in CT and MRI, this problem is not sufficiently solved at present.

Imaging is part of the clinical staging. Tumour size in its greatest dimension can be determined for T1 to T3 categories and for the T4 category invasion of skeletal muscles and/or bone (Table 1). If a tumour is accompanied by inflammatory changes, imaging tends to overestimate the tumour size because both processes cannot be differentiated exactly. Criteria for the single N categories are the number of affected lymph nodes, their size and if they are ipsilateral or bilateral (Table 2).

Ultrasound

In the hand of experts, ultrasound examination can deliver a lot of information. It provides access to most structures of the oral cavity. Usually, tumours appear as hypoechoic space-demanding structures. Especially in the tongue, a tumour and its spread within the internal muscles can sometimes be better delineated than on CT or MRI. The method is of special relevance in the examination of major salivary glands and as duplex-high-resolution-sonography in the assessment of lymph nodes, where malignant lymph nodes show irregular central vessels. If ultrasound is combined with fine-needle aspiration cytology, the specificity of lymph node findings can be increased significantly. A larger tumour extension into deeper spaces, bone invasion and retropharyngeal lymph node metastases cannot be diagnosed sufficiently. Therefore, sonography is not suitable as a solitary method in tumour imaging.

Nuclear Medicine

In the diagnostics of the oral cavity carcinomas, nuclear medicine techniques can provide relevant information in certain cases. Due to the lack of anatomic details, they have to be supplemented by CT or MRI in shape of co-registration or comparative investigation. Nowadays, ▶^{18}FDG PET is the leading procedure, which gives information about the degree of glucose metabolism in different tissues. A certain level of increased uptake of FDG is considered as malignancy. Several reports confirmed an increased ^{18}FDG uptake in primary tumours, lymph node and distant metastases of head and neck squamous cell carcinomas. However, the clinical use of ^{18}FDG PET is discussed controversially. Higher accuracy compared to CT and MRI have been reported in lymph node assessment, detection of unknown sites in patients with cancer of unknown primary (CUP) and in differentiation of recurrent cancer from post-therapeutic changes. Nevertheless, a routine use of PET in pre-therapeutic staging of oral cavity squamous cell carcinomas cannot be recommended; in this situation PET is reserved for cases with equivocal findings by CT or MRI (5).

Diagnosis

The diagnosis of oral cavity tumours is based on histopathology. The dignity of mucosal lesions and their superficial spread can be better judged by clinical methods compared to imaging. Submucosal tumours cannot be assessed clinically with the same safety. Small, superficial and benign appearing neoplasms are excised without imaging. Imaging is needed in larger and/or malignant appearing neoplasms.

Beside of histology, the knowledge about the full tumour extension is important for the therapeutic decision and patient's prognosis: extension into deep soft tissue structures and spaces; infiltration of skeletal muscles, bone, neighbouring spaces and skin; crossing the midline of the tongue or floor of the mouth; perineural spread; relation to the common or internal carotid artery; and metastatic involvement of lymph nodes. The imaging method of first choice to get this information is MRI nowadays (5). In contraindications for MRI or non-compliant patients, CT is the alternative method. PET and sonography can provide relevant diagnostic information as complementary techniques.

Malignant oropharyngeal tumours

Definitions

Neoplasm of the oropharynx means a primary malignancy arising from the mucosa of this anatomic region.

The oral portion of the upper aerodigestive tract is formed by two regions: the oral cavity and the oropharynx. The oropharynx communicates, in addition to the oral cavity, with nasopharynx, hypofarynx and larynx (1).

The boundaries of this anatomical region is the soft palate superiorly and the hyoid bone inferiorly (2). The anterior part of oropharynx includes the posterior one-third of the tongue (posteriorly to the circumvallate papilla); the upper part is formed by the soft palate and uvula. Laterally, there are two facial arches, the anterior (palatoglossus muscle) and the posterior arch (palatopharyngeal muscle) and between them is the tonsillar fossa which harbours the palatine tonsil (1). The posterior oropharyngeal wall is bounded by upper pharyngeal constrictor muscles and is related to the second and third cervical vertebrae.

Moreover, the oropharyngeal region includes the lingual tonsil which lies at the base of the tongue, more concentrated on the lateral surfaces. The lingual tonsil and the palatine tonsils jointly, as well as other collection of lymph tissue in this area, form the Waldeyer's ring.

Pathology/Histopathology

The majority of tumours involving the oropharynx are squamous cell carcinomas antigen (SCCA) which represent about 90% of the total. They arise from oropharyngeal mucosa. The incidence of SCCA of oropharynx increases in patients with a history of tobacco or alcohol abuse (1, 2).

Other histological types of tumours are less common such as lymphoma, minor salivary gland tumours and other rare mesenchymal lesions (1, 2).

The mesenchymal neoplasms of oropharynx are rare and include: rhabdomyoma and rhabdomyosarcoma (most common in childhood), granular cells tumours, fibromatoses, schwannomas, neurofibromas, and hemangiomas (2).

In most cases, imaging techniques have little specificity and histologic diagnosis is needed.

Clinical Presentation

Oropharyngeal tumours can be clinically silent. Sometimes, the symptomatology can be represented by dysphagia or slight pain even if latero-cervical lymphadenopathy is often the only finding.

Imaging

The goal of modern diagnostic imaging is to establish the location, the size and the extent of oropharyngeal tumour. Moreover, it is important the pre-therapeutic evaluation of the relationship between tumoural mass and some critical structures like lingual artery and vein, carotid artery, internal jugular vein, muscles, connective tissue spaces and bone.

Computed tomography (CT) scan and magnetic resonance imaging (MRI) are the techniques of choice in the evaluation of oropharyngeal tumours.

Computed Tomography Scan Method

The oropharynx should be studied during suspended respiration (2).

The region of interest should be extended from the base of the skull to the upper mediastinum (aortic arch). Contrast-medium injection is mandatory to define the tumoural boundaries and metastatic lymphoadenopathies (2, 3).

The axial plane is obligatory for the evaluation of oropharyngeal region.

With modern multislice CT scanners, coronal and sagittal scans can be reconstructed from the volume data set (multiplanar reformation, MPR) or 3D images can be calculated with volume-rendering techniques. Coronal and sagittal images are useful to define the anatomical spread of the tumour and to reduce artefacts due to dental fillings (amalgam, gold or ceramics) (3).

Bone algorithms are essential to evaluate any pathologic bone involvement.

Magnetic Resonance Imaging Method

The advantages of MRI in comparison with CT scan are better tissue contrast and the absence of degradation due to dental fillings. The disadvantages are the long imaging time (20–30 min MRI versus 20–30 sec CT scan) and the subsequent difficulty for the patient to remain motionless (3).

The MRI study of oropharynx is performed primarily in the axial plane. It is essential to obtain axial T1- and T2-weighted images. These images are usually obtained by FSE sequences. Scanning with contrast-medium (Gd-DTPA) is mandatory; the dosage is 0.2 mmol/kg body weight. Optional coronal and sagittal T1-weighted images before and after Gd-DTPA can be obtained, respectively to study lateral and midline tumours. To overcome the problems due to the high fat signal in FSE images, fat suppression techniques are used on both T2-weighted images and T1-weighted images after gadolinium injection (3).

Alternative fat-suppressed technique is short-tau inversion recovery (STIR) without contrast-medium injection. This technique is very sensitive in tumour location.

Moreover, dynamic T1-weighted GE sequences can be used after gadolinium injection to study tumour vascularisation because of their high temporal resolution (3).

Disadvantages of GE sequences are represented by susceptibility artefacts at the air-bone-tissue borders and near dental fillings.

Diagnosis

Imaging techniques play an essential role in the diagnosis and stadiation of oropharyngeal tumours.

The location and the size of the neoplasm, the degree and direction of infiltration into neighbouring structures and the degree of regional lymph node involvement significantly orientate prognosis and therapy (2, 4).

According to the TNM criteria, oropharyngeal tumours are classified:

- Stage T1: <2 cm in maximum diameter
- Stage T2: >2 cm–<4 cm
- Stage T3: >4 cm
- Stage T4: Tumour involving bony structures (mandible or jaws), soft tissues of the neck or extrinsic muscles of the tongue.

Tumour Detection

A malignant oropharyngeal neoplasm appears like a space-occupying growth associated with obliteration of fat planes. Direct sign of an advanced neoplasm is the infiltration of muscle and of bone structures (4).

After contrast-medium injection, squamous cell carcinomas enhance in 85% of cases (4).

The tumoural tissue has a density between 80 and 90 HU, different from the muscle (70 HU) and the fat tissue (100/200 HU).

Moreover, the tumoural mass often shows structural inhomogeneities with intralesional necrosis.

Some oropharyngeal tumours (15%) can be isodense to the muscle on CT scan.

MRI presents an excellent tissue contrast which allows easily differentiation between tumour and normal structures (2–4).

This peculiarity is useful in detection of small neoplasm in the oropharynx (4).

In addition to general diagnostic signs, analogous to CT scan, MRI evaluation offers specific findings.

In T1-weighted images, neoplastic tissue is significantly hypointense in comparison with fat tissue. Also, tumours are slightly hypontense or isointense than muscles.

In T2-weighted images, tumours have high signal intensity. Peritumourous oedema may also produce high signal leading to over-estimation of tumour size.

Therefore, MRI sensitivity can be improved using fat suppression techniques (FS-T2 FSE or STIR sequences). (Fig. 1).

After gadolinium injection, all neoplasms show contrast-enhancement, better depicted using fat suppression techniques on T1-weighted sequences.

Spread Patterns and Lymphatic Drainage

Oropharyngeal tumours present different spread patterns in relation to the site of origin (1, 2, 4).

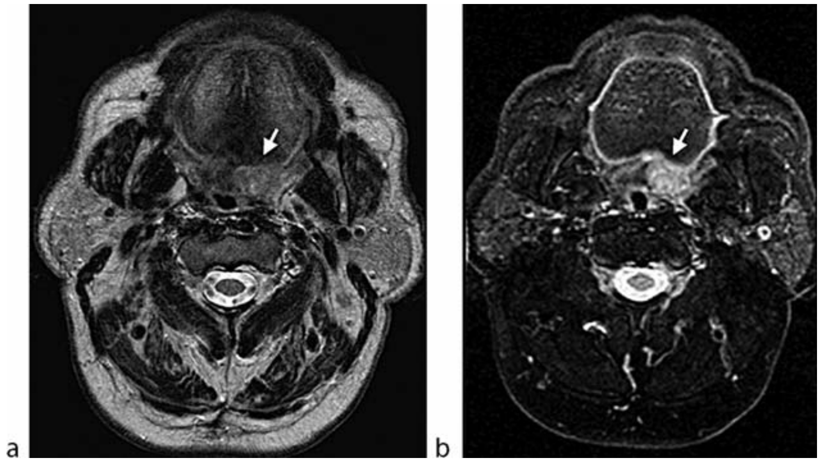
Carcinomas arising on the anterior tonsillar pillar (ATP) tend to spread along the palatoglossus muscle and its fascial attachments as far as to the tongue base.

The neoplasm may spread superiorly to the soft palate and to nasopharynx. Nasopharyngeal infiltration is usually unilateral. The lymphatic drainage of ATP tumours is primarily to the submandibular and internal jugular nodes (2, 4).

Isolated carcinomas of posterior tonsillar pillar (PTP) are rare and usually small.

Carcinomas of the tonsil can spread anteriorly to involve the tongue base, the floor of the mouth and retromolar trigone; laterally, neoplasm can involve

N



Neoplasm, Oropharynx. Figure 1 SCCA of palatine tonsil. Axial FSE T2-weighted image. A small tonsillar tumour is visible on the left side (arrow). The neoplasm is substantially isointense to contiguous normal tissues. Axial fat suppression T2-weighted image. The fat saturation technique allows easier the tumour detection (arrow).

parapharyngeal, masticator and carotid spaces; superiorly, the soft palate and the nasopharynx. (Fig. 2)

Lymph node metastasis occurs primarily in the upper internal jugular or retropharyngeal nodes (2, 4).

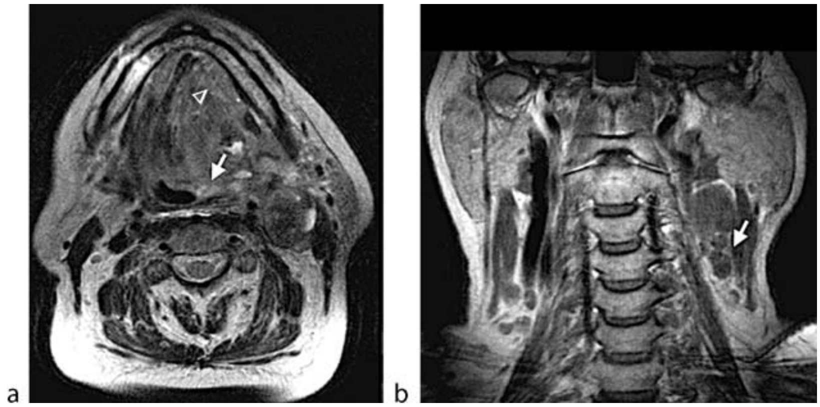
SCCA of tongue base may extend laterally to involve the mandible and medial pterygoid muscles; superiorly, to tonsillar fossae and soft palate; anteriorly to the oral tongue and floor of the mouth; inferiorly, to the vallecula, pre-epiglottic space, epiglottis or hypopharynx. (Fig. 3) Lymphatic drainage is often to internal jugular and submandibular nodes (2, 4).

Tumours arising from the soft palate can spread in any direction. The tonsillar pillars and hard palate are usually involved first. Deeply, these neoplasms can involve parapharyngeal space, the nasopharynx and the skull base. Palatal carcinomas drain first to upper internal jugular and subdigastric nodes, with subsequent involvement of lower internal jugular or retropharyngeal nodes.

SCCA of the posterior oropharyngeal wall spread inferiorly into the hypopharynx and cranially into nasopharynx. They commonly spread submucosally invading the retropharyngeal fat. Lymphatic drainage is to submandibular and jugulo-digastric nodes (2, 4).

For depiction of tumour spreading, sagittal and coronal images on both CT scan and MRI are well-suited. On MRI, T2-weighted FSE with fat suppression, FS T1-weighted FSE or T1-weighted GE after gadolinium injection are very sensitive in lymphadenopathy detection.

(c, d) Axial and coronal Gd-DTPA fat suppression T1-weighted images. The tumoural tissue shows intense enhancement. Note the tumoural spreading to the tongue base, anteriorly (arrows), and to parapharyngeal space, laterally (arrowhead).



Neoplasm, Oropharynx. Figure 3 SCCA of tongue base. Axial T2-weighted image. A neoplastic mass is visible on the left side of the tongue. Note the bulging of the free edge of the tongue (arrow) and the infiltration of the mylohyoid muscle (arrowhead). Coronal T1-weighted image shows ipsilateral lymphadenopathies along the course of the internal jugular chain (arrow).

Nuclear Medicine

18-FDG positron emission tomography (PET) and PET/CT scan fusion have useful role in the follow-up of patients with head and neck cancers to localise tumour remnants or relapses and to define radiotherapic planning of treatment.

Parathyroid adenoma; Parathyroid cancer

Definitions

Parathyroid glands are four small endocrine glands, exceptionally five or six, located behind the thyroid lobes; 80% of superior parathyroid glands are located at the crico-thyroid junction, while inferior parathyroid glands are variably located (61% near the lower pole of the thyroid lobes and 26% in thyrothymic ligament). Incidence of ectopic parathyroid glands reported is variable (2 to 8%).

Parathyroid glands regulate the calcium level through the secretion of the parathyroid hormone (PTH).

Primary parathyroid gland carcinoma is extremely rare, with an estimated annual prevalence of about 0.005%, i.e. five cases of primary carcinoma/100,000 cases of primary hyperparathyroidism (HPT) or less than 1% of all cases of HPT.

Parathyroid adenomas (PA), that are benign tumors, account for 85% of all cases of this disease. Most are functional and cause excessive secretion of PTH, resulting in HPT.

In addition to the solitary or sporadic PA tumors, approximately 5% are associated with hereditary cancer syndromes such as multiple endocrine neoplasia (MEN).

Pathology/Histopathology

Parathyroid glands are composed of chief cells, oxyphilic cells and intermediate cells. Histologically, primary HPT can be attributed to a single adenoma in 80 to 85% of cases, hyperplasia in 15 to 20% of cases and carcinoma in 1% of cases. Double or multiple adenomas have been reported in patients with primary HPT including MEN.

Hyperplasia is defined as an enlargement of more than two glands, whereas adenoma is traditionally considered to be a single gland disorder. The parathyroid adenoma consists of hypercellular parathyroid tissue arranged in solid sheets or cords with a trabecular pattern. Occasionally, interspersed adipocytes are seen with the adenoma. Nuclear pleomorphism may be present; however, mitoses, capsular invasion, or vascular invasion mitigate against a benign lesion. Parathyroid adenomas include the following subtypes: oncocytic adenoma, lipoadenoma, large clear cell adenoma, water-clear cell adenoma and atypical adenoma.

Clinical Presentation

Most PTG tumors are functional and cause excessive secretion of PTH, resulting in HPT.

HPT may be classified as a primary, secondary, or tertiary disorder.

Primary HPT is caused by PA.

Secondary HPT (hyperplasia) develops in response to chronic depression of serum calcium levels, generally due to renal impairment. In a minority of patients, this parathyroid hyperactivity becomes autonomous, resulting in tertiary HPT.

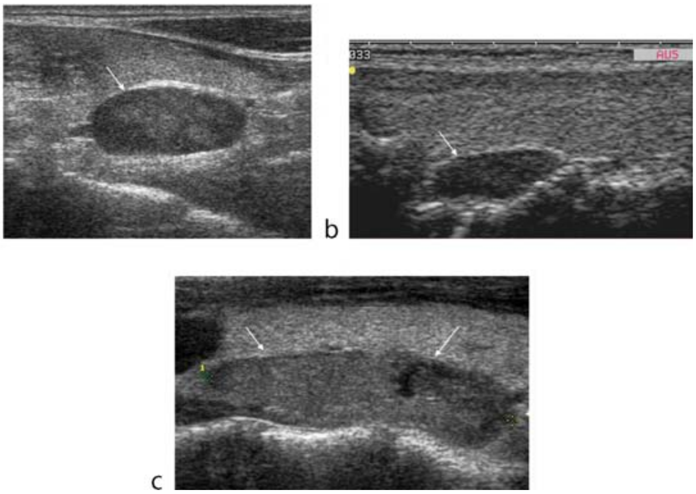
Widespread testing of calcium in blood using automated analyzers in the clinical laboratory has led to the detection of hypercalcemia early in the course of HPT and in the majority of cases before other signs of HPT are apparent. Symptoms of HPT can be variably, aches and pains, depression, abdominal pain, nausea, vomiting, fatigue, excessive urination, confusion, muscle weakness.

The excess calcium released by the bones leads to osteoporosis, osteomalacia and kidney stones, because of high levels of calcium excreted into the urine by the kidneys.

Imaging

Diagnostic imaging of parathyroid is not essentially aimed to diagnose HPT, but to detect hyperplasia or neoplasms in the parathyroids or in ectopic glands. It is still controversial the use of imaging in preoperative evaluation; surgical series shows that the success rate of the intervention is excellent (95%) even if a preoperative imaging is missed. However, there is general agreement that imaging is required in cases with persistent or recurrent HPT after surgery.

At present, ultrasound (US) and SPECT scanning with Tc-99m Sestamibi are the first imaging steps and the preferred methods to identify a pathologic parathyroid gland before surgery. US has a high sensitivity in detecting parathyroid adenomas in patients without thyroid diseases associated (90%) and lower in presence of thyreopaties (70%). Sensitivity reported of SPECT ranges between 70 and 100%. US can be useful mainly in localizing parathyroid cervical adenomas and in perithyroidal region, but it frequently fails in identifying ectopic lesions such as for parathyroid adenomas localized in the mediastinum and retro or paratracheoesophageal compartment (Fig. 1). US must be performed with high resolution linear transducers (at least 10MHz), and a critical factor influencing the accuracy of the technique is the experience of the examiner; this explains the variance of sensitivity among different authors. Therefore, the use of US can be suggested only if an experienced operator is performing the exam.



a b c

Neoplasms, Parathyroid. Figure 1 US: Typical hypoechoic pattern and shape of the lower (a) or upper (b, c) parathyroid lesions (*arrows*).

In case of thyroid goiter, the detection of parathyroid lesion can be more difficult.

The use of color-Doppler US examination is frequently helpful to differentiate parathyroid from thyroid nodules or cervical lymphnodes on the basis of the different vascular pattern.

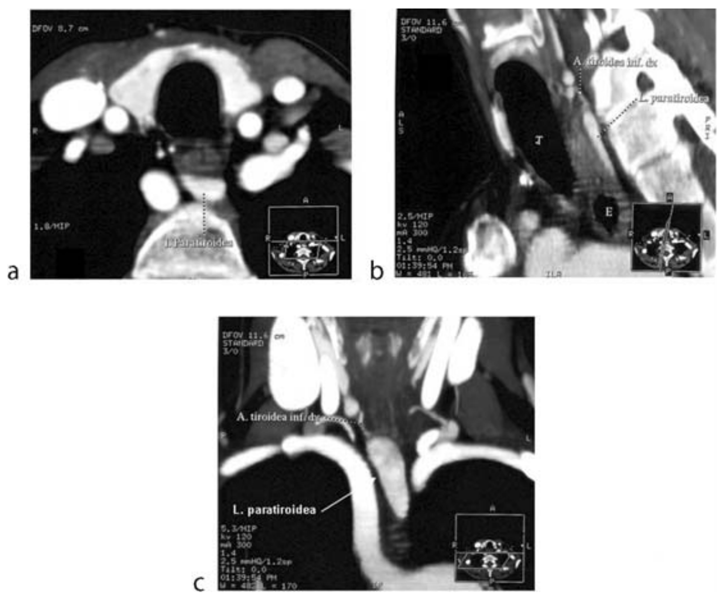
SPECT is performed by injecting 20 to 25 mCu of technetium-99m sestamibi; images are obtained at 10–15 min then 2–3 h after the injection. Late phase is preferable for detecting parathyroid adenomas, as thyroid nodules clear uptake faster than do parathyroid neoplasms.

Sestamibi is taken up by the high mitochondrial content of adenomatous parathyroid cells, greater than surrounding parenchyma. False positive cases can be caused by solid thyroid nodules (adenomas), Hurthle cell carcinoma, malignant thyroid lymph node metastases.

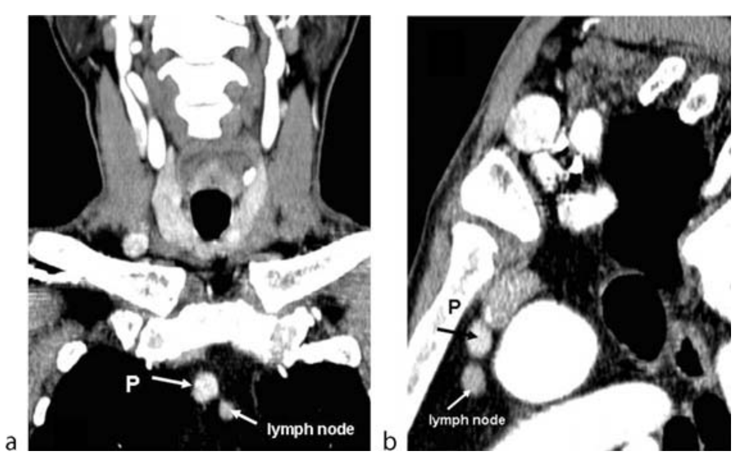
It is proven that a combination of US and SPECT results in improved diagnostic accuracy before surgery in pre-operative diagnosis of parathyroid disease.

MRI can be extremely valuable for localizing a parathyroid adenoma although the sestamibi has decreased the need for it dramatically. At best, an MRI will find less than 10% of diseased parathyroid glands; therefore the indications for getting this scan are very few.

A renewed interest has received CT, with the advent of the multidetector technology. Multidetector CT allows to



Neoplasms, Parathyroid. Figure 2 **Multidetector CT: Retroesophageal parathyroid lesion (ectopic site). Axial (a), sagittal (b) and coronal scan (c).**



Neoplasms, Parathyroid. Figure 3 **Multidetector CT: The scan distinguishes hypervascular retrosternal parathyroid nodule (P) from hypodense lymph-node. Axial (a) and sagittal (b) scan.**

study at very high resolution and with optimal contrast enhancement the mediastinal area. Ectopic parathyroids can be detected as hypervascular nodules and well differentiate from lymph nodes (hypovascular) (Figs 2 and 3).

Diagnosis

Diagnosis of HPT is based on two laboratory evidences, elevated serum Ca and elevated PTH (suppressed in PTH-rp induced hypercalcemia). The 2002 National Institutes of Health (NIH) consensus panel on the management of asymptomatic primary HPT (2002 NIH Panel) classified primary HPT into two categories: asymptomatic and symptomatic. Asymptomatic primary HPT accounts for 75 to 80% of all HPT cases. In both asymptomatic and symptomatic HPT, hypercalcemia in concert with an increased serum PTH concentration is the biochemical hallmark for the diagnosis of primary HPT. Other useful tests can be the dosage of albumin, phosphorous, BUN/Cr, 24-h urine Ca (r/o FHH) and bone mineral density.

Imaging is essentially used for pre-operative planning or in case of recurrent HPT after surgery.

Neoplasms, Phyllodes, Breast

Luis Pina
Department of Radiology, Clínica Universitaria de Navarra, Navarra, Spain
ljpina@unav.es

Synonyms

Cystosarcoma phyllodes; Phyllodes tumor

Definition

Phyllodes tumor is a fibroepithelial tumor of the breast that exhibits a diverse range of biologic behavior (1).

Pathology

The gross appearance is a round to oval well-circumscribed mass without a true capsule. Microscopically, this tumor shows a variety of appearances from those resembling ►fibroadenomas to others like sarcomatous tumors. Many phyllodes tumors show a characteristic leaf-like architecture. The epithelial component is usually single layered, but other changes, such as hyperplasia, atypical hyperplasia, or *in situ* carcinoma, may be seen. However, the stromal component determines their clinical behavior. Four histologic features are important for classifying this lesion (1): (i) stromal cellular atypia, (ii) mitotic activity per 10 high-power fields, (iii) stromal overgrowth, and (iv) tumor margins. Phyllodes tumors can be classified into three categories: benign, borderline, and malignant. The first type shows increased stromal cellularity with mild to moderate atypia, low mitotic rates (<4/10), no stromal overgrowth, and well-circumscribed margins. ►Borderline phyllodes tumors have stromal atypia, mitotic rates between 4/10 to 9/10, no stromal overgrowth, and they can have microscopically infiltrative margins. Malignant cases are characterized by severe stromal cellularity and atypia, high mitotic rates (10/10), infiltrative borders, and stromal overgrowth (Fig. 1).

Clinical Findings

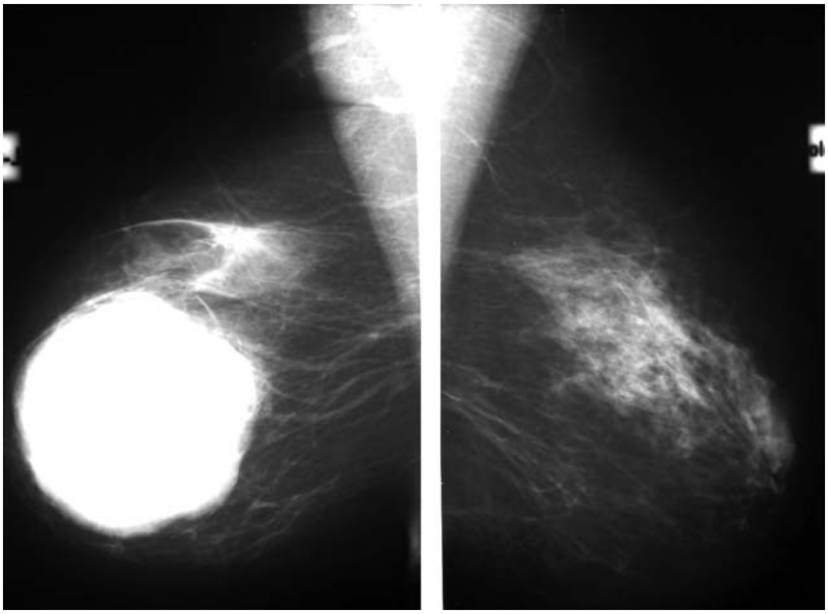
Phyllodes tumors are rare lesions, accounting for no more than 0.3–1% of all primary breast tumors (2). Patients are typically one decade or more older than women with fibroadenomas. Malignant cases still affect older patients (1).

Usually, these lesions present as smoothly marginated, round or polylobulated palpable masses resembling fibroadenomas. An important feature is a rapid growth, sometimes from a previously stable nodule. Very large tumors may cause visible bulging and skin ulceration (1, 2).

Recurrence may be found in 21% of cases (2). A surgical excision with wide margins (>10 mm) is associated with a low risk of recurrence.

Axillary dissection is not routinely performed since nodal involvement is very rare.

Hematogenous metastases of malignant cases are uncommon, accounting for 10% of all phyllodes tumors (2). The lung is the most commonly affected organ.



Neoplasms, Phyllodes, Breast. Figure 1 Well-circumscribed round mass. Notice the high density of the lesion. The patient, a 59-year-old woman, reported a rapid growth in the last 3 months. Pathology: ▶malignant phyllodes tumor.

Imaging

Mammography

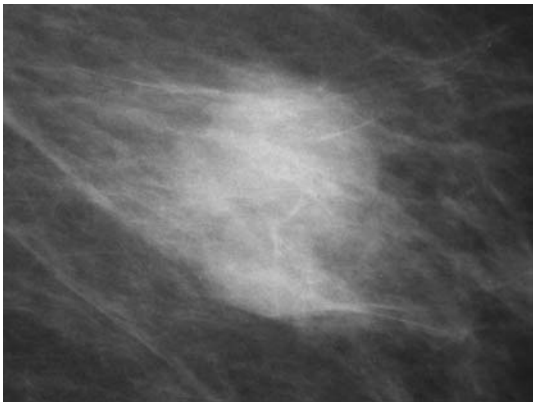
Mammographic features are similar to those of fibroadenomas showing as oval, round or lobulated masses with well-circumscribed margins, but occasionally indistinct margins may be seen (Figs. 1 and 2). However, adjacent fibroglandular tissue may occult the lesion. Sometimes mammography may detect coarse calcifications inside a phyllodes tumor, similar to fibroadenomas. Lesions greater than 30 mm are more likely to be malignant.

Ultrasound

Phyllodes tumors appear as oval, round, or lobulated masses with well-delimited margins and acoustic enhancement, resembling fibroadenomas. However, ultrasound may detect internal cysts and heterogeneous echostructure (Fig. 3). Both findings are not specific, but very often they lead to a biopsy (3, 4).

Magnetic Resonance

Phyllodes tumors present as oval, round, or lobulated well-circumscribed masses, usually hyperintense on T2-weighted images. After contrast medium administration, these lesions enhance rapidly. The role of magnetic resonance is not well established, but it may be useful for planning conservative surgery or evaluating thoracic wall involvement (4).



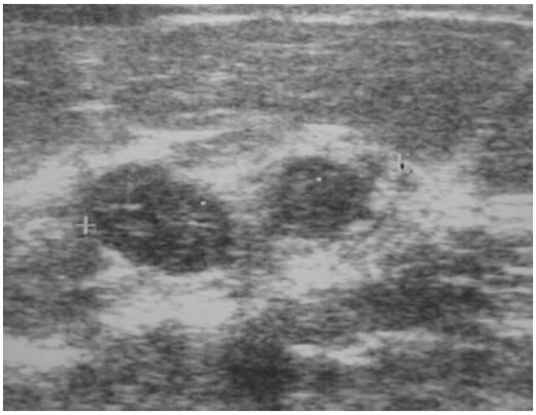
Neoplasms, Phyllodes, Breast. Figure 2 A lobulated mass with indistinct margins. Craniocaudal view, (detail). Biopsy revealed a ▶benign phyllodes tumor.

Nuclear Medicine

There are no indications for the diagnosis of phyllodes tumor.

Diagnosis

The rapid growth of a palpable, round to oval smoothly marginated mass is the main symptom to raise the suspicion of a phyllodes tumor. However, the widespread use of mammography has led to the detection of nonpalpable



Neoplasms, Phyllodes, Breast. Figure 3 Ultrasonography of the case presented in Fig. 2. Lobulated hypoechoic solid mass.

phyllodes tumors. The main goal is to differentiate them from other benign lesions, such as fibroadenomas (1). This differentiation is usually difficult without a biopsy.

The fibroepithelial composition of phyllodes tumors is similar to fibroadenomas, and this feature makes the differentiation between both lesions difficult. Furthermore, the wide spectrum of benign to malignant cases increases this difficulty. Fine-needle aspiration usually fails to distinguish fibroadenoma and phyllodes. The cystic component may be misinterpreted as "fibrocystic change." Core needle biopsy may suggest the diagnosis, but the differentiation with a fibroadenoma may be impossible. In most cases excisional biopsy is needed for diagnosis, especially if a rapid growth of a solid mass is detected (1, 5).

Department of Radiology, Klinikum rechts der Isar, Technical University Munich, Munich, Germany
katharina.marten@roe.med.tu-muenchen.de

Synonym

Pulmonary neoplasms

Definition

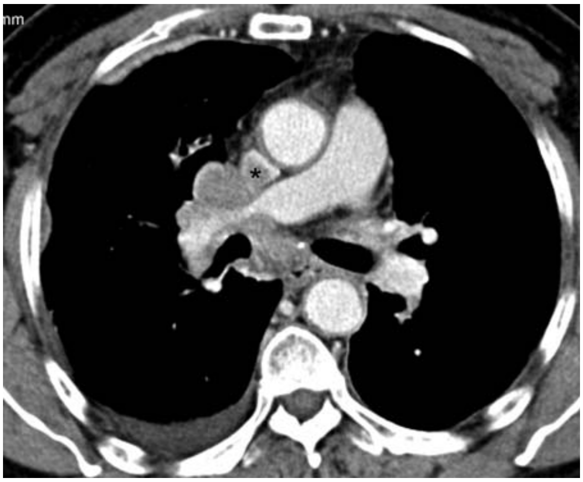
Primary neoplasms of the lung encompass numerous distinct histological entities that arise from various pulmonary tissues and are best categorised according to the classification scheme proposed by the world health organisation (WHO). These tumours include pulmonary carcinoma, neuroendocrine neoplasms, neoplasms of the tracheobronchial glands, tracheobronchial papillomas and rarely among others, primary pulmonary lymphoma, primary pulmonary sarcoma, ►pulmonary haemangiopericytoma and ►malignant angioendotheliomatosis.

Pathology/Histopathology

The term pulmonary carcinoma refers to tumours arising from the epithelial surface of the bronchi and alveoli, and embraces four main histological subtypes: adenocarcinoma, squamous cell carcinoma, small cell carcinoma and large cell carcinoma.

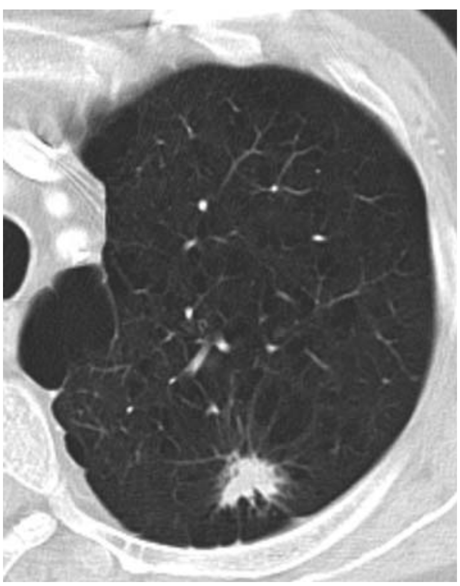
Adenocarcinoma (Figs. 1, 2) is the most common pulmonary carcinoma in the United States, accounting for about 30–35% of all cases, and can be subdivided into four histological subtypes: acinar carcinoma, papillary carcinoma, solid carcinoma with mucin formation and ►bronchioloalveolar carcinoma (BAC). Most adenocarcinomas (except BAC) are peripherally located and well circumscribed. BAC may present as solitary nodule or as parenchymal consolidation. Non-destructive growth is a characteristic feature, as tumour cells spread along the pulmonary framework, commonly forming a single layer. The surrounding interstitium is thickened by fibrous tissue or a chronic inflammatory infiltrate. Focal fibrosis and necrosis occur frequently, while cavitation is relatively rare (1–3).

Squamous cell carcinomas (Fig. 3) account for about 30% of all pulmonary carcinomas. Most frequently they arise from the segmental or lobar bronchial epithelium. Early lesions may expand within the bronchial mucosa



Neoplasms Pulmonary. Figure 1 Sixty-nine year-old woman with stage IV inoperable non-small-cell Lung cancer of the right upper lobe. Note the tumour compression of the right pulmonary artery, the invasion into the ▶superior vena cava (*) and the infracarinal mediastinum. There is right-sided pleural effusion containing malignant cells due to pleural invasion.

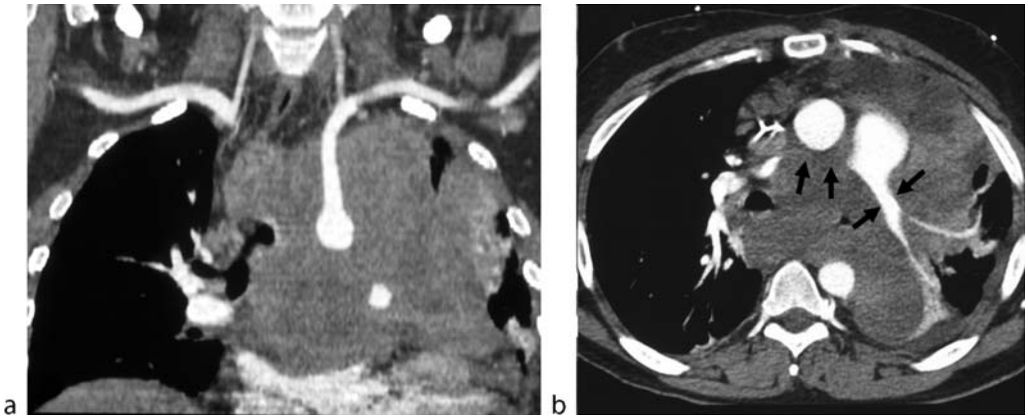
Neoplasms Pulmonary. Figure 3 Fifty-three year-old male smoker with cavitating nodule and solid satellite nodule in the apical right upper lobe segment displaying extensive marginal spiculations and feeding bronchus. Note the moderate centrilobular bilateral emphysema of the upper lobes. The lesions were bioptically confirmed as non-small-cell lung cancers.



Neoplasms Pulmonary. Figure 2 Seventy-one year-old male smoker with incidental finding of a 1.8 cm solid nodule in the posterior left upper lobe segment displaying spiculated margins and pleural tags. Note the advanced centrilobular emphysema of the right upper lobe. The lesion was bioptically confirmed as non-small-cell lung cancer.

without invasion into the airway lumen or the peribronchial tissue. At a later stage, however, most lesions invade and obliterate the bronchial lumen as polypoid or papillary tumours with subsequent airway obstruction expressed by distal atelectasis and obstructive pneumonitis. Large tumours often display central necrosis and erosion into a local bronchus with drainage of necrotic parts and resulting cavitation. Histologically, invasive squamous cell carcinoma is characterised by inter-cellular bridges and/or keratinisation. Tumours may be well differentiated, displaying obvious keratinisation, or are poorly differentiated, rendering differentiation from large cell or small cell carcinoma difficult. Histological variants of squamous cell carcinoma include small cell, papillary, clear cell and basaloid tumours (1, 2).

Small cell carcinoma (Fig. 4) contributes to about 15–25% of all pulmonary carcinomas. Evidence suggests that it is a neuroendocrine tumour, most likely derived from undifferentiated airway epithelial cells capable of neuroendocrine differentiation. Small cell carcinoma is typically located in the vicinity of proximal airways, most commonly of lobar and main bronchi. Rarely, tumours are located in the lung periphery without obvious airway association. Early, centrally located small cell carcinoma is frequently poorly defined and spreads along submucosal and peribronchovascular connective tissues. Advanced lesions invade the adjacent lung parenchyma and obliterate underlying bronchi and vascular structures. Endobronchial growth occurs much less frequently than in squamous cell carcinoma. Histologically, tumour cells may be round or fusiform and may be grouped in clusters, sheets or rosettes; stroma is normally scanty. Necrosis is frequent; a desmoplastic reaction is commonly minimal or absent (1, 2).



Neoplasms Pulmonary. Figure 4 Forty-nine year-old male smoker with extensive disease from small-cell lung cancer. (a) There is complete mediastinal encasement by tumour masses. (b) The patient had massive secondary pulmonary hypertension with dilated pulmonary artery trunk due to compression of the main pulmonary arteries (arrows).

Large cell carcinoma is diagnosed in 15–20% of pulmonary carcinoma cases. Most frequently it occurs in the lung periphery and often has a bulky appearance. Cavitation is rare, but focal necrosis is a common feature. Large cell carcinoma consists of sheets of large cells containing abundant eosinophilic cytoplasm. Inter-cellular bridges, keratinisation, acinar or papillary structures are absent. A number of histological subtypes exist, e.g. large cell neuroendocrine carcinoma, clear cell carcinoma, basaloid carcinoma and lymphoepithelioma-like carcinoma, among others (1, 2).

Neuroendocrine neoplasms encompass carcinoid tumours, pulmonary tumorlets and neuroendocrine cell hyperplasia. These tumours display common ultrastructural and immunohistochemical features resembling neuroendocrine cells, i.e. cells that contain neurosecretory granules and polypeptide hormones that occur in the normal tracheobronchial epithelium. Carcinoid tumours are low-grade malignancies, which are derived from the glandular or surface epithelium of the airways. Clinicopathologically, they are subdivided into typical and atypical forms. About 80–90% of cases are typical carcinoids that most frequently arise within lobar, segmental or proximal subsegmental bronchi (1). Occasionally, multiple tumours occur. Typical carcinoids are histologically well-defined tumours, which may be separated from the adjacent airway epithelium by a thin layer of connective tissue. If there is association to an airway, the epithelium is commonly intact and may display squamous metaplasia or ulceration. The overall histological pattern of atypical carcinoids closely resembles that of typical carcinoids. However, atypical carcinoids display increased mitotic activity, nuclear pleomorphism and hyperchromasia, areas of increased cellularity or necrosis.

The term *neoplasms of the tracheobronchial glands* refers to a group of tumours with the histological appearance of tracheobronchial mucous glands, with close resemblance of oropharyngeal salivary glands. The most common histological types are adenoid cystic carcinoma and mucoepidermoid carcinoma. Adenoid cystic carcinoma most commonly arises within the tracheal and main bronchial lumen and in about 10–15% in the lung periphery. Mucoepidermoid carcinoma develops in the trachea and bronchi (1, 2).

Clinical Presentation

The clinical presentation of lung neoplasms is non-specific, and symptoms commonly occur only at an advanced tumour stage. They may reflect local disease, particularly tracheal or bronchial obstruction (e.g. wheeze, cough, haemoptysis or obstructive pneumonitis), or originate from tumour invasion into neighbouring anatomic structures such as the mediastinum or the chest wall. At late stages distant hepatic, osseous or cerebral metastases may cause symptoms specific to their locations. ►Paraneoplastic syndromes (see keywords) may result from hormone secretion by the tumour or from immunologic reactions. Non-specific symptoms further include fatigue and weight loss.

Imaging

On chest radiography (CXR) and CT, *pulmonary carcinomas* commonly present as a lung nodule (lesser than 3 cm in size) or a pulmonary mass. This is particularly the case in squamous cell and adenocarcinomas, whereas small cell carcinomas may present with isolated hilar or mediastinal lymphadenopathy. Occasionally, obstructive pneumonitis or atelectasis may occur as isolated findings, predominantly in squamous cell and small cell carcinomas. Differentiation of the obstructing tumour from post-obstructive atelectasis may be challenging. On CXR, segmental or lobar atelectasis, consolidation and mucous plugging of bronchi distal to the obstruction are common. A specific feature is 'Golden's S sign' which refers to a focal convexity of the tumour with the concave shape of the inter-lobar fissure resulting from distal atelectasis with a characteristic S-shaped configuration. On CT, the tumour displays moderate contrast enhancement (15–30 Hounsfield units (HU) for most lesions on dynamic contrast-enhanced scans), whereas areas of atelectasis enhance conspicuously (>50 HU).

Peripheral carcinomas presenting as a pulmonary nodule may rarely display calcifications that are typically eccentric and result from tumoural engulfment of a preexisting granuloma. Calcifications are more common in mass lesions larger than 3 cm in size. Carcinomas commonly display irregular, spiculated margins. Smooth or lobulated margins occur less frequently. Air bronchograms or bronchiolograms may be detected after engulfment of these structures by the tumour. Cavitation of peripheral carcinomas occurs most frequently with squamous cell carcinoma and is associated with hilar or mediastinal lymphadenopathy. A very important CT feature is the air-space pattern which almost exclusively occurs in BAC, reflecting the non-destructive growth of these tumours. This pattern may be localised or diffuse ranging from ground-glass opacification to frank airspace consolidation without displacement of normal lung structures. In mixed subtype adenocarcinomas with BAC component, a prominent BAC component is likely to have a ground glass appearance, while adenocarcinomas with invasive component are likely to be solid on thin section CT. This differentiation is important because lesions with large ground glass components are less likely to have vascular invasion or lymph node metastases. Mixed subtype adenocarcinomas with BAC component may occur as solitary or multiple unilateral or bilateral nodules, or a large mass with satellite nodules within the same lobe. The lobar consolidation pattern in BAC which is commonly combined with the 'CT angiogram sign' in BAC refers to well-opacified vessels surrounded by low-density pulmonary parenchyma following contrast administration; however, it is difficult to distinguish from pneumonia and may also occur in other disorders (1, 3).

Carcinoid tumours most commonly present with evidence of airway obstruction on CXR, as a large majority of these tumours (80–85%) are located within lobar or segmental bronchi (1). Complete obstruction will induce peripheral atelectasis, reflected by increased attenuation with loss of volume or precipitate obstructive pneumonitis with features of pneumonia commonly without volume loss. Recurrent infections distal to the obstruction site may result in bronchiectasis and lung abscesses formation. In cases of partial proximal airway obstruction, hypoxic vasoconstriction and volume loss of the dependent lung may suggest the presence of an endobronchial lesion and should prompt bronchoscopy. Peripherally located carcinoid tumours present as pulmonary nodules that are well-defined, homogeneous, often lobulated, round or oval in shape. Most lesions measure 1–3 cm in diameter; however, large lesions also occur, particularly in atypical carcinoid tumours. Intratumoural calcification is frequently detected on CT and may display variable patterns (1).

Adenoid cystic carcinoma presents as a lobulated, polypoid or smooth endotracheal or endobronchial mass on CXR which encroaches onto the airway lumen. CT is an excellent tool for the assessment of extraluminal growth and mediastinal invasion. The radiographic features of *mucoepidermoid carcinoma* are variable, ranging from a solitary nodule or mass to consolidation, atelectasis or a central mass with obstructive pneumonitis. The CT findings include a mass, which is oval or lobulated in shape, and may display punctuate calcifications. With involvement of the trachea there may be an evidence of an intra-luminal nodule on CT and with larger lesions also on CXR.

Tracheobronchial papillomas may be solitary or multiple and are seen on CXR and CT as nodules within the airway lumen. On CT the presence of multiple papillomas may be evident by the detection of diffuse nodular thickening of the tracheal wall. Chronic bronchial obstruction is bound to induce atelectasis, obstructive pneumonitis or bronchiectasis, while partial obstruction may as well cause the decreased perfusion and decreased attenuation pattern of the affected parenchyma. With tumour involvement of the distal airways and lung parenchyma, a nodular pattern may be evident with predilection for the perihilar and posterior lung regions. Cavitation of such nodules, with occasional air–fluid level formation, is more frequent with larger lesions (2).

Primary pulmonary lymphoma may present as single or more commonly multiple pulmonary nodules or masses 2 mm to 8 cm in size, as well as unilateral or bilateral areas of consolidation. Distribution is frequently peribronchial, air bronchograms commonly occur. Less common findings on CT are thickening of the bronchovascular bundles, ground-glass opacification and septal lines (1).

Nuclear Medicine

Positron-emission tomography (PET) using intravenous administration of 2-(fluorine-18)-fluoro-2-deoxy-D-

N

gluose (^{18}FDG) is likely to become more important for the diagnosis of lung neoplasms in the future, particularly for the differentiation of benign from malignant pulmonary nodules larger than 8–10 mm in size. ^{18}FDG-PET imaging relies on physiologic glucose metabolism to diagnose lung cancer and has a high sensitivity and specificity for malignant nodules of at least 0.8 cm in diameter. However, false-positive diagnoses occur in active granulomatous infections, whereas false-negative diagnoses are commonly encountered in BAC and carcinoid tumours. Single-photon emission computed tomography (SPECT) imaging is clearly inferior to PET imaging in the differentiation of benign and malignant pulmonary nodules. Both PET and SPECT, however, play important roles in lymph node staging of lung cancer, with their sensitivities and specificities for diagnosis of malignant lymphadenopathy reaching 80%. Imaging of distant metastasis of lung cancer has also become a domain of PET-imaging, particularly in combination with CT. Octreotide-PET imaging holds promise in the diagnosis of small peripheral carcinoid tumours with ectopic ACTH production, that are difficult to detect on CT (4, 5).

Diagnosis

The capacity of CXR to reveal early stage lung neoplasms is limited. Recent technologic advances with application of computer-aided diagnosis and dual-energy subtraction methods on digital CXR data may offer certain improvements on this. Latest technologies in CT, particularly thin-collimation multislice CT (MSCT) possess a very high sensitivity for the detection of pulmonary nodules, but have a limited specificity for diagnosis of lung cancer (6). Advances in scanning technique such as dynamic contrast-enhanced CT for perfusion imaging, as well as recognition and metric assessment by computer-aided diagnosis with automated nodule volumetry may enhance its ability to determine nodule growth and therefore help to diagnose malignancy at an early stage. Sputum analysis encompasses sputum cytology, sputum immunostaining and newer methods such as sputum polymerase chain reaction based assays for detecting oncogene mutations. Sputum cytology has a relatively low overall sensitivity for detection of lung cancer of 20–30%, showing moderate variation with the employed technique. The sensitivity is highest for squamous cell carcinoma and lowest for adenocarcinoma. Centrally located lesions, lesions larger than 2 cm and lower lobe lesions are best detected with sputum cytology. The false-positive rate is very low (<2%). *Conventional bronchoscopy* is valuable for detection of nodular or polypoid lesions larger than 2 mm and flat or superficially spreading lesions greater than 2 cm. *Autofluorescence bronchoscopy* is an optical imaging method used for localisation of small pre-invasive lesions that are not visible by conventional white light bronchoscopy. *Percutaneous transthoracic needle core biopsy* (PTNB) under CT guidance is performed for histological diagnosis of lung nodules, masses and infiltrates, particularly if malignancy is suspected. A specific benign diagnosis is infrequently made using PTNB, but when obtained, can obviate surgery. CT fluoroscopy offers advantages in needle guidance and permits more rapid and accurate biopsy procedures in pre-selected cases. *Video-assisted thoracoscopy* permits visualisation of the entire hemithorax and lung and allows minimally invasive sampling of pulmonary lesions through a very small access. In many cases it constitutes a viable alternative to exploratory thoracotomy and has largely replaced open lung biopsy in the diagnosis of peripheral lung nodules, including subpleural nodules as small as 3 mm. In few cases *thoracotomy and open lung biopsy* may be required for diagnosis of solitary pulmonary nodules, which can be converted to curative surgery after mediastinal staging in cases with of frozen section diagnosis of lung cancer.

Neoplasms, Small Bowel

J-N. Bruneton, P. Chevallier
Service d'Imagerie Médicale Diagnostique et Interventionelle, Hopital de I'Archet, Nice, France

Pathology/Histopathology

Although the small intestine accounts for approximately 75% of the entire length of the gastrointestinal tract and more than 90% of the mucosal surface, it is rarely the site of malignant tumors (less than 2% of all gastrointestinal malignancies). Approximately 40 different histologic tumor types have been described in the small bowel. While symptomatic tumors are nearly always malignant, three-quarters of all neoplasms discovered at autopsy are benign.

The small bowel sites at greatest risk for malignant tumors are the duodenum for adenocarcinomas and the ileum for ▶carcinoid tumors and lymphomas. Adenocarcinomas are the most common malignant tumors of the small intestine (30–50%), followed by carcinoids (25–30%), and lymphomas (15–20%). Leiomyomas are the most frequent benign tumor, followed by adenomas, lipomas, and hamartomas.

The low susceptibility of the small bowel to malignant change has been attributed to numerous pathogenetic mechanisms, including the relatively rapid transit of intestinal contents (comparatively short exposure of the intestinal mucosa to carcinogens), moderation of mucosal irritation by the liquid nature of small bowel contents, low bacterial load, and the relatively high concentration of lymphoid tissue with a high level of immunoglobulin A.

A number of small bowel inflammatory disorders predispose to malignancy: celiac disease (lymphoma), Crohn's disease (adenocarcinoma), immunoproliferative disease [▶immunoproliferative small intestinal disease (IPSID)], and diffuse intestinal lymphoma.

Various genetic disorders are also associated with an increased incidence of small intestinal tumors: ▶Peutz–Jeghers syndrome (hamartomatous polyps), Gardner's syndrome and familial adenomatous polyposis coli (adenoma, adenocarcinoma), von Recklinghausen's disease (paraganglioma). Juvenile polyposis and Cowden disease are less common.

Clinical Preservation

Aside from those rare acute cases necessitating surgical treatment (for example intussusception of a lipoma or a metastasis of melanoma), small intestinal tumors most often run an insidious course with nonspecific symptoms that include intermittent abdominal pain, anemia, bleeding, and intestinal obstruction (1).

Benign small intestinal tumors are often asymptomatic, although complaints may include bleeding (leiomyoma, hemangioma), intestinal obstruction (desmoid tumor), or intussusception (lipoma).

Adenocarcinoma associates the following presenting symptoms, in decreasing order of frequency: pain, weight loss, vomiting, hemorrhage, obstruction. An average of 5 months generally elapses between the initial clinical complaint and diagnosis. Carcinoid tumors tend to occur in the terminal ileum. After an initial phase with nonspecific clinical symptoms, a carcinoid syndrome (cutaneous flushing, diarrhea) may occur in case of hepatic metastases.

Imaging

Gastric and colonic endoscopy, ultrasound, and small bowel barium examinations are the first-line studies for all nonspecific clinical gastrointestinal symptoms. Lesions demonstrated by small bowel evaluation are usually already advanced (for example infiltrating adenocarcinoma, lymphomatous mass, hepatic metastases of carcinoid tumors). Barium studies are insensitive for the detection of small, and thus resectable, lesions (1).

CT (oral intake of 1 L of water and intravenous administration of an iodinated contrast agent) can visualize smaller lesions with features that may suggest the etiology (hypervascularity of a ▶stromal tumor, fat density of a lipoma). MRI does not provide any supplementary information compared to CT.

Double-contrast barium air enteroclysis performed after duodenal intubation allows visualization of the mucosal surface; the sensitivity of the procedure is markedly better than that of conventional barium follow-through examinations. CT enteroclysis combining the infusion of water through a nasojejunal tube and iv iodinated contrast administration is currently the most sensitive technique and has replaced enteroclysis for most imaging teams (2–4). The procedure does have two major drawbacks, however: its invasive nature that means it is reserved as a second-line technique, and its failure to detect certain small lesions (hemangioma).

Endoscopic ultrasonography (EUS) allows high-resolution imaging of the ampullary region and is more effective than CT or MRI for the work-up of neoplasms in this location. In case of hemorrhage or a negative CT enteroclysis examination, angiography may demonstrate the site of bleeding and the responsible lesion.

Enteroscopy is rarely indicated. The development of swallowable video capsules that transmit images of the small bowel lumen has facilitated early diagnosis of small bowel tumors, but the technique is hampered by the scarcity of available machines, the relatively long operator time, and obstructive phenomena, which constitute a contra-indication.

Nuclear Medicine

Scintigraphy with technetium-labeled red blood cells can identify sites of bleeding even when blood loss is as low as 0.1 mL/min.

Various markers have been tested to improve the detection of carcinoids by nuclear medicine techniques: 131 I-metaiodobenzylguanidine (MIBG), somatostatin, octreotide. The potential role of PET CT for small bowel tumors remains unclear owing to the insufficient number of studies conducted to date.

Diagnosis

Benign Small Intestinal Tumors

Leiomyoma is the most frequent benign small bowel tumor, the peak incidence occurring at approximately 60 year of age. The jejunum is the site of predilection, followed by the duodenum and the ileum. These stromal tumors exhibit a variety of growth patterns: intramural, intraluminal, subserosal, or dumbbell-shape. The ulceration of these hypervascular tumors explains the frequency of hemorrhage (60% of cases). Presence of a palpable mass is correlated with subserosal growth (20%). Obstructive phenomena are observed in cases of intraluminal growth. Prior to the development of CT, angiography allowed the diagnosis by revealing a hypervascular lesion, regardless of location (subserosal tumors in particular are well visualized). MRI and CT enteroclysis can demonstrate lesions as small as 1 cm and obviate the need for angiography (Fig. 1).

Adenoma is nearly always asymptomatic and thus most often a discovery on imaging studies. These tumors are generally solitary, except in cases of familial adenomatous polyposis. As for colonic adenomas, a villous component and size greater than 1 cm are risk factors for malignancy. This risk can exceed 40% in the duodenum, which explains the necessity for resection.

Lipomas are the third most common type of small intestinal neoplasm. More than two-thirds are asymptomatic and these tumors are thus increasingly discovered at CT examination. Less frequently, intestinal obstruction (often intermittent) is the clinical complaint. CT allows pathognomonic diagnosis by revealing a homogeneous mass with low (fat) attenuation. The only risk of lipomas is obstruction; malignant transformation is inexistent.

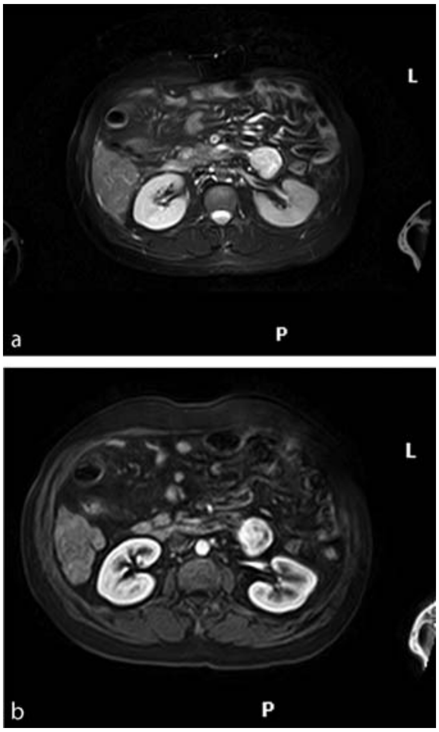
Relatively rare tumors that are sometimes multiple, *hemangiomas* are occasionally visualized by angiography.

Intestinal nodular lymphoid hyperplasia is usually asymptomatic. Characterized by the presence of submucosal masses (enlarged lymphoid follicles), it is encountered in cases of IgA deficiency and involves the distal portion of the small bowel. The risk of transformation to lymphoma is low (5).

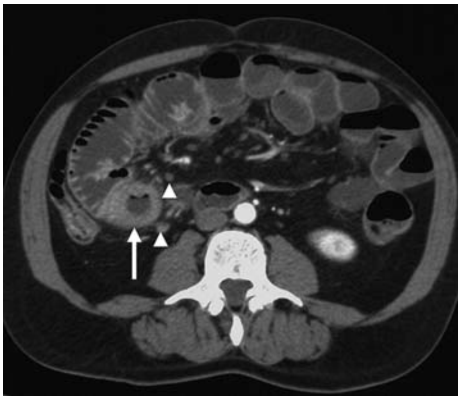
Hamartomas are typically asymptomatic and have no potential for malignant change.

Malignant Small Intestinal Tumors

Adenocarcinoma is the most frequent malignant neoplasm of the small intestine and usually occurs in the duodenum, associated or not with stenosis, tumor infiltration, or ulceration (Figs 2). The ampulla of Vater



Neoplasms, Small Bowel. Figure 1 MRI of a duodenal leiomyoma discovered incidentally. Axial T2-weighted scan with fat suppression (a) revealing a homogeneous, hyperintense tumor; T1-weighted sequence after intravenous gadolinium administration (b) demonstrating tumor hypervascularity.



Neoplasms, Small Bowel. Figure 2 CT examination of the small bowel for unexplained anemia. Thickened jejunal loop (arrow) with enlarged satellite nodes (arrowheads) corresponding to an adenocarcinoma with nodal extension.

is the most common site of small bowel adenocarcinomas. It is also the most common site of degeneration of familial adenomatous polyposis after the colon. Diagnosis of ampullary adenomas is often prompted by symptoms of bile duct obstruction. Adenomas have a better prognosis than other malignant tumors that invade the main bile duct. Diagnosis is made by endoscopy and disease extension work-up is best performed by EUS and MRI.

Leiomyosarcoma occurs predominantly in the jejunum, followed by sites in the ileum and the duodenum. Like leiomyomas, leiomyosarcomas can reach large dimensions before any symptoms appear owing to the frequency of subserosal growth. The frequency of ulceration explains the incidence of bleeding. Differentiation of a leiomyoma from a leiomyosarcoma can be difficult, and molecular determination of the malignant potential of stromal tumors appears to be an effective aide for identification of malignancy. The only effective therapy for these tumors is surgery, even though hypervascular hepatic metastases are already often present at diagnosis.

Primary small bowel lymphoma is a non-Hodgkin's lymphoma, and the small bowel is the second most common gastrointestinal location after the stomach. The majority are B-cell lymphomas of intermediate or high grade malignancy. Clinical symptoms are often minimal, contrasting with the extensive nature of these lesions, and this disparity is a diagnostic factor. Abdominal pain, asthenia, diarrhea, and weight loss are possible, as is regional lymph node involvement. The most characteristic imaging appearance is aneurysmal dilatation of a segment of the small bowel and destruction of the mucosal folds owing to the absence of desmoplastic reaction. Infiltrating polypoid involvement or sprue is less suggestive of the diagnosis. In less than 7% of cases, a complication such as perforation leads to diagnosis. Small bowel sites of Hodgkin's disease and secondary lesions are usually associated with advanced stages of the lymphomatous process (1, 5).

Neuroendocrine Tumors

The most frequent examples are *carcinoids*; other etiologies such as *paragangliomas*, *somatostatinomas*, and *vipomas* are less common. Small bowel carcinoids secrete serotonin or serotonin precursors. Imaging permits early detection of lesions smaller than 1 cm but not etiologic diagnosis. The development of nodal metastases and the presence of retractile mesenteritis, often with calcification, allow presurgery etiologic diagnosis. Patients with hypervascular hepatic metastases may develop a clinical carcinoid syndrome that regresses after surgical resection, associated or not with endovascular treatment of any residual lesions (chemoembolization). Somatostatin scintigraphy allows early detection of carcinoid lesions and characterization of small lesions demonstrated by CT.

Systemic Diseases Associated with Small Bowel Neoplasms

Peutz–Jeghers syndrome is a rare autosomal dominant disease characterized by hamartomatous polyposes of the gastrointestinal tract (in particular the small intestine) and focal melanin pigmentation of the skin and mucous membranes. The intestinal polyps tend to be multiple and vary in form and size. Barium follow-through examination suffices to demonstrate these lesions that involve risks of intussusception and bleeding.

Celiac disease may be complicated by a T-cell lymphoma that is difficult to diagnose by imaging when it manifests as a nonspecific mucosal ulceration in the jejunum.

Immunoproliferative small intestinal disease (Mediterranean lymphoma or diffuse small intestinal lymphoma) is associated with endemic parasitic and microbial colonization that explains why it is seen almost exclusively in underdeveloped countries. This immunoblastic type of lymphoma causes chronic diarrhea and a malabsorption syndrome that may last months or even years. Involvement of the distal duodenum and the initial portion of the jejunum can be demonstrated by a barium contrast examination that shows thickened mucosal folds and ulcerations.

Individuals with *Crohn's disease* have a 5 to 20-fold higher risk of developing an ileal adenocarcinoma than the normal population.

Neoplasms Small Bowel. Figure 3 CT enteroclysis with iv administration of iodinated contrast material and upper GI tract opacification revealing small bowel–small bowel intussusception (arrow) due to metastasis of melanoma to the small bowel.

Metastases

Secondary involvement of the intestine is more common than primary tumors, and may occur by hematogenous spread, local extension, or intraperitoneal seeding. Primaries in the stomach, colon, or genitourinary tract may spread by local extension or seeding to the serosal surface of the intestine, where rounded, centimeter-sized nodules may be demonstrated by enteroclysis (Fig. 3). Malignant cells may implant along the mesenteric border of the small bowel loops and induce fibrosis. Hematogenous spread usually produces a multinodular, polypoid appearance along the antimesenteric border.

University Hospital of Bern, Inselspital Bern, Switzerland
suzanne.anderson@bluewin.ch

Synonyms

Mass lesion of soft tissues

Definition

Benign mass lesion or architectural disturbance not associated with metastatic potential.

Pathology/Histology

The World Health Organization has classified the histological types and names of benign soft tissue tumors (1, 2) (summarized in Table 1). The incidence is 300 per 100,000 population (1). Benign soft tissue tumors are far more common than their malignant counterparts, which have an incidence of 2 to 3 per 100,000 population (1). There are six main benign soft tissue tumors (3): ►lipoma and variants, benign fibrotic histiocytoma, nodular fasciitis, neurogenic tumors, fibromatosis, and ►pigmented villonodular synovitis or giant cell tumor of tendon sheath (summarized in Table 2). If ►ganglion is added to the commonest soft tissue tumor benign list, this makes up some 70% of all benign lesions (2). This percentage is increased if vascular and lymphangioma lesions are included. The age at presentation of the tumor is important as certain tumors are more likely to occur within particular age groups. For example, lymphangioma of the newborn is shown in Fig. 1.

Clinical Presentation

Presentation is usually due to an increasing mass, often accompanied by discomfort or pain. If tumor occurs near a joint, there may be associated joint pain and if it occurs near the essential structures such as a neurovascular bundle, there may be secondary features such as nerve compression (Fig. 2a).

Treatment

If a tumor appears benign and classical in imaging appearances, such as a subcutaneous lipoma or a ganglion cyst associated with a joint, some patients may elect to have conservative nonoperative treatment. More commonly, after biopsy for confirmation of the imaging diagnosis and exclusion of other diagnoses, the tumor is surgically resected. Detailed anatomical review is required before resection for appropriate and complete tumor resection, to identify normal vascularity and tumor vessels, for safety of possible adjacent neurovascular bundle structures, to ascertain if vascular grafting is required, and for cosmetic aspects. Many hemangiomas may not require any further therapy but may need preventative support if a young patient wishes to continue sport. Rarely endocrine manipulation therapy or radiotherapy may be used for benign aggressive desmoid tumors.

Prognosis

As the diagnosis of these tumors is benign, the prognosis is usually excellent. Rarely some benign tumors will reoccur, such as hemangiomas, or more commonly the aggressive desmoid. In the latter, the prognosis may often be guarded, though fortunately these cases are rare.

Neoplasms, Soft Tissues, Benign. Table 1 Modified WHO classification: histological of benign soft tissue tomers

Tumor group	Tumor type
Lipomatous tumors benign	Lipoma and variations
(Myo)fibroblastic tumors

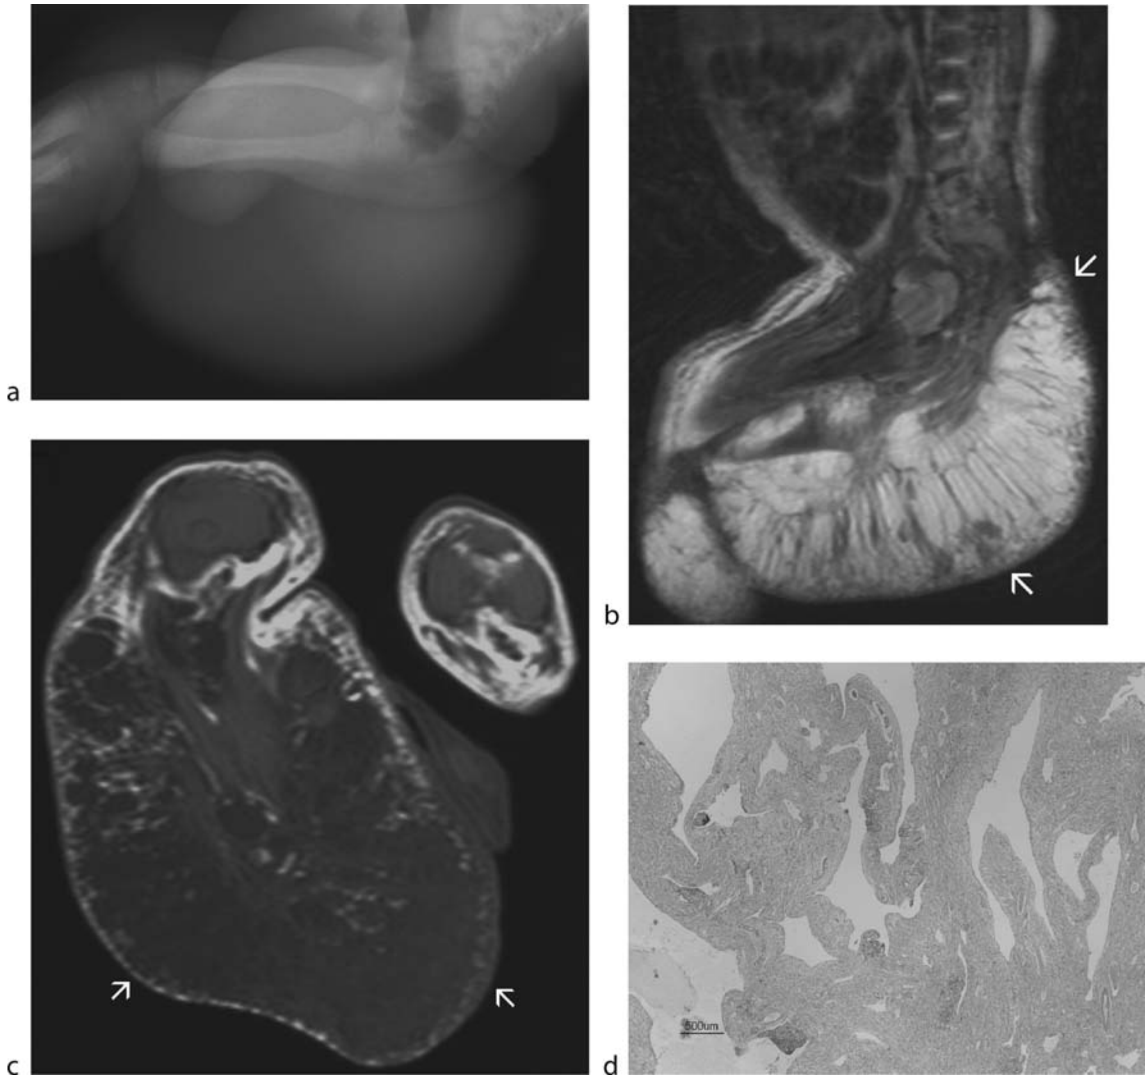
Fibromatosis	7%
Pigmented villodular synovitis (PVNS/GCTTS)	4%

Imaging

Role of imaging in benign soft tissue lesions is to provide a specific or provisional diagnosis, to anatomically locate the lesion, to describe relevant secondary features, and to exclude other diagnoses. The use of at least two imaging modalities in combination is considered best practice. Imaging allows for the diagnosis of a solid versus cystic tumor or components, with either computed tomography



Neoplasms, Soft Tissues, Benign. Figure 1 Eight day old baby with a large benign right thigh soft tissue tumor, a lymphangiohemangioma. (a) Lateral radiograph of thigh showing large benign soft tissue tumor, lymphangiohemangioma. No calcifications are seen. (b) MRI sagittal STIR (short tau inversion recovery) image shows the large high signal intensity mass at the posterior aspect of the thigh (arrows). (c) MRI axial image just below the level of the knee shows the low signal intensity of the mass. (d) Histopathology of the lesion, hematoxylin and eosin staining, magnification factor 2 demonstrates large dilated lymphatic channels. Some areas of hemangioma formation were also found. b

Neoplasms, Soft Tissues, Benign. Figure 2 Importance of MRI signal intensity of soft tissue mass. (a) Axial T1-weighted image of the elbow of a 56-year-old male with ►cubital tunnel syndrome, due to a mass with an increased signal intensity, paralleling that of fat, and consistent with a subcutaneous lipoma (arrows), compressing the ulnar nerve (open arrow). This was confirmed at surgery and with pathology. (b) Sagittal T2-weighted image of the knee of a 51-year-old male with a decreased signal intensity mass (arrow) within the anterior aspect of the knee, within Hoffa's fat pad. Decreased signal intensity within the mass on T2 weighting and an intraarticular knee location, made pigmented villonodular synovitis (PVNS) the most likely diagnosis. Prepatellar bursitis is also evident. The tumor diagnosis was confirmed at surgery and pathology.

(CT) or magnetic resonance imaging (MRI), particularly imaging after contrast administration or with ultrasound (color Doppler imaging has a role here). The demonstration of solid portions of a tumor allows for appropriate selection of a biopsy site. A cystic tumor or one with cystic components may be due to, for example, a myxoma, ganglion of soft tissue, or due to hemorrhage or necrosis within the tumor itself. Clear anatomical delineation of the tumor site is important preoperatively for surgical planning and also for assisting with the diagnosis. Imaging is also important for follow-up after surgical resection, to review for complications or residual tumor, and to follow-up after nonsurgical therapies such as endocrine and radiotherapy treatment for some desmoid tumors.

Radiographs

Are usually performed in two planes to review local anatomy for any bone or joint involvement, presence of calcification or ossification (suggesting myositis ossificans) phlebolith formation (suggesting hemangiomas), or fat density (implying often a benign diagnosis). They may also be used for preoperative review of the thorax.

Computed tomography

Computed tomography depicts the anatomical site, the mass features, and secondary features, such as neurovascular displacement. With multislice technique availability, CT angiography technique for preoperative normal and tumor vascularity is increasing. This technique also allows for excellent depiction of calcification and ossification.

Magnetic Resonance Imaging

MRI is the recognized gold standard for tumor imaging. It should be performed and read out in a combination with radiographs or CT. This is due to the fact that the detection of calcifications on MRI may be obscured and the presence of this feature may alter the differential diagnosis. MRI allows for multiplanar imaging and in site into the appearance of all structures including bone and joint and soft tissues. MRI signal intensity may influence the diagnosis as the signal intensities of some tumors are more commonly associated with a particular appearance on T1 and T2 weighting (Tables 3 and 4). An increased signal intensity mass on T1 weighting in a superficial location is characteristic for a lipoma (see Fig. 2a). A decreased signal intensity mass within a joint on T2 weighting is highly suggestive for a diagnosis of pigmented villonodular synovitis (see Fig. 2b). Other specific signs and features may help with the diagnosis on MRI such as the presence of high vascular flow voids or vascular pooling in tumors consistent with hemangiomas or arteriovascular malformations. *MRI angiography*: An additional sequence may help confirm or further characterize a lesion (4) or give preoperative vascular and tumor anatomy.

Ultrasound

High-resolution ultrasound alone or in combination with color Doppler imaging has been shown to be helpful with tumor imaging allowing solid versus cystic differentiation, vascularity features, and anatomical delineation. However, MRI remains the reported gold standard.

Nuclear Medicine

Bone Scan and Positron Emission Tomography Scan

These techniques of imaging are commonly used to determine any bone involvement or to exclude metastatic tumor in a soft tissue mass initial workup. Their role is more significant in the imaging of malignant soft tissue lesions.

Diagnosis

Initial Radiological Diagnosis

Primary signs of a benign lesion include the presence of a dominant mass, often with well-defined borders, architectural distortion with altered density (on computed tomography), or altered signal intensity (on MRI). The diagnosis is influenced by the appearance of the mass, for example, whether there is evidence of fat or vessels on the location of the mass, on the age of the patient, and whether the lesion is single or multiple.

Secondary signs are usually less than with malignant lesions, however due to the mass effect there may be evidence of neurovascular displacement.

The presence of multiple soft tissue lesions versus a solitary lesion may help with the differential diagnosis. Lipomas and hemangiomas may occur at multiple sites. Some of these multiple lesions may be related to syndromes such as ▶Mazabraud's syndrome, ▶neurofibromatosis NF1, and angiomatous syndromes such as Maffucci, Olser–Weber–Rendu, Klippel–Trenaunay, or Kasabach–Merritt syndromes.

Body location and local anatomical site can be helpful. Lipomas commonly occur in a subcutaneous location. The anatomical center of a lesion may assist in suggesting the cell or tissue origin of the tumor (see Table 1). Some tumors are more likely to occur at specific anatomical sites, such as the synovial hemangioma, though rare, it has a predilection for the anterior knee, or elastofibroma dorsi of the posterior chest wall inferior to the scapula. Intraarticular masses have a relatively specific differential list including pigmented villonodular synovitis (PVNS), synovial hemangioma or synovial chondro/osteomatosis, lipoma arborescens, and intraarticular lipoma.

Differential Diagnosis

Pseudotumors are not uncommon and their imaging may mimic a benign soft tissue. They can be categorized into posttraumatic, sports or occupationally related, associated with aging and degeneration, or congenital or developmental abnormalities or relate to overuse of normal anatomical variants. Some common examples include muscular hematomas after sports injuries associated with various degrees of muscle tears and myositis ossificans (Fig. 3), infection or abscess formation, and foreign body reaction.

Pitfalls

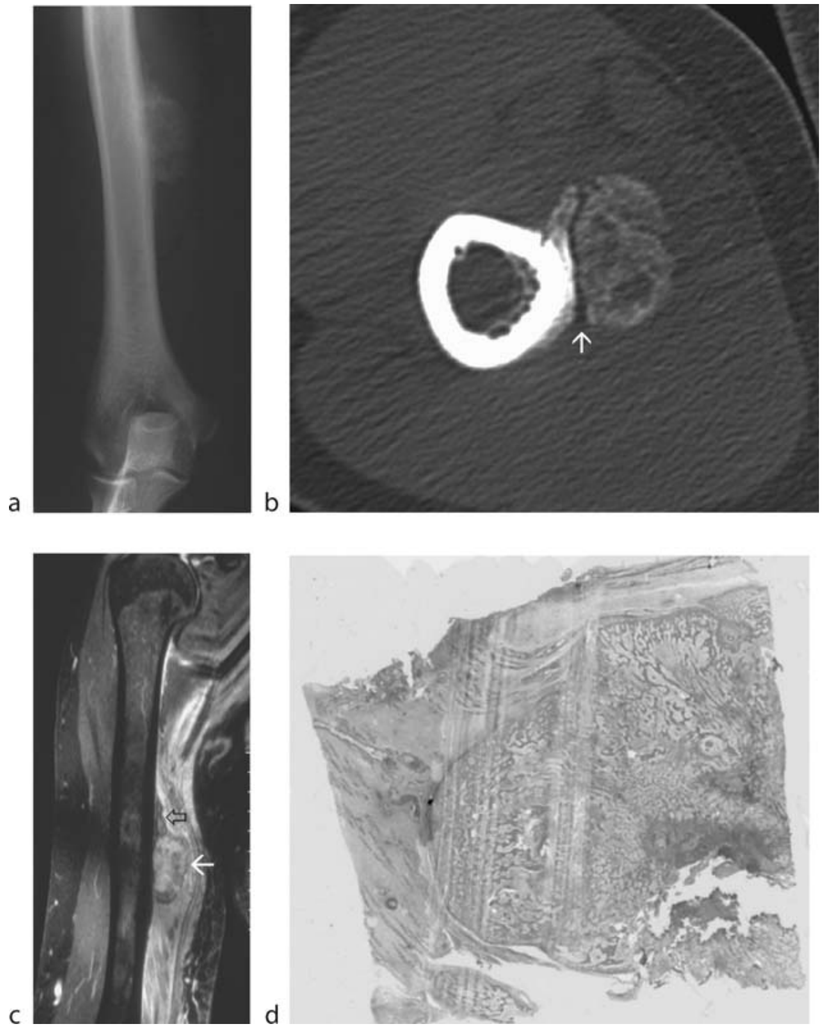
Pitfalls include the differential diagnostic list described earlier. A well-circumscribed, apparently benign-appearing mass may rarely be malignant, such as a small well-defined focal synovial cell sarcoma, 2 cm in size. Due to this issue, good clinical practice supports the use of biopsy preoperatively to achieve histological confirmation of a benign lesion, before final surgery.

Follow-up after Therapy

Imaging after therapy allows for clarification of treatment and response, review of any residual tumor, and any complications.

Interventional Radiology

In relation to benign tumors, the role of interventional radiology may be diagnostic, to delineate tumor vessels and normal vascular anatomy preoperatively or



Neoplasms, Soft Tissues, Benign. Figure 3 **Twenty-four year old female with the history of minor trauma with upper limb mass, myositis ossificans. (a) Radiograph shows characteristic peripheral calcification within the lesion, and some periosteal new bone reaction. (b) Axial computed tomography shows that the calcified mass is separated from the adjacent bone and periosteal reaction (arrow), which is another characteristic feature of myositis ossificans. (c) MRI sagittal STIR image shows the partially calcified mass (arrow) with adjacent periosteal reaction (open arrow) and marked soft tissue increased signal intensity within adjacent soft tissues, which is another characteristic feature of myositis ossificans. This marked adjacent soft tissue reaction would be the most unusual in a malignant soft tissue tumor unless it had undergone trauma or biopsy. Definition

Soft tissue mass characteristically able to invade adjacent structures and to form metastases at distant sites.

Pathology/Histology

Malignant soft tissue tumors are relatively rare, though occur approximately as commonly as multiple myeloma of bone, and twice as common as sarcoma of bone (1–3). There is an incidence of some 2 to 3 per 100,000 population for malignant soft tissue tumors (1, 2). The mortality rate remains relatively high on average at 50%, dependant on tumor stage and histology grade at time of presentation.

The world health organization classified and cataloged the malignant soft tissue tumors (1, 2) (summarized in Table 1). Some seven malignant tumor types are the commonest, being ►malignant fibrous histiocytoma (MFH), ►fibrosarcoma, ►liposarcoma, ►synovial sarcoma, ►malignant peripheral nerve sheath tumor (MPNST), ►rhabdomyosarcoma, and ►leiomyosarcoma (3) (summarized in Table 2).

Clinical Presentation

Commonly patients present with a slowly enlarging soft tissue mass, which is often painless. It may be associated with pain if the mass undergoes tumor necrosis or hemorrhage, traumatized, or if there is a sudden rapid growth phase. Some patients may present at the change of seasons when they alter their clothing habits and only then notice anatomical asymmetry. The commonest site is that of the lower limb, in particular the thigh, due to the presence of a large muscle and soft tissue bulk.

Prognosis

Primary predictors of ►prognostic outcome are initial compartment staging and histological grade and also response to initial therapy.

Leiomyosarcoma	4%

Imaging

Role of Imaging

Is central in the diagnosis and staging of malignant soft tissue tumors. Best clinical practice supports histological confirmation of the tumor prior to definitive surgery. Poorly imaged or nondocumented cases prior to surgery have a vastly poorer outcome due to intralesional surgical technique with increased local tumor recurrence and metastatic rates (4). Larger tumor nodules are easily recognized with magnetic resonance imaging (MRI); however, residual microscopic tumor cell groups remain difficult to determine with current imaging modalities (4).

The initial role of imaging for malignant soft tissue tumors is that of anatomical delineation for local staging for ►compartment anatomy and for ascertaining a diagnosis or provisional diagnosis (Figs 1 and 2). Central to the role of imaging in malignant soft tissues tumors is the concept of compartment anatomy.

Imaging with Staging and Clinical Follow-Up

After initial imaging diagnosis and histological confirmation, imaging is used to follow posttherapy changes prior to surgery. It is also useful in reviewing for complications such as postoperative seromas/hematomas and local tumor recurrence (Fig. 3).

Radiographs

High-quality radiographs of the mass in two planes, including nearby joints are standard requirements. Specific features that are reviewed include the presence of soft tissue calcification, bone erosion or destruction, and joint involvement.

Computer Tomography

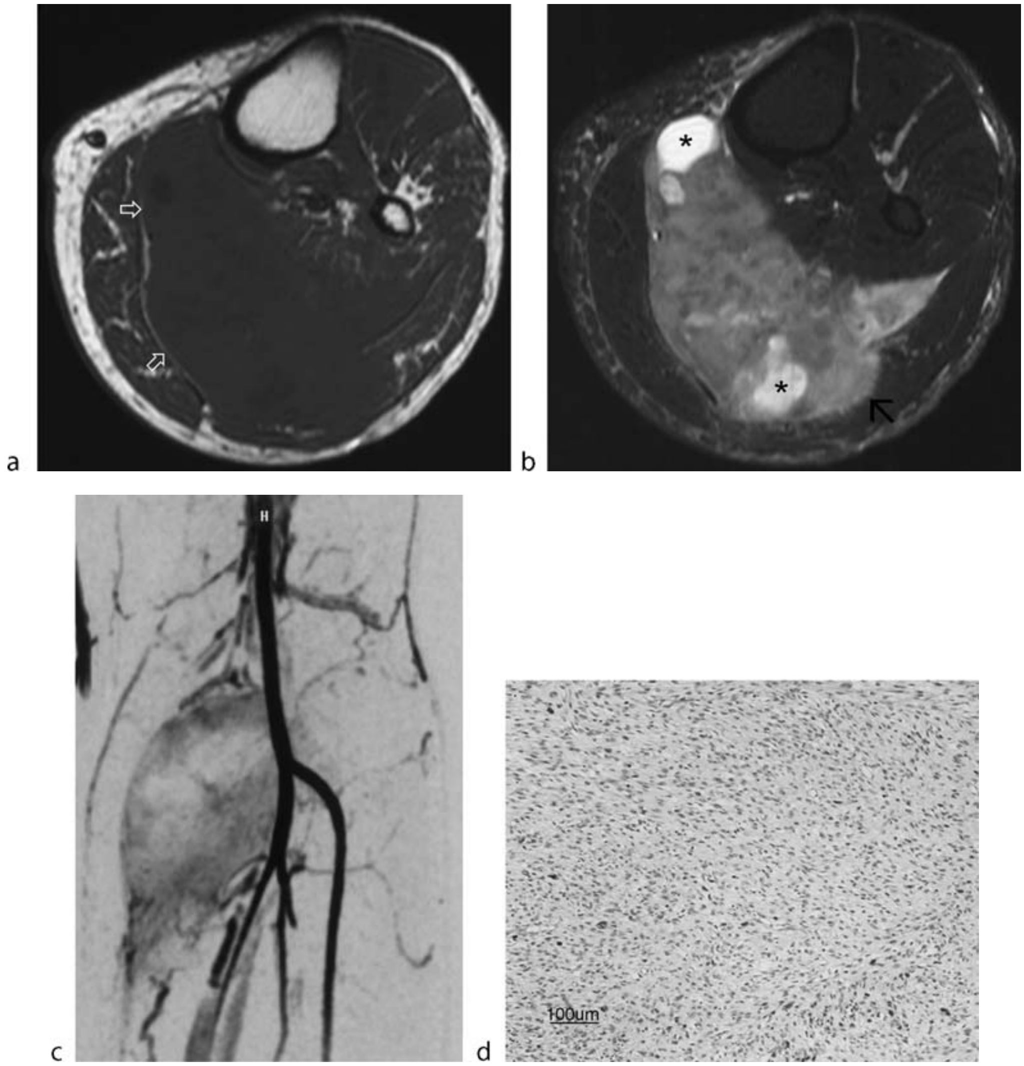
High-resolution computer tomography (CT) is useful for anatomical local staging and may be used to delineate the morphology including the internal structure of the tumor to aid in the diagnosis. It delineates the presence of subtle calcification, which may affect the diagnosis, and be less obvious on MRI. It is commonly used for whole body staging, of chest, abdomen, and pelvis to exclude metastatic disease prior to surgery and in follow-up imaging. CT angiography multislice technique allows for depiction of normal and tumor vascularity. CT is also an important technique to guide biopsy. Especially in this setting compartment anatomy is extremely important and the route to access the lesion should be discussed with the tumor surgeon before the intervention as contamination of compartments that will not be removed during surgery has to be avoided.

Magnetic Resonance Imaging

MRI is the best diagnostic technique for malignant soft tissue tumor diagnosis and local staging. With its multiplanar capabilities, excellent depiction of anatomical detail for bone and joint and soft tissues MRI in combination with radiographs and/or CT is the main stay in imaging. However, MRI is less well suited to diagnose specific tumor entities. Calcification, for example, which may be very influential in the differential diagnostic list, such as with synovial sarcoma in some 30%, may be not obvious or visible on routine MRI, therefore radiographs performed in conjunction with the MRI or CT are essential for making a good diagnosis. Some malignant soft tissue sarcomas have specific or suggestive MRI signal characteristics on T1- and T2-weighting (see Tables 3 and 4) (Fig. 3). *MRI angiography*, an additional sequence, may allow for depiction of normal and tumor vascularity prior to surgery. Both T1- and T2-weighting are important for tumor characterization, with STIR (Short Tau Inversion Recovery) being important for review of adjacent bone structures. Certain tumors may have specific or suggestive signal characteristics (see Tables 3 and 4) which may be helpful in making the diagnosis or the provisional diagnosis. The vast majority of tumors remain nonspecific in their pattern. The correct histological diagnosis based on imaging alone, has been reported as low as 25% (2). However, it may rapidly increase in some tumor subtypes, for example in low-grade liposarcoma where the presence of some regions of relatively normal appearing fat signal make the diagnosis specific. Also increase in experience with imaging readout and working in teams supervised by a senior experienced tumor radiologist can greatly increase the diagnostic accuracy. The delineation of cystic (hemorrhage, tumor necrosis, or tumor mucin production) versus solid lesions or tumor components is important to allow for the optimal planning and biopsy placement. Contrast administration is reported as being very useful in this regard.

Ultrasound

High-resolution ultrasound either alone or used with color Doppler ultrasound is largely used as an adjunct to



Neoplasms, Soft Tissues, Malignant. Figure 1 Fifty-eight year male with increasingly painful calf mass of lower limb. (a) Axial T1-weighted image shows mass (*arrows*) within soleus muscle with some heterogenous signal intensity. (b) Corresponding axial STIR image shows the tumor to have increased signal intensity (*arrows*) with multiple heterogenous higher signal intensity regions (*) consistent with hemorrhage. There is evidence of tumor extension into adjacent muscle into the lateral head of gastrocnemius muscle (*arrow*). (c) Contrast-enhanced 3D MR angiography shows a very vascular tumor blush of contrast, tumor vascularity and normal vascular structures only displaced by the tumor of the lower limb. CT and MRI for biopsy, cystic versus solid differentiation, and for specific enquiries, also for metastatic staging of the abdomen.

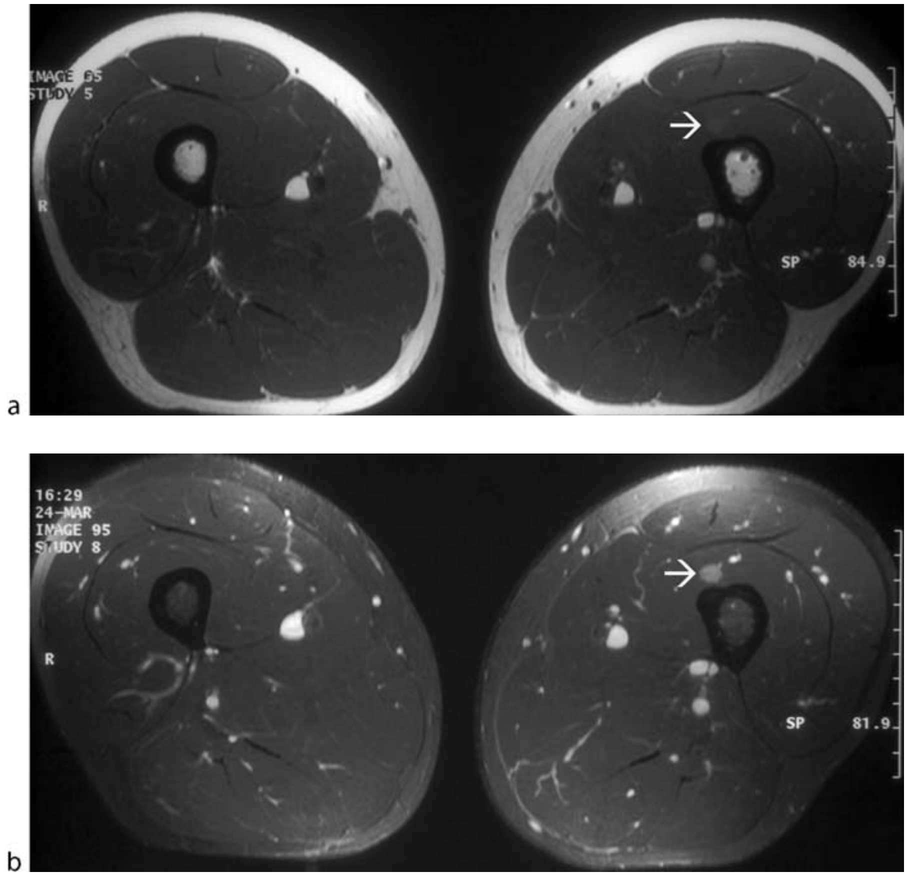
Differential Diagnosis

These include benign soft tissue lesions and pseudotumors such as myositis ossificans (see previous chapter: neoplasms, soft tissue, benign), abscess or infection, postsports or occupational injury or symptomatic normal variants. However, usually with these entities, there is no true mass at the center of the area of abnormality on imaging.

Pitfalls

The tumors' border may be difficult to ascertain with imaging and in particular there may be difficulty in



Neoplasms, Soft Tissues, Malignant. Figure 2 **Forty-year old male with minor thigh discomfort and history of previous malignant melanoma of the skin. (a) Axial T1-weighted image through the thigh shows a focal mass with high signal intensity (*arrow*), suspicious for a melanoma metastasis. (b) Corresponding T1-weighted fat saturated postcontrast administration image showing prominent contrast within the lesion, confirmed at biopsy to be a melanoma.**

determining whether an adjacent joint is involved or not. The ►pseudocapsule of the malignant tumor may mimic a well-defined benign appearing lesion. A very dense cellular homogeneous lesion with decreased signal intensity of T2-weighting may mimic a benign lesion such as a desmoid or a giant cell tumor of tendon sheath. Pseudocystic lesions are a pitfall as they may appear as a fluid-contained benign lesion such as a ganglion or myxoma. These lesions include synovial sarcomas, chondrosarcomas of soft tissue (mesenchymal or myxoid types), and soft tissue metastases. Aspiration of fluid from these lesions notoriously may lack malignant cells, giving false and misleading information supporting a benign diagnosis. Metastatic disease, such as from an esophageal adenocarcinoma primary first presenting in soft tissues may mimic a primary malignant sarcoma. Large hemorrhage into a malignant sarcoma may mask the tumor. This may occur in MFH or with synovial sarcomas, making the diagnosis very difficult; however, short-term follow-up usually shows some evidence of tumor formation.

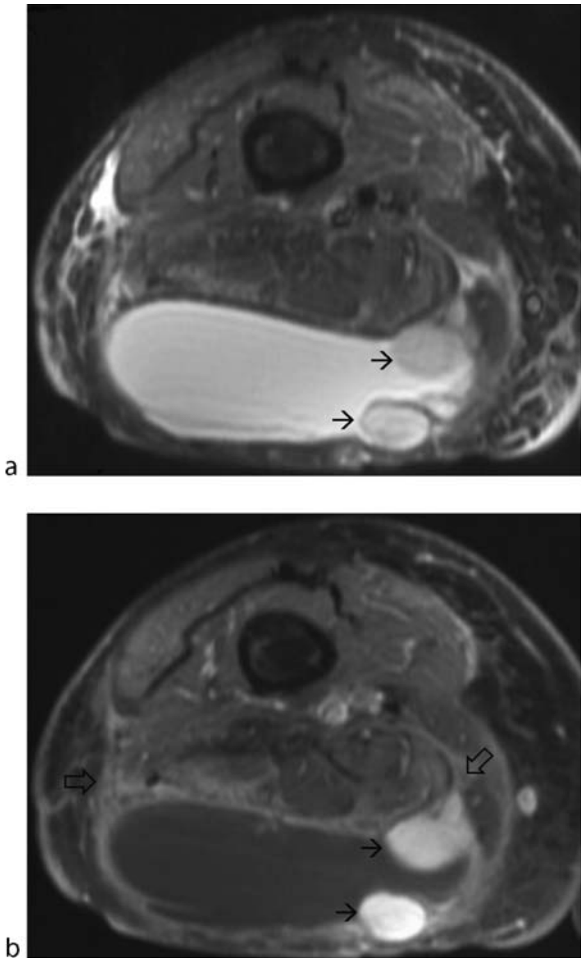
Nuclear Medicine

Bone Scan, PET Scan

Are largely for staging for bone and soft tissue metastases, with an increase in use with positron emission tomography combined with computer tomography (PET-CT) allowing correlation with spurious or dubious findings.

Diagnosis

Malignant soft tissue diagnosis is dependant on the patients' age, clinical history of presentation, presence of solitary or multiple lesions, anatomical site (intracompartmental vs. extracompartmental or multiple compartments), localization within regional anatomy (superficial soft tissue vs. interseptal), and the morphology of the tumor. The sensitivity and specificity of tumor imaging diagnosis have been shown to improve if experienced



Neoplasms, Soft Tissues, Malignant. Figure 3 Seventy-five year female with a history of intralesional surgery for liposarcoma and increasing painless mass of the thigh. (a) Axial STIR image shows a large postoperative high signal intensity fluid collection (*arrow*) with two focal tumor nodules extending from the wall of the lesion (*arrows*). These are consistent with malignant tumor nodules. (b) Corresponding axial T1-weighted fat saturated image after the administration of contrast shows contrast enhancement within the tumor nodules (*arrows*) and extension of contrast-enhancing tumor into adjacent structures (open arrows) consistent with compartment contamination.

radiologists are involved with imaging interpretation and with supervision of juniors in training.

Characteristic Imaging Features

Primary signs are a dominant mass with commonly irregular and ill-defined borders with invasion of adjacent structures, presence of irregular calcifications, anatomical distortion, presence of focally altered density (on CT) and

signal intensity (on MRI). *Secondary features* include distortion, asymmetry or evidence of invasion of adjacent anatomy (e.g., secondary bone destruction), lymphadenopathy, or metastatic disease. Secondary involvement of bone with destruction is often a sign of a higher grade lesion, associated with a poorer prognosis. Neurovascular bundle encasement is also a poor feature. Vascular grafting may be possible; however, limb function may be markedly inferior if nerve sacrifice against amputation is performed. Case by case management is required.

Benign Versus Malignant

A tumor is more likely to be malignant if it has an irregular MRI signal intensity on both T1- and T2-weighting, a high-signal intensity on T2-weighting, surrounding tissues with altered signal intensity, a size greater than 5 cm and located deep in soft tissues. Further criteria include, extension beyond the compartment, i.e., tumor invasion of the fascia, neurovascular incasement, secondary bone involvement, and early and marked contrast enhancement within the tumor. However, if a lesion does not have specific features then a conservative diagnosis or indeterminate diagnosis should be given and followed by biopsy for histological typing of the mass.

Multiple versus solitary lesions. The more common malignant soft tissue tumors are listed in Table 2. The differential list for multiple lesions of soft tissue includes malignant melanoma, Merkel Cell tumor and other skin tumors, and metastatic disease. Some syndromes such as

NFI, neurofibromatosis, with multiple nerve sheath tumors may be at an increased risk of multiple malignant soft tissue tumors.

Interventional Radiological Treatment

Interventional radiology is largely for potential intervention with intraarterial chemotherapy in specific cases or embolization prior to surgery to decrease blood loss.

Synonyms

Benign neoplasms of the spleen; Benign tumors of the spleen; Splenic benign tumors

Definition

Benign focal lesions of the spleen include benign vascular splenic tumors (hemangioma, hamartoma, lymphangioma, littoral cell angioma, hemangioendothelioma, hemangiopericytoma), and splenic cysts (primary or secondary).

Pathology and Histopathology

Hemangioma

Hemangioma is the most common benign primary neoplasm of the spleen. It arises from the sinusoidal epithelium, usually appearing on gross examination as a small, encapsulated, intraparenchymal bluish-red spongy tumor. Histopathologic evaluation reveals a nonencapsulated proliferation of vascular channels of variable size, ranging from capillary to cavernous, which are lined with a single layer of endothelium filled with red blood cells. Areas of infarction, hemorrhage, thrombosis, and fibrosis may be observed within the lesion (1, 2).

Hamartoma

Hamartoma is a rare benign lesion consisting of an anomalous mixture of normal splenic red pulp elements. It is usually a solitary, well-circumscribed, solid nodular lesion. Microscopically it appears as a mixture of unorganized vascular channels lined by endothelial cells and surrounded by fibrotic cords of predominant splenic red pulp. Focal necrosis, cystic components, and minute calcifications may be observed within the lesion (1, 2).

Lymphangioma

Splenic lymphangiomas are rare, benign lesions of vascular origin that show lymphatic differentiation. They may occur in isolation or as a manifestation of systemic lymphangiomatosis. These lesions tend to occur in subcapsular locations, reflecting the anatomic distribution of splenic lymphatics. On cut section, lymphangiomas vary in appearance and may contain large macroscopic interconnecting cysts (cystic lymphangioma) or microscopic cysts (cavernous lymphangioma). The cysts may contain chylous, serous, hemorrhagic, or mixed fluid. Mural or septal calcifications may be present. Histologically, lymphangioma is composed of multiple endothelium-lined vascular channels filled with eosinophilic proteinaceous material. The supporting stroma is composed of collagen and may contain lymphocytes and lymphoid aggregates (1, 3).

Littoral Cell Angioma

Littoral cell angioma is a tumor of vascular proliferation that is unique to the spleen. This very rare neoplasm has characteristic morphologic and immunophenotypic features (vascular and histiocytic antigens) that distinguish it from other vascular splenic tumors. Morphologically it consists of multiple nodules composed of vascular channels of red pulp and usually involves the spleen in a diffuse manner, although a focal form has been described (4).

Hemangiopericytoma

Hemangiopericytoma is a rare neoplasm with a relatively high-malignant potential. Gross examination reveals a well-defined, solid tumor with a pseudocapsule, which has a rich vascularization. Intratumoral hemorrhagic or necrotic areas may be present. At histopathologic evaluation, pericytes proliferating around vascular channels lined with endothelium are observed (1).

Hemangioendothelioma

Hemangioendothelioma is a very rare primary vascular tumor of the spleen and has variable malignant potential. Hemangioendotheliomas are well-circumscribed and nonencapsulated solid splenic masses. Microscopically, hemangioendothelioma is composed of vascular and stromal elements, and several histologic patterns, ranging from well differentiated to highly undifferentiated, have been described (1).

Splenic Cysts

Cysts are relatively common benign splenic lesions and can be divided into primary or true cysts and secondary or false cysts according to their etiology and pathophysiology. Primary cysts have a cellular lining and can be caused by either a congenital event (epithelial cyst) or parasitic infestations (hydatid cyst). Secondary cysts have no cellular lining and may be of posttraumatic, inflammatory, or degenerative origin (2, 5).

Clinical Presentation

Most benign splenic lesions are incidental findings and do not produce clinical symptoms.

However, larger and multiple lesions may manifest with splenomegaly and abdominal pain. Spontaneous rupture and massive hemoperitoneum represent rare complications.

Thrombocytopenia, anemia, and coagulopathy may occur from sequestration of hematopoietic cells either in large hemangiomas (Kasabach-Merritt syndrome) or hamartomas, while malignant degeneration has been reported in splenic hemangiopericytoma and hemangioendothelioma.

Associations between several benign splenic tumors and generalized multisystem disorders such as tuberous sclerosis, Wiskott–Aldrich syndrome, lymphangiomatosis and Klippel–Trenaunay–Weber syndrome, have been rarely reported (1, 2, 3).

Imaging

Hemangioma

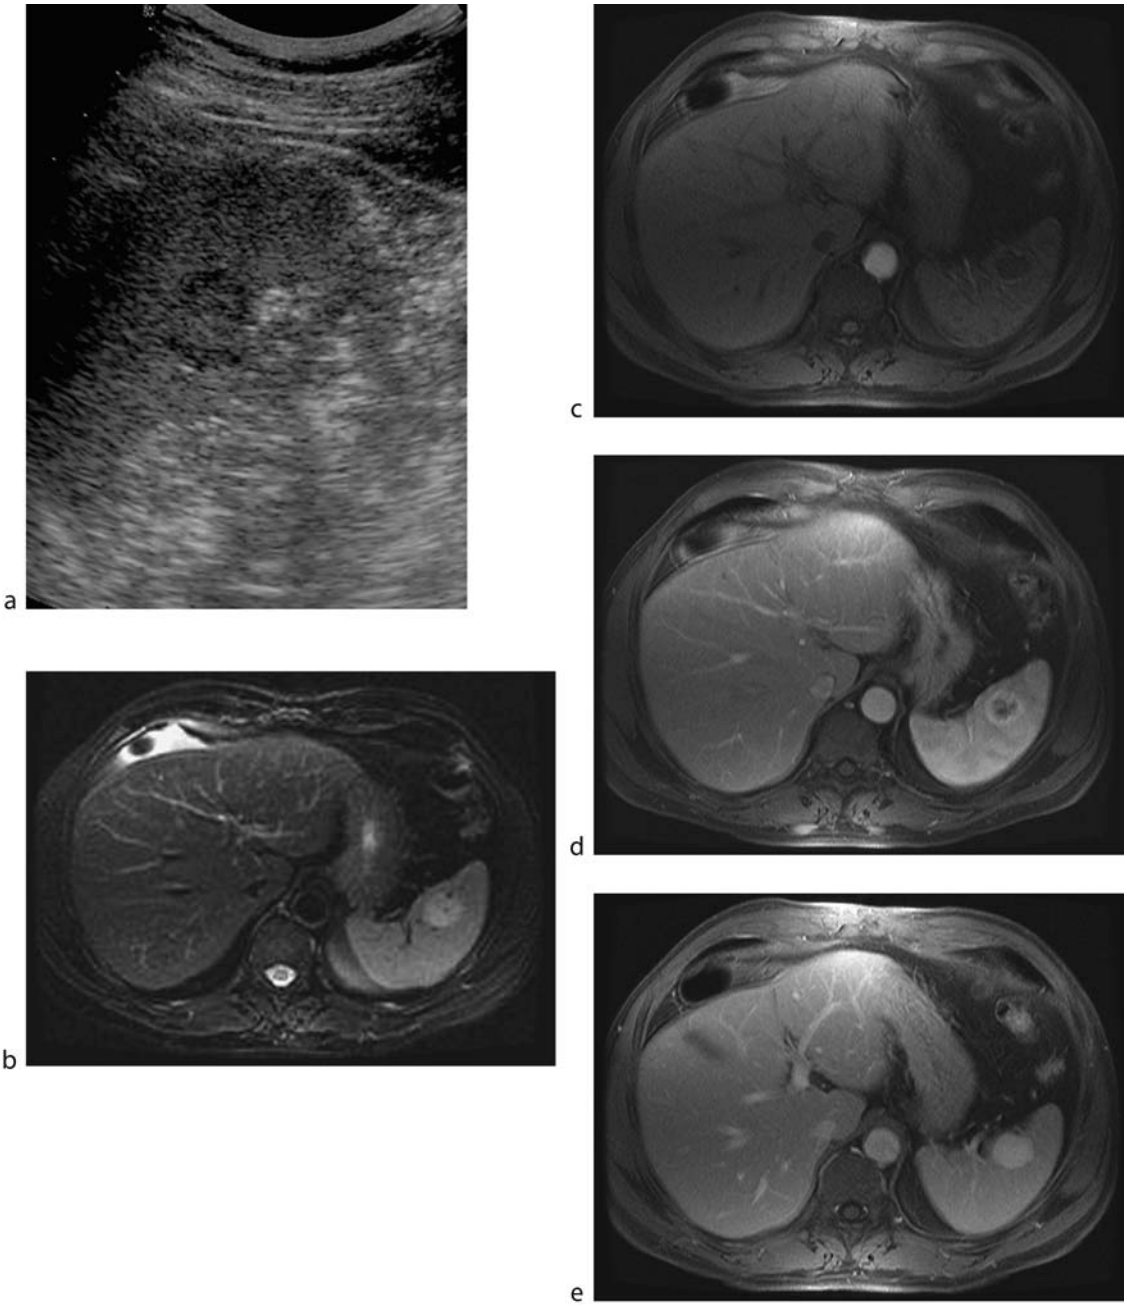
On ultrasound (US), splenic hemangiomas are either well-defined hyperechoic solid tumors (capillary hemangioma) or more complex lesions (cavernous hemangioma). Most capillary hemangiomas are well-defined hypoattenuating or isoattenuating masses on nonenhanced computed tomography (CT) scans, showing a homogeneous and marked enhancement after contrast medium administration, while the cavernous type usually appears as a complex cystic-solid mass with a inhomogeneous nodular centripetal enhancement. Splenic hemangiomas appear as hypointense or isointense lesions on T1-weighted magnetic resonance imaging (MR) and strongly hyperintense on T2-weighted images; however, central areas of low intensity on T2-weighted images corresponding to regions of fibrosis or thrombosis are often observed in large hemangiomas (1). After administration of MR extracellular contrast agents, early nodular centripetal enhancement with uniform enhancement at delayed imaging is the most common pattern (Fig. 1).

Hamartoma

On US images the splenic hamartoma appears as a solid mass with variable, heterogeneous echogenicity. Most hamartomas show high blood flow on color Doppler US, reflecting the hypervascularity of the red pulp within the lesion (1). Most splenic hamartomas are hypoattenuating or isoattenuating on nonenhanced CT scans. On MR imaging, hamartomas are usually isointense on T1-weighted images and heterogeneously hyperintense on T2-weighted images due to the presence of hypointense fibrotic and necrotic areas. After contrast administration, a diffuse, early, and heterogeneous enhancement is usually observed on both CT and MR dynamic contrast enhancement imaging (Fig. 2).

Lymphangioma

US, CT, and MR typically show large, septated, subcapsular cystic lesions. Curvilinear peripheral mural calcifications may be seen on CT, and significant enhancement is usually not observed after contrast medium administration. The cyst contents have high signal intensity on T2-weighted MR images, usually resulting in hypointensity on T1-weighted images. However, high T1 signal intensity due to internal bleeding or to the proteinaceous nature of the intracystic fluid may also be observed. The fibrous septa appear as hypointense bands on both T1- and T2-weighted images (1).



Neoplasms, Splenic, Benign. Figure 1 Hemangioma. On ultrasound, splenic hemangioma appears as a well-defined hyperechoic nodule (a). On T2-weighted magnetic resonance (MR) image, the lesion is slightly hyperintense (b). After administration of MR extracellular contrast agents, the early nodular centripetal enhancement with uniform enhancement at delayed imaging is appreciable (c–e).

Littoral Cell Angioma

Sonographic characteristics of littoral cell angioma include splenomegaly with a diffuse heterogeneous echo texture of the spleen. On early-phase postcontrast CT scan, the spleen presents multiple small areas of low attenuation; delayed filling of the nodules makes the areas isodense with the surrounding enhancing splenic tissue. On MR, littoral cell angioma appears as multiple hypointense nodules on both T1- and T2-weighted images, due to the presence of hemosiderin (4).

Hemangiopericytoma

Hemangiopericytomas appear as hypoechoic nodules on US, and speckled calcifications may be observed on CT scans. They have low signal intensity on T1-weighted MR and are usually hyperintense on T2-weighted images.

Hemangioendothelioma

On US, hemangioendothelioma is usually a hypoechoic mass with intratumoral necrotic areas. Color Doppler US shows an abnormal vascularization characterized by the presence of arterial flow and low resistive index in the solid areas of the tumor (1, 3). On CT scan, hemangioendothelioma usually appears as a low-attenuating mass with enhancement of the solid tumoral portions. On MR, splenic hemangioendothelioma is a heterogeneous solid lesion that, because of the presence of hemosiderin, may show low signal intensity on both T1- and T2-weighted images (1).

Splenic Cysts

On US examination, the typical splenic cyst appears as a homogeneous anechoic area with marked echo enhancement. However, complex cysts are frequently observed. At CT, splenic cysts are typically hypoattenuating, with a thin or imperceptible wall and no rim enhancement. Cystic wall calcification and septations are well demonstrated (Fig. 3). On both T1- and T2-weighted MR images, splenic cysts have a signal intensity equal to that of water; however, in cysts that are complicated by protein or hemorrhage, an increased T1 signal intensity may be

Neoplasms, Splenic, Benign. Figure 2 **Hamartoma. This focal lesion shows high blood flow on color Doppler ultrasound (a, b), reflecting the hypervascularity of the red pulp within the hamartoma. On nonenhanced computed tomography (CT) scanning (c), hamartoma appears hypoattenuating. After contrast administration, a diffuse enhancement is observed on early and delayed CT scans (d, e). At magnetic resonance imaging (MR), hamartoma is isointense relative to normal splenic tissue on both T1- and T2-weighted images (f, g). On postcontrast MR dynamic imaging (h–j), a diffuse and early enhancement is demonstrated.**

N

observed. On MR, cystic septations and endoluminal debris, which are typically present on parasitic cysts, are easily identified (2, 3, 5).

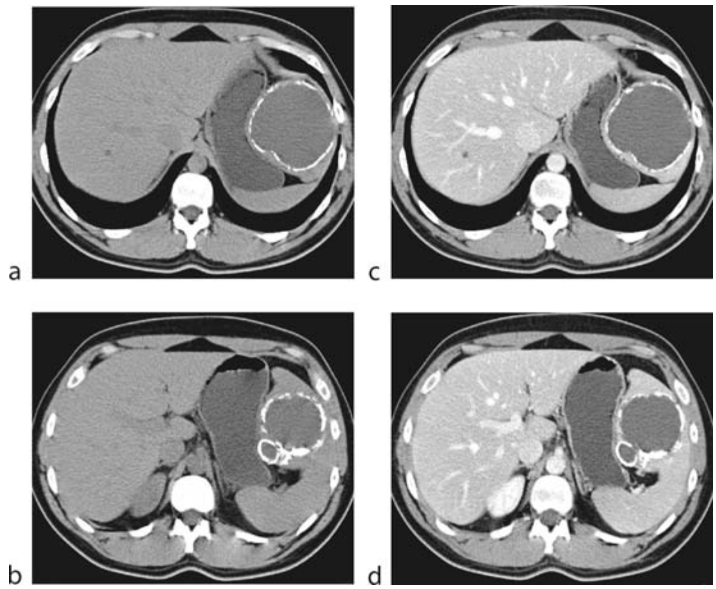
Nuclear Medicine

Nuclear medicine is not useful for evaluating benign focal lesions of the spleen because hypervascular lesions do not show radiotracer uptake on 99m-technetium sulfur colloid scintigrams (3).

Diagnosis

Although benign focal lesions of the spleen are relatively uncommon, they must be correctly characterized and differentiated from malignancies. A cystic lesion usually exhibits a fluid content and a well-defined outline without solid components, but reliable differentiation between primary and secondary cysts is usually not possible at imaging. The characterization of the other benign lesions, including splenic hemangioma, hamartoma, and several rare vascular tumors, is usually difficult. Although the most common hypervascular mass in an asymptomatic patient is splenic hemangioma, the imaging appearance of that lesion is often complex, and differentiation from hamartoma or malignancies, particularly angiosarcoma, may not be possible. Large subcapsular solitary lobulated cystic abnormalities discovered incidentally in pediatric patients are typical for lymphangioma; however, differential diagnosis may also include echinococcal or other splenic cysts.

In conclusion, several imaging modalities are necessary to improve focal splenic lesion characterization and role out malignancies. However, splenectomy is necessary for definitive evaluation of a splenic mass with atypical imaging features (1).



Neoplasms, Splenic, Benign. Figure 3 Hydatid cyst. Nonenhanced computed tomography scans (a, b) show a round, low-attenuating cystic splenic lesion with multiple daughter cysts and peripheral calcifications. No enhancement is seen in the lesion after intravenous contrast material administration (c, d).

Synonyms

Malignant neoplasms of the spleen; Malignant tumors of the spleen; Splenic malignancies; Splenic malignant tumors

Definition

Malignant neoplasms of the spleen include primary lymphoreticular tumors (lymphomas and chronic myeloproliferative disorders), primary nonlymphoreticular tumors (hemangiosarcoma, leiomyosarcoma, and fibrosarcoma), and splenic metastases.

Pathology and Histopathology

Lymphoma

Splenic lymphoma is the most common malignant tumor of the spleen and can be primary (when limited to the spleen and hilar lymph nodes) or secondary (when the spleen is involved as a part of a disseminated disease).

Primary lymphoma of the spleen is an extremely rare entity, with a reported incidence of less than 1%; most of these are low-grade B-cell non-Hodgkin's lymphomas. In contrast, the spleen is commonly involved in systemic lymphoma (approximately 25–40% of patients with Hodgkin's or non-Hodgkin's lymphoma at the time of initial diagnosis).

Grossly, an enlarged spleen with one or more intraparenchymal tumor nodules, often less than 1 cm in diameter, is usually observed; however, a diffuse, infiltrative tumor growth and single large lesions have also been described. Generally, malignant lymphomas show a homogeneous, highly cellulated histologic structure lacking fibrous septa (1).

Chronic Myeloproliferative Disorders

The chronic myeloproliferative disorders consist of *chronic idiopathic myelofibrosis*, *essential thrombocythemia*, and *polycythemia rubra vera*. All of these disorders are thought to result from a hematopoietic stem cell lesion. In many cases these proliferations are clonal and neoplastic (2).

Hemangiosarcoma

Although very rare, splenic hemangiosarcoma is the most common nonlymphoreticular malignant tumor of the spleen. It arises from splenic sinus endothelial cells, and at gross examination it usually appears as a large, poorly defined, nodular red mass diffusely involving the spleen. Areas of hemorrhage and necrosis are usually seen within the tumor. Microscopically the tumor consists of abnormal anastomosing vascular channels lined by malignant endothelial cells. Papillary formations and solid areas within the tumor are common (3).

Leiomyosarcoma

Splenic leiomyosarcoma is an extremely rare nonlymphoreticular malignant tumor that originates from muscular cells. Lesions are hypercellular. Even in poorly differentiated examples, actin and myosin are present in the tumor cells (3).

Fibrosarcoma

Fibrosarcoma of the spleen is another extremely rare nonlymphoreticular malignant tumor. This is a fibroblastic malignant lesion that consists of bundles of spindle-shaped cells arranged at angles to one another (3).

Metastases

Metastases of the spleen are rare and usually associated with disseminated disease. Splenic metastases usually occur as a result of hematogenous spread from lung, breast, prostate, stomach, or ovarian cancer or from malignant melanoma. The gross features of splenic metastases are variable, including either single or multiple lesions with cystic, solid, or complex structure. Microscopically, metastases resemble the primary tumors (4).

Clinical Presentation

Lymphoma

Clinically, patients with primary non-Hodgkin's splenic lymphoma most often present with a palpable mass, splenomegaly, and abdominal pain. In contrast, splenic involvement by systemic Hodgkin's disease is relatively frequent, and splenomegaly is the typical clinical finding. However, nonspecific signs (fever, weight loss, and night sweats) due to the systemic disease are usually also observed (1, 2).

Chronic Myeloproliferative Disorders

The chronic myeloproliferative disorders are chronic diseases that sometimes convert to an acute myeloid leukemic phase. Most patients are over 60 years of age at diagnosis, and one-third of patients are asymptomatic at presentation. Massive splenomegaly is a characteristic finding (2).

Hemangiosarcoma

Unlikely hepatic hemangiosarcomas, no associations with exposure to thorium, vinyl chloride, or arsenic have been observed. The most frequent clinical findings are splenomegaly, abdominal pain, fever, fatigue, weight loss, anemia, and consumptive coagulopathy. Major complications include rupture of the spleen, which often leads to fatal hemoperitoneum. The lymphatic system, liver, lungs, and bone are the most frequent metastatic sites. Hemangiosarcomas are highly aggressive neoplasms, and the prognosis is poor (3).

Leiomyosarcoma and Fibrosarcoma

Leiomyosarcoma and fibrosarcoma, extremely rare primary nonlymphoreticular malignant tumors of the spleen, present clinical findings like those of splenic hemangiosarcoma. These lesions are aggressive with high rates of both local recurrence and metastatic disease.

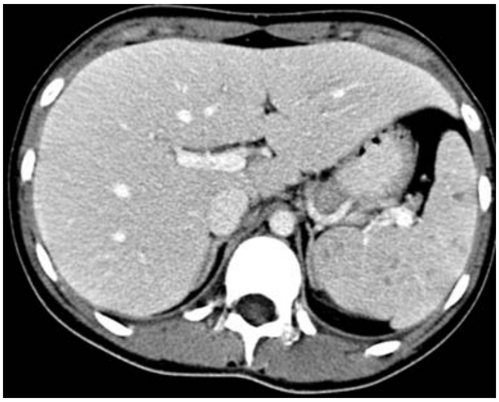
Metastases

Metastatic disease involving the spleen is uncommon, and isolated metastasis to the spleen is extremely rare. Most patients with splenic metastases have widely disseminated metastatic disease usually arising from lung, colorectal, endometrial, ovarian, thyroid, pancreatic, or gastric cancers or, most commonly, melanoma. Although most patients with splenic metastases are clinically asymptomatic, painful splenomegaly, splenic vein thrombosis, and splenic rupture have been rarely reported (4).

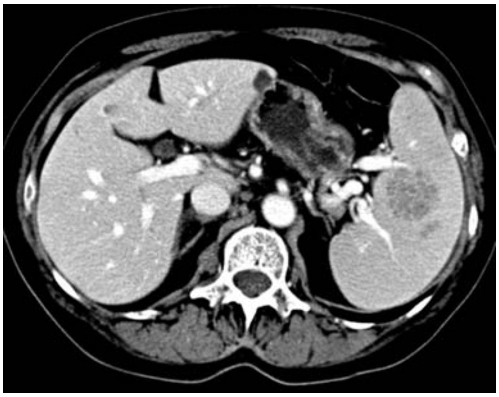
Imaging

Lymphoma

The lymphomatous nodule is typically hypoechoic, and an inhomogeneous hypoechoic mass or multiple hypoechoic lesions less than 1 cm in size are the most common features on ultrasound (US) (2). Computed tomography (CT) findings include a homogeneous enlarged spleen without masses, a solitary mass, multifocal lesions, or diffuse infiltration (Figs. 1, 2). The focal lesions are typically hypodense on nonenhanced scanning and appear demarcated and lightly enhancing after contrast medium administration, while the infiltrative pattern and tumor foci smaller than 1 cm may be difficult to detect on CT (1). On magnetic resonance imaging (MR), splenic lymphoma is usually isointense both on T1- and T2-weighted sequences, with light and heterogeneous enhancement after injection of gadolinium. Reticuloendothelial system (RES)-specific MR contrast agents can improve the accuracy of diagnosis of splenic lymphoma. This contrast is selectively taken up by the normal spleen and not by malignant cells, thus improving the tumor/spleen contrast on T2-weighted images (1, 2).



Neoplasms, Splenic, Malignant. Figure 1 Splenic lymphoma in Hodgkin's disease. Postcontrast-enhanced computed tomography shows an enlarged spleen with numerous hypodense lesions, smaller than 1 cm, corresponding to foci of lymphoma.



Neoplasms, Splenic, Malignant. Figure 2 Primary splenic non-Hodgkin's lymphoma. Postcontrast-enhanced computed tomography demonstrates splenomegaly with a typical low-attenuating mass; a second small lesion is also appreciable.

Chronic Myeloproliferative Disorders

Imaging findings of chronic myeloproliferative disorders are similar to those of lymphoma (Fig. 3).

Hemangiosarcoma

Sonographically, splenic hemangiosarcoma appears as a complex, poorly defined mass with a heterogeneous echostructure. Increased Doppler flow may be seen in the more solid echogenic portions of the tumor. On CT scans, a heterogeneous low-density and poorly defined mass with peripheral enhancement and areas of necrotic degeneration is usually observed. Calcifications and areas of high CT attenuation due to acute hemorrhage may be present. Hypervascular metastasis to the liver, lungs, bones, and lymphatic system are well identified on CT. The tumor usually demonstrates low signal intensity on both T1- and T2-weighted MR images. However, areas of increased and decreased signal intensity due to the intratumoral presence of blood products and necrosis are often observed. Contrast-enhanced MR reveals heterogeneous enhancement within the tumor, corresponding to the pathologic findings of solid tumor with necrotic tissues (3).

Leiomyosarcoma and Fibrosarcoma

Imaging findings of leiomyosarcoma and fibrosarcoma are similar to those of hemangiosarcoma.

Neoplasms, Splenic, Malignant. Figure 3 Acute myeloid leukemia in a patient affected by polycythemia rubra vera. Postcontrast-enhanced computed tomography demonstrates splenomegaly with multiple ischemic areas.

Metastasis

Several different US patterns of the splenic metastases have been described, including multifocal or diffuse hypoechoic lesions, hyperechoic nodules, and cystic tumors. On CT, splenic metastases usually appear as hypoattenuating solid or cystic masses with inhomogeneous contrast enhancement. Intratumoral calcifications or necrotic areas may be present.

Metastases are usually minimally hypointense to isointense with spleen on T1-weighted MR and slightly hyperintense on T2-weighted sequences. Because metastases show a lack of Kupffer cells, no significant loss of signal intensity on T2-weighted superparamagnetic iron oxide (SPIO)-enhanced images is observed, with a significant improvement in detection of secondary involvement of the spleen in oncology patients (1, 4).

Nuclear Medicine

Metabolic imaging allows the recognition of active tumor mass because of its fixed tracer. In patients with Hodgkin's disease and non-Hodgkin's lymphoma, gallium-67 scintigraphy and fluorine-18-fluorodeoxyglucose positron emission tomography (18F-FDG-PET) have been widely employed. Gallium-67 scintigraphy has played an important role in monitoring response to therapy and follow-up of patients with lymphoma; however, recent studies suggest the use of 18F-FDG-PET in place of gallium scanning for staging Hodgkin's disease and non-Hodgkin's lymphoma. Particularly, 18-FDG-PET offers several advantages, including improved spatial resolution, reduced nonspecific abdominal uptake, and a shorter imaging time (5).

Diagnosis

Imaging modalities can delineate focal splenic lesions, but their accurate diagnosis is often difficult, and both incidentally discovered lesions and masses in patients with known malignancies represent diagnostic dilemmas. On imaging, the malignant lesions are more likely to be multifocal due to metastases, or they tend to be diffuse and ill defined due to rapid growth (4). They may present different structures, including a homogeneous composition in lymphoma, variable patterns in metastases, and, usually, a complex cystic appearance in hemangiosarcoma. Irregular borders, signs of infiltration of the surrounding splenic parenchyma, lymphonodal masses, and extrasplenic metastases are highly suggestive for malignancy. Moreover, functional imaging, including both nuclear medicine (18F-FDG-PET and gallium scintigraphy) and MR-SPIO imaging, has the potential to improve the accuracy of tumor diagnosis by exploiting biological and histopathologic differences between malignant and benign tissue (1, 4, 5).

In conclusion, although accurate evaluation with cross-sectional imaging may be helpful in differentiating between benign and malignant splenic lesions, percutaneous biopsy or splenectomy should be performed in doubtful cases.

Neoplasms, Temporal Bone

Gabriele A. Krombach
Department of Radiology, University Hospital, Aachen, Germany
krombach@rad.rwth-aachen.de

Definition

Tumors arising in the temporal bone can originate from all the different types of tissue that occur in the temporal bone, such as bone, nerves, the meninges, and soft-tissue components (skin, fat, lymph nodes, muscle). The tumors can be benign or malignant. Most tumors are acquired, but congenital tumors such as congenital cholesteatoma also occur. Most tumors of the temporal bone have a typical age peak and characteristic symptoms.

Pathology/Histopathology

Exostosis

Exostosis is a broa-based overgrowth of compact bone in the medial osseous part of the external auditory canal. It occurs in ocean swimmers, divers, and surfers and is

N

known as a response to cold water exposure. Thus, it usually occurs bilaterally. Histology shows concentric layers of subperiosteal bone.

Osteoma

Osteoma is a benign bony tumor that can arise in the external auditory canal, the mastoid, or the petrous pyramid. It has all layers of normal bone and occurs unilaterally. It is usually located lateral to the isthmus of the external auditory canal.

Malignant Neoplasm of the External Auditory Canal

Squamous cell carcinoma is a malignant epithelial tumor that may arise from the external auditory canal, pinna, or middle ear.

Basal cell carcinoma is a slowly growing local aggressive tumor that can occur at the outer ear. It is also caused by chronic exposure to sunlight. It arises from the basal cells, which represent the deepest layer of the skin. The tumor consists of basophilic cells of high mitotic activity. Basal cell carcinoma does not metastasize.

Ceruminal gland adenocarcinoma is a malignant tumor of modified apocrine glands, located in the external auditory canal. Ceruminal gland carcinomas are characterized by a loss of the normal glandular double cell layer and presence of pleomorphic luminal epithelial cells.

Squamous cell carcinoma arises from keratinocytes. It is predominantly located at areas that are exposed to sunlight or at which chronic inflammation is present. It represents the most common malignant tumor of the external ear.

Other malignant tumors, such as malignant melanoma and sarcomas, can also occur within the outer auditory canal or ear.

Acquired Cholesteatoma

Cholesteatoma is a sac lined by keratinizing stratified squamous epithelium, trapped and growing in the middle ear space, mastoid, or other pneumatized spaces of the temporal bone. It can arise from the pars flaccida or the pars tensa of the tympanic membrane. It may develop following retraction of the tympanic membrane due to negative middle ear pressure associated with Eustachian tube dysfunction. Cholesteatoma can also develop after invasion of keratinized stratified squamous epithelium from the surface of the tympanic membrane into the middle ear after (small) perforation of the tympanic membrane.

Glomus Tympanicum

Glomus tympanicum is a benign paraganglioma of the middle ear. It arises in the glomus bodies situated along the tympanic branch of the glossopharyngeal nerve (Jacobson's nerve), as it bends around the cochlea. This tumor is strongly vascularized.

Middle Ear Adenoma

Middle ear adenoma is a benign tumor of glandular origin, originating from the mucosa and growing slowly. It can occur at any part of the middle ear.

Schwannoma

Schwannomas are benign neural neoplasms. Possible localizations in the temporal bone are the middle ear (tumors arising from the facial nerve, chorda tympani, or Jacobson's nerve), inner ear (cochlear nerve or vestibular nerve), or the cerebellopontine angle (vestibulocochlear nerve), where it is the most common tumor. Schwannomas arise from the Schwann cells wrapping the nerves. Acoustic schwannomas always arise from the vestibular portion of the cranial nerve VIII. Bilateral acoustic schwannomas are associated with neurofibromatosis type II. Intralabyrinthine schwannomas originate from the Schwann cells surrounding the peripheral fibers of the cochlear nerve or the cristae or maculae of the vestibule.

Meningioma

This benign tumor represents the second most common tumor in the cerebellopontine angle and originates from the dura. This strongly vascularized tumor develops from the arachnoid villi component of the leptomeninges. It may contain calcifications. In larger tumors, areas of cystic degeneration can be present. Meningiomas may express estrogen receptors.

Lipoma

Lipomas of the cerebellopontine angle are congenital benign fatty lesions. They originate from maldevelopment of mesoderm or of meningeal precursor tissue, namely the meninx primitive. Generally, the VII and VIII cranial nerves pass through the mass.

Endolymphatic Sac Tumor

Endolymphatic sac tumor is an adenomatous tumor arising from the pars rugosa (middle third) of the endolymphatic sac. This tumor arises from the cells lining the endolymphatic sac. It is hypervascularized and has been reported to contain a speculated calcified matrix in almost all known cases.

Rhabdomyosarcoma

Rhabdomyosarcoma is a malignant tumor of skeletal muscle origin. It is a highly aggressive neoplasm arising from rhabdomyoblasts, which are embryonal cells that usually differentiate into striated muscle cells. In the temporal bone it is supposed to originate from the muscle cells in the vicinity of the Eustachian tube in the middle ear.

Clinical Presentation

Exostosis

Exostosis is usually asymptomatic. If the tumor is large, it can lead to retention of debris, external otitis, and/or hearing loss. The latter depends on the degree of canal obstruction. Pain and tinnitus are other possible symptoms. Exostosis should be surgically removed if symptomatic.

Osteoma

Osteoma is usually asymptomatic. If the tumor obstructs the outer auditory canal, debris can accumulate and cholesteatoma may result in the long run.

Malignant Neoplasm of the External Auditory Canal and Ear

Basal cell carcinomas are asymptomatic. At the beginning they appear as small erosions. Suspicion should be raised if erosions at sunlight-exposed areas persist over 3 weeks. Squamous cell carcinomas appear crusty and bleed easily.

Ceruminal gland adenocarcinomas cause local pain.

Malignant neoplasms of the external auditory canal and ear have a peak at higher ages (>70 years).

Acquired Cholesteatoma

Individuals of all ages may develop cholesteatoma. The leading symptom is chronic otorrhea and conductive hearing loss. In more advanced stages, symptoms are due to progressing bone erosion and may include vertigo (erosion of the lateral semicircular canal) or facial palsy (erosion of the facial nerve canal). Meningitis, abscess in the temporal lobe, and lateral sinus thrombosis are possible late-stage complications.

Glomus Tympanicum

Due to the vascular nature of the tumor, pulsatile tinnitus is the most common symptom at initial presentation (90%). Conductive hearing loss occurs in 50% of patients and is due to blocked movement of the tympanic membrane.

Middle Ear Adenoma

Dizziness, tinnitus, and conductive hearing loss are the most common symptoms. The age peak is 40–50 years.

Schwannoma

Middle ear schwannoma may cause conductive hearing loss. Intralabyrinthine schwannoma causes vertigo or sensorineural hearing loss. Patients with acoustic schwannoma classically present with sensorineural hearing loss, tinnitus, and disequilibrium. The age peak is 40–60 years.

Meningioma

Symptoms depend on the exact location and size of the tumor and may include dysfunction of cranial nerves V, VII, and VIII. There is a female predominance (2–3:1). The age peak is >60 years.

Lipoma

Most lipomas are asymptomatic. Dizziness and sensorineural hearing loss are the most common symptoms. Only in cases unresponsive to medical therapy is surgical decompression done. Because nerve fibers run through the lipoma, surgical therapy is extremely difficult.

Endolymphatic Sac Tumor

Sensorineural hearing loss and tinnitus are common symptoms. The tumor occurs in patients between 20 and 80 years. Endolymphatic sac tumors have a higher incidence in patients with von Hippel–Lindau disease.

Rhabdomyosarcoma

This tumor is the second most common head and neck malignancy in children and has an age peak at 4–6 years. Otalgia, bloody otorrhea, facial nerve palsy, and sensorineural hearing loss are common symptoms.

Imaging

Exostosis

High-resolution computed tomography (HRCT) with bone algorithm shows a circumscribed tumor that consists of dense compact bone. It has a broad base and begins deep to the isthmus within the medial aspect of the osseous internal auditory canal in the close vicinity of the annulus.

Osteoma

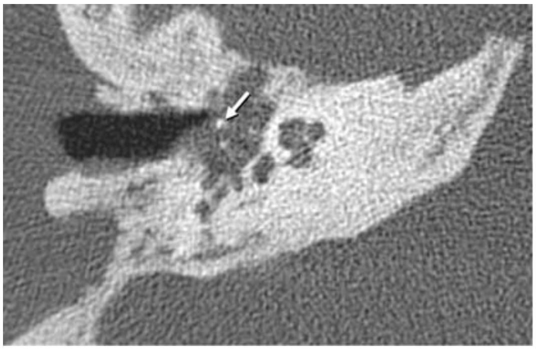
HRCT demonstrates a pedunculated tumor with both layers of normal bone (cortical shell and trabecular bone).

Malignant Neoplasm of the External Auditory Canal and Ear

HRCT and MRI usually do not allow for a specific diagnosis of malignant tumors in adults. However, erosion of the underlying bone and infiltration of neighboring structures are signs of malignancy of a mass. The main role of imaging is to assess the extent of the neoplasm and infiltration of vital structures and determine the presence of metastasis. The periparotid lymph nodes represent the primary lymphatic drainage of the ear. Thus, the parotid gland and upper neck must be included in imaging studies.

Acquired Cholesteatoma

HRCT shows the extent of the soft-tissue mass. Erosion of bone is usually present (Fig. 1) and allows differentiation of cholesteatoma from middle ear adenoma. On MRI, the mass is isointense to cerebrospinal fluid on T1- and T2-weighted images. Cholesteatoma does not enhance after administration of contrast medium, but due to granulation tissue, there is enhancement at the rim of the tumor.



Neoplasms, Temporal Bone. Figure 1 Acquired cholesteatoma. The axial high-resolution computed tomographic image shows a middle ear cavity opacification. The ossicles are eroded (*arrow*).

Glomus Tympanicum

MRI is the modality of choice and demonstrates a hyperintense middle ear mass on T2-weighted images. After intravenous administration of contrast medium, the tumor strongly enhances on T1-weighted images. CT does not demonstrate erosion of the bone. The ossicles are usually spared.

Middle Ear Adenoma

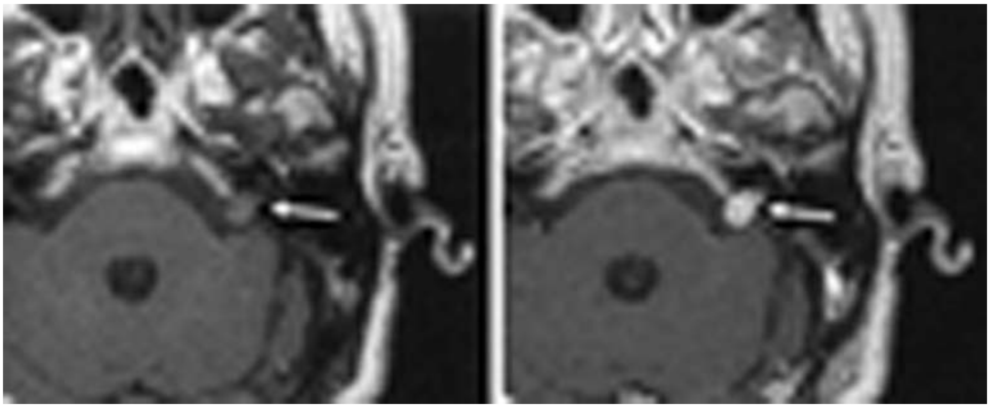
CT shows a mass behind the intact tympanic membrane. The mastoid is usually well pneumatized. The ossicles are encased by the tumor, but usually no bony erosion is present.

Schwannoma

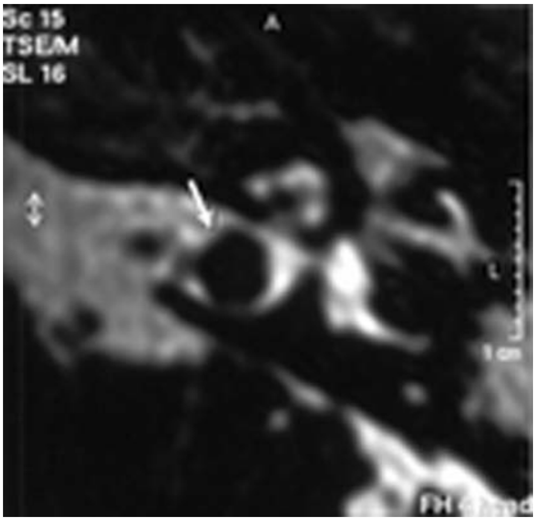
The CT appearance of middle ear schwannoma is nonspecific, and differentiation from paraganglioma is usually not possible. On MRI, schwannomas strongly enhance on T1-weighted images after the administration of contrast medium (Fig. 2). T2-weighted high-resolution images also show the tumor (Fig. 3).

Meningioma

Meningiomas enhance strongly on CT and MRI after intravenous injection of contrast medium. The dural tail sign—linear enhancement along the adjacent dura—is a typical finding on MRI. Brain edema in the vicinity of the tumor is a sign of infiltration of the arachnoid. In these cases the tumor is difficult to remove, and a higher rate of recurrence must be expected.



Neoplasms, Temporal Bone. Figure 2 Acoustic schwannoma. Axial T1-weighted magnetic resonance image before (*left*) and after intravenous administration of contrast medium (*right*). The tumor is isointense to the brain before administration of contrast medium (*arrow* in the *left* image). It strongly enhances after administration of contrast medium (*arrow* in the *right* image).



Neoplasms, Temporal Bone. Figure 3 Acoustic schwannoma. The T2-weighted magnetic resonance image shows a small tumor (*arrow*) in the internal auditory canal.

Lipoma

On T1-weighted MR images, the tumor has the typical high signal intensity of fatty tissue. It loses signal if fat saturation techniques area applied.

Endolymphatic Sac Tumor

HRCT shows a soft-tissue mass located at the posterior wall of the temporal bone, eroding the bone. The tumor matrix contains speculated calcifications. MRI shows foci of enormous enhancement within the mass after intravenous injection of contrast medium.

Rhabdomyosarcoma

HRCT demonstrates a mass that causes extensive bony destruction. On T2-weighted MR images, rhabdomyosarcoma is hyperintense. On T1-weighted images, the mass is hypointense and enhances after intravenous administration of contrast medium.

Nuclear Medicine

In patients with neoplasm of the temporal bone, nuclear medicine has only a limited role.

Bone scintigraphy with technetium 99 m methylene diphosphonate may lead to detection of metastasis to the temporal bone at an early stage or show metastasis from a temporal bone neoplasm to other parts of the body.

Diagnosis

Several tumors, such as schwannoma and lipoma, have a pathognomonic appearance on imaging. In all tumors without such a pathognomonic imaging appearance, biopsy or surgical removal and histology are essential for correct diagnosis.

In patients with exostosis, otoscopy shows a circumferential stenosis of the external auditory canal. In cholesteatoma, otoscopy shows a retraction pocket or perforation of the tympanic membrane and a white mass behind the tympanic membrane.

If otoscopy shows a reddish mass behind the posteroinferior part of the tympanic membrane, glomus tympanicum tumor must be considered. Before biopsy can be performed, imaging is required to rule out an aberrant internal carotid artery. This developmental anomaly causes similar clinical symptoms (pulsatile tinnitus and conductive hearing loss) and has the same appearance at otoscopy. Furthermore, glomus tympanicum must be differentiated from glomus jugulare, which arises from the jugular foramen and may extend through the posterior floor of the middle ear cavity into the middle ear, because the two tumors require different surgical approaches.

University of Messina, Messina, Italy
cvisalli@unime.it

Synonyms

Benign and malignant neoplasm; Thyroid nodules; Thyroid tumors

Definition

Thyroid neoplasms include all lesions caused by abnormal thyroid tissue growth due to excessive cellular division and proliferation. They are comprehensive, including benign and malignant nodules. Nodules are palpable masses in the thyroid gland, often found incidentally on ultrasound examination. They occur in 4–7% of the population and can be solitary lesions or occur in a context of multinodular enlargement of the gland. This pathological condition is four times more common in women than in men and occurs more often in people who live in geographic areas with iodine deficiency or who are exposed to ionizing radiation.

Pathology/Histopathology

In general, nodular disease of the thyroid is common; however, malignancy of the thyroid is rare. Approximately 5–10% of thyroid nodules are malignant, whereas the remainders represent a variety of benign diagnoses, including colloid nodules, degenerative cysts, hyperplasia, thyroiditis, and benign neoplasms (Table 1). A rational approach focal to management of a thyroid nodule is based on the clinician's ability to distinguish the more common benign entities from malignancy in a highly reliable and economic way.

Colloid nodules are the most common and do not have an increased risk of malignancy. Most follicular adenomas are benign; however, some may share morphological aspects with follicular carcinoma. Although carcinoma of the thyroid gland is rare, it is the most common malignancy of the endocrine system.

Neoplasms, Thyroid, Benign and Malignant. Table 1 Types of thyroid nodules

Adenoma	• Macrofollicular adenoma
	• Microfollicular adenoma
	• Atypical adenoma
	• Papillary adenoma
Liquid nodule	• Simple cyst
	• Colloid nodule
Inflammatory nodule	• Focal thyroiditis
Carcinoma	• Papillary (60–80%)
	• Follicular (10–20%)
	• Medullary (5–10%)
	• Anaplastic (5%)
Other malignancy	• Lymphoma (4%)
	• Sarcoma
	• Teratoma
	• Metastases (2–17%)

Thyroid carcinoma usually presents as a solitary nodule. There are four forms: papillary, follicular, medullary, and anaplastic (1). Differentiated tumors (papillary or follicular) are highly treatable and usually curable. Poorly differentiated tumors (medullary and anaplastic) are aggressive, metastasize early, and have a much poorer prognosis. ►Thyroglobulin can be used as a tumor marker for well-differentiated forms.

Women are affected more often than men, and any age group can be affected, although thyroid cancer usually occurs in people between the ages of 25 and 65 years.

Papillary Thyroid Cancer

Papillary thyroid cancer is the most common type of thyroid cancer, accounting for 60–80% of all thyroid malignancies. It occurs more frequently in women and presents in the 30–40-year-old age group. It is also the predominant cancer type in children with thyroid cancer and in patients who have had radiation to the head and neck. In this group the cancer tends to be multifocal, with early lymphatic spread and a poor prognosis.

Papillary carcinoma is a nonencapsulated lesion that histologically consists of a stromal core and packed papillae with a small amount of colloid within follicles. Small calcified bodies, known as psammoma bodies, may be found in the stroma.

Follicular Thyroid Cancer

Follicular thyroid cancer occurs in approximately 20% of patients with thyroid cancer and is more common in women above 50 years of age. A particular form of follicular cancer is Hürthle cell carcinoma, characterized by large polygonal thyroid follicular cells.

Follicular carcinoma is an encapsulated lesion, generally solitary and characterized by angioinvasive behavior with a consequently high frequency of distant metastases. Regional lymph node involvement has been reported to be less than 13%. When lymph nodes are involved, the prognosis is usually poor. Because this cancer is usually very well differentiated, it is difficult to distinguish from follicular adenoma. For the definitive diagnosis, demonstration of capsular or surrounding thyroid tissue invasion is necessary.

Medullary Thyroid Cancer

Medullary thyroid cancer originates from the parafollicular cells (C cells), which produce the hormone calcitonin. Carcinoembryogenic antigen (CEA) is a tumoral marker produced by medullary thyroid cancer. Its prognosis is poorer than that for follicular or papillary thyroid cancer, especially when it has metastasized beyond the thyroid gland. This cancer can develop as a "sporadic form" or as a part of the complex syndrome of ▶multiple endocrine neoplasias, type 2 (MEN 2a and MEN 2b).

Medullary thyroid cancer can cause diarrhea and flushing episodes. The main sites of spread of this cancer are local lymph nodes in the neck and mediastinum, as well as liver, lung, and bone.

Anaplastic Thyroid Cancer

This form of neoplasm has a very poor prognosis, with a high mortality (near 100%) due to its aggressive behavior, rapidly invading surrounding tissue and the trachea.

Other Tumors

The thyroid gland may also be the site of other tumors, including sarcoma, lymphoma, teratoma, and metastasis from other cancers, such as lung, breast, and kidney neoplasms.

Clinical Presentation

At physical examination, thyroid nodules may be diffuse or localized, soft or hard, mobile or fixed, and painful or painless (2). If nodules are less than 1 cm in diameter, they are usually not palpable unless they are located in the anterior portion of the gland. Physical characters indicative of malignancy are a hard, fixed lesion; nodules greater than 4 cm; or hoarseness.

After clinical examination, the diagnostic algorithm for evaluating a thyroid nodule includes the following:

- Laboratory tests: thyroid stimulating hormone (TSH), triiodothyronine (T3), thyroxine (T4), antithyroid peroxidase antibodies, thyroglobulin, calcitonin
- Ultrasonography
- Nuclear medicine imaging (scintigraphy and positron emission tomography)
- Fine-needle aspiration (FNA)
- Computed tomography (CT)
- Magnetic resonance imaging (MRI)

Laboratory Tests

Laboratory tests are important for distinguishing different thyroid diseases, but thyroid function tests should not be used to determine whether a nodule is benign or malignant, even if the presence of clinical and laboratory signs of hyperthyroidism or hypothyroidism is most likely related to a benign nodule.

The serum TSH level allows assessment for thyrotoxicosis (<TSH) or hypothyroidism (>TSH).

Thyrotoxicosis may be due to a diffuse toxic goiter (Graves' disease), toxic multinodular goiter, or single toxic nodule (Plummer's disease).

