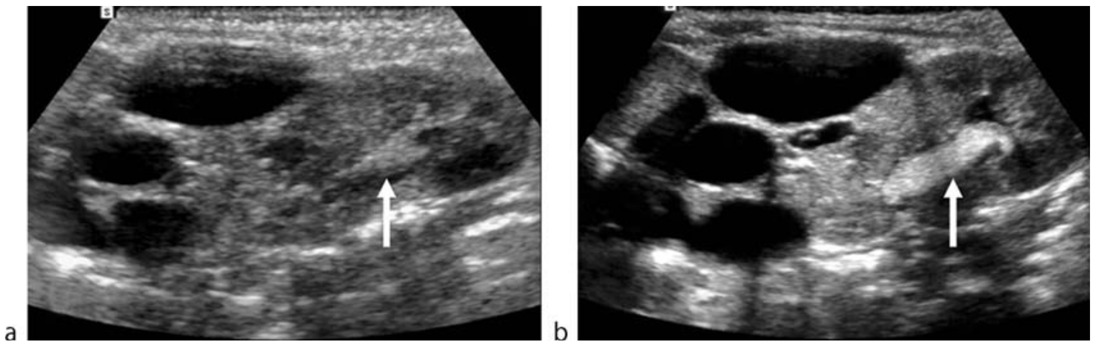
The necessity and extent of the precontrast examination is determined by the availability of a current US examination of the urinary tract and the type of US imaging modality being used. It is crucial that the normal saline instilled into the bladder is not from a container sealed under vacuum. All plastic containers are not sealed under vacuum but almost all glass containers. The normal saline in the latter is desaturated and the air in the microbubbles diffuses very rapidly in the solution with the consequence of fast decrease of echo-enhancement. The contrast medium is administered slowly into the bladder under sonographic monitoring. Reflux is diagnosed when echogenic microbubbles are detected in the ureters or pelvi-calyces. During the postcontrast examinations, the right and left renal pelves are scanned alternatively. The scan during voiding can be carried out when the patient is lying or sitting on a pan or standing and voiding into a urine bottle. The severity of reflux is graded in a similar manner as the international reflux grading system in VCUG from grade I to V. Comparative studies have shown the high concordance rate of over 85% between the reflux grading system in VCUG and VUS (1, 3).

VUS Imaging Modalities

Depending on the availability, different US imaging modalities are employed in VUS to depict the refluxing microbubbles. These imaging options not only affect the conspicuity of the microbubbles but also the overall diagnostic accuracy of the examination. The most widely employed modality for VUS is conventional (=fundamental) US. This can be combined with color Doppler to enhance the detection of reflux. A recent innovation in US and one with major impact on the application of US contrast media is harmonic imaging. When using harmonic imaging for VUS not only do the microbubbles become strikingly conspicuous compared to fundamental mode but also the sensitivity is significantly increased (Fig. 1) (5). Furthermore, it is possible to visualize intrarenal reflux. Advanced contrast-specific imaging modalities tuned for individual contrast medium, e.g., agent detection imaging (Sequoia, Siemens, Issaquah, USA) have brought about a profound improvement in detecting refluxing microbubbles. The microbubbles are not only enhanced and color-coded but it is also possible to visualize only the refluxing microbubbles blocking out the background gray-scale image (Figs. 2, 3).

Dosage of US Contrast Media for VUS

Currently, the US contrast medium Levovist is the most widely used and the one approved for use in VUS. The concentration of Levovist used for VUS is 300 mg/mL. The dose administered depends on the imaging modality being employed. For fundamental US, the volume of Levovist administered is 5–10% of the filling volume of the bladder (1–3). In case of harmonic imaging or advanced contrast-specific imaging modalities 3–5% of the filling volume of the bladder suffices, i.e., for one cycle of examination just one 2.5-g flask of Levovist will be adequate (5). Recently, a second-generation US contrast agent, SonoVue (Bracco, Milan, Italy), has become



Contrast Media, Ultrasound, Applications in Vesico-ureteral Reflux. Figure 1 Longitudinal scan of a duplex kidney with a multicystic dysplastic upper moiety from ventral after intravesical administration of the US contrast medium Levovist in (a) fundamental and (b) harmonic imaging modalities. The refluxing microbubbles in the lower moiety (arrow) are more conspicuous in the harmonic imaging modality (b).

Contrast Media, Ultrasound, Applications in Vesico-ureteral Reflux. Figure 3 **Longitudinal section of a duplex kidney from ventral after intravesical administration of the US contrast medium Levovist using an advanced contrast-specific imaging modality (agent detection imaging). Note the reflux in both moieties (arrowhead—upper, arrow—lower) without (a) and after (b) blocking the background gray-scale image.**

available in Europe. Preliminary comparative studies have revealed that the dose of this contrast medium for intravesical use is less than 1% of the bladder filling (1). This has a huge potential in the future not only in reducing the amount of contrast medium necessary for an examination but also in markedly lowering the cost for a VUS.

Adverse Reactions

There are no reports of adverse reactions with regard to intravesical instillation of US contrast media, in particular of Levovist.

Interactions

No interactions of intravesically administered US contrast media have been reported.

Synonyms

Echo enhancers; Sonographic contrast agent; Sonographic signal enhancers; Ultrasound contrast agents; Ultrasound contrast media; Ultrasound signal enhancers

Definition

An ultrasound contrast medium is a compound that increases the contrast of an ultrasound image. This is obtained by increasing (or decreasing) the echogenicity of a particular compartment within the body. Usually, an ultrasound contrast agent is injected into a blood vessel resulting in an increased echogenicity of the blood and thus in an increased *contrast between blood and tissue*. The currently commercially available ultrasound contrast agents contain ►micro-bubbles with a diameter of a few µm, which consist of an echogenic gas surrounded by a shell for stabilisation. Due to the size of the micro-bubbles, such ultrasound contrast agents are ►blood pool agents not leaving the vascular system. Ultrasound contrast agents of the first generation contain air inside, whereas agents of the second generation contain a gas with low solubility in water (or blood) giving the micro-bubbles a higher stability and longer persistence.

Indication

Currently, there are three major indications described for ultrasound contrast agents:

1. Echocardiography including *left ventricular opacification* (LVO) with the aim to improve *endocardial border delineation* (EBD) and *myocardial contrast echocardiography* (MCE) with the aim to demonstrate and quantify myocardial perfusion,
2. Vascular *Doppler* ►*enhancement* with the aim to overcome insufficient signal-to-noise ratio, especially to obtain higher accuracy in low-flow, no-flow and/or slow-flow conditions,
3. *Sonography of parenchymatous organs* with the aim to detect abnormal vascularity and perfusion.

Not all agents on the market have regulatory approval for all the three indications. To obtain regulatory approval, a significant clinical benefit has to be demonstrated in addition to the sole existence of a contrast effect. In other words, the contrast enhancement should result in diagnostic confidence and not in confusion.

There is a significant difference in the perception of the clinical benefit of contrast enhancement between Europe and the United States. In the United States, the clinical value of contrast enhancement is only recognised for echocardiography and accordingly this is the only indication for ultrasound contrast agents approved by the FDA. In Europe, both echocardiography and vascular/extra-cardiac sonography are accepted indications for contrast enhancement and there are agents with regulatory approval for all the three indications mentioned earlier.

Echocardiography

The improvement of the endocardial border delineation of the heart cavities was the first indication for ultrasound contrast agents. Due to a limited signal-to-noise ratio of the non-digital ultrasound scanners in the early 1990s, the cardiac cavities often appeared not well delineated but obscured by noise signals and signal dropouts in the cardiac wall. Opacification of the blood in the heart cavities resulted in a marked improvement of the endocardial border delineation, allowing a much more reliable determination of *cardiac volumes* and *wall motion*. Even with up-to-date high-end scanners, this clinical advantage is evident (due to the elimination of obscuring echoes from the trabecular structures), as shown in recent controlled multicenter studies (1).

Using recent generations of ultrasound scanners with ►*contrast-specific imaging* modalities (2), the blood distribution can be demonstrated not only in the cavities but also in the micro-vasculature of the myocardium. For this indication called myocardial contrast echocardiography, it is necessary to separate the signals coming from the blood (contrast agent) and those coming from the tissue. This is done by the contrast mode software of the scanner. The visibility and distribution of the contrast enhancement in the myocardium is obvious. However, the evidence for the clinical value of this information has still to be established and is evaluated in numerous clinical research programs currently ongoing. Up to now, none of the agents available has obtained regulatory approval for the myocardial perfusion indication.

Vascular Imaging

The most sensitive method for vascular imaging is *Doppler sonography*. The demonstration of blood with Doppler sonography is based on the movement of blood cells with a certain velocity (higher than the wall motion velocity) towards or away from the transducer. In some cases, only an insufficient Doppler signal can be obtained, mainly when the blood volume is very small (e.g. in high-grade stenoses) or the vessels are behind highly echogenic structures (e.g. in transcranial Doppler sonography). In such cases, the enhancement of the echogenicity of the blood by an ultrasound contrast agent allows in nearly all cases the demonstration of an adequate flow signal (3).

Parenchymal Vascularity and Perfusion

There is a general limitation for Doppler sonography: it does not work in case of nearly stationary blood (e.g. in capillaries) or indeterminate flow direction (e.g. in complex vascular structures), as found in parenchymal structures or focal lesions. The adequate demonstration of blood in the *micro-vasculature* requires a velocity-independent separation of signals from blood and tissue, which can be obtained during contrast enhancement by the contrast-specific elements in the signal. Using this principle, the micro-vascular distribution and geometry can be demonstrated in B-mode with high spatial resolution and without any movement artefacts. Furthermore, when injected as bolus injection the contrast agent can be used as *tracer* to evaluate the dynamic wash-in and wash-out in the tissue, allowing the assessment of parenchymal *perfusion*. For detection and characterisation of focal liver lesions, the clinical benefit of micro-vascular perfusion assessment has already been demonstrated (4) and the use of contrast enhancement is recommended in respective guidelines (5, 6). Fore some other organs, clinical research programs are still ongoing to establish the clinical value of perfusion assessment for diagnosis or therapeutic monitoring. In Europe, some of the agents available obtained already regulatory approval for micro-vascular imaging.

Commercial Products

Echovist is a 'right heart' contrast agent, i.e. an agent which is not stable enough to survive the pulmonary passage after intravenous injection. The active ingredient of Echovist is Galactose micro-particles containing air. The agent is available in two concentrations with 200 and 300 mg/mL micro-particles in the final suspension. Echovist has been approved in 1991 for the examination of the right heart and venous system and for hysterosalpingo-contrast-sonography after transcervical injection. Echovist is marketed by Schering in Germany and UK.

Levovist is an improved formulation of Echovist, also containing Galactose micro-particles with air but coated with palmitic acid, making the micro-particles more stable. Levovist micro-particles survive the pulmonary circulation and allow the enhancement of the whole circulation. The agent can be prepared in different concentrations (200, 300 and 400 mg/mL micro-particles in the final suspension). In 1995, Levovist has been approved in Germany and until now in more than 40 countries including most European countries, Canada, China and Japan. Levovist obtained regulatory approval for Doppler enhancement including diagnosis of cardiac, vascular and tumour diseases and for diagnosis of vesiculo-ureteral reflux after transurethral injection. Levovist is marketed by Schering.

Albunex has been the first transpulmonary agent on the market, approved 1993 in Japan and 1994 in the United States. It consists of human albumin coated micro-bubbles containing air. In the meantime, Albunex has been replaced by Optison.

Optison contains also human albumin coated micro-bubbles, but containing octafluoropropane gas (perflutren), making the micro-bubbles more stable. The gas concentration is 0.19 mg/mL solution. Optison is the first 'second-generation' contrast agent using gas with low solubility in water to increase stability and persistence. Like Albunex, Optison has been developed only for echocardiography (left ventricular opacification) and obtained first approval in 1998 in the United States and later also in most European countries. Developed by Molecular Biosystems, Optison is marketed now after several transitions by GE Healthcare.

SonoVue consists of sulphurhexafluoride micro-bubbles surrounded by a flexible phospholipid shell. The final solution contains 8 μL/mL SF_6 gas, which is enough to obtain an enhancement of several minutes in the whole vascular system. SonoVue has been approved by the EU medical agency in 2001 for a broad range of indications, including echocardiography (left ventricular opacification), (macro-)vascular Doppler enhancement and assessment of vascularity in focal lesions in liver and breast (micro-vascular enhancement). SonoVue is marketed by Bracco in cooperation with several partners in Europe and China.

Definity consists of octafluoropropane (perflutren) micro-bubbles, surrounded by a phospholipid shell. The final solution contains 150 μL/mL C_3F_8 gas. Definity has been approved by the FDA in 2001 for echocardiography (left ventricular opacification) and in Canada also for liver and kidney imaging. In Europe, a submission for regulatory approval has been filed. Definity has been developed by ImaRx and is marketed now by Bristol-Myers Squibb.

Imagent consists of tetradecafluorohexane (perflexane) micro-bubbles, surrounded by a phospholipid shell. The final solution contains 92 μg/mL C_6F_{14} gas. Imagent has been developed and approved in the United States in 2003 for echocardiography (left ventricular opacification). Developed by Alliance Pharmaceuticals, Imagent is now marketed by IMCOR Pharmaceutical in the United States.

Contraindication

In general, ultrasound contrast agents are pharmacologically inactive and, with the exception of known hypersensitivity to any of the ingredients, no absolute contraindications exist. They contain no toxic molecules and there are no toxic effects on organs (e.g. the kidneys). However, there may be side effects after the injection of any contrast agent, which require a benefit/risk assessment to assure the best possible safety for the patient. The only significant adverse effects reported are hypersensitivity reactions following the injection of the contrast agent. Such reactions are rare (in about 0.01%) but can be life-threatening. Considering this potential risk (even if the incidence is very low), contraindications were defined for patients having an increased risk in case of a hypersensitivity reaction which is not balanced by a special benefit for this particular patient group (e.g. patients during acute coronary syndrome not having an immediate clinical need for a contrast examination). For the detailed contraindications of the different agents see the respective SPCs approved by the regulatory authorities.

Pregnancy/Lactation

Since the micro-bubbles are not leaving the vascular compartment, there should be no transition into the foetal blood circulation or breast milk. From pharmacological and toxicological studies no special risks are known. However, as for other contrast agents no special clinical studies were performed in pregnant women. Therefore, the experience in this patient group is limited and special care should be taken.

Use and Dosage

Ultrasound contrast agents are usually administered by intravenous *bolus injection*. Due to the low injection volume, a saline injection for flushing directly after the contrast injection is recommended. To avoid high mechanical forces impairing the stability of the micro-bubbles, injection with strong pressure should be avoided and the needle diameter should not be too small (at least 20G).

Recommended doses for one injection are given in the following list:

- Echovist: 3.0–10.0 mL
- Levovist: 6.5–19.5 mL (2.5 or 4.0 g micro-particles)
- Optison: 0.5–3.0 mL
- SonoVue: 2.0/2.4 mL
- Definity: 10 μL/kg BW
- Imagent: 6.25 μL/kg BW

The injection can be repeated, if required. If a longer, continuous contrast enhancement is useful (e.g. for prolonged left ventricular opacification or vascular enhancement), a continuous *infusion* of the contrast agent is possible. In that case, an infusion pump with a rotating syringe holder is preferable, to avoid rising of the micro-bubbles to the superficial layer due to buoyancy.

Adverse Reactions

The most common side-effects reported after the injection of ultrasound contrast agents are mild and resolved within a short time without sequelae. They include local reactions at the injection site, headache, nausea, flush and sensations of heat, coldness or altered taste. In rare cases (about 0.01%), hypersensitivity reactions were reported as known from other colloidal suspensions and contrast agents. Such hypersensitivity reactions (anaphylactoid reactions) can be life-threatening and require immediate treatment. Adequately trained staff and emergency equipment should be available for that reason.

Interactions

Since ultrasound contrast agents are administered only for a short time during the diagnostic examination and the *elimination* from the blood circulation is quite fast (within a few minutes), possible interaction with other medication is limited. Usually, no special interaction studies are performed with contrast agents. From a theoretical point of view, there may be an influence on the bioavailability of drugs given at the same time point, especially if these drugs are able to adhere to albumin or lipid surfaces (depending on the shell of the micro-bubbles). Therefore, it is recommended to use separate intravenous lines if the contrast agent has to be administered simultaneously with another drug (e.g. in case of pharmacological stress echo).

Contrast-enhanced sonography of the liver; Contrast-enhanced ultrasound (US) of the liver

Definition

The use of ultrasound (US) microbubble contrast agents combined with contrast-specific imaging techniques for the detection and characterization of liver disease (mainly tumors).

Introduction

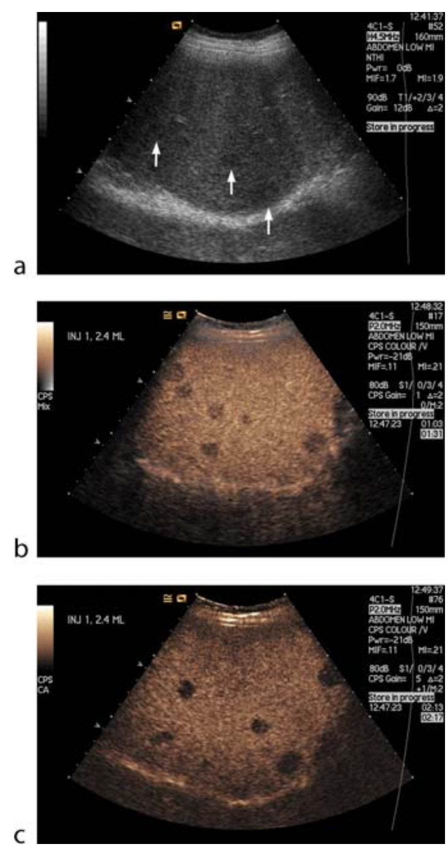
Although often the first-line modality for liver imaging, conventional US without the use of contrast agents has a limited role in the diagnosis of liver tumors. Its ability to detect and characterize focal liver lesions is generally inferior to that of other cross sectional imaging modalities [computed tomography (CT) and magnetic resonance imaging (MRI)].

The advent of microbubble contrast agents has greatly enhanced the role of US in liver imaging. Both detection and characterization of liver lesions can be considerably improved by the use of US contrast agents.

US Contrast Agents for Liver Imaging

US contrast agents consist of microbubbles (cross reference) which are less than 10 μm in diameter. They are safe and effective echo enhancers. When given intravenously, microbubbles produce marked augmentation of the US signal for several minutes with up to 25 dB (greater than 100-fold increase) enhancement in echo strength. The signal enhancement is primarily caused by nonlinear bubble behavior (cross reference). Contrast-specific nonlinear imaging modalities (cross reference) such as phase modulation (cross reference) or amplitude modulation (cross reference) or a combination of the two exploiting the nonlinear bubble behavior (cross reference) must be used for contrast-enhanced US of the liver, since the signal enhancement is insufficiently visualized with conventional fundamental US imaging.

With real-time low ►*mechanical index* (MI) imaging, the dynamic enhancement pattern and the vascular



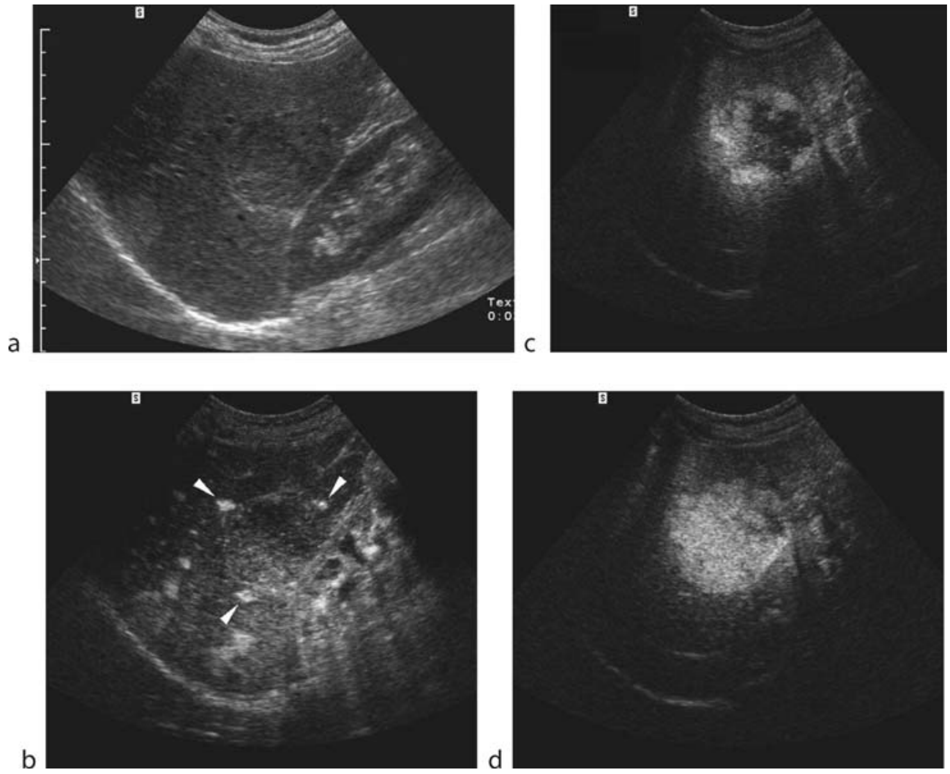
Contrast Media, Ultrasound, Hepatic. Figure 1 Patient with multiple small metastases. (a) Baseline US shows three ill-defined hypoechoic lesions in a slightly heterogeneous liver. (b, c) In the portal venous and delayed phase after SonoVue, multiple lesions are revealed throughout the the liver, some of them only a few millimeters in diameter.

morphology of a lesion are assessed during the arterial (starting 10–20 sec and ending 25–53 sec after injection) and portal venous (starting 30–45 sec and ending 120 sec after injection) phases. The delayed phase (>2 min after injection) is particularly useful for detection of metastases because they appear as nonenhancing defects. Characterization is also aided by delayed-phase imaging.

Some agents have a liver-specific late phase where the bubbles accumulate in normal liver parenchyma starting 2–5 min after injection when the vascular enhancement has faded and persisting there for many minutes to hours, analogous to liver-specific contrast agents used in MRI. This late phase is particularly useful for lesion detection and differentiation of benign and malignant tumors. Microbubbles known to exhibit liver-specific behavior are ►*Levovist*, *Sonavist* (both Schering AG, Germany), ►*Sonazoid* (NC100100; General Electric, USA), and ►*BR14* (Bracco SPA, Italy). In the late phase, the bubbles are stationary or extremely slow moving. The mechanism of hepatic accumulation is not completely understood. Possible explanations are mediation by the reticuloendothelial system or pooling and endothelial adherence in the liver sinusoids. For some agents (Sonavist and Sonazoid), Kupffer cell uptake has been demonstrated.

Two contrast agents are currently licensed for liver imaging in Europe: Levovist (Schering AG, Berlin, Germany) and ►*SonoVue* (Bracco SPA, Milan, Italy). The imaging techniques with these two contrast agents vary considerably. Contrast-specific imaging modes exploiting nonlinear bubble behavior (cross reference) must be used with both agents to achieve clinically useful signal enhancement. Such imaging modes are now available on most medium- and high-end US systems.

Levovist, which was the first agent to be commercially available has liver-specific properties during its late phase; this is advantageous for detection of metastases. High MI imaging (MI>0.7) must be applied when using Levovist. It provides signal enhancement due to strong nonlinear signals from disrupting microbubbles. The disadvantage of this technique is the highly transient nature of the signals, which persist only for a few frames after insonation of an individual area until the bubbles in the imaging plane are destroyed. To exploit the enhancement for clinical use, special scanning techniques such as rapid

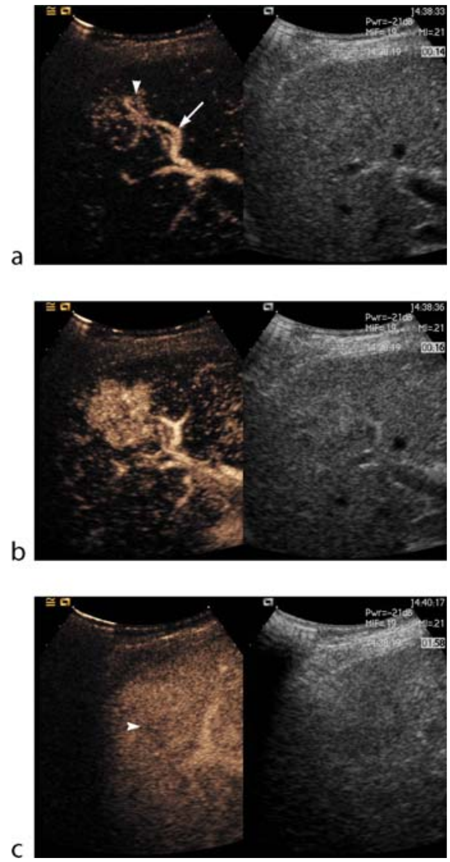


Contrast Media, Ultrasound, Hepatic. Figure 2 Typical dynamic enhancement of a hemangioma using Sonazoid. (a) Atypical baseline appearances: isoechoic lesion (*arrow*) suggestive of metastases in a patient with colon carcinoma. (b) Arterial phase with peripheral nodular enhancement (*arrowheads*). (c) Partial centripetal fill-in in the portal venous phase (45 sec p.i.). (d) Complete filling of the hemangioma in the delayed phase (3, 5 min p.i.).

sweeping through the liver to image intact bubbles with each new frame or intermittent imaging have to be employed. Such scanning techniques are somewhat cumbersome and multiple sweeps through the liver are only possible with repeated injections. For these reasons, Levovist is no longer used on a large scale despite some very good results in the detection and characterization of focal liver lesions.

SonoVue, a more recent agent, provides strong and persistent signal enhancement due to its strong harmonic resonance at low (≤0.2) and very low (<0.1) MI, where minimal or no bubble destruction occurs. This allows for continuous real-time imaging of a lesion during its vascular phase as well as comprehensive surveying of the liver in multiple planes during the delayed phase. Low MI imaging with SonoVue is now preferred in most instances, although it has weaker liver-specific properties than Levovist.

Several experimental agents such as Sonazoid or BR14 combine the advantages of good enhancement at low MI with strong liver-specific properties. Early clinical studies have demonstrated the potential of such agents for detection of metastases. Unfortunately, manufacturers are currently hesitant to continue the clinical development of such agents for commercial reasons.



Contrast Media, Ultrasound, Hepatic. Figure 3 **Typical focal nodular hyperplasia after SonoVue. (a) Large feeding artery (*arrow*) and spoke-wheel vascular pattern in the lesion (*arrow heads*) during the early arterial phase (14 sec after injection). (b) Two seconds later the lesion is completely filled with contrast and appears hyperenhancing to normal liver. (c) In the portal venous/delayed phase (2 min post injection) the lesion is isoenhancing to normal liver with the exception of a small hypoenhancing central scar (*arrow*).**

Indications and Clinical Use

According to the guidelines of the European Federation of Societies for Ultrasound in Medicine and Biology (EFSUMB), the use of contrast agents is indicated in the following clinical situations:

- Detection of focal liver lesions (especially metastases)
- Characterization of focal liver lesions
- Monitoring of liver tumor ablation.

Detection: As with other imaging modalities, the use of contrast agents improves the ability of US to detect liver metastases substantially. As described earlier, metastases are seen as nonenhancing defects in an otherwise homogeneously enhancing liver in the portal venous and particularly in the delayed phase after contrast injection (Fig. 1). The impact on detection is most marked for lesions smaller than 1 cm in diameter and for lesions that are isoechoic on baseline US. Contrast-enhanced US has a sensitivity of approximately 80% in detecting hepatic metastases, which is similar to contrast-enhanced CT. The detection of primary hepatic malignancies such as hepatocellular carcinoma and cholangiocarcinoma is also improved with the use of US contrast agents in comparison to unenhanced US.

Characterization: All common solid liver lesions have rather characteristic dynamic imaging features on contrast-enhanced US (Figs. 2 and 3). Most of these features are analogous to those on dynamic CT and MRI scans. In addition to the vascular phases, the delayed phase is of particular value for differentiating malignant and benign lesions: the great majority of benign lesions show contrast uptake similar to normal liver in this phase, whereas most malignant lesions (especially metastases) appear as enhancement defects. Contrast-enhanced US is an effective tool for liver lesion characterization: approximately 85–90% of liver lesions can accurately be diagnosed as a specific lesion type, and classification of benign and malignant lesions can be achieved in over 90% of the cases.

Monitoring of liver ablation: Treatment monitoring during or after liver ablation (radiofrequency ablation, laser ablation, percutaneous ethanol injection) is based on the assessment of vascularization and tissue perfusion in the target area to differentiate necrosis from residual viable tumor. Unenhanced US, even when combined with color/power Doppler, does not provide any reliable information about the outcome of ablation treatments, which was an important limitation of US-guided ablative procedures before the advent of US contrast agents. Conversely, with the use of US contrast agents, tissue perfusion can be visualized and crucial information about the extent of the thermal necrosis is thus obtained. Complete ablation is indicated by the disappearance of any previously visualized intralesional enhancement on contrast-enhanced images. Residual viable tumor tissue is suspected when a portion of the original lesion shows persistent enhancement in the arterial or portal venous phase.

C

Contrast Media, Ultrasound, High Solubility Gas

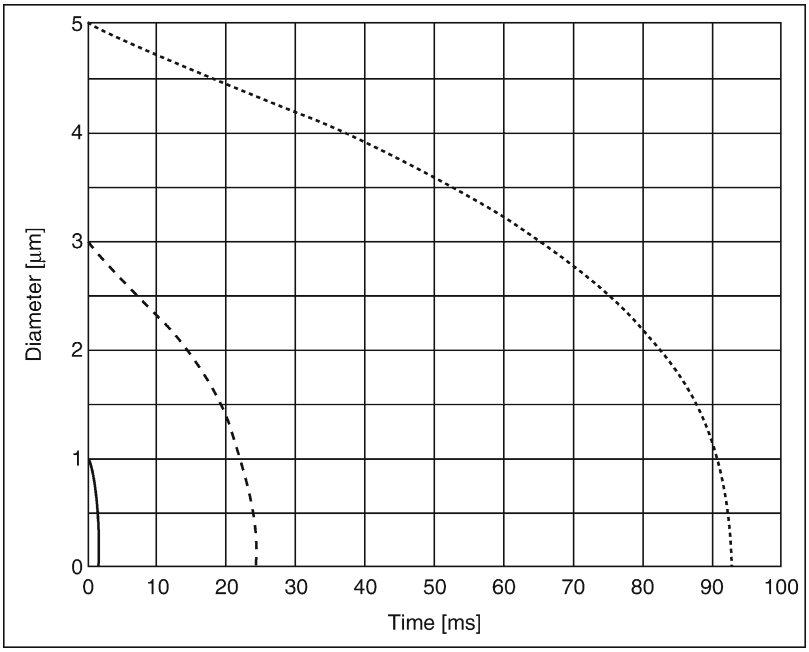
N. de Jong
Erasmus MC, Rotterdam, The Netherlands
n.dejong@erasmusmc.nl

Synonyms

Air agents; First (second) generation contrast agent

Definitions

An agent containing gas bubbles, of which the gas in the bubble easily dissolved in the surrounding liquid (typically water/plasma).



Contrast Media, Ultrasound, High Solubility Gas. Figure 1 Diameter's change versus time for three different sizes; 1, 3, and 5 µm.

Characteristics

Maintaining a gas bubble at a constant size is a technical challenge and many fluctuations in size occur with local environment. Indeed, bubbles suspended in a liquid can coalesce, grow or shrink in response to changes in the environment. Outward diffusion of gases due to surface tension, higher hydrostatic pressures or acoustic pressures induce consequent alterations in bubble size, which can occur very rapidly, within seconds to minutes. Smaller bubbles are more susceptible to these influences. The kinetics of the dissolution of a gas microbubbles is given by the equation of Epstein and Plesset (1):

$$\frac{\mathrm{d}R}{\mathrm{d}t} = DL\left(\frac{\frac{C_i}{C_0} - 1\frac{2\sigma}{RP_0} - \frac{p_{ov}}{P_0}}{1 + \frac{4\sigma}{3RP_0}}\right)\left(\frac{1}{R} + \frac{1}{\sqrt{\pi D t}}\right),$$

where, R is the radius of the bubbles, t is the time, D is the diffusion constant, C_i/C_o is the ratio of the dissolved gas concentration to the saturation concentration, σ is the surface tension, P_0 is the ambient pressure, L is the Ostwald coefficient, p_{ov} is the overpressure.

The equation was numerically solved to extract the size variation of a gas bubble. (Fig. 1) shows the change in bubble size as a function of time at three different sizes: 1, 3, and 5 µm diameter. The gas contained in the bubble is air. We can appreciate that the smallest bubble (1 µm) disappears in less than 2 msec, whereas the predicted lifetime of a 5µm air bubble is ~93 msec. The disappearance of these microbubbles is caused mainly by the diffusion of the contained gas, which dissolves in the surrounding medium.

Contrast Media, Ultrasound, Influence of Shell on Pharmacology and Acoustic Properties

VOLKMAR UHLENDORF
ETH Zürich, Institut für Pharmazeutische Wissenschaften, Zürich, Switzerland
volkmar.uhlendorf@pharma.ethz.ch

Synonyms

Capsule of ultrasound contrast media; Coating of ultrasound contrast media

Definition

When microbubbles are used as ultrasound contrast media, they usually need some coating—a shell. The shell surrounds the microbubble, stabilises it and thus provides transpulmonary stability. The shell influences both the pharmacological and acoustic properties of the microbubble.

Characteristics

When coated by a protective shell, microbubbles are at least nearly spherical, but as free microbubbles (after removal of the shell) they have an exactly spherical shape. Furthermore the shell has one or several of the following basic functions:

1.1 Reduction of gas exchange (outwards or inwards, depending on type of gases involved),
1.2 Stabilisation against aggregation and fusion of microbubbles (during storage or after administration),
1.3 Control of the surface characteristics on a molecular level (important for immune response, or for targeting),
1.4 Control of elastic and acoustic properties (threshold for acoustic disruption of bubble shell).

A further function might be seen in the encapsulation of drug substances within the bubble or within the shell, but this shall not be considered here in detail.

1.1 together with 1.2 allows providing a sufficiently stable population of small microbubbles. 1.3 is very important for the pharmacology of the bubbles. Finally, 1.4 is important for the acoustic behaviour during ultrasound imaging. These points are discussed in more detail.

The shell material typically belongs to the following classes:

- Fatty acids or lipids,
- Proteins—often denatured,
- Bio-degradable synthetic polymers,
- Combinations of the above,
- Surface-active components of the surrounding body fluid may play some role after administration.

In addition, there may be important functional groups or targeting molecules on the shell surface.

The total mass of shell material differs from agent to agent and also depends on the imaging procedure. For two reasons it usually is very low. First, in nearly all cases the shell is relatively thin when compared to the bubble diameter. Second, the injected amount of contrast agent is typically very low, as bubbles are easily detectable.

1.1 Reduction of Gas Exchange

A small, uncoated microbubble of soluble gas (like air) is not stable, even in a gas-saturated liquid. The surface tension is creating an enhanced pressure within the bubble (up to some atmospheres) which will enforce microbubble dissolution, typically within milliseconds. In a closed vial of contrast media and in a very concentrated bolus there may be a local overpressure or oversaturation, respectively, which temporarily can help to stabilise a microbubble population. But, at least after injection these stabilizing factors no longer exist. A shell can slow down the dissolution process, thus providing sufficient time for contrast imaging.

Several ultrasound contrast media contain hydrophobic (often perfluorated) gases of very low solubility in water. Due to their higher molecular weight compared to air, they also have a reduced diffusivity. In this case, diffusion of soluble low molecular weight gas may lead to a net inflow of gas and some growth of the mean diameter of bubbles without shell. One contrast agent claims to use about the steady-state mixture to prevent such a growth. But, even when insoluble gases or mixtures are used, there remain other reasons for having microbubbles coated.

1.2 Preventing Aggregation and Fusion of Microbubbles

For several reasons, aggregation (coagulation) of microbubbles has to be prevented, both during storage of suspensions and after injection. First, aggregates might become too large for unimpeded passage of capillaries and —in severe cases—would even create a safety risk. Aggregates also could lead to bubble growth by fusion of microbubbles, in particular for hydrophobic gases. Finally, any bubble aggregate is likely to respond acoustically similar to one large bubble and would thus reduce the efficiency. A shell of suitable composition helps to prevent these undesired processes. For this purpose, the shell may contain some (usually negatively) charged groups that lead to repulsion of microbubbles. In addition, there may be molecules preventing fusion for sterical reasons.

During development of a particular contrast agent, the effects should have been studied in detail and an adequate formulation found which guarantees stability during shelf life and *in vivo*. It is therefore not advisable to mix an agent with any other substance (unless allowed by the manufacturer) as this may lead to reduced stability.

1.3 Shell Surface and Microbubble Targeting

There are two relatively simple cases. One is the case of unspecific contrast agents, which remain in the blood pool and do not show uptake in certain organs or attachment to any targets. In the early years of ultrasound contrast agents, this was the intended mode of action. The second ‘simple’ case is just the opposite, namely purposeful targeting using one of the several techniques, which may not be limited to ultrasound contrast agents. It typically means to provide a bubble shell with a suitable number of targeting molecules, often attached to a linker on the shell surface. In recent years, in several cases the principle could be shown to work as intended.

Unspecific uptake of coated microbubbles in liver and spleen has been observed for several agents. It is expected as a normal response of the immune system, which tends to remove the coated bubbles as foreign particles. The surface properties of the bubble shell are determining the uptake rate, which can be controlled to some degree. This can be important when a long duration of contrast in the blood pool is intended, but also when rapid clearance is desired to get a low background signal for detection of targeted bubbles.

Delayed liver enhancement is a special case of unspecific uptake, mainly observed for Levovist. Its diagnostic applications in tumour imaging are described in a separate entry. The phenomenon is not completely understood and is still subject to research.

1.4 Influence of Shell on Elastic and Acoustic Properties

The acoustic properties of scatterers are determined by their density, elastic properties, shape and size. A bubble shell may have influence on all of these factors.

In nearly all cases, the shells of contrast agent microbubbles are very thin compared to their total diameters. The density of the shell material is very similar to the density of water, plasma or tissue. Therefore, a coated microbubble is essentially a gaseous inclusion in a medium with the density of water, with a size given by the inner diameter of the shell. While density and size are not much affected by the shell, the shell material has a very important influence on the effective elastic—and thus acoustic—properties.

A rigid, inelastic shell will prevent oscillations like those of a ‘free’ bubble. Therefore, scattering will be weak and about linear. On the other hand, a thin rubber-like, highly elastic shell will allow a bubble response almost like a ‘free’ bubble, preserving most of their highly desirable nonlinear acoustic behaviour. The same would apply to a shell consisting of smaller, loosely assembled pieces, which do not impede bubble motion.

Actually, most shells have properties between these extreme cases. Some types of thin, but almost rigid shells can be ruptured by sufficiently strong excitation in a diagnostic ultrasound pulse. This allows controllable switching from weak, linear scattering to much stronger and non-linear scattering. A broken shell also leads to rapid dissolution of microbubbles consisting of air or other soluble gases (see 1.1). Disappearing bubbles can be detected with very high sensitivity in colour Doppler mode, even a single microbubble can be detected with a normal diagnostic ultrasound scanner.

Contrast Media, Ultrasound, Low Solubility Gas

N. de Jong
ErasmusMC, Rotterdam,
The Netherlands
n.dejong@erasmusmc.nl

Synonyms

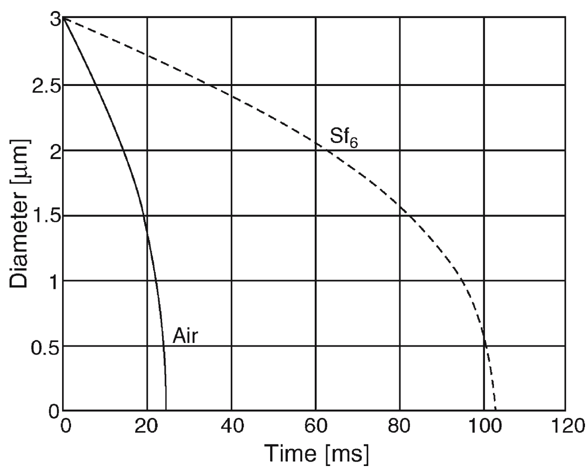
Perfluorocarbon gas agents; Second (third) generation contrast media

Definitions

An agent containing gas bubbles of which the gas in the bubble hardly dissolved in the surrounding liquid (typical water/plasma).

Characteristics

The first generation of ultrasound contrast agents were based on air core, whereas the new generations are composed of gases with higher molecular weights. For the kinetics of the dissolution of a gas, microbubble see—High solubility gas ultrasound contrast media. In that equation, the Ostwald coefficient (L) represents the ratio of the gas solubility in liquid to the gas density (1). From the equation, it is clear that microbubbles containing gases with lower Ostwald coefficients persist longer than bubbles containing gases with higher values. (Fig. 1) displays the dissolution in time of a 3 μm diameter bubble containing two different gases: air and sulfur hexafluoride SF_6. The air gas bubble disappears in less than 25 msec whereas the predicted lifetime of an SF_6 gas bubble with the same size is more than 100 msec. Second-generation contrast agents designed with improved lifetime to enable opacification of LV and myocardial microcirculation are composed of less-diffusable gases such as perfluorocarbons, perfluoropropane (optison), or sulfur hexafluoride (sonovue). These types of inert gases have a high molecular weight. Since the diffusion of a gas is inversely proportional to the square root of its molecular weight (2), the higher the molecular weight, the slower the solubility or diffusion of the gas. Table 1 summarizes, for different gases, the Ostwald coefficient and the predicted lifetime of a bubble of 3-m diameter. The gases chosen here are used in commercially available contrast agents or in those under clinical investigations. Clearly, gases with lower solubility provide the bubbles longer persistence. As a matter of fact, not only the Ostwald coefficient plays an important role in the choice of the type of gas for improved stability, but also the saturated vapor pressure at body temperature. Lower vapor pressures will make the bubble to condense into liquid losing therefore the contrast.



Contrast Media, Ultrasound, Low Solubility Gas. Figure 1 Diameter's change versus time for a bubble of 3 mm diameter; solid: air bubble, dashed: SF_6 gas bubble.

Contrast Media, Ultrasound, Low Solubility Gas. Table 1 Ostwald coefficient and disappearance time for 3-μm diameter bubbles containing different gases

	Ostwald Coefficient ($\times 10^6$)	Disappearance Time (msec)
Air	23,168	24.4
Sulfur hexafluoride (SF_6)	5,950	102.9
Perfluoropropane (C_3F_8)	583	1,110
Perfluorohexane (C_6H_{14})	24	2,000

Contrast Media, Ultrasound, Multipulse Techniques

Multi-pulse techniques are used in microbubble specific imaging for two key purposes. Firstly, a phase and/or amplitude modulated pulse train can be used to preferentially detect the non-linear response of the microbubbles to differing acoustic stimuli against the linear tissue background. Secondly, multiple pulses can be used to provide information on the motion of the microbubbles within the circulation, in the same way that multiple pulses are processed for color or power Doppler imaging.

Synonyms

Drug-delivery systems; Microbubbles; Target-specific microbubbles; Ultrasound contrast agents; Ultrasound contrast media

Definition

A classic ultrasound contrast medium consists of echogenic microbubbles, which, after intravenous injection, are distributed freely within the blood compartment. Several of these agents are already in the market and more are under clinical development. These agents differ in the composition of the shell and the encapsulated gas, which has an impact on the stability and the behavior in the sound field. However, microbubble contrast agents can also be used in a broader sense.

One approach is to modify the shell of the microbubbles to obtain an affinity to structures or tissues in the body. Such *target-specific microbubbles* can adhere to cells or specific molecular structures in the body, thereby allowing the imaging of these targets. Since the sensitivity of recent contrast-specific ultrasound technologies is so high that single microbubbles can be detected, such an agent can be used to image individual target molecules on the surface of cells or structures *in vivo* (*molecular imaging*).

Another approach is to incorporate drugs, genes, or other active substances in microbubbles, with the aim of releasing them at a specific location in the body. Such an agent can be used as a *drug-delivery system* allowing local therapy after intravenous administration of the agent. The local release of the active substance can be obtained either with target-specific microbubbles (distributing the encapsulated compound over time) or by local destruction of free circulating microbubbles using local insonation of the target region with high insonation power.

Indication

Standard ultrasound contrast media are used as markers for blood distribution and perfusion. They can help to delineate vascular structures, demonstrate the vascular geometry separated from the tissue background, and act as tracers for the assessment of blood distribution and perfusion.

For some of the existing agents, a certain affinity to endothelial structures has been described, even if they have not been developed for that purpose. Albumin-based contrast agents can attach to activated endothelial cells (1) and the attached microbubbles can be detected there after wash-out of the freely circulating agent. Other agents are captured by the reticuloendothelial system in the liver and spleen (2) or the microbubbles can even be phagocytosed by cells (3), allowing the imaging of phagocytotic active tissue. The attachment and/or phagocytosis of microbubbles in the liver is facilitated by the fenestration of the endothelium in the liver sinusoids, permitting the close contact of microbubbles and perivascular cells. An intracellular uptake of ultrasound contrast agents can also be obtained by using much smaller echogenic nanoparticles, e.g., consisting of biodegradable polymers (4). Such nanoparticles usually have a very high stability and are stored in the tissue for days and weeks.

Usually, ultrasound contrast agents are delivered, after intravenous injection, *via* the vascular system. However, alternative delivery pathways are possible too. For imaging of lymph nodes, the intravenous administration results in the demonstration of lymph node vascularity and perfusion. However, after subcutaneous injection, the agent is delivered *via* the lymphatic pathway to the lymph nodes (5). This allows the demarcation of sentinel nodes without using a radiotracer. Conventional microbubble agents as well as smaller nanoparticle agents can be used for lymphatic delivery.