The most common cause of hypothyroidism is Hashimoto's thyroiditis.

When the TSH level is normal, nodular aspiration should be considered.

Thyroglobulin levels are useful tumor markers once the diagnosis of malignancy has been assessed, but they are nonspecific with regard to differentiating a benign from a cancerous thyroid nodule (2).

Imaging

After physical examination, ultrasound is the first imaging modality for assessing thyroid disorders. CT and MRI have a small role, but specific indications include staging of cancer or evaluation of the extension of mediastinal goiter (3).

Ultrasonography

Ultrasonography with high-resolution probes is used to confirm the presence of a nodule, to determine whether it is a solitary nodule, and to assess any cystic component. It can also differentiate thyroid from adjacent nonthyroidal masses.

Ultrasonography is sensitive for identifying a focal lesion. In fact, it detects more nodules than palpation. It is suitable for evaluating the size, location, and structure of a nodule (solid or cystic, hypoechoic, hyperechoic, with or without halo sign, microcalcifications) (Fig. 1). In a solid hypoechoic nodule, irregular borders, central microcalcifications, prevalent, intranodular vascularity, and cervical adenopathies are the main signs suggesting malingnance.

Conversely, findings of hyperechoic texture, comet-tail artifacts from colloid, lack of blood flow in the nodule, a peripheric halo, and a smooth border.

Because ultrasonography cannot confidently distinguish benign from malignant nodules, FNA is necessary for this (4). Ultrasonography can guide the biopsy and be used to determine changes in the size of nodules over time, either in the follow-up of a lesion thought to be benign or in detecting recurrent lesions in patients with thyroid cancer (3, 4).

The predictive value of ultrasonography may significantly increase if the ultrasonographic parameters of thyroid nodules, such as microcalcifications, echogenicity, and halo sign, are combined with their vascular pattern. In fact, color Doppler and spectral analysis can demonstrate different vascular patterns as prevalent perinodular or central vascularization (Fig. 2). Many studies have shown that nodules with perinodular vascularization have a lower risk of malignancy than nodules with central vascularization.

Neoplasms, Thyroid, Benign and Malignant. Figure 1 Longitudinal section of the right lobe of the thyroid. Nodule with hypoechoic and dishomogeneous structure, regular borders with halo sign.

Neoplasms, Thyroid, Benign and Malignant. Figure 2 The nodule shows a rich periferic and intranodular vascularization at the evaluation with color Doppler.

CT and MRI

CT and MRI usually have no place in the assessment of patients with thyroid nodules, but nodules may be found incidentally during examination of the neck for reasons not relating to the thyroid gland. CT and MRI do play an important role in evaluating the mediastinal extension of thyroid masses and also in assessing the spread of cancer (3).

Nuclear Medicine

Scintigraphy

Scintigraphy is still the standard method for functional imaging of the thyroid (3). The two isotopes most commonly used are ^{123} I and ^{99m} Tc-pertechnetate.

Thyroid scanning measures the amount of iodine (usually ^{99m} technetium isotope) trapped within the nodule. A normal scan indicates that the iodine uptake is similar in both lobes of gland. A nodule is classified as "cold" (decreased uptake), "warm" (uptake similar to that of surrounding tissue), or "hot" (increased uptake). A large number of thyroid nodules may be cold on radionuclide scan, but only 5–15% of these are malignant. A "hot" nodule is hyperfunctional and is almost always benign.

Nuclear imaging cannot reliably distinguish between benign and malignant nodules and is not required if nodules are present.

FNA biopsy has replaced nuclear imaging as the initial evaluation procedure. However, in patients with a suppressed TSH level, thyroid scanning determines regional uptake or function and can be used as a secondary study (4).

Positron Emission Tomography

Positron emission tomography (PET) with 18F-fluorodeoxyglucose (FDG) is an imaging technique that might improve the diagnostic accuracy, allowing identification of metabolic alterations in tumors. At present it plays only a small role in thyroid imaging but can be particularly useful to evaluate metastatic disease. FDG PET measures the body's metabolic activity, and areas in which cancer is present will show up as brighter on the scan because the disease is more metabolically active than noncancerous cells.

Radiometabolic Therapy

Nuclear medicine plays a specific role in the ablative treatment of differentiated thyroid neoplasms. Ablation therapy is performed with ^{131}I and for the following indications:

- To destroy the small amount of thyroid tissue remaining in the neck after surgery
- To treat functional metastases
- To treat patients with elevated thyroglobulin levels

Before and after ablation therapy, a whole-body ^{131}I scan is necessary to identify metastatic disease and treatment response, respectively.

Diagnosis

For a diagnosis of thyroid neoplasm, evaluation of the patient should start with anamnesis, physical examination, and laboratory tests (TSH, T3, T4, autoantibodies). Ultrasonography should then be done to confirm the presence of a nodule or multiple nodules and their structural characteristics. If a solitary thyroid nodule is found, FNA biopsy should be performed to determine whether the nodule is malignant.

FNA biopsy is believed to be the most effective method available for distinguishing between benign and malignant lesions. This modality has a sensitivity of 68–98% and a specificity of 72–100%. The accuracy of FNA biopsy in diagnosing thyroid conditions depends highly on the expertise and experience of the cytopathologist and the technical skill of the physician performing the biopsy. The results of FNA are interpreted as benign, malignant, suspicious, or indeterminate. False-negative or false-positive cases may occur when nodules are very large or very small; these errors can be minimized by using ultrasound-guided biopsy.

To confirm a thyroid nodule or to obtain functional information, thyroid scintigraphy can be used. Although thyroid scanning may give a probability that a nodule is benign or malignant, it cannot truly differentiate benign from malignant nodules (5).

Synonyms

Proliferative disorders of the urethra; Tumors of the urethra

Definition

Urethral neoplasms include benign and malignant tumors, the latter being either primary tumors of the urethra or metastatic tumors. They are rare entities.

The urethra represents the distal part of the urinary tract. It extends from the bladder neck to the external urethral meatus.

Characteristics

Urethral neoplasms are rare entities with only a few reported series in the radiology literature. Herein, we review the anatomy and histology specific to male and female urethras. We also describe the imaging features of urethral tumors.

Normal Anatomy and Histology of the Male Urethra

The male urethra has a mean length of 18 cm and is subdivided into anterior and posterior portions, each of which is subdivided into two parts:

1. The posterior urethra stretches from the bladder neck to the lower edge of the urogenital triangle and includes:
   a. The prostatic urethra, which is 3 cm long in the young male, is the widest part of the canal. It is spindle-shaped and narrowest at its junction with the membranous urethra.

   On the floor of the canal is a narrow longitudinal ridge, the seminal colliculus. On each side of the ridge lies the prostatic sinus, a depressed fossa into

N

which the periurethral prostate ducts empty. At the summit of the seminal colliculus (verumontanum), lies the blind pouch of the prostatic utricle surrounded by the slit-like openings of the ejaculator ducts of the seminal vesicles.
   b. The membranous urethra, approximately 1.5 cm long, passes through the urogenital triangle, which contains the Cowper glands embedded in the external urethral sphincter. In this tract, the urethra is surrounded by the compressor muscle of the urethra and the perineal muscles.
2. The anterior urethra, 14–15 cm long is subdivided into:
   a. The bulbar urethra, which is of larger diameter (1.5–2 cm), is surrounded by the bulb of the corpus spongiosum, does not have stiff fascia, and extends from the perineal area to the suspensor ligament of the penis. Many small mucous glands of Littré are located at its inner surface.
   b. The penile or pendulous urethra, has a relative uniform diameter approximately 1 cm, stretching from the penile ligament to the external urethral meatus. Before its emergence at the meatus, there is an ampullar dilatation called fossa navicularis. Glands of Littré are also located near the fossa navicularis but fewer than in the bulbar urethra.

Because of its complex embryological origin, the urethral epithelial lining has several histological characteristics: transitional epithelium, from the bladder neck to the seminal verumontanum; then cylindrical, to the fossa navicularis, and, finally squamous epithelium, to the external meatus. These differences explain the histological diversity of urethral tumors.

Normal Anatomy and Histology of the Female Urethra

The female urethra is about 3–4 cm long, nearly equivalent to the length of the male posterior urethra. It extends from the internal urethral meatus at the bladder neck through the urogenital triangle to the external urethral meatus, anterior to the vaginal opening. A sit courses obliquely downward and forward, it is slightly curved with the concavity directed forward and upward. Multiple tiny urethral mucous glands, called the paraurethral glands of Skene, open into the urethral canal.

The same histological diversity as in males is found with transitional, cylindrical, and squamous epithelia.

The outer portion of the urethra is composed of striated muscle, which, in the upper two thirds of the urethra, is primarily circular and extends proximally to blend with the bladder base. The lower portion of the urethra is located close to the anterior vaginal wall and enveloped by common musculature (the compressor muscle of the urethra).

Pathological, Clinical, and Imaging Features

Clinically, these tumors are often heralded by obstructive voiding symptoms and hematuria, which clears near the end of micturition. On urethrograms, urethral tumors appear as filling defects and only the localization provides a clue to determine the origin. Biopsy is mandatory to establish the correct diagnosis.

Benign Tumors

For both men and women, condylomata are found on the anterior urethra: it is the most common abnormality.

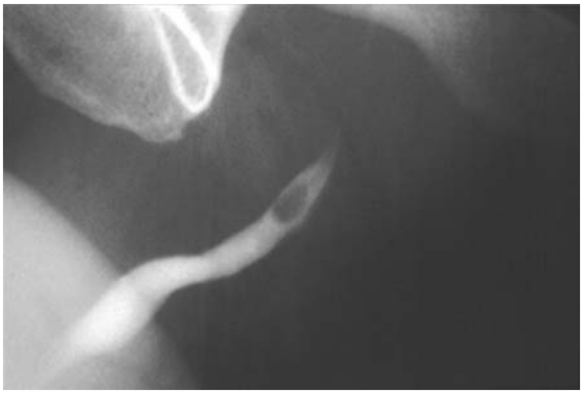
Benign tumors of the urethra are very rare: they may be of epithelial or mesenchymal origin. In women, leiomyoma of the urethra is extremely rare.

In men, a fibroepithelial polyp is of embryonic origin, usually originating in the prostate and projecting into the urethra. The polyp is connected to the verumontanum *via* a stalk, which maintains the polyp in the prostatic urethra or, sometimes, with extension through the bladder neck into the bladder (Fig. 1). MRI cannot differentiate between benign and malignant tumors.

Malignant Tumors of the Male Urethra

Carcinoma of the male urethra is rare, representing less than 1% of all urological cancers, and predominantly concerns men over 50 years old.

Tumors of the male urethra are classified according to their location and histological diversity.



Neoplasms, Urethra. Figure 1 Voiding ►urethrography. Polyp arising from the anterior urethra. (Reprinted with permission from Helenon et al, 2005)

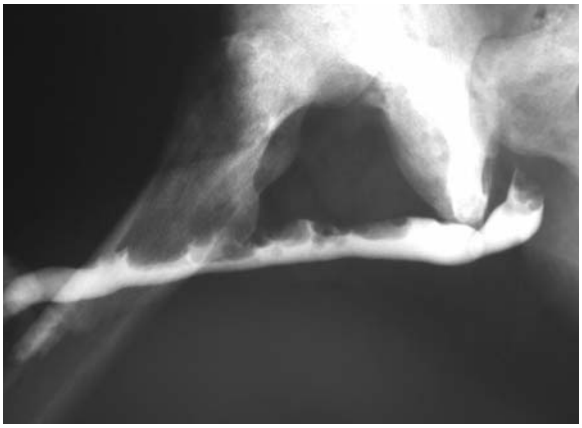
The bulbomembranous urethra is the most frequent site (around 60% of cases), followed by the penile urethra (30%) and the prostatic urethra (10%).

Histologically, 80% of male urethral carcinomas are squamous cell carcinomas, 15% are transitional cell carcinomas, and 5% are adenocarcinomas or undifferentiated carcinomas. The histological subtype of urethral cancers also varies according to the anatomical location. The prostatic urethra gives rise to transitional cell carcinomas in 90% of patients and squamous cell carcinomas in 10%. In the bulbomembranous, squamous cell carcinomas develop in 80% of patients, transitional cell carcinomas in 10%, and adenocarcinomas or undifferentiated carcinomas in 10%. In the penile urethra, squamous cell carcinomas represent 90% of the patients and transitional cell carcinomas the remaining 10%. Adenocarcinomas arise from the Littré or Cowper glands (Fig. 2).

►Urethritis secondary to sexually transmitted infectious disease can cause urethral stricture and is considered a risk factor for malignancy. In fact, more than 50% of patients with a carcinoma of the urethra have a history of urethral stricture, which is always symptomatic and the stricture is most frequently located in the bulbomembranous urethra (most common site of urethral carcinomas).

Urethral Cancer Staging System

1. Ta—Noninvasive carcinoma
2. Tis—Carcinoma *in situ*
3. T1—Tumor is confined to the subepithelial connective tissue
4. T2—Tumor invades the prostate, periurethral muscle or the corpus spongiosum
5. T3—Tumor invades the corpus cavernosum, the bladder neck or beyond the prostatic capsule
6. T4—Tumor invades other adjacent organs
7. N0—No regional lymph node metastasis
8. N+—Evidence of regional lymph node involvement
9. M0—No evidence of distant spread of disease
10. M+—Evidence for distant spread of disease.



Neoplasms, Urethra. Figure 2 **Retrograde urethrography. Multiple recurrent tumors of a transitional cell carcinoma. (Reprinted with permission from Helenon et al, 2005)**

Male urethral carcinomas can disseminate directly to adjacent structures or metastasize to regional lymph nodes. The lymphatic vessels from the anterior urethra drain into the superficial and deep inguinal lymph nodes and, occasionally, into the external iliac lymph nodes. Tumors of the posterior urethra most commonly spread to the pelvic lymph nodes.

On MR images, urethral tumors have signal intensity similar to or lower than that of the surrounding the corpus cavernosum on T1-weighted images and intermediate to low signal intensity on T2-weighted images. On contrast-enhanced MR images, the tumor usually shows mild enhancement. Sometimes, it has very high signal intensity on T2-weighted images due to associated inflammation.

MRI can be especially useful for local staging (extension into the tunica albuginea or septa of the corpus cavernosum) and for detection of tumors that invade the root of the penis when physical examination is poorly accessible.

Surgical excision is the primary treatment of choice: anterior urethral carcinoma usually has a better prognosis than posterior urethral carcinoma, which is often associated with extensive local invasion and distant metastases.

Malignant Tumors of Female Urethra

Carcinoma of the female urethra is four times more frequent than that of the male urethra but still remains an uncommon pathology (less than 0.01% of all carcinomas in women). It predominantly affects women over 50 years old with risk factors, such as chronic irritation, urinary tract infection, and proliferative lesions, such as caruncles, papillomas, adenomas, polyps, and leukoplakia of the urethra.

Anterior (40% of cases) and posterior urethral cancers (60% of cases) can be distinguished.

Anterior tumors are located in the distal third of the urethra and the lymphatic drainage empties into the superficial and deep inguinal nodes. Local surgical excision is the treatment of choice for these lesions.

Because the posterior urethra lymphatic vessels drain into the external iliac, hypogastric and obturator nodes, local spread to the bladder neck and trigone explain the poor prognosis: fewer than 10% of women are still alive at 5 years with a 4 cm tumor. For such advanced lesions, combined surgery, radiation therapy, and, possibly, chemotherapy is necessary.

Two thirds of urethral carcinomas are squamous cell carcinomas, followed by transitional cell carcinomas (20%), adenocarcinomas (10%), undifferentiated tumors and sarcomas (8%), and melanomas (2%).

Urethral Cancer Staging System

1. Ta—Noninvasive carcinoma
2. Tis—Carcinoma *in situ*
3. T1—Tumor is confined to the subepithelial connective tissue
4. T2—Tumor invades periurethral muscle
5. T3—Tumor invades the anterior part of vagina or bladder neck
6. T4—Tumor invades other adjacent organs
7. N0—No regional lymph node metastases
8. N+—Evidence of regional lymph node involvement
9. M0—No evidence of distant spread of disease
10. M+—Evidence of distant dissemination.

On MR images, the tumor has low signal intensity on T1-weighted images and relatively high signal intensity on T2-weighted images. The size of the tumor is best evaluated on sagittal T2-weighted images. Tumors in the distal urethra may extend into the adjacent perineum and the target-like appearance of the normal urethra on axial T2-weighted images may be disrupted. MR is helpful in evaluating the size, location, and local extension of urethral tumors. Its accuracy to assess local tumor extension has been reported to be 90%.

Metastatic Tumors of the Urethra

Metastatic tumors are uncommon and mainly concern the male urethra. Bladder carcinomas may spread to the anterior urethra by means of seeding during urethral instrumentation or at cystectomy. The corpus spongiosum can become involved by carcinoma spread from the spermatic cord, testis, prostate and rectum, and can be responsible for extensive urethral narrowing and irregularity. Hematogenous metastases of malignant melanoma and primary prostate, bladder, colonic, testicle or kidney cancer to the corpora cavernosa and corpus spongiosum have been reported.

In conclusion, the diagnosis is based on urethrography detecting a nonspecific filling defect. MRI is unable to differentiate between benign and malignant tumors, making biopsy mandatory. The aim of MRI is to help stage the malignant tumor to determine the best strategy of treatment.

Synonyms

Nephro- and urolithiasis; Urinary tract calculus; Urinary tract stone

Definition

Nephrocalcinosis (NC) is a microscopic renal tubular or interstitial calcification. Depending on the location a medullary, a cortical or a diffuse type can be differentiated. Note that in a variety of diseases urolithiasis and NC may occur simultaneously, with urolithiasis being a sequelae of the underlying disease that causes NC. Urolithiasis is defined as macroscopic calcification in the urinary collecting system. Urinary stones are composed of crystal agglomerations, sometimes mixed with proteins that form at the papillae, the epithelium or in the collecting system.

Embryology and Pathogenesis

Causes are infection (particularly in children), hypercalciuria, cystinuria or oxaluria (potentially familial), as well as impaired inhibitor function such as low citrate excretion, some (diuretic) drugs and various metabolic disorders (e.g. Bartter's syndrome). Incidence varies widely with a large geographic distribution (more common in the far and middle east), with some age (typical medullary changes in pre-term newborns), gender (boys affected more often than girls), composition (uric acid stones are extremely rare in children) and race variation (less often in black people). Urinary calculi can occur in the kidney, the ureter and the urinary bladder, the latter—as a primary condition—becoming rare. NC and urolithiasis is less common in children than in adults. They should always give reason for a thorough investigation (metabolic causes, familial disease, underlying renal or urinary tract condition) (Table 1).

Clinical Presentation

Nephrolithiasis and urinary tract calculi as well as NC may be clinically asymptomatic; if stones cause obstruction they present with pain, colic, (micro-) haematuria, (secondary) urinary tract infection. In nephrolithiasis clinical presentation depends on the underlying condition and the stage of the disease, ranging from asymptomatic patients to renal insufficiency and urolithiasis with all its potential symptoms.

Imaging

Imaging usually relies on detailed ultrasound (US) as the initial study. There NC is seen as an increased echogenicity of the affected structure that may start with just an increased echogenicity of the cortico-medullary junction, with an inversion of the normal renal parenchymal pattern in medullary NC, an increased cortico-medullary differentiation with a very echogenic cortex in cortical NC, or a diffusely increased echogenicity with loss of differentiation in the diffuse type (Fig. 1). Using the location and amount of echogenicity changes (that correspond with the degree of the disease) US offers a grading possibility (Table 2). In long-standing disease, these areas may eventually become very echogenic and exhibit a stone-like appearance, obviating analysis of the deep renal structures.

Stones—if calcified—sonographically are echogenic and cause posterior acoustic shadowing as well as (often) a twinkling artefact on colour Doppler sonography (CDS) (Fig. 2). Note that for visualisation of a calculus in the

(a) Axial view of grey scale US depicts the echogenic calculus in the renal pelvis (but only little shadowing). (b) Twinkling colour signals on colour Doppler sonography (CDS) in the same view caused by the calculus.

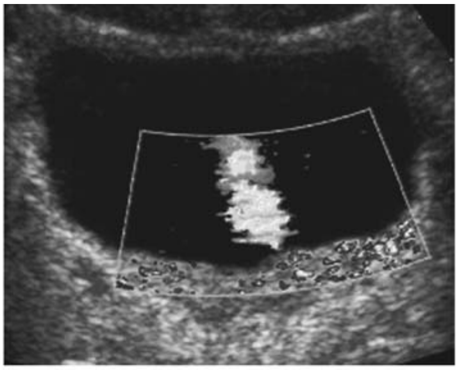
US is usually supplemented by an abdominal *plain film* focused at the kidney, ureter and bladder region ('KUB'). Age-adapted exposure and film-screen combinations should be chosen. It demonstrates calcification projecting on the urinary tract structures.

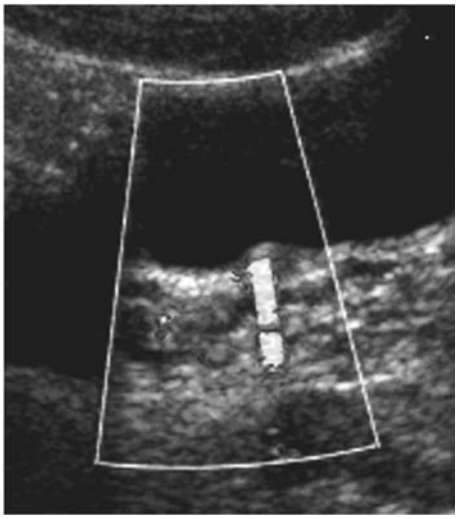
Intravenous urography (IVU) is hardly necessary in children, only in some rare cases, where US and KUB cannot sufficiently diagnose the condition it may become indicated. If applied, age-adapted contrast dose and selected number of individually timed exposures should be used for a tailored investigation to reduce radiation burden.

In difficult cases or complex disease, spiral (multislice) CT is the best method for looking at urolithiasis and particularly ureteral stones. Usually un-enhanced low dose protocols suffice. Only for differentiation of tumour-like lesions with calcifications (e.g. xanthogranulomatous pyelonephritis, tuberculosis) intravenous iodinated contrast is recommended. MR has currently no role in investigating nephrolithiasis and NC in children.

Diagnosis

Diagnosis is made by imaging, with functional information important for clinical decision making, particularly in urolithiasis with colic and acute obstruction. Usually a detailed US study of a properly hydrated urinary tract at sufficiently extended bladder supplemented by a KUB-film—together with clinical and laboratory information—suffices for making the diagnosis in





Nephrocalcinosis and Urolithiasis in Childhood. Figure 3 Colour Doppler sonography (CDS) of the bladder in urolithiasis. infants and children and reveals all treatment relevant information (Table 3). Rarely IVU or CT may become necessary.

Follow-up—particularly in NC—is usually performed by US; and often US appearance persists even when the underlying disease is treated and has diminished or ceased.

Nerves, Cranial

Tarek A. Yousry, Indra Yousry
Institute of Neurology, London, UK
t.yousry@ion.ucl.ac.uk

Definitions

Cranial nerves are the means by which the brain receives information from, and controls the activities of the head, neck and to a lesser extent the thoracic and abdominal viscera. The cranial nerves (CN) consist of 12 pairs of which the CN III–XII are genuine peripheral nerves.

The olfactory tract and the optic nerve are parts of the brain, because their fibres are medullated by oligodendrocytes (central glial cells). The other cranial nerves (CN III–XII) have segments of variable length covered by central glia. These segments are considered to be part of the brain and are known as the root entry or exit zones. These zones are important as symptomatic neurovascular contacts only occur at their site. The central segments of the motor nerves are shorter than those of the sensory nerves; the longest central segment however, is found in CN VIII.

The *olfactory nerve*s (CN I) are the only sensory cranial nerves that project directly to the cerebral cortex rather than *via* the thalamus. They arise from nerve cells within the olfactory mucosa that coats the superior part of the middle and lateral walls of the nasal cavity. They pass through the cribriform plate of the ethmoid bone and terminate in the olfactory bulbs (Fig. 1a). From here the olfactory tract passes posteriorly and terminates by forming three striae: the lateral, the intermediate and the medial olfactory striae.

The *optic nerve* (CN II) is constituted by a great number of nervous fibres arising from cells in the retina which converge towards the optic disc and, pass through the sclera and choroid membranes, and as they emerge from the eyeball form the optic nerve. CN II passes through the orbital cavity, optic canal and ends at the optic chiasm (Fig. 1a).

The *oculomotor nerve* (CN III) is a motor nerve. Its nuclei are situated at the level of the superior colliculus. The nerve emerges along the internal margin of the cerebral peduncle, passes through the interpeduncular fossa to enter the lateral wall of the cavernous sinus (Fig. 1b). It then passes through the superior orbital fissure into the orbit. It innervates the superior, inferior and medial recti as well as the levator palpebrae. CN III also carries parasympathetic fibres to the sphincter ciliary muscles of the pupil.

The *trochlear nerve* (CN IV) is a motor nerve. Its nucleus is situated at the level of the inferior colliculus. It crosses the midline and exits at the posterior surface of the mesencephalon below the inferior colliculus (Fig. 1c). It then travels around the mesencephalon, enters the lateral wall of the cavernous sinus, passes through the superior orbital fissure into the orbit where it innervates the superior oblique muscle.

The *trigeminal nerve* (CN V) has motor and sensory nuclei. The motor nucleus is located in the pons, the sensory nuclei extend in the brainstem from the mesencephalon to the cervical spinal cord. CN V emerges from the pons with a large sensory root and small superior and inferior motor roots (Fig. 2a). All roots enter the trigeminal cavity (Meckel's cave) where the sensory root continues into the trigeminal ganglion and then provides three main branches. The ophthalmic nerve (V1) enters the lateral wall of the cavernous sinus, and passes through the superior orbital fissure into the orbit. The maxillary nerve (V2) enters the lateral wall of the cavernous sinus, and passes through the foramen rotundum into the pterygopalatine fossa. The mandibular nerve (V3) carries in addition to the sensory fibres the motor fibres of the trigeminal cavity. It passes through the foramen ovale.

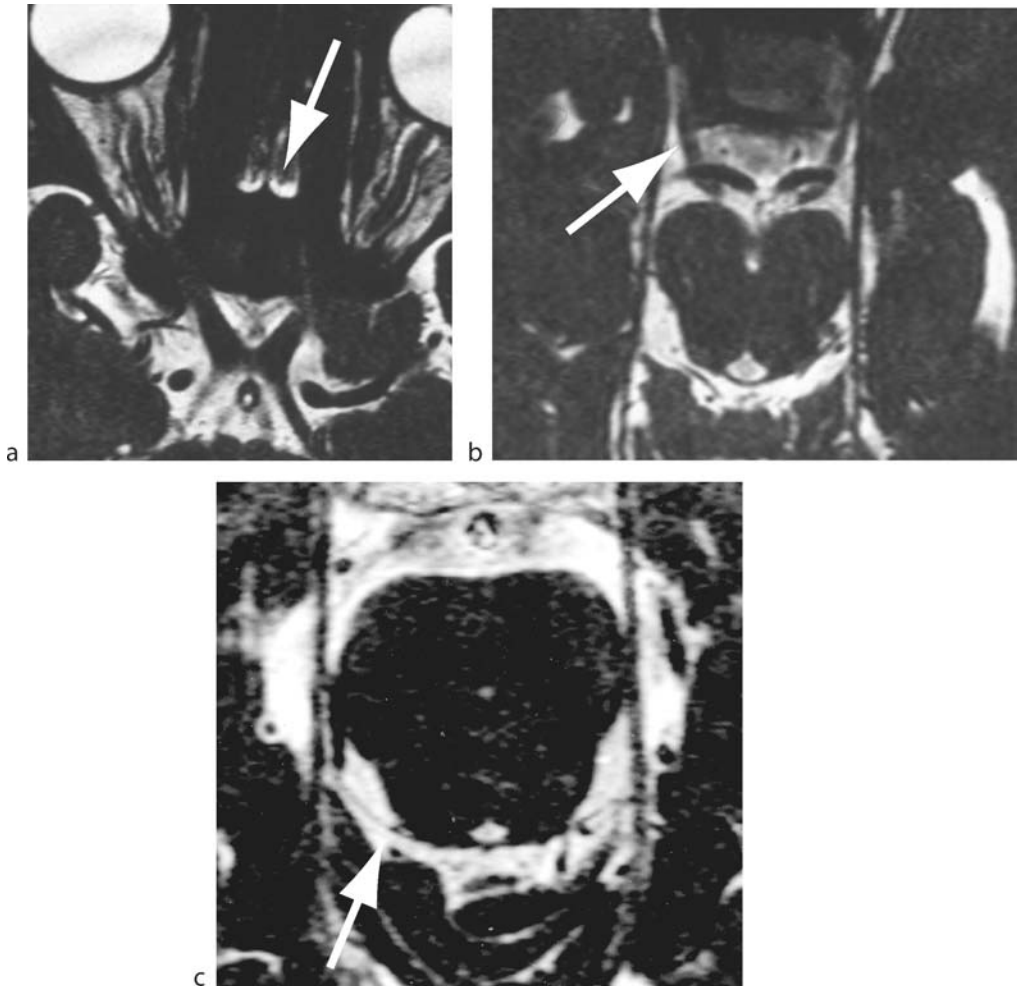
The *abducens nerve* (CN VI) is a motor nerve. Its nucleus is situated at the lower level of the pons. CN VI exits the brainstem at the pontomedullary junction (Fig. 2b). It then travels through the pontine cistern, enters the cavernous sinus through Dorello's canal, and passes through the superior orbital fissure into the orbit where it innervates the lateral rectus muscle.

The *facial nerve* (CN VII) has motor and sensory nuclei. The motor nucleus is located at the floor of the 4th ventricle. The motor fibres for the viscera (parasympathetic) arise from the superior salivatory nucleus and the lacrimal nucleus. The visceral sensory fibres terminate in the nucleus solitarius in the dorsal medulla oblongata.

The motor (CN VII) and the sensory (CN VIIb, intermediate) nerve roots exit the brainstem at the pontomedullary junction and enter the internal auditory meatus (Fig. 2c). CN VII then enters the facial canal and exits the skull through the stylomastoid foramen. The parasympathetic fibres of the lacrimal nucleus and visceral sensory fibres pass as the greater petrosal nerve through the Vidian canal.

The *vestibulocochlear nerve* (CN VIII) is a sensory nerve which consists of the cochlear and the (superior and

N



Nerves, Cranial. Figure 1 CISS images showing the olfactory nerve (*arrow*, a), optic nerve (*arrowhead*, a), oculomotor nerve (*arrow*, b) and trochlear nerve (*arrow*, c).

inferior) vestibular nerves (Fig. 2c, d). The cochlear as well as the vestibular nuclear complex are located in the dorsolateral side of the brainstem at the level of the pontomedullary junction. The medial vestibular nucleus bulges into the 4th ventricle as the 'vestibular area'. The nerve enters the pons at this level coming from the internal auditory canal.

The *glossopharyngeal nerve* (CN IX) is a mixed nerve. The motor fibres arise from the ambiguous nucleus located in the medulla oblongata. The motor fibres for the viscera (parasympathetic) arise from the inferior salivatory nucleus. The visceral sensory fibres terminate in the nucleus solitarius in the dorsal medulla oblongata. CN IX emerges from the posterolateral sulcus of the medulla oblongata, traverses the premedullary cisterns and exits the skull through the anterior compartment of the foramen jugulare.

The *vagus nerve* (CN X) is a mixed nerve. The motor fibres arise from the ambiguous nucleus in the lateral medulla oblongata. The motor fibres for the viscera arise from the dorsal nucleus of the vagus nerve, which bulges into the 4th ventricle as the vagal trigone. The visceral sensory fibres terminate in the nucleus solitarius in the dorsal medulla oblongata. CN X emerges from the posterolateral sulcus of the medulla oblongata and exits the skull together with the nervus accessorius through the intermediate space of the foramen jugulare (Fig. 3a).

The *accessorius nerve* (CN XI) is a motor nerve with two roots. The cranial root arises from the nucleus ambiguous and exits the medulla oblongata anterior to the posterolateral sulcus (Fig. 3b). The spinal root arises from the spinal accessory nucleus in the lower medulla and the upper five spinal cord segments. It courses between the dorsal and ventral roots of the upper cervical nerves, enters the foramen magnum and joins the cervical root in the intermediate portion of the jugular foramen.

The *hypoglossal nerve.* (CN XII) is a motor nerve. Its nucleus is located in the posterior medulla oblongata,

N

causing a bulging of the floor of the 4th ventricle, the hypoglossal trigone. The nerve rootlets emerge from the preolivary sulcus, pass through the premedullary cistern, and pass through the hypoglossal canal as one trunk.

Imaging

The visualisation of the cranial nerves is a function of the thickness of the nerves and of anatomic properties of the segment that is to be identified.

Anatomically the cranial nerves III–XII can be divided into the following segments: (i) intramedullary,(ii) cisternal, (iii) foraminal and (iv) extracranial segments.

Nuclei. The cranial nerve nuclei are currently not accessible to conventional *in-vivo* MR imaging. Some nuclei however, can be identified through the bulges they cause in the floor of the 4th ventricle. These are the nuclei of CN VI (facial colliculus), CN VIII (vestibular area), CN X (vagal trigone) and CN XII (hypoglossal trigone). These bulges are important landmarks for the identification of the corresponding nuclei.

Intramedullary segments. The intramedullary segments are currently not accessible to conventional *in-vivo* MR imaging. However, tractography has the potential to visualise those segments in the future.

Cisternal segments. The visualisation of the various cranial nerves in their cisternal course is determined by, among other factors, the anatomic properties of each individual nerve such as the nerve's diameter, the course and the amount of surrounding cerebrospinal fluid (CSF). The small diameter of some of these nerves is in many instances the main reason for the difficulties encountered in visualising them.

The larger nerves can be well visualised with the regularly used T2 FSE sequences. The smaller nerves can be usually identified with that sequence, though the reliability increases with the use of sequences with a cisternographic effect (3D CISS, 3D DRIVE and FIESTA). Some nerves, for example the trochlear nerve, can only be identified when using these sequences.

A problem encountered when using the CISS, 3D DRIVE and FIESTA sequences is the differentiation of nerves and vessels. This can be achieved by combining the 3D CISS sequence with a plain and an enhanced TOF sequence. The comparison of the source images with the 3D CISS images in the appropriate plane will allow the differentiation of nerves, arteries and veins. It is this combination that enabled the reliable identification of the smallest cranial nerves, CN IV. This combination of sequences also enabled for the first time the reliable identification of an arterial neurovascular contact at the root exit zone of the trochlear nerve in patients with 'superior oblique myokymia', thus supporting the neurovascular compression hypothesis.

The 3D CISS, 3D DRIVE and FIESTA sequences, are therefore the standard sequences to be used in the evaluation of cranial nerves. A further improvement in imaging resolution can be achieved at higher field strength such as 3T.

Foraminal segments. The foraminal segments of CN V1, V2, V3, IX–XII as well as the cavernous segments of CN III, IV, V1 and VI are best visualised on MR using contrast-enhanced 3D CISS, MPRAGE or TOF sequences. The evaluation of the bony structures, however, is best performed by high resolution computed tomography (HRCT).

Definition

Malignant round cell tumor arising from the ►adrenal medulla (commonest), premature neuroblasts of the embryonic neural crest and sympathetic ganglia.

Incidence

The third most common malignancy of childhood after leukemia and primary brain neoplasm.

Neuroblastoma accounts for about 10% of all pediatric neoplasms and is the commonest extracranial solid tumor.

In the majority of cases, it presents between 2 months and 2 years of age, but the lesion may also present in the neonatal period. The tumor is slightly more common in boys than girls, with familial incidence reported.

Pathology/Histopathology

Neuroblastoma is composed of small round cell that characteristically arranged in rosettes. ►Ganglioneuroma represents the most differentiated end of the spectrum and is benign. ►Ganglioneuroblastomas represents an intermediate mixed group.

Approximately two-thirds of the tumors are located in the abdomen, followed by tumors arising in the paravertebral sympathetic chain or the presacral soft tissue region. It can spontaneously transform into more benign ganglioneuroma(blasto)ma.

The International neuroblastoma staging system (INSS) defines the significance of tumor resectability, anatomic "midline," and lymph node involvement (Table 1).

Clinical Presentation

Neuroblastoma is clinically silent until it invades adjacent structures. Symptoms may include bone pain, fever, weight loss, anemia, and hypertension (10%). Two-thirds demonstrate excess of urinary catecholamine excretion and present with flushing, sweating, and irritability. Leg edema due to tumor compression of veins may occur.

Paraneoplastic syndromes may occur and present with myoclonus and watery diarrhea. Horner syndrome can be a clinical presentation of a cervical tumor location. Syndromes associated with neuroblastoma include Beckwith-Wiedemann, Klippel–Feil, and fetal alcohol.

Neuroblastoma. Table 1 The international neuroblastoma staging system (INSS)

Stage	Description
I	Localized tumor confined to the area of origin complete gross excision
IIA	With or without microscopic residual
IIB	Unilateral tumor with incomplete gross excision; ipsilateral and
III	Contralateral lymph node negative microscopically
IV	Unilateral tumor with complete or incomplete gross excision with
IVS	positive ipsilateral regional lymph node identifiable, but the contralateral lymph nodes are negative microscopically.
	Tumor crosses the midline
	Distant metastases
	Metastatic disease confined to liver, skin, and bone marrow, with the primary tumor stage 1 or 2. (Age <1 year)

Imaging

Conventional radiographs may reveal a mass that in two-third of the cases contains calcification (stippled, diffuse, amorphous). Widening of the interpedicular distance and paravertebral mass may be seen on plain abdominal X-ray.

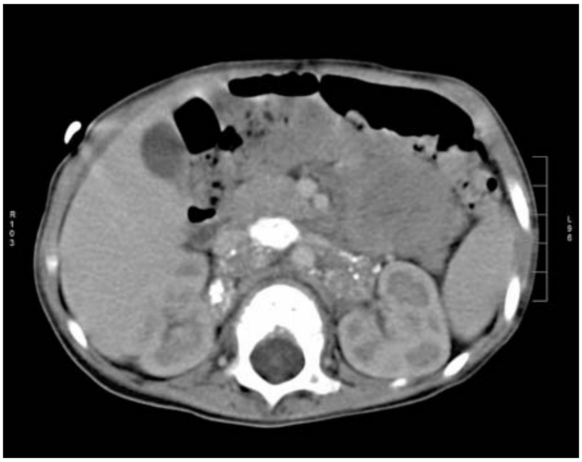
Ultrasound (US) is used as the screening modality for suspected abdominal pathology and shows the organ of origin, liver metastases, and identifies tumor encasement of vessels. The tumor is inhomogeneous on US. It has hypoechoic regions due to hemorrhage, necrosis, or cyst formation and hyperechoic regions due to calcification (Fig. 1). Mainly cystic lesions may be present particularly in neonates.

CT is superior to US in defining the extent and retroperitoneal spread of the primary tumor (Fig. 2). It reveals tumor calcification in about 85% of the patients. The lesions have an attenuation equal to or less than that of the muscle. Enhancement is heterogeneous after contrast injection.

MRI has advantages over CT in that extension to the vertebrae canal, bone marrow involvement, encasement of the superior mesentery artery (SMA) and other vessels can be better evaluated.

Neuroblastoma. Figure 1 Neuroblastoma shows inhomogeneous tumor originating from the adrenal gland indenting the renal upper pole.

N



Neuroblastoma. Figure 2 CT image shows masses containing calcifications originating from both adrenal glands highly suggestive for bilateral neuroblastoma.

The lesion shows a low signal on T1 and high signal on T2 weighted images (WI). Inhomogeneous intensity is a result of necrosis. Neuroblastoma rarely invades into major veins, which occurs more frequently in the case of Wilms' tumor.

Nuclear

Tc 99mMDP identifies bone metastases, commonly located in the metaphyseal regions of long bones and the cranium. I123MIBG uptake occurs in the metabolically active neural crest tumor and this agent can detect primary, recurrent, and metastatic disease.

Diagnosis

Bone marrow aspirate is performed for bone marrow invasion. Increase of urinary catecholamine metabolites (vanillylmandelic acid, homovallic acid, and 3-methoxy-4-hydroxyphenylglycol) is very sensitive sign for the diagnosis.

Differential diagnosis: Suprarenal mass include.

Wilms tumor:
–calcification uncommon
–pelvocliceal distortion (arise from kidney)
–lung metastasis in 20% (neuroblastoma uncommon)
–mean age 3 years (neuroblastoma less than 2 years)
–more frequently invades into major veins

Neonatal adrenal hemorrhage
–avascular
–low signal in T2WI
–resorption in follow up examination

Pheochromocytoma
–mostly occur above 6 years of age
–US: hypoechoic, partly solid mass with small cyst.

Congenital malformation; Ectodermal; Phakomatoses

Definitions

Neurocutaneous syndromes are multisystem disorders affecting mainly structures of ectodermal origin, for example, the skin, the eye, and the nervous system. Although there is a long list of hereditary phakomatoses, the most common include ▶neurofibromatosis type 1 (NF1), ▶tuberous sclerosis, ▶Sturge–Weber syndrome, and von Hippel–Lindau disease (1). The central nervous system is usually involved early during antenatal brain maturation.

Pathology/Histopathology

Although various organs can be involved in neurocutaneous syndromes, the focus of this section is only on central nervous system abnormalities. NF1 involves intracranial as well as cutaneous tumors. While the cutaneous lesions are neurofibromata, the intracranial tumors are often gliomata, involving the anterior visual pathway in particular. In addition, dysplastic lesions can be observed, for example, dural ectasia and skull base bone dysplasia.

Tuberous sclerosis is an autosomal dominant disorder and as a result of the abnormal expression of the genes in the stem cells of the germinal matrix, a maldevelopment occurs. This results in cortical malformations, subependymal abnormalities, as well as white matter abnormalities and the development of tumors at the foramen of Monro.

The pathology in Sturge–Weber syndrome is different and represents a vascular malformation. The abnormality affects multiple meningeal capillaries and small veins. This probably results from a persistence of embryonic vascularization that is present between the fourth and the eighth week of gestation. Often, cortical calcifications are seen in the brain adjacent to this meningeal angiomatosis and these may reflect chronic ischemia due to an ineffective venous drainage.

von Hippel–Lindau disease is another autosomal dominant disorder known as central nervous system angiomatosis. Apart from the occurrence of tumors in various organs, more than one hemangioblastoma is found in the central nervous system.

Clinical Presentation

The observation of café-au-lait spots is often the first manifestation of NF1. The most important central nervous system manifestation is glioma of the anterior visual pathway (2). These may be asymptomatic or may present with loss of vision. Occasionally these gliomas may regress spontaneously. Specific diagnostic criteria exist for NF1. These include, apart from the two already-mentioned abnormalities, plexiform neurofibromata, dysplastic bone lesions, axillary or inguinal freckling, and hamartomata of the iris.

The typical clinical presentation of tuberous sclerosis consists of at least one of the following primary features: adenoma sebaceum (peri)ungual fibroma, cerebral hamartoma (calcified), subependymal tubers, and a fibrous plaque of the forehead; in addition, there should be at least two of the following secondary features: cutaneous lesions, infantile spasms, ocular hamartomata, angiomyolipoma, cardiac rhabdomyoma, and a first-degree relative with tuberous sclerosis.

The typical clinical feature of Sturge–Weber syndrome is the facial port-wine nevus involving the distribution of the trigeminal nerve branches on the same side as the intracranial angiomatosis. Seizures and developmental delay are often present. The characteristic occipital involvement of meningeal angiomatosis can cause homonymous hemianopia.

The clinical presentation of von Hippel–Lindau disease is related to the presence of a neoplasm in the central nervous system or elsewhere. It has been suggested that to diagnose this autosomal dominant disorder one must have at least one cerebellar or retinal hemangioblastoma in addition to a renal tumor, a pheochromocytoma, or a cyst (in the kidney, liver, or pancreas).

Diagnosis

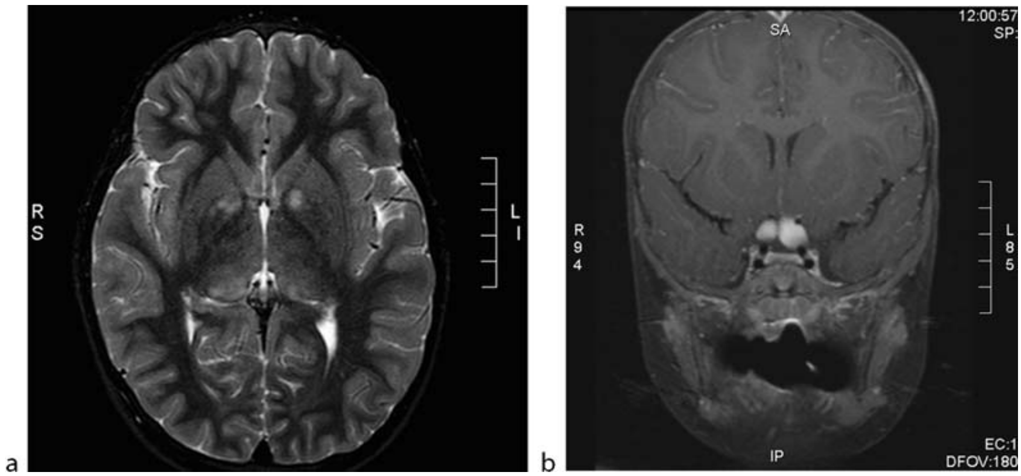
The imaging aspects of the four common neurocutaneous syndromes will be briefly reviewed.

Gliomata involving the anterior visual pathway are common in NF1 and they may extend into the optic radiation. They may show a variable degree of enhancement (Fig. 1). There have been reports on spontaneous regression, but most are slowly progressive tumors. Occasionally, brain stem gliomas can be seen and plexiform neurofibromas involving the skull base. A typical finding in NF1 is the occurrence of bright lesions in the cerebral and cerebellar gray nuclei (Fig. 1). These abnormalities do not enhance and are asymptomatic. The underlying pathogenesis remains unknown. They are often referred to as hamartomata. They appear during the first year of life and tend to disappear in the second decade.

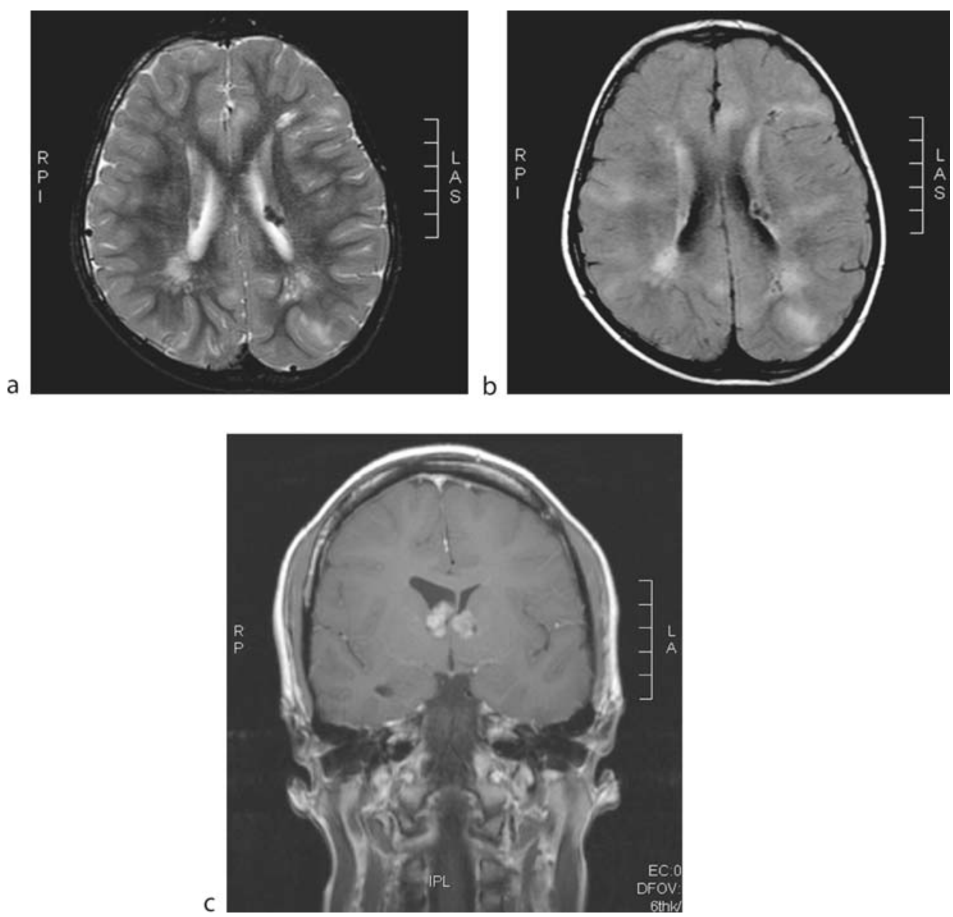
Intracranial manifestations of tuberous sclerosis include subependymal (calcified) hamartomata, subependymal giant cell tumors, cortical tubers, and (linear) white matter abnormalities (3).

Generally, subependymal hamartomata do not enhance and are commonly located in the region of the foramen of Monro. In the first 2 years of life, they are not yet calcified and may be difficult to recognize on computed tomography (CT) images (Fig. 2). It has been demonstrated that these subependymal lesions can show a variable degree of enhancement without any suspicion of development of a giant cell astrocytoma. However, when there is evidence of progressive growth with obstruction at the foramen of Monro, the lesion should be considered a giant cell astrocytoma warranting further treatment (Fig. 2).

Cortical tubers are the most characteristic from a pathological point of view. They are related to the abnormal process of proliferation, migration, and organization of the cortex. They may be difficult to depict on CT, but are clearly seen on magnetic resonance imaging (MRI), particularly on fluid-attenuated inversion-recovery (FLAIR) images (Fig. 2). Occasionally, they may calcify. These lesions are histologically identical to the focal cortical dysplasia with balloon cells. Their



Neurocutaneous Syndromes. Figure 1 **Neurofibromatosis type 1. MRI shows the presence of hamartomata in the globus pallidus on both sides (a). Coronal contrast-enhanced images demonstrate a chiasmatic glioma (b).**



Neurocutaneous Syndromes. Figure 2 **Tuberous sclerosis. T2-weighted (a) and FLAIR (b) images show the different characteristic features: subependymal hamartomata, cortical tubers, and linear white matter lesions. Note that these lesions are seen better on the FLAIR image (b). The enhancing mass at the foramen of Monro is the typical presentation of a giant cell astrocytoma (c).**

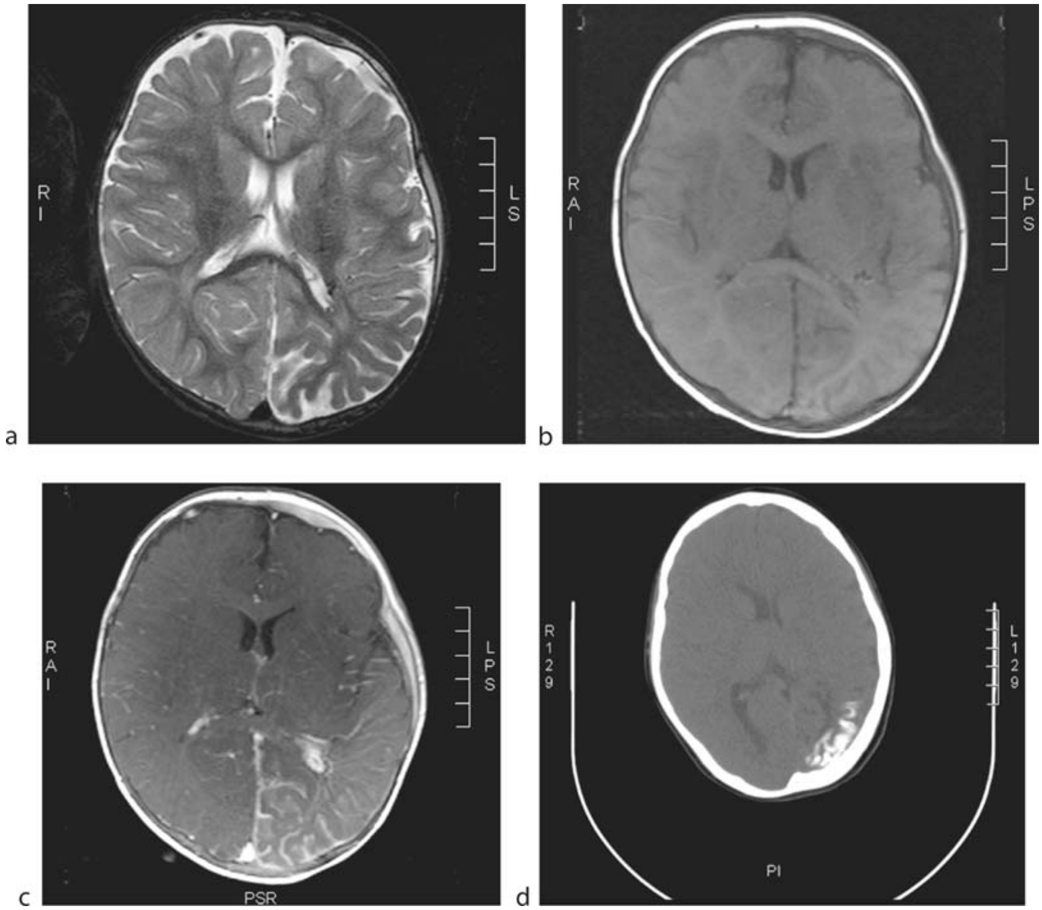
appearance changes as myelination progresses from a low signal to a high signal on T2-weighted images. The high signal of the "mature" cortical tuber results from the presence of astrogliosis, seen on histology sections.

Finally, white matter abnormalities can be observed in tuberous sclerosis (Fig. 2). Histologically, they contain giant neurons and dysplastic balloon cells. Although calcification is rare, it can be seen. One of the particularities of these lesions is the fact that they can be seen to extend in a curvilinear or linear way from the ependymal surface toward the cortex.

Although CT is accurate in demonstrating the cortical calcification in Sturge–Weber syndrome, MRI is more sensitive for imaging pial angiomas (Fig. 3). The changes on the T2-weighted images can be subtle and may be limited to a mild decrease in the signal intensity of the white matter or a mild degree of cortical atrophy (Fig. 3). On contrast-enhanced images, a pial or meningeal enhancement will be seen (Fig. 3). The angioma will compromise the superficial venous flow. Usually, the parietal and occipital lobes will be involved. Enlarged vascular structures may be seen in the periventricular region, most likely representing hypertrophic venous drainage. The ipsilateral choroid plexus is frequently enlarged (Fig. 3). This phenomenon is thought to reflect the increased venous drainage through the deep venous system.

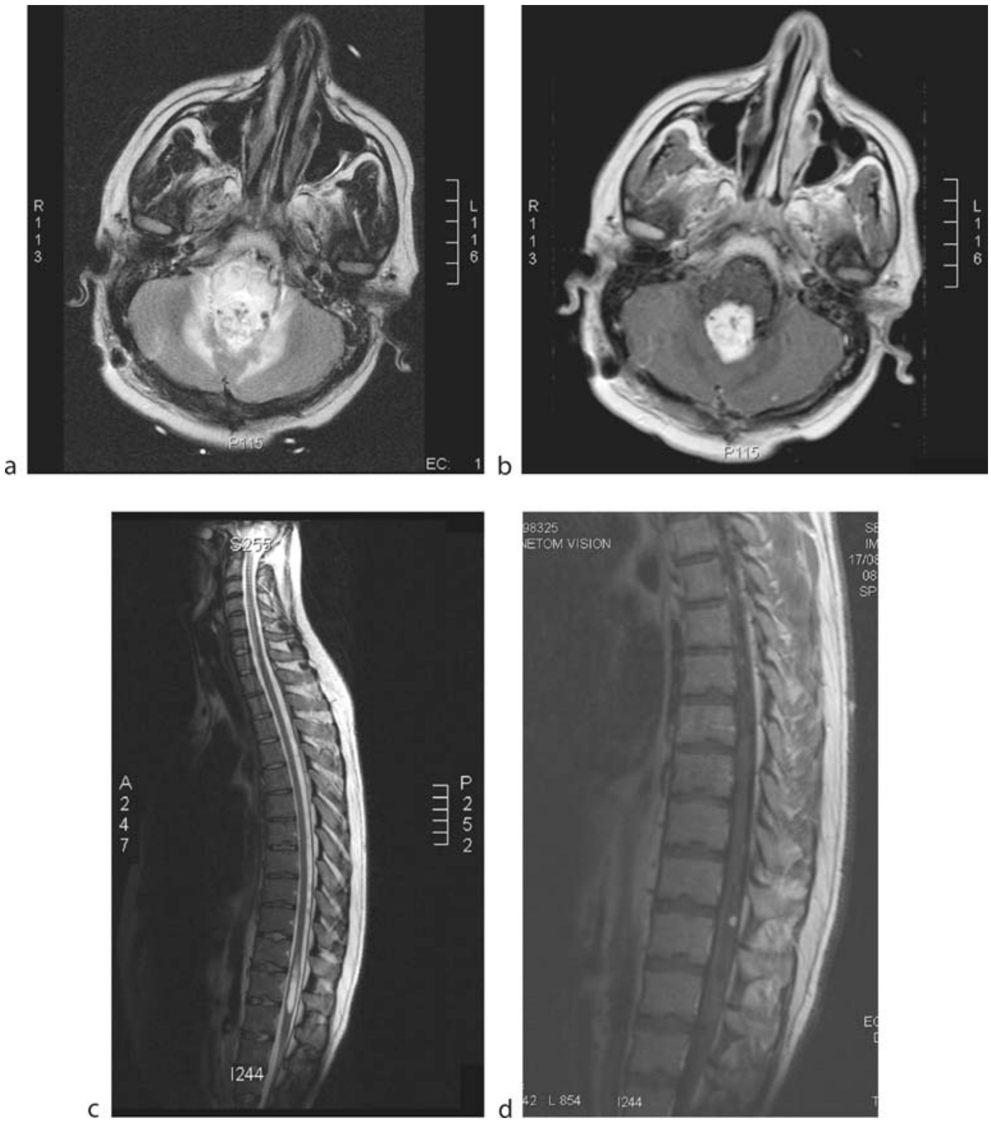
In the later stage, atrophy will develop in the ipsilateral hemisphere and due to a lack of brain growth there will be cranial asymmetry.

von Hippel–Lindau disease is characterized by the presence of hemangioblastomata. The cerebellum and the spinal cord are the most common locations. The typical appearance consists of a fluid-filled cyst with a tumoral vascular nodule within the wall of the cyst (Fig. 4). The small hemangioblastomata appear solid, but when they enlarge, they will become cystic.



Neurocutaneous Syndromes. Figure 3 **Sturge–Weber syndrome. On a T2-weighted image, only a subtle focal atrophy is seen in the left parietal and occipital lobe with an abnormal deep venous drainage (a). The T1-weighted images before (b) and after contrast (c) show leptomeningeal angiomatosis in this area and hypertrophy of the choroidal plexus. CT shows the gyral calcification (d) better.**

N



Neurocutaneous Syndromes. Figure 4 **von Hippel–Lindau disease. On the axial T2-weighted image the hemangioblastoma can be seen with surrounding edema in the vermis (a). Following the administration of contrast medium, the hemangioblastoma in the vermis as well as a second smaller cerebellar hemangioblastoma are visible (b). There is a hemangioblastoma in the thoracic spinal cord with a cystic component (c) and an enhancing mural nodule (d).**

The cystic component of spinal cord hemangioblastoma can sometimes be difficult to differentiate from edema. On T2-weighted images, the cyst has a higher signal and is more sharply delineated than cord edema (Fig. 4). The mural nodule is best seen on enhanced T1-weighted images.

The presence of more than one hemangioblastoma is highly suggestive of von Hippel–Lindau disease.

Neurofibromatosis

Neurofibromatosis (NF) is an autosomal dominant disease which manifest as a neurocutaneous syndrome. There are two principal types: neurofibromatosis 1 (NF-1 or von Recklinghausen disease) and neurofibromatosis 2 (NF-2). Approximately 90% of neurofibromatosis patients are NF-1 and the optic glioma is the most common intra-cranial tumour arising in these patients. NF-2 is much less common, and is associated with intra-cranial tumours originating from Schwann cells and meninges, which are typically multiple. The classic presentation of NF-2 is with bilateral acoustic neuromas. Both NF-1 and NF-2 are associated with spinal tumours, but of different types and frequencies

▶Tumors, Spine, Intradural, Extramedullary

Neurofibromatosis Type 1 (NF1)

One of the more common autosomal dominant disorders, initially described by von Recklinghausen. The NF1 gene, located on chromosome 17, appears to be a tumor suppressor gene that is inactivated in patients with NF1. The most common neuroradiological abnormality is glioma of the anterior visual pathway.

Synonyms

Central neurofibromatosis; Peripheral neurofibromatosis or Von Recklinghausen's disease

Definition

Neurofibromatosis (NF) is an autosomal dominant inherited disorder, involving multiple organ systems. The gene expression is variable.

Eight subtypes of the disease have been described, but generally two clinical subtypes account for 99% of cases: NF type I (peripheral NF or Von Recklinghausen's disease) and NF type II (central neurofibromatosis). A rigorous distinction between central and peripheral types is not completely accurate because NF-1 often has central features.

NF-1 is much more frequent than NF-2. Because skeletal involvement is exclusively seen in NF-1, affecting 50% of patients, further discussion will be focused on NF-1.

NF type I is a neuroectodermal and mesodermal dysplasia, characterized by a triad of pigmented cutaneous lesions, multiple soft elevated, cutaneous tumors, and various osseous manifestations of the axial and appendicular skeleton (1). The long arm of chromosome 17 is abnormal. Its incidence is estimated as 1:3000.

Pathology/Histopathology

The hallmark of the disease is the presence of peripheral neurofibromas. Three subtypes of ►neurofibroma exist: cutaneous, subcutaneous, and plexiform. Both cutaneous and subcutaneous neurofibroma are nonspecific for NF-1, whereas a plexiform neurofibroma is highly specific for the disease.

Grossly, a neurofibroma consists of a grayish brown or gray, firm rubbery mass. Histologically, interlacing strands of elongated foam cells and pigment are arranged in a characteristic palisading pattern.

Malignant degeneration may be seen in approximately 5% of cases (malignant peripheral nerve sheath tumor, previously designated as a neurofibrosarcoma). Other neurogenic tumor types are less frequent.

Clinical Presentation

Cutaneous Manifestations

Cutaneous abnormalities include café au lait spots, fibroma molluscum, and elephantiasis neuromatosa.

Café au lait spots in NF-1 are well marginated macules (in contrast to *café au lait* spots in fibrous dysplasia which are geographically jagged), and develop in 50% of patients with NF-1.

Fibroma molluscum are multiple, asymptomatic cutaneous nodules, which are elevated above the skin's surface. Fibroma molluscum is the most frequent lesion of NF-1.

Elephantiasis neuromatosa is a term designated for thick large soft tissue masses that create skin folds. The histological counterpart of this lesion is a plexiform neurofibroma.

Ocular Manifestations and Intracranial Manifestations

Optic glioma may produce blurred vision, scotoma and transient blindness (1). A defect in the superior orbital wall may result in drooping of the upper eyelid, dislocation of the eyeball, or pulsating exophthalmos, due to temporal lobe herniation with transmission of cerebrovascular pulsation to the globe (1).

Macrocephalus, facial asymmetry, iris hamartomas (Lisch nodules), learning disabilities, neuropsychological abnormalities, and neuroradiological findings (brain gliomas, areas of high signal intensity on T2-weighted images, plexiform neurofibroma in the head and neck area) are other characteristics.

Spinal Involvement

►Kyphoscoliosis and atlantoaxial subluxation may be complicated by paraplegia.

Gastrointestinal tract manifestations.

Location of neurofibromas in the gastrointestinal tract may result in pain, intestinal bleeding, and obstruction (2).

Vascular Manifestations

Vasculopathy may cause occlusive cerebrovascular disease, hypertension due to proximal renal artery stenosis, mesenteric artery insufficiency, congenital heart disease, major branch arterial stenosis and coarctations of the thoracic and abdominal aorta, and aneurysms (2, 3).

Other Extraskeletal Manifestations

Endocrine abnormalities include MEA IIb syndrome (medullary thyroid carcinoma, pheochromocytoma, and multiple mucosal neuromas), osteomalacia, hyperparathyroidism, and small bowel carcinoid tumors (2, 3).

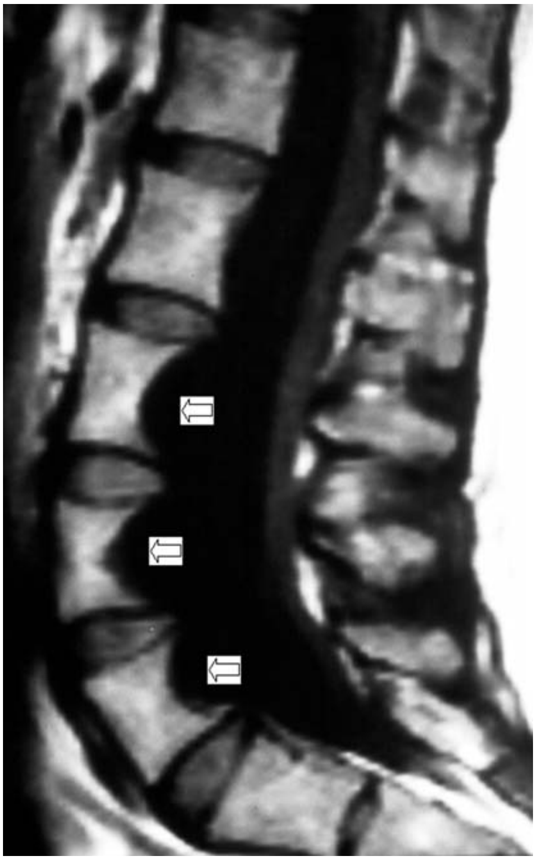
Imaging

Spine

The vertebral column is very frequently affected in NF-1. The most common radiographic feature is the presence of kyphoscoliosis, occurring in 50% of patients (1, 3, 4). Kyphosis predominates usually over scoliosis. Typically, the kyphoscoliosis involves a short segment of 5–7 vertebrae and is acutely angular in presentation. Although the lower thoracic spine is most frequently involved, cervical kyphosis causing reversal of the normal lordosis is another common finding of NF I.

►Scalloping of the posterior vertebral body margins is also very characteristic. There exist two types of scalloping: the posterocentral and the eccentric unilateral type. The posterocentral scalloping affects multiple levels and is secondary to dural ectasia (Fig. 1), whereas the eccentric unilateral type occurs at one level and is due to pressure erosion of a dumbbell neurofibroma, causing enlargement of the neuroforamen.

Erosion of the posterior surface of the vertebral body, pedicles and enlargement of the intervertebral neuroforamen may also be caused by an *intrathoracic meningocele*, which represents a focal protrusion of the



Neurofibromatosis, Musculoskeletal Manifestations. Figure 1 Sagittal T1-weighted spin-echo MR image of the lumbar spine demonstrating posterior vertebral scalloping associated with dural ectasia (white arrows).

dura and the arachnoid. Extension of these meningoceles along the adjacent posterior ribs and transverse processes may cause pencilling and spindling.

Skull

Agenesis of the posterosuperior wall of the *orbit*, the sphenoid wing and the orbital plate of the frontal bone may allow direct contact of the middle cranial fossa contents with the orbital soft tissues (Fig. 2).

Radiographically, the bony abnormalities may result in a harlequin appearance of the orbit. Often there is an associated deformity and/or decreased size of the ipsilateral ethmoid and maxillary sinus. Enlargement of the optic foramen and superior orbital fissure may be caused by an optic nerve glioma or plexiform neurofibroma respectively.

A *lambdoidal defect* is a typical bone defect occurring in the lambdoid suture just posterior to the junction of the parietomastoid and occipitomastoid sutures.

Macrocrania (increased skull size) may be due to associated macroencephaly (increased brain size). Aggregated granular *calcifications* are rarely seen in the area of the temporal lobe (3).

Chest and Ribs

A twisted ribbon appearance of the ribs may be due to both pressure erosion of intercostal neurofibromas or by a mesodermal dysplasia not related to the presence of neurofibromas (Fig. 3).

Appendicular Skeleton

Bowing, *pathologic fracture*, and ►pseudarthrosis of the long bones may occur. The tibia in its lower two-thirds is the most commonly affected bone. Anterolateral bowing is usually present in the first decade and may be associated with a gracile, abnormally formed or hypoplastic fibula. Bone deformity may cause pathologic fracture, which fails to heal (pseudarthrosis). There is no evidence of neural hypertrophy as primary causative factor in the pathogenesis of pseudarthrosis, as neural tissue has never been demonstrated in or near the site of the defective bone healing (1, 3).

Other sites for pseudarthrosis are the radius and the clavicle. A twisted *ribbon like* appearance—similar as seen at the ribs may also occur at the long bones.

Focal gigantism or local overgrowth or hypertrophy of both the skeletal and soft tissues is the result of chronic hyperemia owing to hemangiomas and lymphangiomas associated with NF.

Hypertrophy may involve a single bone or the entire extremity. The bones are usually normal in shape, and the associated muscles and joints are proportionately enlarged along with the soft tissues (1).

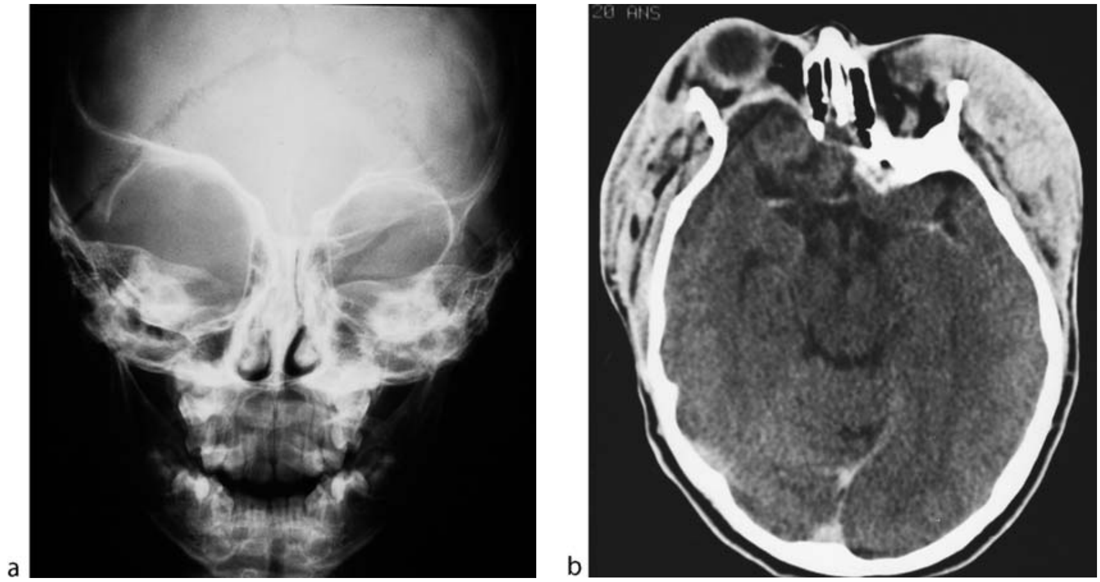
Cystic Lesions Within the Bone

NF-1 may occasionally present with cystic osseous lesions. The term "cystic" is a pure descriptive one, as biopsy has never been performed in these lesions (3).

Two types of cystic lesions have been described, subperiosteal and intraosseous. The subperiosteal type, described as caves, pits, or notches along the external cortex, has been attributed to mechanical pressure from adjacent neurogenic tissue and to focal hemorrhage from poorly adherent, dysplastic periosteum, which then proliferates over the lesion (3).

The pathogenesis of intraosseous cystic lesions is still a matter of debate. Several hypotheses have been proposed. Some authors ascribe them to direct invasion of the periosteum, cortex, and haversian canals by neurofibromatous tissue. Other investigators thought that they represent nonossifying fibromas or fibrous cortical defects

N



Neurofibromatosis, Musculoskeletal Manifestations. Figure 2 (a) Plain radiograph of the skull showing hypoplasia of the posterosuperior wall of the right orbit, distortion of the greater and lesser wings of the sphenoid bone and the orbital plate of the frontal bone. (b) CT scan of another patient showing hypoplasia of the right orbit, with protrusion of the temporal lobe into the right orbit. Note also the presence of subcutaneous plexiform neurofibromas on the ipsilateral and contralateral side.

(1, 3). However, histological proof of the true nature of these lesions was never evident.

Other radiographic manifestations within the appendicular skeleton are *intramedullary longitudinal streaks of increased density. Polydactyly* is also more frequent in NF-1 as compared with the general population (3).

Soft Tissues Tumors

Peripheral nerve tumors in NF-I most frequently involve neural supporting tissue. The two most common benign tumor types are solitary or multiple neurofibromas and neurilemomas (►schwannomas).

Neurofibromas may appear as soft-tissue opacities on standard radiographs. On ultrasonography these lesions appear as a well-demarcated fusiform, hypoechogenic structures, in close relation to the native nerve.

On CT, the lesions have a low density. Magnetic resonance imaging (MRI) is the imaging technique of choice for detection and characterization tumors of the peripheral nerves.

The most important imaging feature that should suggest the diagnosis of a neurogenic tumor is the presence of a fusiform mass, representing the tubular entering and exiting nerve in a typical nerve distribution. Other imaging features suggestive for a neurogenic tumor are the target sign, the fascicular sign, and the split fat sign and associated muscle atrophy. The fascicular sign represents multiple small ringlike structures (with peripheral higher signal intensity) on T2-weighted images, corresponding to fascicular bundles seen in neurogenic neoplasms. The split fat sign represents a rim of fat surrounding the lesion, due to the fact that the normal neurovascular bundle is normally surrounded by fat.

On MRI, neurogenic tumors are of low to intermediate signal intensity on T1-weighted images and of variably increased signal intensity on T2-weighted MR images.

Although the presence of a so-called target sign, consisting of a peripheral hyperintense rim and central hypointensity on T2-weighted images maybe in favor of a neurofibroma rather than a schwannomas, there is substantial overlap, rendering MRI not useful technique to distinguish peripheral located schwannomas from neurofibromas.

Contrast uptake is variable, but strong central zone enhancement and weak peripheral contrast uptake suggest the neurogenic origin.

Malignant degeneration occurs almost exclusively in preexisting (plexiform) neurofibroma, whereas, this is very rare in schwannoma (3). The mean age of appearance is 42 years. The criteria suggestive of MPNST are a large mass (more than 5 cm in diameter), with compression of the adjacent structures, a more nonhomogeneous appearance (due to hemorrhage and necrosis), invasion of fat planes, the presence of associated lymph nodes, adjacent bone destruction, and perilesional edema.

Neurofibromatosis, Musculoskeletal Manifestations. Figure 3 Plain radiograph of the left lower ribs demonstrating a ribbon-like appearance of the inferior aspect of rib 11, due to pressure erosion of an adjacent neurofibroma. Note also widening of the intercostal space between rib 11 and 12.

Osteomalacia

Osteomalacia may be seen in longstanding NF-I, owing to renal tubular dysfunction.

Diagnosis

Diagnostic criteria are based on the presence of the National Institutes of Health criteria. At least two criteria must be present (2, 5).

1. More than six café-au-lait spots (of more than 5 mm in diameter in prepubertal individuals and more than 15 mm in postpubertal individuals).
2. At least two neurofibromas of any type or one plexiform neurofibroma.
3. Freckling in the axilla (Crowe sign) or inguinal region.
4. Optic glioma.
5. More than two Lisch nodules.
6. Distinctive osseous lesions, such as sphenoid dysplasia or thinning of the long bone cortex, with or without pseudarthrosis.
7. First-degree relative (parent, sibling, child) with NF-I.

Neurometabolic Disorders

Zoltan Patay
Department of Radiological Sciences, St. Jude Children's Research Hospital, Memphis, USA
zoltan.patay@stjude.org

Synonyms

Congenital metabolic disorders; Inborn errors of metabolism; Metabolic diseases; Metabolic encephalopathies

Definitions

Metabolic disorders are generally divided into two categories: inborn errors of metabolism and acquired metabolic diseases.

Inborn errors of metabolism represent a vast group of genetically determined pathologies. Classification of disease entities may be based on organ system involvement, cellular organelle involvement, dominant biochemical abnormality, or even age of onset. Those with central nervous system (CNS) involvement may be further broken down according to substance involvement (exclusive white matter or gray matter involvement or both), resulting in subcategories referred to as leukodystrophies, poliodystrophies, or pandystrophies (Table 1).

N

Neurometabolic Disorders. Table 1 Various classification schemes for metabolic diseases

Classification Schemes				
Organ system involvement	Substance involvement	Cellular organelle involvement	Biochemical abnormality	Age of onset
Exclusive involvement of nervous system	Leukodystrophies	Mitochondrial disorders	Organic acidopathies	Neonatal
Exclusive systemic involvement	Poliodystrophies	Lysosomal (storage) disorders	Amino acidopathies	Infantile (early, late)
Mixed system involvement	Pandystrophies	Peroxisomal diseases	Disorders of carbohydrate metabolism	Juvenile (early, late)
		Golgi complex abnormalities	Disorders of metal metabolism	Adult

Strictly speaking, the term "neurometabolic disorders" refers to metabolic diseases with exclusive involvement of the nervous system, but in everyday practice it is used to encompass all inborn errors of metabolism with any degree of nervous system involvement (with or without systemic or other organ system involvement).

Acquired metabolic diseases usually occur in specific clinical (or social) settings, such as hypovitaminoses in malnutrition (Wernicke's encephalopathy, subacute combined degeneration of the spinal cord), ketoacidosis in diabetes mellitus, or neonatal hypoglycemia in premature infants. Severe forms of hyperbilirubinemia may lead to lesions within the deep gray matter structures (kernicterus). Toxic encephalopathies (alcohol, lead, drug, chemotherapy induced) are exogenous sometimes iatrogenic forms of acquired metabolic diseases.

Characteristics

Magnetic resonance (MR) imaging has contributed significantly to early diagnosis and/or characterization of inborn errors of metabolism.

Basic Concepts

The inherently high sensitivity of conventional MR imaging in detecting lesions within brain and/or spinal cord parenchyma is usually not coupled with the desirable degree of specificity. However, the increasing acceptance of the concept of the selective vulnerability of different structures of the CNS to various noxious metabolic insults and the subsequent development of the principles and implementation of the methodology of pattern recognition have significantly enhanced the value of MRI in the diagnostic work-up of neurometabolic diseases. The concepts of selective vulnerability and pattern recognition constitute the foundations of mainstream clinical diagnostic imaging in such conditions. The individual lesions represent the imaging substrates of selective vulnerability and the sum of lesions with resultant lesion patterns defines the imaging phenotypes of various disease entities.

Imaging Techniques

Prerequisites of diagnostically adequate MRI examination in clinically suspected or confirmed metabolic disorders include selection of an optimal plane for all potentially vulnerable structures (e.g., sagittal for cerebellar vermis, coronal for subthalamic nuclei), high spatial resolution (typically 512 matrix or better), and optimized sequences for lesion detection (e.g., myelin sensitive sequences for demonstration of normal or abnormal myelin).

Image Analysis

In order to obtain the most complete data set for pattern recognition, a systematic evaluation of the brain structures is mandatory.

Recognition of various structure involvement and progression patterns has a differential diagnostic value in leukodystrophies (Fig. 1). The cerebral white matter is assessed in different lobes (frontal, parietal, occipital, and temporal) separately. Depending on the magnitude of involvement in different lobes or central and peripheral white matter structures, anteroposterior or posteroanterior as well as centripetal or centrifugal progression gradients of the disease process may be identified. Sparing or involvement of subcortical U-fibers may be characteristic to specific disease entities (metachromatic leukodystrophy vs. Canavan's disease). The corpus callosum should be assessed for signal abnormalities and volume changes (swelling or atrophy); it usually reflects the magnitude and the possible progression gradient of hemispheric white matter abnormalities. The central tegmental structures of the pons are frequent lesion sites in metabolic and neurodegenerative processes. These are nonspecific, but still useful in raising the possibility of a metabolic disorder. In metabolic diseases, the cerebellar hemispheric white matter is perhaps less frequently involved than the cerebral white matter, but the presence of signal abnormalities and their distribution can be of great value in pattern recognition.

The cerebral cortex is quite difficult to assess for atrophic changes; nevertheless, in some diseases (GM2 gangliosidosis, megalencephalic leukoencephalopathy with subcortical cysts, Canavan's disease) thinning of the cortex may be obvious on MR images. Occasionally, cortical dysplasia may be associated with inborn errors of metabolism (Zellweger's disease, fumaric aciduria). In the acute phase of organic acidopathies, swelling of the basal ganglia is a typical finding, whereas in the chronic stage, atrophy is characteristic. These changes are associated with abnormal signal intensities best appreciated on T2-weighted images (Fig. 2). Other gray matter structures, such as thalami, claustra, are less frequently abnormal. The red nuclei are often spared in metabolic disorders, but involvement of the surrounding white matter structures and of the substantia nigra with a resultant hypersignal on T2-weighted images results in the so-called giant panda face appearance, which may be seen in Wilson's disease or glutaric aciduria type 1. The dentate nuclei of the cerebellum may be involved in all kinds of organic acidopathies and mitochondrial diseases.

Published data on the MR imaging findings of spinal cord and cauda equina lesions in neurometabolic diseases are sparse. Histopathological data suggest that

N

both white matter tracts and gray matter structures are prone to damage in a series of diseases, including Canavan's disease, Cockayne's disease, Krabbe's disease, GM2 gangliosidosis, non-ketotic hyperglycinemia, cerebrotendinous xanthomatosis, carbohydrate-deficient glycoprotein syndrome, glutaric aciduria type 2, and cobalamin and methyltetrahydrofolate deficiency (hyperhomocystinemia).

Identification of additional gross morphological abnormalities may also be useful in the process of pattern recognition. Macrocephaly, for example, in some leukodystrophies (megalencephalic leukoencephalopathy with subcortical cysts, Canavan's disease, Alexander's disease), in type 1 glutaric aciduria, GM2 gangliosidosis, and L-2-hydroxyglutaric aciduria is an important pattern element. Other metabolic disorders present with microcephaly (Zellweger's disease, Aicardi-Goutière syndrome, Cockayne's disease, Pelizaeus–Merzbacher disease). Bony abnormalities affecting the skull and spine are typical and very characteristic in some forms of mucopolysaccharidoses.

Common and Uncommon Imaging Findings

Atrophy of different brain structures is common in metabolic diseases. It may be diffuse or focal, affecting specific structures (basal ganglia, cerebellar vermis, corpus callosum). Cerebellar atrophy is consistently associated with some of the metabolic disease entities (neuronal ceroid lipofuscinosis, 3-methylglutaconic aciduria, carbohydrate-deficient glycoprotein syndrome, many lysosomal storage disorders, Menke's disease, mitochondrial diseases). Atrophy is often progressive and may be the sole indicator of an insidious metabolic disorder.

Symmetry of the lesions is a characteristic, although inconsistent, feature. Gray matter structures (basal ganglia, dentate nuclei) are almost always symmetrically involved, but rarely asymmetrical involvement of the basal ganglia may be present in metabolic diseases, especially during early stages of the disease. White matter lesions in metabolic diseases may be patchy, but in extensive leukodystrophies white matter involvement typically shows a strong tendency to symmetry.

Delayed and/or hypomyelination is frequently associated with metabolic disorders, especially in infants during the most active period of myelination. In some diseases (Zellweger's disease, non-ketotic hyperglycinemia) it can be severe; in others, such as Pelizaeus–Merzbacher disease, the imaging findings suggest arrest of the myelination process.

Intravenous contrast injection is usually not indicated in inborn errors of metabolism, since pathological contrast uptake is uncommon and rarely increases specificity. Exceptions exist, however. In X-linked adrenoleukodystrophy, contrast enhancement in the actively demyelinating zone is practically pathognomonic. Contrast enhancement in the brain is a hallmark diagnostic feature in Alexander's disease, and patchy enhancement may occasionally be present within the periventricular white matter in Krabbe's disease.

The incidence of true brain malformations is low in metabolic diseases. This may be explained by the typically postnatal onset of most diseases. In metabolic disease with intrauterine onset (especially if energy metabolism is affected, as in peroxisomal, fatty acid oxidation, and respiratory chain defects), malformations or disturbed development of the CNS (and of other organs) is more frequently encountered (e.g., characteristic bilateral perisylvian polymicrogyria in Zellweger's disease). Documented malformations in various other metabolic disorders include diffuse polymicrogyria, pachygyria, open opercula, callosal abnormalities (hypo- or dysplasia, dysgenesis), cerebellar dysgenesis, Chiari type 1 malformation, and tethered cord.

Imaging Patterns in Metabolic Disorders

Individual parenchymal lesions in metabolic diseases are usually nonspecific. Conversely, compiling positive and negative structure-specific findings during the process of image analysis may yield lesion patterns, many of which are nonspecific; nevertheless, these are still important since they may be useful in raising the possibility of a metabolic disorder along with other differential diagnostic alternatives. In some instances, the lesion pattern may be suggestive of a specific disease entity or group of diseases, whereas occasionally the imaging pattern is actually pathognomonic.

Pathognomonic MR Imaging Patterns

This category includes L-2-hydroxyglutaric aciduria, glutaric aciduria type 1, neonatal maple syrup urine disease, Zellweger's disease, X-linked adrenoleukodystrophy, Canavan's disease, Alexander's disease, megalencephalic leukoencephalopathy with subcortical cysts, leukodystrophy with brainstem and spinal cord involvement, and high lactate, as well as some of the mucopolysaccharidoses presenting with perivascular depositions.

Suggestive MR Imaging Patterns

The best known of these metabolic diseases are methylmalonic aciduria (mut0, mut-, CblA and CblB forms), 3-methylglutaconic aciduria (type 1 and 4), beta-ketothiolase deficiency, late-onset forms of maple syrup urine disease, homocystinuria, biotin-responsive basal ganglia disease, non-ketotic hyperglycinemia, Krabbe's disease, metachromatic leukodystrophy, GM2 gangliosidosis, fucosidosis, mucolipidosis type 4, Pelizaeus–Merzbacher disease, vanishing white matter disease, many of the "mitochondrial diseases" (Leigh's disease, MELAS, Kearns-Sayre disease), cerebrotendinous xanthomatosis, Menke's disease, and Wilson's disease.

Nonspecific MR Imaging Patterns

All other metabolic disorders fall into this group. It comprises many relatively frequent disorders, notably propionic acidemia, ethylmalonic acidemia, HMG-coenzyme A lyase deficiency, biotinidase deficiency, phenylketonuria, homocystinuria, and the so-called urea cycle defects.

Synonyms

Charcot neuroarthropathy; Neuroarthropathy; Neuropathic or neurotrophic joint disease

Definition

Charcot neuroarthropathy is a chronic and progressive disease of bone and joints, characterized by either painful or painless bone and joint destruction on limbs that have lost sensory innervation. Affected joints exhibit synovitis, instability, subluxation, and destruction. Central (upper neuron) and peripheral (lower motor neuron) lesions can lead to neuropathic osteoarthropathy. Central lesions that may produce neuropathic osteoarthropathy include syphilis, syringomyelia, meningomyelocele, trauma, multiple sclerosis, Charcot Marie-Tooth disease, congenital vascular anomalies, and other causes of cord compression, injury, or degeneration. Peripheral causes include diabetes mellitus, alcoholism, amyloidosis, infection, pernicious anemia, and trauma.

Pathology/Histology

The pathogenesis of Charcot neuroarthropathy has been explained by two theories: the neurovascular theory and the neurotraumatic theory. The neurovascular theory suggests that an increase in the blood supply to bone due to damage to tropic nerves causes bone resorption and weakening, leading to fractures and deformities. The neurotraumatic theory, on the other hand, suggests that insensate joints undergo repetitive trauma, resulting in fractures and progressive destruction. This latter theory is supported by several animal experiments and currently thought to best explain the destruction of insensate joints.

Typical sites of joint involvement can be observed (Table 1) depending on the concomitant disease leading to sensory deprivation (1). Early alterations of neuropathic osteoarthropathy include an enlarging and persistent effusion, minimal subluxation, fracture, and fragmentation. These early changes may rapidly progress, and acute subluxations or dislocations may be encountered. More advanced abnormalities consist of depression, absorption, and shattering of subchondral bone, significant sclerosis and osteophytosis, intraarticular osseous fragments, subluxation, massive soft tissue enlargement with effusion, and fracture of neighboring bones. Pathologically, the capsule is thickened, the synovial membrane is indurated and embedded, and metaplastic osteocartilaginous bodies in the synovium produce ossific lesions, which eventually may become far removed from the joint itself (1). Considerable amounts of cartilaginous and osseous debris (detritic synovitis) should suggest to the pathologist that the changes may represent neuropathic joint disease.

Clinical Presentation

The following discussion focuses on diabetic neuroarthropathy of the foot, which is by far the most frequent cause of neuropathic bone disease in the developed world. The majority of patients with pedal neuropathic joint disease present between the fifth and sixth decades of life, and most will have had diabetes mellitus for at least 10 years.

Neuropathic Joint Disease. Table 1 Typical sites of involvement in neuropathic joint disease

Disease	Site of Involvement
Tabes dorsalis	Knee, hip, ankle, spine
Syringomyelia	Glenohumeral joint, elbow, wrist, spine
Diabetes mellitus	Metatarsophalangeal, tarsometatarsal, intertarsal joints
Alcoholism	Metatarsophalangeal, interphalangeal joints
Amyloidosis	Knee, ankle
Meningomyelocele	Ankle, intertarsal joints
Congenital sensory neuropathy, hereditary sensory radicular neuropathy	Knee, ankle, intertarsal, metatarsophalangeal, interphalangeal joints
Idiopathic	Elbow, shoulder

Source: From Resnick D (2002) Neuropathic osteoarthropathy. Diagnosis of Bone and Joint Disorders. 4th edn. vol 3, chapter 72, pp 3564–3595.

Acute presentation: In acute pedal neuroarthropathy, there is usually moderate pain and edematous swelling, although the foot might be completely insensate (2). On examination, the foot is swollen, warm, and tender and can be markedly erythematous. At this stage, the differential diagnosis includes cellulitis, acute gout, deep venous thrombosis, and osteomyelitis, and it can be a considerable challenge to make an accurate diagnosis on clinical examination.

Chronic presentation: Chronic neuropathic pedal arthropathy is characterized by established deformity without symptoms of inflammation (2).

Imaging

Radiographic Changes

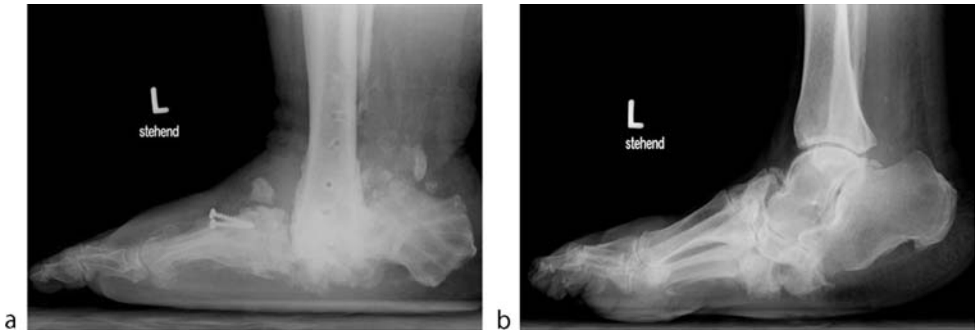
The radiographic changes of neuropathic joint disease are often summarized using the mnemonic of the "6 Ds": dense subchondral bone (sclerosis), degeneration (repair by osteophytes), destruction of articular cortex, deformity, debris, and dislocation.

In acute pedal neuroarthropathy, radiographs may reveal only soft-tissue swelling and joint effusion. Radiographic findings of early neuropathic osteoarthropathy manifested by subluxation or malalignment may be very subtle; for example, at the Lisfranc joint, the medial margin of the second metatarsal shaft should align precisely with the medial margin of the second cuneiform. Computed tomography (CT) or contralateral comparison radiographs may be helpful to confirm early malalignment. In subacute stages of the disease, radiographs may demonstrate collapse and fragmentation of the articular surface, subchondral cysts, and marginal erosions. However, bone density is generally preserved; in fact, the bones may demonstrate proliferation manifested by increased density.

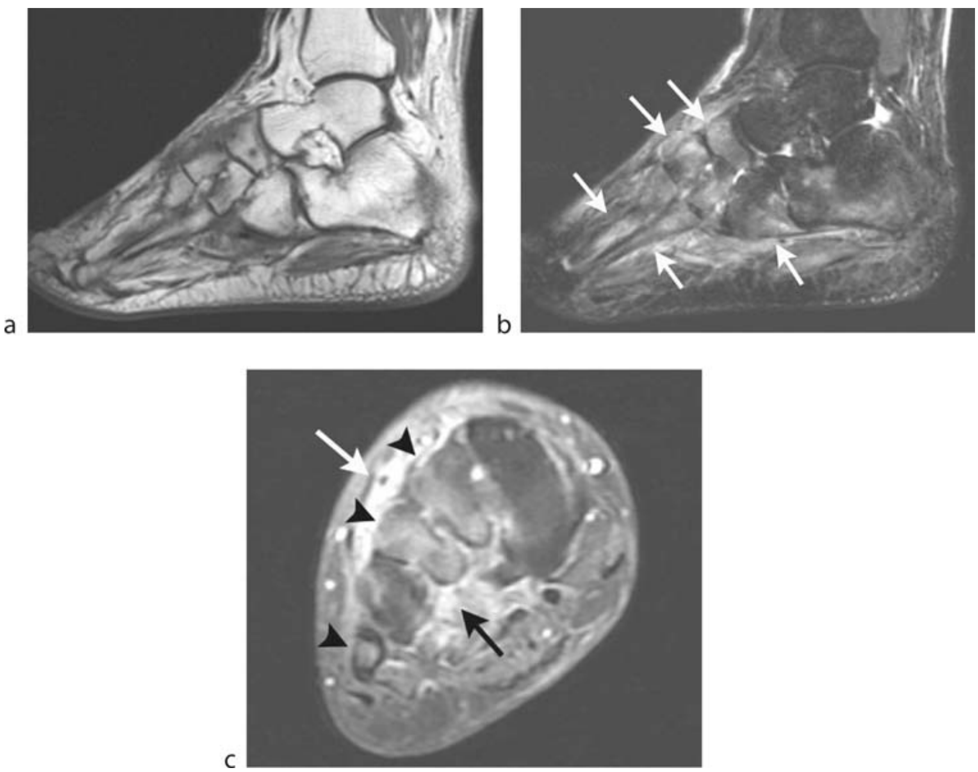
Chronic neuropathic osteoarthropathy results in joint subluxation and dislocation as well as destruction and fragmentation of juxtaarticular bone. In later stages of disease, adjacent bones can become necrotic and collapse (Fig. 1a). The degree of sclerosis, osteophytosis, and fragmentation is greater than in any other process. Collapse, sclerosis, and fragmentation of the metatarsal heads may resemble changes of Freiberg's infraction but can be more aggressive and extensive. Broadening of the bases of phalanges may lead to a cupped appearance. Occasionally, shortening and resorption of the ends of the metatarsals and phalanges occurs. Bony ankylosis represents the end stage of joint destruction but is uncommon. Asymptomatic fractures can be discovered in 22% of diabetic patients with neuropathy. Calcaneal fractures are common, and avulsion by the Achilles tendon may be the first radiographic abnormality at the time of presentation. Neuropathic disease of the Lisfranc joint typically results in superior and lateral subluxation of the metatarsals, leading to a "rocker-bottom" type of deformity (Fig. 1b) with increased weight-bearing stress on the cuboid. In this setting, callus and ulcer formation beneath the cuboid is common. Spinal neuropathic arthropathy affects the disc space, the adjoining vertebral bodies, and the facet joints. The lower thoracic and lumbar spine are most commonly affected. Radiographic changes include loss of disc space, vacuum disc, bone sclerosis, debris, disorganization, osteophyte formation, abrupt curvature, and extensive paravertebral soft-tissue calcification. Involvement of the three vertebral columns, including destruction of the facet joints, is an important sign, distinguishing neuropathic arthropathy of the spine from spondylodiscitis (3).

Magnetic Resonance Imaging

Acute neuropathic osteoarthropathy: The involved joints in this early stage of disease often show little deformity or malalignment. Joint effusion is common, with prominent subchondral edema that may extend far into the medullary cavity (Fig. 2). Signal intensity changes in the bone marrow consisting of low signal intensity on T1-weighted images and high signal on T2-weighted images may be identical



Neuropathic Joint Disease. Figure 1 **(a) Lateral view in standing position, revealing extensive destruction of the upper and lower ankle joint in a diabetic patient with long-standing neuropathic arthropathy. All typical radiographic findings of neuropathic joint disease are displayed: dense subchondral bone (sclerosis), degeneration (repair by osteophytes), destruction of articular cortex, deformity, debris, and dislocation. (b) Lateral view of the left foot in standing position of a diabetic patient with subacute neuropathic arthropathy in the midfoot affecting the Chopart, intertarsal, and Lisfranc joints. Note the plantar subluxation of the hindfoot with typical rocker-bottom deformity and dorsal subluxation of the metatarsal bases.**



Neuropathic Joint Disease. Figure 2 **Acute neuropathic arthropathy in a 37-year-old diabetic patient. (a) T1-weighted sagittal image reveals patchy hypointensity in the bone marrow, affecting all bones around the Lisfranc joint and the navicular and cuboid bone. (b) T2-weighted, fat-suppressed image with corresponding diffuse bone marrow hyperintensity (*arrows*). (c) Coronal contrast-enhanced, fat-suppressed T1-weighted image shows diffuse contrast enhancement in the bone marrow of the second, third, and fifth rays (*arrowheads*) with periarticular soft-tissue enhancement (*arrows*).**

to those observed in osteomyelitis (Fig. 2). Erosions may be seen at the joint margins. On gadolinium-enhanced images, marrow enhancement is typically present, with predominantly subchondral distribution. Periarticular soft-tissue enhancement may also be seen. Recent fractures related to neuropathic osteoarthropathy may contribute to signal intensity changes in the marrow and cortex of bones, which leads to potential diagnostic pitfalls.

Bone destruction and deformation may be less conspicuous on magnetic resonance (MR) exams, and radiographic correlation often helps in understanding the extent of these findings. MR imaging findings of spinal neuropathic joint disease are similar to those of spondylodiscitis. The following findings are, however, indicative of neuropathic joint disease: identification of gas in the affected intervertebral disc, spondylolisthesis, involvement of the facet joints, diffuse abnormalities of signal intensity in the vertebral bodies, and rim enhancement of intervertebral discs (3).

Chronic neuropathic osteoarthropathy typically appears as decreased signal intensity on all sequences, consistent with osteosclerosis. Joint deformity is common, with subluxation or dislocation. Subchondral cysts present as well-marginated foci of low signal intensity on T1-weighted images and high signal intensity on T2-weighted images. Bone proliferation is present, with "debris" or intra-articular bodies.

Differential Diagnosis Between Pedal Neuropathic and Osteomyelitis

Radiologic distinction between neuropathic osteoarthropathy and osteomyelitis on MR imaging may be facilitated considering the following general principles (summarized in Table 2): First, the vast majority of cases of osteomyelitis in diabetic feet occur *via* contiguous spread related to ulceration and cellulitis. Therefore, a bone marrow abnormality without contiguous soft-tissue infection or nearby skin ulceration favors diagnoses other than infection. In addition, neuropathic osteoarthropathy is primarily an articular disease; marrow abnormalities centered in a subarticular location favor such an articular disorder. Distribution of osteomyelitis mirrors that of ulceration, which is most common at the toes, metatarsal heads, calcaneus, and malleoli, whereas neuropathic arthropathy is most common at the Lisfranc and Chopart joints. Finally, neuropathic arthropathy tends to involve a number of joints in a region, whereas infection tends to remain localized or spread contiguously.

Differential Diagnosis Between Noninfected and Infected Neuropathic Joint Disease

It is often clinically impossible to diagnose infection in acute or subacute neuroarthropathy since both entities present with symptoms such as swelling, redness, and tenderness. As stated earlier, MR imaging findings of infection and neuropathic disease overlap, and distinguishing these entities may indeed be difficult. On follow-up MR exams, the following articular and bony MR signal changes suggest new onset of infection: progression of bone erosion, loss of subchondral cysts, progression of bone marrow hyperintensity, and enhancement from the articular surface (4). Progressive replacement of soft-tissue fat, progressive enhancement of periarticular soft tissues, and new development of a sinus tract are periarticular MR signal alterations indicative of a superimposed infection (4). As a general rule of thumb, the greater and the more extensive the marrow signal abnormality from the articular surface, the more likely the bone is to be superinfected (Fig. 3).

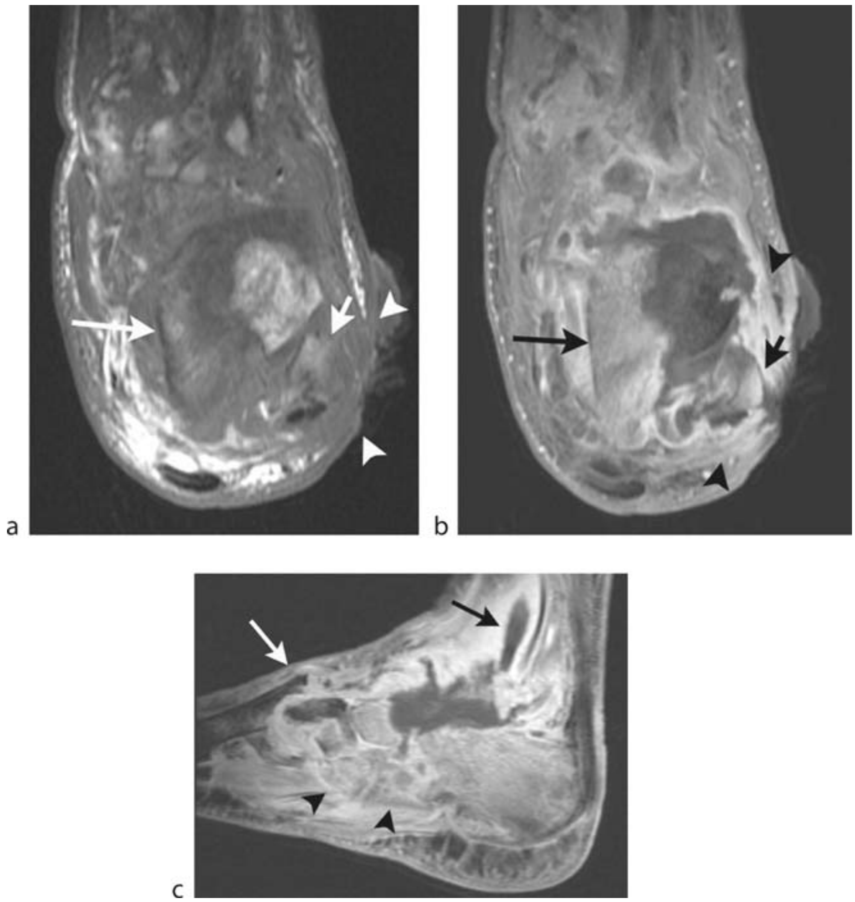
Nuclear Medicine

Radionuclide imaging can sometimes be a useful investigative tool in pedal neuroarthropathy. The three-phase bone scan using technetium labeled phosphonates (Tc-MDP) is often positive in all phases of diabetic pedal arthropathy, reflecting increased vascularity and bone turnover. To discriminate neuroarthropathy from osteomyelitis, labeled white blood cell (WBC) scans or labeled monoclonal leukocytic antibody scans can be used because they show increased activity at the infection site.

In combination, three-phase TcMDP and labeled WBC scanning has a sensitivity and specificity of 80–90% for the diagnosis of bone infection if there is a penetrating ulcer underneath a neuropathic pedal deformity. It may be difficult to distinguish infection in bone and soft tissue

Neuropathic Joint Disease. Table 2 Differentiation of osteomyelitis from neuropathic osteoarthropathy

	Osteomyelitis	Neuropathic	Comments
Typical location	Toes (tips, dorsum), metatarsal heads (especially first and fifth), calcaneus malleoli	Lisfranc joint, Chopart joint	
Distribution	Focal, local—centripetal spread	Multiple joints in a region	
Pattern of edema/ enhancement	Predominant involvement of one bone	Epicenter in joint and subchondral bone	
Deformity	Uncommon (unless there is underlying neuropathic disease)	Common (rocker-bottom)	
Soft tissues	Adjacent ulcer, cellulitis, sinus tract	Enhancement limited to juxtaarticular soft tissues; skin, subcutaneous tissues intact	Diffuse subcutaneous; edema is typical In diabetic feet



Neuropathic Joint Disease. Figure 3 **Diagnosis of osteomyelitis in a patient with long-standing neuroarthropathy. (a) T1-weighted axial image reveals a skin ulcer (*arrowheads*) and adjacent hypointense soft tissue swelling compatible with cellulitis. There is hypointense signal of the bone marrow of the distal fibula (*small white arrow*) and calcaneus (*long white arrow*). (b) T1-weighted axial fat-suppressed and contrast-enhanced image reveals direct contact of the ulcer with the outer surface of the fibula (*short arrow*), with hyperintense marrow signal and extensive periarticular enhancement (*arrowheads*). Note also the diffuse marrow enhancement of the calcaneus (*long arrow*). (c) Sagittal contrast-enhanced and fat-suppressed image with diffuse bone marrow enhancement in the midfoot and hindfoot, including bone fragments (*arrowheads*). Dorsal subluxation of metatarsal bases (*white arrow*) is indicative of neuropathic arthropathy. Note peroneal tendon phlegmon (*black arrow*) with diffuse peritendinous enhancement and hypointense pus in the tendon sheath.**

on labeled WBC scan alone, so this is usually interpreted in conjunction with a three-phase bone scan. Labeled WBC scan can be falsely positive in the presence of recent onset of rapidly advancing neuroarthopathy.

Diagnosis

Diagnosis of early neuropathic joint disease may be difficult, especially if a joint above the foot is involved and if the concomitant disease leading to sensory deprivation is unknown to the radiologist. In advanced stages, radiographic changes are almost pathognomonic, displaying the characteristic alterations starting with “D”: dense subchondral bone, degeneration, destruction of articular cortex, deformity, debris, and dislocation.

Neuropathic or Neurotrophic Joint Disease

▶Neuropathic Joint Disease

Neurophakomatoses

Diseases in this group include tuberous sclerosis, neurofibromatosis, Sturge–Weber syndrome and Von–Hippel–Lindau syndrome.
▶Calcifications, Intracranial, Neonatal

Neurovascular Conflict

A vascular compression of a cranial nerve at the root entry zone that manifests clinically as neuralgia and/or spasm. Strict diagnostic criteria include deviation and/or indentation of the nerve by the offending vessel. Chronic pulsatility and pressure upon this vulnerable area of the nerve lead to segmental areas of axonal ischemia and demyelination. Most common causes include vascular loops, vascular dolichoectasia, aneurysms and vascular malformations. High resolution MRI, MRA and/or CTA are the imaging modalities of choice to evaluate this condition.
▶Facial Nerve Palsy

New Neoplasm

Breast neoplasms detected during the follow-up of patients previously diagnosed and treated for breast cancer. The characteristic of these tumors is that their location (not close to the primary tumor or the surgical scar, even in the contralateral breast) and their histological characteristics indicate that they are tumors different to that initially diagnosed and treated.
▶Recurrent Neoplasms, Breast

NF1

▶Neurofibromatosis Type 1 (NF1)

Nipple Adenoma

Benign tumors located in the collecting ducts of the nipple.
▶Adenoma, Breast

Nipple Discharge

Fluid obtained from the nipple. It may be spontaneous or induced by expression, and it may be milky, clear, green, dark, grey, brown, and/or bloody.
▶Duct Disease, Breast

Nodal Necrosis

Nodal necrosis is a pathognomonic feature for metastatic nodes from head and neck squamous cell carcinomas. Nodal necrosis is considered to occur as cancer cells infiltrate into the medullary portion of the node to surpass the blood supply.
▶Lymphadenopathies, Head and Neck

Nodular Adenosis

▶Sclerosing Adenosis, Breast

Nodular Regenerative Hyperplasia, Hepatic

Tumor-like condition of unknown origin, rare in children, usually underdiagnosed because imaging is nonspecific and may resemble focal nodular hyperplasia or may occur as regenerative nodules in cirrhosis. Frequently described in association with other disorders (myelo-lymphoproliferative diseases, Donohue's syndrome, rheumatic disease) and may be seen in fetuses with malformations. It consists of single or multiple regenerative foci of hyperplastic hepatocytes, probably resulting from a nonspecific tissue adaptation to a heterogeneous distribution of hepatic blood flow.

Definition

A pulmonary nodule or coin lesion is defined as a spherical opacity with well-defined edges and a diameter smaller than 3 cm which is surrounded by lung parenchyma. A lesion larger than 3 cm is described as *mass*.

Pathology/Histopathology

The differential diagnosis for multiple pulmonary nodules is long.

Metastatic solid organ malignancies are the most common cause of multiple pulmonary nodules and account for about 80% of these cases. Lymphoma may also cause multiple nodular lesions (e.g. BALT). Infectious diseases (e.g. septic emboli) as well as vascular malformations or non-infectious inflammatory conditions (e.g. bronchiolitis, granulomatous diseases) may cause multiple nodular opacities of varying size and distribution.

Clinical Presentation

Dependent on the extent and on the underlying disease clinical symptoms are very variable (e.g. hemoptysis, fever, weight loss). To cause loss of respiratory function the nodules have to be extensive and are mostly associated with other thoracic manifestations such as pleural effusion or airway obstruction.

Imaging

Basically the same imaging features listed for the solitary pulmonary nodule to discriminate benign from malignant are also valid for multiple lesions.

With the history of a known primary, newly developed multiple nodules—mostly but not necessarily spherical and sharply demarcated—are highly suspicious for metastases.

Nodules grouped in a cluster and lying in the lung periphery are more suspicious for an underlying infection. Septic emboli produce 0.5–3 cm round or wedge shaped nodules, mostly with cavitations with a predilection for peripheral areas of the lower lobes.

Pulmonary arteriovenous malformations consist of abnormal communications between pulmonary veins and arteries. They present as solitary or in about one-third of patients as multiple intrapulmonary nodules. Strong enhancement after contrast injection and the presence of draining vessels are the diagnostic key features.

There are a number of non-infectious inflammatory conditions that present with multiple intrapulmonary nodules such as Wegener's disease, sarcoidosis, rheumatoid arthritis or lymphomatoid granulomatosis. In most of these cases additional clinical findings and imaging features will help to narrow the differential diagnosis.

Diagnosis

CT is the method of choice for detection of multiple pulmonary nodules. Although CT is very sensitive, it is frequently non-specific. Yet, distribution, localization and morphological details provide important clues for further differential diagnosis.

Definition

A pulmonary nodule, or coin lesion, is defined as a spherical opacity and with well-defined edges, a diameter smaller than 3 cm which is surrounded by lung parenchyma. A lesion larger than 3 cm is described as *mass*.

Pathology/Histopathology

In more than 95% the differential diagnosis of a solitary pulmonary nodule belongs to one of the following entities:

1. Malignant neoplasm (primary or metastatic) (*see entry on bronchogenic carcinoma*).
2. Infectious granuloma (tuberculous or fungal).
3. Benign tumors (mostly hamartoma).

Clinical Presentation

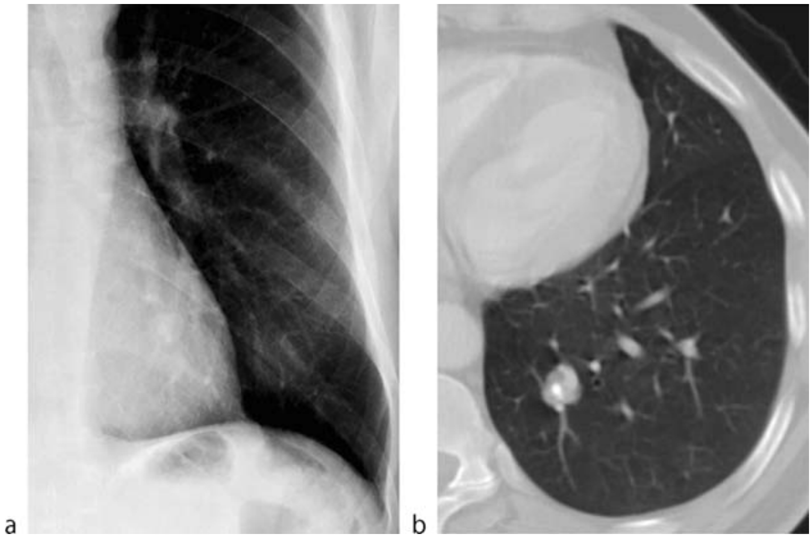
Typically, a solitary pulmonary nodule is an incidental finding in an asymptomatic patient. Rarely, it may cause hemoptysis (dependant on underlying histology).

Imaging

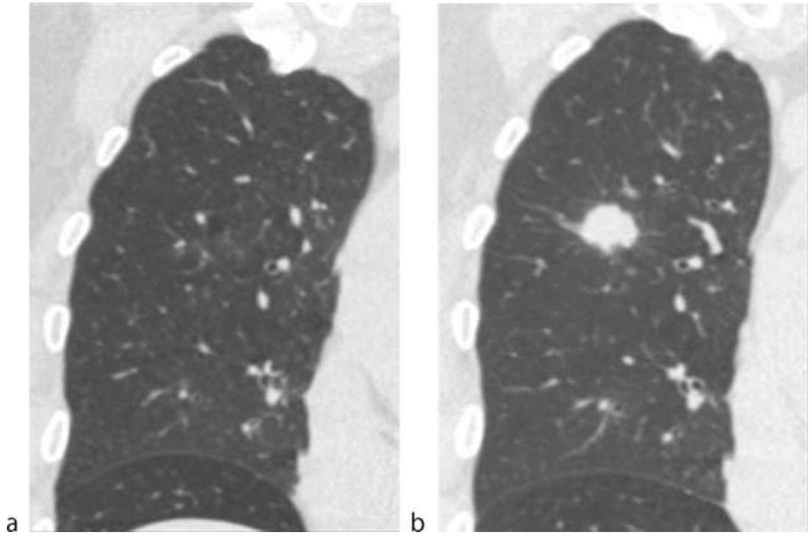
Even 1 cm nodules are frequently missed on a chest radiograph dependant on their anatomic location and the amount of overlying “anatomic noise.” CT is the method of choice for the detection of intrapulmonary nodules. The sensitivity and specificity of FDG-PET for diagnosing a pulmonary nodules as being malignant (e.g., bronchogenic cancer) varies with equipment, technique, and glucose metabolism of the lesion.

Radiological imaging features helpful for determining the differential diagnosis of a solitary pulmonary nodule are

1. Calcification: Various types of calcifications are differentiated such as laminated, punctuate, cloud-like eccentric, or concentric. They have a different probability of being associated with a benign lesion or suspicion for malignancy. Uniform, concentric, or popcorn calcifications are typical for benign lesions (tuberculoma, histoplasmoma, hamartoma, Fig. 1) while cloud-like and multiple punctuate calcifications are seen in adenocarcinomas. The visibility of the calcifications on a chest radiograph depends on their size and whether they are surrounded by soft tissue or air. CT is more sensitive for detection and characterization of calcifications but should only be indicated for questionable cases (not for homogeneously calcified granulomas potentially associated with calcified mediastinal or hilar lymph nodes which virtually diagnostic for inactive tuberculosis).
2. Fat (negative HU): It is almost completely specific for a hamartoma. Rare alternatives are metastases from lipo-sarcoma and lipoid pneumonia. Cave: CT-density measurements have to be performed in thin sections to avoid partial volume effects.
3. Contrast enhancement: Malignant solitary pulmonary nodules show a stronger enhancement after injection of contrast (>20 HE with sensitivity 98%, specificity 73%), while benign lesions show slower and lower enhancement. The latter appears to be a useful criterion for excluding malignancy when using a threshold value of <15 HE. Attention has to be paid to the proper technique with respect to volume and flow of injected contrast.
4. Rate of growth: Bronchogenic carcinomas have a volume-doubling time between 1 and 18 months (Fig. 2). Faster doubling time (<1 month) is suggestive for infection, infarction, lymphoma, or fast growing metastases while a longer doubling time is suggestive for a benign nature of the lesion. Elaborate



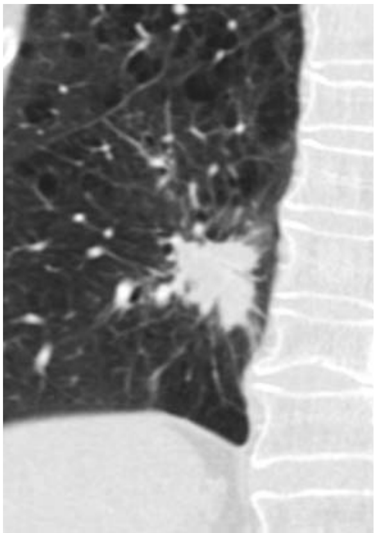
Nodules, Pulmonary, Solitary. Figure 1 A benign intrapulmonary lesion (hamartoma) with a central calcification, a round well-defined margin and a constant size over more than 2 years.



Nodules, Pulmonary, Solitary. Figure 2 Growth of an intrapulmonary nodule in a follow up CT as confident sign for malignancy.

computerized programs were developed for CT to assess lesion growth as early as within 3 months.

5. Size and shape: While the size is a definite tool for stratifying the next diagnostic steps, the role of shape related criteria such as lobulation, notching (*Rigler-sign*), irregularity of borders (*corona radiata*), or the presence of a pleuro-pulmonary tail (*pleural finger*, Fig. 3) remains controversial. None of these criteria provides a reliable discriminating factor. They may be used for complex multifactor likelihood calculations but eventually do not replace invasive procedures for histological proof.
6. Air-bronchogram and bubble-like lucencies: An air-bronchogram within a solitary pulmonary nodule seen on a chest radiograph makes the diagnosis of a lymphoma, rounded atelectasis, or bronchiolo-alveolar carcinoma more likely than a metastasis or primary lung cancer. On the other hand, thin section CT does show in fact air-bronchograms quite frequently also in bronchogenic carcinomas. The *positive-bronchus-sign* (Fig. 3) is a variation of the air-bronchogram and describes an air filled (nonobscured) bronchus running in to a mostly malignant solitary pulmonary nodule and was originally described to predict the likelihood of obtaining a positive transbronchial biopsy. More spherical so-called air bubbles are quite common in adenocarcinoma, especially bronchiolo-alveolar carcinoma.
7. Cavitation: It describes an air containing space within a nodule or mass; wall thickness, wall regularity, and the reaction of the surrounding lung parenchyma vary with the underlying etiology. The most frequent differential diagnoses include a neoplasm, an infectious or granulomatous process, or an ischemic lesion.

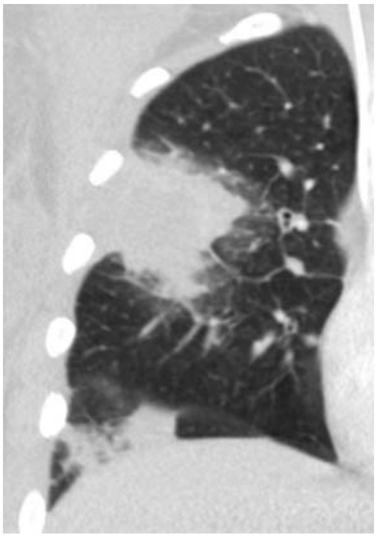


Nodules, Pulmonary, Solitary. Figure 3 A malignant intrapulmonary lesion with spiculae (corona radiata) and a pleural finger.

Pathologically the cavitation is the result of a necrosis of the central portion of the lesion that has been expelled *via* the bronchial tree, leaving an air filled space with or without a fluid-gas level (Fig. 4).

Diagnosis

The diagnostic work up of a solitary pulmonary nodule depends on the size of the lesion, age of the patient as well as the clinical symptoms and history of the patient. Older



Nodules, Pulmonary, Solitary. Figure 4 **Patient suffering from neutropenia after chemotherapy and showing multiple intrapulmonary nodules and masses surrounded by a ▶halo due to an angio-invasive aspergillus infection.**

CT scans or chest radiographs should be obtained whenever possible as they may serve to demonstrate stability or interval growth. Lesions larger than 1 cm in diameter require definite diagnostic work up; smaller lesions are followed under specific conditions (see 4).

Nonalcoholic Steatohepatitis

Nonalcoholic steatohepatitis (NASH), also called nonalcoholic fatty liver disease (NAFLD) is a liver inflammation with fatty degeneration which resembles alcoholic hepatitis on liver biopsy (fat droplets, inflammatory cells, but usually no Mallory's hyalin), but is not due to abuse of alcohol. This condition is more common in women. It is associated with obesity, diabetes mellitus type II, and insulin resistance (Fig. 2). NASH can also be caused by various medications such as amiodarone, antiviral drugs, etc. The diagnosis is based on clinical data, laboratory tests, imaging findings. Liver biopsy may be required. Imaging, especially ultrasound, is the first step for evaluating the presence of fatty infiltration. However, it is not able to identify hepatic inflammation. Therefore, the differentiation between steatosis and NASH often requires a liver biopsy. NASH is becoming recognized as a major cause of cryptogenic cirrhosis of the liver.

Non-linear Bubble Behavior

Volkmar Uhlendorf
Institut für Pharmazeutische Wissenschaften,
Zürich, Switzerland
volkmar.uhlendorf@pharma.ethz.ch

Synonyms

Nonlinear bubble oscillation; Nonlinear bubble response

Definition

If the input to a system is modified by some factor and the resulting output changes by the same factor as the input, the behavior is called linear. Any other type of response indicates a nonlinear behavior of the system. Nonlinear bubble behavior occurs when a microbubble is exposed to an ultrasound field at acoustic pressure levels that are typically used in routine practice. The nonlinear echoes returned from the bubbles constitute the signals that are used for contrast-enhanced ultrasound in clinical practice. So-called nonlinear imaging techniques or contrast-specific imaging techniques are used to exploit these signals.

Characteristics

In many cases, a linear system response is desired. For example, the evaluation of analytic measurements is simplified in the linear part of the calibration curve. Another obvious example is given by high-fidelity audio systems, where the well-known nonlinear response at very high output amplitudes leads to rather unpleasant acoustic distortions. However, in ultrasound contrast imaging, similar distortions caused by nonlinear behavior of microbubbles are highly desirable. Here, the characteristic distortions are useful, as they allow one to distinguish between echoes from tissue and echoes from strongly oscillating microbubbles.

When a microbubble is disturbed by external pressure oscillations like those in an ultrasound pulse, it can easily undergo pulsating oscillations, i.e., expansion and compression. This motion re-radiates an ultrasound signal. As long as the external disturbance is very weak, or when the bubble has a shell of higher mechanical rigidity, the response will be linear. This means the shape of the outgoing reflected or scattered wave is an exact copy of the incoming wave – only the amplitude is more or less reduced. A linear bubble response is usually found when the amplitude of the oscillation is less than a few percent of the bubble diameter at rest. Stronger excitations are more easily obtained at a resonance frequency of a given system. It turns out that small microbubbles without a rigid shell have their resonance frequencies in the MHz range used in medical ultrasound imaging. If these “free” bubbles are excited near their preferred oscillation frequencies, their response (the scattered signal) can be so strong that it becomes nonlinear.

There are several reasons why bubbles can behave in a strong nonlinearly fashion. The main factors are easily understood. If an oscillating bubble is viewed as a mass–spring system, the spring represents the compressible gas core plus some contribution from surface tension. The mass is mainly given by the mass of the fluid next to the bubble, which has to be moved during the oscillation (including the shell if there is any, while the gas contributes almost nothing to the mass). In most textbooks, in examples of mass–spring systems the “mass” and “spring constant” are both very constant, leading to a simple linear oscillation. In the case of a bubble, the corresponding parameters are no longer constant, but are continuously changing during the pulsating oscillations. When a bubble expands or contracts, its effective mass grows or shrinks just like the current volume of the oscillating fluid, i.e., in proportion to the third power of its current diameter. Therefore, the bubble motion is slowed down while it is expanded and the bubble may not be able to follow an external excitation fast enough. It may even skip one or two oscillations of the exciting ultrasound signal and emit at

N

"subharmonics" below the excitation frequency, which is a very typical characteristic of bubbles.

A smaller (or a compressed) bubble has a much smaller effective mass, and thus can rapidly respond even to high frequency variations in the transmitted ultrasound pulse. It reradiates the excitation frequency and high frequencies not contained in the original transmit signal, in particular the higher harmonics (overtones) of the excitation frequency.

Nonlinear bubble behavior also results from an asymmetry in the expansion or compression factor that can be obtained. The gas in an uncompressed air bubble has a specific density of about 1.3 mg/ml. When the bubble is compressed to 1/10 of its initial diameter (1/1000 of the initial volume), its "gas" density increases to 1.3 g/ml (ignoring gas dissolution and heating for simplicity), a value even higher than the density of water or tissue. Obviously, a gas bubble cannot be compressed (or collapse) to much less than 1/10 its initial size.

Bubble expansion is not limited in the same manner, but very large expansion is only possible at very low excitation frequencies. A bubble expanded to twice the initial size effectively has eight times the initial mass. The linear or nonlinear oscillation of a bubble or cavity in liquid is also called "cavitation." Bubble expansion to more than twice the initial size is often followed by a short, violent collapse dominated by inertial forces and therefore called "inertial cavitation." It may lead to fragmentation of a bubble into a number of smaller bubbles. Inertial cavitation also has some potential for bioeffects.

Shell fragmentation (disruption) is a phenomenon that must be distinguished from bubble fragmentation, although sometimes both may occur almost simultaneously. As the shell has an important influence on the lifetime and acoustic response of a bubble, its fragmentation will be discussed in more detail elsewhere in this volume.

In summary, it turns out that nonlinear bubble response is typically a relatively slow expansion followed by a rapid collapse. This motion may be repeated several times, depending on the transmitted ultrasound pulse. It creates higher harmonics and other very characteristic bubble signals like subharmonics, typically 1/2 of the transmit frequency. Furthermore, there may be some ringing of the bubble after the external excitation has ended, much like a bell ringing according to its size – smaller bells or bubbles have higher characteristic frequencies.

Quantitative calculations as well as experimental results indicate that microbubbles in aqueous solution have resonance frequencies in the lower MHz range used in diagnostic ultrasound imaging. This is one of the reasons for the high sensitivity of ultrasound contrast imaging.

Nuclear Medicine – Diagnostic Procedures

Uwe Haberkorn
Radiologische Klinik und Poliklinik,
Universitätsklinikum Heidelberg, Heidelberg,
Germany
uwe.haberkorn@med.uni-heidelberg.de

General Principles and Goals

Although therapy with radioactive isotopes is a substantial and ever-growing part of the discipline, we concentrate here on the principles of diagnostic nuclear medicine procedures. Nuclear medicine is based on the tracer principle introduced by von Hevesy and Paneth. This technique relies on the fact that exchange of stable atoms by their radioactive isotopes does not change the biological properties of organic compounds. The labeling is done using very low amounts of a substance, leading to physiological concentrations in the body. Therefore, the radioactive-labeled molecules (tracer) can be used to display reliably the physiological or biochemical fate of the nonlabeled molecule (tracee). The tracer technique is applied in basic science mainly using the β-emitting isotopes ^{3}H and ^{14}C for the examination of living subjects, such as patients, using γ- or positron-emitting isotopes. In most cases the radiation dose of the patient is in the range of the radiation dose from natural sources per year or even below that. The most important insight resulting from the tracer principle is the realization that living organisms are in a continual state of chemical flux, characterized by a balance between the rate of formation and rate of breakdown of body constituents. Therefore, more emphasis should be placed on function rather than structure. This may lead to the definition of diseases in terms of physiology and biochemistry rather than in terms of

N

anatomy and histopathology. This is useful because of the principle of chemical reserve: the rate of a chemical reaction within a region of the body or an organ can often fall to low levels before symptoms appear. Thus, one can often detect chemical abnormalities earlier than is possible by waiting for structural changes to be detectable. In that respect nuclear medicine procedures offer a high sensitivity in the picomolar range. Labeling of substrates with radioactive isotopes and administration of very low amounts of these tracers allow the assessment of biochemical or physiological processes without any interference with the phenomena to be studied. This allows one to base medical diagnoses on *in vivo* regional as well as global physiological or biochemical abnormalities. If disease is more and more understood in molecular terms, then diagnosis should also be based on molecular techniques. In this respect nuclear medicine must be seen as the pioneering discipline in the field of molecular imaging. The goals of nuclear medicine procedures consist in the development of specific radiotracer molecules, functional characterization of disease, detection of focal disease before overall organ function is impaired, and assessment of the effects of treatment. These goals can be obtained by three types of measurements: transport processes, bioenergetics, and intracellular and intercellular communication.

Imaging Devices

Planar single-photon imaging and single-photon-emission computed tomography (SPECT): Single-photon emission imaging is based on the uniform emission of photons in all directions during the decay of isotopes such as ^{67}Ga, ^{99m}Tc, ^{111}In, ^{123}I, or ^{201}Tl. The measurement of these photons can be used for the generation of planar images or tomographic images. Detection of these photons is achieved by a gamma camera which is composed of scintillation crystals (NaI (Tl)), a photomultiplier tube, and associated electronic devices. Collimators are positioned between the patient and the crystal and are used to reject off-axis radiation. Planar images are obtained by positioning the patient in a definite orientation towards a gamma camera and collecting the counts. This leads to a two-dimensional representation of three-dimensional objects. In contrast to radiographs, which are transmission images, scintigraphic scans deliver emission images. This has considerable impact on the information obtained from scans performed in different positions: an anterior scan, for example, shows mainly anterior tissue structures. Tomographic images can be acquired by viewing a patient's activity distribution from different angles. This can be done by rotating a gamma camera with one, two, or three heads around the patient and recording data from multiple projections. Photons are counted every 3–6° throughout a rotation of 180–360°, which usually requires 20–30 min. The resulting data can be reconstructed analogous to CT images. In comparison to planar images, SPECT images show a five- to eightfold increase in contrast, which is obtained by eliminating the activity superimposed on the structure of interest. However, images with high count density are needed for image reconstruction to avoid error propagation observed at low count rates.

Positron emission tomography (PET): Decay of positron emitters releases a positron with specific kinetic energy which determines the mean travel distance (or mean positron range) from the nucleus. Combination of the positron with an electron causes two annihilation photons each having the energy corresponding to the electron mass (511 keV) with a characteristic spatial orientation (180° apart with a random variation of 0.5°). PET scanners are built of a ring of scintillations crystals (commonly used scintillators are NaI(Tl), bismuth germanate, and lutetium oxyorthosilicate doped with cerium) and identify nearly simultaneous or "coincident" scintillations in opposite detectors. This coincidence detection provides better and more uniform sensitivity and resolution than does conventional imaging. Since the attenuation of photons can be measured by a transmission scan it is possible to obtain quantitatively accurate data of the regional distribution of a radiopharmaceutical.

Fusion imaging: structural and functional data in most cases are complementary because the images refer to different aspects of the disease. Computed tomography (CT) and magnetic resonance imaging (MRI) are used primarily for the imaging of structural/anatomical changes caused by a specific pathological process. In contrast, SPECT and PET studies display functional changes associated with disease. Usually the functional images are interpreted in conjunction with corresponding morphological images from CT or MRI. This information can be combined in fusion images either by use of software approaches or by hybrid systems such as SPECT/CT or PET/CT. Software solutions work well for rigid organs such as the brain. However, other parts of the body may cause more problems due to patient movement and motion of internal organs as well as repositioning errors.

Radiopharmaceuticals

The information obtained by nuclear medicine procedures is determined by the radiopharmaceutical administered to the patient. There are some radionuclides whose natural distribution is of interest: ^{123}I for thyroid function, ^{133}Xe and ^{81m}Kr for lung ventilation, ^{67}Ga for inflammation, and ^{201}Tl for perfusion imaging. Most radiopharmaceuticals consist of two parts: a radioactive label and a molecule whose physical or chemical properties define the biodistribution of the agent. A few agents used in nuclear medicine are radioisotopes of natural physiological substrates, whereas the vast majority are more complicated compounds. The radioisotopes of iodine were the first used in nuclear medicine with the thyroid as target and showed that the rate of iodide incorporation greatly increased in hyperthyroidism. However, today ^{99m}Tc is the ideal choice due to its availability and optimum decay characteristics, although complex chemistry is needed for the coupling of the isotope to the tracer molecules (Table 1).

Nuclear Medicine – Diagnostic Procedures. Table 1
Selected single-photon radiopharmaceuticals in clinical use

^{123}I, ^{131}I as NaI	Thyroid function
$^{99m}TcO_4^-$	Thyroid function
^{99m}Tc-MDP	Bone imaging
^{99m}Tc-MAA	Perfusion
^{99m}Tc-DTPA	Renal function, lung aerosol, liquor scintigraphy
^{99m}Tc-MAG_3	Renal function
^{123}I-Hippuran	Renal function
^{99m}Tc-erythrocytes	Blood pool
^{99m}Tc-albumin	Blood pool
^{99m}Tc-sulfur colloid	Reticuloendothelial function
^{99m}Tc-HIDA	Biliary imaging
^{111}In-leukocytes	Inflammation
^{67}Ga-citrate	Inflammation, tumor
^{133}Xe, ^{127}Xe	Lung ventilation
^{81m}Kr	Lung ventilation
^{201}Tl-chloride	Myocardial perfusion
^{99m}Tc-sestamibi	Myocardial perfusion, tumor
^{99m}Tc-tetrofosmin	Myocardial perfusion
^{99m}Tc-HMPAO	Brain perfusion
^{99m}Tc-ECD	Brain perfusion
^{123}I-IMP	Brain perfusion
^{99m}Tc-HMPAO-leukocytes	Inflammation
^{99m}Tc-TRODAT-1	Dopamine transport
^{123}I-IBZM	Dopamine D_2 receptor
^{99m}Tc-Arcitumomab	Tumor
^{111}In-octreotide	Somatostatin receptor-positive tumor
^{123}I-IMT	Tumor, amino acid transport
^{123}I-MIBG	Neuroendocrine tumor, heart innervation
^{123}I-b-CIT	Dopamine transport
^{123}I-Iomazenil	Benzodiazepine receptor, epilepsy, viability
^{131}I-Norcholesterol	Adrenal glands
^{59}Fe-citrate	Iron kinetics

Radiopharmaceuticals are prescription drugs subject to the same controls and regulations as nonradioactive drugs. All tracers must be tested for quality and safety before they can be given to a patient. Furthermore, most medical radionuclides have short half-lives in the range of hours or days. Therefore, unlike other drugs they must be made and delivered promptly.

Since most commonly used PET radiotracers have a very short half-life, time is a substantial factor in the process of isotope production, tracer synthesis, and PET measurements (Tables 2 and 3). As an example, for ^{11}C-labeled compounds the typically needed time periods are 10 min for cyclotron bombardment, 40 min for tracer production, and up to 90 min for PET imaging. However, the synthetic versatility of carbon with respect to the production of naturally occurring molecules justifies the development of ^{11}C-labeled PET tracers. Furthermore, due to the short half-life of PET isotopes, repeated PET examinations on the same subject are possible within short time intervals (i.e., the same day), allowing a more detailed description of the underlying biochemical or physiological processes.

Nuclear Medicine – Diagnostic Procedures. Table 2
Physical characteristics of commonly used positron emitters

Isotope	Half-life (min)	Maximum energy (MeV)	Range (mm) in H_20
Fluorine-18	110	0.635	2.4
Carbon-11	20.4	0.96	4.1
Nitrogen-13	9.96	1.19	5.4
Oxygen-15	2.1	1.72	8.2

Nuclear Medicine – Diagnostic Procedures. Table 3
Selected PET radiopharmaceuticals in clinical use

^{18}FDG	Glucose metabolism, myocardial viability, epilepsy, tumor
^{18}F-FDOPA	Dopamine pool, decarboxylase activity
^{18}F-FET	Tumor, amino acid transport
^{18}F-fluoride	Bone metastases
^{11}C-methionine	Tumor, protein synthesis
N-methyl-^{11}C-flumazenil	Benzodiazepine receptor, epilepsy
O-methyl-^{11}C-raclopride	Dopamine D_2 receptor
^{82}Rb	Myocardial perfusion
$H_2{}^{15}O$	Perfusion
^{11}C-acetate	Metabolism
^{13}N-NH_3	Perfusion

N

Principles of Functional Measurements

Measurements of radiotracer distribution may be performed as static or as kinetic studies. For static scintigraphy a single static image is obtained at a specific time after tracer administration. This is done when an equilibrium or a stable distribution of radioactivity is reached, which is the case for processes with slow kinetics. Static scintigraphy may differentiate between functional active or inactive tissue. Inactive regions are displayed either as cold spots (examples are pulmonary embolism, myocardial ischemia or scar tissue, brain perfusion defects, or cold nodules in the thyroid) or as hot spots with a high target-to-background ratio (examples are metastases in bone scintigraphy, glucose-consuming tumor tissue in FDG-PET, or binding of antibodies and ligands to surface antigens or receptors).

Alternatively, the time course of tracer accumulation can be measured and data from multiple studies under different biological conditions may also be obtained. If the appropriate tracer and imaging procedures are selected, the time–activity curves generated from regions of interest (ROIs) in the image should be directly influenced by the physiological characteristics of interest, such as blood flow, metabolism, or receptor concentration. The concentration of radioactivity in a given tissue region at a particular time primarily depends on two factors: the local tissue physiology such as blood flow or metabolism and the input function, which is the time course of tracer radioactivity concentration in the blood or plasma. The input function defines the availability of the radioactive tracer to the organ of interest. Quantitation is possible by analysis of time–activity curves using pharmacokinetic models. A model is the mathematical description of the relationship between tissue concentration and physiological control factors. An elaborated model allows prediction of the time course of tracer accumulation in a tissue region from knowledge of the local physiological variables and the input function. Parameters obtained from these models are blood flow and extraction, volume of distribution, biochemical reactions such as glucose transport and phosphorylation, receptor density, and pharmacokinetics of radiolabeled drugs. Parametric images derived from these dynamic studies and model analysis show where and how fast chemical reactions are taking place within the body, for example, revealing the rates of regional glucose utilization within organs such as the heart, brain, and liver. Simpler models predict only certain aspects of the time–activity curves, such as initial slope, area under the curve, or ratio of target to a reference region.

Functional tests can also be performed by physiological or pharmacological modulation of tracer accumulation. This is done in coronary heart disease using exercise or pharmacological stress. In these patients symptoms often occur after exercise. Therefore, perfusion at rest is normal with a decreased coronary reserve during exercise or pharmacological intervention with pyridamole or dobutamine. In the brain the autoregulation of cerebral perfusion can be modulated by pharmacologically induced changes in blood pressure or an increase in plasma CO_2 levels using carbonic anhydrase inhibitors. As in the heart, a normal cerebral blood flow at rest may exist in the presence of a decreased vascular reserve. This can be evaluated by measurement of perfusion after vasodilator stress. In the kidney the sensitivity in detecting renovascular hypertension can be increased using an angiotensin-converting enzyme inhibitor such as captopril, which accentuates the physiological differences between the normal and the dysfunctional kidney. More elaborate studies have been done with receptor ligands in the brain: the tracer 3-*N*-(^{11}C)-methylspiperone (NNSP) binds to dopamine 2 (D_2) receptors in the basal ganglia. Neuroleptic drugs used in the treatment of schizophrenia and certain other neuropsychiatric disorders block D_2 receptors. Therefore, this tracer was used to monitor the degree of blockade of D_2 receptors after administration of neuroleptic drugs by measuring NMSP binding. In addition, the duration of opiate receptor blockade by the blocking drugs naloxone, naltrexone, and nalmefene was monitored using ^{11}C-carfentanil and PET.

Mechanisms of accumulation: Since the information obtained from nuclear medicine measurements is dependent on the selection of the appropriate tracer and the selection is based on biochemical and physiological knowledge of the tracer kinetics, the biological interpretation of the resulting images is clear. Multiple mechanisms of tracer accumulation exist:

- Diffusion processes which are used for ventilation studies of the lung
- Adsorption phenomena obtained after injection of bone-seeking agents and used in bone scintigraphy
- Ion transport observed in thyroid scans with sodium pertechnetate
- Capillary blockade, a classical approach from physiology transferred to patient studies as radiolabeled macroaggregated albumin in lung perfusion scanning
- Phagocytosis of nanocolloids in scans of the liver, spleen, and reticuloendothelial system
- Active transport phenomena such as iodide uptake, tubular secretion of MAG_3 *via* an anion exchange system, ^{123}I-IMT uptake *via* the amino acid transport system L
- Sequestration of cells used for the detection of radiolabeled erythrocytes in the spleen
- Metabolism, exemplified by the use of fluorodeoxyglucose (FDG) in cardiology, neurology, and oncology
- Synthesis of neurotransmitters, measured using ^{18}F-DOPA and PET

- Receptor binding used in the diagnosis of D_2 receptor density in patients with movement disorders with ^{11}C-raclopride or ^{123}I-IBZM or in the detection of somatostatin receptor-expressing tumors with ^{111}In-octreotide
- Antigen–antibody complexes used for bone marrow scan or tumor detection *via* specific tumor antigens such as CEA

Clinical Applications

The above-mentioned techniques have different clinical applications as mentioned in the following examples.

1. Assessment of organ function: Examination of the kidneys, lungs, or salivary glands allows a detailed evaluation of their different parts. Physiological information *in vivo* is obtained by the determination of esophageal transit or gastric emptying.
2. Differential diagnosis: Assessment of D_2 receptor density with ^{123}I-IBZM can be used to differentiate between Parkinson's disease or multiple system atrophy. FDG-PET is useful for the differentiation between scar and recurrence in patients after surgery for colon carcinoma; ^{123}I-IMT uptake is used for the differentiation between radiation necrosis and recurrence in patients with brain tumors. Further examples are $^{99m}TcO_4^-$ for the diagnosis of thyroid nodules and labeled erythrocytes in patients with suspected liver hemangioma.
3. Localization of disease: Multiple procedures are available for different clinical problems. Localization of disease can be the detection of epileptic foci (^{18}FDG or ^{99m}Tc-HMPAO), infectious foci (labeled leukocytes or antibodies), receptor-positive tumors (^{111}In-octreotide), increased tumor marker in tumor patients after surgery or carcinoma of unknown primary tumor (^{18}FDG), and in gastrointestinal bleeding (labeled erythrocytes).
4. Staging: Commonly applied tracers are phosphonic acid derivatives such as ^{99m}Tc-MDP for the visualization of bone metastases and ^{18}FDG for the detection of lymph nodes or distant metastases.
5. Therapy planning: This can be done prior to radioimmunotherapy to estimate the dose obtained in tumors. First, a diagnostic scan is performed using the antibody labeled with a γ emitter. Then, treatment is performed with the same antibody labeled with a β emitter. For radiation therapy, inclusion of functional information such as glucose metabolism, proliferation, or hypoxia in the treatment protocol is expected to be the state of the art in the near future. Furthermore, biodistribution studies of radiolabeled new drugs may expedite the preclinical and clinical procedure for the approval of these drugs.
6. Therapy monitoring: Since most treatment protocols may cause severe side effects to patients it is critical to know whether therapy is successful at an early stage. This can be done by measurements of glucose metabolism using ^{18}FDG. As an alternative, apoptosis measurements with ^{99m}Tc-annexin V are currently under evaluation. A nononcological example of therapy monitoring is the measurement of bone remodeling by repeated bone scintigraphy with ^{99m}Tc-MDP in patients with Paget's disease.

Future Potential

Nuclear medicine is a discipline where a rapid transfer of basic research into clinical practice is possible. The application of principles or insights gained by biochemistry, immunology, molecular biology, or virology will allow new radiolabeled molecules to be established. The isotope used for labeling determines the use of the resulting tracer either for diagnostic or for therapeutic purposes. By the exchange of different isotopes, the same biomolecule can be used first for therapy planning and then for treatment.

Many new molecular structures have been cloned and will be available as potential novel diagnostic or drug discovery targets. The target selection and validation will become the most critical component in this process. The evaluation of genetically manipulated animals or newly designed biomolecules will require information about physiology, biochemistry, and pharmacology and the experimental approaches will apply many technologies including *in vivo* imaging with molecular imaging procedures such as SPECT and PET. Pharmacogenomics will identify new surrogate markers for therapy monitoring, which may represent potential new tracers for imaging. Furthermore, drug distribution studies for new biomolecules are needed to speed up drug approval in preclinical stages of drug development. Finally, bioengineering will lead to the design of new biomolecules by methods such as DNA shuffling or phage display procedures, which may be used for new approaches in isotope-based diagnosis and treatment of disease.

Nucleoplasty

Relies on the principle of 'controlled ablation', a process in which radio frequency energy is used to generate a highly focussed plasma field that is capable of cleaving molecular bonds. After insertion of a special wand into the centre of the intervertebral disc, radio frequency energy is used to ablate nucleus pulposus tissue, decreasing intradiscal volume and thereby lowering intradiscal pressure. This causes the herniated portion of the nucleus pulposus to recede towards the centre of the disc, relieving pressure on the nerve root.

Obstructive Uropathy in Childhood

Michael Riccabona, Richard Fotter
Division of Pediatric Radiology, University Hospital, Medical University of Graz, Graz, Austria
richard.fotter@meduni-graz.at

Synonyms

Obstructive uropathy; Urinary tract obstruction

Definition

Obstructive uropathy is any kind of hindered urine drainage from the renal calyces or pelvis, the ureter or the bladder. However, clinically relevant obstruction means impairment to a degree that in the past has already damaged or in the future will deteriorate renal function of the affected system. Consequences of obstruction initially are dilatation, thickening of the (bladder-, ureteral-, pelviceal- and calyceal-) wall and eventually thinning of renal parenchyma with consecutive diminishing renal function. This may ultimately lead to a decrease in dilatation; therefore, the generally used assessment of dilatation for grading of obstruction may mimic improvement in cases with significant functional deterioration. Depending on the various underlying concepts different definitions are used to define the degree of obstruction as considered relevant for treatment decisions in different parts of the world, with Europe tending to quantify the drainage dynamics, and America focusing on renal function.

Embryology and Pathogenesis

There are several causes for obstruction, with consecutively different embryologic and pathogenetic pathways. They can be divided into congenital anomalies and anatomic variants or secondary and acquired obstruction (Table 1).

Obstructive Uropathy in Childhood. Table 1 Causes of obstructive uropathy

Congenital causes:
• Idiopathic megaureter, with relative narrowing at the uretero-vesical junction (Fig. 1a),
• Ureterocele with megaureter, mostly with a duplex system (Fig. 1b),
• Rare other ureteral variations such as ureteral valves,
• Congenital uretero-pelvic junction obstruction, with narrowing by a fibrotic or dysplastic segment at the uretero-pelvic junction (Fig. 1c),
• Posterior urethral valves and other urethral anomalies, as well as rare ureteric flaps,
• Anatomic variations
• Caliceal neck stenosis or ureteral obstruction caused by prominent or accessory renal vessels (Fig. 1d),
Retrocaval ureter leading to impaired ureteral drainage,
Horse shoe kidney, malrotation and ectopic kidneys, with an unusual coarse of the ureter that may impair drainage,
Secondary obstruction
• Urethral- and bladder polyps,
• Ureteral and urethral fibrosis or stenosis, such as (post-)traumatic urethral stricture leading to bladder outlet obstruction with consecutive bladder pathology and associated obstructive or refluxing uropathy (see entry 'Hydronephrosis'),
• (Post-)infectious causes,
• Motion and peristalsis impairment by dysplasia or dysgenesis and palsy,
• Retroperitoneal processes (tumour, fibrosis, haematoma, ...),
• Acute urinary tract obstruction by an ureteral calculus, a haematoma or blood clot, or fungus ball,
• Post-/peritraumatic obstruction (haematoma, compression, rupture, ...).