A more specific attachment of microbubbles to tissues or structures can be achieved by coupling microbubbles to antibodies, binding to specific molecules on the surface of target cells/structures (6). Such agents can be used for targeted imaging down to a molecular level. Possible indications for targeted imaging include the detection of thrombotic material in the vascular system, the demonstration and quantification of neoangiogenesis in tumors, and the imaging of inflammation.

Beyond the diagnostic use, microbubble agents can also be used as therapeutic agents, e.g., to initiate or enhance local therapy. One capability of microbubbles is the local intensification of mechanical forces induced by the ultrasound wave. In combination with high insonation power, this can increase the endogenous or exogenous thrombolytic activity (*accelerated thrombolysis*) or can result in the transient formation of micropores in the capillary vessels (*sonoporation*), facilitating the transport of substances into the target tissue. Furthermore, the microbubble itself can be used simultaneously for the transport and delivery of active substances, acting as a ▶drug-delivery system. Using such a system, the local concentration and activity of a drug can substantially be increased, allowing local therapy with reduced systemic effects.

For some pathologies, constant treatment over a long period (or lifelong treatment) is required, creating the need for continuous administration of a drug. In such cases, gene therapy may be preferable, resulting in the repair of pathological functions or induction of protective mechanisms. The first preclinical studies have demonstrated that lipid-coated microbubbles can be used as vectors for the transportation of *genes* or *antisense molecules* instead of using viral vectors. The combination of ▶target-specific imaging and local therapy is a very promising opportunity for microbubble contrast agents, and an increasing number of research groups around the world are currently elaborating indications for the diagnostic and therapeutic use of such products. Many positive and encouraging results have already been published, coming from in vitro and animal studies. However, before the first product can be used in clinical studies in humans, extensive pharmacological and toxicological studies have to be performed.

Use and Dosage

Microbubble contrast agents are usually administered intravenously. The shell of the microbubbles ensures stability and integrity until the target region is reached and/or the microbubbles are destructed by a high-power ultrasound pulse. For target-specific imaging, normal doses of the contrast agent can be used. Due to the high sensitivity of contrast-specific imaging modalities, single microbubbles can be detected, so that the current doses used for blood-pool imaging are sufficient. For therapeutic purposes, the dose is mainly dependent on the efficacy of the incorporated drug. However, the lumen in the microbubbles is quite large, and for several drugs as well as oligodendronucleotides (used for gene therapy) it has been shown that effective doses can be obtained.

Adverse Reactions

Since the microbubbles do not contain any toxic substances, no substantial side effects caused by the microbubble carrier are known or expected. As for the current blood-pool imaging agents, allergic reactions can occur due to the colloidal character of the microbubbles. However, such reactions are rare and do not seem to be increased by labeling or loading of the microbubbles. Also for biopolymer nanoparticles, which are accumulated and stored for a long time in the target tissue, no particular side effects have been observed. However, the data available are limited and long-term effects need to be investigated.

Adverse effects of drug-delivery systems seem to be acceptable and are mainly related to the side effects of the encapsulated drug. Due to the local accumulation of the active substance, the side effects of the drug seem to be fewer compared to the systemic administration of the same drug. Therefore, it is expected that higher doses of the drug can be used to increase the local therapeutic effect.

Adverse events to ultrasound contrast media

Definition

All existing ultrasound contrast agents consist of gas bubbles slightly below the size of red blood cells and are stabilised by a shell. This is to ensure their survival in the blood circulation long enough for an ultrasound examination to be made and, in the case of the newer agents, to enable an examination with a reduced ►mechanical index (MI) to be made without significant destruction of the bubbles. They pass through capillary beds and thus can be injected intravenously. As they can be seen as particles, they do not leave the circulation, i.e. they are so-called blood pool agents. The contrast effect is caused, with increasing ultrasound intensity, by reflection, asymmetrical oscillation and finally bursting. Ultrasound contrast media are generally extremely well tolerated. Like with all drugs, adverse reactions to these agents may occur, but are very rare and seldom clinically relevant.

Indication

Ultrasound contrast media increase the reflectivity of blood. This can be used to enhance Doppler signals, both in spectral and colour Doppler. The asymmetrical oscillation, without significant bubble destruction, is the basis for so-called non-linear imaging techniques where dedicated ultrasound machine software can recognise the non-linear signal from a microbubble and produce an image based on contrast agent concentration rather than basic tissue echogenicity.

Many applications have been developed for this type of imaging, most notably to date the detection and characterisation of the liver and other organs. The ability to differentiate perfused from non-perfused tissue also has many applications in several organ systems.

Contraindications

Ultrasound contrast agents should not be used in patients with previous allergic reactions to the same compounds. Caution should be exercised when microbubbles are used in patients with ischaemic heart disease. Right-to-left ventricular shunts and pulmonary hypertension are also stated as contraindications, see below.

Pregnancy/Lactation

There is no evidence that compounds from ultrasound contrast agents would cause harm in pregnancy or when breastfeeding but as their use in pregnancy and paediatrics is contrary to the product information in most of the contrast agents, experience is limited and contrast used with caution.

Dosage

As different contrast agents have different physical properties and vary in the number of microbubbles per volume unit the dosage varies and must be adjusted with regards to the agent used, the ultrasound machine software and the indication for use.

Adverse Reactions

First, it should be pointed out that both ultrasound within recommended MIs and microbubbles as contrast agents seem to be extremely safe (1). Second, that as ultrasound contrast agents have physical rather than chemical properties in common (stabilised gas bubbles) the adverse reactions may vary more between different agents than is the norm for X-ray contrast media.

The most commonly reported adverse reactions are the same as with other types of contrast media, i.e. headache, a feeling of warmth and flushing. Less often reported are nausea, dizziness, chills, altered taste and dyspnoea. Similar findings were, however, also seen in the placebo groups.

Allergic reactions seem to be very infrequent and mild with general flush and erythema (2). Recently, a small number of more severe anaphylactic reactions to the agent SonoVue (Bracco SPA, Milano, Italy) have been reported, though, suggesting that repeated exposure over a short period of time should be considered with some care.

As microbubbles are particles they carry a risk of embolisation if they aggregate (individual bubbles are smaller than capillaries and therefore have no embolic potential). This, however, seems extremely unlikely given their extremely low concentration in the blood pool. Contrast injections are given intravenously and thus any such emboli should be filtered out by the capillary beds of the lungs but the existence of right-to-left shunts is usually a contra-indication for the use of microbubble-based contrast agents.

At higher ultrasound intensities a cavitation phenomenon occurs, i.e. the growth and collapse by implosion of microbubbles. This causes significant changes in pressure and temperature and *in vitro*/animal studies have shown local haemolysis, platelet aggregation and damage to endothelial cells (3). Even though these unwanted side effects have not been seen in clinical practise (4), it would be prudent to perform ultrasound contrast examinations with as low an acoustic output as possible. This is not a problem since most modern contrast-specific software use a low MI in order to minimise bubble disrupture.

It should be pointed out that as ultrasound contrast agents are relatively new products, it will take many more years of surveillance to accurately assess the possible existence of other rare adverse reactions.

Synonym

Segmental/partial priapism

Definition

A partial priapism of the corpus cavernosum is an exceedingly rare condition. Most frequently, it is characterized by thrombosis within a proximal segment of one corpus cavernosum.

Corpus Cavernosum, Thrombosis. Figure 1 Peyronie's disease with typical penile deformity on erect penis.

Clinical Presentation

Patients complain usually a painful perineal mass some days before seeking medical attention. On physical examination, a tender and painful mass is palpable perineally near the base of the penis.

Imaging

Magnetic resonance imaging of the pelvis should be the imaging modality of choice and reveals the underlying pathology. Frequently, an ultrasound of the perineal region or even a transanal ultrasound is performed beforehand to rule out any perianal abscess. Alternatively, a CT scan may be performed (Fig. 1).

Corpus Luteum Cysts

Corpus luteum cysts have thicker, better vascularized walls than follicular cysts. Similar to follicular cysts, the content varies from watery to proteinaceous to hemorrhagic.

►Cyst, Follicular, Ovarium

Coxa Valga

Increased angle between the femoral neck and shaft (normal 150° at birth, then gradually decreasing up to 120–130° in adults).

►Congenital Malformations of the Musculoskeletal System

Coxa Vara

Synonyms

Calcium pyrophosphate deposition disease; Chondrocalcinosis; Pseudogout

Definitions

One of the most confusing aspects of calcium pyrophosphate dihydrate (CPPD) arthropathy is the associated nomenclature. A variety of terms have been used. *Chondrocalcinosis* is a more general term that is reserved for pathologically or radiologically evident cartilage calcification. It can include CPPD, dicalcium phosphate dihydrate, or calcium hydroxyapatite crystals, or combinations of the three. CPPD *crystal deposition disease* is a specific term for a disorder characterized by the exclusive presence CPPD crystals in or around joints. The term "*pseudogout*" is not a radiological diagnosis; rather it is reserved for a gout-like clinical syndrome produced by CPPD crystal deposition disease that is characterized by intermittent acute attacks of arthritis. *Pyrophosphate arthropathy* is a term that describes a particular pattern of structural joint damage that occurs in CPPD crystal deposition disease. This arthropathy is similar to osteoarthritis but has some separate distinct features. *Articular and periarticular calcification* can occur with CPPD crystal deposition disease; however, calcium deposits other than CPPD crystal accumulation also may produce this type of calcification.

Pathology/Histopathology

The deposition of various crystals within the articular tissues can cause an acute inflammatory response and acute synovitis and lead to chronic destructive arthritis. First, deposition of CPPD crystals is observed in the articular cartilage, around the chondrocyte lacunae. This may alter biochemistry of cartilage, e.g., proteoglycan concentrations. The acute synovitis of CPPD is probably due to the rupture of preformed deposits of calcium pyrophosphate dihydrate from cartilage into the adjacent synovial cavity.

Clinical Presentation

The clinical presentations of CPPD crystal deposition disease are highly variable, ranging from asymptomatic disease to severe pain associated with a destructive arthropathy. Indeed, this disease has been called a "great mimicker" of other arthritides. Furthermore, occasionally, several of these clinical patterns present at different times during the course of the arthritis.

The *asymptomatic* form of this arthropathy is probably the most common; however, it is difficult to document this because many asymptomatic patients are never seen by a physician. Absence of symptoms occurs in at least 10 to 20% of documented cases of CPPD crystal deposition disease.

Many patients with CPPD crystal deposition disease present with an arthropathy that simulates *osteoarthritis*. An occasional acute inflammatory component is seen in 35 to 60% of such patients. This osteoarthritic form is a chronic and progressive arthritis that is frequently bilateral and symmetric, presenting in the knee, hip metacarpophalangeal, elbow, ankle, wrist, and glenohumeral joints. Flexion contractures are common, especially in the knee and elbow.

Patients with CPPD crystal deposition disease also may have inflammatory symptoms and signs. For example, attacks of *pseudogout* occur in 10 to 20% of symptomatic patients. The pseudogout syndrome is caused by shedding of pyrophosphate crystals into the joint fluid. Although most cases of pseudogout develop spontaneously, situations that trigger acute pseudogout include direct joint trauma, concomitant medical illness such as stroke and myocardial infarction, surgery (especially parathyroidectomy), blood transfusion, parenteral fluid administration, institution of thyroxine replacement therapy, and joint lavage. Hypocalcemia is present in many of these situations and is believed to provoke some attacks of pseudogout. This produces pain, erythema, and tenderness, which can be mistaken for other disorders such as gout or septic joint. The attacks are self-limited and can last from one day to several weeks. They generally are less painful than those of gout and are most common in the knee, but other sites including the hip, glenohumeral, elbow, ankle, wrist, acromioclavicular, talocalcaneal, and metatarsophalangeal joints also are affected. Fever and elevation of the erythrocyte sedimentation rate may accompany pseudogout attacks.

Two to six percent of patients with CPPD crystal deposition disease present with an arthritis that simulates *rheumatoid arthritis*. These attacks are characterized by morning stiffness, fatigue, synovial thickening, restricted joint motion, and an elevated erythrocyte sedimentation rate, and they persist from 4 weeks to several months.

CPPD crystal deposition disease also can have a *pseudoneurotrophic* presentation in as many as 2% of patients. Indeed, CPPD crystalline arthropathy should be considered in the differential diagnosis of rapidly progressive destruction of large joints.

Imaging

Conventional Radiography

Radiographically, chondrocalcinosis usually is apparent in CPPD crystal deposition disease, but the arthropathy can also precede radiographically detectable cartilage calcification, the calcification may not always be dense enough to be visualized on conventional radiographs, or it may be difficult to identify such calcification if the joint is severely deranged. In one study of 3228 patients undergoing knee arthroscopy, a radiographic diagnosis of chondrocalcinosis was made in only 39.2% of patients with pathologically proven CPPD crystal deposition (1).

Computed Tomography and Magnetic Resonance Imaging

Computed tomography (CT) can accurately demonstrate chondrocalcinosis due to the high soft tissue contrast and tomographic nature of this imaging method. However, CT is rarely used to evaluate the painful joint. Magnetic resonance imaging (MRI) is often the cross-sectional imaging procedure performed for painful joints. It is therefore common to encounter CPPD crystal deposition disease in older patients who are being studied with routine MRI. Calcification can be difficult to detect on MRI. Correlation with conventional radiographs is often necessary. Despite this problem, CPPD crystal deposition disease in hyaline cartilage is occasionally detected with standard MRI techniques. Prominent linear or punctate hypointense areas frequently are demonstrated. A small halo of hyperintense signal intensity surrounding the hypointense areas is occasionally seen, probably related to magnetic susceptibility artifact.

Although the low signal intensity calcification can be detected in routine spin echo, fast spin echo, and short tau inversion recovery (STIR) images, the hyaline cartilage calcification is better seen on gradient echo images in which the difference between the magnetic susceptibility of hyaline cartilage and CPPD crystals is enough to create local magnetic field inhomogeneity resulting in signal distortion. In these types of images, foci of cartilage calcification become larger, the so-called "blooming" effect.

Low signal intensity in the hyaline cartilage may be overlooked on MRI if the reader does not include it in a search pattern for chondrocalcinosis. There is also a differential diagnosis for this pattern, which includes hemosiderin from trauma, pigmented villonodular synovitis, and hemophilia; gas related to vacuum phenomenon;

and magnetic susceptibility artifact around postsurgical intra-articular material such as micrometallic debris.

There are also documented cases of CPPD crystal deposition in which the calcification in the hyaline cartilage or menisci was not seen on MRI. This is more common in cases of meniscal calcification in which the short T2 relaxation times of the meniscus and calcification are similar. Occasionally, with MRI, CPPD crystal deposition disease in a meniscus can mimic a meniscal tear. This has important implications and can lead to inappropriate treatment including unnecessary surgery. Gale et al reported areas of high signal intensity in regions of meniscal chondrocalcinosis with T2-weighted spin echo MR sequences (2). This finding may be attributed to the hyperintense halo artifact seen adjacent to calcification of low signal intensity. No reports have described high signal intensity in areas of chondrocalcinosis in T1-weighted images. Such a finding which would potentially simulate a meniscal tear, is theoretically possible given that increased signal intensity of calcium deposits has been found in the discs of the lumbar spine.

Nuclear Medicine

Skeletal scintigraphy may show increased radiotracer uptake in the joints, but these findings are nonspecific.

Diagnosis

CPPD crystal deposition disease is characterized by calcification in and around joints and structural joint changes termed pyrophosphate arthropathy. This arthropathy resembles osteoarthritis; however, it occurs in articulations not usually affected by osteoarthritis, often affecting non-weight-bearing regions such as the radiocarpal, metacarpophalangeal joints, glenohumeral joints, and elbow. It usually is bilateral and symmetric and is most common in the knee, wrist, and metacarpophalangeal joints. Furthermore, CPPD crystal deposition disease has an unusual intra-articular distribution in certain joints such as the knee and wrist where patellofemoral and radiocarpal joint space narrowing may be seen (3).

CPPD crystal deposition disease frequently presents on routine radiography with normal mineralization, narrowing of various articulations, and subchondral sclerosis. Osteophytes are common, but occur with a frequency less than that of osteoarthritis. Subchondral cysts are one of the hallmarks of this arthropathy. The cysts usually are larger, more numerous and widespread than in osteoarthritis. Cysts may form before cartilage loss is evident. Osseous fragmentation and collapse may be related to fracture of these cystic lesions. Intra-articular osteochondral bodies commonly are associated with CPPD crystal deposition disease. These may be free in the joint cavity or embedded in cartilage or synovium.

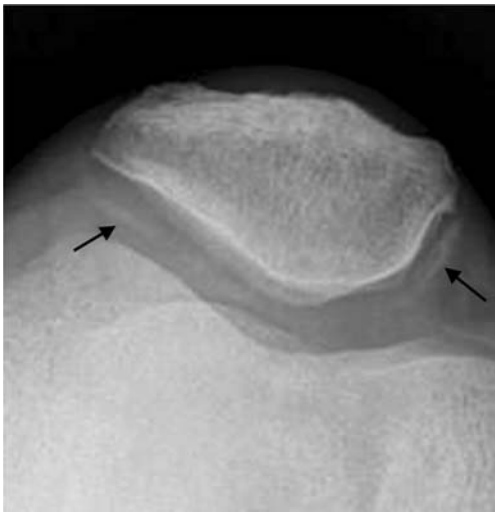
Cartilage

Chondrocalcinosis is usually caused by CPPD crystal deposition. In 5% of cases, however, it can be related to other crystals such as dicalcium phosphate dihydrate and calcium hydroxyapatite (4). Both hyaline cartilage and fibrocartilage can contain CPPD crystals. The CPPD crystal tends to be deposited in the middle layer of degenerated hyaline cartilage. These deposits are thin and linear and parallel the subjacent subchondral bone (Fig. 1). CPPD crystals are also deposited on the surface of the hyaline cartilage, especially when there is superficial chondral erosion. Hyaline cartilage calcification is most common in the wrist, knee, elbow, and hip.

CPPD crystal deposition in fibrocartilage is most commonly observed in the menisci of the knee, triangular fibrocartilage of the wrist, labra of the acetabulum, symphysis pubis, and annulus fibrosus of the intervertebral disc. Other less common sites of CPPD crystal deposition in cartilage include the articular discs of the sternoclavicular and acromioclavicular joints and glenoid labra.

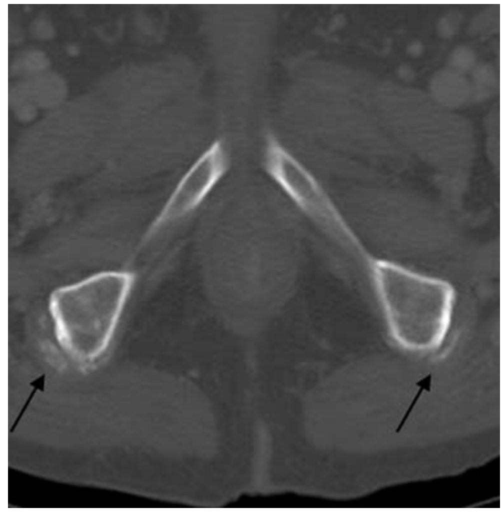
Synovium and Capsule

Synovial calcification is common in CPPD crystal deposition disease. Synovial calcification can be so widespread that it appears to fill the entire joint cavity,



CPPD. Figure 1 Linear calcification is seen along the hyaline cartilage of the medial and lateral facets of the patella (*arrows*) on this Merchant view of the patellofemoral joint.

CPPD. Figure 2 **Synovial calcification is appreciated along the suprapatellar bursa on this lateral knee radiograph (*arrow*). Hyaline and meniscal calcification is also identified (*curved arrow*). Osteochondral bodies lie posteriorly (*).**



CPPD. Figure 3 **Calcium pyrophosphate dihydrate (CPPD) crystal deposition is present in the hamstring tendon origins bilaterally on this CT image (*arrows*).**

mimicking synovial osteochondromatosis. Synovial deposits are more common in the wrist, knee (Fig. 2), metacarpophalangeal, and metatarsophalangeal joints. The synovial membrane may demonstrate acute and chronic inflammatory changes in association with CPPD crystal deposition disease. It is not known if the crystals migrate into the synovium from the adjacent cartilage or are deposited directly within the synovium. Capsular calcification may appear as a linear peripheral density and may be difficult to distinguish from early synovial calcification. It is most commonly observed in the elbow, glenohumeral, metatarsophalangeal, and metacarpophalangeal joints.

Tendons, Ligaments, and Bursae

Tendon calcifications are observed with high frequency in patients with CPPD crystal deposition disease. An incidence of 13.5% was reported in such patients in one study (5). Those tendons more frequently involved include the supraspinatus, triceps, quadriceps, gastrocnemius, and Achilles tendons. Hip adductor, rectus femoris, and hamstring tendon calcification may also be seen (Fig. 3). Tendon calcifications commonly are linear or punctate and usually can be distinguished from the more homogeneous, discrete, and nodular calcifications of calcium hydroxyapatite crystal deposition. Calcification often extends far from the tendon attachment. There is a high correlation between the existence of these tendon calcifications and the extent and intensity of calcific deposits in other joints. Direct translocation of CPPD crystals from the articular or bursal surfaces may be responsible for some of the tendinous calcification.

Ligaments can also calcify. Sometimes, the calcification is not dense enough to be visualized on conventional radiographs. The ligamentum flavum and dura mater can contain calcific deposits. Bursal calcification is most common in the olecranon and subacromial bursae.

Other Extra-Articular Soft Tissues

Soft tissue and vascular calcification may be seen in CPPD crystal deposition disease. In particular, tumor-like masses of CPPD crystals can be seen in the extra-articular soft tissues. This manifestation of CPPD crystal deposition disease, known as "tophaceous pseudogout," is rare. In one study, 7 cases of massive focal CPPD crystal deposition disease were identified in atypical locations (6). The patients ranged in age from 31 to 86 years and 6 of them were women. These crystalline masses have been seen near the elbow, finger, jaw, acromioclavicular joint, and hip. Lesions are solitary and usually occur in areas of chondroid metaplasia without predisposing metabolic abnormality. Although the mechanism for development of these masses is not known, it has been postulated that hypertrophic metaplastic chondrocytes accumulating proteoglycans intracellularly provide a seeding site for crystal formation. These calcified masses may initially be mistaken for benign or malignant chondroid or other soft-tissue tumors, tophaceous gout, and tumoral calcinosis. Misdiagnosis sometimes leads to unnecessary surgery. The patterns of calcification usually can be differentiated from the lobular pattern of calcification in tumoral calcinosis by their granular and more delicate appearance. Calcified soft tissue masses related to CPPD crystal deposition are of intermediate to low signal intensity on MR imaging examinations. They can present as the only manifestation of CPPD crystal deposition disease. Pressure erosion of adjacent osseous structures may be seen. It is important to identify the CPPD crystals, as these masses have also been mistaken for malignant cartilaginous tumors on histologic evaluation because of the presence of chondroid metaplasia.

Definition

Crohn disease is a chronic inflammatory disorder of the alimentary tract of unknown etiology. It is most common in northern Europe, North America, and Japan. The disease most frequently affects the wall of the distal ileum and the right colon, but it may involve any gastrointestinal segment, from mouth to anus, with a typical segmental spreading and a chronic course of relapse and remission.

Generally, the disease has an early onset, around the second to third decade of life, but is not rare in the pediatric age group; a second peak of incidence is observed in an older age group. It can present at virtually any age and lasts for the patient's entire life, with a typical relapsing–remitting course.

Although the pathogenesis of Crohn disease remains unknown, there is an emerging consensus that it results from the complex interaction of multiple genetic, immunologic, and environmental factors. It starts as a breach of the mucosal barrier by a specific infectious agent or environmental toxin, causing inflammation perpetuated by exposure of luminal microflora to the mucosal immune system, and it becomes chronic as a result of a genetically determined failure of immunologic downregulation. Uncontrolled fibrogenesis may lead to stricture formation, and microbial antigens across the mucosa determine the extraintestinal localizations of disease.

Although unpredictable, three main Crohn disease phenotypes (or courses) have been recently identified according to the Vienna classification of Crohn disease (International Working Party for the World Congress of Gastroenterology, 1998): inflammatory (nonfibrostenosing and nonperforating), perforating, and fibrostenosing, with the perforating phenotype being more aggressive and frequently associated with severe complications (1, 2).

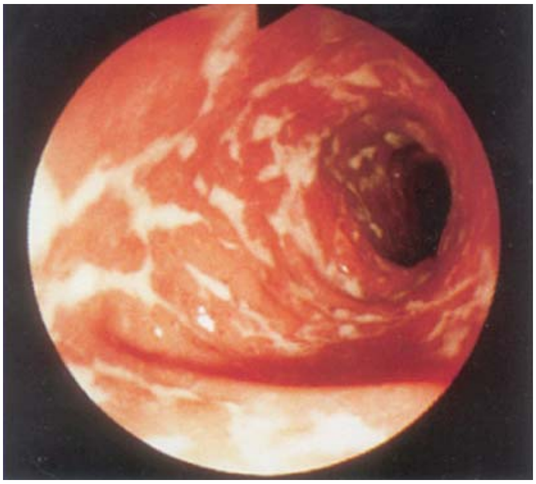
Pathology/Histopathology

The disease may involve any part of the gastrointestinal tract, but preferentially the distal ileum, with the majority of patients having an ileitis or ileocolitis.

The small bowel is affected in approximately 80% of cases, particularly the distal ileum, either alone (in 25–35% of cases) or associated with colon localization (in about 30–55% of cases); in only 15–25% of patients is the colon involved alone, frequently at multiple sites.

Involvement of the esophagus, stomach, duodenum, or jejunum in isolation or in association with other common sites is rare. Perianal disease is usually associated with rectal involvement.

Macroscopically, the disease is characterized by a thickened bowel wall and frequently also by a narrowed bowel lumen, which is associated with edematous and thickened mesenteric fat tissue and enlarged local lymph nodes. On the mucosal surface, longitudinal and irregular



Crohn Disease. Figure 1 **Active Crohn disease of the distal ileum. Endoscopic image shows hyperemic mucosa with multiple serpiginous ulcerations, covered by fibrin exudate, at the level of the distal ileum. (Courtesy of Dr. V. D'Ovidio, Department of Gastroenterology, University of Rome La Sapienza.)**

ulcerations may be present. At endoscopy, in active disease the mucosal surface is usually hyperemic and is associated with aphthoid or more severe ulcerations—linear, irregular, or serpiginous—usually arising on the mesenteric border (Fig. 1).

Microscopically, the main characteristic of Crohn disease is transmural inflammation, with inflammatory cell infiltrates involving all wall layers. The inflammatory process typically starts in the submucosa layer, consisting of lymphocytes, macrophages, and plasma cells and producing lymphoid hyperplasia and mucosal aphthoid ulcers in the early phases. Aphthoid ulcers develop into linear ulcers and fissures to produce an ulceronodular, so-called cobblestone appearance. In more advanced phases, chronic inflammatory cell infiltrates spread to all wall layers, occasionally producing noncaseating submucosal granulomas consisting of macrophages within the lamina propria in relation to cryptic disruption.

In advanced disease, fibrosis, deep mucosal ulcerations, and transmural fissures are common findings. There is a tendency to involve the serosal surface, which is usually inflamed and hyperemic, associated with involvement of mesenteric fat and adjacent tissues. Typically, the inflammatory process progressively extends outside the intestinal wall, involving first the perivisceral fat tissue (thus producing fibrofatty proliferation and mesenteric adenopathies), and then the adjacent bowel loops, muscles, and genitourinary structures, producing adhesions and enteroenteric, enterocutaneous, and enterovesical fistulas, abscesses, and phlegmons. Toxic megacolon and neoplasms such as lymphoma and carcinoma may also occur.

Clinical Presentation

Crohn disease is characterized by cardinal symptoms, including diarrhea (85%) with variable daily and nocturnal evacuation frequency (three to six times per day), caused by bile salt malabsorption and bacterial overgrowth; bloody diarrhea; abdominal pain (55%); weight loss (65%); and bowel distension, reflecting the typical ileocecal disease localization.

Clinical findings may include a fullness in the right iliac fossa, low-grade fever, tachycardia, and elevated laboratory inflammation findings, such as erythrocyte sedimentation rate, C-reactive protein, and white blood cell count. Other blood tests may be helpful in detecting Crohn disease, such as the antiendomysial antibody test, which is related to the differential diagnosis at initial presentation; the anti-*Saccharomyces cerevisiae* antibody (ASCA) test; and the antiperinuclear neutrophil cytoplasmic antibody (pANCA) test. The ASCA test is thought to be relatively specific to Crohn disease, probably reflecting leakage of the yeast antigen across the mucosal barrier. Conversely, the pANCA test has shown a higher specificity for ulcerative colitis. However, neither of the tests is as specific as originally thought, but they can provide useful discriminatory information when used in combination (ASCA positive, pANCA negative in Crohn disease, and vice versa in ulcerative colitis).

In some cases, the disease can be nonspecific in its presentation, with little more than malaise and weight loss; these cases are a major diagnostic challenge.

Lactose intolerance is common, with milk, cream, and rich cheese foods particularly troublesome. Constipation can reflect an intestinal stricture with subacute obstruction or inflammation confined to the distal colon. Abdominal pain is often localized to the right iliac fossa and suprapubic region, is mild to moderate in intensity and cramping, and is exacerbated by spasm, particularly before passing stool. In the majority of patients, the physical signs of Crohn disease may be evident, represented by anemia, glossitis, aphthous ulceration in the oral cavity, and dehydration requiring prompt medical intervention (1, 2).

The presence of a positive family history of ►inflammatory bowel disease markedly increases the probability of a diagnosis of Crohn disease: 10–20% of Crohn disease patients have an affected first or second-degree relative, compared with less than 1% of the general population. There is also a significant association of Crohn disease with ankylosing spondylitis, resulting from a shared genetic susceptibility. Major histocompatibility complex associations observed in the subgroup of Crohn disease patients include ankylosing spondylitis (HLA-B27) and primary sclerosing cholangitis (haplotype A1-B8-DR3).

Imaging

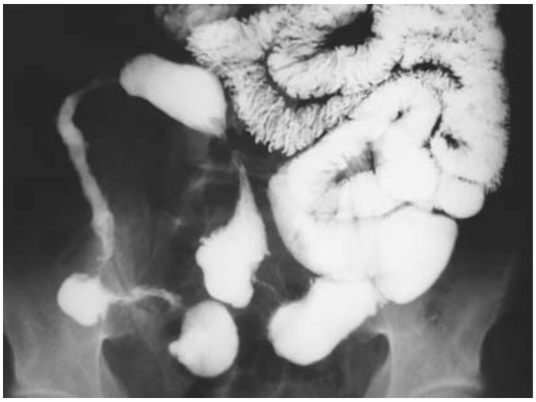
Several imaging modalities are used to detect and assess Crohn disease, including barium studies (conventional enteroclysis, small bowel follow-through, and barium enema studies), colonoscopy, ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI). These modalities can help localize lesions, confirm the clinical diagnosis, assess the extent of disease, and establish inflammatory activity.

Endoscopy and barium studies are widely considered the principal tools for diagnosing and evaluating Crohn disease in the small and large bowel; however, they have a limited capability to demonstrate the transmural extent of disease or extraintestinal complications.

After more than 50 years from their clinical introduction, barium studies of the small bowel are still considered the gold standard for evaluating the small bowel. The contrast agent can be orally administered and its passage followed through the entire small bowel, or it can be administered through a nasojejunal tube. Such administration allows the use of a double-contrast technique, which is otherwise not possible, by adding air or methylcellulose to the barium contrast agent. Barium studies can detect the site and length of lesions, the severity of strictures, and the presence of enteroenteric fistulas with high accuracy. At barium studies, the pathologic segment is usually well separated from the adjacent bowel loops by the fibrofatty proliferation and by bowel wall thickening. However, extraintestinal abscesses, phlegmons, and nonenteric fistulas can be underestimated (Figs 2 and 3).

Colonoscopy allows evaluation of the involvement of colonic mucosa, and in most cases it can be extended to the distal ileum (ileocolonoscopy). Moreover, at endoscopy multiple biopsies are routinely obtained, which is considered extremely important for confirming the diagnosis of Crohn disease.

Cross-sectional imaging, offering three-dimensional visualization and vascular information, has the advantage of identifying the presence of intraperitoneal or extraintestinal complications, such as abscesses and enterocutaneous and extraintestinal fistulas that may require surgical planning. On the other hand, cross-sectional imaging does not allow detection of subtle or advanced mucosal lesions.



Crohn Disease. Figure 2 **Active Crohn disease lesions of the distal ileum. Follow-through barium study shows a long segment of the distal ileum characterized by multiple stenoses and sacculated prestenotic dilations due to the typical segmentary spreading of disease. At the level of the stenotic segments, a cobblestone pattern is also observed.**

Crohn Disease. Figure 3 **Enterocolic fistula. At the barium study, a tight stricture of the distal ileum and irregularity of the cecal fundus are observed, suggestive of ileocecal Crohn disease. A spot view demonstrates a tiny fistulous tract between the terminal ileum and the right colon adjacent to the ileocecal valve, a common extramural bowel complication.**

Ultrasound (US), thanks to its noninvasiveness, low cost, and ready availability, is increasingly used as the initial screening modality and as an alternative examination in patients with atypical abdominal symptoms, either acute or chronic. With modern US equipment, it is possible to make a confident US diagnosis of Crohn disease in most cases.

US can suggest ileocecal Crohn disease quite reliably. The sonographic hallmark is bowel wall thickening that involves all layers of the affected intestinal tract, ranging from 5 to 20 mm. Next to the terminal ileum, the cecum and appendix are not infrequently involved. The layer architecture of the bowel wall is often locally disturbed. In most chronic lesions, the submucosal layer is typically thickened and hyperechoic, likely due to increased submucosal fat either in active or nonactive disease; such submucosal increased thickening and echogenicity produces the typical layered pattern of Crohn disease. The affected bowel shows decreased peristalsis and a narrowed lumen, and it is often surrounded by noncompressible swollen fatty tissue. Mesenteric lymph nodes may be markedly enlarged, and in many cases an abscess, fistula formation, or prestenotic dilatation can be diagnosed as well.

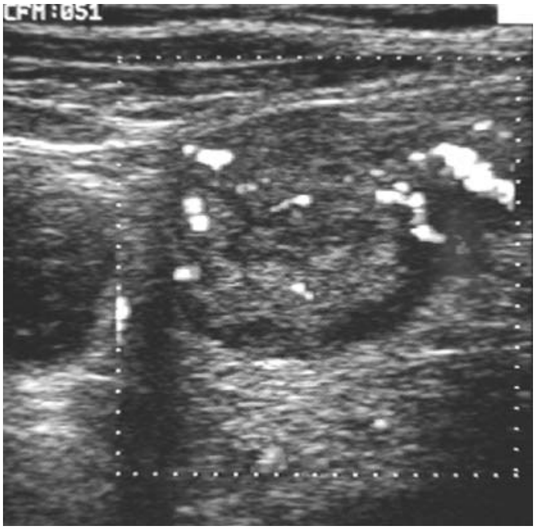
With severe inflammation, the wall may appear diffusely hypoechoic with partial or total loss of layering due to transmural edema, with a central hyperechoic line that corresponds to the narrowed lumen. Peristalsis is reduced or absent, and the diseased segment is noncompressible and rigid, with a loss of haustra. However, the same finding of layering loss may be observed in the presence of diffuse wall fibrosis with nonactive disease.

The accuracy of US is further improved by the use of color Doppler imaging, which is helpful in detecting hyperemia of an inflamed bowel wall and adjacent fat during active disease (Fig. 4).

In conclusion, the liberal use of US in patients with abdominal symptoms constitutes a powerful and reliable tool for the early detection of ileocecal Crohn disease. It decreases the diagnostic delay and prevents unnecessary surgical interventions.

CT is a well-established imaging modality for detecting Crohn disease lesions and is preferred for evaluating the transmural extent of the disease and for diagnosing extraintestinal and intraperitoneal complications. In contrast to US, CT is generally not performed as an initial screening procedure in patients with atypical and protracted and abdominal symptoms. However, because CT is increasingly used as an emergency imaging modality in patients with acute abdominal symptoms, it may undoubtedly help detect clinically unsuspected cases of Crohn disease.

The CT scan is usually obtained in the supine position from the dome of the liver to the level of the perineum to get a panoramic visualization of the entire intestine, with a 5-mm thickness. High-quality multiplanar reformatted images, particularly coronal planes, obtained with multidetector CT equipment can be extremely useful for localizing Crohn disease lesions.



Crohn Disease. Figure 4 Active Crohn disease of the distal ileum. Ultrasound image shows a marked concentric thickening of the bowel wall and a narrowed lumen of the terminal ileum. Increased color Doppler signal suggests a high degree of inflammation of the bowel wall, as well as initial inflammatory involvement of the adjacent mesenteric fat.

To obtain diagnostic CT abdominal images or to provide positive or negative lumen contrast and dilation, various types of intraluminal contrast agents should be administered. Such contrast agents can be administered either orally (about 1–1.5 L given 90 min before the examination) or through a nasojejunal tube (CT-enteroclysis). The contrast agent should provide a homogeneous luminal enhancement, high contrast between the lumen and the bowel wall, and minimal mucosal absorption, and lead to no artifact formation or significant adverse effects.

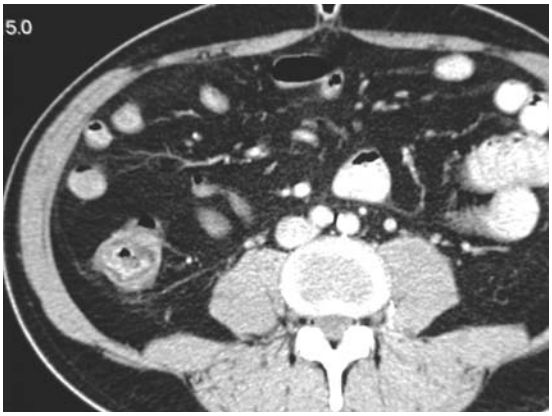
Positive contrast agents at CT (iodinate or barium solutions) can be helpful for distinguishing bowel loops from enlarged lymph nodes or extramural fluid collections. However, using intraluminal positive contrast agents for bowel wall enhancement after intravenous administration of contrast material may obscure submucosal lesions.

Negative intraluminal contrast agents (methylcellulose or water iso-osmolar solutions) can similarly help detect normal or pathologic bowel wall segments, with the advantage of better visualization of the wall contrast enhancement and submucosal lesions (Fig. 5).

The use of an intravenous contrast agent is extremely important for better visualization of the normal and inflamed bowel wall (3, 4).

MRI is currently considered an emerging cross-sectional modality for evaluating abdominal and intestinal diseases, and is the modality of choice for evaluating

Crohn disease lesions at some institutions. In fact, recent technological advances (increased gradient strength, phased array coils, fast sequences, and so on) have greatly improved the quality of abdominal MR images, allowing acquisition of high-resolution images of the intestine during a single breath-hold, with significant increases in temporal and spatial resolution. In the next years, MRI could become the modality of choice for Crohn disease patients, first because it provides a diagnostic capability similar to CT but without radiation exposure, a fact that is particularly important for younger patients and children, who will have multiple studies during their lives. Moreover, it has an intrinsic higher tissue contrast than CT, allowing better assessment of inflammation in Crohn disease lesions. Finally, the multiplanar panoramic capability of MRI allows, differently from US, evaluation of the entire bowel using multiple planes, similar to multidetector CT images, allowing better identification of Crohn disease lesions and their complications. The lack of radiation exposure justifies and allows the use of MRI for the periodic assessment of Crohn disease activity, for clinical trials, and for follow-up studies.

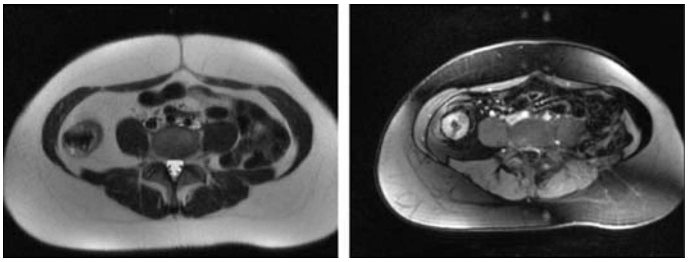


Crohn Disease. Figure 5 Recurrent Crohn disease in a patient who underwent ileocecal resection. The computed tomographic image, on axial plane, shows a marked thickening of the wall of the ileal anastomotic loop, with a narrowed lumen and proliferation of perivisceral fat tissue.

The MRI examination is preferably performed using a high magnetic field (1.5 T) and phased array coil for increased signal-to-noise ratio. The diagnostic imaging protocol should include both T1 and T2-weighted sequences to detect and characterize intestinal lesions, with the acquisition of axial and coronal thin, contiguous images. Acquisition of coronal and axial images is obtained with a 4–6-mm section thickness and a field of view of at least 350350 mm to cover all the bowel loops, adding sagittal plane images if necessary for a complete evaluation of disease.

Various kinds of intraluminal MRI contrast agents have been clinically tested: positive (gadolinium solutions), negative (superparamagnetic), and biphasic (water-like). Negative or biphasic contrast agents are more commonly used for evaluating small bowel diseases. Biphasic intraluminal contrast agents may produce either high or low signal, depending on the pulse sequence used; the more widely used have a water-like behavior, demonstrating low signal intensity on T1-weighted sequences and high signal intensity on T2-weighted sequences.

To assess inflammatory lesion activity, T1-weighted spoiled gradient imaging, after intravenous administration of a gadolinium chelate, and T2-weighted fat-suppressed imaging are used (Fig. 6) (3, 5). On the other hand, to obtain morphologic information, fast T2-weighted sequences (fast half-Fourier acquired single-shot fast spin-echo) and fast T1 and T2-weighted sequences with a steady precession (true-FISP or FIESTA) are preferred. True fast imaging with a steady precession (FISP) sequence provides high-resolution images of the intestine, mesenteric lymph nodes, and vessels. However, this kind of



Crohn Disease. Figure 6 Crohn disease of the right colon. T1-weighted magnetic resonance images on axial plane obtained after intravenous administration of gadolinium chelate contrast agent and with suppression of the fat tissue, showing marked bowel wall enhancement with concentric bowel wall thickening at the level of the right colon. The T2-weighted image, obtained at the same level, shows bright bowel wall signal, and wall thickening can be observed as well.

sequence is susceptible to artifacts from intraluminal air due to chemical shift phenomenon, obscuring subtle bowel wall thickening.

The T2-weighted turbo spin-echo sequence provides excellent soft-tissue contrast and is not susceptible to black luminal artifacts; when used with fat suppression, bowel wall edema and mesenteric inflammation can be highlighted, which is useful for assessing the degree of disease activity.

The gadolinium-enhanced fat-suppressed T1-weighted sequences provide excellent visualization of hypervascular inflamed bowel wall, being extremely useful to localize active and complicated intestinal lesions, as well as assess the degree of disease activity (3–5).

Usually, a variable combination of true FISP, T2-weighted turbo spin-echo, and gadolinium-enhanced echo sequences, with or without fat suppression, is used to evaluate the extramural extent of Crohn disease lesions and complications.

Nuclear Medicine

Nuclear medicine plays little role in the initial characterization of Crohn disease. Leukocytes labeled with either technetium-99m-hexamethyl-propylene-amine-oxime (HMPAO) or indium-111 can be used to assess active bowel inflammation in any inflammatory bowel disease.

Once the histological diagnosis of Crohn disease has been established, technetium-99m-HMPAO-labeled white blood cells, with single photon emission CT imaging, may be used to assess disease activity and disease length.

Compared with the indium-111 label, the Tc-99m HMPAO label is preferred due to the better radionuclide availability and better imaging characteristics; moreover, it allows imaging sooner after injection. However, imaging must be done within an hour after injection of Tc-99m-HMPAO-labeled leukocytes because there is normal excretion into the bowel after this time, unlike indium-111-labeled leukocytes, not having bowel excretion.

Advantages over barium studies include the contemporary examination of both large and small bowel, lower radiation exposure (particularly important in younger patients), and higher patient tolerance.

False-positive bowel activity can be found with gastrointestinal bleeding, swallowed leukocytes, or activity related to in-dwelling enteric tubes. In addition, leukocyte uptake is not specific for Crohn disease and will be seen in most infectious or inflammatory bowel processes. As mentioned earlier, there is often normal bowel excretion of Tc-99m-HMPAO leukocytes if imaging is done more than an hour after injection.

Diagnosis

Complete evaluation of Crohn disease is usually difficult because it should include the characterization of the disease, differentiation from other inflammatory bowel diseases, localization within the small and large bowel, the extent of disease, disease severity and possible complications, and the degree of inflammatory activity.

The early phase of the disease is commonly suspected and assessed based on clinical and laboratory findings. Colonoscopy and barium study are the most commonly used imaging modalities in early phases, being able to appreciate enlarged lymphoid follicles, erosions, and aphthoid ulcers. Because of its noninvasiveness, low cost, and ready availability, US should be performed as a primary imaging modality in the clinical evaluation of Crohn disease in association with conventional imaging and laboratory findings.

CT and MRI are preferred when evaluating more advanced phases to assess the transmural extent of the disease and any intraperitoneal complications. Extraintestinal complications are largely detected on cross-sectional imaging. CT and MRI are also useful for characterizing the different disease courses, thus helping with the planning of medical treatment in cases of active inflammatory disease and of ►surgical treatment in fistulating, fibrostenosing, or perforating disease with abscesses.

Panoramic views and multiplanar images associated with high soft-tissue contrast, static and dynamic imaging capabilities, and the absence of ionizing radiation exposure represent the advantages of the MR modality over CT. On the other hand, CT offers other advantages over MRI, such as shorter examination times, higher availability, higher spatial resolution, and the possibility to choose thickness slices and planes after data acquisition.

Treatment

The ►medical treatment of Crohn disease varies according to the different disease phases, in particular the acute and the remission phases. During acute exacerbation, the main medical management consists of intravenous administration of glucocorticoids (hydrocortisone or methylprednisolone) in addition to metronidazole. Steroid therapy should be limited because of its various adverse effects, including osteonecrosis, myopathy, osteoporosis, and growth retardation. Intravenous cyclosporine may be used to inhibit cell-mediated immunity for further immune modulation and to increase the corticosteroid response.

The target of chronic therapy is remission of bowel inflammation. Local aminosalicylates have been the main therapeutic agents because of their anti-inflammatory activity, each one having a different carrier molecule directed to a specific region of the bowel. Sulfasalazine and balsalazide are primarily released in the colon. Dipentum and Asacol are formulations for targeted release in the distal ileum and colon. Pentasa is released in the duodenum to the distal colon, whereas Rowasa is specific for the rectum and distal colon.

Azathioprine, 6-mercaptopurine, and methotrexate are other nonsteroidal immune modulators that are used as alternatives to glucocorticoids for inducing remission. Adverse effects of azathioprine and 6-mercaptopurine are uncommon (incidence of pancreatitis, allergic reactions, infection). The main disadvantage to the use of azathioprine and 6-mercaptopurine is their slow onset of action; response to therapy is usually noted after 3–6 months of treatment. Methotrexate, the long-standing folic acid antagonist, is effective in many patients with disease refractory to azathioprine and 6-mercaptopurine. Nevertheless, it has well-known adverse effects, mainly leukopenia and gastrointestinal upset.

New therapies are targeting tumor necrosis factor-alpha. Biological agents such as infliximab, a monoclonal chimeric antitumor necrosis factor-alpha antibody, are becoming available and showing promising results, with an increased remission rate. Other agents such as mycophenolate have been developed to inhibit guanine nucleotide synthesis and thereby inhibit B and T lymphocytes.

Most patients with Crohn disease undergo surgery within 20 years of diagnosis. Surgical treatment is required in cases of stricture, intractable or fulminant disease, anorectal disease, and intraabdominal abscess. Commonly, half of the patients who have had one surgical treatment will require further surgery for recurrent disease within 10 years. Recurrence occurs more frequently in cases of younger age of onset, enterocutaneous fistulas, multiple sites of disease, and a perianastomotic site of recurrence in stricturoplasty. Recurrence is often defined as detectable active disease associated with reactivation of symptoms (1, 2).

The basic tendency in surgery for Crohn disease is to limit small bowel resection of the involved segments. Stricturoplasty, performed by incising a stricture longitudinally and then suturing it transversely to widen the lumen, is often done when a severe stricture is present to preserve the small bowel and prevent short-bowel syndrome. In the majority of cases, the lack of perioperative deaths with stricturoplasty is a favorable feature compared with surgical resection.

Finally, CT-guided percutaneous abscess drainage may obviate surgery in selected cases. Recently, this has shown great success both as a temporizing measure and as definitive therapy, with a decreased rate of recurrence compared with that of surgery.

Key Points

Crohn disease is a chronic inflammatory bowel disease that commonly involves the distal ileum and the cecum and right colon, characterized by clinical, radiological, and histological features.

Infectious agents or environmental toxins associated with immunological downregulation cause inflammation of the mucosal layer that becomes chronic, until there is uncontrolled fibrogenesis, strictures, lesions, and extramural complications.

Several imaging modalities can detect and assess Crohn disease. Each has distinct advantages and disadvantages, and the decision of which one to use depends on the patient's condition and the phase of the disease.

Medical management is used in the acute or chronic/relapsing phases of the disease. Glucocorticoids (hydrocortisone or methylprednisolone) in addition to metronidazole represent the main acute therapy. Aminosalicylates, methotrexate, azathioprine, and 6-mercaptopurine are used in the chronic phases. Infliximab (a monoclonal antibody) is a new therapy that targets tumor necrosis factor-alpha.

Surgical treatment is indicated in cases of strictures, bleeding, abscesses, perforation, and carcinoma, which are complications not amenable to medical treatment. There is actually a tendency to conservative surgical management; nevertheless, recurrences are common.

Cross-sectional Imaging

Include ultrasonography (US), computed tomography (CT) and magnetic resonance imaging (MRI).

►Colitis, Ulcerative

Crossing Artery

Accessory renal arteries are frequent at the lower pole of the kidney and may have a close relationship to the ureteropelvic junction.

▶Ureteropelvic Junction Syndrome

Crouzon Syndrome

Crouzon syndrome (acrocephalosyndactyly type II), the most frequent craniofacial dysostosis, is characterised by bilateral coronal synostosis with brachycephalic or oxycephalic vault, maxillary hypoplasia, shallow orbits with proptosis, hypertelorism, cleft palate. Concurrent intracranial anomalies (anomalous venous drainage, hydrocephalus, Chiari I malformation) are common. Other non-obligatory features include calcification of the stylohyoid ligament, cervical spine abnormalities, elbow malformations, minor hand deformities, visceral anomalies, musculoskeletal deformities and skin lesions. Limb anomalies are non-specific.

▶Congenital Malformations, Nose and Paranasal Sinus

Cryotherapy, Hepatic Tumours

Technique for treatment of hepatic neoplasm based on local tumour destruction *in situ* by freezing. The resulting freeze process causes irreversible cellular damage and tissue necrosis is obtained.

▶Interventional Hepatic Procedures

Cryptococcosis

Cryptococcosis is an infection caused by the saprophytic yeast-like fungus Cryptococcus neoformans.

▶Infection, Opportunistic, Brain

Cryptorchidism

Cryptorchidism is the absence of the testis in the ipsilateral hemiscrotum. About 90% of undescended testes are located in the inguinal canal, with the remaining 10% located in the abdomen. Very rarely, the missing testis is ectopic and can be found in the perineum, in the contralateral hemiscrotum, or at the base of the penis.

▶Genital Tract

CSF

Cerebro-spinal fluid.

▶Tumors, Spine, Intradural, Extramedullary

CT

▶Computed Tomography

CT Angiogram Sign

The CT angiogram sign refers to the presence of contrast-enhanced, well-visible vascular structures surrounded by consolidated lung parenchyma with a much lower contrast uptake. Originally it was described as being pathognomonic for bronchioloalveolar carcinoma, but it is also seen in pneumonia and lymphoma. It is not seen in an atelectatic lung (due to the strong enhancement of the atelectatic lung parenchyma) and always indicates a pulmonary process.

▶Atelectasis

CT Dentascan

The CT Dentascan is a special computerized reformatting program that has been developed to obtain true cross section of the mandible and maxilla from CT scan.

▶Neoplasms, Odontogenic

CTA

Computed tomography angiography is based on helical or spiral CT and provides the exploration of one volume with each tube rotation.

Ultra rapid, non-invasive X-ray technique for visualisation of the vascular tree.

▶Cerebral Aneurysms

CTAP

Computed tomography (CT) arterioportography. This technique CT allows a higher level of intrahepatic enhancement to be obtained by means of catheter injection of the contrast medium directly into the celiac axis or hepatic artery. It was introduced to increase the detection rate of CT for small hepatic lesions. The use of CTAP has been largely replaced by multiphase helical scanning and tissue-specific enhanced magnetic resonance imaging.

►Metastases, Hepatic

CTC

►Computed Tomographic Colonography

Cubital Tunnel Syndrome

Compression of ulnar nerve in cubital tunnel of elbow region, may be due to sports or occupational injury or tumor.

►Neoplasms, Soft Tissues, Benign

Cup-and-Saucer Deformity

Cup-and-saucer deformity is a characteristic aspect of inflammatory joint mutilation in the late stage of rheumatic arthritis or psoriatic arthritis, with typical pointed residual bone of the proximal phalanx and grooved destruction of the distal phalanx articulating with each other.

►Spondyloarthropathies, Seronegative

Cushing's Syndrome

Corresponds to the presence of an adrenocorticotropic hormone (ACTH)-producing tumor. Up to 70% of the pituitary tumors will be visible on magnetic resonance imaging (MRI). To find the source of ACTH overproduction in false-negative MRI cases, bilateral inferior petrosal sinus sampling is recommended to measure the ratio of central to peripheral plasma ACTH levels.

►Pituitary Gland

Cutaneous Lesions, Breast

Definition

The skin of the breast can harbour a number of dermatologic pathologies (e.g. eczema, erythema, keratinization disorders, pigmentation disorders, etc.) and manifestations of systemic disease (e.g. scleroderma, dermatomyositis, polyarteritis nodosa, sarcoidosis, lupus erythematosus, etc.). These abnormalities usually do not significantly differ from similar involvement at other sites in the body.

The breast skin may also be involved in a generalized or focal non-skin disease process. A thickened oedematous skin may be seen especially in the dependent parts of one or both breasts due to cardiac decompensation, renal insufficiency, hypoalbuminaemia and fluid overload. Unilateral skin thickening can also be the result of venous or lymphatic stasis caused by venous thrombosis or lymphatic interruption (e.g. axillary dissection, nodal metastases, radiation therapy, etc.). Skin changes such as thickening, erythema and increased temperature, or thickening, dimpling and retraction may be ancillary findings in an underlying inflammatory (mastitis, abscess), post-traumatic (fat necrosis, scar formation) or malignant disease process. Special types of such reactions are Mondor's disease (band-like skin thickening and erythema due to thrombosis of a superficial vein) and ►Paget's disease (eczematous involvement of the nipple–areolar complex due to ductal carcinoma *in situ*, see elsewhere in this Encyclopaedia).

Both benign (naevi, warts, sebaceous cysts, keloids, fibromas, haemangiomas, lymphangiomas, etc.) and malignant tumours (melanomas, sarcomas, metastases and cutaneous infiltration by haematologic malignancies) may be encountered as nodular or diffuse lesions of the skin.

Pathology/Histopathology

The skin can react to primary or secondary irritation with only a limited number of symptoms, such as erythema, oedema, diffuse or focal thickening, desquamation, ulceration, etc. Because of its superficial location, it is obvious that most reactions are readily diagnosed clinically and that imaging techniques only play a secondary role. On the other hand, some skin manifestations may trouble the mammographic assessment, because they obscure the underlying tissue due to oedema, or cause nodular densities or (pseudo) calcifications that can be mistaken for intramammary lesions.

Clinical Presentation

Inspection, clinical examination and patient history are of utmost importance for correct diagnosis of dermatologic pathologies, skin tumours and cutaneous manifestations of systemic disease. A detailed description of these pathologies is beyond the scope of this text.

In unilateral or bilateral skin oedema, in which the skin gets swollen and dimpled, the clinical history, general physical examination and lab results are also important to correctly attribute cutaneous thickening to systemic diseases such as cardiac decompensation, renal or hepatic insufficiency. Focal inflammatory disease, post-traumatic status and tumoral lesions underneath the skin of the breast may elicit secondary skin reactions that are readily explainable when the underlying disease is identified, either clinically or with imaging techniques. In ►Mondor's disease, for example, thrombosis of a subcutaneous vein may cause a painful erythematous cord-like skin thickening, often associated with preceding trauma or surgery to the breast. In inflammatory carcinoma, obstruction of the cutaneous lymphatics by tumour deposits causes skin thickening with accentuated pores, resembling the skin of an orange, frequently referred to as ►'peau d'orange'.

Mammography

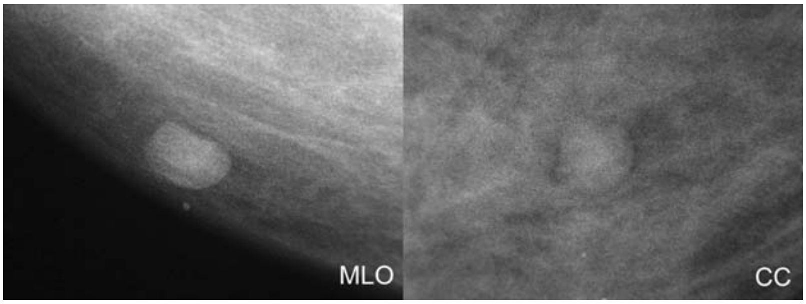
Except for digital mammography, correctly exposed mammograms do not usually show the skin, especially in high-density breasts. The normal breast skin may measure up to 3 mm in thickness and is usually symmetric, but varies individually and thins with ageing.

Dermatologic pathologies and manifestations of systemic disease may not be visible on the mammogram, except when they are large enough to cause nodular or ill-defined densities, or when they become calcified or pseudocalcified (due to ointments, creams or balms containing X-ray attenuating powders). In both cases, tangential views (with or without a marker on the cutaneous lesion) may be necessary to confirm their dermal origin.

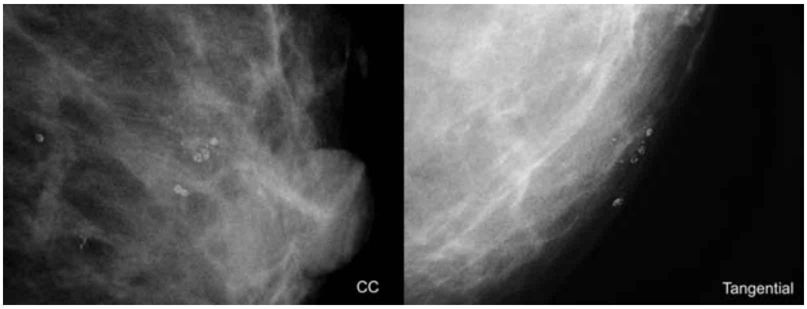
Pathologic skin thickening due to oedema or fibrosis is usually associated with accentuation of the oedematous subcutaneous trabecular framework and may be bilateral, or localized and asymmetric. In the latter case, it can only be well visualized in tangent.

When nodular masses of the skin are visible on the mammogram, they can be distinguished from intramammary lesions by their cutaneous location (on tangential views) and by their characteristic radiolucent rim or fissures caused by soft tissue to air interfaces when the breast is compressed (Fig. 1).

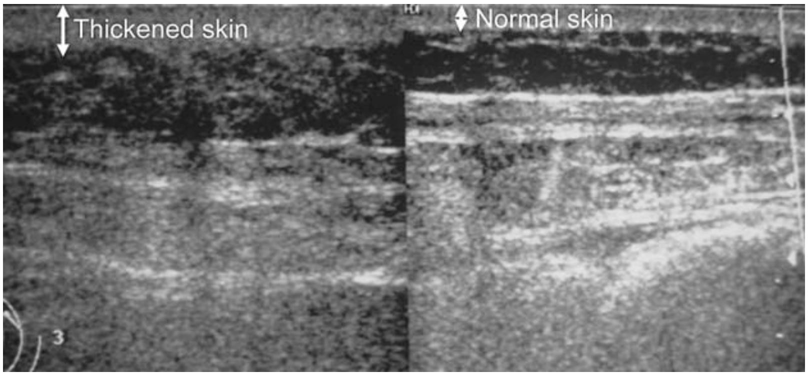
Skin calcifications usually originate in sebaceous glands of the skin. They are characteristically spherical (Fig. 2) and have a lucent centre, but occasionally may be more polygonal or punctate. They are peripherally located (sometimes requiring tangential views) and



Cutaneous Lesions, Breast. Figure 1 Cutaneous nodule with a radiolucent rim along the boundaries of the lesion in both mammographic projections.



Cutaneous Lesions, Breast. Figure 2 Round lucent-centered calcifications. Their cutaneous origin can be demonstrated on tangential views.



Cutaneous Lesions, Breast. Figure 3 Skin thickening after radiotherapy for breast carcinoma, with indistinct deep margin. Note difference with untreated side.

may be scattered or clustered, but typically maintain a fixed position to one another on different projections or on similar projections at different times ('tattoo sign').

Sonography

The thickened skin is visualized as a broadened hyperechoic rim indistinctly marginated from the underlying isoechoic subcutaneous fat (Fig. 3). The visibility of this area may be improved by using an ►acoustic standoff pad.

Although sonography can readily demonstrate skin thickening, its role in the diagnostic work-up of cutaneous lesions is limited, except when performed to detect a subcutaneous lesion as the cause of a secondary skin reaction, or to confirm a ►sebaceous cysts, especially when the latter becomes inflamed. Sebaceous cysts are usually round or oval cutaneous or subcutaneous lesions with varying echogenicity, depending on their relative amount of fluid and echogenic material. Inflamed sebaceous cysts may cause additional skin thickening and increased echogenicity of the surrounding fat.

Magnetic Resonance Mammography

Similar to sonography, MR only plays a minor role in the diagnosis of cutaneous lesions. However, it may be useful for detection or exclusion of underlying disease, especially in mammographically dense breast tissue that could obscure a lesion, or in the post-treatment follow-up to differentiate cutaneous recurrence from post-treatment changes.

Percutaneous Biopsy

Cutaneous lesions that remain indeterminate after inspection, clinical examination, laboratory tests, patient history or even imaging examination(s), may require shave, punch or excisional biopsy for histological diagnosis. These are usually performed under clinical guidance, although imaging may occasionally be used for selection of the most appropriate biopsy site.

Cutaneous Necrosis at the Finger Tips Like Rat Bites

Cutaneous necrosis at the finger tips like rat bites is a complication of long-standing Raynaud's phenomenon with consecutive ischemia and is relatively common in scleroderma.

"Jaccoud hand" was originally described in rheumatic fever after streptococcal infection. Typically the grave deformities contrast the absence of destructive arthritis. Nowadays, thanks to the rigorous antibiotic treatment of streptococcal infection, it is more often seen in systemic lupus erythematosus.

Cyst, Breast

Luis Pina
Department of Radiology,
Clínica Universitaria de Navarra, Spain
ljpina@unav.es

Definition

Cysts are local dilatations of terminal duct lobular units filled with fluid (1, 2).

Pathology

Cysts are lined by an epithelium that consists of two layers: an inner epithelial layer and an outer myoepithelial layer. Occasionally they have no epithelial lining (1, 2). The fluid shows a variety of colors, such as clear, green, gray, brown, or almost black, and chemical substances, including pigmented secretions, lipofuscin, hemoglobin-derived products, and even secretory substances related to the diet. Some cysts show apocrine metaplasia, with low proportion of sodium and high proportion of potassium in the fluid, indicating a more active cellular secretion and more frequent recurrence. Other cysts have a transudate-like fluid, with high concentration of sodium and low concentration of potassium. Papillary tumors in the wall of a cyst are rare. Both papilloma and ▶papillary carcinoma may be found.

Clinical Findings

Cysts are very frequent lesions, affecting more than half of the female perimenopausal population, although they may be found in women under the age of 30 and also in postmenopausal women. Most cysts are multiple and bilateral and tend to disappear in older women, but hormonal replacement therapy may induce cyst formation.

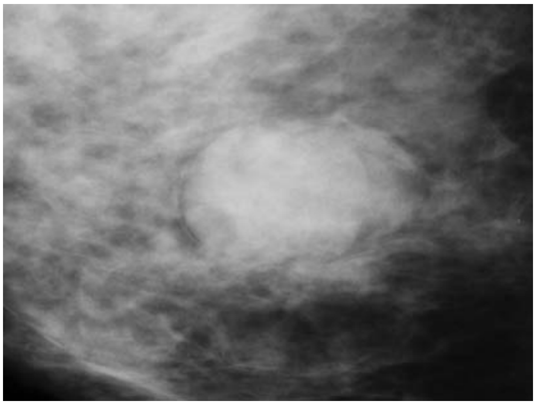
Usually cysts are asymptomatic lesions detected on routine imaging techniques. However, cysts may be palpable and discovered by the patient, who may be concerned about a lump in her breast. Usually these cysts are mobile, smooth-contoured masses, although they may be hard and indistinguishable from breast cancer. Palpation may suggest the presence of a cyst, but ultrasound is required because some carcinomas can simulate benign lesions as cysts.

▶Simple cysts are benign lesions with no significative risk to develop into breast cancer. Whether the concurrence of family breast cancer history and cysts increases that risk is debatable.

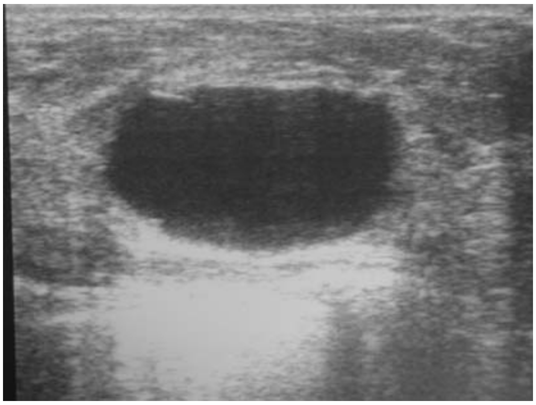
Imaging

Mammography

Cysts present as round to oval well-circumscribed masses if they are surrounded by fat. If cysts are surrounded by fibroglandular tissue, they show obscured margins or may not even be detected on mammography (Fig.1). Curvilinear calcifications in the cyst wall or calcifications inside the cyst cavity (milk of calcium) may be found (3, 4). Cysts usually are multiple and bilateral, but they may also be single.



Cyst, Breast. Figure 1 **Mammographic appearance of a breast cyst. An oval mass with circumscribed and obscured margins is seen.**



Cyst, Breast. Figure 2 **Simple cyst on ultrasonography. An oval, anechoic lesion with posterior acoustic enhancement is seen. A few reverberation echoes are visible peripherally.**

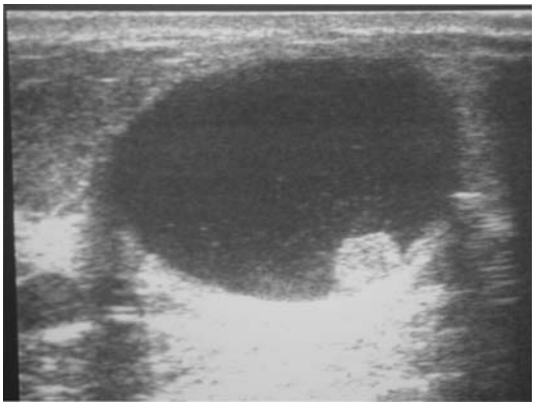
In some cases, a cyst is aspirated and filled with air to evaluate the cyst wall on mammography (pneumocystography). This technique allows a good evaluation of the cyst wall, especially for detecting intracystic masses. Nevertheless, the high accuracy of ultrasonography has largely eliminated the use of pneumocystography.

Ultrasound

Simple cysts are thin-walled, anechoic, round to oval lesions with posterior enhancement (Fig. 2). Acoustic shadows are seen at the margins. Sometimes a reverberation artifact may produce internal echoes (3–5). These lesions are soft and may be compressed with the transducer, changing their shape. If the lesions are too deep or small (<5 mm), the acoustic enhancement may not be seen. New ultrasonographic techniques, such as spatial compound imaging or tissue harmonic imaging, may be useful for characterizing a lesion as a cyst (5). Simple cysts are classified as BI-RADS category 2 (benign finding). Occasionally thin septa are seen inside the cyst. Clusters of small cysts may also be observed (Fig. 2).

►Complicated cysts have many of the features of simple cysts but show diffuse and mobile internal echoes (5). These cysts may contain proteinaceous material, blood, cellular debris, infection, or cholesterol crystals. The positive predictive value for carcinoma in these cysts is 0.3%, and therefore they are classified as BI-RADS category 3 (probably benign finding).

►Complex cysts include cysts with internal masses, thick septations, or thick or irregular wall (5). These lesions are suspicious and should be classified as BI-RADS category 4 (suspicious finding). Papilloma, papillary carcinoma, necrotic tumors, abscesses, and hematomas may correlate with these findings (Fig. 3).



Cyst, Breast. Figure 3 **Complex cyst. Ultrasonography reveals a solid lesion within the cyst. Biopsy revealed ►intracystic papilloma.**

Magnetic Resonance Imaging

Cysts are smooth-contoured hypointense lesions on T1-weighted sequences and hyperintense on T2-weighted sequences. Typically, cysts do not enhance after contrast medium administration, except if there is wall inflammation or an intracystic mass (3).

Nuclear Medicine

Cysts are not an indication for a nuclear medicine study.

Diagnosis

Ultrasonography is the technique of choice for diagnosing breast cysts (5).

Asymptomatic simple cysts detected on ultrasonography do not need further diagnostic procedures. A 6-month follow-up may be proposed for asymptomatic complicated cysts showing diffuse and mobile internal echoes, as an alternative to fine-needle aspiration.

Symptomatic cysts (palpable, painful) may be aspirated after an ultrasound examination. If the fluid is green or yellow, there is no need for cytologic examination. However, if the fluid is hemorrhagic or if the cyst is complicated, a cytologic study is recommended.

Complex cysts are suspicious lesions that need to be carefully studied. If a negative cytology result is obtained after aspiration of a complex cyst, a biopsy should be performed. Cytology, and even core needle biopsy, may be unable to differentiate between benign papilloma and papillary carcinoma. Sometimes the cytologic examination result of the fluid of a cyst with a carcinoma may be negative (3).

Huisman T. A.
Johns Hopkins University, Baltimore, USA
thierry.huisman@kispi.unizh.ch

Synonyms

Arachnoid cyst; Cystic hygroma; Branchial cleft cyst; Leptomeningeal cyst; Lymphangioma; Neuroepithelial cyst; Thyroglossal duct cyst

Definition

Epithelial-lined, fluid-filled, well-circumscribed, nonneoplastic benign lesions.

Pathology and Histopathology

Most cerebral and cervical cysts are benign disorders of development. Cysts can also develop as complications of surgery or trauma. Next to esthetic concerns, head and neck cysts can be symptomatic due to compression of vital structures. Intracranial cysts may be incidental findings on imaging or the leading cause of focal neurological deficits. Cysts within the neck may compress neurovascular structures as well as the upper airways. Hemorrhages within these cysts may result in a rapid increase in size, aggravating displacement, and compression of adjacent structures. Finally, secondary infection may complicate the spontaneous course of head and neck cysts (1, 2).

Arachnoid cysts are benign, fluid-filled lesions that are lined by a thin layer of arachnoidea. Arachnoid cysts are believed to result from a duplication or splitting of the arachnoidea. They are located in the space between the dura and pia mater. These cysts are filled with a clear fluid that resembles cerebro-spinal fluid (CSF). The protein content may be elevated compared to CSF. Intralesional hemorrhages are frequently complicated by the development of fibrous membranes dividing the cyst in multiple compartments. Cysts are isolated from and consequently do not communicate with the subarachnoid space or ventricular system. Arachnoid cysts may remodel the adjacent skull (thinning and scalloping) by chronic compression.

Leptomeningeal cysts are complications of skull fractures due to an entrapment of lacerated meninges within the fracture. Chronic CSF-pulsations may prevent fracture consolidation, the fracture may even be widened (growing fracture). Meninges and underlying brain tissue can protrude through the growing skull defect into the subcutaneous tissues. Surgical repair with a dural patch covering the skull defect may be necessary (3).

Neuroepithelial cysts are benign, nonneoplastic malformative fluid-filled cysts lined by a single layer of ependymal like cells. The exact etiology is not yet fully understood. These cysts occur at multiple locations and are named accordingly: intraventricular ependymal cysts, choroid plexus cysts, and choroid fissure cysts. Large cysts may compress adjacent structures. Intraventricular cysts may lead to an entrapment of parts of the ventricular system depending on their location.

Lymphangioma or cystic hygroma is a congenital malformation of the lymphatic channels within the neck.

Lymphangiomas can show multiple small cystic components (capillary lymphangioma), multiple medium-sized cysts (cavernous lymphangioma), or large fluid-filled compartments (cystic lymphangioma or hygroma). They can occur in combination with hemangiomas (lymphhemangioma). Lymphangiomas may involve multiple anatomical spaces within the neck simultaneously. Cysts are lined by a thin endothelial cell layer. Connective tissue stroma may be intermixed.

Branchial cleft anomalies include cysts, sinus tracts, and fistula that result from an anomalous development of the branchial apparatus. Depending on the involved branchial component, different locations of the branchial cleft anomalies are encountered. Anomalies of the first and especially the second branchial apparatus are most frequent. Anomalies of the third and fourth branchial apparatus are rare. Because the branchial apparatus is ectodermal in origin, the branchial cleft anomalies are lined by stratified squamous epithelium. Occasionally, respiratory epithelium is incorporated. Cysts result from a failure to obliterate parts of the branchial apparatus. In sinuses, a residual opening exists into the deep cervical spaces or skin while in fistulas two openings are seen connecting the skin with the deep cervical compartments. Secondary infection may complicate branchial cleft anomalies.

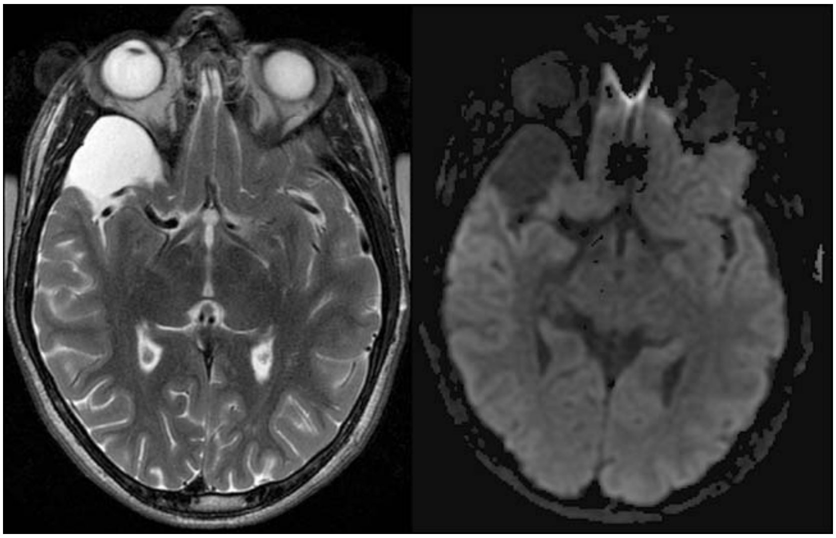
Thyroglossal duct cysts are developmental anomalies that result from a failure of a segment of the thyroglossal duct to obliterate. The thyroglossal duct is the "path" that the thyroid gland follows during its descent from the foramen cecum at the tongue base to its final position in the infrahyoid neck. Cysts may occur at any location along the thyroglossal duct and are lined by squamous or respiratory epithelium. Cysts are usually filled with a serous/mucinous fluid. Small, "lost" thyroid gland components may accompany the cysts.

Clinical Presentation

Arachnoid, leptomeningeal and neuroepithelial cysts are symptomatic due to compression or displacement of functional center of the central nervous system (CNS). Depending on the location, focal neurological deficits, seizures or CSF-circulation disturbances (hydrocephalus) are observed. In many instances however, these cysts are clinically silent and only found incidentally on imaging that is performed for other reasons.

Lymphangioma or cystic hygroma are primarily symptomatic due to a displacement and/or compression of adjacent neuro-vascular structures or upper respiratory tract. In addition, large lesions may interfere with the normal development of the viscerocranium. This may require a more aggressive treatment. On the occasion of viral infections, lymphangiomas may show an intermittent increase in size. Accompanying hemangiomas with involvement of the skin are easily identified on visual inspection.

Branchial cleft and thyroglossal duct cysts usually present as a soft, compressible, painless mass in the neck. Depending on the embryological origin, lesions are in the median or lateral neck. Cysts may enlarge during viral infections. In rare cases, bacterial infection complicates



Cysts, Cerebral and Cervical, Childhood. Figure 1 **Axial T2-FSE and DWI of a middle cranial fossa arachnoid cyst. The arachnoid cyst is CSF isointense on both sequences. The adjacent temporal lobe is hypoplastic. The dorsal border of the orbit is displaced anteriorly.**

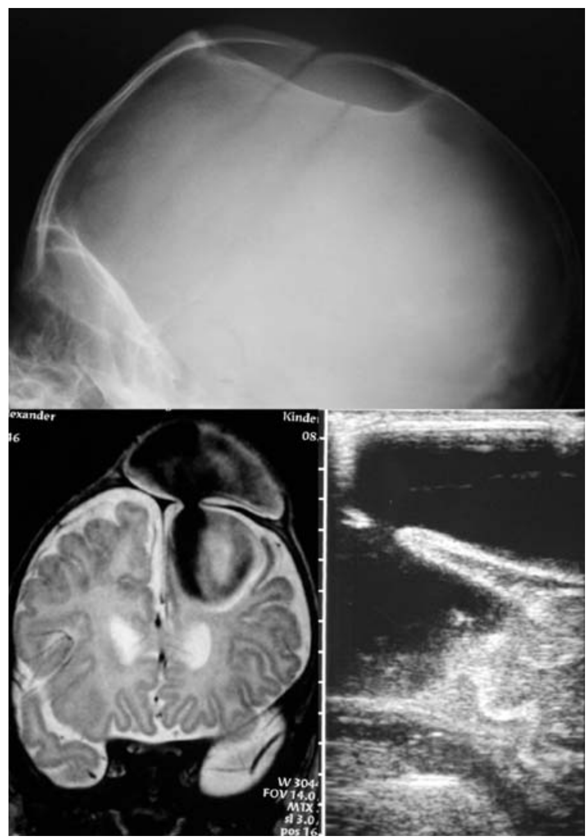
the cyst requiring incision or resection of the cyst including fistula and/or sinus tract. Life-threatening compression or displacement of vital structures is rare.

Imaging

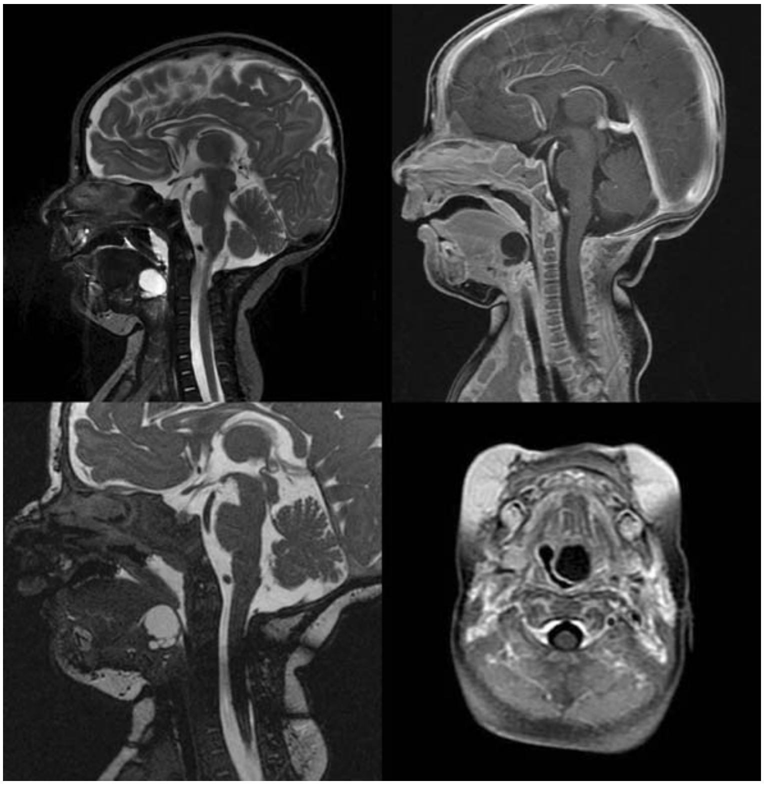
Ultrasound is the first line imaging modality in the evaluation of cystic head and neck lesions. Ultrasound usually allows to differentiate between cystic and solid lesions/tumors. Cystic lesions are hypoechoic on ultrasound and may display an accompanying dorsal signal enhancement. Calcifications are equally well delineated with a dorsal signal loss or shadowing. Compared to CT and MRI, ultrasound is more sensitive in identifying intracystic membranes or septae (e.g., in lymphangioma). The real time imaging technique is also very helpful to delineate the exact boundaries of lesions and their relation to neighboring structures. This may be especially helpful in e.g., complex branchial cleft cysts. Duplex sonography allows to evaluate the vascularity of the lesions as well as the relation to adjacent vascular structures. CT and MRI may be used as second line imaging tool. The high spatial resolution and the high tissue contrast as well as the large field-of-view are especially helpful in complex anatomical malformations or lesions. Intracranial cystic lesions can also be examined by ultrasound as long as the fontanelles are not yet closed and may serve as an acoustic window. Transcranial sonography is usually limited because the spatial resolution does not allow to identify accompanying smaller intracerebral lesions.

Arachnoid cysts are sharply marginated extraaxial fluid collections (Fig. 1). On computer tomography (CT) the fluid is isodense with the CSF, on magnetic resonance imaging (MRI) isointense with CSF on all sequences. Acute intralesional hemorrhages increase the density on CT and intensity on T1-weighted imaging. Fluid-sedimentation levels may be identified. Increased protein contents may alter the density and signal intensity of arachnoid cysts. This is especially obvious on FLAIR-imaging. The cyst wall should not enhance. Adjacent brain tissue will be compressed and displaced. The interface between cyst and brain tissue is smooth. Occasionally, an intraparenchymal FLAIR and T2-hyperintense gliosis may be observed. There is no direct communication between the arachnoid cyst and subarachnoid space or ventricular system. The overlying skull or adjacent skull base can be remodeled with outpouching of the skull away from the arachnoid cyst. The internal tabula may be thinned but remains intact. On diffusion weighted imaging (DWI) signal intensity parallels CSF (no restricted diffusion). DWI is especially helpful in differentiating arachnoid cysts from subarachnoidal epidermoids (restricted diffusion). Cisternography can be used to study the exact location and possible communication with additional lesions. This is especially helpful in complex postoperative cases in which recurrent arachnoid cysts developed. Ultrasonography can be helpful in neonates. Uncomplicated arachnoid cysts rarely increase in size. Arachnoid cysts may increase in size after an intralesional hemorrhage or postoperative due to adhesions.

Leptomeningeal cysts may be located next to a skull fracture or extend through a widened fracture into the subcutaneous tissues. Fracture margins are usually smooth. The chronic pulsations may enlarge the fracture (growing fracture) preventing consolidation (Fig. 2). The adjacent subarachnoid space may be widened, brain tissue may protrude through the fracture. On ultrasonography



Cysts, Cerebral and Cervical, Childhood. Figure 2 Lateral skull X-ray shows a widened anterior fontanel with smooth osseous borders. Coronal T2-FSE (second row, first image) reveals a large cystic defect within the superior frontal gyrus that communicates across a dural tear with an extracranial cystic component. A T2-hypointense CSF-flow void is seen across the dural tear and within both cystic components. High resolution ultrasonography (second row, second image) confirms MRI findings.



Cysts, Cerebral and Cervical, Childhood. Figure 3 Sagittal T2-FSE, contrast enhanced T1-SE (upper row), sagittal thin slice strongly T2-weighted and contrast enhanced axial T1-SE MR image. A large T2-hyperintense, nonenhancing thyroglossal duct cyst is seen within the floor of the posterior tongue, caudally to the foramen cecum. Several smaller, additional cysts are seen along the lower border of the large cyst.

and MRI, CSF-flow and pulsation artifacts may be seen across the fracture (3). T2*-weighted sequences can be helpful to identify hemorrhagic lacerations within the adjacent cortex. CT is especially helpful to examine the margins of the fracture line. Leptomeningeal cysts can also occur within the skull base after skull base fractures.

Neuroepithelial cysts have similar imaging characteristics as arachnoid cysts. *Lymphangioma or cystic hygroma* appear as hypodense cystic masses on CT. On MRI the cysts are strongly T2-hyperintense and moderately T1-hypointense. Depending on the category of lymphangioma, the lesion may be uniloculated or multiloculated. Cyst walls are usually thin and do not enhance after contrast medium injection unless there is associated infection or hemorrhage. Lymphangiomas often cross the borders of the neck compartments and may displace or wrap neuro-vascular bundles. Fluid–fluid levels may occur spontaneously but are more frequently seen after trauma or punctures. Intralesional hemorrhage changes the density (CT) and intensity (MRI) of the cyst contents. Similar to intracranial arachnoid cysts, elevated protein contents increase density/signal intensity on imaging. Frequently, lymphangiomas show additional contrast enhancing hemangiomatous components. Ultrasonography is the primary imaging modality. The high sensitivity for intralesional septa is especially helpful. In large lymphangiomas the limited field-of-view and penetration depth of ultrasound waves are however disadvantageous to determine the exact extent of large lesions. CT and MRI are used for preoperative planning.

All *branchial cleft (1st to 4th branchial apparatus) and thyroglossal duct cysts* have similar imaging appearances. The cysts are fluid-filled (CT-hypodense, T1-hypointense, T2-hyperintense), well-marginated round or ovoid structures lined by thin walls. Calcifications are rare. The wall of the cysts may show an enhancement if there has been associated recurrent infection. The location and relation to adjacent neck structures allow differentiation between the different cysts. First branchial cleft cysts are located in the area between the external auditory canal and submandibular triangle or in the parotid area. Second branchial cleft cysts are along the anterior border of the sternocleidomastoid muscle, lateral to the carotid arteries and posterior to the submandibular gland. Third branchial cleft cysts are posterior to the carotid arteries and superior to the superior laryngeal nerve while the fourth branchial cleft cysts are located between the left pyriform sinus apex and thyroid gland, inferior to the superior laryngeal nerve. Thyroglossal duct cysts are midline cysts located somewhere between the foramen cecum and the pyramidal lobe of the thyroid gland (Fig. 3).

Nuclear Medicine

Nuclear medicine studies are used to identify ectopic thyroid gland components.

Diagnosis

Diagnosis relies on the combination of a good clinical examination and high resolution imaging. The differentiation between the different cystic neck masses is based on the proper identification of the anatomical landmarks. Ultrasonography can be especially valuable to differentiate between a uniloculated and multiloculated cystic neck lesion. Thin septa can be missed on CT or MRI. Finally, necrotic neoplastic lesions may mimic cystic lesions and should be considered and consequently be out ruled.

Cystadenoma

Cystadenoma is the most common type of cystic benign ovarian tumor. It accounts for up to 50% of benign ovarian tumors in the reproductive age, and for up to 80% in the postmenopausal age. Cystadenomas are thin-walled unilocular or multilocular cystic lesions filled with serous, mucinous, and sometimes hemorrhagic contents.

Synonyms

Cystic kidney disease; Renal cysts

Definition

Fluid- or urine-filled compartments/cysts replacing a varying amount of renal parenchyma. There are a variety of renal cystic diseases that need to be considered and often can be classified on imaging based on their position, size and appearance: besides the simple renal cyst and rare acquired cystic renal diseases (e.g., in renal failure, posttraumatic), the polycystic kidney disease (PKD, i.e., autosomal recessive or autosomal dominant PKD, medullary cystic disease complex and juvenile nephronophthisis, and glomerulocystic kidney disease), syndromal cystic kidney disease (hereditary and non-hereditary), ►multicystic dysplastic kidney (MCDK) and dysplastic cysts, ►medullary sponge kidney, as well as complicated renal cysts (haemorrhaged or infected cysts, multiloculated cysts including segmental MCD and ►cystic nephroma), as well as cystic renal tumours have to be considered.

Embryology and Pathogenesis

Cystic renal disease is far less common in childhood than in adults. Inherited diseases as well as a disturbed renal embryogenesis and renal development create a wide spectrum of manifestations that spans from diffuse severe bilateral congenital disease to simple single renal cysts. One of the main mechanism is a disturbance at the junction between metanephrogenic tissue and the ureteral bud, other mechanism in differentiation of the renal parenchyma/genetic origin are also discussed, furthermore degenerative and hyperproliferative changes as well as neoplasms and injuries to the renal parenchyma can lead to cyst formation. Depending on its pathogenesis and the individual entity more or less regular imaging is indicated. Secondary cysts develop after trauma, after infections, in tumours, in chronic renal insufficiency and in inherited cystic kidney disorders.

Clinical Presentation

Presentation and symptoms vary with the underlying condition, from completely asymptomatic in incidental findings to haematuria, hypertension, palpable mass and pain in cystic tumours.

Imaging

Imaging usually relies on ultrasound (US), sometimes (for differentiation of complex cysts, e.g. suspected caliceal diverticula, differential diagnosis against abscesses or tumours, post-traumatic cysts) sectional imaging (usually magnetic resonance imaging (MRI), if unavailable contrast-enhanced computed tomography (CT)) and for rare indications intravenous urography (IVU, e.g. medullary sponge kidney) may be become indicated.