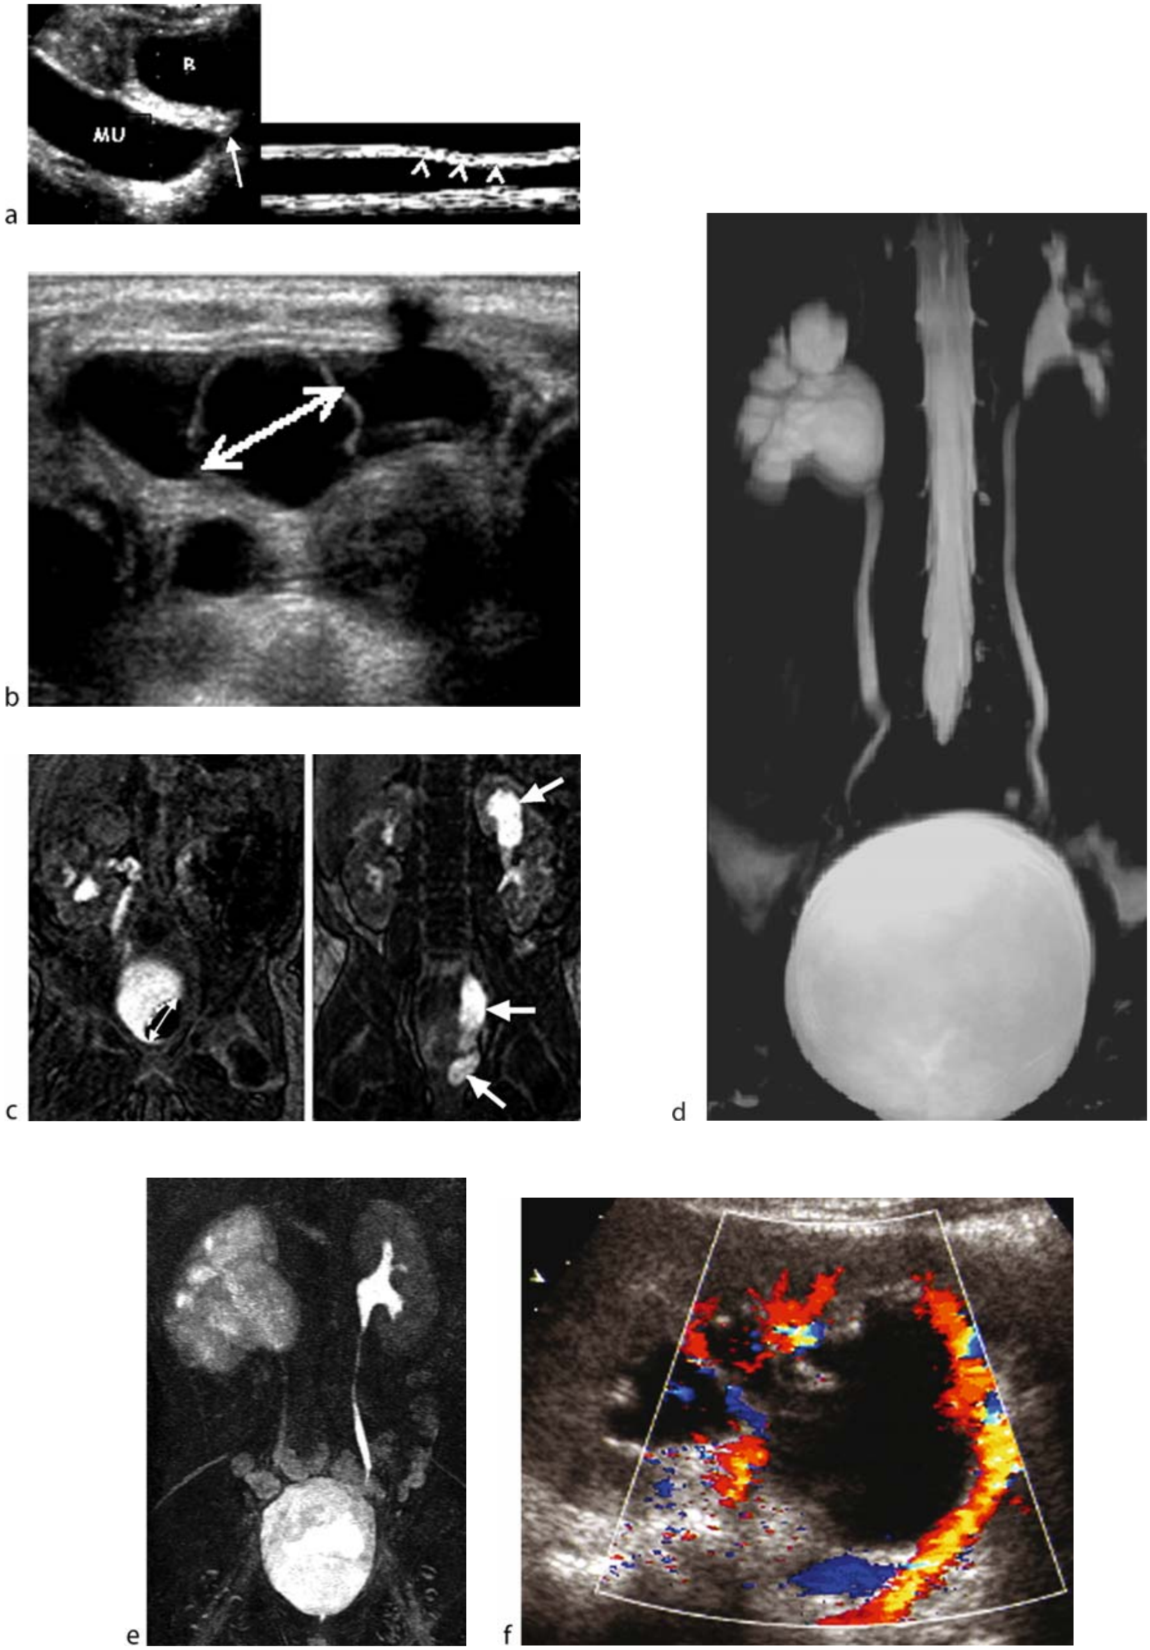
Clinical Presentation

Typical clinical presentation of obstructive uropathy includes abdominal or flank pain, renal colic, abdominal distension or palpable abdominal mass (in gross HN) and (micro-)haematuria. Lower urinary tract obstruction (urethral obstruction) may additionally exhibit anuria or oliguria, e.g. in a neonate with posterior urethral valves (PUV).

Imaging

The purpose of imaging is not only to detect urinary tract dilatation and obstruction, but to provide a detailed anatomic display of the patient's individual situation, to describe the obstruction anatomically (high-, middle-, low/ureteral obstruction? obstruction at the uretero-vesical- or at the uretero-pelvic junction? obstruction of the urethra?) and finally to grade obstruction and—in particular—to differentiate dilative or non-obstructive uropathy from (partial) obstruction, since obstruction may need treatment and follow-up, as well as to assess renal function.

Imaging methods: Imaging is primarily performed using *ultrasound* (US), which can only be successfully applied in sufficiently hydrated children and should always include an assessment at full and post-void bladder. Furthermore, (colour) Doppler sonography (CDS) as well as less common approaches (such as perineal US of the urethra) and application of modern methods (e.g. 3DUS) may offer additional valuable information. For anatomic assessment of the urethra in suspected lower urinary tract obstruction or for differentiating refluxing units from obstructive dilation, an *urethrography*, a *cystogram* or a VCUG is indicated. For anatomic assessment of the upper urinary tract (ureter, renal collecting system and kidney) IVU has been the major imaging tool in the past, in addition to US; however, increasingly *MR-urography* (MRU) is taking this role not only offering an anatomic assessment but also allowing for functional evaluation and MR-angiography in the same investigation. CT is rarely used in children due to its radiation burden—in complicated stone disease a low dose protocol multi-detector CT may become indicated. For grading of obstruction and functional evaluation diuretic renal scintigraphy still is the most commonly used tool (Fig. 2). It allows differentiating dilative from (partially) obstructive systems using various protocols (depending on the time of administration of diuretics) that are applied not only for initial assessment, but also during follow-up, particularly of equivocal findings. Increasingly this functional assessment can also be performed by functional diuretic MRU, however, availability and technical aspects as well as sedation needs have yet hindered a wide spread use of this approach. Retrograde or antegrade *ureterography* and pyelography are rarely performed; in rare cases or in complicated malformations they may be

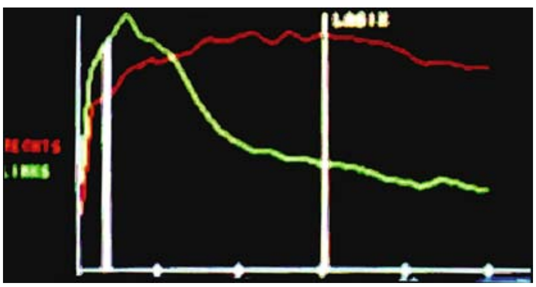


Obstructive Uropathy in Childhood. Figure 1 (continued)

O

used as well as peri-operatively, and in acute events with indication for *percutaneous nephrostomy*. *Whitaker test* (percutaneous nephrostomy with a flow pressure curve derived from intrapelvic fluid infusion *via* the nephrostomy tube with simultaneous pressure measurement) has been the gold standard for assessment of upper urinary tract obstruction. Due to its invasiveness and the reliable results from diuretic scintigraphy or functional MRU this method is today restricted for complicated cases with equivocal results of standard imaging, potentially in a peri-operative setting, as well as for research purposes.

Imaging indications and algorithms: Basically obstructive uropathy is primarily diagnosed using US. Further imaging depends on the initial findings (Table 2).



Obstructive Uropathy in Childhood. Figure 2 Diuretic scintigraphy in a patient with severe uretero-pelvic junction obstruction. Note the different perfusion, excretion and drainage curves on this diuretic Tc ^{99m} MAG3 renography, with delayed and reduced renal transit indicating diminished function and causing a flattening of the early activity curve (red (dark) line) and poor drainage in the right obstructed kidney, with only poor response on diuretic stimulation (yellow (light) line). Normal renography curve of the normal left kidney (green (gray) line).

- Low degree hydronephrosis (HN) is followed up by US without any other imaging,
- High degree HN is assessed by diuretic renal scintigraphy and MRU (or IVU), the latter pre-operatively or in case of complex malformations,
- VCUG for differentiation of refluxing from obstructive uropathy
- In acute renal colic (note that acute urinary tract obstruction often only exhibits mild dilatation!) US can often sufficiently diagnose the condition. US is supplemented by an abdominal plain film of the kidney, ureter and bladder ('KUB') for assessment of additional calculi or positioning of a sonographically diagnosed calculus for lithotripsy. In unclear cases an adapted IVU or even an un-enhanced (spiral multi-detector) CT may still become indicated. In case of renal parenchymal findings that indicate an underlying disease such as nephrocalcinosis or medullary sponge kidney adequate imaging of these entities is performed (see entry: 'Nephrocalcinosis', 'Cystic Renal Disease'),
- In complex cases, particularly in combined infection and obstruction, CT- or MR-urography may become indicated. Percutaneous nephrostomy offers an image guided treatment option, and in PUV with lower urinary tract obstruction a suprapubic catheterism may become necessary,
- For follow-up, regular (diuretic) US examinations at 1–3–6 month intervals and diuretic scintigraphy or MRU are recommended, with some variation of timing and protocol in different centres.

Note that imaging indication and method depends on the indication for treatment, which varies between the continents; whereas in Europe usually diuresis impairment indicates surgical action, loss of kidney function expressed by relative renal function (usually assessed by

Obstructive Uropathy in Childhood. Figure 1 Imaging findings in typical obstructive uropathies. (a) US of a primary megaureter. This longitudinal section of the retrovesical dilated ureter (MU) with a short tight uretero-vesical junction (⇒) into the urinary bladder (B) documents the existing ureteral peristalsis (>) using an m-mode track recorded at the site of the dotted line. scintigraphy) is considered the indication for surgery in the US, were as some other areas relay on the degree of dilatation and basically operated all grossly dilated systems.

Diagnosis

Imaging allows diagnosis of the underlying anatomy and pathology, enables deciding on the level of obstruction, and allows for functional evaluation particularly necessary for treatment decisions. Imaging criteria are different for the various modalities, the underlying pathology and the different treatment paradigms.

Small intestinal obstruction

Definition

►Small bowel obstruction (SBO) is the impedance of the progression of intestinal content due to a mechanical obstacle (1).

Pathology/Histopathology

The small bowel extends from the duodeno-jejunal junction to the ileocaecal valve. It is approximately 6.5 m long. The jejunum represents the proximal two-fifths and the ileum, the distal two-fifths. The small bowel gradually changes from the beginning of the jejunum to the end of the ileum. The jejunum (2.5 cm diameter) is wider than the ileum (2 cm diameter). The mucosa is arranged in circular folds which are larger and more numerous in the jejunum. These folds are a distinguishing feature from large bowel on an adult plain film of abdomen (PFA).

Secreted fluid and swallowed air contribute to bowel distension in SBO. Ischaemia is a serious complication, which may be venous, arterial or both and may lead to infarction. Ischaemia is more likely in ►closed-loop obstruction (CLO). In CLO, a loop of bowel is occluded at two points by a single constrictive lesion. The mesentery and intestine are occluded. This is usually due to adhesions or hernias.

The causes of SBO are outlined in the Table 1.

The commonest causes are adhesions (50–80%), hernias (10–15%) and neoplasms (10–15%). Other causes are uncommon in the adult population.

Clinical Presentation

SBO accounts for 20% of all acute surgical admissions (1). Classic symptoms are abdominal pain, distension, vomiting and constipation. Clinical presentation depends on the severity of SBO and the presence or absence of ischaemia. In early, uncomplicated SBO, abdominal pain may be crampy and intermittent, but when ischaemia occurs, pain becomes more severe and continuous.

On examination, high frequency bowel sounds and abdominal distension are observed. Dehydration and electrolyte imbalance can occur.

Imaging

The goals of imaging in SBO are

1. Confirm the diagnosis
2. Determine the level of SBO
3. Diagnose the cause
4. Assess for evidence of ►strangulation or mesenteric ischaemia
5. Determine need for surgery

PFA

A PFA is usually the first radiological test in SBO. The PFA has a sensitivity of 64% for SBO diagnosis but does not reliably allow diagnosis of cause, level of SBO, or ischaemia. Some advocate that the PFA should be performed erect to assess for air-fluid levels (1). If an erect PFA is not possible, a horizontal beam lateral film can also be used to evaluate for air-fluid levels. An erect chest X-ray is the plain radiograph of choice to assess for perforation.

Contrast Studies

There are limitations to the use of contrast studies in acute SBO. Barium is contraindicated if perforation is suspected. Water-soluble contrast can be used, but is diluted by the excess intra-luminal fluid. If hyper-osmolar agents are used, these can worsen dehydration by osmotic effect on the bowel wall, encouraging further fluid loss into the lumen. Enteroclysis reduces dilution by intraluminal fluid, facilitates propulsion toward the level of obstruction and also allows a means for drainage of some of the administered fluid.

Since computed tomography (CT) became available, enteric contrast studies have been of limited value in SBO. There are two situations in which contrast studies are useful.

1. Enteroclysis can be used in the investigation of intermittent or low-grade obstruction for which the sensitivity of CT is only 48%.
2. Water-soluble follow through (WSFT) can be used to distinguish which clinically stable patients are likely to have spontaneous resolution of SBO (2). About 100 mL of water-soluble contrast is administered via a nasogastric tube and a PFA is taken 4 h later. If the contrast column has reached the caecum by this time, then the obstruction is very likely to resolve. If not, SBO is unlikely to resolve spontaneously.

Ultrasound

US is not used as a first line investigation in SBO if CT is available. It confirms dilated fluid-filled in SBO in up to 95.3% of cases. Ultrasound is not as good as CT for ruling in SBO but it is better for ruling out SBO, which is unlikely in the absence of dilated, fluid-filled loops (3).

Extrinsic	Intrinsic	Intra-luminal
Adhesions (most common)	Neoplasm (common)	Gallstones
Hernias (common)	Inflammation	Intussusception
Neoplasm (common)	Ischaemia	Meconium ►ileus equivalent (in cystic fibrosis)
Inflammation	Haematoma	

(*continued*)

Dilated small bowel loops are also seen in ►paralytic ileus. In SBO versus paralytic ileus, hyper-dynamic intestinal motility can be observed in real time.

Computed Tomography

CT has high accuracy in the diagnosis of SBO and in determining the cause. Enteric contrast is optional depending on clinical severity of obstruction. In high-grade SBO, there is usually sufficient fluid within the bowel to allow accurate evaluation of obstructed loops. Intravenous contrast (150 mL contrast bolus at 3 mL per second) is used to demonstrate bowel wall enhancement, which is important in the diagnosis of ischaemia.

In practice, most patients are initially evaluated with PFA and subsequently with CT.

Nuclear Medicine

Scintigraphy does not currently play an important part in the diagnosis of SBO.

Diagnosis

Confirming the Diagnosis of Obstruction

The PFA is diagnostic of SBO in up to 64% of cases. Dilated loops of bowel are seen, usually within 5 h of the onset of obstruction (Fig. 1). If the dilated loops are entirely fluid-filled, then the diagnosis may be occult on PFA. Dilated bowel loops can also be seen in paralytic ileus.

Obstructive Uropathy in Childhood.
Figure 1 PFA of SBO. Multiple dilated loops of small bowel shown.

CT is more than 95% accurate in the diagnosis of SBO (4). The diagnosis depends on demonstrating dilated small bowel loops (>3 cm) with a focal discrepancy in the calibre of the bowel at the transition between obstructed and non-obstructed bowel (Fig. 2). In paralytic ileus, the small bowel is also dilated, but the right colon is usually also dilated, often tapering to normal at, or distal to, the hepatic flexure (4).

Determining the Level of Obstruction

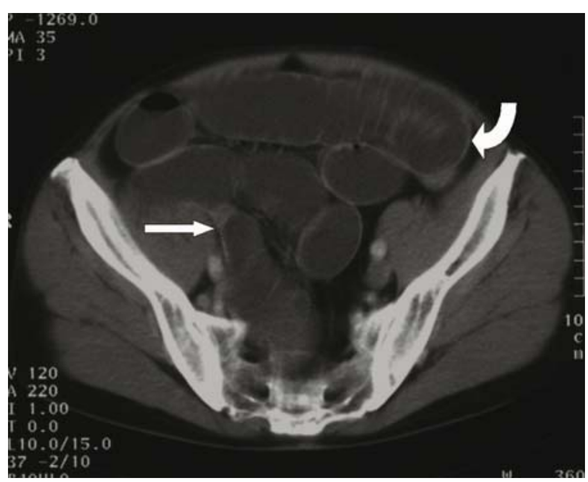
On PFA, the presence of dilated small bowel superiorly in the abdomen may indicate proximal SBO. Dilated pelvic loops more frequently imply distal SBO. In SBO, dilated small bowel loops align along the long axis of the mesentery and jejunal loops can be found in the pelvis, with ileal loops in the upper abdomen.

In order to distinguish large bowel obstruction from SBO on PFA, the following features are helpful:

Megibow (4) describes the systematic assessment of the bowel on CT in bowel obstruction. The bowel should be systematically evaluated in a retrograde way, beginning at the rectum, and proceeding to the caecum. After

Small bowel obstruction	Large bowel obstruction
Haustra absent	Haustra present
Valvulae in jejunum	No valvulae
Many loops	Few loops
Central distribution	Peripheral distribution

(continued)



Obstructive Uropathy in Childhood.
Figure 2 SBO due to adhesions. ►Zone of transition in distal small bowel (arrow). Note normal bowel wall enhancement (curved arrow).

'clearing' the colon, the distal ileal loops should be identified and assessment should proceed proximally to the level at which the calibre of the small bowel is increased (Fig. 2). Review of the images on cine-mode and multiplanar reconstructions [particularly with multidetector-row CT (MDCT)] are helpful in this evaluation.

Diagnosis of the Cause of Obstruction

Adhesions, hernias and neoplasms account for over 80% of cases. CT is the primary diagnostic tool in determining aetiology of SBO, with accuracy of 70–95% (1).

In developed countries, adhesions account for 50–80% of causes. A history of prior abdominal surgery is usual, although previous peritoneal inflammation may also cause adhesions. Even in patients with known intra-abdominal malignancy, SBO is due to adhesions in 21–38% (4). On CT, diagnosis of adhesions is based on an abrupt change in small bowel calibre without another cause of obstruction at the transition point. A beak-like narrowing can be seen. Although the adhesions cannot be visualised with CT, it is important to make the diagnosis of obstruction secondary to adhesions when no other cause is seen (4).

Hernias account for 10–15% of cases (1). External hernias are more common than internal and include inguinal, femoral, paraumbilical, obturator, Richter, Spigelian and incisional hernias. Internal hernias include paraduodenal hernias, transmesenteric hernias, and herniation through the foramen of Winslow. These can be recognised by an abnormally positioned segment of small bowel often with protrusion of mesentery through the internal defect, with proximal bowel dilatation. With increasing use of laparoscopic surgery, port-site hernias are a cause of SBO to recognise. Laparoscopic port sites vary in diameter, generally from 5 to 10 mm. Herniation through laparoscopic fascial defects as small as 5 mm has been described. SBO due to port-site hernias is more common in the early post-operative period (5).

Neoplasia is the third most common cause of SBO. Infiltration of the bowel wall may be caused by adenocarcinoma, carcinoid or metastatic carcinoma. Extrinsic masses such as peritoneal carcinomatosis can also cause obstruction. In these cases a mass is seen at the transition point. Mural mass lesions may also lead to obstruction by causing intussusception.

Assessing for Evidence of Strangulation or Mesenteric Ischaemia

The presence of ischaemia in SBO increases mortality from between 5 and 8% to between 20 and 37% (4). It requires urgent surgical management. CT is 83% sensitive and 93% specific for ischaemia in SBO.

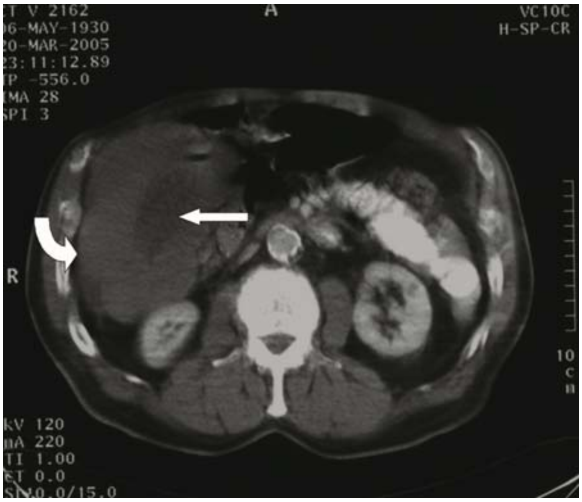
Strangulation is defined as CLO associated with intestinal ischaemia. In CLO (Fig. 3), a loop of bowel is occluded at two adjacent points along its course. CLO usually occurs due to constriction by adhesions or a hernia. The CT signs of CLO are

- Radial distribution of small bowel loops with mesenteric vessels converging toward apex
- U or C-shaped dilated bowel loop
- Two adjacent collapsed or triangular loops at the site of obstruction

CLO is prone to twisting of the affected bowel and mesentery leading to venous congestion with subsequent arterial ischaemia and infarction. This is termed strangulation. The CT signs of strangulation are

- Circumferential mural thickening
- 'Target' sign—concentric mural rings of different attenuation, post-intravenous contrast, a more specific form of mural thickening
- 'Whirl' sign—corkscrew configuration of mesenteric vessels due to twisting
- Increased attenuation of bowel wall
- Lack of bowel wall enhancement
- Air in bowel wall (intestinal pneumatosis)
- Mesenteric haemorrhage
- Ascites

In SBO complicated by ischaemia, the bowel wall appearance depends on the balance between venous obstruction, reduced arterial perfusion and reperfusion. If reduced arterial perfusion predominates, in the absence



Occlusion and Subocclusion, Small Bowel in Adults. Figure 3 Closed-loop obstruction. C-shaped loop of bowel. Note congested mesentery (arrow) and poor enhancement of bowel wall (curved arrow).

of significant reperfusion, then the bowel wall will be of normal thickness and many of the above signs will be absent. Therefore, CT is good at ruling in ischaemic SBO, but poor at ruling out ischaemic SBO (3).

Determining the Need for Surgery

The impact of imaging on management and indications for surgery have been summarised by Taourel et al. (1).

1. Strangulation and ischaemia (emergency)
2. Obstruction due to a tumour
3. Obstruction due to irreducible hernia (urgent)
4. Obstruction due to adhesions, without ischaemia, should be managed conservatively, where possible

As stated above, if SBO is slow to resolve with conservative management, WSFT is a useful test to determine the likelihood of successful non-operative treatment (2).

Ingolstadt, Germany
dierk.vorwerk@klinikum-ingolstadt.de

Synonyms

Femoral arterial obstruction; Femoral arterial occlusion; Infrainguinal arterial obstruction; Infrainguinal arterial occlusion; Popliteal arterial obstruction; Popliteal arterial occlusion

Definition

An arterial obstruction of the infrainguinal arteries is an occlusion or narrowing of an arterial segment between the groin and the lower limbs.

Pathology/Histopathology

Occlusions are complete obstructions of the infrainguinal arterial lumen and are due to thrombus formation, mainly on preexisting atherosclerotic plaque. In stenoses, the lumen is still patent but narrowed, with a diameter reduction of more than 50% causing symptoms. Alternatively, acute occlusions occur because of thrombotic emboli from the heart.

Clinical Presentation

Clinical indications for treatment include claudication, pain at rest, and nonhealing ulceration. The severity of the symptoms depends on the acuteness of the occlusion, the condition of collateral pathways, the lesion's location, and concomitant disease such as diabetes or renal insufficiency.

Imaging

Many imaging modalities allow the physician to diagnose infrainguinal artery obstruction. Color-coded duplex sonography as well as magnetic resonance angiography (MRA), computed tomography (CT), computed tomography angiography (CTA), and intra-arterial angiography are useful tools for detecting the location and extent of an iliac obstruction.

Nuclear Medicine

Nuclear medicine plays no particular role in the diagnosis of aortic stenosis.

Diagnosis

Diagnosis is reliably achieved by angiography or MRA. Detection by duplex sonography is a reliable tool for the femoropopliteal segment but is sometimes limited for detection and exact lesion description in the lower limbs. In stage IV (Fontaine) disease, MRA may be limited because of low arterial flow, movement artifacts, or artifacts due to superimposed venous flow.

Interventional Radiological Treatment

Endovascular Versus Surgical Treatment

Endovascular therapy is known to be of low invasiveness with good technical success, achieving fair overall patency. In data taken from eight publications reporting on 1,469 procedures, the weighted average technical success of femoropopliteal endovascular interventions was 90%, the complication rate was 4.3%, and the 3-year patency rate was 51%. Stents did not improve patency, showing a patency of 58% after 3 years (1).

Surgery offers acceptable results for distal reconstruction: An average 5-year patency of 80% for vein bypasses and 65–75% for expanded polytetrafluoroethylene (ePTFE) bypasses has been reported. The combined mortality and amputation risk was calculated to be about 2.2% for aortobifemoral reconstructions and 1.4% for femoropopliteal reconstructions (1).

Location of Lesion

Claudication is mainly related to lesions in the aortoiliac and femoropopliteal regions. It is unlikely to be due to infrapopliteal lesions, and there is general agreement that treatment below the knee should be strictly limited to patients with critical limb ischemia, that is, stages III and IV (Fontaine) or categories 4–6 (Rutherford).

Type of Lesion

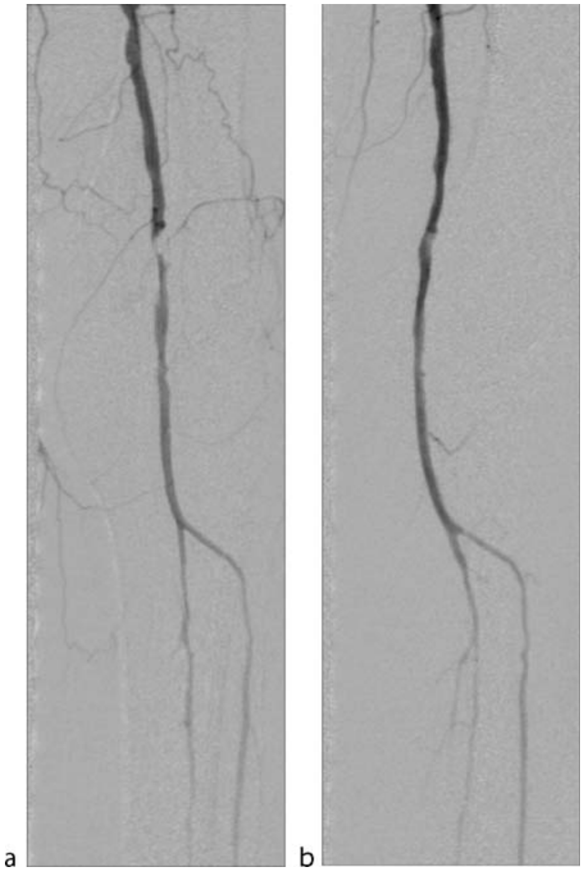
The morphology of a treated lesion influences the technical outcome, follow-up results, and also the risk of treatment. Therefore, the TransAtlantic Inter-Society Consensus (TASC) document introduced a classification system that tries to categorize lesions with regard to their accessibility to either percutaneous treatment or surgery: type A lesions, which are ideal for a percutaneous approach; type B lesions, in which the percutaneous approach is still the preferred technique; type C lesions, in which a surgical approach should be preferred; and type D lesions, in which surgery is the option of choice. The TASC classification overrides older classifications because it takes into account all of the available and published techniques (including stent technology), which offer a much wider variation of treatment as well as effective tools to deal with acute complications of balloon angioplasty, such as occluding dissection and vascular rupture.

If we consider percutaneous therapy as the preferred method to treat those patients presenting with mild or moderate claudication, treatment might be offered to those presenting with type A and B lesions but should be discussed in depth with patients with type C lesions, as the risk and the potential benefit of treatment are related to the underlying morphology.

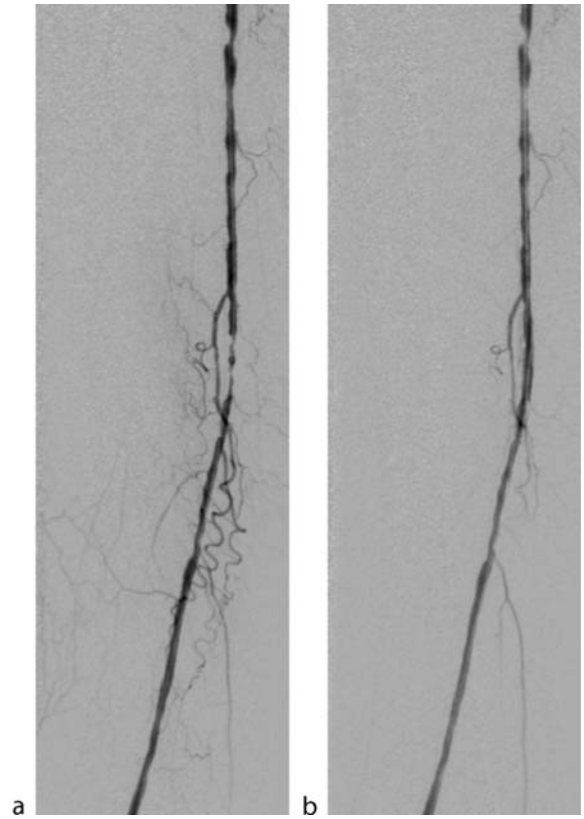
In the femoropopliteal field, type A lesions are single stenoses up to 3 cm in length not involving the very proximal superficial femoral and the distal popliteal artery. Type B lesions include stenoses 3–5 cm in length, heavily calcified stenoses, multiple lesions (each up to 3 cm), and lesions with no sufficient tibial run-off (the latter are unlikely to meet the criteria of mild or moderate claudication). Type C lesions are classified as stenoses or occlusions longer than 5 cm and multiple midsize lesions (3–5 cm). Total common femoral, superficial femoral, and popliteal occlusions are classified as type D lesions. There was some dissenting discussion on the definition of type B lesions: Interventional radiologists represented by the Cardiovascular and Interventional Radiological Society of Europe wished to express their assumption that even longer lesions of up to 10 cm may be justified as being classified type B instead of type C; they claimed that the reported results were mainly due to underdeveloped techniques and instruments that have substantially improved and that no data exists comparing the efficacy of percutaneous transluminal angioplasty (PTA) versus bypass surgery for lesions between 4 cm and 10 cm. (See Figs 1 and 2)

Other than in the iliac area, few femoral lesions meet the criteria for types A and B lesions, especially if limited to 5 cm in length. Thus, few patients with mild or moderate claudication due to femoropopliteal lesions will be ideal candidates for percutaneous treatment. Moreover—without limiting the importance of the TASC document, which certainly means a step forward in the joint approach to peripheral vascular disease—the morphological classification does not take into account some technical considerations that depend on the age and composition of a lesion. Particularly in femoral occlusions, the degree of organization of the occluding thrombus or the composition of the lesion with the original stenosis at the proximal and distal ends or in the middle are factors that are not very predictable but may influence the technical outcome of the intervention or its complication rate. (For instance, distal embolization might aggravate symptoms.) Other than in the iliac arteries, the liberal use of stents and stent grafts may help overcome a failed balloon angioplasty and resolve the technical outcome, but it does not achieve an improved long-term efficacy, and it may start a lifetime dependency on recurrent interventional or surgical procedures. These associated potential drawbacks have to be carefully balanced against the potential benefits and need to be discussed in depth with the patient before treatment is performed, especially in association with mild or moderate claudication.

These considerations restrict the use of endovascular treatment in femoropopliteal lesions to mainly stages IIb and IIa patients presenting with type A or less pronounced type B lesions.



Occlusion, Artery, Femoral. Figure 1 Popliteal artery stenosis. (a) Short-segment stenosis at the level of the joint. The stenosis is eccentric, which sometimes indicates insuffient reaction to percutaneous transluminal angioplasty (PTA). Stenting in that region is problematic because it is in the flexure zone of the popliteal artery. If needed as a bail-out treatment, a very flexible stent is preferred. (b) After PTA, sufficient opening has been achieved, and no further treatment is necessary.



Occlusion, Artery, Femoral. Figure 2 Superficial femoral artery lesion. (a) Short stenosis of a small superficial femoral artery close to the adductor's canal in a patient with stage IV disease and diabetes. (b) After percutaneous transluminal angioplasty, the arterial lumen is wider, but a dissection remains. No stent was used due to good flow, absence of collateral filling, and small arterial lumen.

Assisting Forms of Treatment

It is widely accepted that well-conducted physical exercise should precede any type of interventional treatment and that cessation of smoking is mandatory. Nevertheless, it is also true that in many institutions it is very difficult to find an infrastructure that allows instruction of state-of-the-art physical exercise for claudicants. And as far as smoking is concerned, there is a major difference between wanting to stop and actually stopping.

Moreover, even with state-of-the-art exercise, young patients will not recover completely from claudications in all activities, including sports. The process will be long and will compromise their abilities in their professional lives. Therefore, it should perhaps be discussed whether young and active patients, especially, should be held to the axiom of "physical exercise first" or whether invasive treatment might be offered even as a first approach to this group of patients.

Treatment Options with Relation to Location and Lesion

Treatment of femoropopliteal lesions in claudicants has to be seen as more critical and less liberal compared with the iliac region. The main reasons are less favorable technical success, a higher complication rate, and poorer long-term success. There are many more lesions in the femoropopliteal arteries that do not meet the criteria for suitability for endovascular treatment. On the other hand, the versatility of endoluminal techniques opens treatment options in many particular lesions, and taking clinical symptoms as the only criteria to indicate or exclude treatment is not justified because—depending on the type of lesion—a simple and limited intervention can mean considerable improvement for the patient.

Additional Morphological Factors (not Included in the TASC Classfication)

Femoropopliteal occlusions may especially become a source of complications, particularly if they occurred recently. Simple PTA may result in downward embolization of occlusion material that may aggravate the symptoms or may turn the condition into a limb-threatening situation. Even in short occlusions, PTA may be insufficient to reopen the vessel, necessitating additional treatment such as stent placement (which does not result in better patency compared with balloon angioplasty alone). Reobstruction of stents, however, is more difficult to treat compared with simple restenosis. Eccentric calcified stenosis is frequently insufficiently treated. Because stenting is a technical but not necessarily a long-standing solution to such lesions, alternative techniques such as atherectomy may be considered if available. Unfortunately, these niche techniques are difficult to place in the market because of the costs involved, and some of the well-advanced devices such as the Simpson atherectomy catheter have been withdrawn from the market. (See Fig. 1)

Techniques

Balloon Angioplasty

Balloon angioplasty remains the working horse in femoropopliteal lesions. Modern angiographic units allow a built-in, fairly exact measurement of the true arterial diameter, and with the use of semicompliant balloons, adaptation to the diameter is well performed. We prefer not to grossly overdilate the artery in order to avoid dissection. Dilation times of 1–3 min are preferable by using pressure gauges. Balloon lengths of 2–4 cm are mainly used. In cases of major dissection, the first step should be an additional attempt to improve the result by prolonged balloon dilatation over 4–5 min; in many cases, the result will be improved by this cost-effective and simple approach (Fig. 1).

Stent Placement

The use of all kinds of stents should be limited to those cases in which balloon angioplasty in all its variations did not achieve a sufficient result. This is particularly true for occluding dissections. Other than in the iliac field, stents should not be used liberally.

The stented segment should be as short as possible. Balloon-expandable stents normally allow coverage of only short segments and might therefore be preferred for those lesions. In longer segments or in parts where bending of the artery is an issue, a self-expanding stent is advantageous if a stent cannot be avoided at all.

The overall results of femoral stenting are disappointing. New developments with drug-coated stents are on the way that allow elusion of drugs, such as rapamycin (Sirolimus) or taxol, from the stent surface. Especially for rapamycin, the first results from the coronary arteries are very promising, but no valid data yet exist on their use in the femorals. Radiation in stents, primarily at the time of insertion, did not show improved patency but was followed by an increased risk of thrombosis. Afterloading might therefore be a potential tool in the treatment of stent reobstruction.

Stent Grafts

Stent grafts still play a limited role in the femoropopliteal field. ePTFE-covered self-expanding stent grafts such as the Hemobahn device (Gore, Flagstaff, AZ, USA) yielded promising results in a multicenter trial even in the femoropopliteal field and stimulated the hope of offering a percutaneous alternative, especially for those patients presenting with long femoropopliteal occlusions. But there is also a risk of midterm or late rethrombosis.

Below the inguinal ligament, an ePTFE covering should be used exclusively because in animal experiments it has shown much less tendency to induce neointimal growth compared with Dacron covering. Other than in extraluminal bypasses, transcovering growth of tissue has been demonstrated, probably due to the long-segment wall contact between the stent graft and the original vascular lumen (2, 3).

A considerable disadvantage of stent grafts is that important collaterals frequently have to be covered by the full body of the stent graft. In the event of reocclusion, these collaterals will not be available anymore, which might cause aggravation of symptoms. This is particularly true for the popliteal artery, for which development of compensating collaterals is limited. Therefore, we favor limiting the use of stent grafts to the proximal two-thirds of the superficial femoral artery, especially in claudicants.

Results

Balloon Angioplasty

In femoropopliteal endovascular interventions (data taken from eight publications reporting on 1,469 procedures), the weighted average technical success was 90%, the complication rate was 4.3%, and the 3-year patency rate was 51% (1).

Long-term patency was positively influenced by a good outflow tract (two or three lower limb arteries), absence of diabetes, and absence of residual stenosis. The latter would favor the use of stents, but unfortunately, there is no proof that stenting will improve overall patency.

Analyzing subgroups after femoral PTA, Huninck et al found different patencies for patients with stenotic and occlusive femoral lesions and good run-off (62% vs. 48% after 5 years) as well as those with poor run-off (stenoses: 62% vs. 43% after 5 years; occlusions: 43% vs. 27% after 5 years) (4).

Stents

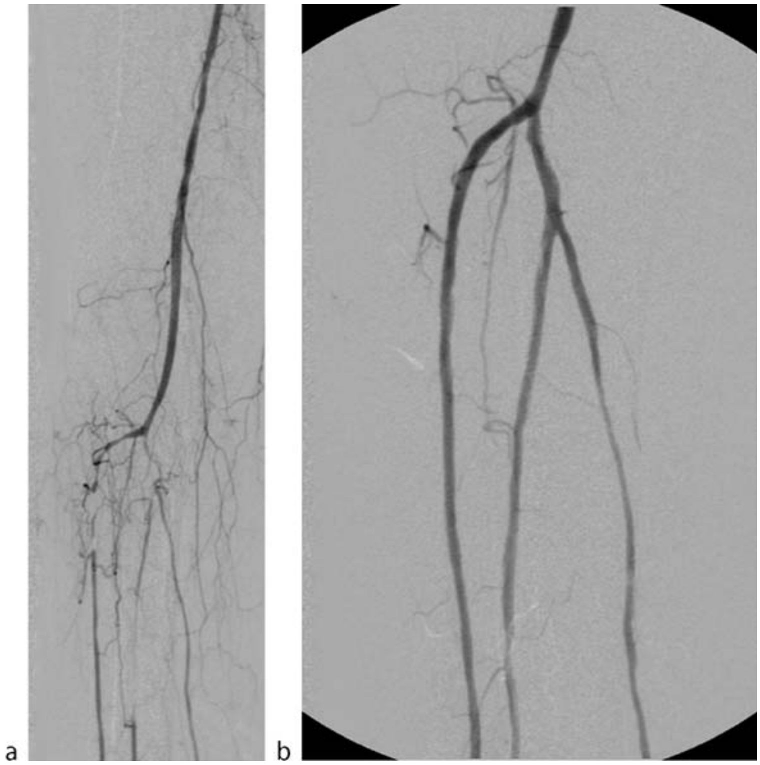
Follow-up results from stent implantation into the femoropopliteal arteries have not yielded improved results compared with balloon angioplasty alone. In a meta-analysis, Muradin et al found a 3-year patency of 63–66% after 3 years for stents, compared with 61% for PTA of stenoses. They also found, however, that in patients with more severe disease and more severe lesions, the patients achieved a higher benefit from stenting compared with those with less severe disease (5). In a randomized trial, Cejna and colleagues found no significant difference between patients who received PTA alone and those who received stenting (6).

Endoluminal radiation therapy with afterloading or beta irradiation as well as drug-eluding stents may change the overall results in the future. To date, stenting in the femoral arteries should be used as a bail-out therapy in the case of PTA failure. Failure, however, needs to be defined strictly as severe dissection refractory to prolonged balloon dilatation, antegrade dissection with increasing obstruction, or severe residual obstruction. Minor irregularities of the wall are not enough to justify stenting because treatment of restenosis is more difficult compared with treatment after PTA alone. (See Figs 3 and 4).

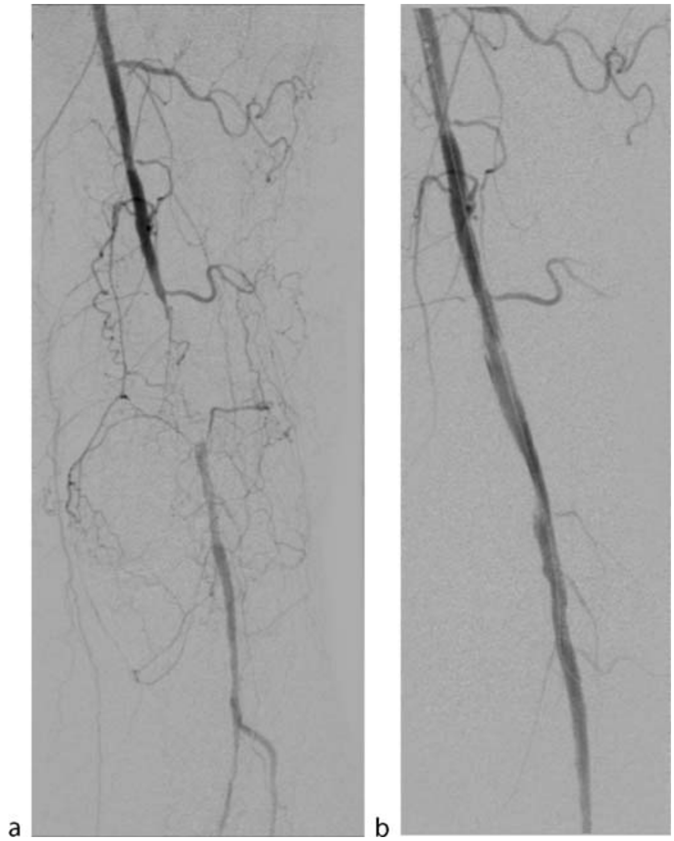
Stent Grafts

Little data exist on the usefulness of stent grafts in the femoropopliteal arteries. In a multicenter trial using the Hemobahn endoprosthesis, Lammer and colleagues achieved a primary patency of 90% after 6 months and 79% after 12 months with 80 limbs treated. Secondary patency was 93% at 12 months after treatment (7).

These encouraging results are in contrast to many single-center experiences in which endografts showed a high rate of thrombosis that was frequently due to development of stenoses adjacent to the stent graft.



Occlusion, Artery, Femoral. Figure 3 Infrapopliteal occlusion. (a) Occlusion of all lower limb arteries in their proximal segments in a patient with stage IV disease. (b) After mechanical passage and percutaneous transluminal angioplasty, all three arteries have been sufficiently recanalized. No peripheral embolization has occurred.



Occlusion, Artery, Femoral. Figure 4 **(a) A 7-cm-long occlusion of the popliteal artery in a patient with stage IV disease. (b) After subintimal recanalization and percutaneous transluminal angioplasty, sufficient reopening with stent placement.**

Complications

The nature and quality of complications in the femoropopliteal arteries do not differ principally from those in the aortoiliac area: dissection, perforation, and embolization of occluding material. With stents, the risk of early thrombosis was a problem in the very beginning but has since become rare with combined treatment that includes modern antiplatelet drugs.

In occlusions, the risk of embolization of the occluding material is the most potentially dramatic complication. Aspiration embolectomy in combination with selective thrombolysis is the treatment option of choice. Especially in claudicants, the risk therefore needs to be well balanced with the potential benefit.

Adjunctive Drug Regimen

In iliac and femoral PTA in claudicants, heparinization during the intervention and for 24 h after it—either by low-molecular-weight heparin or conventional heparin—is usually sufficient. A dose of 100 mg of aspirin daily is usually prescribed. After femoral stent placement or in patients with marked irregularities after PTA, heparinization may be prolonged up to 72 h, and an additional platelet inhibitor such as Clopidogrel is recommended for 4–6 weeks.

Synonyms

Iliac artery occlusion; Iliac artery stenosis artery

Definition

An arterial obstruction of the iliac arteries is an occlusion or narrowing of an arterial segment between the aortic bifurcation and the groin, not including the common femoral artery (CFA).

Pathology/Histopathology

Occlusions are complete obstructions of the iliac arterial lumen due to thrombus formation, mainly onto a preexisting atherosclerotic plaque formation. In stenoses, the lumen is still patent but narrowed, with symptoms occurring with a diameter reduction of more than 50%.

Clinical Presentation

Unilateral claudication is the leading clinical symptom and has a predilection for the upper thigh. Depending on the collateral pathways, the walking distance may vary between a few meters and a few hundred meters. Severe ischemic syndromes are rare unless there is no additional involvement of the infrainguinal arteries.

Imaging

Many imaging modalities allow clinicians to diagnose iliac artery obstruction. Color-coded duplex sonography as well as magnetic resonance (MR) angiography, computed tomography (CT), CT angiography, and intra-arterial angiography are useful tools for detecting the location and extent of an iliac obstruction. Because of access limitations, angiography is preferably performed *via* transbrachial or contralateral access if the clinical findings suggest iliac artery obstruction.

Nuclear Medicine

Nuclear medicine plays no particular role in the diagnosis of aortic stenosis.

Diagnosis

Diagnosis is reliably achieved by angiography or MR angiography. Detection by duplex sonography is sometimes difficult due to unfavorable anatomic conditions.

Interventional Radiological Treatment

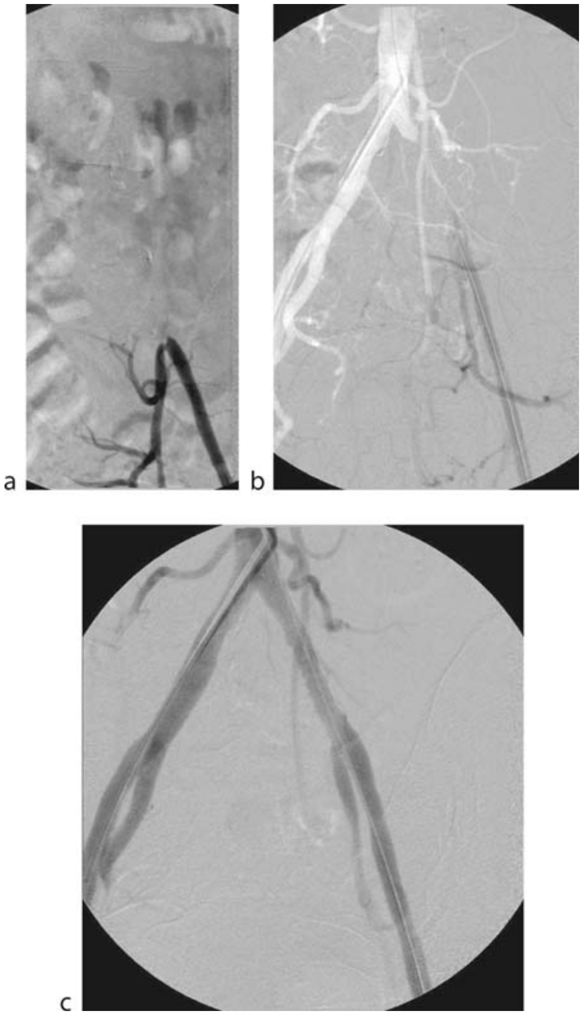
In the iliac segment, many lesions are amenable to percutaneous treatment with an acceptable outcome. Thus, a lesion's location and type must be taken into consideration before treatment is recommended. Whereas most lesions in the aortoiliac segment will be conducive to an endovascular approach, this is not generally true for femoropopliteal lesions. In addition, the risk of treatment is related to its location and has to be addressed before an endovascular approach is recommended.

Type of Lesion

The morphology of the treated lesion will influence the technical outcome, follow-up results, and also the risk of treatment. The Transatlantic Inter-Society Consensus (TASC) document therefore introduced a classification system that tries to categorize lesions with regard to their accessibility to either percutaneous treatment or surgery: Type A lesions, for which the percutaneous approach is ideal, type B lesions, for which the percutaneous approach is still the preferred technique; type C lesions, for which a surgical approach should be preferred; and type D lesions, for which surgery is the option of choice. The TASC classification overrules older classifications because it takes into account all available and published techniques, including stent technology, which offer a much wider variation of treatment and are also effective tools for dealing with acute complications of balloon angioplasty such as occluding dissection and vascular rupture.

If we consider percutaneous therapy as the preferred method to deal with patients presenting with mild or moderate claudications, treatment might be offered to those presenting with type A and B lesions but should be discussed in depth with patients with type C lesions, since the risk and the potential benefit of treatment will be related to the underlying morphology.

For iliac lesions, single stenoses up to 3 cm in length both in the common iliac artery (CIA) and external iliac artery (EIA) are classified as type A lesions, while single stenoses of 3–10 cm (not involving the CFA), double stenoses not longer than 5 cm each, and unilateral occlusions of the CIA are classified as type B lesions (Fig. 1).



Occlusion, Artery, Iliac . Figure 1 Occlusion of the left common iliac artery. (a) Occlusion of the left common iliac artery imaged *via* a retrograde access. The internal iliac artery is open. (b) After passage of the occlusion, the complete occlusion is visible with a stump at the orifice. (c) After primary stenting followed by careful balloon dilation, patency is fully restored.

Type C lesions include bilateral long stenoses (5–10 cm in length), unilateral EIA occlusions not extending into the CFA, and unilateral EIA stenoses extending into the CFA. More advanced lesions are classified as type D.

Using this classification, many iliac lesions will fall into the A and B groups, opening a potentially growing field for endovascular procedures performed on mild to moderate claudicants. Even in some type C lesions, percutaneous treatment has no major technical concerns, complication risks, or compromised outcomes. This is particularly the case for EIA occlusions not extending into the CFA. However, published data are lacking to back up this experience.

Multilevel Disease

Even mild symptoms may be associated with multilevel disease (e.g., iliac stenosis and a well-collateralized femoropopliteal lesion). There is some chance that exclusive intervention in the iliac region may be sufficient to improve the clinical situation. If present, multilevel disease does not preclude treatment in these patients.

Assisting Forms of Treatment

It is widely accepted that well-conducted physical exercise should precede any type of interventional treatment and that cessation of smoking is mandatory. Nevertheless, it is also true that in many institutions it is very difficult to find an infrastructure that allows teaching of state-of-the-art physical exercise to claudicants, and as far as smoking is concerned, there is a major difference between willing and doing.

Moreover, even with state-of-the-art exercise, young patients will not recover completely from claudications in all their activities, including sports. The process will be longer and compromise their abilities in their professional lives. Therefore, it might be discussed whether young and active patients should be vigorously kept to the axiom of “physical exercise first” or whether invasive treatment might be offered to this group of patients even as a first approach.

Treatment Options with Relation to Location and Lesion

The aorta and the iliac arteries have been a primary field for percutaneous interventions for a long time. Easy access to the lesion, the relatively large diameter of the target vessels, and the comparably benign outcomes even with major complications contribute to the wide acceptance of percutaneous interventions in that area. Over the years, the indications have been extended and now include not only stenotic but also occlusive disease and treatment of aneurysms. The introduction of vascular stents has especially been very helpful for overcoming major problems and offers a tool to treat major complications that otherwise remained a domain for surgical repair.

Iliac occlusive disease accounts for approximately one-third of occlusive arterial disease, while two-thirds is located subinguinally. However, iliac percutaneous transluminal angioplastry (PTA) plays a major role in interventional radiological routines because it is well-established in most institutions and by most surgeons, many lesions are amenable to percutaneous treatment, and technical as well as clinical results are satisfying.

Clinically, intermittent claudication starting in the upper thigh in combination with lower limb claudication is the leading symptom. Erectile dysfunction in men may also be present. In isolated iliac lesions, critical ischemia is rare if not combined with additional subinguinal disease. Rarely, blue-toe syndrome might be present if cholesterol embolization has occurred from an ulcerated plaque in the iliac axis.

Weakened femoral pulses and a reduced ankle-arm index are simple clinical signs that can indicate iliac obstruction and that can be verified by direct or poststenotic color-coded or duplex studies. For planning a percutaneous intervention, angiography is still the most helpful procedure.

Clinical indications for treatment depend on the severity of symptoms and how they limit the daily life of an individual patient.

Stent placement in stenotic lesions should be indicated from a technical point of view if angioplasty remains insufficient, as defined by visibly poor outflow or major pressure gradients. Because follow-up data are now available showing that iliac stent placement is safe, a liberal approach is justified, although primary stenting of stenoses does not seem to be generally recommended because of socioeconomic reasons and potential follow-up problems.

Furthermore, primary stenting is not beneficial over successful balloon dilation (8). Thus, primary stenting is recommended only if PTA fails or if technical requirements compromise the success of simple PTA, such as with iliac occlusions.

Iliac Artery Stenoses

Although balloon angioplasty has proved to be an effective procedure in treating iliac stenoses in particular, the indication for stent placement should be restricted to lesions that are not primarily amenable to PTA alone. An inadequate postangioplasty result has been suggested as a general indication for stent placement, although the term “inadequate” remains ill-defined. Residual pressure gradients are certainly a useful way to assess the angioplasty result, but it is still unclear what the borderline gradient ultimately requiring additional intervention is. Moreover, the decision should not be made without referring both to morphologic criteria and visibly reduced flow.

Long-segment stenoses with irregular surfaces, aneurysm formation, or markedly ulcerated plaques may be included in the group of complex lesions. Eccentric stenoses and ostial lesions with extension to the aortic bifurcation are known to not respond well to balloon angioplasty.

A stenotic lesion may respond well to balloon inflation but may collapse after the balloon is deflated.

Complications of balloon angioplasty can be treated well by stent placement. These include intramural hematoma and flow-obstructing dissections complicating PTA, which may be an acute indication for stent placement in order to maintain the vascular lumen, obviating emergency surgery.

Iliac restenosis after previous PTA does not require stent placement in general since there is no proof that stenting prevents restenosis under those circumstances. However, stenting may be considered from a technical point of view in cases in which the result of balloon angioplasty remains compromised.

An inadequate result after state-of-the-art balloon dilatation of the iliac stenoses is a prerequisite for secondary stent placement in stenotic lesions.

Iliac Artery Occlusions

Percutaneous treatment of iliac occlusions is technically feasible. In cases of acute thrombosis, thrombolysis as an alternative to surgical thrombectomy might precede PTA of an underlying lesion. Mechanical thrombectomy *via* percutaneous access is still in its infancy and cannot be recommended as a routine approach because potential risks such as downward or cross-over embolization are possible, and no data are yet available to determine the overall complications of such an approach.

In chronic occlusions with an occlusion time exceeding 3 months, balloon angioplasty alone, thrombolysis with subsequent balloon angioplasty, and elective stenting or mechanical passage of the occlusion followed by primary stent implantation have been described as alternative techniques.

Metallic stents—and self-expandable endoprostheses in particular—offer a new concept of percutaneous revascularization in chronic iliac occlusion, which we believe is a primary indication (9). Self-expandable stents are used to cover the occluding thrombotic material, thereby preventing peripheral dislodgement, a well-known complication of percutaneous recanalization of occlusions.

Indications for the use of metallic stents into arteries should always be technical. The type and morphology of the lesion, the outcome of balloon angioplasty, and complicated situations are important considerations, although stenting has been tested and shown to be a safe procedure.

This is particularly true for treatment of restenosis. There is currently no proof that stent placement is more effective in preventing restenosis than balloon angioplasty with good technical success. Furthermore, there is no proof that in a restenosed vessel, the use of a stent would be beneficial to prevent recurrent stenosis.

Technical Considerations in the Iliac Arteries

Balloon Dilatation

Balloon dilatation of the iliac arteries is relatively simple to perform. A retrograde transfemoral approach provides the easiest access to that type of stenotic lesions. Crossover dilatation may be performed in special indications such as double-sided stenoses in the event that both lesions should be dilated in one session, or if an external iliac stenosis extends far down into the CFA. After the diseased segment is carefully traversed, a suitable balloon is placed across the lesion, and dilatation is performed either manually or by using a pressure-monitoring syringe. The size of the balloon can be depicted either by film measurements or in digital subtraction angiography images by use of graduated catheters that allow fairly exact measurement of vessel size.

There is wide agreement that both the hemodynamic relevance of a lesion as well as post-PTA success can be accurately monitored by measuring the pressure gradient across the lesion. However, there is some dispute about the level of the pressure. A mean pressure gradient of 10 mmHg and less after peripheral drug-induced vasodilation is accepted by most authors to indicate successful PTA even if the morphological result is not excellent. Some authors use a systolic gradient of 10 mmHg.

There is no uniform agreement on whether PTA of simple iliac lesions requires any additional anticoagulation afterward. We regularly keep our patients on full heparinization (500–1,000 IU/h) for 12–24 h and recommend lifetime aspirin therapy (100 mg/day).

Stent Implantation

If balloon angioplasty fails by morphologic and functional criteria, stent implantation can be considered in stenotic lesions. The technique depends on the type of stent used. There is no stent preference because most clinical series have shown similar results. The length and location of the lesion, the experience of the investigator, and the availability of appropriately sized stents are important details that may lead to the preference of one or another type.

Exact placement is mandatory to avoid major complications, especially if the stent has to placed close to the aortic bifurcation. While self-expanding Wallstents can be corrected during placement to a limited extent, balloon-expandable stents and self-expanding nitinol stents cannot undergo correction of their localization once inflation of the balloon has begun.

Chronic iliac artery occlusions are primarily indicated for stent placement. We avoid predilatation and place the stent directly into the occluded segment. After stenting, careful balloon dilatation is performed to avoid dislodgement of occluding material.

Atherectomy

Directional atherectomy does not play a major role in treating iliac arterial disease. This is because the ratio of introduction and working diameters in most atherectomy systems is relatively low, which requires a considerably large puncture to achieve atherectomy in larger iliac diameters of 8–12 mm. The Simpson atherectomy catheter—which is no longer available commercially—required an 11F sheath to sufficiently treat iliac lesions. Atherectomy plays a more important role in the recanalization of stent reobstruction in order to debulk stents from reobstructing neointimal tissue.

Stent Reobstruction

In cases of in-stent stenosis, directional atheterectomy or balloon dilation are both recommended. If PTA is used, a balloon size according to the outer diameter of the stent in place is recommended in order to compress the neointimal intima to a maximum, especially if occurring within a self-expanding stent that does not allow overexpansion. If a balloon-expandable stent has been used, slight overdilation of the stent is recommended to gain a larger diameter despite neointimal tissue. Some authors prefer atherectomy to debulk the stent. This is achievable in smaller stents such as in the femorals, but it may require very large instruments in iliac stents.

In stent occlusion, treatment is more difficult. In acute occlusions early after placement, technical problems are mainly responsible, and it is mandatory to overcome these problems to maintain long-term success. Recent thrombosis should be treated by thrombolysis followed by PTA and/or additional stent placement.

Late occlusion is mainly due to reobstruction by neointima within or adjacent to the stent. There is not much published experience about how to treat complete stent occlusion at a chronic stage. Thrombolysis, atherectomy, and mechanical aspiration followed by balloon angioplasty are possible techniques. One of the simpler techniques is the stent-in-stent technique: After traversal of the occluded stent (which is usually easy to accomplish), a stent is placed within the occluded segment, bridging it at both ends. It is then carefully dilated with a tendency to underdilation of 1–2 mm. This is considered safe in order to avoid embolization of occlusion material.

Infrainguinal arterial obstruction

Definition

An arterial obstruction of the infrainguinal arteries is an occlusion or a narrowing of an arterial segment between the groin and the lower limbs.

Pathology/Histopathology

Occlusions are complete obstructions of the infrainguinal arterial lumen and are due to thrombus formation, mainly on preexisting atherosclerotic plaque. In stenoses, the lumen is still patent but narrowed, with a diameter reduction of more than 50% causing symptoms. Alternatively, acute occlusions occur because of thrombotic emboli from the heart.

Clinical Presentation

Clinical indications for treatment include claudication, pain at rest, and nonhealing ulceration. Severity of the symptoms depends on the acuteness of the occlusion, the condition of collateral pathways, the lesion's location, and concomitant disease such as diabetes or renal insufficiency.

Imaging

Many imaging modalities allow the physician to diagnose infrainguinal artery obstruction. Color-coded duplex sonography as well as magnetic resonance angiography (MRA), computed tomography, computed tomography angiography (CTA), and intraarterial angiography are useful tools to detect the location and extent of an iliac obstruction.

Nuclear Medicine

Nuclear medicine plays no particular role in the diagnosis of aortic stenosis.

Diagnosis

Diagnosis is reliably achieved by angiography or MRA. Detection by duplex sonography is a reliable tool for the femoropopliteal segment but is sometimes limited for detection and exact lesion description in the lower limbs. In stage IV (Fontaine) disease, MRA may be limited because of low arterial flow, movement artifacts, or artifacts due to superimposed venous flow.

Interventional Radiological Treatment

Endovascular versus Surgical Treatment

Endovascular therapy is known to be of low invasiveness with good technical success, achieving fair overall patency. In femoropopliteal endovascular interventions (data taken from eight publications reporting on 1,469 procedures), the weighted average technical success was 90%, the complication rate was 4.3%, and the 3-year patency rate was 51%. Stents did not improve patency, showing a patency of 58% after 3 years (1).

Surgery offers acceptable results for distal reconstruction; an average 5-year patency of 80% for vein bypasses and 65–75% for expanded polytetrafluoroethylene (ePTFE) bypasses has been reported. The combined mortality and amputation risk was calculated to be about 2.2% for aortobifemoral reconstructions and 1.4% for femoropopliteal reconstructions (1).

Location of Lesion

Claudication is mainly related to lesions in the aortoiliac and femoropopliteal regions. It is unlikely to be due to infrapopliteal lesions, and there is general agreement that treatment below the knee should be strictly limited to patients with critical limb ischemia, i.e., stages III and IV (Fontaine) or categories 4–6 (Rutherford).

Type of Lesion

The morphology of a treated lesion influences the technical outcome, follow-up results, and also the risk of treatment. Therefore, the TransAtlantic Inter-Society Consensus (TASC) document introduced a classification system that tries to categorize lesions with regard to their accessability to either percutaneous treatment or surgery: type A lesions, which are ideal for a percutaneous approach; type B lesions, in which the percutaneous approach is still the preferred technique; type C lesions, in which a surgical approach should be preferred; and type D lesions, in which surgery is the option of choice. The TASC classification overrides older classifications because it takes into account all of the available and published techniques (including stent technology), which offer a much wider variation of treatment as well as effective tools to deal with acute complications of balloon angioplasty, such as occluding dissection and vascular rupture.

If we consider percutaneous therapy as the preferred method to treat those patients presenting with mild or moderate claudication, treatment might be offered to those presenting with type A and B lesions, but should be discussed in depth with patients with type C lesions, as the risk and the potential benefit of treatment are related to the underlying morphology.

In the femoropopliteal field, type A lesions are single stenoses up to 3 cm in length not involving the very proximal superficial femoral and the distal popliteal artery. Type B lesions include stenoses 3–5 cm in length, heavily calcified stenoses, multiple lesions (each up to 3 cm), and lesions with no sufficient tibial run-off (the latter are unlikely to meet the criteria of mild or moderate claudication). Type C lesions are classified as stenoses or occlusions longer than 5 cm and multiple midsize lesions (3–5 cm). Total common femoral, superficial femoral, and popliteal occlusions are classified as type D lesions. There was some dissenting discussion on the definition of type B lesions: Interventional radiologists represented by the Cardiovascular and Interventional Radiological Society of Europe wished to express their assumption that even longer lesions of up to 10 cm may be justified as being classified type B instead of type C; they claimed that the reported results were mainly due to underdeveloped techniques and instruments that have substantially improved and that no data exists comparing the efficacy of percutaneous transluminal angioplasty (PTA) versus bypass surgery for lesions between 4 and 10 cm.

Other than in the iliac area, few femoral lesions meet the criteria for types A and B lesions, especially if limited to 5 cm in length. Thus, few patients with mild or moderate claudication due to femoropopliteal lesions will be ideal candidates for percutaneous treatment. Moreover—without limiting the importance of the TASC document, which certainly means a step forward in the joint approach to peripheral vascular disease—the morphological classification does not take into account some technical considerations that depend on the age and composition of a lesion. Particularly in femoral occlusions, the degree of organization of the occluding thrombus or the composition of the lesion with the original stenosis at the proximal and distal ends or in the middle are factors that are not very predictable but may influence the technical outcome of the intervention or its complication rate (for instance, distal embolization might aggravate symptoms). Other than in the iliac arteries, the liberal use of stents and stent grafts may help overcome a failed balloon angioplasty and resolve the technical outcome, but it does not achieve an improved long-term efficacy, and it may start a lifetime dependency on recurrent interventional or surgical procedures. These associated potential drawbacks have to be carefully balanced against the potential benefits and need to be discussed in depth with the patient before treatment is performed, especially in association with mild or moderate claudication.

These considerations mainly restrict the use of endovascular treatment in femoropopliteal lesions to stages IIb and IIa patients presenting with type A or less-pronounced type B lesions.

Assisting Forms of Treatment

It is widely accepted that well-conducted physical exercise should precede any type of interventional treatment and that cessation of smoking is mandatory. Nevertheless, it is also true that in many institutions it is very difficult to find an infrastructure that allows instruction of state-of-the-art physical exercise for claudicants. And as far as smoking is concerned, there is a major difference between wanting to stop and actually stopping.

Moreover, even with state-of-the-art exercise, young patients will not recover completely from claudications in all activities, including sports. The process will be long and will compromise their abilities in their professional lives. Therefore, it should perhaps be discussed whether young and active patients, especially, should be held to the axiom of "physical exercise first" or whether invasive treatment might be offered even as a first approach in this group of patients.

Treatment Options with Relation to Location and Lesion

Treatment of femoropopliteal lesions in claudicants has to be seen as more critical and less liberal compared with the iliac region. The main reasons are less favorable technical success, a higher complication rate, and poorer long-term success. There are many more lesions in the femoropopliteal arteries that do not meet the criteria for suitability for endovascular treatment. On the other hand, the versatility of endoluminal techniques opens treatment options in many particular lesions, and taking clinical symptoms as the only criteria to indicate or exclude treatment is not justified because depending on the type of lesion, a simple and limited intervention can mean considerable improvement for the patient.

Additional Morphological factors (not Included in the TASC Classfication)

Femoropopliteal occlusions may especially become a source of complications, particularly if they occurred recently. Simple PTA may result in downward embolization of occlusion material that may aggravate the symptoms or may turn the condition into a limb-threatening situation. Even in short occlusions, PTA may be insufficient to reopen the vessel, necessitating additional treatment such as stent placement (which does not result in better patency compared with balloon angioplasty alone). Reobstruction of stents, however, is more difficult to treat compared with simple restenosis. Eccentric calcified stenosis is frequently insufficiently treated. Because stenting is a technical but not necessarily a long-standing solution to such lesions, alternative techniques such as atherectomy may be considered if available. Unfortunately, these niche techniques are difficult to place in the market because of the costs involved, and some of the well-advanced devices such as the Simpson atherectomy catheter have been withdrawn from the market.

Techniques

Balloon Angioplasty

Balloon angioplasty remains the working horse in femoropopliteal lesions. Modern angiographic units allow a built-in, fairly exact measurement of the true arterial diameter and by use of semicompliant balloons, adaptation to the diameter is well performed. We prefer not to grossly overdilate the artery in order to avoid dissection. Dilation times of 1–3 min are preferable by using pressure gauges. Balloon lengths of 2–4 cm are mainly used. In cases of major dissection, the first step should be an additional attempt to improve the result by prolonged balloon dilatation over 4–5 min; in many cases, the result will be improved by this cost-effective and simple approach (Fig. 1).

Stent Placement

The use of all kinds of stents should be limited to those cases in which balloon angioplasty in all its variations did not achieve a sufficient result. This is particularly true for occluding dissections. Other than in the iliac field, stents should not be used liberally.

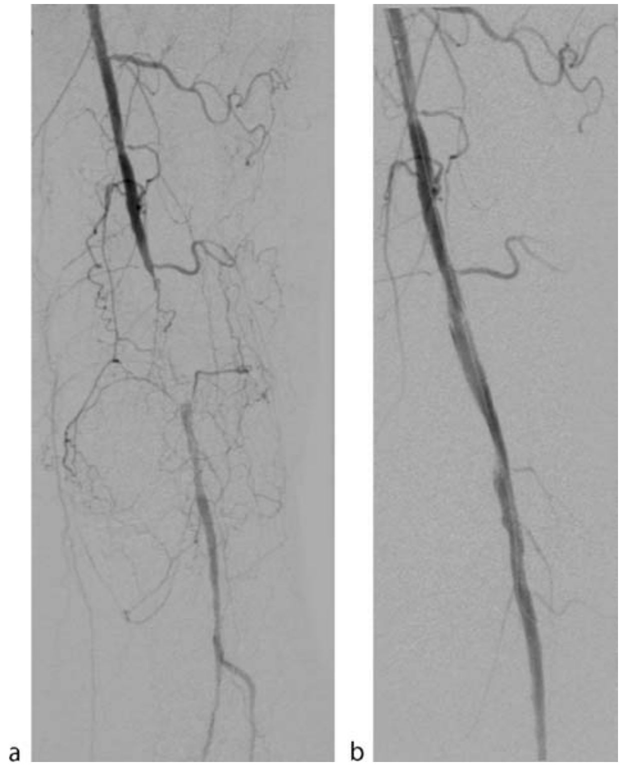
The stented segment should be as short as possible. Balloon-expandable stents normally allow coverage of only short segments and might therefore be preferred for those lesions. In longer segments or in parts where bending of the artery is an issue, a self-expanding stent is advantageous if a stent cannot be avoided at all.

The overall results of femoral stenting are disappointing. There are new developments with drug-coated stents on the way that allow elusion of drugs, such as rapamycin (Sirolimus) or taxol, from the stent surface. Especially for rapamycin, the first results from the coronary arteries are very promising, but no valid data yet exist on their use in the femorals. Radiation in stents, primarily at the time of insertion, did not show improved patency but was followed by an increased risk of thrombosis. Afterloading might therefore be a potential tool in the treatment of stent reobstruction.

Stent Grafts

Stent grafts still play a limited role in the femoropopliteal field. ePTFE-covered self-expanding stent grafts such as the Hemobahn device (Gore, Flagstaff, AZ, USA) yielded promising results in a multicenter trial even in the femoropopliteal field and stimulated the hope of offering a percutaneous alternative, especially for those patients presenting with long femoropopliteal occlusions. But there is also a risk of midterm or late rethrombosis.

Below the inguinal ligament, ePTFE covering should be used exclusively because in animal experiments it has



Occlusion, Artery, Popliteal. Figure 1 (a) A 7-cm-long occlusion of the popliteal artery in a patient with stage IV disease. (b) After subintimal recanalization and percutaneous transluminal angioplastyPTA, sufficient reopening with stent placement.

shown much less tendency to induce neointimal growth compared with Dacron covering. Other than in extraluminal bypasses, transcovering growth of tissue has been demonstrated, probably due to the long-segment wall contact between the stent graft and the original vascular lumen (2, 3).

A considerable disadvantage of stent grafts is that important collaterals frequently have to be covered by the full body of the stent graft. In the event of reocclusion, these collaterals will not be available anymore, which might cause aggravation of symptoms. This is particularly true for the popliteal artery, for which development of compensating collaterals is limited. Therefore, we favor limiting the use of stent grafts to the proximal two-thirds of the superficial femoral artery, especially in claudicants.

Results

Balloon Angioplasty

In femoropopliteal endovascular interventions (data taken from eight publications reporting on 1,469 procedures), the weighted average technical success was 90%, the complication rate was 4.3%, and the 3-year patency rate was 51% (1).

Long-term patency is positively influenced by a good outflow tract (two or three lower limb arteries), absence of diabetes, and absence of residual stenosis. The latter would favor the use of stents, but unfortunately, there is no proof that stenting will improve overall patency.

Analyzing subgroups after femoral PTA, Huninck et al. found different patencies for patients with stenotic and occlusive femoral lesions and good run-off (62% versus 48% after 5 years) as well as those with poor run-off (stenoses: 62% versus 43% after 5 years; occlusions: 43% versus 27% after 5 years) (4).

Stents

Follow-up results from stent implantation into the femoropopliteal arteries have not yielded improved results compared with balloon angioplasty alone. In a meta-analysis, Muradin et al. found a 3-year patency of 63–66% after 3 years for stents, compared with 61% for PTA of stenoses. They also found, however, that in patients with more severe disease and more severe lesions, the patients achieved a higher benefit from stenting compared with those with less severe disease (5). Cejna and colleagues found no significant difference between patients who received PTA alone and those who received stenting in a randomized trial (6).

Endoluminal radiation therapy with afterloading or β irradiation as well as drug-eluding stents may change the overall results in the future. To date, stenting in the femoral arteries should be used as a bail-out therapy in the case of PTA failure. Failure, however, needs to be defined strictly as severe dissection refractory to prolonged balloon dilatation, antegrade dissection with increasing obstruction, or severe residual obstruction. Minor irregularities of the wall are not enough to justify stenting as treatment of restenosis is more difficult when compared with treatment after PTA alone.

Stent Grafts

Little data exist on the usefulness of stent grafts in the femoropopliteal arteries. In a multicenter trial using the Hemobahn endoprosthesis, Lammer and colleagues achieved a primary patency of 90% after 6 months and 79% after 12 months with 80 limbs treated. Secondary patency was 93% at 12 months after treatment (7).

These encouraging results are in contrast to many single-center experiences in which endografts showed a high rate of thrombosis that was frequently due to development of stenoses adjacent to the stent graft.

Complications

The nature and quality of complications in the femoropopliteal arteries do not differ principally from those in the aortoiliac area: dissection, perforation, and embolization of occluding material. With stents, the risk of early thrombosis was a problem in the very beginning but has since become rare with combined treatment that includes modern antiplatelet drugs.

In occlusions, the risk of embolization of the occluding material is the most potentially dramatic complication. Aspiration embolectomy in combination with selective thrombolysis is the treatment option of choice. Especially in claudicants, the risk therefore needs to be well balanced with the potential benefit.

Adjunctive Drug Regimen

In iliac and femoral PTA in claudicants, heparinization during the intervention and for 24 h after it—either by low-molecular-weight heparin or conventional heparin—is usually sufficient. A dose of 100 mg of aspirin daily is usually prescribed. After femoral stent placement or in patients with marked irregularities after PTA, heparinization may be prolonged up to 72 h, and an additional platelet inhibitor such as Clopidogrel is recommended for 4–6 weeks.

O

Synonyms

Bile duct obstruction; Cholestasis; Obstruction of the biliary tree

Definition

Any condition in which there is a complete obstacle to the biliary flow.

Pathology and Histopathology

Cholestasis may be related to mechanical, cellular, and metabolic causes.

Mechanical biliary obstruction may be due to intrinsic or extrinsic obstruction of bile flow, which can occur either at the intrahepatic or extrahepatic level (Table 1).

Occlusion, Bile Ducts. Table 1 Mechanical biliary obstruction

Intrahepatic	Intrinsic	Congenital cause • Biliary atresia • Alagille syndrome • Intrahepatic calculi complicating Caroli disease • Cystic fibrosis
		Benign cause • Intrahepatic stones • Sclerosing cholangitis • Biliary parasitosis
		Malignant cause • Cholangiocarcinoma
	extrinsic	Benign and malignant tumors
Extrahepatic	Intrinsic	Congenital anomalies • Choledochal atresia • Choledochal cysts
		Benign conditions • Gallstones • Parasitosis • Cholangitis • Inflammatory strictures • Postinterventional strictures • Vater's papillary stenosis • ►AIDS-related cholangiopathy • ►Biliary tuberculosis • ►Sump syndrome
		Malignant tumors • Cholangiocarcinoma • Vater's papillary carcinoma
	extrinsic	Benign causes • ►Mirizzi syndrome • Enlarged lymph nodes • Pancreatitis • Local benign tumors and cysts
		Malignant conditions • Gallbladder carcinoma • Malignant lymphadenomegalies • Pancreatic head carcinoma • Stomach and colon cancer

Overall, gallstones are the most common cause of biliary obstruction.

Intrahepatic intrinsic biliary obstruction can be due to: congenital affections (biliary atresia, Alagille syndrome, intrahepatic calculi complicating Caroli disease and cystic fibrosis), benign conditions (intrahepatic ductal stones, sclerosing cholangitis, and biliary parasitosis), and malignant conditions, with cholangiocarcinoma as the most important malignant cause. Extrinsic causes of intrahepatic obstruction include compression by benign and malignant tumors. Extrahepatic intrinsic biliary obstruction can be due to: congenital anomalies (choledochal atresia, choledochal cysts), benign conditions (gallstones representing the first cause, parasitosis, cholangitis, inflammatory and postinterventional strictures, Vater's papillary stenosis, AIDS-related cholangiopathy, biliary tuberculosis, sump syndrome), and malignant tumors (cholangiocarcinoma, and Vater's papillary carcinoma). Extrinsic compression of extrahepatic biliary tract includes benign conditions (Mirizzi syndrome, enlarged lymph nodes, pancreatitis, local benign tumors, and cysts), and malignant conditions (gallbladder carcinoma, malignant lymphadenomegalies, pancreatic head carcinoma, stomach and colon cancers) (1).

Clinical Aspects

Symptoms are determined by abnormal elevation of primary and secondary bile products in blood and the absence of the extrinsic intestinal bile function. Additionally, cholangitis may represent a concomitant complication in biliary obstruction. Common symptoms are jaundice, pale coloured stools, dark urine, itching, fever, and right upper quadrant pain. Blood tests show increase of bilirubin, alkaline phosphatase, and hepatic enzymes.

Imaging

Plain radiographs are of limited value to detect abnormalities in the biliary system. Frequently, calculi are not visualized because of their low radiopacity.

Biliary obstruction results in dilatation of bile ducts involving the biliary tree proximally to the obstruction; depending on the site of obstruction, the bile ducts dilatation may involve an isolated lobe or segment or both lobes. Especially in biliary stone disease, mostly both lobes present ductal dilatation. Nevertheless, the absence of bile ducts dilatation does not exclude recent or intermittent obstruction.

Ultrasound (US) is the method of first choice to establish the presence and extent of bile duct dilatation (Fig. 1). While peripheral ductal branches can be visualized only if dilated, the normal common bile duct is easily displayed (2). In general, US is able to establish the level of obstruction and reveal the cause of obstruction, as intrahepatic calculi, gallbladder stones, lymphadenopathy, hepatic and pancreatic masses. The demonstration of common bile duct calculi is strongly dependent on their location within the biliary system; in fact, calculi in the lower part of the common bile duct may be obscured by duodenal gas.

Computed tomography (CT) is more accurate than US in determining the specific cause and level of obstruction, but it is of limited value in detecting radiolucent bile duct stones. On the other hand, US can

Occlusion, Bile Ducts. Figure 1 **Biliary dilatation. Ultrasound can easily demonstrate dilatation of both intrahepatic and extrahepatic bile ducts in mechanical biliary obstruction.**

be significantly limited in the differentiation of cholangiocarcinoma from sludge accumulation since both appear hypoechoic. In these cases, the different enhancement behaviour (absence of contrast enhancement in case of sludge) allows differential diagnosis on CT.

With the advent of easy applicable magnetic resonance (MR) techniques displaying fluid-filled structures (i.e., heavily T2-weighted, snap-shot techniques, "MR-hydrography"), MR cholangiopancreatography (MRCP) is the reference standard for noninvasive imaging of the biliary tree.

In comparison to invasive endoscopic retrograde cholangiopancreatography (ERCP), MRCP provides non-invasive detailed evaluation of the biliary tree. Since MRCP is generally combined with complementary cross-sectional MR a comprehensive evaluation of in- and extrinsic factors that might affect the biliary tree is possible. With high-resolution techniques in- and extrinsic bile duct, obstructions and dilatations can be visualized by MRCP with a superior high sensitivity and specificity. Since the MR visualization of ducts is strongly correlated to the presence of fluid (bile) within the lumen, severe strictures, sludge, small stones or postoperative scars and clips may appear as short segments of signal void. In general, this condition can be clarified by additional unenhanced and contrast-enhanced T1- and T2-weighted axial (and/or multiplanar) sequences. In characterizing the features of the biliary tree, the same characteristics already known from cholangiography may be applied to MRCP. In general, stone-related obstruction can be displayed easily with the concave transition from fluid-filled ductal lumen to the stone and the usually smooth, regular outlining of the lumen. An irregular tapering of the lumen can often be seen in malignant obstructions due to an extrinsic or infiltrating mass that can be uncovered by cross-sectional imaging. Typical examples for that are tumors of the pancreatic head affecting the common bile duct alone or together with the pancreatic duct (so called "double duct sign," in about 5% of cases of pancreatic cancer). In case of such malignancies, MR can provide a comprehensive evaluation in terms of staging for intrahepatic metastases, lymph node metastasis, peritoneal tumour spread, and vascular encasement. However, comparing MR and multidetector CT there is no significant difference in staging of biliary and pancreatic malignancies regarding recent literature.

Due to the noninvasive, high diagnostic accuracy of MRCP, in most centres percutaneous (PTC) and endoscopic procedures (ERCP) are performed in selected cases for diagnostic purpose (e.g., tissue sampling by brush) and interventional procedures (e.g., balloon dilatation, stone extraction, stent placement) avoiding pure diagnostic interventions which may cause procedure related complications in up to 5% (e.g., acute pancreatitis) (1).

In patients with external biliary drainage (i.e., Kehr, Bracci), trans-catheter cholangiography is performed to evaluate the placement of the catheter, the patency of the common bile duct and the transpapillar drainage.

Nuclear Medicine

In patients with biliary obstruction, cholescintigraphy with ^{99m}Tc IDA (iminodiacetic acid) or analogs demonstrates a "congestion" of the radiotracer mostly associated with a normal hepatic distribution/activity in absence of delayed (>1 h after tracer injection) biliary activity.

Interventional Radiology

Radiologic interventional procedures in biliary obstruction may be performed using either a percutaneous or an endoscopic approach or a combination of both (i.e., "rendevouz procedures"). Possible interventions are catheter placement, biliary stenting, balloon dilatation of biliary strictures, stone removal, and tissue sampling.

Stone removal is the most common biliary intervention and generally performed by endoscopy. Usually a papillotomy is necessary, followed by stone extraction by balloon or basket instruments guided by the endoscope. Larger stones (>2 cm in diameter) are less prone to endoscopical removal and present a higher risk of perforation, bleeding, secondary pancreatitis, and cholangitis (3, 4). In the era of advanced endoscopic techniques, the use of percutaneous transhepatic radiological interventions is restricted to the treatment of intrahepatic stones and cholangitis where an internal–external drainage may be needed to relieve the biliary system. Sequentially, a stone can be removed or an obstruction can be treated. In cases of unsuccessful or impractical endoscopic maneuvers, stone removal, or stone fragmentation and stent placement are also percutaneously possible.

Balloon dilatation can be necessary both in patients with benign and malignant biliary strictures. Stenoses are safely and minimally invasively treated by balloon dilatation. Among the benign strictures biliary-enteric anastomotic strictures respond best to dilatation whereas a temporarily support by a drainage tube may enhance the result (5). In case of recoiling, redilatation may be necessary. Malignant strictures, due to the high radial force compressing the ductal system or the intruding mass within the duct, often require the combination of balloon dilatation, temporarily drainage and stent placement.

Stenting of the biliary tract is performed both in benign and malignant stenoses. There are three types of stents, which are used in biliary intervention: plastic endoprostheses (polyethylene stents), balloon-expandable metallic stents, and self-expandable metallic stents with and without covering. They can be placed either percutaneously or endoscopically. Metallic stents become strongly adherent to the bile duct and are impossible to remove. In the setting of malignancy, stents are mainly indicated for the palliation of patients with unresectable tumors. In such cases, metallic stents are preferred because they remain patent much longer than polyethylene stents and usually a single session of metal stenting maintain ductal patency for the reminding lifetime of the patients (6). Occlusion of metallic stents usually is determined by tumoral in-growth and can create the need for further interventions.

For treatment of benign biliary strictures, plastic endoprostheses are preferred, since they are needed in most cases only for limited time. Nevertheless, in chronic recurrent biliary stenoses where a long-term treatment is needed, they may be occluded by biliary encrustations, while in metallic stents reactive epithelial hyperplasia may occur.

Diagnosis

The diagnosis of biliary obstruction is suggested by the presence of jaundice, hypocholic stools, dark urine, itching, increase of serum levels of bilirubin, with prevalence of conjugated bilirubin, and alkaline phosphatase.

Imaging has the role to confirm biliary obstruction and to establish the level and the cause of obstruction. US is performed in the initial evaluation to demonstrate bile duct dilatation, the level of obstruction and sometimes the cause of obstruction, such as stones, hepatic masses, pancreatic masses, lymphadenopathies. The main limitations of US are the inconsistent visualization of the distal tract of the choledochal duct and the retroperitoneum. CT provides a more comprehensive examination that permits evaluation of the liver, biliary tree, pancreas, portal and retroperitoneal lymph nodes, and vascular structures, but it has a limited value in case of radiolucent stones of common bile duct. MRCP offers a noninvasive accurate assessment of the biliary tract. Associated cross-sectional images adequately demonstrate extra-ductal findings (1). Invasive techniques include ERCP and PTC. Currently they should be performed only to guide interventional procedures and cannot be recommended as diagnostic imaging techniques (2).

Occlusion, Bowel in Childhood

Melanie Hiorns
Radiology Department
Great Ormond Street Hospital for Children
London, UK
HiornM@gosh.nhs.uk

Synonyms

Small bowel obstruction (SBO); Large bowel obstruction

Definition

The lumen of the small or large bowel is occluded. This may be due to extrinsic compression of the bowel, an intrinsic abnormality of the wall or lumen of the bowel, or due to a filling defect in the lumen of the bowel. It may be congenital or acquired. Complete occlusion of the bowel is described as ‘obstruction’.

Pathology/Histopathology

Any of the pathologies listed in the tables may give rise to bowel obstruction and if the diagnosis is delayed this may go on to cause bowel ischaemia with necrosis and possible perforation.

Clinical Presentation

The infant or child will usually present with abdominal distension, irritability, pain and vomiting, or high nasogastric aspirates if a tube is in place. The timing of the clinical presentation may be partly determined by the underlying causes: congenital causes will usually present in the first few hours or days of birth and 95% of small bowel obstruction in the perinatal period is due to an atresia of some type. Meconium ileus will present within the first 48h of life and occurs almost exclusively in patients with cystic fibrosis. Fifteen to twenty per cent of cystic fibrosis patients present in this way (2). Small left colon syndrome (also termed meconium plug syndrome and functional immaturity of the colon) presents with failure to pass meconium and an increasingly dilated abdomen. Intussusception is the most common cause of obstruction in infants of 3 to 6 months. Strictures secondary to NEC most commonly occur within 1 to 6 months of the initial episode and are usually in the terminal ileum and the colon. Post-operative adhesions may occur at any time but most frequently in the first 6 months following surgery and in approximately 2% of patients who have had a laparotomy, accounting for 7% of small bowel obstruction overall.

Congenital causes of bowel occlusion	Acquired causes of bowel occlusion
Stenosis (jejunal, ileal, colonic)	Intussusception
Atresias (jejunal, ileal, colonic)	Malrotation with midgut volvulus

Imaging

The initial investigation is usually an abdominal radiograph, but this may be supplemented by an upper GI series in the case of a suspected high obstruction or by a contrast enema for a suspected low obstruction. Ultrasound has been used in some centres to examine the large bowel following the introduction of saline per rectum.

The abdominal radiograph will show dilated gas and fluid-filled loops of bowel (Fig. 1). In the neonate and infant it may not be possible to differentiate small and large bowel obstruction and hence the level of obstruction is described as high or low in the GI tract depending on the pattern of distended loops. If only a few high central loops are seen this is termed a 'high' obstruction and the level of obstruction is most likely to be in the small bowel. If distended loops are seen throughout the abdomen it is likely to be a 'low' obstruction with the level of obstruction being in the most distal ileum or in the colon. Further investigation of a high obstruction is by an upper GI series and of a low obstruction by a contrast enema. Water-soluble contrast should be used in both cases due to the increased risk of perforation and the high probability of the patient subsequently undergoing surgery to resolve the obstruction. On a contrast enema a long filling defect of meconium in the left side of the colon is indicative of small left colon syndrome and the colon proximal to this will be dilated (Fig. 2). The neonate will usually clear the meconium plug spontaneously after the contrast enema. However, meconium ileus will demonstrate a micro-colon on contrast enema (Fig. 3). The colon will be thin and long, having not been used and dilated loops of bowel will be confined to the small bowel loops above the level of obstruction by meconium in the distal ileum.

Meconium ileus is the only cause of obstruction that may be treated in the fluoroscopy room. A standard contrast enema is performed first to establish the diagnosis. Having established the diagnosis, ensuring that

Occlusion, Bowel in Childhood. Figure 1 Abdominal X-ray showing typical appearances of a high (upper GI) obstruction. The stomach and two loops of bowel are shown to be dilated and gas filled. Bowel gas is absent below this level indicating complete obstruction. Fluid levels are present as this film was taken erect. The patient was confirmed to have jejunal atresia.

Occlusion, Bowel in Childhood. Figure 2 Contrast enema showing in 'small left colon syndrome' with dilated colon seen proximally and meconium plugs seen in the descending colon.

Occlusion, Bowel in Childhood. Figure 3 Contrast enema showing a micro-colon and meconium causing obstruction in the distal ileum in a neonate with meconium ileus.

standard non-ionic water soluble contrast has reached beyond the obstructing meconium to the dilated bowel loops may be enough to precipitate clearing of the meconium. However, some centres value the use of a gastrograffin® enema: if the infant is stable and appropriately fluid resuscitated, a ►gastrograffin enema can be performed using diluted gastrograffin (for details see also entry 'meconium ileus'). The gastrograffin should be instilled until it is observed to have reached and be filling dilated loops of bowel, therefore being above the level of the obstructing meconium. Gastrograffin is hyperosmolar and is believed to draw water into the gut thereby loosening the sticky meconium, allowing it to be passed, and relieving the obstruction.

Nuclear Medicine

Has no role to play in this condition.

Diagnosis

The diagnosis of obstruction is made by a combination of the clinical findings and the imaging as earlier. The underlying cause is usually confirmed at surgery.

Interventional Radiological Treatment

Only for meconium ileus as described above (also see entry 'meconium ileus'); note that sonographically guided saline reduction of meconium ileus is performed in some centres at the bedside of babies too ill to be transported to the fluoroscopy suite (3); some also recommend the use of a C-arm for fluoroscopic guidance on such occasions.

Synonyms

Benign central venous obstruction; Benign central venous thrombosis

Definition

Acute or chronic thrombotic uni- or bilateral occlusion of one or more central veins.

Pathology/Histopathology

Central venous occlusion can broadly be divided into two eliciting categories: benign and malignant. Regardless of the underlying malady, early detection and treatment of complications is essential to provide adequate care for patients suffering from central venous obstruction. The most common cause for benign central venous obstruction is hemodialysis related; other benign reasons are rather uncommon, but are picking up due to the increased use of permanent central venous access catheters and implantable cardiac rhythm management devices.

Clinical Presentation

Clinically these patients present with arm swelling and occasionally obvious widespread subcutaneous collateral vessels around the shoulder and thoracic aperture. Additional swelling of the face, neck, and breast may develop.

Imaging

Consequently, the diagnostic and therapeutic regimen of hemodialysis related central venous obstruction will be the centre of attention and discussed herein.

In the hemodialysis patient, chronic swelling of the access arm is the most indicative clinical symptom of central venous obstruction. Striking superficial collaterals veins may be observed accompanied by pain and paresthesia. In such an obvious case of impeded central venous flow, digital subtraction angiography of the fistula or graft and the complete venous outflow tract must be executed, since the central veins cannot be confidently examined with ultrasonography. Direct antegrade puncture of the access is suggested (1).

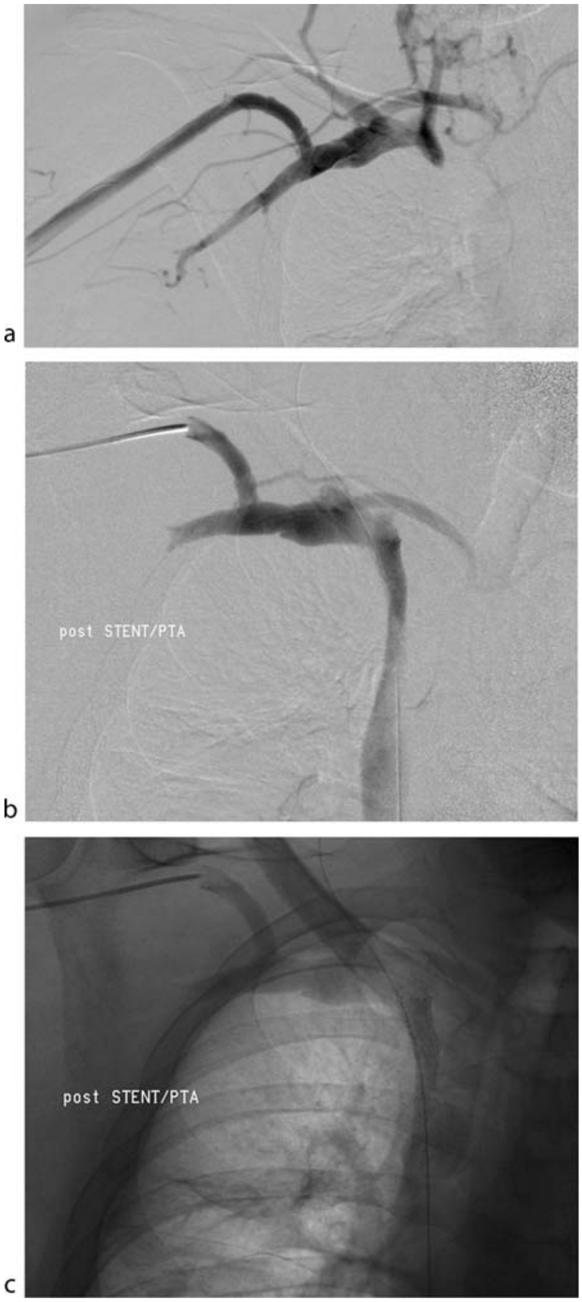
O

Diagnosis

Since clinical diagnosis is often unreliable, imaging techniques need to be incorporated in the diagnostic process.

Interventional Radiological Treatment

Interventional treatment of central venous lesions is indicated when they are impairing hemodialysis or arm swelling is painful and limiting. Reported primary patency rates in patients treated with PTA alone were 10% or less at one year with frequent restenoses (2). Primary stent implantation has clearly been shown to improve primary one-year patency rates to 56% and more, similar to those reported from surgical intervention (1, 3). Yet, due to the invasiveness of surgery for central venous obstructions, the less invasive percutaneous interventional therapy can be considered primary choice for treatment (1). Regular follow-up and reinterventions are however required to maintain patency and achieve long-term clinical success (4). Reports show that symptomatic central venous obstruction in dialysis patients can be treated with a high success rate through radiological intervention (5, 6).



Occlusion, Venous Central, Benign. Figure 1 (a) Digital subtraction angiogram demonstrates complete occlusion of the right brachiocephalic vein draining a Brescia–Cimino fistula; (b) & (c) after unsuccessful transbrachial negotiation of the occlusion, angiogram shows restoration of flow and vanishing of collateral veins after placement of a self-expanding stent and subsequent PTA *via* a transfemoral approach.

Regarding the placement technique, stent placement should evade overlapping the ostium of a patent internal jugular vein to achieve a secure and satisfactory result, since this latter vein is important for future placement of central venous catheters. Correspondingly, a stent placed in the innominate vein if possible should not overlap the ostium of the contralateral vein; otherwise contralateral stenosis may come about and prohibit later use of the contralateral arm for access creation (1). A suitable endoprosthesis for central veins should be flexible enough to be used in curved and tortuous vessels. To avoid stent dislocation and proximal embolization, a self-expanding stent is necessary, in view of the fact that venous occlusions may undergo progressive luminal enlargement after stent placement (Fig. 1). Mechanical thrombectomy should not be regularly used as a primary therapy for dialysis-related central venous occlusions, because of the sharp angles and slim vessel walls observed in this vascular region. Furthermore, modest data are available on the application of thrombolytic agents in hemodialysis-related ►benign central venous thrombosis. It can therefore not be recommended as a primary treatment regimen.

In any case reocclusion is a frequently observed complication and is more likely to occur after thrombosis has occurred for the first time (7). The radiologist should be prepared for repeat interventions.

To summarize, treatment of the hemodialysis patient population is specific due to the unusual underlying pathophysiology in dialysis outflow veins, which are exposed to much higher flow volumes. In the event of hemodialysis-related central venous occlusion, primary stent deployment is very effective in ensuring long-term vascular access for hemodialysis with superior long-term patency rates compared with percutaneous PTA alone or other therapeutic approaches.

Synonyms

Malignant central venous obstruction; Malignant central venous thrombosis

Definition

Acute or chronic thrombotic uni- or bilateral occlusion of one or more central veins.

Pathology/Histopathology

The central venous vasculature, in particular the superior caval venous system, may be obstructed by two types of lesions. The so called SVC syndrome is in more than 90% of cases caused by malignancy. Bronchogenic carcinoma is the most common causative malignant tumor and often leads to edema of the upper thorax, shortness of breath, cough, dysphagia, hemoptysis, and headaches. Less often, direct extension or compression due to the primary tumor or by invasion of the mediastinal lymph nodes is triggered by lymphoma, extra-thoracic tumors, mesothelioma, and lymph node metastases (1). Benign diseases causing SVC obstruction are often iatrogenic due to central venous catheters and pacemaker leads.

Clinical Presentation

Clinical signs and symptoms of SVC obstruction (SVCO) are scored according to Kishi (2, Table 1). Clinical manifestations of venous obstruction can be extremely serious, requiring prompt treatment (also see ►Benign central venous occlusion). Although the primary diagnostic suspicion can be rendered clinically, imaging is required for demonstrating the extent of the pathology.

Imaging

Contrast venography for decades has been the standard of reference for benign and malignant central venous obstruction; however this procedure has its shortcomings. Venous puncture can be challenging in a swollen extremity, the procedure may cause thrombophlebitis and there is a low risk of an allergic contrast agent reaction. Ultrasonography is not reliable for detection of central venous pathologies, owing to difficult access to these vessels. In addition enlarged collateral veins and nonocclusive thrombi may cause false negative results. Sensitivity can be improved with the demonstration of normal cardiac pulsatility and respiratory phasicity within the examined vessels (read ►Thrombosis, vein brachial).

Occlusion, Venous Central, Malignant. Table 1 Kishi scoring system for superior vena cava obstruction with the total score for signs and symptoms calculated as the sum of the highest grades in each category

Signs and symptoms grade
Neurologic symptoms
Stupor, coma, or blackout 4

Cough or pleural effusions 1
Nasal and facial signs or symptoms
Lip edema, nasal stiffness, epistaxis, or rhinorrhea 2
Facial swelling 1
Venous dilatation
Neck vein or arm vein distension, upper extremity swelling, or upper body plethora 1

Nowadays contrast enhanced spiral or preferably multislice computed tomography is employed to define the site of the obstruction and the presence of possible thrombosis and reveal surrounding soft tissue alterations (3). Alternatively, MRI is of comparative or even higher sensitivity and specificity in evaluating the patency of the central chest veins and may just as well hint at impending SVCO (►Thrombosis, caval vein inferior).

Another drawback of digital subtraction angiography is that it can only evaluate one single venous drainage system for each injection and other major draining vessels, for instance the internal jugular veins, may remain indeterminate. CT and MR venography more clearly depict the site and extension of the obstruction in clinically relevant venous vessels segments (4).

O

Both cross-sectional modalities provide a fast, virtually noninvasive evaluation of the central chest veins. If a percutaneous therapy is anticipated, naturally, digital subtraction venography should be carried out immediately prior to, during, and after the intervention.

Diagnosis

Due to the deficiencies of a clinical diagnosis, imaging techniques need to be incorporated in the diagnostic process.

Interventional Radiological Treatment

Especially in acute central venous obstruction, traditional treatment methods in malignancy have been nonoperative, such as steroids, radiation therapy, and chemotherapy. These however may require up to 4 weeks to show an effect and thus often are too time consuming (5). In benign and malignant lesions, anticoagulation alone is not efficient but may be used combined with other treatment modalities (6). Thrombolysis is ineffective in 75% of cases when the event is older than 5 days. In early chronic and chronic occlusions, thrombolysis is outright unsatisfactory (7). If a stenosis is the trigger for thrombosis, sole lysis will also be inefficient (8).

In conclusion, an approach which offers urgent and rapid nonoperative relief should be the preferred treatment of choice.

Admittedly, with balloon angioplasty alone early restenosis can be expected; plus, interventional success is limited because of the well-known fibrous and elastic features of venous lesions (6, 8). It however can be valuable before stenting by allowing the stent to uncomplicatedly cross relatively tight lesions.

For all the above mentioned reasons percutaneous endovascular stenting of obstructive central venous lesions, which are symptomatic and caused by benign or malignant lesions, is an effective therapeutic option with acceptable patency rates and proven efficacy (9).

Stenting results in a rapid and consistent relief and maintains patency throughout the life span of most patients suffering from malignant tumors. Different vascular access sites like the femoral vein, internal jugular vein, subclavian vein, and basilic vein are possible. Recanalization can be attempted with a hydrophilic-coated steerable 0.035 inch guide wire or a straight guide wire with a movable core, combined with a selective catheter.

The obstruction may require predilation after safe passage through the segment, but only if presence of thrombus material can be excluded. To avoid venous rupture, which in the worst case may lead to cardiac tamponade, PTA should be performed carefully and by hand. Next, a stent which is flexible enough to allow implantation even in kinked vessels should be introduced. Coverage of the obstructed segment is advised to be at least 1 cm free at the proximal and distal end to cover beyond the obstruction. Sometimes the placement of an additional stent may be necessary, especially if there is obstruction of both anonymous veins and the superior vena cava. In this case recanalization and revascularization of one anonymous vein lead to good clinical results and are associated with fewer complications provided that sufficient venous collaterals from left to right or vice versa are present (10).

Stent size should be adapted to the diameter of the adjacent nonobstructed vessel segment. Postprocedural balloon dilatation is advised. Stent size should be at least 10% above the venous diameter. To avoid stent dislocation and central embolization, a self-adjusting, self-expanding stent is advantageous because especially chronic venous occlusions may undergo progressive luminal enlargement after stent placement (11). Previously, many interventionalists preferred balloon expandable stents because of their flexibility and their marginal risk of migration. Current self-expanding stents however have overcome these problems of significant foreshortening and migration.

Often a superimposed thrombosis can be observed which can be treated with thromboaspiration or fibrinolytic therapy before stenting (1). The significant bleeding risk in patients with corresponding contraindications must be considered though. The chance of hematoma formation and gastrointestinal and intracerebral hemorrhage must be taken into account. Nevertheless the presence of extensive thrombus may require the use of thrombolytics. The thrombolytic agent should be infused with the tip of the infusion catheter inside the thrombus at a rate of $\sim$0.02 mg tissue plasminogen activator/kg body weight/hr (12). To save time, pulse spray injection can be employed. Active thrombus removal with mechanical thrombectomy devices may be an adjunct or even alternative to intralesional thrombolysis, however it must be handled with care and expertise.

The peri- and postprocedural anticoagulation for stent placement with or without additional thrombolysis is still unclear. Heparinization during stenting and postprocedural intravenous or subcutaneous heparin can be administered. Subsequent antiplatelet therapy, typically aspirin and/or clopidogrel is recommended. Thrombosis may occur after the stent insertion in up to 45% (13). Long-time anticoagulation therefore helps in avoiding clinical deterioration.

To recapitulate, the efficacy and safety of stent placement in central venous occlusion of benign and malignant origin have been proven with rapid relief and less invasiveness for the often extremely ill patients. Stenting is widely accepted now; it provides fast and durable symptomatic relief and can nowadays be favored to radiation and chemotherapy or used in combination with them. If clinical symptoms are severe or worsen rapidly, stenting is indicated while surgical therapy should be reserved for patients undergoing refractory to percutaneous therapy. Repeated percutaneous intervention can prolong the cumulative patency rate.

Pharmacologic/pharmacomechanical/mechanical thrombolysis may be necessary to improve the final result in case of superimposed central venous thrombosis; they should however not be employed as a single means for revascularization.

Achalasia; Gastro-oesophageal reflux; Gastro-oesophageal reflux (GOER); Oesophageal atresia; Oesophageal duplications (and other foregut duplications); Oesophageal foreign body; Oesophageal stenosis (corrosive ingestion); Oesophageal webs; Tracheo-oesophageal fistula

Definition

►*Oesophageal atresia* is the congenital occlusion of the oesophagus. It has an incidence of between 1 in 3,000 to

4,500 live births. Oesophageal atresia is associated with ►tracheo-oesophageal fistula in more than 85% of cases. There are several different anatomic variations of the oesophageal atresia and the insertion of an associated tracheo-oesophageal fistula. Tracheo-oesophageal fistula is the abnormal connection between the trachea and the oesophagus and occurs in isolation only in 8% of cases. The remainder of the time it occurs in conjunction with oesophageal atresia.

Oesophageal webs may be congenital or acquired and are a thin, 2–3 mm, eccentric, smooth extension of the normal oesophageal wall that can occur anywhere along the length of the oesophagus but typically is located in the anterior post-cricoid area of the proximal oesophagus.

►*Oesophageal duplications* are part of a wider group of foregut duplications. Duplications may cystic or tubular and may contain gastric mucosa. They can be associated with sequestrations or congenital stenosis or atresia of the oesophagus. Oesophageal duplications may be separated from the oesophagus or may share a common wall. Duplications of the oesophagus are sometimes associated with vertebral anomalies and intraspinal cysts and often are associated with intra-abdominal intestinal duplications.

►*Oesophageal stenosis* is a narrowing of the oesophagus at any point along its length and over a variable distance. A stenosis my be congenital or may be acquired such as after surgery for oesophageal atresia, secondary to acid or alkali ingestion, or to another disease process such as epidermolysis bullosa.

►*Achalasia*: Abnormal dilatation and motility of the distal oesophagus with failure of relaxation of the lower oesophageal sphincter.

►*Oesophageal foreign body*: An object that is ingested but does not pass freely through the oesophagus. The most common sites for hold-up are at the level of cricopharyngeus, at the aortic knuckle and at the gastro-oesophageal junction.

►*Oesophageal inflammatory change:* Inflammation of the mucosa of the oesophagus in response to an irritant. This in most commonly secondary to reflux or to ingested corrosives but may also be seen in Crohn's disease, epidermolysis bullosa, pemphigoid and other systemic or dermatological diseases.

►*Gastro-oesophageal reflux*: Reflux is the retrograde movement of fluid across a sphincter and in the context of the oesophagus is the movement of stomach contents up into the oesophagus.

Pathology/Histopathology

Oesophageal atresia is due to posterior deviation of the tracheo-oesophageal septum leading to incomplete separation of the oesophagus from the laryngo-tracheal tube. There is failure of recanalisation of the oesophagus in the eighth week of foetal development. There are several variations on how the fistula may connect the trachea and oesophagus. The most common is that of a blind-ending upper pouch with a fistula then connecting the distal trachea to the lower, patent, part of the trachea. A fistula that joins a patent oesophagus to a patent trachea is termed an 'H'-shaped fistula (8%). Oesophageal atresia and tracheo-oesophageal fistula is the most common congenital malformation of the oesophagus (1).

Oesophageal webs may represent incomplete recanalisation of the oesophagus during foetal life. They are made of the normal structures in the wall of the oesophagus.

Oesophageal duplications: It is believed that these anomalies are due to failure of the notochord to detach from the endoderm, resulting in a persisting neurenteric canal. They often contain gastric mucosa.

Oesophageal stenosis: Congenital stenosis is believed due to poor canalisation of the oesophagus in embryonic life. Acquired stenoses are usually secondary to an insult and will therefore show scar tissue.

►*Achalasia:* Aetiology unknown.

Oesophageal foreign body: No specific pathology.

Oesophageal inflammatory change: The inflammatory change may be superficial involving only the mucosal surface or maybe transmural.

Gastro-oesophageal reflux: In GOER the lower oesophageal sphincter (LES) opens inappropriately or is incompetent and there is transient complete relaxation of the sphincter. Due to a pressure difference across the LES (with negative pressure in the oesophagus during inspiration) or a transient rise in intra-abdominal pressure the stomach contents move up into the oesophagus This may result in chronic inflammation in the oesophagus and in severe cases can lead to stricture formation.

Clinical Presentation

Oesophageal atresia and tracheo-oesophageal fistula: Most neonates present at birth with difficulty swallowing secretions, drooling, choking and respiratory distress as secretions and feeds spill over into the airway. In complete OA, the neonate will present with difficulty swallowing secretions and will be unable to tolerate the first feed. If a fistula is present between the trachea and oesophagus, air can still reach the gastrointestinal (GI) tract. An ►H-fistula may present later with blue episodes or repeated chest infections and aspiration as some fluid tracks from the oesophagus through the fistula into the airway. A blind-ending upper pouch is often detected when there is failure to pass a nasogastric tube and/or this becomes coiled in the upper oesophagus. With the increase in antenatal scanning oesophageal atresia may be detected *in utero*. The mother may present with polyhydramnios and on ultrasound there will be very little if any fluid present in the stomach or GI tract of the foetus.

A complication of repair of oesophageal atresia is a stricture of the oesophagus and the child may present with dysphagia and regurgitation of food.

Oesophageal web: The very young child will present with drooling and aspiration, and may suffer repeated chest infections. The older child will may have dysphagia and regurgitation of solids.

Oesophageal duplication: Completely separated duplications can present as a mediastinal mass and may or may not be associated with symptoms. Incompletely separated duplications may give rise to dysphagia, regurgitation and rarely airway obstruction (2).

Oesophageal stenosis: Dysphagia and regurgitation.

Achalasia: Chronic regurgitation of undigested food, repeated aspiration pneumonia, retrosternal discomfort in the older child.

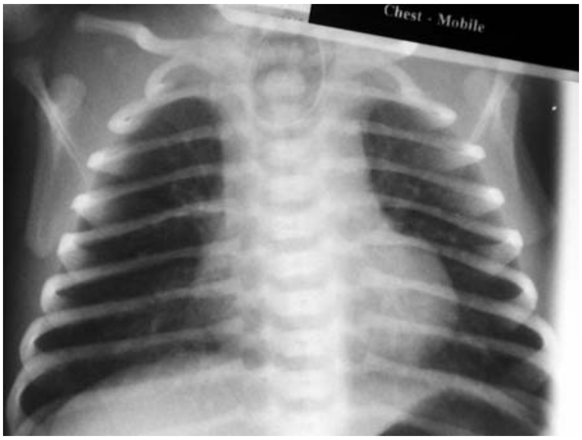
Oesophageal foreign body: The patient will usually be drooling and may be dysphagic.

Oesophageal inflammatory change: Presentation will depend on the underlying cause but the patient will usually have retrosternal pain. With chronic change going on to stricture formation they may present with dysphagia.

Gastro-oesophageal reflux: GOER is most common in infants and young children and a minor degree of reflux in the first few months of life may even be considered within normal levels. The symptomatic infant will present with recurrent regurgitation of feeds and/or pain. In severe cases, the child may fail to gain weight or even lose weight if it is not possible to maintain adequate calorific intake. Older patients may present with retrosternal pain, food aversion or less commonly with a stricture. Alternatively, young children and patients with neurologic deficits may present with recurrent chest infections secondary to aspiration as a result of GOER.

Imaging

Oesophageal atresia and tracheo-oesophageal fistula: A chest X-ray will often show an air-filled, dilated and blind-ending upper oesophageal pouch. If the passing of a nasogastric tube (Fig. 1) has been attempted this is likely to be coiled in the upper pouch (1). A Replogle tube (identified by a dashed radio-opaque marker allowing easy identification on X-ray) may have been placed in the upper oesophagus to allow aspiration of the secretions.



Oesophageal Disease, Childhood. Figure 1 Chest X-ray showing a nasogastric tube coiled in a blind-ending upper pouch in a patient with oesophageal atresia.

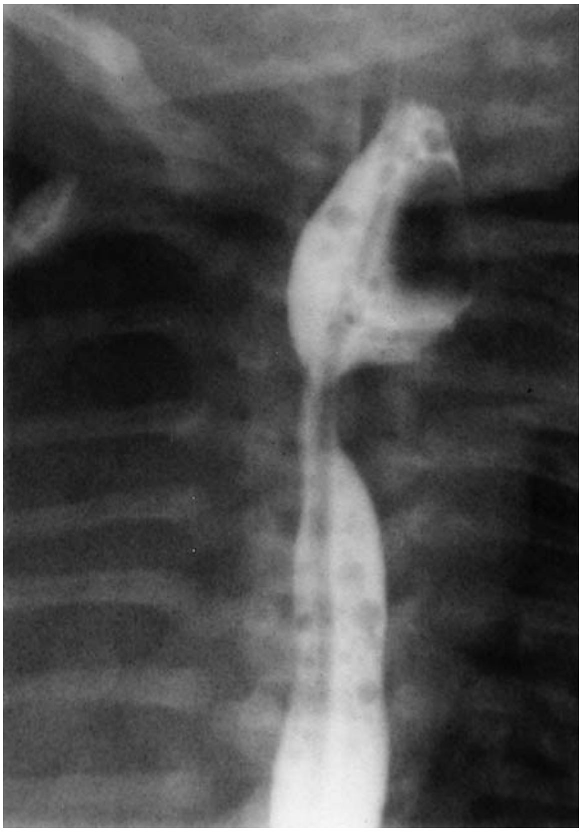
This is a dual lumen tube which allows secretions to be continually sucked from the blind-ending upper oesophagus thereby preventing aspiration. It is used almost exclusively in this condition. The abdomen will be gasless unless there is an associated fistula, and indeed the presence of gas in the abdomen will confirm that a fistula is present, this being the only route for air to get from the airway into the GI tract. A contrast study is not required and the immediate management is usually surgical. Imaging for an H-type fistula (a fistula between a patent airway and a patent oesophagus) is by a tube oesophagram. With the patient prone and with lateral screening water-soluble contrast is injected into the oesophagus whilst the nasogastric tube is slowly withdrawn. If a fistula is present, the contrast should flow through the fistula from the oesophagus into the airway. This procedure therefore carries a significant risk of acute respiratory compromise and should only be undertaken if suction, oxygen, nursing support and appropriate resuscitation facilities are available.

Stricture formation as a delayed complication of repair of oesophageal atresia is best demonstrated by upper GI (UGI) series (Fig. 2).

Oesophageal web: Imaging is by upper GI series or direct visualisation on endoscopy.

Oesophageal duplication: If the duplication is not completely separated it may be demonstrated on an upper GI series (Fig. 3). A closed duplication may be best demonstrated on MRI of the mediastinum, although CT and ultrasound may also be used. Ultrasound would generally use an approach through the sternal notch or between the ribs, but in very young patients a trans-sternal approach can sometimes be used as the sternum has not ossified.

O



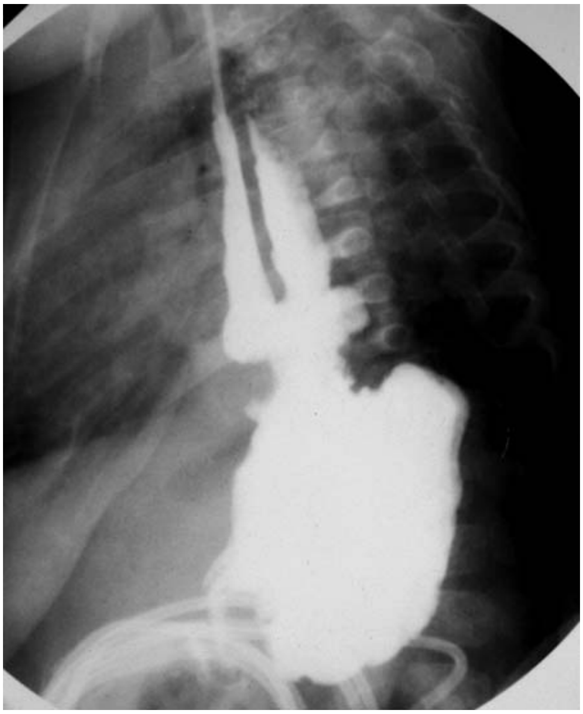
Oesophageal Disease, Childhood. Figure 2 Upper GI series demonstrating a tight oesophageal stenosis at the site of previous surgery for oesophageal atresia with tracheo-oesophageal stenosis.

Oesophageal stenosis: Upper GI series will show the level and extent of the narrowing.

Achalasia: An upper GI series will show the accumulated food debris in the dilated oesophagus and poor opening of the lower oesophageal sphincter with a characteristic fine jet of contrast passing through or an abrupt point ('birds beak') at the gastro-oesophageal junction through which no contrast passes.

Oesophageal foreign body: Chest X-ray (AP and lateral) will show radio-opaque foreign bodies; an upper GI series may demonstrate the filling defect on a radiolucent foreign body. Endoscopy allows direct visualisation and simultaneous removal (see entry Foreign body, ingestion, children).

Oesophageal inflammatory change: Very subtle superficial changes may not be detected by imaging and will only be identified under direct vision with endoscopy. An upper GI series using barium will demonstrate mucosal surface irregularity with an uneven appearance to the barium column (Fig. 4). If a double contrast image is achieved ulceration may be visible. Endoscopic ultrasound will show the degree of intramural thickening.

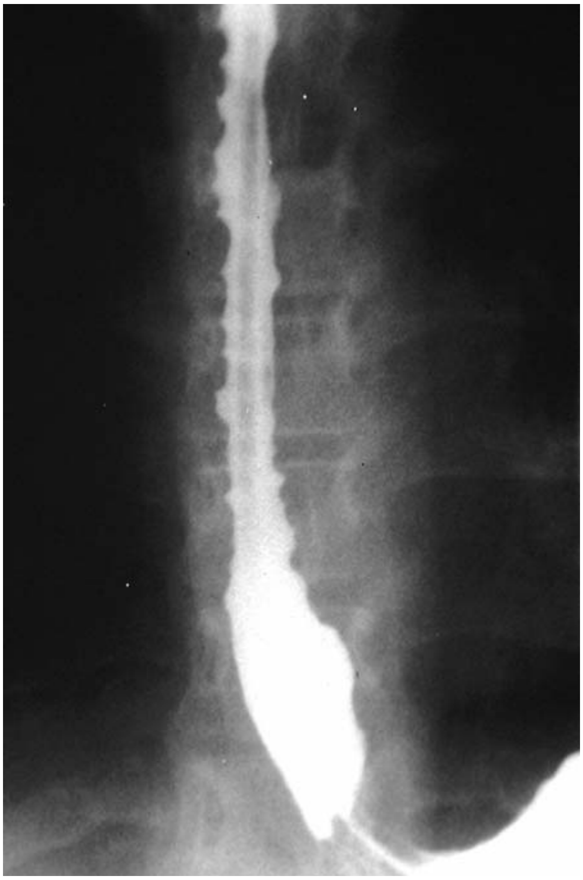


Oesophageal Disease, Childhood. Figure 3 Contrast outlines an oesophageal duplication with two, parallel, fluid-filled cavities opacified.

Gastro-oesophageal reflux: An upper GI series or ultrasound of the lower oesophagus are the modalities of choice. Reflux is usually self-evident in infants by the regurgitation of feeds so much of the value of the UGI is to exclude anatomical causes for the reflux such as hiatus hernia or gastric outlet obstruction and in preparation for surgery if a fundoplication is being considered. GOER is characteristically intermittent and it would be inappropriate to image the patient with prolonged screening to try and demonstrate an occasional episode. Only intermittent screening should be performed and the absence of demonstrable reflux during a UGI does not exclude the diagnosis. Ultrasound is increasingly used to demonstrate relaxation of the lower oesophageal sphincter and fluid tracking into the lower oesophagus. It has the advantage that the sphincter can be observed directly and for prolonged periods but the disadvantage that it cannot show the rest of the stomach and duodenal anatomy. An UGI is also useful for assessment of the complications of GOER such as stricture formation.

Nuclear Medicine

No role to play in this condition.



Oesophageal Disease, Childhood. Figure 4 Upper GI series with contrast outlining an irregular and narrowed oesophagus following ingestion of caustic fluid.

Diagnosis

By imaging as detailed above. GOER may also be diagnosed by monitoring with pH probe.

Interventional Radiology

Image guided balloon dilatation of strictures (3), and sometimes removal of oesophageal foreign bodies may be carried out by the interventional radiologist (see also entry 'foreign body, ingestion, children').

Synonyms

Esophagitis; Gastroesophageal reflux disease (GERD); Oesophagitis

Definition

In the literature the term "esophagitis" (oesophagitis) is sometimes used synonymously with "reflux esophagitis" because gastroesophageal reflux is the most common cause of esophagitis. However, numerous etiologic factors may cause esophagitis:

- Infectious esophagitis
  1. Fungal infections
  2. Viral infections
     (a) Herpes simplex virus (HSV)
     (b) Cytomegalovirus (CMV)
     (c) Varicella-zoster virus (VZV)
  3. Bacterial infections
  4. Parasitic infections
- Drug-induced esophagitis
- Radiation-induced esophagitis
- Caustic esophagitis
- Reflux esophagitis
- Miscellaneous
  1. Skin disorders
- Dystrophic epidermolysis bullosa
- Pemphigus vulgaris
- Bullous pemphigoid
- Benign mucous membrane pemphigoid
- Stevens–Johnson syndrome
- Lichen planus
- Acanthosis nigricans
- Darier's disease
- Leukoplakia
  1. Behcet's disease
  2. Graft-versus-host disease (GVHD)
  3. Crohn's disease
  4. Ulcerative colitis
  5. Sarcoidosis
  6. Collagen vascular diseases.

Pathology/Histopathology

Infectious Esophagitis

In Candida esophagitis, plaques consist of heaped-up areas of necrotic epithelial debris or actual colonies of *C. albicans* on the esophageal mucosa; the esophagus itself as an irregular or shaggy appearance. Three viral infections cause ulcerative esophagitis: HSV, CMV, and VZV.

In HSV the earliest esophageal lesions are vesicles, the centers of which slough to form discrete, circumscribed ulcers with raised edges. Routine histologic stains may show epithelial cells with occasional multinucleation, "ground-glass" nuclear staining, and intranuclear inclusions. More specific and sensitive is immunohistologic identification with monoclonal antibodies to HSV antigen and *in situ* hybridization for HSV nucleic acid.

CMV infection occurs only in immunosuppressed patients. CMV may be activated from latency or acquired from blood-product transfusions. CMV lesions first appear as serpiginous ulcers in otherwise normal mucosa but coalesce to form giant ulcers, particularly in the distal esophagus. Infection occurs within submucosal fibroblasts and endothelial cells, not in epithelium, and is usually part of widespread visceral infection. Routine histologic stains show large cells in the submucosa bearing amphophilic intranuclear inclusions and intracytoplasmic inclusions. Immunohistology with monoclonal antibodies to CMV antigens and *in situ* hybridization for CMV DNA are useful for finding infected cells that are neither large nor inclusion bearing.

Drug-induced Esophagitis

In drug-induced esophagitis, affected individuals ingest the medication with little or no water immediately before going to bed. When such drugs dissolve in the esophagus, they cause mucosal injury either by creating an acid pH (analogous to a form of caustic esophagitis) or by direct irritating the epithelium.

Radiation Esophagitis

A radiation dose of 4,500–6,000 rad over a 6- to 8-week period or more to the mediastinum may cause severe injury to the esophagus. Acute radiation-induced esophagitis usually occurs 2–4 weeks after the initiation of radiation therapy. The mucosa typically has a granular appearance because of edema and inflammation. Ulceration and decreased luminal distensibility are other frequent findings.

Caustic Esophagitis

Caustic esophagitis causes injury similar to that from thermal burns. Liquid lye causes liquefactive necrosis, resulting in the most severe form of caustic injury to the esophagus. Alkaline agents can produce deep coagulation necrosis in minutes. Necrosis from acids tends to be more superficial. The severity and extent of esophageal injury depend on the type, concentration, and volume of the caustic agent. By 2–6 weeks, healing is well in progress, often accompanied by severe fibrosis.

Gastroesophageal Reflux Disease, Esophagitis (Reflux Esophagitis)

This type encompasses reflux esophagitis and is characterized histologically by inflammatory cells and reflux changes consisting of epithelial hyperplasia without inflammation. The multiple determinant factors in the production of reflux disease include the frequency and volume of GER, the volume of gastric contents available to reflux, the potency of the reflux material, the efficacy of esophageal clearance, and the tissue resistance to injury.

Miscellaneous Esophagitis

Eosinophilic esophagitis (IEE) is a chronic inflammatory disease characterized by eosinophilic infiltration of the esophagus with an increased number of intraepithelial eosinophils (more than 20 eosinophils per high-power field) in endoscopic biopsy specimens from the esophagus. Alkaline reflux esophagitis is caused by reflux of bile or pancreatic secretions into the esophagus after partial or total gastrectomy. Pemphigus and pemphigoid are nonhereditary conditions in adults, and epidermolysis bullosa dystrophica occurs as an autosomal recessive condition in children. Pemphigus, pemphigoid, and epidermolysis bullosa can produce esophagitis.

Pemphigus vulgaris affects skin, mouth, and other mucous membranes with weeping bullous lesions. Histology shows acantholysis and intraepithelial bullae, and specific immunohistology should be used. Bullous pemphigoid is a chronic disease of the elderly, in whom tense, pruritic skin bullae arise. Esophageal bullae occur rarely, with sloughing of the epithelium as a cast. The histology shows subepithelial bullae and circulating antibodies to the basement membrane.

Behcet's disease is a multisystem inflammatory process characterized by oral and genital ulcers, ocular inflammation, skin lesions, and vasculitis. Esophageal lesions include ulcerations that can tunnel under the mucosa, strictures, and perforations.

GVHD is an immunologic reaction against host tissues by donor lymphoid cells. The esophagus shows webs, rings, and tight strictures but often fails to show generalized desquamation apparent on endoscopy. Crohn's disease rarely affects the esophagus but may show small aphthous ulcers, inflammatory strictures, filiform polyps, and fistulas. Granulomas can occasionally be found in endoscopic biopsy specimens.

Clinical Presentation

Infectious esophagitis is seen with increasing frequency in debilitated individuals, alcoholics, diabetics, immunocompromised or transplant patients, individuals with impaired T-cell function from acquired immunodeficiency syndrome (AIDS), and patients receiving steroids, antibiotics, radiotherapy, or chemotherapy. Candida esophagitis (and infectious esophagitis generally) is usually characterized by the abrupt onset of odynophagia (painful swallowing), chest pain, or dysphagia. Clinical symptoms can occasionally be absent. Symptoms of tuberculosis esophagitis include dysphagia and chest pain, but esophageal symptoms are commonly absent. Patients with HSV esophagitis present with odynophagia, retrosternal pain, and heartburn. Infection can also start with mild symptomatology of nausea and pyrosis (heartburn) or with very severe symptoms of hematemesis. The clinical presentation of CMV esophagitis is nausea, vomiting, painful swallowing, heartburn, and/or hematemesis.

Symptoms of *drug-induced esophagitis* are usually sudden in onset and consist of chest pain, odynophagia, or dysphagia. A typical location is the aortic arch level, where tablets are delayed because of the aortic indentation on the esophagus and the low contractile force of peristalsis. Bleeding or esophageal perforation may occur.

Radiation esophagitis typically produces mild heartburn or dysphagia several weeks after the onset of treatment. Some patients may have progressive dysphagia due to strictures 4–8 months after completion of radiation therapy.

In *caustic esophagitis*, the initial clinical symptoms are the rapid onset of chest pain and dysphagia. These symptoms tend to resolve in several days. Acute complications include shock, fever, respiratory distress, mediastinitis, and perforation. Late complications are related primarily to fibrosis and stricture, which may cause dysphagia several weeks after the initial injury.

Symptoms of *GERD esophagitis* (*reflux esophagitis*) can be divided into typical (esophageal) symptoms (heartburn, regurgitation, dysphagia) and atypical (extraesophageal) symptoms (chronic cough, respiratory complaints, laryngeal symptoms). Dysphagia is usually due to esophageal narrowing. Some patients complain of a lump in the throat (globus). In young children the predominant reflux symptoms are regurgitation, repetitive vomiting, and failure to thrive.

IEE appears in the adult population. It typically affects young men (20–40 years of age) with long-standing dysphagia and recurrent food impactions who have not responded to the usual forms of antireflux therapy. Other findings include chest pain and vomiting.

Imaging

Barium examination continues to be the primary radiologic modality for evaluating patients with dysphagia, reflux symptoms, or other clinical findings of esophageal disease. The double-contrast phase optimizes the ability to detect all kinds of esophagitis, particularly reflux disease, whereas the single-contrast phase optimizes the ability to detect hiatal hernia and lower esophageal rings or strictures. Barium contrast studies are useful for evaluating mucosal surface lesions but provide little information about the extramucosal extent of disease. Computed tomography (CT) and magnetic resonance imaging (MRI), on the other hand, permit evaluation of wall thickness, mediastinal involvement, adjacent lymphadenopathy, and distant spread.

Diagnosis

Infectious esophagitis: Candida esophagitis is characterized on esophagrams by plaques or a "shaggy" esophagus. Plaquelike lesions are seen as linear or irregular filling defects that tend to be oriented longitudinally and are separated by normal mucosa. The luminal contour may show fine speculations, irregularity, a cobblestone pattern, or bizarre thickened folds simulating varices. Barium may dissect beneath a pseudomembrane, causing a shaggy contour that gives the appearance of ulceration. The esophagus tends to be atonic. Peristalsis may be feeble or incomplete. Because of muscular hypotonia, the esophagus is generally slightly dilated or normal in caliber but may show areas of moderate narrowing. *Monilia* organisms are a frequent companion of esophageal intramural pseudodiverticulosis.

Double-contrast esophagrams have been found to have a sensitivity of 90% for detecting Candida esophagitis, primarily because of the ability to show these plaques.

CT findings are nonspecific and commonly seen in various kinds of esophagitis (circumferential esophageal wall thickening of >5 mm, with relatively long segmental involvement). Enhanced scans may also depict the target sign (circumferential wall thickening and enhancing internal mucosa). Morphologic abnormalities caused by tuberculosis esophagitis are often eccentric and may show skip areas. The luminal contour may show mild irregularity, large or deep ulcers, and sinus tracts. Fistulas are common. The esophageal wall is generally thickened and the lumen often narrowed. Enlarged mediastinal nodes may displace or compress the esophagus and widen the mediastinum.

In HSV, barium contrast X-ray shows multiple ulcers. Small ulcers surrounded by edema give the appearance of targets or shallow irregularities in the profile view. Diagnosis requires endoscopic brushing and biopsies. The first, presumptive diagnosis can be made in patients with esophageal symptoms and HSV infections of the mouth or nares.

CMV esophagitis is characterized by one or more giant flat ulcers that are several centimeters or more in length. The ulcers may have an ovoid or diamond-shaped configuration and are often surrounded by a thin radiolucent rim of edematous mucosa. Endoscopy with multiple biopsies targeting the center of the ulcer formation is mandatory. Brushing of overlying exudates is seldom useful.

Drug-induced esophagitis: Signs are luminal irregularity, frank ulceration, and luminal narrowing. Tetracycline and doxycycline are associated with the development of small shallow ulcers in the upper or middle part of the esophagus. Other drugs may cause more severe esophageal injury.

Radiation esophagitis: A morphologic abnormality consists of diffuse ulceration. Late findings consist of strictures that are generally smooth with tapering margins and that rarely show irregularity or ulceration.

Caustic esophagitis: In the acute stage, the examination should be initiated with water-soluble contrast medium to exclude esophageal or gastric perforation. Such studies may also reveal marked edema, spasm, and ulceration of the affected esophagus. During the first week, characteristic frank ulcerations are seen. A pseudomembrane may cause intramural trapping of barium. Long, ulcerated strictures may be observed in patients who ingested lye or other caustic agents, and in severe cases, diffuse esophageal narrowing may reduce the thoracic esophagus to a thin, tight stricture. Cross-sectional images depict narrowing or obliteration of the esophageal lumen, and perifibrotic tissue may be observed. Reformatted CT images may be useful for demonstrating the surrounding fibrotic change to which caustic esophagitis leads.

GERD esophagitis: Reflux esophagitis manifests at esophagography as finely nodular or granular relief with poorly defined radiolucencies that fade peripherally due to edema and inflammation of the mucosa. Endoscopy is the gold standard for diagnosing erosive GERD, and the Los Angeles classification for esophagitis is generally accepted as the endoscopic assessment of GERD. Most patients—approximately 60% referred for endoscopy with typical reflux symptoms—do not have erosive reflux disease. The spectrum of GERD can be subdivided into endoscopy-negative, nonerosive GERD (NERD), reflux esophagitis (GERD), and GERD with esophageal columnar metaplasia (Barrett). Further changes include irregularity of luminal contours, discrete ulcerations, transverse esophageal folds, thickened longitudinal folds, esophageal wall thickening, smooth polypoid protuberance (also known as an inflammatory esophagogastric polyp), and segmental narrowing.

The ulcers can have a punctate, linear, or stellate configuration and are often associated with a surrounding halo of edematous mucosa, radiating folds, or sacculation of the adjacent wall. Predominant involvement of the distal esophagus and the presence of an associated hiatal hernia and gastroesophageal reflux should suggest the correct diagnosis.

Thickened folds wider than 3 mm are best seen on mucosal relief views of the collapsed esophagus. Multiple delicate transverse folds 1–2 mm wide may also be found in patients with gastroesophageal reflux disease. Between 10 and 20% of patients with reflux esophagitis develop peptic strictures as a result of circumferential scarring of the distal esophagus. The classic appearance of a smooth, tapered area of concentric narrowing in the distal esophagus above a sliding hiatal hernia should be virtually pathognomonic of a benign peptic stricture. Most peptic strictures range from 1 to 4 cm in length and from 0.2 to 2.0 cm in width. Between 25 and 50% of patients with reflux esophagitis have abnormal esophageal motility, manifested by feeble or absent primary peristalsis associated with an increased frequency of nonperistaltic contractions.

Miscellaneous esophagitis: Alkaline reflux esophagitis is characteristic by mucosal nodularity or ulceration or, in severe disease, by distal esophageal strictures that often progress rapidly in length and severity over a short period of time. During the acute stage of pemphigus, pemphigoid, and epidermolysis bullosa esophagitis, bullae may cause multiple esophageal filling defects on esophagograms, or ruptured bullae may appear as ulcerations. Repetitive insults often lead to strictures that are generally smooth but sometimes have an irregular contour. IEE manifests at esophagography as segmental esophageal strictures (sometimes ringlike—the so-called ringed esophagus at endoscopy and/or barium studies) and occasionally with diffuse esophageal narrowing, which produces a "small-caliber" esophagus.

Interventional Radiological Treatment

Esophageal dilation is usually indicated for benign stenoses and strictures, which can be caused by esophagitis. The main indications are strictures after caustic and reflux esophagitis. All esophageal strictures should be carefully evaluated with esophagography or endoscopy before dilation.

Open and Closed Spinal Dysraphisms

Etymologically, the term "dysraphism" implies defective closure of the neural tube, and should therefore be used to refer to abnormalities of primary neurulation only. However, the term has gained widespread use as a synonym to congenital spinal cord malformation.

Spinal dysraphisms are categorized into open (OSD) and closed (CSD). OSDs are characterized by exposure of nervous tissue to the environment through a congenital defect of the child's back. On the contrary, CSDs are covered by skin, although cutaneous birthmarks, such as angiomas, dimples, overgrowing hair, dyschromia, and dystrophy, are present in greater than 50% of cases. Use of the term "occult spinal dysraphisms" is discouraged as it suggests complete absence of external abnormalities, a condition that occurs only in a minority of CSDs.

Definition

Optical imaging is a broad term which can be used to describe a large range of imaging systems, from tissue microscopy, through macroscopic imaging of tissue with endoscopic, laparoscopic, or telescopic systems. Generally, this wording is used to describe optical imaging, when compared with other imaging systems which do not use optical detection, such as X-ray, ultrasound, or magnetic resonance. Optical imaging is carried out with a light sensitive system for capturing the images. Standard optical imaging systems use a charged coupled device (CCD), for detecting the image, having many pixels and a lens or fiber optic system, which is customized for the application. Analysis of the system performance in terms of resolution and contrast are always specific to the geometry and the tissue being imaged.

Imaging of tissue *in vivo* is largely based upon the effects of absorption and scattering of the light as it interacts with tissue, causing chromatic changes or allowing viewing of morphologic features. Some *in vivo* imaging relies upon tracking temporal changes or changes in response to a stimulus, but this is less common. Preclinical or *ex vivo* imaging, such as in pathology typically relies upon contrast from exogenously introduced agents which are specific to chemical features of the tissue.

Optical imaging of contrast agents *in vivo* is also used in experimental and developmental work as well as a few clinical applications, looking at fluorescence imaging of tissue, where a filter is used on the image detection side to remove the excitation light and only allow the longer wavelength emission light into the imaging camera. Recent developments in biochemistry and experimental biology have introduced a large number of fluorescent proteins and bioluminescent agents that can be transfected into the DNA of cells and animals, thereby allowing optical imaging of organs or specific gene-expression. The use of optical imaging in experimental biomedical research has increased substantially due to these developmental areas.

Fiber Coupled Systems

Fiber optic coupled systems are used throughout routine medical practice in imaging the interior cavities of the body, or imaging organs during surgical intervention or exploratory examination see Endoscopy, Brochoscopy or Laparoscopy. Generally, the optical fibers bundle is used to translate the image from a lens inside the body to a remote camera which is mounted on the exterior end of the device being held by the person doing the procedure. The endoscope is used in this way for imaging the digestive tract, and similarly a bronchoscope is used to image the airways. These are typical flexible fiber bundles which allow movement through these complex structures. The video or CCD camera is usually fed to a television for viewing of the procedure in real time by the endoscopist or bronchoscopist.

Lens Coupled Systems

Lens coupled imaging systems are used routinely in ophthamoscopic imaging, cervix imaging, ear imaging, as well as most experimental biology imaging systems. The commonality in this area is that if broadband light imaging is required, the lenses used must be compound lenses to avoid issues of chromatic aberration in the resulting image at the camera. Thus, significant care is taken to design and optimize the lens system and how it focuses onto the camera. Generally, lower the f-number of the objective lens and the closer the lens is to the tissue, the more light will be captured in the imaging procedure.

Microscopy

Microscopy is by far the most widely used application of optical imaging in medicine, yet it is often considered in a different category because it is so specialized. Pathological analysis of biopsied tissue is the most common application here, where the tissue is fixed and stained for imaging.

Tomographic Imaging

Tomographic imaging of tissue is sometimes called more generically optical imaging, but is better described in the Optical Tomography section or Fluorescence Imaging section. The major difference between tomography and imaging is largely considered to be the acquisition of signals from below the surface, thereby allowing reconstruction or backprojection of the image below the surface.

Surface Topography and Tracking

Optical imaging systems are used in many different applications for surface tomographic mapping, and several commercial systems exist either using patterned light generation to measure surface topography or using stereovision cameras together with computed algorithms to create surface maps. These are used in applications where the three-dimensional topography of a tissue surface is needed to be known.

Definition

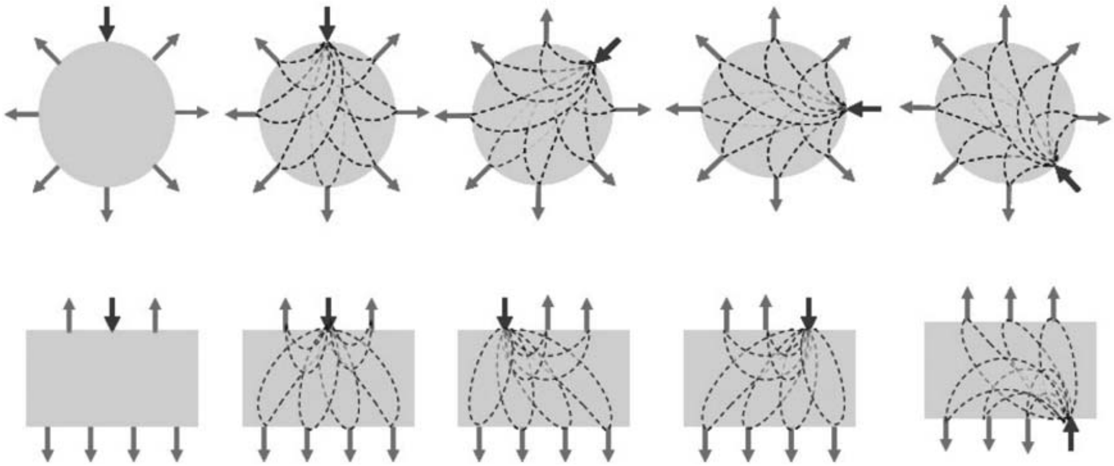
Optical tomography has been an active area of research study since the late 1980s, when both technological and algorithmic breakthroughs led to workable methods to understand light transport in tissue and solve the inverse image reconstruction problem. The exact tools for tomographic imaging vary widely in terms of hardware and software, but the commonality is that the method allows imaging of the interior of tissue, by recovering the interaction coefficients or chromophore and scattering parameter maps. Near-infrared light, in the range of 650 to 950 nm, is most commonly used in optical tomography as it has the lowest scattering and absorption values, thereby providing the best penetration through tissue possible. Imaging through volumes of up to 10–14 cm is possible given sufficiently designed equipment. Tomographic measurements in this wavelength range are most sensitive to the molecules that absorb light, which are hemoglobin, oxyhemoglobin, water, and lipids. Thus imaging tissue function related to blood concentration and oxygen saturation is possible with near-infrared tomography. In addition, injection of absorbing or fluorescent contrast agents is possible, providing further information about the tissue function. The latter application of imaging fluorescent agents is often called fluorescence tomography, and described in another section on Fluorescence Imaging. Imaging with optical tomography is commonly applied to imaging brain tissue for functional physiology studies, or neonatal cerebral imaging for tracking disease, or female breast cancer imaging. There are few commercially available devices which do optical tomography, but a larger number of experimental and investigational devices have been developed in research labs (1).

Tomography of tissue requires measurement of multiple cross-sectional measurements of light transmission from several different source and detector locations. When overlapping paths are measured, as with X-ray computed tomography, it is possible to mathematically reconstruct the interaction coefficient maps of the tissue interior. In the case of optical tomography, this inverse problem is not as analytically tractable as in the filtered backprojection methods used in X-ray tomography (2). The path of the light is highly scattered, and so the transport mechanism is dominated by elastic scatter. Optical tomography became more intensively studied when it was established the optical path length through a scattering medium could be measured by time-resolved or frequency-domain signals, by directly measuring the signal propagation time. Through modeling the transmission process as a diffusive transport problem, it is possible to mathematically quantify independent absorption and transport scattering coefficients (1). Existing systems typically use this approach to them compute concentration maps of hemoglobin, or relative oxygen saturation of the hemoglobin, or water and lipid fractions in the tissue, through computation of the exact absorption coefficient spectrum.

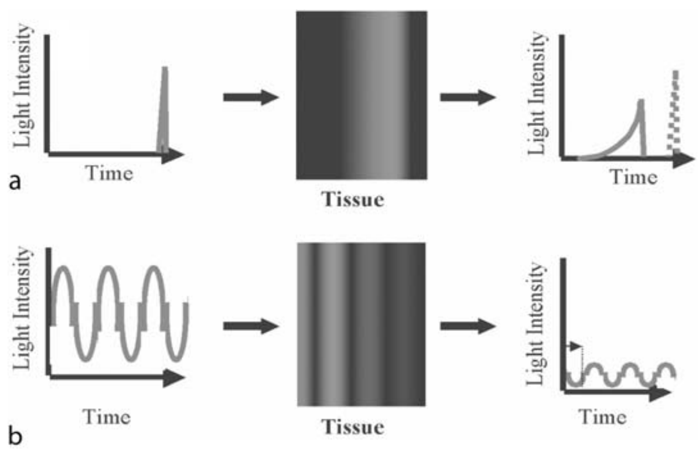
Characteristics

Most systems are based upon multiple fiber optic placements upon the tissue to be imaged, and illuminating the source light into the tissue while detecting the remitted light at all other fiber points. When this is completed, the light is cycled to each of the source fibers in turn to provide multiple overlapping measurements through the tissue volume, as indicated in Fig. 1. Recovery of the remitted light can also be done with noncontact application as well, delivering the light through a scanned beam and picking up the remitted intensity with optics to fibers or charge coupled devices (CCD) (3).

The type of light signals used in these systems are divided into time-resolved signals or frequency-domain signals or continuous wave signal illumination, as illustrated in Fig. 2. Each of these provide slightly different information about the tissue, but all have been shown to allow separation of absorption and scattering effects with different levels of success. It is largely agreed that time-resolved signals provide the optimal separation of the scattering and absorption coefficients, whereas frequency domain provides nearly equal ability. However, continuous wave signals are thought to be insufficient for separation of the effects of absorption versus scatter, without the use of multiple wavelengths or other



Optical Tomography. Figure 1 Illustrating two common geometries for imaging with optical tomography, namely an effectively circular or thick slabs of tissue volume with a single source and multiple detectors. The source location is cycled around to make multiple overlapping projection measurements, and the banana-shaped projections are the diffuse photon paths, which represent the dominant measurement path. *Inward arrows* represent the sources here and *outward arrows* represent the detectors.



Optical Tomography. Figure 2 An illustration of a time-resolved measurement (a) where a short pulse of light is transmitted through a hypothetical block of scattering tissue, spreading the pulse out in time, and a frequency-domain measurement scheme (b) using a sinusoidally modulated light intensity transmitted through the tissue.

constraining information. Measurement detectors are either photomultiplier tubes for the weakest light signals, or photodiodes, diode arrays or CCDs. Multichannel detector devices have been produced in many different configurations.

Diffusion theory based reconstruction requires the iterative solution to a perturbation type equation or a Newton method approach (2). Both of these require some initial guess of the tissue properties, often assumed to be the best homogeneous estimate, and then the image reconstruction process uses the Jacobian or sensitivity matrix to iteratively improve the estimate of the coefficients at each pixel within the image. The goal of the reconstruction is to minimize an objective function, which is often calculated as the normalized square difference between the calibrated data set and the calculated diffusion theory prediction of the signal. This minimization process requires inverting the Jacobian matrix, which is an ill-posed problem, and therefore requires careful regularization (addition of a constant term to the diagonal of the matrix) to make it invertible. This process inherently smooths the overall resulting image, and the value of the regularization parameter is often estimated for each particular problem, often in a Levenberg–Marquardt methodology.

Most current systems use multiple spectra measurements, thereby allowing recovery of the absorber concentration maps from the absorption coefficient spectra, and with *a priori* knowledge of the chromophore extinction coefficients. It has been shown that direct reconstruction of the chromophores can also be achieved by including the spectral fitting process within the inverse image reconstruction problem, and this process reduces the ill-posed nature of the problem, and improves the accuracy.

Applications in Preclinical Studies

Small animal imaging with near-infrared tomography has been a highly used avenue, for studies in brain function and tumor imaging. Imaging of tumor characteristics *in vivo* has been possible both without and with a scattering coupling medium. Imaging of brain tissue function, in terms of hemoglobin and oxygen saturation has been done extensively and used for functional brain activation studies.