Imaging Strategy

Renal cysts in paediatric patients are generally detected by US. As simple renal cysts are far less common in children than in adults, at least follow-up exams and a detailed family history with nephrourological workup should be considered. If these are just simple cysts, US is sufficient as the single imaging modality. If these cysts grow and cause symptoms, an image-guided drainage and sclerotherapy may become a therapeutic option. If there is a congenital or hereditary (poly-)cystic kidney disease, additional scintigraphy may be valuable for the assessment of (split) renal function during the course of the disease. If the cysts appear to be complicated and do not match any congenital PKD, they should be studied by IVU (for DD against calyceal cysts or detection of a medullary sponge

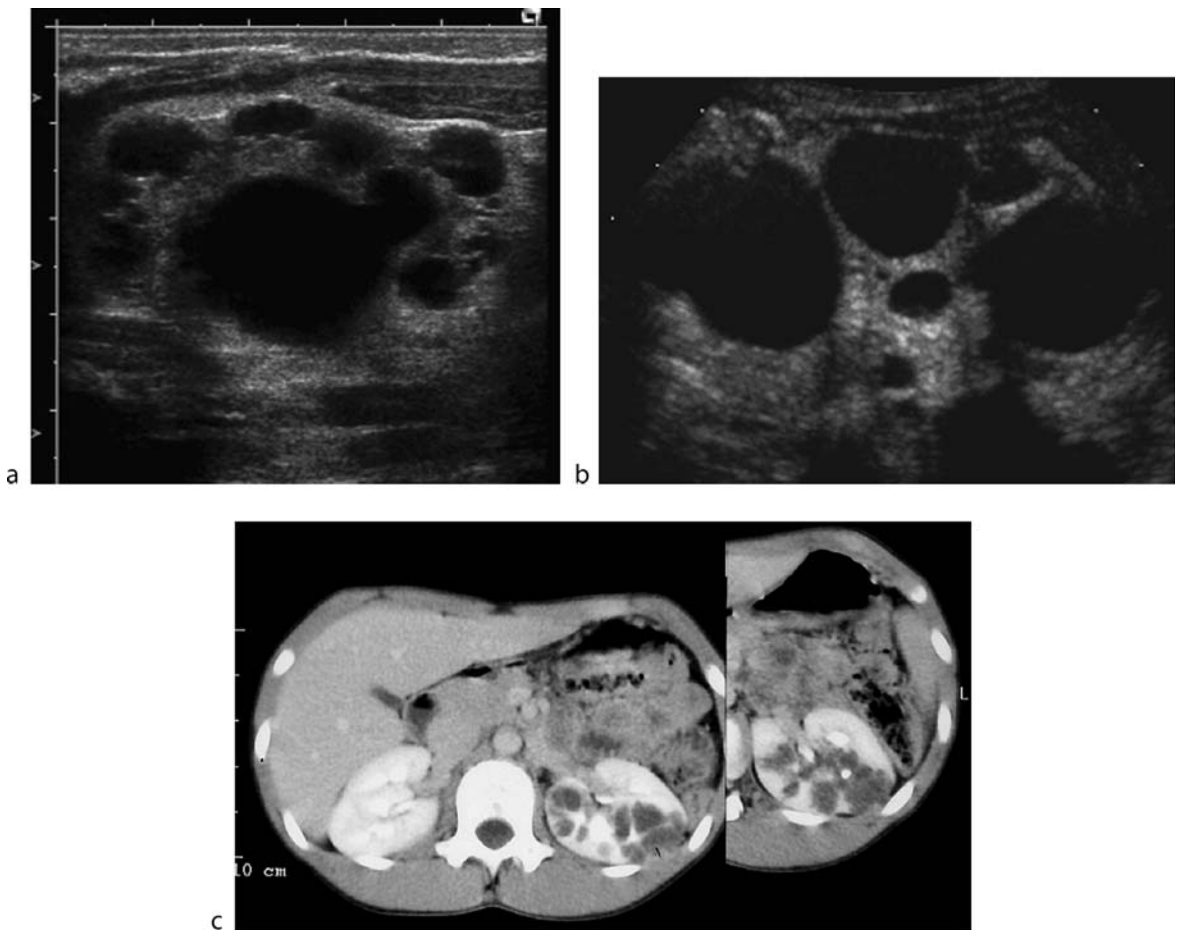
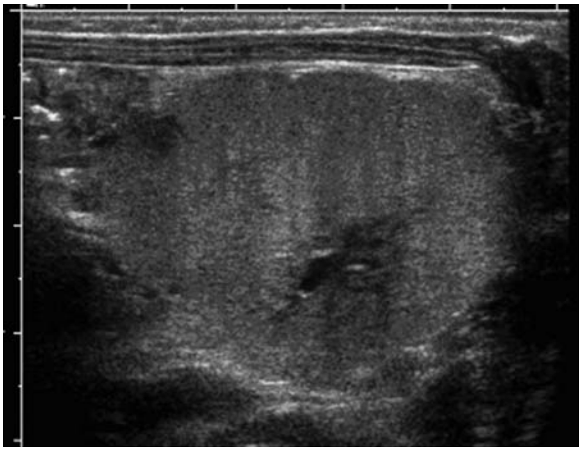
kidney) and/or MRI or contrast-enhanced CT. If there are still equivocal findings, they should be monitored or—particularly when showing growth or atypically shaped and vascularised areas—should undergo biopsy or surgery.

Diagnosis

Diagnosis is made by imaging, with sometimes only histology revealing the final entity (Fig. 1). Imaging criteria for the simple *uncomplicated renal cysts* on US are small, echo-free, fluid-filled defects, with a regular border and without regional parenchymal abnormalities or solid components. *Dysplastic cysts* look similar and may occur in any form of either primary or secondary dysplastic kidneys, the latter potentially due to a congenital urinary tract malformation such as high-degree vesicoureteral reflux (VUR, reflux nephropathy) or high-grade obstruction (Fig. 2a). The cysts usually are small, may be situated in all renal compartments, and on US the kidneys exhibit some degree of other parenchymal changes such as reduced cortico-medullary differentiation or increased parenchymal echogenicity. In some cases, one can also find a diffuse vascular rarefaction on (amplitude-coded) colour Doppler sonography. As dysplastic cysts may not only grow in size and number, but potentially may undergo malignant transformation (e.g., during renal



Cystic Disease, Renal Childhood (MCDK, PCKD). Figure 2 **DD of renal cysts—imaging examples. (a) Cystic renal dysplasia. US of a hydronephrotic and dysplastic kidney with echogenic and undifferentiated parenchyma and multiple dysplastic cortical cysts. (b) Longitudinal US view of a multicystic dysplastic kidney. Note the missing connection between the cysts of varying size that have no parenchymal outer rim, the lack of a normal collecting system, but some central echogenic-dysplastic residual renal parenchyma, enabling a clear sonographic differentiation from a severe ureteropelvic junction obstruction (UPJO). (c) Contrast-enhanced CT (late phase) of a segmental cystic nephroma. (Adapted from Riccabona M, Ring E (2001) In: Fotter R (ed) Pediatric Uroradiology. Springer, Berlin-Heidelberg, p 246.)**



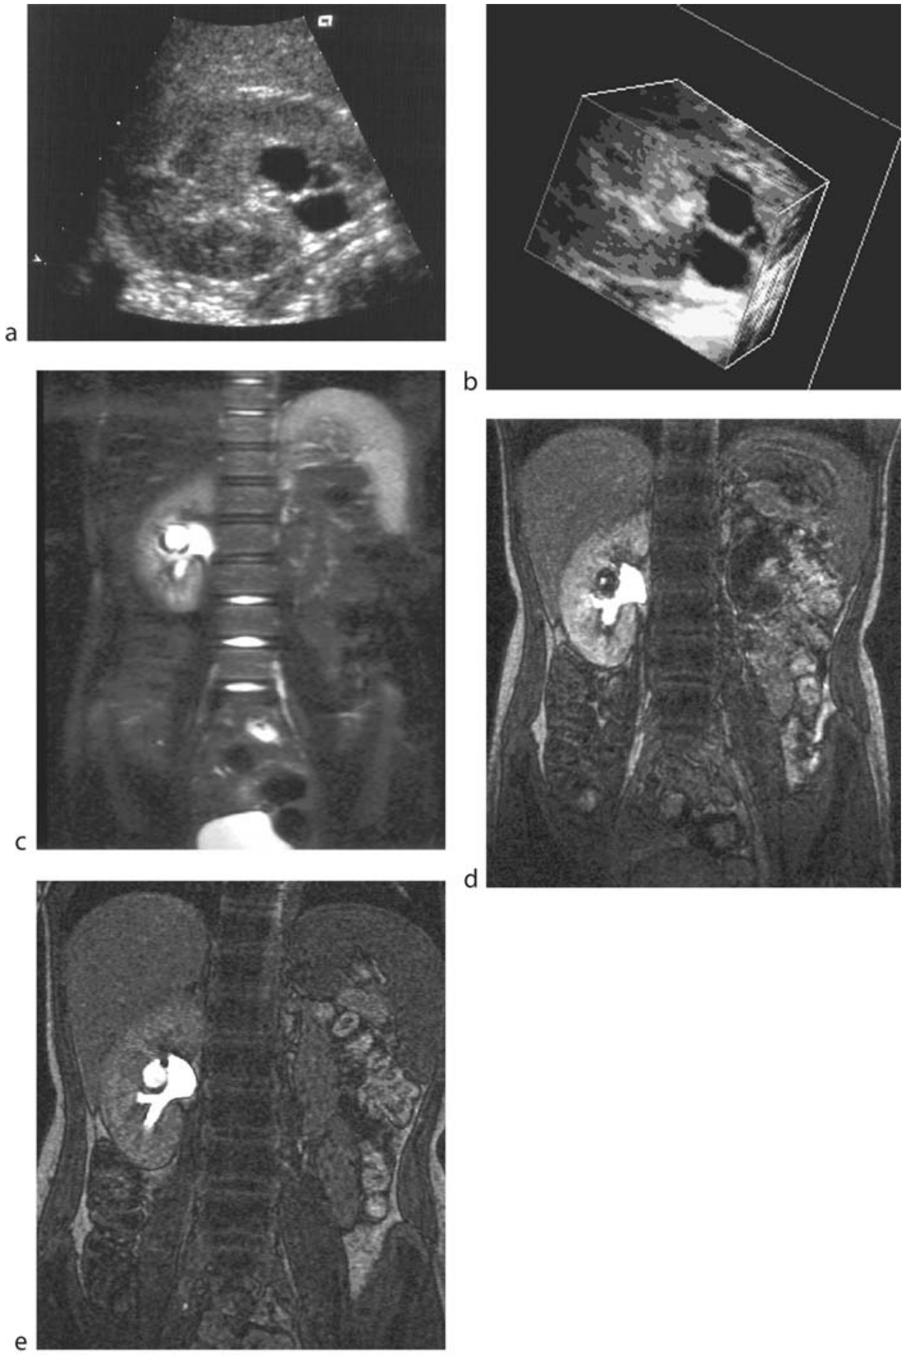
Cystic Disease, Renal Childhood (MCDK, PCKD). Figure 3 Axial view of a neonate with ARPKD. Not the increased echogenicity, the tiny hyperechic parenchymal dots with some shadowing causing the 'salt and pepper' appearance, and that the microcysts may not or hardly be visible in spit of high-resolution US.

insufficiency), a regular follow-up—not only of the cysts, but also of the entire urinary tract for following the primary condition—is recommended. For this, US is substituted by static renal scintigraphy (Tc99m dimercaptosuccinic acid, DMSA) for the assessment of split renal function, which in future may be replaced by MR-urography.

The most severe form of cystic dysplasia is the *MCDK* (bilateral MCDK is called ▶Potter syndrome or Potter sequence, incompatible with extra-uterine life due to complete renal insufficiency and pulmonary hypoplasia), where the renal parenchyma is nearly entirely replaced by huge cysts, that can more or less resemble a collecting system (Fig. 2b). There may be some (central) residual parenchyma, usually echogenic and undifferentiated on US; sometimes residual perfusion may be depicted on Doppler sonography. Usually there is no renal function. As MCDK has a tendency to regress and vanish spontaneously, nephrectomy is usually postponed and only indicated in those kidneys that cause compression of adjacent structures or grow monstrously, or cause clinical symptoms such as hypertension, infection or malignant transformation. For initial diagnosis US is used, then voiding cystourethrogram (VCUG), MR-urography or DMSA-scintigraphy are performed additionally for the confirmation of the diagnosis and complete work-up which includes assessment of potential residual renal function (i.e. duplex system or segmental MCDK, severe ureteropelvic junction obstruction) and differentiation from severe reflux-nephropathy. Further more, a thorough work-up of the entire genitourinary tract is advocated, as a higher incidence of other urinary tract malformations and ipsilateral genital malformations is reported. Regular US follow-ups are recommended after establishing the initial diagnosis.

The so-called *multicystic nephroma* or multilocular nephroma or multiloculated renal cyst is another rare entity that is a cystic 'malformation' of (parts of) the kidney. On US (as well as on CT or MRI), it is characterised by a conglomeration of small cysts of similar size, with thin membranes and straight borders, without renal tissue involved in the tumour-like formation; usually no or only minimal contrast enhancement or perfusion is seen in the walls of the cysts (Fig. 2c). It is basically a benign tumour that may grow, but usually does not cause destruction or metastasis. Therefore, once imaging (and biopsy, as metanephric tissue making it a potential tumour can only be detected on histology) has established the diagnosis, a conservative approach can be considered. However, in cases with abnormal growth or other indecisive features such as irregular borders of the cysts, destructive behaviour or atypical parenchyma these need to be resected.

Polycystic kidney disease is an inherited familial condition of either autosomal dominant (ADPKD) or autosomal recessive promotion (ARPKD). Different types are established and the age of manifestation varies. On US, the recessive form usually manifests with diffuse parenchymal changes in a diffusely enlarged kidney due to microcysts not depictable by imaging. It may present already neonatally with renal insufficiency (infantile form), or in any other age (juvenile and adult forms). The cysts can be seen unilateral or bilateral, and often they initially are too small to be detected, creating a bilaterally speckled appearance of the kidneys with increased echogenicity of the renal tissue, with inhomogeneously reduced tissue differentiation, also called the 'pepper-salt kidney' (Fig. 3). During the course of the disease, the cysts constantly increase mainly in number, but also in size, eventually leading to an end-stage kidney and chronic renal insufficiency. Additional imaging of the other parenchymal abdominal organs for extra-renal manifestation such as liver fibrosis or pancreatic cysts is recommended. ADPKD is one of the most common inherited diseases that may be detected during childhood, but usually manifests only in adulthood (adult PKD) and exhibits some isolated, uncomplicated (macro-)cysts that tend to grow in size and number, then gradually replacing renal parenchyma—in childhood, this rarely needs treatment and usually is only followed up by US, once the diagnosis is established by family history and US



Cystic Disease, Renal Childhood (MCDK, PCKD). Figure 4 Imaging and diagnostic criterial in caliceal diverticulum A: axial conventional to the ultrasound image, demonstrating a cystic lesion located centrally in the kidney close to the renal pelvis. B: 3D-US of the same cyst, suggesting a connection of the cyst to the urinary collecting system (diverticula neck, see arrows and description). C–E: dynamic MR-urography images demonstrate initially the topographic anatomic situation of the "cyst" in a T2-weighted coronal unenhanced image (D), then the contrast enhancement dynamics with a well contrasted collecting system and no contrast within the "cyst" (arrow) in the early phase (E), and the filling of the "cyst" (arrow) in the delayed phase of a gadolinium enhanced T1-weighted 3D-gradient echo sequence proving the connection of the cyst with the collecting system, enabling the diagnoses of a caliceal diverticula.

assessment of the family. Note that ADPKD has a high coincidence with cerebral vessel malformations (particularly cerebral artery aneurysm), thus potentially indicating an active search for them. As PKD has typical US appearances, no other imaging is needed in childhood usually; rarely cysts may haemorrhage or get infected, needing contrast-enhanced CT or MRI for establishing the diagnosis. As we must consider coexisting conditions of the spleen, the liver and the pancreas, all other abdominal parenchymal organs should be included in the regular US follow-up studies.

Glomerulocystic kidney disease is a rare congenital condition with small cystic degeneration of the glomeruli. These tiny cysts are often situated subcapsularly in the renal cortex and—particularly in neonates—may be missed or only be depicted by high-resolution imaging. The kidneys usually are large, with an increased echogenicity of a widened cortex. As diagnosis is made by histology and family history, only US is performed.

Medullary cystic disease (complex) is an autosomal dominant inherited disease with a late onset of chronic renal failure. Histology shows glomerular cysts with thickening of the multilayered membrane, accompanied by some tubular cysts. Depending on the disease state, a growing amount of interstitial fibrosis, chronic inflammation and tubular atrophy with consecutive chronic sclerosing tubulo-interstitial nephropathy is observed. No specific imaging or US features are known.

Medullary sponge kidneys usually exhibit a cyst-like dilatation of the tubules with congestive sludge and calcification in the ectatic tubuli, which easily may be missed during early stages on US. The imaging modality of choice particularly in early stages of a suspected medullary sponge kidney still is IVU.

There are a number of hereditary and non-hereditary *syndromal cysts* as well as cysts in aneuploidies, with partially autosomal recessive, partially autosomal dominant transmission. They usually are part of a complex systemic disease with disturbance of nephrogenesis, combined with dysplastic features. They can present as multiple renal cysts as GCKD, MCDC or ▶ARPKD and ADPKD. The pediatric radiologist needs to consider these entities for differential diagnosis and further diagnostic imaging of associated malformations or abnormalities, otherwise the presentation and imaging of syndromal renal cysts does not differ from the imaging of the other cystic renal entities.

(*Post-*)*traumatic, post-surgery and* (*post-*)*inflammatory cysts* may be tricky. Particularly if infected or after haemorrhage, sedimentations may be present, with a more or less distinguished wall and local parenchymal structural abnormalities. The may also be difficult to differentiate from an urinoma (particularly on US). When the suspicion is raised clinically or sonographically, MR-urography or contrast-enhanced CT may help to distinguish these entities or rare malformations such as a *tertiary calix* or a *calyceal diverticula*, with delayed excretory phase acquisition of either CT- or MR-images being mandatory to differentiate these entities. Note that post-infectious cysts should be considered particularly after uncommon infections such as tuberculosis or after renal abscesses.

Most renal tumours can exhibit cysts, either as part of their entity (e.g. multicystic nephroma) or as regressive or necrotic parts of the tumour (e.g. renal cell carcinoma). Even Wilm's tumour may present in a rare cystic form. Therefore all unusual cysts should be monitored by US and—at least when they grow, develop other signs, or present with a 'complicated' unusual appearance—additional sectional imaging with MRI (or—if unavailable—contrast-enhanced CT) should be considered. Surgery or biopsy with histology remains the ultimate possibility to define the entity in an unclear or equivocal cystic lesion.

Mucoviscidosis

Definitions

►Cystic fibrosis is an autosomal recessive inherited disease, caused by a defect in the gene for cystic fibrosis transmembrane conductance regulator (CFTR) on chromosome 7. The incidence in Europe is approximately 1:2500. The disease is characterised by viscous mucous production of exocrine glands resulting in airway plugging and obstruction, bronchiectasis and bacterial infection.

Pathology/Histopathology

The lungs of patients with cystic fibrosis show a variety of abnormalities such as atelectasis, ►mucoid impactions, acute and chronic inflammation, ►bronchiectasis, cyst formation, and fibrosis. Airway mucosal oedema and inflammation, respiratory muscle weakness and fatigue, contribute to the development of respiratory failure.

Histologically luminal neutrophils, neutrophilic and lymphocytic mural inflammation of the bronchial walls, squamous metaplasia of large and small airways, peribronchial and peribronchiolar fibrosis, obliterating fibroproliferative bronchiolitis and prominent hypertrophy of peribronchiolar smooth muscle are found (1). The alveoli adjacent to the bronchi show collapse and epithelialisation, the adjacent intra-alveolar septa are cellular infiltrated. The terminal bronchiole is often completely destroyed due to peripheral abscesses.

Clinical Presentation

Infants with cystic fibrosis have normal lungs at birth and present often initially with gastrointestinal problems like meconium ileus. With the onset of recurrent pulmonary infection, coughing (chronic), wheezing, dyspnoea on exertion, respiratory distress with retractions, chest pain, pneumothorax and haemoptysis occur. The sputum may be purulent, and on physical examination, clubbing, cyanosis and crackles during auscultation are found. Pulmonary infections are predominantly caused by *Staphylococcus aureus*, *Pseudomonas*, *Haemophilus influenza* and fungi. Other symptoms are caused by the involvement of the nose and sinuses, the gastrointestinal system, liver, pancreas, hepatobiliary system, urogenital tract, skin and skeletal system. Severe intra-abdominal manifestations of cystic fibrosis include neonatal meconium ileus, distal intestinal obstruction syndrome (DIOS), biliary cirrhosis, pancreatic cysts, pancreatic fibrosis and atrophy. Cor pulmonale and pulmonary hypertension are late-stage complications, but death is predominantly caused by chronic respiratory failure at a mean age of 33 years (2).

Imaging

Plain chest radiography is performed routinely in almost all patients. Several scoring tests have been established for the assessment of the disease severity, but image findings on chest X-rays may be subtle especially in mild disease and in early stages. High-resolution CT (HRCT) reflects most accurately the morphologic changes in patients with cystic fibrosis with excellent spatial resolution. CT-scoring systems provide a sensitive method for monitoring disease status and progression. MRI is useful for the assessment of mediastinal and vascular anatomy. In recent times, new MRI techniques for functional ventilation imaging with use of inhaled contrast aerosols, oxygen, hyper-polarised noble gases (Helium-3, Xenon-129) and fluorinated gases (sulphur-hexafluoride) have been developed (3). A higher sensitivity in the detection of ventilation defects compared to ventilation scintigraphy, CT or standard pulmonary function tests with lack of radiation is expected for this new MRI technique (3).

The abdominal manifestations of cystic fibrosis are efficiently imaged by ultrasound. Routine sonographic follow-up examinations of the liver, the biliary system, the pancreas and the bowel tract should be performed in each patient. In case of severe abdominal disease, such as liver cirrhosis with ascites or DIOS, CT may be necessary for further evaluation.

Nuclear Medicine

Ventilation perfusion scintigraphy may provide useful information in demonstrating marked functional impairment and abnormal matched ventilation and perfusion defects (1).

C

Diagnosis

In most children the diagnosis is based on clinical findings, positive newborn screening tests and sweat tests with measurement of sweat chloride concentrations. The chest radiographs of newborns are normal. Early findings on chest radiographs are hyperinflation of the lungs with flattening of the diaphragm and bronchial wall thickening (1). In later stages, peribronchial interstitial thickening, mucoid impactions, bronchiectasis, ring shadows (empty cavities of bronchiectasis), atelectasis, bulla, interstitial emphysema, pneumothorax, hilar lymphadenopathy and cor pulmonale occur (Fig. 1). The disease has a predilection for the upper and middle lung zones.

In HRCT bronchiectasis, peribronchial wall thickening, mosaic perfusion pattern and mucous plugging are the most frequently observed morphologic CT abnormalities in patients with cystic fibrosis. Less frequent are emphysema, collapse, sacculations and bullae observed (4) (Fig. 2). The disease is often accompanied by hilar and mediastinal lymph node enlargement (Fig. 3). The most common morphologic CT abnormalities increase in extent and severity with increasing patient age and correlate significantly with worsening of non-morphologic parameters of pulmonary status (4).

There are only a few studies using ►functional ventilation imaging with MRI in children with cystic fibrosis. Donelly et al. examined 4 children with cystic fibrosis using H-1 and ^{3}He MRI. In all subjects, areas of absent lung ventilation were depicted on the hyperpolarised ^{3}He MR images. These areas of absent ventilation ranged from wedge-shaped peripheral defects to signal voids in entire lung zones. Ventilation was most severely impaired in the upper posterior lung zones, and normal in the lower lung zones (3, 5).

Interventional Radiological Treatment

In patients with long-standing cystic fibrosis, haemoptysis may occur as a complication. Abnormal thin walled and tortuous bronchial arteries, commonly found in areas of bronchiectasis, are eroded secondary to chronic infection. In case of severe haemoptysis, arteriography of the bronchial arteries with subsequent embolisation may be

Cystic Fibrosis. Figure 1 A 17-year-old boy with cystic fibrosis. The chest radiograph demonstrates marked hyper-aerated lungs, bronchial wall thickening, bronchiectasis, peribronchial fibrosis, mucoid impactions and bilateral hilar lymphadenopathy.

necessary. As embolic materials, polyvinyl alcohol particles, gelatine sponge particles or coils are usually used. Bronchial artery embolisation has shown good results in controlling acute and chronic haemoptysis but in up to 50% of cases repeated embolisation procedures have to be performed due to a high incidence of bleeding from non-bronchial systemic collateral vessels. As major complications of bronchial artery embolisation transverse myelitis, bronchial infarction, oesophago-bronchial fistula, ischaemic colitis and—most feared—spinal infarction and paraplegia due to embolisation of a spinal artery have been described.

Cystic-Like Lesions, Hepatic

Chiara Franchini, Riccardo Lencioni
Department of Diagnostic and Interventional Radiology, University of Pisa, Italy
lencioni@med.unipi.it

Definition

Cysts and cystic-like lesions are any focal lesions that contain fluid (liquid or semisolid) material.

True cysts are closed cavities lined by epithelium, while cystic-like lesions do not have necessarily an epithelium and are not necessarily closed cavities.

Pathology and Histopathology

Cysts and cystic-like lesions of the liver in the adult can be classified as developmental, inflammatory, neoplastic, and miscellaneous. Developmental cystic lesions include simple cyst, autosomal dominant polycystic liver disease, ►biliary hamartoma, ►Caroli's disease. Inflammatory cystic lesions include pyogenic, amoebic and tubercular abscesses, and intrahepatic hydatid cyst. Neoplastic cystic lesions include biliary cystadenoma and cystadenocarcinoma, cystic subtypes of primary liver neoplasms, and cystic metastases. Other cystic lesions are intrahepatic haematoma and biloma (1).

Simple Cysts (Bile Duct Cysts)

Simple or true hepatic cysts are very common benign congenital lesions that do not communicate with the biliary tree (1, 2). They result from the obstruction of congenitally aberrant bile ducts, with subsequent stasis and retention of bile. They can be solitary or multiple and their size is very variable, even though frequently is inferior to 5 cm. They tend to increase in number and size with age. They are more common in women. Cysts are cavities lined by epithelium, with a thin wall and a serous content. Rarely they may present as "complicated" cysts due to the presence of hemorrhage or inflammation (1, 2).

Polycystic Liver Disease

►Polycystic liver disease is an autosomal dominant disorder characterized by the presence of multiple, sometimes innumerable cysts in the liver. In some cases, polycystic liver disease appears to occur sporadically. It is characterized by the presence of cysts ranging in size from less than 1 cm to more than 10–15 cm; the cysts are lined by cuboidal or flattened biliary epithelium and contain straw-colored fluid. They do not contain pigmented bile and appear to be detached from the biliary tree (1, 2–5). Polycystic liver disease is thought to be due to a ductal plate malformation of the small intrahepatic bile ducts, which lose communication with the biliary tree. Spontaneous intracystic hemorrhage, infection, and rupture may occur. Polycystic liver disease is often found in association with adult renal polycystic disease (1). Hepatic cysts are found in 40% of cases of autosomal dominant polycystic disease involving the kidneys; nevertheless, they may be seen without identifiable renal involvement at imaging.

Biliary Hamartoma

Bile duct hamartomas, also called von Meyenburg complexes, originate from a failure in involution of embryonic bile ducts (1, 3). They are small clusters of slightly dilated bile ducts embedded in a fibrous, sometimes hyalinized stroma, close to or within the portal tracts. These bile duct microhamartomas contain bile concrements. At pathologic analysis, they appear as grayish-white nodular lesions 0.1–1.5 cm in diameter scattered throughout the liver parenchyma. The nodules may coalesce into larger masses. They do not communicate with the biliary tree (3).

Caroli's Disease

Caroli's disease was described by Jacques Caroli in 1958 as a congenital communicating cavernous ectasia of the biliary tree. It is a rare, autosomal recessive condition characterized by segmental, nonobstructive saccular, or fusiform dilatation of the intrahepatic bile ducts. Other typical pathologic features are the presence of intraluminal bulbar protrusions, bridges across the dilated lumina, and portal radicles partially or completely surrounded by dilated bile ducts. The abnormality may be segmental or diffuse. The pure form of the disease is quite rare, while a various degree of congenital hepatic fibrosis is usually associated. ►Caroli's syndrome is the condition in which features of both congenital hepatic fibrosis and Caroli's disease are simultaneously present (1, 4).

Both varieties may be associated with cystic renal disease, more often autosomal recessive polycystic kidney disease, but also autosomal dominant polycystic kidney disease, medullary sponge kidney, nephronophtisis. There is also an association with cystic dilatation of extrahepatic bile ducts (1, 4). Caroli's disease is supposed to be due to an insufficient resorption of ductal plates, resulting in large dilated segments of the primitive bile duct surrounding a portal vessel (4). If the large intrahepatic bile ducts are affected, the result is the pure form of Caroli's disease, while abnormal development of the small interlobular bile ducts leads to congenital hepatic fibrosis.

Clinical Presentation

Simple Cysts

Hepatic cysts are a common finding, being found in 1% to 3% of the liver routine examinations. They are more often discovered in women and are usually asymptomatic (1, 2); rarely they may cause symptoms like pain, palpable abdominal mass, hepatomegaly, jaundice. Complications occur rarely and are mainly represented by intracystic hemorrhage, infection, compression of adjacent structures, occasionally torsion of the cyst, and rupture.

Polycystic Liver Disease

Usually, patients with polycystic liver disease are asymptomatic and liver dysfunction is quite unlikely to occur (5). However, advanced disease may cause hepatomegaly, which may results in abdominal discomfort and dyspnea. Symptoms may arise in relation to complications, such as intracystic bleeding, infection, or rupture of a cyst, which are quite frequent due to the great number of cysts (1, 5).

Biliary Hamartoma

Bile duct hamartomas are rather common and usually represent an incidental finding at imaging or laparotomy in asymptomatic patients, or at autopsy. The estimated incidence in autopsy series is 0.69–2.8% (1, 3). Complications such as superinfection with formation of microabscesses and degeneration into cholangiocarcinoma are extremely rare (3).

Caroli's Disease

The clinical onset of Caroli's disease usually occurs during childhood. In the pure form it is related to complications including stone formation, cholangitis, and hepatic abscesses. Clinical symptoms are recurrent attacks of right upper quadrant pain, fever, and, more rarely, jaundice. In Caroli's syndrome the clinical scenario is dominated by hepatic fibrosis and portal hypertension, with splenomegaly, oesophageal varices, hemorrhage of the gastrointestinal tract.

Cholangiocarcinoma complicates Caroli's disease in 7% of cases (5).

Imaging

Simple Cysts

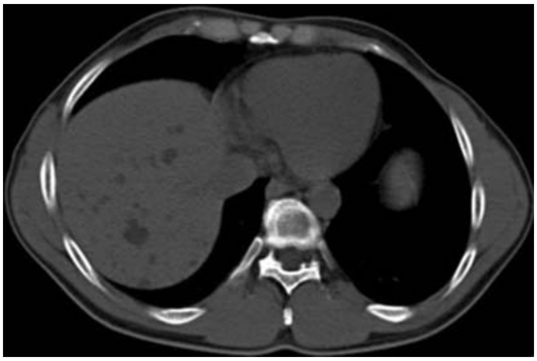
At ultrasound (US) a cyst has the typical appearance of an anechoic, round or ellipsoid structure, with posterior acoustic enhancement, and sharply delineated margins, without an own wall. The solid–liquid interfaces appear as highly hyperechoic lines. Sometimes, subtle lateral acoustic shadows can be seen. Rarely, septa or calcifications may be present. Cysts may behave sometimes as occupying-space masses, displacing intrahepatic vessels or biliary branches, or causing swelling of the hepatic margin. A complicated cyst (intracystic bleeding or infection) presents internal echoes (1). At CT scans an hepatic cyst appears as a round or ovoid well-defined lesion, with no evident wall. The content is homogeneous and hypodense with attenuation values similar to the water (<20 HU). Both the wall and their content do not show any enhancement after contrast media administration. In small lesions, attenuation values can be higher due to partial volume effect; in these cases a thin section thickness should be used in order to avoid misdiagnosis of solid nodule; the absence of contrast enhancement will confirm the cystic nature of the lesion. Any enhancement in the periphery or thickening of the wall suggests an inflammatory or neoplastic nature, rather than a simple cyst. Internal inhomogeneity and higher attenuation values (>20 HU) are present in complicated cysts, in which the differential diagnosis from metastases arising from cystic carcinomas (as pancreatic or ovarian ones) can be difficult (1). The ipointensity on T1-weighted images and homogeneous very high signal intensity on T2-weighted images is due to their high water content. On heavily T2-weighted images an increase in signal intensity is seen. This behavior allows differentiation of these lesions from metastatic disease. The wall is never seen and no enhancement is present at the dynamic study. Intracystic bleeding determines high signal intensity, sometimes with a fluid–fluid level, on both T1- and T2-weighted images; the hemorrhage may be dated on the basis of the different appearance of the different phases of degradation of hemoglobin. Fat-saturation sequences may be helpful in confirming the blood content (1).

Polycystic Liver Disease

At ultrasound polycystic liver disease is characterized by the presence of multiple anechoic lesions of various size, often clustered, which causes a diffuse dishomogeneity of the liver parenchyma. The appearance of cystic lesions does not differ from that of simple cysts (1, 2). At CT the typical finding is the presence of multiple homogeneous water-density lesions with regular borders, without a detectable wall. The lesions do not show peripheral neither internal enhancement after contrast media administration. Hemorrhagic cysts, more frequently encountered than in cases of simple hepatic cysts due to the great number of lesions, have attenuation values higher than water at unenhanced CT scans; calcification of the cyst walls, due to previous hemorrhage, may also be detected (1). At MR, hepatic cysts in polycystic liver disease have a homogenous signal intensity and appear markedly hypointense on T1-weighted images and markedly hyperintense on T2-weighted images. Because of their serous content they become even brighter on heavily T2-weighted images. They do not enhance after administration of gadolinium chelates. The intracystic hemorrhage is characterized by signal intensity inhomogeneity (1). Although the diagnosis of polycystic liver disease is easily made with both CT and MR imaging, MR imaging is more sensitive for the detection of complicated cysts.

Biliary Hamartoma

At ultrasound biliary hamartomas have been described as either hypoechoic or anechoic small nodules with posterior acoustic enhancement. Hyperechoic biliary hamartomas or a combination of hypo- and hyperechoic lesions, however, has also been reported (3). In almost all described cases, unenhanced CT showed hypodense small hepatic nodules, scattered throughout the liver and typically measuring between 0.5 and 1.0 cm in diameter. The latter feature is the most essential one in the differential diagnosis from multiple simple cysts. Furthermore, simple cysts are typically regularly outlined, whereas bile duct hamartomas have a more irregular outline. Although homogeneous enhancement of these lesions has been noted in some cases, in most reports no enhancement was seen after contrast media administration (1, 3). The MR appearance of bile duct hamartomas has been reported sporadically. All lesions were hypointense compared with liver parenchyma on T1-weighted images and markedly hyperintense on T2-weighted images. On heavily T2-weighted images, the signal intensity increases further, nearly reaching the signal intensity of fluid. Biliary hamartomas do not exhibit a characteristic pattern of enhancement after administration of gadolinium chelates; some authors observed homogeneous enhancement of these lesions, some others a thin rim enhancement, whereas others did not find any enhancement. At MR cholangiography, bile duct hamartomas appear as multiple tiny cystic lesions that do not communicate with the biliary tree, helping in the differential diagnosis with Caroli's disease (1, 3).



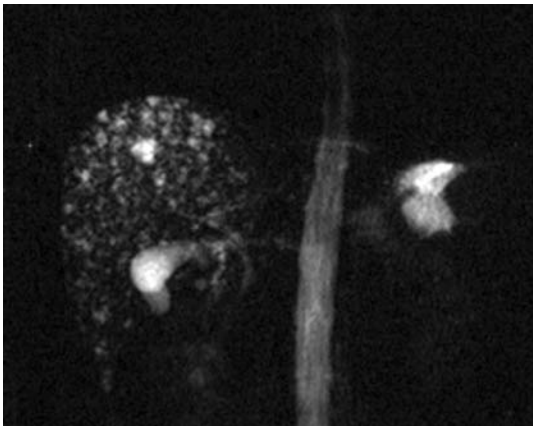
Cystic-Like Lesions, Hepatic. Figure 1 **Caroli's disease. Unenhanced CT shows multiple hypoattenuating water-density areas.**

Cystic-Like Lesions, Hepatic. Figure 2 **Caroli's disease. Bridging septa within the cystic dilatations may be depicted (*arrow*). The presence of small dots showing strong contrast enhancement during the portal-venous phase within the dilated lumina, also known as "central dot sign," is considered very suggestive of Caroli's disease (*dashed arrow*).**

Caroli's Disease

US reveals localized saccular dilatations of intrahepatic bile ducts which appear as multiple cystic lesions. Besides these findings, peculiar features may be demonstrated such as intraluminal bulbar protrusions, complete or incomplete bridging across the dilated ducts, and small portal branches within the cystic structures. The Doppler mode should be used in order to demonstrate this typical aspect. Inside the dilated segments stones or debris may be present, appearing as hyperechoic deposits with or without shadowing. CT typically shows hypoattenuating water-density structures which communicate with the biliary tree (Fig. 1). The presence of small dots showing strong contrast enhancement during the portal-venous phase within the dilated lumina, also known as "central dot sign," is considered very suggestive of Caroli's disease. Bulbar protrusions and bridge formation may also be depicted. Intraluminal biliary calculi may be demonstrated (Fig. 2) (1, 4).

At MR imaging, the cystic dilatations of the biliary tree appear hypointense on T1-weighted images and strongly hyperintense on T2-weighted images. The intraluminal portal radicles present clear enhancement in the portal phase at the dynamic study. MR can demonstrate internal septa and protrusions inside the dilated lumina. MR cholangiography can be extremely useful in diagnosis of Caroli's disease by demonstrating the communication between the saccular or fusiform dilatations of the intrahepatic bile ducts and the biliary tree (Fig. 3). Furthermore, stones, when present, are evident as signal voids within ducts and cystic spaces. Sludge or debris may be also evident. The use of a hepatobiliary contrast medium by imaging the liver in the biliary phase can more confidently demonstrate the biliary nature of the cystic dilatations, which show contrast enhancement. The cholangiographic features of Caroli's disease are well established as saccular or fusiform



Cystic-Like Lesions, Hepatic. Figure 3 Caroli's disease. MR cholangiography demonstrates the communication between the saccular or fusiform dilatations of the intrahepatic bile ducts and the biliary tree.

dilatation of the intrahepatic bile ducts. Alternating areas of stricture and dilatation are a common observation with cholangiograms (1, 4).

Nuclear Medicine

Hepatobiliary scintigraphy with ^{99m}Tc (IDA iminodiacetic acid) agents reveals large, irregular, multifocal collections of the radiotracer in the liver. These collections correspond to the segmental dilatations, and no extrahepatic obstruction is present, although bile stasis and stone formation may result in atypical obstruction. On early images, if the ducts are dilated enough, they appear as photopenic branching areas within the liver. Overall, scintigraphy is not helpful compared with cross-sectional imaging techniques. Cholangitis can impair hepatic uptake of radiotracers. Obstruction related to stones or debris from the ducts may cause misdiagnosis.

Diagnosis

The diagnosis of a hepatic cystic lesion is based on US, which is the most accurate technique for establishing its cystic nature compared to solid lesions in the liver. At contrast CT or MR, any enhancement in the periphery or thickening of the wall suggests an inflammatory or neoplastic nature, rather than a simple cyst. MR is indicated when cystic lesions have atypical appearance on US. MR allows the distinction between complicated hepatic cysts presenting with hemorrhage inside and other cystic lesions such as underlying metastatic disease with target or halo sign. In the majority of cases, imaging findings in combination with critical clinical information allow an adequate lesion characterization.

Synonyms

Cystic pancreatic tumors; Exocrine cystic neoplasms of the pancreas

Definitions

Cystic tumors of the pancreas are relatively uncommon, accounting for about 10% of cystic lesions of the pancreas and for 1% to 5% of primary pancreatic neoplasms. The incidence is increased in patients with von Hippel–Lindau disease.

According to the AFIP (Armed Forces Institute of Pathology) system, the pancreatic cystic tumors represent primary exocrine lesions and they are distinct into benign, borderline (with an uncertain malignant potential) and malignant. Serous cystic tumors, mucinous cystic neoplasms and intraductal papillary-mucinous tumors/neoplasms (IPMTs/IMPNs) represent the majority of the cases encountered in practice, accounting for more than 90% of the primary cystic neoplasms of the pancreas; solid pseudopapillary neoplasms represent less than 10%; other cystic neoplasms are represented by other tumors with cystic appearance (e.g. cystic neuroendocrine tumor, acinar cystadenocarcinoma, ►lymphangioma, cystic teratoma) (1).

Pathology and Histopathology

Serous cystic tumors were also known as microcystic adenomas or glycogen-rich cystadenomas. They have an extremely low potential for malignant disease: malignant serous cystadenocarcinomas have been reported, but they are exceedingly rare, accounting for less than 1% of cases. Serous cystadenomas are generally well circumscribed, lobulated tumors, consisting of single (macrocystic or oligocystic adenoma) or multiple (microcystic adenoma) cysts, separated by delicate fibrous septae. The cysts are filled with clear, watery fluid and are often arranged around a central stellate scar, which may be calcified and that lacks in oligocystic adenomas. Cysts are lined by a simple, glycogen-rich cuboidal epithelium. When the cyst is large, it can be difficult to differentiate them from mucinous cystic neoplasms.

The histopathological features of mucinous cystic neoplasms and IPMNs are similar except for a dense mesenchymal ovarian-like stroma which is a requisite feature of mucinous cystic tumors. Moreover characteristically mucinous cystic neoplasms lack a communication with the pancreatic ductal system, whereas a communication is a key feature of IPMN (1).

Mucinous cystic tumors of the pancreas are multiloculated tumors. The inner surface is smooth, but sometimes, especially in large malignant tumors, papillary excrescences and solid nodules can be observed. Microscopically 3 distinct layers can be recognized: the inner epithelial layer producing mucin; the middle layer, which is the densely cellular ovarian-like mesenchymal stroma; the outermost layer, which is the hyalinized connective tissue. The epithelial cells lining the cysts produce abundant mucoid secretion; therefore the cysts contain viscous material, which can also be hemorrhagic. These tumors are classified on the basis of histology as benign, borderline or malignant based on degree of dysplastic changes of the epithelium. According to the model of neoplastic progression, mucinous cystic neoplasms progress through stages of increasing dysplasia from mucinous cystadenoma to borderline mucinous cystic neoplasm to mucinous cystic neoplasm with in situ carcinoma, finally to reach the stage of invasive carcinoma. Cystadenomas contain a single layer of epithelium without significant atypia. In borderline neoplasms the epithelium may form papillae; an in situ carcinoma or invasive carcinoma can arise focally within a mucinous cystic lesion. All these lesions are different from IPMNs, because they are grossly visibile neoplasms that do not involve the duct system of the pancreas (1).

IPMNs are papillary, villous neoplasm that arises within the main pancreatic duct or its branches. They are usually classified into 3 types: main duct, branch duct and mixed, according to the site and extent of involvement. The tumors hypersecrete mucin, which often leads to duct dilatation and/or chronic obstructive pancreatitis. Histologically the involved duct is lined by mucin-producing columnar epithelium which forms papillary proliferations; the tumor can shows varying degrees of atypia and can progress from adenomas without atypia to IPMN borderline with a moderate amount of atypia, to IPMN with carcinoma in situ and finally to infiltrating carcinoma. The tumors generally show intraluminal growth, but they can invade periductal tissues (1).

Clinical Presentation

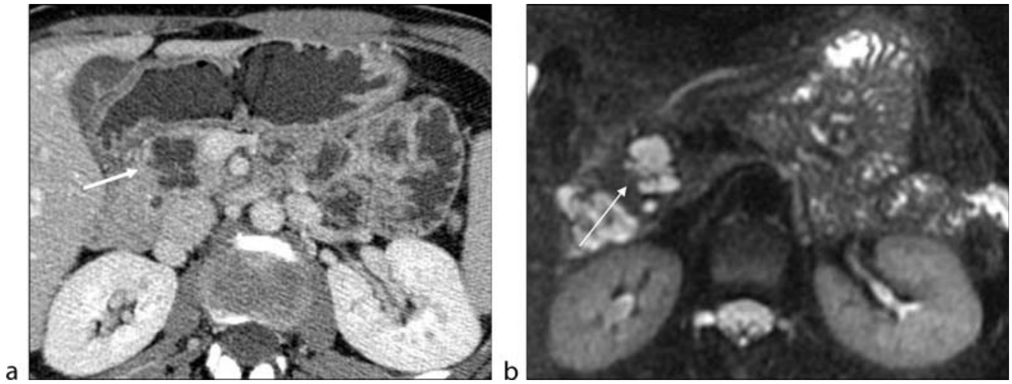
Many patients with a pancreatic cystic tumor present with no relevant signs or symptoms and such tumors may be discovered incidentally at abdominal ultrasound (US) or computed tomography (CT). Most of the remaining patients present with a variety of non-specific symptoms such as abdominal pain, anorexia, nausea, vomiting, also related to recurrent pancreatitis. If the tumor is large enough, symptoms related to mass effects may predominate, such as a palpable abdominal mass and biliary obstruction. Patients with malignant changes may have a history of weight loss and jaundice.

Imaging

Classically, serous cystic lesions have a lobulated external contour and are composed of a grapelike cluster of cysts. A central stellate scar with calcification is pathognomonic and small septae and internal debris may be seen in individual cysts. Approximately 10% of all serous cystadenomas have cystic components larger than 2 cm and can't be distinguished from mucinous cystic neoplasms. Because the capsule of these tumors is poorly developed, poor distinction of the tumor from the surrounding pancreatic parenchyma is often observed. However, when the cysts are small, it can be difficult to identify the cystic nature of the neoplasm. The central scar and calcifications may be demonstrated on CT scans, but are not well depicted on US. Endoscopic ultrasonography (EUS) allows better resolution of the honeycomb structure (2). Magnetic resonance (MR) is the modality of choice for the depiction and characterization of cystic pancreatic masses. Serous cystadenomas are usually hyperintense on T2-weighted images and hypointense on T1-weighted images. Occasionally, debris and hemorrhage in the cysts can alter this signal intensity pattern. The septae are well depicted on T2-weighted images, but the central scar is not. Magnetic resonance cholangiopancreatography (MRCP) is helpful in demonstrating the relationship of the mass to the main pancreatic duct. Usually no communication occurs with the pancreatic duct. The main duct is almost never obstructed, but the duct and its branches may be displaced (3,4) (Fig. 1).

Mucinous cystic neoplasms are often larger than 5 cm. US reveals a large, cystic mass sometimes with internal septa, excrescences, mural nodules and debris. The tumor usually has sharply marginated walls and smooth borders. CT shows a well-defined, unilocular or multilocular mass with fluid attenuation. Compared with serous cystic tumors, the cysts are larger (>20 mm in diameter) and less numerous (usually <6). Larger cysts may demonstrate small daughter cysts along their internal surface. Thick internal septae separating the different cystic cavities are typical. Visualization of nodular or papillary excrescences with irregular borders of the septae is possible. If present, calcifications are curvilinear or punctate and confined to the wall or septa. After the contrast medium administration, enhancement of the cyst wall, internal septations, mural nodules and other intracavitary projections is present. The presence of papillary excrescences, mural nodules and other intracavitary projections suggests the differentiation between benign mucinous cystadenoma and cystadenocarcinomas; however, the absence does not indicate that the tumor is benign. At MR, mucinous cystadenoma and cystadenocarcinoma are hypointense or hyperintense on T1-weighted images depending on protein content. T2-weighted images show multiple hyperintense cysts separated by multiple hypointense septa. Intracystic excrescences and mural nodules also have low signal intensity, but they enhance significantly after gadolinium-based contrast agents administration (3,4) (Fig. 2).

Main ductal type of IPMN may be focal or diffuse, the findings of which are reflected on imaging. When there is diffuse involvement of the pancreatic duct, dilatation is present along its whole length. This dilatation is often associated with diffuse and generally uniform pancreatic atrophy. In the early stages of focal or segmental involvement, the features may be difficult to differentiate from focal chronic obstructive pancreatitis. Branch IPMT is most frequently encountered in the region of the uncinate process. It may be microcystic or macrocystic. The microcystic variety may mimic serous cystadenomas on imaging, but communication with the main pancreatic duct (which is frequently dilated) is characteristic. The macrocystic variety may mimic a peripheral mucinous cystic tumor. IPMN can be more confidently diagnosed when imaging reveals a filling defect in the main duct or a branch pancreatic duct. The filling defects are hyperechoic on US (but extremely difficult to visualize), hyperdense on CT and hypointense on T2-weighted MR images. The thickness of the cyst wall and septa is variable with benign tumors; they tend to be thin and regular. In malignant



Cystic Neoplasms, Pancreatic. Figure 1 Serous cystoadenoma of the head of the pancreas (arrows). Multidetector CT study (a) and MR study (b). At CT is possible to appreciate a well circumscribed lesion, presenting lobulated borders, constituted by few microcysts. The borders are poorly defined from the normal pancreatic parenchyma and the lesion does not show evidence of contrast enhancement; a thin stellate central scar is also visible but there are no signs of calcifications (a). In an axial fat-suppressed fast spin-echo T2-w, it is possible to appreciate the same lesion as a lobulated hyperintense area with no relationship with pancreatic ducts (b).

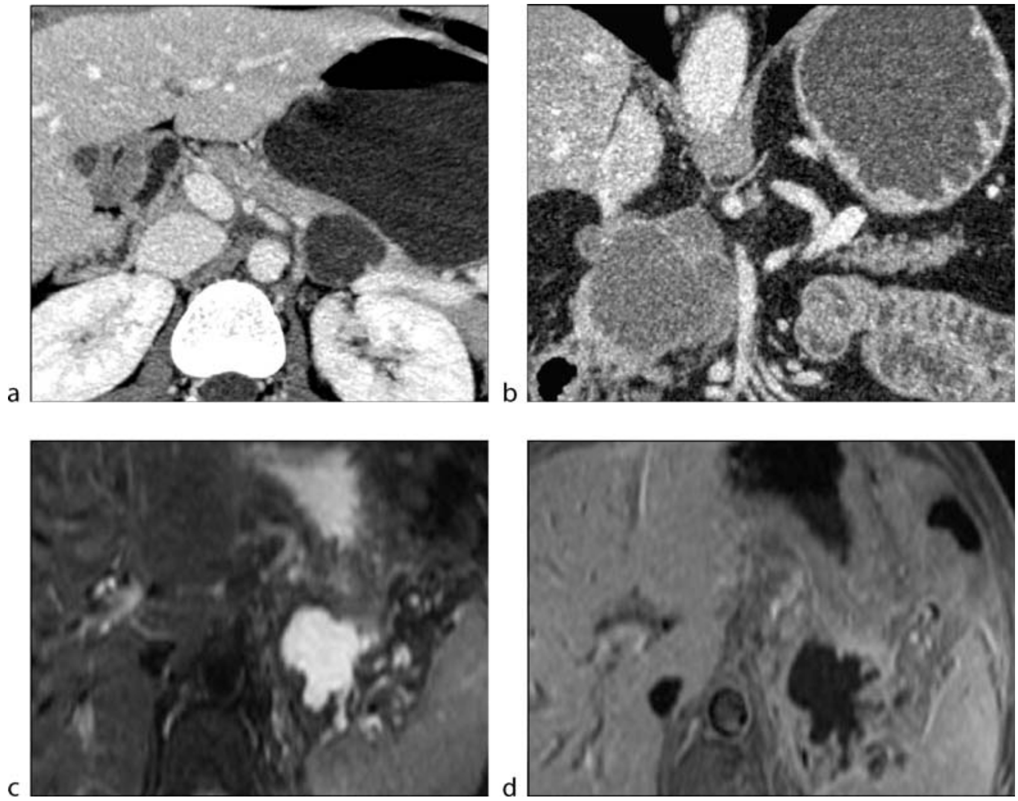
tumors, the walls and septa appear irregular and thick, with solid nodules. MRCP study represents the technique of choice for visualizing the typical communication between the IPMN and the ductal system and to evaluate the extent of the tumor. A main pancreatic duct with a maximum diameter of greater than 15 mm, and diffuse dilatation of the duct are suggestive of malignancy in main duct type tumors. Among branch duct-type tumors, malignant tumors tend to be larger than benign tumors (Fig. 3). The intravenous administration of secretin allows the improvement of the pancreatic ducts delineation and therefore the depiction of typical findings of IPMN (5,6).

Because of the anatomical location of the pancreas near to the gastric and duodenal loop, EUS appears to be reliable in distinguishing between solid and cystic lesions. However the features that can be visualized often do not appear to be sufficiently accurate to allow a differentiation between benign and malignant tumors.

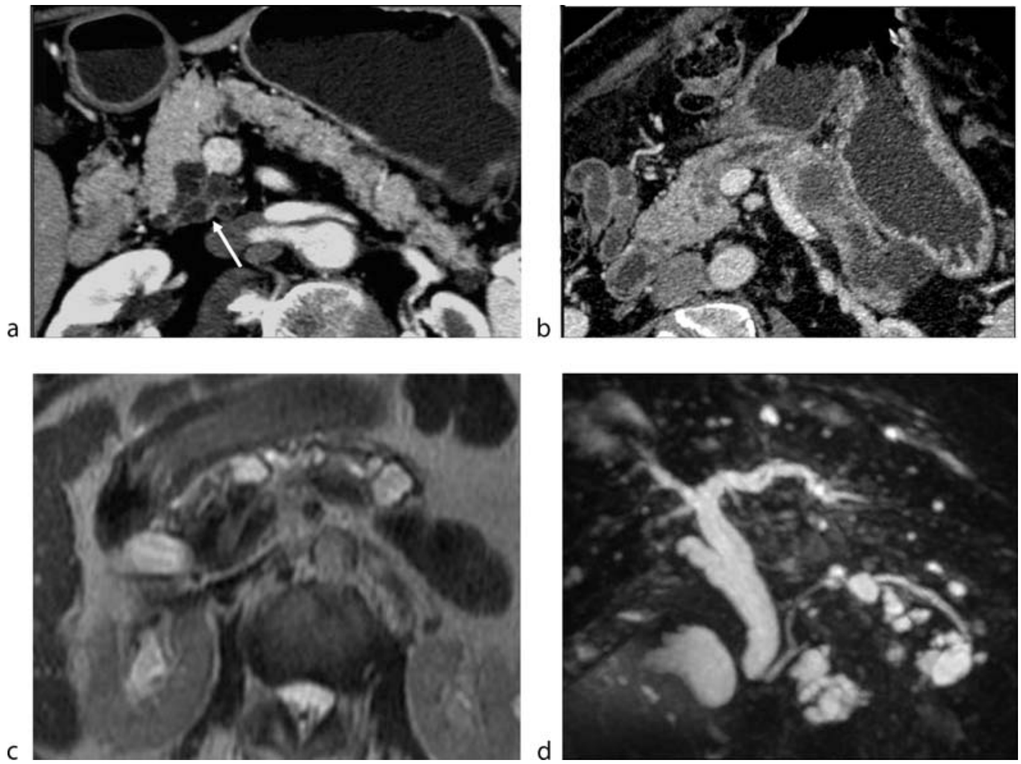
Endoscopic retrograde cholangiopancreatography (ERCP) may depict ductal changes in cystic tumors of the pancreas in approximately 80% of patients, allowing also tissue sampling and therapeutic intervention. In particular, in IPMN the communication with the pancreatic duct and an anomalous ampulla of Vater with discharging mucus may be visualized.

Nuclear Medicine

Positron emission tomography (PET) imaging can depict cystic malignant tumors, because it is sensitive to



Cystic Neoplasms, Pancreatic. Figure 2 **Mucinous tumors of the pancreas at multidetector CT (a,b) and MR (c,d). In (a) a uniloculated, well defined benign mucinous tumor of pancreatic body/tail is depicted. It is possible to appreciate the smooth borders of the lesion, the absence of internal septa and the smooth inner surface. Multiplanar reconstruction (b) on the coronal plane shows a multiloculated malignant mucinous tumor of the pancreatic head: the irregular profile and the thickness of the borders as well as the presence of contrast enhancement are depicted. There is no presence of internal septa or intracavitary projections. The neoplasm infiltrates the fat tissue around the pancreatic head and it is contiguous to the superior mesenteric artery wall, without certain signs of vascular compression. In (c) and (d) a mucinous cystadenocarcinoma of the pancreatic tail is shown by MR images. Axial fat-suppressed fast spin-echo T2-w (c) and gadolinium-enhanced fat-suppressed SPGR T1-w (d) images well exhibit a prevalently cystic lesion at the level of the pancreatic tail. The lesion shows irregularly lobulated, thickened internal walls presenting marked contrast enhancement.**



Cystic Neoplasms, Pancreatic. Figure 3 IPMN of the pancreas at multidetector CT (a,b) and MR (c,d). In (a) a IPMN "branch duct-type": a multilobulated lesion constituted by a grape-like cluster of microcysts originating from secondary pancreatic ducts is shown in the uncinate process (a); these microcystic lesions, differently from the serous ones, do not present a central scar. The lesion also shows thin margins and there are no internal septae. The main pancreatic duct is not dilated. In (b) a IPMN "main duct-type": two uniloculated macrocystic lesions, localized in the tail and in the body of the pancreas and originating from the Wirsung duct can be appreciated; the cystic lesions appear filled with an ovarian like stroma fluid and their growth has determined the Wirsung dilatation and the consequent glandular atrophy, due to compression. In (c) and (d) a branch duct-type IPMN can be appreciated at MR. Axial single-shot fast spin-echo T2-w image (c) and coronal oblique MIP reconstruction of MRCP (d) show multiple, diffuse cystic dilatations of secondary pancreatic ducts. The main pancreatic duct appears slightly dilated at the level of the pancreatic tail. Extraepatic biliary tree is also dilated.

hypermetabolic processes. FDG PET is more accurate than CT in identifying malignant lesions and could be used, in combination with CT and tumor markers, in the preoperative evaluation of patients with pancreatic cystic lesions. A positive result on FDG PET strongly suggests malignancy and, therefore, a need for resection. A negative result shows a benign tumor that may be treated with limited resection or follow-up. However, PET is not yet approved for use in the workup of pancreatic lesions.

Diagnosis

With the widespread use of advanced imaging techniques, cystic lesions of the pancreas are now diagnosed relatively frequently. US may aid in the differentiation of solid and cystic lesions, but a complete evaluation of the pancreas is often difficult. CT is excellent not only for the initial detection of the lesion but also for the characterization (by visualization of calcifications, septa, mural nodules) and the staging of malignant lesions (by assessing vascular invasion, infiltration of the adjacent structures and the presence of lymph node metastases, distant metastases or peritoneal carcinosis). MR has the added advantage of providing better characterization of the features of a cyst and its relationship with the pancreatic duct by means of MRCP sequences. Despite advances in imaging, often the differential diagnosis of pancreatic cystic lesion remains difficult; however an accurate diagnosis is imperative for appropriate patient management because the most important determinant of the prognosis is the identification of malignant or premalignant cysts that require resection. Serous cystadenoma is usually benign, whereas some serous cystadenomas show progressive growth; therefore, surgery is indicated, because complications, such as obstructive jaundice, can result. Surgical removal of the mucinous cystic neoplasms and IPMNs is recommended because of the potential malignant behaviour of these lesions. Therefore obtaining fluid cyst or tissue for histologic confirmation may be essential. A variety of tumor markers that may be present in cyst fluid have been proposed for use in the differentiation among the major types of cystic lesions. Ca 19.9 concentration in cyst fluid has not been confirmed as a useful indicator for discriminating between mucinous and non-mucinous cystic lesions but serum levels of Ca 19.9 are slightly elevated in some patients who have malignant cystic lesions. Levels of cystic carcinoembryonic antigen (CEA) can be increased in the mucin content of the cysts, and they proportionally rises with the degree of malignancy of the tumor. Although amylase is not a tumor marker, its presence in cyst fluid is often used as an indicator of a communication between a cystic lesion and the ductal system, as in cysts that are associated with IPMNs.

The differential diagnosis includes other tumors with cystic appearance and pancreatic lesions with a cystic presentation (including pancreatic pseudocysts or pancreatic fluid collections, ▶congenital pancreatic cysts, retention pancreatic cysts, ▶parasitic cysts, ▶lymphoepithelial cysts).

Cystic Nephroma

A basically benign, sometimes semi-malignant multicystic renal lesion, usually comprised of multiple small, similar sized cysts that may include some areas of nephroblastomatosous cells (potential malignant transformation), that may replace the entire or parts of the kidney.

Cystic Renal Disease, Acquired

JM Correas, O Hélénon
University of Paris V,
Paris, France
jean-michel.correas@nck.ap-hop-paris.fr

Definition

Acquired cystic kidney disease (ACKD) is defined as the development of multiple renal cysts (at least three per kidney) in patients with end-stage renal disease, before or after starting dialysis, without hereditary cystic disease. It can affect the native kidneys in renal transplanted patients, whatever the renal function and the renal graft during chronic rejection.

Pathology/Histopathology

Pathology reveals multiple renal cysts in both atrophic kidneys from the cortex and the medulla. They are typically small, ranging in size from a few millimeters to 30 mm. The presence of hemorrhagic cysts or oxalate crystal deposition in cystic walls and septations as well as within the cysts is common. Atypical cystic walls exhibit multilayered epithelial lining, and papillary proliferations are not unusual (1). Multiple renal tumors are associated with ACKD, including adenomas and carcinomas of various types, with a strong increase in papillary tumor incidence compared with the general population (1). Renal cancer can be detected in approximately 5% of ACKD patients. Tumors are typically multifocal, bilateral, and aggressive, with a rate of metastases of 15% (2). The mean duration of dialysis before development of renal cancer is about 12 ± 7.9 years (2).

Clinical Presentation

The incidence of ACKD increases with the duration of end-stage renal failure. Before patients start dialysis, ACKD is found in about 10% of them. This number increases to 10–20% within the first 3 years of dialysis and can reach 90% after 10 years of dialysis (3), whatever the cause of renal failure. The kidneys regularly increase in size because of the development of cysts in patients undergoing dialysis, whereas they remain small in transplanted patients.

In most cases, ACKD is detected incidentally because the disease is asymptomatic. The recovery of normal renal function after transplantation has no demonstrated impact on the development of ACKD.

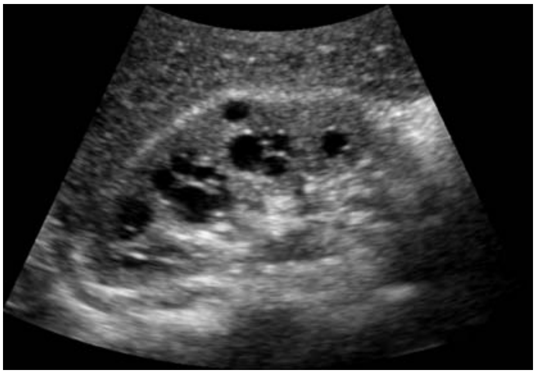
Cyst complications, including bleeding and infection, can also appear and reveal the disease. The presence of hemorrhagic cysts is frequent at imaging procedures. Rarely, the hemorrhage is symptomatic and provokes back pain. Severe cyst bleeding can extend to the retroperitoneum or the collecting system and result in reduced hemoglobin serum level, hypotension, and even shock.

Renal tumors are rarely symptomatic and are detected in most cases by incidental imaging studies or systematic follow-up in hemodialyzed or transplanted patients. The incidence of renal cell carcinomas is significantly increased up to seven times in patients undergoing dialysis (2). Seven percent of dialyzed patients can develop small solid renal tumors. In transplanted patients, the prevalence of renal cell carcinoma discovered incidentally is 1.6%.

Imaging

Ultrasonography and Color Doppler Ultrasound

At ►ultrasound (US), the cysts are detected as sonolucent round lesions with increased posterior acoustical energy. They are typically bilateral, localized within the parenchyma in small kidneys with reduced corticomedullary differentiation. Harmonic tissue imaging is helpful to detect and characterize small hypoechoic lesions (Fig. 1). Almost 50% of hemorrhagic cysts can exhibit a pseudosolid echoic pattern on US. ►Contrast-enhanced computed tomography (CT) or magnetic resonance imaging (MRI) is then required. Hemorrhagic cysts can remain anechoic, and US can be useful to characterize hyperattenuating cysts at CT in the case of absence of iodinated contrast agent administration or when the enhancement remains equivocal. On color Doppler US (CDUS), typical cysts do not exhibit any signals. Contrast-enhanced US might be useful for diagnosing pseudotumors and to detect vascularity within echoic renal lesions to confirm the presence of a solid renal mass (Fig. 2).



Cystic Renal Disease, Acquired. Figure 1 Harmonic compounding imaging of the native kidney in a renal transplanted patient. Many typical cysts are detected within the cortex and the medulla.

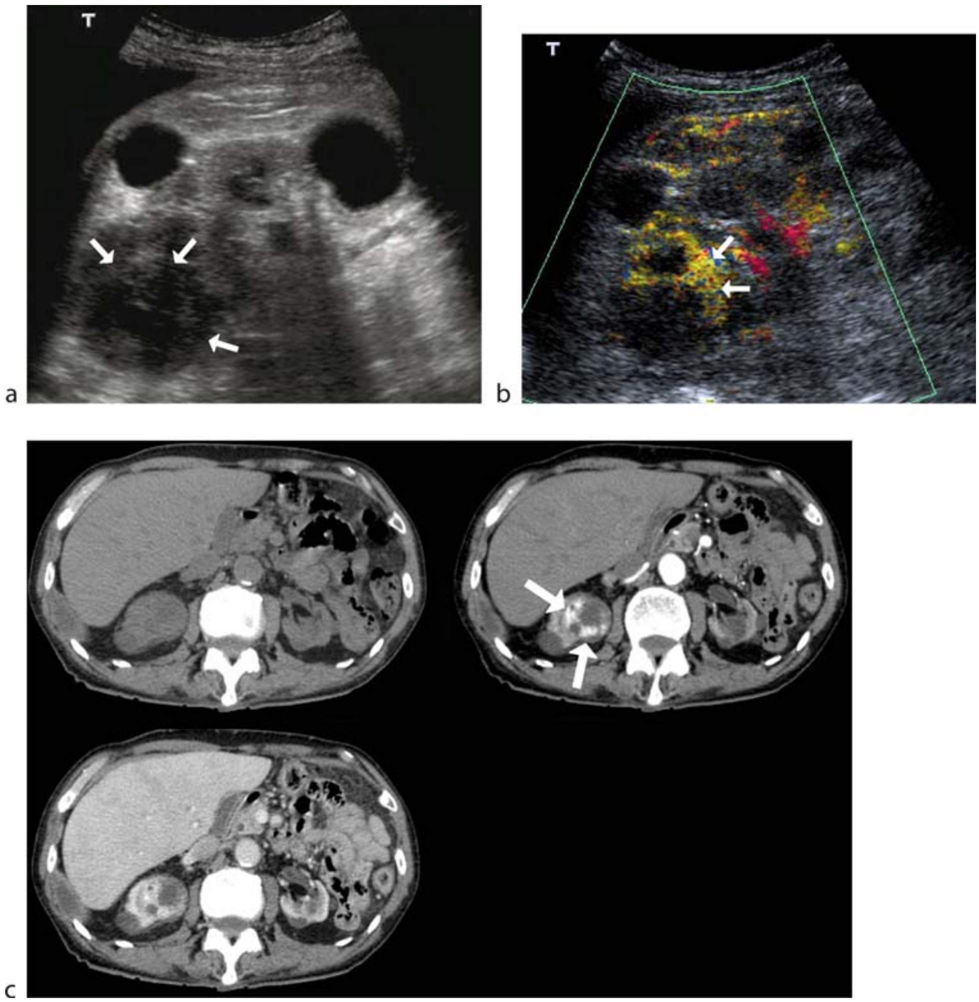
However, US examination in ACKD is difficult due to the reduced size of the kidneys and the hyperechoic parenchyma, making identification of the kidney difficult within the retroperitoneal fat.

CT and MRI

Contrast-enhanced CT remains the gold standard in the diagnosis of ACKD as well as in the characterization of renal masses. Baseline CT is mandatory to detect hyperattenuating cysts and to provide baseline attenuating values. Contrast-enhanced CT improves the detection of numerous small cysts located in both kidneys, predominantly in the cortex (Fig. 3). CT can also detect calcifications in cystic walls or septations.

Hemorrhagic cysts are very common (up to 50% of ACKD patients). They typically exhibit increased attenuation values at baseline (above 50 HU) and no enhancement after iodinated contrast agent administration. Delayed acquisitions during nephrographic and excretory phases are necessary to differentiate these lesions from solid renal tumors. In the case of acute back pain revealing renal bleeding, CT can detect an enlarged hemorrhagic cyst and/or a subcapsular hematoma. The hematoma can extend to the retroperitoneal space. The disappearance of the hematoma should be monitored until disappearance to avoid the misdiagnosis of a bleeding cystic carcinoma.

Solid renal masses are seen as round lesions significantly enhanced after iodinated contrast agent injection. The threshold varies from 15 to 20 HU. In the case of hemorrhagic mass, the enhancement is typically poor and remains below the threshold value. The change in the shape of the lesion that becomes heterogeneous



Cystic Renal Disease, Acquired. Figure 2 **Ultrasound (US) follow-up of a patient under hemodialysis. (a) At tissue harmonic imaging, a heterogeneous and echogenic mass was detected at the upper pole of the right kidney (*arrows*). (b) Contrast-enhanced US following the administration of SonoVue confirmed the presence of vascularity within the mass, strongly enhancing during arterial phase (*arrows*). (c) Contrast-enhanced computed tomography (CT) with baseline (*top left*), arterial (*top right*), and nephrographic (*bottom left*) acquisitions. CT confirmed the presence of a partially necrotic mass with strong peripheral enhancement. At pathology, the lesion corresponded to a renal cell carcinoma.**

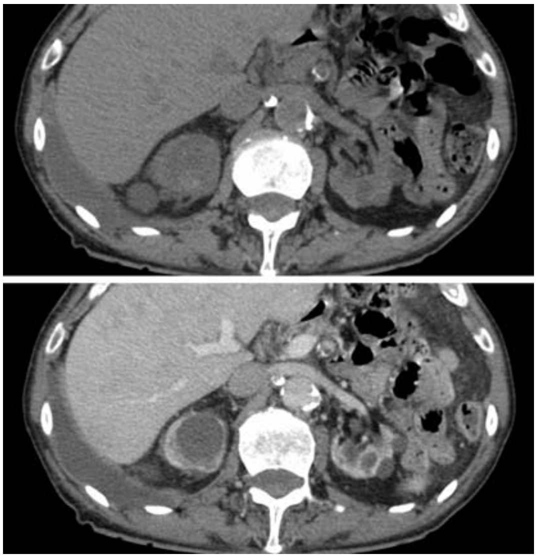
indicates the presence of vascularity, and thus is highly suspicious for solid tumors. Solid renal masses should be differentiated from focal renal parenchyma hypertrophy. These pseudotumors exhibit a similar enhancement compared with the normal atrophic parenchyma at all phases of the transit of the iodinated contrast agent, and they remain homogeneous. In the case of equivocal diagnosis, MRI can be useful to confirm the diagnosis of pseudomass.

The staging of a solid renal mass primarily relies on contrast-enhanced CT to detect venous and lymph node extension.

If contrast-enhanced CT can be performed in patients undergoing dialysis, CT cannot be used in patients with persistent renal function. In this case, contrast-enhanced MRI becomes the modality of choice for the diagnosis of ACKD and the characterization of renal masses.

MRI examination should include at least T2-weighted spin-echo sequences with fat suppression and dynamic breath-hold T1-weighted gradient-echo sequences with fat suppression, before and after bolus administration of gadolinium chelate contrast agent. Typical cysts are easily characterized as round lesions of high signal intensity on T2-weighted sequences, of low signal intensity on

T1-weighted sequences at baseline, and with no enhancement after injection of contrast agent (Fig. 4). Hemorrhagic cysts are typically hyperintense on both T1- and T2-weighted sequences and do not exhibit any enhancement. The presence of a fluid iron level indicates the presence of a hemorrhagic cyst.



Cystic Renal Disease, Acquired. Figure 3 Computed tomography in ►acquired cystic kidney disease (*top*: baseline scan; *bottom*: nephrographic phase). Multiple bilateral small cysts are detected within the atrophic parenchyma.

In hemorrhagic cystic tumors, the enhancement can be masked by the baseline hypersignal of the lesion. Follow-up is then necessary to confirm the absence of enhancement when the signal of the lesion will be changed due to metabolism of methemoglobin.

Solid renal masses are typically slightly hyperintense on T2-weighted sequences, and they significantly enhance after contrast agent injection. MRI participates in the staging of renal masses when the administration of iodinated contrast agents is contraindicated or when CT and sonographic findings are inconclusive, particularly regarding tumor extension to the inferior vena cava, the spleen, and the liver.

Angiography

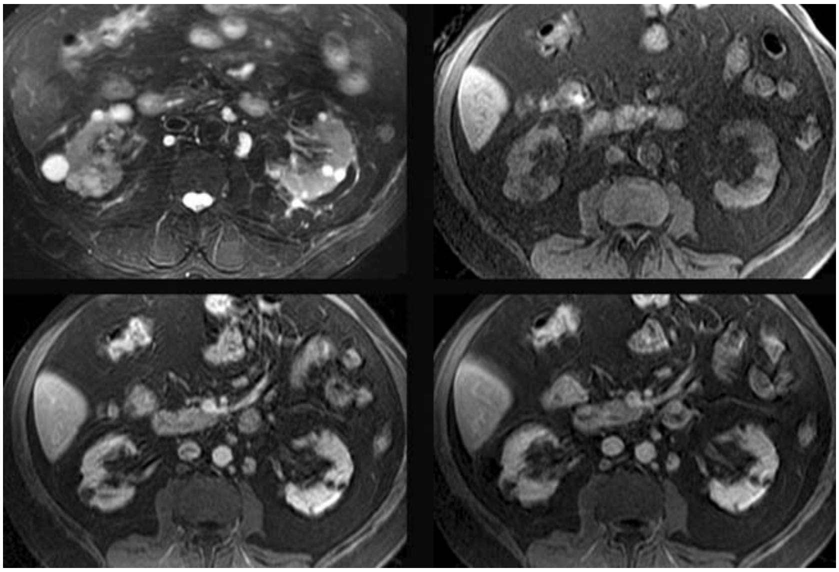
Renal angiography is not done for ACKD diagnosis but for selective embolization in patients with severe active bleeding. To avoid the misdiagnosis of a bleeding tumor, CT needs to be performed until the hematoma disappears.

Nuclear Medicine

Scintigraphy has no value in the diagnosis of ACKD.

Diagnosis

The most difficult ►differential diagnosis of ACKD is the presence of multiple simple cysts. The size of the cysts and



Cystic Renal Disease, Acquired. Figure 4 Typical magnetic resonance imaging (MRI) aspects in acquired cystic kidney disease. *Top left*: T2-weighted acquisition; *top right*: T1-weighted baseline dynamic acquisition; *bottom left*: T1-weighted dynamic acquisition during nephrographic phase; *bottom right*: T1-weighted dynamic acquisition during excretory phase.

their location are not helpful for differentiating the two diseases. When renal function is preserved, the diagnosis is likely to be ACKD, but multiple renal cysts can be found in patients with chronic renal failure.

In medullary cystic disease, the cysts are small and strictly located within the medulla.

At the moment of diagnosis of ACKD, the size of the kidneys is normal or reduced, in contrast to autosomal dominant polycystic kidney disease (ADPKD). In ADPKD, the renal cysts are much bigger than in ACKD, as they typically exceed 5 cm. Cysts can be detected in other locations such as the liver, the spleen, and the pancreas.

Other diseases such as von Hippel Lindau and tuberous sclerosis are easily ruled out with the context (family cases), the presence of associated tumors (hemangioblastoma of the central nervous system, pheochromocytoma, pancreatic cysts, or angiomyolipoma).

There is no definite imaging modality recommended for screening ACKD patients. US offers a clear advantage in terms of cost (Fig. 2). However, the examination is often difficult due to the size and echogenicity of the kidney. CT has the disadvantage of higher cost and secondary effects of iodinated contrast agents (renal toxicity and allergic reactions). However, it is an effective imaging technique and allows comparison when repeated examinations are performed over the years. MRI is probably the most effective modality because it does not have the limitations of iodinated contrast agents. However, its use is limited by restricted access to the machine, the cost of the examination, and some contraindications. The screening test should be repeated once a year, even after successful transplantation.

Still under debate is the efficacy of a screening program for elderly patients undergoing dialysis due to numerous comorbidity factors that reduce the impact of early treatment of renal cancer on the survival rate (4). Minimally invasive treatment of renal tumors such as radio frequency ablation might improve the tolerance of treatment compared with radical nephrectomy in this population at risk for cardiovascular complications. The screening program can be directed at patients at high risk of cancer (male, prolonged dialysis, enlarged kidneys) with good clinical status after 3 years of dialysis (5, 6). The incidence of renal tumors may have been underestimated by imaging techniques. The screening program can also include patients undergoing peritoneal dialysis.

In patients awaiting renal transplantation, the native kidneys should be scanned by either US or CT before the surgical procedure.

After renal transplantation, the native kidneys can be studied by US at the same time as the examination of the renal graft. Despite the lack of published data, transplanted patients, including children, might represent the best population to benefit from a renal tumor screening protocol (7). The decrease in ACKD after successful transplantation should be balanced against the increased aggressive behavior of renal cancers. When an echoic renal mass is detected, contrast-enhanced CT or MRI should be performed, depending on renal function.

Cystitis

Lorenzo E. Derchi, Pietro Pavlica
University of Genova, Largo R. Benzi, 8,
I-16122 Genova, Italy
derchi@unige.it

Definition

The term cystitis indicates the presence of an inflammatory disease of the urinary bladder. Such diseases are a common clinical problem, with more than half of the population experiencing an episode of cystitis during life. They can have a large variety of causes and can be divided, according to their etiology, into two broad categories:

those due to infectious causes, and those of noninfectious origin. In the first group, bacterial lesions are the most frequent, but viral, fungal, and parasitic diseases can also be encountered. Noninfectious inflammations can be congenital, such as the chronic irritative changes of the bladder mucosa in exstrophy of the urinary bladder, or acquired such as lupus erithematosus cystitis, eosinophilic cystitis, pelvic lipomatosis, involvement of the bladder from inflammatory diseases of adjacent organs, and iatrogenic lesions (1, 2).

Pathology/Histopathology

Pathological changes can be limited to the mucosal surface of the bladder or extend to the deep layers of the wall, and vary according to the etiology of the disease process.

Infectious Cystitis

In patients with bacterial cystitis, the main finding is edema of the mucosa, with thickening of the mucosal folds. When severe, edema can cause decreased capacity of the bladder. Bullous edema, that is fluid-filled cystic areas in the lamina propria of the mucosa, can develop, and is often more prominent at the level of the bladder base. The inflammatory process can be focal, and presenting as inflammatory polypoid lesions. In emphysematous cystitis, a condition that is most commonly encountered in patients with poorly controlled diabetes mellitus, bacterial fermentation of excessive glucose causes development of carbon dioxide within the bladder wall. Gas can extend also into the bladder lumen (3). Immunocompromised or debilitated patients can develop, after urologic procedures, infection from urease-producing microorganisms, able to transform urea into ammonia. This causes modification of pH in urine, which becomes alkaline, leading to formation of struvite and calcium phosphate that form stones and encrustations on the bladder wall. The disease, called alkaline-encrustation cystitis may also extend to the ureters and the kidneys. Encrustations are usually thin and regular, covering the urothelial surface, but may be irregular and thick; thickening of the bladder wall and perivesical soft-tissue edema can be associated (4). Mycotic infections of the bladder can cause formation of "fungus balls" within the bladder lumen; these are clusters of pseudomicelia, usually mobile according to patient's decubitus. In diabetic patients with Candida infection, gas can be present in the bladder given the capability of Candida to ferment sugar. If a fungus ball is in the bladder, gas can remain trapped within it. In patients with infestation from schistosomiasis, the disease process is caused by eggs deposited by the female parasite in the small veins of the submucosal layer of the bladder wall, around which a granulomatous reaction and embolic vasculitis develop. The deposited eggs calcify, and this is a macroscopic hallmark of the disease (5). Involvement of the urinary bladder occurs in about one third of patients with urinary tract tuberculosis, usually late in the course of the disease. The mucosa is edematous, with tubercles that coalesce and undergo ulceration. Calcifications can develop.

C

Noninfectious Cystitis

A large variety of noninfectious conditions can cause inflammatory changes of the bladder mucosa. In lupus erithematosus cystitis, a marked vasculitis of the bladder develops, with immune-complex deposition along small vessels and smooth muscle in the lamina propria of the bladder. Biopsy of the bladder wall in cases of eosinophilic cystitis shows pancystitis, with eosinophils, mast cells, and lymphocytes within the mucosa and tunica propria. Muscle necrosis and fibrosis can be found. Interstial cystitis is a pancystitis of unknown cause, often associated with systemic diseases. Biopsy shows transmural inflammation and fibrosis, submucosal edema and vasodilatation, and presence of mast cells in the submucosa and muscular layers. Cystitis can develop in most patients with pelvic lipomatosis, a condition characterized by benign overgrowth of pelvic fat. The pathogenetic relationship between cystitis and pelvic lipomatosis is not clear; however up to 80% of these patients develop cystitis glandularis. When the bladder is involved by neoplastic or inflammatory disorders arising within surrounding pelvic organs, histology shows an infiltrating inflammatory process, most marked in the outer part of the bladder wall. Perforation into the bladder may occur. Iatrogenic inflammation from foreign bodies, drugs, or radiation can develop in the bladder. The most common one is due to indwelling urethral catheters, in which histology shows vascular dilatation on the mucosa and lamina propria, with bullous edema visible on the surface of the mucosa, especially at the point where the tip of the catheter is in contact with the wall. Such changes can regress very quickly after catheter removal. Drug-induced cystitis may be related to either to direct toxic effect of drug metabolites on the urothelium or to an allergic-type of reaction of the bladder mucosa. Cyclophosphamide cystitis is the typical example of the first type of reaction. Biopsy reveals fibroblastic proliferation with associated atypia; wall fibrosis may develop after several months of therapy. Infiltration of the tunica propria with eosinophils and lymphoreticular cells develops in patients with the allergic-type of induced cystitis. Inflammatory changes of the bladder following pelvic radiotherapy are characterized, in the acute phase, by mucosal ulcerations and panvesical fibrosis; later effects produce vasculitis and fibrosis with reduced bladder capacity.

Chronic Cystitis

Patients with chronic inflammation of the urinary bladder undergo changes that follow a predictable pathway. Bladder lesions start from Brunn's nests, solid nests of urothelial cells lying in the lamina propria of the wall. Degeneration of the central part of these nests leads to the development of fluid-filled cysts (cystitis cystica). Further chronic irritation leads to the development of these lesions into glandular structures (cystitis glandularis). At last, squamous metaplasia may occur.

Clinical Presentation

Symptoms of cystitis include urgency, frequency, incontinence and suprapubic pain, or discomfort. Hematuria may be the prominent symptom, and in these cases, the term hemorrhagic cystitis is frequently used. Such symptoms, however, are nonspecific, and do not allow to differentiate among the different forms of the disease. Taking into account clinical history can help in the differential.

In bacterial cystitis symptoms vary according to the age of the patient: in neonates, failure to thrive may be observed as a result of poor feeding, vomiting, and diarrhea. In the older child, fever becomes a more prominent symptom. In the adult, the classic symptoms are present. A history of diabetes is commonly found in patients with emphysematous cystitis or in those with mycotic infections. Patients with alkaline encrusting cystitis are usually immunocompromised, with previous urologic procedures. Schistosomiasis is encountered in subtropical Africa, Middle East and in part of southern Europe. A history of tuberculous infection of the upper tract is commonly found in patients with tuberculous cystitis.

For patients with *noninfectious cystitis*, a history of radiation exposure or chemotherapy, or presence of an indwelling catheter allow to address the diagnosis when urinary symptoms develop. Patients with eosinophilic cystitis have predisposing factors such as asthma, bladder trauma, food allergies, and a history of eosinophilic gastroenteritis. Eosinophilia is associated in 50% of cases. When a pelvic inflammatory process extends to the bladder, symptoms are those of the primary process, with the addition of irritative voiding complaints. If a fistula develops, fecaluria and/or pneumaturia are associated.

Interstitial cystitis is a chronic inflammatory disease of the urinary bladder of unknown cause, often associated with systemic diseases such as rheumatoid arthritis, polyarteritis and lupus erithematosus, and/or an allergic condition, predominantly affecting middle-aged women. The diagnosis can be made on presence of chronic unexplained irritative bladder symptoms, sterile urine, and cystoscopic demonstration of urothelial lesions (Hunner's ulcers).

Imaging

Usually, imaging is not needed for the diagnosis of cystitis, which is commonly suspected on clinical grounds and confirmed by urinary cultures. When requested, radiologic studies are chiefly aimed at identifying underlying pathology that may predispose to the development of infection, such as reflux and urinary outlet obstruction. This is especially needed in patients with recurrent episodes of cystitis. Furthermore, it must be remembered that changes affecting the mucosa of the urinary bladder are better analyzed by cystoscopy, and this technique has the capabilities to provide clues for the differential diagnosis of the different forms of the disease and, most important, to allow for biopsy (1, 2).

Imaging is pointed at detecting changes of the wall and content of the bladder. Plain films can show calcifications and gas within the bladder wall, while urography can show irregularities of the mucosal surface. Such findings can be better evaluated when the bladder is not completely full. CT, ultrasonography and MRI can show thickening of the wall, as well as focal lesions. Calcifications are easily seen at CT, but can be appreciated also by ultrasonography.

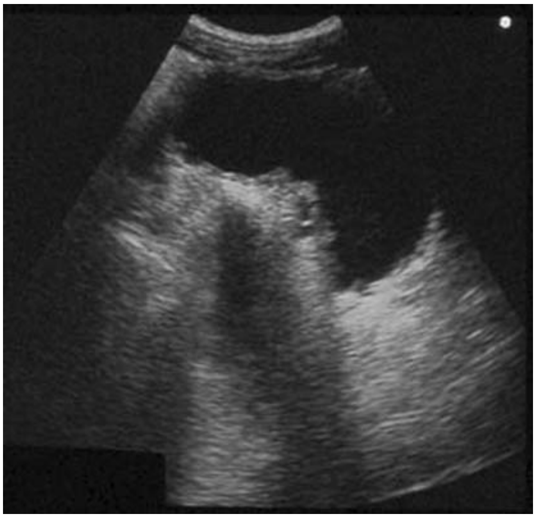
Nuclear Medicine

Nuclear medicine studies do not offer clues for demonstration of cystitis. Radionuclide retrograde cystography can be used in the pediatric age group to show reflux in children who present with recurrent urinary infections.

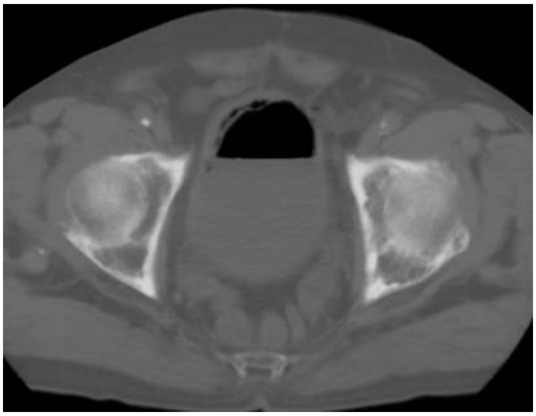
Diagnosis

The imaging diagnosis of cystitis is based on demonstration of changes of the bladder wall and content. At urography, thickening and irregularity of the mucosa can be seen, together with decreased capacity of the inflamed, irritated bladder. Such findings are often more prominent at the level of the bladder base, and can be better demonstrated when the bladder is only partially filled in with contrast or in the postvoiding films. Ultrasonography and CT can show diffuse thickening of the wall of the bladder. In patients who develop bullous edema, focal filling defects of rounded shape may be seen, especially near the bladder base. On ultrasonography, bullous edema has been described to cause hypoechoic regions of wall thickening with smooth transition to normal bladder wall (Fig. 1). Focal forms of cystitis can also present with polypoid lesions that can be difficult to differentiate from malignancies (1).

The diagnosis of emphysematous cystitis is based on demonstration of gas within the bladder wall. Gas within the bladder lumen can be associated. On a plain abdominal film, this can be difficult to distinguish from bowel gas or an adjacent abscess, but can be easily recognized at urography, CT, or ultrasound (Fig. 2). The bladder wall can be thickened, with an irregular outline. Presence of gas in the bladder lumen and not within the bladder wall is usually described as a separate entity (pneumocystis); intraluminal gas has to be differentiated from gas entering from an enteric fistula or following catheterization maneuvers (3).



Cystitis. Figure 1 Bullous edema of the posterior wall of the urinary bladder demonstrated by ultrasonography. There is focal thickening of the wall, with smooth transition toward the normal portions; areas of hypoechogenicity are visible within the thickened region.



Cystitis. Figure 2 Emphysematous cystitis. CT obtained without i.v. contrast medium shows presence of gas both within the wall and within the bladder lumen.

In patients with alkaline encrusting cystitis, the bladder wall is characterized by presence of encrustations; the disease may also involve the ureters and the kidneys, and calcifications and stones can be seen also at these levels. Detection of wall calcifications in the proper clinical setting on conventional radiographic studies is diagnostic; however, calcifications may be thin, and impossible to recognize. Ultrasonography can detect the encrustations as a linear hyperechogenicities on the mucosal surface of the bladder. Nonenhanced CT is regarded as the best technique to diagnose encrustations. Lesions are usually thin and regular, covering the urothelial surface, but may be irregular and thick; there is also thickening of the bladder wall, and perivesical soft tissue stranding can be associated (4). In mycotic infections, imaging can be normal or show only nonspecific inflammatory changes of the bladder wall; on sonography, echogenic urine can be shown, A "fungus ball," that is a cluster of pseudomicelia, can develop within the bladder, presenting as a nonopaque mass. Such balls are usually mobile within the bladder: on ultrasonography, it is easy to demonstrate changes of position of the fungus ball according to changes in patient decubitus. In diabetic patients with Candida infection, gas can be present in the bladder given the capability of Candida to ferment sugar. In some cases, gas can be seen within the "fungus ball" (1). Schistosomiasis infestation can be imaged at urography as edema of the bladder wall in the early stages. When eggs calcify, they can be seen on plain films or urography; the pattern of calcifications may vary, from thin and regular to thick and irregular, involving the bladder wall completely or only focally (Fig. 3). In the early stages of the disease, contraction capability of the calcified bladder is preserved. Both ultrasonography and CT can detect easily the calcifications in the bladder wall. Involvement of the ureter is the rule, and is early during the disease process. Urography can detect filling defects and stenoses of the distal portions of the ureters, while ultrasound can show thickening of the ureteric walls (5). In patients with tuberculosis of the bladder, diffuse wall thickening, ulcerations of the mucosal surface, fibrous bands, and mural nodules have been described at urography and ultrasound. Calcifications may develop in the wall, and can be seen radiographically.

Patients with pelvic lipomatosis have a typical pear-like appearance of the urinary bladder; when cystitis is associated, imaging can show irregularities of the bladder mucosa. In case of bladder involvement from an adjacent inflammatory process, focal inflammatory changes such as edema, nodularity, or thickening of the wall may be

Cystitis. Figure 3 Schistosomiasis of the bladder. Plain radiograph of pelvis shows linear calcifications involving the whole bladder wall.

observed on intravenous urography. CT and ultrasound can show both the primary disease and bladder changes. Fistulous tract may be difficult to demonstrate directly, and can be inferred by presence of air in the bladder. Nonspecific thickening of the bladder mucosa can be detected by urography. Patients with drug-induced and radiation cystitis present with bladder wall edema in the early phases, but late effect of these diseases may cause wall fibrosis and reduction of bladder capacity (1).

Cystocele

Descent of the posterior bladder wall during Valsalva maneuver below the level of the vesico-urethral junction of more than 1 cm is called a cystocele. A cystocele impresses the anterior vaginal wall (grade II) and may evert it to outside the introitus (grade III). A cystocele may persist after relaxation and need manual reposition.

Corpus luteum cysts; Follicle cysts; Follicular cysts; Luteal cysts; Physiologic ovarian cysts; Simple ovarian cysts

Definitions

Physiologic cysts including follicular and luteal cysts constitute the vast majority of cystic ovarian lesions. They typically result from failure during folliculogenesis, most often from rupture or regression of the ovarian follicles. They may also result from continued hemorrhage in a corpus luteum. Follicle cysts are usually larger than the mature ►graafian follicle and range from 3 to 5 cm in size; however, they may attain a diameter of 8–12 cm. ►Physiologic ovarian cysts are an extremely common incidental finding during the reproductive ages. However, they may be found in all age groups, particularly in adolescents and in the early postmenopausal period. Functional ovarian cysts may also develop due to irregularities of pituitary gonadotropin hormone release or due to external hormonal replacement therapy.

Pathology/Histopathology

In women who do not take birth control pills, numerous small, thin-walled cystic follicles and a dominant follicle are seen within the ovarian peripheral stroma. At midcycle the latter attains a size of 15–25 mm and can be identified partially protruding from the ovarian surface (1). After ovulation the rupture stigma is sealed by a mass of coagulated follicular fluid, fibrin, and connective tissue (1). The normal corpus luteum demonstrates a convoluted yellow lining and usually measures 1.5–2 cm in diameter. If it is larger than 3 cm, it is defined as a corpus luteum cyst (1).