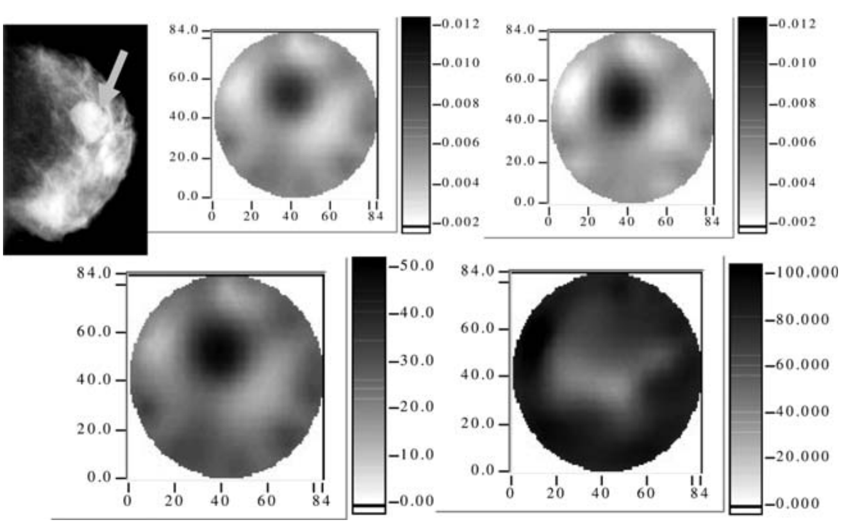
Applications in Brain Diagnostics

Significant interest in optical tomography was initiated with the possibility of monitoring or measuring neonatal cerebral hemodynamics *in vivo*. Commercial systems are available for spectroscopy monitoring of the brain in neonates with single point transmission measurements, and the desire to extend this to a full tomographic system was the driving force for much of the development of optical tomography throughout the past 20 years. Prototype systems have been developed in several labs and are still undergoing feasibility assessment for their potential use. Point spectroscopy of hemodynamics in the brain during childbirth and in utero have both also been shown and used in studies. Measurement of cytochrome oxidase changes in oxygenation within the brain have also been studied, with limited success in this area.

Brain topography systems have been studied extensively and commercialized by Hitachi as a tool to study cognitive function in humans. The difference between topography and tomography lies in the depth penetration of the light, with topography being surface measurements across large areas of the brain, without any reconstruction of the lower lying areas. This approach is simpler and more successful than tomography, and provides important information about the outer cortical layers where blood flow and oxygen consumption issues can readily be measured in response to energy demand in the brain cells. Study of cognitive function with optical topography and optical tomography is a highly active area of research and development (4).

Applications in Breast Cancer

Breast cancer imaging with optical tomography has been shown in many laboratories, with large clinical trials ongoing and being sponsored by the US National Cancer Institute. Commercial prototype systems have been created by a number of companies, with each having very different technological approaches and different clinical goals. Initial feasibility as a screening tool for widespread use has largely proven unsuccessful, however niche applications in screening high-risk groups, younger women or complicated tissue



Optical Tomography. Figure 3 **(a) Radiographic image of a patient's breast, showing a well-localized fibroadenoma in the upper central region of the breast (marked with an *arrow*). The resulting NIR images of absorption coefficient at (b) 750 nm and (c) 800 nm wavelength are shown, along with the computed images of (d) total hemoglobin and (e) oxygen saturation. The gray-scale bar units for absorption coefficient are mm^{-1}. The units for total hemoglobin are in micromolar, and the units for oxygen saturation are in percent relative to 100% oxygenated hemoglobin.**

cases remains a possible avenue for use. Integration of optical tomography into MRI scanners has been demonstrated and continues under development. A set of example images from a subject with a focal fibroadenoma tumor in the breast is shown in Fig. 3 (5).

The ability to image tumor properties of hemoglobin, oxygen saturation, water fraction, and scattering has undergone rapid development in the past 5 years. Direct recovery of these concentration images has been shown to improve the accuracy of the values, through multispectral fitting and reconstruction in a single step.

Optical tomography has also been coupled into standard clinical imaging systems, including MRI, ultrasound, X-ray tomography, X-ray tomosynthesis, MEG, EEG and is thought to provide complementary information, predominantly related to hemoglobin, oxygen saturation and uptake and retention of injected contrast agents.

Inflammation; Inflammatory lesion

Definition

An inflammation is a non-specific immune response in reaction to any type of injury: pathogenic organisms, injuries, foreign bodies or ionising radiation. It may remain localized, sub-clinically and temporarily if the body's defensive mechanisms are effective. An inflammation can be acute, primary-chronic or an acute inflammation may persist and spread by extension to become a subacute or chronic state. Inflammations of the oral mucosa are called depending on their localization as follows:

- Glossitis—inflammation of the tongue
- Stomatitis—inflammation of larger parts of the oral mucosa
- Gingivitis—inflammation of the gum
- Cheilitis—inflammation of the lips

If deeper structures are involved it might be a ►phlegmon or ►abscess.

Pathology

Regarding the severity, macroscopic appearance, pathogenic agent and extent of the inflammatory process, various kinds of inflammation in the oral cavity do occur.

Aphthae are intra-epithelial cavities with a size up to 5 mm filled with serous fluid. They are caused by virus, toxic substances or medicaments. Habitual aphthae are characterized by chronical recurrent aphthae of unknown aetiology. A ►vasculitis is the underlying lesion of Behcet's disease—a seldom, systemic, HLA-B51 associated illness—in which recurrent aphthae of the oral cavity and genital region appear together with other organ manifestations as uvea, skin, joints and central nervous system.

In herpes simplex labialis, small vesicles at the border between the dermis and mucosa of the lips appear due to herpes simplex ►infection. If the inflammation extends on the entire oral cavity it is called herpetic stomatitis (synonym: stomatitis aphthosa). In a later stage of the disease, vesicles proceed to mucosal erosions and deeper ulcerations with red border.

Ulcerative stomatitis (synonym: necrotizing ulcerative gingivitis) is an extended, severe, necrotizing, oedematogenic inflammation caused by a complex of different organisms (streptococci, spirillum, fusiform bacteria and fungi) in immune-compromised patients or bad oral hygiene.

Oral herpes zoster infection is caused by the reactivation of varicella-zoster virus in the area of innervations of the maxillary, mandibular or seldom glossopharyngeal nerve. It is characterized by unilateral crops of clustered vesicles.

O

Oral candidiasis (synonym: thrush), an opportunistic infection especially in immune-compromised patients, is mainly caused by *Candida albicans*. It is usually limited to the skin and mucous membranes. White pseudomembranes consisting of mycetes and necrotic epithelium are a characteristic finding.

Acquired immunodeficiency syndrome (AIDS) favours the development of opportunistic bacterial, viral or mycotic infections including oral candidiasis and herpes simplex viral infection. Hairy leukoplakia—a column-shaped hyperkeratosis of the acanthoticaly broadened epithelium—can proceed years before the outbreak of AIDS.

In a phlegmon or ►cellulitis, there is a diffuse spread of granulocytic infiltrates within the tissue. An ►abscess consists of a necrosis—resulting from purulent colliquation of tissue—and a membrane, which borders on vital tissue. Both are kinds of bacterial infection (streptococci, staphylococci). Most often, they occur in the floor of the mouth due to secondary involvement from other spaces: masticator space (dental infection) or submandibular space (sialolithiasis).

Ludwig's angina is an extensive bacterial infection of the floor of the mouth that always involves both the sublingual and submandibular space. It is frequently bilateral and produces gangrene or serosanguinous phlegmon, but little or no frank pus; involves connective tissue, fascia and muscle, but not glandular structures (1).

In necrotizing fasciitis, there is severe or extensive phlegmon that extends into the superficial and deep fascia, producing thrombosis of the subcutaneous vessels and gangrene of the underlying tissues. The oral cavity may be involved.

The oral cavity can be involved in syphilis (synonyms: lues, treponemiasis), a *Treponema pallidum* infection. Primary affection shows a coarse infiltrate or ulceration of deep red colour (ulcus durum); secondary affection flat the infiltrates, ulcers with red halo and whitish blur on mucosa; tertiary affection causes bleeding, necrotizing and rubbery infiltrations, the so-called gumma.

Actinomycosis, caused by *Actinomyces israelii*, is characterized by hard, bluish-violet infiltrates—actinomyces drusen with leucocytes and foam cells—and fistulas to the skin as well as to bone (2, 3).

Clinical Presentation

Characteristic signs of nearly all oral cavity inflammations are pain, burning of the tongue and/or mucosa and dysphagia. Primary and tertiary affection in syphilis and infiltrates in actinomycosis are painless. In oral herpes zoster, the pain is of severe neuralgic character. Disturbances of tasting are typical for glossitis and oral candidiasis.

A reduced general condition and fever occur in ulcerative stomatitis, herpetic stomatitis, oral herpes zoster, purulent infections, Ludwig's angina, secondary syphilis and Behcet's disease. The fever is very high in purulent infections and subfebrile in Behcet's disease.

Swelling of lymph nodes accompanies ulcerative stomatitis, herpetic stomatitis, purulent infections, Behcet's disease and primary syphilis. Except for syphilis, the enlarged lymph nodes are usually painful. The clinical pictures of necrotizing fasciitis which occurs seldom in the head and neck region is characterized by a fulminating onset of the disease, painful edema, erythema, warmth, tenderness and septicemia.

Sialism, redness, necrotic odour, haemorrhage and swelling of the gingiva as well as the oral mucosal are seen in ulcerative stomatitis. Sialism also occurs in herpetic stomatitis and oral herpes zoster; necrotic odour in herpetic stomatitis and oral candidiasis. Some pseudomembranes in oral candidiasis are easily wiped off from the affected oral tissues and leave an erythematous, eroded or ulcerated surface, which may be tender.

Phlegmon and abscess of the floor of the mouth show a reddish, oedematous mucosa; they are hard in palpation; trismus may be present (2).

Imaging

Most oral cavity inflammations are diagnosed by inspection due to their typically macroscopic appearance. An indication for imaging is given in patients in whom a deeper spread, mainly an abscess, is suspected or for exclusion of a tumour in chronic inflammation as actinomycosis or ulcerative stomatitis.

Ultrasound is the first performed imaging modality in acute inflammatory diseases of the oral cavity. If there are equivocal findings, CT or MRI can provide similar information. CT is clearly faster performed, less susceptible to motion artefacts, the better available technique and therefore the preferred method in adults. Considering the lack of radiation exposure, MRI should be given the preference in children.

Ultrasound

The floor of the mouth can be well investigated by ultrasound. The appearance of an abscess depends generally on its stage. In early stage, it is poorly defined and its demarcation against surrounding soft tissue is worse. With maturation it becomes more and more hypoechoic and has finally a dorsal sound-amplification. Fine echoes within the mass are suspicious of gas. If the infection starts from the submandibular gland, the gland is painful enlarged and hypoechoic. Calculi can be identified up to a size of 3 mm. Ultrasound has limitations in the detection of mandibular involvement, the demonstration of spread into the retropharyngeal space and the visualization of phlegmonous processes.

Oral Cavity, Inflammatory Diseases. Figure 1 Axial contrast-enhanced CT of a patient with clinically suspected abscess in the floor of the mouth. CT shows an area of low density as a sign for and abscess surrounded by swollen tissue of increased contrast enhancement and prominent lymphoid tissue on the left. Calculus as a cause could be detected (arrow). The patient was treated by incision and antibiotic therapy.

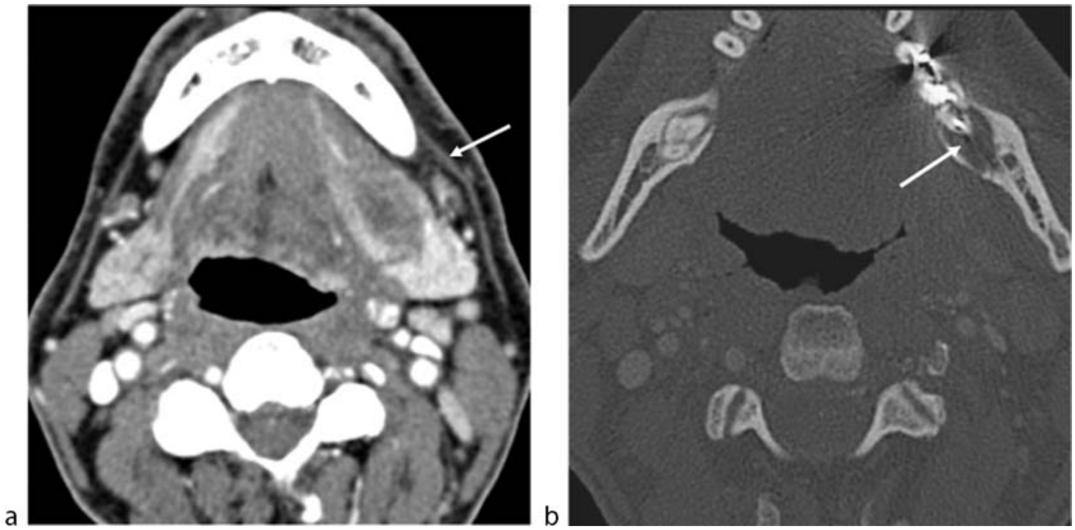
Computed Tomography

On CT, an abscess appears as an area of low density, with or without gas collection. In mature abscesses a rim enhancement is seen. Surrounding structures are usually involved: muscles are thickened, fat is oedematous with increased density, overlying fascia and skin are thickened showing an enhancement and draining lymph nodes are enlarged. Calculi in the salivary glands or major ducts, erosions of the mandibular cortex and a dental origin can be demonstrated (Figs 1 and 2). A phlegmon and an abscess cannot always be differentiated by clinical methods. Changes—as described in the neighbourhood of an abscess—without abscess formation are found on CT. In necrotizing fasciitis, CT supports the clinical diagnosis; identifies gas, the spread of the disease along vascular sheaths and into the mediastinum (4).

Magnetic Resonance Imaging

On MRI, an abscess has low T1-weighted and high T2-weighted signal intensities. As in CT only mature abscesses show a rim enhancement. Oedematous changes within the fat are not quite well visible as on CT. MR-sialography

O



Oral Cavity, Inflammatory Diseases. Figure 2 CT of a patient with dysphagia and swelling of the mouth floor for 2 days. After ultrasound a phlegmon was suspected. (a) Contrast-enhanced scan demonstrates a diffuse swelling of soft tissue in the floor of the mouth without clear abscess formation on the left. The neighbouring fat has an increased density and the fascia is thickened (arrow). (b) High-resolution scan in bone window gives a hint of the underlying dental infection (arrow). The molar was extracted and the infection treated by antibiotics.

has to be performed for the visualization of calculi. MRI is superior to CT in the demonstration of the medullary component, if there is an accompanying ▶osteomyelitis in the mandible.

Nuclear Medicine

In diagnostics of oral cavity inflammations, nuclear medicine plays a limited role. In suspected osteomyelitis of the mandible, bone scintigraphy can demonstrate an increased tracer uptake, but MRI has the same sensitivity and gives additionally exact anatomic information.

Diagnosis

The diagnosis of the oral cavity inflammation is based on anamnesis, inspection, mirror investigation and laboratory tests. In bacterial and mycotic diseases, smears are taken for identification of germs. In lues, spirochetes can be serologically proved 4 to 5 weeks after infection. Varicella-zoster-virus-titer is increased in herpes zoster. In Behcet's disease and oral candidiasis the differential diagnostics should include a HIV-test; in the first one also a lues-serologic-test. Actinomycosis and syphilitic gummas need a histological proof.

Imaging—ultrasound or CT, seldom MRI—is performed in suspected deeper inflammation to demonstrate the extent, to document gas-forming infection, to show the relationship to neighbouring bony structures and to give a support in the decision on a conservative or surgical therapy. CT is able to reveal underlying dental infection and sialolithiasis. The latter one can also be found by ultrasound.

Organized Screening

Screening program organized at the locoregional or national level. With an explicit policy, it is a team responsible for organization and for delivery of the screening services, and a structure for quality assurance.

▶Screening, Breast Cancer

Oropharyngeal Foreign Bodies

▶Foreign Bodies, Gastrointestinal

Orthotopic Liver Transplantation

OLT represents the most common procedure for liver transplantation and consists in the replacement of the diseased liver by a liver coming from a cadaveric donor.

▶Transplantation, Liver

Os Carpale

The postarthritic ankylosis of two or more (incomplete os carpale) or all carpal bones as a typical feature of late-stage rheumatoid arthritis.

▶Rheumatoid Arthritis

Osgood–Schlatter Pattern

Overgrowth and fragmentation of the secondary growth center of the anterior tibial tubercle with swelling of the inferior patellar tendon; may be an overuse syndrome or related to repeated minor trauma.

▶Osteonecrosis in Childhood

Osmotic Myelinolysis

Osmotic myelinolysis, also referred to as central pontine myelinolysis when it involves the pons, is a disorder associated with chronic alcoholism and malnutrition. It is due to chronic electrolyte imbalances, most commonly hyponatremia. Osmotic myelinolysis is frequently precipitated by rapid iatrogenic sodium correction, resulting in breakdown of the blood–brain barrier and a noninflammatory demyelination with relative preservation of neurons and their axons. The central pons is the most commonly affected site. Clinically, patients present with seizures, dysphagia, pseudobulbar palsy, dysarthria and movement disorders.

▶ Toxic Disorders, Brain

Ossification of Posterior Longitudinal Ligament

OPLL results from growth of lamellar bone posterior to the vertebral bodies involving (by calcification) the posterior longitudinal ligament. It is usually diagnosed in elder patients from its characteristic radiographic appearance and may lead to severe neurologic deficit due to spinal canal stenosis.

▶ Dish

Ossification or Calcification of Ligamenta Flava

Enthesopathy, ossification (mostly thoracolumbar spine), and calcification (often cervical spine) in (frequently) thickened ligamanta flava may contribute to the entity of OLF. There is coexistence of OLF with both DISH and OPLL.

▶ Dish

Osteitis Condensans ilii

A benign condition characterized by sclerosis in the iliac bones adjacent to the sacroiliac joints. The sclerosis is generally bilateral and usually asymptomatic. The adjacent sacroiliac joint is unaffected. This entity is thought to represent a stress reaction and is most commonly found in postpartum patients.

▶ Fractures, Stress

Osteitis Deformans

▶ Paget Disease

Osteitis Pubis

A noninfectious inflammatory condition involving the pubic bone and pubic symphysis that is thought to occur secondary to periosteal trauma. It occurs most commonly in postsurgical patients or in athletes. Radiographic abnormalities include sclerosis and osteolytic changes. Its imaging characteristics resemble osteomyelitis, However, it is a separate clinical entity and responds to rest and anti-inflammatories.

▶ Fractures, Stress

Osteo Sarcoma

▶ Neoplasms, Bone, Malignant

Osteoarthritis

'Osteoarthritis' and 'osteoarthrosis' are both used in medical terminology, however, osteoarthrosis may be the more appropriate term since inflammatory changes are not pronounced in most of the joints. The best phrase to describe degenerative changes of articulations is 'degenerative joint disease'.

▶ Degenerative Joint Disease, Peripheral Joints

▶ Gout

Osteoblastoma

Osteoblastoma is a benign osteoblastic tumor that differs from osteoid osteoma in having a "nidus" larger than 1.5 cm in diameter, by showing more variable histologic features, and by possessing a potential for local bone destruction and aggressiveness.

Osteochondrodysplasia

▶ Osteodysplasia

▶ Dysplasia, Skeletal

Osteochondroma

Osteochondroma (osteocartilaginous exostosis) represents a benign cartilage-forming lesion that consists of a bony outgrowth covered by a cartilaginous cap.

▶Neoplasms, Bone, Benign

Osteochondrosis Dissecans

Sometimes called osteochondritis dissecans, it is a traumatic osteochondral injury, usually along a convex articulating surface of a bone.

▶Osteonecrosis in Childhood

Osteoclast-Like Giant Cell Tumor, Pancreatic

Osteoclast-like giant cell tumor is a rare pancreatic tumor that closely resembles giant cell tumor of bone. It is composed of undifferentiated spindle-shaped epithelial or mesenchymal cells mixed with non-neoplastic osteoclast-like giant cells. Some tumors also contain areas of ductal adenocarcinoma. At imaging, the tumor may present as a solid inhomogeneous mass or as a cystic lesion. Invasion of adjacent structures is common, but metastatic spread is found in only 50% of patients. Prognosis is more favorable than for ductal adenocarcinoma.

Osteodysplasia

Alan E. Oestreich
Cincinnati Children's Hospital Medical Center,
Cincinnati, Ohio, USA
Alan.Oestreich@cchmc.org

Synonym

Osteochondrodysplasia

Definition

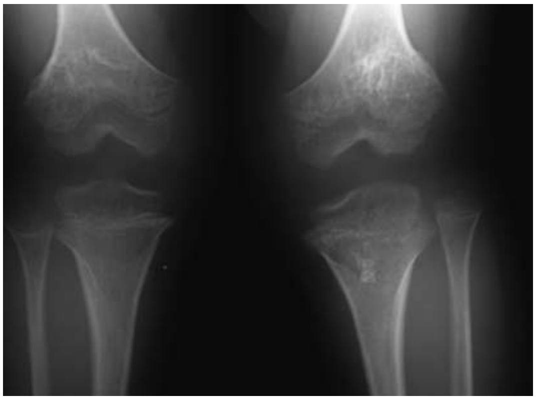
Osteodysplasias are well-defined abnormalities of bone growth, typically genetic in origin. They may be systematic, affecting one aspect of skeletal development, typically in proportion to growth potential of each site, or else "aleatoric," affecting sites of an aspect of bone development in a chance distribution, with a higher likelihood of occurrence at sites of greater normal growth. [I have borrowed the term aleatoric from modern music composition in which chance plays a role (1)] The aspect of growth may be slowed, disordered, or accelerated. The aspect involved is most often exclusively enchondral in nature or membranous in nature, with only secondary changes in the other. Most, but not all, dysplasias result in short stature (dwarfism). Kindred disorders include dysostoses, in which individual aspects of growth are affected, and sequences, in which an abnormal aspect of development causes a chain of consequent effects on bone (and other tissue) development. As more genetic markers for dysplasias are determined, more conditions are being grouped into "families" of dysplasias of like genetic origin.

Pathology/Histopathology

Various histologic manifestations of various dysplasias are known, some of which help explain radiographic findings. In multiple exostoses, the cartilage cap has a growth plate histologically close to the pattern of a normal physis, but somewhat more disorganized. In ▶achondroplasia, not only are the physeal and acrophyseal enchondral columns shorter and slower to progress from resting cartilage to provisional calcification, but also the columnar cells are grouped into separated clusters. The clustering and subsequent lack of ossification of the zones between the clusters, within the primary spongiosa zone of the metaphysis, may account for the enchondromatous areas in achondroplasia metaphyses and diametaphyses (Fig. 1). In Kniest disease, growth cartilage is characteristically irregular in pattern, described as Swiss cheese-like. Osteogenesis imperfecta shows osteoporosis. Cultured fibroblasts from persons with this dysplasia help characterize the condition. Osteopetrosis has denser than normal bone, similar to the hibernating bat, perhaps due to a temporary failure of osteocytic osteolysis, although most investigators favor a failure of osteoclast function as the direct cause.

Clinical Presentation

Disproportionate short stature is found in many systemic dysplasias; limb length discrepancy, with limp, is frequent in aleatoric dysplasias. Fractures (and blue sclerae) are a



Osteodysplasia. Figure 1 Example of prominent enchondral rests in the metaphyses of distal femur of a 9-year-old boy with achondroplasia. The medial and lateral margins of the femur metaphyses and diametaphyses are more concave than normal, partly as a manifestation of achondroplasia enchondral growth slowing and partly because the knees are somewhat flexed.

hallmark of osteogenesis imperfecta; teeth tend to show dentinogenesis imperfecta crowding and irregularity as well. Tall stature is seen in the ▶dolichostenomelias, notably Marfan syndrome and homocystinuria. With regard to characterization of short limbs in dysplasias, the term rhizomelic refers to shortening of limbs most pronounced proximally, such as achondroplasia; ▶mesomelic dysplasias have most of the relative shortening in the intermediate segments (radius/ulna and tibia/fibula); and acromelic refers to the greatest shortening distally. Other rather specific findings include hitchhiker thumb in diastrophic dysplasia; thumb extension beyond the fist in Marfan syndrome; early-in-life shortening, especially of the limbs and later shortening of the trunk in metatropic dysplasia; gargoyle-like facies in the mucopolysaccharidoses; and occasionally the ability to draw the shoulders together in front of the chest in cleidocranial dysplasia/dysostosis.

Imaging

Skeletal surveys for osteochondrodysplasia or dysostosis need to be customized for the suspected diagnoses; once certain findings appear, other views may be required. For example, whenever platyspondyly (flatter than normal vertebral bodies) is observed, one needs to check the dens and C1 region in detail, with careful flexion and extension views as necessary, to evaluate for associated subluxability between C1 and C2. The small tubular bones of the hand and feet should be included in any survey because they may show diagnostic features key to the diagnosis. Tall patients with dolichostenomelia (such as Marfan) need good lateral chest or thorax images to evaluate for pectus excavatum or carinatum. In aleatoric disorders such as multiple exostosis or enchondromatosis, two orthogonal views of each part are needed for complete evaluation of the lesions, even if not necessary for diagnosis.

In utero imaging for dysplasia or dysostosis begins with high-detail ultrasound. Questions that arise may then be further investigated with magnetic resonance imaging (MRI). If the answer is still not given, but is important, selected radiographs of the mother's abdomen may be considered, under close supervision by a specialized pediatric radiologist. If possible, for radiation protection considerations, radiographs of one twin should be avoided if the other is considered unaffected. Abnormal bone length, shape, or a positive family history of dysplasia or dysostosis should initiate the careful prenatal evaluation for specific entities.

MRI can give insight into the nature and quantity of cartilage in several dysplasias, including Kniest disease (2). MRI of the spinal cord is prudent before planned spinal surgery in children with any severely abnormal spinal curvature. Three-dimensional reconstruction of abnormal joints assists in surgical planning for specific procedures.

Accurate measurement of long bone lengths requires perpendicular X-ray beam images at each end of the bone with a radiopaque ruler alongside that is not shifted between the exposures. Alternately, measurements can be made from a computed tomography (CT) scout view.

Long bones for dysplasia evaluation need to be parallel to the film or screen, lest foreshortening in space be mistaken for dysplastic growth foreshortening through time.

Nuclear Medicine

Multiple cartilaginous exostoses each have a cartilage cap with a growth plate (I call it "paraphysis") that will have uptake on bone scan similar to physes. Fractures in such conditions as osteogenesis imperfecta, Ollier enchondromatosis, and osteopetrosis will be hot on bone scan. The periosteal reaction causing the thick cortices of Engelmann disease will be hot on bone scan in the active stage, as it will be in other membranous bone overactivity dysplasias or dysostoses, such as van Buchem disease. Osteopetrosis usually gives a superscan of high activity of all involved bone segments. Uptake is also increased in active fibrous dysplasia.

Diagnosis

Only a few dysplasias and dysostoses will be described here.

Systematic dysplasias are symmetric side-to-side and generally change one rule or rate of growth, with the sites of greatest normal growth being affected the most. The prototype is achondroplasia with rhizomelic shortening; lumbar pedicles abnormally close side-to-side with the distance decreasing downward, greater than normal concavity of medial and lateral margins of metaphysis (Fig. 1), frontal bossing of the skull, petrous ridges closer to each other than normally, frequent cartilage rests in metaphyses, smooth but delayed growth centers with epiphyseal shape following the shape of abnormally concave physes, proximal ends of the femurs in infancy showing the pattern of an ice cream scoop on end, horizontal sacrum, shorter than normal metaphyseal collar, and trident (Vulcan salute) hands, among the many imaging findings. Hypochondroplasia, an allelic (due to the same gene locus) disorder, is less severe; thanatophoric dysplasia, also allelic, is more severe (demonstrating femurs resembling European telephone receivers and quite pronounced platyspondyly). Achondroplasia and its family results from slowed enchondral growth, whereas Marfan syndrome and homocystinuria have dolichostenomelic (predominant proximal segment) lengthening due to accelerated enchondral growth. The medial and lateral margins of long bone metaphyses are less concave than normal. Children with Marfan syndrome show pectus carinatum or excavatum, tortuous aortic arch, and wide lumbar canal; homocystinuria shows truncal osteoporosis.

Among the aleatoric dysplasias, the findings of exostosis or enchondromas occur in a chance distribution, more likely occurring in areas of greater growth potential. The more and the larger the exostosis, the greater the impairment of longitudinal growth of an affected long bone. If one paired bone is more affected than its mate, bowing and, often, dislocations occur (Fig. 2). Exostoses of epiphyses and their equivalents are termed Trevor disease (also known as dysplasia epiphysealis hemimelica); exostoses also can occur at terminal tufts of phalanges and the nonepiphyseal ends of other short tubular bones. Osteogenesis imperfecta is systemic with regard to osteoporosis but aleatoric with regard to fractures. The multiple wormian bones also show side-to-side symmetry in distribution. The weakened bones may lead to tam-o'-shanter skull (protrusio occipiti; basilar invagination) from the calvarium sinking on the cervical spine (if this deformity is severe, the clivus may run upward). Teeth are numerous and irregularly placed. The lateral clavicles may show increased upward convexity; the ribs resemble coat hangers. Prenatal sites of fracture may yield bones that look wide at birth from healing fractures. Treatment of osteogenesis imperfecta with bisphosphonates results in tell-tale nearly parallel thin lines similar in shape to the growth plates in the metaphyses (and equivalent areas in secondary growth centers) that record the jolt to the skeletal system from each dose.

Osteodysplasia. Figure 2 Growth disparity from multiple cartilaginous exostosis/osteochondromatosis in a 10-year-old boy. The ulna has far more exostoses than the radius distally, resulting in a shorter ulna and a secondary lateral bowing of the radius. The more the exostoses, the greater the impairment of longitudinal growth. (From Oestreich AE, Crawford AH (1985) Atlas of Pediatric Orthopedic Radiology. Thieme Verlag, Stuttgart, p 27)

Chondrodysplasia punctata (multiple stippled epiphyses) in infancy consists of dense dots of calcification within unossified growth cartilage; the involved bones are short, irregularly shaped, or even abnormally unossified (Fig. 3). As the child gets older, the stipples resolve, and the pattern becomes one of misshapen epiphyses and their equivalents, a pattern then called multiple epiphyseal dysplasia (Fig. 3).

In metatropic dysplasia, the metaphyseal collar bone bark seems to lack its usual ability to restrict too rapid transverse growth of physis and metaphysis, so that bones resemble dumbbells with unusually broad metaphyses. The megaepiphyseal dysplasia Kniest disease shows coronal cleft vertebral bodies and delayed ossification of the (large) centers for the femoral head. Severe cervical kyphosis is seen (when lateral images are obtained) in diastrophic dysplasia and camptomelic dysplasia and is one of the cervical vertebral anomalies seen in Larsen

Osteodysplasia. Figure 3 **From multiple stippled epiphyses to multiple epiphyseal dysplasia. (a) In infancy, one sees the multiple epiphyseal stipples of the distal carpal row as well as the (longitudinally short) first metacarpal. (b) In a 16-year-old, one sees highly dysplastic and narrow distal carpals (i.e., multiple epiphyseal dysplasia) with relatively normal proximal carpals, as well as the longitudinally short first metacarpal. [After F. Silverman. From Oestreich AE (2004) Epiphyseal dysplasias and dysostoses. In: Ferrucci JT (ed) Taveras and Ferrucci's Radiology on CD-ROM Diagnosis Imaging Intervention, Vol 5, chapter 5]**

syndrome. A small mandible with an abnormally concave undersurface is the key finding of Pierre-Robin sequence and is seen in camptomelic dysplasia, cerebrocostomandibular syndrome, and Seckel syndrome. Progressive pseudorheumatoid dysplasia has joint region changes closely resembling rheumatoid arthritis, but also has both early and unusually large os trigonum centers behind the talus, and bullet-shaped or Scheuermann-like (irregular endplates) thoracolumbar vertebral bodies unlike rheumatoid arthritis. Every normal child, incidentally, has at least one small os trigonum center that appears near the end of the first decade of life and fuses with the talus in about a year, appearing somewhat earlier in girls than in boys. Then, in the second decade, another os trigonum center appears in some 10–20% of children, which may or may not also fuse to the talus to remain as a posteriorly protruding process.

Postaxial polydactyly and mesomelic short limbs are characteristic in Ellis–van Creveld syndrome. An interesting accompaniment to hand polydactyly is the ham-shaped hamate (a wider than normal hamate ossification in the form of a cured ham).

Various characteristic vertebral body shapes on lateral images occur in the several spondyloepiphyseal and spondylometaphyseal dysplasias, as well as mucopolysaccharidosis dysostosis multiplex conditions. Twisted ribs and long bones are the prime feature of Melnick–Needles osteodysplasty.

On *in utero* imaging, achondrogenesis, the second most frequent lethal skeletal dysplasia, is characterized by a lack of ossified vertebral bodies. Very short ribs, such as in short rib polydactyly syndromes, also predict neonatal demise, as do features of thanatophoric dysplasia (the best-known lethal dysplasia). The shorter the ribs in Jeune syndrome, the less likely the neonatal survival.

Osteofibrous Dysplasia

Osteofibrous dysplasia (ossifying fibroma, Kempson–Campanacci lesion) is a benign fibroosseous lesion which mostly occurs in the tibia of young children. Histologically, the entity differs from fibrous dysplasia by containing scattered bony trabeculae that are rimmed by active osteoblasts.

▶Neoplasm-Like Lesions, Bone

Osteoid

Uncalcified organic bone phase consisting of collagen fibers (approximately 94%), proteoglycans, and glycoproteins.

▶Osteomalacia

Osteoid Osteoma

Osteoid osteoma is a benign bone-forming lesion of limited size that usually induces reactive new bone formation. The lesion itself has classically been described as the “nidus” and should, by definition, not override a maximum diameter of 1.5 cm. Larger lesions should be termed osteoblastoma.

▶Neoplasms, Bone, Benign

Osteoidosis

▶Osteomalacia

Osteoma

The most frequent benign osseous tumor of the face and sinusal cavities, usually affecting men over 50 years of age. These tumors are commonly asymptomatic, fortuitously discovered on a radiologic examination, in the frontoethmoidal cavity or in the external auditory canal.

▶Fibro-Osseous Lesions, Facial Skeleton

Osteomalacia

Osteomalacia (OM) is a pathological condition in adult bone metabolism characterized by the impaired and delayed mineralization of osteoid, causing the accumulation of osteoid and altering the mechanical properties of bone.

▶Osteomalacia

Osteomalacia

Ahi Sema Issever
Institut für Radiologie, Charité Campus Mitte, Schumannstr, Berlin, Germany

Synonym

▶Osteoidosis

Definition

In adult bone metabolism – after closure of the epiphyseal growth plates – ▶osteomalacia (OM) is defined to be a condition of impaired and delayed mineralization of ▶osteoid (organic bone phase) in cortical and trabecular bone. In children, this condition is known as ▶rickets and includes the defective mineralization of the cartilaginous part of the epiphyseal growth plates.

Pathology/Histopathology

Physiological bone remodeling is a dynamic process of constant bone formation and resorption, respectively, carried out on the cellular basis through osteoblasts and osteoclasts. Chronologically, bone formation can be divided into two phases. In phase I the osteoblasts produce osteoid in the organic bone matrix consisting of collagen fibers, proteoglycans, and glycoproteins. In phase II the osteoblasts produce calcium, phosphate, hydroxyl, and carbonate creating a plate-like crystal known as hydroxyapatite, which mineralizes on the osteoid-forming calcified bone. Pathophysiological disturbances in phase II based on alterations of the calcium phosphate homoeostasis – in which the serum calcium X phosphorus product is low – lead to the condition of OM in adults and to rickets in children. The calcium phosphate homoeostasis is maintained by a multitude of factors, and thus the etiology of OM and rickets is very diverse. A large number of disorders are associated with OM and rickets. Nonetheless, hypovitaminosis D is considered to be the most frequent cause of OM. The primary role of vitamin D is its physiological function in opposing a decline of serum calcium. Examples of disturbances in vitamin D metabolism that may cause OM are:

- Low dietary intake
- Insufficient UV absorption of the skin (reduced natural sunlight exposure, skin covering garments, dark skin complexion which leads to the absorption of only certain spectra of the UV light)
- Intestinal malabsorption, e.g., after gastrectomy, bowel resection, or nontropical sprue
- Accelerated vitamin D excretion by virtue of anticonvulsive drugs inducing liver enzymes
- Chronic renal failure leading to a deficient hydroxylation of the liver 25(OH)-vitamin D_3 into the active 1,25$(OH)_2$-vitamin D_3 form

As described above, a low calcium X phosphorus product is the pathophysiological starting point for the genesis of OM and rickets, and therefore conditions leading to low phosphorus levels must also be considered:

- Acquired phosphate depletion due to malnutrition, alcoholism, and use of aluminum-containing antacids which bind phosphorus intestinally
- Increased renal excretion of phosphorus caused by an impaired tubular resorption (e.g., adult-onset vitamin D-resistant hypophosphatemic osteomalacia, Fanconi syndrome)

Attention should also be paid to oncogenic conditions causing OM (tumor-induced or oncogenic OM), although they occur seldom. This paraneoplastic syndrome is associated with several different neoplasms, of which the majority are of benign and mesenchymal origin, namely, bone and soft tissue tumors. These tumors release circulating factors that increase the phosphorus renal clearance consecutively causing low serum phosphorus levels, while the calcium serum concentration is normal.

Clinical Presentation

The clinical presentation of OM is unspecific. Frequent complaints of patients suffering from OM are bone pain and muscle weakness. Bone pain is of diffuse and dull character. In general the symptoms begin as lower back pain and spread symmetrically into the pelvic region and the hips, or upward to the vertebral column into the rib cage and the shoulder girdle. Compression, vibration, or mere muscular activity of symptomatic regions may provoke and increase pain, in some cases leading to the adjusted pain-avoidance behavior of the patient, such as cautious walking, in extreme cases even immobilization or the fear of coughing.

OM-related muscle weakness is generally localized proximal to the body trunk, e.g., around the hips involving the gluteal muscle group leading to a waddling gait in late stages of the disease. Whether muscle weakness is secondary to bone pain or of primary genesis is difficult to distinguish. In advanced stages of OM, morphological deformities of the skeleton – due to bone softening and hence reduced mechanical strength – can be observed resulting in hyperkyphosis of the thoracic vertebral column or coxa vara and a high fracture susceptibility.

In children suffering from rickets, morphological deformities of the skeleton vary in their dimension according to the time of onset in relation to the phase of epiphyseal bone growth. In periods of rapid growth, rickets tends to achieve high clinical severity. Craniotabes (softening of the calvaria), late fontanelle closure, rachitic rosary (palpable bloating of the costochondral junctions), Harrison's groove (indentation of the lower ribs at the diaphragm), bowing of the long bones (tibia, femur, radius, ulna), and thickening of the wrist, knees, and ankles (on grounds of metaphyseal widening) are the most visible clinical complications. Muscle weakness to severe muscle hypotonia is another major complication of rickets.

Imaging

With conventional radiographs, computed tomography, and magnetic resonance imaging, a wide range of modalities for diagnosing OM are at hand.

In OM, conventional radiographs are usually obtained first. The overall radiographic appearance of bone can be described as homogenous and fuzzy. The reason for this is the decline of contrast differences between bone marrow and calcified bone due to the increased density of unmineralized osteoid. In contrast to this rather nonspecific "ground-glass" appearance, so-called ►Looser's zones – found in only 5–10% of patients suffering from OM – are considered to be typical. Looser's zones – also known as ►milkman's zones or ►pseudofractures – are radiolucent bands of unmineralized osteoid usually oriented perpendicular to the surface of the bones ranging in size from a few millimeters to several centimeters. Looser's zones are frequently found bilaterally, symmetric, at sites where larger arteries are adjacent to the bones (inner aspects of the femur, pubic rami, the lateral edge of the scapula, and the metatarsals); the hypothesis being that the pulsation of these vessels and the reduced mechanical strength of the bones cause pseudofractures of the latter which heal only insufficiently with osteoid.

On computed tomography images the fuzzy "ground-glass" appearance of bones affected by osteomalacia is also observed, and Looser's zone may be identified more accurately in contrast to pathological fractures of other genesis.

The relative increase of unmineralized osteoid in relation to mineralized bone or the relative decrease of mineralized to unmineralized bone can be quantified measuring the overall bone mineral density using either dual x-ray absorptiometry or quantitative computed tomography.

Pseudofractures may be identified as hypointense lines or fissures on T1- and T2-weighted magnetic resonance (MR) images as well as on images acquired using short T1 inversion recovery (STIR) sequences. High signal intensity around the fracture area on T2-weighted and STIR MR images reveals an acute process, whereas isolated hypointense regions are considered to be chronic. Therefore, the clinical activity of OM may be determined using MR imaging.

Nuclear Medicine

For isotope bone scanning, technetium 99m-labeled methylene diphosphonate – which preferably adsorbs onto bone surfaces undergoing new bone formation – is being used. The diagnostic strength of isotope bone scanning for metabolic bone diseases is based on its high sensitivity in detecting and localizing functional alterations before structural changes have taken place. In OM the bone scan often shows a nonspecific increased uptake of technetium 99m involving the entire skeleton. However, Looser's zones may be identified on bone scans before they are visible on conventional radiographs. For the diagnosis of oncogenic OM and the identification of the primary tumor, it has been reported that tracers selectively binding onto somatostatin receptors (octreotide) may improve the detection rate.

Diagnosis

The difficulty in diagnosing OM arises from its very nonspecific clinical presentation as described above. In the population of elderly patients, diffuse bone pain and muscle weakness can be misinterpreted as rheumatological conditions, thus OM remains undiagnosed, although in most cases it is a curable diseases. Higher awareness and suspicion of osteomalacia in daily clinical routine is therefore essential.

Laboratory test results are given in the form of a table.

Imaging modalities for the diagnosis of OM have been described above; nonetheless, a brief summary in the context of the overall diagnostic procedure is as follows: patients presenting with unspecific symptoms and laboratory findings suggesting that OM might be the underlying cause may first undergo isotope bone scanning in order to identify typical Looser's zones. Conventional radiographs of suspicious regions can validate the diagnosis in some cases, but one should keep in mind that radiographically visible morphological changes may occur rather late in the course of OM as compared to pathological uptake behavior on bone scans. On the other hand, if patients can localize peak pain spots, conventional radiographs may be sufficient for identifying Looser's zone without the use of isotope bone scan. Bone mineral density measurements are rather unspecific for the diagnosis of OM because a multitude of disorders, particularly osteoporosis, are associated with a decreased bone mineral density. Besides having a higher spatial accuracy, computed tomography can be used if it is difficult to ascertain with conventional radiographs whether fractures are caused by OM or other pathological conditions. MR imaging, in addition, can help describe the acuteness of fractures. If all imaging modalities and laboratory tests fail, the best – gold standard – diagnostic modality for identifying OM is the histological analysis of bone biopsies in which the accumulation of osteoid is visible as an increase in the average osteoid volume (>10%) and thickness (>15 µm).

Serum concentration	Vitamin D deficiency	Chronic renal failure	Renal tubular disorders
Ionized calcium	Normal/↓	↓	Normal
Inorganic phosphorus	↓	↑	↓
25(OH)-vitamin D_3	↓	Normal	Varies

Synonym

Bone infection

Definition

The term *osteomyelitis* implies an infection of bone and bone marrow, whereas *osteitis* indicates contamination of the cortical bone only. *Chronic osteomyelitis* results most commonly after trauma or surgery and results from unsuccessful treatment of acute bone infection. A *sequestrum* represents a segment of necrotic bone that is separated from living bone by granulation tissue. An *involucrum* denotes a layer of living bone that has formed about the dead bone. An opening in the involucrum is termed a *cloaca*. A Brodies abscess is an intraosseous abscess, frequently seen in children caused by *Staphylococcus aureus* and represents a subacute or chronic infection. *Chronic recurrent multifocal osteomyelitis* is a rare sterile (noninfectious) disorder primarily involving children and adolescents and characterized by a prolonged, fluctuating course most often involving the tubular bones, the clavicle, and less often the spine.

Pathology/Histology

Pathology: Osseous structures can be contaminated by three principal routes (1):

1. Hematogenous spread of infection through the blood stream as in osteomyelitis of the child or spondylodiscitis.
2. Direct spread from a contiguous source of infection as seen in diabetic foot infections or decubital ulcers in paralyzed patients.
3. Direct implantation of infectious material into the bone as seen after penetrating injuries, punctures, or other surgical procedures.

Hematogenous osteomyelitis of the *child* is most frequently located in the metaphysis of long bones. In the infant up to 1 year of age, bone infection may be complicated by epiphyseal involvement. Subperiosteal abscesses and septic arthritis may complicate osteomyelitis in older children.

In *adults*, osteomyelitis most frequently results from direct spread from a contiguous source of infection and most of these patients have pedal osteomyelitis due to longstanding diabetes mellitus. Prevalence of *posttraumatic* osteomyelitis directly depends on the degree of traumatization of the involved limb (extensive soft tissue damage, necrotic bone, and presence of foreign bodies). Infection results from direct implantation of microorganism in most cases and *S. aureus* is the most common pathogen. *Postoperative* infection occurs via direct implantation, spread from a contiguous septic focus or hematogenous contamination.

Histology: Bone biopsy is performed if clinical and radiologic evaluation is not conclusive, if a neoplasm is suspected or if microbial diagnosis is attempted. Definite diagnosis of osteomyelitis relies on positive culture results of causative organisms from a biopsy sample. Characteristic histologic findings of bone infection include aggregates of inflammatory cells (including neutrophils, lymphocytes, histiocytes, and plasma cells), erosions of trabecular bone and marrow changes that range from loss of normal marrow fat in acute osteomyelitis to fibrosis and reactive bone formation in chronic disease. Limitations of percutaneous and surgical bone biopsy include sampling error, false negative cultures in patients receiving antibiotics, difficulties in distinguishing other osteopathy from osteomyelitis histopathologically, and the risk to damage the bone as a result of trauma or iatrogenic infection. Culture results of percutaneous bone biopsy specimens in pedal infection may be unreliable due to contamination from underlying infected soft tissue. Bone biopsy cultures in osteomyelitis may be false negative in up to 50%, whereas accuracy of histopathologic diagnosis of osteomyelitis is high.

Clinical Presentation

The clinical manifestations of the different forms of bone infections vary considerably depending on the activity of infection. Childhood osteomyelitis is often associated with a sudden onset of high fever, a toxic state, and local signs of inflammation. Diabetic foot infection most commonly has a chronic, relatively indolent course but may quickly lead to septicemia and toxic shock. Tuberculous osteomyelitis differs from pyogenic osteomyelitis by the absence of fever and pain. Posttraumatic and postoperative infections may, in the acute and early stages, lead to exquisite focal symptoms with significant inflammation, fever, and leukocytosis. If the infection can not be cured in the acute stage, chronic recurrent osteomyelitis develops with chronic recurrent bouts of infection, abscesses, bony sequestra, and fistula.

Imaging

Radiographs

Radiographs are usually the first radiological examination performed if bone infection is suspected. In children, first signs of hematogenous osteomyelitis may be perceptible a few days after onset of symptoms. First radiographic signs of hematogenous osteomyelitis are a subtle swelling of the juxtacortical soft tissues, which may only be evident by direct comparison with the other extremity. Destructive metaphyseal osteolysis and periostitis become visible after 8 to 10 days. Brodies abscesses are typically seen radiographically as well-defined metaphyseal radiolucencies with sclerotic borders, "dripping" to the physeal plate.

In adults, radiographic findings of osteomyelitis do not appear in adults for 10 to 14 days after infection and until 35 to 50% of the bone has been destroyed. Radiographic changes of osteomyelitis are not only delayed, but sensitivity is poor. Typical radiographical signs of acute osteomyelitis are permeative bone destruction with periosteal reaction and surrounding soft tissue swelling (Fig. 1a). Beginning cortical bone resorption can be identified as endosteal scalloping, intracortical tunneling, and poorly defined subperiosteal bony defects. Radiographs are also the basic imaging modality in posttraumatic and postoperative osteomyelitis displaying postoperative bony remodeling, sequestra, foreign bodies and osteosynthetic material, and deformities. Acute

Osteomyelitis. Figure 1 Illustration of typical radiographic signs of acute osteomyelitis. (a) Advanced osteomyelitis of the first metatarsal head in a diabetic patient with an ulcer at the plantar aspect of the first metatarsophalangeal joint. The radiograph reveals extensive permeative bone destruction of the first metatarsal head (arrow) with fragmentation (arrowhead). Also note the narrowing of the joint space due to concomitant septic arthritis. (b) Postoperative acute osteomyelitis of the distal fibula with permeative bone destruction (arrowheads) around the second most distal screw (arrow), which is loosened at the plate with a fine radiolucent rim around the screw head.

postoperative and posttraumatic osteomyelitis leads to ill-defined bone destruction, which usually develops in bone directly adjacent to the metal (Fig. 1b). Chronic osteomyelitis can lead to reactive bone formation, periosteal reaction, bony fistula, intraosseous abscesses, and bony sequestra. Presence of surgical implants and posttraumatic bone remodeling may considerably complicate evaluation of chronic osteomyelitis. To evaluate activity of chronic osteomyelitis, it is very helpful to compare current and old films together as changes such as a new linear periosteal reaction, osteolysis, and sequestration are suspicious of active infection. Delayed union or nonunion of fracture may also be caused by chronic infection.

Computed Tomography

Computed tomography has been largely replaced by magnetic resonance (MR) imaging to evaluate osteomyelitis. CT may however be useful to evaluate the presence of sequestra and involucra in chronic osteomyelitis. Since CT offers exceptional detail of the bony architecture in a cross-sectional display, it can also be used to evaluate cortical destruction and fistula, periosteal new bone formation, and the presence of intraosseous gas (Fig. 2), all of which are less conspicuous on MR images.

Magnetic Resonance Imaging

MR imaging allows early detection of osteomyelitis in contrast to radiographs and CT. Diagnosis of osteomyelitis on MR images is based on the identification of altered bone marrow signal (Fig. 3). Infection of the marrow compartment results in loss of the normal fatty marrow signal on T1-weighted images, with edema on T2-weighted or STIR images, and enhancement on post-gadolinium T1-weighted images. MR protocols should include fat-saturated T2-weighted images and contrast-enhanced, T1-weighted fat-suppressed images (2). Identification of such marrow signal alterations away from the subchondral bone results in high sensitivity for osteomyelitis; however, other entities can alter the bone marrow signal in similar fashion, including fracture, tumor, severe inflammatory arthritis or neuropathic disease, or recent postoperative changes. The lack of bone marrow edema on STIR images excludes osteomyelitis with a specificity of 98% (2).

Pedal osteomyelitis, which is by far the most frequent form of osteomyelitis in adult diabetic patients, results in over 95% of patients from contiguous spread of a soft tissue infection; the majority of these patients have some combination of adjacent skin ulceration, cellulitis, soft tissue abscess, and sinus tract. These signs are also called "secondary signs" of osteomyelitis, and can improve specificity. Ischemic tissue in pedal infection is best visualized on fat-suppressed, contrast-enhanced images (3). Osteomyelitis and abscesses may not enhance in necrotic tissue (3).

In complicated posttraumatic cases, postoperative bone marrow signal alterations can persist as long as 1 year (4). MR protocols in postoperative osteomyelitis should include fast spin-echo (FSE) sequences with high bandwidth to decrease susceptibility artifacts from the

Osteomyelitis. Figure 3 Typical MR signal alterations of osteomyelitis in a diabetic patient with an ulcer dorsal to the proximal interphalangeal joint of the second toe. (a) Fat-suppressed T2-weighted image reveals hyperintense signal in the bone marrow of the proximal and middle phalanx (arrows) and interruption of the dorsal skin surface with hyperintense sinus tract (arrowhead). Note the destruction of the proximal interphalangeal joint with subluxation indicating septic arthritis. (b) Contrast-enhanced, T1-weighted fat-suppressed image with diffuse hyperintense signal in the bone marrow of the proximal and middle phalanges confirming osteomyelitis. Note the delineation of the small dorsal ulcer (arrowhead) and the linear hypointense sinus tract extending to the destroyed joint.

images with rim enhancement. Chronic osteomyelitis and sclerosing osteomyelitis are indolent processes with areas of bone necrosis and sclerosis; as a result, MR imaging may show areas of low signal on T1- and T2-weighted images. Differentiation between reactive, noninfective tissue edema with inflammation from true bacterial infection may be difficult using MR imaging in the following situations (1): (a) differentiation of secondary osteomyelitis from reactive bone marrow edema in septic arthritis, (b) differentiation of postoperative and posttraumatic reparative signal alterations from infection (4), and (c) differentiation of pedal osteomyelitis and diabetic neuroarthropathy (see also Neuropathic Joint Disease).

Ultrasound

Ultrasound imaging can be very useful in pediatric patients due to the lack of radiation. Sonographic signs of osteomyelitis include asymmetric juxtacortical soft tissue swelling, thickening of the periosteum, and demonstration of an adjacent hypoechoic collection. In advanced cases, frank cortical destruction can be seen.

Nuclear Medicine

Technetium-99m MDP three-phase bone scan has a high sensitivity for osteomyelitis and is excellent for excluding bone infection in case of a normal radiograph, but specificity is low. Increased accumulation of tracer can be seen in other conditions such as bone tumors, neuropathic osteoarthropathy, fractures, and following trauma and surgery. One advantage of Tc99m MDP studies over radiography is that it can detect osteomyelitis within 24 to 48 h of onset.

Labeled white blood cell scans or Tc99m labeled monoclonal antigranulocyte antibodies raise the specificity to detect osteomyelitis, and may be helpful in excluding infection in a Charcot joint.

Diagnosis

Timely diagnosis of acute osteomyelitis is best achieved by either MR imaging or scintigraphy if radiographs are normal. Sonography may be very useful in acute pediatric osteomyelitis or septic arthritis. Activity of chronic posttraumatic or postoperative osteomyelitis is often best evaluated by comparison of recent and older radiographs. In complex cases with chronic posttraumatic osteomyelitis, a multimodality approach involving specialists from different disciplines (infectious disease, radiology, orthopedic surgery) is usually required.

Bone infections; Bone marrow infections; Joint infections; Soft tissue infections

Definition

Infections of individual bony parts, joints, and other supporting musculoskeletal tissue, including combinations of the three.

The responsible agent may be bacterial, fungal, parasitic, viral, or other organisms. A condition resembling osteomyelitis, but without a known agent, is chronic recurrent multifocal osteomyelitis (▶CRMO), with various skeletal manifestations behaving symptomatically and radiographically similar to infection. An open fracture is associated with a break in the skin or at the nail bed. A closed fracture has no such direct communication with the outside environment.

Pathology/Histopathology

According to the causative organism, the histopathology of bone (and joint and soft tissue) infection varies. Additionally, the histopathology of subacute and chronic infection is different from the acute type. Moreover, failures in body defense mechanisms vary between these underlying conditions – for example, in ▶chronic granulomatous disease of childhood, white cells can ingest bacteria and other organisms, but not digest them when the organisms do not contain hydrogen peroxide (for this reason, Ed Neuhauser called the condition "dyspeptic granulomatosis"). The physis is a relative barrier to passage of infection in bones, except in infancy or when affected by trauma. The bone bark of the metaphyseal collar is a relative barrier to pus in bone, so that breaking through cortex to form periosteal reaction generally stops at the step-off between periosteum and bone bark (in luetic bone disease, this feature is known as the Wimberger sign). In those joints that surround metaphyseal bone, infection travels readily between bone and joint. Neonates of mothers infected with syphilis who show "leukemic lines" at birth do not, at the time of neonatal x-ray imaging, have skeletal infection yet, but rather show the generalized effect of intrauterine stress (of the same nature of such lucent bands when the mother is given magnesium sulfate during late pregnancy (2)). Later in childhood syphilitic bone disease may or may not include local spirochetes. Biopsy of lesions in chronic recurrent multifocal osteomyelitis shows many plasma cells, but no microorganisms.

Clinical Presentation

Cardinal signs and symptoms of osteomyelitis include fever, malaise, pain, tenderness, swelling, warmth, redness, and loss of motion. The same signs occur with septic arthritis, and most are found with pyomyositis and other soft tissue infections, so that clinically the differentiation of the sites of infection may be difficult indeed. In patients with immune deficiency and other disorders of defense mechanisms, symptoms may be more silent.

Any ▶stubbed toe or stubbed finger fracture (dorsal Salter II fracture of a distal phalanx) must be suspected of being infected (3) (Fig. 1). Bones adjacent to tissue sites of tuberculosis or actinomycosis are vulnerable to becoming infected, as those infections tend to cross tissue planes. In osteopetrosis, one should be alert for jaw osteomyelitis.

Imaging

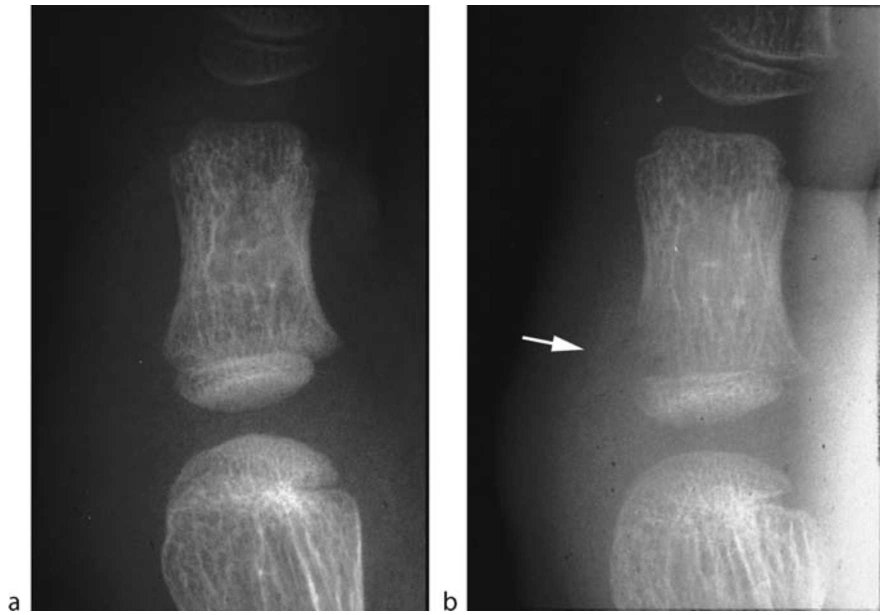
Since bone local demineralization and periosteal reaction do not appear on plain radiographs for 10 days after an infection begins, it is essential that the radiologist not dismiss a "normal" study before 10 days as ruling out infection (Fig. 2). It is also wrong to give the advice of solely a return for repeat imaging before the 10 days have elapsed or even after that time – the time to diagnose and treat osteomyelitis is right away (not only after plain film abnormality is evident). Nuclear imaging, ultrasound, and magnetic resonance imaging (MRI) are particularly good for early detection of infection. With ultrasound, elevation of the periosteum may be detected within a day, far earlier than the 10 days required for plain imaging.

Osteomyelitis, Neonates, Childhood. Figure 1 Osteomyelitis of the distal phalanx of the great toe in a boy several weeks after a stubbed toe Salter II fracture. Bone destruction and periosteal reaction have appeared. From Oestreich AE, Crawford AH (1985) Atlas of Pediatric Orthopedic Radiology, Thieme Verlag, Stuttgart p. 70.

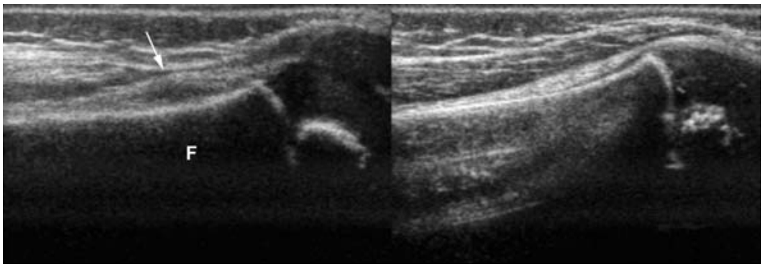
The echogenic periosteum is separated by a hypoechoic zone from the echogenic cortex (Fig. 3). MRI can reveal edema in marrow and surrounding soft tissue, as well as show the organizing fluid elevating periosteum. A needle stick under fluoroscopic, ultrasound, or computed tomography (CT) guidance can also give a diagnosis quickly. CT can distinguish soft tissue infection from its normal surroundings, as can ultrasound and MRI. Dental films give high detail of the periapical region if infection beyond teeth is suspected. Fluid surrounding a tendon is well depicted by ultrasound in tendonitis.

Nuclear Medicine

Acute osteomyelitis that has caused necrosis or avascularity will be cold (less activity than normal bone) on bone scan, unlike the majority of bone infection – acute, subacute, or chronic – which will be hot. A bone scan alone may not distinguish infarction from new sterile infarction in sickle cell anemia, but gallium scanning gives relatively much stronger uptake in infection than infarction. Infection limited to joint or soft tissue should not increase activity in adjoining bone on precise nuclear images. Since it takes 10 days for bone demineralization or periosteal reaction to become visible on radiographs,



Osteomyelitis, Neonates, Childhood. Figure 2 **(a) Less than 10 days from onset of symptoms, a plain image of the great toe shows some soft tissue swelling, but the bone is normal in appearance. (b) Ten days later, destruction of the proximal medial metaphysis and metadiaphysis is evident (arrow). It is a medical error to wait until the radiograph is abnormal; other imaging or some treatment should have been initiated at the time of presentation. From Oestreich AE, Crawford AH (1985) Atlas of Pediatric Orthopedic Radiology, Thieme Verlag, Stuttgart p. 247.**



Osteomyelitis, Neonates, Childhood. Figure 3 **A young child with acute osteomyelitis of the proximal femur (F), with no plain image bone abnormality yet. The arrow points to periosteum elevated by the sonolucent pocket of pus external to the femoral shaft (F) on longitudinal ultrasound. The right-sided image is the normal contralateral side.**

the radiologist should strongly consider bone scanning for diagnosis if symptoms have lasted less than that time. Gallium 67 citrate is generally positive in osteomyelitis by 24–48 h. Labeled white cells with indium 111 or Tc99m HMPAO are other means for seeking infection by nuclear scanning. Active chronic recurrent multifocal osteomyelitis is expected to be positive on bone scan during active phases. In Langerhans cell histiocytosis (one theory considers the disease formerly known as histiocytosis X to be of infectious origin), increased bone scan activity with a photopenic center may be seen. For spondylodiskitis in a child, gallium scan shows high activity; MRI is an alternative useful modality.

Diagnosis

Perhaps the most important point to restate about radiographs of osteomyelitis is that bone demineralization and periosteal reaction are not visible until 10 days after the infection begins; so the diagnosis should not wait for that. Something else should be done (nuclear imaging, needle biopsy, ultrasound, CT, MRI, or heuristic treatment possibly guided by blood culture). Tarsal and carpal bones and the patella and other growth centers have no periosteum, so they will not have periosteal reaction. Infection around the roots of teeth leads to loss locally of the lamina dura and bone demineralization. Infection of

Osteomyelitis, Neonates, Childhood. Figure 4 **Four weeks after only soft tissue swelling and a positive elbow fat pad, this 6-month-old infant has full-blown osteomyelitis seldom seen today, with an involucrum (I) surrounding sequestrum (S) of the ulna and a distal cloaca evident (arrow). From Oestreich AE, Crawford AH (1985) Atlas of Pediatric Orthopedic Radiology, Thieme Verlag, Stuttgart p. 66.**

the long bone shaft usually does not disturb the 1–3 mm metaphyseal collar, but bone demineralization and periosteal reaction begin beyond it. Untreated or unsuccessfully treated tubular bone osteomyelitis may eventually lead to involucrum (from periosteum) surrounding sequestrum (the damaged avascular bone) and discharge of pus through a radiographically evident cloaca (Fig. 4). Subacute osteomyelitis (Brodie abscess) tends to be seen as ovoid bone demineralization, longitudinally directed, near a physis or perhaps crossing it.

Infection, and other fluid, in the hip or humerus is generally not perceived on plain images (until eventual local bone infection or regional demineralization occurs). Infection in the knee and ankle is easily seen (but not specific) from interfaces, the suprapatellar bursa and the ankle tear drop just adjacent to the talus, respectively.

Soft tissue infections on plain images are seen as soft tissue swelling and disturbance of the local interfaces between tissues, including subcutaneous fat. Exceptionally, gas density is seen from gas-forming organisms.

Interventional Radiological Treatment

Interventional pediatric radiologists may be asked to drain deep abscesses, generally done under ultrasound, but sometimes CT, guidance. If fluid is obtained, it should be investigated for organisms, including tuberculosis, regardless of the gross appearance.

christian.krestan@meduniwien.ac.at

Synonyms

Aseptic bone necrosis; Avascular necrosis

Definition

Negative bacteriologic studies from well-documented cases of bone necrosis led to the use of the term "aseptic necrosis." Subsequent observations indicated that such cases were not only aseptic but also avascular. Hence, the terms "ischemic necrosis," "▶avascular necrosis," and "▶bone infarction" were suggested (1). By convention, the term "bone infarction" is reserved for bone necrosis in the metaphyseal and diaphyseal regions, whereas "avascular necrosis" (ischemic necrosis) applies to the epiphyseal and subarticular regions.

Pathology/Histopathology

Knowledge of the anatomy and histology of the articular and subarticular region are important for understanding the pathophysiology of osteonecrosis.

In the hyaline cartilage, four different zones can be differentiated microscopically because of different orientation of the fibers. Below the three superficial zones lies the very thin zone of calcified cartilage, divided from the uncalcified zone by the so-called tide mark that represents the zone of new cartilage formation. The chondrocytes produce the fibers and the ground substance, which is composed of collagens (5–10%), proteoglycans (10–30%; important for osmotic pressure), and water (65–80%).

At its base, adult articular hyaline cartilage is bordered by the subchondral plate (cortical endplate) with a high number of arterial vessels, capillaries, sinusoids, and venous vessels, with a declining number by 20% from adolescence until the seventh decade. While the upper (outer) zones of cartilage get their nourishment from the synovial fluid, there is some evidence that the very important zone of calcified cartilage and, definitely, the subchondral regions are fed by the subchondral vessels. The medullary bone has a dual blood supply, from the medullary arteries and periosteal arteries (2). Bony structures with a relatively high amount of cartilage surface (head of femur, talus) are very prone to problems in vascularization.

Ischemic necrosis of bone and bone infarction occur in areas of predominantly fatty marrow, which has a much lower blood flow. Infarcts (ischemic necrosis) occurring within the epiphysis or in small round bones (such as the talus) are covered by compact subchondral bone and cartilage.

Mineralized bone does not appear to be directly materially altered by ischemic necrosis. Bone density is unchanged within the dead bone but is usually lowered in the surrounding bone due to reactive changes (osteopenia).

Clinical Presentation

The clinical symptoms depend on the anatomic location of the osteonecrosis. A small proportion of patients may even present without symptoms, but usually in ▶Association Recherche Circulation Osseous (ARCO) stage 2 avascular necrosis is associated with considerable pain. If the femoral head is affected, patients suffer from slight pain in the hip joint, groin, or buttock or may experience limping and even be unable to walk at all. The symptoms are unspecific, so many other conditions, including arthrosis, insufficiency fractures, and sciatica, have to be considered in the differential diagnosis. In patients with Ahlback's disease the clinical onset is relatively abrupt, with pain that worsens during the night and accompanying effusion and tenderness. The clinical presentation may mimic meniscal disease or arthrosis and can only be diagnosed with ▶magnetic resonance imaging (MRI). Avascular necrosis of the lunate bone leads to localized pain and swelling of the wrist. Again, without proper imaging modalities, the diagnosis can be delayed. Early diagnosis is of utmost importance for proper treatment of the disease because failure to promptly initiate appropriate therapy can lead to bone and joint destruction with subsequent need for total joint replacement.

Imaging

Standard radiographs, computed tomography (CT), and MRI are used in the diagnosis of osteonecrosis/bone infarction.

The early diagnosis must be based on the visualization of changes in the soft tissue/bone marrow, which are altered on MRI. The role and relevance of high-resolution CT in detecting subchondral (micro)insufficiency fractures in early diagnosis of epiphyseal osteonecrosis is still under discussion. The only existing imaging modality to visualize necrotic marrow tissue is MRI. The combination of the inner linear, high-intensity rim with the parallel-running outer, low-intensity rim on T2-weighted or contrast-enhanced MR images is typically called the "double-line" sign and is characteristic for epiphyseal ischemic osteonecrosis with repair (3) (Fig. 1a–c). In this stage (ARCO 2), an arc-shaped subchondral lucent lesion with a thin sclerotic rim can be seen on standard radiographs. These findings are even better demonstrated with CT. CT also shows the abnormal configuration of the trabeculae resulting in irregular localized tiny defects with neighboring sclerosing areas. This ARCO stage 2 may last for weeks and months, but subchondral bony fractures ("crescent sign") representing ARCO stage 3 may finally develop. They are best seen on standard radiographs and/or CT (4). Finally, a complete impression fracture will occur. In ARCO stage 4, all typical signs of degenerative osteoarthritis are summarized, which includes joint deformity with flattening of the most involved part, subchondral "cystic" and sclerotic changes, formation of osteophytes, and joint space narrowing. Application of intravenous MR contrast medium is advocated by some authors, which could be helpful in unclear cases to exactly differentiate the necrotic part with no contrast enhancement from the surrounding viable tissue (5). As the most sensitive MR sequence, STIR images should be used first. If any abnormality is seen, T1-weighted fat-suppressed and T2-weighted gradient-echo (or fast spin-echo) should be added.

In (medullary) bone infarction the early phase with central necrosis and surrounding reactive and usually irregularly shaped tissue, which shows significant contrast enhancement, is followed by increasing calcification. Finally, either the medullary calcification can be found as the only remaining sign, or there will be complete healing.

Nuclear Medicine

Cessation of blood flow can be visualized by a three-phase bone scan, in which the first, vascular phase shows a low uptake of the radioactive marker, which is surrounded by a circular area of elevated uptake in later phases ("cold in hot

Osteonecrosis, Adults. Figure 1 (a) Anteroposterior view of both hips in a 30-year-old man. Ill-defined translucency represents ARCO stage 2 of right hip necrosis. (b) Coronal magnetic resonance imaging (STIR) shows marked edema of the right femoral head. (c) Coronal magnetic resonance image (T1-SE) shows hypointense demarcation in the right femoral head; ARCO stage 2.

spot"). Nuclear medicine studies, however, have been largely replaced by MRI because of better specificity and availability and the lack of ionizing radiation with MRI (6).

Diagnosis

The most preferred classification system for the staging of epiphyseal osteonecrosis was published by ARCO, in which emphasis was placed on a four-part staging system comparing radiographs, CT, bone scintigraphy, and MRI with histology and including prognostic factors (Table 1).

Osteonecrosis can be differentiated in necrosis of the epiphysis (usually called osteonecrosis) and in necrosis of the metadiaphysis (usually called infarction). Spontaneous medullary bone infarcts are often incidental findings in the metaphyses of long tubular bones. They appear as peripheral rims or shells of calcifications in the humerus, femur, tibia, or fibula and must be distinguished from enchondromas.

In the majority of cases, the exact etiology of osteonecrosis is unknown and hence is called idiopathic osteonecrosis. Most commonly, the femoral head or femoral condyles are involved in idiopathic epiphyseal necrosis (Ahlback's disease, or SONK). The differential diagnosis of idiopathic (epiphyseal) osteonecrosis includes bone marrow edema syndrome (BMES), osteomyelitis, bone tumor, and malignancies such as leukemia. BMES is a self-limiting disease with a relatively large zone of bone marrow edema and accompanying joint effusion and demineralization ("transient osteoporosis") but without double-line sign.

Secondary osteonecrosis may be due to trauma, corticosteroid therapy or hypercortisolism (such as after transplantation), hemoglobinopathies, Caisson disease (dysbaric conditions), small vessel disease (such as collagen disease), alcoholism and pancreatitis, gout and hyperurecemia with reactive vessel obstructions, Gaucher disease, irradiation/chemotherapy with direct vessel damage, and high intra-articular pressure (such as in infection and hemophilia).

The prognosis of osteonecrosis depends on the size and location of the ischemia. Osteonecrosis that occurs in a weight-bearing position and involves more than 30% of the articular head (such as the femoral head) has a much worse prognosis than lesions in a nonweight-bearing position and involving less than 15% of the articular head.

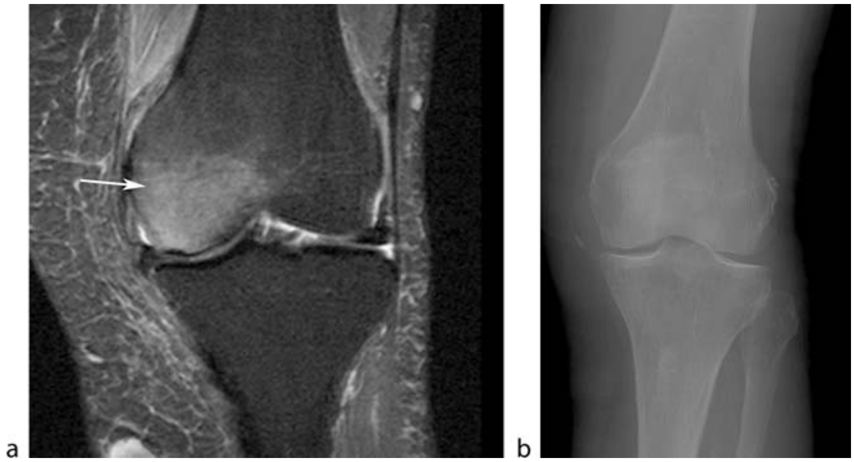
Osteonecrosis, Adults. Table 1 ARCO Classification (1992)

ARCO stage	Histology	Radiographs	Computed tomography	Bone scintigraphy	Magnetic resonance imaging
0	Microosteonecrosis	0	0	0	0
1	• Osteopenia, fractures • Microosteonecrosis • Marrow edema • Hyperemia	0	• Osteopenia • Insufficiency-micro-fractures	• Centrally in lesion low uptake	• Localized edema
2	• Osteonecrosis • Reactive changes: hyperemia, osteopenia, new bone formation	• Osteopenia • Reactive • sclerosis • Cysts	• Osteopenia • Sclerosis • Cysts • Asterisk sign	• High uptake	• Double-line sign (reactive margin of infarct with hyperemia and new bone formation) • Single-line sign in insufficiency fractures
3	• Subchondral impression fracture in weight-bearing area	• Crescent sign	• Crescent sign	• High uptake	• Crescent sign • Cartilage fracture (loss)
4	• Reactive degenerative changes	• Flattened articular surface • Joint space narrowing • Subchondral cyst formation • Reactive osteophytes • Subchondral sclerosis • Deformity, malpositioning, atrophy		• High uptake, deformity	• Cartilage defects • Deformity • Effusion, • Subchondral sclerosis • Osteophytes

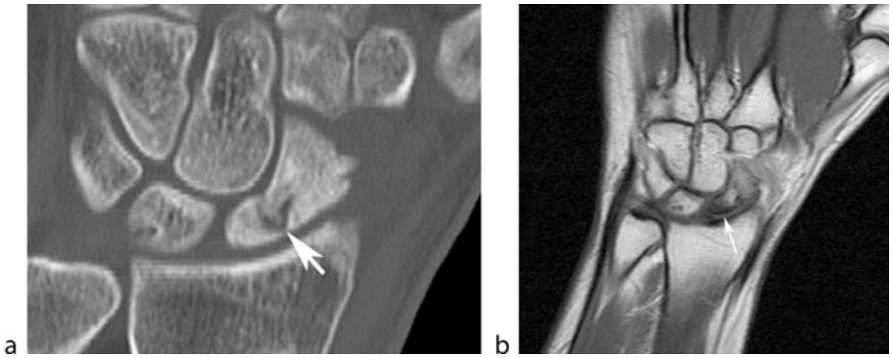
The most common sites for posttraumatic osteonecrosis are the femoral head, the body of the talus, the humeral head, and the carpal scaphoid (Preiser's disease). Rarely, the tarsal navicular, capitate, carpal hamate, or lunate bone is involved. The development of the osteonecrosis may take 6–36 months. The likelihood of development of osteonecrosis gets higher with the severity of the trauma. The principal blood supply of the affected bones is responsible for the risk and location of osteonecrosis. Early diagnosis is made by MRI, and sequential follow-up is with CT and standard radiographs. MRI shows persistent edema with localized zones of necrosis. The osseous flattening, collapse, and fragmentation are usually delayed for a period of 9 months and also depend on the weight-bearing load of the epiphysis. Finally, the involved bony parts may become very dense, smaller, and irregularly shaped (Fig. 3).

Adult idiopathic osteonecrosis may be due to chronic overloading of the hip joint (head of femur) and the femoral condyle (Ahlback's disease). Early diagnosis is possible with MRI and three-phase bone scan. Primary necrosis of the femoral head probably affects men more frequently than women and is usually seen between the fourth and seventh decades of life. The reported prevalence of bilateral disease varies between 35 and 72%. The typical radiographic signs are round, oval, or triangular low densities that are neighbored by a high-density rim, followed by the crescent sign and impression fracture (ARCO stages 1–3). Early diagnosis depends on proof of bone marrow edema (with MRI) or diminished blood supply (with three-phase bone scintigraphy).

Femoral condyle osteonecrosis (Ahlback's disease, spontaneous osteonecrosis) is a typical condylar idiopathic osteonecrosis localized in the medial condyle of the femur and occurs in patients older than 50 years and in women more than in men, but it may be also found in the lateral condyles and the tibial plateau. On standard radiographs, the first sign is a subtle flattening of the neighboring joint surface, followed by a narrow zone of increased density adjacent to the depressed osseous surface. A radiolucent area in the condyle can be detected over the ensuing weeks, becoming more sharply demarcated by time. If untreated, further depression of the bony margins and progressive sclerosis and intra-articular osseous bodies will follow. Over a period of months or years, all signs of secondary degenerative osteoarthritis will develop. Bone collapse, varus deformity, and displacement can also be noted (Fig. 2).



Osteonecrosis, Adults. Figure 2 (a) Coronal magnetic resonance image (STIR) shows marked edema of the medial condyle in a 90-year-old woman (Ahlback's disease). (b) Anteroposterior view shows no evidence of osteonecrosis in this digital radiograph.



Osteonecrosis, Adults. Figure 3 (a) Coronal MPR of multidetector computed tomography reveals nonunion of the scaphoid in a 35-year-old woman after trauma. (b) Coronal magnetic resonance image (T1-SE after intravenous gadolinium) demonstrates no contrast enhancement in the proximal fragment (Preiser's disease) of the scaphoid bone.

Kienbock's disease occurs most commonly between the ages of 20 and 40 years and has a predilection for the right lunate bone. The male-to-female ratio is 2:1, with the following stages:

In stage I the radiograph is normal or shows a subtle fracture. MRI visualizes a bone marrow edema, and bone scintigraphy a hot spot. In stage II, abnormalities in radiodensity with changes in size and shape are seen. MRI will reveal necrotic hypointense areas in all sequences. In stage III, the lunate bone collapses and shows a high density with irregular borders. In stage IV, signs of degenerative osteoarthritis are demonstrated. The etiology seems to be chronic trauma. In patients with short ulnae (ulnar minus variant), the loading forces on the lunate are much higher than normally.

In dysbaric osteonecrosis (Caisson disease), in cases of too rapid decompression the released nitrogen may produce bubbles that act as gas-emboli. Those may occlude vessels partially or completely. A delay of at least 6 months or years between the exposure and the onset of radiologically evident juxtaarticular or diaphyseal and metaphyseal radiodense foci/radiodense lesions is typical. Early diagnosis is possible with three-phase bone scintigraphy and whole-body MRI.

Cincinnati, Ohio, USA
Alan.Oestreich@cchmc.org

Synonyms

Avascular necrosis (Perthes disease = Legg–Calvé–Perthes disease = idiopathic avascular necrosis of the hip in childhood); Bone infarction; Chondrolysis (of cartilage)

Definitions

Arterial or venous ischemia leading to cell death and/or disturbance of growth in bone. Historically, several (eponymous) variations in skeletal growth, now known not to be due to necrosis, were once so considered and are still often discussed in the context of true necrosis states. Death or disturbance of the zone of resting cartilage leads to delay, deformity, or cessation of enchondral growth; other conditions such as frostbite and ▶Kashin–Beck disease may locally impair enchondral growth as well. The conditions in infancy known as multiple stippled epiphyses may well be secondary to necrosis of growth cartilage not yet in a growth plate.

Pathology/Histopathology

Clinical bone necrosis is usually more dynamic than mere death of osteocytes. The body has ways of repairing damage, so that the histopathologic pattern may be composed of both destruction and rebuilding. In Perthes disease, for example, the first step is impairment of vascular supply. The first irreversible structural change is a crumbling fracture of bone just below the lateral zone of provisional calcification, seen on frog leg radiographs. Then waves of bone necrosis appear with lack of viable osteocytes, followed by waves of overlying new bone (creeping substitution). Years later, a viable but deformed head is usually formed, more or less congruent with its acetabulum. However, because the shape is less spherical than normal and does not fully fit in its acetabulum, secondary arthrosis tends to appear relatively early in adulthood. Because of avascularity in the femoral neck and primary spongiosa in Perthes' disease, cartilage from the physis persists in the otherwise ossified neck, giving gouges of lucency on X-ray images. Both the head and neck of the femur widen transversely compared to normal as the disease progresses—perhaps related to increased periosteal formation in the neck from the processes of healing. An adverse event in the progress of Perthes is tethering across the physis in some patients. The greater trochanter growth is generally not impaired in Perthes, so it is relatively overgrown, leading to varus deformity of the hip, which is further exaggerated if tethering of the main physis occurs.

Osteochondrosis (some still refer to it as osteochondritis) dissecans is an injury to bone and overlying cartilage, which is painful and more severe, indeed unstable, whenever joint fluid enters the space between the lesion and normal bone.

Schmorl nodes are protrusions of normal vertebral disk substance through weak areas in the vertebral end plates (zones of provisional calcification). Schmorl nodes are often a component of Scheuermann disease of the spine.

In frostbite and Kashin–Beck disease (1), portions or the entire involved physis or acrophysis becomes nonviable, leading to local lack of growth (and perhaps early physeal fusion). A cone epiphysis is a result of a similar loss of viability of the central (more senior) portion of a physis, whether due to injury, infection, or genetic causes.

Clinical Presentation

Pain (in the groin, thigh, or referred to a knee), limping, and favoring a limb may reflect Perthes disease; however, Perthes may be clinically silent for months and discovered serendipitously on radiographs acquired for other reasons. Symptoms for avascular necrosis from other causes and at other sites are similar. In Gaucher disease, the spleen is often quite large; in sickle cell anemia, the spleen is usually small or absent. Traumatic avascular necrosis occurs after hip dislocation. For steroid-induced hip necrosis, other symptoms of steroid use could be sought. The incidence of osteochondrosis dissecans rose when teenagers were dancing The Twist, which indicates that certain challenging repetitive motions might be a predisposing factor. For frostbite, the history of severe cold exposure if available is helpful for the diagnosis (although the pattern of involvement on X-ray images is virtually diagnostic—especially if the thumb is spared by being held in the fist during the exposure). Kashin–Beck disease is geographically limited to China, Mongolia, and Tibet, where thousands of cases have occurred.

Imaging

In Perthes disease, magnetic resonance imaging (MRI) and nuclear images show avascularity earlier than the first plain image finding, which, in turn, appears first on the frog-leg view (Fig. 1). However, unilateral retarded maturation of one femoral head might be appreciated on the frontal radiograph as well. Ultrasound shows associated hip effusion easily; plain images do not. As Perthes disease progresses, computer tomography (CT) images show the current integrity of bone, extent of involvement, and nonosseous components; however, MRI is preferred because it does not use radiation and also displays the femoral head and neck and acetabulum throughout the long course of Perthes (2).

►Osteochondrosis dissecans of the distal femur is usually situated posteriorly in the involved condyle, and thus is better seen on a notch (angled) view tangential to it. Evaluation for instability or fluid between the osteochondrosis and adjacent healthy bone could be made with MRI or a CT arthrogram.

When there is doubt about whether a normal variant of ossification or an osteonecrotic bone is present, a display of the osseous and cartilaginous elements on MRI may help one decide, with overlying normal cartilage favoring the normal variant. For example, Meyer dysplasia of the hip (3) can be distinguished from Perthes disease by the finding of normal cartilage and normally vascularized bone. Ultrasound can show the findings in Osgood–Schlatter condition of the patellar tendon and anterior tibial apophysis.

Osteonecrosis, Childhood. Figure 1 Perthes disease lucent crescent (*arrowhead*) of the outer femoral head on frog-leg view in an 8-year-old boy. From Oestreich AE, Crawford AH (1985) Atlas of Pediatric Orthopedic Radiology. Thieme Verlag, Stuttgart p 190.

Nuclear Medicine

Nuclear imaging, like MRI, shows findings earlier in Perthes disease than the upper outer lucent crescent found on radiographic frog-leg images. On bone scans, the earliest finding is a cold defect in the femoral head, a larger zone indicating more extensive disease. This phase, however, is reversible without progression to irreversible definitive Perthes disease. The perthetic femoral head eventually regains scan activity in the reparative phase later in the disease evolution. One week after the onset of sterile infarction of bone, whether from sickle cell disease, Gaucher disease, pancreatitis, or other noninfectious causes, bone scans begin to show high activity (as healing begins) rather than the earlier lower than normal (cold) activity. Lack of bone scan activity is also a sign of avascularity after certain fractures, for example, in the proximal scaphoid following a transverse fracture of the scaphoid waist. The differential diagnosis between infection and infarction of bone in sickle disease can be assisted by dual scanning: in infection, gallium 67 should be much more avidly taken up than technetium in conventional bone scan.

Diagnosis

Bones with osteonecrosis are generally denser than the nearby bones, whether because of the loss of volume putting more bone substance into a smaller space from collapse or because living bones demineralize from local irritation whereas dead bones do not. A classic example is the proximal scaphoid being denser than the distal one when its blood supply is lost from a fracture across the bone's waist. Infarction of bone shafts can also incite callus, which is denser than the nearby bone.

The early plain image changes of Perthes disease are a smaller epiphysis than contralaterally because of decreased vascularity and, on the frog-leg view alone, a slit of lucency below the outer femoral head zone of provisional calcification, representing crumbling fracture (Fig. 1). The extent of the slit reflects the severity of involvement. As the disease progresses (with or without surgery to improve position or protect the hip), the head becomes irregularly denser and longitudinally shorter, while the head and neck become transversely wider (and thus incompletely covered by the bony acetabular roof). Gouges of lucency may extend down the metaphysis of the neck from the physis, reflecting avascular zones in the primary spongiosa. Without ultrasound or cross-sectional imaging, one cannot determine whether effusion accompanies Perthes disease. The perthetic hip through the progress of disease becomes varus as the greater trochanter continues to grow nearly normally, while the femoral physis is slowed, or occasionally tethered, by premature fusion across part of the physis.

Osteonecrosis, Childhood. Figure 2 Frostbite sequelae: distal phalanges 2 through 5 are short from physeal closure, as are middle phalanges 4 and 5. The distal (acrophyseal) ends of the middle phalanges are also irregular from enchondral damage. As is often the case, the thumb was presumably spared by being protected in the fist during the cold exposure. From Oestreich AE, Crawford AH (1985) Atlas of Pediatric Orthopedic Radiology. Thieme Verlag, Stuttgart p 169.

Sickle cell infarction of small tubular bones, generally about 1 year of age, is painful accompanied by periosteal reaction and called "hand–foot" syndrome. This may be the presenting symptom of previously unknown sickle cell disease. The typical Lincoln log vertebral bodies in sickle cell disease result from infarction or impairment of the more central portions of the vertebral end plates. Distinguishing infarction from infection in long bones in sickle cell disease by imaging can be quite difficult; dual nuclear scanning with bone scan and gallium scan (or labeled white blood cells) may help by showing especially high activity on the latter.

In frostbite, Kashin–Beck disease, and some sequelae of rat bite (1), enchondral bone growth is locally destroyed, so that portions or the entire bones do not grow (Fig. 2). Cone-shaped epiphyses, fused epiphyses, pumice-shaped carpal bones, and irregular nonepiphyseal ends of small tubular bones are manifestations. In frostbite the distribution is acral, from the fingertips proximally, because of the nature of the cold injury, often sparing the thumb if it had been protected in the fist. Distribution of enchondral damage in Kashin–Beck disease is more scattered—involvement asymmetrically of the lower extremity bones leads to length discrepancy and hence limp.

The apophysis of the posterior calcaneus normally appears denser than the rest of the bone. It is no longer considered "Sever disease" unless localized symptoms occur and the nuclear scan is abnormal. Many diagnoses of "Köhler disease" of the tarsal navicular are actually an overlap of multiple ossification centers rather than true osteonecrosis (Fig. 3). Close perusal of oblique and lateral images will usually solve the question. Similarly, the ossification across the closing inferior ischiopubic synchondrosis is often both vigorous and asymmetric from

a

b

Osteonecrosis, Childhood. Figure 3 Mimic of Köhler disease in a 6-year-old patient. Lateral image suggests sclerosis and irregularity of the navicular; but the frontal view shows it results merely from overlap, the bone developing from three normal-density growth centers. The pain, incidentally, was lateral, not medial.

side-to-side. Unless abnormally increased bone scan activity can be shown, van Neck osteonecrosis should not be considered. Kienböck disease or lunatomalacia is a real entity, however, often associated with ulna minus.

Meyer dysplasia of the hip in the early years of life is an irregular appearing ossification of the femoral head. However, it has normal vascularity on nuclear scan or MRI and uncommonly progresses to true Perthes disease.

Synonyms

Osteoporosis and osteopenia are precisely defined according to the World Health Organization (WHO) Criteria (see later)

Definitions

Osteoporosis is defined as a disease associated with a loss of bone mass and a deterioration of bone structure, both resulting in increased bone fragility and susceptibility to fracture (1). In 2000, the definition given by the National Institutes of Health consensus development conference in 1993 was modified (2). Osteoporosis was now defined as a skeletal disorder characterized by compromised bone strength predisposing to an increased risk of fracture. Because this definition appears fairly abstract, the following statements were added.

Bone strength reflects the integration of two main features: bone density and bone quality. Bone density is expressed as grams of mineral per area or volume and in any given individual is determined by peak bone mass and amount of bone loss. Bone quality refers to architecture, turnover, damage accumulation (e.g., microfractures), and mineralization.

Because bone density is the parameter that can be determined best *in vivo*, has a high precision, and correlates well with the biomechanically determined bone strength [it explains approximately 70% of bone strength (2)], the WHO defined osteoporosis on the basis of bone mineral density (BMD) (3). A BMD that is more than 2.5 standard deviations below that of a white, young, healthy female adult reference population (T-score) is defined as osteoporosis. A BMD that is 1–2.5 standard deviations below that of the young and healthy reference population is defined as ▶osteopenia. This definition, however, was originally only established for BMD of the proximal femur determined using ▶dual-energy X-ray absorptiometry (DXA), but it has been applied to define diagnostic thresholds at other skeletal sites, such as the spine (anterior–posterior) and the distal radius, and for other technologies.

Pathology/Histopathology

Osteoporosis is characterized by reduced activity of osteoblasts and increased activity of osteoclasts. Because trabecular bone has a turnover up to seven times higher than the cortical shell, bone loss occurs here first. The trabecular network transforms from a platelike to a rodlike structure with thinner trabeculae and wider intertrabecular spaces. Connections between trabeculae

O

are lost as osteoclasts form resorption lacunae that may have the size of thinner trabeculae. To quantify trabecular structure changes, histomorphologic parameters can be calculated from biopsies of the iliac crest, or noninvasively using high-resolution magnetic resonance imaging (MRI) or peripheral MicroCT at the distal radius, the tibia, or the calcaneus.

Clinical Presentation

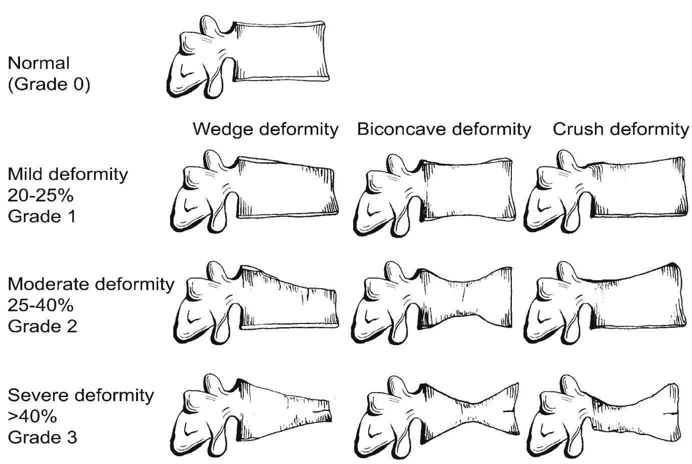
Osteoporosis may be undiagnosed for a long time and frequently manifests itself with insufficiency fractures. Early symptoms such as back pain and height loss are nonspecific, and a hunchback represents already advanced osteoporosis that is frequently associated with several vertebral fractures. The most severe insufficiency fractures affect the proximal femur with high associated disability and mortality. Osteoporosis-related vertebral fractures also have important health consequences for older women and men, including disability and increased mortality. The presence of one vertebral fracture increases the risk of any subsequent vertebral fracture fivefold, and 20% of women who have had a recent diagnosis of fracture will sustain a new fracture within the next 12 months. Since a number vertebral fractures do not come to clinical attention, the radiographic diagnosis is particularly important. Because these fractures can be prevented with appropriate medications, recognition and treatment of high-risk patients is warranted.

Imaging

Conventional radiographs of the spine are not suited to determine bone mass in the early stage of osteoporosis because it takes a bone loss of more than 20–40% before a loss of bone mass is visualized on radiography. Morphological signs described on spine radiographs, such as a coarse trabecular structure and a framelike appearance of the vertebrae, are also not very reliable. Conventional radiographs, however, are important in diagnosing fractures and in the differential diagnosis of osteoporosis because a number of other diseases may present with bone loss and fractures.

According to Genant et al (4), a vertebral deformity in T4-L4 of more than 20% of loss in height with a reduction in area of more than 10–20% is defined as a fracture. Using this fracture threshold, a semiquantitative score to grade the severity of vertebral fractures as visually determined from radiographs has been described (Fig. 1). In rare cases, osteoporosis may present with a coarse trabecular structure with thick vertical trabeculae suggestive of vertebral hemangioma. This so-called hypertrophic atrophy, however, is generalized, and the trabecular bone structure appears more coarse than in hemangioma. Important differential diagnoses in osteoporosis are osteomalacia, hyperparathyroidism, renal osteopathia, and malignant bone marrow disorders such as multiple myeloma and diffuse metastatic disease. Endplate fractures are found in Scheuermann's disease and malignant lesions. The differential diagnosis of osteoporotic and malignant pathologic fractures may be difficult. Fractures located above the Th 7 level present with a soft tissue mass, osseous destruction, and fractures of the posterior part of the vertebrae in conventional radiographs are more likely to be malignant.

Conventional radiographs of the proximal femur and the distal radius are usually obtained after a low-impact trauma with persistent symptoms in postmenopausal elderly individuals. It should be noted that osteoporotic



Osteoporosis. Figure 1 Spinal fracture index as defined by Genant et al (4) used to classify osteoporotic vertebral fractures.

fractures may be difficult to detect on conventional radiographs due to demineralization of the bone and are not infrequently occult.

Computed tomography (*CT*) *and MRI* may be helpful in detecting occult fractures (Fig. 2), differentiating osteoporotic and malignant fractures, depicting multiple lesions, and soft tissue masses or destructive changes. Bogost et al showed that 37% of proximal femur fractures were not detected in conventional radiographs, which were demonstrated in MR scans of these patients (5). Nonenhanced T1 and STIR (respectively T2-weighted fat-saturated) sequences are recommended in patients with a high clinical suspicion of fracture but negative radiographs. Diffusion-weighted MR sequences and iron oxide contrast media in MRI have been successfully used to differentiate malignant and benign bone marrow pathology. CT is less sensitive in depicting bone marrow pathology; however, it is better suited to assess the stability of an osteolytic lesion or fracture because it directly visualizes the bony structures and demonstrates fracture lines in a detailed fashion.

Nuclear Medicine

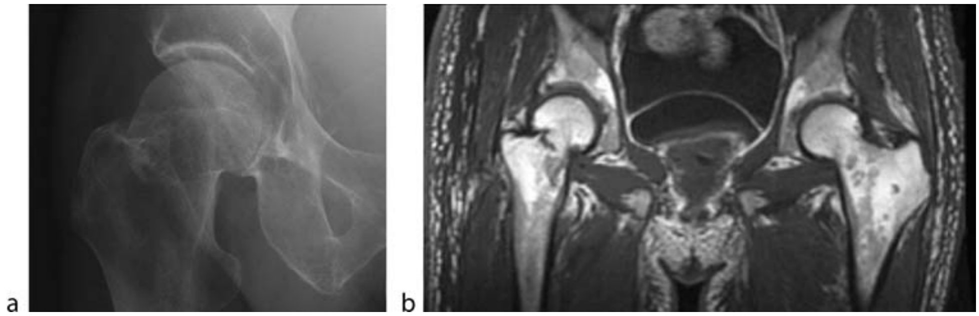
Bone scintigraphy has a limited role in the assessment of osteoporosis. The technique may be useful to detect occult fractures (though it is less sensitive than MRI), to depict multiple lesions, and to differentiate between old and new vertebral fractures.

Diagnosis

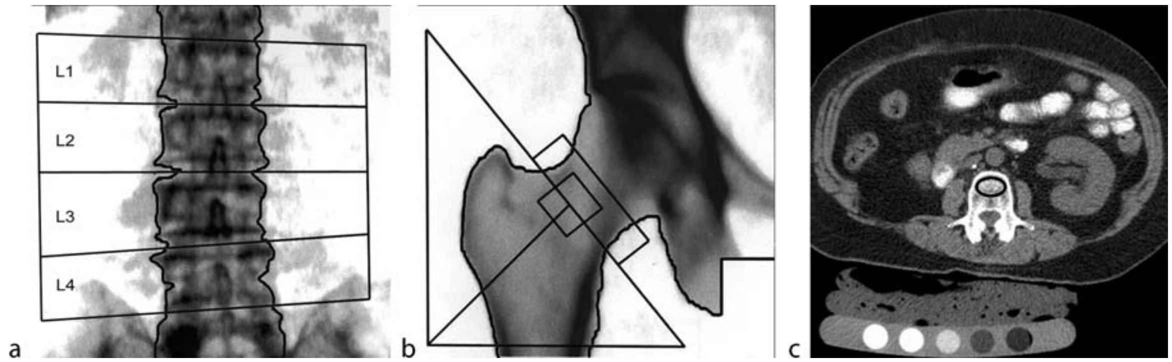
Diagnosis of osteoporosis is usually made on the basis of bone density or the presence of osteoporotic fractures. Currently the most important techniques in osteodensitometry are DXA and ▶quantitative computed tomography (QCT).

DXA: The principle of DXA is a dual-energy measurement that is based on the fact that radiation of distinct energies is attenuated by tissues to different extents. In both soft tissue and bone, a low-energy beam is attenuated to a greater degree than a high-energy beam is. Contrast in attenuation between bone and soft tissue is greater for the low-energy beam than for the high-energy beam, such that the attenuation profile of bone may be determined by subtracting both the low- and high-energy attenuation profiles. DXA scanners provide either pencil or fan beam techniques. Fan beam techniques are faster. The precision of DXA is high, and radiation exposure is low. BMD is most frequently determined at the spine (anteroposterior or lateral) (Fig. 3a) and at the proximal femur (Fig. 3b). Whole-body measurements as well as measurements at the distal radius and the calcaneus may also be obtained. The anteroposterior examination of the lumbar spine is a standard procedure with a precision *in vivo* of 1%, a radiation exposure of 1(-50) μSv (the higher dose is required for digital high-resolution images), and a fairly high accuracy (4–10%). For monitoring BMD, the precision alone, however, is not the only parameter required to assess the diagnostic performance of a technique. We also need to know the annual rate of BMD loss in normal patients using this technique as well as the least significant change between two measurements, which are 1–2% and 3–4%, respectively, for the anteroposterior spine.

Using automated software, areal BMD (g/cm^2) is determined, usually at L1–L4 (Fig. 3a). These projection images, however, have a number of limitations: (i) vertebrae with a larger size have a higher BMD, (ii) aortic calcification and all other soft tissue calcifications in the regions of interest (ROIs) increase BMD, and (iii) degenerative changes of the spine including osteophytes, facet sclerosis, and degenerative disc disease may also falsely increase BMD. In elderly patients with substantial degenerative changes of the lumbar spine, anteroposterior DXA of the lumbar spine may therefore not be a suitable technique. Lateral



Osteoporosis. Figure 2 Radiographically occult insufficiency fracture of the right proximal femur in a postmenopausal woman. On the radiograph of the right femur (a), no fracture is shown, whereas the coronal T1-weighted magnetic resonance image (b) clearly shows a fracture of the right femur neck.



Osteoporosis. Figure 3 Standard techniques to measure bone mineral density: dual-energy X-ray absorptiometry images of the anteroposterior spine (a) and the proximal femur with standard regions of interest (b) as well as quantitative computed tomography of the lumbar spine (c) with an oval region of interest in the vertebral body.

DXA is influenced less by these changes because it assesses only the vertebral bodies and thus focuses more on trabecular bone. However, drawbacks of this technique are a lower precision, a higher radiation exposure, and superimposition of the pelvis and the ribs, which may limit analysis of the lumbar spine to L3. So far, anteroposterior DXA is still the standard DXA procedure to assess the lumbar spine. When analyzing DXA scans, a number of pitfalls have to be considered that may be operator-dependent, such as mislabeled vertebrae, misplaced disk space markers, wrongly sized ROIs, and artifacts in the analysis region. These analysis errors are of greater magnitude than the machine's intrinsic precision errors.

DXA of the proximal femur is a particularly important examination because it is currently one of the best techniques to assess fracture risk of the hip (Fig. 3b). But the examination of the hip is more demanding than that of the spine; the proximal femur has to be positioned in a standardized fashion, and a number of ROIs have to be placed correctly. The correct location of these ROIs varies according to the manufacturer. Standard ROIs are the neck region, the trochanteric region, and the intertrochanteric region. The ROI used most frequently is the total femur. The total femur ROI consists of the neck region, the trochanteric region, and the intertrochanteric region. Ward's triangle has an inferior precision compared with the other ROIs and is currently not used as a standard ROI. The precision for hip BMD and the annual rate of loss are lower compared with anteroposterior spine, and the least significant change is higher.

As in DXA of the lumbar spine, a number of operator-dependent errors may occur in the proximal femur and should be detected by the radiologist. Most of these errors are due to improper positioning of the patient and the ROIs. Correct positioning of the patient includes internal rotation of the hip with a straight femoral shaft (the lesser trochanter should not or just barely be visualized). Correct positioning and size of the ROIs, in particular the neck box, may vary according to the manufacturer; for example, Lunar/GE systems have a standardized size of the neck box, which is placed automatically in the region of the neck with the smallest diameter. Osteoarthritis, Paget's disease, fracture, vascular calcifications, calcific tendinitis, enostosis, and avascular necrosis of the hip are also potential sources of error. Conventional radiographs may be required if an atypical density profile is shown. If these lesions are too large or if developmental dysplasia of the hip is found, BMD has to be determined at a different site.

QCT: In contrast to DXA, QCT allows a true densitometric measurement (in mg/mL) of trabecular bone, whereas DXA gives an areal BMD (in mg/cm^2) that includes trabecular and cortical bone. Since the trabecular bone has a substantially higher metabolic turnover, it is more sensitive to changes in BMD (annual rate of bone loss in QCT 2–4% vs. 1% in anteroposterior DXA of the spine). On the other hand, the precision of two-dimensional (2D) QCT (but not of volumetric QCT) is lower than that of DXA (1.5–4% vs. 1%). A big advantage of QCT is that it is not as susceptible to degenerative changes of the spine as DXA is. Osteophytes and facet joint degeneration as well as soft tissue calcifications (in particular of aortic calcifications) usually do not falsely elevate the BMD in QCT. As in DXA, however, fractured or deformed vertebrae must not be used for BMD assessment because these vertebrae usually have an increased BMD.

QCT may be performed with any CT system; however, a calibration phantom is required to transform the attenuation measured in Hounsfield units (HU) into BMD (mg/mL). Dedicated software improves the precision of the examination. The patient is examined lying supine on the phantom, usually with a water- or gel-filled cushion in between to avoid artifacts due to air gaps. Standard 2D QCT is performed of the lumbar spine; usually, the first to third lumbar vertebrae are analyzed using a single midvertebral section that is aligned along the endplates. Volumetric QCT can be performed of the spine and the proximal femur using axial, contiguous 3-mm sections of each site.

BMD data obtained by QCT are compared to an age-, sex-, and race-matched database. T-scores used for the assessment of osteoporosis according to the WHO definition have been established for DXA but not for QCT, though they may be given by the manufacturers of the software. If these T-scores are used to diagnose osteoporosis, a substantially higher number of individuals compared to DXA will be diagnosed as osteoporotic, since BMD measured with QCT shows a faster decrease with age than DXA. Researchers have therefore advocated using BMD measurements analogous to the WHO definition but with thresholds corresponding to lower T-scores. Thus, BMD values from 80–120 mg/mL have been classified as osteopenic, and BMD values below 80 mg/mL as osteoporotic (6), which corresponds to a T-score of approximately -3.0.

Peripheral QCT and DXA are less frequently used and clinically of limited significance. New techniques to assess microarchitecture and macroarchitecture of bone have not been introduced into the clinical arena but may give additional information on fracture risk and have future potential.

Osteoporotic Vertebral Fractures

According to the spinal fracture index, deformities of the vertebrae of more than 20% are defined as fractures. These are not infrequently asymptomatic but are excellent indicators for future fractures. Even if bone mineral density is not below a T-score of -2.5, the presence of fractures is indicative of osteoporosis.

Ovarian Cancer

Ovarian cancer is in the majority (85%) of cases epithelial in origin. Familial evidence of ovarian cancer is the strongest risk factor for ovarian cancer. At diagnosis in more than 75% of patients with epithelial ovarian cancer, peritoneal tumor spread outside the pelvis or lymphatic metastases are detected.

▶Carcinoma, Ovarium

Ovarian Cancer Screening

Screening with CA-125 and sonography are currently only suggested in high-risk patients. These are patients with a positive family history of ovarian cancer or BRCA1 or BRCA2 gene mutations.

▶Carcinoma, Ovarium

Ovarian Cancer Staging

The most commonly used staging system of ovarian cancer is the FIGO (International Federation of Gynecologists and Obstetricians) classification system. Alternatively, ovarian cancer is staged on the basis of the TNM classification. Staging is based on the findings detected during explorative laparotomy including cytologic assessment of the peritoneum.

Ovarian Metastases

Ovarian metastases comprise approximately 5–15% of malignant ovarian tumors, and derive most commonly from colon, stomach, breast, and melanomas as primary cancers. Krukenberg tumors display characteristic imaging features, which include bilateral, solid ovarian tumors, often with central necrosis. Other ovarian metastases present with similar imaging findings as ovarian cancer.

Oxygen–Ozone Therapy

A mixture of oxygen–ozone gas is injected into the centre of the intervertebral disc at non-toxic concentrations. Ozone has a direct lytic effect on the proteoglycan molecules that form the nucleus pulposus. The resulting proteoglycan fragments have limited water-binding abilities, which leave intradiscal water molecules free to diffuse into the surrounding tissues. The resulting loss of water causes a decrease of intradiscal pressure. This causes the herniated portion of the nucleus pulposus to recede towards the centre of the disc, relieving pressure on the nerve root.

Synonym

Osteitis deformans

Definition

Paget's disease of bone named after the nineteenth century British surgeon Sir James Paget is a localised or multifocal disorder of bone characterised by abnormal bone turnover with increased osteoclastic activity and compensatory increased osteoblastic activity. It has three phases, lytic, mixed and sclerotic. The aetiology of the disease is unknown with two principal theories. One is thought to be a genetic predisposition and the other a 'slow' virus infection.

Pathology/Histopathology

Mirroring the radiographic features, the microscopic appearances depend on the phase of the disease. In the initial osteolytic phase there is active osteoclastic bone resorption with loss of trabeculae and replacement of the marrow by highly vascular fibrous tissue. In time osteoblastic activity predominates with increased bone density and thickening of the remaining trabeculae. The disordered bone turnover produces cement lines or reversal fronts that gives the classic histological 'mosaic pattern'. In the late 'burnt-out' phase bone turnover may return to an almost normal level and the degree of hypervascularity is also reduced. In this situation, the microscopic appearances show thickened trabeculated bone with a prominent mosaic pattern and restoration of the marrow.

Clinical Presentation

There is increasing prevalence of Paget's disease of bone with age. It is rare in patients under 40 years of age. There are also significant geographic/ethnic variations being relatively common in the Caucasian races of northern Europe and yet rare in blacks and Asians. In northern Europe, the incidence has been estimated to be 3% of the population over the age of 40 rising to 10% in the elderly. There is a male predominance. Studies of the past two decades, however, have suggested that Paget's disease is disappearing. The majority of cases are an incidental finding on radiographs obtained for an unrelated clinical indication. The remainder present due to the complications of the disease (Table 1). The disease predominates in the axial skeleton-spine (75%), pelvis (60%) and proximal femur (75%). About 75% cases are polystotic and 25% monostotic. Clinical laboratory findings include a grossly elevated serum alkaline phosphatase with normal calcium and phosphorus levels. Urinary hydroxyproline levels are also raised due to increased bone tissue breakdown.

Imaging

The initial osteolytic phase is the least frequent manifestation identified on radiographs with the exception of the skull vault. In the skull, there is a large area of demineralisation with a sharp line of demarcation. This appearance, known as osteoporosis circumscripta, commences at the skull base most commonly affecting the

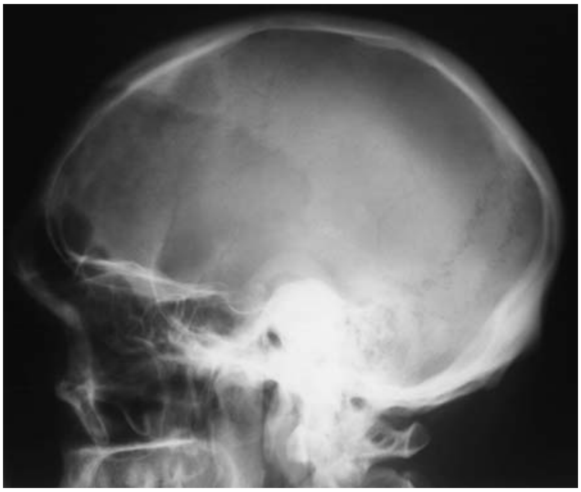
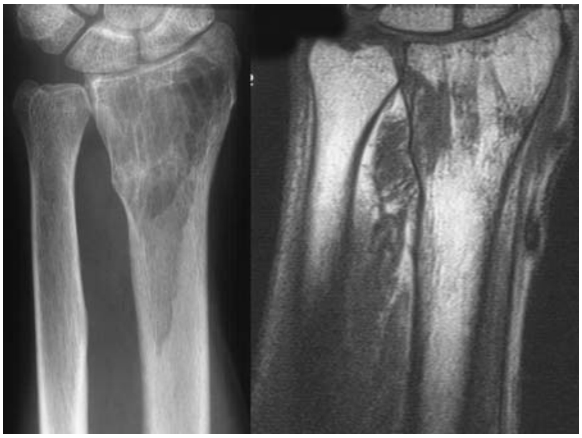
occipital bones (Fig. 1). In the long bones, the lytic process commences in the subarticular region and in time extends along the diaphysis. The sharp zone of transition between the pagetic and normal bone is variously termed, 'V-shaped', 'flame-shaped' or 'blade of grass' (Fig. 2). Rarely, Paget's disease may arise in the diaphysis without subarticular/metaphyseal involvement.

In the intermediate osteolytic and osteosclerotic phase there is a mixed pattern. In the skull this produces a 'cotton wool' appearance and in the spine a 'picture frame' vertebra. In the long bones the initially affected



Paget Disease. Figure 1 Osteolytic phase of Paget's disease affecting the frontal bones (osteoporosis circumscripta).



Paget Disease. Figure 2 Osteolytic phase of Paget's disease arising in the subarticular portion of the distal radius and extending cranially with a well defined V-shaped leading edge. The coronal T1-weighted MR image shows some thickening of the residual trabeculae and relative preservation of the marrow fat signal in the affected bone.

subarticular and metaphyseal bone is the first to show sclerosis and expansion with the distal lytic area preserved for the time being. In the late osteosclerotic phase, the pathognomonic triad in Paget's disease is expansion of bone with cortical and trabecular thickening (Fig. 3). The expansion of bone is particularly helpful in distinguishing this condition from other cause of widespread osteosclerosis such as diffuse metastases or myelofibrosis. In the pelvis there is expansion of the affected bone as compared with normal bone and thickening of the iliopectineal line (Fig. 3).

Fractures, typically transverse, can occur in any phase of Paget's disease due to weakening of the bone (1). In the sclerotic phase with bowing of the long bones it is not unusual to see incremental transverse fractures confined to the cortex on the convex side (Fig. 4). These are a form of insufficiency fracture that may or may not heal and can propagate across the whole diameter of the bone to produce a complete fracture.

The most significant of the complications of Paget's disease is malignant transformation that occurs in approximately 1% cases. Typically the patients have both longstanding and polystotic disease. The femur, pelvic bones and humerus are the commonest sites. The most common histological diagnosis is osteosarcoma followed by spindle cell sarcoma (malignant fibrous histiocytoma and fibrosarcoma) and rarely chondrosarcoma. Clinical features that should alert the physician to the possibility of malignancy include progressive non-mechanical pain and swelling at the affected site. The majority of cases can be identified as an aggressive lytic lesion arising within an area of pre-existing Paget's disease. Cortical destruction and a soft tissue mass is a relatively early finding (Fig. 5) (2). Despite most cases being an osteosarcoma, malignant mineralisation is uncommon.

CT will show cortical and trabecular thickening with normal fat attenuation of the marrow. Typically on MR imaging in uncomplicated Paget's disease the marrow fat signal is preserved on all sequences (Fig. 2) (3). However, it is possible to see cortical and marrow oedema when the disease process is particularly hypervascular. In complicated Paget's disease (i.e. in the presence of fracture, oedema, etc.) the fat signal from the marrow is replaced (4). Features suggestive of malignancy include cortical destruction and the presence of a soft tissue mass.

Nuclear Medicine

Bone scintigraphy can be used in Paget's disease to make the diagnosis, identify the extent of disease and monitor response to treatment with bisphosphonates (5). The bone scan tends to show relatively uniform, increased activity with evidence of expansion in flat bones such as

Paget Disease. Figure 3 Late phase of Paget's disease with sclerosis, expansion of the right hemipelvis and a mild protrusio deformity. The bone scan shows the uniform increased activity in an expanded right hemipelvis with involvement of several vertebrae.

Paget Disease. Figure 4 Late phase of Paget's disease with sclerosis, expansion and bowing (sabre deformity) of the tibia. There are several small transverse incremental fractures over the convex border.

the pelvis, scapula and sternum (Fig. 3). The typical appearance in the long bones is increased activity commencing at one bone end and extending along the shaft, with a V-shaped leading edge corresponding to the radiographic abnormality. In the spine the whole vertebra, including the posterior elements, is involved giving the variously termed 'heart', 'mouse's face' or 'clover' appearance. Unlike most sarcomas of bone, malignant transformation may appear relatively photopenic against the background increased activity of the pre-existing Paget's disease.

Paget Disease. Figure 5 Malignant transformation with an osteosarcoma arising in pre-existing Paget's disease. There is lysis, cortical destruction and a soft tissue mass all indicative of malignancy. Note the V-shaped edge of the Paget's disease distally.

Diagnosis

Incidental late phase Paget's disease is readily diagnosed on radiographs as showing the triad of bone expansion with cortical and trabecular thickening. Similar appearances with preservation of the marrow fat signal are characteristic of uncomplicated Paget's disease on MR imaging. Presentation with bone pain should suggest the possibility of complicated Paget's disease be it fracture or malignant transformation. It should be stressed that not all tumours arising in association with Paget's disease are sarcomas. There is a rare association with giant cell tumour of bone and metastases, myeloma and lymphoma may all arise in pagetic bone. Therefore, it is important to surgically stage and biopsy a suspected malignancy in Paget's disease as the management and prognosis may differ considerably. Other rare conditions causing loss of bone density in Paget's disease that may mimic a sarcoma include post-immobilisation lysis, otherwise known as accelerated disuse osteoporosis, and drug-induced osteomalacia.

Acute inflammation of the pancreas

Definitions

According to the 1992 International Symposium on Acute Pancreatitis, acute pancreatitis is defined as an acute inflammatory process of the pancreas with variable involvement of other regional tissues or remote organ systems. Acute pancreatitis is classified further into mild and severe forms. Mild acute pancreatitis is associated with minimal organ dysfunction, whereas the severe acute pancreatitis, which exhibits extensive hemorrhagic necrosis of the organ, may lead to organ failure and/or local complications. Previous classifications have been based on the extent and degree of pancreatic injury, which could only be assumed at the time of diagnosis and which could sometimes be confirmed later during surgical exploration. This new classification is based on the presence of multiorgan failure and on the morphology of the pancreatic gland as depicted in Computed tomography (CT) imaging (1).

Pathology and Histopathology

It has been assumed that the ultimate pathogenetic process in acute pancreatitis is the destructive effect of pancreatic enzymes released from acinar cells, leading to autodigestion of the pancreatic parenchyma and peripancreatic tissues. The basic alterations are proteolytic destruction of acinar and islet cells, pancreatic ductal system, necrotizing vasculitis of blood vessels with subsequent thrombosis or hemorrhage, necrosis of fat, and an accompanying inflammatory reaction. The extent and predominance of each of these features depend on the duration and severity of the process. In the early stages only interstitial edema is present. Soon after, focal and confluent areas of necrosis of endocrine and exocrine tissue are found. Neutrophilic infiltration and interstitial hemorrhage eventually ensue. The most characteristic histological lesions are the focal areas of fat necrosis that occur in the pancreatic and peripancreatic fat, but also in the omentum and mesentery. During the first 30 min of an acute attack of pancreatitis a variety of toxic, biologically active compounds are produced and released in the blood and ascitic fluid, leading to multiorgan involvement (1).

Clinical Presentation

Gallstones are the leading cause of acute pancreatitis and can account for more than 80% of cases worldwide. Microlithiasis also is a well-known cause of acute pancreatitis and represents the cause of presumed idiopathic acute pancreatitis in 50–73% of patients. Alcohol abuse also is typically considered as a causative factor. Other causes include: drug reaction; pancreatic and ampullary tumors; hypertriglyceridemia; hypercalcemia (almost always due to hyperparathyroidism); congenital anomalies of pancreatic and biliary anatomy (pancreas divisum, annular pancreas, choledochocele); trauma (including iatrogenic damage, such as ERCP); infectious etiologies; vascular abnormalities (atherosclerotic emboli, hypoperfusion, vasculitis); cystic fibrosis. These miscellaneous causes account for approximately 10% of cases of acute pancreatitis (1).

The cardinal symptom of acute pancreatitis is moderate to severe epigastric abdominal pain that radiates to the back quite commonly, owing to the retroperitoneal location of the pancreas. It may also radiate to the flanks, chest, shoulders, and lower abdomen. The character of the pain is constant, but not colicky. Frequently nausea and vomiting are associated symptoms. Fever in the first week is due to acute inflammation and with inflammatory cytokines. Fever in the second or third week in patients with acute necrotizing pancreatitis is usually due to infection of the necrotic tissue and is much more significant. On physical examination, the abdomen may be distended and tenderness may exist. Flank ecchymosis (Grey-Turner sign) or periumbilical ecchymosis (Cullen sign) are rarely present and they often appear 48–72 h after the onset of symptoms (1).

Systemic complications can occur: multisystem organ failure (ARDS, renal failure), shock, hemorrhage, pleural effusions, pneumonia, and atelectasis, ileus. Local complications of acute pancreatitis include fluid collections, pancreatic necrosis, pseudocyst formation, ►abscess, hemorrhage, venous thrombosis, and pseudoaneurysm formation. Pancreatic necrosis is defined as focal or diffuse areas of nonviable pancreatic parenchyma. Secondary bacterial contamination of such necrotic areas or collections is the usual cause of late mortality in severe acute pancreatitis. A pseudocyst is a collection of pancreatic juice and inflammatory fluid enclosed by a wall of fibrous or granulation tissue. A pseudocyst lacks a true epithelial lining and communicates with the pancreatic duct. A pancreatic abscess is a circumscribed intra-abdominal collection of pus. The development of both pseudocyst and abscess usually requires 4 or more weeks from the initial clinical onset of acute pancreatitis (1).

Imaging

Conventional abdominal radiograph is the initial diagnostic examination in case of acute abdominal pain. The most commonly recognized radiological signs associated with acute pancreatitis include the following: air in the duodenal C-loop; the "sentinel loop sign," which represents a focal dilated proximal jejunal loop in the left upper quadrant; the "colon cut off sign," which represents distension of the right and transverse colon with a paucity of gas distal to the splenic flexure. However, the abdominal radiograph can be completely normal in patients with acute pancreatitis. The chest radiographs can demonstrate pulmonary findings (infiltrates, pleural effusion).

Ultrasound (US) is often employed early in an acute episode of pancreatitis, to exclude other causes of acute abdomen and to help evaluation of the biliary tree dilatation and the presence of stones in the biliary system. The pancreas may appear normal in some cases, especially in mild cases, while possible findings include a diffusely enlarged and hypoechoic gland. Complications of acute pancreatitis also may be identified (peripancreatic fluid collections, pseudocysts, pancreatic abscesses) (2).

CT of the abdomen is the standard imaging modality for evaluating acute pancreatitis and its complications. In addition, CT can be used as a prognostic indicator of the severity of acute pancreatitis. Lastly, CT can be used to guide percutaneous interventional procedures such as diagnostic fine needle aspiration or catheter placement. CT allows complete visualization of the pancreas and retroperitoneum. Oral and intravenous administration of contrast material is essential, particularly in patients with severe pancreatitis, to enable visualization of the pancreas and differentiation of the gland from adjacent collections of fluid and peripancreatic inflammatory tissue. Typical CT findings in acute pancreatitis include focal or diffuse enlargement of the pancreas, with inhomogeneous enhancement, irregular contour of the pancreatic margins, thickening of peripancreatic fat planes, thickening of fascial planes, and the presence of intraperitoneal or retroperitoneal fluid collections. The fluid collections most commonly are found in the peripancreatic and anterior pararenal spaces but can extend down to the pelvis (3–5) (Fig. 1, Fig. 2).

Pancreatitis, Acute. Figure 1 Multidetector spiral CT in severe pancreatitis. Pancreas is diffusely enlarged with inhomogeneous enhancement. Irregular contour of the pancreatic margins, thickening of peripancreatic fat planes, thickening of fascial planes, and an intra- and retroperitoneal fluid collection can be depicted.

Pancreatitis, Acute. Figure 2 Multidetector spiral CT in severe pancreatitis. The body of the pancreas is replaced by an area of fat necrosis that is depicted as a collection without enhancement after intravenous administration of contrast medium. The pancreatic head is enlarged while the tail is not significantly involved. Marked thickening of the fascial planes is associated.

Complications of acute pancreatitis, such as pseudocysts, abscess, necrosis, venous thrombosis, pseudoaneurysms and hemorrhage, can be easily recognized with CT. A pseudocyst appears as an oval or round water density collection with a thin or thick wall, which may enhance. A pancreatic abscess can manifest as a thick-walled fluid collection with gas bubbles or a poorly defined fluid collection with mixed densities. Areas of fat necrosis can be depicted as collections without enhancement after the intravenous administration of the contrast medium. Infection of the collection can be suspected when gas bubbles are present within the necrotic areas (3–5).

CT can also be used to assess the severity and estimate the prognosis of acute pancreatitis. Balthazar in 1985 developed a grading system in which patients with acute pancreatitis are classified into one of the following 5 grades (4):

- Grade A—Normal-appearing pancreas
- Grade B—Focal or diffuse enlargement of the pancreas
- Grade C—Pancreatic gland abnormalities associated with peripancreatic fat infiltration
- Grade D—A single fluid collection
- Grade E—Two or more fluid collections.

The development of rapid gradient-echo breath-hold techniques and fat-suppression techniques has made magnetic resonance (MR) imaging an excellent alternative modality to evaluate patients with acute pancreatitis. MR imaging is particularly useful in patients who cannot receive iodinated contrast material due to allergic reactions or renal insufficiency. The morphologic changes of the gland in acute pancreatitis are similar on both CT and MR. The pancreas may be enlarged focally or diffusely. Acute inflammatory changes appear as low signal intensity strands in the surrounding peripancreatic fat. Gadolinium-enhanced T1-weighted gradient-echo MR images can depict pancreatic necrosis as unenhanced areas. Fat-suppression images are also helpful for defining subtle, diffuse, or focal parenchymal abnormalities. T2-weighted images can accurately depict fluid collections, pseudocysts, and areas of hemorrhage, whereas MR is limited in detecting gas and calcifications. The association of MR cholangiopancreatography sequences is useful for depicting the biliary tract, for example to demonstrate biliary stones (3, 6).

Vascular complications of acute pancreatitis result from the proteolytic effects of the pancreatic enzymes that cause erosion of blood vessels, which often results in pseudoaneurysm formation or free rupture. The splenic artery, followed by the pancreaticoduodenal and gastroduodenal arteries, are affected most commonly. If acute hemorrhage or pseudoaneurysm is suspected or diagnosed by US or CT, a celiac and superior mesenteric angiography can be performed to definitively assess the extent of vascular involvement. In addition, permanent or temporary therapeutic embolization can be performed (4, 5).

Diagnosis

The diagnosis of the acute pancreatitis is based on the combination of the clinical, laboratory, and imaging findings.

Common laboratory abnormalities include elevated serum amylase and lipase levels, hyperglycemia, hypocalcemia, decreased lactic dehydrogenase levels, elevated serum glutamic-oxaloacetic transaminase, bilirubin and alkaline phosphatase levels, and leukocytosis. The serum amylase level is nonspecific and often returns to normal in 48–72 h; furthermore a normal amylase level does not exclude an acute pancreatitis. Instead, the increase in the serum lipase level is specific for pancreatic disease. Plasma levels of the pancreatic enzymes are useful diagnostic indicators, but have no role in the assessment of disease severity. More specific markers for pancreatic injury are methemalbumin and pancreatic ribonuclease (an intracellular enzyme liberated by necrotic tissue). The presence in serum of methemalbumin indicates hemorrhagic pancreatitis. C-reactive protein has been reported to be a prognostic indicator of disease severity with a sensitivity and specificity of 80%. However, none of the individual clinical or laboratory parameters, while useful in clinical practice, is sufficiently sensitive or specific to help identify most patients with necrotizing pancreatitis. For this reason, various scoring systems that combine clinical and laboratory parameters have been proposed to help identify patients with severe pancreatitis. The first, proposed by Ranson in 1974, is still the most widely used. It is based on 11 objective signs: 5 determined initially, and 6 within 48 h. With an increased number of risk factors, there is a corresponding increase in the morbidity and mortality rates. Moreover, the system requires all the 11 measurements, which necessitates a total of 48 h of observation. More recently, the Acute Physiology and Chronic Health Evaluation (APACHE II) assessment and monitoring system has been used. This system also results complex, requiring 12 physiologic measurements. It has been suggested that a cutoff APACHE II score of greater than 8 indicates severe pancreatitis. The major advantage of the APACHE II numeric system, when compared with the other systems, is that it can be used in monitoring the response to therapy. The test is useful as an early prognostic indicator of disease severity to help identify patients for intensive treatment (1).

Interventional Radiological Treatment

Approximately 50% of acute fluid collections (►Fluid Collections, Pancreatic, Acute) resolve spontaneously within the first 4 weeks. Failure of resolution can lead to infection or to the formation of pseudocysts (sterile or infected) and abscesses. Diagnostic fine needle aspiration is performed to distinguish infected from noninfected pseudocysts and to delineate pancreatic abscess from infected necrosis. Therefore, they may be drained by inserting a needle or tube through the skin under ultrasonographic or CT guidance, or by laparoscopic or open surgery. CT and US are the guidance modalities of choice in performing diagnostic fine needle aspirations and percutaneous drainages. Noninfected pseudocysts can be left untreated since approximately 50% resolve spontaneously. Rarely, inflammation can cause sudden rupture or severe bleeding inside the cyst from blood vessels damaged by inflammation. Intervention is mandatory only in the presence of symptoms or complications such as obstruction or infection. The abscess tends to be circumscribed and may be treated by methods identical to pancreatic pseudocyst, but external drainage is favored. A pancreatic abscess may be drained percutaneously, whereas infected necrosis usually requires surgical debridement. If acute hemorrhage or pseudoaneurysm is suspected or diagnosed by US or CT, a celiac and superior mesenteric angiography can be performed to definitively assess the extent of vascular involvement. In addition, permanent or temporary therapeutic embolization can be performed (2–5).

Chronic inflammation of the pancreas

Definitions

Chronic pancreatitis represents a continuous or relapsing inflammatory and fibrosing process of the pancreas leading to irreversible morphological changes associated with permanent endocrine and exocrine dysfunction. Chronic pancreatitis may not simply be the result of repeated attacks of acute pancreatitis; it is believed to be a separate and distinct disease entity (1).

Pathology and Histopathology

Morphological changes of chronic pancreatitis include necrosis and fibrosis, atrophy of acini with relative sparing of the islets of Langerhans. Proteinaceous material can fill the ducts and calcify. These concretions together with periductal fibrosis lead to variable obstruction and dilatation of pancreatic ducts. A chronic inflammatory infiltrate around lobules and ducts is usually present. The ductal epithelium may be atrophic or hyperplastic or may show squamous metaplasia. The lesions may involve portions of the gland (focal chronic pancreatitis) or the entire pancreas. Grossly the gland is hard and calcifications and calculi can be observed. Pseudocyst formation is common (1).

Clinical Presentation

The main cause of chronic pancreatitis is excessive chronic alcohol consumption. Chronic pancreatitis can also result from obstruction of the ducts (caused by tumours, anatomical variations), cholelithiasis, cystic fibrosis, haemochromatosis, congenital causes (pancreas divisum), autoimmune conditions, hereditary causes.

The dominant clinical symptom of chronic pancreatitis is epigastric pain, which may also radiate to the back. This can be very severe and continuous, but is more often intermittent, and occurs in attacks. Weight loss related to malabsorption due to pancreatic exocrine deficiency and signs of endocrine dysfunction (diabetes) are also common symptoms. Other complications include pseudocyst and fistula formation, pseudoaneurysms of the arteries close to the pancreas, splenic or portal venous obstruction, stenosis of the common bile duct (1).

Imaging

Plain radiographs of the abdomen may show pancreatic calcifications, which represent a common and pathognomonic finding of the chronic pancreatitis. Calcifications are punctiform or coarse and may have a focal, segmental, or diffuse distribution. Gastrointestinal tract barium study still has a place in the management of chronic pancreatitis because it may provide information about complications involving the upper gastrointestinal tract: peripancreatic fibrosis may involve the antrum of the stomach or duodenum, resulting in stenosis; pancreatic enlargement or pseudocysts may compress and displace the stomach, duodenum or jejunum (2, 3).

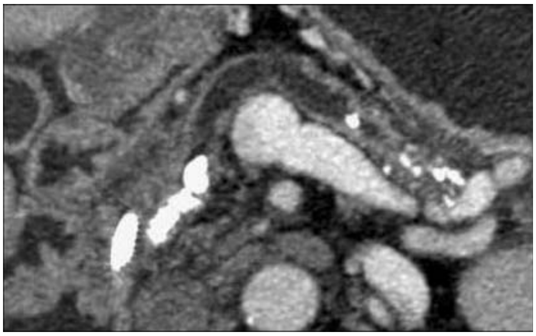
Ultrasound (US) is the first modality to be used in patients presenting with upper abdominal pain, although the direct diagnosis of chronic pancreatitis is not always possible. The main findings are hypoechoic enlargement, diffuse or focal (focal chronic pancreatitis), with irregular pancreatic contour, calcifications and ductal dilatation. In late stages of the disease, the pancreas becomes atrophic and fibrotic with a heterogeneous aspect. When marked fibrosis is present, the gland appears diffusely but irregularly hyperechoic. The pancreatic duct is dilated and multiple stenoses may be evident. US can help also in determining the cause of chronic pancreatitis (e.g. demonstrating the presence of cholelithiasis) and it is a highly accurate non-invasive technique to assess the complications (pseudocysts, ascites, splenic/portal venous obstruction) (2, 3).

Contrast US has resulted to be helpful to provide an enhanced overall image quality and a better detection of pancreatic lesions in focal chronic pancreatitis.

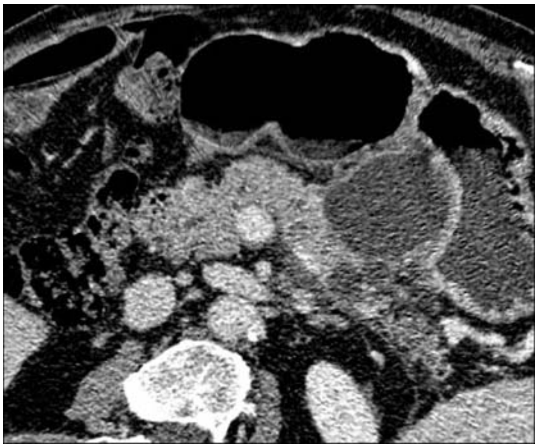
Endoscopic ultrasonography (EUS) is more sensitive and the typical changes can be seen at an earlier stage of disease. The most characteristic EUS findings in chronic pancreatitis are parenchymal changes presenting as small hypoechoic areas separated by hyperechoic fibrous septa.

Computed tomography (CT) represents the modality of choice for the evaluation of suspected chronic pancreatitis. In early phases, CT findings may be entirely normal, whereas advanced disease is readily recognized on CT. Parenchymal atrophy with or without fatty replacement can be appreciated; in some cases chronic pancreatitis can present as a focal non-calcified mass that would be indistinguishable from a carcinoma. Focal enlargement found in association with calcification and ductal dilatation is suggestive of chronic pancreatitis. In addition, dilatation of the main pancreatic duct is a characteristic finding: irregularities in duct calibre are more frequently seen in chronic pancreatitis, whereas smooth dilatation is most commonly associated with carcinoma. CT is more sensitive than plain radiography and ultrasonography in the depiction of pancreatic calcification, which may appear tiny and punctate or larger and coarse (Fig. 1). Chronic pancreatitis can also be associated with obstruction of the biliary tree: in most instances, the involvement of the common bile duct may be visualized as a gradually tapering of the lumen, whereas an abrupt transition is commonly associated with carcinoma. Obliteration and thickening of peripancreatic fat can be seen, usually in case of acute exacerbations of chronic pancreatitis. Pseudocysts can occur both in acute and chronic pancreatitis. When pseudocysts are associated with ductal dilatation or calcifications chronic pancreatitis is suggested (Fig. 2). Vascular complications of chronic pancreatitis are best depicted by using contrast-enhanced CT scans; arterial pseudoaneurysms and portal and/or splenic vein thrombosis represent possible findings (2, 3).

Characteristic magnetic resonance (MR) signal changes are evident in advanced disease. T1-weighted SE images show a loss of signal intensity of the glandular parenchyma, as a result of pancreatic fibrosis which



Pancreatitis, Chronic. Figure 1 Multidetector CT study of chronic pancreatitis. Markedly enlarged pancreatic duct, due to the presence of intra-ductal stones, is depicted. The pancreas has become atrophic and tiny calcifications are present in the pancreatic tail.



Pancreatitis, Chronic. Figure 2 Multidetector CT study of pseudocyst in chronic pancreatitis. A pseudocyst can be appreciated in the pancreatic tail. The surrounding pancreatic parenchyma of the tail is inhomogeneous as a result of repeat exacerbations of chronic pancreatitis.

diminishes the proteinaceous fluid content in the glandular acini. The loss of signal is seen more easily on fat-suppressed images. On T2-weighted images the parenchymal signal intensity may be normal, or variably modified. Small calcifications are difficult to detect by using MR, but larger calcifications may be visible as foci of signal void on both T1 and T2. Pseudocysts associated with chronic pancreatitis can be demonstrated as well-defined masses with low to medium signal intensity on T1-weighted images and high signal intensity on T2-weighted sequences, similar to other fluid collections. Parenchymal gadolinium enhancement results less intense and more gradual than in the normal pancreas, because fibrosis produce the obliteration of small capillary vessels. With respect to CT, MR is more sensitive in detecting early changes of fibrosis, which manifest as reduction in signal intensity on T1-weighted images and reduced gadolinium enhancement. Mangafodipir trisodium (Mn-DPDP) should help to highlight focal pancreatitis, because inflammatory alteration of the parenchyma in focal pancreatitis results in lack of MnDPDP uptake into the parenchyma. However also neoplastic lesions cannot demonstrate uptake of the MnDPDP. MR cholangiopancreatography (MRCP) sequences are able to visualize the characteristic dilatations and strictures of the main pancreatic duct and of the side branches. MRCP also displays the intra-ductal filling defects due to intra-ductal plugs and stones. Intravenous secretin administration is useful to enhance the delineation of the main pancreatic duct and can improve the detection of subtle changes of the side branches and allow the earlier non-invasive diagnosis of chronic pancreatitis. Secretin-enhanced pancreatography also has the capability to depict the anatomic relationships of pancreatic ducts and pseudocysts and also provides additional functional information regarding pancreatic exocrine function (2, 3).

ERCP represents at present the most sensitive imaging procedure for detecting early and minimal ductal abnormalities in chronic pancreatitis. However, it is an invasive procedure, actually almost completely replaced by MRCP. The earliest signs of chronic pancreatitis are observed in side branches of pancreatic duct and include dilatation with or without stenosis, intra-luminal mucosal irregularity and intra-luminal filling defects due to protein plugs or calcifications. The number of opacified side branches may be reduced because of ductal occlusion. In advanced disease, ductal changes involve also the main pancreatic duct. In the pancreatic parenchyma small cavities may be observed. Occasionally, contrast material may fill large pseudocysts *via* fistulous communications. Common bile duct may be involved in chronic pancreatitis; the most common finding is a long smooth narrowing with gradual tapering due to periductal fibrosis. Pancreatic juices can be collected for laboratory analysis and cytology brushings can be performed, to differentiate between focal chronic pancreatitis and pancreatic cancer (2, 3).

Angiography is reserved for patients with suspected vascular complications resulting from chronic pancreatitis. The major vessels around the pancreas may be involved. Pseudoaneuysms of the intra-pancreatic and peripancreatic arteries or dilated segments alternating with narrowing can be depicted and, if necessary, treated. Venous compression or thrombosis, particularly in the splenic vein, represents a possible angiographic finding (2, 3).

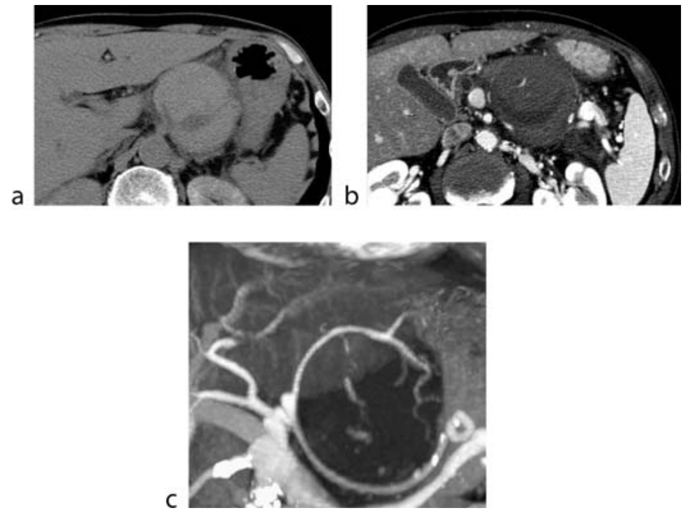
Nuclear Medicine

Positron emission tomography (PET) is able to differentiate focal chronic pancreatitis from pancreatic malignancy, thanks to the absence of FDG uptake in inflammatory lesions. Carbon-11-acetate can also be employed for the PET evaluation. The normal pancreas demonstrates prompt uptake of carbon-11-acetate and is visualized as early as 2 min post-injection, with maximal activity achieved by 5 min. Pancreatic uptake is absent in chronic pancreatitis complicated by exocrine insufficiency. Moderately reduced uptake can be observed in focal chronic pancreatitis whereas pancreatic cancer demonstrates no significant uptake.

Diagnosis

The diagnosis of chronic pancreatitis is obvious in advanced phases with typical clinical, laboratory and imaging features. However, most patients present with pain only and in this case cancer of the pancreas, biliary, colic, gastric or duodenal ulcer must be excluded. First of all, an accurate medical history is fundamental. There are also many laboratory tests that can be used for chronic pancreatitis: serum amylase and lipase levels may show elevations but can normalize in advanced disease when a loss of pancreatic function occurs. Tests for diabetes, fecal fat and chymotrypsin test together with secretin test may assess a pancreatic endocrine and exocrine dysfunction.

The critical issue is the differential diagnosis between focal chronic pancreatitis and pancreatic carcinoma. Both carcinoma and inflammatory mass may present with back pain and weight loss; when the lesion involves the head of the pancreas, jaundice is also a presenting feature. If the inflammatory masses arise in the early stages of chronic pancreatitis when the characteristics imaging findings are absent, the differential diagnosis is challenging. Further complicating factors arise in patients in whom carcinoma may obstruct pancreatic ducts, leading to pancreatic inflammatory reaction.



Pancreatitis, Chronic. Figure 3 Multidetector CT study of a bleeding pseudocyst in chronic pancreatitis. The pseudocyst of the tail is hyperdense at baseline CT scans, due to hemorrhage (a). The bleeding was due to the erosion of the vascular wall of a branch of the left gastric artery as depicted in arterial axial (b) and maximum intensity projection reconstructed (c) images.

At CT examination, both carcinoma and chronic pancreatitis are typically hypovascular. The CT finding of pancreatic calcifications do not exclude pancreatic cancer, since there may be a tumour in co-existing chronic pancreatitis. MR may in some cases help the differentiation, because a signal intensity diminished but equal to or greater than that of the liver on T1-weighted fat-suppressed spin-echo images can suggest a benign inflammatory lesion, whereas carcinoma is often hypo-intense to liver. At MRCP examination, the neoplastic lesion does not contain pancreatic ductal structures, whereas focal pancreatitis may display dilated side branches.

In general, differentiation between cancer and focal pancreatitis is difficult with a single imaging modality and may sometimes require the use of contrast-enhanced CT, MR, PET examination, biopsy and eventually the surgical inspection.

Interventional Radiological Treatment

In chronic pancreatitis vascular arterial complications can occur, such as pseudoaneurysm. The majority of pseudoaneurysms occur in association with pancreatic pseudocysts, which can gradually erode the vascular wall of the adjacent vessels (Fig. 3). The more commonly involved vessels are the splenic artery, the gastroduodenal artery, the pancreatic-duodenal arcades and the left gastric artery. Angiography therefore plays role for treating lesions by means of embolization.

Patients with acute biliary obstruction can be treated by using temporary biliary stents, whereas established biliary strictures in end-stage of chronic calcific pancreatitis usually do not respond to endoscopically placed stents.

Pancreatoblastoma

Pancreatoblastoma is an extremely rare carcinoma of the pancreas, which usually occurs in children younger than 15 years of age. The tumor is usually surrounded by a fibrous capsule. Typical microscopic findings include nests of squamoid cells separated by dense fibrous stroma on a background of uniform, undifferentiated cells. Imaging reveals a well-demarcated solid and often multilobulated tumor that may contain fine calcifications. Due to the large size at diagnosis, there are often cystic components with hemorrhagic necrosis and degeneration within the tumor. Metastases to the liver and lymph nodes can be present at diagnosis. Elevated serum alpha-fetoprotein levels are reported in one fourth to one third of patients. The survival rate after resection is better than adenocarcinoma.

Parametric Imaging

The visualization of a (semi)-quantitative parameter value in its spatial distribution. In contrast-enhanced ultrasound, it can provide a particularly user-friendly presentation of information derived from complex perfusion examinations.

▶Time Intensity Curves

Paraneoplastic Syndromes

Paranesplastic Syndromes of lung cancer are extrapulmonary, remote effects of the tumours. They lead to metabolic and neuromuscular disturbances unrelated to the primary tumour or metastases. They may be the first sign of occurrence or recurrence, but they do not necessarily indicate that a tumour has spread outside the chest. In hypertrophic pulmonary osteoarthropathy clubbing of the fingers and toes and periosteal elevation of the distal parts of long bones occur. All levels of the nervous system may be affected principally causing encephalopathy, subacute cerebellar degeneration, encephalomyelitis, the Eaton–Lambert syndrome and peripheral neuropathy. Polymyositis and dermatomyositis or metabolic syndromes due to production of substances with hormonal activity may develop. Small cell carcinomas may secrete ectopic ACTH, resulting in Cushing's syndrome or ADH, causing water retention and hyponatremia, and are also associated with the carcinoid syndrome (flushing, wheezing, diarrhoea and cardiac valvular lesions). Squamous cell carcinomas may secrete parathyroid hormone-like substances that produce hypercalcemia. Other endocrine syndromes associated with primary lung carcinomas include gynecomastia, hyperglycaemia, thyrotoxicosis and skin pigmentation. Haematologic disorders, including thrombocytopenic purpura, leukaemoid reaction, myelophthisic anaemia, polycythemia and marantic thrombosis, may also occur.

▶Neoplasms, Pulmonary

Paraoesophageal Varices

Terminology used to describe varices located adjacent to but outside the oesophageal wall. Normally co-exist with intramural oesophageal varices.

▶Varices, Oesophagus

Parapneumonic Effusion

A pleural effusion associated with pneumonia, lung abscess or bronchiectasis. Not all parapneumonic processes are empyemas.

▶Pleural Effusion

Parasitic Cyst

Parasitic cyst is extremely uncommon and is usually identified as a hydatid cyst. Echinococcus granulosus cysts may be unilocular, multilocular, or complex. Echinococcus multilocularis cysts may show an infiltrative aspect. On imaging alone, differentiation between hydatid and other cystic lesion is difficult; serologic tests may be useful in the appropriate clinical setting.

▶Cystic Neoplasms, Pancreatic

Parasyndesmophytes

Intervertebral and paravertebral osteophytes with characteristic appearance seen in psoriatic spondyloarthropathy. Three morphological types are distinguished: (i) bull-horn intervertebral osteophyte, which is the most common type and which has to be differentiated from degenerative disease, (ii) paravertebral ossicle, and (iii) paradiscal ossicle. In known psoriatic spondyloarthropathy the diagnosis is easy, but without it, it is not very specific.

Pediatric Radiology

Pediatric radiology is one of the recognized subspecialty areas of radiology. In the last decade remarkable advances in the ability to vividly image both normal and abnormal anatomic and functional aspects have been accomplished. Various imaging modalities, such as ultrasonography, projection radiography, computed tomography, magnetic resonance imaging, angiography, and nuclear medicine examinations are applied to children. Technology and techniques must be tailored with respect to their particular advantages and disadvantages related to their properties and to the specific requirements of children. Not only anatomy and physiology differ from the adult situation; there are also specific pediatric diseases and conditions, congenital malformations, and problems in ▶neonates and preterm babies. Furthermore, fetal imaging is gaining importance and is being again introduced more and more into pediatric radiology in terms of ▶fetal MRI. Further specific adaptations of imaging protocols and techniques are essential to reduce ▶radiation hazards to neonates, infants, and children. Additionally, pediatric radiology tries to promote and use nonionizing ▶imaging techniques leading to different imaging algorithms compared to adult radiology. This entry tries to include all relevant aspects of pediatric radiology from head to toe focusing on those conditions that significantly differ from imaging in adults.

The utility and limitations of modalities will be presented for each particular disease and clinical situation enabling a profound knowledge and understanding much easier than by retrieving the respective information. Perception, understanding, and interpretation of imaging findings require a profound knowledge of anatomy throughout childhood as well as of physiology of growth with consecutive changing imaging patterns during growth. And it requires a profound knowledge of pathology and pathophysiology of neonatal and pediatric diseases, as well as the recognition of the broad range of normal variants; as such radiological–pathological as well as structural–functional correlations are important.

Pediatric radiology includes two major areas: imaging of congenital diseases and malformations and assessment of acquired disease. These two groups all comprise the various anatomical systems such as the ▶musculoskeletal system (including small part diseases), the ▶cardiovascular system, ▶chest and the respiratory tract, ▶the gastrointestinal tract, the ▶urinary and the ▶genital and tract, the central and peripheral nerve system, the ▶endocrine organs, and—mostly congenital—systemic diseases. Additionally, imaging plays a major role for diagnosis, treatment, and monitoring of critically ill neonates and children, also including pediatric ▶extracorporeal membrane oxygenation (ECMO).