Microscopically, follicle cysts are lined by an inner layer of granulosa cells and an outer layer of theca interna cells (1). They may be luteinized in both layers. ►Corpus luteum cysts demonstrate a convoluted inner lining consisting of large luteinized granulosa cells and an outer lining of luteinized theca interna cells (1). Capillaries from the theca interna penetrate the granulosa layer to reach the central cavity (1). The contents of follicle and luteal cysts vary from serous to serosanguinous to clotted blood.

Follicles may persist for several years after menopause and give rise to sporadic ovulations or cyst development. Solitary ►follicular cysts are a different entity from follicular cysts that occur during the reproductive age (1). They tend to be larger and are most commonly found during menarche and menopause, but may also be seen in the fetus. Cysts related to anomalies in the release of anterior pituitary hormones tend to recur and manifest as multiple large cysts in both ovaries (1).

Clinical Presentation

Most functional cysts are asymptomatic and not hormonally active. Vague abdominal or pelvic pain, pelvic pressure, and lower back pain may be caused by larger functional cysts. Corpus luteum cysts may be hormonally active and become clinically apparent by menstrual disorders and prolonged hemorrhage. Complications of functional cysts include rupture, hemorrhage, and torsion. Intraperitoneal hemorrhage following rupture is characterized by an acute onset of pelvic pain. Similarly, patients with ovarian torsion most commonly experience abrupt onset of severe lower abdominal pain. Follicle cysts in precocious puberty are manifestation of McCune–Albright syndrome (1).

Imaging

Ovarian cysts are a common incidental finding in ovarian imaging.

Transabdominal in combination with *endovaginal sonography* is the primary imaging modality in assessing the ovaries. If physiological cysts do not exceed a size of more than 3 cm they cannot be differentiated from normal follicular derivates in women of reproductive age.

Other imaging modalities for assessing cystic ovarian lesions include *computed tomography (CT) and magnetic resonance imaging (MRI)*. They are infrequently used for further characterization of sonographically detected cystic lesions. More often, functional cysts are incidental findings in pelvic imaging studies for other indications.

Due to partial volume average and proteinaceous contents, follicles are often missed in CT. Furthermore, CT usually does not allow differentiation between ►hemorrhagic functional cysts and hemorrhagic cysts in endometriosis. Hemorrhagic cysts may also mimic solid ovarian lesions in CT. This problem can be overcome by performing a noncontrast series before application of intravenous contrast media. This technique and thin-slice multispiral CT also improve the detection of smaller ovarian cysts. In cystic ovarian lesions, contrast-enhanced images provide better detail of the internal morphology of cystic lesions. They also assist in the differential diagnosis between simple ovarian cysts and other cystic ovarian lesions, for example, cystadenomas, hydrosalpinx, and cystic ovarian cancer.

In MRI imaging, sequences for assessing cystic ovarian lesions include T1-weighted imaging (WI), T2-WI, and contrast-enhanced imaging. If lesions display high signal intensity (SI) on T1-WI, fat saturation techniques are useful to differentiate between proteinaceous or hemorrhagic contents and fat that is pathognomonic for dermoid cysts.

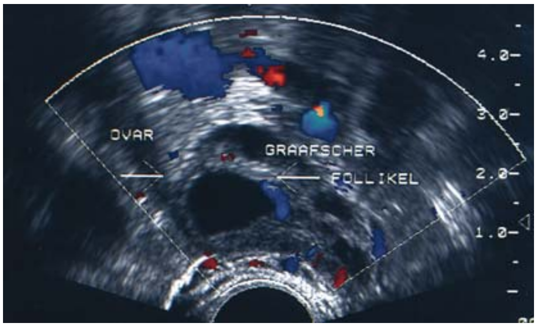
Nuclear Medicine

Nuclear medicine usually does not contribute to the diagnosis of functional ovarian cysts.

Diagnosis

Sonography, particularly endovaginal sonography, is the modality of choice in monitoring follicles and ovarian follicle cysts (Fig. 1).

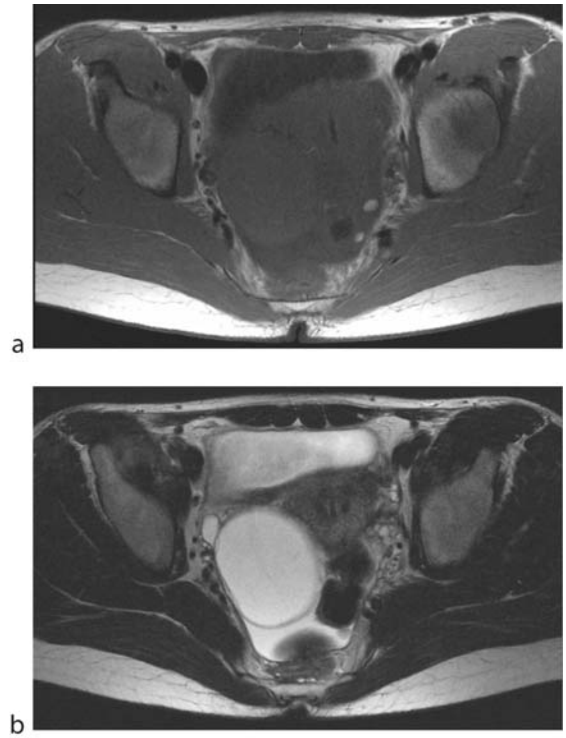
Ovarian cysts larger than 3 cm in diameter are regarded as follicular cysts (2). Follicle cysts are thin-walled ovarian lesions most commonly filled with watery contents. Compared with follicle cysts, corpus luteum cysts have thicker, well-vascularized walls. The internal echoes depend on the quality of the contents. Bleeding in an unruptured cyst causes a spectrum of sonographic findings related to the temporal sequence of clot formation (3). Corpus luteum cysts often display mildly echogenic echoes, most likely presenting partially solid



Cyst, Follicular, Ovarium. Figure 1 Color Doppler sonography of a normal ovary at midcycle in a 25-year-old female patient. Transvaginal sonography demonstrates a normal ovary which is located medial of the iliac vessels. Within the ovarian parenchyma, ovarian vessels and small follicles are demonstrated. The graafian follicle presents the largest cystic lesion and measures 15 mm in diameter. (Courtesy of R. Gruber, Salzburg)

Cyst, Follicular, Ovarium. Figure 2 Hemorrhage in a physiologic cyst. In a 29-year-old female patient with acute pain, a 6-cm right ovarian lesion is demonstrated. It is well delineated and is composed of a solid area with irregular borders surrounded by liquid. The sonographic follow-up showed continuous decrease in size and change in morphology of the internal clot. (Courtesy of R. Gruber, Salzburg)

clots (3). They may also present as cystic lesions with irregular walls due to an adherent clot or may contain internal debris that is not vascularized. Recent hemorrhage frequently appears as an irregular echogenic mass (3) (Fig. 2). A complex mass with internal echoes enhanced through transmission is also a common finding of hemorrhagic functional cysts (3).



Cyst, Follicular, Ovarium. Figure 3 Follicle cyst in a 31-year-old female patient. Transaxial T1-weighted imaging (WI) (a) and T2-WI (b) show a 6-cm right adnexal lesion. It is cystic and displays higher signal than water on T1-WI (a) due to proteinaceous contents. Thin walls and no evidence of mural thickening or solid areas are demonstrated on T2-WI. Small amounts of ascites in the cul-de-sac are a physiologic finding in this age. The differential diagnosis from unilocular cystoma was only possible by a follow-up.

Echogenic free fluid in the cul-de-sac is a typical finding of cyst rupture into the peritoneal cavity. However, in women of reproductive age, a pregnancy test is mandatory for differentiation of hemorrhagic functional cysts and ►ectopic pregnancy.

The clue for establishing the diagnosis of functional cysts with watery contents or hemorrhage and for their differentiation from cystadenomas is the decrease in size and change of the internal architecture during a sonographic follow-up. The vast majority of functional cysts will regress within a 2-month observation period (2).

MRI is usually performed complementary to sonography in indeterminate cases. It is particularly helpful for differentiating functional cysts with a complex pattern from hemorrhagic ovarian lesions of other etiologies and teratomas.

Simple ovarian cysts display well-defined, thin walls (<3 mm). Most ovarian cysts have a low to intermediate signal on T1-WI and very high SI on T2-WI due to the presence of simple fluid (2). Cyst walls are usually clearly identified on T2-WI, they display low SI, and enhance mildly following contrast media application. Hemorrhagic and corpus luteum cysts display high to intermediate signal on T1-WI and intermediate to high SI on T2-WI (2). Their appearance varies according to the quantity and age of their hemorrhagic and proteinaceous contents (Fig. 3). Corpus luteum cysts tend to have thicker walls that display smooth distinct contrast enhancement (2). Internal debris is often present, but does not enhance. Enhancement is a sign of solid internal contents, and is highly suggestive of malignancy. Low-signal intensity on T2-WI presenting shading is due to repetitive hemorrhage and allows the diagnosis of endometriomas (2). The diagnostic feature of benign teratomas is demonstration of intralesional fat, which can be diagnosed by fat-suppression techniques.

If an ovarian cyst does not decrease in size, unilocular cystoma, which can present with the same imaging features as functional cysts, is the most important differential diagnosis (2). ▶Mesothelial and tubal inclusion cysts occur in the same age group and can also display similar imaging findings to simple ovarian cysts. They can only be differentiated from physiologic ovarian cysts when they are visualized separate from the ipsilateral ovary.

Annular Fissures; Degenerative Disease of the Spine; Degenerative Facet Disease; Facet Arthropathy; Spondylarthrosis; Spondylosis

Definitions

Degenerative disease of the spine is a common disorder, which involves the bony and soft tissue structures of the spine and may result in back pain, radicular pain, and neurological deficits. In spondylosis, all anatomical structures of the so-called "▶disco-somatic unit" (intervertebral disk, vertebral bodies, facet joints, ligamenta flava, longitudinal ligaments) are involved in the degenerative process, usually at multiple levels. Other terms associated with spinal degeneration like "spondylarthrosis" and "degenerative disk disease" refer to more specific anatomical locations i.e., facet joints and intervertebral disk, respectively. However, degenerative changes of one structure e.g., intervertebral disk, sooner, or later lead to the involvement of the whole disco-somatic unit.

Degenerative changes of the spine are part of normal aging; they start in late adolescence and progress with age, and may or may not manifest themselves clinically. Many factors can accelerate the development of degenerative changes, e.g., developmental anomalies or infectious disease of the spine. However, the most important factor is trauma, both acute and chronic, including chronic overload.

Degenerative disease is located most frequently in lumbar spine, followed by the cervical spine and the thoracic spine. The lower sections of the lumbar spine (L4-S1 segments) and cervical spine (C4-C7 segments) are most commonly involved.

Pathology/Histopathology

The first stage of disease is usually degenerative dehydration of the nucleus pulposus of the intervertebral disk, combined with fissuring in the adjacent annulus fibrosus (▶annular tears) and endplate cartilage microfractures.

These annular tears (concentric, transverse and radial) are present in almost all individuals over forty, however some of them (especially radial tears) can result in disk herniation. Other expressions of disk degeneration are vacuum phenomenon (gas collection, mostly nitrogen within the disc) and calcifications.

Injury of the endplate cartilage causes an aseptic reaction of the subchondral bone, with increase of the water content (discovertebritis, aseptic spondylodiscitis). The further stages of the ▶vertebral body degeneration are fatty degeneration and osteosclerosis, as well as formation of marginal osteophytes. The degeneration of the endplates can result in irregularities (erosive osteochondrosis) or intravertebral disk herniations.

▶Facet joint degeneration appears as hypertrophy with formation of osteophytes of articular processes, narrowing of the joint space; less commonly as vacuum phenomenon, synovial hypertrophy, or synovial cysts. Facet degeneration together with disk degeneration may lead to ▶degenerative spondylolisthesis (anterolisthesis-anterior displacement of the upper vertebra or rethrolisthesis-posterior displacement of the upper vertebra). Involvement of the ligamenta flava results in flaval hypertrophy. All the changes mentioned above can lead to spinal stenosis, either central (narrowing of the central part of the spinal canal) or lateral (narrowing of the lateral recesses of the spinal canal and the intravertebral foramina). This in turn can lead to compression of the spinal cord, (with cord ischemia, edema, myelomalacia or gliosis) or of the cauda equina.

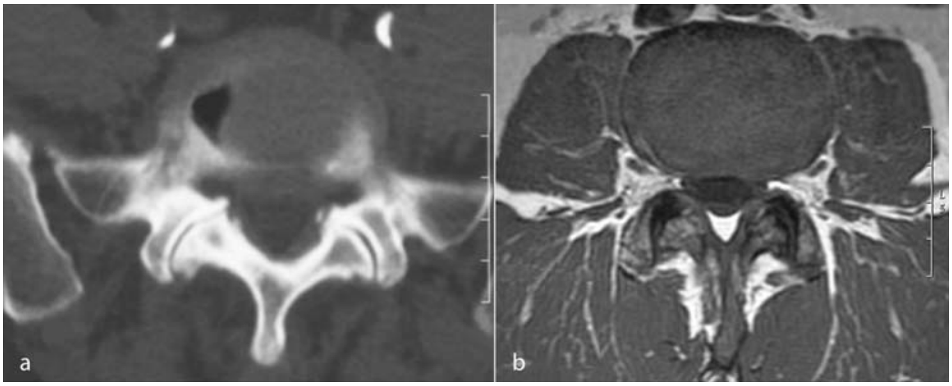
Clinical Presentation

The most common clinical symptom is back pain of variable severity, constant or intermittent, located at the level of the involved spinal segment. Asymmetric disk herniation, lateral spinal stenosis or osteophytes compressing the nerve roots, cause radicular pain or deficit located according to the affected root. Lumbar spinal stenosis may lead to neurologic claudication (pain and numbness of the legs while walking and standing, relieved by sitting) and in cervical or thoracic region to myelopathy with disorders of gait and micturition and reflex abnormalities due to the chronic compression of the spinal cord.

Imaging

Conventional radiography still is usually initial radiological study in these patients, and enables preliminary assessment of bony changes (osteophytes, sclerotic areas in the vertebral bodies, spondylolisthesis, erosive osteochondrosis, scoliosis) as well as direct and indirect signs of disk degeneration (narrowing of an intervertebral space, vacuum phenomenon, disk calcifications), associated congenital anomalies such as transitional vertebrae and in some cases pathology like neoplasms or spondylodiscitis. Lack of direct visualization of soft tissues however severely limits the diagnostic utility of plain films in degenerative, neoplastic, and infectious disease.

Computed tomography (CT) can be applied especially in degenerative bone lesions. It provides good visualization of vertebral body osteophytes and osteosclerotic reaction, facet joint degeneration (Fig. 1) and spinal stenosis, as well as presence of gas (vacuum phenomenon) and calcifications in the degenerated intervertebral disk. However, degenerative bone marrow changes are not detected (see later). CT is also inferior to MRI in evaluating soft tissue lesions such as disk herniation and spinal cord compression. A major disadvantage of CT was formerly the limited coverage of the study in axial plane, now overcome with the introduction of multislice spiral CT units, which also provides excellent multiplanar and 3D reconstructions of bony spinal elements.



Degenerative Conditions of the Spine. Figure 1 Facet degeneration. (a) CT bone-window image. Degenerative changes in the facet joints, with hypertrophy of the articular processes and osteophytes, narrowing of the lateral recesses of the spinal canal. Note also the vacuum phenomenon in the intervertebral disk. (b) Axial T1-weighted MR image in another patient. Marked degenerative changes of the facet joints, with hypertrophy of the articular processes, narrowing of the intervertebral foramina bilaterally.

D

Magnetic resonance imaging (MRI) is the method of choice in patients with spondylosis who demonstrate persistent back pain or neurological symptoms. MRI provides excellent visualization of all spinal structures involved in degenerative process (Fig. 2).

The basic MRI protocol includes spin-echo (SE) or fast spin-echo (FSE) T1 and T2-weighted images in the sagittal plane as well as SE/FSE T2-weighted or gradient-echo (GRE) $T2^*$-weighted images in axial planes. Fat suppression techniques allow better assessment of the bone lesions and MR myelography a better evaluation of root involvement. Gadolinium enhancement can be used to differentiate scar from recurrent herniation in postoperative cases or degenerative changes from infectious and neoplastic lesions.

Desiccation of the nucleus pulposus is seen as a signal loss on T2-weighted images, annular tears as linear areas of increased signal on T2-weighted and postcontrast T1-weighted images (high intensity zones - HIZ) (Fig. 3). Vacuum phenomenon and calcifications may occasionally be visible on gradient-echo images.

Disc bulging and disc herniation should be evaluated on both sagittal and axial images.

Degenerative bone marrow changes adjacent to vertebral endplates were described by Modic: Type 1 lesions (aseptic spondylodiscitis) exhibit decreased signal on T1-weighted images and increased signal on SE T2-weighted images. Type 2 changes (fatty degeneration) have increased signal on T1-weighted images and intermediate signal on SE T2-weighted images, increasing with FSE T2 weighting. Type 3 (osteosclerosis) have low signal on both T1 and T2-weighted images. MRI also enables diagnosis of vertebral osteophytes (especially with GRE sequence) and erosive osteochondrosis.

Facet joint and ligamenta flava degenerations are well seen on axial images as hypertrophy of the articular processes and thickening of the ligamenta flava, which can contribute to stenosis of the spinal canal and intervertebral foramina (Fig. 1b, Fig. 3).

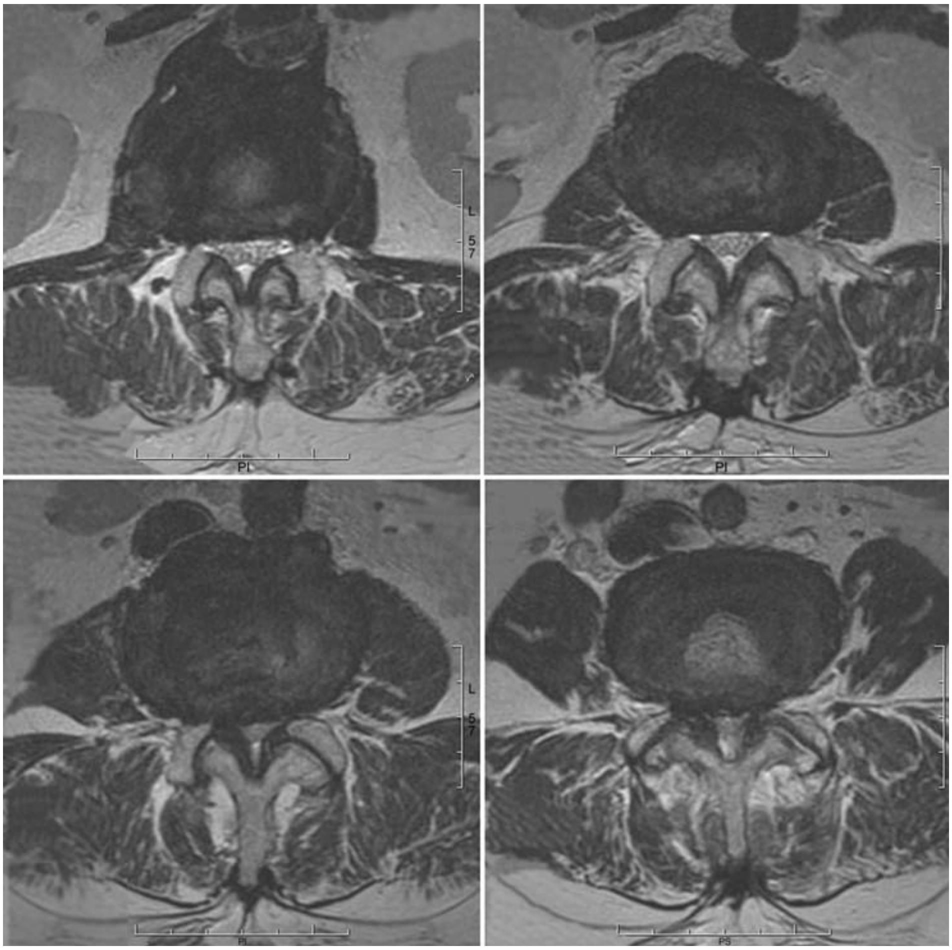
Degenerative spondylolisthesis and its impact on intraspinal structures can be easily assessed on sagittal images. Stenosis of the spinal canal is best demonstrated on axial images (Fig. 2), and stenosis of the intervertebral foramina on lateral sagittal images.

A major advantage of MRI is the direct visualization of the spinal cord. Compression of the cord and the changes caused by chronic compression can be detected on T2-weighted images.

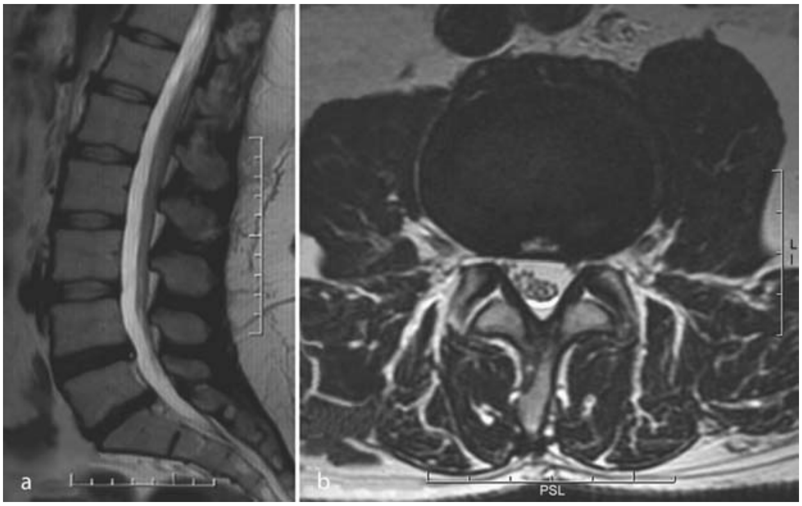
Postoperative scar tissue enhances homogenously after gadolinium injection and thus can be differentiated from recurrent herniation.

Myelography and radiculography (lumbar myelography) used to be the main method of diagnosing dural sac and nerve root compression due to disk herniation or spinal stenosis. Nowadays, being an invasive study it has been almost completely replaced by CT and MRI, including MR myelography. CT myelography provides more accurate information than conventional myelography/radiculography; however, it is also invasive and was thus abandoned as well.

Discography and CT discography (imaging after injection of contrast medium into the intervertebral disk) are used mainly in centers performing interventional spine procedures. The aim of discography/CT discography is, on one hand, to visualize leakage route of the nucleus pulposus material and, on the other hand, to provoke pain and thus confirm that the examined disk is responsible for the patient’s symptoms.



Degenerative Conditions of the Spine. Figure 2 Axial T2-weighted MR images. Degenerative changes in the intervertebral disk (bulging), vertebral bodies (osteophytes), facet joints (hypertrophy of articular processes) and ligamenta flava (hypertrophy) result in severe stenosis of the spinal canal and intervertebral foramina.



Degenerative Conditions of the Spine. Figure 3 Sagittal (a) and axial (b) T2-weighted MR images in two different patients. High intensity zones (HIZ) in the posterior annulus fibrosus, indicating radial tears. In the sagittal image there are also decreased signal intensities and bulging of L4/L5 and L5/S1 intervertebral disks indicating degeneration.

Vascular studies (Doppler sonography, MR angiography, CT angiography) are advocated in patients with severe cervical spondylosis and cerebellar symptoms, to detect possible compression of the vertebral artery by osteophytes or disk herniation.

Nuclear Medicine

Bone scintigraphy has a limited role in the evaluation of degenerative spine disease. It is usually performed if X-ray/CT/MR images are not clear and do not allow differentiation of vertebral degeneration from neoplastic or infectious lesions of the vertebrae. Usually the latter have markedly increased radiotracer uptake, while degenerative lesions do not show abnormal radioactivity or exhibit a slight, unspecific increase in uptake.

Diagnosis

Diagnosis of degenerative disease of the spine is based on clinical history, physical and neurological examinations as well as imaging studies. In patients with slight or moderate back pain without radicular symptoms and neurological deficit, or “red flags” indicating for example possible neoplastic or infectious disease, imaging can be dispensed with or limited to conventional radiography.

In patients with severe, persistent pain and/or radicular symptoms and/or neurological deficits, MRI or CT is indicated. MRI is the method of choice in such cases, because it provides the best visualization of degenerative changes, soft tissue pathology and nerve root or spinal cord compression (see earlier). CT is performed in patients with the contraindications to MR (e.g., pacemakers) and in cases where detailed assessment of the bone structures is needed (e.g., in central spinal stenosis or facet joint degeneration). Myelography/radiculography and CT myelography are almost completely abandoned. Discography or CT discography is performed in selected groups of patients to confirm the association of clinical symptoms with the imaging findings (see earlier). Vascular studies (Doppler sonography, MR angiography, and CT angiography) are advocated when compression of the vertebral artery by degenerative changes is suspected.

Interventional Radiological Treatment

Interventional procedures in degenerative spinal conditions form a rapidly growing therapeutic field, which have become serious alternatives to surgical procedures and other treatment options. The most frequent interventional procedures are:

- epidural steroid injections
- anesthetic nerve root or facet block
- radiofrequency pulse techniques of denervation of the nerve structures
- injection of spinal cysts (e.g., synovial cysts of the facets) to remove fluid
- transcutaneous discectomy
- electrotherapy of the intervertebral disk

Definition

OA is a non-inflammatory joint disease characterized by degeneration of the articular cartilage, hypertrophy of bone at joint margins and changes in the synovial membrane. It is best described as a disease of organ failure in which injury to one joint component leads to damage of other components and finally to joint failure ('whole organ disease').

Traditionally, osteoarthrosis was classified as either *primary*, when there is no obvious predisposing cause or underlying abnormality, or *secondary*, when the disease results from anatomic, metabolic or traumatic predisposing factors. However, this classification is misleading as it seems that some mechanical alteration can be found in most of the affected joints so that the term 'primary DJD' seems to merely reflect limited diagnostic capabilities.

OA is common in most populations. It disables about 10% of people older than 60 years with estimated costs of more than \$60 billion per year in the US economy (1). More than 75% of individuals over 70 years of age show definite radiographic evidence of osteoarthrosis. OA occurs with equal frequency in men and women with different patterns of joint involvement predominating in each gender. Osteoarthritis of the hands and knees is slightly more common in women while a male preponderance is noted for osteoarthritis of the hip.

Degenerative disease of peripheral joints often affects the joints of the hands, including the proximal and distal interphalangeal joints and the carpometacarpal joint of the thumb, the hip, the knee and the first metatarsophalangeal joint. It is less common in the ankle, wrist, elbow and shoulder which are rarely affected without previous trauma.

Pathology/Histopathology

Although the incidence increases with age, the disease is not solely caused by ageing of articular tissues. Joint trauma, pre-existing articular disease such as rheumatoid arthritis or haemophilia may accelerate the development of OA. Evidence is growing for the role of systemic factors (e.g. genetics, bone density) and of local biomechanical factors (e.g. muscle weakness, obesity) which are particularly important in weight-bearing joints (2). Biochemical forces also play an important part. Cytokines (interleukin-1, tumour necrosis factor-b) and other mediators released from cartilage, synovium or bone affect chondrocyte function and may result in increased enzymatic proteolytic activity. Collagenase 1, 2 and 3 contribute to further breakdown of the cartilage.

Recent findings have re-introduced the potential role of abnormal subchondral bone cell metabolism in the etiopathogenesis of OA. Although the initiating event for cartilage degradation in OA is still unclear one hypothesis is that cartilage breakdown is stimulated by cytokines and growth factors (interleukin-1ß, interleukin-6) locally produced by osteoblasts within the subchondral bone. Considerable evidence indicates that channels and fissures between cartilage and bone provide a route for these biological signals between the compartments. Insulin-like growth factor-1 promotes bone remodelling and proliferation, leading to increased bone stiffness, a situation exacerbating cartilage breakdown; hepatocyte growth factor activates collagenase 3 involved in cartilage degradation and vitamin A derivates induce ectopic collagen type 1 promoting the dedifferentiation of chondrocytes.

In weight-bearing joint areas, progressive thinning of the cartilaginous surface occurs resulting in joint space loss. The involved cartilage develops crevices and cracks which in a later stage progress to large areas of erosions and ulcers of variable depth. Eventually, entire segments of cartilage may be lost. When the cartilage is thinned or absent from the articular surface, the underlying bone is subject to greater local stresses. The weakened subchondral bone shows trabecular fractures, flattening and collapse. Vascular invasion, bone marrow bleeding, infarction and necrosis of subchondral trabeculae account for the bone marrow oedema (BME) like signal pattern in MRI. In addition, bony sclerosis and cyst formation develop. In the less weight-bearing segments at the joint margins, hypervascularity of bone marrow is observed in histologic specimen accounting for remodelling of the bone and the formation of osteophytes. Synovial membrane changes are not as prominent in most patients with DJD as in rheumatoid arthritis. However, synovial inflammation is seen in some phases of the disease and becomes more frequent with increasing disease severity. Osseous or cartilaginous debris leads to local irritation and cause proliferative synovial alterations. This may lead to a vicious circle with release of new mediators of synovial inflammation that cause progressive cartilage damage, more debris and by this contribute to persistent inflammation.

Clinical Presentation

DJD is characterized by pain and loss of the joint's form and function. Pain is typically insidious in the onset of the disease and gradually progresses, usually for many years. Significant cartilage damage may have occurred before relevant clinical symptoms and radiographic signs appear. Pain is commonly present when the joint is in motion and is—at least in early stages—relieved by rest. Joints often stiffen for short durations after periods of rest, and stiffness tends to abate after a few minutes of motion. Examination of the involved joints may reveal mild tenderness, pain, restricted range of movement, joint effusion and crepitus. In advanced OA, gross deformity, bony enlargement, angulation and marked loss of joint movement may be seen. Frequent complications are misalignment and subluxation of joints. Fibrous or bony ankylosis is rare. Most routine blood tests are normal in patients with uncomplicated OA; however, in inflammatory episodes elevated CRP values and leucocytosis may be noted. Analysis of synovial fluid usually reveals a white cell blood count of less than 2,000/mm^3.

Imaging

Conventional radiographs. There are known inconsistencies between findings on conventional radiographs and clinical symptoms, with only 50% to 60% of subjects with radiographic OA being clinically symptomatic. Clinical symptoms may precede radiographic findings by up to approximately 10 years. The diagnosis of osteoarthrosis in day-to-day practise typically relies on radiographic findings that include joint space loss, cyst formation, subchondral bone sclerosis and osteophytosis (Fig. 1a) findings observed on CT images, too.

MR imaging. MR imaging with high spatial resolution proves to be an important tool in the early detection of OA by identifying cartilage alterations that precede loss of cartilage thickness as identified by joint space narrowing on radiographs. Additionally, MRI is helpful in the follow-up of OA since it directly shows cartilage defects, BME and concomitant internal joint derangement (Fig. 2). Especially meniscal damage and BME are thought to be related to the progression of OA, pathologies that are not visualized by radiographs. Since the development of rapid high resolution 3D gradient echo techniques, such as FLASH or DESS sequences, MRI has been used to diagnose early stages of the disease and to monitor disease progression. Two groups of MR sequences are currently recommended for cartilage imaging: moderately T2-w TSE FS and T1-w 3D GRE FS/WE sequences. In T2-w TSE FS sequences (Fig. 2a, b) the high signal of joint fluid provides an arthrogram-like effect visualizing irregularities and focal defects of the cartilage surface. In addition, these sequences depict internal cartilage signal alterations and allow the assessment of subchondral BME. However, differentiation of deeper cartilage zones from subchondral bone may be difficult. T1-w FS/WE 3D GE sequences (Fig. 2c) profit from high SNR values and spatial resolution for the assessment of gradual cartilage loss. The homogeneous hyperintense signal of cartilage provides a good differentiation of cartilage from subchondral bone. However, there is low sensitivity to internal cartilage matrix changes and differentiation of cartilage from the joint surface can be difficult in (especially proteinaceous) joint effusion.

In addition to clinical diagnosis, more experience has been gained with modern techniques to detect and monitor subtle changes in cartilage structure and metabolism that precede cartilage substance loss. In view of development of disease-modifying drugs or OATS, ACI, microfracture procedures, these tools may alter routine diagnostic in the future. Currently, most data are available from *quantitative volumetric MRI* studies aiming at accurately identifying reduced cartilage volume and ongoing cartilage loss in OA (3). *T2 relaxation time measurements* are related to the collagenous fibre architecture and water content of cartilage. Findings in several studies have indicated that an increase in ►cartilage T2 is a characteristic of cartilage degeneration. (4). ►*Delayed gadolinium enhanced MRI (dGEMRIC)* (5) has been introduced to examine the relative distribution of glycosaminoglycans (GAGs)within the cartilage whose reduction may indicate reversible early damage of cartilage. The dGEMRIC index (longitudinal relaxation time, T_1 (Gd) index) is related to GAG content and differs between asymptomatic and OA joints with a higher index in healthy than in osteoarthritic joints.

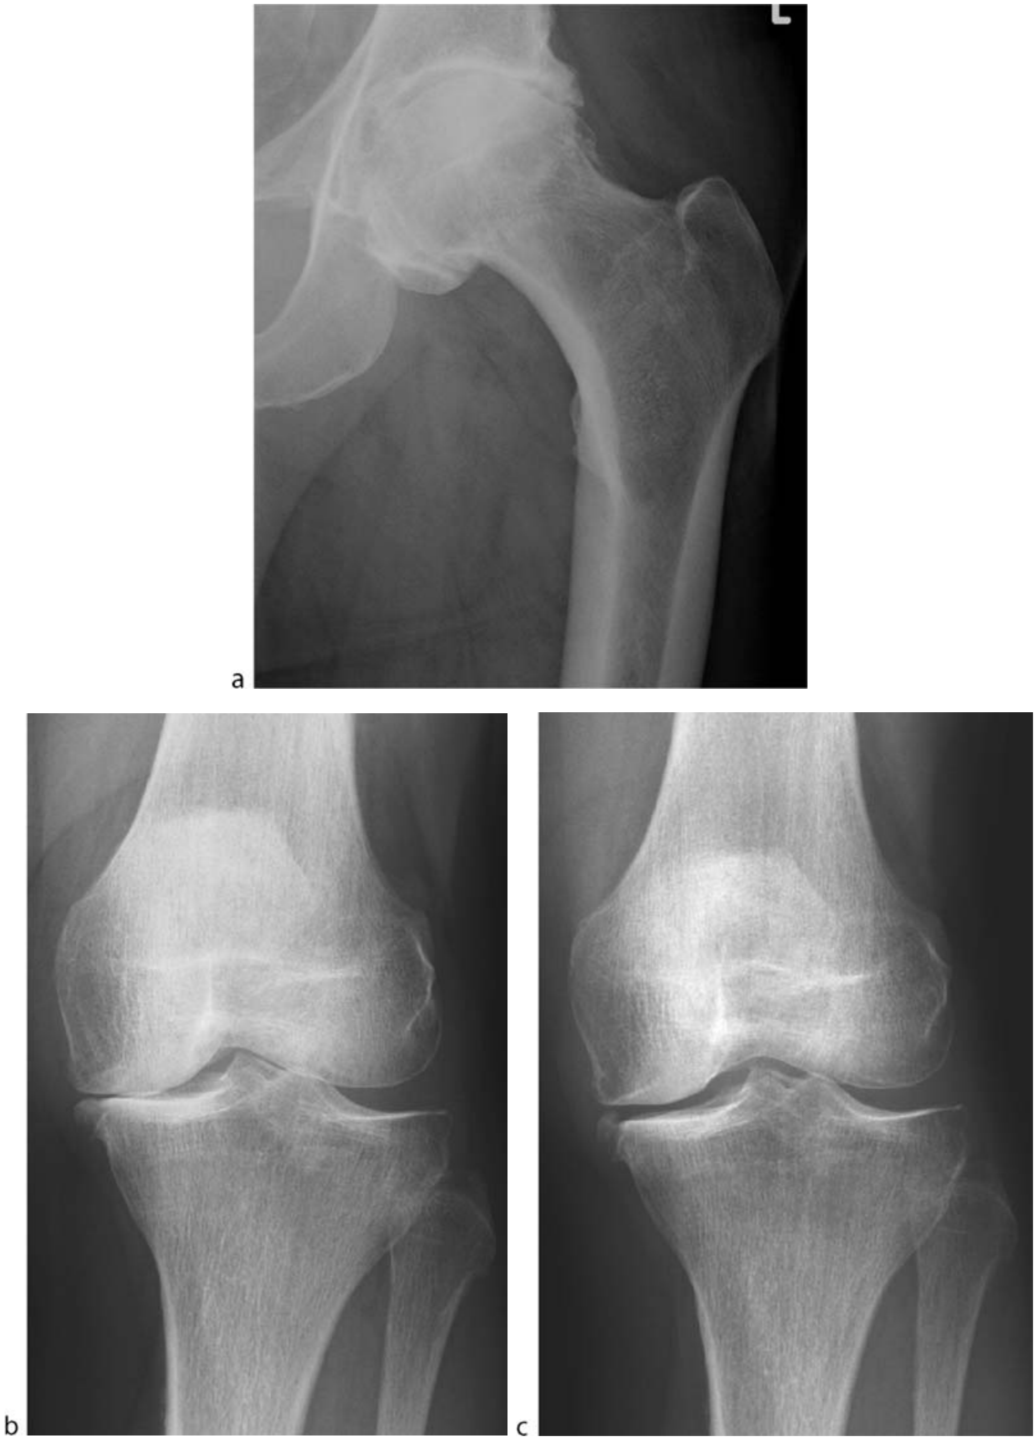
Nuclear Medicine

Bone scintigraphy does not play an important role in the diagnostic process of DJD.

Diagnosis

In clinical routine, the diagnosis 'osteoarthrosis' is commonly suspected after physical examination due to pain and loss of joint function. Conventional radiography then confirms the clinical suspicion.

The *American College of Rheumatology* (*ACR*) has developed *diagnostic criteria* for osteoarthritis at various sites (hip, knee and hands). They comprise pain, patient



Degenerative Joint Disease, Peripheral Joints. Figure 1 **OA in the hip (a) and knee (b, c). There is bony outgrowth, ►joint space narrowing and subchondral sclerosis. Please note the reduction in the apparent joint space width and the more pronounced varus alignment in the weight bearing (b) as compared to the non-weight bearing knee radiograph (c).**

age, morning stiffness lasting 30 min or less, deformity of joints, crepitus on motion, erythrocyte sedimentation rate of less than 20 mm/h and osteophytes/joint space narrowing on radiographs.

In daily routine, radiological confirmation is usually made on (whenever possible weight-bearing) conventional radiographs. Imaging under weight-bearing is capable to demonstrate joint space width narrowing to

Degenerative Joint Disease, Peripheral Joints. Figure 2 (a, b) Moderately T2-w fs TSE MRI (TE 3000/TR 30) allows excellent differentiation of cartilage from both, joint effusion and subchondral bone. In addition to joint space narrowing, MRI shows bone marrow oedema (BME) of the medial femoral condyle, mild joint effusion and thinning of the cartilage. Please note the associated meniscal pathology, potentially indicating further progression of disease. (c) Coronal 3D-FLASH WE MRI (TE 21/TR 9/FA 25) shows cartilage with uniformly high signal intensity, good differentiation from subchondral bone and (apart from proteinaceous effusion) reasonable differentiation of cartilage from joint effusion. Profiting from the high spatial resolution even more subtle cartilage thinning can be visualized. Please note the intra-articular osteophyte in the medial femoro-tibial compartment and the lateral meniscal extrusion.

a better extent than imaging in the unloaded position (Fig. 1b, c). The semi-quantitative ►*Kellgren–Lawrence Grading System* (developed in 1957) uses joint space narrowing, the formation of osteophytes, subchondral sclerosis and cysts and joint deformity to grade disease severity into four grades, from normal to severe osteoarthrosis (6).

In addition and among others the WOMAC, KOSS and WORMS scores are used for the assessment of osteoarthrosis. Since its development in 1982 the validated *WOMAC* (*Western Ontario McMasters University*) ▶ *Osteoarthritis Index* is used for clinical evaluation (questionnaire) of disease severity. The latest revised version is available in 65 alternate language forms and assesses pain, disability and joint stiffness using 24 questions. For monitoring of disease progression in the knee, the MRI-based semi-quantitative *MR Knee osteoarthritic scoring system* (▶ *KOSS-score*) has been described by Kornaat et al (2005). Images are scored for the presence of cartilaginous lesions, osteophytes, subchondral cysts, BME, meniscal abnormalities, effusion, synovitis and Baker's cyst. Similarly, the MRI-based *Whole-organ Magnetic Resonance Imaging Score* (▶ *WORMS-score*) described by Peterfy et al (2004) incorporates 14 features among them in addition to the KOSS-score the integrity of cruciate and collateral ligaments and intra-articular loose bodies providing a morphologic 'whole organ' assessment of the knee.

Degenerative Joint Disease (DJD)

▶ Degenerative Joint Disease, Peripheral Joints

Degenerative Spondylolisthesis

Displacement of the vertebral body in relation to the one below, in the course of degenerative disease of the spine, mostly due to facet joint arthropathy and ▶ intervertebral disk degeneration. Anterior displacement is called anterolisthesis and posterior displacement – retrolisthesis. Spondylolisthesis could be diagnosed on the plain films or CT sagittal reformatted images. MRI provides additional information concerning disk degeneration and degenerative signal changes in adjacent parts of vertebral bodies as well as facet degeneration.

▶ Degenerative Conditions of the Spine

Dejerine–Klumpe Paralysis

Injury to the eighth cervical and first thoracic nerve roots or lower trunk.

▶ Trauma Birth

Delayed Adverse Reactions to Intravascular Contrast Media

Reactions occurring between 1 h and 1 week after contrast medium injection.

▶ Adverse Reactions, Iodinated Contrast Media, Delayed

Delayed Adverse Reactions

▶ Adverse Reactions, Iodinated Contrast Media, Delayed

Delayed Gadolinium-enhanced Magnetic Resonance Imaging (dGEMRIC)

A method to examine the relative distribution and content of glycosaminoglycans (GAGs) throughout the cartilage. It contributes to detect early degeneration of cartilage by depicting proteoglycan loss.

▶ Degenerative Joint Disease, Peripheral Joints

22q11.2 Deletion

This genetic abnormality (as frequent as 1 in 4,000 live births) often results in several characteristic abnormalities of the upper cervical spine. It encompasses several syndromes including DiGeorge, Shprintzen, and Sedláčkova syndromes. Heart defects and palate defects may be associated.

Synonym

Osteopenia

Definitions

Decreased bone substance or mass; may be generalized or localized. In childhood, generalized demineralization (i.e., osteopenia) is either due to ▶osteoporosis or to ▶hyperparathyroidism. After physes have fused, osteomalacia is the third possible cause. The World Health Organisation (WHO) definitions of osteopenia and osteoporosis are not pertinent to pediatrics (1). In general, bone demineralization leads to a lower threshold for fracture; a consequence of immobilization for fracture is disuse osteoporosis, generally a reversible phenomenon. It should be noted that the human eye-and-brain is not a densitometer, but a recognizer of interfaces. Bone density measurement by X-ray densitometry techniques is less accurate in children than adults. Recognition of osteoporosis and hyperparathyroidism by evaluations of interfaces works well in childhood. The amount of bone mass in childhood and adolescence affects quantity of bone mineral later in adulthood.

Pathology/Histopathology

In osteoporosis, a child has less osseous tissue than normal. Eventually, cortical bone is thinner than normal. In acutely and chronically demineralized bone, the trabeculae are thinner than normal, although remaining trabeculae may thicken to buttress the bone. Such bones are more susceptible to fracture. Increased fragility may be caused by osteocytic osteolysis or by decreased bone formation. In hyperparathyroidism, less bone is also present, but cortices are more tunneled than normal, rather than thinned. Since some trabeculae are lost by the process, the remaining trabeculae thicken (possibly an attempt to maintain bony strength). Primary hyperthyroidism is due to parathyroid overactivity from adenoma or hyperplasia. The lamina dura around teeth, the equivalent of tubular bone cortex, becomes washed out and difficult to define on radiographs. In rickets, enchondral growth cartilage remains unmineralized at the ▶zone of provisional calcification (ZPC) and continues as osteoid. With initiation of treatment of nutritional rickets, matrix vesicles at the ZPC rapidly ossify, followed by gradual ossification of rickets-affected osteoid between that zone and the already ossified metaphysis. The bony changes of hyperparathyroidism secondary to rickets take longer to heal than treated rickets.

Metaphyseal lucent bands on radiographs during stress represent bone laid down without as much mineral content as otherwise, presumably because the body is expending energy elsewhere during a relative crisis or stress. The lucent bands are known as leukemic lines, but are also seen from intrauterine stress, from adapting to extrauterine life, or from serious illness that lasts for some time. The ZPC remains normally calcified in these situations.

Clinical Presentation

Almost all conditions of generalized bone demineralization are associated with increased incidence of fracture (as do the "overmineralization" conditions of osteopetrosis). Back pain may be related to collapsing vertebrae in osteoporosis. Children under 10 years of age who have a slip of their capital femoral epiphysis usually have an underlying endocrine abnormality, especially hyperparathyroidism or hypothyroidism (some also have Down syndrome). In former times, irradiation of the hip was another cause. Children with scurvy osteoporosis may have a slip the distal femoral epiphysis. Children with rickets may have swollen wrists and knees and knobby anterior rib ends (rachitic rosary) at presentation. The child who walks despite secondary hyperparathyroidism and rickets may develop bowed femurs and tibias.

Imaging

For generalized osteoporosis on plain images, a single lateral image of a calcaneus and nearby bones should be selected. For rickets, a frontal image of the left knee and one of the left wrist should be obtained. For hyperparathyroidism, a hand and wrist image and, if possible, an oblique image of the mandible to observe for lamina dura around the teeth should be obtained. The hand and wrist image is a good study for all three of the above metabolic demineralization conditions. For fracture search, a full skeletal survey is needed.

Densitometry techniques use computed tomography (CT) images, X-ray transmission technology, and ultrasound techniques. Standards are now available for infants and children. Importantly, they differ from adults, and adult standards should *not* be used. It should be noted that physes are open in children and are of cartilaginous density except for the ZPC, and if included in the sampled region they would lower the value recorded. Similarly, in rickets, unmineralized cartilage extends even further into the expected metaphyseal region. Bone densitometry is valuable in clinical use especially in the evaluation of bone mineralization (see Table 1).

Nuclear Medicine

Bone scanning is useful for detecting or confirming fractures in osteoporosis or hyperparathyroidism. Technetium-99m sestamibi scanning is used to investigate for parathyroid tumors in primary hyperparathyroidism. In oncogenic rickets or osteomalacia, nuclear imaging may identify the responsible benign or malignant causative lesion that is secreting ►fibroblast growth factor 23 (FGF-23) (2). In hyperparathyroidism, brown tumors may take up radionucleotide. In active hyperparathyroidism, a superscan of generalized increased activity is seen on technetium bone scan. Apparent reflex sympathetic dystrophy in children is almost always pain- or immobilization-induced disuse osteoporosis, and hence not hyperactive on bone scan, except at a fracture.

Diagnosis

Human beings are not densitometers, but are excellent recognizers of interfaces. In osteoporosis, the cartilaginous ZPCs are not demineralized, therefore a greater than normal difference is noted between them and adjacent demineralized bone. The ZPC becomes a sharply seen thin line, for example, at the outer edge of growth centers, tarsal (Fig. 1) and carpal bones, and the nonepiphyseal ends of small tubular bones. In rickets, the ZPCs are not calcified, so that the edges of these bony parts are indistinct. As rickets becomes established, more of what should have been metaphysis is unossified, so that the ►metaphyseal collar (with its 1–3 mm straight margin) disappears. After successful treatment of the rickets, the ZPC rapidly returns, in less than 10 days, followed by filling in of the metaphyseal collar (Fig. 2). As osteoporosis is established, cortices (from membranous bone)

Demineralization, Bone, Childhood. Figure 3 An extraordinarily severe secondary hyperparathyroidism in an infant, with very coarse remaining trabeculae and cortex so washed out as to be barely perceivable. Metaphyseal fracture of at least the radius is one result of the metabolic change.

become thinned in width, but remain well defined. In hyperparathyroidism, cortices have increased tunneling and appear washed out and indistinct (Fig. 3), unlike those of osteoporosis. In hyperparathyroidism, the lamina dura around teeth vanishes by a similar process, and the calvarium may appear demineralized in a salt and pepper pattern. In rickets with hyperparathyroidism, the end plates of vertebral bodies, which are ZPCs in childhood, become indistinct; in osteoporosis, they are more than normally distinct because of demineralized adjacent bone. In both forms of osteopenia, namely, osteoporosis and hyperparathyroidism, fractures are common because of bone of decreased strength. In severe hyperparathyroidism, callus from fracture may, however, not calcify sufficiently to be seen on radiographs after 10 days, a rarity. The margins of the terminal tufts of phalanges may become discontinuous in rickets/hyperparathyroidism. Sharply defined lucent bone lesions, the so-called brown tumors, can appear in advanced hyperparathyroidism. If rickets is clearly evident without hyperparathyroidism, phosphate-losing renal disease, very early rickets, ifosfamide therapy, or FGF-23 fetal growth factor-secreting benign or malignant tumor should be considered as the cause of the rickets.

Densitometry imaging methods usually define a value deviating from an age-matched expected value; the greater the deviation, the less bone substance is judged present.

Metaphyseal and metaphyseal-equivalent (areas adjacent to acrophyseal growth plates) lucent bands are a sign of general stress for some time on the body, be it intrauterine stress, birth, leukemia and other major illness, and occasionally child abuse. If present in the first few days of life, then intrauterine stress is likely. A well-documented cause of lucent bands at birth is infants whose mothers received magnesium therapy late in the pregnancy. The most common cause of “leukemic lines” is birth, with the lucency appearing after about 10 days of age and lasting for a few months in most infants. Bone-in-bone vertebrae, normally seen in all infants several weeks to months of age, is a manifestation similar to the normal metaphyseal lucencies following the stress of birth and adjustment to extrauterine life: prenatal bone and vertebral end plates (ZPC) are not demineralized, causing the bone-in-bone appearance.

Local demineralization is relatively well defined (termed “geographic”) from slow-growing, frequently benign processes. Less-defined margins (“moth-eaten” and more severely “permeated”) are signs of aggressiveness or malignancy, as popularized by Gwilym Lodwick (3). Interestingly, the sharpest margins of all are from the most sudden situation, acute fracture. Although Langerhans cell histiocytosis skull lesions tend to have geographic margins, long bone lesions in this condition often have poorly defined margins, although associated periosteal reaction can be quite solid. In general, thick, solid periosteal reaction reflects slower processes than thin, multilayered, or perpendicular hair-on-end periosteal reaction.

Developmental Venous Malformation

Congenital vascular malformation formed by dilated, radially arranged veins draining into an enlarged vein, with normal intervening brain. It is considered an extreme variation of normal venous drainage. Also known as venous angioma.
▶Congenital Malformations, Vascular, Brain

Di-Ethyl-Stilbestrol (DES)

DES invented in 1948, was mainly prescribed for women who experienced recurrent abortions and premature deliveries. DES induced an increased synthesis of placental steroidal hormones. As a major adverse effect, DES was associated with the development of clear cell carcinoma of the vagina and therefore withdrawn in 1971. Further teratogenic changes included structural anomalies of the uterine corpus, cervix, and vagina. The structural changes are highly variable; mainly hypoplasia of the uterocervical portions can be observed (T-shaped uterus). DES exposure is associated with premature delivery, perinatal mortality, and ectopic pregnancy.
▶ Müllerian Duct Anomalies

Diabetes Mellitus

Diabetes mellitus is a chronic metabolic disorder resulting from absolute or relative insulin deficiency. Patients with longstanding diabetes mellitus are especially prone to osteomyelitis of the feet due to contiguous spread of infection from chronic pedal ulcers. Peripheral neuropathy, peripheral arterial occlusive disease and neuropathic osteoarthropathy are important complications of longstanding diabetes mellitus, which all promote chronic pedal infection and subsequent osteomyelitis.

Dialysis Graft

A synthetic vascular graft, which is placed in between a suitable afferent artery and an efferent vein. The graft can have the form of a loop or can be a straight graft. Most commonly, PTFE is used as graft material because of its good tolerance for repeated cannulation and better patency compared to other synthetic graft material.

Diffuse Alveolar Damage (DAD)

A descriptive term for the sequence of events that occurs after acute severe lung injury and results in necrosis of type I pneumocytes and alveolar endothelial cells. During its acute exudative phase, HRCT usually shows scattered or diffuse ground-glass opacities (GGOs), and in the reparative phase HRCT may show findings of fibrosis, such as irregular linear opacities and bronchiectasis.
▶Diffuse Alveolar Pulmonary Damage and Acute Respiratory Distress Syndrome

Diffuse Alveolar Hemorrhage

Bleeding into the lung parenchyma can be secondary to a wide group of disorders. Initially, HRCT features are widespread lobular GGO with gravity-dependent density gradients through to air-space consolidation often with interspersed areas of GGO. In the process of resorption of intraalveolar blood, parenchymal abnormality is accompanied by inter- and intralobular septal thickening superimposed on areas of GGOs, which may give rise to the appearance of crazy paving.

Diffuse Alveolar Pulmonary Damage and Acute Respiratory Distress Syndrome

KAUCZOR HANS-ULRICH
Department of Radiology,
German Cancer Research Center, Heidelberg, Germany
hu.kauczor@dkfz-heidelberg.de

Synonyms

Acute lung injury (ALI); Adult respiratory distress syndrome (ARDS); Diffuse alveolar damage (DAD)

Definition

Adult respiratory distress syndrome (ARDS) is defined by an inhomogeneous distribution of ventilation and perfusion followed by low oxygenation [oxygenation index (PaO_2/FiO_2) ≤200 mmHg] without cardiac dysfunction (pulmonary capillary wedge pressure ≤18 mmHg) and bilateral infiltrates at chest radiography (1).

Pathology/Histopathology

Adult respiratory distress syndrome (ARDS) is characterized by a general inflammatory reaction of the lung, which results in severe impairment of the permeability of the pulmonary capillaries with subsequent interstitial and alveolar edema. This ▶diffuse alveolar damage (DAD) is the determining factor for reduced pulmonary compliance, depletion of surfactant, gravity-dependent atelectasis, hyaline membranes, vascular congestion, hemorrhage, and fibrosis. Atelectasis is supposed to be responsible for a pulmonary right-to-left shunt as well as an increase of the pulmonary vascular resistance. Although ARDS may be combined with hydrostatic edema, patients with volume overload or heart failure (left-atrial hypertension) are not considered to have ARDS.

The underlying inflammatory processes of ARDS are reflected by a rather typical time course. In the initial, very early exudative stage of ARDS there is minimal fluid leakage into the interstitium caused by sequestration of neutrophils. Mild hypoxia and pulmonary hypertension are already present. In the following, there is increased leakage of fluid into the interstitial space, which is referred to as permeability edema. It is DAD that permits the proteinaceous permeability edema to leak out into the alveoli and result in alveolar collapse. Microscopic hyaline membranes can be found within respiratory bronchioles and alveolar ducts. Soon the other manifestations of DAD dominate: cellular necrosis, epithelial hyperplasia, inflammation, and eventual fibrosis. The pathological picture is dominated by epithelial damage, which overwhelms any manifestations of capillary endothelial damage. Traditionally, the pathological findings of ARDS are divided in four stages: (1) initial, early exudative phase with swelling and damage of the endothelial cells, microatelectasis and subtle interstitial edema; (2) exudation with massive alveolar edema, accumulation of fibrin, and formation of hyaline membranes; (3) proliferation of alveolar cells, accumulation of collagen, destruction of microvasculature, and hyperplasia of pneumocytes type II; and (4) fibrosis (4).

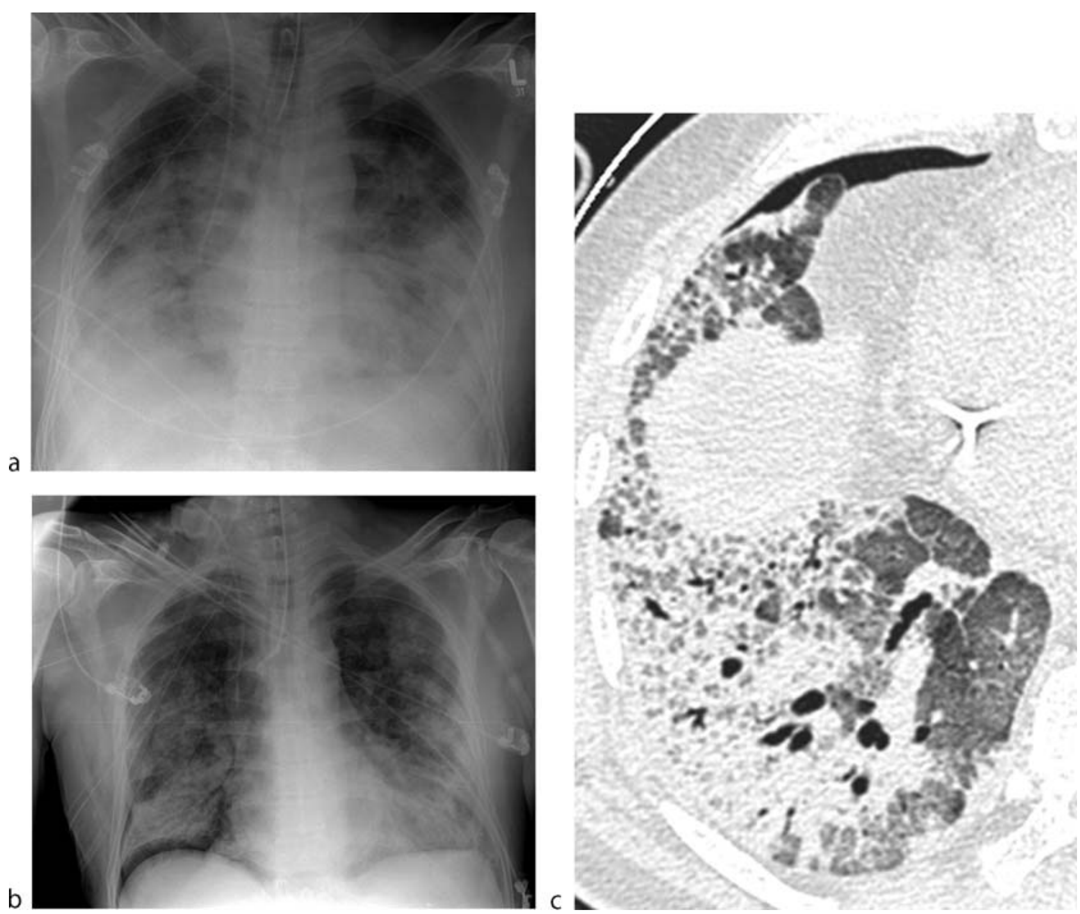
Clinical Presentation

ARDS is a severe form of respiratory failure and goes along the following symptoms: severe dyspnea, tachypnea, cyanosis refractory to oxygen therapy, decreased pulmonary compliance, and bilateral diffuse alveolar infiltrates on chest radiography. ARDS can be caused by multiple different underlying diseases, either pulmonary, such as pulmonary infection, toxic inhalation, or extrapulmonary, such as trauma, sepsis, renal or hepatic failure. ARDS has a high mortality rate of up to 50%.

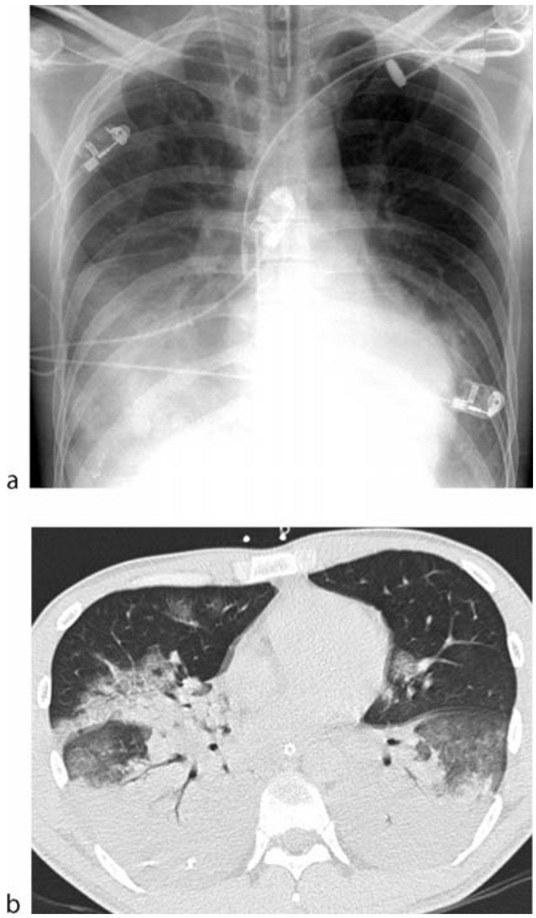
Imaging

Since bilateral infiltrates are part of the definition of ARDS, chest radiographs are taken regularly. CT is an important adjunct, since it is much more sensitive showing complications early, surrogates of functional compromise as well as hints that are important for the differential diagnosis. The classical radiographic findings of ARDS include patchy or diffuse airspace disease, combined with normal heart size and normal vascular pedicle. Additional abnormalities are reported with varying frequencies: septal lines, peribronchial cuffing, and thickening of the fissures. The typical clinical course is reflected by a rather typical time course of radiological patterns, but with fluent transitions. In the *early exudative phase* (1st–24th h), the very first chest radiograph in a patient with acute onset of dyspnea and hypoxemia will not show any abnormalities. There is a time gap of approximately 12 h between onset of respiratory failure and the appearance of radiographic abnormalities characteristic for ARDS. Since CT is much more sensitive, it will demonstrate subtle ground-glass opacities (GGOs) with a predilection in the middle and perihilar or even peripheral subpleural regions. Fluid leakage into the peripheral interstitium is minimal, but occasionally there will be signs of interstitial edema, such as septal lines. Over time, the findings will become more obvious and convert to patchy and ill-defined opacities. They will show a more homogenous appearance throughout both lungs combined with broadening of the peribronchovascular interstitial tissue. These findings indicate the transition to the *exudative phase* (2nd–7th day) with more ill-defined hazy opacities and visible vessels. As alveolar leakage and collapse progress, the opacities become denser and more homogenous, and positive air bronchograms may be a prominent feature (Fig. 1a). At CT, GGOs and consolidations with a patchy, peripheral distribution will be the leading pattern. The patchiness of mild or moderate ARDS at CT reflects the heterogeneous nature of the disease as well as subsequent differences in local compliance and aeration. Often the nondependent lung regions have a normal or ground-glass appearance and the dependent and dorsal lung regions will exhibit some consolidations. Thus, a ventrodorsal and a cephalocaudal gradient of lung attenuation may be observed. These findings are frequently accompanied by CT demonstrated pleural effusions. Depending on the severity of ARDS

D



Diffuse Alveolar Pulmonary Damage and Acute Respiratory Distress Syndrome. Figure 1 ARDS chest radiographs in the exudative phase (a) shows bilateral dense infiltrates and positive bronchograms, in the proliferative phase (b) it shows decreased overall lung density with a mixture of ground-glass opacities and a reticular pattern as well as pneumothorax on the right. Close-up CT (c) of the proliferative phase also a mixture of ground-glass opacities and a reticular pattern, dilated bronchi due to positive end expiratory pressure as well as pneumothorax on the right.



Diffuse Alveolar Pulmonary Damage and Acute Respiratory Distress Syndrome. Figure 2 ARDS chest radiograph (a) and CT (b) in the exudative phase views show large area of atelectasis in both lungs.

massive airspace consolidations and alveolar infiltrations of both lungs will develop which correspond to "full-blown ARDS (Fig. 2)." Later the consolidations become inhomogeneous and change into a reticular pattern. The development of persistent patchy spots may correspond to secondary pneumonia. Artificial respiration may cause typical changes in lung morphology or even complications referred to as ventilator-associated lung injury (VALI), which consists of four major factors: (1) gross air leaks induced by large transpulmonary pressures (barotrauma); (2) overdistention of aerated lung parenchyma which manifests as increased alveolo-capillary permeability (volutrauma); (3) cyclical recruitment and collapse of atelectasis leads to high shear forces between collapsed and aerated alveoli as well as varying shunt fractions during the respiratory cycle (atelectrauma); (4) continuous release of various inflammatory mediators (biotrauma) (3). Typical signs of VALI are abnormal air collections such as interstitial emphysema, cysts, pneumatoceles, pneumothorax, pneumomediastinum, pneumoperitoneum, or pneumoretroperitoneum. For detection and diagnosis, CT is highly superior to supine chest radiographs.

After the exudative phase, ARDS turns into the organizing and *proliferative phase*. The overall lung density decreases as the consolidations give way to a mixture of GGOs and parenchymal distortion (Fig. 1b, c) later turning into a coarser reticular, partly bubbly pattern due to the development of fibrosis (*fibrotic phase*). Cysts may form ranging from a few millimeters to several centimeters in diameter. They can be subpleural or deep in the parenchyma. Rupture of a cyst can cause pneumothorax and/or pneumomediastinum. Not every patient will go through all the mentioned phases in the same way. Although the findings may be decreasing or constant, this scheme gives the basic structure of the development of ARDS over time (2).

In many ARDS survivors, reticular or cystic patterns will prevail. There seems to be a relationship between the preferential site of cyclic recruitment and collapse with the later localization of fibrosis, air cysts, and bronchiectasis.

Diagnosis

The diagnosis of ARDS is made when the definition criteria, including radiology, are met. In the following, radiological examinations play a pivotal role in the clinical management of ARDS patients.

Synonyms

Liver storage diseases

Definition

Group of hepatic diffuse disorders characterized by anomalous storage of specific substances within the liver, followed by functional and morphological liver abnormalities, which may lead to hepatic dysfunction.

Pathology and Histopathology

The most common hepatic storage diseases are fatty infiltration, ▶hemochromatosis, ▶Wilson disease, and ▶glycogen storage diseases. Rare hepatic storage diseases are ▶Gaucher's disease and ▶amyloidosis.

Iron Overload: Hemochromatosis and Hemosiderosis

▶Iron overload can be separated into two general categories of iron distribution: parenchymal cell iron deposition in hemochromatosis, cirrhosis, intravascular hemolysis, and iron deposition in cell of the reticulo-endothelial system, also called ▶hemosiderosis, which is seen most commonly after multiple transfusions or in diseases with extravascular hemolysis. Iron deposition in hepatocytes causes cellular damage, while iron deposition in reticulo-endothelial cells does not produce a significant organ dysfunction (1). Hereditary hemochromatosis is autosomal recessive disease that is characterized by an anomalous increase in iron absorption from the gastrointestinal tract. This excess of iron is deposited in the form of ferritin and hemosiderin within the parenchymal cells of the liver, pancreas, endocrine glands, heart, skin, and joints. It leads to cellular damage and organ dysfunction. In patients with advanced disease, liver cirrhosis develops (1, 2).

In cirrhosis of various origins, a mild increase in the iron content of the hepatocytes occurs in about 50% of patients, although the exact mechanism responsible for this increase is unknown. It has been suspected that this form of iron overload is a predisposing factor for the development of hepatocellular carcinoma.

In transfusional iron overload, iron is deposited in the reticulo-endothelial cells of the liver, spleen, and bone marrow. When the reticulo-endothelial system is saturated with iron, additional iron deposits are seen in the parenchymal cells of the liver, pancreas, and heart leading to organ dysfunction similar to that seen in primary hemochromatosis (2).

Intravascular hemolysis causes iron deposition in hepatocytes. This is different from extravascular hemolysis, in which senescent native or transfused erythrocytes are removed from the circulation by reticulo-endothelial cells. When red blood cells are destroyed within the circulation, the free hemoglobin binds to plasma haptoglobin and is taken up by hepatocytes, not by reticulo-endothelial cells. In thalassemia major, there is an increased demand for iron in the bone marrow because of ineffective erythropoiesis. This results in increased absorption of iron which accumulates in parenchymal cells. Patients received transfusions may also develop iron deposition in the reticulo-endothelial system (1).

Wilson Disease

Wilson disease, or hepatolenticular degeneration, is a rare autosomal recessive disorder of copper metabolism, due to a deficient synthesis of ceruloplasmin, the copper-binding protein. Copper accumulates in the liver, basal ganglia, and cornea. Copper accumulation in hepatocytes results in cellular necrosis and finally leads to cirrhosis. Kayser–Fleischer rings consist of copper granules in the stromal layer of the eye (1).

Glycogen Storage Diseases

Glycogen storage diseases affecting the metabolism of glycogen, in which an enzyme deficiency results in glycogen accumulation in tissues. Most of these disorders are inherited in an autosomal recessive manner. More than 12 glycogen storage diseases are discussed in the literature (3).

Gaucher's Disease

Gaucher's disease is glycolipid storage disease, characterized by lysosomal storage of glucocerebrosides in pathological macrophages, called Gaucher's cells. It is caused by an autosomal-recessive inherited deficiency of glucocerebrosidase activity. Gaucher's cells infiltrate parenchymal tissues, predominantly the bone marrow, spleen, and liver. There are three clinical forms; type I, or nonneuronopathic Gaucher's disease, is by far the most common (4).

Amyloidosis

Amyloidosis consists in the extracellular deposition of the fibrous protein amyloid in one or more sites in the body. Amyloidosis may be primary or secondary to other conditions, such as chronic inflammatory conditions and multiple myeloma. Familial forms of amyloidosis have also been described. Primary amyloidosis tends to involve peripheral nerves, skin, tongue, joints, heart, and liver while secondary amyloidosis mainly affects parenchymatous organs, such as spleen, kidneys, liver, and adrenals. Although the liver and spleen are frequently involved in primary systemic amyloidosis, the clinical manifestations of hepatic and splenic involvement are usually mild (5).

Clinical Presentation

Hemochromatosis

In hereditary hemochromatosis, the liver is the mainly affected organ, and, if untreated, the hepatic iron overload may lead to cirrhosis. Approximately 20–30% of patients with cirrhosis develop hepatocellular carcinoma. The pancreas is also commonly involved with various degrees of dysfunction, ranging from insulin resistance to insulin-dependent diabetes mellitus. Hyperpigmentation of the skin is often observed. Cardiac involvement includes cardiomyopathy and arrhythmias and is a common cause of death. Arthropathy may occur early in the course of the disease and classically affects the second and third metacarpophalangeal joints. Later in the course of the disease some patients develop pituitary hypogonadism.

Wilson's Disease

Younger patients typically present hepatic manifestations, such as loss of appetite, nausea, jaundice, while the initial symptoms in adults are usually neurologic or psychiatric ones, including dystonia, incoordination, abnormal behavior, depression. Kayser–Fleischer rings are always present. They appear as greenish-yellow or brown rings seen at the limbus of the cornea. Wilson disease is invariably fatal if untreated.

Glycogen Storage Diseases

Patients with Von Gierke disease are at risk for neonatal hypoglycemia. They exhibit hepatomegaly and hypoglycemic seizures at the age of 3–4 months. Long-term complications include short stature, hyperuricemia, renal insufficiency, and hepatic adenoma. In these patients, the adenomas are also more likely to be multiple and to undergo malignant transformation, although the latter is still quite rare (3). In other types of glycogen storage diseases, patients experience muscle symptoms, such as weakness and cramps.

Gaucher's Disease

The principal manifestations are caused by bone marrow infiltration, with consequent skeletal disease including deformities, pathological fractures, and avascular necrosis. These patients develop splenomegaly with hypersplenism. Hepatomegaly is frequently observed in type I Gaucher's disease. For most patients, hepatic involvement has no significant clinical consequences. Nevertheless, in sporadic cases a massive infiltration of the liver by Gaucher's cells is associated to fibrosis and cirrhosis, with development of portal hypertension (4).

Amyloidosis

The liver is frequently involved in primary systemic amyloidosis, but the clinical hepatic manifestations are usually unimportant. Few cases of spontaneous rupture of the liver associated with hepatic amyloidosis have been reported (5).

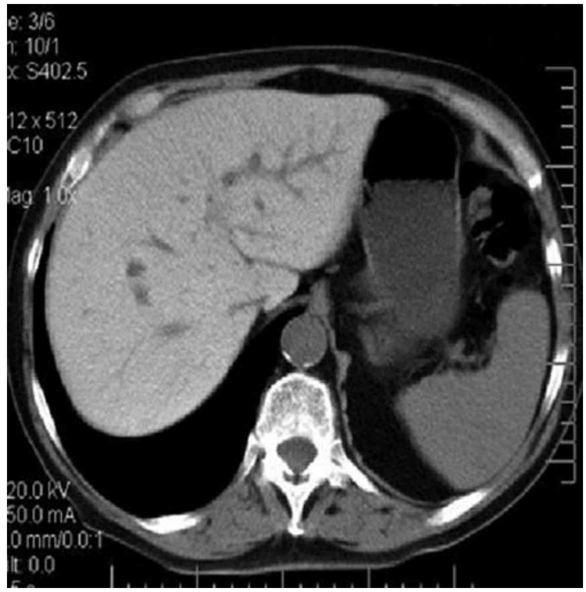
Imaging

Hemochromatosis

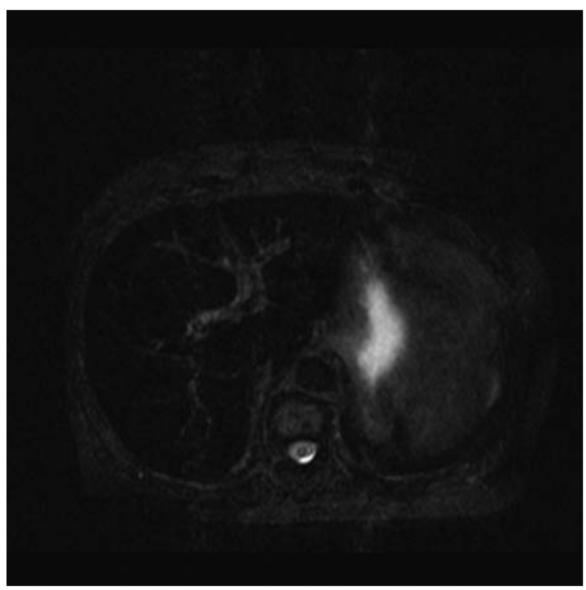
Sometimes, computed tomography (CT) or magnetic resonance (MR) examinations may reveal signs of hemochromatosis in a preclinic stage of disease. At ultrasound (US), iron deposits in the liver do not determine specific findings. The evidences are secondary to chronic liver disease, cirrhosis, or hepatocellular carcinoma. At CT, the increase in hepatic iron content determines diffuse homogeneous hyperdensity of the liver on unenhanced scans. The hepatic vessels appear particularly prominent in contrast with the hepatic parenchyma (Fig. 1). CT demonstrates signs of cirrhosis and a biphasic contrast-enhanced study is required for the detection of hepatocellular carcinoma. MR is more sensitive than CT for detection of hepatic iron deposition, since iron causes inhomogeneity of the magnetic field, leading to spin dephasing and decreasing of signal intensity of liver parenchyma on T2-weighted MR images (Fig. 2). Gradient-echo MR sequences are the most sensitive for mild degrees of iron overload (2). Skeletal muscle does not accumulate iron, so it can be used as a term of comparison. If the liver signal intensity is lower than that of skeletal muscle, increased iron accumulation in the liver can be diagnosed. Iron deposits in parenchymal cells and in reticulo-endothelial cells cause an identical loss of signal intensity; in most patients with hereditary hemochromatosis the spleen is not involved, while in hemosiderosis a splenic involvement coexists. In case of pancreatic involvement, low signal intensity of the pancreas is usually demonstrated. Since several studies have suggested that MR may enable an accurate quantification of hepatic iron concentration, it may be used in assessing the response to treatment in patients with hemochromatosis, avoiding the risks inherent in percutaneous liver biopsy (2). Hepatic iron overload facilitates the detection of focal lesions, namely hepatocellular carcinomas, particularly on T2-weighted sequences, due to the increased natural contrast between the hypointense liver parenchyma and the nodules, which do not contain excess of iron and appear hyperintense (1).

Wilson Disease

US findings in Wilson disease are indistinguishable from those of cirrhosis of other causes. Multiple round foci of decreased echogenicity have also been reported. Hyperechoic nodules are less frequently observed. CT of the liver offers little information. Hepatic attenuation values are usually within normal limits. Concomitant fatty infiltration may hide the increase in density due to copper deposition. Although copper has a paramagnetic effect, substantial changes in liver signal intensity are



Diffuse Infiltrative Diseases, Hepatic. Figure 1 Liver CT scan: the increase in hepatic iron content determines diffuse homogeneous hyperdensity of the liver on unenhanced scans. The hepatic vessels appear particularly prominent in contrast with the hepatic parenchyma. Hyperdensity of liver is evident compared to the spleen.



Diffuse Infiltrative Diseases, Hepatic. Figure 2 STIR MR axial acquisition: MR is more sensitive than CT for detection of hepatic iron deposition, since iron causes inhomogeneity of the magnetic field, leading to spin dephasing and decreasing of signal intensity of liver parenchyma on T2-weighted MR images. We can see low signal intensity of liver in this patient with hemochromatosis. Skeletal muscle does not accumulate iron, so it can be used as a term of comparison.

not observed. In fact, copper has a slight paramagnetic effect and copper concentration within the liver is relatively low (1).

Glycogen Storage Diseases

Type I glycogen storage diseases generally have more severe US changes than other types. The most frequent US findings are hepatomegaly, hyperechogenicity of the liver, enlarged kidneys. On CT scans, glycogen deposition results in increased hepatic parenchyma density, whereas fatty infiltration causes a decrease in density. Ultimately the density of the liver depends on the relative amounts of each component. Sometimes, the liver may show a geographic pattern. Biphasic contrast-enhanced CT is mandatory in order to detect and characterize hepatocellular adenomas (3). Glycogen is characterized by high signal intensity on T1-weighted MR images.

Gaucher's Disease

Hepatosplenomegaly is a constant finding. US can demonstrate the organomegaly and may be useful in monitoring the reduction in size of liver and spleen in patients undergoing enzyme treatment. In a small number of patients multiple focal lesions, usually hypoechoic, are observed in the spleen and, more rarely, in the liver (4). Very few cases of severe involvement of the liver with massive hepatic fibrosis causing portal hypertension have been described: CT and MR show distortion of liver parenchyma.

Amyloidosis

Imaging findings are not specific. The liver is usually enlarged and shows heterogeneous echogenicity on US. Unenhanced CT scans show diffuse or focal regions of decreased attenuation of hepatic parenchyma, with or without extensive calcification. Postcontrast scans show inhomogeneous enhancement of the liver parenchyma. On T1-weighted MR images, the liver parenchyma has increased signal intensity, while on T2-weighted images the signal intensity is not significantly altered. However, the reason for high signal intensity on T1 is not known (5).

Diagnosis

Hemochromatosis

The standard method of diagnosis is the quantification of hepatic iron concentration by means of liver biopsy with spectrophotometry. A skin biopsy specimen of a hyperpigmented cutaneous area may confirm the diagnosis. MR seems to be a useful tool which may replace liver biopsy, in the follow-up of treated patients (2).

Wilson Disease

Blood copper, ceruloplasmin, urine copper, eye test for Kayser–Fleischer rings, and liver biopsies are used to make the diagnosis. Imaging findings are not specific.

Glycogen Storage Disease

Clinical data, laboratory tests such as creatine kinase levels, muscle biopsy, and liver biopsy are used in the diagnostic work-up. Imaging findings are not specific neither sensitive. Biochemical assay for enzyme activity allows the final diagnosis.

Gaucher's Disease

The final diagnosis is done on the basis of measurement of beta-glucocerebrosidase activity in lymphocytes or in fibroblasts.

Amyloidosis

The combination of imaging findings, particularly liver CT, may suggest the presence of amyloidosis; however, confirmatory diagnosis can usually only be achieved by biopsy (5).

Diffusion-Tensor MRI

An MR-based technique which allows to measure water molecular motion in biological tissues. Diffusion is defined as the microscopic random translational motion of molecules in a fluid system. Pathological processes can alter tissue integrity, resulting in a loss or increased permeability of “restricting” barriers, which determines an increase of the apparent diffusion coefficient values. Diffusion measurements can give information about the size, shape and orientation of tissues. A full characterization of diffusion can be obtained in terms of a tensor, a 3×3 matrix that accounts for the correlation existing between molecular displacements along orthogonal directions. From the diffusion tensor, it is possible to derive the mean diffusivity (MD), which is a measure of diffusion that is independent of the orientation of structures, and the fractional anisotropy (FA), which indicates the structural integrity and degree of structural alignment within fiber tracts.

▶Aging Brain

Diffusion-weighted MR Imaging

Diffusion-weighted MR imaging is a technique in which phase-defocusing and phase-refocusing gradients are used to evaluate the rate of microscopic water diffusion within tissues. With the evolution of echo-planar MR imaging with a preparation pulse that is sensitive to diffusion, high-speed imaging has become possible, thus reducing the motion artifacts during image acquisition.

▶Lymphadenopathies, Head and Neck

▶Neoplasms, Salivary Glands

DiGeorge Syndrome

Congenital immunodeficiency syndrome characterised by velofacial abnormalities, congenital heart disease, hypocalcaemia, and increased susceptibility to infections.

▶Congenital Malformations, Thymus

Digital Radiography (DR)

DR uses an X-ray detector made of caesium iodide crystals layered onto an amorphous silicon photodiode panel. No latent image is formed; the photodiode converts the light emitted from the crystals into an electronic signal, from which the image is generated. The image can be viewed on hard-copy film or as soft copy on a workstation.

▶Children, Imaging Techniques

Dilating Uropathy

Dilated collecting and draining system (ureter, renal pelvis, calyxes): any condition of the urinary tract that causes or is associated with dilatation of the urinary system. Note that dilatation does not equal obstruction; obstruction may be one cause for dilatation, other reasons for a dilated urinary tract are laxity, dysplasia, infection or congenital variations such as megacalicosis.

▶Obstructive Uropathy in Childhood

DIN

Ductal intra-epithelial neoplasia.

Targeted Imaging

Definition

Direct imaging generally refers to the imaging of a specific molecular target and/or process (e.g., a receptor protein target imaged with a ligand molecular imaging probe). This is done to determine the location(s), activity, and/or numbers of the target. This is in contrast to indirect imaging where the target is not directly imaged and an indirect readout of that target is performed. Since the target is directly imaged, the direct approach is one of the best ways to determine properties of the target of interest and any changes over time determined through repetitive imaging.

Imaging

Almost any imaging probe can be utilized to image a target directly, including but not limited to radiolabeled probes, optical fluorescence or bioluminescence probes, magnetic resonance imaging (MRI) compatible probes, etc. Direct imaging can be accomplished using two broad categories of molecular imaging probes. The first one involves the use of radiolabeled probes (e.g., labeled with Fluorine-18) that produce signal continuously before and after interacting with their targets through the decay of the radioisotope. Direct imaging of radiolabeled probes can be accomplished by positron emission tomography (PET), single photon emission computed tomography (SPECT), MRI, functional magnetic resonance spectroscopy (fMRS), and autoradiography. A time delay between injection of the probe and imaging will allow the clearance of untrapped/unbound probes and enhance the signal to background ratios, since the scanner cannot distinguish the parent tracer from the bound or metabolized tracer. Another strategy for direct imaging involves the use of activatable or "smart" probes (also referred to as sensors or beacons), which produce signal only when they interact with their targets. Direct imaging of activated probes can be accomplished by optical/fluorescence imaging, but a time delay between the injection and imaging will be required to allow the accumulation of sufficient numbers of activated probe at the target site. Bioluminescence optical imaging has also recently been shown to be able to be used for direct imaging through creation of an imaging probe in which a luciferase protein (not a reporter gene) is attached to an antibody (1). On the other hand, direct imaging of physiological processes and vascular distributions such as changes in blood volume flow can be accomplished with non-specific imaging probes including contrast media, nuclear medicine-based tracers and fluorochrome reporters. Disadvantage of direct imaging: a new substrate must be discovered and labeled to yield a different probe for each new protein to be targeted. Furthermore, each imaging probe must be characterized in lining subjects for optimization of pharmacokinetics and pharmacodynamic properties.

Applications of Direct Imaging

Imaging of Protease Activity in Extracellular Space

Direct imaging utilizing activatable probes have been coupled with near infrared (NIR) imaging to measure protease activity, including cathepsin B, metalloproteinase-2 and metalloproteinase-7 in tumor-bearing nude mice (2). These NIR protease probes (NPP) consist of fluorochromes (with excitation and emission wavelengths in the NIR spectrum) that are covalently coupled to a poly-L-lysine backbone and sterically protected by a methoxy(polyethylene glycol) side chains by means of a synthetic peptide substrate specific for each protease. In the absence of protease activity, the NPPs produce low-fluorescence signals due to the quenching of the proximal fluorochromes. In the presence of active protease activity, the peptide spacer specific for the particular protease is cleaved and fluorochromes in the NPPs are released and become brightly fluorescent. Most recently, the NPP has also been used to image gelatinase activity in macrophages in an inflammatory arthrosclerosis mouse model in combination with fluorescence molecular tomography (3).

Imaging of Cell-Surface Receptors and Ligand Binding

Radiolabeled antibodies have been utilized to image the expression of cell-surface receptors and antigens in tumor xenograft models (4–6). Examples include using iodinated recombinant antibodies for imaging cell surface Human epidermal growth factor receptor 2 (HER2) in breast cancer (7), as well as iodinated and ^{64}Cu-labeled antibodies for imaging carcinoembryonic antigen expression (CEA) in colon cancer using microPET (8). The presence of the large numbers of targets (such as HER2 and CEA) on the cell surface helps to increase the signal to background ratio. MRI has also been used to detect the expression of cell-surface HER2 receptors. HER2-overexpressing cells were imaged in cell culture studies and a murine mammary tumor xenograft model, using biotinylated Her2 antibodies in combination with avidin conjugated gadolinium (9). Dopamine type 2 receptor (D_2R) occupancy has been imaged by a variety of iodinated probes, including ^{123}I-iodobenzamide for imaging hypoxic–ischemic brain injuries in neonates (10, 11) using SPECT. The gastrin-releasing peptide receptor was imaged by microPET in a rat pancreatic cancer model using a ^{68}Ga-labeled bombesin analog (12) and in prostate cancer model using a ^{18}F-labeled bombesin (13) in mice. The somastatin receptor that is highly expressed in neuroendocrine tumors was imaged using ^{111}In-pentetreotide (14–16) whereas the sodium iodide symporter was imaged with ^{123}I or ^{99m} Tc-pertechnetate in metastatic breast cancers (17, 18) and thyroid cancers (19) by SPECT. Most recently, a CEA diabody fused to the Renilla luciferase was used to examine CEA expression in a colorectal cancer xenograft model in nude mice using optical bioluminescence imaging (1). Direct imaging has also been used to image ligands binding to their respective receptors. 6-α-[^{18}F]fluoroestradiol (FES) was used to image the expression of estrogen receptor in breast cancer tumor xenografts in nude mice during tumor progression in response to chemotherapy and hormonal therapy (20).

Imaging of Reporter Gene and Transgene Activities

Although imaging of reporter genes usually is considered indirect imaging (since reporters are often used to infer levels of endogenous proteins), if the goal is to infer levels of reporter protein instead of some other protein, then direct imaging is applicable (4–6). Direct imaging has been utilized for evaluation of transgene and reporter gene expression by mircroPET and optical bioluminescence imaging (6). Herpes Simplex Virus Type I Thymidine kinase gene (HSV-TK) delivered *in vivo* by adenoviral vectors and lentiviral vectors as well as stably expressed in a rat glioma xenograft model was imaged by microPET using radiolabeled HSV-TK substrates such as 8-[^{18}F] fluoropenciclovir, 8-[^{18}F]fluoroganciclovir and -(4-[^{18}F]-fluoro-3 hydroxymethylbutyl) guanine ([^{18}F]-FHBG), and 2-fluoro-5-[^{124}I]iodo-1-beta-D-arabinofuranosyl-uracil (FIAU). The D2R gene was also used an *in vivo* reporter gene in the liver and tumor xenografts for noninvasive, repetitive and quantitative imaging in conjugation with radiolabeled by microPET in living mice. In order to monitor cardiac reporter gene expression noninvasively, a single vector expressing the HSV-TK gene or a bicistronic adenoviral vector carrying the HSV-TK and D2R reporter genes was delivered via intramyocardial injection and HSV-TK and D2R expression were subsequently imaged with [^{18}F]-FHBG and [^{18}F]-FESP respectively by microPET. Likewise, optical reporter genes such as Firefly luciferase and Renilla luciferase have also been used to monitor tumor xenografts, skeletal muscles as well as cardiac gene expression in cell transplantation in living mice and in living rats. Direct monitoring of transgene expression can also be achieved by MRI, in which an engineered transferrin receptor was used to internalize transferrin conjugated monocrystalline iron oxide nanoparticles and superparamagnetic iron particles (21).

Definition

According to its pathologic and epidemiologic features, diffuse idiopathic skeletal hyperostosis (DISH) is considered a (systemic) skeletal disorder of unknown etiology described in the elderly and characterized by abundant bone formation/ossification and calcification of connective tissue in spinal and extraspinal sites. The first description of the vertebral findings as "senile vertebral ankylosing hyperostosis" was by Forestier and Rotes-Querol (1950), which was then extended by Resnick et al (1975) including extraspinal manifestations to the more comprehensive concept of DISH (1).

Pathology/Histopathology

Bone formation, ligament ossification, and bony enthesial and periosteal proliferation are characteristic of DISH. Histologically, ossification in DISH is described to exhibit organized Haversian bone. The new bone formation is attributed to increased proliferation and activity of osteoblasts. An association of metabolic disorders such as dyslipidemia, hyperuricemia, and diabetes mellitus with DISH has been suggested. Elevated levels of insulin-like growth factor and serum growth hormone have been described, peptides recognized to stimulate osteoblastic proliferation and activity. An increased number and size of nutrient foramina in a pathologic study suggested hypervascularity to be involved in the pathogenesis of DISH as a predisposing (local?) factor for onset, progression, and localization in affected ligaments and vertebrae. To date, no clearly accepted association between DISH and HLA-B27 has been demonstrated.

In the spine, linear, mainly craniocaudally oriented, paravertebral and paradiscal bone formation and ►osteophytes are present (Fig. 1). Typically, the anterior longitudinal ligament is affected. Ossification seems to start in the innermost layer of the longitudinal ligament at its junction with the vertebral body and then progresses vertically toward an adjacent vertebra. Alterations in the thickness of bone apposition may create a wave-like or "flowing" appearance. There is anterior vertebral body cortical hyperostosis. At the level of the disc space, a more horizontal extension of bony outgrowth can be found, leading to a bumpy appearance of the anterolateral vertebral aspect. In areas of incomplete ►ankylosis, fibrous tissue extends anteriorly from the level of the disc into the space between the opposing ends of ligament ossification. This feature and incomplete ossification of the deeper portions of the longitudinal ligaments correspond to radiographic lucencies interspersed between the (anterior or posterior) longitudinal ligament and the vertebral body or between struts of ossification in the ligament.

A predilection of the right anterolateral vertebral aspect in the thoracic spine is ascribed to some inhibitory effect of the pulsating descending aorta. This notion is supported by reports on a left-sided predominance in patients with situs inversus.

In 50% of cases, the posterior longitudinal ligament shows ossifications [►ossification of the posterior longitudinal ligament (OPLL)] as well, often found in the cervical spine together with posterior cortical hyperostosis and osteophytosis. Conversely, DISH is found in 20% of patients with OPLL. Less frequent, coexisting ►ossification of the ligamenta flava may be found.