Interventional procedures such as diagnostic punctures or therapeutic drainages often require image guidance particularly in children in order to reduce risks and complications. And various etiologies have to be considered, part of them are more important than in adults (e.g., inborn errors of metabolism), some have different manifestations, patterns and clinical symptoms or locations: infective disease, toxically induced conditions, trauma [including ▶battered child syndrome and birth complications], genetic and congenital or metabolic disorders, ▶tumors and malignancies, disorders of growth and development, and deregulations.

Assessment of regular anatomy and abnormalities requires the knowledge of normal variants and physiologic changes during growth and maturation as well as their imaging appearance on the different modalities. It is important to recognize normal characteristics, structures, and patterns, which can be solitary, multiple, or disseminated. Individual findings on imaging studies can represent signs or a complex pattern of signs, which are related to certain anatomic-pathologic substrates. The way to diagnosis is based on a standardized process of pattern analysis and taking into consideration patient history and clinical data. The mentioned analysis of imaging findings with regard to size, number, morphology, localization, distribution, contrast dynamics and perfusion, and correlation to age and development is the prerequisite for any profound radiological diagnosis. However, the radiological patterns reflect the macroscopic consequences of any disease, and are just a "snap shot" at a certain stage of an age correlated disease process. This aspect is particularly important in children, as we often observe very early stages of diseases and/or a certain phase of an evolutionary process, which changes with growth and development. Additionally—due to the specific conditions particularly in early childhood—(modern) ultrasound plays a much more important role in imaging diagnostics in many body compartments, whereas CT is used more reluctantly; thus imaging approaches that are valid and established in adults do not necessarily apply for children.

Finally a specific aspect of pediatric radiology must be mentioned—its importance in recognition and diagnosis of child abuse and ▶battered child syndrome/non-accidental injury (NAI). The specific imaging features potentially enable early life saving recognition and intervention putting additional burden and responsibility on the radiologist who not only has to consider the individual small patients, but often has to deal with the entire family and their fears and expectations.

As such, in summary, the task of pediatric radiology—additional to the general purpose of radiology—is to establish a diagnosis as early as possible in order to prevent permanent damage. This aim may be difficult to achieve by modalities that focus mainly on visualization of structure, anatomy, and morphology. Thus functional and molecular imaging aiming at evaluation of disease activity, vascularization, blood flow, and perfusion, or visualization of metabolic processes is gaining importance also in pediatric radiology, however, with yet limited clinical application only in some entities and body areas in routine of pediatric imaging.

Peliosis Hepatis

Hepatic peliosis is an uncommon benign pathological entity characterized by focal, multifocal, segmental, or diffuse dilatation of liver sinusoids. It often occurs in patients treated with anabolic steroids, corticosteroids, or oral contraceptives and a frequent association with chronic wasting diseases has also been reported. Hepatic peliosis is usually asymptomatic and focal liver lesions are discovered incidentally. Imaging findings in peliosis hepatis are variable and often nonspecific. On US, numerous poorly defined foci of varying hypoechogenicity may be usually observed. Multiple small hypodense hepatic lesions with slight peripheral enhancement represent the most common findings on contrast-enhanced CT, while the hepatic foci in peliosis hepatis show a high signal on T2-weighted MR images and a variable signal on T1-weighted images, presumably reflecting various stages of subacute hemorrhage.

Synonyms

Anismus - spastic pelvic floor syndrome - diskinetic puborectalis muscle - pelvic floor dyssynergia; Conventional defecography - evacuation proctography; Fecal incontinence - anal incontinence; Internal rectal prolapse – intussusception; Outlet obstruction syndrome - obstructed defecation; Posterior rectocele - posterior perineal hernia.

Definition

Pelvic floor dysfunction is represented by a group of conditions associated with anatomic and functional abnormalities of pelvic structures. The anorectal manifestations of these dysfunctions are responsible for two major syndromes: ▶fecal incontinence and ▶outlet obstruction syndrome. Fecal or anal incontinence is defined as an involuntary loss of rectal content at a socially inappropriate time or place of at least 1 month in duration in an individual with a developmental age of at least 4 years. Outlet obstruction syndrome, also called obstructed defecation, is characterized by incomplete evacuation of fecal contents from the rectum.

Although a detailed clinical examination still represents the cornerstone of diagnosis in these patients, imaging techniques are decisive for reliably evaluating anorectal functional and anatomic disorders, which include ▶anal sphincter weakness or defect, ▶anterior rectocele, ▶enterocele, ▶rectal prolapse, ▶rectal descent, and ▶anismus. Moreover, treatment decisions highly depend on the imaging assessment.

Pathology/Histopathology

In patients with anorectal dysfunctions, functional and structural abnormalities of the posterior pelvic compartment lead to fecal incontinence or outlet obstruction. Within the anorectum there are a number of structures responsible for normal evacuation, including the internal and external anal sphincters, the puborectalis muscle, the anal canal, and the rectum, as well as the pudendal and sacral nerves. Anorectal dysfunction can result from impairment of any of these structures. Obstetric trauma and anal and pelvic surgery (such as hemorrhoidectomy and low anterior rectum resection) are closely correlated with anal sphincter injuries, enterocele formation, and rectal descent. A weakness of the rectovaginal septum is probably responsible for rectocele formation. The insufficient septum can be congenital, or it can occur after tearing caused by excessive straining at defecation, hysterectomy, or complicated vaginal delivery. However, in most cases the etiology is multifactorial, and the presence of an isolated pelvic floor abnormality is unusual. Anismus, internal rectal prolapse, rectocele, and enterocele are often combined. Moreover, it is well known that the posterior compartment dysfunctions are often accompanied by middle and anterior pelvic compartment disorders (1).

Clinical Presentation

The clinical examination and history is the cornerstone of obtaining an accurate diagnosis in patients with anorectal dysfunction. Fecal incontinence is a significant disability that affects quality of life and can lead to social isolation. The true prevalence is not well known. It increases with age, from approximately 4% in the fifth decade of life to 11% in patients aged 80 years and older. Several etiological factors that may cause fecal incontinence have been reported. Congenital malformations, such as anorectal agenesis, can cause fecal incontinence in children. A greater proportion of adult patients suffering from fecal incontinence have acquired the condition. Sphincter defects resulting from complicated vaginal delivery or anorectal surgery are the most common type of sphincter injury. Diabetes mellitus, dementia, and pudendal neuropathy are examples of neurological causes leading to fecal incontinence. In most patients, a combination of several factors contributes to the emergence of fecal incontinence.

Although an international consensus regarding symptom evaluation and scoring does not yet exist, most clinicians use the Wexner score to assess the severity of fecal incontinence.

In chronically constipated patients, it is important to differentiate between slow transit constipation and outlet obstruction. Slow transit constipation is represented by delayed transit throughout the colon and is associated with a reduced number of propagating contractions. Outlet obstruction syndrome is present in half of constipated patients and is the result of pelvic floor dysfunction. Patients present with difficulty in rectal evacuation, and the symptoms may vary from the feeling of incomplete evacuation to a severe obstruction. In some cases, such as in the presence of an anterior rectocele, digital maneuvers are needed for a complete evacuation.

Imaging

Different imaging modalities are used for assessing patients with posterior pelvic floor dysfunctions, including endoanal ultrasonography, conventional defecography, and magnetic resonance imaging (MRI). The choice of imaging technique depends on the etiological factor, patient symptoms, physical examination, and technique availability.

Endoanal Ultrasonography

Endoanal ultrasonography is routinely used for assessing anal sphincter anatomy in patients with fecal incontinence. The technique enables evaluation of the structural defects or degeneration of the internal and external anal sphincters and can diagnose lesions that were undetected at physical examination. Radial endoscopic probes with either 7-MHz or 10-MHz frequency are used with similar results. The probe is covered by a plastic cone 15–17 mm in diameter, which enables high-quality images. The procedure is rapid, minimally invasive, and without radiation exposure. Moreover, a high sensitivity and specificity of endoanal ultrasonography for evaluating the anal sphincter has been reported compared with surgery. Isolated external sphincter tears are much harder to recognize because of the mixed echogenicity of the external sphincter. The disadvantages are interobserver variability and difficulty in imaging deep pelvic structures. However, the new generation of three-dimensional endoanal ultrasonography allows an observer-independent more specific diagnosis in structural sphincter defects.

Conventional Defecography

Conventional defecography or evacuation proctography is the most commonly used imaging technique for evaluating patients with anorectal dysfunction. The examination is usually performed without bowel preparation. The rectum is opacified using an enema of thickened barium suspension, and the patient is imaged in a seated position on a radiolucent commode. Images are obtained at rest, at squeezing, at straining, during evacuation, and after evacuation. This technique enables evaluation of the anorectal disorder, but it provides no information regarding other pelvic floor organs. Since it was demonstrated that posterior compartment changes are often accompanied by middle and anterior pelvic compartments disorders (1), some authors have proposed opacifying the small bowel as well as instilling contrast into the bladder and vagina to obtain more information about these structures.

This technique has some limitations. The irradiation is significant because fluoroscopic X-ray proctography produces a mean effective dose of up to 4.9 mSv. Moreover, the technique is limited by its projectional nature (2) and its inability to accurately assess the pelvic organs.

Endoanal Magnetic Resonance Imaging

MRI using an endorectal coil is an accurate technique for evaluating the normal anatomy and pathological conditions of the internal and external anal sphincters. This method provides high-contrast images and excellent spatial resolution. T1- and T2-weighted sequences are used in transaxial, sagittal, and coronal planes with respect to the axis of the endorectal coil. Endoanal MRI has proved to be superior to endoanal ultrasonography for evaluating the external sphincter (3).

Dynamic Pelvic Magnetic Resonance Imaging

Dynamic pelvic MRI is a noninvasive method that enables an overall view of all pelvic structures. The free selection of imaging planes, the good temporal resolution, and the excellent soft-tissue contrast have transformed this method into the preferred imaging modality for evaluating patients with pelvic floor dysfunction (4). Dynamic pelvic MRI can be done in either a closed-configuration MR system with the patient in supine position or an open-configuration MR system with the patient in sitting position. It has been shown that no clinical significant finding was missed when comparing dynamic pelvic MR in supine position with dynamic pelvic MR in sitting position (5). There is general agreement that neither premedication nor oral or intrarectal preparation for bowel cleansing is necessary when dynamic pelvic imaging is performed. Before examination, the rectum is filled with a contrast agent, of which the viscosity should be similar to that of normal rectum content because the manifestations of anorectal disorders may vary with fecal consistency. Ultrasound gel or mashed potatoes spiked with a small amount of gadolinium chelate (2, 5) are used for the rectal enema. Some authors have proposed tagging the middle compartment (i.e., the vagina) and/or the anterior pelvic compartment (i.e., the bladder) to clearly delineate these compartments (1). In our experience, there is no need for contrast agent administration either in the vagina or in the bladder because MRI allows easy identification of all the anatomic structures of the three pelvic compartments. However, it is of outmost importance to perform the examination at rest, at maximal contraction of the anal sphincter (squeezing), at straining, and during evacuation because relevant findings may be missed when dynamic pelvic MRI does not encompass all of these phases. For dynamic MRI, various sequences can be used with similar results: T2-weighted single-shot fast spin-echo sequences (SSFSE) or steady-state free precession (SSFP) sequences in the midsagittal plane at rest, at squeezing, at straining, and during defecation. When ultrasound gel or mashed potatoes mixed with a small amount of gadolinium chelate is used as an enema, a T1-weighted multiphase gradient-recalled echo (GRE) sequence should be used because this sequence offers an imaging window long enough for continuous imaging of the evacuation, even in patients with prolonged evacuation time (4).

Diagnosis

In patients with pelvic floor dysfunction, the diagnosis is the result of a detailed clinical examination, anorectal physiology tests (anorectal manometry, electromyography), and imaging assessment. The imaging evaluation provides detailed information regarding the functional and anatomic abnormalities, contributes to the clinical diagnosis, and influences the treatment strategy.

Anal Sphincter Weakness

Anal sphincter weakness is defined as reduced anal resting and/or squeeze pressure, having as a result a recurrent uncontrolled passage of fecal material. The cause is either a well-defined lesion of the anal sphincters or a primary degeneration and weakness of the anal sphincters without structural damage. The diagnostic tests include anal manometry, pudendal nerve latency, and endoanal ultrasonography. Although the incontinence is attributable to a combination of pelvic floor disorders, anal sphincter injuries represent the most important cause of fecal incontinence.

Endoanal ultrasonography has proved to be more accurate than manometry for characterizing anal sphincter defects. The technique identifies the location and extent of sphincter injuries and permits a correct assessment for surgical treatment and follow-up. The internal sphincter appears as a ring of low reflectiveness, and any disruption is indicative of an injury. Endosonography reveals internal sphincter degeneration as a thin and hyperechogenic ring with a poorly defined edge. The external sphincter is more difficult to assess because of its fibrillar structure and the low image contrast.

The anal sphincter complex may also be imaged using endoanal MRI, which has proved superior to endoanal ultrasonography for external sphincter evaluation. It has been demonstrated that if only one technique is to be used, MRI findings result in the optimal surgical decision (3).

Anismus

Anismus is an abnormal activity of pelvic floor musculature that results in outlet obstruction characterized by difficulties in rectal evacuation. In the literature, anismus is also known as spastic pelvic floor syndrome (2), dyskinetic puborectalis muscle, or pelvic floor dyssynergia. The obstruction is caused by paradoxical contraction or insufficient relaxation of the puborectalis or external sphincter muscles, and in most cases, these dysfunctions are not confined to a single muscle. The diagnosis is based on anorectal manometry, balloon expulsion, electromyography, and dynamic pelvic imaging (conventional defecography or dynamic MRI). Although various imaging findings have been described in patients with anismus, the best single finding of the functional outlet obstruction is represented by a prolonged attempted defecation and incomplete evacuation (4). An evacuation time longer than 30 s is highly suggestive for anismus, having a positive predictive value of 90%. Another imaging parameter that has been extensively used for diagnosing anismus is the anorectal angle. However, data in the literature show that the configuration of the rectum and anorectal junction is irrelevant to the diagnosis and that this finding cannot differentiate patients with anismus from asymptomatic subjects.

Rectocele

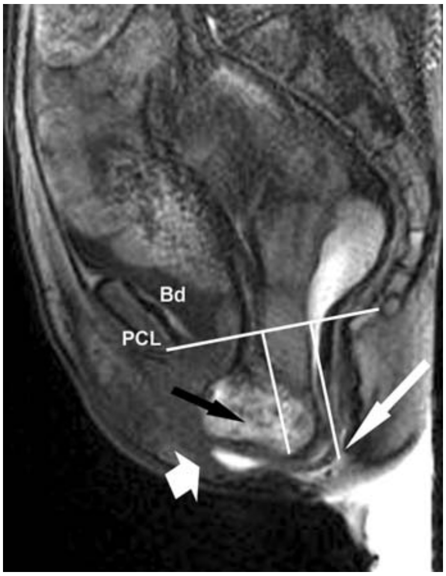
A rectocele is defined as a rectal wall protrusion or bulging during defecation. The anterior wall is most commonly involved, but a rectocele may also be located in the posterior rectal wall. Posterior rectoceles are also referred to as posterior perineal hernia by some authors, based on the fact that the bulging is through a puborectalis muscle defect. Most of the rectoceles are diagnosed during physical examination, but reliable classification with regard to the size, emptying, and associated abnormalities is provided only by imaging examinations. With dynamic pelvic imaging, an anterior rectocele can be classified with regard to its size, expressed as the depth of wall protrusion beyond the expected margin of the normal anterior rectal wall, into small (< 2 cm), moderate (2–4 cm; Fig. 1), and large (> 4 cm) (2). In addition, rectoceles are classified into those with complete evacuation and those with incomplete evacuation (Fig. 1), depending on the presence or absence of contrast material retention at the end of defecation. A clinically significant rectocele should be considered based on the following criteria: patient history, size exceeding 2 cm in sagittal diameter, retention of contrast medium, reproducibility of the patient's symptoms, and the need for evacuation assistance.

Rectal Prolapse

Rectal prolapse is an invagination of the rectal wall and may be classified as internal or external (1). Internal rectal prolapse, also called intussusception, may be classified as intrarectal internal prolapse if the invagination is confined to the rectum or as intraanal internal prolapse if its apex penetrates the anal canal and remains in it during straining (Fig. 2). External rectal prolapse is an invagination of the rectal wall through the anal canal (Fig. 3) and is a clinical diagnosis. Regardless of its extension, internal rectal prolapse may involve all rectal wall layers (full-thickness prolapse; Fig. 2) or only the mucosa (mucosal prolapse) (2). Dynamic MRI is superior to conventional defecography for diagnosing internal rectal prolapse because it enables differentiation between a mucosal internal prolapse and a full-thickness internal prolapse. These two types of rectal prolapse have different treatment strategies.

Enterocele

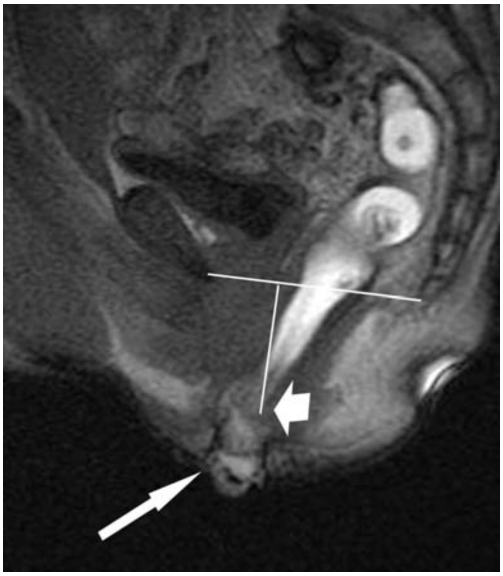
An enterocele is an internal herniation of the peritoneal sac into the rectovaginal space below the pubococcygeal line (PCL). The PCL is used as the reference line for quantifying various abnormal findings of the pelvic floor, including quantification of the severity of an enterocele and the severity of pelvic floor descent. The PCL is defined as the line that joins the inferior border of the symphysis pubis to the last coccygeal joint on midsagittal images (Fig. 1). Enteroceles most frequently occur at the end of evacuation and can be filled with omental fat (peritoneocele), small bowel (enterocele), or sigmoid colon



Pelvic Floor Dysfunction, Anorectal Manifestations. Figure 1 A 63-year-old woman with fecal incontinence and diffuse pelvic pain after hysterectomy. A T1-weighted spoiled gradient-recalled echo magnetic resonance (MR) image obtained during evacuation (patient in supine position in a closed-configuration MR system) shows a moderate anterior rectocele with incomplete evacuation (*small arrow*). The anorectal junction is below the ►pubococcygeal line (PCL), with formation of a moderate rectal descent (*large arrow*). In addition, the patient has a moderate sigmoidocele (*black arrow*). The bladder (Bd) is in the normal position.

Pelvic Floor Dysfunction, Anorectal Manifestations. Figure 2 A 25-year-old man with chronic constipation and incomplete evacuation. A sagittal T1-weighted spoiled gradient-recalled echo magnetic resonance image with the patient in sitting position obtained during defecation shows a full-thickness intraanal rectal prolapse (*large arrow*). The anorectal junction (*small arrow*) is below the pubococcygeal line, with formation of a moderate rectal descent.

P



Pelvic Floor Dysfunction, Genitourinary. Figure 3 A 49-year-old man with incomplete evacuation. A sagittal T1-weighted spoiled gradient-recalled echo magnetic resonance image obtained during defecation with the patient in sitting position shows a full-thickness external rectal prolapse (*large arrow*). In addition, the patient presents a moderate rectal descent (*small arrow*).

(sigmoidocele; Fig. 1). While most enteroceles spontaneously disappear at rest, only a few are fixed down at the rectovaginal space. The extent of an enterocele is measured 90° to the PCL from the lowest margin of herniation content during evacuation and is classified as small if it extends less than 3 cm below the PCL, moderate if it extends from 3 to 6 cm below this line, and large if it extends 6 cm or more below this line.

Rectal Descent

Rectal descent is an excessive caudal movement of the anorectal junction during evacuation. Pelvic floor descent is a common finding in patients with fecal incontinence and outlet obstruction. Although the clinical examination and electrophysiological tests play a significant role in diagnosis, dynamic pelvic MRI provides the most accurate assessment of pelvic floor descent. Rectal descent is usually associated with descent of the middle and anterior pelvic compartments. MRI enables evaluation of all three pelvic compartments (posterior, middle, and anterior) in a manner superior to conventional defecography (4). The grading of the rectal descent is assessed with respect to the PCL (5). A rectal descent is considered small when the anorectal junction is less than 3 cm below the PCL, moderate when the distance between the anorectal junction and PCL is between 3 and 6 cm (Fig. 1), and large when the distance between the anorectal junction and PCL is more than 6 cm (5).

Cystoceles are expressions of the descent of the anterior compartment, and descent of the vaginal vault (or any part of the remaining cervix in the case of hysterectomy) represents descent of the middle compartment. The descent of these compartments is quantified in a similar fashion as described for rectal descent.

Pelvic Floor Dysfunction, Genitourinary

THOMAS C. TREUMANN
Kantonspital Luzern, Luzern, Switzerland
thomas.treumann@ksl.ch

Definition

Pelvic floor dysfunction describes a wide range of problems of the three organ systems passing the pelvic floor: the urinary system, the genital system, and the colorectal system. It is associated with pelvic floor weakness or with organic or functional neuromuscular disorders.

Conditions may include pelvic floor pain, urinary incontinence, bowel incontinence, stool outlet obstruction, pelvic organ descent, pelvic organ prolapse, and pelvic floor dyssynergy or spasm.

Pathology

Anatomically, the pelvic floor is formed by the genitourinary diaphragm and the levator ani muscle. The two parts of the levator ani muscle are the puborectalis muscle sling and the iliococcygeus muscle. The puborectalis muscle sling originates from the posterior surface of the pubic symphysis and goes around urethra, vagina, and anus. Urethra, vagina, and anal canal pass the pelvic diaphragm within the midline. Contraction of the muscle pulls the rectum toward the symphysis and closes urethra, vagina, and rectum. Weakness of this muscle causes laxity of the genitourinary hiatus.

The iliococcygeus muscle plates originate at the genitourinary diaphragm and insert at the lateral inner surfaces of the pelvis. Contraction of this muscle elevates the pelvic floor. Weakness of this muscle leads to descent of the pelvic floor.

Pelvic floor dysfunction is a disease of elderly female patients. The underlying cause for incontinence and organ prolapse is pelvic floor laxity, usually resulting from compromised levator ani and puborectalis muscle function and endopelvic fascia laxity and fascia defects. Predisposing factors are multiple childbirths, vaginal delivery, menopause, age, hysterectomy, and inherited connective tissue laxity from collagen defects.

The cause of urinary incontinence is not fully understood. Incontinence correlates with obesity and smoking, and only to a lesser extent with pelvic floor laxity and bladder neck hypermobility. The normal process of urination involves coordination between the bladder and pelvic floor muscles; the pelvic floor muscles relax whereas the bladder contracts. In most patients, the bladder contracts normally but the urine flow is poor due to continued tightening of the pelvic floor. The sensation of urinary frequency and urgency seem to be linked to pelvic floor laxity. The natural tendency for many patients is to strain and push the last drop of urine out so they can prolong the intervals between bathroom sessions. Unfortunately, pushing and straining appear to further damage the pelvic floor muscles and worsen the symptoms. Hence, a vicious cycle develops.

Pelvic organ descent and prolapse is the result of laxity of the connective tissues in the pelvis, especially defects in the lateral fascial bands of the endopelvic fascia between the vagina and lateral pelvic wall, and defects in the rectovaginal septum. Hysterectomy seems to be a risk factor for pelvic organ descent.

Organ descent develops during Valsalva maneuver, voiding, and defecation. Descent of the posterior bladder wall below the internal urethral orifice is called a ►cystocele. Bulging of the rectum toward the posterior vaginal wall is called a ►rectocele. An ►enterocele is the descent of the peritoneal sac between vagina and rectum down to the level of the perineum with bulging of the posterior vaginal wall. An enterocele may follow a rectocele after defecation (Fig. 1).

A cystocele Grade II leads to impression of the vaginal wall inside the vagina. A cystocele grade III everts part of the vaginal wall to below the introitus. Rectoceles and enteroceles are graded similarly. Descent of the uterus can be quantified by measurement of the change of the vaginal length during Valsalva. Prolapse of the uterus begins with descent of the portio below the introitus.

Enterocele (E) between rectocele and posterior vaginal wall (*black arrow*). Partial prolapse of the posterior vaginal wall (*white arrow*) as result of the enterocele. S is the sigmoid colon, A is the anus, U.bl. is the urinary bladder, and Ur is the urethra.**

Stool outlet obstruction may be caused by two conditions: pelvic floor laxity and pelvic floor dyssynergy.

Pelvic floor laxity can lead to descent of the peritoneal sac or uterus and to compression of the rectum by these organs. A large rectocele can retain stool. Compression of a rectocele by the peritoneal sac may intussuscept the anterior rectal wall into the anal canal. Detachment of the rectum from the sacrum in pelvic floor descent may lead to intussusception of the rectum in itself.

In dyssynergy, the pelvic floor contracts during pressure raise in the abdomen. In anism, the anal sphincter is spastic and hypertrophies. This may be a behavioral problem or may be part of an organic neurologic pathology, such as Hirschsprung's disease. Damage to the nerves in the pelvis and pelvic floor can be a result of pelvic floor laxity with permanent stretching of the nerves.

P

Clinical Presentation

Symptoms associated with anterior compartment may be ►stress urinary incontinence, urinary urgency with increased frequency of urination and decreased urinary flow, and sensation of incomplete urination with residual bladder volume.

In genital descent, patients may present with protrusion of parts of the anterior vaginal wall by a cystocele or of the posterior vaginal wall by a rectocele or enterocele. Protrusion may go as far as complete prolapse and eversion of the vagina to the outside. Descent and prolapse may occur only during straining, or it may be fixed with permanent vaginal prolapse. If the uterus is still present, the portio may descend down to the pelvic floor, or the uterus may protrude partially or completely to outside the body. In the posterior compartment, rectal mucosa prolapse or rectal wall prolapse may develop in patients with functional disorders with permanent high-pressure defecation. Muscular spasm causes pelvic floor pain.

In stool outlet obstruction by rectal descent and intussusception, the patient complains about defecation in small fractions. Large rectoceles with retention of bowel content raise the need to digitize from the vagina to empty the rectocele. In anisms or dyssynergy, defecation needs high intraabdominal pressure, and the defecation process is prolonged.

Imaging

Ultrasound is usually performed by the gynecologist as part of the diagnostic work-up of stress urinary incontinence and genitourinary prolapse. It allows for the morphological and dynamic assessment of the lower urinary tract. Transvaginal ultrasound enables the detection of pathologies of the bladder and uterus. Introital ultrasound can detect urethral diverticula, periurethral masses, funneling of the urethra and cystoceles. Color Doppler may be used to document stress urinary incontinence. Translabial ultrasound detects defects in the rectovaginal septum and helps to identify rectoceles.

Roentgen colpocystodefecography is the original imaging method to evaluate pelvic floor descent. It requires filling of the urinary bladder, vagina, rectum, bowel, and peritoneum with roentgen contrast medium and is associated with a high-dose radiation exposure. The method is now replaced by MRI.

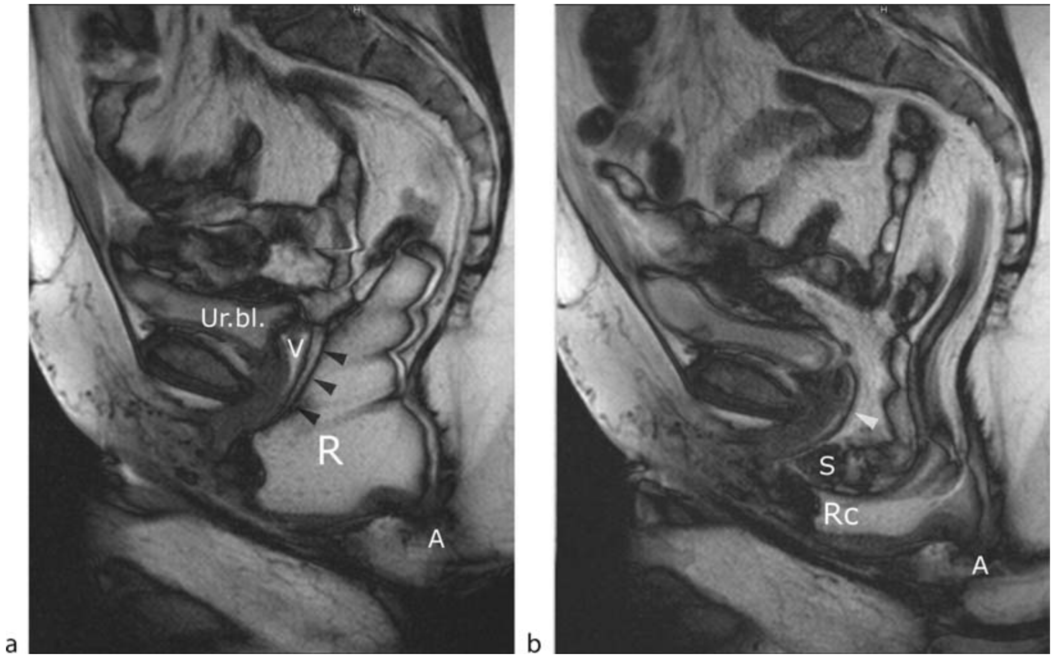
MRI of the pelvic floor is performed as a combination of static and dynamic sequences. Static MRI is done with T2-weighted images of the pelvis in three imaging planes. These images give an overview of the pelvic organs and the pelvic floor muscles in the resting position. T1- or proton density images may be used for the pelvic floor muscles additionally.

Dynamic MRI is performed with repetitive fast single shot T2-weighted images. Best contrast-to-noise, excellent T2 contrast, and shortest acquisition times are provided by True FISP sequences. Acquisition times of 0.5 to 0.7 sec per image can be achieved with a 1 mm in plane resolution. Parallel imaging can even shorten the imaging time. A delay of 0.1 to 0.2 sec between should be left between images to reduce signal loss by spin saturation. Alternatively, half Fourier single shot turbo spin echo (HASTE) sequences can be used, but are not as fast as True FISP. T2-weighted imaging requires filling of the vagina and the rectum with watery contrast material. Ultrasound gel is recommended. The patient should empty the bladder before going into the magnet. Normal urine production leads to sufficient opacification of the bladder during investigation (Fig. 2).

A repetitive single slice in the mid sagittal plane of 10 mm thickness is acquired during pelvic floor contraction and Valsalva maneuver with defecation. For contraction series, we use 30 images per series, for Valsalva and defecation, 80 to 100 images are required. The series is repeated as often as necessary to see best contraction and relaxation and maximum descent of pelvic floor, best relaxation of levator ani and puborectalis muscle, maximum organ descent and organ prolapse and complete emptying of the rectum. The investigation is performed in supine position of the patient, with the knees slightly flexed and thighs abducted. The patient is equipped with a pampers. Studies have shown that no relevant pathology is missed in supine position compared to upright position.

MR images are evaluated qualitatively and quantitatively. We recommend to use the HMO-system introduced by Comiter et al in 1999. Pelvic floor laxity is described by the length of the Hiatus line from the posterior border of the pubic symphysis to the sling of the puborectalis muscle behind the anorectal junction. Normal range is 7±1.5 cm. Pelvic floor descent is described by the position of the puborectalis muscle sling in relation to the pubococcygeal line (PCL). Normal range is between 4 and 6 cm (Fig. 3).

Organ descent is seen directly on the MR images and can be graded according to the description in the pathology section. Organ descent can be measured in relation to the Hiatus line. Mobility of the bladder neck can be quantified using the rotation angle of the long axis of the urethra. The pathologic threshold is not clearly defined, but the 30° rotation, adapted from the ►Q-tip test, seems to be oversensitive. A rotation of more than 90° or beyond the horizontal plane is definitely abnormal.



Pelvic Floor Dysfunction, Genitourinary. Figure 2 **Midsagittal T2-weighted MR images of the pelvis and pelvic floor during defecation. Marked anterior bulging of the anterior rectal wall, representing a rectocele (Rc), with partial prolapse of the posterior vaginal wall (a). Incomplete evacuation of the rectocele because of fold formation in the posterior rectal wall covering the anal canal (b). Descent of the peritoneal sac and sigmoid colon (S) in between the posterior vaginal wall (*white arrowhead*) and the anterior wall of the rectum (*black arrowheads*). Ur.bl. is the urinary bladder, V is the vagina, and A is the anus.**

Diagnosis

The diagnosis of pelvic floor dysfunction is made on the basis of symptoms, clinical findings and of the exclusion of other causes for the clinical disorder. Urinary incontinence requires urodynamic studies, a pad weigh test, and the exclusion of urinary tract infection.

Stool outlet obstruction requires exclusion of drugs, slow transit constipation, dolichocolon, and neoplastic disease. Endoscopy should be performed in any colorectal disorder. Anal manometry is required to exclude Hirschsprung's disease and anal sphincter hypertrophy, spasm, or laxity. Stool incontinence requires neurologic assessment. In any suspicion of a neurologic disorder, MRI of the spinal canal should be performed to rule out tumor or damage to the spinal cord.

Palpation and visual observation of the pelvic floor, electromyography, ultrasound, and magnetic resonance imaging (MRI) during rest, contraction, Valsalva maneuver, voiding, and defecation measure different aspects of pelvic floor function. Since there is no specific test for pelvic floor dysfunction, several methods have to be combined to focus the problem.

MRI is the most helpful imaging method to illustrate pelvic floor function. It is less investigator-dependent than ultrasonography, does not need ionizing radiation and provides us with high-quality images not only of the pelvic floor, but also of the pelvic organs, and generates dynamic information, playable as video sequences. It is superior to clinical investigation and ultrasound in detection of enteroceles and differentiation of rectoceles from enteroceles and combined problems. Up to 60% of enteroceles are missed by clinical investigation.

In pelvic floor dysfunction and anism, MRI is the method of choice to demonstrate the problem to the patient.

Pelvimetry

Definition

Magnetic resonance (MR) pelvimetry is a method for determining pelvic dimensions and narrowness of the ▶birth canal by MR imaging.

Characteristics

MR pelvimetry is a safe way (for both the fetus and the pregnant woman) to measure the diameters of the birth canal, in particular the entrance and the outlet, to detect a mismatch between the fetal head and the birth canal. The measurements help guide the physician in deciding whether vaginal birth is possible or a cesarean section should be performed.

Clinical Presentation

The Birth Canal

The fetus has to pass only 15 cm through the vagina to reach the light. However, this short way can require a lot of time, pain, and energy for both of the pregnant woman and the fetus. The birth canal has several narrow areas that the fetus must pass through. The measuerments of the diameters of these key areas are performed in different planes through the pelvis. First of all, is the entrance consists of two diameters: the diameter transversa (axial) and the ►obstetric conjugate (conjugata vera obstetrica, sagittal). If the head is too big, the fetus cannot enter the birth canal which may be indicated a persisting distended abdomen of the pregnant woman. Therefore, in the last days before birth, the abdominal size usually decreases with the descent of the fetal head into the entrance of the birth canal. Within the birth canal, the two most critical points of narrowness are the ►interspinous (axial) and the ►intertuberous distances (axial).

Finally, the ►sagittal outlet (sagittal) is a measure of the birth canal's exit.

Although the pelvis consists of bone, all distances can be modified by the birthing position due to the pelvis' flexibility, which is increased during pregnancy (1). Probably the most important distance for successful vaginal delivery is the interspinous distance, which can be taken as the "point of no return." Once the fetus passes this landmark, performing an emergency caesarean-section becomes dangerous.

Why Do Pelvimetry?

There are several indications for measuring the natural narrowness of the pelvis. When a baby is oversized or overweight there may be a mismatch between the birth canal and the size of the fetal head (2), preventing the fetus from entering the birth canal, so that, a cesarean section must be performed. Even more critical is when the baby becomes stuck in one of the critical inner narrow points. In these cases, the fetus may become wedged in the pelvis, putting the fetus and mother at risk for life-threatening complications.

In most instances, we can overcome these problems by measuring the baby and the size of its head by ultrasound and then perform pelvimetry early enough. However, pelvimetry is also indicated after a prolonged delivery when the mother decides to have another baby. If the pelvic measurement shows a small birth canal compared with the fetal head, a cesarean section should be planned early enough to avoid an emergency intervention. After a primary cesarean section, pelvimetry may indicate the possibility of vaginal birth with the next baby, if desired. Another indication for pelvimetry is after a previous pelvic fracture.

The decision of whether birth can proceed vaginally is ultimately up to the treating obstetrician in agreement with the pregnant woman. Birth-limiting pelvic dimensions can be revealed radiographically and with recently updated published data on birth outcomes (3), the risk of a vaginal birth can be estimated.

Imaging

External Pelvimetry by the Obstetrician

External measurements of the pelvis can be determined very easily and allow an approximate calculation of the internal pelvic parameters of the birth canal. The most widely used formula for the obstetric conjugate is based on the external conjugate (usually 20 cm) minus 9 cm. These values are, however, very indefinite, mainly due to the different thicknesses of the underlining tissues.

The pelvic form can also be assessed easily, which may be helpful in decision making prior to birth (Table 1).

Radiological Measurements

In the early days, pelvimetry was performed with radiographs (lateral: Colchner-Sussmann, frontal: Martius/Guthmann) and was often the indicator for cesarean section. But now we know that the concomitant radiation exposure, although low, may damage fetal DNA. Therefore, in pregnant women, MR pelvimetry is preferable in any case.

Although conventional radiographic pelvimetry in a non-pregnant woman probably will not lead fetal damage, but the ovaries will nonetheless be exposed to significant levels of radiation. It must be noted that radiographic pelvimetry is a projection examination, and the distances have to be modified by a correction factor based on a ruler placed within the examined field. Again, the surrounding tissue may cause some error. In contrast, MR pelvimetry assesses these diameters directly and much more accurately.

MR Pelvimetry

MR utilizes radio waves and a magnetic fields many times stronger even than that of the earth. There has been much

Pelvimetry, Magnetic Resonance. Table 1 Pelvic forms and their risks

Forms	Measurements	Expected problems during birth
Gynecoid	Pelvic inlet diameter 12 cm, about 11 cm, pelvic outlet 10 cm	Normal
Anthropoid	Pelvic inlet diameter 12 cm, about 11 cm, pelvic outlet <10 cm	Dorsoposterior position, protracted birth
Android	Pelvic inlet diameter <12 cm approximately >11 cm, pelvic outlet 10 cm	Dorsoposterior position, protracted birth
Platypelloid	Pelvic inlet diameter ≥12 cm, approximately ≤11 cm, pelvic outlet 10 cm	Protracted birth, head not entering the canal, deflected head

research regarding the safety of MR imaging. None of these studies has been able to prove a risk either to the baby or the mother. Due to its high degree of accuracy and safety, MR pelvimetry has become a widely accepted examination (4) and has largely replaced convention pelvimetry. Some there has been some concern about noise during the MR examination which is considerable and originates from the on-and-off switching of magnetic gradients. However, studies have shown that physiologic aortic pulsations are louder than MR scanner noise intraadominally (5).

The noise in MR is completely harmless, although the unprepared patient may get the impression that the scanner is defective. It should be noted that pregnant women sometimes have heightened senses and therefore may be more anxious than non-pregnant women. Most women examined in MR pelvimetry experience some anxiety due to the noise, however most of them would undergo the examination again for the well-being of their babies (5).

A pregnant woman with claustrophobia guided very carefully through the examination considering of the narrowness of the MR system and the mass of the gravid abdomen (5). A claustrophobic patient should be examined in an open system if available (5). In MR pelvimetry, the lower image quality of low-field or open systems is not limiting for diagnositic purposes (5). In extreme cases of claustrophobia, sedation (e.g., benzodiazepine through the nose) can be helpful if there is no contraindication.

As usual, before the examination is planned, the known contraindications for MR imaging should be excluded (this can easily be forgotten). The examination within the MR bore is short—a maximum of 3–8 min (5). The pregnant woman should be in the supine position if possible; if not, the examination can also be done while she is lying on her side.

These days, a T1-weighted fast gradient echo sequence (FSPGR) is preferred; for example, TR 150 msec, TE 1.6 msec, FOV 32 cm, Matrix 256 x 192 -256, slice thickness/gap 6/1.6. Chemical shift artifacts tissue interfaces should be minimized. The examination is performed in three planes covering the whole pelvis (4). The ►obstetric conjugate is assessed on a midsagittal section from the sacral promontory to the top of the symphysis (Fig. 1), and the ►sagittal outlet from the distal end of the sacrum to the bottom of the inner cortex of the symphysis (Fig. 1). The ►interspinous (Fig. 2) and ►the intertuberous distances (Fig. 3) are measured in an axial plane as the narrowest distance between the ischial spines and the ischial tuberosities, respectively. On oblique sections, the ►transverse diameter, the largest transverse distance of the pelvic inlet, is measured. In contrast to X-ray, no correction factors are needed because these measurements are direct in the correctly chosen plane. The measurements are usually performed by a MR technician on the scanner system within 3 min, depending on the documentation required. Although the technique is advanced, interobserver and intraobserver error should be considered (4).

Although there are monitoring techniques to asseess the mother's wellbeing, such as electrocardiography and pulse oximetry, the fetus's well-being usually cannot be monitored by CTG. However, if the fetus is perceived to be in distress, a cesarean section will usually will be performed emergently, so that completion of MR pelvimetry exam becomes superfluous. In cases where time plays an important role, a conventional radiograph can be justified due to the low and not completely understood risk of the radiation to the fetus.

During MR pelvimetry, the baby can also be assessed, although with an increase in examination time. If desired, fetal brain diameters can be measured, and further fetal and maternal anomalies can be detected. However, the indications for MR fetal examinations are different, and there is usually no compelling indication as ultrasound can be done faster and more cheaply.

Diagnosis

Recently updated data about MR pelvimetry are shown in Table 2 (3). The classification of pelvic forms in Table 1 serves as a rough guide but is less relevant than MR pelvimetric determinations. Pregnant women with lower

Pelvimetry, magnetic resonance. Table 2 **Magnetic resonance pelvimetry: reference values (from Keller TM et al. (2003) Obstetric MR pelvimetry: reference values and evaluation of inter- and intraobserver error and intraindividual variability. Radiology 227(1): 37–43)**

Pelvimetric Measurements	Mean ± SD (mm)	Range (mm)
Obstetric conjugate	121.7 ± 8.6	101–143
Interspinous distance	112.3 ± 7.9	95–136
Intertuberous distance	120.6 ± 11.3	94–143
Transverse diameter	129.5 ± 8.7	110–152
Sagittal outlet	115.8 ± 9.9	81–137

values, especially of the obstetric conjugate and the interspinous distance, should be treated with care, as mentioned earlier, especially in cases of suspected fetopelvic disproportion. Again, MR pelvimetry alone should not establish the indication for a cesarean section. The decision is up to the treating obstetrician in agreement with the pregnant woman, depending on the context of the birth setting.

Penile Disorders

Penile disorders are frequently diagnosed late because patients feel embarrassed to talk about these problems. With the advent of effective oral therapy for erectile dysfunction (PDE-5-inhibitors e.g., Sildenafil) and thus, increasing media interest in sexual dysfunction, male patients feel more confident to share their penile disorders with their doctor. As it is true for other diseases, diagnosing penile disorders requires to take a patient's history, physical examination, laboratory examination, and if necessary selecting an appropriate imaging modality. Frequently, the patient's history and clinical appearance are very characteristic and allow for diagnosing a penile lesion/disorder sufficiently reliable. However, to further characterize or to choose a specific treatment for these disorders, knowledge regarding the most adequate imaging technique is very important.

Penile Fracture

RÄTO T. STREBEL
Department of Urology, University Hospital Zurich, Zurich, Switzerland
raeto.strebel@usz.ch

Definition

Penile fracture is defined as a rupture of the tunica albuginea of one or both corpora cavernosa from trauma to the erect penis.

Penile Fracture. Figure 1 Patient with a penile fracture with marked swelling and haematoma (typical "eggplant deformity").

Clinical Presentation

Typically, patients report that they heard a crack followed by pain with an immediate return to detumescence of the penis. Most commonly the above condition occurs when striking the penis against the symphysis or perineum during intercourse, which is the predominant mode of action in the western world. In other regions of the world, the self-inflicted bending of the penis to achieve fast detumescence after masturbation is frequently described (1). Thereafter, penile swelling and haematoma appears rapidly, leading to the typical "eggplant deformity" (Fig. 1). On physical examination, a palpable defect in the tunica albuginea may be present.

Imaging

Because of the typical history and clinical presentation, additional imaging is rarely necessary for diagnosing a penile fracture or planning further treatment. However, when an urethral injury is suspected (voiding difficulties, macrohaematuria) which is associated with penile fracture of up to 40%, an urethrography may be warranted. However, it might be difficult to perform an urethrography properly in the presence of marked swelling of the penis and prepuce. An ultrasound examination of the tunica albuginea can be helpful in localising the site of rupture. A cavernosography is a sensitive imaging modality to prove a cavernosal injury. In conclusion, additional imaging with cavernosography or ultrasound is only necessary when the clinical presentation is ambiguous.

Pepper's Syndrome

Massive metastatic involvement of the liver occurring in patients younger than 6 months of age with neuroblastoma. Prognosis can be favorable.

▶Hepatic, Pediatric Tumors, Malignant

Peptide

Compound of a relatively small number of amino acids (up to 100) linked by amide bonds. Peptides used for receptor imaging are often neuropeptides with a short amino acid sequence (<20). This feature results in rapid pharmacokinetics, which is beneficial for in vivo receptor imaging.

▶Receptor Studies, Neoplasms

Percutaneous Ethanol Injection (PEI), Hepatic Tumours

Radiological percutaneous interventional technique of tumour ablation consisting in the direct, usually US guided, injection of ethanol within the tumour lesion in order to obtain local tumour necrosis.

▶Interventional Hepatic Procedures

Percutaneous Laser Disc Decompression

Laser energy is used to vaporise the watery content of the nucleus pulposus. A small laser fibre is inserted through a hollow needle into the centre of the intervertebral disc. When the laser fibre is in place, laser energy is applied into the nucleus pulposus in order to evaporate its water content, thereby reducing intradiscal pressure. This causes the herniated portion of the nucleus pulposus to recede towards the centre of the disc, relieving pressure on the nerve root.

▶Radicular Syndrome of the Spine, Percutaneous Therapy for

Percutaneous Nephrolithotomy

PCNL is a procedure for removing medium-sized or larger renal calculi (kidney stones) from the patient's urinary tract by means of a nephroscope passed into the kidney through a track created in the patient's back. The term "percutaneous" means that the procedure is done through the skin.

▶Stone Disease, Urinary

Percutaneous Nucleotomy

Nucleus pulposus material is mechanically removed using an automated nucleotome. The nucleotome is introduced through a cannula that is placed into the centre of the nucleus pulposus under fluoroscopic guidance. The tip of the nucleotome is alternatingly rotated, depressed and elevated within the nucleus in order to optimise the removed amount of nucleus pulposus material. The resulting loss of nucleus pulposus mass causes a drop in intradiscal pressure. This causes the herniated portion of the nucleus pulposus to recede towards the centre of the disc, relieving pressure on the nerve root.

▶Radicular Syndrome of the Spine, Percutaneous Therapy for

Percutaneous Transhepatic Cholangiography

Percutaneous catheterization of an intrahepatic bile duct that is outlined on radiographs by means of contrast medium injection.

▶Biliary Anatomy

Percutaneous Transluminal Renal Angioplasty

Interventional radiological techniques allowing endovascular treatment of RAS with balloon catheters, stents, or both.

▶Stenosis, Artery, Renal

Percutaneous Treatment of Tubo-Ovarian Abscesses

Interventional radiological treatment is an alternative to the laparoscopic or surgical approach. Technique and access depend on size, location, and morphology of the abscess. Small abscesses are usually treated by needle punctures. Large and multiloculated abscesses are better treated by a catheter drainage if a safe route is possible.

▶Abscess TuboOvarian

Perfluorocarbon Gas Agents

▶Contrast Media, Ultrasound, Low Solubility Gas

Perforation, Gallbladder

A serious complication of ▶acute cholecystitis occurring in about 10% of cases, characterized by high morbidity and mortality. Three categories (acute, subacute, and chronic) of gallbladder perforation are described according to the Niemeier classification. The acute form develops in generalized peritonitis where the subacute perforation may also occur, resulting in a pericholecystic abscess. Chronic perforation may generate an internal biliary fistula (to the duodenum or common bile duct). Both US and CT can depict the presence of a defect in the gallbladder wall.

Synonym

Blood flow

Definitions

▶*Perfusion* is the nutritive flow of blood through tissues. There is a growing interest in imaging perfusion in tumours. Perfusion can be a measure of pharmacodynamic response to anti-angiogenic drugs and vascular disrupting agents and many chemotherapeutic agents. Perfusion is also a prognostic factor, with perfusion being both a poor and good prognostic factor.

Volumetric imaging with CT or MRI is less useful for assessing efficacy of anti-angiogenic drugs as these are cytostatic rather than causing tumour shrinkage. Hence, the increased need for direct imaging of effects on tumour vasculature.

Perfusion is governed by tumour vasculature and perfusion pressure. Tumour blood vessels have structural and functional abnormalities. This includes irregular branching, increased permeability and independence from normal flow control mechanisms. Such abnormalities lead to variable and inadequate perfusion. ▶*Angiogenesis* is the formation of new vessels, essential for tumour growth. This depends on matrix metalloproteases produced by activated endothelial cells, which degrade the basement membrane, and also integrins which enable endothelial cell migration towards the tumour. This process involves a plethora of cytokines, including *vascular endothelial growth factor* (*VEGF*) which promotes angiogenesis and also vascular permeability. *Fibroblast growth factor* (*FGF*) also has a role in angiogenesis. Expression of FGF and VEGR is upregulated in tumours, and levels correlate with vascularity (1).

Perfusion in tumours is not the same as blood flow, which may occur without nutrition in the case of arteriovenous shunting, where the capillary bed is bypassed. In nuclear medicine imaging, regional tumour flow is the usual parameter measured, which is flow standardized to a unit quantity of tissue, and typically has the units mL blood/min/dL tissue.

A further important parameter is regional ▶volume of distribution (V_d), which is the steady-state ratio of the activity in tissue to activity in blood/plasma. In the case of perfusion measurements using a freely diffusible tracer, this can be thought of as the fractional volume of tumour which is being perfused.

Nuclear Medicine

Nuclear Medicine Imaging of Blood Flow

The classical way to measure perfusion in nuclear medicine is to use methods based on the Fick principle. The measurement of tumour perfusion depends on the injection of a tracer into the blood stream and subsequent measurement in the tumour

$$P = \frac{C_0}{\int (C_a - C_v)\mathrm{d}t},$$

where (C) is the concentrations of tracer in tissue (C_0), arterial (C_a) and venous (C_v) blood.

This gives quantitative measurements of blood flow. However, this method is not used in practice as it requires both arterial and venous dynamic measurements and assumes homogeneity of venous blood. Instead, the freely diffusible tracer method is used. This measures the rate of tracer uptake, and therefore does not require venous data.

Perfusion may be derived using the steady-state or dynamic methods using a freely diffusible tracer. The isotope ^{15}O is often used as $^{15}[O]CO_2$ or $^{15}[O]H_2O$, and has a half-life of 123 sec. This is created in an on site cyclotron.

Steady-State Method

Early studies of PET and blood flow involved the steady-state method. This involves inhalation of $^{15}[O]CO_2$, which is converted to $^{15}[O]H_2O$ in the lungs. Equilibrium is reached after 10 min, so that tracer diffusion from arterial blood to tissue is matched by that from tissue to venous blood, and radioactive decay. Flow is given as

$$\text{Flow} = \frac{\lambda}{[H_2{}^{15}O]_a^c / [H_2{}^{15}O]_t^c - 1/V_d},$$

where λ is the decay constant for ^{15}O, $[H_2{}^{15}O]_a^c$ is the arterial concentration of $H_2{}^{15}O$, $[H_2{}^{15}O]_a^t$ is the tissue concentration of $H_2{}^{15}O$.

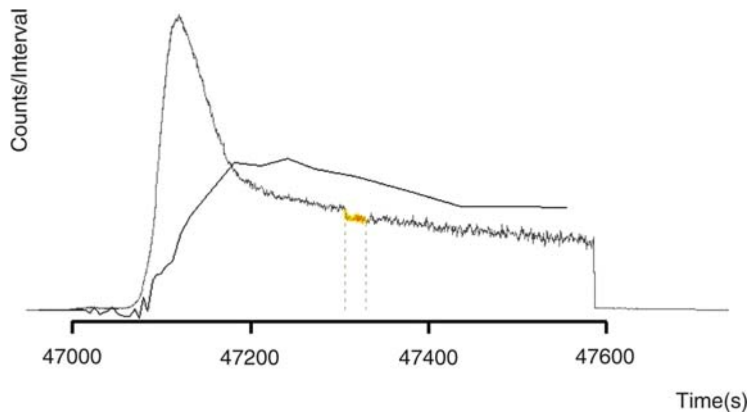
Tissue radioactivity concentration is measured quantitatively from the region of interest on the PET scan, and the arterial concentration is assessed by arterial sampling using a cross-calibrated well counter, or from a large arterial pool from the PET image.

Advantages of this method are that it requires only a simple calculation, and minimal blood sampling. However, compared to the dynamic method, it is particularly sensitive to effects from tissue heterogeneity and inaccuracies in the predefined partition coefficient which is often not known in diseased tissues such as tumour (2). Tissue heterogeneity leads to underestimation of perfusion in heterogeneous tissues (2, 3).

Dynamic Method

Both steady-state and dynamic methods can employ inhalation of $^{15}[O]CO_2$ or injection of a bolus of $^{15}[O]H_2O$. Modern dynamic methods usually involve the $^{15}[O]H_2O$ bolus method (Fig. 1). Compared to steady-state inhaled $^{15}[O]CO_2$, a lower dose is needed, and the scan time is shorter—a steady-state acquisition would typically be approximately 30 min compared with 10 min for dynamic scanning. Kinetics of activity is measured in tissue within individual timeframes. Continuous or rapid discrete arterial data are obtained from the image or arterial blood sampling. For blood samples, the data are corrected for delay and dispersion of the arterial curve due to blood passage through sampling tubing.

Kinetic data are modelled using the Kety–Schmidt model and estimates of blood flow and V_d. This incorporates a term for radioactive decay. Estimates of flow and V_d are perturbed until a good fit obtained.



Perfusion, Neoplasms. Figure 1 **Time activity curve using ► ^{15}O-water dynamic method. Arterial input corrected curve of changing ^{15}O-water activity in region of interest. The first curve to peak is for arterial blood concentration, and the second peak is for a tissue concentration. The *dashed line* on the blood curve indicate the drawing of a calibration blood sample. (Courtesy of Dr G Laking, Manchester Molecular Imaging Centre)**

Change in tissue concentration with time is given by:

$$\mathrm{d}C_\mathrm{t}(t)/\mathrm{d}t = FC_\mathrm{a}(t) - (F/V_\mathrm{d} + \lambda)C_\mathrm{t}(t),$$

where $C_\mathrm{t}(t)$ is the regional tissue concentration of $H_2{}^{15}O$ ($\mathrm{Bqml^{-1}}$ tissue) as a function of time, $C_\mathrm{a}(t)$ is the arterial concentration of $H_2{}^{15}O$ ($\mathrm{Bqml^{-1}}$ tissue) as a function of time, F is the regional flow in mL(blood)/mL (tissue) min^{-1}, V_d is the volume of distribution of water in mL (blood)$\mathrm{mL^{-1}}$ (tissue), is the decay constant of ^{15}O (0.338 $\mathrm{min^{-1}}$).

The solution is given by the equation

$$C_\mathrm{t}(t) = FC_\mathrm{a}(t)^* \exp(-(F/V_\mathrm{d} + \lambda)t),$$

where * is the operation of convolution, $C_\mathrm{t}(t)$ is the tissue response to an arterial input function $C_\mathrm{a}(t)$.

This method has several advantages. Scans can be repeated every 10 min, and the model is less sensitive to heterogeneity. Flow and V_d are estimated separately. Data acquisition is faster, so a lower radiation dose can be delivered to the patient. However, long reconstruction times and large datasets are needed, data are noisier, data modelling is highly complex and extensive blood sampling is required (50 mL per scan). As for the steady-state method, it makes the assumption that water is freely diffusible and fully extracted from circulation, and is poor for high blood flow regions.

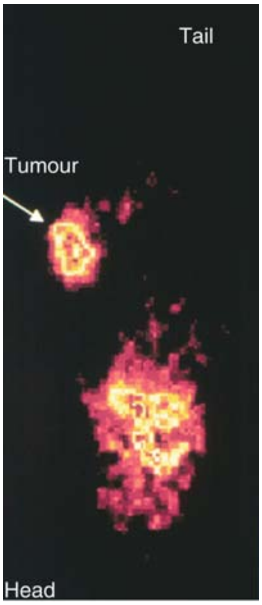
Imaging Blood Volume

This involves inhalation of a tracer dose of ^{15}[O]CO in oxygen, then breathing room air, until arteriovenous C^{15}O–Hb carboxyhaemoglobin equilibrates within blood, which typically only takes 1–2 min. Tissue radioactivity and arterial C^{15}O–Hb are recorded. Carboxyhaemoglobin remains in vessels, so the ratio of activity in tissue to blood is the blood volume within the imaged tissues.

Nuclear Medicine Imaging of Angiogenesis

Angiogenesis has a significant role in determining tumour perfusion. Non-invasive molecular imaging can detect molecules, which are selectively expressed on tumour vasculature and involved in angiogenesis. Imaging involves production of a labelled ligand or a labelled antibody to the ligand. Many of these studies are still in an early phase of clinical development, or indeed preclinical. Preclinical studies are underway with labelled FGF antibody. VEGF expression has been imaged clinically by labelling the molecule or its antibody.

The integrin alpha v beta3 is expressed selectively on activated tumour vasculature. This has been imaged in a phase II study using a labelled antibody specific for this integrin. Retention occurred only in the patient who had alpha v beta3 positive tumour (4). There have been some clinical developments in imaging matrix metalloproteinases (MP)—an inhibitor of MP labelled with indium-111 has been administered safely to patients with Kaposi sarcoma, but without tumour uptake (5) (Fig. 2). Progress in this field depends on development of new-labelled ligands or antibodies involved in tumour angiogenesis. Candidate tracers should demonstrate a relatively high level of specific signal bound to the site, but also have kinetics that are amenable to correction for background/non-specific binding and thereby enable quantitation.



Perfusion, Neoplasms. Figure 2 [124I]VG76e-PET image

Nuclear Medicine Imaging of Hypoxia

Hypoxia both stimulates angiogenesis and blood flow in tumours and occurs as a result of the aberrant tumour vasculature that develops. A number of PET probes are being developed for measuring hypoxia, including ^{64}Cu-ATSM and ^{18}F-fluoromisonidazole (^{18}F-FMISO), and of these ^{18}F-FMISO is the most widely studied. This is a member of the group of nitroimidazoles, which diffuses into a cell, and undergoes electron reduction to form reactive species. In the presence of oxygen, the molecule is reoxidized. In hypoxic conditions, the reactive species forms covalent bonds with intracellular macromolecules and is trapped in the cell.

There are studies of hypoxic imaging with ^{18}F-FMISO in a wide range of human cancers. ^{18}F-FMISO has been tested as a hypoxic imaging tool against a range of standard hypoxic markers.

The early delivery of ^{18}F-FMISO into tumours is controlled by blood flow. Later activity measurements are dominated by the oxygen-dependent retention within the tissue. Consequently, typical scans are performed around 90–120 min following injection, to minimize the effect of blood flow confounding the hypoxia measurements. Tumour retention is generally expressed relative to plasma or muscle levels. However, a kinetic model for analysis of dynamic ^{18}F-FMISO PET data has been described (6) which reflects oxygenation of tumours and presence of necrosis, and was able to predict prognosis of patients undergoing radiotherapy.

New nitroimidazole tracers are being developed for example, etanidazole, which may have better imaging characteristics than ^{18}F-FMISO.

Perineural Spread

Perineural spread describes the process by which a tumour exits its primary side and reaches distant locations by travelling along the neural sheath. It can be directed antegradely or retrogradely and may be clinically silent.

►Neoplasms, Oral Cavity

Perineural Spread of Tumour

A mechanism whereby pathologic conditions spread along the connective tissues of the perineurium. This type of spread is often associated with malignant disease of the head and neck, but can also be seen in infectious and inflammatory conditions that show neural tropism, such as fungal infections and granulomatous disease processes. The most common histopathologies associated with perineural spread are epidermoid carcinoma, arising from mucous membranes or from the skin, salivary gland neoplasms (adenoid cystic and mucoepidermoid carcinomas), melanoma and lymphoma.

►Facial Nerve Palsy

Periodontal Disease

Synonyms

Periodontitis

Definition

Periodontal disease consists in a progressive destruction of periodontal tissues: gums, alveolar dental ligament, cementum, and alveolar bone. Periodontal disease is really frequent and it is mainly induced by dental plaque, which usually grows up on the enamel where a large amount of germs are present. When plaque is mineralized, it turns into oral calculus. Calculus and plaque can both be the cause of gingival inflammation (3).

Pathology/Histopathology

Factors that induce periodontal disease are a bad oral hygiene, nicotinism, overflowed treatments, malocclusion, age, genetic factors, and diabetes.

The first clinical manifestation is represented by gingivitis: if the phlogistic process becomes chronic, the periodontal membrane and the alveolar bone are destroyed and radicular lacunae start growing. Radicular lacunae represent a pathological lowering of the groove between tooth and gum. When the alveolar bone is totally destroyed and gums become shorter, tooth starts moving (1).

Clinical Presentation

Radiology is not as important as the clinical approach in case of periodontal disease, but it can be useful to determine the rate of periodontal attachment and radiographic bone loss (4, 5). A limit is constituted by the bidimensionality of the representation.

Imaging

Imaging allows a classification of the pathological lesion and a posttherapeutic control.

Pantomography can be useful only to have a first valuation of the disease.

The radiological approach includes periapical radiographs of all dental elements, taken with the paralleling technique. Usually 16 radiographs are taken using e-speed dental film. The paralleling technique assures a minimum level of deformity and enlargement, allowing the bone loss' measurement (Fig. 1). A better anatomical evaluation can be provided with volumetric CT and 3D reconstruction (1).

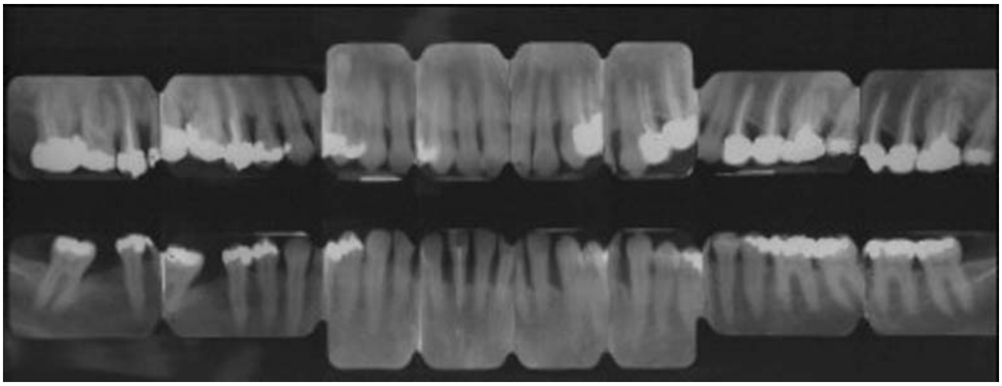
Nuclear Medicine

Bone scintigraphy has a limited role in the assessment of periodontal diseases.

Diagnosis

Initial lesions of the disease consist of bone crest loss and interradicular septa reduction. Moderate lesions are characterized by horizontal bone loss and bone defects. Advanced lesions consist of vertical bone erosion with the development of bone lacunae along root margins. In the advanced stage of periodontitis a molar furcation involvement can be observed.

The periodontal abscess occurs when a deep radicular lacuna is obstructed. From a radiological point of view, a wide osteolysis with the development of fistulas is observed.



Periodontal Disease. Figure 1 **sixteen intraoral radiographs taken with the paralleling technique.**

The juvenile periodontitis usually concerns women from 15 to 25 years old, and it does not generally come with gingival inflammation. An expansion of the periodontal region and the growth of lacunae due to bone reabsorption can be noticed with the radiological approach.

Peritoneal Collections

Panos K. Prassopoulos
Department of Radiology, University Hospital of Alexandronpolis, Medical School of Thace, Alexandronpolis Greece
pprasopo@med.duth.gr

Synonyms

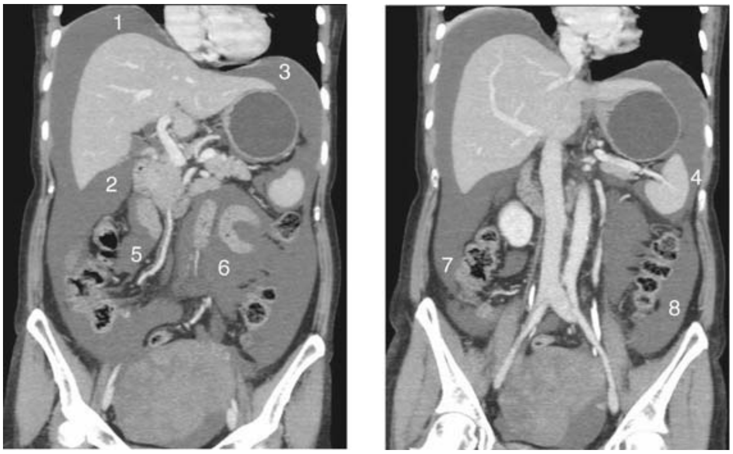
The term "peritoneal collection" can be substituted by other terms only when the composition or nature of the fluid is known or evident. Under this condition the terms ▶Ascites; Hemorrhagic collection/Hematoma; Bile collection/biloma; Urinoma; ▶Seroma; Pancreatic fluid collection; or Abscess may be used and can precisely indicate the underlying process that is responsible for peritoneal fluid accumulation

Definition

Accumulation of fluid in the peritoneal ▶cavity is not a disease in itself, but it is the manifestation of a wide spectrum of pathologic processes that may involve intraperitoneal or extraperitoneal organs. The biochemical composition of fluid or the presence of cells within it depends on the disease that is responsible for fluid productivity (1). Transudative collections may be associated with portal hypertension, cirrhosis, heart failure, nephrotic syndrome, or obstruction of the inferior vena cava, hepatic vein, or portal vein. Exudative fluid may be related to infections or peritoneal carcinomatosis. Blood collections may be the result of trauma, hemorrhagic diathesis, or tumor rupture. Bile collections may follow rupture of the biliary tree; chylous collections may develop after obstruction of lymphatics; pancreatic fluid collections may be the consequence of acute pancreatitis; urine collections may represent extension of a retroperitoneal urinoma; and purulent collections may be the consequence of visceral inflammations, intestinal perforations, or surgery.

Anatomy/Physiology

The peritoneal cavity normally contains a small amount of serous fluid (less than 100 mL) for lubrication. Normal peritoneal fluid and ascites move along predictable pathways that are influenced by gravity, capillary forces, fluid composition, and intraabdominal pressure gradients (hydrostatic pressure is lower in subphrenic recesses than in the pelvis) and are governed by mesenteric reflections or adhesions (2). Fluid collections in the ▶inframesocolic spaces (Fig. 1) flow to the pelvis, the most dependent portion of the peritoneal cavity. Fluid spread in the right inframesocolic space occurs along the small bowel mesentery; it may stagnate at the ileocecal area and then overflow into the pelvis. In the left inframesocolic space, fluid may temporarily accumulate along the superior



Peritoneal Collections. Figure 1 Ascitic fluid in peritoneal compartments: right subphrenic (1), right subhepatic (2), left subphrenic (3), perisplenic (4), right and left inframesocolic (5, 6), right and left paracolic gutters (7, 8).

surface of the sigmoid mesocolon and gradually flow into the pelvis. The pouch of Douglas is first filled in the pelvis, followed by the lateral perivesical recesses. From the pelvis, fluid ascends both paracolic gutters (Fig. 1), forced by the negative subdiaphragmatic pressure during inspiration. The major flow occurs along the right paracolic gutter, which is deeper than the left. In addition, the phrenicocolic ligament on the left acts as an anatomic barrier to fluid exchange. Thus, the right paracolic gutter represents the main communication channel between the inframesocolic and ►supramesocolic spaces. It continues to the right subhepatic and subphrenic spaces (Fig. 1) and allows movement of collections from the pelvis to the right upper abdomen, and vice versa.

Fluid in the supramesocolic spaces tends to accumulate in Morrison's subhepatic recess, which is the most dependent portion in the supine position. From the right subhepatic space, fluid can move to the right subphrenic or left subhepatic space, and vice versa. However, fluid exchange between the right and left subphrenic cavities is prevented by the falciform and coronary ligaments. Fluid moves freely between the left subphrenic, left perihepatic, and perisplenic compartments, but the transverse mesocolon and the phrenicocolic ligament act as barriers for the extension of small or medium collections to the inframesocolic spaces. Fluid in the lesser sac may flow to the posterior subhepatic space through Winslow's foramen.

Pathology/Histopathology

The peritoneal serous lamina reacts strongly to a wide spectrum of conditions—including injury, inflammation, the presence of neoplastic cells, and contact with irritating biochemical factors in the extravasated blood, urine, bile, or pus—by forming adhesions to limit collections, isolating inflammatory processes, or plugging perforations. Thus, hematic, biliary, urinary, or purulent collections may be limited by an active peritoneal reaction. Consequently, they may not move freely in the peritoneal cavity and are usually located or isolated at the area where they developed. On the contrary, transudative or exudative effusions diffuse in the peritoneal cavity because they may not stimulate a significant peritoneal reaction. In addition, ascites or gases are more easily absorbed by the peritoneum at the diaphragmatic or omental level, in contrast to decreased absorption of other kinds of fluid collections.

Clinical Presentation

The clinical presentation of fluid collections depends on the underlying disease that causes the peritoneal fluid accumulation. Peritoneal fluid of less than 2 L is difficult to detect clinically. The earliest sign of ascites is dullness to percussion in the flanks. Shifting dullness and a fluid thrill mean that more fluid is present. Ascites may be manifested by an increase in abdominal girth accompanied by weight gain. The abdomen is distended, often with fullness in the flanks and an everted umbilicus. Scrotal edema is frequent. Other signs and symptoms are mostly related to the primary disease: hypovolemic shock in hematic collections; upper abdominal pain, vomiting, or tenderness in acute pancreatitis fluid collections; fever in abscesses; and distended abdominal wall veins that radiate from the umbilicus in ascites due to portal hypertension.

Imaging

Small to moderate transudative or exudative collections usually accumulate in the most dependent peritoneal recesses. In the presence of large ascites, the small bowel is usually positioned centrally within the abdomen. Ascitic fluid under tension may result in an extraperitoneal mass effect and may be associated with displacement of bowel loops from the central position. Purulent, hematic, biliary, and urinary collections may become loculated due to adhesions as a result of peritoneal reactivity stimulation, and they may be seen as cystic lesions with mass effect (3).

Hemorrhagic collections may either be localized next to the bleeding organ or, more frequently, tend to diffuse and accumulate to Morrison's pouch when bleeding is supramesocolic or to the pouch of Douglas when it is inframesocolic. Computed tomography (CT) attenuation values of the hemorrhagic collection are similar to those of circulating blood. They increase within a few hours due to clot formation or concentration and thereafter gradually decrease from the periphery toward the center (4). A focal high-density area within the collection in trauma patients corresponds to localized clotted blood and is indicative of the bleeding site. Active bleeding may be disclosed by contrast medium extravasation on CT. Old hemorrhagic collections may have a cystic appearance surrounded by a pseudocapsule of variable thickness.

Bile collections are usually located in the subhepatic or gastrohepatic recesses and may have a loculated cystic appearance with thin wall and water-like density/signal intensity content. Contrast agents excreted along with bile may be valuable in disclosing active bile extravasation on CT or magnetic resonance imaging (MRI).

Peritoneal urine collections follow retroperitoneal extravasation of urine through communication at the level of the mesenteric or mesocolic subperitoneal spaces. They have a cystic appearance and water-like density/signal intensity. Late post-contrast-enhanced CT or MRI may be helpful in demonstrating active urine leakage.

P

Seromas have a cystic appearance surrounded by thickened peritoneum. They contain secretions of peritoneal serosa displaying water density/signal intensity characteristics.

Fluid collections with pancreatic juice may be seen early in the course of acute pancreatitis. They lack a capsule and thus are confined by the anatomic space within which they developed, most commonly the anterior perirenal space or, intraperitoneally, the lesser sac. They are seen as poorly defined fluid collections without recognizable walls, exhibiting low attenuation on CT or high signal intensity on T2-weighted MR images. An acute fluid collection may resolve spontaneously or evolve—after 4 or more weeks—to pseudocyst, a round or oval fluid collection with a thin capsule or a thick wall that may demonstrate contrast enhancement. Pancreatic abscess may also develop late in the course of disease as a result of tissue necrosis with subsequent liquefaction and superinfection. Imaging findings of an abscess on CT include a local fluid collection with slightly higher than water attenuation values, with or without gas bubbles, surrounded by a thick wall that usually exhibits contrast enhancement.

Peritonitis is characterized by a generalized collection of intraperitoneal fluid and is usually the result of an abscess extension or rupture of hollow viscera. CT features include ascites in association with peritoneal and mesenteric thickening. Tuberculous peritonitis is characterized by a high-density ascites on CT (20–45 HU), thickening and nodularity of peritoneal surfaces, and enlarged lymph nodes with central low attenuation.

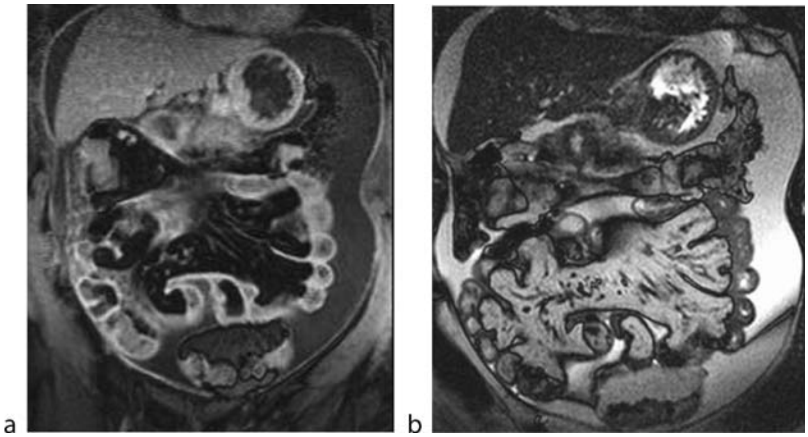
A primary abdominal neoplasm arising in the stomach, colon, pancreas, or ovaries may seed cells into the ascitic fluid that is induced. Location and growth of intraperitoneally seeded metastases follow the pathways of the flow of ascitic fluid (5). When the implants are very small, ascites may be the only imaging manifestation of peritoneal carcinomatosis (Fig. 2). Ascitic fluid is often loculated/septated in carcinomatosis.

Nuclear Medicine

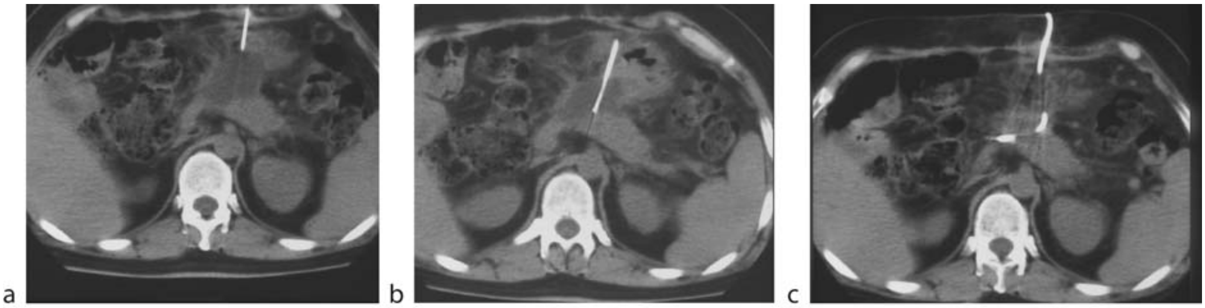
Nuclear medicine techniques have a limited role in evaluating peritoneal fluid collections. Gallium-67 scintigraphy has been proposed for the diagnosis and treatment monitoring of inflammatory peritoneal collections, especially tuberculous peritonitis, and PIPIDA scintigraphy for assessing active bile leakage in bilomas. Intraperitoneal administration of yttrium 90 has been suggested as an alternative treatment option in cases of malignant ascites.

Diagnosis

Ultrasound (US), CT, and MRI are sensitive in diagnosing and localizing peritoneal fluid collections. US may be more sensitive than CT for detecting small amounts of ascites in the pelvis or perihepatic spaces. Ascites is anechoic on US; in the presence of a more viscous fluid collection or blood, acoustic reflections may be seen. The CT attenuation values of ascites range from 0 to 20 HU; they increase with increasing protein or blood content (more than 30 HU) and decrease in the presence of chylous fluid. However, CT attenuation values are not specific. On MRI, ascites renders low signal intensity on



Peritoneal Collections. Figure 2 (a) Post-gadolinium-enhanced three-dimensional fast low-angle shot T1-weighted image with fat saturation on the right and (b) true fast imaging with steady-state precession on the left on coronal planes in a patient with malignant ascites. Note enhancement of the parietal peritoneum and the surface of the small bowel mesentery, which is thickened due to diffuse peritoneal seeding. Partially loculated ascites is present in the right subhepatic space and the right paracolic gutter.



Peritoneal Collections. Figure 3 **Percutaneous drainage of an infected pseudocyst. (a) Needle insertion for fluid aspiration. (b) Guide wire placement through a dilator. (c) Drainage catheter in place.**

T1-weighted images and a "bright" signal on T2-weighted images. MRI is superior to CT for differentiating a hematoma from other collections, but it may miss a small amount of gas in an abscess.

A percutaneous fine needle aspiration may reveal the nature of a fluid collection and is important for abscess diagnosis by aspirating pus.

Interventional Radiological Treatment

Percutaneous drainage under CT or US guidance has been successfully applied in most types of loculated fluid collections, including hematomas, bilomas, pseudocysts, and abscesses (Fig. 3). Selection of catheter diameter depends on the degree of collection liquidation that can be determined by US or MRI.

Synonyms

Drug discovery and development; Molecular imaging; Positron emission tomography

Definitions

Positron emission tomography (*PET*) is a functional imaging technique that tracks radionuclides in the body, as they decay by positron emission. Coincidence detection of two gamma-rays, simultaneously emitted at 180° to each other, as a result of an annihilation reaction between a positron and an electron, forms the basis of PET.

P

Positron-emitting nuclides do not normally exist in nature and are predominantly produced in a cyclotron. While, positron-emitting nuclides for commonly occurring elements such as carbon, oxygen and nitrogen have a short half-life, requiring an on-site cyclotron, fluorine-18 and iodine-124, with longer half-life can be produced, remote from the imaging centre. These radionuclides can be used to substitute the elements in the compound of interest and evaluated with PET.

Drug discovery and development is a process that begins with discovery of new agents and proceeds through pre-clinical and clinical development (phase I, II, III clinical trials) until the drug is finally accepted for clinical use. It takes several years and millions of dollars before a drug is registered for clinical use and attrition rates are high, with more than 70% of drugs failing in the process. Drug discovery and development is currently undergoing enormous changes due to an increase in our understanding of disease pathology at the molecular level and the identification of potential therapeutic targets such as receptors, proteins, genes, antigens and pathways involved in cell cycle, signal transduction, cell death, drug resistance and angiogenesis. Due to an increase in the number of potential targets in the post-genomic era, as well as the use of new technologies such as combinatorial chemistry and high-throughput screening to produce large numbers of anticancer agents, the need to revise the way we test new drugs has become apparent.

Characteristics

PET Methodology

Molecular imaging with PET is based on the ▶tracer principle. A tracer is a substance that follows or traces the path or behaviour of a substance that is being investigated. In PET, a very small mass of the molecule of interest is radiolabelled with the positron-emitting nuclide, when it is called a ▶radiotracer. Since, any isotope effect should be negligible or at least quantitatively predictable and the mass of the radiotracer should be small compared to the mass of the substance being traced, molecules of high-specific activity (activity/mole) are required, necessitating expert radiochemical input.

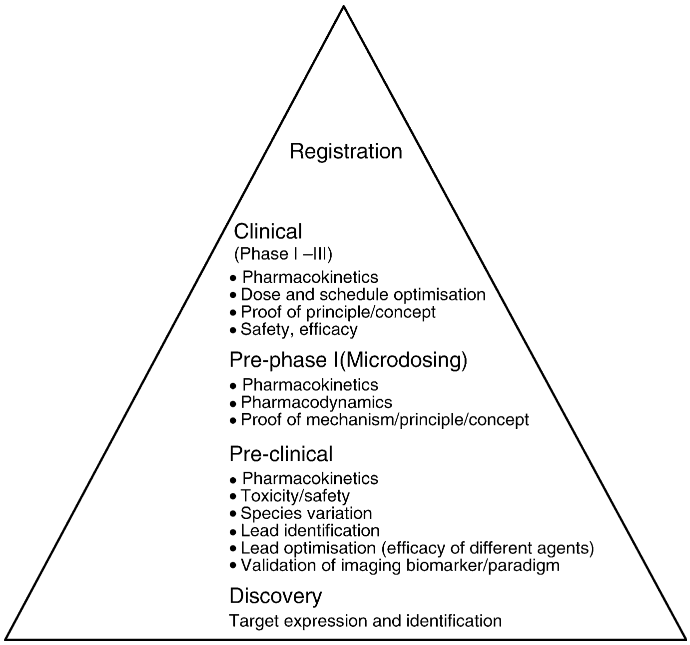
In vivo kinetics of the radiotracer in the body can be assessed by methods such as simple visual inspection, semi-quantitative methods, which measure radiotracer uptake at a certain time point (standardised uptake value) or quantitative methods, which use complex analytical methodology. Quantitative parameters of interest can be derived using either model-led compartmental techniques or data-led methods such as spectral analysis, where limited *a priori* assumptions are made. For this, generation of tissue and arterial blood time-activity curves (TACs) is required. While tissue TACs are generated from the dynamic imaging data, arterial blood TACs require arterial or arterialised venous blood sampling or can be derived from PET images, representative of arterial blood such as the left ventricle or aorta. The lack of specificity of PET to distinguish between the radioactive chemical species presents additional challenges in PET data analysis. A number of strategies have been adopted to account for the tissue contribution of metabolites such as a dual radiolabelling strategy or performing additional metabolite correction scans (1).

The Role of PET in Drug Discovery Processes

The ability to provide quantitative *in vivo* tissue functional data of high sensitivity, makes PET an ideal complementary tool in the drug developmental process (2). Specifically, PET is ideally suited to provide *in vivo* tissue information on both the drug's behaviour within the body (▶pharmacokinetics) and its effects (▶pharmacodynamics), which have so far relied on surrogate data obtained from body fluids. While PET-pharmacokinetic studies require radiolabelling of the target drug and therefore early involvement of radiochemical expertise as soon as the lead compound is identified, radiolabelling of the therapeutic target is required for PET-pharmacodynamic studies. Although, such selection of a pharmacodynamic target will be based on the status of our biological knowledge at that time and may be time consuming, once a pharmacodynamic target is identified and validated, this can be used as an imaging ▶biomarker to generically evaluate a number of agents that target the specific pathological process. This will allow hypothesis-testing clinical-trial designs to be incorporated to obtain proof of principle of mechanism of action during early drug development and in the establishment of the optimal therapeutic dose for biological agents that result in disruption of specific functional processes. A summary of the potential role of PET in drug discovery and development is illustrated in Fig. 1.

Pharmacokinetic Evaluation

Improvements in radiochemical synthetic strategies and the availability of animal PET scanners of high spatial resolution (~1 mm) (3) allow for the early evaluation of novel agents in animals for lead identification and optimisation. Pre-clinical studies can also provide important information on drug metabolism and inter-species variation in drug handling. Clinical 'microdosing' strategies, wherein tracer quantities of drug, several thousand-fold lesser than therapeutic concentrations are administered (4), are likely to provide valuable pharmacologic information and aid in the drug discovery process.



PET in Drug Discovery Imaging. Figure 1 Potential areas where PET can complement the drug discovery and developmental process. The pyramidal structure denotes the current high-attrition rate from discovery to drug registration.

An efficient radio synthetic strategy and production to GMP standards is required for clinical pharmacokinetic evaluation of radiolabelled therapeutic agents. As an example, the development of *N*-[2-(dimethylamino)ethyl] acridine-4-carboxamide, an anti-cancer agent radiolabelled with carbon-11 ([^{11}C]DACA) is described. Pre-clinical PET studies demonstrated no unexpected inter-species differences in metabolism of [^{11}C]DACA that would have alerted a change in the planned phase I study. Subsequent clinical 'microdosing' PET studies performed prior to phase I studies at 1/1000th of the phase I starting dose and during a dose escalating phase I study showed myocardial uptake that demonstrated saturation kinetics at phase I doses (Fig. 2), suggestive of potential cardiotoxicity. [^{11}C]DACA pharmacokinetics in the brain did not suggest potential neurotoxicity, in contrast to animal studies, where neurotoxicity and not cardiotoxicity was observed (1). In another clinical [^{11}C]DACA-PET study, it was concluded that the 120 h infusional schedule was unlikely to be efficacious despite the maximal tolerated dose being reached as saturation was not observed in the primary target tissue that is the tumour (1). Such information of tissue drug pharmacokinetics will aid in dose and schedule selection.

PET is also likely to contribute substantially in the quantitative evaluation of targeted therapies such as gene therapy. In particular, the assessment of successful gene delivery, the location, magnitude and timing of gene expression can be evaluated with PET without the need for serial biopsies. The method is based on the linkage of the therapeutic gene under investigation to a so called 'PET reporter gene', which codes for an enzyme or receptor that can be imaged using a PET tracer.

Pharmacodynamic Studies

Imaging Receptor–Ligand Binding

PET imaging of receptor–ligand binding has proven to be especially important in the development of agents that target the central nervous system. This has been greatly aided by the availability of several receptor-specific ligands, most of which do not undergo metabolism (Table 1). Theses studies focus on the regional uptake of ligands and are used to derive parameters such as receptor number (B_{max}), affinity (K_d) and binding potential (BP) and can be used to examine if drugs reach their receptor targets providing proof of mechanism. In addition, information on dose occupancy in phase I and II studies, will aid in rationalising the choice of dosing in clinical trials and microdosing studies with potential drugs could guide in lead selection and optimisation at early stage in drug development (5).

Imaging Glucose Metabolism

Monitoring of glucose metabolism by the analogue tracer [^{18}F]-fluoro-deoxy glucose (FDG), has been used for delineation of ischaemic myocardium, areas of epileptic focus and for staging, response and prognostic evaluation in oncology. FDG follows the same route as glucose into

5-HT$_2$-serotonin-receptor	[^{18}F]-Setoperone	Affective disorders
Benzodiazepine-receptor	[^{11}C]-flumazenil	Anaesthetics, Epilepsy
Opioid receptor	[^{11}C]-diprenorphine	Pain
	[^{11}C]-carfentanil	Drug addiction
Oestrogen receptor	16-α[^{18}F]-fluoro-17β-oestradiol	Breast cancer

cells where it is phosphorylated to FDG-6-phosphate, but unlike glucose, there is little further metabolism and FDG-6-phosphate remains essentially trapped within cells. FDG-6-phosphate has low membrane permeability and although dephosphorylation does occur, it is very slow in brain, heart and tumour, which have very low levels of glucose-6-phosphatase. FDG uptake in tumours probably reflects a combination of factors including phosphorylating activity of mitochondria, degree of hypoxia and levels of glucose transporters and is reflective of viable number of cancer cells.

The limitations associated with the use of structural changes in tumour volume as a measure of therapy efficacy, especially with targeted cytostatic anti-cancer agents, which do not produce a decrease in tumour volume despite an anti-cancer effect, has led to an increasing use of functional imaging as a pharmacodynamic marker of response. Since, changes in glucose metabolism in responding tumours are seen as early as a few days after treatment, FDG-PET can be used in the evaluation of novel targeted cancer therapy. Additionally, functional imaging methods would aid in the determination of the optimal therapeutic dose by relating the response to the drug dosage.

Imaging Cell Proliferation and Perfusion

Physiological uptake of FDG in the brain, accumulation in inflammatory conditions and the low or variable glycolytic activity of some tumour types has led to the evaluation of other PET pharmacodynamic markers in the development of targeted therapies. Validated PET markers of cell proliferation such as [^{11}C]-thymidine and the thymidine analogue [^{18}F]-fluoro-thymidine (FLT) have been used clinically. The short half-life and low radiation exposure associated with [^{15}O]H_2O-PET allows repeated scanning in the same subject and has been used as a pharmacodynamic perfusion marker in the evaluation of vascular targeted cancer therapies in man (1). Perfusion studies with PET have also been used to evaluate the effects of cardiac drugs like ß-adrenergic- or calcium-channel blockers on myocardial blood flow and flow reserve.

Development of Imaging Biomarkers

Imaging biomarkers are in various stages of development for hypoxia ([^{18}F]-fluoro-misonidazole, [^{62}Cu]-diacetyl-bis(*N*-methyl-thiosemicarbazone) which contributes to resistance to radiotherapy and some cytotoxic agents. Biomarkers for apoptosis or programmed cell death (Annexin V), a target of increasing importance in anticancer therapy, neuroprotective therapy designed to inhibit ischemic brain injury and screening for early transplant rejection, are also under development. It is envisaged that development and validation of such imaging biomarkers and their use would complement the drug discovery and developmental process and lead to a significant saving in time, money and health and lives lost to disease.

PET in Viability Imaging

U. Schnöckel, M. Schäfers
Department of Nuclear Medicine, University of Münster, Münster, Germany
schafmi@uni-muenster.de

Definition

In the management of patients with ischemic heart disease, assessment of myocardial viability is important in different clinical scenarios. This is especially relevant in patients with regional (hypo-/akinesia) or global (low ejection fraction) contractile dysfunction to estimate the individual benefit of revascularization [percutaneous transluminal coronary angioplasty (PTCA) vs. bypass surgery] with respect to improvement of contractile function and preoperative assessment of individual perioperative risk. In principle, methods assessing myocardial viability should aim to distinguish between ischemic but viable myocytes (so-called hibernating myocytes/myocardium) and scar tissue because only viable cells will profit from restoration of perfusion. In this respect, viable myocardial cells are characterized by a variety of various features, including cell membrane integrity, intact mitochondria, preserved glucose metabolism, preserved fatty acid metabolism, intact resting perfusion, and a preserved contractile reserve. However, viable myocardium need not fulfill all of these characteristic features.

Therefore, the combination of metabolic and perfusion imaging is a powerful clinical tool to predict myocardial functional recovery, since patients with preserved myocardial glucose metabolism despite reduced perfusion should benefit from revascularization. Furthermore, besides identifying ischemic but viable myocardium, parameters such as the extent of viable myocardium (e.g., at least ~25% of viable myocardium of the left ventricle, as assessed by viability imaging, is necessary to result in improved left ventricular ejection fraction after revascularization) are required for a careful selection of patients who are more likely to benefit from revascularization.

Imaging

Scintigraphic Perfusion Imaging

Scintigraphic methods currently used for imaging of the heart are primarily based on the injection of perfusion tracers (Tl-201, Tc-99m-tetrofosmin/-sestamibi) in conjunction with single photon emission tomography (SPECT), thus being capable of imaging myocardial ischemia. However, the myocardial uptake and retention of Tl-201 depends on both regional perfusion and normal cell membrane function because Tl-201 is taken up into myocytes *via* the energy-dependent Na^{+}/K^{+} exchanger. Accordingly, the myocardial uptake of the modern Tc-99m-labeled agents such as tetrofosmin and sestamibi depends on regional perfusion and intact mitochondria. Therefore, when these tracers are used, the fraction of viable myocytes is often underestimated because perfusion can also be reduced in ischemic but still viable myocardial segments. An inconspicuous perfusion, on the other hand, is definitive proof of viable myocardial cells.

In addition to scintigraphic perfusion imaging by the earlier described SPECT tracers, different positron-emitting tracers for perfusion imaging (N-13-ammonia, O-15-water, Rb-82) with positron emission tomography (PET) are available. In contrast to SPECT, PET has an established correction for photon attenuation and is therefore able to quantify myocardial perfusion in absolute units (mL/min/g tissue), which, apart from superior resolution and image quality, offers advantages over SPECT in diagnostic accuracy, sensitivity, and specificity.

Imaging of Myocardial Metabolism

F-18-fluordesoxyglucose (F-18-FDG) is a tracer by which regional myocardial glucose uptake and phosphorylation and thus an ATP-dependent process can be assessed. Physiologically, most myocardial energy production occurs through the beta-oxidation of free fatty acids, whereas only $\sim$30% of the energy is generated through glucose metabolism. In the presence of hypoxic and/or ischemic conditions, however, oxidative metabolism of free fatty acids is decreased, and glucose becomes the preferred substrate for the myocardium. F-18-FDG enters the myocytes by the same transport mechanism as glucose, namely by glucose transporter 4 (GLUT4). In the absence of insulin, GLUT4 exists in intracellular vesicles where it cannot facilitate glucose transport. Binding of insulin to its receptor on the plasma membrane initiates a signaling cascade that promotes translocation and fusion of GLUT4-containing vesicles with the plasma membrane, thereby enabling GLUT4 to transport glucose through the cell membrane. F-18-FDG is intracellularly converted to F-18-FDG-6-phosphate (phosphorylation) by the enzymatic hexokinase reaction. Differences in the affinity of FDG to hexokinase compared with the affinity of glucose to hexokinase have been discussed (and eventually corrected by a so-called lumped constant). Most importantly, different from glucose-6-phosphate, F-18-FDG-phosphate does not continue being converted enzymatically by glucose-6-phosphatase, but it stays trapped in the cell as F-18-FDG-6-phosphate.

Therefore, the accumulation of F-18-FDG depends on GLUT4 and hexokinase activity, and its trapping in myocytes characterizes these as being viable. Accordingly, nonreversible damage of the cell must be assumed when cellular F-18-FDG uptake is missing.

Another positron-emitting tracer to assess myocardial metabolism by PET is C-11-acetate. C-11-acetate characterizes the oxidative metabolism of the heart muscle. However, due to the short half-life of ^{11}C of 20.3 min (F-18-FDG has a half-life of 109 min) and the necessity of a cyclotron unit in direct proximity to PET, it is available in only a few centers worldwide.

More tracers have been developed to assess fatty acid metabolism and such; however, these have not yet been implemented in clinical algorithms.

Clinical Protocol

Because the energy demand of the heart muscle is accomplished primarily by fatty acids and only a smaller fraction by carbohydrates, it is fundamentally necessary that the metabolism at the time of tracer injection and the subsequent acquisition period be switched to glucose to get a reproducible and reliable myocardial signal when imaging with F-18-FDG-PET. In about 50% of examined patients, the assessment of viability using F-18-FDG-PET under fasting conditions cannot be interpreted because of very low F-18-FDG uptake. An increased glucose uptake can be achieved by hyperinsulinemia, which also induces a lowering of the concentrations of free fatty acids, in addition to the direct stimulation and to effects on the glucose metabolism, through an inhibition of lipolysis. In nondiabetics, hyperinsulinemia can be easily reached by oral glucose loading, resulting in increased insulin levels thereafter.

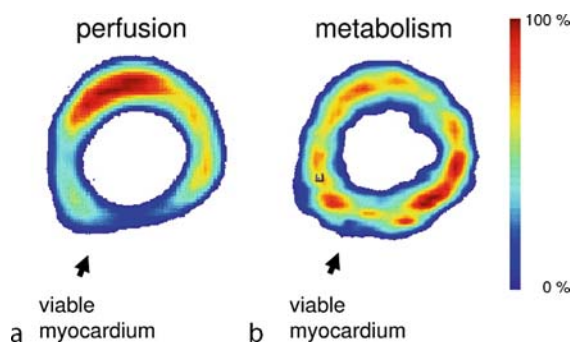
Switching the myocardial metabolism toward glucose is technically more challenging in diabetics, who represent a significant subgroup of patients with coronary artery disease. In diabetics, an intravenous infusion of basal human insulin with parallel and adjusted infusion of glucose is recommended to gain a hyperinsulinemic state (hyperinsulinemic euglycemic clamp protocol) besides. As an alternative or in addition to hyperinsulinemia, an increasing F-18-FDG uptake in the heart muscle can be induced by pharmaceutical lowering of free fatty acids in the plasma using nicotinic acid derivatives, such as acipimox. Acipimox inhibits peripheral lipolysis, thus reducing plasma free fatty acid levels and indirectly stimulating cardiac F-18-FDG uptake. Typically, the PET acquisition starts about 1 h after the F-18-FDG injection, allowing for significant trapping of F-18-FDG in viable myocardium.

Image Interpretation

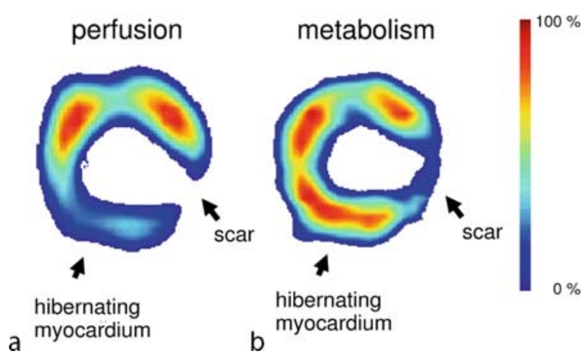
When F-18-FDG is used without a perfusion tracer, cut-off values of normalized F-18-FDG uptake are applied. In the quantification of the extent of viable myocardium, a cut-off value of about 50% is usually given to identify viable myocardium. However, especially when looking for the pathophysiological state of myocardial hibernation (characterized by reduced perfusion and preserved or enhanced glucose metabolism), it is crucial to correlate glucose metabolism with perfusion.

PET in Viability Imaging. Table 1 Typical patterns of perfusion and F-18-FDG uptake observed in dysfunctional myocardium (↔: normal, ↓ reduced, ↑ increased)

	Hibernation	Scar	Stunning
Perfusion	↓	↓	↔
FDG uptake	↔/↑	↓	↔



PET in Viability Imaging. Figure 1 Perfusion SPECT (a) and F-18-FDG-PET (b) in a patient with known coronary artery disease. The perfusion image shows reduced perfusion in the inferior wall (*arrow*, a), whereas F-18-FDG uptake is preserved in this region (*arrow*, b). This is a typical example for the imaging correlate of *hibernating myocardium* (perfusion-metabolism mismatch).



PET in Viability Imaging. Figure 2 Perfusion SPECT (a) and F-18-FDG-PET (b) in a patient with known coronary artery disease. The images show a matched reduction of perfusion and F-18-FDG uptake in the inferolateral wall, demonstrating a scar (*arrows* a, b). In the inferior wall, the perfusion is reduced despite preserved F-18-FDG uptake, demonstrating myocardial hibernation (*arrows* a, b).

A combination of several patterns of myocardial perfusion and F-18-FDG uptake can be seen in dysfunctional myocardium (Table 1).

Myocardial areas with reduced perfusion despite preserved glucose metabolism (so-called mismatch) indicate the presence of *myocardial hibernation*, typically associated with significantly improved contractile function after revascularization (Fig. 1).

Scar tissue shows a matched reduction in myocardial perfusion and F-18-FDG uptake. A revascularization is not likely to improve function of the myocardium (Fig. 2).

In dysfunctional segments, perfusion and F-18-FDG uptake may be preserved. These segments may represent *stunned myocardium*, evolving from repetitive episodes of myocardial ischemia. Stunned myocardium is characterized by prolonged but reversible postischemic dysfunction despite reperfusion.

The positive and negative predictive values of the combination of a perfusion SPECT and an FDG-PET for assessing myocardial viability are 72–95% and 75–100%, respectively. Therefore, F-18-FDG-PET is the assumed gold standard of noninvasive imaging of myocardial viability.

Synonym

Induratio penis plastica (IPP)

Definition

Peyronie's disease (PD) is a localized disorder of the tunica albuginea of the penis with fibrous scar tissue replacing the normal elastic fibres. Characteristically, penile deformation of the penis is evident during erection. Marked penile deformity might interfere with the ability to have satisfying sexual intercourse (1).

Clinical Presentation

On the flaccid (and erect) penis the typical plaque tissue is palpable. Occasionally, signs of a systemic fibromatosis (e.g. Dupuytren's contracture) are observed. The penile deformity is only seen on the erect penis (Fig. 1).

Phakomatoses. Figure 1 Peyronie's disease with typical penile deformity on erect Penis.

Imaging

Imaging studies are rarely necessary in patients with Peyronie's disease. An ultrasound examination (or eventually MRI) allows assessing the exact size of the scar tissue and calcified plaque will cast acoustic shadowing. Colour duplex ultrasound after stimulation of the corpora cavernosa might be necessary to rule out coexistent erectile dysfunction and to distinguish between arteriogenic insufficiency and veno-occlusive erectile dysfunction. Furthermore, a penile blood flow study can depict the relationship between the plaque and dorsal arteries and collaterals to the cavernous arteries. In order to assess the penile deformity photographs of the erect penis either taken by the patient himself or by the treating urologist after pharmacostimulation is mandatory before planning surgery (see Penile Fracture Fig. 1).

Synonyms

Hypophysis; Sella turcica

Definition

Sellar pathology usually concerns pituitary lesions, often ►microadenoma or ►macroadenoma (1, 2). The diagnostic work-up of a patient with endocrine disease has changed with the advent of magnetic resonance imaging (MRI). Other tumors can arise in the sella turcica, and tumors in the surrounding structures may occasionally extend into the sella turcica (1).

Pathology/Histopathology

The two most common pituitary gland tumors are microadenoma and macroadenoma. Macroadenoma is by definition larger than 1 cm. There have been attempts to correlate hormonal activity with the tumor type, but nonhemorrhagic solid prolactin and growth hormone-secreting adenomas could not be distinguished on imaging.

The search for a microadenoma, by definition less than 1 cm and often smaller than 5 mm, remains a challenge. The diagnostic work-up of patients with ►Cushing's syndrome is even more difficult, and MRI can detect only up to 70% of the pituitary adrenocorticotropic hormone (ACTH)-producing tumors.

There is a long list of nonpituitary sellar tumors. The most common are ►craniopharyngioma and Rathke cleft cyst. Craniopharyngiomas arise from remnants of Rathke's pouch, which forms part of the intermediate part of the anterior lobe and pituitary stalk. The craniopharyngioma that is seen in teenagers is the adamantinous type, whereas in the elderly population the squamous-papillary type is more common. A Rathke cleft cyst is a pathological enlargement of the remnant of Rathke's pouch and is located between the two lobes of the pituitary gland.

There are several lesions that extend from outside the sellar region into the sella and cavernous sinus. Only meningioma will be mentioned here. This tumor arises from the meningoendothelial cells of the dura.

In lymphoproliferative disorders such as leukemia, involvement of the skull base can be associated with dural pathology extending into the sella turcica.

Clinical Presentation

Because of the complex anatomical relationships in the sellar and parasellar region, patients may present either with endocrinological abnormalities or with neurological symptoms such as headache and visual disturbances.

Patients with nonfunctioning macroadenomas may present with symptoms of hypopituitarism. In the acute stage, patients may present with pituitary apoplexy, and hemorrhage will be seen in the pituitary adenoma.

Hyperprolactinemia is a common sign of microadenoma. Cushing's syndrome is due to overproduction of adrenocorticotrophin.

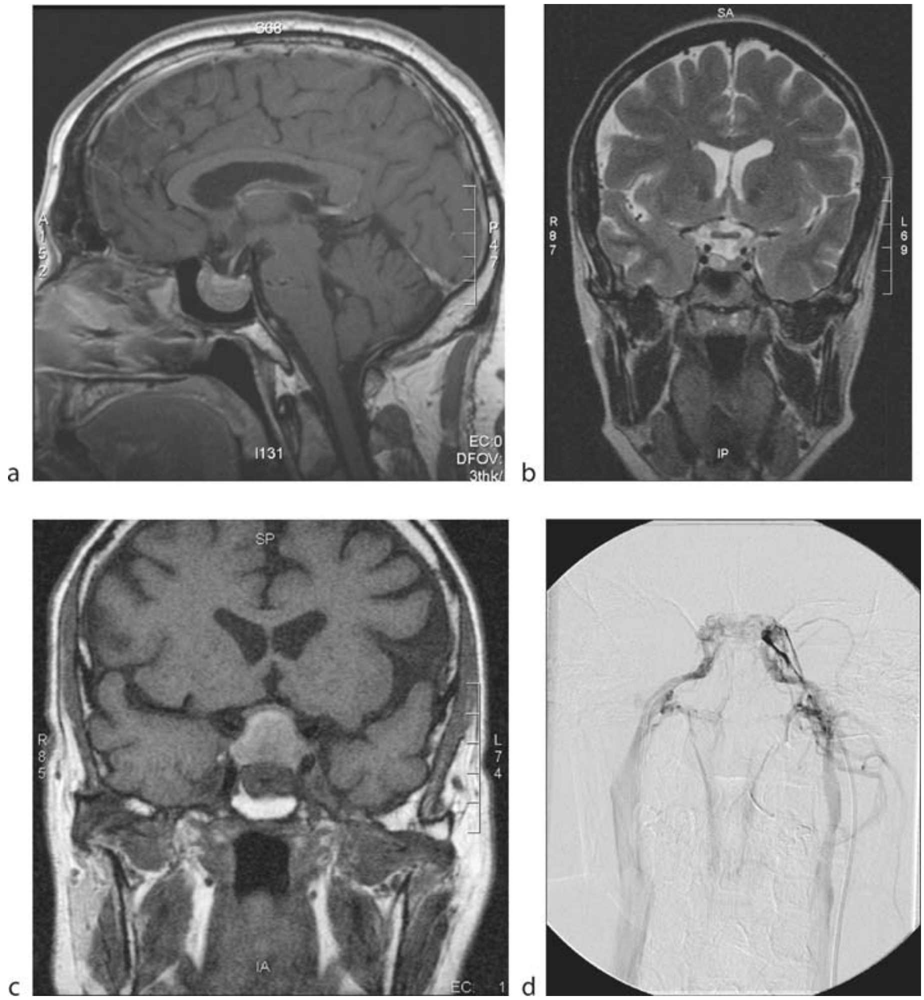
Diagnosis

Imaging of the sellar region is usually best achieved by using multiple planes. Coronal images are often considered the most useful. MRI is certainly preferred, but computed tomography (CT) can occasionally contribute to the diagnosis by showing the presence or absence of calcification. A precise description of the tumor's location and extension and of the anatomical course of the arteries and nerves is required.

A macroadenoma will show a variable degree of enhancement and may contain areas of necrosis, hemorrhage, or cystic degeneration (Fig. 1). In pituitary apoplexy, hemorrhagic changes will be recognized as spontaneously hyperintense signal in the adenoma (Fig. 1). Macroadenomas measure at least 1 cm, but they can become huge tumors before they become symptomatic, particularly when they grow in the direction of the skull base (the so-called aggressive pituitary adenoma). A macroadenoma can invade the cavernous sinus and may cause encasement of the carotid arteries, or it can grow upward and compress the optic chiasm. Following surgery, the first scan is recommended at 4 months, provided there are no postoperative complications. Further scans can be obtained after 1 year and 5 years. Following medical treatment, MRI is also recommended to monitor the tumor size and signal changes.

The suspicion of microadenoma is probably best examined by MRI, although some radiologists may still recommend CT (1). CT is often requested to assess the bone thickness when transsphenoidal resection is planned.

Microadenomas are typically hypointense on coronal T1-weighted images and hyperintense on T2-weighted

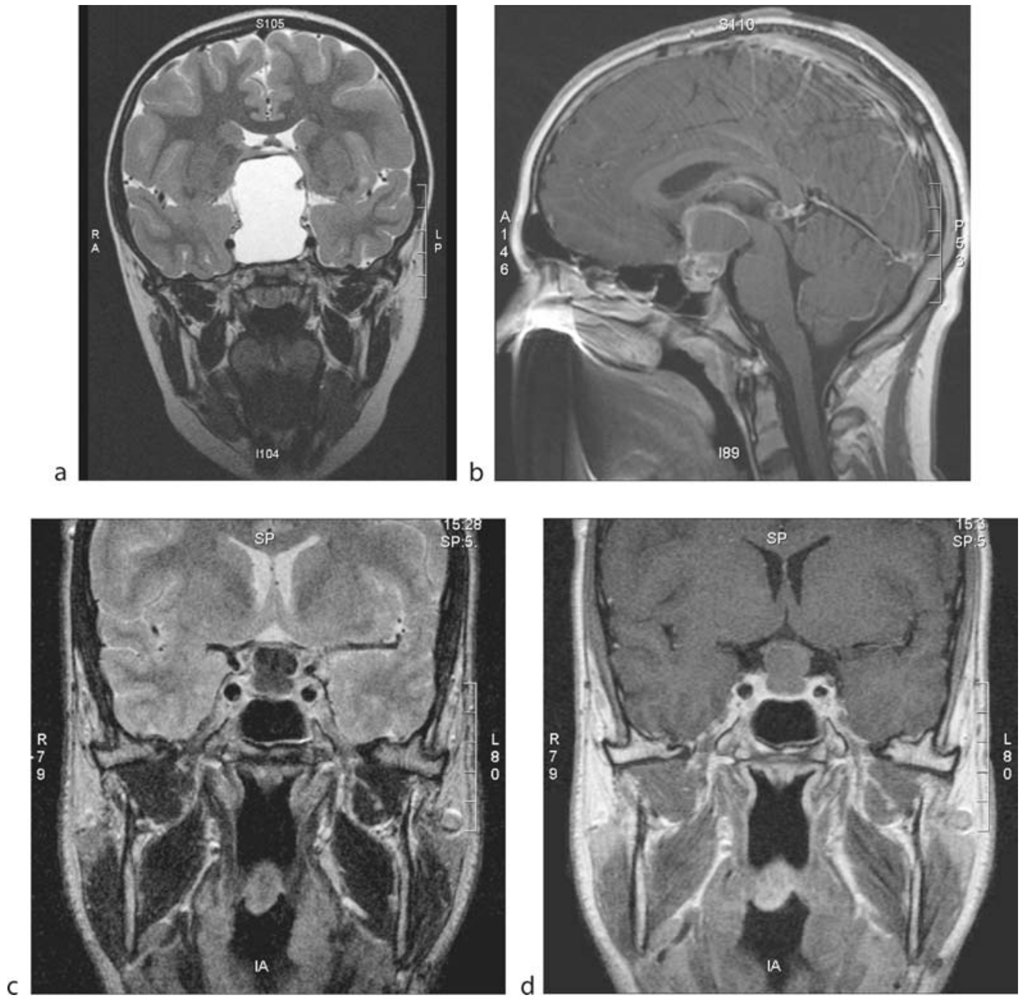


Pituitary Gland. Figure 1 Macroadenoma and microadenoma. (a) The sella turcica appears enlarged, and a macroadenoma is seen on the sagittal image. (b) Coronal image demonstrating a microadenoma on the right side. (c) Pituitary apoplexy can be recognized as a spontaneous high signal on a T1-weighted image, reflecting the presence of hemorrhage. (d) Patient with Cushing's syndrome and no microadenoma on magnetic resonance imaging. Positioning of the catheter in the right and left inferior petrosus sinuses prior to sampling is confirmed by injecting a contrast agent.

images compared with normal pituitary gland (Fig. 1). Following contrast administration, this will become even more evident. The sensitivity of pre- and postcontrast T1-weighted images is estimated to be approximately 80%. A few additional tools can help to increase the sensitivity: Dynamic T1-weighted images provide a set of contrast-enhanced images within 1 min thanks to the faster acquisition times. This may lead to the detection of a further 5% of lesions. Occasionally, T2-weighted images can detect a microadenoma. Finally, delayed contrast-enhanced T1-weighted images (20–25 min after the injection of gadolinium) will slightly improve the detection rate.

In Cushing's syndrome and when there is no evidence of a pituitary tumor, inferior petrosal sinus sampling is recommended in order to measure the ratio of central to peripheral ACTH levels (Fig. 1). Sampling is performed bilaterally and allows localization of the source of excessive production of ACTH.

Craniopharyngiomas are characterized by the presence of contrast enhancement, cyst formation, and calcification (Fig. 2). This tumor is located along Rathke's pouch, and this will cause the tumor to be oriented posteriorly in the suprasellar region. In the differential diagnosis, macroadenoma can be differentiated by its



Pituitary Gland. Figure 2 **Craniopharyngioma and Rathke's cleft cyst. (a) Intrasellar and suprasellar craniopharyngioma on a coronal image. Note that the signal is higher than the cerebrospinal fluid signal. (b) Sagittal image of a suprasellar craniopharyngioma. The pituitary gland is normal. (c) Coronal T2-weighted image of a Rathke's cleft cyst. The low T2 signal is a common feature of these lesions. (d) Coronal contrast-enhanced image of the same patient shows the absence of enhancement of the core of the lesion with a mild peripheral enhancement.**

straight upward orientation and usually major involvement of the sella turcica. The cystic component of craniopharyngioma contains a variable amount of cholesterol, triglycerides, methemoglobin, and epithelial remnants. It is not possible to differentiate the two histological subtypes of craniopharyngioma.

Rathke's cleft cysts can be an incidental finding, but they may be symptomatic if they are large enough to cause local compression. The content of the cyst has typically been compared to motor oil. The MR appearance can vary from hypointense to hyperintense both on T1- and T2-weighted images (Fig. 2).

In meningiomas the relationship to the dura is the most useful differential diagnostic sign (Fig. 3). Metastases in the sphenoid sinus will be associated with bone destruction and local invasion of the surrounding structures. Occasionally, leukemia can manifest as skull base changes and dural involvement extending into the sellar region (Fig. 3).

Placode

A segment of nonneurulated embryonic neural tissue, i.e., frozen at the neural plate stage. All OSDs are characterized by the presence of a placode that grossly corresponds to the segment of the spinal cord that is exposed externally. Several, but not all, forms of CSDs also have a placode, but in this case the integuments cover it. A placode may be categorized into terminal and segmental depending on location along the spinal cord. A terminal placode lies at the caudal end of the spinal cord and may in turn be either apical or parietal, depending on whether the defect involves the apex or a longer segment of the cord. Conversely, a segmental placode lies at an intermediate level along the spinal cord, which regains normal morphology and structure caudad to the abnormality.

Definition

Atherosclerosis is a systemic inflammatory disorder that affects primarily large and medium-sized arteries. The disease involves multiple vascular beds simultaneously, such as the aorta, coronary, carotid, and superficial femoral arteries (1). Symptoms are most often related to significant luminal stenosis or occlusion. However, clinical events are frequently due to acute complications in plaques that cause only mild to moderate narrowing, particularly in the coronary tree. Reliance on changes in luminal caliber is therefore insufficient for adequate predictions of disease burden or probability of events.

Pathology/Histopathology

Atherosclerosis is characterized by the accumulation of various components in the intima of medium and large sized arteries. The main components of atherosclerotic plaque are: fibrous elements such as connective tissue extracellular matrix (collagen, proteoglycans, fibronectin, elastic fibers); lipids (crystalline cholesterol, cholesteryl esters, phospholipids); inflammatory cells (monocyte-derived macrophages, T-lymphocytes, smooth-muscle cells). The occurrence of these components in varying proportions in different plaques gives rise to a spectrum of lesions. Furthermore, the characteristics of "high-risk" or "vulnerable" plaque vary depending on the arterial region (i.e., coronaries, carotids, or aorta) in which it is located. In an attempt to categorize these complex lesions, the American Heart Association (2) created a detailed classification scheme that is designed to be used as a histological "template." An accurate tracking of lesion types *in vivo*, using noninvasive imaging techniques would be very useful clinically to determine the status of atherosclerosis.

Clinical Presentation

The clinical presentation is widely variable and depends on the affected vascular beds. Atherosclerosis is a chronic disease that affects medium and large arteries resulting in plaque formation that may grow to obstruct the lumen or may disseminate material into the blood stream and may cause myocardial infarction, stroke, and peripheral vascular disease.

Imaging

Imaging modalities applied to the evaluation of cardiovascular disease must be able to examine multiple vascular territories and to visualize not only luminal caliber, but also the arterial wall characteristics with high spatial and tissue contrast resolution. Magnetic resonance imaging (MRI) meets all of these requirements. Invasive X-ray angiography is generally considered the *gold standard* for the diagnosis of vascular stenoses, but provides minimal information on the status of the vessel wall and may be associated with significant complications. Computed tomography (CT) is an alternative noninvasive modality, particularly for the coronary arteries, although it is limited in the evaluation of plaque composition and involves the use of nephrotoxic contrast agents and ionizing radiation. Ultrasonography can provide quantitative measures of arterial wall thickness, particularly in superficial vessels, but shows limitations in the evaluation of deeper structures or in plaque characterization. In this context, cardiovascular MRI has become the modality offering the broadest capabilities for the assessment of systemic and regional atherosclerotic disease. Various MRI techniques and applications for the evaluation of arterial wall and atherosclerotic lesions are available now. Spin-echo (or black-blood) sequences are commonly employed because they render the moving blood invisible. Subsequent technical developments have enabled the simultaneous acquisition of multiple slices, resulting in significant shortening of imaging times.

The characteristics of the signal originated from a particular tissue depend in part on the amount of water and intrinsic magnetic properties. These can be characterized by two parameters: the T1 (longitudinal relaxation time) and T2 (transverse relaxation time). In so-called T1-weighted (T1W) images tissues with long T1 times will have low signal intensity. Conversely, in T2-weighted (T2W) images tissues with long T2 times will have high signal intensity in comparison with those with short T2. In proton density-weighted (PDW) images, the amount of signal depends on the concentration of water (or fat) molecules (Fig. 1). The use of "multicontrast" imaging (the combination of different weightings

and sequences, usually 3–4) improves the ability to characterize atherosclerotic plaques with MRI. The most commonly employed approaches include T1W, T2W, and PDW spin-echo sequences. Frequently, bright-blood techniques such as 3D TOF are used to depict specific plaque characteristics. Additional sequences include diffusion weighting, magnetization transfer weighting or SSFP. The imaging characteristics of various plaque components in different sequences are summarized in Table 1.

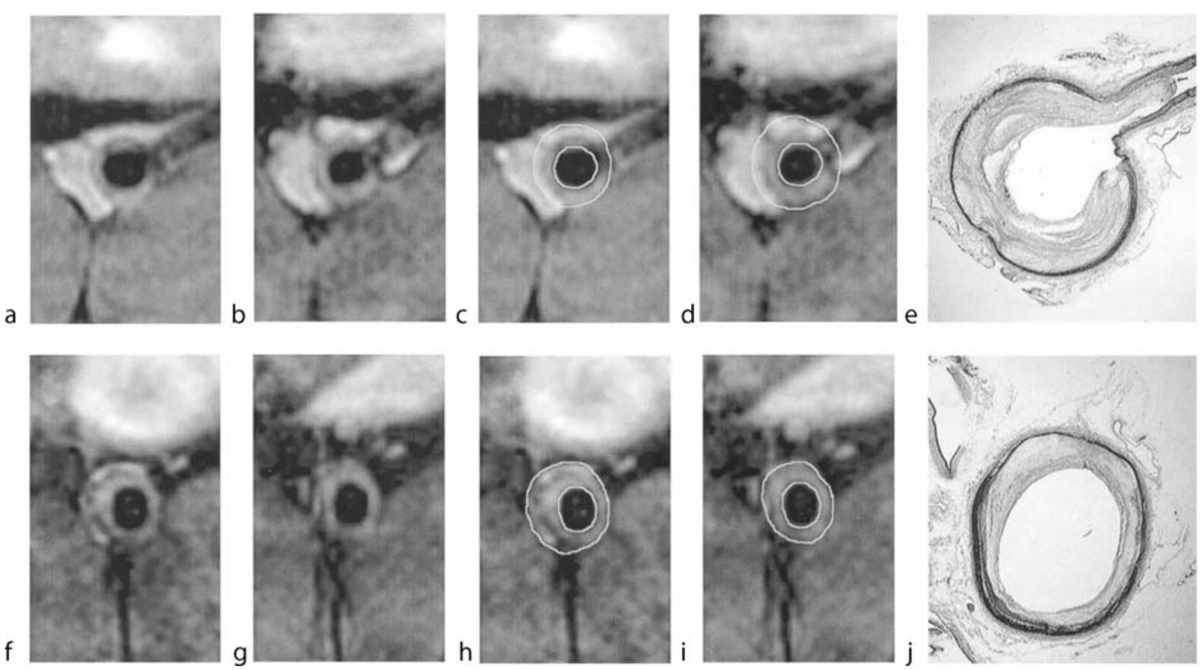
Nuclear Medicine

The use of radiotracers has a potential utility for diagnostic and imaging atherosclerotic lesions *in vivo*. The main advantage of single photon emission computed tomography (SPECT) and positron emission tomography (PET) is that they both benefit from imaging agents that can be detected in extremely low concentration (picomolar range). However, the main disadvantage of this technique is the poor spatial resolution and paucity of anatomical information regarding atherosclerotic lesions. In addition, the slow clearance of labeled particles from circulating blood contributes to a low target-to-background count ratio. To overcome this issue, images can be acquired by coregistration of scintigraphic images with CT or MRI. Therefore, PET–CT has emerged as a promising alternative technique for the detection of vulnerable atherosclerotic plaque by the association of the high CT spatial resolution and the PET high sensitivity for metabolic activities detection.

Diagnosis

Initial MRI validation studies were performed with *ex-vivo* specimens and compared with histopathology. Subsequently, the feasibility of *in-vivo* imaging and detection of plaque composition was demonstrated both in animal models and patients. Multicontrast imaging allows for detection of all main plaque components with high sensitivity and specificity: fibrous cap, fibrocellular tissue, lipid core, adventitia, calcium and thrombus/hemorrhage. Most human investigations have evaluated carotid arteries due to their superficial location and the ease to obtain histopathologic correlates with surgical endarterectomy samples. In evaluations of carotid artery atherosclerosis *in-vivo*, black-blood MRI provides accurate measurements of luminal caliber, wall thickness, and plaque areas. Using TOF it is possible to visualize the fibrous cap as a hypointense band in the wall inner boundary. This approach enables to differentiate thin versus thick fibrous caps, and to identify the presence of cap disruption. MRI depicts also the presence and extent of intra-arterial thrombosis or intra-plaque hemorrhage and might differentiate occlusive versus subocclusive clot.

Additionally to the proven MRI diagnosis accuracy, there is an excellent agreement with histopathology for the delineation of lesion size, extent, and morphology. The inter- and intraobserver agreements for both luminal and plaque dimensions are very high. Importantly, so is the interscan reproducibility, making it possible to detect small changes in indexes of plaque burden when serial scans are performed. The positive vascular remodeling associated with early stages of atherosclerosis progression is readily identified with MRI. Moreover, progression and regression of atherosclerotic plaques, as well as sequential changes in composition, can be measured with MRI. After prolonged Statins therapy significant reductions in both carotid and aortic plaque size has been demonstrated. Other therapies for atherosclerotic disease



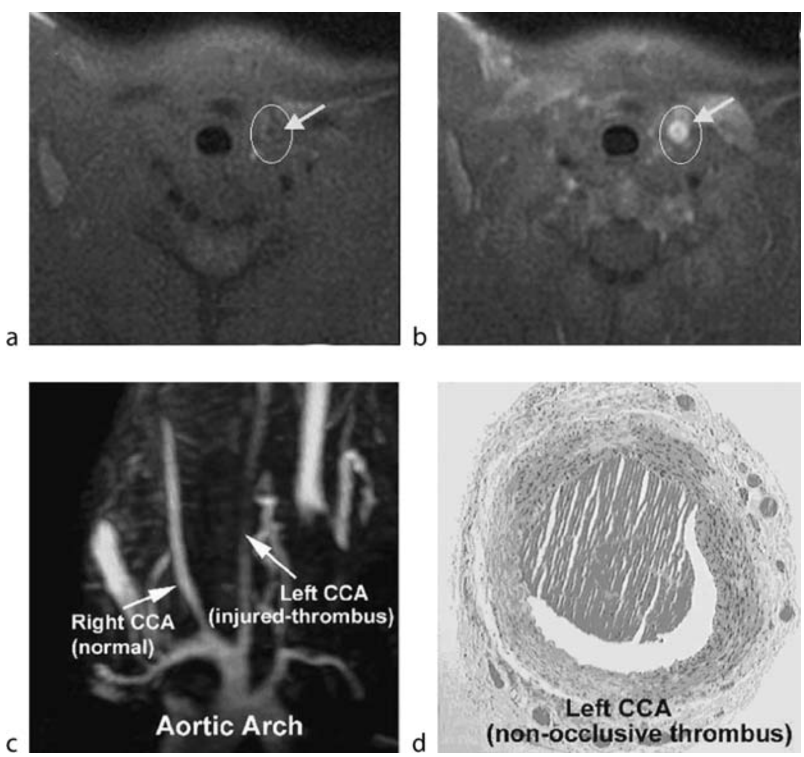
Plaque Imaging, MRI. Figure 2 Serial MRI studies of rabbit abdominal aortic plaques. The upper panels show the progression in the high-cholesterol diet group: baseline images (a, c) and at the end of treatment (b, d). The lower panels demonstrate the regression of the disease in the normal chow diet plus simvastatin plus PPARγ group: baseline images (f, h) and at the end of treatment (g, i). The right panels (e, j) show the matched histologic section at the end of treatment. (From Corti et al, 2004)

tested *in-vivo* with MRI (either in animal models or in humans) include peroxisomal proliferator-activated receptor-gamma agonists (PPAR) (3), thromboxane inhibitors or percutaneous interventions in the femoropopliteal territory (Fig. 2).

Because of the limited signal-to-noise ratio (SNR) available, in particular in small vessels and superficial structures, contrast agents such as gadolinium chelates have been used to increase MR signal. Gadolinium-based extracellular contrast agents can improve contrast amongst plaque components and better delineate the fibrous cap in human carotid and aortic lesions. However, the use of conventional contrast agents for plaque characterization is limited to a certain extent by their nonspecificity, as they tend to distribute indistinctly in multiple tissues and organs. The emerging field of molecular imaging is devoted to the visualization of pathophysiological processes at the cellular and molecular level. Highly specific contrast agents can be constructed by linking the contrast to a compound with high affinity for a particular cell, molecule, or metabolic pathway (i.e., an antibody or an enzymatic substrate). Occasionally, the resulting contrast agent can be "activated" by the enzyme, and therefore will only be detected if the metabolic process of interest is ongoing. MRI is particularly attractive for molecular applications due to good spatial resolution, high contrast agent affinity, and safety profile.

In the specific context of atherosclerosis there are multiple attractive targets with the potential to highlight specific features of disease activity or plaque vulnerability. Gadolinium has been attached to peptides with high affinity for fibrin (Fig. 3) , allowing for the visualization of experimental acute, subacute and chronic arterial thrombosis (4, 5). Additional potential targets for MRI contrast agents include both low-density and high-density lipoprotein cholesterol, platelets, activated factor XIII, endothelial adhesion molecules, tissue factor, proteins involved in apoptosis, or stem cells. This modality provides with one of the most promising diagnosis technique for plaque characterization toward detection of plaque with high risk of rupture.

Novel image analysis methods that combine automatic wall contour detection and multicontrast weighting



Plaque Imaging, MRI. Figure 3 ***In-vivo*** **MR thrombus imaging of the carotid artery in a guinea pig. Transverse MR images obtained before (a) and after (b) injection of a fibrin-specific contrast agent. Thrombus (*light arrow*) in the injured left common carotid artery (CCA) demonstrates marked contrast enhancement after injection. The contralateral uninjured CCA does not show any enhancement. The MRA (c) shows normal patency in the uninjured right CCA, and decreased flow in the thrombosed left CCA. The corresponding histopathological section of the left CCA is shown in D (Hematoxylin-and-Eosin staining). (Adapted from Sirol et al, 2005)**

analysis are being developed and promise to simplify the application of MRI for the assessment of atherosclerosis both in the research and clinical arena.

Conclusions

At the present time, MRI has emerged as the imaging modality with better suitability for the comprehensive evaluation of atherothrombotic disease. MRI accurately depicts arterial wall abnormalities and atherosclerotic plaque extent and composition. Obtained in a noninvasive fashion, with a high safety profile, and with excellent spatial and tissue contrast resolution, MRI is believed to even improve further both plaque detection and characterization, when molecular techniques become clinically available. Molecular MRI, with its ability to depict highly specific physiopathologic processes, shows potential for further improving our understanding of atherothrombosis. Such an approach will provide estimations of the burden of disease, and potentially, depiction of plaque with high risk of rupture, improving patient risk stratification.

Synonyms

Fibrous mesothelioma; Mesothelial fibroma; Pleural fibromas

Definition

These tumors are rare, primarily arise from the visceral pleura, and account for less than 5% of all pleural tumors. Synonyms used to describe these tumors include pleural fibromas, fibrous mesothelioma and mesothelial fibroma. These inconsistencies in nomenclature arise due to the unpredictable histological and biological behavior of these tumors.

Pathology

The macroscopic appearance is either of a smooth or lobulated pedunculated uni- or multifocal pleural mass with a translucent serosa. In larger masses, areas of hemorrhage and degeneration may be evident. Histologically a number of patterns have been described, the commonest being a patternless and hemangiopericytoma pattern.

Clinical presentation

Clinical symptoms have been shown to be related to tumor size. Tumors measuring less than 10 cm are usually asymptomatic. Whereas those greater than 16 cm can cause nonspecific respiratory symptoms such as cough, hemoptysis, chest heaviness and occasionary rarer systemic paraneoplastic symptoms including hypoglycemia, hypertrophic pulmonary osteoarthropathy and clubbing (1).

Patients can present at any age, although most present during the 6–7th decade. A slight female predominance has been noted.

Imaging

On chest radiography small tumors are smooth lobulated masses within the lower thorax, although they may conform to the shape of adjacent structures thereby mimicking diaphragmatic eventration and mediastinal masses. A vascular pedicle is rarely visualized, however its presence is inferred by the tumors, change in position on sequential radiographs.

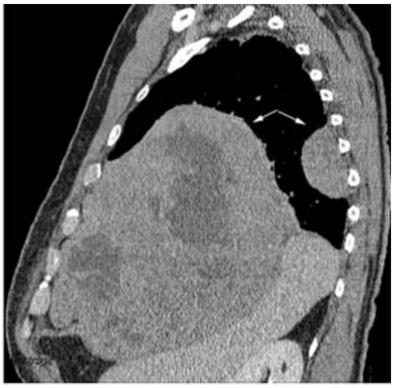
The pleural origin of these tumors is suggested by their well-defined inferior border but ill-defined superior border, the so-called “incomplete border sign.”

The tumors are typically homogeneous with an intermediate attenuation similar to that of muscle on CT, and uniformly enhance following intravenous contrast. Small tumors are well defined with tapering edges forming an obtuse angle to the pleural surface. Larger tumors are typically heterogeneous, displace adjacent structures and form an acute pleural angle. Calcification is rare, occurring in 10% of cases and often punctate when present. Pleural effusions have been reported in 20% of cases (Fig. 1).

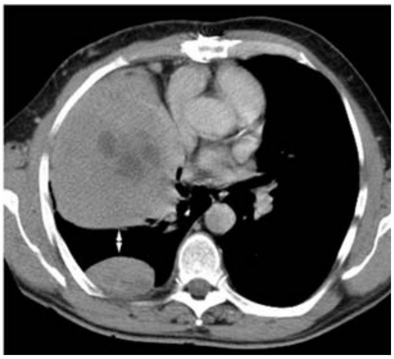
There are no categorical radiological features to differentiate a benign from a malignant pleural fibroma. The presence of mass effect, compressive atelectasis, heterogenicity and a pleural effusion should raise the possibility of malignancy.

Pleural fibromas return a low/intermediate signal on T1W, T2W, and PD MR sequences. As with CT, post contrast these tumors avidly enhance. In larger tumors areas of high signal on T2W images correspond to areas of necrosis and myxoid degeneration. The serosal covering may be visualized as a rim of low signal (2).

a



b



Pleura, Localized Fibrous Tumor. Figure 1a Typical appearance of localized fibrous tumors of the pleura on CT (arrows).

Diagnosis

The CT and MR appearances are invariably characteristic. Definitive treatment involves en bloc surgical resection which is curative in most cases. Pre-operative biopsy is therefore rarely indicated especially as percutaneous biopsy may not necessarily exclude underlying malignant transformation.

Definition

Numerous primary malignancies are known to metastasize to the pleura. Bronchogenic carcinoma is the commonest accounting for 40% of cases. Breast carcinoma metastases account for 10%, ovarian and gastric carcinoma 5% and lymphoma 10% of cases. Pleural lymphomatous deposits usually represent disease recurrence or occur with synchronous mediastinal and parenchymal disease. Invasive thymoma may also spread contiguously along the pleura.

Clinical Features

Clinical symptoms and signs conform to the origin of the primary malignancy. Thoracic symptoms include cough, increasing shortness of breath and chest pain.

Imaging

The radiographic, ultrasound, CT and MR appearance of pleural carcinomatosis especially if unilateral are indistinguishable from mesothelioma.

Numerous studies have shown that on CT, malignant pleural disease is suggested by the presence of parietal pleural thickening greater than 1 cm, circumferential parietal thickening, nodular pleural thickening and mediastinal pleural thickening with specificities of 94–100% (1).

fergus.gleeson@radiology.oxford.ac.uk

Definition

A pleural effusion is defined as excess fluid within the pleural space. The normal pleural space usually contains 5–10 mL of fluid.

Clinical features

Most patients present with increasing breathlessness. Associated symptoms of productive cough and fever, chest pain and weight loss are suggestive of an inflammatory effusion or probable malignant effusion respectively.

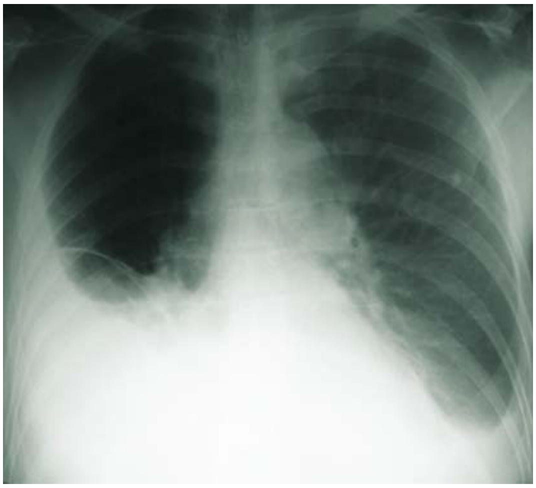
Imaging

On an erect chest radiograph 50 mL of fluid results in blunting of the costophrenic angle, whereas 200 mL is necessary to blunt the lateral costophrenic angles. The lateral decubitus view is the most sensitive view and allows 5–10 mL to be demonstrated.

As fluid fills the recess, it extends laterally along the chest wall to form a characteristic meniscus (Fig. 1). Larger effusions cause increased opacification of the hemithorax with mediastinal shift. Absence of shift suggests underlying collapse or mediastinal fixation

On a supine film, fluid tends to accumulate posteriorly and at the lung apex, with an apical cap on occasion the only manifestation of a supine effusion. Other features include hazy opacification of the hemithorax, blunting of the costophrenic recess, elevation of the hemidiaphragm and reduced lower zone vascularity.

Ultrasound is superior to CXR at demonstrating small amounts of pleural fluid and guiding thoracentesis. Pleural transudates are nearly always anechoic. Whereas exudates may appear simple and anechoic, complex effusions appear multiseptated or homogeneously echogenic. The latter appearance is usually suggestive of an ►empyema or haemorrhagic effusion and may mimic a solid echogenic mass. The presence of diaphragmatic nodularity and nodular pleural thickening is indicative of a malignant effusion.



Pleural Effusion. Figure 1 Semi-supine chest radiograph showing a haze like opacification of the left hemithorax in keeping with posterior layering of fluid and the characteristic meniscus sign of pleural effusion on the right.

CT should be performed for all pleural exudates of unknown aetiology. Most exudates are due to malignancy, inflammation/infection or thromboembolic disease. CT following intravenous contrast allows differentiation of pleural thickening from fluid, characterisation of thickening as malignant or benign and can distinguish a pleural transudate from an exudate, with ▶pleural enhancement indicative of an exudate.[1]

In complicated parapneumonic effusions and empyemas where conventional management has failed, CT may demonstrate the development of an infected pleural collection, underlying visceral pleural thickening or drain misplacement accounting for failure of drainage. Classical findings of an empyema include the '▶split pleura sign' which refers to enhancing thickened visceral and parietal pleura separated by pleural fluid, increased thickening and attenuation of the extrapleural fat and loculation.

MR is rarely necessary in the diagnosis of pleural effusions due to the availability and accuracy of ultrasound and CT. Pleural effusions are typically low signal on T1W and high signal on T2W sequences. More recently triple echo and single shot diffusion weighted sequences have been shown to differentiate between pleural transudates and exudates. Transudates are invariably low signal in contrast to the high signal of a pleural exudate, with the degree of signal intensity being proportional to the complexity of the exudate.[2] Similarly MR may allow for visualisation of pleural nodules which are poorly defined on CT. In this situation axial and sagittal T2W sequences should be performed with the low signal pleural nodules being clearly delineated against the high signal of the pleural effusion.

Definition

Mesothelioma is a primary malignant tumor that arises from the mesothelial cells which typically line the pleura, peritoneum, and pericardium.

Pathology

Macroscopically mesothelioma appears as multiple nodules which stud the visceral and parietal pleura, these subsequently coalesce to form a white sheet like rind that encases the lung. Transdiaphragmatic infiltration is typical in advanced disease.

Microscopically there are three histological subtypes:

1 Epithelial: It is the commonest subtype and accounts for 60% of cases and is associated with the best prognosis with a median survival of 12.5 months. Microscopically differentiation from metastatic adenocarcinoma can be difficult and usually requires special staining.

P

2 Sarcomatoid: It occurs in 15% of the cases and needs to be distinguished from renal, pancreatic, and synovial sarcomatoid metastatic carcinomas.
3 Mixed: It occurs in 25% of the cases.

Clinical Features

Most patients present with increasing shortness of breath and chest pain. Other symptoms include anorexia, weight loss, and cough. A history of prior asbestos exposure can be elicited in approximately 50% of the cases following a latency period of 35–40 years. In female patients, there may be a history of indirect contact with clothing exposed to asbestos.

Imaging

Characteristic radiographic features include unilateral lobulated pleural thickening which gradually extends, encases and fixes the pleural cavity causing volume loss (Fig. 1). The right hemithorax is more frequently involved possibly due to the larger right pleural surface area. A pleural effusion is seen in most cases, though may be absent in up to 20% of patients. Fissural extension occurs in 40–90% of cases (1).

On ultrasound, mesothelioma can appear as either an echogenic or hypoechoic lobulated area of visceral and parietal thickening with associated diaphragmatic thickening and nodularity. Pleural thickening measuring less than 1 cm can be difficult to visualize and is much more operator and patient body habitus dependent.

Contrast-enhanced CT including multiplanar reformatting is the imaging modality of choice. This allows for detailed assessment of the pleural thickening and readily demonstrates chest wall and diaphragmatic invasion. Findings suggestive of chest wall invasion include loss of the extrapleural fat planes, bone destruction, and intercostal muscle invasion. Nodular pleural thickening is the commonest manifestation on CT, usually involving the lower zones, although in 15% of cases only upper zone involvement is seen. Other findings are diaphragmatic thickening, fissural involvement and pleural effusion. Pleural calcification is visualized in 20% of the cases (Fig. 1).

MRI is only performed when radical surgery is being considered and multislice CT has proved inconclusive at differentiating T3 (potentially resectable) disease from irresectable T4 disease. To minimize motion artifact all MR sequences should be cardiac gated. Typical sequences include T1W, T2W, and T1W fat saturated postgadolinium. The latter sequence is particularly sensitive at demonstrating focal thickening and enhancement of the intercostal fissures which may be the only manifestation of disease (2). On T1W images mesothelioma returns an intermediate signal compared to the adjacent muscle and a high signal on T2W and T1 postgadolinium sequences. Apical mesothelioma is the most readily visualized due to reduced motion artifact at the apices.

PET can accurately demonstrate the primary tumor and distal metastasis with a sensitivity of 90%. Although it is poorer at delineating nodal spread and distinguishing mediastinal tumor extension from contiguous nodal involvement (3). PET may prove helpful where previous pleural biopsy has been negative by demonstrating focal areas of uptake and more suitable sites for biopsy.

In patients being considered for surgery, a *V*/*Q* scan should also be performed to assess the function of the contralateral lung.

Pleural Mesothelioma, Malignant. Figure 1 CT demonstrating left sided circumferential nodular pleural thickening (*arrow*). Note the presence of a contralateral pleural plaque. Percutaneous biopsy confirmed mesothelioma.

Diagnosis

Definitive diagnosis requires cytological or histological confirmation. Thoracentesis is frequently nondiagnostic with a sensitivity of 30%, whereas image guided biopsy has a sensitivity of greater than 90%, this is comparable to thoracoscopy.

Churchill Hospital, Headington,
Oxford OX3 7LJ, UK
nagmiqureshi@doctors.org.uk
fergus.gleeson@radiology.oxford.ac.uk

Pathology

Microscopically plaques comprise foci of dense hyaline collagen within the mesothelial layers primarily involving the parietal pleura.

Clinical Features

Pleural plaques do not cause symptoms.

Imaging

Pleural plaques are the commonest manifestations of prior asbestos exposure and are readily diagnosed on a frontal chest radiograph. Plaques are bilateral in 75% of cases and involve the posterolateral aspect of the 6–10th ribs (1). Calcification is seen in 15–25% of patients following a latency period of 30–40 years. The presence of diaphragmatic calcification with relative sparing of the apices and costophrenic angles is considered pathognomonic of previous asbestos exposure.

CXR sensitivities for demonstrating plaques range from 30–80% with a false positive rate of 20%. This can usually be attributable to overlying composite shadows.

When viewed en-face plaques appear as irregular, stippled calcified opacities with a 'holly leaf' appearance. When viewed obliquely plaques are smooth usually measuring less than 1 cm in thickness.

HRCT and low-dose multi-slice CT is more sensitive than the CXR at detecting pleural plaques and assessing the underlying lung parenchyma for possible asbestosis (2). The absence of superimposed structures allows even small non-calcified plaques to be visualised. These characteristically are seen as well-circumscribed areas of pleural thickening separated from the underlying rib by a layer of fat (Fig. 1). On MRI, plaques are low signal on T1W, T2W and proton density sequences, and foci of calcification appear as signal voids.

Fibrothorax

Definition

Diffuse pleural thickening typically represents the late sequelae of a previous benign pleural effusion. This may be secondary to trauma, tuberculous empyema, drugs and asbestos related pleural disease.

Diffuse pleural thickening can be defined either by its chest radiograph or CT appearance. Radiographically diffuse pleural thickening is characterized by a smooth uninterrupted pleural density, which extends over at least a quarter of the chest wall with obliteration of the costophrenic angle (1). On CT, the presence of a continuous sheet of thickening at least 5 cm in lateral extent, 8–10 cm in cranio-caudal extent and 3 mm in thickness is generally accepted as diffuse pleural thickening (2).

Pathology

Pathologically, diffuse pleural thickening predominantly involves the visceral pleura and is usually preceded by a pleural effusion with subsequent visceral pleural fibrosis and adherence to the parietal pleura.

Clinical Features

Irrespective of the cause, unilateral thickening is commonly asymptomatic. Bilateral involvement is frequently associated with increasing shortness of breath and a restrictive pattern on pulmonary function tests.

Imaging

Chest radiography is the initial imaging modality for demonstrating pleural thickening. Occasionally, the presence of bilateral involvement may be confused with overlying composite shadows from prominent extrapleural fat. As a rule, asymmetrical bilateral thickening is suggestive of diffuse pleural thickening rather than composite shadowing.

The radiological features often reflect the underlying aetiology. In addition to the previously described features: unilateral volume loss, amorphous pleural calcification, with rib crowding and enlargement, with thickening of the extrapleural fat is suggestive of a tuberculous empyema. Associated parenchymal apical fibrosis and calcified granuloma may also be demonstrated.

Pleural thickening secondary to trauma is commonly associated with multiple rib fractures and otherwise normal underlying lung parenchyma.

Following talc pleurodesis characteristic findings include high-attenuation talc which mimics calcification sandwiched between soft tissue parietal and visceral pleural thickening—the so-called ‘talc sandwich’.

Ultrasound may also be helpful in demonstrating diffuse pleural thickening. This typically appears as a smooth hypo- or hyperechoic line. In the absence of a pleural effusion or presence of calcification delineation can be difficult. Similarly, differentiating thickening from effusion may also prove problematic. In this situation an effusion shows color flow, the so called ‘fluid color sign’, whereas thickening does not.

MRI offers little additional information over CT with minor advantages for demonstration of pleural thickening, extrapleural fat and pleural effusion. CT was better at demonstrating calcification (3). Furthermore, pleural signal hypointensity relative to the intercostal muscle on long TR MR sequences have been found to be particularly sensitive at confirming benign disease.

Diagnosis

CT appearances are usually diagnostic. If clinical doubt still exists image-guided percutaneous biopsy can be performed.

Occupational lung diseases; Work-related lung disorders

Definition

The term pneumoconiosis—from the Greek *pneuma* (air, wind) and *konis* (dust)—was introduced by Zenker in 1867 to define changes in the lungs caused by the retention of and reaction to inhaled inorganic as well as organic dusts.

Another definition of pneumoconioses was adopted at the Fourth International Conference in Bucharest in 1971: "Pneumoconiosis is the accumulation of dust in the lungs and the tissue reactions to its presence. For the purpose of this definition, "dust" is meant to be an aerosol composed of solid inanimate particles."

"Inorganic" refers to any substances that do not contain carbon (sometimes named "mineral dust"), excluding certain simple carbon oxides such as carbon monoxide and carbon dioxide (Table 1). "Organic" refers to any substances that do contain carbon, excluding simple carbon oxides, sulfides, and metal carbonates (Table 2) (1).

Pathology/Histopathology

Repeated and long-term exposure to inhalational irritants can lead to changes of the lung and pleura that may have lasting effects, even after exposure ceases. But even a severe, single exposure to a hazardous agent can damage the lungs. Smoking can increase both the severity of an occupational lung disease and the risk of lung cancer. The tissue reaction of the pulmonary parenchyma to an accumulation of hazardous dust may be more or less well defined and focally dense, as in "chronic" silicosis and coal worker pneumoconiosis (CWP), or linear and irregular as in asbestosis (1).

The development of pneumoconiosis depends on several factors:

- The nature and properties of the inhaled dust
- The particle size and density

Pneumoconioses. Table 1 Some types of pneumoconioses due to "inorganic" dust

Inorganic dust	Type of disease	Lung reaction
Asbestos	Asbestosis	Diffuse interstitial fibrosis
	Asbestos-related pleural disease	Focal pleural plaques Diffuse pleural thickening Pleural calcification Benign pleural effusion Rounded atelectasis
	Asbestos-related malignancies	Pleural, pericardial, and peritoneal Mesothelioma Increased risk of lung cancer, especially in smokers with asbestosis
Silica (quartz)	Silicosis	Simple nodular silicosis Conglomerate silicosis Silicotuberculosis
Coal	Coal workers' pneumoconiosis (CWP)	Simple CWP Complicated CWP (progressive massive fibrosis) Caplan's syndrome
Beryllium	Berylliosis; beryllium disease (*B. granulomatosis*)	Acute berylliosis = chemical pneumonitis Chronic berylliosis = diffuse pulmonary and hilar lymph node granulomatous reaction
Tungsten carbide	Hard metal disease	Interstitial pneumonitis with fibrosis; pattern of desquamative interstitial pneumonitis
Iron	Siderosis	Pure form without fibrosis due to "inert" dust; frequently exposed to other noxious dusts, including asbestos and silica (siderosilicosis)

P

Pneumoconioses. Table 2 **Some types of pneumoconioses due to "organic dust"**

Organic dust	Type of disease	Antigen	Lung reaction
Moldy hay, straw, and grain	Farmer's lung	Thermophilic bacteria (*Micropolyspora faeni*, *Thermoactinomyces*, others)	Extrinsic allergic alveolitis Acute, subacute, and chronic forms; in acute form complete recovery might be possible; in subacute and chronic forms, fibrosis of variant degree will occur
Droppings and feathers	Bird Francier's lung	Avian proteins contained in serum, excreta, or feathers	Same as Farmer's lung
Cotton trash	Byssinosis	"Organic dust toxic syndrome" (the syndrome covers a variety of reactions as grain fever, pig fever, cotton fever, pulmonary mycotoxicosis)	Bronchoconstriction in cotton, flax, and hemp workers during work; occasionally, mild airway obstruction may develop and persist
Dust or mist	Humidified fever	*Thermoactinomyces* species, *Penicillium* species, *Sphaeropsidales* species, others	Symptoms during work or during the first day back at work after vacation; no fibrosis

- The degree of fibrogenity
- The duration and intensity of exposure
- The time elapsed from initial exposure
- The individual susceptibility

1. Pneumoconiosis due to inorganic (mineral) dusts (Table 1):
   The reaction of the lung tissue may be a noncollagenous or a collagenous pneumoconiosis.
   a. Noncollagenous forms are caused by lessfibrogenic or nonfibrogenic (inert) dust with the following characteristics:
      i. The alveolar architecture remains intact.
      ii. The stromal reaction is minimal and consists mainly of reticulin fibers.
      iii. The dust reaction is potentially reversible.
   b. Collagenous forms are characterized by:
      iv. Permanent alteration or destruction of alveolar architecture
      v. Collagenous stromal reaction of moderate to maximal degree
      vi. Permanent scarring of the lungIn addition, it may be caused by an altered tissue response to a nonfibrogenic dust.
2. Pneumoconiosis due to organic dusts (Table 2):
   - Organic dusts can cause a wide variety of diffuse interstitial granulomatous lung diseases as an allergic response to the inhaled dust. The term "extrinsic allergic alveolitis" (EAA, hypersensitivity pneumonitis) includes numerous examples that are caused by specific antigens. The prototype, associated with repeated inhalation of dusts from hay containing thermophilic actinomycetes, was described in 1932 as "farmer's lung." Hypersensitivity pneumonitis and its variants are immunologically mediated. Precipitating antibodies to the causative antigen are usually demonstrated, suggesting a type III reaction. Type IV hypersensitivity is suggested by the granulomatous primary tissue reaction.
   - The histologic pattern is quite uniform. During the acute phase of the disease, a combination of bronchiolitis and alveolitis with granuloma formation is predominant. Chronic progressive parenchymal disease may result from continuous or frequent low-level exposure to the antigen. Thus may result in a variable degree of interstitial fibrosis, often most prominent in the peribronchial or periseptal areas. Sometimes it is more diffuse and may resemble advanced idiopathic pulmonary fibrosis with honeycombing.

Clinical Presentation

The most common symptoms of lung diseases, regardless of the cause, include coughing, shortness of breath, chest pain, chest tightness, and abnormal breathing pattern. There is a wide individual variety of symptoms and functional impairment.

Imaging

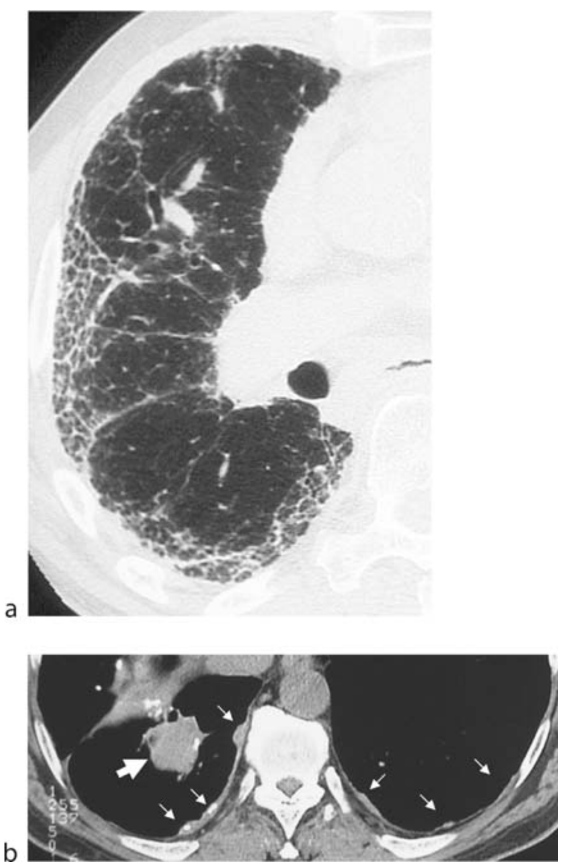
Traditional biplane chest films continue to be the radiographic baseline studies for initial evaluation and follow-up of occupational lung disease (1).

Computed tomography (CT) is a valuable diagnostic supplement, and it is increasingly mandatory to clarify findings on prior conventional chest films or to search for early and/or additional findings (2). Sonography is of limited value for chest examinations because of its physical properties. The use of magnetic resonance imaging does not yet have enough evidence to justify routine application.

Although *silicosis* and *CWP* are distinct diseases, histologically their radiographic findings are similar.

Small, round, well-defined, and relatively dense opacities, primarily located in the upper zones, are characteristic findings in silicosis (Fig. 2a, b). Small irregular opacities—especially in CWP—are due to differences of fibrogenous activity of the inhaled dust: If there is less fibrogenous activity, a roundish patchy or branching pattern of alveolar and/or bronchiolytic damage may dominate.

Asbestos-associated disease is primarily characterized by pleural changes, since the pleura is the prime target even of low doses of asbestos exposition. Involvement of the pulmonary parenchyma is associated with high-dose exposure. CT is indeed increasingly mandatory for the early and more precise diagnosis of any pulmonary or pleural changes (Fig. 1a, b).



Pneumoconioses. Figure 1 (a) Asbestosis with peripheral subpleural predomination, intralobular interstitial and interlobular septal thickening, and traction bronchiectasis. (b) Different types of pleural plaques, partially calcified. With subpleural fibrosis, more on the right than on the left side (*small arrows*).

The following pleural changes are highly suggestive of prior exposure to asbestos:

- *Pleural plaques*, generally circumscribed, with calcification or without (hyaline plaque)
- *Pleural thickening* with or without subpleural parenchymal fibrosis (mostly focal but sometimes also "diffuse"); due to scar-like thickening of the parietal but also visceral pleura
- Three forms of *sequelae of pleural effusion* (not only asbestos-associated): nonspecific pleural effusion, pleural scarring ("complicated hyalinosis"), rounded atelectasis ("folded lung").

All other CT and high-resolution CT (HRCT) findings definitely present—especially those of the pulmonary parenchyma—remain ambiguous with regard to their possible etiologic connection to any hazardous type of dust exposure, since they may also be due to any other cause of interstitial fibrosis. Their specificity may, however, "increase in value" if characteristic pneumoconiotic findings such as plaques are present.

Lung cancer can be associated with hazardous dust exposure, especially asbestos. A definitive amount of proven exposure is required for etiologic correlation and possible compensation. *Pleural mesothelioma* also has a strong association with asbestos exposure. This neoplasm, however, can arise separately in the pericardium or peritoneum.

Exposure to so-called "*inert*" *dusts* (such as iron or tin) causes aggregation of particle-laden macrophages with none or only minimal accompanying fibrosis, making the radiographic image less valid, but possibly detectable by CT.

Carbon black pneumoconiosis (caused by industrial carbon byproducts) may radiographically result in a fine reticular pattern, predominant in the lower zones, and is often detectable only by CT.

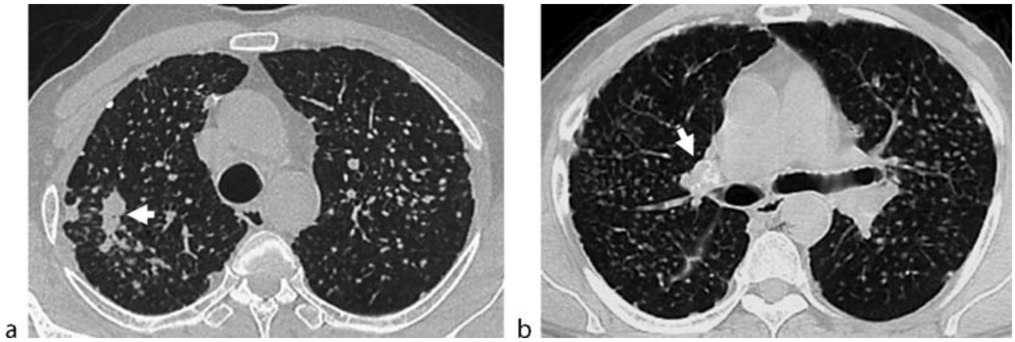
Hard metal pneumoconiosis (such as tungsten or cobalt) usually assumes the pattern of giant cell interstitial, desquamative, or "usual" interstitial pneumonia, usually requiring CT for better definition.

The radiographic features of "*organic*" pneumoconioses are often noncharacteristic because of the similar histologic patterns of the different varieties. They vary with the stage of the disease, and the radiographic abnormalities could resemble the same impression of different causes.

Acute (normally reversible) changes are a diffuse ground glass pattern, a reticulonodular interstitial pattern, and patchy areas of consolidation.

Chronic (normally irreversible) changes are a pattern of progressive interstitial fibrosis with honeycombing.

During the course of the disease, the abnormalities of acute-, subacute-, and chronic-stage different patterns may overlap; therefore, the chronic stage of hypersensitivity



Pneumomediastinum. Figure 2 Silicotic nodules. (a) Centrilobular and randomly distributed pleural nodules and large opacity (*arrow*) due to complicated silicosis (progressive massive fibrosis). (b) Egg-shell calcification (*arrow*) in lymph nodes.

pneumonitis is frequently associated with features of subacute disease.

Nuclear Medicine

Perfusion or ventilation scintigraphy does not play a role in the diagnosis of pneumoconioses. As for positron emission tomography, there are currently not enough valid data to use it to differentiate benign from malignant nodules or rounded atelectasis and advanced pleural fibrosis from mesothelioma.

Diagnosis

Diagnosis requires a history of occupational exposure, radiological findings, and, in some diseases, compatible functional impairment.

For the radiologic report and international comparison, the internationally well-established ILO classification system remains in use for screening and surveillance of occupationally dust-exposed individuals, at least for the time being. Recently, a revision was done, called the International Classification of Radiograph of Pneumoconioses (ILO 2000) (2).

There have been many requests to introduce standardization of CT technique, reporting, and classification. In 2005, the document "International Classification of High-Resolution Computed Tomography for Occupational and Environmental Respiratory Diseases" was published (3, 4). A set of CT/HRCT films will also be available for reference. It is important to note that the CT/HRCT classification is to serve as a supplement and not as a replacement of the existing traditional ILO system.

The new CT/HRCT coding system is descriptive and covers all aspects of occupational and environmental disorders dealing with parenchymal and pleural sequelae. Some patterns are characteristically associated with pneumoconioses (for instance, small rounded opacities with silicosis, or interlobular septal and intralobular nonseptal lines, honeycombing, and typical pleural changes with asbestosis). However, overlapping patterns have to be considered for differential diagnostic ranking.

Pneumomediastinum

Koji Takahashi
Department of Radiology, Asahikawa Medical College, Japan
taka1019@asahikawa-med.ac.jp

Definition

Pneumomediastinum connotes abnormal accumulation of gas in the mediastinal space. Gas in the mediastinum most commonly originates from the lung and, less commonly, the central air way, esophagus, abdominal cavity and neck. Pneumomediastinum can be subtle or massive, and gas may extend into the neck, subcutaneous tissue, retroperitoneum, peritoneal space, and spinal canal (epidural emphysema) (1).

Pathology

Alveolar rupture is the most common cause of pneumomediastinum, which can be spontaneous with or without pulmonary disease. It usually results from a sudden rise in alveolar pressure, including Valsalva maneuvers, asthma, vomiting, artificial ventilation or close chest trauma. The air leak from alveolar rupture tracks into the interstitial tissue and extends through the peribronchial and perivascular interstitial tissue into the mediastinum (2). As well as proximal tracking into the mediastinum, interstitial air also extends peripherally to the visceral pleura and ruptures into the pleural space resulting in pneumothorax (1). In neonatal intensive care units, alveolar rupture is common in patients with hyaline membrane disease, meconium aspiration, and neonatal pneumonia who are on mechanical ventilation.

Rupture of the trachea or main bronchi is most frequently due to trauma, while bronchoscopy and bronchoscopic biopsy may also accidentally result in pneumomediastinum. Rupture of the esophagus occurs during the episodes of severe vomiting and asthmatic attack or as a result of trauma.

Pneumomediastinum. Figure 1 Chest radiograph shows lucent lines outlining the bilateral main bronchi. Lucent lines overlying the upper mediastinum are also seen.

Pneumomediastinum. Figure 2 Chest radiograph shows a lucent line parallel to the left heart border. Laterally displaced mediastinal pleura is also visualized along the lucent line.

Imaging

The most common radiographic manifestation of pneumomediastinum is lucent streaks outlining and overlying the mediastinal structures (Fig. 1). On the frontal chest radiograph, lucent line parallel to the heart and great vessel border is typically seen. Laterally displaced mediastinal pleura is occasionally visualized along the lucent line (Fig. 2). Gas in the mediastinum readily extends to the neck and also into the subcutaneous tissue in the chest wall and appears as lucent streaks projecting over the neck and linear and bubble-like gas in the chest wall (Fig. 3). In younger persons, the thymus may be outlined by air and this finding is specific for pneumomediastinum. The term "angel wings" or "spinnaker sail" sign have been suggested as descriptive terms (3). Mediastinal air may also track extrapleurally along the upper surface of the diaphragm giving rise to "►continuous diaphragm sign" since air beneath the heart combines the margins of the diaphragma bilaterally (4). This sign enables us to differentiate pneumomediastinum from subpulmonary pneumothorax. Pneumopericardium can mimic pneumomediastinum, but pneumopericardium will not extend around the aortic knob or into the superior mediastinum. A radiolucent line is frequently seen along the mediastinal borders in healthy individuals due to "Mach band" (5). A lateral boundary of Mach band is usually unrecognizable whereas lucent streaks due to pneumomediastinum are typically marginated with the displaced mediastinal pleura. Pneumomediastinum is more readily diagnosed on the

Pneumomediastinum. Figure 3 Pneumomediastinum associated with subcutaneous emphysema. Chest radiograph shows multiple lucent lines in the neck and chest wall, representing subcutaneous emphysema.

lateral radiograph in some cases. On the lateral projection, a lucent line marginates the ascending aorta, aortic arch, and pulmonary arteries (1). In the diagnosis of pneumomediastinum, chest CT is quite more sensitive and specific than chest radiograph.

Definitions

Pneumonia is defined as an inflammation or infection of the lung, caused by bacteria, viruses, fungi, or parasites.

Neonatal pneumonia is characterized by pulmonary infections, that become clinically evident within 24 h of birth and includes pneumonias, which are already established at birth (congenital) or that are acquired intrapartal or postnatal within 24 h.

►*Round pneumonia* is a spherical pneumonic consolidation mimicking an intrapulmonary mass.

Complications of pneumonia include ►pneumatoceles, *parapneumonic effusion*, ►empyema, ►cavitary necrosis, and ►lung abscess (1). Pneumatoceles are thin-walled cystic lesions usually developing after pneumonias caused by *Staphylococcus aureus*. Parapneumonic effusion is a pleural effusion associated with bacterial pneumonia or lung abscess, empyema is defined as a collection of pus within the pleural space. A lung abscess is a localized cavity of pus within the lung, whereas cavitary necrosis represents fluid- and air-filled cavities within necrotizing lung tissue (2).

Pathology/Histopathology

Most pneumonia develop as a complication from lower respiratory tract infection, but also hematogenous spread or aspiration of microorganisms may be a cause for pulmonary infection. In *bacterial lobar pneumonia*, the inflammation of the alveolar spaces begins with vascular congestion and alveolar edema and many bacteria and neutrophils are present (stage of congestion). About 2–3 days later, erythrocytes, neutrophils, desquamated epithelial cells, and fibrin within the alveoli are present, giving the lung the consistency of liver (stage of red hepatization). In the next stage, the gray hepatization, fibrinopurulent exsudate, disintegration of red cells, and hemosiderin are identified. In the final stage of resolution, resorption and restoration takes place. However, due to early antibiotic treatment these classical four stages of bacterial lobar pneumonia are not commonly seen in recent years.

Viral pneumonia is characterized by centrifugal spread of neutrophil exsudate through the bronchi and bronchioles to the adjacent alveoli. In *interstitial pneumonia*, the interstitium is infiltrated by lymphocytes, macrophages, and plasma cells, whereas the alveoli are free of exsudate.

Pneumatoceles result from air trapping and valve mechanism, due to plugging of distal bronchi by inflammatory exsudate in *S. aureus* pneumonia. Cavitary necrosis develops in necrosis complicating pneumonia. Thrombotic occlusion of alveolar capillaries associated with adjacent inflammation results in ischemia and eventually necrosis of the lung parenchyma (2). A lung abscess is characterized by a collection of pus surrounded by a well-defined fibrous wall.

Clinical Presentation

Neonatal pneumonia is most often due to infection with group B streptococcus, *Chlamydia trachomatis*, *Escherichia coli*, *Hemophilus influenza*, *Listeria monocytogenes*, enterococcus, and *S. aureus* (3). The sick neonates may present with tachypnoea, nasal flaring, intercostal retractions, poor feeding, unstable temperature, irritability, or lethargy.

In young infants, until 3 months of age, *Streptococcus pneumonia*, *Streptococcus viridans*, *S. aureus*, and *H. influenza* are the most common cause for pneumonia, but also infections with *Ureaplasma urealyticum* or *Bordetella pertussis* are observed. Viral pneumonia is often caused by adenovirus, respiratory syncytial virus, influenza, or parainfluenza virus.

In older children pulmonary infections with *Mycoplasma pneumonia*, *Pneumococcus* species, influenza viruses, or respiratory syncytial virus (RSV) are frequently observed. Older infants typically present with cough, vomiting, chest or abdominal pain, and fever, adolescents may complain about additional headache, pleuritic chest pain, and dyspnea (1).

If bacterial pneumonia is complicated by parapneumonic effusion or empyema, the children present with persistent fever or sepsis, pleuritic chest pain, dyspnea, and possible cyanosis. Abdominal pain and vomiting are commonly observed as side symptoms. Other complications such as cavitary necrosis and lung abscess have to be considered in persistent symptoms of infectious pulmonary disease.

Imaging

Plain chest radiography is the primary imaging modality for the diagnosis of pneumonia and associated complications such as parapneumonic effusions or empyema (1). *Ultrasound* is especially valuable for the assessment of associated parapneumonic effusions or empyema, and may be helpful for the detection of cavitary necrosis in peripheral-localized consolidations. *Contrast-enhanced CT* is most efficient in demonstrating the complications of pneumonia, and allows accurate identification of lung abscess formation, parapneumonic effusions, and empyema (4). *MRI* may be used as an alternative method to CT, especially to differentiate lung abscess formation from intrapulmonary tumor masses.

Nuclear Medicine

Lung scintigraphy is not routinely performed in children with acute pneumonia or pneumonia-associated complications. It may provide additional information in chronic or recurrent pneumonia, although the findings are often nonspecific, or in pneumonia secondary to pulmonary infarction.

Diagnosis

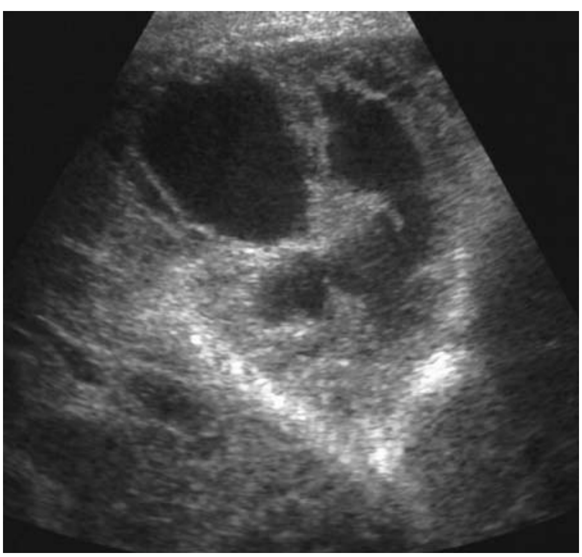
Chest radiographic findings in neonatal pneumonia may vary due to the causing microorganism between reticulogranular, interstitial, and alveolar patchy opacities. Bacterial pneumonia in older infants and children often presents with segmental or lobar consolidations with air bronchograms (1) (Fig. 1), whereas in viral pneumonia patchy multifocal interstitial opacities and hyperinflated lungs are demonstrated on the chest X-rays (3). Small parapneumonic effusions are identified on chest radiographs by blunting of the costophrenic angle,

P

larger effusions present as opaque fluid collections along the chest wall, in severe cases with complete opacification of the involved hemithorax. Parapneumonic effusions are reliable diagnosed by ultrasound, which demonstrates echogenic fluid collections within the pleura space. If the fluid collection within the pleural cavity becomes echogenic and contains fibrinoid septations, empyema has to be suspected (Fig. 2) (5). Pneumatoceles appear as multiple thin-walled cysts on chest X-rays (Fig. 3), whereas lung abscesses are characterized by thick-walled cavities often associated with effusion. Round pneumonias are often located in the posterior segments of the lower lobes and are characterized by a circularly configured opacification mimicking an intrapulmonary mass (3) (Fig. 4).

On contrast-enhanced CT images, noncompromised lung parenchyma consolidated with pneumonia shows typically a diffuse enhancement (2). Cavitary necrosis is identified on CT by fluid- and air-filled cavities without rim-enhancement located in areas with a low-attenuation lung parenchyma. On contrast-enhanced CT, a lung abscess appears as a fluid-or air-filled cavity with a thick enhancing wall and no evidence of necrosis in the surrounding lung. Enhancement and thickening of the parietal and visceral pleura, thickening of the extrapleural subcostal tissues and increased attenuation of extra-pleural subcostal fat are typical CT findings of empyema (Fig. 5).

Pneumonia in Childhood. Figure 1 Chest radiograph of a 5-year-old boy with lobar pneumonia of the left upper lobe.



Pneumonia in Childhood. Figure 2 Ultrasound image of an empyema, which occurred as a complication of bacterial pneumonia in a 7-year-old boy. Characteristic thick fibrinoid septations and echogenic fluid collections within the pleural cavity are visible.

Pneumonia in Childhood. Figure 3 Chest radiograph of a 1.5-year-old boy with *Staphylococcal pneumonia* in the right lower lobe (a). The radiography 3 weeks later showed multiple thin-walled air-filled cysts representing pneumatoceles (b).

Pneumothorax. Figure 4 **Chest X-ray of round pneumonia in the left lower lobe of a young adolescent. The spherical configured consolidation disappeared completely after antibiotic treatment.**

Pneumothorax. Figure 5 **A 7-year-old boy with empyema on the right side. The contrast-enhanced CT examination demonstrates a multiloculated parapneumonic effusion with only minor enhancement of the pleura, but thickening of the extrapleural subcostal tissues and increased attenuation of extrapleural subcostal fat.**

Interventional Radiological Treatment

Percutaneous fine needle aspiration is an alternative method used to identify causative pathogens in selected patients with pneumonia, and should be considered in patients who have not responded to initial therapy, who may have nosocomial superinfection, who are immunocompromised, or in whom tuberculosis is suspected but has not been confirmed by examination of the sputum or gastric lavage (4). Parapneumonic effusions may be punctured with help of ultrasound guidance. Ultrasound or CT-guided percutaneous catheter drainage may be performed as an alternative to chest tube placement and fibrinolysis in children with lung abscess or empyema. In case of multiloculated pleural empyema resistant to these more conservative treatment efforts, thoracotomy with decortication is usually the treatment method of choice.

Definition

Pneumothorax is defined as air in the pleural space. Pneumothoraces may be spontaneous, primary or secondary; or traumatic.

P

Clinical Features

Patients typically present with sudden onset of pleuritic chest pain and breathlessness. The severity of symptoms may not necessarily correlate with the size of the pneumothorax, and is in part dependent on the aetiology and the patient's lung function.

Imaging

On an erect chest radiograph a pneumothorax is diagnosed by the presence of a well-defined line which represents the visceral pleura, separated from the parietal pleura by a hyperlucent air filled space (Fig. 1). Generally a 2 cm margin of air equates to a 50% pneumothorax. If small, a lateral decubitus chest radiograph has been shown to be as sensitive as CT, and can help confirm a pneumothorax.

Pneumothoraces are often subtle on a supine radiograph. Findings include hyperlucency of the hemithorax with depression of the ipsilateral hemidiaphragm, increased sharpness of the cardiomediastinal border and deepening of the costophrenic recess. Skin folds and gowns may mimic the visceral pleura of a pneumothorax. In contrast, to the visceral pleura these artifactual lines tend to be ill defined, with vascular markings visible lateral to them.

On ultrasound the normal pleura appears as either a single echogenic line, which slides forward and backward relative to the lung, or two discrete echogenic lines the visceral and parietal pleura which slide over each other during normal respiration, the sliding sign. Similarly at the pleuro-parenchymal interface the difference in acoustic transmission results in reverberation artifact which appears as horizontal echogenic lines parallel to the chest wall. Exaggeration of this reverberation artifact and loss of the "sliding sign" is suggestive of air in the pleural space.

CT has an almost 100% sensitivity and specificity in the detection of pneumothorax, but is mostly not required to make this diagnosis.

The main indications for CT are in differentiating a pneumothorax from bullous lung disease, detecting pneumothoraces in trauma and ICU patients and small pneumothoraces not seen on CXR in patients with impaired lung function and rarely for guiding drain placement.

Pneumothorax. Figure 1 Frontal chest radiograph demonstrating an approximately 40% left sided pneumothorax (*arrow*).

Podagra

►Gout

Poland Syndrome

A unilateral congenital condition with short or missing middle phalanges and soft-tissue syndactyly of the hand, with ipsilateral hypoplastic pectoral muscle.

►Congenital Malformations, Bone

Polycystic Liver Disease

Presence of multiple cysts within the liver. Two forms are described: the infantile and the adult form. The infantile type is less common and shows an autosomal recessive inheritance while the adult type is autosomal dominant. These forms may be associated with congenital hepatic fibrosis. The association of polycystic liver/kidney disease and hepatic fibrosis is also known as 'fibropolycystic disease'.

►Congenital Malformations, Liver and Biliary Tract

Polycythemia Rubra Vera

Polycythemia rubra vera is one of the chronic myeloproliferative disorders. It is characterized by an increased number of red blood cells, white blood cells, and platelets, resulting in an increased blood volume and hyperviscosity of the blood. Splenomegaly is a characteristic finding; splenic infarction is not uncommon and is accompanied by pain.

▶Neoplasms, Splenic, Malignant

Polydactyly

Accessory or supernumerary fingers or toes.

▶Congenital Malformations, Musculoskeletal System

Polymicrogyria

Polymicrogyria consists of multiple abnormally small gyri and is the result of an abnormality during the process of cortical organization.

▶Congenital Malformations, Cerebrum

Polyp, Nasal

Nasal polyps are outgrowths of nasal mucosa made up of edema fluid with sparse fibrous cells, a few mucus glands and a surface epithelium invaded by some inflammatory cells.

▶Inflammation, Chronic, Nose, and Paranasal Sinus

Polyphosphonates

Osteotrophic molecules that can be labeled with ^{99m}Tc and are used for bone scintigraphy.

▶Bone Scintigraphy

Polyps, Gallbladder

This is defined as mucosal projections into the gallbladder lumen. The term gallbladder polyp includes different entities such as cholesterol polyps, adenomyomas, inflammatory polyps, adenomas, and other miscellaneous polyps. These polyps are nonneoplastic in most cases and rarely cause symptoms. Cholecystectomy is required for polyps larger than 10 mm because of the increased risk of adenomatous or carcinomatous transformation.

▶Cholecystoses

Polysplenia

The presence of multiple small spleens is a rare condition usually associated with other congenital malformations. It may be seen in association with abdominal situs ambiguous and has classically been called polysplenia syndrome. Polysplenia syndrome is more common in females. The typical anatomic features of classic polysplenia syndrome are bilobed lungs with bilateral hyparterial bronchi, bilateral pulmonary atria, midline liver, and multiple spleens of variable size and number that may be located in either the left or right side of the abdomen, more often along the greater curvature of the stomach, which occurs in variable locations. In rare cases these patients have a single, lobulated spleen or even a normal spleen. Malrotation of the bowel is frequently associated. In polysplenia, numerous small splenic masses can be seen predominantly in the right upper quadrant at US, CT, MR, or scintigraphy.

▶Congenital Abnomalies, Splenic

Polysplenia Syndrome

Polysplenia syndrome is characterized by polysplenia, or the presence of multiple small spleens, associated with abdominal situs ambiguous. Polysplenia syndrome is more common in females. The typical anatomic features of classic polysplenia syndrome are bilobar lungs with bilateral hypoarterial bronchi, bilateral pulmonary atria, midline liver, and multiple spleens of variable size and number that may be located in either the left or right side of the abdomen, more often along the greater curvature of the stomach, which occurs in variable locations.

▶Splenic Anomalies

Popliteal Arterial Obstruction

Popliteal Arterial Occlusion

►Occlusion, Artery, Femoral

Porcelain Gallbladder

Also termed calcified gallbladder, calcifying cholecystitis, or cholecystopathia chronica calcarea, it is a form of accumulating cholecystosis consisting in the presence of extensive dystrophic calcifications within the chronically inflamed gallbladder wall. The term porcelain gallbladder emphasizes the brittle consistency and blue discoloration of these calcifications that may appear as a broad continuous band in the muscularis resembling a sac-like appearance or as multiple punctate calcifications in the mucosal glandular spaces.
►Cholecystoses

Portal Cavernoma

Portal cavernoma, also called cavernous transformation of the portal vein, consists of a network of venous channels, which replaces a previously stenosed or occluded portal vein. It functions as a portoportal shunting, so it is characterized by hepatopetal flow. The veins are usually insufficient to bypass the entire splenomesenteric inflow, and signs of portal hypertension frequently co-exist.

Clinical signs of portal cavernoma are usually related to extra-hepatic portal hypertension (bleeding from oesophageal varices, splenomegaly, etc.).

Diagnosis is mainly done by imaging. At US, a mass of tortuous veins can be observed at the portahepatis. Doppler US displays hepatopetal flow. An increased flow in hepatic artery may be seen, representing a compensatory mechanism to the reduced portal flow. On contrast-enhanced CT scans, a characteristic mass of veins replacing the portal trunk is the most common finding. Involvement of intra-hepatic branches with a normal-appearing main portal vein has also been described.
►Portal Hypertension, Adults

Portal Hypertension

The presence of portal hypertension is the expression of the failure to alter either portal venous inflow to the liver or resistance to that inflow. In the vast majority of cases, increased resistance in the prehepatic, hepatic, or posthepatic vascular tree is responsible. Portal hypertension leads to a significant diversion of blood from the portal circulation into the systemic venous circulation.
►Splenomegaly

Portal Hypertension, Adults

Synonyms

Increased pressure in portal venous system

Definition

Any increase in the portal vein pressure due to obstruction to blood flow in the portal venous system. Portal hypertension is defined as pressure in the portal system higher than 12 mm Hg (the normal portal pressure is 5–10 mm Hg).

Pathology/Histopathology

Portal hypertension can be classified into five major types relative to location of portal flow obstruction:

1. Extra-hepatic (portal or splenic vein thrombosis or obstruction, arterioportal fistula)
2. Intra-hepatic pre-sinusoidal (congenital hepatic fibrosis, primary biliary cirrhosis, schistosomiasis, sarcoidosis, myelofibrosis)

3. Intra-hepatic sinusoidal (post-necrotic cirrhosis, hepatitis)
4. Intra-hepatic post-sinusoidal (alcoholic cirrhosis, veno-occlusive disease, obstruction or compression of hepatic veins)
5. Supra-hepatic (Budd–Chiari syndrome, congestive heart failure or pericarditis).

The most common cause of portal hypertension is liver cirrhosis.

The increased portal pressure reduces the portal venous flow. When the pressure in the portal venous system becomes higher than the systemic venous pressure, a reversal of flow occurs and porto-systemic shunts develop. Since in post-uterine life the portal venous system is without valves, blood can flow in any direction, and when normal or hepatopetal flow is blocked, blood is free to flow along the course of least resistance (tributary or newly developed collaterals). Tributary collaterals are represented by the normal tributaries of the portal system that are immediately available for collateral blood flow. These important tributaries are the left gastric vein, the short gastric veins, the superior mesenteric vein and the inferior mesenteric vein. Blood flowing in reverse direction over the left gastric vein and the short gastric veins reaches the systemic circulatory system *via* the emiazygos and azygos systems. The systemic circulatory system may be reached from the inferior mesenteric vein *via* the haemorrhoidal plexus and hypo-gastric veins, as well as from the superior mesenteric vein *via* retro-peritoneal communications in the mesentery, which includes the veins of Retzius. Newly developed collateral channels may arise from vessels that previously existed but do not function as main tributaries of the portal system. The paraumbilical collaterals arise from the left main intra-hepatic branch of the portal vein and terminate at the umbilicus, although they frequently communicate with anterior abdominal wall veins. The splenorenal collaterals extend from the spleen or the splenic vein to the left renal vein. The gastric renal collaterals extend from the stomach to the left renal vein. The splenoperitoneal collateral is found in the lateral aspect of the abdomen, extending from the spleen to retroperitoneal vessels along the lateral abdominal wall. All these vessels carry blood in a hepatofugal direction. All may appear in the presence of intra-hepatic obstruction. When extra-hepatic obstruction exists, the parumbilical collaterals do not develop; the more distally located collaterals may develop depending on the site of obstruction. In case of splenic vein obstruction, bridging collaterals appear between the spleen and the portal vein over the short gastric veins and the gastroepiploic vein.

Clearly reduced portal flow velocity is associated with increased risk of thrombosis, which may involve the main portal trunk and its branches, the splenic and the superior mesenteric veins.

Chronic portal thrombosis may lead to the formation of a ►portal cavernoma, which consists of a network of venous channels replacing the previously occluded portal vein and functioning as a portoportal shunting. Aneurysms of the portal venous system have been described in association with portal hypertension (1).

Clinical Aspects

Portal hypertension is typically a consequence of cirrhosis. In the clinical setting of patients with portal hypertension, stigmata of cirrhosis, including jaundice, spider nevi, palmar erythema and manifestations of liver insufficiency may be associated. Furthermore, complications such as variceal bleeding, ascites, splenomegaly and hepatic encephalopathy may occur. The development of oesophageal varices is a troublesome complication, because the rupture of these varices, either spontaneously or after vomiting, may lead to life-threatening haemorrhage. The development of anorectal shunts results in the presence of haemorrhoidal varices, while the reopening of paraumbilical veins may lead to the dilatation of veins of the anterior abdominal wall, which form a sort of net, the so called 'caput medusae'. When numerous porto-systemic collaterals develop, the pressure in the oesophageal varices decreases and the risk of rupture is reduced. Anyway, the increase in porto-systemic shunting results in a decrease of portal flow to the liver. This correlates with liver atrophy and with a worsening in liver function. Furthermore, toxic metabolites, such as ammonia, which are usually catabolized by the liver, go directly into the systemic circulation and cause hepatic encephalopathy.

Imaging

Ultrasound

Conventional ultrasound (US) alone often allows to establish the presence of portal hypertension. The diagnosis of portal hypertension is suggested by the dilatation of portal system veins, the diminished response of portal vessels to respiration, the demonstration of portosystemic collaterals, the presence of splenomegaly and ascites. Finally, US may demonstrate typical findings of chronic liver disease.

The calibre of the portal vein is not a sensitive criterion in assessing portal hypertension; it shows a wide variability in normal subjects and it is influenced by the presence of collateral vessels. When collaterals develop, the calibre and the flow of the portal vein decrease. Consensually to the reduction of portal flow, the flow within the hepatic artery increases; this explains the increase of calibre of hepatic artery, often observed in cirrhotic patients. In standard conditions, a portal vein calibre greater than 13 mm indicates portal hypertension with a high specificity.

The calibre variation of the portal trunk and the splenic and superior mesenteric veins during respiration is a sensitive and reliable sign of portal hypertension. A lack of normal calibre variation (an increase during inspiration and a decrease during expiration) in these vessels is the most constant and sensitive US sign of portal hypertension (2).

In some cases, the demonstration of porto-systemic anastomoses represents the first clue to the presence of portal hypertension. US can document some of these shunts. In particular, the depiction of a dilated coronary vein within the lesser omentum, as well as gastroesophageal varices, demonstrated as tortuous anechoic structures near the gastroesophageal junction, are the most common and reliable US finding in patients with portal hypertension. There is a good correlation between the size of the varices and visualization of dilated coronary vein. The remnant of the umbilical vein, the ligamentum teres is seen at US in a high percentage of normal individuals as a hyperechoic band. In patients with portal hypertension, the umbilical vein often reopens and becomes visible within the hyper-echogenicity of the falciform ligament and coursing along the ventral abdominal wall. The resulting 'bull's-eye' appearance is indicative for a patent umbilical vein. Doppler US displays a hepatofugal flow. Less common venous collaterals may be visualized at US, such as splenorenal and gastrorenal veins, pancreatico-duodenal veins, retroperitoneal-paravertebral veins, gallbladder varices, intrahepatic shunts, such as anastomoses between portal branches and hepatic veins or between portal branches and inferior vena cava. US limitations in detecting porto-systemic shunts are related to bowel gas, obesity, ascites, deep location and paucity of collaterals (3).

Doppler US gives information about flow direction and velocity in the portal vein and its branches. The portal flow velocity is usually reduced in portal hypertension. A mean velocity lower than 16 cm/sec in the portal trunk suggests portal hypertension. Nevertheless, recanalization of the umbilical vein causes an increase of the velocity in the portal vein. In fact, flow velocity is dependent on a great variety of factors, such as portal calibre, degree of resistance, presence and type of collaterals. The presence of reversal of flow within the main portal vein or in the splenic and superior mesenteric veins is related to hepatofugal portosystemic collaterals and is a certain sign of portal hypertension.

Splenomegaly is a constant finding in portal hypertension, although the size of the spleen is not correlated with the degree of hypertension.

Finally, US may be useful in diagnosing cavernous transformation of the portal vein, and in demonstrating portal vein, splenic vein or superior mesenteric vein thrombosis (1).

Computed Tomography

Computed tomography (CT) gives useful qualitative information when US evaluation is inconclusive. Splenomegaly and ascites are easily documented at CT.

Signs of underlying chronic liver disease may be demonstrated. However, CT findings in cirrhosis are highly variable and in some patients the liver may appear normal.

CT angiography, with the possibility to perform three-dimensional reconstructions, may depict accurately the portal vasculature and porto-systemic collaterals, being superior to US in demonstrating retroperitoneal veins. Porto-systemic shunts appear as dilated, often tortuous, tubular structures which show clear enhancement in the portal-venous phase. The main limitation of CT in evaluation of portal hypertension is that it cannot demonstrate the venous and arterial flow profile.

CT arterial portography can be used to achieve better delineation of the portal venous system, but, although it can produce elegant images, it is invasive and it has not gained widespread acceptance.

CT is very reliable in demonstrating ►portal vein thrombosis, which appears as hypo-dense material completely or partially filling a portal vessel, which fails to enhance in the portal-venous phase.

Another possible finding at CT is congestion and edema of splanchnic viscera, resulting in thickening of intestinal walls and ground-glass appearance of perivisceral fat.

Magnetic Resonance

Magnetic resonance (MR) does not offer relevant advantage over CT and US in the assessment of portal hypertension. MR angiography may offer a non-invasive evaluation of the portal venous system, enabling also to provide information about flow dynamics (4). Further manifestations of portal hypertension, such as ascites and splenomegaly can be easily demonstrated at MR.

The so called '►Gamna–Gandy bodies' represent siderotic nodules within the spleen and can arise in patients with portal hypertension. They may be detected on T2-weighted images, as tiny hypo-intense nodules scattered throughout the splenic parenchyma. These nodules are pathognomonic of portal hypertension (5).

Barium Study

Oesophageal varices, consisting in dilated sub-mucosal veins in the caudal portion of oesophagus, represent a common and important complication of portal hypertension. At barium study, they appear as serpiginous filling defects. Gastric varices may also be seen. Varices in the stomach usually are confined to the gastric cardia and are difficult to recognize. Gastric antral and duodenal varices are sometimes seen, usually in association with gastric fundal and oesophageal varices.

Angiography

Angiographic techniques have been largely replaced by non-invasive imaging modalities in the evaluation of portal hypertension.

Arterial portography is usually performed before transcatheter intra-arterial procedures to assess the patency of portal vein and the presence of venous collaterals. Arterial portography consists in the indirect opacification of the portal venous system after the injection of contrast material into the celiac axis or into the superior mesenteric artery.

Splenoportography, consisting in the direct puncture of the spleen and injection of contrast material, had a primary role in the investigation of portal hypertension in the past. In percutaneous transhepatic portography the portal vein is punctured directly and incannulated with a catheter; then, contrast material is injected.

Nuclear Medicine

Liver-spleen scintigraphy with sulphur colloid has been superseded by US and CT scan in the diagnosis of portal hypertension.

Sulphur colloid is taken up by the reticulo-endothelial system cells. A shift of the uptake from liver to the spleen or bone marrow is suggestive of increased portal pressure. Anyway, portal hypertension cannot be ruled out in the absence of this shift.

Diagnosis

US and Doppler US often provide findings which strongly suggest the presence of portal hypertension. Widely accepted signs of portal hypertension, demonstrated at US, are portal vein calibre greater than 13 mm, diminished response of portal vessels to respiration, demonstration of portosystemic collaterals, and presence of splenomegaly and ascites.

The most specific Doppler findings for portal hypertension are mean velocity lower than 16 cm/sec in the portal trunk and reversal of flow within the portal system veins. CT and MR allow a more accurate depiction of porto-systemic collaterals.

Interventional Radiology

Transjugular intra-hepatic porto-systemic shunt (TIPS or TIPSS) is a percutaneous interventional procedure, consisting in the creation of a communication between a hepatic vein and a portal branch through the liver parenchyma, *via* the internal jugular vein.

The procedure is performed under US and fluoroscopic guidance in combination. Under deep sedation, the right internal jugular vein is punctured, and the sheat is advanced into the hepatic vein. A track is created through the liver parenchyma connecting the hepatic to the portal vein. A stent is placed in the track. Blood from the portal vein is shunted to the hepatic vein.

Accepted indications for TIPS include gastroesophageal variceal bleeding despite emergency endoscopic or pharmacological treatment and recurrent variceal bleeding after endoscopic treatment. Potential indications include refractory ascites and Budd–Chiari syndrome.

The main cause of failure of TIPS is stent dysfunction, which may be related to stenosis, occlusion or displacement. A relevant complication of TIPS is hepatic encephalopathy, related to portosystemic shunting. Other complications of TIPS are related to the procedure and include entry site haematoma, peri-hepatic haematoma, extra-hepatic puncture of portal vein, arterioportal fistula, portobiliary fistula, haemoperitoneum.

After the procedure patients undergo close follow-up. Shunt patency is monitored by colour Doppler US. Portography is performed in cases of suspected shunt malfunction. CT may be useful for a better depiction of liver and vascular anatomy and stent position and patency.

Portal Vein Thrombosis

▶Thrombosis, Vein, Mesenteric

Portal Vein, Aneurysm

An aneurysm of the portal venous system is a segmental, saccular or fusiform, dilatation of a vein of the portal system. Aneurysms of the portal venous system may be related both to congenital and acquired causes. There is a significant association with portal hypertension, which has been advocated as a cause of acquired portal vein aneurysm. Various theories have been proposed for congenital portal-vein aneurysm, including abnormal weakness of the vein wall. The most common locations are the splenomesenteric venous confluence, main portal vein, and intra-hepatic portal vein branches at bifurcation sites; rare locations are the splenic, mesenteric and umbilical veins.

Portal venous system aneurysms are usually asymptomatic. Possible complications are abdominal pain, thrombosis, portal hypertension, rupture.

Doppler US alone is usually able to achieve a definite diagnosis and is also used in the follow-up, which frequently demonstrates the stability of the aneurysm.

▶Portal Hypertension, Adults

Portal Vein, Cavernoma

Portal cavernoma, also called cavernous transformation of the portal vein, consists of a network of venous channels, which replaces a previously stenosed or occluded portal vein. It functions as a portoportal shunting, so it is characterized by hepatopetal flow. The veins are usually insufficient to bypass the entire splenomesenteric inflow, and signs of portal hypertension frequently coexist. Clinical signs of portal cavernoma are usually related to extra-hepatic portal hypertension (bleeding from esophageal varices, splenomegaly, etc.). Diagnosis is mainly done by imaging. At US a mass of tortuous veins can be observed at the porta hepatis. Doppler US displays hepatopetal flow. An increased flow in hepatic artery may be seen, representing a compensatory mechaninsm to the reduced portal flow. On contrast-enhanced CT scans, a characteristic mass of veins replacing the portal trunk is the most common finding. Involvement of intrahepatic branches with a normal-appearing main portal vein has also been described. MR angiography and transarterial angiography may be useful for a more accurate and precise depiction of the vascular abnomalities.

PET

Definition

Positron emission tomography (PET) is a functional nuclear medicine technique that produces four-dimensional tomographic images of different biochemical processes in the human body. Unlike radiological methods, which provide information about the anatomy of the human body, PET provides information on the function. The information obtained depends on the radiopharmaceutical used for the PET study.

Characteristics

Principle

Positrons are antiparticles, the antimatter counterpart of electrons and are positively charged. When a positron annihilates with an electron, their mass is converted into the energy of two ray photons. Each of these photons (annihilation photons) has an energy of 511 keV and the emission angle of the photons is 180°; therefore they are moving in opposite directions. The simultaneous detection (within a given time interval of a few nanoseconds) of two 511 keV photons by detectors located in opposite position (180°) is called coincidence measurement. PET measurements are based on the principle of the coincidence measurement. Therefore, if one decay is recorded simultaneously by two detectors, then by connecting the two events by a straight line, the assumption is that the anatomical region (origin) of the event is along this line.

Device

A PET scanner consists of a ring system, which contains small detectors of a dedicated scintillation material for the detection of the annihilation photons. The detectors are connected in coincidence. Only 511 keV photons, which arrive in a certain fixed time period of nanoseconds, are registered. The detector material used for PET is bismuth germanate (BGO), gadolinium orthosilicate (GSO), or lutetium oxyorthosilicate (LSO). The light emitted from the crystal is usually detected by an array of photomultiplier tubes (PMT). These PMTs are arranged with respect to the crystals used, and they are system specific (Fig. 1).

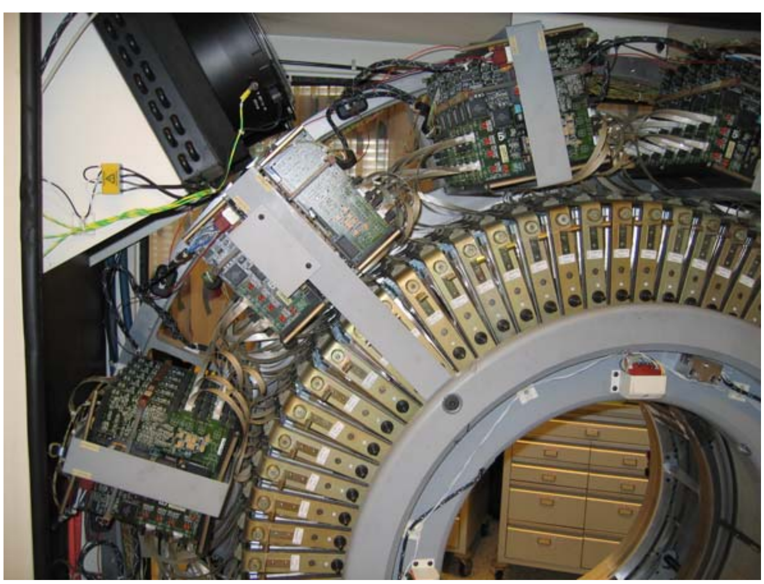
Radioisotopes

For PET studies, positron-emitting isotopes, which decay by emitting a positron, are required. Positron-emitting isotopes are fluorine-18, carbon-11, nitrogen-13, and oxygen-15. All these positron-emitting radionuclides have a short half-life and require a cyclotron for their production. The half-life of fluorine-18 is 110 min, of carbon-11 20 min, of nitrogen-13 10 min, and of oxygen-15-water 2 min.

Recently, positron-emitting radioisotopes produced by a germanium-68/gallium-68 radionuclide generator have been used for the production of gallium-68, a positron emitter with a half-life of 68 min.

Radiopharmaceuticals

Dedicated radiopharmaceuticals are required for PET studies. A radiopharmaceutical is a substance labeled with a radioactive isotope. Different substances that are



Positron Emission Tomography. Figure 1 **Image of the ECAT PET scanner located at the DKFZ, demonstrating the photomultipliers and the detectors located in a ring system.**

involved in biochemical pathways in the human body can be used for PET, when labeled with a positron-emitting isotope.

The most commonly used pharmaceutical is fluorodeoxyglucose (FDG) labeled with fluorine-18 (half-life: 110 min), abbreviated as FDG. FDG is a glucose analog, which is transported into the cells like glucose, phosphorylated, and then trapped. No other metabolic steps occur afterwards. PET studies with FDG are used to examine glucose metabolism. Another radiopharmaceutical that can be used for perfusion studies is O-15-water. Oxygen-15 has a very short half-life of 2 min. Labeled amino acids, like C-11-methionine, C-11-aminoisobutyric acid, F-18-tyrosine, or F-18-dihydroxyphenylalanine (DOPA) can be used for measurements of amino acid transport. Labeled peptides, which are small proteins, have been developed and are already in use for PET studies.

Technique

After the injection of a radiopharmaceutical, acquisition starts. The radiopharmaceutical is distributed in various body-compartments. Static or dynamic imaging can be performed. A static data acquisition consists of a single measurement of a part of the body (target area) at a defined time after the tracer injection and is the most commonly used approach. A dynamic acquisition consists of continuous data collection starting immediately after the tracer injection of a predefined target area and for a definite time integral (e.g., 60 min). The acquisition time is divided in so-called frames, which are time windows for the collection of the counts. Dynamic studies are used to assess the time-course of the distribution of a radiopharmaceutical.

Correction measurements are performed on a daily basis for the calibration of the detectors. A transmission measurement is accomplished for each bed position before the emission measurement (usually done by three germanium sources). Reconstruction of the acquired data is applied based on dedicated iterative algorithms.

Data Evaluation

A visual, semiquantitative and quantitative data evaluation can be accomplished. Visual evaluation of PET images is used to assess areas with a pathologically enhanced tracer uptake (e.g., enhanced FDG accumulation due to viable tumor tissue). A semiquantitative approach allows the calculation of the so-called standardized uptake values (SUVs), which are distribution values without a unit. An SUV of 1 means a uniform tracer distribution. The semiquantitative data evaluation is based on regions of interest (ROIs) or volumes of interest (VOIs), which are representative areas with a high or a low tracer uptake or which serve as reference tissue. A VOI consists of more than two consequent ROIs. The SUVs are robust values, which can be easily calculated by dividing the activity concentration in an ROI or VOI by the rate of the injected dose and body weight.

More sophisticated evaluation procedures may be applied in dynamic data acquisition. Using the VOI technique, time activity curves can be created for the target area (e.g., tumor) and for the reference tissue. Furthermore, a VOI in an arterial vessel (input) is required in order to perform a pharmacokinetic data analysis. Based on compartment models, which originated from the pharmacology, transport rates can be calculated depending on the radiopharmaceutical used. In FDG, the most common radiopharmaceutical used for PET studies is applied: a two-tissue compartment model with a blood compartment. The first compartment represents the transport of nonmetabolized tracer in tissue (by glucose transporters), whereas the second compartment describes the first metabolic step, namely, the phosphorylation of FDG (by hexokinases). The parameters that can be calculated by the two-tissue compartment model are fractional blood volume (VB) as well as the transport rates for FDG transport (k1, k2) and phosphorylation (k3, k4). Noncompartmental models may also be applied to a dynamic data set, such as principal component analysis, Fourier transformation, similarity mapping, or calculation of the fractal dimension. Advantages of noncompartmental methods are the reproducibility of results and the fact that no input function is needed.

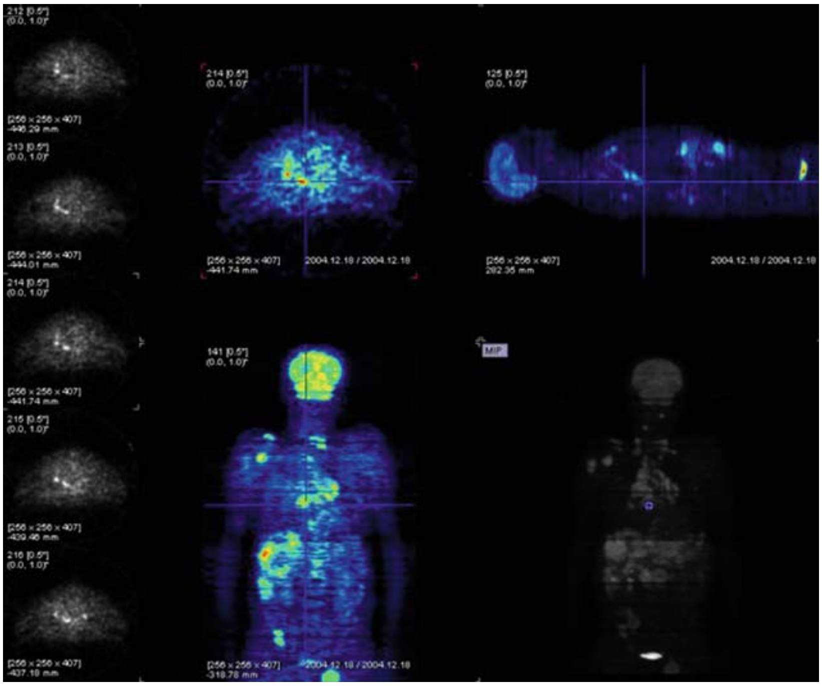
Applications

PET is used in oncology, cardiology, and neurology. Although PET was started in neurology, the main application for PET is oncology.

Oncology

For oncological studies, the radiopharmaceutical fluorine-18-fluorodeoxyglucose (FDG) is mainly used. FDG is taken up by malignant tumors and can therefore be used for diagnosis, staging, and monitoring of treatment effects following primarily chemotherapy and also radiation therapy (1). In particular, diagnosis of tumor recurrence is the domain of PET with FDG (Fig. 2). Aggressive tumors accumulate FDG and can be visualized without problems. Problems may arise in slow-growing (so-called grade I) tumors, like soft tissue sarcomas, prostate carcinomas, well-differentiated hepatocellular carcinomas, or neuroendocrine tumors, which may not accumulate glucose.

Other radiopharmaceuticals, like O-15-water, are used in clinical studies for measurements of tumor perfusion or for assessment of the access to a tumor using



Positron Emission Tomography. Figure 2 **FDG-PET study in a patient with multiple metastases of a melanoma. Upper row: Left: Transversal image of the thorax demonstrating lung metastasis and mediastinal lymph node metastases. Right: Corresponding sagittal image of the same level. Lower row:Left: Corresponding coronal view of the same patient. Right: Maximum intensity projection images (MIP).**

a systemic or an intra-arterial application of a radiopharmaceutical (2).

Labeled cytostatic agents, like F-18-fluorouracil, N-13-cisplatin, F-18-paclitaxel, and others, are used in experimental studies to examine pharmacokinetics *in vivo*.

Labeled peptides, like Ga-68-DOTATOC, a substrate for the somatostatin receptor II, are used in neuroendocrine tumors for tumor visualization and therapy planning.

Labeled amino acids, like C-11-methionine, which reflect the amino acid transport, are in use for the visualization of brain tumors, particularly for high-grade gliomas.

Neurology

PET enables the examination of brain functions. Brain studies are performed by FDG to assess glucose metabolism. A reduction of FDG in the brain is associated with a brain dysfunction, such as epilepsy or Alzheimer disease. Perfusion studies with O-15-water are used for the study of brain perfusion. For the diagnosis of movement disorders, as in Parkinson's disease, dedicated radiopharmaceuticals like F-18-dihydroxyphenylalanine (F-18-DOPA) have been developed. F-18-DOPA is taken up by the dopaminergic neurons and provides information about the function of presynaptic dopaminergic receptors. For the detection of an epileptogenic focus, C-11-raclopride (a D2-repeptor ligand) is used. C-11-Flumazenil (FMZ) is applied for the detection of an epileptogenic focus. FMZ binds to GABA (-aminobutyric acid), the principle inhibitory neurotransmitter in the brain, which is reduced in epilepsy.

Cardiology

PET with FDG is primarily used for cardiac studies to detect the viability of the myocardium. Other radiopharmaceuticals like O-15-water or N-13-ammonia can be used for cardiac perfusion studies.

Fusion Images

The accurate anatomic localization of PET findings often requires knowledge of the morphology. Morphological, tomographic imaging modalities, like computed tomography (CT) and magnetic resonance imaging (MRI) are used for the allocation of PET images. The combination of anatomic and functional imaging information can be performed using three methods:

1. Site-by-site evaluation: The fusion of anatomic and morphologic imaging modalities is made mentally by the physician.

Positron Emission Tomography. Table 1 Physical characteristics of commonly used positron emitters

Isotope	Half-Life (min)	Max. Energy (Mev)	Range (mm) in H_2O
Flourine-18	110	0.635	2.4
Carbon-11	20	0.96	4.1
Nitrogen-13	10	1.19	5.4
Oxygen-15	2	1.73	7.3
Gallium-68	68	1.9	8.1

Positron Emission Tomography. Table 2 Selected PET radiopharmaceuticals in clinical and experimental use

^{18}FDG	Glucose metabolism, myocardial viability, epilepsy, tumor
^{18}F-dihydroxyphenylalanine (FDOPA)	Dopamine pool, decarboxylase activity, amino acid transport
^{18}F-FET	Amino acid transport
^{18}F-fluoride	Bone metastases
^{11}C-methionine	Tumor, protein synthesis
^{11}C-ethanol	Tumor, pharmacokinetics
^{18}F-Fluorouracil	Tumor, pharmacokinetics
^{18}F-Fluorodeoxythymidine (FLT)	Proliferation
^{11}C-aminoisobutyric acid (AIB)	Tumor, amino acid transport (A-type)
N-methyl-^{11}C-flumazenil	Benzodiazepine receptor, epilepsy
O-methyl-^{11}C-raclopride	Dopamine D2 receptor
^{82}Rb	Myocardial perfusion
$H_2{}^{15}O$	Perfusion
^{11}C-acetate	Metabolism
^{13}N-NH_3	Perfusion
^{68}Ga-DOTATOC	Somatostatin receptor expression

2. Software-based fusion: Based on appropriate algorithms (mostly mutual information), anatomic images (e.g., CT or MRI) can be fused using dedicated software packages.
3. Hard fusion: Is based on combined PET/CT machines. Both studies are performed sequentially with a combined system consisting of a CT and a PET scanner.

Synonyms

Fibrothorax; Lobectomy; Lung resection; Lung transplantation; Lung volume reduction; Pneumonectomy; Serothorax

Definition

The postoperative chest describes any condition after surgical treatment during which at least one of the thoracic cavities has been opened or parts of the thoracic wall have been resected.

In lung resection a part of the lung is surgically removed. This part can be represented by a lung lobe, a segment or subsegment. Resections in which lobar or segmental borders are respected are called typical, those which ignore them are called atypical. Resection of a whole lobe is called a lobectomy. Resection of all two or three lobes is called a pneumonectomy. Lung resections are performed for the elimination of benign or malignant masses, or for treatment of interstitial lung disease. This latter form of lung resection is called lung volume reduction and is most often performed in pulmonary emphysema. It describes the surgical removal of parts of the lung which are most severely affected to allow better ventilation of parts which are less involved.

When smaller parts of a lung are removed, the remaining tissue fills out the extra space (Fig. 1). The removal of lobes or a whole lung leaves a space which can be too large to be filled by the remaining lung tissue. In this case, the extra space is filled by fluid. This condition is called a serothorax. The later invasion of connective tissue converts the serothorax into a fibrothorax.

In end stage lung disease the ultima ratio form of therapy is to replace the diseased lung by a healthy one. This kind of therapy is called lung transplantation. For transplantation one can use double or single lungs, in children also lung lobes or a bloc of heart and lungs. Most grafts are extracted from cerebrally dead organ donors. In rare cases living related donors may donate single lobes usually for children.

Positron Emission Tomography. Figure 1 69-year old female patient after upper lobectomy on the right for bronchial carcinoma. CT shows anterior displacement of the lobar fissure and mild hyperventilation of the right lower lobe (*n* = 3).

Pathology/Histopathology

The postoperative thorax is characterized by different stages of wound healing. In early stages the remaining cavity is filled with blood and protein containing fluid. Granulocytes induce the cellular invasion which continues with the appearance of macrophages and lymphocytes. From the margins of the wound capillaries begin to grow into the defect zone and connective tissue is formed by proliferation of fibroid cells. This formation of connective tissue also begins at the margins and succeedingly fills out the defect zone. Later stages are characterized by consecutive forming of collagen type I fibres and decreasing cell progeny. The concluding shrinking process of the connective tissue forms the chronically remaining scar by reduction of the fluid content.

This process of healing concerns the repair of soft tissue defects in the thoracic walls after surgical treatment as well as the thoracic cavity itself after lung resections, transplantations or pneumonectomies. If small defects can heal primarily, a small, linear scar forms which provides good functional and cosmetic properties. In larger defects greater amounts of fluid invade the remaining defect zone, later an amount of scar tissue persists which depends on the size of the defect. Thus, a pneumonectomy results in a large amount of intrathoracic blood and fluid which is called a serothorax. The final stage of the reparatory process with persisting scar tissue in the thoracic cavity is called a fibrothorax. In the clinical setting over a long time a mixture of fibrous and fluid fractions persists. This combined stage of wound healing is called a fibroserothorax. The shrinkage of the scar tissue causes a volume loss of the concerned hemithorax. This results in a mediastinal shift and herniation of the contralateral lung with regional overinflation.

Lung transplantation produces a unique histopathologic situation due to the different presentation of HLA-antigens on the cellular surface of the grafted organ. The usual clinical setting implements human organ donation and subsequently a situation of allo-transplantation. This situation describes transplantation of organs of the same species which are genetically different. It determines different forms of organ rejection. Hyperacute rejection occurs in patients who have antibodies against the graft. Antibody activation in this case leads to intravascular thrombosis and coagulation due to endothelial damage. Consecutively, pulmonary oedema and alveolar hemorrhage occur. Acute rejection in contrast happens by activation of T-cells by the foreign major histocompatibility complex presented on the surface of endothelial cells or temporally resident leukocytes. It leads to perivascular or peribronchial/peribronchiolar mononuclear and lymphoid cell infiltration. More severe forms show wide infiltration of the alveolar septae and spaces with consequent necrosis and diffuse alveolar damage. Chronic graft rejection is mediated by mononuclear cell infiltration and proliferation of myofibroblasts. It concerns primarily small peripheral airways. The infiltration as well as the deposition of collagen matrix leads to a process called obliterative bronchiolitis.

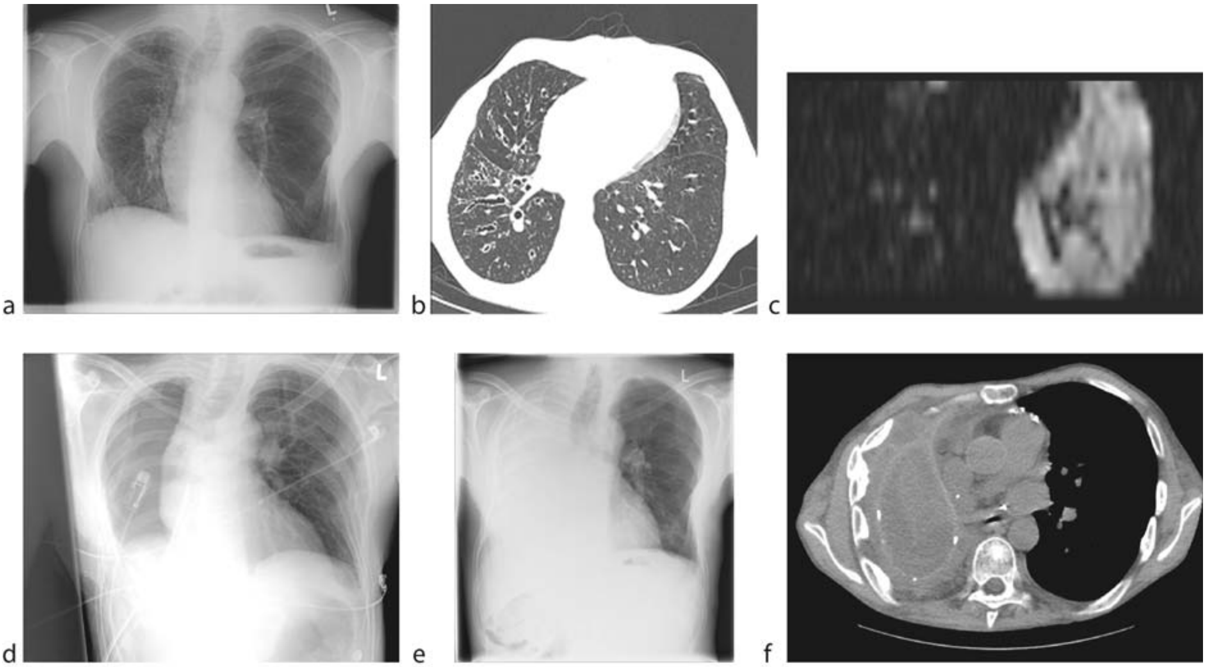
Clinical Presentation

All patients surgically treated within the thorax present with a different extent of dermal scarring. Thoracic deformity, possibly combined with scoliosis and unilateral elevation of the shoulder, results after larger resections, such as lobectomy or pneumonectomy. Also resections of the thoracic walls produce thoracic deformities. Shortness of breath on exertion can occur both due to thoracic deformities as well as to lung volume loss after resections, especially lobectomy or pneumonectomy. Lung transplant recipients usually present with similar symptoms. Complications of transplantation such as infections or graft rejection present with unspecific symptoms, such as with fever or subfebrile temperatures, cough and shortness of breath.

Imaging

The initial imaging modality in all postoperative chest patients is the chest radiograph (Fig. 2). It is used for follow-up of the early postoperative period, monitoring of pulmonary congestion or oedema, infections, pleural effusions and pneumothoraces. Later indications include the follow-up of patients after tumor resection, the development of fibro- or serothoraces and the initial exclusion of complications after lung transplantation.

CT of the chest is widely used in patients in whom the chest radiograph did not clarify a clinical suspicion or reveals unclear findings because the sensitivity of CT for most intrapulmonary and soft tissue complications of postoperative chest patients is much higher than for chest radiography. The assessment of lung transplant recipients by CT is nevertheless limited by its moderate sensitivity for graft rejection. In these immuno-compromised patients with unspecific symptoms CT is mostly used for the exclusion of pneumonia. Additional scans taken in expiration are performed for the detection of air trapping, which is caused by expiratory collapse of peripheral airways and can be a sign of bronchiolitis obliterans or bronchiolitis obliterans syndrome.



Positron Emission Tomography. Figure 2 37-year old male patient after double lung transplantation due to cystic fibrosis and left sided retransplantation because of chronic graft rejection. (a) Cchest radiograph shows mediastinal shift to the rejected right lung as well as compensatory overinflation of the retransplanted graft on the left. (b) CT shows marked cylindric bronchiectasis as sign of advanced bronchiolitis obliterans in ongoing chronic rejection. (c) Transversal reformat of ^{3}He-MRI reveals good ventilation of the normal left regraft and poor to nonexistent ventilation of the rejected graft on the right. (d) First chest radiograph after pneumonectomy of the rejected graft shows pneumoserothorax on the right and a mediastinal shift to the operated side. (e, f) Progressive conversion to a fibroserothorax shown by chest radiograph and CT.

The role of ultrasound is usually limited to the early postoperative period for the determination of pleural effusions and their volumes.

Diagnosis

In the early postoperative period complications after thoracic surgery are routinely diagnosed by chest radiography. Images show pleural effusions as well as hematothoraces, pneumonias, and congestion. Laboratory values are often helpful in the differential diagnosis. Pleural effusion for example cannot be differentiated from hematothorax on a chest x-ray. A follow up of the hemoglobin concentration helps with the differentiation. Leucocyte counts and c-reactive protein levels help in the differentiation between pneumonia and atelectasis. Measurements of the central venous pressure can assess the severity of congestive heart failure. CT differentiates proteinous fluid and blood in their density. It can often differentiate between atelectasis and pneumonia and shows the extent of a pleural effusion much better than the chest radiograph.

Later complications in postoperative chest patients are usually diagnosed by their clinical history and clinical symptoms such as fever, cough, wheezing and shortness of breath. Further diagnostic steps are chest radiographs, blood tests and CT similar to the early postoperative period. Lung function tests may help in patients with further complicating diseases such as pulmonary emphysema, chronic obstructive pulmonary disease, cystic fibrosis or pulmonary fibrosis.

Lung transplant recipients instead are routinely monitored by pulmonary function tests. Usually a chest radiograph is performed to rule out pulmonary infections. An otherwise unexplained decrease of the forced expiratory volume in one second is a hint for the presence of either acute or chronic graft rejection. CT should be performed early to rule out other reasons.

Interventional Radiological Treatment

Drainage of pleural effusion, thoracic empyema or abscesses after surgical therapy of the chest is a routinely performed intervention and is usually performed under CT guidance. Nevertheless, pleural effusions may be drained blindly. Afterwards a chest radiograph has to be performed to rule out pneumothorax. Regarding the preoperative period, CT guided biopsies are often performed for histopathologic diagnosis and decisions for surgical versus conservative treatment.

Priapism

Räto T. Strebel[1], Hubert John[2]
[1]Department of Urology, University Hospital Zurich, Zurich, Switzerland
[2]Klinik Hirslanden, Leiter Zentrum für Urologie, Zurich, Switzerland
raeto.strebel@usz.ch

Definition

Priapism is a persistent penile erection that continues hours beyond (commonly erections greater than 4 h in duration) or is unrelated to sexual stimulation (1). Two subtypes of priapism, i.e., low-flow and high-flow priapism are distinguishable.

1. Low-flow priapism (veno-occlusive, ischemic): This subtype is characterized by little or no blood flow in the corpus cavernosum and decreased outflow. Consequently, cavernous blood gas analysis reveals hypoxic, hypercarbic, and acidotic values. There is a wide variety of etiologic factors that may trigger this functional disorder.
2. High-flow priapism (arterial, nonischemic): Typically, normal cavernous blood gas values are present and the persistent erection is caused by an abnormally high arterial inflow. Vascular abnormalities and penile and perineal trauma are the most common causative factors.

Clinical Presentation

There is not much doubt about the clinical presentation of patients with a priapism. On clinical examination, patients with a low-flow (ischemic) priapism show typically rigid and tender corpora cavernosa and complain of pain. In contrast, patients with a high-flow (nonischemic) priapism usually present with a penis that is neither fully rigid nor painful. In both forms, on palpation the corpus spongiosum and glans penis are not affected. For the management of priapism it is of predominant importance to distinguish between high- and low-flow priapism. It is therefore very important to perform an analysis of the cavernous blood gases.

Imaging

Additionally to the blood gas testing a color Doppler ultrasonography of the cavernosal arteries might be helpful in differentiating between high- and low-flow priapism. Very low or absent arterial inflow is indicative for a low-flow priapism. Once the diagnosis of a high-flow priapism is established, a penile arteriography should be performed if the priapism does not resolve. Vascular abnormalities can be identified and treated accordingly to decrease the abnormally high arterial inflow.

A patient with a persistent high-flow priapism with failure to conservative treatment should be referred to a skilled interventional radiologist for superselective embolization of vascular abnormalities or cavernous arteries.

Synonyms

Cell doubling; Cell growth

Definitions

In biology and medicine, the phrase *proliferation* refers to the growth of cell populations by means of cell division. During the process of proliferation, one "parent" cell divides into two "daughter" cells. The process of cell proliferation consists of two major parts. In the first part, which takes place during the S-phase of the ▶cell cycle, the DNA of the parent cell is replicated. In the second part, during the mitosis phase, the duplicated DNA is separated into two equally sized groups of chromosomes, followed by the division of the entire cell, called cytokinesis.

The synonym *cell growth* may also refer to an increase in cell size *without* an increase in number. However, when used in the context of proliferation, "cell growth" means growth of cell populations by cell reproduction.

The phrase *neoplasm* describes any abnormal tissue mass arising from transformed cells. Neoplasms can be benign or malignant. The most common type, melanocytic nevus ("beauty spot"), is benign. In clinical medicine, however, neoplasm usually means a malignant tumor.

This article is deliberately restricted to malignant neoplasms, as nuclear medicine imaging of proliferation is almost exclusively focused on malignant tumors.

Characteristics

The Significance of Proliferation in Normal and Malignant Cells

Proliferation is a key factor for understanding the natural history of a malignant tumor as well as its response to treatment. However, proliferation is not at all restricted to malignant cells. It is a typical feature of any living organism and a necessary precondition for growth as well as for maintenance of normal function. Most human cells are differentiated cells. They are specialized to fulfill specific functions as part of the well-organized functional network of the human body.

Cells usually die after a few cell cycles. Because death of differentiated cells is genetically determined (referred to as planned cell death or apoptosis), cell lifetime can vary between a few hours up to many years; it mainly depends on the specific type of cell. Many highly differentiated cells do not undergo further replication at all. These cells are known as terminally differentiated cells. For the remainder, cell reproduction is necessary to maintain homoeostasis. This is achieved by initiating a pool of stem cells to proliferate and form differentiated cells. In normal tissue, the amount of proliferation is fine-tuned to the actual need by factors stimulating or suppressing cell replication. This control is lost in most malignant tumors.

Besides the ability to invade other tissues and form metastases, the growth rate resulting from loss of control is the most important feature to describe the aggressiveness of a given tumor. In other words, the higher the proliferation rate, the faster an (untreated) malignant tumor will lead to death. Essential mechanisms to treat a tumor successfully by chemotherapy or ionizing irradiation are (i) to (re-)activate signaling for apoptosis and (ii) to damage vital cell functions involved in the process of proliferation. Hence, stopping or slowing down tumor cell proliferation is a major goal of cancer therapy.

Proliferation Assays

Because of the importance of proliferation for both prognosis and treatment of neoplasms, investigators have long tried to measure tumor cell growth in patients. Analyzing tumor size affords repetitive measurements, is time-consuming, and lacks precision. Other determinants often used in experimental situations, such as tumor weight or cell counts, are not applicable to clinical medicine. Therefore, tests have been developed to measure proliferation in tumor samples.

By staining tumor DNA, cell division can be visualized at the latest stage of the cell cycle—at mitosis when chromosomes are divided to form two daughter cells. Using light microscopy, the percentage of cells undergoing mitosis can be calculated and expressed as the mitotic index of a tumor. Since the mid-1960s, investigators have targeted DNA replication as a characteristic feature of tumor proliferation. The radiolabeled nucleoside thymidine (tritiated thymidine or H-3-thymidine) is incorporated into DNA during the S-phase, forming the DNA base T, which pairs with a adenosine in double-stranded DNA. To measure thymidine incorporation, patients have to be injected before tumor resection, or living tumor cells have to be explanted and incubated under stable conditions. It has been shown that the amount of H-3-thymidine incorporated into cells strongly correlates with DNA synthesis. H-3-thymidine labeling can only be performed using viable cells, and any change in growth conditions might severely affect the test results. Despite these shortcomings, the test is still considered the gold standard for measuring proliferation in experimental settings.

To obtain information on proliferation in clinical situations, investigators have focused on simpler methods that can be performed on fixed tumor samples. Two tests have gained wide acceptance. They both use antibodies against cellular antigens associated with proliferation. The proliferating cell nuclear antigen (PCNA) is a 36 kDa molecular-weight protein also known as cyclin' (1). The protein is synthesized in early G1 and S-phases of the cell cycle. PCNA is present in two basic forms, a soluble form sensitive to organic fixation that is not involved in DNA replication, and a second form that is insoluble and associated with ongoing DNA synthesis. The expression of the Ki-67 protein is also strongly associated with cell proliferation (2). The fact that Ki-67 is present during all active phases of the cell cycle (G1, S, G2, mitosis) but absent in resting cells (G0) makes it suitable to determine the growth fraction of cell populations. Although the functional significance of Ki-67 is still unclear, findings indicate that Ki-67 expression is required for progression through the cell cycle.

Both Ki-67 and PCNA can be visualized in formalin-fixed and paraffin-embedded tissue ("antigen retrieval"). Therefore, these tests are frequently used routinely and can be regarded as the current standard for immunohistochemical characterization of tumor cell proliferation. Because their results are derived from small tumor samples, they might not be representative for the entire tumor burden of a given patient.

Nuclear Medicine Imaging

In contrast to the above-mentioned *in vitro* proliferation assays, nuclear medicine procedures have the potential to image the biological behavior of all of a patient's tumor sites without invasive biopsies. Furthermore, nuclear medicine tests can be easily repeated during treatment to monitor the response to therapy. Positron emission tomography (►PET) appears to be the method of choice to fulfill this aim. It is quantitative and therefore suitable for detecting subtle changes of molecular processes under treatment, and it provides optimal image quality because of high spatial resolution. Having short-lived positron-emitting isotopes such as carbon-11 or fluorine-18 available, various organic molecules can be radiolabeled to characterize cell function.

Today, fluorine-18 deoxyglucose (►FDG) is generally accepted as the best radiopharmaceutical for PET imaging of malignant neoplasms (3). This is due to its high uptake by most solid tumors and hematological malignancies and its comparably low background activity in most normal tissues (except for brain and kidney). FDG-PET uses the increased glycolytic activity of cancer cells. FDG is transported into cells by glucose transporters and subsequently phosphorylated to FDG-6 phosphate by hexokinase. Further metabolism occurs very slowly, causing metabolic trapping of FDG in the cells. It has been known for a long time that tumors largely depend on glucose as an energy substrate. Therefore, tumor uptake of FDG is interpreted to represent energy consumption of tumor cells. Obviously, the faster tumors grow, the more glucose they will consume. This view is supported by positive FDG-PET findings in practically all fast-growing tumors. In contrast, it has been shown that FDG-negative malignancies are usually highly differentiated tumors with a low proliferative activity. Among them are slow-growing tumors such as differentiated thyroid cancer and low-grade lymphomas. However, some of them reveal intense FDG uptake similar to that seen in rapidly growing neoplasms. In addition, experimental studies (4) have shown that FDG accumulation may remain stable in tumor cells after stimulation of proliferation. Thus, FDG is not considered to reliably reflect the proliferative state of malignant tumors.

More recently, investigators have focused on DNA replication, particularly pyrimidine metabolism similar to the classic H-3-thymidine assay (see earlier), to develop a proliferation marker that can be measured by PET. Preliminary *in vitro* data (4) showed that following radiotherapy or chemotherapy, uptake of radiolabeled thymidine decreases more rapidly than that of FDG, indicating the potential use of thymidine as marker for treatment response. Using carbon-11 as a positron emitter, thymidine can be labeled for PET imaging. *In vitro*, this compound is incorporated into DNA, correlating with proliferation as measured by the H-3-thymidine assay. Initial clinical studies in patients with small-cell lung cancer treated by chemotherapy demonstrated a rapid decline of uptake exceeding that of FDG. However, interpretation of C-11-thymidine PET studies is impaired by various radiolabeled metabolites occurring due to the rapid degradation of C-11-thymidine in humans. 3′-deoxy-3′-[^{18}F]fluorothymidine (▶FLT) (5), an analog of thymidine, exhibits better *in vivo* stability. FLT is a substrate of the thymidine kinase 1 (TK-1), which phosphorylates FLT to FLT-5-phosphate. A significant correlation between TK-1 expression and cellular FLT accumulation has been shown for several tumor cell entities. Pilot studies in humans showed intense FLT uptake in a number of malignant tumors but also in normal bone marrow and liver. The latter could be attributed to a glucoronidated metabolite.

While some authors have reported a correlation between FLT uptake and Ki-67 staining (see earlier) in solitary pulmonary nodules and lung cancer, such an association was not confirmed in other malignant tumors. A number of animal studies showed that FLT uptake decreased early after chemotherapy (3). However, FLT uptake was also shown to be *increased* in tumor cells successfully treated with antimetabolites such as 5-fluoro-uracil or methotrexate. Such an increase could be due to induction of TK-1 activity involved in the salvage of thymidine reactive to the block of *de novo* DNA synthesis induced by this group of chemotherapeutic agents. Thus, in such treatment FLT appears not to be suitable for measuring cell proliferation.

Conclusion

Noninvasive evaluation of tumor cell proliferation is a highly attractive goal for tumor imaging. Together with emerging new treatment modalities, it becomes more and more relevant to characterize tumors before and during therapy to distinguish responders from nonresponders as early as possible. PET with FLT is a possible approach to fill this diagnostic gap, although many aspects of FLT imaging are still under study and not completely understood. Ongoing studies will have to show whether FLT or other compounds will be able to gain significance as prognostic markers or probes to monitor tumor response to treatment.

Synonyms

Male chronic pelvic pain syndrome; This term encompasses only the chronic nonbacterial form of prostatitis [i.e. type III of the NIH classification (1)]

Definitions and Epidemiology

Until recently epidemiological data on prostatitis was scarce. The prevalence and incidence figures of chronic prostatitis are spread, with prevalence ranging between 2–16% (2). Contrary to benign prostatic hyperplasia or prostate cancer, it may occur at any age, although the incidence increases with age (3). No impact of race on incidence was found. It was calculated that it compounded 8% of all visits to urologists in the United States (4). Thereby, it was associated with substantial economic health care costs and lower quality of life scores (5).

Classification

The National Institutes of Health (NIH) divided prostatitis into four main categories (1) (Table 1). Thereby, a distinction is made between acute and chronic as well as between symptomatic and asymptomatic prostatitis. It is unclear how large the prevalence of type IV prostatitis is, since men do not have any symptoms, although this may be as high as 32% (6).

Symptoms

Perineal pain, increased frequency of voiding, nightly voiding, as well as painful voiding are the most frequent symptoms of chronic prostatitis. Other symptoms can be pain during ejaculation or orchialgia (3, 7, 8). In acute prostatitis an acute onset of fever and severely tender prostate are present (9).

Etiology and Pathology

Acute and chronic bacterial prostatitis is most commonly caused by Gram-negative microorganisms, particularly *Escherichia coli* (9). In contrast, chronic nonbacterial prostatitis is a multifactorial syndrome. Possible factors revealed as factors leading to occult infection, a change in the prostatic epithelial surface or mucin production, neurogenic inflammation, mast cell activation and psychological stress (8, 10). Reports on autoimmune disturbances have not been conclusive in determining whether this is a factor. Another rarer form of prostatitis is granulomatous prostatitis which may be idiopathic, secondary to prostatic surgery or caused by *Myobacterium tuberculosis* (11).

For an in-depth review of the histopathological features of prostatitis, the authors refer the reader to the paper by Roberts et al. (9).

Diagnostic Imaging Techniques of Prostatitis

Transrectal ultrasound (TRUS)—In acute bacterial prostatitis in many cases an area of hypoechogenicity was found with high Doppler flow within and around the

Prostatitis. Table 1 The NIH classification system of prostatitis

Type	Classification	Features
I	Acute bacterial prostatitis	Episode
II	Chronic bacterial prostatitis	Recurrent
III	Chronic nonbacterial or abacterial prostatitis (also referred to as chronic pelvic pain syndrome)	Absence of detectable infection
A	Inflammatory	Leukocytes detected in semen, prostatic fluid or urine
B	Noninflammatory	Absence of leukocytes in semen, prostatic fluid or urine
IV	Asymptomatic inflammatory prostatitis	Absence of symptoms with presence of leukocytes in semen, prostatic fluid or urine

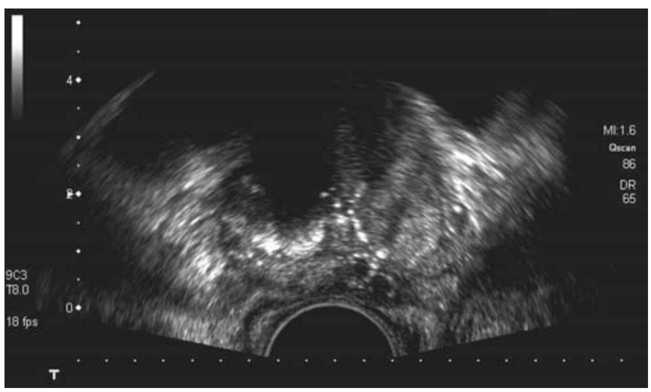
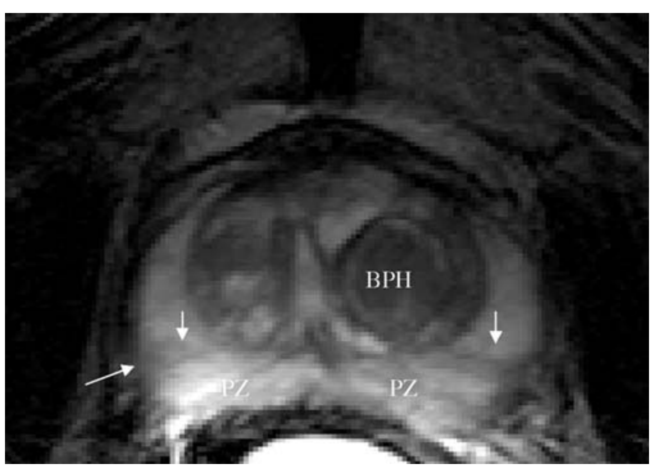
lesion. These abnormalities regressed during therapy (12). Also, a dark halo around the urethra which did not regress was observed. Prominent, engorged periprostatic veins were seen in half of the patients in the acute phase. In case of acute bacterial prostatitis, TRUS can be used for treatment follow-up by determining whether the prostate volume decreases (13, 14), although some authors propose to use TRUS only to exclude prostate abscesses.

In a case–control study, on color Doppler TRUS an enhanced blood flow to the prostatic capsule and diffuse flow in the parenchyma was observed compared with patients without chronic prostatitis and healthy volunteers (15). In areas of focal hypervascularity on color Doppler TRUS in the peripheral zone of the prostate, the chance of detecting prostate cancer or prostatitis increased (16). In acute prostatitis, the enhancement occurred particularly around the urethra, ejaculatory ducts, and close to the seminal vesicles (17). Other features that have been described were capsular thickening and irregularity (18), constant dilatation of the periprostatic venous plexus, dilated and elongated seminal vesicles with thickening of their inner septa, and bladder neck hypertrophy (19). Frauscher et al. reported that also chronic prostatitis could produce (multiple) areas that enhance after contrast agent administration, causing many false positive findings in detecting prostate cancer (20). The presence of prostatic calcifications is a strong indication of chronic prostatitis (Fig. 1; 21).

Magnetic resonance (MR) imaging—Few studies have been published reviewing the features of prostatitis on MR imaging. The greatest challenge is to differentiate it from prostate cancer because many MR imaging characteristics are applicable to both diseases. Both prostatitis and prostate cancer are recognizable by an area of lower signal intensity within the prostate gland (22, 23). MR imaging demonstrated indeterminate focal low signal intensity that was not nodular (contour deforming) in 58% of chronic prostatitis lesions that were greater than 6 mm in largest diameter (22) (Fig. 2). Features found in prostatitis were



Prostatitis. Figure 1 Benign prostatic hypertrophy (BPH); Peripheral zone (PZ); Arrows are low signal intensity triangular areas (not nodular) indicating focal areas of prostatitis.



Prostatitis. Figure 2 Well-delimited areas with calcifications (*arrows*) in the right central gland ad to lesser extent in the left central gland of the prostate.

Prostatitis. Table 2 Features of chronic prostatitis and prostate cancer on MR imaging

Feature	Prostatitis	Prostate cancer
MR imaging		
Signal intensity on T2-weighted imaging	Low or equal to rest prostate	Mostly low
Diffuse or focal	Focal or diffuse	Focal
MR spectroscopic imaging

transitional zone cysts, prostatic utricle cysts and abscesses of the seminal vesicles (Table 2) (24).

MR spectroscopic imaging of chronic prostatitis revealed that normal spectra in areas of chronic prostatitis were rare. Most areas exhibited the same features as prostate cancer: an elevated choline peak and reduced or absent citrate (22). This mimicking of prostate cancer by chronic prostatitis is a frequent cause of false-positive findings in prostate cancer diagnostics (Table 2).

Therapy

Acute and chronic bacterial prostatitis—Antimicrobial treatment is the therapy of first choice in these patients (25). For acute prostatitis immediate parenteral bactericidal antibiotics ought to be initiated while for the chronic form high-dose oral administration for 4–6 weeks is proposed (26). After initiation of treatment, rarly (<48 h) vigilance about the presence of prostatic abscesses is strongly advised (12).

Chronic nonbacterial and asymptomatic prostatitis—No consensus has been reached on the treatment of these categories of prostatitis. The effect of antimicrobial therapy in chronic nonbacterial prostatitis has not been proven in randomized clinical trials. However, it was found to decrease the amount, frequency and severity of symptoms (27). Other therapies are alpha blockers (28), antiinflammatory agents, nonpharmaceutical therapies such as biofeedback and thermal therapies (29).

Definition

Investigation of protein–protein interactions is the study of how, when and where proteins work with each other in biological process.

Importance of Protein–Protein Interactions in Biological Processes

Almost all cellular functions and activities involves proteins, which can act as enzymes in catalyzing the chemical reactions of metabolism, components of cellular machines in decoding genetic information and synthesizing proteins as well as regulating gene expression. Proteins can be localized in special cellular compartments or shuttle between the different compartments and acting as "messengers". Proteins work in concerto and constantly influence each others functions through different temporal and spatial interactions with one another. The interactions between different proteins that control many cellular functions are therefore interdependent. To understand the biological basis of different cellular events, it is essential to know and to understand the types of interactions that occur between the various proteins required for a given process. Even though isolation and structural characterization of all proteins that exist in the cell are necessary, it is not sufficient in explaining how they interact and assemble into the molecular machines. Therefore, identifying and studying different protein-protein interactions are indispensable in the understanding of the fundamentals of cellular process.

Methods for Studying Protein–Protein Interactions

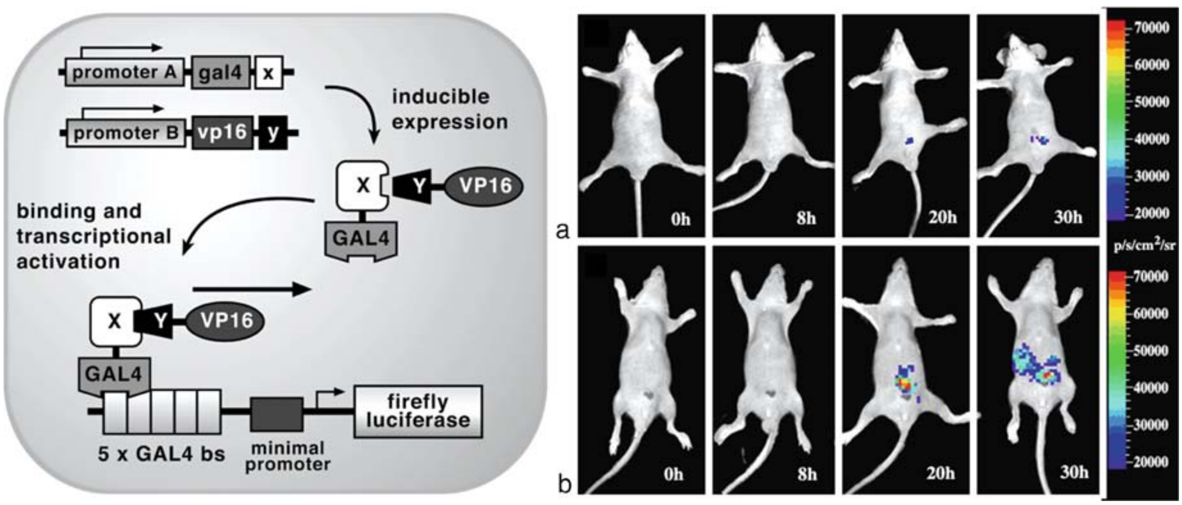
Different methods have been developed to study protein–protein interactions, and can be classified into three different categories: *in vitro* essays with purified proteins and cell lysates, cell-culture studies and in living subjects (1). *In vitro* techniques include coimmunoprecipitation, gel-filtration chromatography, analytical ultracentrifugation, calorimetry, optical spectroscopy and the yeast two-hybrid system. Cell culture-based methods utilized for studying protein-protein interactions include the split ubiquitin system, Sos recruitment system, dihydrofolate reductase complementation, β-galactosidase complementation, split-GFP/split-luciferase reconstitution, β-lactamase complementation, G-protein fusion system and the resonance energy transfer (RET)-based systems, such as fluorescence RET (FRET) and bioluminescent RET (BRET). Furthermore, improvement in noninvasive technologies for detection of signals from deep tissues within the living subjects and the rapidly expanding field of molecular imaging have facilitated the investigation of protein–protein interactions occurring inside intact cells in small living animals. Imaging technologies including but not limited to bioluminescence imaging, fluorescence imaging, small animal positron emission tomography (PET), and small animal single photon emission computed tomography (SPECT) have been utilized to noninvasively image different classes of molecular events, including protein–protein interactions. Bioluminescence and fluorescence imaging depend on light transmission through the animal, while PET and SPECT depend on γ-ray transmission through the animal. Each of the above mentioned systems has its own merits and demerits, and some of methods that are most pertinent for studying protein–protein interactions are discussed in details below.

Modified Mammalian Two-Hybrid System

The yeast two-hybrid system is one of the most widely used assays to examine protein–protein interactions. The two interacting proteins of interest are individually fused to a DNA-binding domain (BD) and a transcription activation domain (AD) and expressed in yeast. Interactions between two proteins of interest lead to transcription of a reporter gene that is distal to binding sites for the BD (2). The yeast two-hybrid system has been adopted for mammalian cells by replacing the reporter gene and expression plasmids. An example of the modified mammalian yeast two-hybrid systems involves the investigation of the interactions between the transcription factors MyoD and Id in intact cells and in living animals. The plasmids which carry the yeast GAL4 DNA-binding domain fused to the Id (GAL4-Id) and Herpes Simplex Virus VP16 activation domain fused to a segment of MyoD (VP16-MyoD) were expressed as the two hybrid proteins in 293T human embryonic kidney cells. Interaction between Id and MyoD in the hybrid proteins and subsequent binding of VP16 (in VP16-MyoD) to the GAL4 binding site in the minimal promoter containing the TATA box activates transcription of the Firefly luciferase (FL) reporter gene (Fig.1). The expression of the two hybrid proteins can also be transcriptionally modulated using a tumor necrosis factor-alpha (TNF-α) responsive promoter. In both cases, the protein expression and/activity of FL can be imaged in transfected cells in cell culture studies as well as cells implanted in nude mice, using D-Luciferin as the substrate and a cooled coupled-charge device (CCD) camera for optical bioluminescence imaging. The main limitation for the modified mammalian yeast two-hybrid system is the lack of real time measurement of protein–protein interaction since the two fusion proteins have to interact, translocate to the nucleus and activate the transcription of the reporter gene prior to any detectable FL activity. Furthermore, FL activity may persist long after the interactions between the fusion proteins cease.

Split Protein Strategies

Changes in the connectivity of amino acids can alter and form different protein conformations. Different split protein strategies have been used to examine the efficiency of real time protein–protein interactions based on the observation that functional proteins can be assembled from one or more noncovalently attached polypeptides. β-D-Galactosidase from Escherichia coli (*E. coli*) was a prime example of utilizing protein fragments coupled with an enzymatic assay to gauge protein–protein interactions (3). Each monomer of the tetrameric β-galactosidase protein can be cleaved into a small N-terminal ω-fragment (50–90 residues) and a large (135 kDa fragment) ω-fragment. With the addition of purified ω-fragment, dimers of enzymatically inactive, purified ω-fragments achieve a dynamic equilibrium to form a tetrameric active

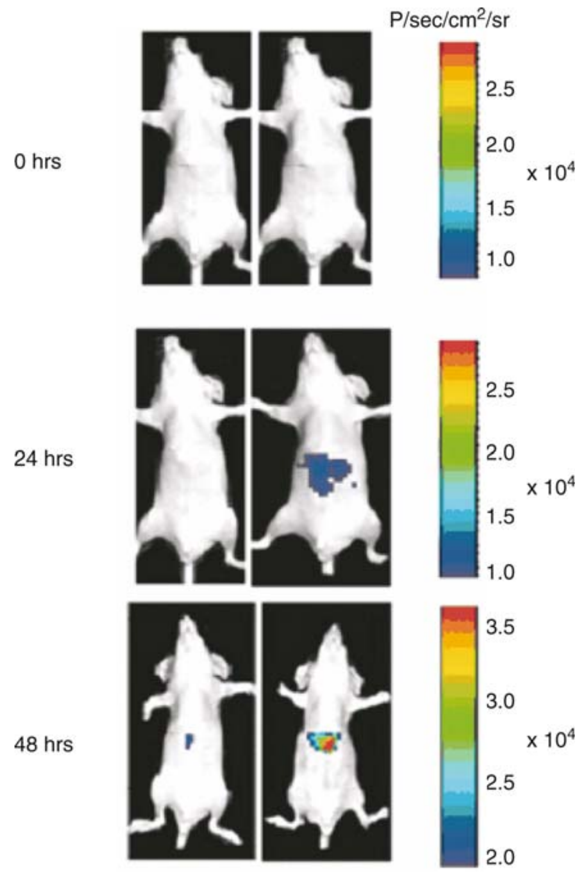


Protein–Protein Interactions. Figure 1 Imaging protein–protein interaction in living mice with a modified yeast two-hybrid strategy. Schematic diagram of the system for imaging the interaction of proteins X and Y. The first step involves the vectors pA-gal4-x and pB-vp16-y, which are used to drive transcription of *gal4-x* and *vp16-y* through use of promoters A and B. In the second step, the two fusion proteins GAL4-X and VP16-Y interact because of the specificity of protein X for protein Y. Subsequently, the GAL4-X-Y-VP16 binds to GAL4-binding sites (five GAL4-binding sites [bs] are available) on a reporter template. This leads to VP16-mediated transactivation of Firefly luciferase (FL) reporter gene expression under the control of GAL4 response elements in a minimal promoter. Transcription of the FL reporter gene leads to FL protein, which in turn leads to a detectable visible light signal in the presence of the appropriate substrate (D-Luciferin), ATP, Mg^{2+}, and oxygen. The NF-B promoter can be used for either pA or pB and TNF--mediated induction. *In vivo* optical CCD imaging of mice carrying transiently transfected 293T cells for induction of GAL4-X and VP16-Y fusion proteins. All images shown are the visible light image superimposed on the optical CCD bioluminescence image with a scale in photons/s/cm^2/steridian (sr). Mice in top row were imaged after injection of D-Luciferin but with no TNF--mediated induction. Mice in bottom row were imaged after injection of D-Luciferin after TNF- -mediated induction, showing marked gain in signal from the peritoneum over 30 h (Reproduced with permission from Ray P et al (2002) Proc Natl Acad Sci U S A 99, 3105–3110).

enzyme, in a process called α-complementation. This process suggested that synthetically separated fragments of a single polypeptide might be able to complement and give rise to an enzymatically active protein. By adopting the α-complementation strategy for the "split protein" strategy, a single reporter protein/enzyme is cleaved into N-terminal and C-terminal segments with each segment fused to one of two interacting proteins. Physical interactions between the two proteins restore the functional reporter protein/enzyme activity and lead to signal generation that can be measured. This split protein strategy can work either through protein–fragment complementation assays (described in details below), or intein-mediated reconstitution assays. In the latter case, reconstitution of the full reporter protein occurs and, in the former, reconstitution of the reporter protein does not occur. To date, several reporter proteins (e.g., β-lactamase, β-galactosidase, ubiquitin, dihydrofolate reductase, FL, Renilla luciferase (RL) and green fluorescent protein) have been adapted for split-protein strategies by finding various split sites for each reporter protein (1) for imaging protein–protein interactions in living subjects. The appropriate split point should lead to two fragments that do not have significant affinity for each other and yet, when brought together through interaction of two other proteins, lead to detectable signal.

Protein–Fragment Complementation Strategy

The protein–fragment complementation of many globular proteins shows activities that are similar to full-length proteins and has been extended for studying protein–protein interactions. For example, the FL was rationally split between amino acid positions 437 and 438 and used in conjunction with inteins to detect insulin-induced interaction of phosphorylated insulin receptor substrate 1 (IRS-1) and the N-terminal SH2 domain of PI 3-kinase in a cell-culture assay (4). Activation of insulin receptor by insulin led to phosphorylation of IRS-1 and subsequent interaction with the SH2 domain, leading to reconstitution of the full length FL. This split FL strategy with inteins has also been adapted for split-reporter complementation for imaging protein–protein interactions in small living animals. Interaction between Id and MyoD, as previously done with a modified yeast two-hybrid strategy (Modified mammalian two-hybrid system), was monitored using the split FL reporter complementation and an intein-mediated reconstitution strategy (1). The complementation strategy was shown to be as sensitive as the intein-mediated reconstitution strategy under the conditions tested and can be used to image protein–protein interactions in living subjects. In addition to FL, RL has also been used as another bioluminescence imaging reporter protein. RL is also the smallest monomeric protein (36 kDa) used for studying protein–protein interactions through a protein–fragment-assisted complementation strategy (1). The N-(amino acids 1–229) and C-terminal half (amino acids 230–311) of split RL were fused to interacting protein partners of interest and have been validated in both cell culture and living animals. Interactions between the two interacting protein partners bring the two inactive halves of the split RL in closer proximity and partially restore the RL activity, which can be imaged by optical bioluminescence imaging in the presence of the substrate coelentarazine. This split RL complementation system has been used to study rapamycin-mediated mTOR kinase FRB and the immunophilin FKBP12 interactions (Fig. 2), interaction between the transcription factors MyoD and ID and homodimerization of Herpes Simplex Virus Type I thymidine kinase. The limitation associated with the use of RL as an optical reporter is its relatively rapid reaction kinetics, requiring early time-point measurements (5). Nevertheless, the RL split-reporter system appears highly suitable for studying protein–protein interactions in cells and in living animals because of its optical bioluminescence and its signal,



which can be amplified through an enzymatic process. Furthermore, the complementation strategies based on RL fragments (13 kDa and 23 kDa for the C-terminus and N-terminus fragments respectively), with smaller fragment size than FL (~33 kDa), are hindered less with interacting protein partners.

Fluorescence Resonance Energy Transfer (FRET) and Bioluminescence Resonance Energy Transfer (BRET)

FRET/BRET involves the nonradioactive transfer of energy between the donor and acceptor molecules that are in close proximity via the FORSTER mechanism, leading to a change in FRET/BRET ratios (6). The energy transfer primarily depends on an overlap between the emission and excitation spectra of donor and acceptor molecules, respectively; as well as the close distance between the donor and acceptor molecules (>100 Å). BRET/FRET ratios can be measured in cell culture studies using a microplate reader equipped with specific filter sets for detection of donor and acceptor emission peak, and in living animals using a CCD camera. The advantages of BRET include the in-depth knowledge of the interacting proteins in terms of their proximity and real-time measurement and higher signal to noise background relative to FRET since no external light excitation is required. BRET imaging has been extended to study rapamycin-mediated FRB/FKBP 12 interactions in living subjects, by fusing full length RL (electron donor) to FRB fragment and mutant GFP (electron acceptor) to the FKBP12 fragment (6).

Applications of Methods Used for Studying Protein–Protein Interactions:

Measurement of the rate of interaction between two proteins by intracistronic complementation of β-galactosidase, protein-fragment-assisted complementation of split proteins as well as FRET and BRET. Most recently, the protein-fragment-assisted complementation system has also been extended for imaging the efficacy of heat shock protein 90 inhibitors (7). Efforts are currently underway to develop novel sensors to study intramolecular folding and protein phosphorylation sensors pertaining to studying signal transduction and for preclinical drug development and target validation in living subjects.

Conclusion

The overall application of different systems to study/image protein–protein interactions in living small-animal models of cancer and other cell pathology depends on adapting them so that signal(s) can be noninvasively detected from outside the living subjects upon the interaction of two proteins of interest.

Proteinuria

Abnormally high amount of protein in the urine. Most proteins are too large to pass through the glomeruli into the urine. The glomeruli are negatively charged, so they repel the negatively charged proteins. Thus, a size and charge barrier keeps protein molecules from entering the urine. But when the glomeruli are damaged, proteins of various sizes pass through them and are excreted in the urine.

▶Glomerulonephritis

P

Proton MR Spectroscopy

An MR-based technique which allows to quantify the concentrations of important brain metabolites. Water suppressed, proton MR spectra of normal human brain at long echo times reveal four major resonances: one at 3.2 ppm from Choline (Cho) and Phosphorylcholine (PCho), one at 3.0 ppm from creatine (Cr) and phosphocreatine (PCr), one at 2.0 ppm from *N*-acetyl aspartate (NAA), and one at 1.3 ppm from lactate (Lac). NAA is a marker of neuronal integrity, while Cho and Lac are considered as chemical correlates of inflammatory/demyelinating changes. ^{1}H-MRS studies with shorter echo times can detect additional metabolites, such as lipids (which can be associated to increased membrane turn over) and myoinositol (mI), which is considered a marker of glial activity.

▶Aging Brain

Proton Spin Density

This term relates to the concentration of nuclei in tissue processing at the Larmor frequency. It is one of the main factors influencing the strength of the magnetic resonance imaging signal.
▶Contrast Media, MRI, Oral Agents

Protruded Disk

A protruded disk is a herniated disk in which the greatest distance in any plane between the edges of the disk material beyond the disk space is less than the distance between the edges of the base in the same plane.
▶Hernia, Disk, Intervertebral

Protruded or Extruded Intervertebral Disk

▶Hernia, Disk, Intervertebral

PS

▶Phosphatidyl Serine

Psammoma Bodies

Psammoma bodies present tiny intratumoral calcifications. They are typically found in serous adenocarcinomas and are detected at histology in 30% of cases and on CT scans in approximately 12%.
▶Carcinoma, Ovarium

Psammomatous Meningiomas

Psammomatous meningiomas are tumors with concentric lamina of calcium salts (psammoma bodies). Although psammoma bodies are often found in meningiomas, when abundant, they characterize the tumor as psammomatous meningioma.
▶Neoplasms, Brain, Extraaxial

Pseudarthrosis

A pathologic condition occurring often after fracture nonunion.
▶Neurofibromatosis, Musculoskeletal Manifestations

Pseudo-TORCH Syndrome

Infants with clinical and imaging features of TORCH syndrome, with normal work-up for congenital infection. There is a positive family history and parental consanguinity in one-third of the patients.
▶Calcifications, Intracranial, Neonatal

Pseudoaneurysm

Dilation of the outer aortic wall caused by dissection with progression to the subadventitial aortic layers.
▶Dissection, Aortic, Thoracic

Pseudoaneurysm, Hepatic Artery

Hepatic artery pseudoaneurysm is rare and is usually of iatrogenic origin. It consists of a perforation of the intima and media, causing a focal dilatation contained only by the adventitia. Extrahepatic pseudoaneurysms usually develop at the vascular anastomosis after liver transplantation or arise as a complication of angioplasty. Because they can rupture intraperitoneally and lead to massive hemorrhage, surgical resection, embolization, or exclusion with stent placement should be considered. Intrahepatic pseudoaneurysms can occur after percutaneous needle biopsy or local infection. A ruptured intrahepatic pseudoaneurysm may result in portal vein or biliary fistulas. Intrahepatic pseudoaneurysms can be treated with endovascular coil embolization.
▶Trauma, Hepatobiliary

Pseudocapsule

The peripheral zone of the malignant tumor causes a compression zone with a reactive zone and this may appear falsely as a well-defined tumor, giving the appearance of a benign lesion. May have potential malignant extension of tumor cells in or around the capsule.

▶Neoplasms, Soft Tissues, Malignant

Pseudocyst, Pancreatic

A pancreatic pseudocyst is a collection of pancreatic juice enclosed by a wall of fibrous or granulation tissue, which arises as a consequence of acute pancreatitis, pancreatic trauma or chronic pancreatitis. The presence of a well-defined wall is what distinguishes a pseudocyst from an acute fluid collection. It is most often sterile, but infection may occur. Formation of a pseudocyst requires 4 or more weeks from the onset of acute pancreatitis.

▶Pancreatitis, Acute

Pseudogout

Pseudogout or calcium pyrophosphate dihydrate crystal deposition disease is a joint disease caused by calcium pyrophosphate dihydrate crystal deposits with intermittent attacks of acute arthritis and degenerative arthropathy. A radiographic feature is a linear calcification in articular cartilage, especially fibrocartilages.

Pubococcygeal Line

The pubococcygeal line (PCL) is the line that joins the inferior border of the symphysis pubis to the last coccygeal joint on midsagittal images.

▶Pelvic Floor Dysfunction, Anorectal Manifestations

Pulmonary Alveolar Proteinosis

Pulmonary alveolar proteinosis is a rare disorder characterized pathologically by alveolar filling with a lipid-rich, proteinaceous material (positive to periodic acid-Schiff stain), while the lung interstitium remains relatively normal. The chest radiograph usually shows bilateral consolidation or ground glass pattern, occasionally with a perihilar predominance suggestive of the "bat wing" appearance of pulmonary edema but without other radiographic signs of left-sided heart failure. Although a single type of opacity can dominate the computed tomographic appearance of pulmonary alveolar proteinosis, more commonly there is a combination of patterns. The so-called "crazy paving" appearance, due to ground-glass opacity with superimposed intralobular and interlobular septal thickening, is suggestive of pulmonary alveolar proteinosis.

Characteristics

Lung Scan

The major field of application for ▶lung scintigraphy is in the diagnosis of ▶pulmonary embolism (PE). Besides PE, lung scans are also used for detecting bronchial airways obstruction, increases in pulmonary perfusion pressure, or right-to-left shunts. In addition, the method can be applied to assess mucociliary clearance or alveolar-capillary membrane permeability (1, 2). However, lung scintigraphy is used more frequently for the evaluation of nonembolic disease than for the diagnosis of PE.

The term "lung scan" refers to two different examinations: ventilation (V) and perfusion (Q) scintigraphy. The perfusion scan is done by applying ^{99m} technetium (Tc)-labeled macroaggregated albumin particles intravenously. With a mean diameter of about 40 μm, the particles lead to an occlusion of pulmonary vessels up to the size of the terminal arterioles (1). Between 100,000 and 400,000 of these microspheres are applied per scan, leading to a hemodynamically irrelevant occlusion of about 0.01% of the peripheral pulmonary arterial tree. Within the lungs, the particles are degraded by endogenous proteolysis and thereby cleared from the pulmonary circulation with a half-life of 2–3 h (1).

In contrast to the perfusion scan, two different types of radiopharmaceuticals are used for ventilation scintigraphy: radioactive inert gases and ^{99m}Tc-labeled aerosols. The two most frequently employed radioactive inert gases are ^{133}xenon and the short-lived ^{81m}krypton. Nowadays, however, even these two are of limited clinical relevance when compared to aerosol scintigraphy. An aerosol is defined as a dispersion composed of gas and very small liquid or solid particles. There is widespread use of an aerosol consisting of ambient air and ^{99m}Tc-labeled diethylenetriamine pentaacetic acid (DTPA). The DTPA particles have a mean aerodynamic diameter of about 450 μm and yield a deposition rate within the lungs of roughly 2%. Accordingly, only 2% of the applied activity can be used for imaging (1, 2). A substantially higher deposition rate can be achieved by using the recently developed ultrafine aerosol Technegas. Due to the low aerodynamic diameter of only 10 nm, the pulmonary deposition rate of this carbon-based ventilation agent reaches values of up to 20%, thus being about 10 times more efficient than conventional aerosols (1–3). Depending on the type of radiopharmaceuticals used and the applied activities, the radiation exposure induced by V/Q lung scans ranges between 1 and 3 mSv (1, 2).

Other new developments in the field of radiopharmacy aim at establishing an alternative to conventional lung scintigraphy. Labeled antibodies, antibody fragments, or specific peptides have been designed for the direct detection of thrombotic clots. The target structures of these substances are either parts of the fibrin polymer or fragments of platelets (2). However, at present, none of these radiopharmaceutical compounds is ready for market launch.

Current acquisition protocols employ two techniques: planar imaging and single photon emission computed tomography (▶SPECT). With regard to planar scans, it is recommended to acquire eight views of both ventilation and perfusion (anterior view, posterior view, two lateral views, four oblique views). However, SPECT acquisitions have proved to be superior to planar imaging (3, 4). In the course of a SPECT scan, a three-dimensional image is obtained by rotating the detectors of the gamma camera around the patient. For evaluation, slices in any orientation can be reconstructed from this three-dimensional data set. SPECT is a well-established imaging method that is widely used in modern nuclear medicine diagnostics. Particularly in the field of cardiology and neurology, tomographic scans have almost completely replaced planar acquisitions. Therefore, it is quite remarkable that this technique took such a long time before finally reaching lung scintigraphy. The effect of SPECT imaging on the efficiency of diagnosing PE is striking: while planar lung scans yield a sensitivity between 0.76 and 0.81, SPECT leads to a substantial improvement of up to 1.0 (3–5). The same is true for the specificity, which is reported to reach values of between 0.91 and 0.96 when using SPECT, compared to values between 0.74 and 0.85 achieved by planar scintigraphy (3–5). In this context it should be mentioned that SPECT scanning of the ventilation can only be done with aerosols because inert gases are of limited use for this type of acquisition.

Pulmonary Embolism

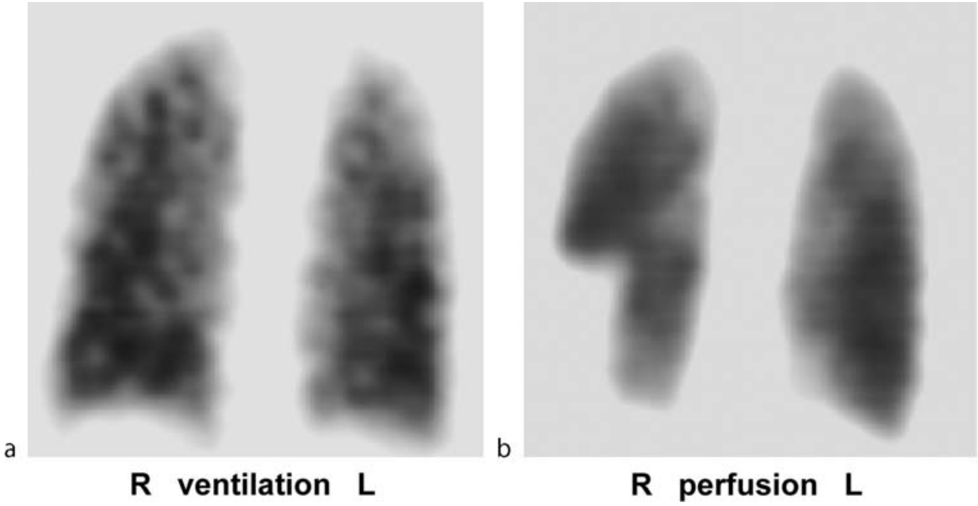
PE is defined as an occlusion of pulmonary vessels by an intravascular solid, liquid, or gaseous substance carried there by the bloodstream from its point of origin. The most common cause of PE is a thrombus (thromboembolism) that has formed in the deep veins of the lower limbs and becomes dislodged from its site of formation. PE is frequent, dangerous, and difficult to diagnose.

Lung scintigraphy was introduced in clinical routine in 1964, thus being one of the longest established noninvasive imaging modalities in the diagnosis of PE (1). Unlike angiography, lung scintigraphy is an indirect imaging procedure that detects the perfusion defect caused by an embolus instead of the embolus itself. Such an indirect approach has advantages as well as disadvantages. On the one hand, the method is exceptionally sensitive because the perfusion defect is a great deal larger than the causing clot. Therefore, even small embolisms on a subsegmental level are easily detected by this method. Additionally, only lung scintigraphy is able to quantify exactly the functional fraction of lung tissue that is unaffected by an embolic incidence. Specificity, on the other hand, is the weak point of the procedure, since pulmonary perfusion defects are not only caused by embolism but by a multitude of other diseases and pathological processes. To amend this deficit, the acquisition protocol of lung scintigraphy was complemented by the ventilation scan in 1968 (1). Today, the term lung scintigraphy always includes both the perfusion and the ventilation scan.

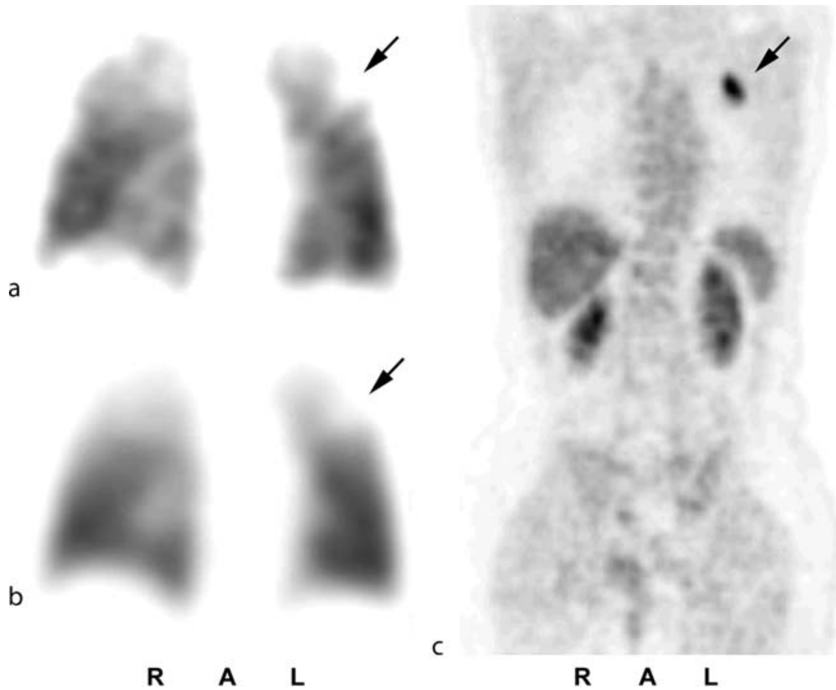
Assessment

The scintigraphic manifestation of PE is the ▶mismatch defect, which is defined as a pulmonic region with regular ventilation but severely reduced or no perfusion. Apart

P



Pulmonary Function, Nuclear Medicine Methods. Figure 1 Coronal slices of a ventilation/perfusion lung scan acquired with a tomographic technique (SPECT): while the ventilation (a) shows no substantial pathological changes, a large perfusion defect can be found in the lower lobe of the right lung (b). Diagnosis: mismatch defect caused by pulmonary embolism. R = right; L = left.



Pulmonary Function, Nuclear Medicine Methods. Figure 2 Coronal slices of a ventilation/perfusion lung scan acquired with a tomographic technique (SPECT): both ventilation (a) and perfusion (b) images show a subsegmental defect in the upper lobe of the left lung (arrows). Diagnosis: match defect induced by nonembolic disease. In fact, the match defect is caused by a malignant tumor, as shown in the positron emission tomography with ^{18}fluorine-labeled glucose (c, arrow). R = right; A = anterior; L = left.

from embolism, mismatch defects are induced by only a few and, more importantly, rare nonembolic diseases. Accordingly, the specificity of lung scintigraphy is substantially improved by the ventilation scan. Figure 1 shows a typical mismatch defect caused by PE. In contrast, most of the nonembolic pulmonary diseases lead to match defects in scintigraphy which are defined as regions affected by a severe reduction or complete loss of perfusion, while ventilation in the same region is likewise distinctly reduced. Figure 2 shows such a ▶match defect caused by a malignant tumor.

In the late 1980s, the PIOPED study was initiated, which aimed at developing a diagnostic system for the analysis of ventilation/perfusion (V/Q) lung scans. Based on the PIOPED data, a complex set of criteria was established which yields the patient's probability of having PE instead of a definitive diagnosis (6). According to the PIOPED system, a V/Q scan is categorized in one of five probability classes: normal, very low probability, low probability, intermediate probability, and high probability. One of the major weak points of this diagnostic system is the ambiguous intermediate class with a probability range for embolism of between 20% and 80%. Even a revision of the criteria in 2000 (PIOPED II) could not amend this deficit, so that the use of the PIOPED system can no longer be recommended. Instead, all mismatch defects of at least half-segment size should be assessed as PE. By doing so, the method reaches an accuracy of 0.94 (3). Not only is the higher accuracy of this system advantageous, but also its simplicity, as well as the fact that it always leads to a definitive diagnosis.

Pulmonary Hemangiopericytoma

A mesenchymal neoplasm originating from pericytes—a cell type that surround capillaries. Its primary localisation in the lung is extremely rare. It occurs at any age but most commonly in the fifth and sixth decades. It is a highly vascular tumour that usually contains dilated vessels and occasionally may cause significant arteriovenous shunting.

Pulmonary Infection

Claus Peter Heussel
Diagnostic and Interventional Radiology, Thoraxklinik Heidelberg, Heidelberg, Germany
heussel@thoraxklinik-heidelberg.de

Synonyms

Abscess; Pneumonia; Pneumonitis

Definitions

Pneumonia: Pneumonia is inflammation of the lung parenchyma (excluding the bronchi) caused by infection or irritants. It may be defined by localization and distribution or by the origin of the underlying infection.

Typical pneumonia

Lobar pneumonia: Lobar pneumonia is an exudative inflammation involving a whole lobe or a large portion (segment) of the lung.

Bronchopneumonia: Bronchopneumonia is characterized by focal areas of suppurative inflammation in a patchy distribution within one or multiple lobes.

Atypical pneumonia

Focal or diffuse affliction of the lungs. The historical term is generally used for organisms that usually do not cause lobar pneumonia (Fig. 3).

Community-acquired pneumonia: Pneumonia contracted outside a hospital.

Hospital-acquired (nosocomial) pneumonia: Pneumonia contracted inside a hospital.

Abscess: A localized suppurative process characterized by a cavity filled with pus (necrosis of tissue).

Immunocompromised host: Patients with reduced functionality of the immune system.

Pathology/Histopathology

Community-Acquired Pneumonia

In the community setting, pneumonia frequently follows a viral infection of the respiratory tract.

Typical Pneumonia

About 30% of community-acquired pneumonias are caused by the gram-positive bacterium *Streptococcus pneumoniae* (also known as Pneumococci).

Lobar Pneumonia

Four stages of lobar pneumonia are classically described:

1. Congestion: This stage is characterized histologically by vascular engorgement, intra-alveolar fluid, small numbers of neutrophils, and often numerous bacteria.
2. Red hepatization: Vascular congestion persists, with extravasation of red cells into alveolar spaces, along with increased numbers of neutrophils and fibrin. The filling of air spaces by the exudate leads to the appearance of solidification or consolidation of the alveolar parenchyma. This pathological appearance is similar to that of the liver, hence the term "hepatization."
3. Gray hepatization: Red cells disintegrate, whereas neutrophils and fibrin persist. The alveoli still appear consolidated, but the color is paler and the cut surface drier.
4. Resolution: The exudate is digested by enzymatic activity and cleared by macrophages or by cough.

Abscess

Although the majority of bacterial pneumonias resolve with healing, in some cases complications such as abscess formation occur. A lung abscess may also occur as an isolated process at single or multiple locations (hematogeneous spread). An abscess is a localized suppurative process characterized by a cavity filled with pus (necrosis of tissue). If communication with an airway exists or occurs, the exudate may partially drain, and the remaining cavity will exhibit an air–fluid level.

Bronchopneumonia

In bronchopneumonia, the inflammatory exudate typically involves small airways and the surrounding alveolar space. Histologically, the same stages of evolution as in lobar pneumonia (congestion, red and gray hepatization, resolution)

P

are believed to occur. However, they involve relatively small areas in a metachronous fashion. The temporal differences of the disease stage among the individual foci lead to a heterogeneous appearance and make perceiving the typical evolution more difficult than in lobar pneumonia.

Atypical Pneumonia

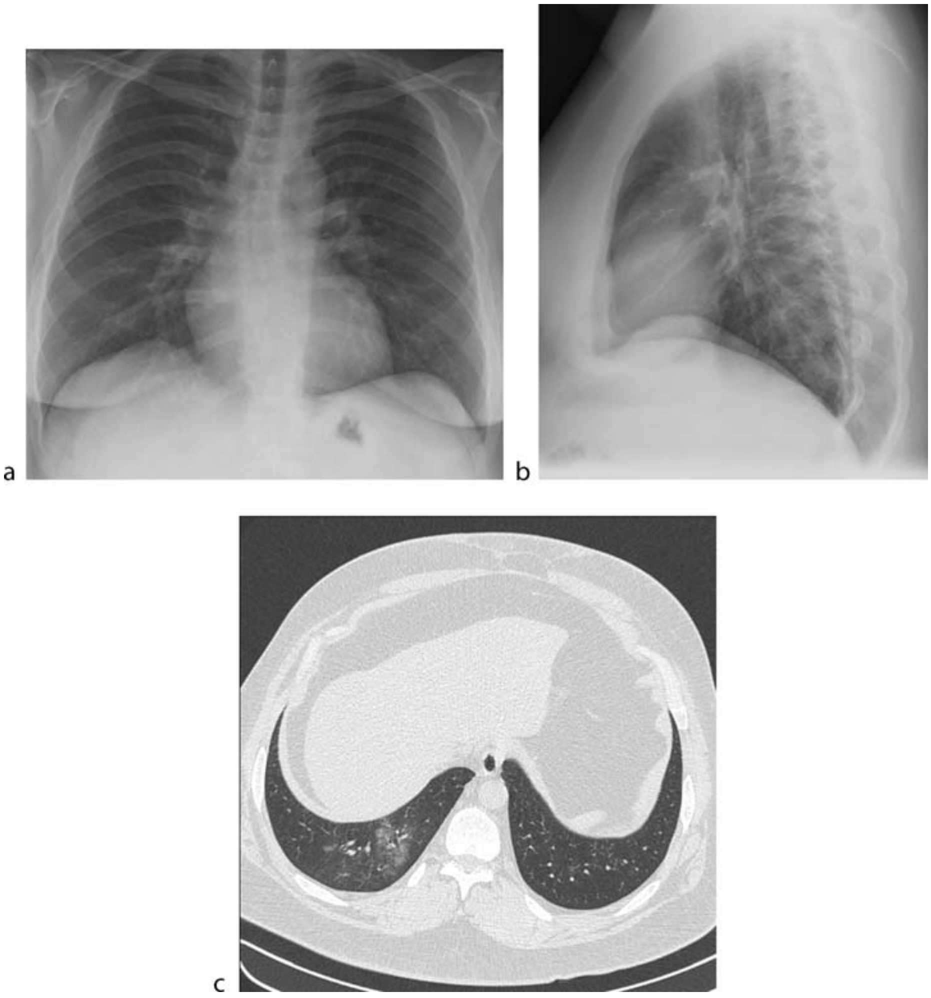
Most atypical pneumonias are community-acquired and generally caused by intracellular organisms including *Mycoplasma pneumoniae, Chlamydia pneumoniae, Legionella pneumophilia* (up to 30% each), viruses [influenza, respiratory syncytial virus (RSV), herpes group, and adenovirus (up to 10%)]. In immunodeficient patients (including those with AIDS), other organisms such as *Pneumocystis jiroveci* (PcP, formerly *P. carinii*) might cause atypical pneumonia (Figs 1 and 2).

Hospital-Acquired Pneumonia

The gram-positive *Staphylococcus aureus* is one of the main causes of nosocomial pneumonia. It is uncommon in healthy adults but can develop about 5 days after viral infection, usually in individuals with a weakened immune system. Especially in hospitalized or nursing home patients, or in patients suffering from cystic fibrosis or other chronic lung diseases, *Streptococcus pyogenes* and *Pseudomonas aeruginosa* are common infectious agents.

Ventilator-Associated Pneumonia

Hospitalized patients, especially those who are ventilated mechanically are particularly vulnerable to gram-negative bacteria and staphylococci.



Pulmonary Infection. Figure 1 40 year-old male who underwent liver transplantation due to Wilson disease 12 years ago. He presented with moderate fever and abdominal pain. Chest x-ray was normal, CT done the day after demonstrated ground-glass opacification in the right lower lobe. The patient defervescented with empirical treatment of atypical pneumonia.

Pulmonary Infection. Figure 2 55 year-old female suffering from acute lymphogeneous B-cell leukemia and fever during neutropenia due to chemotherapy. Chest x-ray demonstrated new development of mild basal infiltrates, especially on the right, while CT demonstrated diffuse ground-glass opacification in both lungs. The patient defervescented with empirical treatment of atypical pneumonia.

Opportunistic Pneumonia

Fungi (e.g., *P. jiroveci*, *Aspergillus* species, *Candida* species), mycobacterial species, viruses (cytomegalovirus, herpes simplex virus, RSV) are the opportunistic organisms that are either ubiquitous or resident. AIDS patients and other immunocompromised hosts (such as individuals undergoing chemotherapy or long-term users of corticosteroids) are at major risk for opportunistic pneumonia.

Aspiration Pneumonia

Whether aspiration pneumonia represents a primary bacterial infection or a chemical inflammatory process remains a subject of significant controversy. Depending on the acidity of the aspirate, a chemical pneumonitis can develop, and gram-negative bacteria may particularly add to the inflammation. The middle lobe and right > left lower lobe are the most common locations due to the anatomy of the bronchial tree and to gravity.

Infarction Pneumonia

Infarction pneumonia consists of segmental infiltrates in cases of pulmonary embolism. During acute obliteration of the pulmonary artery, the bronchial arteries (vasa privata) cannot provide sufficient oxygen to the distal lung parenchyma. This leads to hemorrhagic necrosis of the tissue and is especially relevant in elderly patients and in those with underlying left cardiac failure.

Retention Pneumonia

Obstructive pneumonia occurs in the lung distal to an obstructed bronchus. A blockage by a tumor or foreign body results in poor aeration and retention of secretions, predisposing to superinfection in the obstructed portion of the lung.

Pulmonary Sequestration

Pulmonary sequestration is an embryonic mass of lung tissue that has no identifiable bronchial communication and that receives its blood supply from anomalous systemic arteries.

Clinical Presentation

Pneumonia is the most frequent fatal infectious disease. The clinical presentation of community- and hospital-acquired pneumonia is based on the following main clinical courses.

Typical Pneumonia

The symptoms of bacterial pneumonia develop abruptly and may include chest pain, fever, shaking, chills, shortness of breath, tachypnea, tachycardia, and general deterioration. Coughing up of sputum containing pus or blood is an indication of serious infection. Painful respiration is a sign of concomitant pleuritis and pleural effusion. Severe abdominal pain may accompany pneumonia occurring in the lower lobes of the lung. It is important to note that older people may have fewer or different symptoms than younger people.

Atypical Pneumonia

Symptoms progress gradually, often beginning with general flu-like symptoms, such as fatigue, fever, weakness, headache, nasal discharge, sore throat, earache, and stomach and intestinal distress. Symptoms of Legionnaire's disease usually evolve more rapidly and include high fever, a dry cough, and shortness of breath, often accompanied by headache, muscle pains, fatigue, gastrointestinal problems, and mental confusion.

Friedlander Pneumonia

This type of pneumonia is caused by gram-negative *Klebsiella*, especially in alcoholic and diabetes patients. It causes varying infiltrates, typically lobar pneumonia, and occasional basal cavitations (abscesses). Patients frequently have blood in the sputum, which indicates necrosis. About one-third of these patients lose weight.

Imaging

Chest X-ray

Chest X-ray in two planes is the basis of imaging in pneumonia. Because of the projection technique, superimposition leads to limited sensitivity in detecting pneumonia. Even when done upright and in two planes, 5 out of 19 lung segments cannot be seen without substantial superimposition. Sensitivity is therefore limited for detecting mild or atypical pneumonia. This holds true even more if the chest X-ray is taken in the supine position. Thus, its sensitivity for early detection of pneumonia is low.

Computed Tomography

Thin-section computed tomography (CT) for early detection or exclusion of pneumonia is indicated in patients at high risk (such as immunocompromised hosts) (Figs 1 and 2). CT is also the method of choice in the characterization of lobar, bronchial, and atypical pneumonias.

Sonography

For bedside detection and quantification of effusion, ultrasound is a valuable tool.

Diagnosis

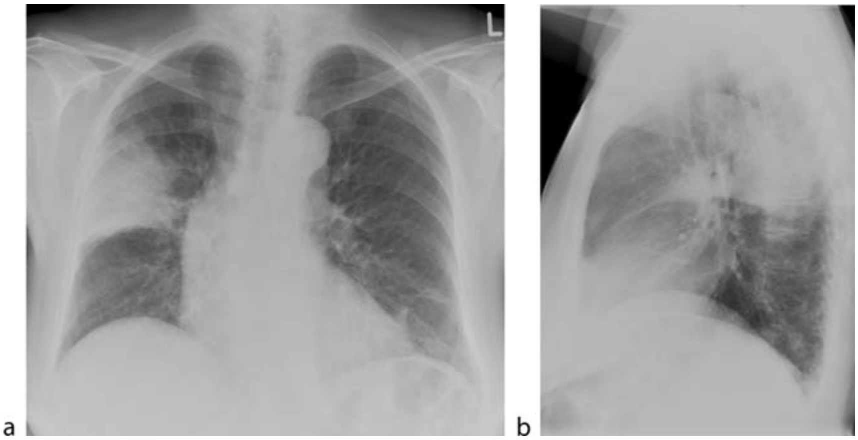
Besides the detection of pneumonia, imaging is a fast and valuable tool for characterizing the underlying disease. Because of its higher sensitivity, CT also has the ability to better distinguish patterns as compared with chest X-ray. By the differentiation into the following major groups of pneumonia, the underlying disease and a list of probable microorganisms can be suggested for the differential diagnosis. This diagnosis is faster compared to invasive procedures followed by histological or microbiological analysis; however, the results represent only hints of the disease.

Typical Pneumonia

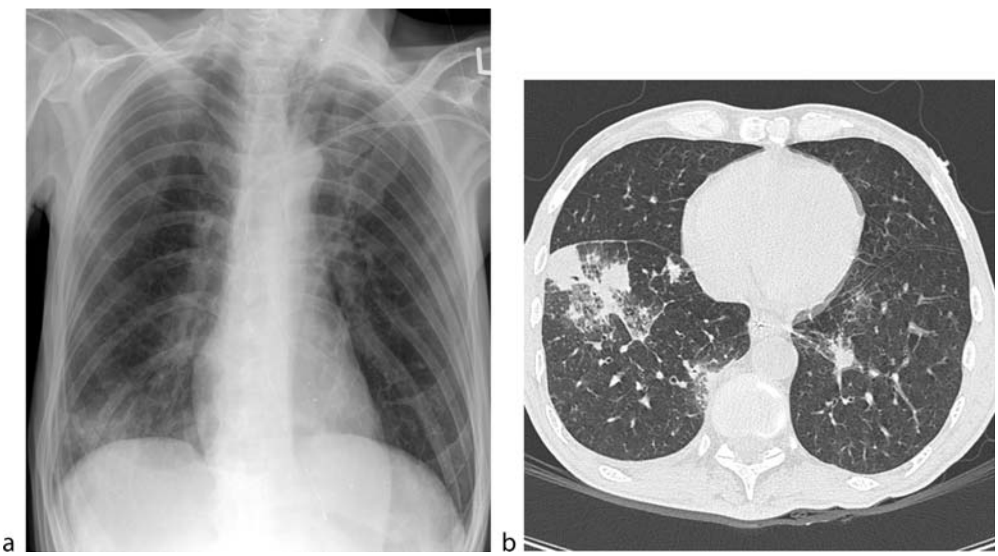
Lobar Pneumonia

A typical finding is the respecting of anatomical borders, such as the fissure, by the affected area of consolidated lung parenchyma. Because the bronchi remain aerated, they give the *positive bronchogram sign* at chest X-ray or CT within the consolidation. The required volume of the affected lung compartment is equal to or a little increased compared to the nonaffected condition. This is in contrast to atelectasis, in which the volume is decreased (Fig. 3).

Gram-negative pneumonia is a very rapidly progressing disease. Infiltrates appear or escalate within hours. Lung abscesses appear, especially in the basal regions with central necrosis, fluid levels, and pseudocapsula.



Pulmonary Infection. Figure 3 71 years-old female with rheumatoid arthritis under long-term corticosteroid therapy. Dyspnoea, fever and respiratory depending pain led to hospitalisation. Chest x-ray demonstrates consolidation and positive bronchogram in the apical segment of the right lower lobe (S6) respecting lobar and segmental borders representing the typical findings of a lobar pneumonia. Resolved with empirical antibiosis.



Pulmonary Infection. Figure 4 63 years-old male after chemotherapy due to hypopharynx carcinoma suffering from fever. Chest x-ray in supine position demonstrates a focal infiltrate in the right lower field with positive silhouette sign suggesting to be located in the right lower lobe. Thin-section CT done 2 days later revealed diffuse focal infiltrates in both lower lobes representing bronchopneumonia. Resolved with empirical antibiosis.

Bronchopneumonia

Small foci of consolidated lung parenchyma with ill-defined margins in a patchy distribution are seen possibly all over the lung. The *positive bronchogram sign* may be visible, especially on CT. Severe cases of bronchopneumonia may show confluent areas of involvement that resemble the pattern of lobar pneumonia (Fig. 4).

Atypical Pneumonia

A diffuse manifestation of atypical pneumonia gives a summation effect and can easily be seen at chest X-ray as diffuse cloudiness (Fig. 1). If atypical pneumonia is small and localized, it might be hard to depict on chest X-ray (Fig. 2). At CT, ground-glass opacification is the leading pattern, demonstrating the remaining ventilation even in the affected alveoli associated with moderate clinical symptoms (Figs 1 and 2).

Immunocompromised Hosts

In patients with reduced function of the immune system, the appearance and the typical underlying microorganism may differ substantially depending on the immune status. Immunocompromised hosts are especially at risk for development of fungal and viral pneumonia. Viral pneumonia (such as *Herpesviridae* and RSV) is associated with ground-glass opacification in a mosaic pattern (affected and nonaffected secondary lobules lying side by side) and also small (<1 cm) nodules of low density (air-space nodules). In contrast, fungal pneumonia (such as *Aspergillus* and *Mucoraceae*) is characterized by larger ill-defined nodules (1–3 cm) or consolidation (>3 cm, negative bronchogram sign) surrounded by the halo sign (area of ground-glass opacification).

Interventional Radiological Treatment

Especially in abscesses, covered pleural effusion, and empyema, image-guided drainage is helpful. Even small and central lesions can be safely treated. In cases of hemorrhage, embolization can treat vascular erosion. Besides treatment, interventional biopsy techniques should be used as an alternative to bronchoalveolar lavage for identifying the underlying microorganisms.

Pulmonary Opacity, Cystic Pattern

Cornelia Schaefer-Prokop
AMC, Amsterdam, Netherlands
c.m.schaefer@amc.uva.nl

Definition

Pulmonary opacity is a non-specific term describing an area of increased pulmonary attenuation caused by an intra-parenchymal process. There are various types of pulmonary opacities, easily categorized as extensive, nodular, reticular or cystic. Cystic patterns describe focal areas of decreased attenuation.

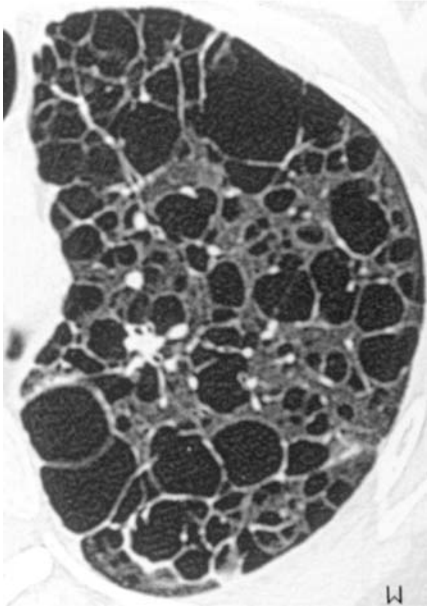
Characteristics

Lung Cysts

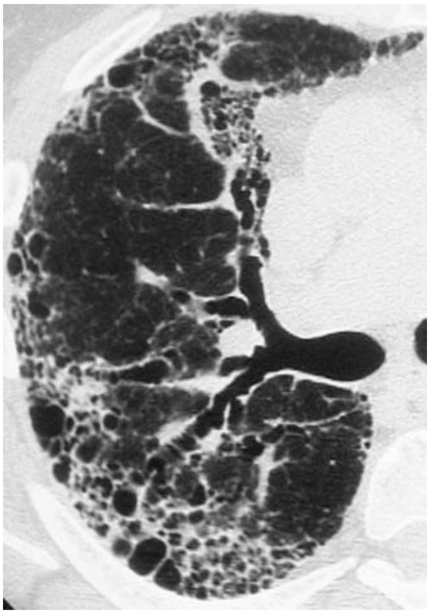
Lung cysts are well-defined rounded lesions, delineated by a well-defined wall of less than 3 mm thickness. Most cysts contain air but may rarely also contain fluid or solid material. The term *cystic air-space*—frequently used as synonym–on the other hand refers to a cyst exclusively containing air. Cysts are seen in multiple diffuse interstitial lung disease such as Langerhans' cell histiocytosis (LCH), lymphangiomyomatosis (LAM) (Fig. 1) or lymphocytic interstitial pneumonia (LIP). Features such as the profusion and distribution of air spaces and the wall characteristics determine the differential diagnosis and are superiorly appreciated on CT. On a chest radiograph the walls might not be visible at all or multiple walls—superimposed over each other—will result in a reticular pattern. Occasionally the differentiation between a bronchiectasis and cystic air spaces of other origin such as pneumatoceles, bullae and ►blebs may be difficult.

Honeycombing

Honeycombing refers to a rather rough (meaning thick-walled) reticular pattern that is produced by clustered cystic air spaces surrounded by clearly definable walls (Fig. 2). The cysts may vary in size from millimetres to centimetres. They occur in several layers and typically share their walls. They are predominantly located in the sub-pleural and basal areas and represent the hallmark of interstitial fibrosis, especially in usual interstitial pneumonitis on CT.



Pulmonary Opacity, Cystic Pattern. Figure 1 Cystic destruction of the lung parenchyma in a young female with lymphangiomyomatosis.



Pulmonary Opacity, Cystic Pattern. Figure 2 Honeycombing and irregular thickening of the peribronchovascular interstitium are the hallmarks of usual interstitial pneumonia (UIP).

Ring Shadows and Cavitations

Cavitating lesions, which mostly have thick walls and irregular inner wall contours produce a ring shadow on CXR. They have to be differentiated from thin-walled cysts or pneumatoceles which both have much thinner and more regular walls. The differential diagnoses of pulmonary cavities include infections, inflammatory, granulomatous, neoplastic and post-traumatic aetiologies. Differentiation from cystic Bronchiectasis with a ►signet-ring sign, pre-existing emphysema and a ►pneumatocele may be difficult.

Pulmonary Opacity, Extensive Pattern

Cornelia Schaefer-Prokop
AMC, Amsterdam, Netherlands
c.m.schaefer@amc.uva.nl

Synonym

Radio-opacity (the term density should be avoided)

Definition

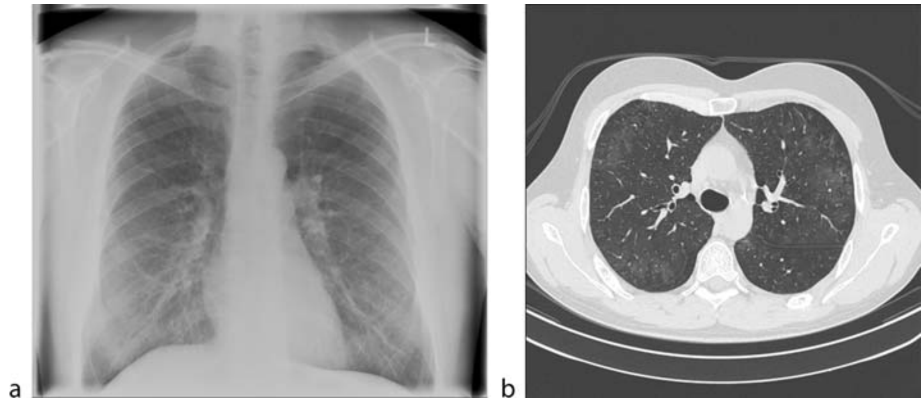
Pulmonary opacity is a nonspecific term describing an area of increased pulmonary attenuation caused by an intraparenchymal process. There are various types of pulmonary opacities, easily categorized as extensive, nodular, reticular, or cystic.

Characteristics

Air Space Filling

Synonyms: Consolidation, infiltration (cave: the term infiltration is differently defined by pathologists and radiologists).

Pathologically, air space filling is caused by replacement of air within the distal airways and alveoli by fluid or cellular material. In practice the term is used for filling of the air spaces with tumor or inflammatory cells, blood or



Pulmonary Opacity, Extensive Pattern. Figure 1 (a) Chest radiograph without any opacity; (b) CT of the same patients shows the typical pattern of ground glass opacity in upper lung zones.

exudates. When filled with transudate, it is called edema, although by definition it also represents air space filling.

Imaging: Dependant on the extent it appears as an ill-defined nodular or patchy opacity that may coalescence and then potentially show an air-bronchogram. When abutting a fissure, the opacity is sharply marginated on a chest radiograph.

Ill-defined nodular shadows between 0.5 and 1 cm are called "acinar shadows," cave: they do not represent the pathologic unit of a single acinus.

Ground Glass Opacity

Pathologically it represents filling in of air spaces and/or thickening of the alveolar walls and may be caused by reversible (e.g., edema, bleeding, acute alveolitis) and irreversible diseases (e.g., interstitial fibrosis). This explains why the term ground glass opacity is merely descriptive and nonspecific.

Imaging: In CT it refers to an increase in attenuation of the lung parenchyma without obscuration of the underlying bronchovascular structures (Fig. 1a). In chest radiography, ground glass opacity similarly describes a homogeneous hazy opacity, which makes the underlying interstitial and vascular structures indistinct but preserves their visibility. Often ground glass opacity visible at CT is not observed on a chest radiograph.

Ground glass opacity is a major component of the crazy-paving pattern.

Pulmonary Opacity, Nodular Pattern

Cornelia Schaefer-Prokop
AMC, Amsterdam, Netherlands
c.m.schaefer@amc.uva.nl

Definition

Pulmonary opacity is a non-specific term describing an area of increased pulmonary attenuation caused by an intra-parenchymal process. There are various types of pulmonary opacities, easily categorized as extensive, nodular, reticular or cystic.

A *nodular pattern* refers to round opacities 1–10 mm in size. They are a feature of both, interstitial and air-space disease. Important features are the location of nodules, their uniformity, density and edge characteristics. Nodules within the interstitium are usually well-defined and in a periseptal, centrilobular, peribronchovascular or perilymphatic location, while nodules in air-space disease—so-called acinar nodules—are unsharp and centrilobular or randomly distributed.

A random distribution of well-defined, small (*miliary*) nodules is seen in hematogenous spread of disease, while a widespread distribution of ill-defined acinar nodules with a tendency for coalescence and associated with airways and air trapping is seen in exogenous allergic alveolitis.

See also 'Nodules, Pulmonary, Solitary' and 'Nodules, Pulmonary, Multiple'.

Pulmonary Opacity, Reticular Pattern

Cornelia Schaefer-Prokop
AMC, Amsterdam, Netherlands
c.m.schaefer@amc.uva.nl

Definition

Pulmonary opacity is a nonspecific term describing an area of increased pulmonary attenuation caused by an intraparenchymal process. There are various types of pulmonary opacities, easily categorized as extensive, nodular, reticular, or cystic.

Characteristics

Line Shadows and Band Shadows

Linear opacities >5 mm in diameter are described as *band shadow*, while linear opacities <5 mm are described as *linear densities.*

Septal Lines

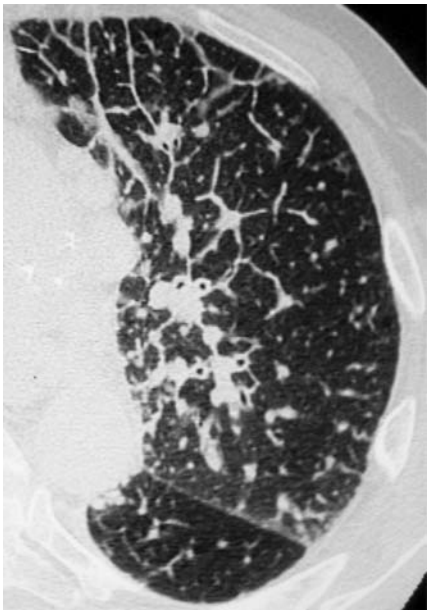
Interlobular septa belong to the interstitial framework of the lung and contain veins and lymph vessels. Normal interlobular septa are not seen on a chest radiograph. When thickened they may be seen as "*Kerley lines*" on a chest radiograph. Dependent on their anatomic location there are Kerley A, B, or C lines, among which the Kerley B lines are most important and frequently seen. They represent thickened interlobular septa running perpendicular to the peripheral pleura best seen at the lung base especially in lymphangitic carcinomatosis (Fig. 1), interstitial fibrosis and interstitial edema.

CT offers further classification of the underlying etiology by analyzing the type of thickening (smooth, irregular, beaded), distribution (peripheral, central, homogeneous, localized), and associated findings. On CT, thickening of the interlobular septa is differentiated from thickening of the intralobular interstitial septa. Thickened interlobular septa produce a *coarse reticular pattern* and are mostly associated with interstitial fibrosis but also seen in interstitial edema or lymphangitic carcinomatosis (Fig. 1). It is frequently associated with thickening of the interstitium along the central perihilar bronchovascular bundle, a finding described as *interface sign* in fibrosis (Fig. 2). Thickened intralobular septa produce a *fine reticular pattern* and are typically associated with interstitial fibrosis.

Bronchial Wall Thickening

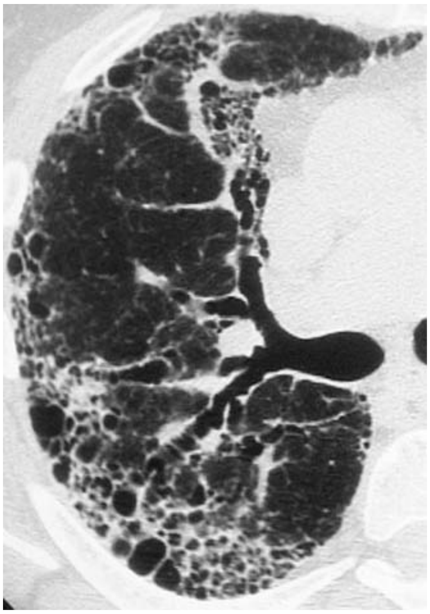
Synonym: Peribronchial thickening.

Normal bronchial walls are only seen in the perihilar region and when radiographed en face. In edema, lymphangitic carcinomatosis, interstitial fibrosis or inflammatory conditions the wall of the bronchi, and the peribronchial interstitium may be (irregularly) thickened. The ring shadow of a bronchus radiographed en face is described as *bronchial cuffing* (Fig. 1), the linear shadows



Pulmonary Opacity, Reticular Pattern. Figure 1 Patient with thickened interlobular septa and thickened central peribronchial interstitium (bronchial cuffing) due to lymphangitis carcinomatosa.

P



Pustulotic Arthroosteitis. Figure 2 Honeycombing and irregular thickening of the peribronchovascular interstitium are the hallmarks of usual interstitial pneumonia (UIP).

when radiographed longitudinally are described as *tram lines*. Again extent and severity of bronchial wall thickening are better appreciated on CT than on chest radiography. The same is true for associated bronchial dilatation.

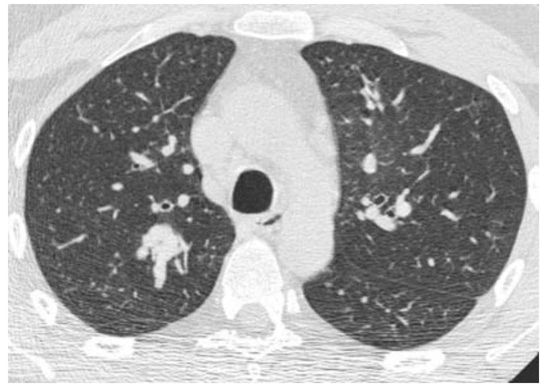
Reticulo-nodular Opacities

On a chest radiograph an only rough differentiation is made between a nodular and a reticulo-nodular shadow, because it always reflects a summation of multiple superimposed lesions, and does not represent the anatomic opacity seen on CT. The classification of the pattern meaningful for the type of diffuse interstitial lung disease is the domain of CT.

Mucoid Impaction

Synonym: Mucocele, bronchocele.

This refers to filling-in of bronchial structures with mucoid secretion leading to y-shaped or band-like opacities pointing toward the hilum and producing a form that is also described as *finger-in-glove-sign* (Fig. 3). It is described to be typically for allergic bronchopulmonary aspergillosis (ABPA) and cystic fibrosis (CF) but may be generally seen peripheral to any obstructing endobronchial lesion (metastases, carcinoid, endobronchial carcinoma) provided that collateral air drift



Pulmonary Opacity, Reticular Pattern. Figure 3 A finger in glove sign due to mucoid impaction of focal dilated bronchi in a patient with ABPA.

maintains aeration of the peripheral segment. The *tree-in-bud-sign* describes dilated bronchioli either with wall-thickening and/or filled with mucus, pus, or fluid resembling the appearance of a branching or budding tree. It indicates "small airways disease" but is rather nonspecific for the underlying etiology, for example, endobronchial spread of infection, chronic airway infection, or inflammation (see Airway disease).

Nephritis, Bacterial, Acute; Lobar nephritis; Lobar nephronia (1)

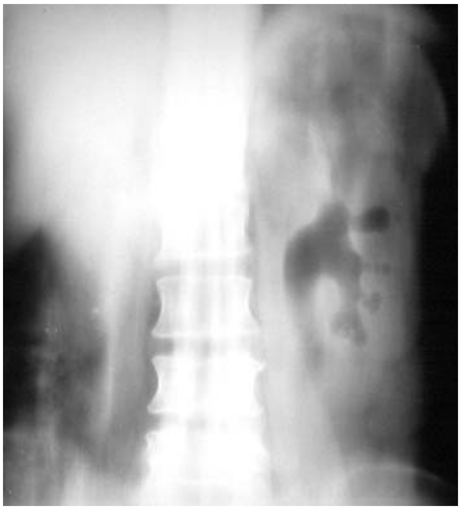
Definition

Two definitions exist: a clinical definition, based on clinical and laboratory findings and a pathological one, related to macro- and microscopic anomalies (1).

- *Clinical definition*: clinical syndrome consisting of costovertebral or lumbar pain, fever, as well as laboratory findings suggestive of bacterial renal infection, including leukocytosis, pyuria, bacteriuria, and positive urine culture, sometimes with bacteremia and hematuria.
- *Pathological definition*: bacterial renal infection with acute inflammation that involves both the renal pelvis (collector system) and the parenchyma, often multifocal.

In addition, two types of pyelonephritis are distinguished: not complicated and complicated.

- Not complicated or uncomplicated: It appears in immunocompetent patients without anatomical or functional alterations of the urinary tract.
- Complicated: Infection that may occur in patients who present one or more of the following factors: (1) male sex, especially with prostatic hypertrophy; (2) advanced age (more than 65 years); (3) carrier of a indwelling catheter or intermittent catheterization; (4) postmictional urine residue larger than 100 mL; (5) obstructive uropathy; (6) vesicoureteral reflux or other urologic anomalies; (7) renal transplantation; (8) diabetes; (9) chronic renal insufficiency; (10) neutropenia; (11) pregnant women; (12) recent hospitalization, in the previous month; (13) recent ingestion of antibiotics, in the previous month; (14) history of recurrent acute pyelonephritis (AP); (15) septic shock. These patients have a major risk of infection, failure of treatment, and possibility of resistance to the antibiotics (2).



Pyelonephritis, Acute. Figure 1 Emphysematous pyelonephritis. Abdominal plain film shows the presence of gas in the left pyelocaliceal and ureteral system, a characteristic, although unspecific, finding of emphysematous pyelonephritis.

►*Emphysematous pyelonephritis*: severe infection of the renal tissue with gas formation, produced generally by *Escherichia coli* or other gram-negative organisms. It occurs in diabetic patients (Fig. 1).

Pathology/Histopathology

The most frequent etiologic agent is *E. coli*.

The infection can originate *via* two/three routes (1):

- *Ascending route*: the most frequent. By vesicoureteral and intrarenal reflux, the bacteria reach the pyelocaliceal system, papillary ducts, and collector tubules, where an inflammatory response is generated. Its intensity depends on several factors such as the grade of reflux, the bacterium virulence, and the host defenses. Once the bacterium reaches the tubules, the leukocytes migrate from the interstice into the tubules and the liberated enzymes destroy the tubular cells, so the bacterium invades the interstice within 48–72 h. A real tubulointerstitial nephritis appears, where intratubular neutrophils and interstitial infiltrates of mononuclear cells and neutrophils are found (3). The tubules filled with leukocytes and other materials can produce a focal intrarenal obstruction. Macroscopically, the kidney undergoes an increase in size and it is possible to visualize white-yellow streaks radiating from the papillae to the kidney surface, following the medullary beams. An intense vasoconstriction of the arteries and arterioles exists also in the affected regions, which show a patchy, sometimes lobar, distribution. The inflammation can spread to the perinephric fat, Gerota's fascia, and to the extrarenal space (this is infrequently seen) (1).

- Hematogenous route: It occurs especially in patients addicted to drugs taken *via* a parenteral route, immunocompromised patients, or those who present with a source of extrarenal infection. The lesions begin in the cortex and involve the medulla by 24–48 h. Initially, the lesions are small, peripheral, and multiple (1).
- Lymphatic route: Theoretically, the anatomical disposition of the lymphatic vessels allows the bacteria to travel from the low urinary tract towards the kidney and from the colon towards the right kidney.

In short, the factors that influence imaging findings are (3):

- Focal decrease in perfusion, consequence of the edema that compresses and/or the aggregation of intravascular granulocytic cells.
- Tubular obstruction due to accumulation of granulocytes and/or edema.
- Alteration of the tubular cell membrane transport mechanism, with consequent cellular death.

Clinical Presentation

The signs and symptoms suggestive of upper urinary tract infection are fever, flank pain, nausea, vomiting, and costovertebral angle pain. Sometimes they are accompanied by symptoms that suggest cystitis (low urinary tract infection): dysuria, high urinary frequency, urinary emergency, and suprapubic pain (2).

In 20% of older women, fever is present, with gastrointestinal and respiratory symptoms being the predominant findings (2).

Imaging

The indications for imaging studies are: (1) patients with clinical diagnosis of AP that present with a condition that prevents the improvement of the disease and (2) patients with suspicion of obstruction, lithiasis, or a coexistent abscess (1).

Intravenous Urography

Approximately 75% of intravenous urography (IVU) studies are normal. In the remaining 25%, AP shows global enlargement of the kidney (the most frequent finding), decreased contrast material density, effacement of the collecting system, and delayed caliceal appearance time. Rarely, it shows mass, edema of the pelvic mucosa, focal areas of increased or decreased nephrographic opacity, or mild ectasia of the pyelocaliceal system and ureter (1).

Echography/Ultrasonography

Ultrasonography (US) is a very useful tool for pointing out dilatation of the urinary excretory system. It is not suitable for demonstrating signs of tubulointerstitial inflammation, being less sensitive than renal cortical scintigraphy with technetium-99m dimercaptosuccinate (Tc-99m DMSA) (1). Thus, it allow to rule out renal stones, dilatation, or abscess (4).

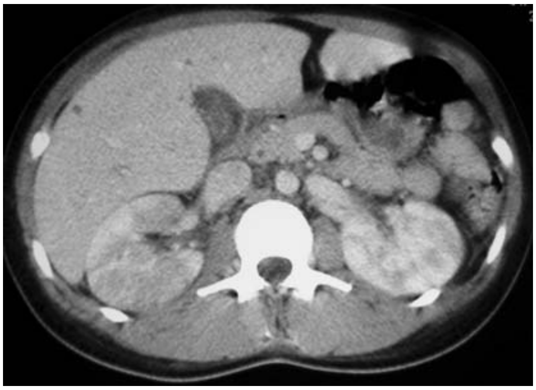
The majority of explorations show normal kidneys. Typical findings of uncomplicated AP, when present, are focal or widespread increase of renal size, alteration in parenchymatous echogenicity, and loss of corticomedullary boundary. Sometimes, a hypoechoic mass is seen, badly defined, with diffuse low-amplitude echoes (1).

Complicated AP can show hypo- or anechoic focal masses, with well-delimited borders, corresponding to abscesses (1).

Power/Doppler US shows triangular areas of decrease or absence of cortical or parenchymatous perfusion (3).

Computed Tomography

The characteristic findings of AP are: (1) renal tumefaction, which produces an increase in the size of the involved kidney; (2) focal hypoattenuation and (3) mass effect. Without intravenously administered (i.v.) contrast material, the renal parenchyma can present grooved, rounded, or triangular areas (with cortical base) with variable attenuation (edema or necrosis, hemorrhage). Dynamic studies show anatomical and functional renal anomalies. After administration of i.v. contrast material, these areas (from the papilla to the renal surface), with well-delimited outline, present a minor intensification compared to the normal parenchyma in the corticomedullar and nephrographic phases; these findings are secondary to focal ischemia, tubular obstruction, and the interstitial inflammation, which causes a minor clearance of contrast medium (Fig. 2). In delayed series, there can be an increase in density, i.e., persistence of the contrast material in these areas or in the periphery, due to the progression of the contrast material through the tubules and the compression of the adjacent tissue (1). The "nephrographic" or "parenchymatous" phase is the one that best defines the entire extension of lesions (3, 4) and complications such as abscesses (4). In focal pyelonephritis a single zone with the appearance of a mass is shown (Fig. 3).



Pyelonephritis, Acute. Figure 2 Acute pyelonephritis. CT after i.v. contrast administration. Nephrographic phase that shows an increase in the size of both kidneys, with well-delimited triangular hypodense areas compared to the normal renal parenchyma, characteristic of bilateral acute pyelonephritis.

Pyelonephritis, Acute. Figure 3 Acute lobar nephronia. CT after i.v. contrast administration. The nephrographic or parenchymatous phase shows a localized inflammatory right renal mass, solid, with small hypodense areas and slight involvement of the perirenal structures. Two weeks later, after antibiotic treatment, the lesion disappeared.

Perinephric involvement is frequent, with thickening of the Gerota's fascia and bridging septa in the perinephric space (1).

If treatment is not administered, or if it fails, microabscesses might appear, which tend to coalesce. These are shown as one or more irregular areas with attenuation values near water, without enhancement after i.v. contrast administration. The mature abscesses present well-defined outlines showing only peripheral or rim enhancement (1).

CT is capable of differentiating between located tubulointerstitial inflammation and abscess, being very sensitive for evaluating parenchymatous and perinephric extension (4).

In emphysematous pyelonephritis, CT shows gas in both the renal parenchyma and collecting system, even it is possible to define its extension to the subcapsular, perinephric, and pararenal spaces and counterside retroperitoneal spaces.

Magnetic Resonance Imaging

The indications of magnetic resonance imaging (MRI) in the detection of AP are the following: (1) patients with fever of unknown origin, without evidence of infection of the urinary tract; (2) chronic bacteriuria, with uncertain diagnosis of urinary infection; (3) children with known vesicoureteral reflux with suspicion of urinary infection and fever in spite of antibiotic prophylaxis and (4) children without demonstrable reflux or urinary anatomical anomaly, with recurrent infections of the urinary tract and fever.

Without i.v. contrast, on "inversion recovery" sequences, the kidneys have high signal intensity (SI), with pyelonephritic lesions appearing relatively hyperintense. A fast inversion recovery sequence, after the i.v. administration of gadopentate dimeglumine, has a high sensitivity in the detection of AP. This sequence diminishes notably the SI of the normal parenchyma (due to shortening of T2), and thus inflammatory lesions appear as focal zones of moderate or high SI, as a consequence of the minor concentration of gadolinium due to defective perfusion (3, 5). On MR images, scar lesions do not show any signal change (5).

Nuclear Medicine

Cortical scintigraphy with Tc-99m DMSA allows to obtain images of the same zone, on anterior, posterior, left posterior oblique, and right posterior oblique views, within 2–4 h of the injection. The zones of AP are depicted as focal or diffuse cortical photopenic areas (4, 5), hypoactive, secondary to focal ischemia and tubular malfunction. This finding is unspecific, being common in renal cysts and abscesses, hydronephrosis, calculi, and chronic scars. Thus, this technique does not allow differentiation between a focus of AP and a renal permanent scar (5), in addition to undervaluing the extension of the AP (4).

In children, it is more sensitive than CT in the detection of focal anomalies (4).

Diagnosis

- Symptoms compatible with the diagnosis.
- Urynalisis: especially "pyuria," which is determined by means of a leukocyte esterase test, which is indicative of AP in the presence of more than 10 leukocytes per mL of urine. In the sediment, more than five

leukocytes per field is considered pyuria. The level of nitrites is also determined. Hematuria may be present.

- Gram stain analysis of urine without centrifuging: It is indicated when the clinical picture is not very demonstrative and when a differential diagnosis is needed, or when the presence of gram-positive flora is suspected. It helps select the initial antibiotic therapy.
- Urine culture: Over 10,000 colony-forming units per mL (CFU/mL) is considered as positive. In men and pregnant women, lower counts are of concern. It must be carried out before the beginning of treatment.
- Blood culture: It is indicated in patients with complicated AP who need hospitalization, in cases of uncertain diagnosis, when the patient is immunosuppressed or a hematogenous source is suspected. Three samples must be taken.

Interventional Radiological Treatment

It is possible to drain renal or perinephric abscesses or collections by puncture guided ultrasound scan or CT.

Chronic atrophic pyelonephritis; Chronic interstitial nephritis; Reflux nephropathy

Definition

Chronic pyelonephritis is a chronic inflammatory disease that involves the renal parenchyma, characterized by the focal loss of renal substance with presence of deep scars and decrease of the renal size. It is an interstitial nephritis often related to vesicoureteral reflux, especially in childhood and in female patients.

▶Reflux nephropathy can also be caused by infections due to urinary tract obstruction or by the acquired forms of adult vesicoureteral reflux. Other etiologies for this entity include urolithiasis (Fig. 1) and papillary necrosis.

Other causes that provoke chronic infection of the kidney, such us ▶xanthogranulomatous pyelonephritis (XGP), ▶renal tuberculosis (RTB), and mycotic infections, should be considered (1).

Xanthogranulomatous pyelonephritis is the result of a chronic infection produced by gram-negative bacteria, especially *Proteus mirabilis* or *Escherichia coli*, related to a long evolution of obstruction of the urinary tract, causing destruction of the renal parenchyma and its replacement by lipid-laden macrophages. It is usually associated to nephrolithiasis (70%). This process is often unilateral and appears more frequently in middle-aged women.

Renal tuberculosis is produced as a consequence of the hematogenous dissemination of *Mycobacterium tuberculosis* from the lungs to the genitourinary system. About 4–8% of patients affected by tuberculous pulmonary disease will develop symptomatic genitourinary infection (2).

Pyelonephritis, Chronic. Figure 1 Chronic renal infection. CT after intravenous contrast administration. The left kidney appears with decreased parenchymatous thickness and size, findings related to obstruction due to a pyeloureteral junction stone. It also presents a minor nephrographic density than the right kidney. There is involvement of the left psoas and abdominal wall muscles by the chronic inflammatory process. The right kidney shows compensatory hypertrophy. A stone can be seen within the gallbladder.

Mycetoma or fungus ball is a mycotic infection that is caused by an ascending infection of the urinary tract or by hematogenous seeding, usually produced by *Candida albicans* or *Aspergillus*. It usually affects immunocompromised patients or those under long treatments with antibiotics or steroids (1).

Lipomatous renal replacement is an unusual form of renal sinus lipomatosis associated with parenchymatous atrophy, related to chronic renal inflammation and nephrolithiasis in 75% of cases (1).

Pathology/Histopathology

Reflux nephropathy is often preceded by renal infection episodes (acute pyelonephritis), with gram-negative bacteria most usually involved, especially *E. coli*.

Vesicoureteral reflux is an important factor in the infection ascending to the superior urinary tract, and considered a fundamental risk factor, although not the only one, for the development of reflux nephropathy. Once the bacteria reach the pyelocalyceal system, they access the renal parenchyma through the papillary holes of the collector ducts; this is known as intrarenal reflux.

Vesicoureteral reflux depends on the length and the insertion angle of the ureteral distal portion, which goes through the bladder and is canalized under the mucosa to end up in the trigonum. Thus, it is frequent in childhood and progressively improves during normal growth. In the case of serious reflux, it might cause significant harm to the renal parenchyma. There are two kinds of alterations. One is reflux atrophy or reflux diffuse nephropathy caused by the reflux of an important volume of high-pressure urine, causing variable degrees of dilatation of the pyelocalyceal system and renal atrophy. In the second alteration, the reflux coexists with a urinary tract infection. The reflux causes the ascent of bacteria to the superior urinary tract and together with the intrarenal reflux will lead to parenchymatous scars and other alterations of ►chronic atrophic pyelonephritis.

Intrarenal reflux takes place in the renal areas where the shape of the papillary orifices has been deformed by the lobular fusion process; thus, intrarenal reflux can be produced in one or more parts of a lobe, but not in the entire lobe.

The pathologic characteristics of this entity are:

- A total involvement of the renal thickness due to the reflux in the collector ducts that extend from the papilla to the cortex.
- Lobular involvement with normal areas of partial neighboring tissue.
- Major occurrence of scars in the renal poles than in the interpolar region due to a larger quantity of composed papillae.

In animal studies the condition of reflux nephropathy with the coexistence of vesicoureteral reflux and sterile urine has been reproduced, leading to controversy on the role of the infection in the etiopathogenesis of this process.

The earliest involvement of this entity is an acute tubulointerstitial nephritis in the portion of the affected renal lobe. This condition usually occurs in childhood without producing significant radiologic alterations, but with impairment of capillary perfusion and glomerular filtration secondary to the interstitial inflammatory infiltrate and pus accumulation in the collector ducts. In this state, radioactive isotopes or radiologic techniques that allow the evaluation of perfusion are used in the diagnosis (3).

If the infection, with or without reflux, continues, the inflammatory infiltrate is substituted by fibrous tissue producing a scar and the retraction of the renal surface and the underlying papilla.

In the pathogenesis of XGP, the usual finding is diffuse infiltrate of the renal parenchyma by plasmatic cells and lipid-laden macrophages that produce yellow-tan masses. In 90% of cases of XGP, renal lithiasis is found, generally presenting a “stag horn” morphology, made of struvite. The calyces are dilated and with thickened walls and are filled with pus. The histologic response is thought to be related to the release of lipids from the tissues damaged by bacteria.

In RTB small granulomas are found bilaterally in the cortex, adjacent to the glomerulus. The high rate of perfusion and the existing oxygen tension increase the probability of bacillary proliferation in that area. In immunocompetent patients, the bacterial duplication is inhibited and so the process remains latent in the renal cortex, with the possibility of absence of symptoms for decades. In the case of an immunity alteration, a reactivation of the cortical granulomas is produced, which increase in size and tend to coalesce.

Breaking of the capillary vessels gives the bacilli access into the proximal tubule and Henle’s loop, producing caseous granulomas and papillary necrosis. The granulomas, the caseous necrosis, and the cavity are stages of active infection that can destroy the kidney.

The link of these granulomas with the collector system can cause seeding of bacilli in the renal pelvis, ureters, bladder, and genital organs. The host response induces fibrosis, calcium deposits, and stenotic areas, favoring the obstruction and alteration of renal function (2).

Clinical Presentation

Urinary tract infection is more often found in girls and women, and during the first year of life in uncircumcised boys. The combination of urinary infection and severe reflux shows fever, flank pain, dysuria, and higher mictional frequency as symptoms. Aspecific symptoms such us drowsiness and abdominal pain associated with fever are often found. Many children show bacteriuria and renal scars on intravenous urography without presenting any symptoms.

More serious cases of bilateral reflux nephropathy are more frequently found in young adults, especially women. Hypertension and chronic renal failure are the usual findings.

Xanthogranulomatous pyelonephritis is more frequent in women, regardless of age. It is often preceded by a few months of undiagnosed chronic disease. The clinical symptoms are abdominal and flank pain, fever, weight lost, and weakness. Many patients do not have any symptoms related to the inferior urinary tract. In some cases, a renal mass can be palpated. In the analytic tests, anemia, leukocytosis, albuminuria, and pyuria can be found (1).

The most frequent symptom of RTB is polyuria. Suprapubic, inguinal or flank pain, micro- or macroscopic hematuria, dysuria, and epididymitis can appear. Constitutional symptoms such as fever, anorexia, weakness, weight loss, and night sweating are not frequent in the renal forms. Of the patients, 10% show no symptom. Sterile pyuria is characteristic in standard culture media (2).

Imaging

Chronic Atrophic Pyelonephritis

By means of intravenous urography (IVU), we can appreciate the existence of scars in the entire lobe or in a part, located over a retracted papilla, whose calyx is dilated with smooth margins. Usually the lesions are unilateral, but bilateral involvement can also exist.

There is a decrease in the parenchymatous thickness with compensatory focal hypertrophy in the unaffected areas. The nephrographic phase is characterized by a failure of contrast captation in the affected area.

Ultrasonographic studies show rounded and dilated calyces, with either adjacent cortical scar or the presence of cortical atrophy. If the disease is unilateral, the presence of compensatory hypertrophy can be seen in the contralateral kidney. In some cases sinusal lipomatosis can appear, being identified by an increase in the echogenicity of the sinusal complex (4).

By means of computed tomography (CT), the focal parenchymatous scar that covers the club-shaped dilated calyx can be identified.

Sometimes these calyces can be similar to a renal cyst or a hypovascular mass during the cortical nephrographic phase. In these circumstances a delayed study allows us to confirm the presence of dilated calyces filled with contrast material. CT helps establish the diagnosis of hypertrophic focal areas adjacent to the scar zones. Lobar infarcts can also be identified by means of this technique by their predominant cortical participation and the absence of calyceal involvement (1).

Magnetic resonance imaging (MRI) shows small kidneys with an absent or blurred corticomedullary junction. The fat of the renal sinus is abundant and the rest of the parenchyma can show low signal intensity. Focal scars of chronic pyelonephritis may appear with low signal intensity on both T1- and T2-weighted images.

Diffuse Xanthogranulomatous Pyelonephritis

The urographic findings include a coraliform or staghorn stone on abdominal plain films as well as a kidney increased in volume or a renal mass.

Other possible alterations might be blurring of the psoas silhouette or the absence or reduction of renal function. In the case of contrast media elimination or by means of retrograde pyelography, hydronephrosis with irregular calyces and papillary necrosis can be seen.

On ultrasonography the increase in renal size with smooth contours is identified, as well as the absence of any corticomedullary differentiation. There is dilatation of the calyces that appear filled with detritus from the inflammatory process, which are visualized as hypoechogenic structures with thin internal echoes. The echogenic image with acoustic shadow in the renal sinus represents the stone. Xanthogranulomatous parenchymatous masses appear as isoechogenic focal areas compared with the rest of the renal parenchyma. Perirenal involvement can be more clearly seen by means of CT (5).

With CT, the findings obtained in the other imaging examinations can be confirmed. Enlargement in renal size or a renal segment is demonstrated, with the presence of the central stone, usually a coraliform stone. There is a poor elimination of contrast material to the collector system. There are multiple focal masses of low attenuation (–10 to + 30 HU) in the involved areas, which represent dilated calyces filled with detritus and xanthomatous collections. They do not present postcontrast enhancement, but they show peripheral enhancement related to the inflammatory hypervascularization. Renal lipomatosis can also be identified. CT is very useful in identifying the extent of the infection in the psoas muscle and in the para- and perirenal spaces. Renocolic and cutaneous fistulous tracts can appear (1, 5).

By means of MRI, the inflammatory mass presents a mixed intensity signal that can simulate a neoplastic process. The signal void produced by the renal stone can help in the diagnosis.

Angiographic examinations evaluate the lack of branching out of the interrenal arteries, the displacement of the vessels around the dilated calyces, or the existence of granulomatous mass and the attenuation of the arterial caliber.

Focal Xanthogranulomatous Pyelonephritis

The radiologic findings are similar to those in the diffuse form but are limited to the calyces and the parenchyma of a part of the kidney, frequently associated to an obstructive calyceal stone or to an obstructed duplicated pyelocalyceal system.

Renal Tuberculosis

On abdominal plain films, we can see either speckled or dispersed parenchymatous calcifications, or thicker ones with an annular form, or a ground-glass appearance. In the final stage of the disease, total renal calcification may occur. This can be amorphous, granular, or curvilinear.

The initial urographic anomaly consists of the irregularity of one or more papillae or calyces (ulceronecrotic papillitis). The papillary surfaces are blurred and there is contrast extravasation to the medullary space due to necrosis and dilatation of the calyceal fornix. Hydrocalyces related to infundibular stenosis are also seen. There is infundibular pyelic retraction and pyelocalyceal granulomas (tuberculomas). Ureteral involvement with presence of ulcerations and granulomas might occur, as well as intramural calcification and stiffness.

We can also find thickening of the vesical wall with ulcerations and a decrease in vesical capacity, vesicoureteral reflux, and tuberculous fistulae (2).

Ultrasonographically, small focal lesions (less than 15 mm) can be identified, with an echogenic border and a hypoechoic center, similar to focal bacterial nephritis. Calyceal ectasias that suggest infundibular stenosis and papillary involvement can be detected, which are depicted as echogenic masses without posterior acoustic shadow. The filling calyceal faults, such as clots, fungus masses, and detritus, can present the same echographic appearance as the papillary necrosis, and therefore a fine-needle aspiration punction (FNAP) is required for the cytologic study.

CT is useful for the evaluation of the morphology and distribution of the calcifications, in order to demonstrate the presence of renal parenchymatous abscesses and the extrarenal extension. It also offers an accurate evaluation of the renal parenchyma (1).

Nuclear Medicine

Renal scintigraphy with dimercaptosuccinic acid (DMSA) is useful for confirming the diagnosis of acute pyelonephritis in children and for identifying kidneys with potential risk to develop renal scars (3).

The isotopic findings usually consist of the presence of an area of lack or diminished uptake that extends throughout the parenchymatous thickness in one or more areas of the involved kidney. This is due to the areas of altered perfusion related to the increase of interstitial pressure associated with the inflammatory infiltrate.

DMSA shows higher sensitivity than IVU in the detection of renal scars, especially in children and teenagers (3).

Diagnosis

In the initial stages of reflux nephropathy, the radiologic findings are similar to those of acute pyelonephritis. In these cases, CT after intravenous contrast administration or isotopic renography with Tc-99m DMSA can make diagnosis easier.

Radiologic evaluation after these initial stages aims to detect significant vesicoureteral reflux, evaluating the renal parenchyma, detecting delay in its growth or scar formation; a follow-up is advised in these cases. The reflux can be observed by mictional or isotopic cystography.

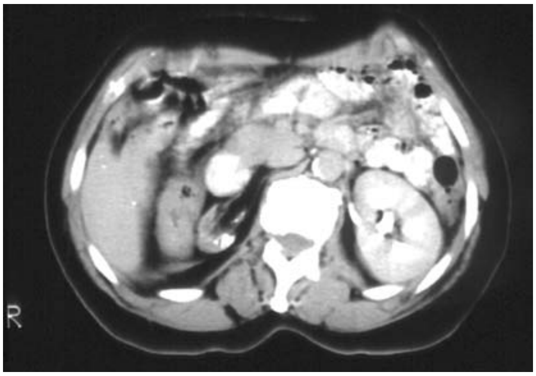
Imaging modalities for the evaluation of renal structure are IVU, ultrasonography, CT, and isotopic studies.

Specific criteria for the diagnosis of reflux nephropathy are the existence of a scar that involves the whole parenchymatous thickness, with irregular depression on the surface, and the presence of papillary retraction and dilatation of the underlying calyx.

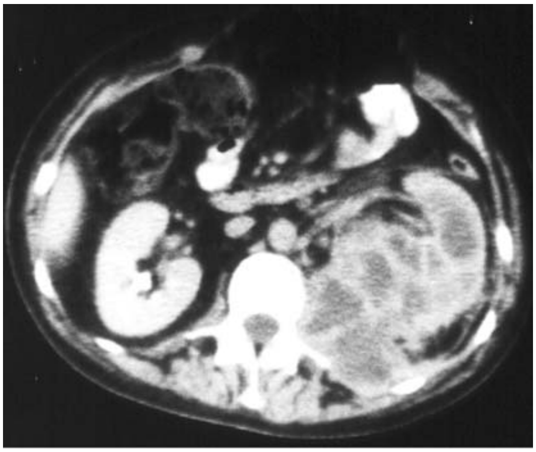
The adjacent renal tissue is normal or hypertrophic. The distribution of the lesions is either uni- or multifocal and can be either uni- or bilateral. A global reduction in renal size is characteristic (Fig. 2).

In the case of XGP the urographic study identifies the stone, generally coraliform, and the impairment of renal function. This finding can be confirmed with ultrasonography, by observing an increase in renal size without contour alteration, the existence of dilated calyces and hypoechogenic masses, as well as the stone.

In the focal or segmentary forms, it is difficult to establish whether these masses correspond to an inflammatory accumulation, an abscess, or a tumor. CT is very helpful in these cases, as the urographic and ultrasonographic findings are nonspecific. CT is very sensitive in detecting perirenal extension (Gerota's fascia, psoas muscle,



Pyelonephritis, Chronic. Figure 2 Chronic atrophic pyelonephritis. CT after intravenous contrast administration. The right kidney presents an atrophic appearance secondary to the chronic infection. There is a compensatory hypertrophy of the left kidney.



Pyelonephritis, Chronic. Figure 3 Xanthogranulomatous pyelonephritis, diffuse form. CT after intravenous contrast administration. There is enlargement of the left kidney with multiple focal inflammatory masses of low attenuation that present a slight peripheral enhancement. The left psoas muscle is also involved by the chronic inflammatory process.

fistulous tracts) (Fig. 3). Most angiographic studies are nonspecific.

The diagnosis of RTB requires the existence of clinical symptoms in accordance to the demonstration of acid-alcohol-resistant bacilli in microscopic urine tests using special stains and urine cultures specific for mycobacteria (2). *M. tuberculosis* is isolated from urine in 80–90% of patients affected by genitourinary tuberculosis. Mantoux test results will be positive in most of these patients, but the test is not specific for the development of RTB.

Imaging techniques such as IVU and CT are very useful, because 10–15% of patients with signs of tuberculous activity will have normal urographic findings. These modalities depict a series of genitourinary lesions related to the mycobacteria infection depending on the disease stage.

CT findings are less sensitive than those of IVU for the early detection of urothelial mucosa changes, but it proves useful in determining the renal and extrarenal extension of the infection (2).

Pyogenic Cerebritis and Abscess

E. TURGUT TALI, SERAP GULTEKIN
Gazi University, Ankara, Turkey
turgut.tali@gazi.edu.tr
segultekin@yahoo.com

Definition

Cerebritis represents the earliest phase of parenchymal infection. Brain abscess is a focal intracerebral infection that begins as a localized area of cerebritis and develops into a collection of pus surrounded by a well-vascularized capsule. Streptococcus is the most common causative organism (30–50%).

Pathology/Histopathology

Infection progresses through four stages: early cerebritis, late cerebritis, early capsule, and late capsule. The cerebritis phase typically lasts from 10 to 14 days. Pathologically, cerebritis is described as a poorly demarcated area of parenchymal softening with scattered necrosis, edema, vascular congestion, and petechial hemorrhage without tissue liquefaction. The focus of cerebritis progresses to abscess when the central zone of necrosis becomes liquefied, better defined, and encircled by a collagen capsule, which itself is surrounded by a prominent zone of gliosis (1).

Clinical Presentation

Patients present with the cardinal features of fever, epilepsy, headache, nausea, vomiting, and occasionally a depressed level of consciousness (1).

Imaging

Computed Tomography

In cerebritis, an ill-defined, low-density lesion without contrast enhancement is seen. In mature abscess, an area of low density with a ring enhancement pattern is observed.

Magnetic Resonance Imaging

In early cerebritis, an area of increased signal intensity on T2/fluid attenuation inversion recovery (FLAIR) sequences with or without ill-defined, patchy, irregular enhancement in the depth of the sulci is seen. The differentiation of cerebritis from infarction can be made on diffusion-weighted imaging (DWI). Acute infarction appears bright with a matching area of decreased signal on the apparent diffusion coefficient (ADC) map. Cerebritis shows a high signal on DWI and ADC maps due to the T2 shine-through effect.

After the second week, the abscess starts to form and is characterized by an incomplete rim of enhancement. By the end of the third week, a mature abscess forms. Peripheral edema is nearly always present. Mature abscesses have a capsule that is hypointense on T2-weighted images. The abscess capsule shows ring enhancement. The ring is usually smooth and thin walled (approximately 5 mm) and is often thinner along the medial margin (Fig. 1) (2).

DWI is helpful in differentiating abscess from necrotic tumor (3). On DWI, an abscess demonstrates high signal intensity with a corresponding reduction on ADC maps. Magnetic resonance spectroscopy (MRS) adds another layer of certainty by identifying the metabolites that are specific for pyogenic brain abscesses. MRS reveals end-products of bacterial breakdown and the proteolytic enzyme degradations (e.g., lactate, acetate, succinate, and amino acid peaks) that can be found in all abscesses, but not in necrotic/cystic tumors (4).

Diagnosis

The diagnosis largely depends on imaging studies. It is very important to stress that occasionally patients may not present with suggestive clinical symptoms. Therefore, in cases of a ring-enhancing mass in an afebrile patient, abscess should still be considered.

Pyogenic Cerebritis and Abscess. Figure 1 Mature brain abscess. Axial (a) T2-weighted and FLAIR (b) images show a lesion in the left posterior parietal lobe with marked surrounding edema, mass effect, and a hypointense capsule on the T2-weighted image. The central necrotic part of the lesion is hyperintense to cerebrospinal fluid on T1-weighted imaging and shows heterogeneous hypointense signal on T2-weighted imaging due to the debris and proteinaceous material content. Sagittal (c) postcontrast T1-weighted images demonstrate the regular, thin, enhancing capsule with necrotic center. Corresponding trace DWI (d) shows that the center of the abscess is very bright. On ADC map (e), the lesion is hypointense due to restricted water diffusion in the purulent abscess.

Pyogenic, Abscess, Hepatic

Localized intrahepatic collection of pus due to bacteria (most commonly *Clostridium* species and gram-negative bacteria, such as *Escherichia coli* and *Bacteroides* species). Ascending cholangitis and portal diffusion are the most frequent causes of pyogenic hepatic abscesses. Other possible ways of diffusion are arterial diffusion, direct extension from adjacent organs, and traumatic penetrating lesions. In a large number of patients the origin of the liver abscess remains unknown. Fever and pain are the most common symptoms. Anorexia, nausea, vomiting, weight loss, and pleural effusion are often present. Computed tomography (CT) and ultrasound (US) have a high sensitivity in detecting pyogenic abscesses. In the colliquative phase, US shows an irregular lesion containing a variable quantity of hyperechoic spots, corresponding to necrotic debris; the appearance may vary from anechoic to hyperechoic. At CT, in the subacute or colliquative phase, the pyogenic abscess appears as an irregular hypodense area with density values higher than those of simple cysts. Typically the lesion has a thick irregular wall and presents a characteristic rim enhancement, while the central necrotic portion remains unenhanced. A CT finding suggestive of abscess is the “double target” sign; it represents a hypodense lesion surrounded by an enhancing rim, corresponding to the wall, and an outer hypodense halo, due to perilesional edema. The presence of gas within the lesion represents a specific sign of pyogenic abscess. At magnetic resonance imaging (MRI), pyogenic abscesses appear as hypointense areas on T1-weighted images and hyperintense areas on T2-weighted images. Perilesional edema can be seen on T2-weighted MR images. After contrast medium administration, the lesion shows marked peripheral enhancement. Miliary pyogenic microabscesses are usually found in patients with generalized septicemia and may appear as multiple lesions scattered throughout the liver or as a cluster of small lesions which tend to coalesce.

▶ Abscess, Hepatic

Pyomyositis

▶ Infection, Soft Tissue

Pyonephrosis

An obstructed and infected kidney, with dilated pyelocaliceal system filled with purulent material.

▶ Pyelonephritis, Acute

Pyosalpinx

Dilated fallopian tubes become visible on imaging as tubular tortuous adnexal structures, which contain incomplete interdigitating septations. They contain pus that displays higher proteinaceous contents than fluid in hydrosalpinx. Mural thickening is another feature of pyosalpinx.

▶ Abscess TuboOvarian

QCT

▶Quantitative Computed Tomography

Q-tip Test

A cotton-tipped stick lubricated with Xylocaine gel is placed into the urethra up to, but not through the internal urethral sphincter (Q-tip test). With straining or coughing, the stick rises more than 30° from its resting angle. This demonstrates urethral hypermobility and differentiates genuine stress incontinence from an intrinsic urethral sphincteric insufficiency (ISD) without hypermobility.
▶Pelvic Floor Dysfunction, Genitourinary

Quadrantectomy

Breast surgical technique that consists of removal of up to one-quarter of the breast and an ellipse of skin and reaching the fascia of pectoralis major muscle.
▶Breast Conserving Therapy

Quantification

The quantitative assessment of the contrast enhancement in a target region (region of interest). For quantification, it is necessary that the relationship between contrast agent concentration and signal intensity is known. For ultrasound contrast agents there is a linear relationship between both parameters, unless the concentration is becoming too high resulting in attenuation effects in deeper regions.
▶Contrast Media, Ultrasound, Commercial Products

Quantitative Computed Tomography

Technique to measure volumetric bone mineral density using computed tomography (CT) and transforming CT density values with a calibration phantom into mg calcium-hydroxyapatite/mL. Can be performed in single sections obtained at the lumbar vertebrae (L1–L3) (two-dimensional QCT) or in volumetric datasets obtained at the lumbar spine and the proximal femur (three-dimensional QCT).

Synonyms

Benign sclerosing ductal proliferation; Complex sclerosing lesion; Indurative mastopathy; Infiltrating epitheliosis; Non-encapsuled sclerosing lesion; Radial sclerosing lesion; Scleroelastotic scar; Sclerosing papillary lesion; Sclerosing papillary proliferation

Definition

Radial scars are benign complex lesions that may simulate carcinomas on imaging techniques, as well as in gross and microscopic examination. The term *complex sclerosing lesion* is similar but it is used for lesions measuring more than 10 mm (1–3).

Pathology

On gross examination radial scars are firm lesions, with a pale retracted centre and bands of pale stroma extending radially into the fat from the core, mimicking invasive carcinoma (3). On microscopic examination, these lesions show a fibroelastotic core from which ducts and lobules radiate. Several combinations of typical ductal hyperplasia, ►atypical ductal hyperplasia, adenosis, lobular neoplasia and sometimes ductal carcinoma *in situ* or even infiltrating ductal carcinoma may be found. Entrapped ducts are present in the central core with distorted or angular appearance, and may mimic ►tubular carcinoma (1–3). The presence of myoepithelial cells, that may be confirmed immunohistochemically with markers such as actin, smooth muscle myosin, p63 and calponin, is useful to differentiate both entities (3).

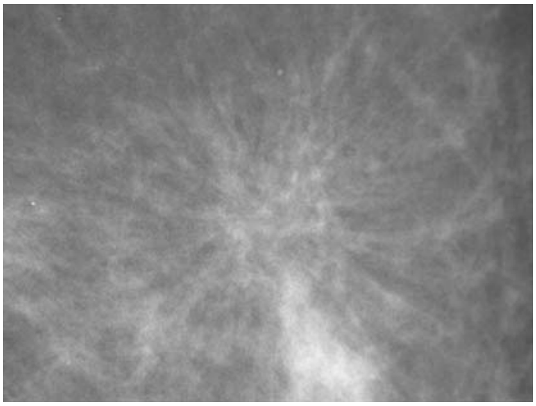
Clinical Presentation

Most radial scars are non-palpable microscopic findings incidentally diagnosed in a surgical biopsy performed for other lesion. Radial scars occur in a wide pre- and post-menopausal age group. However, occasionally complex sclerosing lesions may be palpable or may retract the skin (2). The widespread use of mammography has led to an increasing detection of radial scars, with a reported incidence in screening programs between 0.1 to 0.5 per 1,000 women (2). Multiple radial scars in one breast or in both breasts may be found. However, the incidence in mastectomy specimens is higher, from 4 to 26%. In addition, the incidence in benign specimens ranges from 1.7 to 28% (3). These broad and overlapping ranges suggest that radial scars occur similarly in benign and malignant lesions. Nevertheless, the relationship between radial scars and breast cancer remains unclear. Some studies find that radial scars may increase the risk to develop breast cancer, but others suggest that the risk can be originated by the hyperplasic lesions accompanying radial scars, especially atypical ductal hyperplasia (1, 2).

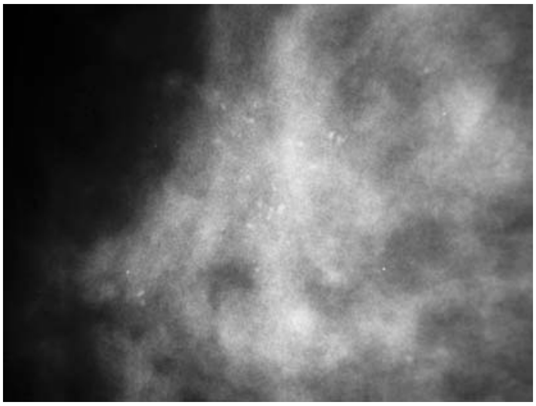
Imaging

Mammography

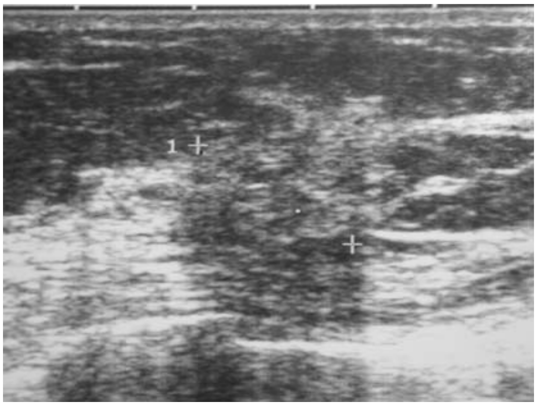
The typical appearance of a radial scar on mammography is an architectural distortion, sometimes with accompanying microcalcifications (Fig. 1). The presence of a radiolucent centre, long spicules or the difficulty to identify the lesion on both conventional views may suggest the diagnosis. However, there are no reliable signs to diagnose it, so a biopsy should be performed. Occasionally the mammographic appearance of a radial scar is a cluster of microcalcifications or a mass (4) (Fig. 2).



Radial Scar, Breast. Figure 1 **Typical architectural distortion caused by a radial scar-complex sclerosing lesion. Craniocaudal view (detail).**



Radial Scar, Breast. Figure 2 **A radial scar-complex sclerosing lesion manifested as a cluster of pleomorphic calcifications. Mediolateral oblique view (detail).**



Radial Scar, Breast. Figure 3 **Radial scars are difficult to be detected on ultrasonography. In this case, a hypoechoic ill-delimited lesion is seen with slight posterior shadowing.**

Ultrasonography

Radial scars are not easily identified on ultrasonography. Subtle hypoechoic irregular masses, that may be less visible rotating the transducer, and acoustic shadowing without a distinguishable mass, are ultrasonographic features of radial scars (4) (Fig. 3).

Magnetic Resonance

T1- or T2-weighted images may reveal an architectural distortion in some cases. Radial scars are usually non-enhancing lesions on contrast enhanced magnetic resonance studies, but also may enhance mimicking breast cancer. Thus, magnetic resonance cannot be used to differentiate both lesions and a biopsy is needed.

Nuclear Medicine

The usefulness of nuclear medicine scans has not yet been proven.

Diagnosis

Both radial scars and complex sclerosing lesions are diagnosed by biopsy. The management of these lesions with percutaneous biopsy techniques remains controversial. Most authors recommend the complete excision of the lesion due to its complexity (4). Conventional core needle biopsies (14 G) may underestimate an occult carcinoma, especially if atypical ductal hyperplasia is demonstrated in the specimens. Moreover, nests of hyperplastic epithelium trapped in the stroma may be misdiagnosed as invasive carcinoma (3). However, if more than 12 samples are obtained with directional vacuum-assisted devices, and the result is concordant with the mammographic findings, further surgery may be avoided (5). Nevertheless, more experience is needed to support these results.

Radiation Exposure, Mammography

SILVIA OBENAUER
Department of Radiology, Georg-August-University of Goettingen, 37099 Goettingen, Germany
obenauerheuser@yahoo.de

The striking advantage of digital systems is the high dynamic range and the linear relationship between the dose at the detector and the signal intensity, as opposed to the sigmoid relationship between optical density and dose in screen-film systems. Digital image processing technology can display overexposed or slightly underexposed images with normal image quality. This capability has prompted a discussion about the possibility of dose reduction in digital mammography. Phantom studies demonstrated a potential of dose reduction for CsI/a-Si full-field digital mammography systems. Studies with the contrast detail mammography phantom (CDMAM, University Medical Center, Nijmegen, The Netherlands) showed a possibility of 25% reduction of the radiation dose in digital techniques compared to screen-film mammography. Hermann et al. presented a clinical study based on data from 1,116 mammograms of 591 women examined with a CsI/a-Si digital system. The mean average glandular dose was 1.51 mGy for a single view. Therefore, about 25% less dose is needed in digital mammography than in conventional screen-film mammography. Gennaro et al. evaluated four different CsI/a-Si systems in routine clinical work and reported a mean average glandular dose ranging from 1.25 to 1.89 mGy depending on the glandular composition of the breast. The possibility of using higher energy exposures by various anode track–filter combinations may result in additional patient dose reduction with no loss in clinical performance. In an anthropomorphic phantom study, a Mo/Rh anode–filter combination with a tube voltage of 31 kVp (25% dose reduction) and a Rh/Rh with 32 kVp (37% dose reduction) did not show significant differences in the analysis of the receiver operating characteristics for the detection of microcalcifications in comparison with the Mo/Mo combination with 28 kVp. Due to a higher detective quantum efficiency and therefore lower noise, digital systems can compensate for the relative loss of contrast *via* windowing and leveling.

In conclusion, a dose reduction seems to be possible in digital mammography.

Radiation Hormesis Theory

The term hormesis is taken to be any stimulatory or beneficial effect, induced by low doses of an agent (in this case radiation), that can not be predicted by the extrapolation of detrimental or lethal effects induced by high doses of the same agent.

Radiation Issues in Childhood

ANNE PATERSON
Royal Belfast Hospital for Sick Children, Belfast, UK
annie.paterson@royalhospitals.n-i.nhs.uk

Definition

Ionizing radiation is high-energy radiation that is capable of causing ionization in matter through which it travels. In the electromagnetic spectrum, only high-frequency radiation such as X- and gamma rays are capable of ionizing body tissues. Natural radioactive sources in the air (radon gas and cosmic rays) and earth's crust contribute to our exposure to ionizing radiation, along with small quantities of radioisotopes present in the human body and in the food chain. This environmental exposure is termed "►background radiation" and accounts for approximately 80% of the annual radiation dose received by the world's population. The remainder of the radiation received by humans is manmade, coming from both industrial (1%) and medical sources (19%). By far the largest contributor to medical radiation is computed tomography (CT) scanning. CT may be responsible for only around 15% of a radiology department's workload, but it accounts for 70–75% of the collective population dose from medical radiation (1, 2).

The average background radiation dose to the world's population is 2.4 mSv/year, though in some countries this figure can be 5–10 times higher.

Units of Measurement for Radiological Procedures

To interpret the radiation risks from different radiological procedures, it is necessary to be familiar with descriptors of dose and their units of measurement.

- The absorbed dose is the amount of energy absorbed per unit mass of an organ or tissue. The absorbed dose cannot be directly measured in patients. The absorbed dose is expressed in Gray (Gy).
- The equivalent dose takes into account the type or quality of radiation an organ is exposed to. It is numerically equal to the absorbed dose, when X-rays are involved. The equivalent dose is measured in Sievert (Sv).
- The entrance skin dose (ESD) is the absorbed dose to the skin at the point where the X-ray beam enters the body. It is measured in Gy and is easily measured using an ionization chamber.
- Dose area product (DAP): As the ESD does not specify the area of tissue irradiated by the X-ray beam, the concept of DAP was developed. It has units of mGy cm^2 and can also easily be measured with an ionization chamber (the DAP meter). All modern fluoroscopic units are fitted with DAP meters.
- The effective dose (ED) takes into account all of the organs irradiated during an examination and incorporates a tissue weighting factor based upon the individual organ radiosensitivity. ED allows us to estimate the amount of radiation a patient receives during a radiological procedure. The unit for ED is also the Sv. Measurement of ED relies upon the use of phantoms or mathematical equations and models.
- CT dose index (CTDI) is used to approximate the dose within one "slice" of a CT examination. It is measured using an acrylic phantom and a pencil ionization chamber, over a length of 100 mm. CTDI is expressed in mGy.
- $CTDI_W$ takes into account the variations in absorbed dose, from the periphery and center of the phantom, and is weighted accordingly.
- $CTDI_{VOL}$ is numerically equivalent to the $CTDI_W$/pitch.
- The dose length product (DLP) has units of mGy cm and is calculated as the product of $CTDI_{VOL}$ and scan length. DLP can be converted into ED measurements, using mathematical equations. All scanner manufacturers are now required to display CTDI values on the user interface and some systems will also display the DLP. Whilst these measures do not tell us the actual radiation dose a patient receives, these measures will give information about relative changes in dose that result from alterations in CT-scanning parameters. Effective doses in CT can be higher for infants and small children than adults given identical CT parameters. This is because the lower absorbed energy in a child is distributed in an even smaller organ (absorbed energy/organ weight = dose).
- In nuclear medicine procedures, the radiation dose received by the patient depends upon the radionuclide administered and the type of radiation it emits. The total number of radioactive decays and the amount of radiation that is absorbed depend upon the dose of the radionuclide that is administered, its half-life, and the biological distribution and clearance of the chemical to which the radionuclide is tagged. The administered radioactivity is measured in Becquerel (Bq), where 1 Bq equates to 1 decay/s.

Radiation Risks

Risks associated with ionizing radiation can be divided into two groups:

- ►*Deterministic risk* is dependent upon cell killing and can be quantified in terms of the radiation dose the patient or organ has received. Below a certain threshold (approximately 2 Gy), the effect does not occur. However, above the threshold dose, the effects of radiation are seen. The higher the radiation dose received, the more severe the effect. Problems such as skin erythema, burns, and hair loss are deterministic effects. In diagnostic radiology, deterministic effects are rarely seen, though they may become a problem with angiographic procedures and CT fluoroscopy (3).
- ►*Stochastic risk* is dependent upon cell transformation and can lead to the development of cancer in the irradiated individual or genetic problems in their offspring. The severity of a stochastic effect is independent of the radiation dose received, though the greater the absorbed radiation dose, the more likely a stochastic effect is to be seen. Diagnostic radiologists are more concerned with the likelihood of stochastic effects occurring in their patients.

Pathology

Risk of Cancer Development Following a Radiological Procedure

Radiation doses less than 100 mSv are considered "low level" and whilst a single radiological procedure will fall within this dose range, a patient undergoing multiple investigations over the period of their lifetime has the potential to exceed this dose. The scientific data available about the risks of low-level radiation comes mainly from the epidemiological follow-up studies on the atomic bomb survivors. This database now contains information extending back almost 60 years (4–6).

The ▶linear, no-threshold risk model states that "the risk of cancer proceeds in a linear fashion at lower doses without a threshold and that the smallest dose has the potential to cause a small increase in risk to humans." This model is supported by the BEIR VII report, which also concluded that the risk of developing cancer from a radiation exposure of 10 mSv is approximately 1 in 1,000 (5). On the other hand, the ICRP report of 1990 whilst supporting the linear, no-threshold risk model, estimated a cancer risk of 5% per Sv when all ages are considered, elevating this figure to 15% if the individual is exposed in the first decade of life (8). Such risks persist throughout life, but are greater in children (who have a longer life expectancy and more chance of a radiation-induced cancer becoming manifest) and females (6). Putting these doses in context, the average effective dose from a CT scan of the abdomen (adult-scanning parameters) is 10 mSv.

A paper by Brenner et al., published in 2001 (9), used the available atomic bomb data alongside the statistics for pediatric CT examinations. The authors calculated that as many as 500 children may ultimately die from cancer, following a single CT scan of either the head or abdomen. The authors were at pains to explain that these figures were based upon the presumption that children were being imaged using adult CT parameters—an assumption which was largely accurate at that time (10)—and that the figures represented only a 0.35% increase in cancer deaths over the background rate. In other words, the risk to the individual may be small, but the implications for public health are large. Such risks can be reduced significantly if pediatric imaging protocols continue to be developed and refined.

The counterarguments against low-level radiation and cancer risks were summarized by Cohen in a review paper of 2002 (11). He concluded that the linear, no-threshold risk model fails at low doses and that the cancer risk from diagnostic radiography may well even be zero.

The linear, no-threshold risk model is based upon the assumption that a single particle of radiation interacting with a single DNA molecule may trigger cancer development. Higher radiation doses generate more radiation particles, and a greater chance that a cancer will develop; theoretically speaking, cancer risk is proportional to radiation dose. However, supporters of the ▶radiation hormesis theory argue that DNA repair enzymes, cellular apoptosis, and the immune system are all stimulated by low-level radiation, reducing the risk of cancer initiation, and the development of chromosomal aberrations (11).

Ionizing radiation is carcinogenic in high doses; this fact is not disputed. The risks from low-level radiation continue to be debated. At the present time, it would seem sensible to limit the amount of radiation to which the patients are exposed to during each individual radiological examination and cumulatively throughout their lives.

Imaging

Radiologist's Role in Limiting the Radiation Dose to the Patient

The radiologist should always adhere to the *a*s *l*ow *a*s *r*easonably *a*chievable (ALARA) principle and aim for images which are of diagnostic quality, but which minimize the radiation dose to staff and patients.

Regular review of imaging protocols and the audit of imaging algorithms for given clinical situations, alongside staff education and effective communication with clinical colleagues, are extremely important in reducing the radiation dose to patients. The list below outlines some of the more specific ways in which the radiation dose to the patient can be reduced, though it is obviously not exhaustive:

- Justify each radiology request and avoid unnecessary examinations (having the previous films available on Physics and Astronomy Classification Scheme (PACS) or hard copy format may be beneficial in this regard)
- Utilize modalities such as ultrasound and magnetic resonance imaging (MRI) whenever possible
- Optimize patient preparation and avoid having to repeat exposures
- Use appropriate lead and bismuth shields
- Pay attention to radiographic technique, for example, the selection of imaging parameters (particularly during CT examinations), appropriate collimation and the use of cones, and avoidance of a grid, wherever possible
- Limit the number of radiographic exposures. Avoid comparison views in orthopedic work. Avoid views such as the lateral chest radiograph and oblique spine radiograph. Consider carefully the questions to be answered by an intravenous urography (IVU) or small bowel series, reducing the number of films taken, wherever possible

R

- Utilize newer technologies during plain radiography and fluoroscopy. Digital imaging can significantly reduce the radiation dose and postprocessing techniques can limit the need for repeat exposures. The use of "fluorograb" images during fluoroscopy is to be encouraged, when anatomical rather than mucosal detail is required
- Limit the exposure time. In fluoroscopy, use a slower pulse-rate technique. In CT, use a rapid gantry rotation time, reduce the scan range, and avoid multiphase imaging

Diagnosis

The continued development of radiological technology (particularly CT scanners) has led to an increase in the collective population dose from medical radiation. The effective dose from repeated CT examinations overlaps (and can exceed) those doses that are argued to increase the risk of cancer developing. Children are more radiosensitive than adults and have a long life span ahead of them, during which time radiation-induced cancers may become manifest. The ▶ALARA principle must be adhered to when carrying out any radiological investigation necessary/indispensable for diagnosis or treatment.

Definitions

The lumbosacral radicular syndrome (LRS) is a complex of signs and symptoms indicating a lumbosacral nerve root disorder. It is essentially a pain syndrome with an irradiating pain into the buttock and/or leg as hallmark. This radicular pain is commonly referred to as ▶sciatica. Further components of the syndrome may include tendon reflex disturbances, muscle weakness, sensory loss, and urinary incontinence. Because a specific anatomical substrate is generally presumed in the radicular syndrome, it stands out from a specific low back pain.

Pathology

While the anatomical substrate for the clinical findings of the LRS is generally acknowledged to be the nerve root, the etiology of the nerve root disorder is diverse.

The foremost cause of lumbosacral nerve root disorders is a lumbosacral ►disc herniation. When such a disc herniation protrudes in the spinal canal it may lead to compression of the nerve root. Such compression may disrupt the axons in the nerve root, leading to signs such as muscle weakness and sensory loss. This happens only in a minority of patients. More commonly the chronic compression leads to an inflammatory reaction in the nerve root. This inflammation seems critical in the causation of the sciatic pain, as acute compressions without inflammation have been shown not to cause pain. Another mechanism implicated in the production of the nerve root disorder is the chemical irritation of the nerve root by constituents of the nucleus pulposus. Contact with nucleus pulposus material has shown to cause inflammation of nerve roots in animal studies in the absence of compression.

While disc herniations are considered the predominant mechanical cause of a lumbosacral radicular syndrome, any structure that impinges on the nerve root may contribute to the clinical picture. Such impingements may be caused by e.g. spondylolisthesis, facet arthrosis, or ligamentum flavum hypertrophy. They may be further accentuated by congenital narrowing of spinal canal or lateral recess. Quite frequently compression of the nerve root is due to a combination of the factors mentioned above. Epidural haematoma or abscess formation occasionally gives rise to a radicular syndrome. Finally, neoplasms of nerve root or surrounding meninges such as neurinoma, Schwannoma and meningioma may lead to radicular pain and loss of function. About one in a hundred patients with a radicular syndrome has a vertebral malignancy (often metastatic).

Rarely, the nerve root may be affected by metabolic disturbances, inflammation or infection in the absence of any mechanical compression. Diabetes mellitus not only leads to polyneuropathy, but may cause mononeuropathy, plexopathy or radiculopathy as well. Nerve roots are involved in the Guillain-Barre syndrome. This is, however, uniformly an affliction of multiple nerve roots. Various infections, such as neuroborreliosis and herpes zoster, may lead to a nerve root disorder.

Clinical Presentation

Most patients who present with LRS are in their fourth or fifth decade. Rarely do they indicate a causative activity. In general, a sedentary occupation, professions involving much driving and smoking are factors that increase the likelihood of developing disc herniations. Often, patients note low back pain of insidious or acute onset, which subsequently starts irradiating into the leg. Sometimes low back pain is absent. In 20–40% the radicular pain is accompanied by neurological deficit, 25% have muscle weakness, 35% have sensory loss and 15% have reflex disturbances. Micturition disturbances occur in less than 10% of patients. While neurological loss may be present at the start, it often develops insidiously and remains unnoticed by the patient at first. Sometimes the patient suffers severe sciatic pain for several days to weeks, to be followed by both a sudden relief of the pain and a sudden muscle weakness. This rare but classical account is referred to as 'sciatique paralysant'.

Of all patients with pain that irradiates into the leg, about 70% are considered to have the clinical diagnosis of LRS. The 30% that do not exhibit the complex of signs and symptoms indicating nerve root involvement, are generally considered to have pseudoradicular pain caused by such various diseases as trochanteric bursitis, sacroiliitis and plexus neuritis. Unfortunately, such clinical impressions are inaccurate. MR imaging in patients clinically diagnosed with LRS demonstrates a symptomatic disc herniation in only 70%. This means that about 30% of patients with LRS either have a non-mechanical cause of the root disorder or the diagnosis of a root disorder is incorrect in the group of patients with clinically diagnosed pseudoradicular pain MRI shows veritable nerve root compression in about 30%.

While usually the LRS is caused by disc herniation and has a favourable natural history, treating physicians should look both for warning signs that may imply a particular cause such as a post traumatic onset, a previous history or physical examination suggesting malignancy, diabetes mellitus, tick bites and spinal procedures and also for warning signs that indicate close monitoring or urgent therapy such as progressive paresis or a ►cauda equina syndrome.

Conservative Management (1, 2)

Disc herniation, which is most frequently responsible for nerve root compression, can be easily demonstrated by CT or MRI. Considering the costs of imaging, the high rate of findings of asymptomatic disc herniation and the benign spontaneous course of the LRS, imaging can be deferred in most patients until the consideration of surgical therapy necessitates imaging of the nerve root and its surroundings. In cases where there is diagnostic uncertainty as to whether the nerve root is involved at all, imaging can be helpful. In these instances, however, the imaging will have no direct therapeutic consequences. Imaging for this purpose also has the drawback of showing many structural abnormalities with uncertain clinical significance. Other diagnostic modalities such as electromyography and diagnostic nerve root block may be helpful in such cases.

In general, the considerable lack of correlation between clinical findings and imaging findings serves as a warning to hinge too much on either one in the evaluation of the patient with pain in lower back and leg.

Relying exclusively on clinical findings may have the drawback of labelling pain as a disc-related LRS while this is not the case, which may delay the correct diagnosis being made. Conversely, there is a real danger of patients

Radicular Syndrome of the Spine, Conservative Therapy for. Figure 1(a and b) Sagittal T1 and T2 weighted MR images of a large disc extrusion originating at the L4–5 level with extensive cranial migration to the midvertebral L3 level. (c and d) Post-Gadolinium sagittal and axial T1 weighted images show the mass to consist largely of strongly-enhancing peripheral granulation tissue. (e-h) Same case, six weeks later, showing marked resorption of the extruded disc material by surrounding granulation tissue. The patient presented with sciatica, made a full recovery without surgical intervention, and at no time showed signs of an infectious lesion.

unjustly being withheld therapeutic measures for root compression because the clinical findings do not appear to support the diagnosis of root compression.

Relying too much on imaging on the other hand carries the risk of too much significance being attributed to incidental findings of disc herniations, which may be encountered in asymptomatic volunteers in up to 30%. The drawback at the other side of the spectrum is that if imaging does not show root compression, such root compression is considered to be ruled out. However, it should be appreciated that imaging protocols for spinal imaging provide sectional anatomical information and as a consequence important information may be missed, for instance when a lesion is mainly located in the interslice gap or in the gap in which some scan protocols occur between slice sets limited and angulated to individual discs. CT and MR images are acquired with the patient lying down in a supine position. Most patients experience relief of radicular pain in this position. This is likely due to a decreased compression of the root. This would mean that these images are made when the compression of the root is minimal. Precluding mechanical compression on the basis of such MRI pictures is therefore very difficult. Mechanical devices for loading the spine in the supine position, and the use of upright MRI systems presently available, are likely to alleviate this problem.

Conservative Treatment Measures (3)

The initial management is aimed at providing adequate information, pain relief and if need be, aiding sleep by hypnotic medication. Patients should be instructed that the pain originates in the nerve root and that a disc herniation is the probable cause. Such disc herniations show a high tendency towards regression (as documented by repeat imaging studies, (Fig. 1)) and up to 75% of patients will experience spontaneous recovery within three months (4). This does not necessarily imply that the patient is without any complaints. The back pain may persist or recur frequently.

Pain medication should be prescribed time contingent (on a fixed time schedule). Acetominophen, tramadol, codeine, non-steroidal anti-inflammatory drugs (NSAID) and narcotic analgesics may all be used. Their mode of action is strictly symptomatic. None of the agents including NSAID's have added curative benefits.

The benign natural course explains the high rate of success of most conservative therapies in case series. Whether patients are selected for these studies directly after pain onset, at the start of the natural course or much further down the track, will explain much of the variance in reported success rates of conservative measures (anywhere from 35 to 97%). Randomised controlled trials (RCT) are called for. Unfortunately, the benign natural course has left many RCTs underpowered to demonstrate smaller but relevant benefits of conservative strategies.

►Bed rest has been a mainstay of conservative therapy for LRS for decades, but the only RCT studying its effects has found bed rest to lack effectiveness (5). Manipulation of the spine is the only form of physical therapy that has been shown to have a positive effect on the natural course of LRS in two trials. These trials had multiple methodological shortcomings, however.

►Epidural steroid injection has been the subject of several trials with negative, neutral and positive results. Overall, in a recent meta-analysis epidural steroid injections were shown to possess borderline effectiveness. Further studies to elucidate the effectiveness of epidural steroids especially in subgroups of patient with sciatica seem warranted.

Radicular Syndrome of the Spine, Percutaneous Therapy for

Barry Schenk, Patrick A. Brouwer
Leids Universitair Centrum Leiden, The Netherlands
b.schenk@lumc.nl

Introduction

Radicular syndrome, caused by herniation of an intervertebral disc, is a common problem with an annual incidence of 5 per 1,000 (1). In 60–80% of patients, experiencing their first episode of radicular pain, the symptoms recede to a non-disabling level within a period of 6 weeks (1). Patients with persistent symptoms qualify for (surgical) intervention. Because of the considerable morbidity and convalescence period inherent to conventional lumbar disc surgery, there has been an ongoing search for less invasive methods of treatment. This has led

R

to the development of several minimally invasive spinal interventions, such as ▶chemonucleolysis (2), ▶percutaneous laser disc decompression (PLDD) (3, 4), ▶percutaneous nucleotomy (5), ▶nucleoplasty (6) and ▶oxygen–ozone therapy (7). These interventions are all performed percutaneously under local anaesthesia, therefore morbidity and convalescence period are postulated to be less than for conventional surgery. Traditionally, spinal interventions for radicular syndrome have been the area of expertise of neurosurgeons and orthopaedic surgeons. The development of percutaneous techniques, together with their dependence on imaging techniques such as fluoroscopy, magnetic resonance imaging (MRI) and computed tomography (CT), have led to an increasing participation of interventional radiologists in this field.

Pathology of Lumbar Disc Herniation

The relationship between disc herniation and radicular syndrome has been known for over 70 years. The mechanical concept of nerve root compression by a herniated portion of the nucleus pulposus as a cause of radicular pain offers a satisfying explanation for most symptomatic patients, but biochemical, vascular and inflammatory factors are also thought to play a role in the pathogenesis of radicular syndrome.

The Principle of Disc Decompression

The intervertebral disc can be considered a closed hydraulic system (3). The nucleus pulposus, which is highly water containing, is surrounded by the inelastic annulus fibrosus. When the water content of the nucleus pulposus increases, it leads to a disproportional increase in intradiscal pressure. Reduction of the amount of water in the nucleus pulposus causes the opposite effect, with minor changes in water content leading to a disproportional drop in intradiscal pressure (3). A decrease in intradiscal pressure causes the herniated disc material to recede towards the centre of the disc, hence leading to reduction of nerve root compression and relief of radicular pain. This mechanism forms the basis for a number of percutaneous interventions, such as chemonucleolysis, nucleoplasty, PLDD and oxygen–ozone therapy. In case of percutaneous nucleotomy, disc decompression is achieved by mechanically removing nucleus pulposus tissue from the centre of the disc.

Criteria for Patient Selection

The main indication for percutaneous intervention is a contained disc herniation (4–6), with corresponding radicular symptoms. Inherent to the treatment principle mentioned before, only non-sequestered herniations can be expected to respond to reduction of intradiscal pressure (2–7). The presence of disc extrusion or sequestered herniation is considered to be a criterium for exclusion (2–7). Furthermore, patients with severe neurological symptoms, such as cauda equina syndrome, severe paresis or other conditions that require acute surgical intervention are excluded from percutaneous intervention. Intervertebral disc height should be at least 50% of normal (5), without vertebral abnormalities that might obstruct needle placement.

Interventions for Radicular Syndrome

A common factor for all percutaneous interventions for radicular syndrome is the fact that they all require percutaneous access to the intervertebral disc (2, 4–7), without direct contact with the dural sac or nerve roots. This can be achieved by inserting a needle or other instrument by means of a dorsolateral approach. Biplane fluoroscopy or CT imaging can be used to determine the desired needle path, during needle placement and to verify the correct position before commencing treatment. Careful monitoring of patient reaction and the appropriate use of visual guidance is crucial to prevent damage to nerve roots and surrounding tissues during needle placement or subsequent treatment. As is inherent to all percutaneous procedures, there is always a risk of inoculation of microorganisms into the centre of the intervertebral disc, with resulting discitis. Taking appropriate antiseptic measures during the procedure can minimise this risk. When infectious discitis does occur, it is usually responsive to appropriate antibiotic therapy.

Chemonucleolysis

Chemonucleolysis is the oldest percutaneous intervention for radicular syndrome. A proteolytic enzyme called chymopapain is injected into the centre of the intervertebral disc under fluoroscopic guidance in order to induce hydrolysis of the proteoglycan molecules that form the nucleus pulposus (2). The resulting proteoglycan fragments have limited water-binding abilities, which leave intradiscal water molecules free to diffuse into the surrounding tissues. The resulting loss of water causes a decrease in intradiscal pressure. The chymopapain molecules remain attached to the proteoglycan fragments, permanently limiting the nucleus pulposus' abilities to attract water (2).

Although literature on chemonucleolysis shows good clinical results (73–90% success rate), it is no longer widely used because of the risks associated with the injection of chymopapain. Enzyme leakage into extra-discal tissue has been reported, with the possibility of damage to nerve roots, dural sac or spinal cord. Severe anaphylactic reactions have been reported in 0.2% of patients (2). The overall mortality rate following chymopapain injection is approximately 1 in 5,000 patients (0.02%).

Nucleoplasty

Nucleoplasty is one of the newest percutaneous interventions for radicular syndrome. It relies on the principle of 'controlled ablation', a process in which radio frequency energy is used to generate a highly focussed plasma field that is capable of cleaving molecular bonds (5). In nucleoplasty, nucleus pulposus tissue is ablated using a special wand, which is inserted into the centre of the intervertebral disc under fluoroscopic guidance. By rotating the curved tip of the wand, up to six channels are created within the nucleus pulposus, decreasing intradiscal volume and hence lowering intradiscal pressure. Subsequently, the channels are sealed thermally by coagulation (5). Literature on clinical results of nucleoplasty is still limited. The results of several non-randomised trials show success rates that vary from 78% to 89% (5). Specific complications of nucleoplasty have not yet been reported.

Percutaneous Laser Disc Decompression

In PLDD, laser energy is used to vaporise the water content of the nucleus pulposus (3, 4). A small laser fibre is inserted through a hollow needle into the centre of the intervertebral disc under fluoroscopic guidance. CT is used to verify the correct needle position. When the laser fibre is in place, up to 2,000 J of laser energy are applied into the nucleus pulposus in order to evaporate its water content, thereby reducing intradiscal pressure. The temperature increase also induces protein denaturation and subsequent renaturation. This causes a structural change of the nucleus pulposus, limiting its capability to attract water and therefore leading to a permanent reduction of intradiscal pressure (3, 4).

The results of several non-randomised trials that have been published over the years show success rates ranging from 75% to 87% (4). The most important complication of PLDD is aseptic (spondylo-) discitis as a result of thermal damage to the intervertebral disc or vertebral end plates (0–1.2%) (4). This complication can be largely avoided with careful monitoring of patient complaints during the procedure, with adjustment of laser parameters when heat sensations occur. In this fashion, an excessive buildup of heat can be countered before structural damage is caused to the surrounding tissues.

Oxygen–Ozone Therapy

Oxygen–ozone therapy is a percutaneous intervention for radicular syndrome, relying on the chemical properties of ozone (7). A mixture of oxygen–ozone gas is injected into the centre of the intervertebral disc at non-toxic concentrations. Ozone has a direct lytic effect on the proteoglycan molecules that form the nucleus pulposus (7). As in chemonucleolysis, the resulting proteoglycan fragments have limited water-binding abilities, which leave intradiscal water molecules free to diffuse into the surrounding tissues (7). The resulting loss of water causes a decrease in intradiscal pressure. The degenerated nucleus pulposus tissue is gradually replaced by fibrous tissue, with limited water-binding capabilities. The result is a reduction in disc volume. In addition to the proteolytic properties, ozone also has certain anti-inflammatory and analgesic effects that may help counteract disc-induced pain. The antiseptic activity of ozone is thought to further reduce the risk of infectious complications associated with percutaneous interventions (7). No specific neurological or infectious complications of oxygen–ozone therapy have been reported.

Percutaneous Nucleotomy

Percutaneous nucleotomy is a minimally invasive intervention, in which nucleus pulposus material is mechanically removed using an automated nucleotome. This nucleotome is a 2-mm blunt-tipped device, equipped with a reciprocating suction cutter (6). The nucleotome is introduced through a cannula that is placed into the centre of the nucleus pulposus under fluoroscopic guidance. When the nucleotome is in place, nucleus pulposus material is cut and aspirated at a rate of 180 times per minute. The tip of the nucleotome is alternatingly rotated, depressed and elevated within the nucleus in order to optimise the removed amount of nucleus pulposus material (6). The resulting loss of nucleus pulposus mass causes a drop in intradiscal pressure.

Clinical success rates for percutaneous nucleotomy range from 70% to 80% (6). The main complication of percutaneous nucleotomy is infectious discitis (0.2%). Serious neurological complications are extremely rare, although two cases of cauda equina injuries have been reported due to probe misplacement (6).

Radicular Syndrome of the Spine, Surgical Therapy for

Wilco Peul
Medisch Centrum Haaglanden, Netherlands
w.peul@mchaaglanden.nl

Synonyms

Laminectomy; (Micro)discectomy

Definition

A radicular syndrome is characterized by pain radiating in the dermatome of a spinal nerve root. Occasionally, more than one root is involved. Pain may be accompanied by one or more of the following: lumbar muscle spasm, reflex abnormalities, motor and sensory disturbances. Surgical therapy for a radicular syndrome refers to all procedures which have the goal to decompress the exiting nerve roots. Anatomical approaches differ according to the origin of the pathology.

Pathology

Disc herniations are the most frequent cause of a radicular syndrome, followed by stenosis of the lateral recess and occasionally narrowing of the neuroforamen. The latter occur more frequently in the cervical spine in elderly populations, where progressive disc degeneration leads to spine deformities with compression at the spinal outlet of nerve. Disc herniations can be divided into contained and uncontained protrusions of nuclear material, and the latter may give rise to a sequester or free fragment of disc material.

Clinical Presentation

Most radicular syndromes resolve naturally with time (1). However when conservative treatment fails, surgery is an option depending on preferences of patients and their treating physicians. Guidelines regarding management of lumbar radicular syndromes propose that an indication exists for surgery after 6–8 weeks of persisting radicular pain. Cervical and thoracic radicular syndromes are managed conservatively for a longer period. Complaints in these cases are as severe as in lumbar radicular syndromes, but the functional disability seems more tolerable and a higher proportion of patients are cured in the natural course of the disease. Severe neurological deficit is a compelling reason for surgery, whereas pain is a relative indication. The following subheadings refer to the different spinal regions.

Cervical Spine

Cervical radicular syndromes are most frequently associated with a soft disc herniation or hard osteophytes, which compress the nerve root within the spinal canal or foramen. As a rule compression occurs far laterally with anterior impingement of the nerve. All anatomical approaches have been used, employing posterior, lateral and anterior techniques.

- Posterior approaches are divided into laminectomy and laminotomy techniques. A laminectomy consists of the complete removal of posterior bony elements except for the facet joint. This historical technique is occasionally used in present times, when patients present with a combined radicular and spinal cord compression. The exiting nerve root is decompressed by the removal of the posterior medial facet joint. If the procedure is solely intended to decompress the nerve root, a small hole may be drilled in this area, leaving the posterior elements intact. This so-called Scoville procedure has been abandoned by most neurosurgeons. However, recent microendoscopic discectomy (MED) techniques using tubular dilators have popularized this approach again, because trauma to muscle is less and cervical mobility is better preserved.
- Lateral approaches to the cervical spine for the treatment of radicular syndromes have historical interest but are sometimes used for more complex pathologies compressing the exiting root.
- The anterior approach presently comprises more than 90% of all surgical techniques employed in cervical radicular syndromes. The main reason for this is the origin of the pathology anterior to the root and cord, and the sparing nature of the technique leaving intact all spinal anatomical structures except for the disc. The latter is removed including osteophytes which may be present, and the posterior longitudinal ligament is

opened. No consensus exists about supplementary fusion of the vertebral end plates. In the past, autologous bone from the iliac crest was used to fill the gap in the open disc space. Pain in the iliac crest area directed surgeons to the use of cement and later to cages filled with bone, the latter followed by an anterior plate and screw fixation of both vertebrae in some countries. Recently, disc prostheses have been used with the goal of preserving cervical mobility and thus preventing future disc degeneration at adjacent levels. To emphasize the variety of procedures used for the same disease, it can be noted that many surgeons prefer to perform a discectomy without any graft, cement, cage, or prosthesis. Lack of scientific data and huge industrial influence are the main reasons for this lack of consensus. Randomized trials are started to provide better insight in the value and (cost-)effectiveness of the different techniques.

Thoracic spine

Thoracic disc herniations are frequently ossified and have a very low incidence. Furthermore, patients with a thoracic disc herniation most frequently present with spinal cord compression, with the risk of severe motor and sensory disturbances of the lower extremities and bladder dysfunction. This leaves the thoracic radicular syndrome as a comparatively minor problem. Probably, because of the calcifications within thoracic disc herniations, posterior approaches have had poor results with frequent neurological complications leading to a more severe deficit compared to the preoperative status. Two approaches exist at present. Because of the low incidence of thoracic disc herniations patients are treated in specialized centers, reducing the risks of surgery.

- The posterolateral approach employs costotransversectomy, and provides access by removing the proximal rib and transverse process. This classical approach has recently been replaced by a less invasive microscopic approach. This posterolateral approach is suitable for soft disc herniations.
- The anterolateral approach makes use of a transthoracic technique. These procedures have less risk of spinal cord injury, but are more complex. Large thoracotomy approaches with division of the diaphragm at the disc level between the 12th thoracic and 1st lumbar vertebrae have nowadays been replaced by thoracoscopic techniques and more recently by mini-open thoracotomies using an incision of less than 4 cm and normal ventilation of both lungs.

Lumbar Spine

The procedure most frequently performed in neurosurgical practice is the lumbar (micro)discectomy. One in every 1,000 person is operated for a lumbar disc herniation in the United States. The timing of surgery varies considerably as well as the surgical technique. The timing of surgery is subject of a randomized trial in Europe (2), whereas a trial in the United States sets out to determine the effectiveness of surgery compared to conservative treatment (3). Surgical interventions can be divided into percutaneous techniques indirectly decompressing the nerve root by intradiscal action and posterior surgical techniques, actually removing the disc herniation and therefore direct decompression. Anterior decompressions are highly unusual.

- After the first description in 1934 of removal of a lumbar disc herniation by laminectomy (4), this technique was the method of choice for many years. The goal was a complete posterior decompression of the dural sac and removal of as much disc material as possible. This historical technique was suitable in the times before CT and MRI but did destabilize the spine and is not considered as the usual care any more.
- After the introduction of the microscope for intracranial procedures, application of this technique to spine surgery is followed. The major difference with the classical broad laminectomy is the less invasive approach with limited bone removal. Randomized trials have not shown any benefit of the microdiscectomy when compared with classical approach (5). Recent reports deal with selective removal of extruded material leaving the disc intact. This procedure lacks evidence of effectiveness, so far prohibiting worldwide implementation.
- The MED approach uses a 14–18 mm wide tubular dilator system splitting the paravertebral muscles without dividing them. Use of an endoscope facilitates angulation of the optics in the spinal canal, but most surgeons use the microscope. This technique has recently been introduced and is the subject of a randomized trial comparing MED with microdiscectomy with the goal to look at the effectiveness of early recovery and resumption of daily activities.

The main disadvantage of all new techniques is the relatively high recurrent rate of disc herniations of up to 10%. Until randomized controlled trials present at least comparable effectiveness and a low recurrence rate, the classical microsurgical approach is the gold standard.

Imaging

MRI scanning is now the method of first choice to define the surgical approach with the goal of decompressing a lumbar nerve root. However in the cervical spine, a CT scan may be beneficial when bony compression is suspected or even an ossified posterior longitudinal ligament. The surgical procedure may be altered depending on the presence and location of calcifications. The same holds true for the thoracic spine, where some surgeons also prefer to have spinal angiography performed to localize the Adamkiewicz artery, the major spinal cord feeder, before deciding on the side of a transthoracic approach.

Postoperative imaging is done frequently as a routine measure in thoracic and cervical pathology, but after surgery of lumbar disc herniations only when complaints persist or recur.

Radiculopathy

▶Spinal Nerve Roots, Clinical Syndromes

Radio-Opacity

▶Pulmonary Opacity, Extensive Pattern

Radiocontrast Media

▶Contrast Media, Iodinated, Applications in Conventional Radiography and CT

Radiofrequency Ablation, Hepatic Tumours

Percutaneous image-guided technique in which radiofrequency (RF) waves are used to induce thermal ablation of neoplastic tissue. It represents the most assessed method for percutaneous thermal ablation of hepatic malignancies.

▶Interventional Hepatic Procedures

Radiographic Contrast Media

▶Contrast Media, Iodinated, Applications in Conventional Radiography and CT

Radiographic Iodinated Contrast Media

A radiographic iodinated contrast medium is an imaging contrast agent in which iodine, bound to organic molecules, provides the increased attenuation to X-rays required for visualization.

▶Adverse Reactions, Iodinated Contrast Media, Acute Renal

Radiolabeled Colloid Particles

For the purposes of SLN detection and lymphoscintigraphy, labeled colloids are the most appropriate radiotracer.

▶Sentinel Node, Scintigraphy

Radiological Tumour Ablation, Hepatic Tumours

This consists in the direct, image guided, application of chemical (ethanol or acetic acid) or thermal (radiofrequency, laser, microwaves and cryoablation) therapies

to a specific focal liver tumour in an attempt to achieve eradication or substantial tumour destruction.
▶Interventional Hepatic Procedures

Radionuclide Cystography

Scintigraphic examination with direct or indirect administration of radionuclide for exclusion or detection of vesicoureteral reflux.
▶Contrast Media, Ultrasound, Applications in Vesicoureteral Reflux

Radiotracer

A very small mass of the molecule of interest that is radiolabelled to evaluate the behaviour of the compound of interest.
▶PET in Drug Discovery Imaging

Ramsay-Hunt Syndrome

A herpetic inflammation of the sensitive ganglia of cranial nerves usually affecting cranial nerves V, VII and VIII. It manifests clinically with acute peripheral facial nerve paralysis and vesicular eruptions over the ear, face and neck.
▶Facial Nerve Palsy

Raynaud's Phenomenon

Raynaud's phenomenon describes a neurovascular dysregulation with pathological excessive vasoconstriction and a consecutive ischemic phase as a reaction to cold application affecting the fingers, hands, and facultatively the forearms. Typically the skin discoloration follows a time course with primary paleness, then a livid aspect, and subsequent reddening in the phase of painful hyperemia. Raynaud's phenomenon occurs primarily (idiopathic) and secondarily, for example, in association with scleroderma, thromboangiitis obliterans, cryoglobuline disease, or intoxication.
▶Connective Tissue Disorders, Musculoskeletal System

Raynaud's Syndrome

The most common cause of upper limb ischemia. It is characterized by episodic attacks of vasospasm caused by closure of the small arteries of the most distal parts of the extremity in response to cold or emotional stimuli.

Definitions

Receptors are proteins on the cell membrane, in the cytoplasm, or in the nucleus of the cell that bind ligands such as neurotransmitters, hormones, or others. This interaction between the receptor and its ▶ligand initiates a cellular response. The profile of expressed receptors is different for cells with different functions. In many neoplasms, the cellular production of certain receptors is upregulated, and therefore they are overexpressed.

The specificity of different receptors for their ligands varies. While certain receptors bind mainly one specific ligand (e.g., somatostatin receptor), others, like megalin, have a broad array of ligands.

Ligands are molecules that bind to the receptor. They can be divided into receptor agonists and antagonists. Agonists initiate a cellular response after their binding to the receptor, whereas antagonists occupy the binding site of a receptor without causing a response.

R

Characteristics

Nuclear medicine offers the opportunity to visualize receptors by labeling a ligand with a radionuclide suitable for imaging. The radiolabeled ligands used are mainly molecules similar to the natural ligand, often peptides. Beside peptides, other ligands such as antibodies, parts of antibodies, or artificial molecules can be used. These ligands can be from both categories, either receptor agonists or receptor antagonists. Both are potentially suitable for receptor imaging. Antagonists have the disadvantage that they are mostly not internalized into the cell, which often results in a shorter retention time of the radioactivity in the target.

Radiolabeled ligands have to fulfill a number of prerequisites such as metabolic stability, high receptor affinity, favorable toxicity profile, and stable binding of the radionuclide to be useful for *in vivo* imaging.

Not only the radiolabeled ligand but also the receptor must fulfill a number of prerequisites. To visualize a tumor, the target receptor has to be overexpressed on the tumor cells. In addition, an exclusive expression of the target receptor on the tumor is desirable to achieve a higher tumor-to-non-tumor ratio with the radiolabeled ligand. Generally, the higher the expression of the target and the more exclusively the target is expressed on the tumor, the higher the sensitivity for the consecutive imaging procedure. Other important parameters determining the success of tumor receptor imaging are localization of the receptor on the cell and the biological behavior of the receptor after the binding of the ligand (e.g., internalization or receptor recycling).

Receptor-Mediated Radionuclide Therapy

Apart from receptor imaging, receptor-mediated radionuclide therapy is an emerging field in nuclear medicine for treating malignant, metastatic tumors. Receptor-mediated therapy represents a derivative of receptor imaging. The diagnostic radionuclide is replaced by a therapeutic most often beta particle emitting. All the aspects mentioned in receptor imaging about vector and target receptor hold true for therapy as well or are even more important, such as the exclusive expression of the target receptor on the tumor.

Somatostatin Receptor Imaging

The ▶somatostatin receptor (sst) as a target molecule and octreotide or related peptides as cognate ligands can be regarded as a well-established model of tumor receptor imaging and therapy. This model is exemplary for receptor imaging, and the principles hold true for the whole field of receptor imaging (1).

Although somatostatin receptors are present in a large number of healthy organs, including the pancreas, adrenals, pituitary gland, and many more, these receptors have been proven to be highly valuable for tumor imaging and therapy in nuclear medicine. The reasons for the success are multifaceted. A crucial point is that in many neoplasms, mainly neuroendocrine tumors, the overexpression of the sst is very pronounced, resulting in a high tumor-to-non-tumor ratio for the radioligand. Besides the neuroendocrine tumors, a number of tumors, including pheochromocytoma, paraganglioma, lymphoma, small cell lung cancer, and many more, express the sst as well (2).

Two natural somatostatins are known and consist of 14 or 28 amino acids, respectively. Accordingly, the peptides are called SS-14 and SS-28. As neurotransmitters with endocrine and paracrine function *in vivo*, the peptides are degraded rapidly by peptidases. The serum half-life of these peptides in blood is approximately 2 min, which is too short to qualify natural somatostatin as a candidate for imaging when radiolabeled.

The breakthrough in sst imaging was made when the octapeptide octreotide was developed. This small ▶peptide is metabolically more stable and has a plasma half-life of approximately 1.7 h. Initially, the nonradiolabeled octreotide was developed to be used as drug for inhibiting the secretion of growth hormone, which is the physiological action of somatostatin.

Later on, octreotide was conjugated with a ▶chelator for radiolabeling. A chelator is the link between the vector and the radionuclide. It is needed for stable binding of the radionuclide. Labeling of peptides without a chelator is possible by halogenation—for example, with iodine isotopes—but the binding between the vector and the isotope is often not as stable after injection as with a chelator, and free radionuclide may reduce image quality or, especially in therapeutic applications, cause serious side effects. For octreotide and related peptides, the most frequently used chelators are diethylene triamine pentaacetic acid (DTPA) and tetra-azacyclo-dodecane-tetraacetic acid (DOTA). Both chelators can be labeled with a number of isotopes of different elements, such as indium, yttrium, lutetium, or gallium. Recently a number of octreotide analogs with other chelators, such as HYNIC were developed to enable labeling with the widely available ^{99m}Tc. The advantages of peptides labeled with ^{99m}Tc are various; the most important are that the physical characteristics of ^{99m}Tc are ideal for imaging, that ^{99m}Tc is relatively cheap, and that it is constantly available in nuclear medicine departments.

Five subtypes of the sst are known (sst 1–5). From an oncological point of view, sst subtype 2 is the most relevant, as mainly this subtype is overexpressed in neoplasms. Over the last years, many improvements of the ligand's characteristics have been achieved. Modifications in amino acids have resulted in a number of peptides with higher affinity for the sst, which leads to a more favorable biodistribution.

Most recently, several octreotide derivatives, labeled with positron emitters, were developed. These allow scanning of patients in a positron emission tomography (PET) scanner, resulting in higher resolution and, therefore, higher accuracy. The radionuclides used for this purpose are mainly ^{18}F, ^{68}Ga, ^{86}Y, and ^{64}Cu. Depending on the radionuclide used, differences in chelators and, consequently, in radiochemistry apply. Yttrium-86 plays a special role in this context: It is the ideal surrogate for ^{90}Y, and therefore it allows pretherapeutic dosimetry. However, the physical characteristics are not ideal for PET imaging because of additional, highly energetic gamma radiation (Fig. 1).

Iodine-labeled compounds, briefly mentioned earlier, are most valuable for *ex vivo* receptor imaging, such as autoradiographies. This form of receptor imaging with ^{125}I-labeled compounds allows precise correlation of receptor density and localization with histology.

For ►*in vivo* receptor imaging by means of nuclear medicine, it is mandatory that the receptor–vector complex after the binding of the radiopharmaceutical remain stable among the targeted tumor. The sst is a transmembrane receptor. The binding domain is located on the cell surface and therefore easily accessible for the ligand. After binding, the receptor–ligand complex is internalized, and chelated radionuclides remain captured in the cell. This results in a fairly stable residence of the radioactivity in the target cell. Consequently, a higher target-to-non-target ratio for imaging can be expected after most of the nonreceptor-bound radiopharmaceutical is cleared from the organism, which in turn is necessary for therapeutic applications.

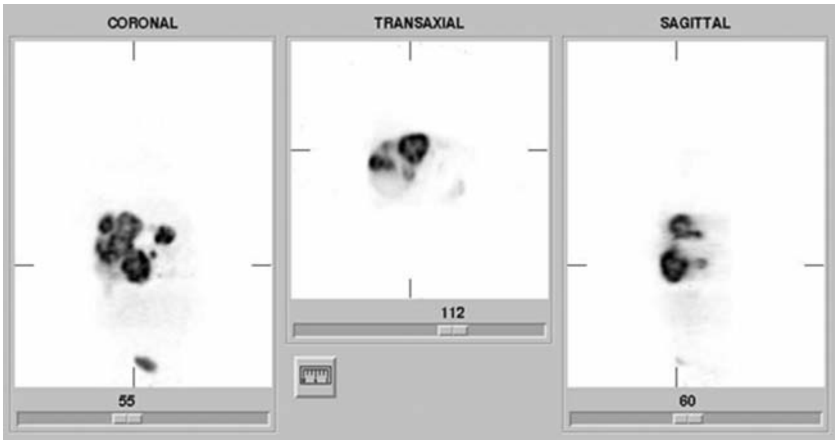
Imaging of somatostatin receptors became a standard procedure for staging patients with sst-positive tumors and for characterizing suspect nodules *in vivo*. Moreover, it is prudent to perform an sst scan to prove the presence of a sufficient density of receptors on a tumor before planning a receptor-mediated radionuclide therapy.

In summary, sst imaging plays a key role in the following:

1. Diagnosis and Characterization of tumors
2. Determining the extent of disease (staging)
3. Selecting patients who are candidates for targeted radionuclide therapy
4. Predicting the response during targeted radionuclide therapy
5. Monitoring therapy.

Other Cell Surface Receptors, Imaging with Peptides

Besides somatostatin receptors, a number of other cell surface receptors are overexpressed in tumors and are



Receptor Studies, Neoplasms. Figure 1 **Coronal, transaxial, and sagittal slices of a positron emission tomography scan acquired with [^{68}Ga-DOTA^{0},Tyr^{3}]-octreotide (^{68}Ga-DOTATOC) in a patient with a metastatic neuroendocrine tumor and multiple liver metastases. DOTATOC is an octreotide analog with a high affinity for sst 2. Because of the high affinity and specificity of the radiotracer, high uptake is seen in the multiple strongly sst-positive liver metastases. Low physiological uptake is found in the liver. The tracer is rapidly cleared from the body *via* the kidneys to the urine; therefore, the urinary bladder is visible as well. The fast clearance results in very low background activity; therefore, no activity is present in the thorax. (Scan acquired at Deutsches Krebsforschungszentrum, Heidelberg, Germany, courtesy of Professor U. Haberkorn)**

suitable for imaging with radiolabeled peptides. A selection of the most promising combinations of peptides and receptors that are currently under investigation or that are used in clinical trials is summarized in Table 1 (3).

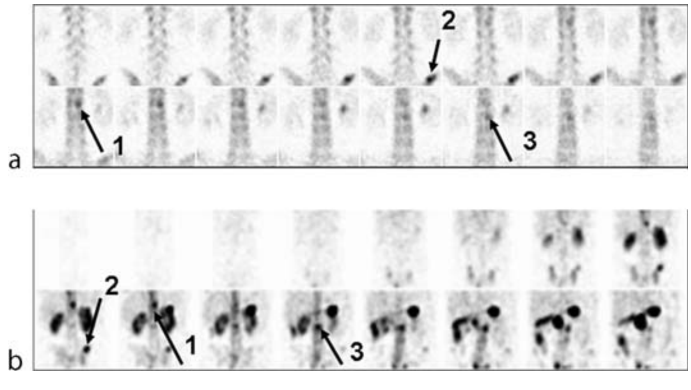
As one of the peptides binding to a cell surface receptor, bombesin deserves highlighting. Bombesin is a 14-amino-acid neuropeptide. In mammals, it binds to three known receptors: bombesin receptor 1–3 also called neuromedin B receptor, gastrin-releasing peptide (GRP) receptor, and bombesin receptor subtype 3. Several peptides with high affinity for the GRP receptor have been developed, comparable to somatostatin, labeled with an array of radionuclides. Overexpression of GRP receptors has been found on many neoplasms, especially in prostate and breast cancer. Remarkably, the GRP receptor is not expressed in healthy prostate tissue. This might provide the chance to distinguish *in vivo* between benign and malignant prostate nodules by means of receptor imaging (Fig. 2).

Another highly promising combination for imaging is gastrin or cholecystokinin (CCK) analogs and the CCK subtype 2 (CCK 2) receptor, also called gastrin receptor. The CCK 2 receptor is overexpressed in medullary thyroid cancers (MTC). Relapse of MTC can be diagnosed by elevated levels of calcitonin in the blood, but localization is often inconclusive. In these cases, scintigraphy with radiolabeled gastrin analogs is of high value.

A third example is the combination of radiolabeled neurotensin and the three subtypes of the neurotensin receptor. Neurotensin receptors are overexpressed in ductal pancreatic adenocarcinoma. First clinical evaluations for diagnostic purposes have been made with a metabolically stabilized ^{99m}Tc-labeled peptide.

Receptor Studies, Neoplasms. Table 1 Selection of promising peptide-receptor combinations for *in vivo* receptor imaging with radiolabeled peptides

Tumor	Receptor	Vector
Gastroenteropancreatic tumors, neuroendocrine tumors, paraganglioma, pheochromocytoma	Somatostatin	Octreotide and derivatives
Prostate carcinoma	Gastrin-releasing peptide	Bombesin analogs
Medullary thyroid carcinoma	Cholecystokinin (CCK) subtype 2	Gastrin/CCK analogs
Ductal pancreatic adenocarcinoma	Neurotensin	Neurotensin analogs
Gastrointestinal cancers	Vasoactive intestinal peptide (VIP) receptor	VIP analogs
Insulinoma, gastrinoma	Glucagon-like peptide 1 (GLP 1) receptor	GLP analogs
Glioma	Neurokinin 1 receptor	Substance P analogs



Receptor Studies, Neoplasms. Figure 2 Coronal slices of two single photon emission computed tomography scans in a patient with metastatic prostate carcinoma. (a) Bone scan with ^{99m}Tc-dicarboxypropane-diphosphonate (DPD). Three bone metastases can be identified in the spine and pelvis (*arrows* 1–3). (b) Corresponding images from a scan with [^{111}In-DTPA-Pro^{1},Tyr^{4}]-bombesin. The same metastases as in the bone scan are detected (*arrows* 1–3). The high tumor-to-background ratio indicates a high density of GRP receptors.

Intracellular Receptors

To date, intracellular receptors are of minor relevance in oncological imaging. A number of studies have been published using radiolabeled estrogens to visualize estrogen-receptor-expressing breast cancers, or radiolabeled androgens to visualize prostate cancers. Although a first study with bromated (^{77}Br) estrogen was published in 1982, it never reached broad clinical impact. These days, fluorinated (^{18}F) derivatives for PET imaging, consecutively achieving better resolution, are available (4).

Receptor Imaging with Antibodies

▶Antibodies are of emerging importance for medicine in general. Development of immunohistochemistry was revolutionary for pathological diagnostics. Clinically, antibodies are widely used in oncology, and the first radiolabeled antibodies recently received US Food and Drug Administration approval for cancer treatment. Nevertheless, the use of radiolabeled antibodies for *in vivo* receptor imaging is limited. The long circulation time, the slow pharmacokinetics in general, and the physiological uptake of radiolabeled antibodies in a number of organs result in high background activity and, therefore, in an unfavorable tumor-to-background ratio. However, visualization of the HER2 receptor, which is overexpressed in many breast cancers, with radiolabeled trastuzumab is feasible. These findings are of clinical interest because nonradiolabeled trastuzumab is an established treatment for HER2-positive breast cancers.

A possible way to overcome the slow pharmacokinetics of antibodies is the use of fragments or artificial derivatives such as diabodies, triabodies, minibodies, and dimers and trimers. The advantage of antibodies and derivatives is that these molecules can be bioengineered to target a specific receptor (5).

The eligibility of antibodies to be designed for a specific target makes them highly valuable for *in vitro* and *ex vivo* receptor studies when the kinetics are negligible.

Synonyms

breast cancer recurrence; Breast cancer relapse; ipsilateral breast tumor recurrence; recurrent breast cancer

Definition

In general terms, breast recurrent neoplasms (BRNs) are neoplasms that are diagnosed during the follow-up of patients with breast tumors, after some kind of treatment. Normally, surgical removal has been carried out on the breast and the primary neoplasm has apparently been completely removed or disappeared. It can occur either in the scar margins or near the place where the primary neoplasm was removed (▶local recurrence or LR), in close areas around the same breast (▶regional recurrence or RR), or in other distant organs (distant recurrence or metastasis, ▶DR).

Characteristics

Benign and malignant breast tumors can recur. With benign tumors, it is well known that cysts may appear full again some weeks or months after aspiration and pneumocystography. Fibroadenomas, papillomas, adeno-myoepitheliomas, and other benign masses can also recur after cryoablation and even after surgical removal, always in the same place or on the margins of surgical scar.

The most characteristic recurrent benign breast tumor is cystosarcoma phyllodes. This tumor, arising from the stroma, may be categorized benign or malignant. Both types increase in size very quickly and should be suspected if a fibroadenoma grows too fast or recurs following surgical removal. LR may predict metastases even in patients with histologically benign disease. Distant metastases are not frequent and tend to locate in the lung and more rarely in bone and liver. Consequently, when a phyllodes tumor is diagnosed, wide local excision is the treatment of choice, with a 2-cm margin or fascia included in the specimen. Axillary node dissection (AND) is not usually carried out, as lymph node metastases are extremely infrequent.

For malignant tumors, four different kinds of BRNs are usually considered (1):

Local Recurrence (LR)

Breast cancer very frequently (75%) recurs in the same area as the original cancer was located. Women with a ductal carcinoma *in situ* (DCIS) who are treated with breast-conserving therapy (BCT) are at a slightly higher risk of recurrence than those who are treated with mastectomy. However, an LR following BCT of DCIS does not imply a poorer long-term prognosis than mastectomy as initial surgical treatment. Even after mastectomy, portions of the breast skin and fat remain, and LR is possible although more uncommon.

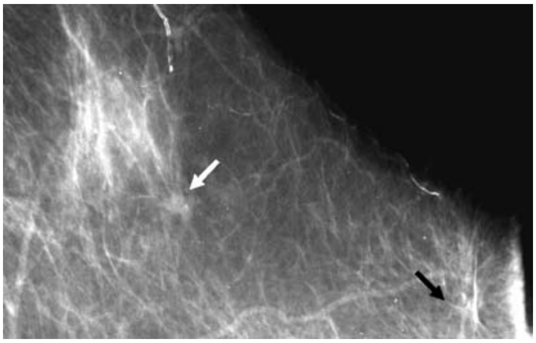
Most reports of patients treated with BCT indicate a median time to recurrence of 40–52 months. Although most recurrences develop within 5 years, a small but constant risk remains for several decades thereafter. Interestingly, the recurrence rate in the tumor bed is approximately 2% per year until year 5, after which it drops significantly. LR can also be *in situ* or invasive. The first is less serious than an invasive recurrence, since this means a second chance of metastasis.

Regional Recurrence (RR)

It is a situation where tumor cells can be demonstrated in the axillary lymph nodes or well in the pectoral muscles, internal mammary lymph nodes, or supraclavicular or cervical nodes. RR of breast cancer is uncommon, occurring in approximately 2% of the cases. Most often, RR appears as a cancerous axillary lymph node not removed during primary lymphadenectomy. RR in the cervical lymph nodes or above the collarbone usually indicates more aggressive cancers.

▶New Neoplasm (NN)

During follow-up after breast surgery, apart from LR and RR new, different neoplasms can be detected. In fact, patients who have had breast cancer are considered at high risk of suffering from a second breast cancer. Usually, this new tumor is in a different area of the breast and does not have the same pathological characteristics (histological type, grade, or hormonal receptors) (Fig. 1). Second cancers are treated as new cancers, independent of the first one.



Recurrent Neoplasms, Breast. Figure 1 **Patient treated with breast-conserving therapy for ductal carcinoma *in situ* 7 years previously. There is a new density (*white arrow*) that was not present in the mammogram taken 1 year earlier. The surgical scar presents normal characteristics (*black arrow*) and the new tumor is more than 5 cm away from it. The location of this lesion and the time elapsed from surgery suggest a new tumor, more than a local recurrence. This was an invasive lobular carcinoma.**

Distant Recurrence (DR)

It is also known as metastatic disease and means that malignant cells are present in a distant place, most commonly in bones, lungs, liver, brain, or other organs. This is a serious event and the survival rate of women with this disease is considerably lower than for women whose cancer is confined to the breast or axillary lymph nodes. Breast cancer has the potential to spread to almost any region of the body.

Diagnosis

Local and Regional Recurrences

Women whose initial breast cancer was aggressive are more likely to have LR. Inflammatory breast cancer often recurs. Also, women with large tumors or several affected axillary nodes may frequently experience recurrence. The LR for DCIS can be intraductal or invasive and the rates appear somewhat higher than those of invasive tumors. Multifocal DCIS with microinvasion has a high LR rate. Patients at exceptionally high risk of recurrence or development of a second primary tumor should be watched more closely.

LR after mastectomy will usually present itself as a small lump in the mastectomy scar or under the skin. This type of recurrence often goes undetected for some time because it may be mistaken for a leftover stitch or scar tissue from the mastectomy. Breast reconstruction rarely hides recurrent breast cancer. LR with implants is most often in front of the implant, and recurrences with ▶transverse rectus abdominis musculocutaneous (TRAM) flap procedures are along the edge of the breast skin, and not in the flap. LR following BCT usually appears at the surgical site.

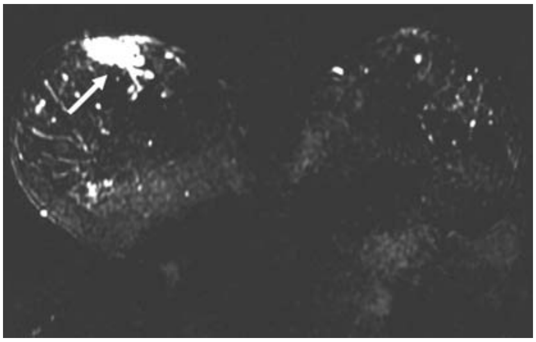
Detection of LR and RR is usually made by clinical history, physical examination, and breast imaging techniques. An adequate clinical examination of patients after BCT or mastectomy should include the breasts, especially the scars, but also axillary, supraclavicular, and cervical areas. Mammography (MX), ultrasonography (US), and magnetic resonance imaging (MRI) are the most useful imaging techniques. Nonpalpable LR or RR can be diagnosed using needle localization with excision biopsy or imaging-guided percutaneous biopsy, using stereotactic MX, US, or MRI to localize and puncture the suspicious lesion through a small incision (several millimeters in length) with the patient under local anesthesia. US is preferred whenever the lesion is clearly identifiable by this technique. According to the thickness of the needle, the most widely used techniques are fine-needle aspiration cytology (FNAC), large core needle biopsy (LCNB), and vacuum-assisted biopsy (VAB).

Patients must be routinely followed up by physical examination and should annually undergo bilateral MX after BCT. In patients with radical mastectomy, with or without reconstruction, only contralateral MX will be done. MX is important for the early recognition of recurrence; unfortunately, however, normal changes seen on mammograms resulting from BCT may mimic the signs of malignancy. Baseline MX should be performed approximately 6 months after BCT and the completion of all treatments.

The natural history of the postirradiation mammogram includes a slow but progressive return to normal degrees of breast fibrosis, skin thickening, and glandular parenchyma. The radiological signs of LR are the same as those in an unirradiated breast and include new cluster calcifications, asymmetric densities, or occasionally a preexisting scar increasing in size. Breast fibrosis in the area of the tumor bed can persist for many months and can be confused with recurrence. Dynamic MRI studies have shown the highest sensitivity in making a differential diagnosis between hypertrophic scar fibrosis and LR (Fig. 2).

Frequently, fat necrosis and oil cysts may also appear near the surgical scar, resembling recurrence. Dystrophic calcifications or early calcifications of liponecrosis can also simulate recurrence. In these cases, percutaneous biopsy should be undertaken in order to detect recurrence.

US is a well-known adjunct technique and is more necessary in investigations of dense breasts or areas where density is higher, because the sensitivity of MX is lower. US should also be carried out in patients with BCT, mastectomy followed by reconstruction, and even simple



Recurrent Neoplasms, Breast. Figure 2 Dynamic MRI study with subtraction technique, showing a captation of contrast in the margins of the surgical scar (*arrow*). The patient had been treated 3 years previously with breast-conserving therapy.

mastectomy in order to detect LR, especially the characteristics and evolution of the scar, and also to detect RR in axillary, supraclavicular, or cervical lymph nodes. The size, shape, outline, echogenicity, and proportion of the hilus/cortex must be evaluated. This is more important in cases when only a sentinel lymphatic node biopsy (SLNB) was done with benign results and consequently AND was not carried out. Suspicious nodes should be punctured under US guidance, by FNAC or even by LNCB.

US is also very accurate in studying implants in patients with postmastectomy reconstruction.

Once an LR or RR is detected, several tests must be ordered to determine whether the tumor has metastasized to distant organs.

New Neoplasms

Patients who have had previous breast cancer have a higher risk of presenting a second neoplasm. These tumors, which can appear clinically or on a follow-up mammogram, are usually located in a different place or in the contralateral breast.

The recurrence rate outside the immediate tumor bed is negligible until the 5th year, after which it increases to 1% per year.

Detection and diagnosis of new neoplasms following BCT are made in a way similar to primary carcinomas and to LR: by clinical history, physical examination, or by imaging techniques (MX, US, and MRI). Nonpalpable lesions are usually diagnosed by needle localization with excision biopsy or by imaging-guided percutaneous biopsy. US is preferred if the lesion is clearly identifiable by this technique. FNAC, LCNB, and VAB are the most common procedures.

Distant Recurrence

Metastatic disease is the most advanced stage (IV) of breast cancer. It can spread to almost any organ of the body, but the most common sites are bone, lung, liver, and brain. The ovaries, spinal cord, eye, and other areas are less commonly affected. Symptoms of DR may include bone pain, shortness of breath, lack of appetite, weight loss, weakness, headaches, and other symptoms depending on location of the lesions.

Systemic relapse is more frequent after LR and even more so in patients who have suffered RR.

DR is usually diagnosed by bone scan, chest X-ray, US, computed tomography (CT), MRI, or liver blood tests. The two most important marker tests for breast cancer are CEA (carcinoembryonic antigen) and CA 15-3, which tend to be elevated in women with metastatic breast cancer, although their sensitivity and specificity are not too high.

Prognosis and Treatment

Young age, positive surgical margins, and omission of radiation therapy (RTP) significantly predict ipsilateral breast tumor recurrence and this situation is correlated with DR. Among the patients who develop LR, initial lymph node metastasis and short interval to LR are significant risk factors for subsequent DR (2). The prognosis for patients with LR after initial BCT for invasive breast cancer has been reported by multiple groups, with 5-year survival statistics ranging from 35 to 81%. The prognosis is clearly better when LR is diagnosed more than 5 years after BCT (3). The high incidence of DR in this group suggests that these patients might benefit from systemic adjuvant therapy. Little information is available on this subject, but prospective trials are being planned to address this issue.

Patients treated for intraductal cancer with breast conservation have an excellent survival prognosis with LR figures of 6–10%. However, at least 20% of recurrences have an invasive component of low volume. Further observation is necessary in order to determine whether these patients are at substantial risk for systemic cancer spread.

LR following BCT can be treated with conservative re-excision or, more often, mastectomy with or without reconstruction, since RTP cannot be delivered twice to the same area. Patients who undergo reconstruction with an implant have poor cosmetic results and an increased incidence of complications. These complications may be related to loss of skin elasticity due to prior surgery and irradiation. However, to achieve optimal cosmetic results, most patients undergoing reconstruction will undergo a tissue transfer procedure such as a TRAM flap.

If the initial treatment was mastectomy, recurrence near the mastectomy site is treated by removing the tumor whenever possible, usually followed by RTP. In either case, hormone therapy and/or chemotherapy may be used after surgery and/or RTP. If breast cancer is found in the other breast, it may be a new tumor unrelated to the first breast cancer. Treatment includes a lumpectomy or mastectomy and, sometimes, systemic therapy. NN are treated as new cancers, independent of the first tumor.

Surgery is rarely an option for metastatic breast cancer because the cancer is not usually confined to one specific spot on the given organ. It may be recommended only to relieve certain symptoms. Treatment options include one or more of the following: chemotherapy, hormonal therapies, or RTP. Radiofrequency can be carried out as a treatment for lesions that are not extensive. Bisphosphonates and RTP may be helpful in treating the effects of bone metastases. Immunotherapy with trastuzumab (Herceptin) alone or with chemotherapy may be recommended for women whose cancer cells have high levels of the HER2/neu protein.

The outcome and treatment of LR of breast cancer depends more on a patient's menopause status and the clinical and tumor characteristics of the initial tumor than on other factors. The risk of death significantly increases in women with LR of breast cancer when the initial tumor was greater than grade 2, the time interval without cancer was less than 8 years, and the age at diagnosis of the primary tumor was greater than 60 years.

The type of surgery for the initial, primary breast cancer does not alter mortality risk. Although no specific treatment can change the risk of death after LR in postmenopausal women, premenopausal women benefit from treatment with either surgical or irradiative ovarian suppression or chemotherapy.

In a recent retrospective study of 1,636 patients with early stage breast cancer who were treated surgically with either breast-conserving surgery or mastectomy, two cohorts were identified. The first comprised 105 patients who experienced an isolated LR. Seven potential factors were considered: initial size of the primary tumor, tumor grade by pathology, axillary lymph node status, date of initial diagnosis, age at diagnosis, time interval without cancer recurrence, and the type of treatment for initial tumor and LR. The authors identified a second subgroup of 335 patients who developed distant metastases as the first recurrence. Data from these two subgroups were analyzed for survival.

Patients with a grade 3 tumor had a threefold increased risk of death. Patients over 60 years old at the time of diagnosis of the primary cancer had a twofold increased risk of death. Patients who experienced over 8 years without recurrent tumor had a threefold decreased risk of death (4). Significantly, the risk of death after an LR was independent of whether or not the patient's primary cancer was treated with breast-conserving surgery or mastectomy. However, the type of treatment of the LR altered the mortality risk, but only in women of premenopausal age.

Ovarian suppression by either surgical removal of the ovaries or pelvic irradiation and chemotherapy significantly reduced the risk of death, with relative risk values of 0.2 for each category.

Neither breast surgery nor radiation or tamoxifen was associated with statistically significant alterations in the risk of death.

Women with an LR were more likely to survive 10 years than women with a DR; the 10-year survival rates were 56% and 9%, respectively. The median survival for women with LR was 12.9 years compared to 2.2 years for women with a DR.

Because an isolated recurrence carries a relatively good prognosis, mastectomy does not appear to be mandatory for LR after the patient has undergone BCT (4).

Local RTP may be indicated in patients who previously underwent mastectomy, and the use of chemotherapy at the time of recurrence in premenopausal patients may be appropriate.

Synonyms

Gastro-oesophageal reflux; GERD; GORD; Hiatus hernia; Hiatal hernia; Barrett's oesophagus; Columnar lined oesophagus

Definition

All adults in industrialized nations reflux gastric contents into the oesophagus, though most are asymptomatic. Reflux takes place when transient complete relaxations of the lower oesophageal sphincter occur when an individual is recumbent with a sufficient volume of fluid in the stomach. Such relaxations normally occur several times each day, especially when the stomach is full after a meal, usually only two or three times in the day for up to 5 min, and uncommonly at night. At night, when it does occur, it is usually during episodes of light arousal, in REM sleep.

Gastroesophageal reflux disease is defined as an excessive number of such relaxations causing an increase in the time that the oesophagus contains acid, accompanied by symptoms and/or complications of acid reflux into the oesophagus. It is possible, though unusual, for the severest complications to present with very little in the way of preceding symptoms and this is more likely in the elderly amongst whom GERD is much commoner.

Pathology of GERD

The pathophysiology of GERD has been discussed in the previous section on GERD and hiatal hernia, and is intended to be read first. This section describes the clinical presentations of the disease, and the roles of imaging.

Clinical Presentation

In the western industrialized world GERD is common, with between a third and a half of all adults reporting ►heartburn or ►regurgitation at least monthly, though it is much less common in some countries such as Japan where obesity is less common, and there is less fat in the diet (1). Most patients with characteristic symptoms require no imaging and can be managed with anti-acid medication for symptom relief, though this has no effect on the underlying disease process. Five factors exacerbate reflux including pregnancy. Those which are amenable to life style change include being overweight, going to bed at night with a full stomach, caffeine, and alcohol. Smoking has traditionally been included in this list but the evidence for this is very poor. These four life style factors are important in curing or downgrading reflux disease, though once the LES has been totally destroyed it may be too late for recovery. Obesity is critical, and many sufferers find that weight loss provides rapid improvement in symptoms. The radiologist often has the opportunity to discuss these issues briefly after a ►barium meal examination, with those patients who ask questions about their diagnosis.

Obesity and these life style changes however are not the whole story. Patients are seen who are slim, who have reflux disease, and who have had reflux symptoms for years. Rarely, patients are seen in their 20s with long segment Barrett's oesophagus. There is thus a small group of children in whom the "chalasia" of infancy, most often seen with prematurity, persists throughout childhood and may be present in early adult life with symptoms or complications.

Symptoms of reflux arise from any or all of the affected organs. A retrosternal burning is most common, and in advanced disease, acid and gastric content regurgitation which may be positional. Pharyngeal and laryngeal effects include the symptoms of globus, hoarse voice, sore throat, and choking. Cough and asthma are common associations. The oesophageal response with spasm may cause ►chest pain which may mimic angina or myocardial infarct. Stricture or spasm may cause ►dysphagia, and narrowing at the gastro-oesophageal junction may cause dysphagia. Accurate localisation of dysphagia by patients is poor. Hold up at the gastro-oesophageal junction may be experienced higher up and even in the throat, although patients do not normally experience dysphagia below the level of the causative lesion. Oesophagitis may also cause odynophagia - painful swallowing, though this is more common in herpes oesophagitis than in peptic reflux oesophagitis. It is a common experience that patients with globus symptoms often have reflux, but one study from Edinburgh in 1986 failed to confirm an excess time with reduced pH in a group of patients with globus. Prolonged reflux may lead to Barrett's oesophagus and carcinoma. Night time reflux is much more strongly associated with complications than symptoms restricted to the day time, presumably because of prolonged acid contact time.

Recently it has become clear that a number of unexpected symptoms are also part of the GERD clinical complex, including sleep disturbances, bloating, nausea, dry cough, throat clearing, and diarrhoea. Although it is not clear exactly how these symptoms relate to acid reflux, or how distinct GERD is from irritable bowel syndrome and non ulcer dyspepsia, nevertheless several studies have shown that the whole broad symptom complex does respond to the most effective PPI drugs in the majority of patients.

Airway Aspects of GERD

Although minor reflux is usually effectively cleared by oesophageal peristalsis, advanced disease is associated with major regurgitation of large volumes of gastric contents that may overwhelm pharyngeal defences and affect the airways. This may cause choking, asthma or recurrent pneumonia. The typical choking sufferer is an overweight middle aged male patient who, sitting back in an easy chair after a large meal, is surprised by a dramatic attack of choking due to laryngeal spasm associated with reflux. Direct inspection may show laryngeal erythema and oedema and barium study of the pharynx may be normal, or may show a cricopharyngeal bar or mucosal herniation, and sometimes incoordination of the pharynx with supraglottic laryngeal penetration by barium, usually without frank aspiration.

The relationship between asthma and reflux is complex. There are reasons why asthma may cause GERD including that 30% of asthma sufferers have hiatus hernia perhaps because of straining and coughing, and because theophylline medications impair the LES function. There are also reasons why GERD may cause asthma, including microaspiration. The use of PPI therapy sometimes improves cough and wheezing in asthmatics leading to a decreased drug requirement but without change in spirometry. Twenty four hour pH monitoring may not always diagnose GERD, and is positive in only about 45% of GERD sufferers with erosion negative disease, 70% of those with oesophageal erosions and 85% of those with Barrett's. The empirical approach for asthma patients is that where there is a high clinical suspicion of GERD it is reasonable to use high dose PPI therapy with complete acid suppression, as a therapeutic trial for two to six months, and if there is a low suspicion of GERD and the asthma is poorly responsive, then to consider 24 h pH monitoring and to treat those with a positive result (2).

The relation between chronic cough without asthma and GERD is even more problematic. In one study, only 3% with GERD and chronic cough showed response of the cough to PPI therapy, but they responded quickly, so a short trial of PPI of two weeks or so may be sufficient in this group of patients. In chronic laryngitis due to GERD, both symptoms and endoscopic laryngeal findings will resolve though not as fast as in chronic cough, and high dose PPI therapy may be recommended for up to 2–3 months as a therapeutic trial. The radiologist will often be asked to assess patients with cough or asthma for GERD and should assess pharyngeal function for penetration as well as assessing the evidence for GERD.

Some authors suggest that oesophago-pharyngeal reflux occurs excessively after gastro-oesophageal reflux in those GERD patients with respiratory symptoms. However the best way to study this has not been identified, and there is no good data on how to evaluate this phenomenon.

Cardiac Aspects

The relationship between the heart and the oesophagus is no less complex than the respiratory linkage. Indeed, of a series of 200 consecutive patients admitted to a coronary care unit with suspected myocardial infarct, who in fact did not have cardiac disease, extensive investigation showed that 95% were suffering from GERD (3). In distinguishing angina from heartburn it is often helpful that angina lasts 1–2 min or less. However instillation of acid into the oesophagus can cause coronary artery spasm and change in cardiac rhythm, and coronary angiography can cause oesophageal spasm. A drug such as Nifedipine is often used for the treatment of oesophageal spasm, and it can also reduce coronary spasm. A therapeutic trial of PPI drugs to see if chest pain is due to GERD had a test sensitivity of 80% and specificity of 74% in one study. However one PPI drug has been shown to improve angina, with a 10% improvement in stress test, with exercise limit improved by 30% and a decrease in ST segment depression. In difficult cases empiric therapy is required and the diagnosis may be elusive, with GERD and angina not mutually exclusive diagnoses.

Imaging for Gastro-Oesophageal Reflux Disease (4)

Investigation is appropriate for those patients whose symptoms do not respond to simple therapy, or who have alarm symptoms such as dysphagia or anaemia, or who are suspected of having Barrett's oesophagus. In most centres gastroenterologists and surgeons prefer endoscopy as the initial investigation, and some regard barium studies as totally obsolete for this purpose. Barium radiology suffers from there being little scientific data on its value. Most of the abnormalities are observational and not amenable to objective measurement. However endoscopy services are overstretched, and in many countries thousand of patients still have barium meals, often referred by family physicians who do not have ready access to endoscopy. Barium studies are less sensitive for diagnosis of mild and moderate oesophagitis, and for detection and assessment of Barrett's oesophagus. They do however provide a broader overview of the spectrum of abnormalities seen in GERD and, when used with a ►marshmallow solid bolus, are more sensitive than endoscopy for the detection of mild strictures and Schatzki rings. Barium radiology will also allow better identification of that minority of patients with virtually no lower oesophageal sphincter mechanism who will almost certainly require life time therapy and who are at most risk of complications. It is in these patients, particularly if they are young, that operative treatment may be a more sensible option.

Other investigations sometimes useful include nuclear medicine, manometry, and 24-h pH monitoring and these will not be discussed in any detail. Manometry is of most value in patients with chest pain in whom differentiation between cardiac and oesophageal disease remains problematic after endoscopy, barium studies and therapeutic trials; and is also valuable when the simpler studies suggest a primary motility disorder such as achalasia or diffuse spasm. Twenty four hour pH monitoring is mainly helpful for those few patients with heartburn symptoms or chest pain, thought to be of oesophageal origin, who do not respond to PPI therapy.

Barium Meal Examination

There are many ways to perform a barium study of the upper GI tract, but there are two principal choices which depend on the clinical question being posed. One type of study is best suited for the demonstration of peptic ulceration and gastric neoplasm and the other is tailored for the assessment of GERD. The peptic ulcer study requires the use of hyoscine butyl bromide (Buscopan) to paralyse the stomach and duodenum and this interferes with the assessment of oesophageal motility and will promote GE reflux in normal individuals by paralysing the LES. The radiologist therefore has to decide whether the priority is to focus on detection of ulcers, erosions and neoplasms, or to assess reflux disease, but cannot do both optimally in one examination.

Before starting the examination, it follows from the above that the radiologist should first confirm the details of the clinical history with the patient, in order to tailor the examination, and ask specifically about pharyngeal symptoms and dysphagia.

The rest of this section will describe one approach to the assessment of GERD. This also is divided into two groups depending on whether the patient has simple reflux symptoms or has in addition either dysphagia or pharyngeal symptoms, with some additional comments on the investigation of chest pain.

The examination should be planned to answer the following six questions.

Is there GE reflux disease present, and if so what grade? Does it occur only slightly with the water siphon test (normal), is it major with the water siphon test, does it occur with dry swallowing with the patient supine oblique, is it spontaneous on turning, or is it free and constant throughout the examination: in other words is it medical or potentially surgical?

Is there effective clearance of any refluxed material by normal peristalsis?

Is there a motility problem that might contraindicate surgery?

Is there evidence of complications: severe oesophagitis, stricture, scarring, Schatzki ring, or Barrett's oesophagus?

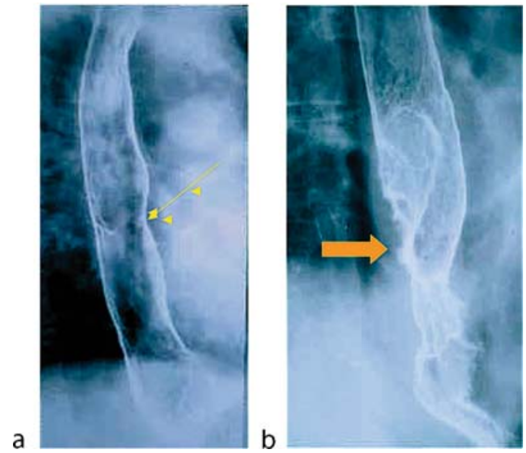
Is there evidence of pharyngeal disease?

Is there a short oesophagus?

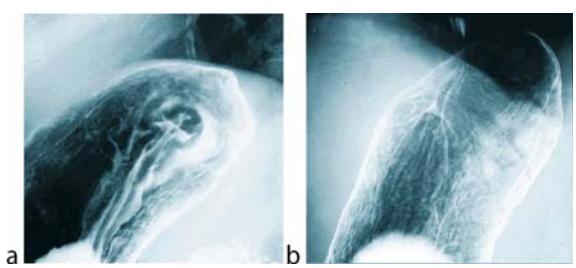
Simple Reflux Examination

The exam is started with the patient erect, turned 45° to the left holding a 150–200 mL cup of high density barium in the left hand and a small cup with 5–10 mL water in the right. Rapid release CO_2 granules are tipped into the small cup and the patient swallows the granules at once followed rapidly by the barium. In countries in which these granules are not available, other granules and citric acid solutions are used to achieve oesophageal distention before the barium is swallowed. Double contrast views of the entire oesophagus and pharynx are taken while the barium is being swallowed, with attempts made to show the LES well distended in double contrast view (Fig. 1). A 16′ intensifier provides a superior examination over smaller intensifiers as the larger field of view allows the tail of the barium column to be seen in the pharynx where premature contraction of the upper sphincter may be noted, while still visualizing the main part of the bolus going down the oesophagus. With smaller intensifiers premature contraction of the cricopharyngeus is more likely to be overlooked.

The table is then rapidly placed horizontal, while the patient is instructed to dry swallow in order to minimize belching of gas. The patient is then turned left and prone, shaken and turned again on the left and supine. A supine film of the entire stomach is taken. The table head is elevated 45°, and the patient turned on the right for an end face view of the cardia and the fundus in double contrast (Fig. 2). With the table horizontal the patient rotates back into supine left side raised position such that half the barium is in the fundus and half in the antrum, for another exposure of the stomach showing the high lesser curve in double contrast. The patient is turned to the left 45° for a double contrast view of the distal stomach, and then views of the duodenum are taken supine oblique to left and right and, if necessary, prone.



Reflux, Gastroesophageal in Adults. Figure 1 (a) This standard double contrast view of the oesophagus shows a dilated oesophagus, with lax lower end, and some slight narrowing and mucosal irregularity in mid oesophagus. These are the characteristic appearances of a long segment of Barrett's oesophagus, in an engineer aged 50. (b) Six years later the patient returned, telling his physician that he had the cancer that he had been warned about as he was having difficulty in swallowing. The films show a long tumour with central ulceration.The patient survived surgery and was well ten years later.



Reflux, Gastroesophageal in Adults. Figure 2 (a) This shows the cardia end face—an essential view in any barium meal examination. It shows the rosette appearance of a competent LES, and it symmetry rules out any tumour at the cardia. (b) In this patient, the sphincter is relaxed and partially opened producing a crescent shadow. If Buscopan or Glucagon has not been given this is moderately reliable evidence of a low pressure sphincter, but the relaxant drugs can change the sphincter tone from the appearance in A to that in B within a few minutes.

Assessment of Reflux

During the traditional gastric and duodenal examination, described above, the lower oesophagus is observed and if hiatus hernia or spontaneous reflux is seen, appropriate films (or video frame grab images for less radiation dose) are taken to document this and clearance of any refluxed barium by oesophageal peristalsis is observed.

If there is free reflux throughout the examination as the patient is turned then the diagnosis of advanced disease is easy. If there is no spontaneous reflux it is more difficult, since for most patients reflux is intermittent. Most radiologists therefore will attempt to provoke reflux, but the correlation of the ease of provokable reflux with severity of GERD has never been clarified. The rate of gastric emptying is relevant, since if the stomach is empty of almost all barium it may be hard to demonstrate reflux even in those with a permanently defective sphincter. At the other end of the spectrum, with a very full stomach, provocative manoeuvres can promote a puff or two of reflux in normal individuals.

Provided that plenty of barium remains in the stomach, the patient is placed supine, left side elevated such that the cardia is lying in a pool of barium, and the patient is asked to make a dry swallow. Some patients who do not reflux spontaneously will reflux on dry swallowing. If there is still no reflux, application of abdominal pressure with the patient in the same supine oblique position may elicit reflux. If there is still no reflux, the patient stays in the same position and is given a cup of water to hold and drinks the entire cup through a straw. Normal individuals will often show a small puff or two of reflux of barium while drinking the water, while GERD patients will often flood the entire oesophagus with this provocative manoeuvre. If reflux has occurred, the water cup is taken away and the patient is asked to make a single dry swallow after which the effectiveness of ►oesophageal clearance of the barium/acid mixture is observed.

Free reflux lying supine with a visibly lax sphincter or repetitive spontaneous reflux to the aortic arch on rolling around with the table horizontal both indicate that the patient has GERD. Reflux to the arch provoked by the patient swallowing water while lying supine with the left side raised (water siphon test) is usually associated with patients with heartburn, with or without a hiatus hernia, but does not indicate advanced disease. Minor reflux to the lower oesophagus with the water siphon test is normal.

Some authors question the value of provocative manoeuvres on the ground that they can make anyone reflux. This however is untrue and also partly misses the point. The vast majority of patients with GERD reflux only intermittently, with occasional LESp collapses. The purpose of this part of the barium study is find out how readily reflux can be provoked by distending the fundus (accepting that a puff or two of reflux into the lower oesophagus with the water siphon test is normal) and just as important, to allow assessment of the effectiveness of oesophageal peristalsis in clearing refluxate. Most patients with advanced GERD have impaired motility with poor clearance which will reduce the effectiveness of medical treatment and predispose them to need surgery.

If during the examination, oesophageal motility has not definitely been seen to be normal, then at the end the patient is turned prone, left side elevated, and is asked to make a single swallow of barium to assess the effectiveness and completeness of primary oesophageal peristalsis. If not totally efficient, three or four more single swallows are observed, to assess whether there is proximal escape, or whether some other motility disorder may be present. It helps if the radiologist warns the surgeon prior to fundoplication if there is significantly impaired motility as these patients are more likely to develop dysphagia following surgery.

If reflux has been observed some advocate doing a detailed examination of the pharynx at this point, at the end of the examination, to look for any associated pharyngeal incoordination.

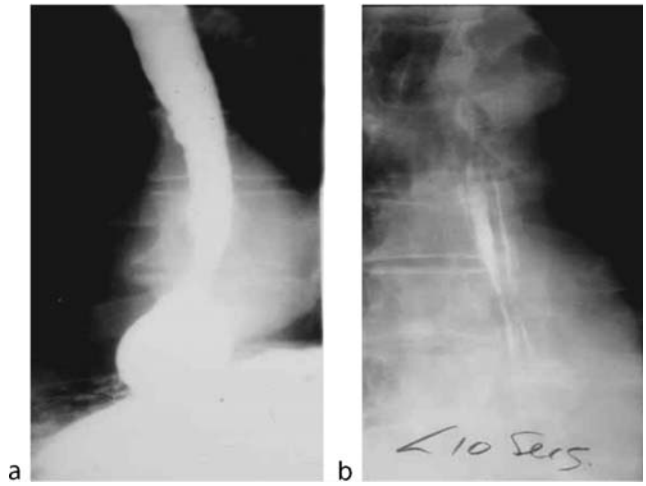
Assessment of Clearance of Refluxed Barium and Acid

Dodd's work showed that clearance of refluxed acid in normal subjects is usually by primary peristalsis. Therefore the radiologist wishing to assess clearance must ask the patient to make a single swallow after reflux has occurred and then observe the efficiency of clearance (Fig. 3). Fine grading is difficult, but after two or three swallows it is usually apparent that clearance is either complete (frequently with a single swallow), only partial or that there is very little clearance. A reflux episode of a substantial volume of barium often produces sufficient distension to initiate a secondary peristaltic wave which may also be observed to be either completely or partially effective. If this secondary peristalsis fails to empty the oesophagus, the patient should be asked to make some discrete single swallows so that the effectiveness of primary peristalsis can be assessed

Examination of Patient with Dysphagia or Pharyngeal Symptoms

In these patients, in addition to the standard examination described above, examination of the pharynx is required at the start, motility is assessed towards the end of the study and a solid bolus is used at the end.

The examination starts with the patient standing, at right angles to the table to allow a lateral view of the pharynx. Oblique views of the pharynx should be avoided as they are hard to interpret, but if the shoulders are slightly turned while the neck is maintained in the lateral projection, this allows visualization of the upper oesophagus as well as the lateral view of the pharynx. The unit is set for either rapid sequence digital filming or video-recording, whichever is available. The patient is asked to take in a small mouthful of barium and hold it in the mouth. Recording is started and the patient is asked to swallow. If normal, a larger single swallow is then used. The patient is then positioned for an AP projection and a further swallow is made and recorded. 30 frames/sec video recording will usually show any webs clearly, but these are more readily appreciated with dilute barium and a true lateral projection. For this reason, some radiologists prefer to examine the pharynx at the end of the examination so that they can use dilute barium without impairing coating of mucosa in the early part of the study.



Reflux, Gastroesophageal in Adults. Figure 3 (a) This patient has had a major episode of reflux on dry swallowing while lying supine left side raised, but only a few seconds later (b) complete clearance of the reflux has occurred with a single effective primary peristaltic contraction.

These images will show well any cricopharyngeal bar, premature closure of the cricopharyngeus, or transient mini Zenker's diverticula, as well as any pharyngeal lesions or incoordination, and laryngeal penetration.

The examination then continues with the erect double contrast oesophageal views as described above. Because the erect double contrast views often fail to distend the LES adequately to show a mild Schatzki ring, if the erect views are normal it is important to include the prone oblique views of the LES while swallowing barium. The pathology at this point can be made more apparent by having the patient take and hold a deep inspiration as the bolus passes through the LES segment. Maximal distension can also be achieved by rapid and repeated swallowing of dilute barium in this position. At the end of the examination of a patient with dysphagia, if the cause of the dysphagia has not been clearly demonstrated, a solid bolus swallow must be used. One half of a large marshmallow with a diameter around 18–20 mm (or home made gelatin equivalent) is given to the patient while standing erect, to put in their mouth and try to swallow with a small amount of barium for lubrication and visibility. Some mild encouragement is usually necessary and 90% of patients can after a few tries swallow a bolus of this size. A further mouthful of barium may be required if the first peristalsis only carries it part way down the oesophagus. A positive result occurs if the marshmallow arrests at a point of narrowing, supports a column of barium and reproduces the patient's dysphagic symptoms.

Examination of Patients with Chest Pain

Chest pain is a frequent referral symptom for patients coming for barium meal, often after a stress test or other investigation has 'ruled out' cardiac pathology. Oesophageal disease and musculoskeletal pain are the two remaining likely diagnoses. The standard examinations described above are usually sufficient to assess for reflux disease, but in addition there may also be an explicit request to exclude oesophageal motility disorders such as vigorous achalasia, diffuse oesophageal spasm and nutcracker oesophagus. The former is straight forward as the patients always have dysphagia, and the triad of tight lower oesophageal sphincter, non peristaltic contractions and impaired primary wave usually make the diagnosis of vigorous achalasia straightforward. There is little or no oesophageal dilatation in this early form of achalasia. The retained barium in the oesophagus can be moved on with carbon dioxide gas granules which allows distension of the fundus in order to exclude a cardia neoplasm. Exclusion of diffuse spasm and nutcracker oesophagus can not be achieved by barium meal. The abnormalities may be intermittent and in nutcracker oesophagus in particular the only abnormality may be a super efficient primary stripping wave that leaves not a drop of barium behind. There is no way for the radiologist to tell that this is of very high amplitude. There is sometimes a rather tight LES with poor oesophageal emptying and this may be the only clue that there is pathology present. Manometry is required to make these diagnoses accurately.

The injection of intravenous Tensilon (Edrophonium chloride) sometimes exacerbates the abnormalities in these disorders and produces chest pain, but the test is unreliable. The use of Bethanicol for the same purpose is contraindicated in a radiology department because of the risk of producing cardiac arrhythmias.

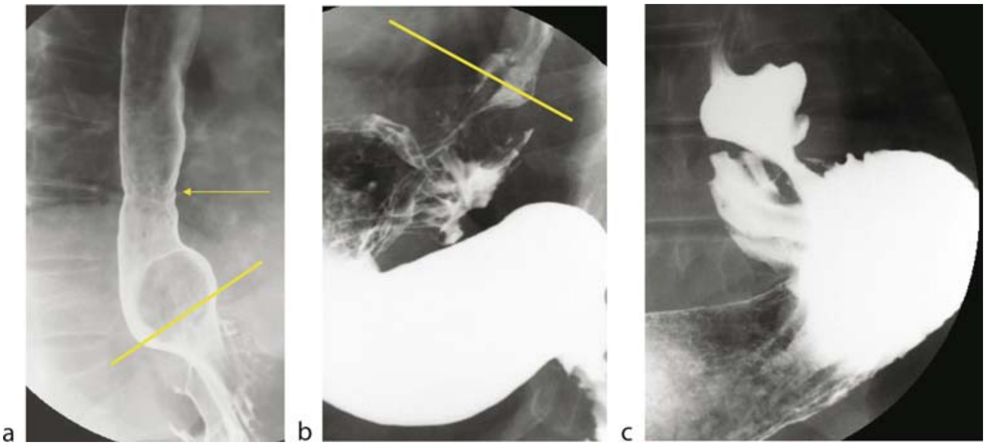
Examination of Post Surgical Patients

Patients may have recurrent symptoms post fundoplication or develop dysphagia. The barium examination is useful in these patients. A fundoplication 'mass' may be shown (the size is very variable) and this should be subdiaphragmatic. The usual manoeuvres to induce reflux should not show any in a patient with a successful fundoplication. It is our experience that even the water siphon test does not produce reflux. Fundoplication surgery may fail in several ways and these can usually be identified at barium study (Fig. 4). The whole wrap may slip up into the chest if the anchoring sutures to the diaphragmatic crura pull out. If these sutures hold, the oesophagus may pull free from the stomach and slide up into the chest, often with some kinking of the lower part of the wrap. In this case the upper end of the rugal folds will be pulled up above the wrap. Endoscopy is better at showing that the oesophagogastric junction lies above the fundoplication wrap in some failed fundoplications, but this can also be surmised if gastric folds are seen above the wrap on barium examination. Gastric folds should normally only be seen above the wrap in patients who have had a Collis gastroplasty. Finally, the entire wrap may come undone and there may be no radiological evidence that the patient has had surgery, with recurrence of the hiatus hernia, a lax sphincter and free reflux again.

Some patients complain of dysphagia following a fundoplication; this is common in the immediate post-operative period but should not persist beyond 2–3 months. Barium examination is useful in showing how widely the lower oesophagus opens and a marshmallow swallow can demonstrate hold up (with reproduction of symptoms) at the level of the wrap.. If a tight wrap is demonstrated then patients may require gentle endoscopic dilatation.

Communication Between Radiologist and Patient

Radiologists vary in their practice. Some never discuss results of an examination with the patient leaving this to



Reflux, Gastroesophageal in Adults. Figure 4 This patient has a failed fundoplication operation. (a) The erect double contrast film shows the hiatus hernia with the upper end of the rugal fold shown by a line, and the lower endo of oesophagitis shown by the arrow. The arrow thus indicates the squamo-columnar mucosal junction, and the area between is Barrett's mucosa. (b) This right side down the lateral film shows the wrap in the upper stomach but again the line shows the upper end of the rugal fold indicating that the wrap has pulled out and stomach is wrapped around stomach. (c) This single contrast view shows the wrap and recurrent hernia but does not provide the detail afforded by the double contrast projection. This case illustrates what often happens when a fundoplication is performed without a Collis gastroplasty in a patient with a short oesophagus (and in this case with Barrett's oesophagus).

the referring doctor, while others always do so. Patients with reflux disease are also variable in their desire for information. Some request information on how their reflux should be managed and this provides the radiologist the opportunity for a brief discussion on the four life style issues that are relevant to exacerbation of the disease. This discussion can be carried out in such a way that it does not impinge negatively on the later discussions between the patient and the referring doctor and these patients are usually grateful that the radiologist has taken the time to explain the findings.

The Radiology Report

The report should have several components. A brief summary of the history and indication for the exam, followed by a description of the anatomy discovered (position of the GE junction, hiatus hernia, post-surgical status). There should be mention of any upper sphincter changes, whether oesophageal motility is normal or not, how readily any reflux was induced, how effective was oesophageal clearance of refluxate and whether gastric emptying was normal or so rapid as to prevent assessment of reflux.

Then secondary findings should be noted if present such as pharyngeal diverticula, pharyngo-oesophageal web, Schatzki ring or stricture, the result of the marshmallow swallow if there was dysphagia and whether evidence of oesophagitis or Barrett's oesophagus was found.

The conclusion should be clear that either there was no evidence of GERD, that there is mild or moderate reflux disease with or without visible complications, or that there is advanced reflux disease with a defective sphincter that may be potentially surgical. If there is clear indication for endoscopy this should also be stated, with the reason for the opinion.

Conclusion

Endoscopy is the prime examination for the investigation of reflux disease in patients being looked after by surgeons and gastroenterologists. In many countries there are long waiting lists for endoscopy while a barium examination can often be obtained quickly. In Canada about one half of patients investigated for reflux disease have a barium study and half have endoscopy. The choice is usually made on logistic grounds rather than on the nature of the clinical problem. Only a minority of patients with GERD have endoscopic evidence of oesophagitis and endoscopy overlooks many of the functional abnormalities that are seen in reflux disease, as well as being less sensitive for detection of minor stenoses. Endoscopy is not an absolute gold standard for the diagnosis of GERD. Indeed, lack of unified sound criteria for the diagnosis or GERD makes the decision between barium study and endoscopy difficult. A study from Cleveland showed that barium study is less costly, especially as only a small number of patients with the final diagnosis of GERD had evidence of oesophagitis.

In specialist units undertaking a significant work load in reflux disease, barium radiology still has a role. Barium examinations give a good overview of oesophageal function and structure, and are particularly helpful in identifying the small number of patients with severe disease who lack any effective lower oesophageal sphincter. Barium radiology will also give a quick and useful assessment of oesophageal motility and identify the pharyngeal complications of reflux disease some of which make endoscopy hazardous.

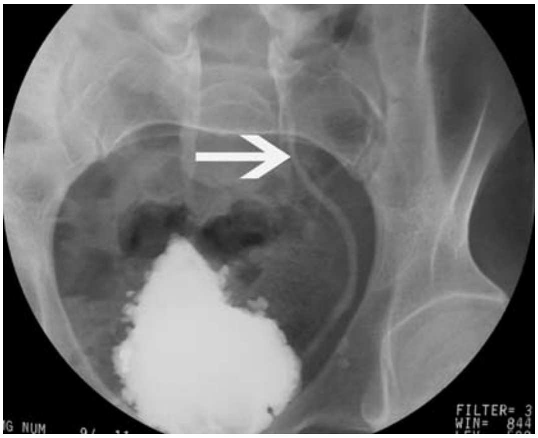
Definition

Vesicoureteric reflux (VUR) is defined as the retrograde flow of urine from the bladder to the kidneys. It may be divided into primary and secondary types with primary VUR being the predominant process. Primary VUR occurs in the absence of any underlying pathology whereas secondary VUR in the adult occurs due to conditions such as obstruction, previous surgical procedures, or a neurological disorder. The incidence of primary VUR is estimated at 1%. While the condition is well recognised in children, it is less recognised in adults. VUR in adults does, however, account for 10% of patients with end-stage renal disease requiring dialysis or transplantation. With early detection and careful management, this is potentially a preventable end point. Among patients who present with symptomatic urinary tract infection (UTI), the incidence of VUR declines with advancing age: It accounts for 49% of infants under the age of 1 year, 26% of children under the age of 12 years and 4.4% of adults. A family history of the condition is common, with a prevalence of 8–26% of VUR in siblings of a child found to have VUR. Advances in genetic mapping have led to the localisation of the genetic abnormality to chromosome 1. The condition is more common in females with a female to male sex ratio in children usually quoted as 5:1. The female:male ratio found in children may reflect the fact that UTI is more common in girls than boys (except in the first year of life) leading to more investigations and a consequent increased detection of VUR in girls. In adult patients, there is an even greater female preponderance mainly due to two factors: first, as in children, UTIs are more common in females, leading to more investigations and increased diagnosis of VUR. Second, there is an increased likelihood of detection of VUR in young females who become pregnant.

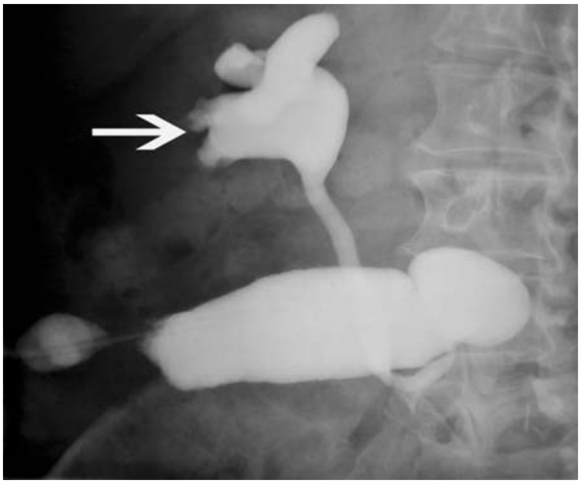
Overall, there are two categories of adult presentation of patients with primary VUR: (i) Patients who have had VUR since childhood that has remained undetected and presents in adulthood with complications. (ii) Patients who develop VUR in adulthood *de novo* with no prior history of UTI. Regarding secondary VUR in adults, it typically occurs secondary to obstruction or to neurological disorders of bladder function (Fig. 1). It may also occur following surgical procedures such as renal transplantation or cystectomy with ileal conduit formation (Fig. 2).

The first descriptions of retrograde flow of urine from the bladder to the kidney came from the 'Prince of Physicians': Galen (130–200 AD) of Pergamon. Later, Leonardo da Vinci (1452–1519) questioned the mechanism of urine formation and was the first to describe and depict the ureterovesical junction. VUR was demon-



Reflux, Vesicoureteral, Adults. Figure 1 Micturating cystourethrogram in adult patient with known spina bifida and deteriorating renal function. The bladder is irregular in keeping with a neurogenic bladder. There is free reflux seen in the left ureter (*arrow*).

R



Reflux, Vesicoureteral, Adults. Figure 2 **Adult patient with previous cystectomy and ileal conduit formation. Contrast has been infused into the ileal conduit through a Foley catheter inserted into the proximal portion of the conduit. Contrast is seen to reflux freely into the right ureter and collecting system of the right kidney (*arrow*).**

strated experimentally in 1903 by Sampson who injected blue dye into the bladder and noticed it subsequently effluxed from the ureter. The condition is caused by a mechanical abnormality at the ureterovesical junction. The ureter in patients with VUR is located lateral to its normal position. The ectopic location of the ureter shortens the normal course of the ureter within the detrusor muscle. This leads to incompetence of the normal valve-like closure system when the intravesical pressure rises on filling and micturition.

Clinical Presentation

VUR may be asymptomatic. The most common presentation is with the symptoms and signs of UTI and/or pyelonephritis. Symptoms are often non-specific and include a feeling of being generally unwell, tired, lack of energy, anorexia, nausea, vomiting and pyrexia. Dysuria and frequency as well as bladder discomfort may also be present. The majority of females diagnosed with VUR initially present with a UTI. Some females may be asymptomatic and have incidental bacteria noted on urinalysis. Males more commonly present late with symptoms of complications of VUR and reflux nephropathy such as hypertension and proteinuria. The increased UTI rate in females is explained by the anatomical differences between the male and female urethra such as the shorter length of the female urethra and the proximity of the urethral orifice to the vagina and anus. Pregnancy and reflux nephropathy have profound effects on each other. More than half of pregnant females with VUR experience complications during pregnancy. Physiological dilatation of the urinary tract and increased glomerular filtration predispose the pregnant mother with VUR to UTI, eclampsia and progression of renal disease. Preconception renal function has a significant impact on pregnancy related complications.

Diagnosis

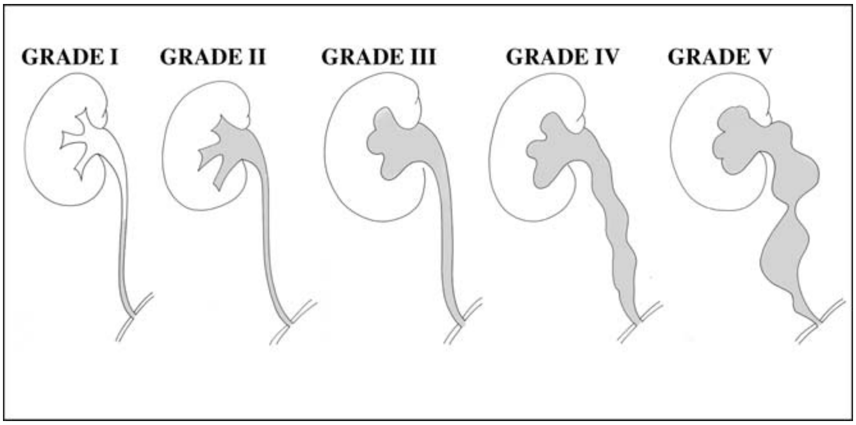
The spectrum of clinical presentations of adults with VUR is very broad. A screening programme for this condition is not feasible. VUR should be considered in adults with recurrent UTIs, pregnant females with UTI, proteinuria or pre-eclampsia, and patients with unexplained renal failure. Initial evaluation should include blood pressure assessment and biochemical assessment of renal function including serum creatinine, creatinine clearance and 24 h urinary protein assessment. Preliminary radiological investigation includes micturating cystogram to detect reflux followed by ultrasound and DMSA to evaluate for secondary changes of VUR. In the case of a pregnant female, MRI permits evalution of the renal system without exposure to ionising radiation.

Much attention is paid currently to the workup of patients who present with hypertension in search of a treatable cause. Though 95% of cases are idiopathic, if a cause can be identified and treated the complications of hypertension such as stroke and renal failure can be reduced. It is believed that up to 20% of adult patients with hypertension who have no evidence of renal involvement on routine work up may have undiagnosed VUR. If VUR remains undiagnosed, these patients are then erroneously categorised as having essential hypertension.

Imaging

Micturating Cystourethrogram

The gold standard test in making a diagnosis of VUR is a micturating cystourethrogram. With this examination, contrast is instilled into the bladder and the patient then micturates while the radiologist visualises the process with fluoroscopy. In the normal person, contrast (urine) should remain in the bladder during the full procedure and not reflux into the ureters. If reflux is present, its level of reflux is classified according to a designated grading system. There are several classification systems of VUR. The International reflux grading system is probably the best recognised. Depending on the degree of retrograde filling and dilation of the renal collecting system as seen at micturating cystogram; the International reflux grading system classifies VUR into five grades: (Fig. 3).



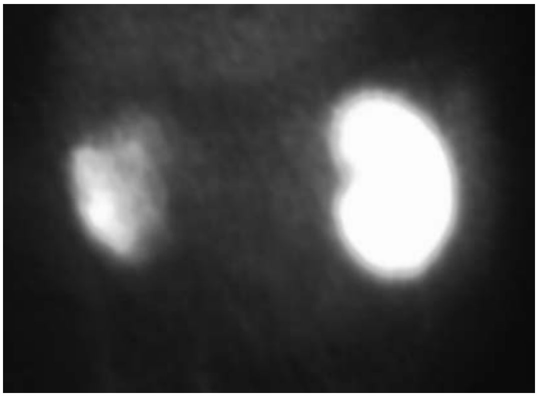
Reflux, Vesicoureteral, Adults. Figure 3 **Diagrammatic representation of the International reflux grading system. VUR is classified into five grades. (Courtesy of Tony Geoghegan)**

1. Grade I: Urine refluxes into the ureter only with normal renal pelvis and calyces
2. Grade II: Urine refluxes into the ureter, renal pelvis and calyces but they appear normal
3. Grade III: Urine refluxes into the ureter and collecting system. The ureter appears mildly dilated and there is evidence of some blunting of the calyces
4. Grade IV: Urine refluxes into the ureter and collecting system. Evidence of moderate dilatation of the ureter and moderate blunting of the calyces
5. Grade V: Urine refluxes into the ureter and collecting system. The pelvis appears severely dilated and the calyces are severely blunted. The ureter appears very dilated with a tortuous course.

Nuclear Medicine

Nuclear medicine techniques permit direct and indirect evaluation of VUR as well as assessment of renal scarring secondary to VUR. Reflux may be detected by both direct and indirect techniques. With direct radionuclide cystography, the bladder is infused with 500 mL of saline mixed with ^{99m}Technetium labelled sulphur colloid *via* a catheter. The bladder is filled and the patient subsequently micturates under direct visualisation of the gamma camera. Any nuclide appearing in the ureters and kidney is abnormal and diagnostic of reflux. With indirect radionuclide cystography, a standard renogram is initially performed. Twenty minutes following this, when the patient feels the need to micturate they are asked to do so in front of the gamma camera. The radio labelled urine in the bladder is monitored and any amount of refilling at the end of micturition is suggestive of VUR.

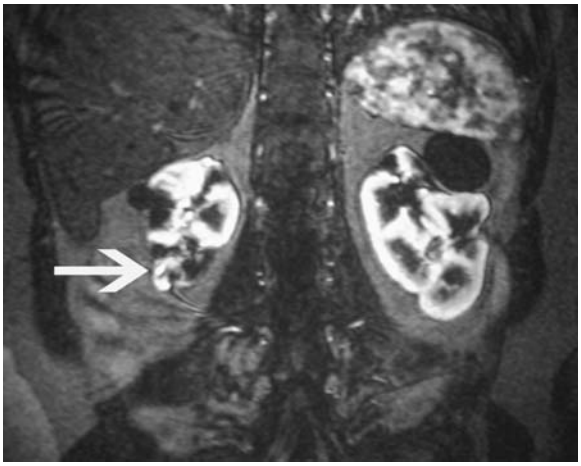
Technetium labelled DMSA is used to illustrate the size, shape and position of the kidneys and also to identify scarring or thinning of the cortex (Fig. 4). DMSA scanning has a sensitivity of 87% in detecting changes in the renal parenchyma and is more sensitive than US in this regard. The changes seen at DMSA may be transient in patients with acute pyelonephritis. DMSA imaging also plays a complementary role to US in the follow-up of renal transplants. VUR is relatively common in transplanted kidneys. Although it is controversial as to whether VUR does equivalent damage in transplant kidneys as in native kidneys, both DMSA imaging for scarring as well as dynamic renal scintigraphy scans using radio labelled DTPA or MAG-3 for renal function are both useful modalities to assess the transplanted kidney.



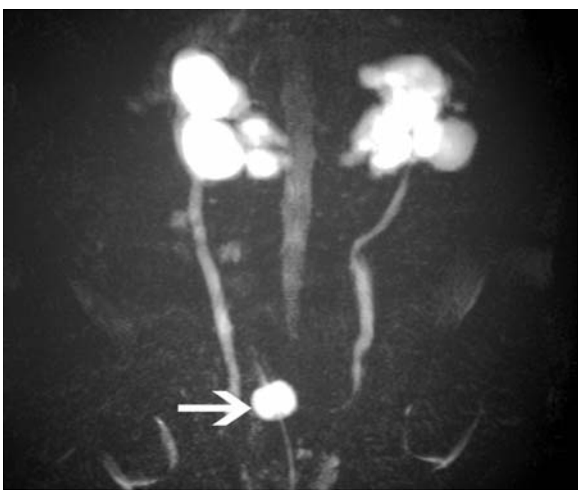
Reflux, Vesicoureteral, Adults. Figure 4 **^{99m}Tc-DMSA renogram in a patient with chronic reflux disease demonstrates marked parenchymal loss and scarring of the upper pole of the right kidney.**

Ultrasound

Ultrasound is an inexpensive, widely available technique that can be used to screen for reflux. Ultrasound permits assessment of renal size, shape, cortical abnormalities as well as ureteric abnormalities. A dilated system and



Reflux, Vesicoureteral, Adults. Figure 5 3D Gadolinium-enhanced source image using a fast low angled shot (FLASH) protocol in a patient with VUR demonstrates marked scarring of the lower pole of the right kidney (*arrow*). Non-enhancing simple cysts are incidentally noted in both kidneys.



Reflux, Vesicoureteral, Adults. Figure 6 Coronal multiple intensity projection (MIP) in a patient with a known horseshoe kidney image using a fluid sensitive HASTE magnetic resonance urography (MRU) protocol demonstrates a Foley catheter in the bladder (*arrow*) with dilatation of both ureters and the collecting system of the kidneys in keeping with reflux disease.

scarring in the appropriate clinical context are predictors of reflux and if needed, patients may proceed to a formal micturating cystourethrogram. Initial studies with ultrasound however showed that it was not a sensitive method for the diagnosis of VUR. Recently, some authors have advocated the use of echo-enhanced cystosonography in the diagnosis of reflux. With this method, a galactose suspension of fluid is instilled into the bladder and the presence of reflux is detected by continuous scanning. Advantages of ultrasound include the absence of ionising radiation as well as better anatomic resolution compared with radionuclide studies. Limitations included poor sensitivity at detecting grade 1 reflux as well as the length of time required for the procedure.

Intravenous Pyelogram

The role of intravenous pyelogram is rapidly decreasing in assessing the patient with VUR. It may detect secondary changes of VUR but does not provide a dynamic assessment of the refluxing urine. Secondary changes include evidence of parenchymal scarring, calyceal clubbing, ureteric dilatation and mucosal striations.

CT/MRI

Multi-slice CT with multi-format reconstructions can illustrate the renal tract and any secondary changes that have results from chronic VUR. CT does, however, expose the patient to considerably more radiation than other techniques for the evaluation of this condition. MRI on the other hand is a radiation-free technique a particular advantage when the pregnant female requires evaluation. As well as conventional sequences, the addition of heavily T2-weighted HASTE sequences results in MR urographic images that are highly fluid sensitive and allow evaluation of the collecting system of the urinary tract particularly when the system is dilated (Figs. 5 and 6).

Conclusion

VUR is less recognised in the adult than the child and still accounts for a significant proportion of patients with end-stage renal failure entering the dialysis pool. Imaging plays a key role in making the diagnosis. Although traditional modalities such as nuclear medicine studies and micturating cystourethrograms continue to play a key role in the evaluation of VUR, cross-sectional imaging and especially MRI will play a greater role in the future.

Synonyms

Vesicoureteric or vesicoureteral reflux; Vesicoureterorenal reflux

Definition

►Vesicoureteral reflux (VUR) is defined as reflux of urine from the urinary bladder into the ureter and up to the renal collecting system, with potential "intrarenal reflux" into the distal tubules—particularly at the compound papilla—with consecutive segmental renal damage and development of renal scarring by ascending urinary tract infection (UTI).

Embryology and Pathogenesis

There are several *causes* for VUR, with different entities and appearances in boys or girls, and a potential familial predisposition. First, there is primary or congenital VUR, caused by immaturity of the mechanisms at the ureterovesical junction, such as a short intramural tunnel that hinders sufficient valve mechanism at the junction, or a lateralized or pathologically configured ostium. Another form of congenital VUR is the severe, even bilateral VUR with intrauterine renal damage and dysplastic elements ["congenital ►reflux nephropathy (RNP)"] that usually is seen in baby boys. Low-grade VUR without (initial) renal scarring is seen particularly in school girls. Additionally, there is secondary VUR, for example, in bladder dysfunctions (particularly when there is an increased bladder pressure leading to a decompensation of the valve mechanism at the ureterovesical junction as in a neurogenic bladder or high-grade dysfunctional voiding) or in bladder outlet obstruction (e.g., caused by urethral polyp, posterior urethral valves). The congenital, typically short-lasting, high-pressure, low- to medium-degree VUR during voiding has a high tendency to diminish spontaneously and eventually disappear, whereas high-grade VUR with congenital RNP in baby boys, VUR in anatomic malformations at the ureterovesical junction, and secondary VUR persist and only improve after treatment of the underlying bladder condition and/or relief of the obstruction. Usually, surgical options must be considered (e.g., PUV, urethral polyp, Hutch's diverticulum, golf hole, or lateralized ostium, etc.).

The *long-term sequelae* of VUR depends on some basic factors. First, the amount of preexisting renal dysplasia or congenital RNP (probably due to a combined dysplastic growth of renal tissue and "water hammer" effects of ongoing high-grade and high-pressure VUR during fetal life causing mechanical damage to the renal units). Second, renal parenchymal changes secondary to recurrent UTI with renal involvement (upper UTI) and consecutive scarring, which may lead to hypertension and—if severe and bilateral—to renal insufficiency. Bladder dysfunction may be another predisposing factor maintaining the risk for UTI and preventing VUR resolution.

Clinical Presentation

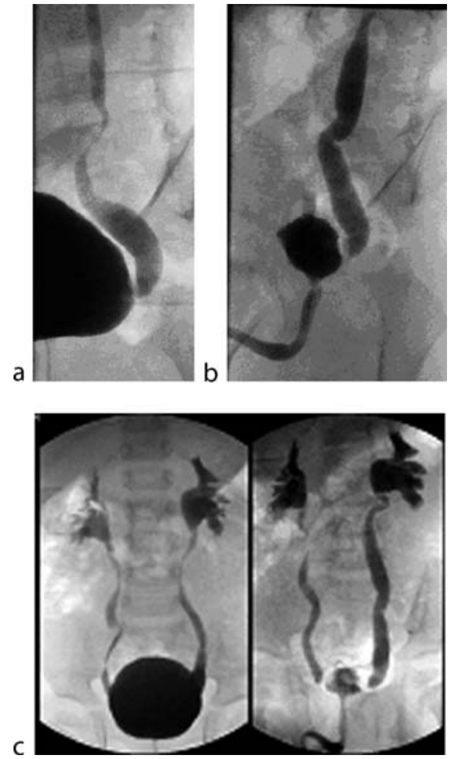
VUR itself has no clinical symptoms; all forms of presentation derive from secondary phenomena such as UTI, renal scarring or renal insufficiency, or bladder function disturbance. VUR has increasingly been picked up by (fetal) screening investigations. VUR *management* consists of regular urine checks, at least, with early treatment of any UTI; the present widely performed antibiotic prophylaxis is under discussion. Surgical options are cystoscopic injection of material into the bladder wall at the ureterovesical junction (e.g., Macroblast®, silicon, teflon, myoblasts, etc.) or open surgical antireflux procedures with different techniques leading to a reimplantation of the ureter and reformation of a longer intramural ureteral tunnel, thus preventing VUR.

Imaging

In light of new insights into the etiology and pathogenesis as well as the sequelae of VUR, the diagnostic and therapeutic concept is presently undergoing significant changes toward less generalized and less invasive imaging, which—if indicated—is aimed at those patients who have an increased risk of renal damage or have already suffered renal scarring. Furthermore, a wider range of partially new imaging techniques have increasingly been accepted for VUR diagnosis and have thus impacted imaging algorithms.

Imaging procedures: The gold standard imaging technique for VUR is still *voiding cystourethrography* (VCUG). This is performed after catheterization of the bladder (usually transurethral, sometimes suprapubic), mild (nasal) Midazolam sedation may be used. Ideally, the bladder should be empty before instilling the radiopaque contrast material *via* infusion. The infusion speed and pressure should be as physiological as possible to allow a more or less physiologic imaging situation with additional functional information by observing infusion speed and potential stops of the contrast infusion indicating moments of increased bladder pressure (e.g., in bladder instability or premature detrusor contraction during filling). Furthermore, to grant a high VUR detection rate, patients may be fastened for several hours. Particularly during the first years of life, cyclic VCUG with at least three fillings is recommended. Filling, voiding, and the postvoid situation are evaluated fluoroscopically with child-adapted digital fluoroscopy units using pulsed fluoroscopy. No blinded films should be taken. Fluoroscopy-guided spot films can be taken to document the anatomy of the distal ureter and the ureterovesical junction in lateral or oblique views (Fig. 1a). Furthermore, spot films are helpful for evaluating intrarenal reflux and properly assessing the anatomy of the urethra (lateral film) (Fig. 1b). All other information (time, degree and side of VUR; residual volume; postvoid urinary drainage) can be assessed and documented by images taken with digital fluoroscopy without additional exposures (Fig. 1c). VUR is radiographically graded into low- and high-pressure VUR (depending on when it occurs: at low bladder or high/increased bladder pressure such as during voiding), VUR during filling or voiding, VUR in an anatomically normal bladder and ureterovesical junction or in patients with malformations such as diverticula or duplex systems, and the degree of VUR (grade I is the VUR into the distal ureter, grade II is the VUR up to the renal pelvis, grade III is the VUR into the calices, grade IV is the VUR into a dilated system, grade V is the VUR into a grossly dilated system with ectatic ureter, pelvis, and calices) (Fig. 2).

Radionuclide cystography (RNC) uses radioactive tracers instilled in the urinary bladder for VUR detection. Direct RNC uses catheterization of the bladder to instill the radioactive tracer, with any activity in the ureter or the renal collecting system demonstrating clear evidence of VUR. Indirect RNC is performed during late phases of a dynamic renography at full bladder capacity and particularly during or after voiding. The tracer is the intravenously applied Tc^{99m}-labeled MAG3 that is excreted and transported into the bladder by physiological pathways after application for dynamic renal scintigraphy, with an increased activity over the proximal ureter and the renal pelvis in late phases in VUR. Indirect RNC is a



Reflux, Vesicoureteral, Childhood. Figure 1 **VUR demonstration on VCUG (a) Refluxing ureterovesical junction in a lateral oblique view on a conventional VCUG image (b) Neonatal male urethra in lateral view during voiding with eminent VUR (c) Bilateral VUR documented by a fluoroscopy images; VCUG images taken at full bladder capacity and after voiding: note VUR increase during voiding.**

more physiological approach, but only applicable to cooperative and toilet-trained children. In general, RNC has lower radiation burden at the cost of decreased anatomic resolution and less grading potential, although a certain amount of grading can be achieved. This method is usually used for screening and for follow-up studies, particularly in girls.

The third method for VUR evaluation, which is increasingly gaining importance, is *contrast enhanced cysto(uro)sonography* (ee-US). It uses ultrasound (US) contrast material which is instilled into the urinary bladder *via* catheterization to demonstrate VUR. By constant scanning of the bladder and the retrovesical space as well as—alternating—the renal collecting system and the proximal ureter, VUR of contrast material into the upper urinary collecting system can be detected and demonstrated. Modern US techniques such as harmonic imaging or high- and low-mechanical index (MI) contrast-specific imaging features (contrast pulse sequencing, stimulated acoustic emission (SAE)) may be applied to enhance VUR detection (Fig. 3). Furthermore, simultaneous evaluation of the renal pelvis, the kidney parenchyma, and other surrounding structures as well as nonrefluxing dilated urinary tracts is achieved. A grading similar to that for VCUG has been suggested, additionally incorporating the unenhanced US image information such as preexisting dilatation of the upper urinary tract or parenchymal lesions. Similar to fluoroscopic VCUG, cyclic evaluation is recommended in neonates and infants, and evaluation during and after voiding for detection of high-pressure VUR and validation of residual volume and urine drainage dynamics is obligatory. The method, however, is only applicable in

According to the *international system of radiographic grading of vesicoureteric reflux* (Lebowitz RL, Olbing H, Parkkulainen KV et al, 1985. International Reflux Study in children: International system of radiographic grading of vesico-ureteric reflux. Pediatr Radiol 15: 105-109)

Grade I:	VUR limited to the ureter
Grade II:	VUR up the renal cavities without dilatation
Grade III:	VUR into the renal cavities inducing dilatation and eversion of the calices
Grade IV:	Moderate to marked dilatation of the ureter and pyelocaliceal system
Grade V:	Marked tortuosity and dilatation of the ureter and pyelocaliceal system

Reflux, Vesicoureteral, Childhood. Figure 2 VUR grading.

countries where US contrast material is approved for pediatric use. The benefit of ee-US is not only the simultaneous visualization of the collecting system and the renal parenchyma, but also that US is free of ionizing radiation. Setbacks are restricted visualization of the urethra, a less panoramic display of the entire urinary tract, and the lack of anatomic information about long parts of the ureter. Additionally, restricted availability, a suboptimal visualization of the urethra, a lower sensitivity toward short-lasting first-grade VUR and diverticula (which may only arise during or at the end of voiding), as well as less functional information must be acknowledged. Some of these aspects can be partially overcome using novel scanning techniques such as a perineal approach during voiding for evaluation of the posterior urethra. Indications for ee-US are screening conditions, VUR evaluation in girls, and follow-up examinations. However, particularly in infant boys, VCUG with accurate anatomic evaluation of the urethra seems to be irreplaceable.

Indications for VUR assessment: VUR evaluation at present is indicated in UTI in neonates and infants up to 2 years of age and (recurrent) upper UTI in children (particularly with renal damage or scarring), urinary tract malformations that are accompanied by a higher risk of VUR (i.e., duplex system, ureterocele, multicystic dysplastic kidney, complex malformation, etc.), a dilated upper urinary tract such as megaureter and hydronephrosis (for differentiation of obstructive vs. reflexive disease), children with bladder diverticula, bladder dysfunction (with recurrent infections), and other (systemic) conditions with a potential involvement of the urinary tract (e.g., myelomeningocele with neurogenic bladder). Furthermore, a follow-up evaluation or postoperative reassessment may be indicated particularly in patients with ongoing symptoms, with a VCUG being recommended in all situations in which the most anatomic information is mandatory, such as in preoperative assessment.

Diagnosis

Diagnosis and grading are entirely based on imaging using the earlier-described features for the various methods.

Regenerative Nodule, Hepatic

Nodules of regenerating hepatocytes in a cirrhotic liver. Regenerating nodules may vary from micronodules (lesser than 3 mm in diameter) to macronodules (3 mm to several centimeters in diameter). They determine a typical superficial nodularity of the liver surface appreciable at ultrasound US, computed tomography CT and magnetic resonance MR. Larger nodules may be visibile as distinct nodules and need to be differentiated from dysplastic nodules and hepatocellular carcinoma (HCC). Regenerative nodules do not have an arterial blood supply. At contrast US, CT and MR studies they usually appear hypoenhanced, sometimes isoenhanced, in the arterial phase, hypo-isoenhaced in the portal–venous phase, while in the delayed phase they are more easily depicted as hypoenhanced nodules. MR is much more sensitive than CT in demonstrating regenerative nodules, especially when they contain iron (siderotic nodules). Typically, regenerative nodules appear as small (<2 cm) nodular lesions, with low signal intensity on T2-weighted images and variable signal intensity on T1-weighted images. When they contain iron they appear hypointense both on T1-weighted and in T2-weighted scans. In some cases, regenerative nodules may present increased signal intensity on T1-weighted images due to high triglyceride content in zones of fatty degeneration. They are never hyperintense on T2-weighted images.

►Cirrhosis, Hepatic

Regional Ileitis

►Crohn Disease

Regional Osteoporosis

Regional osteoporosisis an unspecific finding occurring, for example, in disuse, neighborhood inflammation, and arthritis. In the periarticular distribution, it refers to the old term of collateral phenomenon.

►Connective Tissue Disorders, Musculoskeletal System

Regional Recurrence

Recurrence that is located in close areas around the same breast. Most frequently, this event occurs in the axillary lymph nodes or well in the pectoral muscles, internal mammary lymph nodes, or cervical or supraclavicular nodes.

▶Recurrent Neoplasms, Breast

Regurgitation

Regurgitation of recently swallowed food with acid into the mouth.

▶Reflux, Gastroesophageal in Adult

Relapsing Polychondritis

It is an uncommon and severe episodic inflammatory condition involving cartilaginous structures, predominantly those of the laryngotracheobronchial tree. Chondritis weakens the tracheal cartilage rings, resulting in wheezing, dyspnea, cough and hoarseness. The airways eventually become stenosed and are replaced by collapsible fibrotic tissue. Chest radiography will demonstrate tracheal stenosis, calcification of cartilaginous structures and coexisting systemic vasculitis may be revealed by the presence of pulmonary infiltrates. CT or MRI will readily identify tracheal and bronchial thickening, inflammation, stenosis and calcification, as well as airtrapping and diffuse or focal thickening of the airways.

▶Airway Disease

Renal Artery Stenosis

Decrease of arterial lumen diameter due to atherosclerosis or fibromuscular dysplasia. It is the main cause of renovascular hypertension. It may also be responsible for artherosclerotic (or ischemic) nephropathy.

▶Hypertension, Renal
▶Stenosis, Artery, Renal

Renal Artery Stenosis (RAS)

▶Stenosis, Artery, Renal

Renal Carbuncle

Multiple coalescent intrarenal abscesses due to hematogenous spread, usually caused by *Staphylococcus aureus*.

▶Pyelonephritis, Acute

Renal Cell Carcinoma

Renal cell carcinomas (RCC) are clinically, histologically and genetically a heterogeneous group of tumors involved the kidney.

▶Carcinoma, Renal Cell

Renal Colic

Sharp pain in the lower back that radiates into the groin, associated with the passage of a renal calculus through the ureter.

▶Stone Disease, Urinary
▶Colic, Acute, Renal

Renal Corticomedullary Abscess

▶Abscess, Renal

Renal Cysts

▶Cystic Disease, Renal Childhood (MCDK, PCKD)

Renal Dysplasia

A congenital condition with an impaired development of the renal parenchyma leading to cystic and cartilaginous or fibrous lesions in the kidney and usually accompanied by renal functional impairment as well as restricted growth potential.

▶Congential Malformations, Geni tourinary Tract; Including Ureter and Urethra

Renal Failure

Condition where the kidneys fail to function properly. Physiologically, renal failure is described as a decrease in the glomerular filtration rate. Clinically, this manifests in an elevated serum creatinine. It can broadly be divided into two categories: acute renal failure and chronic renal failure.

▶Glomerulonephritis

Renal Infarction

This results from renal arterial occlusion and produces a pale area of ischemic renal tissue. Some blood supply from capsular vessels is responsible for the presence of a viable subcapsular band of cortex.

▶Infarction, Renal

Renal Osteodystrophy

End-stage, chronic renal failure leads to a bone disease characterized by secondary hyperparathyroidism, osteomalacia, and osteoporosis. Chronic hemodialysis may also cause aluminum-induced bone disease and deposition of amyloid.

▶Hyperparathyroidism

Renal Tuberculosis

Chronic infection produced as a consequence of the hematogenous spread of *Mycobacterium tuberculosis*, usually from the lungs.

▶Pyelonephritis, Chronic

Renal Tubular Ectasia

▶Medullary Sponge Kidney

Renovascular Disease

Complex entity involving renal arterial lesions, renal disease, and hypertension. The relationships between these three entities are variable from patient to patient and difficult to assess.

▶Hypertension, Renal

Renovascular Hypertension

Reversible and infrequent cause of hypertension secondary to a decrease in renal perfusion pressure, which activates the renin–angiotensin system and causes renovascular hypertension. It is curable by renal revascularization.

▶Hypertension, Renal

▶Stenosis, Artery, Renal

Replenishment

The dynamic refilling of a capillary bed in parenchymatous tissue after transient destruction of the micro-bubbles of an ultrasound contrast agent. The specific interaction of the micro-bubbles with the incident ultrasound wave allows the transient destruction with a high energy ultrasound pulse (flash or burst). After clearance of the micro-vessels, the immediate refill (replenishment) with contrast agent already present in the feeding arteries outside of the image plane allows the realtime assessment of micro-vascular flow independently from the cardio-pulmonary transport of the agent.

Definition

Reporter systems in the context of imaging are methods that allow the detection of one or more biological/molecular events.

Imaging

Reporter Gene

A reporter gene allows the imaging of gene expression in cell culture and in living subjects. It can be directed at genes externally transferred (transgene) into cells and organ systems (See Applications of Direct Imaging in "Direct Imaging".) or at endogenous genes (See Applications of Indirect Imaging in "Indirect Imaging".). In all cases, expression of the reporter gene can be tracked using different imaging modalities and confirmed using standard techniques, including but not limited to reverse transcription-polymerase chain reaction (RT-PCR), Northern blotting, Western blotting, immunohistochemistry and flow cytometry.

Characteristics of an ideal reporter gene/probe for imaging in living subjects include: (a) The reporter gene should be present in the mammalian cells (but not normally expressed otherwise it would lead to background signal) or if an exogenous reporter gene is used, the gene product should be not be expressed on the cell surface in order to prevent an immune response, (b) the accumulation of the reporter probe should be site-specific, (c) the reporter probe should be stable in the living subjects and not be metabolized before reaching its target, (d) the reporter probe and its metabolites should not be toxic in the living subjects, (e) the reporter probe should have good pharmacokinetics, including rapid clearance from circulation and nonspecific sites and noninterference with specific signal detection, (f) the reporter gene with the promoter should be small enough to fit into a delivery vehicle, (g) the reporter probe should be able to reach its destination instead of hindered by natural biological barriers (e.g., the blood brain barrier), and (g) good correlations between level of reporter gene mRNA expression and reporter probe (protein) expression in living subjects.

To deliver the reporter gene in to the cell type of interest, a complementary DNA expression cassette containing the reporter gene of interest is often used. The reporter gene can be driven by different promoters (including constitutive, inducible, endogenous and cell-specific) to allow temporal and spatial control of gene expression. Transcription and subsequent translation of the gene product into an enzyme or a receptor product, and in the presence of a substrate of an enzyme or a ligand for a receptor, an imaging signal is produced. The trapping and/or catalyzing of the imaging probe leads to an imaging signal, which can be in the form of a radioisotope (detected by positron emission tomography [PET] and single photon emission computed tomography [SPECT] imaging), See Applications of Reporter Systems: Small Animals PET and SPECT, a photochemical reaction (detected by bioluminescence imaging) or a magnetic resonance metal cation (detected by MRI) or other techniques (e.g., Ultrasound).

Classification of Reporter Systems

Reporter systems can be classified into two categories according to the location of the reporter gene products: intracellular and cell membrane-based (1).

►Intracellular reporter systems utilize gene products that are present within the cells. Intracellular reporter systems include enzyme-based bioluminescence imaging (Firefly, Renilla and Gaussia luciferase), fluorescence-based imaging (green fluorescent protein [GFP], monomeric red fluorescence protein [mRFP]), (PET) imaging (Herpes Simplex Virus Type 1-thymidine kinase [HSV1-TK] with 8-[^{18}F]fluoropenciclovir (^{18}F-FPCV), ^{124}I- or ^{131}I-labeled 2´-fluoro-2´-deoxy-1-β-D-arabinofuranosyl-5-iodouracil (FIAU), 9-[4-[^{18}F]fluoro-3-(hydroxymethyl) butyl]guanine (^{18}F-FHBG) as substrate and cytosine deaminase with 5-fluorouracil as substrate), as well as SPECT with different radioactive tracers and MRI with different contrast agents. The advantages of intracellular reporter system include relatively uncomplicated expression strategy, lower likelihood of immunogenicity since the product is intracellular and therefore less likely to be recognized by the immune system, the ability to achieve specificity by controlling the expression of the reporter genes and signal amplification for enzyme-based reporter probes (since many imaging probes can be trapped for each reporter enzyme).

Cell membrane-based reporter systems utilize gene products that are associated with the cell membrane, such as cell-surface receptors. Extracellular reporter systems can also be applied for PET imaging and MRI. For example, dopamine 2 receptor (D_2R), somatostatin receptor and sodium iodide symporter can be used for PET/SPECT imaging. Other engineered receptors that consist of a membrane-anchoring domain and a binding domain for the radiolabeled isotopes can also be used for PET imaging. On the other hand, transferrin receptor can be used as an intracellular transporter of iron oxide nanoparticles for MRI imaging. Advantages of extracellular reporter systems that are associated with cell membrane includes favorable kinetics, and no requirement for tracer uptake into cells and the ability to engineer reporters that can recognize approved imaging probes.

Applications of Reporter Systems

Reporter genes can be used to monitor the location(s), magnitude, and time variation of reporter gene expression and to target a specific biological process or pathway in intact living animals and humans. They can also be used to study promoter/enhancer elements involved in regulation of gene expression, examine induction of gene expression using inducible promoters, and examine endogenous gene expression by fusing endogenous promoters to a reporter gene.

1. Gene marking of static (unchanged location such as non-metastatic tumor xenografts) and trafficking cells (cells that migrate or metastasize considerable distances from the point of origin) to follow the behavior and location of cells in living subjects. Gene marking can be achieved by first introducing the reporter gene by *ex-vivo* stable transfection of the vector containing an imaging cassette into cells of interest prior to implantation/transplantation in living subjects such that the reporter gene is always expressed. This will allow the tracking of the cells and their progeny for their entire life span within the living subjects assuming there is no silencing of the reporter gene. Transient transfection of cells can also be used for *ex-vivo* gene marking of cells for short-term follow up (7–10 days), depending on the cell type and other parameters. Gene marking of the reporter gene in the living subjects can also be accomplished through tail vein or intraperitoneal injection of the vectors carrying the reporter gene along with the recombinant genome of viruses into the cells of interest within the living subjects. Gene marking can also be used for understanding the localization and quantification of viral accumulation in living subjects that will facilitates analysis of viral and host interactions using suitable viral vectors.
2. Imaging of gene therapy—Molecular imaging of reporters in combination with particular therapeutic genes could be critical in achievement and optimization of controlled and effective gene delivery to target cells and avoidance of expression in non-target tissues. The therapeutic gene and the reporter gene can be linked together using a fusion protein approach, in which their coding sequences fused together in the same reading frame and the expression between the therapeutic gene and the reporter gene will be coordinated at the protein level. Likewise, using a bicistronic vector, an internal ribosomal entry site (IRES) can be inserted in between the therapeutic gene and the reporter gene are expressed from the same promoter such that the expression between the two genes can be coordinated at the transcriptional level and each protein will be translated separately. Likewise, the two therapeutic can be coexpressed from distinct promoters within a single vector, two different vectors with the same promoter, or a bidirectional single vector in which the expression of the two genes are driven by the same promoter but in opposite directions (2). The levels, location and duration of the therapeutic gene expression can then be quantitatively assessed by imaging of the reporter gene. The ability to monitor expression of the therapeutic gene using the reporter gene can be generalized for different therapeutic genes of interest, and thus allow insights into cancer biology as well as the location, spread and persistence of the viral vector in patients undergoing gene therapy.
3. Indirect Imaging of endogenous gene expression—In order to utilize reporter system to study gene expression in transgenic animals, the reporter gene is stably integrated into the genome and its expression can be controlled by different promoters of choice. Using this approach, one can indirectly image expression of endogenous genes using a cell/tissue specific promoter to drive expression of reporter gene (e.g., HSV1-TK with PET and luciferase with bioluminescence imaging (3) and characterize the role of different promoter elements in regulation of gene expression and measure promoter activity in real time, and image/monitor pharmacologic induction of gene expression in transgenic animals.
4. Imaging of molecular interactions (4)—Different reporter systems have been developed to image different molecular events in intact cells in living subjects, including the regulation of gene expression and protein–protein interactions. The two-step transcriptional amplification (TSTA) approach can be used to image gene expression using endogenous/weak promoters whereas modified yeast two-hybrid system, complementation and intein-mediated reconstitution of split Firefly and Renila Luciferase can be used to image protein–protein interactions in intact cells. The applications of reporter systems will be covered in more details in the sections on Direct Imaging, Indirect Imaging, and Reporter Systems: Small animal SPECT and PET.

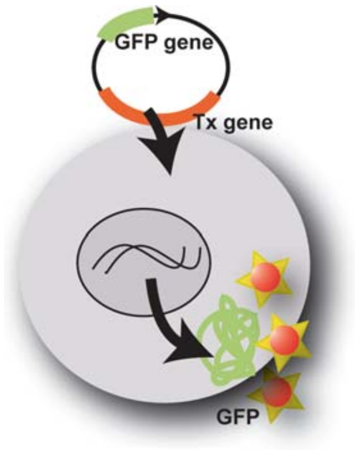
Reporter Systems, Optical

Christoph Bremer
University of Münster, Münster, Germany
bremerc@uni-muenster.de

Definition

Optical signatures are defined as intrinsic substances that significantly interfere with the regular photon propagation in the tissue for example, by absorption, induction of fluorescence, or by emitting photons upon chemical reactions (bioluminescence). These optical signatures are intrinsically present and thus a part of the cellular environment (either naturally present of artificially introduced) and not systemically injected.

Major intrinsic absorbers of light are hemoglobin, deoxyhemoglobin, water, and fat and tissue can be characterized regarding its composition of these compounds (1). Besides these naturally occurring chromophores, artificial proteins can be introduced into cells that either fluoresce (fluorescent proteins) or emit photons upon oxidation (bioluminescence). The genetic information encoding for these proteins has also been called "imaging marker gene" (IMG, Fig. 1) alluding to the fact that these optical signatures can be incorporated into therapeutic genetic vectors and help to monitor successful gene transfer. IMGs can be linked to genes of interest so that the coexpression of both genes occurs and regulation of the gene of interest can be visualized. Green fluorescent protein (GFP) is one prominent example of an IMG, which has been cloned from various organisms such as the jellyfish *Aequoria victoria*. GFP fluoresces in the visible light and thus does not penetrate the tissue very



Reporter Systems, Optical. Figure 1 **Imaging marker genes (IMG) encode for a transcriptional product (fluorescent protein, luciferase) which can be detected by optical methods (e.g., microscopy, reflectance imaging, optical tomography). IMGs can be linked to genes of interest so that the coexpression of both genes occurs and gene regulation of the gene of interest can be visualized. A prominent example of an IMG is the green fluorescent protein (GFP; shown in this graph), which has been cloned from various organisms such as the jellyfish *Aequoria victoria*. (Reprinted with permission from Bremer et al, 2003)**

efficiently. More recently red-shifted proteins offering better tissue penetration could be isolated from reef coral *Heteractis crispa* or designed by somatic hypermutation techniques, respectively (2).

Bioluminescence is a phenomenon known from fireflies that emit light upon oxidation of luciferin *via* the enzyme luciferase. Similarly like described for GFP the genetic code for luciferase can be exploited as an IMG. Luciferase mediated oxidation of the substrate luciferin results in an emission of light with can be detected by highly sensitive charged coupled device (CCD) cameras. Different luciferase types could be isolated, which show emission spectra between 400 to 620 nm. Since luciferase is not found in mammalian cells bioluminescence operates without background noise thus yielding extremely high SNRs.

Use and Dosage

Intrinsic optical signatures have frequently been used in the medical community. In fact simple optical inspection of tissue surfaces is probably the most frequently applied "optical imaging technique" (e.g., diagnosis cutaneous pathology) in medical practice worldwide. Diaphanography is another example of a simple medical imaging technology that helps to characterize tissue composition by application of visible light.

More sophisticated optical imaging approaches ranging from infrared diaphanography and dual wavelength transillumination to spectral light analysis have focussed on probing the tissue for blood (water and fat) contents. Diagnostic optical imaging applications exploiting these techniques in the 1980s and 1990s have been applied to study breast cancer detection in a clinical setting. The underlying theory was that oxy- and deoxyhemoglobin, which can be detected by these technologies, could serve as surrogate markers for tumor angiogenesis. However, data obtained in these studies showed a limited sensitivity and specificity of this imaging approach.

In the preclinical and experimental arena optical IMG play a major role for the *in vivo* monitoring of gene expression and gene regulation. Cell lines stably transfected with fluorescent proteins or luciferase can for example, be visualized *in vivo* to monitor cell migration (e.g., metastases, stem cell therapy, and inflammation), tumor-progression and -treatment. Gene regulation has been accurately studied using bioluminescence approaches.

Small animal positron emission tomography (small animal PET): A dedicated PET scanner for high resolution imaging of small animals for biomedical research.

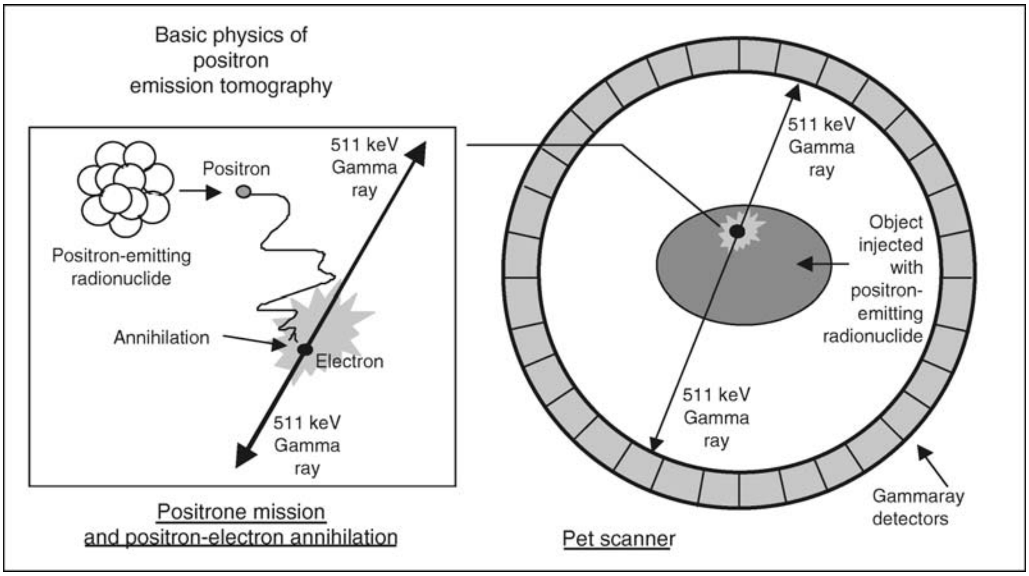
Small animal single photon emission computed tomography (small animal SPECT): A dedicated SPECT scanner for high resolution imaging of small animals for biomedical research.

Imaging

Small Animal PET

Methodology: Positron-emitting isotopes used for small animal PET imaging are produced by a cyclotron and/or generator (1, 2). They are capable of producing two γ-rays through emission of a positron from its nucleus, which then annihilates with a nearby electron to produce two 511 keV γ-rays at approximately 180°C apart. Biological molecules and chemical tracers can be directly or indirectly radiolabeled with positron-emitting isotopes, including ^{11}C, ^{13}N, ^{15}O, ^{18}F, ^{62}Cu, ^{64}Cu, ^{68}Ga, ^{76}Br, ^{82}Rb and ^{124}I . The mass of probe injected is usually in the nanogram–microgram range. Upon injection into living animals, the PET imaging probes circulate from the intravascular to the extravascular compartments and upon radioactive decay, high energy γ-rays are emitted from within small animals. A bank of detectors placed around the living animals are used to detect γ-rays through scintigraphic instrumentation consisting of an array of scintillation crystals (to convert γ-ray energy into visible light), suitable light sensors, readout electronics, and image processing units to produce tomographic images (Fig. 1). The small animal PET machine has a resolution attaining $\sim(1\text{–}2)^3$ mm^3 and can be used to follow the distribution and concentration of the injected tracers/probes for the purpose of developing molecular imaging assays before their application in humans.

Quantitation: The detection of one γ-ray results in the opening of an electronic time window during which detection of another γ-ray in another detector results in the counting of a coincident event. In order to be detectable, this coincidence event must have occurred along a straight line connecting the two detectors. The near coincidence detection of both γ-rays that are 180° apart in small animal PET within nanoseconds of each other defines the line of response in space and the direction of flight. The coincidence events measured at all angular and linear positions can be reconstructed using different mathematical reconstruction algorithms, including filtered back projection (FBP), ordered subset-expectation maximization (OSEM), and maximum a posteriori (MAP) assuming enough events are detected from the subject under study. Using electronic collimation, the localization and concentration of the positron-emitting radioisotope within a plane of the organ that was scanned can be quantified. Attenuation of the emitted radiation can be corrected using the attenuation factor, which is determined by total length through the body of the small animals such as rats. Tomographic images of relative probe concentration related to the underlying biochemical processes can be then reconstructed in the sagittal, coronal, and transverse imaging planes. The time-kinetics of the tracers can also be determined by dynamic (multiple acquisitions over time) scans.



Reporter Systems, PET and SPECT. Figure 1 **Basic principles of small animal positron emissions tomography (small animal PET) imaging. Biologically active molecules can be radiolabeled with positron-emitting radioisotopes. The positron-emitting isotope decays by emitting a positron from its nucleus that eventually collides with a nearby electron, resulting in an annihilation event where two 511,000 eV photons in the form of gamma rays are emitted ~180° apart. The two emitted photons travel extracorporeally and are detected nearly simultaneously as they interact with a ring of detectors (composed of scintillation crystals and photomultiplier tubes) surrounding the subject. Detection of a single annihilation event results in the "activation" of detectors opposing one another, which is recorded as a "coincident event." The recording of multiple detector pair combinations yields a large number of these coincident lines. Sophisticated mathematical analyses of the coincident lines yields the location of cell populations or tissues that contain the molecule labeled with the positron emitter. Tomographic images of relative probe concentration can be reconstructed in the conventional sagittal, coronal and transverse imaging planes or, actually, in any arbitrary plane. The resultant image depicts the distribution and concentration of the radiolabeled tracer.**

Specifications: The sensitivity (ability to detect a molecular probe relative to background) small animal PET is in the range of 10^{-11} to 10^{-12} moles/L, independent of the location depth of the probe. The temporal resolution (frequency at which the final interpretable version of images can be recorded/captured from the animal once the imaging process is initiated) that relates to the time required to collect enough events to form an image and the responsiveness of the imaging system to rates of any change for small animal PET imaging is about 10 s to minutes. The spatial resolution of small animal PET can be as high as 1 mm^3, compared to 5–6 mm^3 for clinical PET scanner.

Applications: Small animal PET can be used for imaging perfusion in the heart (e.g., ^{13}N-Ammonia), receptor densities on the cell-surface (e.g., Dopamine 2 Receptor, D_2R), reporter gene expression (e.g., Herpes Simplex Virus Type I Thymidine Kinase), as well as metabolic/cytoplasmic enzyme expression (e.g., hexokinase and thymidine kinase), cell trafficking, cell proliferation as well as monitoring of endogenous mRNA expression using anti-sense technology. It can also be used to establish the pharmacokinetics and pharmacodynamics of novel tracers and chemotherapy agents for diagnosis, prognosis and preclinical drug development. See Sections X.X and X.X for more applications involving direct and indirect imaging using small animal PET.

Pros: Small Animal PET is quantitative and highly sensitive. When compared to other modalities, the sensitivity of small animal PET is relatively high, on the order of 10^{-11} to 10^{-12} moles/liter (M) (Magnetic Resonance Imaging (MRI)'s intrinsic sensitivity is ~10^{-4} to 10^{-5} M). Since positron-emitting isotopes can substitute naturally occurring atoms (C, F, N,O), the relative ease of labeling tracers and biological molecules also allow the generation of multiple PET probes. Repetitive imaging using radioisotopes with short half-lives (e.g., ^{18}F and ^{11}C) also allow longitudinal studies, thus providing the detailed location(s), magnitude, and persistence of probes or tracers for *in vivo* use in animals.

R

Compared to optical imaging, small animal PET is much less affected by the location depth of the probes, thus enabling quantitative translational research from small animal models to human clinical trials.

Cons: The constant decay of the radioisotopes leads to production of γ-rays, thus a time delay between injection and imaging is required for clearance of nonsequestered probes. Since a lot of positron-emitting isotopes have relative short half-lives (e.g., ^{18}F has a half-life of 110 min), efficient PET probe synthesis strategies and close vicinity of an on-site cyclotron and/or generator to the small animal PET machines are required. Furthermore, since all PET isotope decays result in two γ-rays of the same energy (511 keV), small animal PET cannot be used to simultaneous detect multiple PET probes. Therefore, separate injection/scanning of individual probes are required to achieve multiplexing.

Small Animal SPECT

Methodology: Small Animal SPECT imaging with a gamma camera is similar to small animal PET, but the isotope emits gamma rays instead of positrons (2, 3). Small Animal PET is used for imaging low energy γ-emitting isotopes (^{99m}Tc, ^{111}In, ^{123}I, and ^{131}I). Different radiolabels with their characteristic photon energies (^{111}In [171, 245 keV], ^{125}I [27–35 keV], ^{131}I [364 keV], and ^{99m}Tc [140 keV]) can be attached to molecules of interest. A chelating moiety is required for radiolabeling with ^{99m}Tc and ^{111}In. The type of molecular probe (in the nanogram range) used can be directly or indirectly radiolabeled. Upon injection into the small animals, most of these tracers circulate from the intravascular to the extravascular compartments and emit γ-rays at their specific energies in different directions upon decay. γ-rays are detected using a gamma camera, a scintillation detector consisting of collimator, a sodium iodide crystal (to convert γ-ray energy into visible light), and a set of photomultiplier tubes, suitable light sensors, readout electronics (the electrical signals produced are proportional to the energy of the γ-rays), and image processing units (Fig. 2).

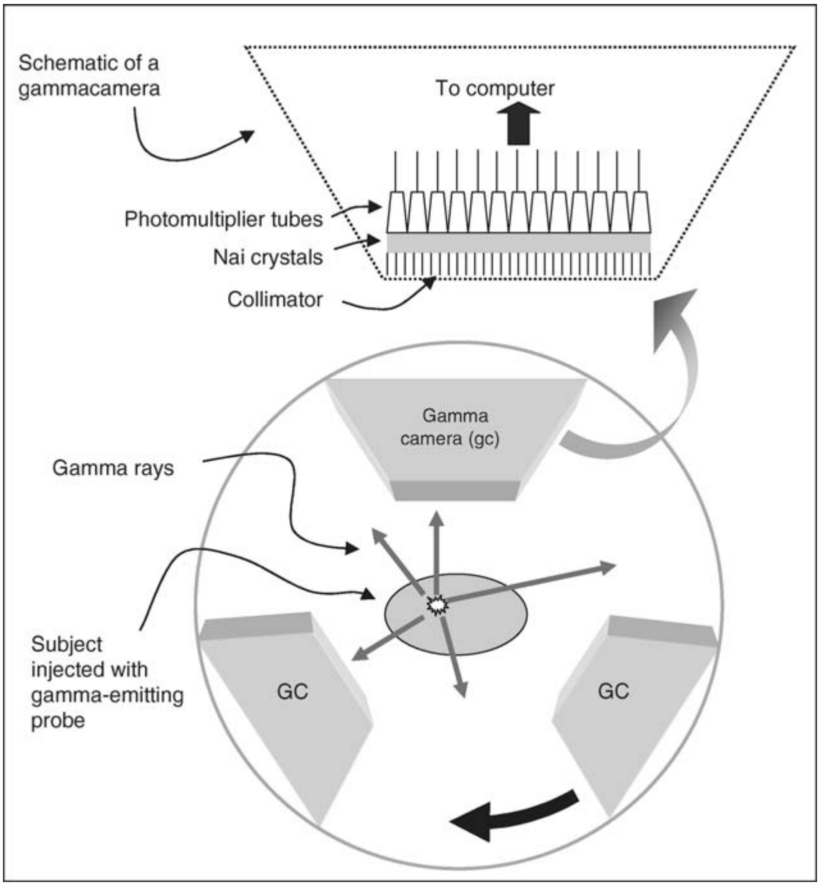
Quantitation: Since the SPECT camera is situated only on one side of the subject, only γ-rays directed toward the camera will be "captured," while others will be lost. Furthermore, only γ-rays that are parallel to and successfully reach the collimator will be converted into photons and detected since the collimator will absorb scattered γ-rays. In order to produce tomographic images, the SPECT camera rotates around the small animals. This is in contrast to small animal PET imaging, in which the small animals are surrounded by a bank of detectors. For single photon emitters, in order to correct for attenuation, the direction of flight/angle of incidence is determined by the geometric lead collimation to restrict data to γ-rays of certain predefined directions. γ-rays of lower energy resulting from scattering are devoid of their geometrical information, small animal SPECT imaging provides a planar image (a two-dimensional image from a three-dimensional subject).

Specifications: The temporal resolution of small animal PET is in minutes. The spatial resolution of small animal PET using pinhole SPECT for animal imaging can be as high as 1.7 mm. Only 10^{-4} times the emitted number of γ-rays will be detected by the collimator due to scattering or energy lost.

Applications: Small animal SPECT can be used for imaging gene expression and regulation, receptor densities on cell surface (e.g., dopamine transporter), reporter gene expression (e.g., sodium iodide symporter), apoptosis (e.g., Annexin V), studying cardiovascular disease, diagnosis of thyroid and neuroendocrine cancer, skeletal diseases (e.g., degenerative osteo-articular disorders), and detection of bone metastasis as well as neuroreceptor imaging in the brain. See Applications of Direct Imaging in "Direct Imaging" and Applications of Indirect Imaging in "Indirect Imaging" for more applications involving direct and indirect imaging using small animal SPECT.

Pros: The advantages of small animal SPECT imaging include no depth limit and a plethora of available molecular probes using different radiolabeling strategies. Since the radioisotopes used for small animal SPECT have longer half-lives than that of positron-emitting isotopes, an on-site cyclotron is not required. Furthermore, two or even more radioisotopes of different energies can be imaged simultaneously, allowing for the concurrent study of two distinctly radiolabeled molecules with different energies (e.g., one radiolabeled with ^{99m}Tc and another radiolabeled with ^{125}I), with the ease of adaptation to for multiplexing in clinical setting.

Cons: Compared to small animal PET, the sensitivity of small animal SPECT is an order of magnitude lower (10^{-12} to 10^{-11} mole/L). The low detection efficiency of γ-rays is due to loss of decay events that do not arise parallel to the collimator. To accommodate for the loss of sensitivity, more radiolabeled probes and thus higher levels of radioactivity have to be injected into the subject to maximize signal to noise, though the amount of radioactivity that can be injected will still be limited. Another disadvantage of small animal SPECT is the relatively low spatial resolution due to overlapping of different foci/organs in planar imaging, which may be overcome using rotating gamma camera to acquire volumetric data. Furthermore, the clearance of the SPECT probes through the urinary and hepatobiliary tracts may also hinder the detection and quantitation near these organ systems.



Reporter Systems, PET and SPECT. Figure 2 **Basic principles of small animal single photon emission computed tomography (small animal SPECT) imaging. A variety of radioisotopes, each emitting at characteristic photon energies, can be attached to a variety of molecules. Once introduced into the small animals, detection of these radiolabeled probes is a performed with a gamma camera, a scintillation detector consisting of collimator, a sodium iodide crystal and a set of photomultiplier tubes. Upon decay, these radionuclides emit a gamma ray at their characteristic energies in different directions. Some of the gamma rays will scatter or lose energy and others may never interact with the camera. Since the gamma camera is situated only on one side of the subject, only rays directed towards the camera will potentially be "captured." Furthermore, only those gamma rays that arise parallel to collimator will be detected since scattered gamma rays will be absorbed by the collimator. Those rays that successfully reach the crystal and stopped by it will be converted into photons of light. In turn, the photomultiplier tubes convert the light into an electrical signal that is proportional to the incidental gamma ray. Gamma rays that arrive at detector lower than the expected characteristic energy are thought to be the result of scattering and summarily rejected from the analysis. Since gamma cameras acquire data in a single plane, the resultant images are a two-dimensional representation of a three-dimensional subject (referred to as planar imaging). Small animal SPECT acquires volumetric data by rotating a gamma camera around the subject and/or using multidetector systems (shown above).**

Residual Tumor

After neurosurgical resection, the amount of residual tumor must be defined by imaging (magnetic resonance imaging or computed tomography) within the first 72 h because after 3 days, nonspecific enhancement within the brain may mimic tumor. For follow-up, the behavior of a residual tumor allows important therapeutic decisions.

Response to Treatment

Antonia Dimitrakopoulou-Strauss
Medical PET Group-Biological Imaging (E0601),
Clinical Cooperation Unit Nuclear Medicine,
German Cancer Research Center,
a.dimitrakopoulou-strauss@dkfz.de

Definition

Assessment of treatment response is important to optimize and individualize therapy. This is particularly important in oncological patients who receive combined chemotherapeutic protocols, which may cause severe side effects without producing the expected therapeutic result. Treatment response is also important for cardiac and neurological patients.

Characteristics

Applications

The main application of treatment response is for monitoring cancer therapy. Positron emission tomography (PET) with F-18-fluorodeoxyglucose (FDG) is currently the most powerful noninvasive tool for imaging of metabolic processes in patients. The greatest advantage of FDG-PET over morphological imaging modalities is assessing treatment effects, since the anatomic changes that follow treatment frequently lag behind tumor response in terms of viability. By using FDG-PET to predict therapy response early in the course of a prolonged treatment regimen in patients with carcinomas, it is possible to predict the therapeutic effect more accurately. The idea is that an accurate prediction of treatment failure may allow the oncologist to apply an alternative treatment regimen without subjecting the patient to the toxicity of the full treatment scheme.

Limitations of Conventional Techniques

Conventional response criteria for monitoring chemotherapy are based on changes in tumor volume, generally assessed by radiological methods. According to the criteria defined by the World Health Organization (WHO), response to therapy is classified as a therapy-induced reduction in tumor volume by at least 50%. The size of the tumor volume should be measured in two perpendicular diameters. Complete response is classified as disappearance of all lesions following therapy. One problem of this approach is the accuracy and reproducibility of the tumor volume measurement in a clinical environment.

Another problem is the fact that a reduction in tumor volume may take considerable time even after an effective therapy, particularly in solid tumors. As a consequence, tumor response is generally assessed after several weeks or months following the start of therapy. Patients who do not respond to chemotherapy may be treated over a long time period because of the lack of a sensitive parameter for early determination of therapy response. This situation reflects a common problem in the therapy management of oncological patients and in particular in patients with solid tumors, a high percentage of whom do not respond to chemotherapy.

The formation of scar tissue or edema following radiation therapy may be another obstacle in evaluating therapy response in oncological patients using radiological methods.

Monitoring of Chemotherapeutic Effects Using ^{18}F-FDG-PET

PET with ^{18}F-FDG is a sensitive method for detecting viable tumor tissue, and therefore for tumor diagnosis, staging, and therapy monitoring. A focally enhanced FDG-uptake besides the normal biodistribution is indicative of viable tumor tissue. However, it is important to examine whether morphological findings correlate with the PET findings and to exclude an acute inflammatory lesion, which may mimic viable tumor tissue. However, enhanced ^{18}F-FDG-uptake following chemotherapy is a relatively reliable sign of viable tumor tissue. For this purpose, visual evaluation may be adequate. But if the task is to assess response to therapy, more than one FDG-PET study should be performed, before and during the therapy-free interval. Quantitative measurements of ^{18}F-FDG-uptake are necessary to assess the metabolic activity. Patients who respond to therapy demonstrate a decrease in glucose metabolism, whereas nonresponders show an increase even after one chemotherapeutic cycle. Therefore, this approach allows early detection of nonresponders (Fig. 1).

PET-FDG Methodological Aspects

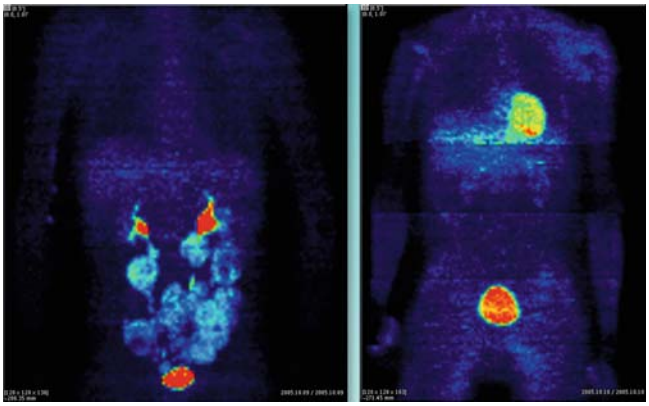
Semiquantitative measurements are mainly used for evaluating a therapeutic effect. For that purpose, static images are acquired, and the so-called standardized uptake values (SUVs) are calculated. The SUV is a distribution value that allows comparison of a radioactivity concentration between different patients and different studies. An SUV of 1.0 reflects a homogenous tracer distribution.

However, SUV is modulated by several factors, including the plasma glucose level, partial volume effects due to lesion size, reconstruction parameters, and the time after the tracer injection. Therefore, the calculation of SUV should be performed under standardized conditions concerning the time after tracer application, the blood glucose level in cases of ^{18}F-FDG, partial volume correction, and the choice of reconstruction parameters.

Besides the use of SUV, it is possible to acquire kinetic parameters of the ^{18}F-FDG kinetics using dynamic data acquisition. Dynamic studies are superior because they provide information about tracer distribution with respect to time and space in a region of interest (ROI). A detailed analysis of the kinetic data can be performed to acquire the most relevant information about the tracer pharmacokinetics. Analysis of kinetic PET data can be performed using compartment and noncompartment models. In the case of ^{18}F-FDG, a two-tissue compartment model with a blood component can be used, and transfer rates can be calculated. The blood component represents the amount of nonmetabolized ^{18}F-FDG in the vessels; the first compartment describes the intracellular amount of nonmetabolized ^{18}F-FDG; and the second compartment describes the intracellular amount of the metabolized ^{18}F-FDG. Therefore, using a compartment model it is possible to separate the metabolized amount of ^{18}F-FDG, which is directly related to tumor viability. A prerequisite for this approach is the time course of ^{18}F-FDG in the target area, such as in the tumor and in a blood vessel (input). The input can be obtained by blood sampling (venous or arterial), or it can be derived from an early image of an arterial vessel, such as the aorta, within the field of view.

Interpretation of the Change in Metabolic Activity

A measurable change in ^{18}F-FDG metabolism following one chemotherapeutic cycle does not necessarily mean that the patient will profit from the therapeutic regimen with respect to long-term therapy outcome. In patients with metastatic colorectal carcinoma who received a



Response to Treatment. Figure 1 **^{18}F-FDG-PET studies in a patient with gastrointestinal stromal tumor and multiple abdominal metastases before and after therapy with Glivec, a tyrosine kinase inhibitor. *Left*: maximum intensity projection images (MIP) before therapy. *Right*: MIP images after therapy.**

combined chemotherapeutic protocol (FOLFOX), the change in ^{18}F-FDG-uptake after one chemotherapeutic cycle did not correlate to overall survival. However, based on the SUV data before the onset to chemotherapy, it was possible to identify patients who survived longer than 1 year (1). By adding kinetic model parameters of the baseline study and of a study performed after completion of four chemotherapeutic cycles, it was possible to classify the majority (78%) of patients according to a 1-year survival rate. Therefore, a detailed analysis of tracer kinetics provides more accurate results for predicting individual survival rates.

The situation may be different for other tumor types and other chemotherapeutic protocols used for treatment. In patients with adenocarcinoma of the gastroesophageal junction who received preoperative chemotherapy, the change in ^{18}F-FDG-uptake between the baseline ^{18}F-FDG study and the study 14 days after onset to chemotherapy (cisplatin-based) correlated with therapy outcome (2). A 35% reduction in the ^{18}F-FDG-uptake correlated with treatment response. However, it is unknown whether these data can be transferred to other tumors and treatment protocols.

Standardization of the Criteria Used for Metabolic Treatment Response

At present, there are no generally accepted criteria for defining response. Generally, a reduction in the ^{18}F-FDG-uptake is a good prognostic sign. A threshold of at least 20% has been proposed by some authors as a response criterion. Although even a 20% change does not necessarily correlate with the survival rate, it is associated with at least a palliative effect. In contrast, an increase in ^{18}F-FDG-uptake is associated with lack of response. Thresholds depend on the tumor type and the expected curative or palliative treatment effect. In patients with malignant lymphomas, who primarily respond to chemotherapy, a decrease of 45% has been reported within 24 h after onset of therapy. The threshold for metabolic response in high-grade lymphomas is therefore higher, because the intention is to cure the tumor. In cases of palliative chemotherapy, the threshold may be lower. Thus, using metabolic measurements seems to be feasible for individualizing and optimizing chemotherapy.

Other Tracers

Perfusion studies with ^{15}O-water can be used in combination with ^{18}F-FDG studies to monitor the effect of a neoadjuvant therapy. In patients with locally advanced breast carcinoma who received neoadjuvant chemotherapy, an increase in tumor perfusion was noted in nonresponders by a concurrent decrease in the metabolic rate of ^{18}F-FDG (3). Furthermore, patients with breast carcinoma whose tumors demonstrated a higher ratio for the metabolic rate of ^{18}F-FDG and tumor perfusion survived longer (4).

Perfusion studies with ^{15}O-water PET can be used to monitor the effect of an antiangiogenic therapy. This is a difficult task because inhibitors of angiogenesis are not primarily cytotoxic, and therefore it takes a longer time to determine the clinical effect. In cancer patients treated in a phase I (dose-finding) study by a human recombinant endostatin analog that has an antiangiogenic effect, PET studies with ^{15}O-water demonstrated a change in tumor perfusion that was significant to the dose escalation (5).

Studies with ^{68}Ga-DOTATOC are used for research purposes to assess the effect of a radioisotope therapy with ^{90}Y-DOTATOC, which is an experimental therapy used for treating metastatic neuroendocrine tumors. DOTATOC is a peptide that primarily binds to the somatostatin receptor subtype 2 (SSTR II). Neuroendocrine tumors, which show an enhanced uptake on ^{68}Ga-DOTATOC PET, are candidates for the radioisotope therapy.

Other Applications

Perfusion studies can be used in patients with myocardial infarction to assess the effect of reperfusion. Another approach consists of apoptosis measurements with ^{9m}Tc-Annexin V, a procedure that is currently under evaluation. Annexin is a phospholipid-binding protein with high affinity for phosphatidyl-serine, which is externalized by cells undergoing programmed cell death. ^{9m}Tc Annexin accumulates in the infarct site, indicating that cardiomyocytes with externalized phosphatidyl-serine are present in the infarcted area.

A nononcological example of therapy monitoring is the measurement of bone remodeling by repeated bone scintigraphy with ^{99m}Tc-MDP in patients with Paget's disease.

Retention Cyst

A smooth marginated, soft tissue mass, caused by obstruction of a small seromucinous gland occurring especially in the presence of sinusitis.

▶Cystic Neoplasms, Pancreatic
▶Inflammation, Chronic, Nose, and Paranasal Sinus

Reticuloendothelial System (RES)

The RES is part of the immune system consisting of phagocytic cells which take up, digest or retain several biological or nonbiological materials such as cell debris, bacteria, dyes or particles. All organs and tissues containing e.g., dendritic cells, monocytes or macrophages are part of the RES.

▶Targeted Microbubbles

Retrograde/Anterograde Urography (Pyelography)

Conventional radiologic studies with retrograde contrast administration *via* cystoscopically inserted ureteral catheters or anterograde through percutaneous nephrostomies, both performed under fluoroscopic control, provide the most precise delineation of the collecting system. However, diagnostic retrograde studies are performed rarely in obstruction, only when renal function is impaired and other imaging modalities are inconclusive, but mainly for selective urine sample collection in suspected tumor, and prior to URS and double-J stent placement. Therapeutically inserted PNS can be used for anterograde urography.

Definition

Malignant soft tissue tumor of ▶striated muscle.

Incidence

The most common ▶soft tissue sarcoma of the pediatric age group. Approximately 8% of solid tumor in childhood, slightly more than half of pediatric soft tissue sarcomas. Peaks of incidence: 2–5 years (70% cases occurring before the age of 10) and adolescence. It is slightly commoner in boys than girls.

Pathology/Histopathology

It is divided into ▶botryoid, ▶spindle cell, embryonal, and alveolar types with an increasingly poorer prognosis in that order.

Botryoid usually occurs in hollow organs: the bladder, nasal sinuses, vagina, and common bile duct.

The muscular tumor is of mostly alveolar histology in contrast with the embryonal type that is linked with the pelvic region and the head and neck.

Rhabdomyosarcoma is a very aggressive tumor and infiltrates along fascial planes, lymphatic and hematogenous routes.

Clinical Presentation

Rhabdomyosarcoma may arise anywhere in the body, excluding the brain. An international definition of anatomical sites was adopted in 1986 by the international society of pediatric oncology (SIOP) (Table 1).

The most common sites for rhabdomyosarcoma are head and neck, genitourinary tract, and skeletal muscle. Presentation is often a painless mass and symptoms depend on tumor location.

Head and neck area: proptosis, chronic otitis media, polypoid mass obstructing the ear canal, sinusitis,

R

Rhabdomyosarcoma. Table 1 Clinical SIOP

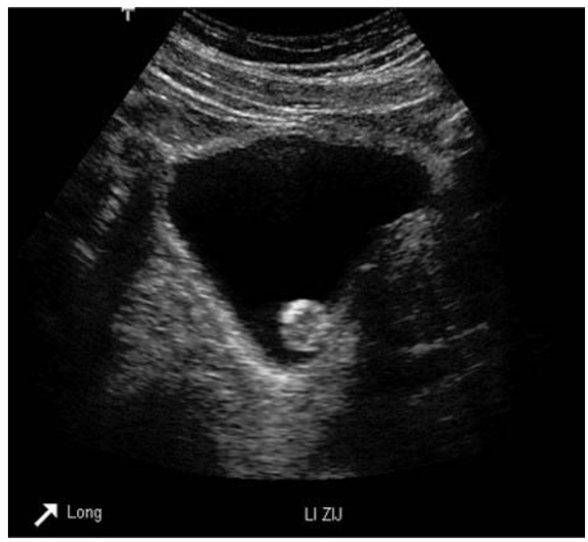
Stage	Description
IA	Localized tumor confined to site of origin, completely resected
IB	Localized tumor infiltrating beyond site of origin, completely resected
IIA	Localized tumor, gross total resection, but with microscopic residual
IIB	Disease
IIC	Locally extensive tumor (spread to regional lymph nodes) completely
IIIA	Resected
IIIB	Extensive tumor (spread to regional lymph nodes, gross total resection, but with microscopic residual disease)
IV	Localized or locally extensive tumor, gross residual disease after biopsy only
	Localized or locally extensive tumor, gross residual disease after major resection (50% debulking)
	Any site of primary tumor with or without regional lymph node involvement, with distant metastases, irrespective of surgical approach to primary tumor

obstruction of the airway, epistaxis, swelling, hoarseness. Extension to central nervous system (CNS) by direct extension: meningeal symptoms, cranial nerve palsies, respiratory disturbance.

Genitourinary tract: hematuria, vaginal bleeding, voiding problems.
Extremities and trunk: indolent mass, spinal compression.
Biliary tract: cholecystitis, hyperbilirubinemia.

About 20% of the patients present with distant metastases at diagnosis, mostly in the lung.

Metastases are also found in lymph nodes, mediastinum, brain, liver, and skeleton. Prognosis is less favorable for patients with rhabdomyosarcoma of the extremities than genitourinary tract or head and neck region and depends also on histopathological classification.



Rhabdomyosarcoma. Figure 1 US of bladder

Imaging

The radiological appearance depends on the site of the tumor. Classic imaging appearance: noncalcified soft tissue fullness with possible bone erosion and periosteal reaction.

Ultrasound (US): aspecific appearance, the echogenicity is variable, and may be hypoechoic, isoechoic, or hyperechoic to adjacent soft tissues. The margin may be poorly or well defined. Increased vascularity is noted on color Doppler sonography (Fig. 1).

CT scan and MRI show the extent of the disease and distant metastasis (Fig. 2).

MRI: aspecific appearance, signal indeterminate or low on T1 and high on T2. The masses tend to vary from homogeneous to heterogeneous and may undergo central necrosis. STIR and T1 + C show enhancement, necessary for evaluation of liver or lymphatic involvement in paratesticular rhabdomyosarcomas.

Rhabdomyosarcoma. Figure 2 A soft tissue mass (rhabdomyosarcoma) originating from the iliopsoas

Nuclear Medicine

Tc 99m MDP bone scan: for evaluation of bone metastases.

Diagnosis

The presumptive diagnosis can be made from the presentation and the tumor location but tissue typing requires biopsy, often under imaging guidance. Bone marrow aspiration/biopsy should be performed for bone marrow invasion and lumbar puncture for evaluation of the liquor.

Rhabdomyosarcoma of the Biliary Tree

Rare mesenchymal malignancy originating in and along the bile ducts in infancy. When arising in the major bile ducts, it shows a botryoid feature with biliary tract dilatation and jaundice. Lesions within the peripheral intrahepatic ducts are indistinguishable from other intrahepatic malignancies. Peak of incidence is between 2 and 5 years of age with a slight male predominance. The tumor usually is a unique spherical mass, very large, usually located in the right lobe. Metastatic spreading involves the liver, lungs, peritoneal cavity (omentum, mesentery, and diaphragm).

▶Hepatic, Pediatric Tumors, Malignant

Rheumatic Discitis

Rheumatic discitis is a feature of rheumatic arthritis. It is characterized by intervertebral space decrease and tiny erosions of the subchondral bones. Prevertebral soft tissue swelling is not a sign of rheumatic disease. Discitis may heal within years, with subsequent premature degenerative disease or bony bridging of parts of the intervertebral space, or persist and lead to instability.

▶Rheumatoid Arthritis

Rheumatic, Fever, Acute

The classic form of rheumatic fever, an inflammatory disease, occurs as a delayed, nonsuppurative consequence of an upper respiratory infection (group A streptococci). Clinical manifestations include varying combinations of polyarthritis, carditis, subcutaneous nodules, erythema marginatum, and chorea. These patients are usually younger and the findings are more generalized compared to gout.

Synonyms

Chronic polyarthritis

Definition

Rheumatoid arthritis (RA) is a systemic autoimmune inflammatory disorder of unknown etiology, primarily affecting the synovial membranes and articular surfaces. It leads in varying degree to articular destruction, and natural history may end in disability. There is a hereditary predisposition in patients with HLA DR4.

Pathology/Histopathology

Chronic inflammation of the synovial membrane with vasculitis leads to exudation of an aggressive joint effusion and immigration of inflammatory cells. Proliferation of destructive pannus tissue into the joint space with

►cartilage destruction and bone destruction primarily in the bare areas and marginal, later mutilation of the entire epiphysis is the consequence. Characteristic deformities are the result of ligamentous destruction. Synovial membranes are affected not only in joints but also in bursae and tendinous sheaths.

Clinical Presentation

There is a threefold female predominance. Disease onset is insidious. Stiffness, especially long-standing morning stiffness, and arthralgia are the first symptoms. Patients complain about symmetric tenderness and swelling of the ►small joints. Larger joints are usually affected later. Rarely, there are atypical features such as monarticular or sudden polyarticular onsets.

Joint effusion, periarticular edema, and synovial hypertrophy lead to the typical pasty appearance of the ►soft tissue swelling. Laboratory findings are elevated erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), rheumatoid factor, and antibodies directed to citrullinated proteins.

Rheumatoid arthritis commonly affects the cervical spine. The morbidity of neck disease is considerable. Neurologic dysfunction is a rare but severe complication of late-stage cervical arthritic deformity, and therefore the cervical spine should be evaluated with caution. Imaging, however, gives no unfailing predictors for myelopathy, only risk factors. The first clinical symptoms are neck and/or occipital pain. In patients with known cervical arthritis, clinical symptoms including muscle weakness (diminished motor power in arms and legs), muscle spasm, gait disturbance, paresthesia, and numbness should raise suspicion of myelopathy. Restless legs as a consequence of spinal automatism and bladder dysfunction suggestive of early neurogenic bladder are later symptoms. Neurologic examination of patients with myelopathy reveals hyperreflexia, Babinski's sign, and loss of pain sensation or vibratory or position sense.

Organ manifestations in RA are pulmonary fibrosis, pleural effusions, and pulmonary nodules.

Imaging

The primary imaging tool for the diagnosis of rheumatoid arthritis is X-ray views of both hands and feet, even if there is no clinical feet involvement at all. Images are typically taken employing high-resolution screen–film combinations. Two projections (dorsovolar and standardized angulated with a 20° wedge, elevated on the radial side) are recommended. Among radiographic alterations described to date, erosion seems to be associated with the best reliability and discriminating power. However, X-ray imaging is insensitive to bone damage at its earliest stages and is incapable of capturing the primary feature of rheumatoid disease, the synovitis. Magnetic resonance imaging (MRI) and ultrasound can directly visualize and monitor changes in synovium and bone that precede actual bone erosion. On the other hand, these advanced imaging techniques are confined to relatively small areas, and considering the polyarticular nature of the disease, there is a lack of general information.

Affection of the *large joints* is also imaged with X-ray. In cases of clinical involvement of the cervical spine, a lateral projection in inclination is mandatory in addition to normal anteroposterior and lateral views.

Follow-up studies are important to evaluate therapy success, progression, or complications. Nuclear bone scans can help find inflammatory foci with no or small clinical symptoms. Ultrasonography is the major tool for tendovaginitis, bursitis, and synovial cysts, such as Baker's cyst. In cases of cervical spine arthritis, MRI is the best feature for visualizing the spinal cord and arthritic involvement.

Signs and Patterns in Rheumatoid Arthritis

Typically, arthritis affects the *small joints* (metacarpophalangeal joint, proximal interphalangeal joint, wrist, metatarsophalangeal joint) symmetrically. Proximal joints are affected later in the classic disease course, but may be the first manifestations in atypical cases, especially in late-onset rheumatoid arthritis (►LORA). Involvement of the *cervical spine* is frequent. In these cases, atlantoaxial and especially atlantodental joints are the major location of inflammatory activity. Inflammatory rheumatic subaxial cervical spine disease such as discitis with instability and appendicular joint arthritis is less common. Involvement of the thoracic and lumbar spine is unusual.

Soft tissue swelling with the typical fusiform appearance of joint or tendon sheath effusion is one of the first signs of the inflammatory process (e.g., at the processus styloideus ulnae, which indicates tenosynovitis of extensor carpi ulnaris, or of the metacarpophalangeal joint and proximal interphalangeal joint as a sign of articulosynovitis). Periarticular, subchondral, epiphyseal, and metaphyseal demineralization are an early manifestation and refers to the old term ►"*collateral phenomenon*." The demineralization process progresses in the disease course due to pain-related rest, corticoid therapy, and inflammatory activity leading to excessive peripheral osteoporosis. A concentric pattern of joint space diminution indicates *cartilage destruction* in inflammatory arthritis, unlike eccentric joint space diminution, which is a sign of degenerative osteoarthritis. Erosions of the subchondral bone begin in the bare areas and at the joint margins (Fig. 1). At the metacarpophalangeal joint, they can

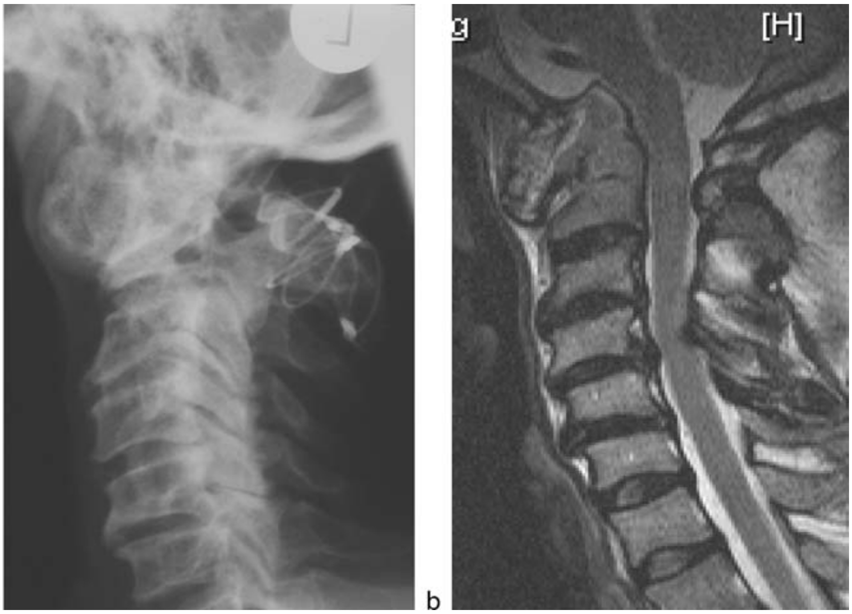
Rheumatoid Arthritis. Figure 1 **Rheumatoid arthritis. (a) dorso ventral view of the left hand of a patient suffering from rheumatoid arthritis for 5 years shows mild arthritic erosions of the MCP and moderate arthritis of the wrist (joint space diminution), already with postarthritic secondary degenerative osteoarthritis (subchondral sclerosis) and scapholunate instability (rotation of os scaphoideum). PIP joints show unspecific microcystic changes. (b) Twelve years later, the arthritis of the wrist has been massively progressive. Now mutilation of the distal epiphysis of the radius and ulna are present. The proximal carpal row is completely destroyed and shifted ulnar. MCP V has developed erosions and subluxation.**

be found in the voloradial and dorso-ulnar aspects of the metacarpal heads, and similarly at the metatarsophalangeal joint. ►*Bony destructions* progress to mutilation of the joints. Postarthritic ankylosis is not very common in adult RA, in contrast to juvenile arthritis. The wrist, however, is a characteristic location where postarthritic ankylosis, the so-called ►*os carpale*, is a possible and functionally relatively satisfying end stage of the arthritic process. A partial os carpale with ankylosis of only two or three carpals is not uncommon. Radiolunar ankylosis can especially occur spontaneously. Mutilation and complete destruction of the proximal carpals along with subluxations is, in fact, more common than os carpale.

Frequently, destruction of ligamentous support leads to *deformities*. In hands and feet, some deformities are characteristic: ►*swan-neck deformity*, ►*boutonniere deformity*, *ulnar deviation of the* metacarpophalangeal joint, ►*fibular deviation of the toes*, ►*ulnar drift and palmar subluxation of the carpus*, ►*zig-zag deformity*, *dorsal intercalated segmental instability, scapholunate instability and* ►scapholunate advanced collapse, *hallux valgus, dorsal subluxation of the* metatarsophalangeal joint, "*cock-up toe.*" In the shoulder, rotator cuff destruction with consecutive cranial subluxation and subacromial nearthros formation is frequent and often exceeds the arthritic signs at the humeral head and glenoid.

In the cervical spine, inflammation most often affects the minute joints and facets of the occiput-C2 region. It causes ►*erosions of the odontoid process* basally, laterally, ventrally, and at the tip. These erosions may progress to major destruction of the odontoid process. Atlas erosions are often tiny. Ligament laxity and lysis increase the mechanical instability. V*entral atlantoaxial subluxation and* ►*cranial settling* are typical and crucial deformities (Fig. 2). A distance between the anterior arch of C1 and the odontoid process exceeding 2.5 mm is pathologic (the normal measurement is ≤2.1 mm, which is 2.5 mm for a 6-foot target to film distance). Often subluxation is provoked or increased in inclination and may reach values of 10 mm or more. The distance between the odontoid process and the posterior arch of C1 gives the diameter of the osseous spinal canal and may be of higher importance. A distance of less than 14 mm is an alarming sign.

Nevertheless, in X-ray imaging the encroachment is often underestimated due to the lack of soft tissue (pannus) visibility. Arthritis of the lateral atlantoaxial joints with considerable destruction of the massa lateralis atlantis leads to *cranial settling* of the odontoid process. Its superior aspect passes the foramen magnum line, and the anterior arch of C1 assumes an abnormally low position in relation to C2. Progressive cranial settling is regarded as an ominous sign of impending neurologic catastrophe.



a b

Rheumatoid Arthritis. Figure 2 Rheumatoid arthritis. The lateral view of the cervical spine shows arthritis in the occipital-C2 region (a) with ventral atlas subluxation and wire fixation of C1–C2. There is considerable cranial settling and persisting ventral atlas dislocation. (b) MR imaging reveals the cause of recent pain and neurologic symptoms subaxial as discovertebral and apophyseal joint degenerative disease with encroachment C4/5. The ►cervicomedullary angle however is decreased to 135˚. The atlantoaxial deformity and the extent of cranial settling is far better visualised than by means of X-ray imaging. Together with subaxial polysegmental encroachment these signs indicate risk factors for myelopathy.

If the apex of the odontoid process is visible in the lateral view, its distance to the foramen magnum line of McRae should be measured. The tip of the odontoid process is normally located 5 mm below it and should not migrate above this line. If the odontoid process is destroyed or obscured, the distance between the base of the axis and the basion is a reasonable substitute measurement, at least for follow-up evaluations.

►*Subaxial cervical arthritis* comprises *discitis* and ►*apophyseal joint arthritis*. ►Rheumatic discitis is characterized by intervertebral space diminution and tiny erosions of the end plates. Prevertebral soft tissue swelling is not a sign of rheumatic disease. Discitis may heal within years, with subsequent premature degenerative disease or bony bridging of parts of the intervertebral space, or persist and lead to instability. Subaxial instability, often multisegmental, is another high risk factor for myelopathy. Apophyseal joint arthritis is not very conspicuous in X-ray imaging; in late stages, however, microcysts and erosions as well as postarthritic degenerative osteoarthritis occur.

MRI for evaluation of the spinal cord and cervical spine should be used in patients with cervical pain not controlled with conservative management, with clinical symptoms suspicious of cervical myelopathy, and with C1 ventral subluxation (at least when it exceeds 5 mm). On MR images, the best diagnostic clues for patients at risk are subarachnoid space encroachment, cranial migration of the odontoid process, and a markedly decreased *cervicomedullary angle* <135° (which is the angle between two lines on, respectively, the ventral side of the medulla oblongata or brainstem and the cervical cord in degrees) (Fig. 2). Additional or polysegmental subaxial subarachnoid space encroachment is another high risk factor.

Other common findings on MRI are odontoid process erosions and atlas erosions and displacement or absence of the fat body caudal to the clivus. Pannus is identified in varying amounts as a soft tissue mass around the odontoid process. It can be hyperintense on T2-weighted images and enhance intensely contrast material in the more acute phase, or it can be isointense on T2-weighted images not enhancing, which is thought to be fibrous pannus.

►*Subcutaneous rheumatoid nodules* can be seen in seropositive rheumatoid arthritis. They are characteristic but not very common and are typically located at bony prominences (proximal interphalangeal joint, processus styloideus ulnae, olecranon). Patients with peripheral rheumatoid nodules tend to show more specialties, such as pulmonary nodules.

Patients with RA are very prone to osteoporosis due to pain-related rest, steroid therapy, and the inflammatory activity itself. Osteoporotic fractures are very common in the lumbar and thoracic vertebral column. Insufficiency fractures occur in the os sacrum, the lower leg, and the os calcis. In the os sacrum the fracture exhibits a typical H-shaped aspect. In X-ray images it is often not very conspicuous at all. There may be an indistinct faint sclerosis of the spongiosa. Bone scanning shows an H-shaped hyperactivity (*Honda-sign*). The fracture is best seen on computed tomography.

Nuclear Medicine

Radionuclide studies done with technetium-99m-labeled phosphonates (bone scan) are accomplished by a so-called three-phase study: perfusion phase (0–60 sec p.i.), blood pool phase (2–5 min p.i.), and bone (turnover) phase (2–5 h p.i.). The perfusion and the blood pool phases demonstrate the hyperemia and allow judgment of inflammatory (soft tissue) components of joint disease. The bone phase discloses the longer-lasting bone processes. Bone scintigraphy directs the further diagnostic work-up to otherwise occult inflammatory foci. It is very sensitive, but its role in the diagnostic work-up of initial changes is limited because of low specificity. It may be employed for staging and follow-up.

(18)F-FDG positron emission tomography is a unique imaging technique that can assess the metabolic activity of synovitis and measure the disease activity in RA. However, the clinical significance of this potential has not been proven.

Diagnosis

The diagnosis and management of RA are predominantly based on clinical parameters. Radiologic and serologic findings are also integrated into the diagnostic criteria set (Table 1). Additionally, current clinical work-up relies heavily on serologic tests for the prompt and accurate diagnosis of rheumatic diseases. Serologic testing should be used to support the findings of the history and physical examination and to monitor disease activity.

Rheumatoid Arthritis. Table 1 ARA criteria (1987) for the diagnosis of rheumatoid arthritis

Morning stiffness >1 h >6 weeks
Arthritis of >3 joints simultaneously >6 weeks
Arthritis of wrist or finger joints >6 weeks
Symmetric arthritis >6 weeks
Rheumatoid factor
Subcutaneous rheumatoid nodules
X-ray signs of rheumatoid arthritis

In accordancce with the ARA criteria (1987), rheumatoid arthritis is diagonised when four of seven criteria are positive.

Inflammation can be assessed by the ESR. The CRP (an acute-phase protein) test correlates more closely than ESR with clinical and radiographic parameters of RA inflammation. The rheumatoid factor is unspecific as a screening test for RA accounting for the existence of seronegative RA. However, high titers of rheumatoid factor are associated with progressive joint inflammation and disability. Antibodies directed to citrullinated proteins (anti-ccp) facilitate diagnosis during the early stages of disease, when all clinical symptoms have often not manifested yet. Particularly high specificity is reported. Its prognostic potential may provide an indication for aggressive treatment.

Interventional Radiological Treatment

Intra-articular radionuclide therapy is a promising tool for local control of synovitis. It works like a synovectomy and is performed mainly in the larger joints (e.g., rhenium or yttrium), but it works at the smaller joints as well. Radiosynovectomy is not useful in advanced cases or excessive joint effusions, nor does it modify the disease course.

Spherical configured pneumonic consolidation mimicking a rounded intrapulmonary mass.

▶ Pneumonia in Childhood

Roux-en-Y Gastric Bypass

The surgical procedure consists of forming a small gastric fundal pouch to exclude the remainder of the stomach and duodenum. A jejunal loop is anastomosed to the gastric pouch. A distal side-to-side anastomosis of the excluded jejunal limb and the antegrade-flowing jejunal-limb is formed; creating a "Y" shaped intestinal junction.

Salivary gland inflammation; Sialoadenitis

Definition

Sialoadenitis is a condition characterized by inflammation of one or more of the salivary glands.

Inflammatory diseases are the most common illness affecting the major salivary glands.

There are both acute and chronic forms. Acute inflammation of the salivary glands has only few causes, most commonly being of viral or bacterial origin. On the other hand, chronic salivary inflammation may be caused by numerous processes as infectious, systemic, autoimmune and certain neoplasms.

Pathology/Histopathology

Acute ►sialadenitis is a condition characterized by inflammation and swelling of one or more salivary glands. The gland may be diffusely or focally enlarged. The pathologic process is characterized by very important interstitial edema with limited infiltration of periductal and interacinar connective by granulocytes, lymphocytes, and monocytes. Moreover, acinar-ductal epithelium is swollen and desquamed. Granulocytes and round cells can be observed in the ductal lumen. During acute sialadenitis, abscess formation may take place. Predisposing factors include dehydration and excretory duct obstruction caused by stones or fibrosis. Purulent material may be expressed from the ductal orifice in most bacterial infections.

In chronic inflammation, salivary glands are normal sized or smaller. In chronic sialadenitis, there are varying degrees of acinar atrophy, lymphoid infiltrate with or without germinal centers, and fibrosis. The ducts exhibit dilatation and hyperplasia of the lining epithelium with metaplasias. Extensive dilatation can result in cyst formation. Goblet cell metaplasia produces abundant mucin. The overall architecture of the gland is usually maintained.

Clinical Presentations

Acute inflammation of the salivary glands is usually of viral or bacterial origin; viral and bacterial infections are the most common causes of salivary abnormalities. Mump represents not only the most common cause of parotid swelling, but also the most common viral disorder of the salivary glands. Children are most often affected with peak of incidence at approximately 4–6 years of age. Typically, there is a 2–3 week incubation period with associated fever, malaise, myalgia, and headache which may precede the observed parotid swelling. Salivary gland involvement may be seen in a wide range of other viral illnesses including those caused by cytomegalovirus, lymphocytic choriomeningitis virus, coxsackievirus A, echovirus, and parainfluenza virus type C among others.

Acute suppurative sialadenitis is most commonly bacterial in origin and most often involves the parotid, and to a lesser extent, the submandibular glands. This is in part due to the fact that the serous saliva of the parotid has a lower bacteriostatic effect than the more mucous saliva of the ►submandibular gland. The most common offending agent is *Staphylococcus aureus.* Other aerobic organisms isolated are *Streptococcus pneumoniae, Hemophilus influenzae,* and *Escherichia coli.* Salivary stasis secondary to either obstruction (e.g., sialoliths, ductal strictures) or decreased production, often as a result of dehydration, is thought to be an integral component in the pathogenesis of this condition. Common clinical settings in which this entity may occur include the elderly postoperative patient after cardiothoracic or gastrointestinal surgery and more frequently the debilitated, dehydrated patient, usually with poor oral hygiene. The typical presentation involves sudden, diffuse enlargement of the gland with associated induration and tenderness. Massage of the involved gland results in the secretion of purulent material from the duct. Patients with an undiagnosed or incompletely treated acute suppurative sialadenitis can develop an intraglandular abscess. Small abscess may form and coalesce to form a larger abscess, or a solitary abscess may develop. It usually manifest as painful swelling of the salivary gland with skin reddening.

Decreased salivary flow with stasis is a key factor in chronic sialadenitis. Like acute sialadenitis, this condition is more common in the ►parotid gland. Its development is often associated with a previous episode of acute suppurative inflammation with subsequent glandular destruction. Another possibility is the recurrent parotitis of childhood which has continued into adulthood.

Symptoms include intermittent swelling of the gland, often painful, that may or may not be associated with food assumption. Approximately 80% of patients experience permanent xerostomia. It is very important to differentiate the obstructive and nonobstructive disease, since their treatment and prognosis often vary significantly. The chronic obstructive disease involves the submandibular gland more frequently than the parotid gland. Conversely, the nonobstructive disorders are more common in the parotid glands.

Other infectious agents, like *Mycobacterium tuberculosis*, atypical mycobacteria, *Toxoplasma gondii*, *Actinomyces israeli* can determine chronic sialadenistis either as an ascending infection from the oral cavity or as a part of a systemic process.

Noninfectious conditions such as autoimmune disease, previous irradiation, or idiopathic causes may also lead to chronic inflammation. Sjogren Syndrome is a chronic, slowly progressive, relatively benign autoimmune disease characterized by lymphocyte-mediated destruction of the exocrine glands resulting in keratoconjunctivitis sicca and xerostomia. The disease primarily affects middle-aged women, but can be seen in all ages.

Imaging

Ultrasonography. The examination should be carried out with the highest-frequency transducer possible. Usually, 5–12-MHz wide-band linear transducers are used. In acute inflammation salivary glands are enlarged and with reduced echogenicity (1–3). They may be inhomogeneous for the presence of multiple, small, oval hypoechoic areas in their content. Increased intraglandular blood flow can be depicted at US. Abscesses are hypoanhechoic lesions with posterior acoustic enhancement and blurred borders (1). Central colliquation may be distinguished as an avascular area or identified by means of moving debris. A hyperechoic halo can surround an organized abscess (1). In chronic inflammation, salivary glands are normal sized or smaller, hypoechoic and non homogeneous; usually they do not have increased blood flow at Doppler examination. Salivary glands' US is the technique to be used in the suspect of calculosis. US features of scialolithiasis include strongly hyperechoic lines or points with distal acoustic shadowing, which represent stones. However, in chronic ductal scialolithiasis complicated by chronic or recurrent inflammation, the gland may lose its function and stones located in a nondilated duct may be difficult to demonstrate.

Conventional radiographs. The plain radiographic examination is rarely used today for the evaluation of the major salivary glands.

Although conventional radiographs can be obtained quickly and at low cost they are of limited clinical value since they only identify reasonably large, fairly dense calcifications (2).

Sialography. Sialography is a radiographic examination of the parotid or submandibular gland that uses a positive contrast agent to demonstrate the ductal salivary anatomy. It is an invasive procedure in which radiopaque contrast medium is injected retrograde into the glands ductal system *via* the intraoral opening of either Wharton's or Stensen's duct. Conventional sialography has been used for investigating the ductal system of major salivary glands. Imaging is performed to delineate inflammatory or obstructive changes within the ductal system of parotid and/or submandibular glands (2, 3). The technique is contraindicated in the acute setting of sialoadenitis, as it could cause retrograde spreading of the infection into the gland. Sialography should be used essentially for assessing chronic sialoadenitis as well as Sjogren's syndrome (2, 3).

Computed tomography. CT examination performed very early in an acute infection, allows to demonstrate dilatation of the central ducts and enhancement of the central ducts and of Stensen's duct. The salivary gland can appear variably enlarged and has an increased attenuation on basal scans due to the cellular infiltration (2, 3). There may be diffuse enhancement of the gland on postcontrast images, reflecting the increased vascularity. Presence and location of sialoliths can be clearly detected at CT. If present, inflammatory stranding into the overlying subcutaneous tissue is usually identifiable. CT scans obtained in the coronal plane for inflammatory conditions of the parotid and submandibular glands may be helpful for evaluating the extent of the lesion; in particular the relationship of the inflammatory mass to the floor of the mouth for submandibular lesion and the skull base for the parotid gland masses, both findings of great importance with respect to the surgical approach (2, 3). Because of the fatty attenuation that is intrinsic to the parotid glands, abscesses are particularly well seen on contrast-enhanced CT scan. Most important CT findings in chronic sialadenitis are related to changes from chronic scialolithiasis that may result in a small atrophic gland with focal intraglandular calcifications. More rarely a large ductal stone without signs of acute glandular inflammation can be seen.

Magnetic resonance imaging. Magnetic resonance provides better imaging of soft tissue than CT, but it is less suitable to investigate the suspected inflammatory diseases of the salivary glands due to its inability to visualize small potential clinically significant calcifications. In acute inflammation, on MRI the interested gland is variably enlarged with a reduced visualization of both interstitial and ductal component compared to a normal gland. The gland can have either higher o lower signal intensity than normal one on T2-weighted images, depending on whether edema or cellular infiltration predominates (2, 3). The MR sialographic technique with heavily T2-weighted images for depiction of static or nearly static fluids represents a noninvasive technique for the detection of ductal abnormalities in major salivary glands (4). The most obvious advantage of this technique is the fact that images can be obtained without use of ionizing radiation and its noninvasiveness as well. No contrast material has to be injected, and images can be obtained with short acquisition times of less than 10 sec. Contralateral salivary glands can be easily visualized without further positioning of the patient and can serve as controls. Contraindications for conventional sialography such as acute sialadenitis are not contraindications for MR sialography. Ductal structures can also be visualized in cases of complete obstruction of the ductal system. Also, additional cross-sectional images of the glandular parenchyma can be obtained by using conventional T1- and T2-weighted sequences. Furthermore, MR sialography has an excellent sensitivity for visualization of edema in the salivary parenchyma, which is more difficult to diagnose with CT.

Nuclear Medicine

Nuclear medicine has a limited role in the assessment of sialadenitis. Sequential scintigraphy is currently employed for assessing the functional status of all the four major salivary glands and evaluating the chronic evolution of glandular damage.

Diagnosis

Most of the salivary glands diseases are characterized only by a few distinct clinical and laboratory tests patterns. Clinical judgment with a careful history and physical examination are still considered of great relevance. However, to obtain a definite diagnosis, imaging techniques are required in most cases. Salivary glands US is the technique to be firstly used because in many cases the nature of underlying disease can be promptly suggested. However, as the imaging identification of calcification is important in the diagnosis of inflammatory process of the salivary glands, in doubtful cases at US, CT represents the examination of choice. In particular, CT is more accurate than US in detecting the presence and the number of sialoliths and in distinguishing multiple clusters of stones from single large stones. Usually, CT in this setting is best performed without administration of contrast material, since small opacified blood vessels may simulate small sialoliths. If an abscess or inflammatory process is suspected, adding enhanced scans after identifying stones on nonenhanced scans may be useful. Conventional sialography today should be used essentially for assessing chronic sialoadenitis unrelated to ►sialolithiasis. At present, MR sialography should be preferred because of the greater sensitivity in diagnosing inflammatory diseases of the salivary glands so that incannulation of the salivary duct is not required.

Finally, in case of suspected autoimmune sialadenitis, the disease could be usefully assessed by mean of needle biopsy.

Salivary Glands, Neoplasms

Misa Sumi, Takashi Nakamura
Department of Radiology and Cancer Biology, Nagasaki University School of Dentistry, Nagasaki, Japan
misa@nagasaki-u.ac.jp

Definition

Epithelial (adenomas and carcinomas) and nonepithelial tumors arising from the major and minor salivary glands. Salivary gland neoplasms represent 3–5% of all head and neck tumors, and occur most frequently (approximately 80%) in the parotid gland. The majority (70–80%) of the parotid gland tumors are benign. Tumors of the submandibular gland and sublingual glands occur less frequently, but are more likely to be malignant; approximately 40% and 70% of tumors are malignant in the submandibular and sublingual glands, respectively. On the other hand, 50% of all minor salivary gland tumors are malignant.

Pathology/Histopathology

WHO's histological classification of salivary gland tumors includes 13 adenomas and 24 carcinomas (1). Pleomorphic adenomas are the most common benign epithelial tumors of the salivary glands. This benign tumor usually appears as an ovoid, well-circumscribed mass that may exhibit a pedunculated outgrowth, for example, from the superficial to deep lobes of the parotid gland. The lesion may be associated with cystic change, hemorrhage, and calcification. In major parts of the tumor contain glandular, ductal, or solid structures of epithelial elements. The lesion also contains mesenchymal tissues, which may be frequently associated with chondroid and fibromyxomatous tissues.

Warthin's tumor exclusively occurs in the parotid gland, typically in the tail of the gland, and is the second most common benign lesion of the parotid gland. It may occur as multiple masses within one or both parotid glands. Cystic change is among the characteristic features of the lesion. Warthin's tumor is composed of a double layer of oncocytes that line the papillary projections, extending into the cystic spaces.

Mucoepidermoid carcinoma represents approximately 30% of the malignant tumors of the salivary glands, and arises most commonly (approximately 50%) in the parotid gland and the second most commonly (approximately 45%) in the minor salivary glands. The tumors may be classified as low, intermediate, or high grade. Low-grade tumors are well-circumscribed, usually contain large cystic areas with mucinous components, and abundant goblet cells that are lined by squamous components. Low-grade tumors are rarely associated with nuclear polymorphism, mitotic features, or necrosis. In contrast, high-grade tumors are poorly circumscribed, infiltrative, and exhibit dominant proliferation of the squamous components; goblet cells are rarely observed.

Adenoid cystic carcinoma represents the most common malignancy arising from the submandibular and sublingual glands, accounting for approximately 12% and 15% of tumors of these glands, respectively. The tumor is partially encapsulated and is rarely associated with cyst formation and hemorrhage. Histopathologically, adenoid cystic carcinoma is classified into the tubular (low grade), cribriform (intermediate grade), or solid (high grade) type; occasionally, some of these types are occasionally seen in a single tumor. This tumor has a tendency to spread via the nerves. Perineural invasion is a hallmark of this tumor; it may be present distally in a nerve, and the proximal segment may appear normal (perineural skip extension).

Acinic cell carcinoma represents approximately 9% of all malignant tumors of the parotid gland. The parotid gland is the most common site of origin of this tumor, and bilateral involvement is observed in 3% of patients. It is a solid mass or is partially cystic. Histologically, the acinic cell carcinoma recapitulates serous cells with bubbly basophilic cytoplasm containing zymogen granules.

Salivary duct carcinoma is an extremely aggressive tumor, and histologically displays squamoid appearance, reminiscent of mucoepidermoid carcinoma or squamous cell carcinoma. Perineural spread is also common in this malignant neoplasm, and lymph node metastasis is not uncommon.

Clinical Presentation

Benign tumors are usually slow growing, movable, painless masses. Malignant tumors present as firm, fixed and painless masses; in advanced stage, symptoms can include pain, otorrhoea, paraesthesia, facial nerve palsy, dysphagia, trismus, and cervical lymph node involvement. Pain or itching over the course of the facial nerve suggests a malignant parotid tumor. In addition, the combination of cranial nerve VII and V3 neuropathy suggests adenoid cystic carcinoma of the deep lobe of the parotid gland.

The American Joint Committee on Cancer proposed the clinical staging of the malignant tumors of the major salivary glands chiefly based on the tumor size. Minor salivary gland tumors are staged as those arising from the corresponding anatomical sites.

The anatomical region of a malignant salivary gland tumor is an important prognostic factor for local control and overall survival (3). The T-stage is an independent prognostic factor for local control. The histological type is an independent prognostic factor for distant metastasis. The T- and N-stages, and skin involvement are prognostic factors for distant metastasis and overall survival. The N-stage and facial paralysis are prognostic factors for local control. Metastasis to the regional lymph nodes is relatively rare in malignant salivary gland tumors, while it occurs in 40% of squamous cell carcinomas. Distant metastasis occurs in approximately 20% of malignant salivary gland tumors (most frequently seen in adenoid cystic carcinomas).

Imaging

Preoperative prediction of the malignancy or benignancy of salivary gland tumors is clinically very important, because this information strongly influences the surgical plan. In general, MR imaging is the first choice for the imaging of the salivary gland tumors. CT and sonography are alternatives to MR imaging.

Magnetic Resonance Imaging

Although conventional T1-weighted MR imaging with or without gadolinium enhancement and T2-weighted MR imaging techniques have been used for the diagnosis of salivary gland tumors, many investigators have reported difficulty in the differentiation of these tumors, particularly between benign and low-grade malignant tumors.

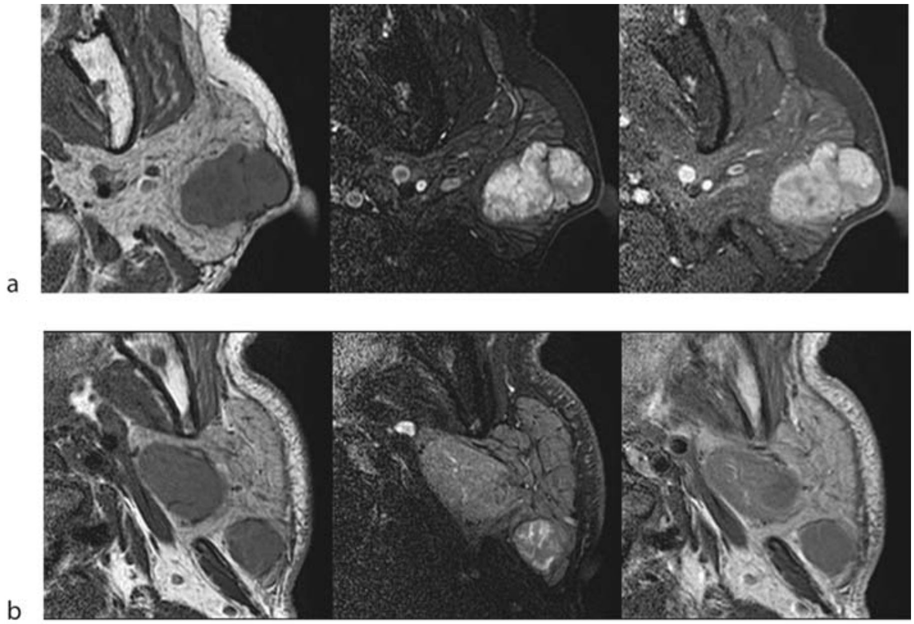
▶*High-resolution MR imaging* of the salivary gland tumors using a small surface coil well delineates the detailed structures of the tumors and can provide important clues regarding their histologies and for prediction of their benign or malignant nature (Fig. 1).

Pleomorphic adenomas are usually well-defined, homogeneously intermediate to hypointense on T1-weighted images, and heterogeneously hyperintense on fat-suppressed T2-weighted images (Fig. 1a). Warthin's tumors exhibit various features ranging from hypointense to hyperintense on T1-weighted and fat-suppressed T2-weighted images (Fig. 1b). Cyst formation is observed in one-third of Warthin's tumors, resulting in hyperintense foci on fat-suppressed T2-weighted images. Hyperintensities in the cystic areas on T1-weighted images indicate the presence of proteinaceous fluids, colloidal materials, or hemorrhage.

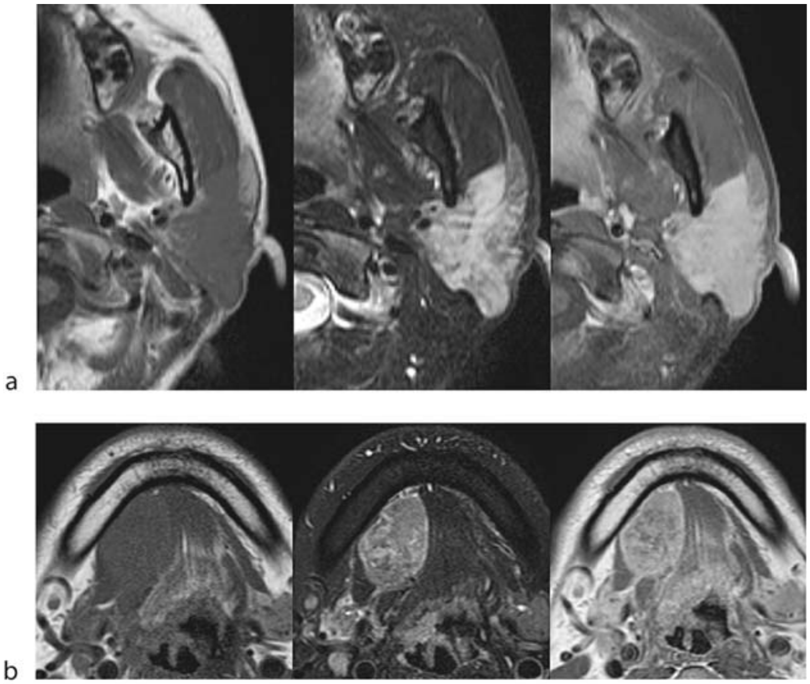
In general, high-grade malignancies have irregular, infiltrating margins (Fig. 2). Compared with low-grade malignancies and benign lesions, high-grade malignant tumors are associated with high cellularity, and thus have lower signal intensities on fat-suppressed T2-weighted images.

Differential diagnosis of benign and malignant salivary gland tumors based on the descriptive characterization on conventional T1-weighted and fat-suppressed T2-weighted imaging may be further substantiated by using quantitative parameters obtained by functional MR imaging, for example, ▶*apparent diffusion coefficient* (*ADC*) maps obtained by ▶*diffusion-weighted MR imaging* and ▶*time-signal intensity curves* (*TICs*) obtained by ▶*dynamic contrast-enhanced MR imaging*.

The increased nuclear-to-cytoplasmic ratio and hypercellularity, both of which are frequently observed in highly malignant tumors, reduce the extracellular matrix and the diffusion space of water protons in the extracellular and



Salivary Glands, Neoplasms. Figure 1 High-resolution MR imaging of benign salivary gland tumors using a 47-mm microscopy coil. Axial T1-weighted images (left panels), and fat-suppressed T2-weighted images (center panels), and gadolinium-enhanced T1-weighted images (right panels) show pleomorphic adenoma (a) and Warthin's tumor (b) of parotid glands. High-resolution imaging reveals detailed architectures of salivary gland tumors. Note that multiple occurrences of Warthin's tumor as in (b).



Salivary Glands, Neoplasms. Figure 2 MR imaging of malignant salivary gland. Axial T1-weighted images (left panels), fat-suppressed T2-weighted images (center panels), and gadolinium-enhanced, T1-weighted images (right panels) of adenoid cystic carcinoma (a) and carcinoma ex pleomorphic adenoma (b) of parotid and sublingual glands, respectively.

intracellular dimensions, along with a resultant decrease in the *ADCs*. Therefore, the ADCs of malignant solid lesions are lower than that of benign tumors, except Warthin's tumors. The ADCs of solid lesions of Warthin's tumors are low and mimicked values of malignant tumors. A proliferation of the epithelial component and intense lymphoid accumulation in the stroma may have decreased the ADCs of the Warthin's tumors.

Based on the time of peak enhancement (T-peak) and the washout ratio (WR), salivary gland tumors could be categorized into four types (4). In type A, the *TIC* has a long T-peak, and is characteristic of pleomorphic adenomas. In type B, the *TIC* has a short T-peak and a high WR and is characteristic of Warthin's tumor. In type C, the *TIC* has a short T-peak and a low WR and is characteristic of cancers. In type D, the *TIC* is flat and is suggestive of cystic or necrotic area. The combined use of the *ADC* maps and *TIC* criteria could greatly improve the diagnostic ability of MR imaging.

Sonography

The sonographic examination of the salivary glands is usually performed using a high-frequency (10–14 MHz) transducer. This yields high-resolution images of superficial organs such as the parotid and submandibular glands (Fig. 3). However, sonographic images of the deeper parts of the glands may be of poor quality. This is the chief reason that sonography is not used as frequently as CT or MR imaging in examining patients with possible deep extensions of salivary gland tumors. Differentiation of benign and malignant salivary gland tumors on the basis of descriptive studies on gray-scale images is difficult. On the other hand, quantitative sonographic analysis could be employed for effective diagnosis of benign and malignant tumors of the parotid gland; the combined use of the sonographic criteria (the mean gray level and the standard deviation of the echo levels) greatly improved the diagnostic accuracy when compared with that of qualitative diagnosis (5).

It is not clear which differences in tumor tissues may result in the characteristic differences in internal architectures of sonographic images of the salivary gland tumors. We often observe cystic areas, connective tissues, hyalines, and necrotic and keratinized materials in tumor tissues. Probably, these microscopic changes may result in the observed differences in echogenicity.

Salivary Glands, Neoplasms. Figure 3 Sonographic images of benign and malignant parotid gland tumors. Sonography shows well-defined tumor margins in pleomorphic adenoma (a) and Warthin's tumor (b), while ill-defined margin in adenoid cystic carcinoma (c). Tumor echogenicity is homogeneous in pleomorphic adenoma (a), while heterogeneous in Warthin's tumor (b) and adenoid cystic carcinoma (c).

S

Nuclear Medicine

Nuclear imaging is most frequently employed for examination of salivary gland tumors such as Warthin's tumors and oncocytomas, both of which highly accumulate technetium (Tc) 99m. Positron emission tomography (PET) studies using 2-[F-18]fluoro-2-deoxy-D-glucose (FDG) are capable of demonstrating high-grade malignant tumors with increased metabolic activity. However, significant overlaps occur with benign tumors such as Warthin's tumors.

Diagnosis

In addition to the assessment of the benign or malignant nature of salivary gland tumors, the imaging should be mainly focused toward evaluating the following points: (1) whether a tumor is confined to the parenchyma of the gland or extends outside the gland into the upper neck and skull base; (2) whether a tumor involves the facial nerve; although the precise identification is difficult even on *high-resolution MR imaging*, the tumor location relative to the main trunk of the facial nerve (pes anserinus) may be identified by using anatomical landmarks such as the “tragal cartilaginous pointer” (the facial nerve trunk runs 1 cm caudal and 1 cm medial to the “pointer”), the stylomastoid process (the nerve runs lateral to the process and in the fat tissues), and the vascular plain (which lies lateral to the superficial temporal, retromandibular, and anterior facial veins); (3) whether the tumor has smooth or infiltrative margins; (4) whether lymph node metastasis is absent or present; and (5) whether multiple tumors are present; multiple occurrence is observed particularly in Warthin’s tumors, pleomorphic adenomas, oncocytomas, acinic cell carcinomas, basal cell adenomas, and lymphomas.

Salt-Losing Crisis

A deficiency of aldosterone that results in hyponatremia and hyperkalemia, leading to dehydration, hypotension, circulatory collapse, and, when severe, death.

▶Adrenogenital Syndrome

SAPHO

G M Lingg, C Schorn
Department of Radiology,
Sana Rheumazentrum Rheinland Pfalz,
Bad Kreuznach, Germany
dr.lingg@sana-rheumazentrum-rlp.de

Synonyms

Acquired hyperostosis syndrome; Pustulotic arthroosteitis; Sternoclavicular hyperostosis

Clinical Presentation

SAPHO is an association of skin and bone disease. The skin manifestation is either acne conglobata or fulminans or, more typically, psoriasis pustulosa palmaris and plantaris. Eighty percent of patients present with anterior chest wall affection, with relapsing and migrating symmetrical or asymmetrical pain and a tough swelling around the sternoclavicular joints that is often aggravated by cold exposure. There is no gender predilection. Children exhibit CRMO, whereas adults show multiforme osteitis such as sternoclavicular. The location of the osteitic focus may be quite variable, causing a variable clinical presentation. The sacroiliacal and vertebral affection is facultatively associated.

Imaging

In anterior chest wall involvement, plain X-rays of the sternoclavicular joints show a varying degree of enostal and periostal sclerosis of the sternum and medial clavicular ends. Sternoclavicular arthritis with mild destruction may occur. Ligament and costal cartilage ossification is typical. In late stages, broad ossification bands from the sternum to the clavicle and upper rips obscure the normal anatomy. In early case, the plain films may show no abnormality. Sternoclavicular CT is employed. Sclerosis, bone formation, and enostal and periosteal and extrathoracal and intrathoracal (retrosternal fibroostitis) as well as sternoclavicular arthritis are seen with more conspicuity. MR imaging is not recommended because the sclerotic foci are a predominant finding and are best visualized by means of CT. MRI is, however, sensitive to the inflammatory process.

Sacroiliitis is a typical feature, mainly indistinguishable from ankylosing spondylitis, but sometimes with atypical asymmetrical marked sclerosis or destruction.

The affection of the spine may be similar to ankylosing spondylitis, but it presents with certain atypical features in a number of cases, such as marked vertebral sclerosis, ►giant shining corners, and ►bamboo-cane fragments. The latter refers to an oligosegmental sclerosing, but in these few segments, completely syndesmophytic ankylosed spine is in contrast to the otherwise normal radiologic appearance. In some cases the osteoproliferative features are heavily pronounced and the aspect is more like an atypical DISH (atypical because of, for instance, destructive and sclerotic details or ankylosis of the appendicular joints).

Osteitic foci in other locations are erosive or nonerosive, multiforme, and expansile. Severe differential diagnostic problems can arise because of the resemblance to bacterial spondylitis/osteomyelitis, osteoblastic metastases, and osteogenic tumors.

Nuclear Medicine

Bone scans show foci of increased osteoblastic activity (hot spots), especially in the sternoclavicular region. As a rule, in degenerative disease, which also causes sternoclavicular hot spots, the tracer accumulation is not intense enough to be seen from the back, and costal cartilage ossification does not expose tracer accumulation at all. In contrast, in SAPHO the costal cartilage ossification is an inflammatory-promoted process and does accumulate markedly. Bone scans are very sensitive but unspecific and can show foci in any location and direct the diagnostic work-up to these areas.

SAPHO

SAPHO syndrome (synonyms: acquired hyperostosis syndrome, pustulotic arthroosteitis, sternoclavicular hyperostosis) is a varied rheumatic symptom complex mainly with involvement of the anterior chest wall (sternoclavicular arthritis, sternal [clavicular] sclerosing hypertrophic osteitis with marked bony apposition, ligament ossification, osteoproliferation) and skin manifestation (acne fulminans or psoriasis pustulosa). Frequently, it is associated with spondyloarthropathy; then, sacroiliitis and oligosegmental sclerosing or ankylosing vertebral involvement are typical.

►Fractures, Stress
►Spondyloarthropathies, Seronegative

Sarcoid Arthropathy

There are three patterns of sarcoidosis joint involvement–Löfgren's syndrome, and early and late patterns of sarcoidosis arthropathy. Löfgren's syndrome is characterized by arthralgias, erythema nodosum and bilateral hilar lymphadenopathy. The early sarcoidal arthropathy pattern is manifested by polyarticular involvement of the distal extremities. The late manifestation of sarcoid arthropathy (6 months or more after sarcoidosis diagnosis) is a granulomatous synovitis. The diagnosis of sarcoidosis arthropathy is usually based on clinical presentation rather than imaging.

Nonnecrotizing granulomatous disease

Definition and Pathology/Histopathology

►Sarcoidosis is an inflammatory disorder of unclear etiology, characterized by the presence of noncaseating ►granulomas in the tissues. This is usually confirmed by fiber optic bronchoscopy, biopsy of lung or lymph node, a positive Kveim-Siltzbach test, or a combination of these methods, revealing nonnecrotizing epithelioid granulomas in the absence of other granulomagenic agents.

Clinical Presentation

Sarcoidosis most commonly affects the pulmonary and lymphatic systems, but may involve the muscles, joints, and bones, with osteoarticular complaints commonplace. These include muscle weakness, generalized muscle pain, soft tissue swelling and/or multiarticular stiffness, and pain. Lesions detected at imaging in sarcoidosis patients maybe symptomatic or asymptomatic.

Imaging

Neither skeletal survey nor conventional bone scan reliably detects sarcoidal bone lesions, except in the small bones of the hands and feet (1). The radiographic appearance of lacy osteolysis in the bones of the hands is familiar to radiologists, but there are myriad musculoskeletal manifestations, which may be revealed in advanced imaging (specifically MRI), including subcutaneous infiltration, various muscle lesions, sarcoidal arthropathy, and large and axial bone lesions (2).

Sarcoidosis Soft Tissue Masses

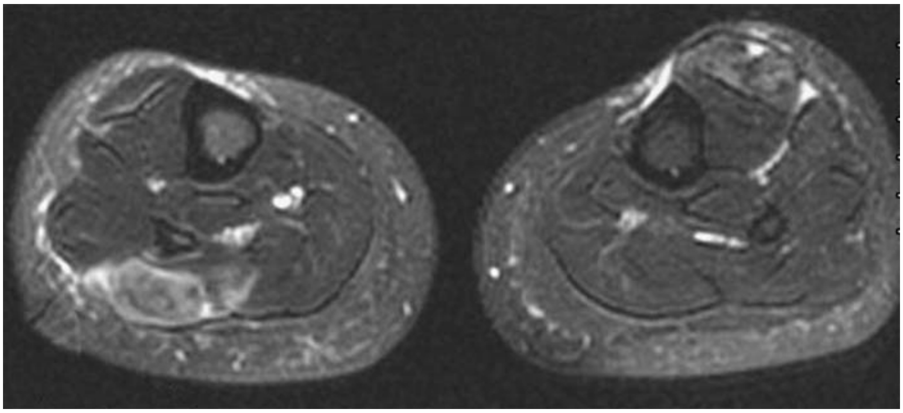
Sarcoidosis soft tissue lesions are uncommon, and present as palpable mass or swelling. These may be well defined or indistinctly marginated, with nonspecific signal characteristics—low on T1 weighted sequences, high on fluid sensitive sequences, and enhancing. These can be detected in the subcutaneous, inter- or intramuscular spaces. Differential diagnosis includes cellulitis (if subcutaneous and reticulated), or an inflammatory versus neoplastic mass. Biopsy is usually required, as MR imaging features are not pathognomonic.

Sarcoidal Muscle Lesions

Sarcoidal muscle involvement includes myopathy/atrophy, myositis, and sarcoidal muscle nodules (3). Sarcoid-related myopathy presents clinically with elevated serum creatine kinase and aldolase, symmetric proximal weakness, and electromyographic evidence of myopathy. On MRI, there is fatty replacement of muscle. Sarcoidal myopathy cannot be differentiated from atrophy secondary to corticosteroid treatment on the basis of MR appearance, however MRI is useful to delineate the extent and severity of involvement and determine optimal muscle biopsy sites. Sarcoidal muscle nodules are uncommonly observed, and present as tender palpable masses. On MRI these show a central low signal and rim enhancement, due to fibrosis, which has been described as a "dark star" (Fig. 1).

Sarcoidal Arthropathies

Three patterns of sarcoidosis joint disease may be encountered—Löfgren's syndrome, and early and late patterns of sarcoidosis arthropathy. Löfgren's syndrome is characterized by arthralgias, erythema nodosum, and bilateral hilar lymphadenopathy. The early sarcoidal arthropathy pattern (presenting during the first 6 months of sarcoidal symptoms) is manifested by polyarticular involvement of the distal extremities—ankles, knees, PIP joints, wrists, and elbows. Radiographs are usually negative, or show osteoporosis and soft tissue swelling, with rheumatoid arthritis as the principal radiographic differential diagnosis. A later manifestation of ▶sarcoid arthropathy (6 months or more after the diagnosis of sarcoidosis) usually involves 2–3 joints including the knees, ankles, proximal interphalangeal joints, and



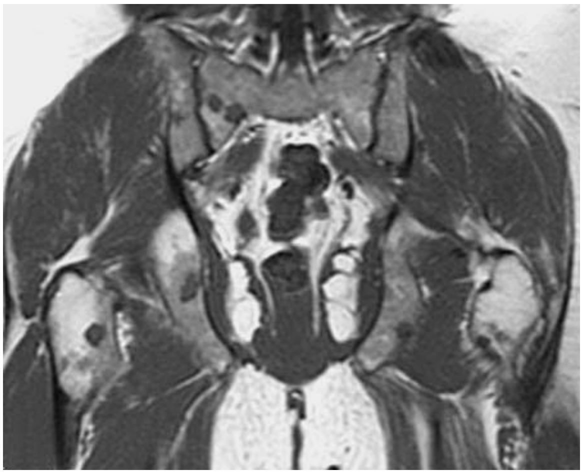
Sarcoidosis, Musculoskeletal System. Figure 1 Fifty-one year-old woman with sarcoidosis who presented with tender nodules along both calves. T2 weighted axial image demonstrates edematous nodules within the right posterior and left anterior compartment muscles. After contrast administration, these enhanced peripherally (not shown), with "dark star" appearance characteristic of nodular muscle sarcoid lesions. Noncaseating granulomas were found at biopsy.

occasionally the wrists or shoulders. Dactylitis may occur. These patients usually have granulomatous synovitis, and the disease course is transient or relapsing. Radiographic changes consist of subchondral cystic change. The joint abnormalities detected on radiographs and MRI in sarcoidosis patients reflect nonspecific arthropathy of indeterminate origin, which includes the common arthritides. Whether sarcoidosis contributes to the imaging findings is speculative, as synovial biopsy is not routinely obtained, and the diagnosis is usually based on clinical rather than imaging parameters. When MRI is performed, joints affected by sarcoidosis arthropathy may show lesions that are occult on plain films. Tenosynovitis, tendonitis, bursitis, synovitis, and prominent subchondral cysts can be demonstrated on MRI, but are nonspecific findings. Large subchondral cysts in the absence of osteophytosis may be seen in patients younger than those usually presenting with osteoarthritis with geodes.

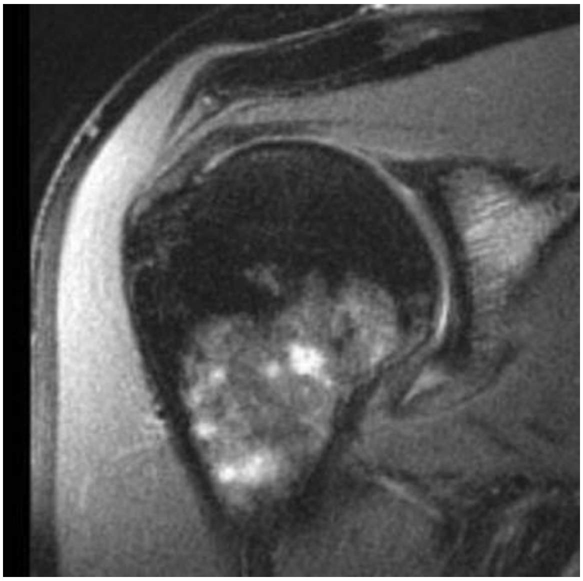
Bone Sarcoidosis

Osseous involvement is estimated to occur in about 5% of sarcoid patients, although it is important to consider that this percentage is derived from radiographic studies and may underestimate disease occult on radiographs (4). The diagnosis of sarcoidosis has usually been established by clinical criteria prior to the detection of suspicious bone lesions. Bone lesions may be biopsied to confirm sarcoidosis if the diagnosis is in doubt, or to exclude neoplasm. The radiographic appearance of lacy osteolysis in the bones of the distal extremities is considered virtually pathognomonic of sarcoidal involvement.

The alignment deformities in the hands and feet are often due to periarticular pathologic fractures rather than joint abnormalities. Large bone and spinal sarcoidal lesions, often occult on radiographs, maybe detected on MRI either incidentally, or in evaluation of musculoskeletal symptoms (5). On MRI, osseous sarcoidosis demonstrates a range of morphologies, from indistinctly marginated marrow infiltration, to discrete "cannon ball" and "starry sky" type lesions (Figs 2 and 3). The signal characteristics—low on T1 weighted images, increased signal intensity on water sensitive images, enhancing with contrast—are nonspecific. The principal differential considerations include bone metastases, lymphoma, myeloma, or rarely, disseminated nonmalignant entities such as fibrous dysplasia, disseminated fungal disease or tuberculosis, or serous atrophy. In some cases, we observed that the sarcoidosis lesions resolved on follow-up studies, with "ghosts" of the prior lesions showing central low signal correlating with fat and/or fibrosis (2). More study is needed to understand the natural history of these lesions on MRI. Our preliminary experience with



Sarcoidosis, Musculoskeletal System. Figure 2 Forty-eight year-old man with sarcoidosis and hip pain. Radiographs were negative. T1 weighted coronal image through the posterior of the pelvis demonstrates multiple rounded ("cannon ball") low signal foci. Six months later, these showed resolution on MR images.



Sarcoidosis, Musculoskeletal System. Figure 3 Forty-six year-old man with shoulder pain. T2 fat saturated oblique coronal image of the shoulder demonstrates multiple round and irregular intramedullary high signal foci. These were detected throughout the shoulder girdle. Subsequent whole body MRI (not shown) revealed innumerable similar foci in bilateral upper and lower extremities, spine, and pelvis. Biopsy of the right humerus demonstrated noncaseating granulomas.

opposed phase imaging suggests that signal intensity changes on out-of-phase images is variable (i.e., may or may not drop significantly), which maybe related to the chronicity and/or activity of these lesions.

Nuclear Medicine

Sarcoidosis lesions show variable uptake on bone scan (1). Sarcoidosis bone lesions also may present a false positive for metastases on PET scanning.

Whole body MR scanning may be superior to PET imaging for the detection of diffuse sarcoidal bony lesions.

Conclusion

There are numerous musculoskeletal manifestations of sarcoidosis, many of which require advanced imaging for detection. The MRI findings of musculoskeletal sarcoidosis lesions may reveal a greater granulomatous burden than had been previously appraised. When musculoskeletal manifestations are detected, MRI is useful to follow response to treatment, and can guide biopsy in patients with unproven sarcoidosis.

With routine MRI technique, with the exception of sarcoidal muscle nodules, no pathognomonic imaging findings allow differentiation from other pathologies, including neoplasm. Therefore correlation with clinical and laboratory findings is essential for correct diagnosis. Radiologists should consider sarcoidosis in the differential diagnosis of musculoskeletal lesions detected at MRI in the appropriate setting (i.e., clinically proven sarcoidosis), and should be alerted that bony sarcoidosis lesions encountered on MRI can resemble metastatic lesions. In some patients in whom sarcoidosis is not proven or a second comorbidity is suspected, or to confirm sarcoidal histology, biopsy of the musculoskeletal lesion would be indicated.

Definition

Diagnostic procedures in nuclear medicine are based on the external detection of the γ-radiation emitted by incorporated radionuclides. The spatial distribution of these radionuclides in the (three-dimensional) object (patient) is recorded as a two-dimensional ▶projection image by means of a ▶gamma camera. This projection method is called planar ▶scintigraphy, and the image itself assigns measured data to spatial coordinates and, if applicable, to time information. It is referred to as a ▶scintigram.

Characteristics

Types of Scintigraphy

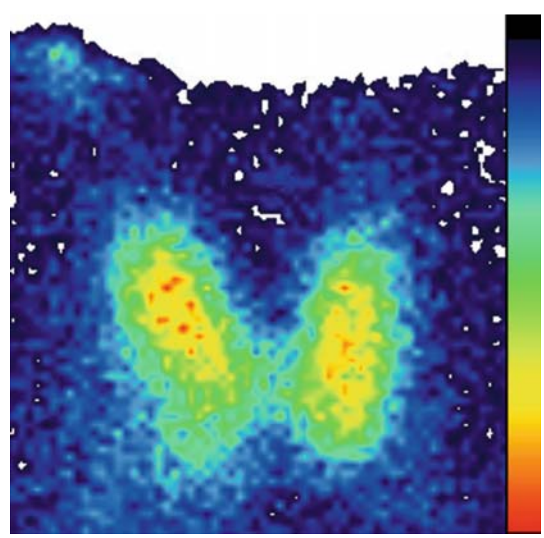
Planar scintigraphy can be performed as single-frame (static), multiple-frame (dynamic or gated), or whole-body imaging.

In static scintigraphy, the spatial distribution of activity in an organ is measured under the assumption that there is no significant change of activity distribution during the time interval of measurement (see Fig. 1). If appropriate, the organ under study can be measured from different views, e.g., ventral, dorsal, lateral, or oblique.

In dynamic scintigraphy, attention is focused on the temporal change of activity distribution of the radiopharmaceutical used. The organ under study is imaged in a temporal sequence of frames maintaining the viewing angle. Usually, from this sequence and one or more regions of interest (ROI) within the images, time–activity curves are generated for each ROI. The subsequent analysis of these curves (e.g., maximum rise time, decay time) results in the determination of numerous physiological parameters (e.g., organ clearance, perfusion).

Whole-body scintigraphy is the obtainment of scintigraphic information for the whole human body during one acquisition. As the dimensions of the human body are much larger than the axial field of view of a gamma camera, the detector head(s) and the patient must be moved relative to each other in the direction of the body's long axis. In addition, the data acquired must be combined by appropriate means to form the final image.

Gated scintigraphy is a multiple-frame imaging, controlled by external physiological signals of periodic cycles, e.g., triggered by ECG or respiratory signals, either to overcome the image blur caused by organ movement of or to collect information on organ movement. The cycle is divided into a number of phase intervals, and driven by the external trigger the scintigraphic information is sorted into the corresponding interval. Mostly, data are summed over a multitude of cycles. The final outcome is a series of images associated with the corresponding phase intervals.



Scintigraphy. Figure 1 Scintigram of the thyroid gland.

S

Imaging

The most often used imaging device in nuclear medicine is the gamma camera with a detector head utilizing the Anger principle (2) (see Fig. 2). The actual detector is formed by a large-scale single crystal scintillator, which is coupled *via* a light guide to a number of photomultiplier tubes (PMTs). In addition to the detector, the detector head is composed of a ►collimator, detector shield, and positional electronics.

When a γ-quant (photon) is absorbed in the detector crystal, the absorbed energy is emitted partly as non-directional scintillation light. These flashes of light, whose integral is proportional to the absorbed energy, are distributed *via* a light guide, which is designed to optimize the spatial spread of the scintillation light, to the photocathode of a PMT. To prevent light from exiting the crystal *via* surfaces not facing the PMTs, these crystal boundaries are coated by reflective materials such as magnesium or aluminum oxide. The photocathode converts the scintillation light to electrons by means of the outer photo effect. These electrons are accelerated by an electrostatic field toward the dynodes (usually 10–12), thereby generating new electrons when crashing on a dynode. When finally reaching the anode of the PMT, each electron emitted by the photocathode has been multiplied by a factor of approximately 10^6. This avalanche of electrons generates an electrical pulse at the anode, which after additional shaping amplification and integration has to pass pulse height analysis until finally being processed and registered by the positioning electronics.

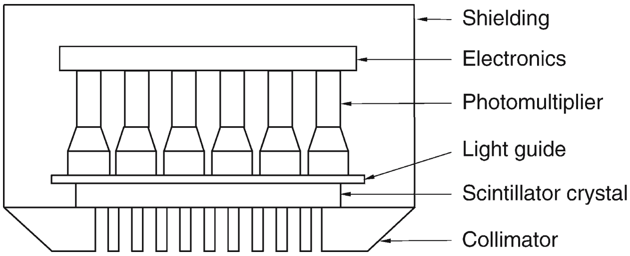
Looking at just one PMT and one detected event, the amount of light and, hence, the magnitude of the measured signal are dependent on the absorbed energy and on the location of the absorption event relative the wore of the light to the position of the PMT (the shorter the distance the more the light is seen). Now, taking into account all PMTs coupled to the crystal, the weighted sum of all PMT output signals (after correcting for the absorbed energy) yields the detected position of the scintillation, whereas the unweighted sum results in an estimate of the absorbed energy, which is independent of position (1, 3). The accuracy of positioning is mostly dependent on the efficiency by which the light is collected, i.e., on the light yield of the detector material (conversion from γ-energy to light photons) and on the proper design of the detector. To a lesser degree it also depends on the number of PMTs per area (usually ranging from 37 to 105 per detector head). For a scintillation detector, there is a linear relationship between absorbed energy and the amount of light emitted and hence output pulse amplitude. Thus, comparing pulse amplitude with appropriate discriminator levels, the energy range of photons to be included into the detection process can be selected by pulse height analysis.

The emission of γ-rays from the patient is nondirectional (as is the emission of normal light). In order to generate an image, directional information must be added. This is done by inserting a device called a collimator between the object and detector crystal, which can be penetrated only by γ-rays striking the collimator out of well-defined directions. The principle of mechanical collimation is absorption: a thick plate made from highly absorbing material (usually lead or tungsten) and containing thousands of well-defined bores can be penetrated only by γ-rays that pass through the long bores. The most often used geometry is a parallel hole collimator, but other geometries exist, e.g., converging, diverging, and conical collimators. Other construction parameters are energy range (thickness of septa and plate), resolution (hole diameter and length), and sensitivity, which is inversely related to resolution (and energy).

The detector head itself is attached to a gantry designed to facilitate detector positioning. Today, the gamma camera is interfaced to computers for data acquisition, processing, and storage.

To summarize, the four physical steps of gamma camera imaging are

1. Preselection of patient volume, in which the spatial distribution of activity is to be measured, by proper detector positioning and collimation.
2. Absorption of γ-quants emitted under directions preselected by collimation in the detector crystal and energy transfer by scintillation.
3. Transformation of the scintillation light to an electrical signal (PMT).
4. Determination of the absorbed energy and the position of the scintillation, energy discrimination, and final registration and storage.



Scintigraphy. Figure 2 Detector head of an Anger camera (principle).

The scintigraphic information is given by the sum of all events, which are registered along a ▶projection beam by the detector head. This projection beam is defined as the smallest possible volume that can be resolved by the detector head when detecting the radiation emitted by the object. Its shape is limited by the detector head's spatial resolution in all three dimensions. Mostly, it is a long, thin, diverging cone, as a gamma camera has no spatial resolution in the direction perpendicular to the detector, i.e., the direction of collimator bores. Supposing that there is no absorption or scattering of γ-radiation in the object and that sensitivity and spatial resolution are constant, the ray sum is proportional to the linear sum of activity concentrations along the projection beam. No information is contained about the depth of the source (its distance to the detector). In order to collect information on the third dimension of the object, it must be looked at from a multitude of different projection angles. In addition, the data measured have to be reconstructed by appropriate mathematical algorithms—the principle of tomography. Tomography requires either detectors that rotate around the patient or a detector ring surrounding the patient. The most prominent tomographic methods in nuclear medicine are single photon emission computed tomography (SPECT) and positron emission tomography (PET).

Definition

Sclerosing ▶adenosis is a benign proliferative lobulocentric lesion, consisting of stromal sclerosis and proliferative adenosis.

Pathology

Sclerosing adenosis is composed of distorted epithelial, myoepithelial and sclerotic stromal elements arising in association with the terminal duct lobular unit (1). Sclerosing adenosis is part of the proliferative lesions without atypia, but it may be involved by atypical lobular hyperplasia, lobular carcinoma *in situ*, atypical ductal hyperplasia, or ductal carcinoma *in situ*. Perineural pseudoinvasion is seen in 2% of cases. Because of the distorted glandular pattern, sclerosing adenosis may be confused with tubular carcinoma or with radial scar (1, 2).

Clinical Presentation

Sclerosing adenosis is usually an incidental finding in surgical specimens, although it may be detected on mammography (1, 2). Most cases are non-palpable, but occasionally may present clinically as a palpable mass (adenosis tumour) that can be confused with breast cancer. Sclerosing adenosis is also a cause of breast pain.

S

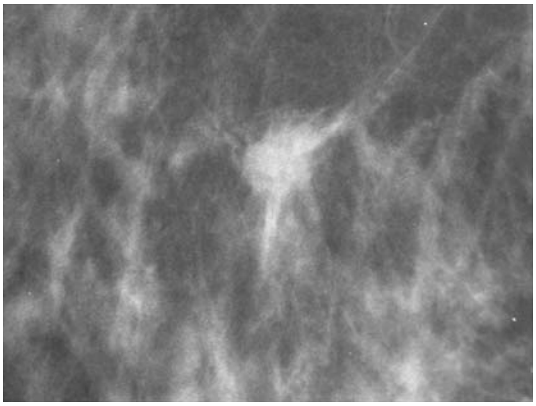
Imaging

Mammography

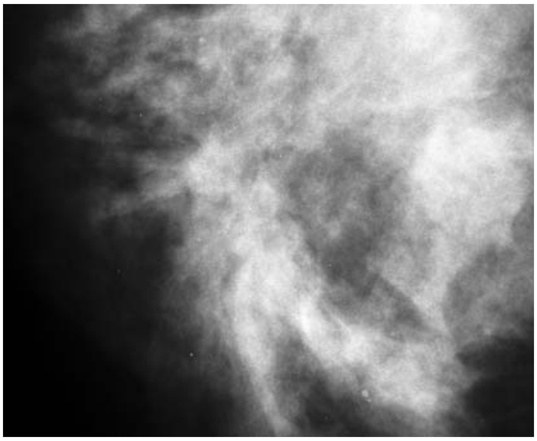
There are not specific mammographic features to diagnose sclerosing adenosis. Round, punctate, or pleomorphic microcalcifications are usually the most frequent finding. Also well circumscribed to spiculated masses, ►architectural distortions and asymmetric densities have been reported to be associated with sclerosing adenosis (3, 4) (Figs 1 and 2).

Ultrasound

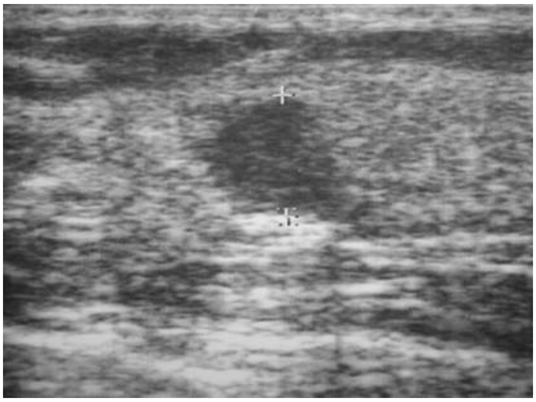
Focal acoustic shadowing without a mass and both well- and ill-delimited hypoechoic masses have been reported (3, 4) (Fig. 3).



Sclerosing Adenosis, Breast. Figure 1 Irregular spiculated mass, highly suspicious of carcinoma (mediolateral oblique view, detail). Biopsy revealed sclerosing adenosis.



Sclerosing Adenosis, Breast. Figure 2 Architectural distortion with punctate calcifications. The lesion was palpable. Biopsy revealed sclerosing adenosis.



Sclerosing Adenosis, Breast. Figure 3 Ultrasonography reveals an irregular ill-delimited hypoechoic mass. Sclerosing adenosis.

Magnetic Resonance

Areas of sclerosing adenosis may enhance after the injection of paramagnetic contrast, simulating breast cancer.

Nuclear Medicine

Nuclear medicine techniques do not play any role in the diagnosis of sclerosing adenosis.

Diagnosis

The diagnosis of sclerosing adenosis is made by biopsy. Imaging techniques usually show suspicious findings, mimicking malignancy, so a biopsy is recommended. Due to the possible association with premalignant or even malignant lesions, a result of sclerosing adenosis in a core biopsy should be carefully evaluated. It may be acceptable for circumscribed masses and non-palpable indistinctly marginated masses. The result may be concordant also for vacuum-assisted biopsy of punctate, amorphous, or pleomorphic calcifications. However, the result is not acceptable for BI-RADS 5 lesions. In these cases, a surgical biopsy is recommended (5).

Scoliosis

KARL LUDWIG, CORINNA E.E. NIERHOFF
Department of Diagnostic Radiology, Orthopedic University Hospital Heidelberg, Heidelberg, Germany
karl.ludwig@ok.uni-heidelberg.de

Definition

Scoliosis is defined as a fixed lateral curvature and torsion of the spine.

According to the criteria of the Scoliosis Research Society, the diagnosis of structural ▶scoliosis should be reported only if the curve in the frontal plane, as viewed on an anteroposterior radiograph, is greater than 10°.

Pathology/Histopathology

Scoliosis represents a deformity of growth. The vertebral bodies grow slower on the concavity than on the convexity. This disturbance of growth of one or more vertebral bodies results in a rotation and lordosis of the spine. Eighty-five percent of scolioses are idiopathic, which means there is no known underlying pathology. Idiopathic scoliosis worsens mainly in the growth period. Generally, curvatures less than 30° will not progress after childhood. With greater curvatures after adolescence, the degree of scoliosis may progress by about 1° per year.

Studies have shown that the incidence of idiopathic scoliosis is higher in relatives, which suggests an autosomal-dominant inheritance pattern with variable phenotypic expression (1).

Clinical Presentation

The incidence of idiopathic scoliosis with lateral curvatures of 10° or greater varies between 1 and 3% in the general population. The female:male ratio is 4:1. According to the onset of symptoms, idiopathic scoliosis can be classified into three groups:

- Infantile: birth to age 3 years
- Juvenile: 3–11 years
- Adolescent

An etiological classification of scoliosis differentiates between different entities:

- Idiopathic
- Neuropathic: cerebral palsy, syringomyelia, Charcot Marie-Tooth, polio, spinal muscle atrophy, myelomeningocele
- Myopathic: muscular dystrophies
- Congenital: diastematomyelia, neurofibromatosis,
- Mesenchymal: Marfan syndrome, Ehlers–Danlos syndrome
- Systematic diseases: achondroplasia, spondyloepiphysary dysplasia, mucopolysaccharidosis
- Metabolic: rickets, juvenile osteoporosis, osteogenesis imperfecta
- Radiation-associated: radiotherapy in childhood
- Posttraumatic
- Neoplastic
- Inflammatory
- Vertebral malformations (hemivertebrae, block vertebrae, butterfly and wedged vertebra, unsegmented bars)

If scoliosis progresses in the thoracic region, it can create significant physical deformity. Respiratory problems can result in severe cases with curvatures approaching 90°.

Imaging

The role of radiology in scoliosis management is to confirm the diagnosis, identify any underlying pathology, and monitor the degree of curvature. Early diagnosis and treatment help prevent curve progression and deformity.

Plain Radiography

Images of the erect entire spine in anteroposterior (AP) and lateral views are mandatory. In the AP projection, the iliac crest should be visible. Images are usually taken on a 36-in. cassette with a film focus distance of 3 m with the central beam in the middle of the thoracic spine.

For distinguishing between reversible functional scoliosis and fixed structural scoliosis of babies and small children (not yet able to walk), a supplementary stress picture is taken in the prone position (Bending test). The child is actively bent to the opposite side of the scoliosis while the image is taken.

Is the scoliosis is fully compensated, a functional scoliosis is assumed. In structural scoliosis, muscle contractures or changes at the vertebral bodies, the disks, and the facet joints prevent compensation of the curvature.

Cobb Method

A quantitative assessment of scoliosis is performed using the ►Cobb angle.