Unlike in seronegative spondylarthropathies, the facet joints are not involved and intra-articular ossification of the sacroiliac join (SI) joint is not found in DISH. However, coexisting DISH and ankylosing spondylitis have been reported in a few cases.

In the extraspinal manifestations, juxta-articular, sometimes bridging (symphysis pubis, SI joint), osteophytes are typical. Prominent bony spur formation is in contrast to the lack of joint space reduction. Bony proliferation at the insertion site of tendons and ligaments may be

Dish. Figure 1 Coronal (a) and sagittal (b) CT reformations show the characteristic "flowing" aspect of the multisegmental bridging right-sided ossifications. There is increased apparent vertebral body depth (b) and in some of the segments, the fibrous tissue interspersed between the opposing ends of ossified struts is evident. Note the relative sparing of disk height.

prominent. In the pelvis this is along the iliac crest, ischial tuberosity, and trochanters. There is ossification of the iliolumbar and sacrotuberal ligaments. In the heel and foot, the dorsal and plantar aspect of the calcaneus, the dorsal aspect of the talar and navicular bones, as well as the lateral aspect of the cuboid and the base of the fifth metatarsal bones are affected. Anterior patellar hyperostosis and ossification extending into the ligamentous/tendinous portions of the knee extensor mechanism as well as prominent olecranon enthesiophytes are encountered. In the hand, ossification of the phalangeal joint capsules and hyperostosis may be prominent.

An increased rate of postoperative ossification (periarticular and scar tissue) has been described and has led to the recommendation of perioperative prophylactic NSAID administration (2).

Clinical Presentation

DISH is more common in the Caucasian population. The age of patients with a radiographically established diagnosis of DISH is usually 50–75 years and there is a predominance in male (2:1) patients. Prevalence increases with age from 0.3%/0.2% below 50 years to 11.2%/6.9% above 70 years (Scandinavian men/women).

There is a predilection for the spine, but peripheral manifestation occurs in up to two-thirds of documented cases. Most often, the lower thoracic spine (≤100%) is involved, followed by the upper lumbar (68–90%) and the lower cervical (65–78%) spine. In order of decreasing frequency, sites of extraspinal affection are the pelvis (53–66%), heel and foot, elbow, knee (29%), hand, and wrist. Often extraspinal affection is bilateral and symmetric.

Symptoms include (back) stiffness, which is described to be worse in the morning and relieved under mild activity, as well as a restricted range of motion and signs of tendinosis. Usually, symptoms are minor if not absent and some studies fail to demonstrate an increased incidence of back pain attributable to DISH in comparison to spondylosis. Thus, care should be taken to not falsely attribute more severe back pain to DISH instead of investigating other potentially underlying causes. Clinical history may reveal episodes of elbow and ankle pain.

More severe symptoms are usually related to complications in more advanced disease. Dysphagia is attributable to prominent ossifications in the cervical spine. Fused spinal segments are predisposed to fractures, often in the cervical spine, following even minor trauma. This may lead to underestimation of the severity of bony damage and delay in or inadequate treatment. Similar to ankylosing spondylitis, a distraction type of mechanism seems to account for many of the fractures which then follow a horizontal course, either transvertebral or transdiscal. Ultimately, even if no initial neurologic deficit is present, this may result in subsequent quadriplegia and death (3–5). In addition to trauma energy, the severity of injury seems to be related to the extent (number of fused segments) of ankylosis. Awareness of this special situation and meticulous analysis of imaging studies are mandatory, and early computed tomography (CT) studies improving the diagnosis of instability or even magnetic resonance imaging (MRI) is warranted. Advanced OPLL or ligamentum flavum may result in cervical spinal cord compression with eventual myelomalacia or lumbar spinal canal stenosis with concomitant neurological manifestations.

Among rare complications ascribed to DISH are stridor, vocal cord immobilization, compression of the inferior vena cava attributed to local mass effect, and chronic obstructive pneumonia and dyspnea with fibrobullous change related to bronchial obstruction and secondary mechanical thoracic deformity.

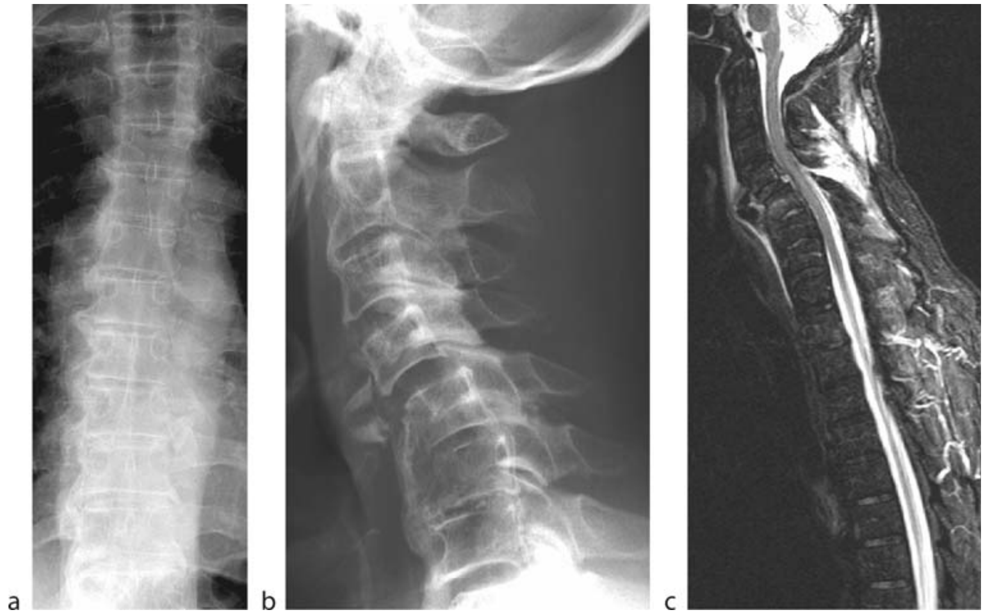
Imaging

The diagnosis of DISH is established from radiographic findings of the spine (for criteria, see later). The radiographic morphology of extraspinal affection is also quite characteristic, and is at least strongly suggestive of DISH (1) (Figs 1 and 3).

If visible, linear vertically oriented radiolucencies between the ossified anterior longitudinal ligament and the vertebral body in the (thoracic and cervical) spine are a characteristic feature. Similarly characteristic findings are linear horizontally oriented radiolucencies between the opposing ends of struts of anterior longitudinal ligament ossification.

In contrast to degenerative (osteo)chondrosis, the disk height is preserved in DISH, and end plate sclerosis and vacuum phenomenon are absent. Lack of intradiscal calcification and of vertebral osteoporosis contributes to differentiating DISH from ochronosis. Conversely, marked vertebral sclerosis is characteristic of fluorosis. A history of convulsions and laboratory values help in differentiating DISH from hypoparathyroidism.

Pseudarthrosis subsequent to fracture and marked destructive and reactive end plate changes in the segment immediately adjacent to a fused area of the spine have been described and potential instability in these locations with the risk of development of neurologic deficit has been underlined.



Dish. Figure 2 **This patient presented with persistent pain for several weeks after minor trauma. There is extensive ossification in the thoracic (a) and lower cervical spine (b). In addition, please note the anterior displacement of the fourth against the fifth cervical vertebral body and the two fragments of ossification anterior in this segment consistent with fractured osteophytes (b). MRI (c, sag. T2-weighted TSE) demonstrates high signal intensity anterior and posterior to the affected segment as well as in the prevertebral and nuchal soft tissues. In the lower cervical spine there is ossification in the posterior longitudinal ligament and marked narrowing of the spinal canal, but no signs of myelopathy are present.**

Fluoroscopy may illustrate displacement of the esophagus in patients with cervical affection and—sometimes severe—dysphagia. Bone scan, occasionally performed, usually reveals an increased, diffusely distributed, unspecific tracer uptake.

Although not routinely indicated, CT may demonstrate mass effect on the esophagus or the inferior vena cava. Coronal and sagittal reformations may illustrate the typical distribution pattern and the extent of ossification. CT is helpful in the evaluation of spinal canal affection and in the assessment of vertebral fractures, especially in revealing destruction of the posterior elements and thus pointing out unstable fractures (3, 4). Further, CT may contribute to differentiating para-articular bridging osteophytes in DISH from intra-articular ossification in seronegative spondylarthropathies, for example, in the SI joint.

Similarly, MRI can be of value in cases of spinal canal stenosis or vertebral fractures where it demonstrates mass effects on and affection of the thecal sac and the medulla (Fig. 2). A linearly confined area of fluid-like signal intensity extending through most of the anteroposterior diameter of a vertebra may indicate an instable fracture subsequent to a hyperextension mechanism (5). As an incidental finding in MRI primarily conducted for other purposes, areas of thick bone formation may demonstrate high signal intensity on T1-weighted sequences similar to bone marrow fat.

Diagnosis

The diagnosis of DISH primarily relies on radiographic imaging findings. Three imaging criteria are necessary to establish the diagnosis:

1. Continuous "flowing" calcification and ossification at the anterolateral aspect of four or more consecutive vertebral bodies.
2. Absence of pronounced degenerative changes in the "Bewegungssegment" and gross preservation of disc height.
3. Absence of ankylosis in apophyseal joints as well as absence of changes in the SI joint attributable to seronegative spondylarthropathies (erosions, sclerosis, intra-articular bony bridging).

As these criteria already indicate, DISH should and (by consequent application of the above given criteria) can be differentiated from spondylosis deformans, intervertebral (osteo)chondrosis, and seronegative spondylarthropathies.

Dish. Figure 3 **Sagittal reformations (a) show marked anterior and—to a lesser extent—posterior longitudinal ligament ossification in the cervical spine as well as nuchal ossification. Axial CT (b) underlines the mass effect on the pharynx, presumably explaining dysphagia in this patient. There is marked ossification in proximal portions of the ligamentum patellae (c).**

Etiology of Aortic Wall Dissection

▶Aortic dissection is defined as a separation of aortic wall layers. In the majority of cases, an intimal tear through which blood surges into the media is the initial event. Less common is a dissection caused by intramural hemorrhage and an intramural hematoma (IMH) without a detectable intimal tear. Chronic systemic hypertension is the most common factor predisposing the aorta to dissection. Further causes such as inherited connective tissue disorders (i.e., Marfan's syndrome, Ehlers–Danlos syndrome, and annuloaortic ectasia and familial aortic dissection), degenerative, atherosclerotic, inflammatory, or toxic processes, as well as traumatic events, may precede the aortic dissection (Table 1).

Characteristics

Diagnostic Imaging

Aortic dissection may occur anywhere within the aorta. If there are clinical suspicions for aortic dissection, identification of the aortic segments involved is mandatory for further management. It is mandatory to visualize the entire aorta including arch vessels and iliac arteries. The imaging modalities that are highly accurate in diagnosis include multislice computed tomography (MSCT), magnetic resonance imaging (MRI), and transesophageal echocardiography (TEE). Due to technical limitations, such as narrow intercostal spaces, obesity, pulmonary emphysema, and patients on mechanical ventilation, the value of transthoracic echocardiography (TTE) remains limited. Intra-arterial angiography is invasive, and is not the current standard method for initial diagnosis.

MSCT: Multislice scanners allow rapid diagnosis and their accuracy has been improved by the availability of two- and three-dimensional reconstructions. An optimized vascular enhancement is essential for the diagnosis of dissection. Therefore, the use of an automated bolus tracking system for contrast injection in combination with the saline chaser bolus technique is recommended (1). Acquisition parameters depend on the performance of the scanner used.

Diagnostic difficulties might be caused by artifacts such as streak artifacts and aortic motion artifacts. Streak artifacts are caused by sharp contrast interfaces or cardiac motion. These straight lines of low attenuation are usually restricted to a few transverse images. Aortic motion artifacts, which may mimic aortic dissection, are predominantly seen in the ascending aorta (2). They appear as a localized duplication or pseudo-thickening of the aortic wall. These artifacts are caused by pendular movements of the aortic wall between the systolic and diastolic phase. To overcome this diagnostic uncertainty caused by cardiac motion, retrospective or prospective electrocardiography-assisted MSCT has been shown to be relevant in imaging of the ascending aorta. With a 16-slice CT scanner, cardiac gating is limited by a reduced volume coverage; however, 64-slice scanners do not have this limitation.

MRI: A combination of three-dimensional contrast-enhanced MR angiography with cross-sectional MR images provides an overview of the aortic anatomy and details of the dissecting membrane and the aortic wall. Furthermore, flow in the false and true lumen can be quantified with phase contrast cine MRI or tagging techniques. A further advantage is the accurate assessment of aortic regurgitation. Moreover, MRI permits detection of acute and subacute intramural hemorrhage on the basis of methemoglobin which occurs after several days and persists for several months. However, MRI is contraindicated in patients with pacemakers and certain metallic implants, and is inappropriate in hemodynamically unstable patients.

TEE: Besides the ability to identify the entry site of dissection, the presence of an intimal flap, abnormal flow characteristics within the false and true lumen, involvement of coronary and arch vessels, TEE is highly accurate in the diagnosis of aortic valve regurgitation. A disadvantage of TEE is the limited field of view, with inability to visualize the distal extension below the celiac trunk.

Classification and Diagnostic Requirements in Aortic Dissection

Regarding the radiological and pathological variants of aortic dissection, a differentiation of subtypes (Table 2) has been proposed (3, 4). Diagnostic considerations must include extension of the dissection, involvement of aortic side branches, and concomitant complications (Table 3). All dissection subtypes can be seen in their acute and chronic stages. A dissection is classified as acute if it is 2 weeks old or less.

Class 1: Classic aortic dissection. Due to the anatomical location of the dissection, the Stanford classification distinguishes between type A and type B. A type A dissection includes the ascending aorta regardless of the entry site location, whereas a type B dissection presents with the primary intimal tear in the descending thoracic aorta, mostly located just beyond the insertion of the ligamentum arteriosum. The DeBakey classification subdivides the aortic involvement in a type I dissection, involving the entire aorta, a type II dissection that involves the ascending aorta, and a type III dissection that involves the descending aorta.

It is important to differentiate between the true and the false lumen and to visualize the extension of the dissection. The true lumen is usually compressed and is close to the inner curvature of the aortic arch. Intimal calcification indicates the true lumen in acute dissection. The false channel often enhances later than the true lumen. However, the contrast gradient between the aortic channels may reverse during the acquisition.

Malperfusion of abdominal branches and iliac arteries may be caused by the so-called static and dynamic mechanism, as proposed by Williams et al (5). The dynamic narrowing of a branch vessel occurs when the dissection flap is positioned across the vessel origin provoked by the hyper-pressure of the false lumen. In the static mechanism, the intimal flap intersects the vessel origin and in the absence of a peripheral intimal tear, the false lumen constricts the vessel origin.

Class 2: Intramural hematoma/hemorrhage. Intramural hematoma (IMH) and hemorrhage may be the result of ruptured vasa vasorum. There are two types of IMH/hemorrhage. Type I shows a smooth inner aortic lumen and the aortic diameter is usually less than 3.5 cm with a wall thickness greater than 0.5 cm. Type II occurs with atherosclerosis. It demonstrates a rough inner aortic surface and is found more often in the descending than in the ascending thoracic aorta. The aortic diameter is dilated and the wall thickness has a range of 0.6–4 cm. On

Dissection, Aortic, Thoracic. Table 2 Classification of variants of aortic dissection

Class	
1	Classic aortic dissection Separation of intima/media; dual lumen
2	Intramural hematoma/hemorrhage Separation of intima/media; no intraluminal tear or flap imaged
3	Subtle–discrete aortic dissection Intimal tear without hematoma (limited dissection) and eccentric bulge
4	Atherosclerotic penetrating Ulcer penetrating to adventitia with localized hematoma
5	Traumatic/iatrogenic dissection

Pleural effusion
Perfusion deficit/infarction in organs

unenhanced CT scans, IMH appears as a crescent-shaped area of attenuation in the aortic wall and remains unenhanced after injection of contrast material. IMH tends to maintain a constant circumferential relationship with the aortic wall, differentiating it from a thrombosed false lumen in a classic aortic dissection which usually spirals longitudinally around the aorta.

Class 3: Subtle–discrete aortic dissection. A subtle dissection has been described as a partial intimal tear covered by thrombus. When the tear forms a scar, this constellation is called a discrete dissection.

Class 4: Penetrating atherosclerotic ulcer. A penetrating ulcer occurs from an atherosclerotic plaque that has penetrated the internal elastic lamina into the media. A *penetrating atherosclerotic ulcer* (PAU) can lead to an IMH and aortic dissection, to a ►pseudoaneurysm, and to rupture. Diagnosis is made by demonstrating a focal contrast material-filled outpouching that might be associated with an IMH or an aneurysmal formation.

Class 5: Traumatic/iatrogenic aortic dissection. Blunt chest trauma may cause aortic dissection frequently at the region of the ligamentum botalli at the aortic isthmus. Untreated dissections often lead to pseudoaneurysms and may rupture.

Iatrogenic dissections are mostly catheter-induced and retrograde, and usually they decrease in size as the false lumen thromboses.

Therapy

Alternatively to conventional open repair, less invasive endovascular techniques for the treatment of dissections have gained widespread application, and encouraging results have been reported (6–10).

Acute uncomplicated type B dissections are preferably managed by conservative medical treatment. Complicated type B dissections with signs of rupture or imminent rupture, compromised branch vessels, rapidly expanding aortic diameter, refractory pain, or malignant hypertension require surgical or endovascular therapy. Stent grafts have a self-expanding stent structure covered by polyester or expanded polytetrafluoroethylene (ePTFE). Closure of the entry tear by stent-graft placement may lead to thrombosis of the false lumen with remodeling of the true lumen. Primary closure of the entry tear is reported in 89–100% of cases, with consecutive thrombosis of the false lumen in the descending aorta in 70–100%. Furthermore, lowering the pressure in the false lumen restored the perfusion in branch vessels that were compromised by a dynamic mechanism, as reported by Dake et al (6). However, in vessels with a narrowed origin caused by an intimal flap (dynamic mechanism) additional stenting of the vessel lumen may be required in up to 60% of cases (6). In cases were the branch vessel perfusion is compromised by a hypertensive false lumen, fenestration of the dissection membrane may be necessary (10). The puncture is performed from the true lumen of the infrarenal aorta into the false lumen, which generally tends to have a larger diameter. After placement of a stiff guide wire, the dissection membrane is fenestrated with a balloon until equalization of pressure is achieved.

In traumatic transection, the reported numbers of patients who were treated with stent-graft therapy are still limited. However, perioperative mortality rates in endovascular repair were between 0 and 13%, and were related to comorbid injuries and not associated with the stent-graft procedure (8, 9). Furthermore, paraplegia was not reported after endovascular repair, which compares favorably with surgical results.

Distant Recurrence

Also called systemic recurrence or metastatic disease. In this situation, malignant cells can be demonstrated in a distant organ, such as bone, lungs, liver, brain, or other places. The survival rate is considerably lower than for local or regional recurrences.

►Recurrent Neoplasms, Breast

Diuretic Renogram

Diuretic renal scintigraphy: A nuclear medicine study using medically induced standardized diuresis and Technetium 99m labelled MAG3 as a tracer for assessment of renal function and urinary drainage, which is essential for grading obstruction. MR-urography: A new MR technique that allows for assessment of the urinary tract. Originally this term was only used for heavily T2-weighted sequences that showed the (dilated) urinary system after diuretic stimulation. Now this term is more generously used for all MR techniques applied in assessment of urinary tract malformations, including (diuretic) dynamic assessment of renal function and urinary drainage after Gadolinium application using various fast T1-weigheted sequences.

NHS Foundation Trust, Cambridge, UK
nicholas.carroll@addenbrookes.nhs.uk

Definitions

▶Diverticulitis is defined as inflammation of diverticula or small out-pouchings of the colon. The condition depends on pre-existing ▶diverticular disease, smooth muscle hypertrophy and narrowing of the colonic lumen, most commonly affecting the left colon, resulting in ▶diverticulosis characterised by the formation of diverticula. These are in fact, for the most part, pseudo-diverticula, consisting of mucosa and sub-mucosa only.

The Hinchley classification separates diverticulitis into four stages, (i) ▶pericolic abscess or phlegmon, (ii) pelvic, intra-abdominal or retroperitoneal abscess, (iii) generalized purulent peritonitis and (iv) generalized faecal peritonitis.

In about 20% of all people with diverticula, acute or chronic-recurrent diverticulitis develops, often with serious complications as perforation, abscess or fistula formation, obstruction, inflammatory pseudotumor and intestinal bleeding (1).

Pathogenesis

The muscle abnormality in diverticular disease is seen most often in surgically excised specimens in the sigmoid colon, though a pan colonic form of the disease without muscle thickening also exists in the elderly. This is associated with increased colonic wall compliance which is most likely due to collagen failure.

Colonic diverticula therefore results from herniation of the mucosa through weak spots in the muscular wall. The majority of evidence suggests that the morphological changes are the response to a lifelong consumption of a low-residue diet. However, there are complex relations between colonic structure, motility and dietary factors, and it is likely that all of these (and possibly genetic influences) play a role in the pathogenesis to a greater or lesser degree (2).

Clinically manifested diverticulitis has been thought to have its pathologic basis in an abscessed ▶diverticulum obstructed by a faecalith, but studies of resected sigmoid colons have failed to produce evidence to support this view. Instead, the outstanding lesion was found to be a perforation in the fundus of a diverticulum, with surrounding peridiverticular or pericolic inflammation. Another surprising finding in pathologic studies was that one out of three sigmoid colons resected for 'diverticulitis' showed no inflammation in or around the diverticula, but the wall of the sigmoid was impressively thickened. This type of diverticulosis, which is frequently symptomatic, has been referred to as painful diverticular disease or spastic colon diverticulosis. Micro perforations of the tip of the diverticula are an important factor leading to inflammation and symptomatic disease (3).

The involvement of diverticula by granulomatous colitis may cause an increased incidence of diverticulitis.

Clinical Presentation

The clinical diagnosis of diverticulitis is suggested by abdominal pain that is most commonly located in the left lower quadrant. The classic clinical features are left lower quadrant pain, tenderness, fever and leukocytosis. Young people often develop severe forms of diverticulitis. Urinary symptoms may occur if the affected colonic segment is close to the bladder. A lower quadrant abdominal or rectal mass may be palpated, but associated rectal bleeding is uncommon and suggests an alternative diagnosis. About 85% of cases of acute diverticulitis involve the descending or sigmoid colon; however, right-sided disease may also occur and is reported more frequently in persons of Asian descent. Sigmoid diverticulitis may mimic acute appendicitis if a redundant colon is in the suprapubic region or lower right quadrant.

Complications

The complications of diverticulitis include

1. Pericolic abscess
2. Perforation.
3. Fistulation, e.g. colovesical fistula
4. Haemorrhage
5. Small bowel obstruction
6. Large bowel obstruction
7. Septic thrombosis of the portal vein
8. Liver abscess

Imaging

The radiological evaluation of patients with acute diverticulitis has a number of objectives: to confirm the clinical findings and rule out other colonic or pelvic disease and to evaluate and stage the degree of inflammatory disease. Direct visualisation of the colon with sigmoidoscopy or colonoscopy has little or no place in evaluation except where bleeding is a major feature or the presence of a significant polyp or carcinoma is suspected.

Plain Radiographs

Plain films may reveal the consequences of complicated diverticulitis such as free air or loculated air within sealed-off collections. In most patients, however plain radiographs are unhelpful except to exclude significant complications on admission to hospital.

Contrast Enema Examination

Contrast enema examination has been the traditional method of imaging patients with suspected diverticulitis whether with water soluble agents or barium.

Diverticulitis, Gastroinstestinal Tract. Figure 1 Double contrast barium enema. Some distortion of the diverticula arising from the lateral wall of the descending colon (*arrow*), indicating moderate diverticulitis.

Although the process of diverticular disease and diverticulosis are well-visualised, the changes associated with diverticulitis are less reliably demonstrated. Although distortion and spiculation of the diverticulae may suggest diverticulitis (Fig. 1), contrast studies often underestimate sinus tract and abscess cavity formation and even frank perforation. Although fistulous connection to the bladder and other structures may be visualised, the sensitivity of CE may be as low as 20% in the case of colovesical fistulae.

The main limitation of CE is the inability to assess pericolic inflammatory disease and abscess formation which are the hallmarks of more advanced diverticulitis.

Ultrasound

Ultrasound is the most commonly requested investigation for non-specific abdominal pain. Hypo-echoic wall thickening with associated collection may often be seen in the affected sigmoid segments particularly in a patient with a full bladder as an acoustic window. Some authors claim similar diagnostic accuracy for Ultrasound and CT (4).

Computed Tomography

CT has contributed more to the diagnosis and management of diverticulitis than any other imaging technique. CT clearly visualises not only intramural disease but in particular the mesenteric, peritoneal and retroperitoneal components of diverticulitis. CT is now the examination method of choice for patients with the classic combination of pain, fever, left iliac fossa mass and leukocytosis.

Images are best obtained following prolonged oral preparation, i.e. four doses of 5 mL of diatrizoate meglumine in 100 mL of water over 24 h. Shorter oral preparation up to 1 h prior to imaging or no oral preparation may be appropriate depending on degree of clinical condition. It is however preferable in all cases except where there is absolute contraindication to image during intravenous contrast administration e.g. 100 mL of 300 mg/mL non-ionic iodinated contrast medium at 60 to 70 sec following commencement of injection at 2–3 mL/sec. Multi-detector CT with the facility for coronal and sagittal reformat from isometric voxels improves interpretation of extra-mural disease particularly involvement of other organs such as the bladder.

The findings in acute diverticulitis are listed in Table 1. The most consistent feature is the presence of inflammatory change in the pericoloic fat (Fig. 2). The changes range from very fine linear stranding to large phlegmonous collections or frank abscess formation. Although most collections or abscesses are confined to the sigmoid mesocolon sepsis can spread to involve other spaces and planes such as the psoas muscle. Higher resolution or MDCT can demonstrate fine intramural or extramural fistulae and connections to other organs. (Fig. 3). CT has a high sensitivity and specificity in diagnosis of diverticulitis, up to 97% and 100% respectively (5).

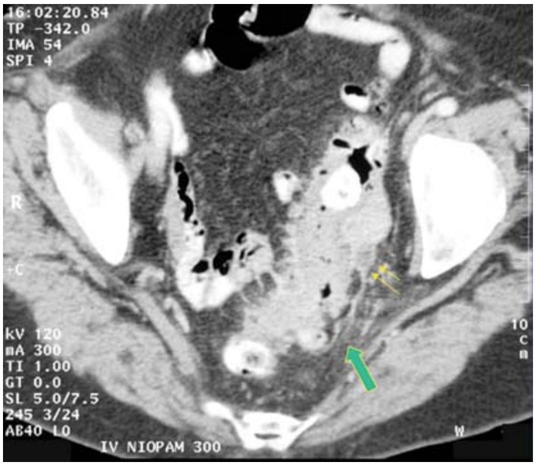
Diagnosis and Staging

CT staging can be correlated with surgical staging methods, see Table 2. Stage 0, the most common, being confined to the serosa of the colon, and represented by CT as moderate mural thickening with little or no extramural inflammation. Conservative management is usually adequate and imaging follow up not required.

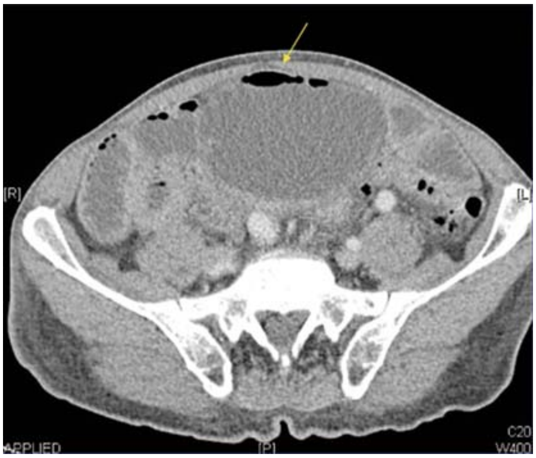
Stage 1 is characterised by an abscess or inflammatory mass less than 3 cm in diameter confined to the mesocolon. Antibiotic therapy usually suffices and patients rarely progress to more significant disease. Follow-up CT can be helpful to ensure resolution. Stage 2 disease is signified by CT evidence of spread outside the mesocolon but still confined by pelvic organs. Often at this stage CT drainage can aid in management. Once signs of inflammation are seen throughout the abdomen the disease has become Stage 3 and surgical intervention is invariably required. Faecal peritonitis signifies Stage 4 disease and urgent laparotomy is required.

Diverticulitis, Gastrointestinal Tract. Table 1 CT findings in patients with diverticulitis

Intramural and extramural diverticula
Induration, thickening or increased vascular markings within sigmoid mesentery
Inflammation, phlegmon or abscess in pericolic fat
Pericolic sinus or fistulae
Associated pelvic abscess or peritonitis
Signs of perforation. Free fluid and peritoneal gas
Faecal peritonitis
Other organ involvement e.g. thickening of bladder mucosa and gas within the urine.



Diverticulitis, Gastroinstestinal Tract. Figure 2 Image from intravenous contrast medium enhanced CT examination of the abdomen and pelvis demonstrating classical features of diverticulitis. Thickened sigmoid loop with intramural and extramural sinus and fistula formation, (solid *arrow*), pericolic inflammation and phlegmon (double *arrow*).



Diverticulitis, Gastroinstestinal Tract. Figure 3 Image from intravenous contrast medium enhanced CT examination of the abdomen and pelvis demonstrating gas in the bladder due to colovesical fistula (*arrow*).

Diverticulitis, Gastroinstestinal Tract. Table 2 Hinchley classification of stages of diverticulitis

Surgical stage	Findings	Management
0	Thickened colon. Some distortion of diverticula and minor pericolic inflammation.	May settle spontaneously or with antibiotic treatment
1	< 3 cm pericolic abscess. Contained within sigmoid mesocolon	Conservative. Antibiotics
2	Pelvic abscess broken out of mesocolon but confined by pelvic organs	Antibiotics aided by percutaneous image guided drainage
3	Peritonitis	Surgery
4	Faecal peritonitis	Surgery

Differential Diagnosis

The most commonly encountered differential dilemma in interpretation of CT of the colon is that between colonic carcinoma and diverticular disease/diverticulitis. Diverticulitis is usually only associated with mild concentric thickening compared to the thickening of carcinoma which is often greater or eccentric but there is considerable overlap. The presence of diverticulosis may suggest diverticulitis but carcinoma may frequently complicate colon affected by diverticular disease. Perforation of a cancer may be particularly difficult to differentiate from diverticulitis. The presence of enlarged nodes may favour the former. Other conditions to differentiate include ischaemic, infectious and inflammatory colitis. Longer segmental involvement and absence of extramural disease may suggest other conditions. Primary epiploic appendagitis is frequently misdiagnosed as either appendicitis or diverticulitis, depending on its location.

Intervention

Patients with pericolic abscess greater than 4 cm in diameter are best managed with a combination of CT guided drainage and intravenous antibiotics. Emergency surgery is reserved for those patients with peritonitis or free perforation. Elective surgery may follow successful conservative management particularly following repeated relapse or bleeding. CT or US guided drainage may also be suitable for draining liver abscess complicating diverticulitis.

Diverticulosis, Colon

Defined as the formation of out pouchings of mucosa and sub mucosa, or diverticula, secondary to the process above. These diverticula form through natural weaknesses where the vasa recta perforate the muscularis propria to penetrate the sub mucosa either side of the mesenteric taenia and on the mesenteric side of the anti-mesenteric taenia.

▶Diverticulitis, Gastrointestinal Tract

Diverticulosis, Gallbladder

This condition of unknown etiology, also termed cholecystitis glandularis proliferans or adenomyomatosis, is characterized by widening of the Rokitansky–Aschoff sinuses, normally represented by small fingerlike invaginations of gallbladder mucosa. These become more evident in the case of diverticulosis and may extend into the muscular or serosal layers as variably cystic spaces.

▶Cholecystoses

Diverticulum(a)

The out pouchings of mucosa and sub mucosa which are therefore pseudo-diverticula rather than true diverticula which contain all layers of the gut and are seen in rare hereditary form arising from the caecum.

Definition

A diverticulum is defined as a circumscribed pouch or sac of variable size created by herniation of the lining mucous membrane through a defect in the muscular coat of the tubular oesophagus. An acquired diverticulum is produced secondarily, mechanically, or by disease. A pseudo-diverticulum is defined as a diverticulum created by an outpouching of the full thickness of the intestinal wall including the muscular layer.

This chapter will deal with three types of diverticula: *Intramural diverticula* that are millimetre-sized diverticula confined to the oesophageal wall. *Pulsion diverticula*, often less than 3–5 cm in size, is located in the midportion of the oesophagus. These are by definition pseudo-diverticula. *Epiphrenal diverticula* that are usually 10–20 cm big diverticula located in the most distal part of the oesophagus.

Pathology/Histopathology

Oesophageal Intramural Pseudo-diverticulosis

In patients with chronic oesophagitis, either due to infection or reflux of gastric content, dilatation of ducts of mucous glands in the oesophagus occurs. These excretory ducts are 2–5 mm in depth and located in the oesophageal wall. Particularly infections of *Candida albicans* has been related to such pseudo-diverticula. There have also been observations that pseudo-diverticulosis is associated with strictures of the oesophagus.

Diverticula of the Oesophagus

These are almost invariably associated with oesophageal motor disorders. This means that a diverticulum has been formed by pulsion due to increased intraluminal oesophageal pressure. Prior hypotheses about a traction mechanism due to fibrosis in adjacent peri-oesophageal tissues, i.e. lymph nodes, have not been verified.

Epiphrenic Diverticula

Also these diverticula are probably due to oesophageal motor disorders. They are located in the distal part of the oesophagus. It is unclear why the diverticula in the distal part of the oesophagus have a tendency to grow to particularly larger size than the mid-oesophageal diverticula.

Clinical Presentation

Oesophageal Intramural Pseudo-diverticulosis

Oesophageal intramural pseudo-diverticulosis usually occurs in elderly. Dysphagia may be present. However, concomitant infections and associated strictures are more symptomatic than the small diverticula *per se*.

Diverticula of the Oesophagus

The symptoms of these diverticula are probably only related to the motor disorders. Patients may experience crampy thoracic pain, regurgitation or even vomiting.

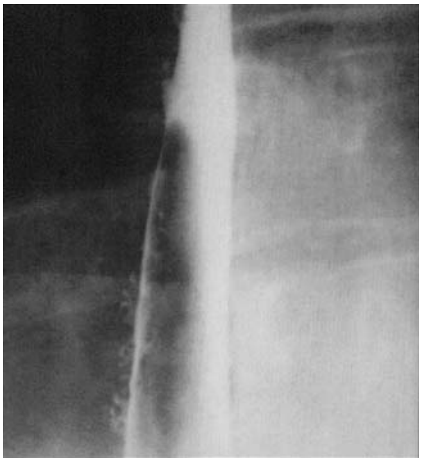
Epiphrenic Diverticula

Also in these patients symptoms from the oesophageal motor disorder predominate. However, these big diverticula also retain food. This food may regurgitate when the patient is recumbent. The retained food may also harbour and grow bacteria. Therefore, a foul smell may be a leading symptom. Patients may also experience pain and this has sometimes been referred to as ischemic.

Imaging

Oesophageal Intramural Pseudo-diverticulosis

The diverticula are best seen when filled with high-density barium contrast medium (Fig. 1). When the



Diverticulum, Oesophagus. Figure 1 Intramural oesophageal diverticulosis. There are several millimetre-sized enlarged mucosal glands on the right side of the oesophagus. The rest of the oesophagus looks normal.

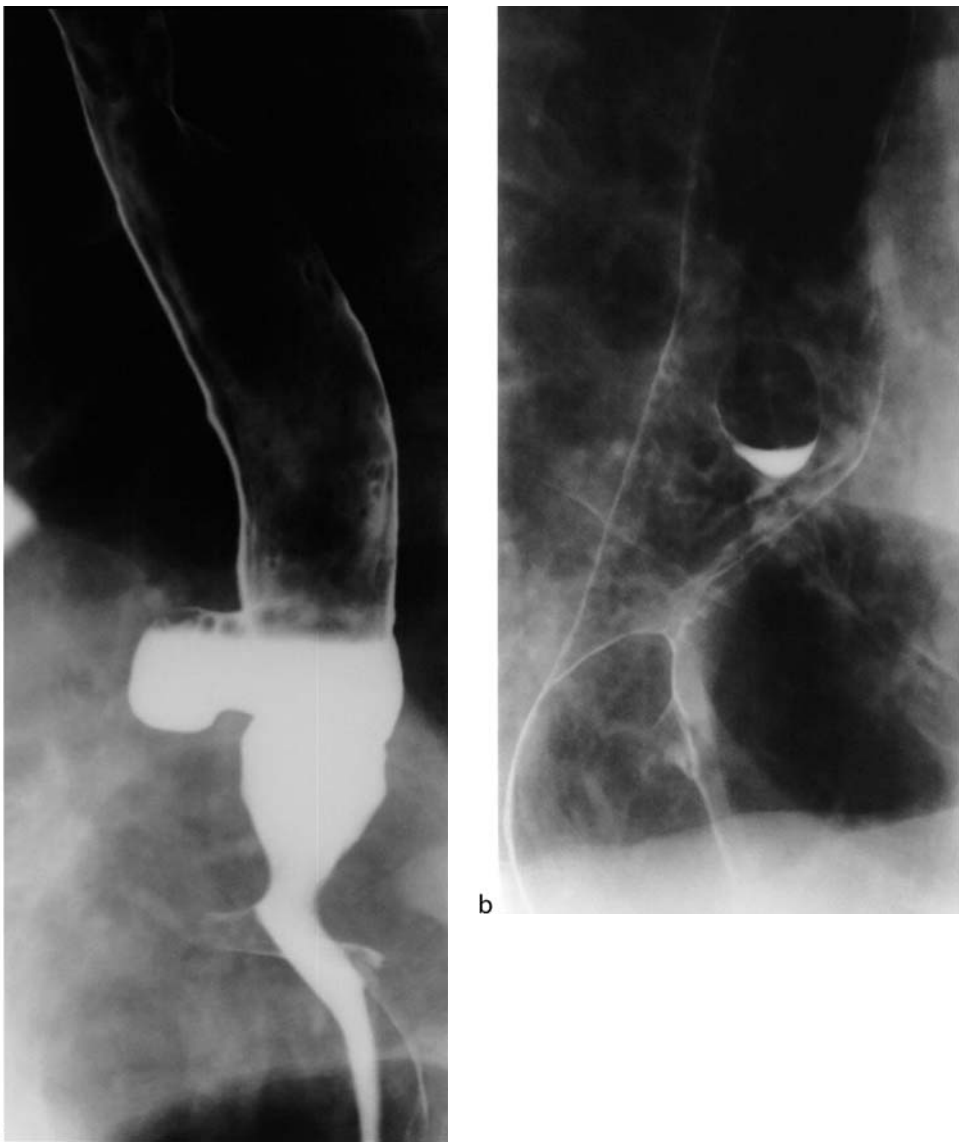
oesophagus is examined with double-contrast technique using effervescent agents the diverticula may be obscured if the oesophagus is dilated and the diverticulum is not particularly demonstrated in profile. On iodine contrast studies, it is an advantage to use 350 mg I/mL in order to enhance visualisation.

Diverticula of the Oesophagus

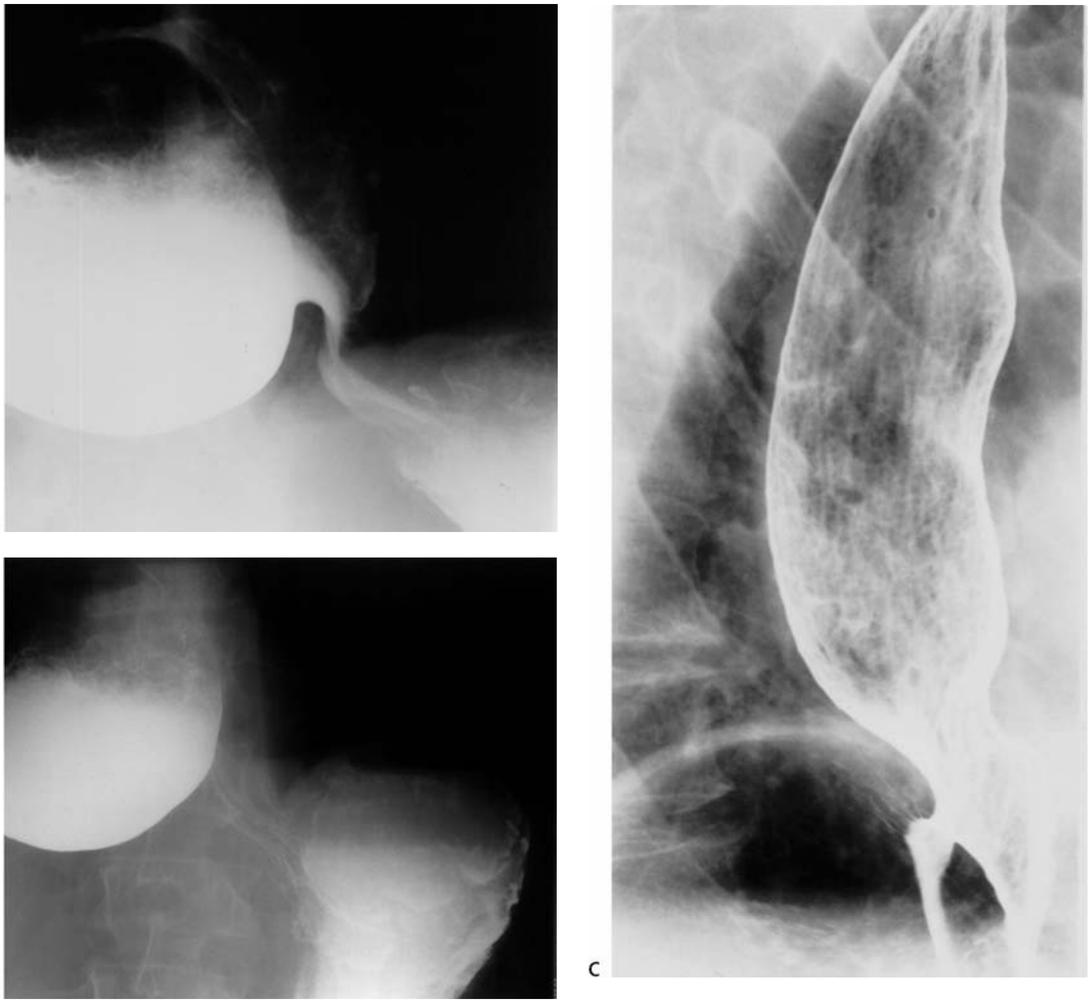
A diverticulum of the mid-oesophagus is seen as a localised bulge of one up to several centimeters in size (Fig. 2). The contour is smooth and often variable. The diverticulum moves in symmetry with the adjacent oesophagus during the propulsion of the bolus through that particular segment of the oesophagus. The diverticulum may or may not contain air. During double contrast ►oesophagogram, the diverticulum regularly harbours gas. When the diverticulum does not empty the contrast material, it is likely that it lacks muscular coating indicating that it is a true diverticulum. Usually the diverticula in the mid-oesophagus are of pseudo-diverticular type and contain a muscular layer. Therefore, they empty after the passage of the bolus. However this emptying may be delayed or slow.

Epiphrenic Diverticula

These diverticula are usually diagnosed during radiologic evaluation of dysphagia, regurgitation or thoracic pain. They are often 10 cm or larger in size and often contain



Diverticulum, Oesophagus. Figure 2 A 2-cm sized diverticulum in the mid-oesophagus. The diverticulum contains barium and small amounts of air (a). In (b), the diverticulum contains mostly air.



Diverticulum, Oesophagus. Figure 3 **A 15-cm sized epiphrenal diverticulum from the right side of the oesophagus. The d is the diverticulum, s is the stomach and e is the distal oesophagus (a–c). The proximal oesophagus is somewhat dilated. Arrow is the opening of the diverticulum.**

retained food particles. Endoscopy may also reveal the orifice of the diverticulum but will usually not give any information about the size of the diverticulum (Fig. 3).

Nuclear Medicine

Large diverticula are able to retain isotopes and can thereby be diagnosed.

Diagnosis

Oesophageal Intramural Pseudo-diverticulosis

These diverticula are usually diagnosed on barium contrast oesophagograms. Endoscopically, these diverticula are not discerned due to there very small and narrow openings.

Diverticula of the Oesophagus

The mid-oesophageal diverticula are usually diagnosed during barium oesophagograms performed for evaluation of dysphagia or vomiting. Endoscopy may also reveal these types of diverticula. However, the diagnosis is more difficult.

Drug Delivery Systems

A drug-delivery system consists of microbubble or biopolymer contrast agents containing an active compound (drug) attached or encapsulated in the shell. The active substance is transported with the agent to the target region, inhibiting the extravascular distribution outside of the target region. The local release of the drug is obtained by local destruction of the shell (using high-power ultrasound) or by slow release after binding of the shell to the target region.

Drug-induced Hepatitis

A large number of drugs can cause hepatitis. The so-called drug-induced hepatitis or medication-induced hepatitis, is similar to acute viral hepatitis, but hepatocellular destruction is usually more extensive. Halothane (a specific type of anesthetic gas), methyldopa (antihypertensive), isoniazid and rifampicin (tuberculosis-specific antibiotics), oral contraceptives, amiodarone (antiarrhythmic) are only few examples of the innumerable hepatotoxic drugs. The clinical course and severity of drug-induced hepatitis are extremely variable, both dependent on the drug and the individual reaction to the drug. Virtually any drug can be a cause of hepatitis. Manifestations of hepatotoxicity to a medication may occur on the first or second day of use or not until several months later. Usually, the onset is abrupt, with fever, rash, pruritus, anorexia, arthralgia, and nausea. If such symptoms occur after the administration of a drug, its use should be stopped immediately. Laboratory analyses show altered liver tests and eosinophilia.

▶ Hepatitis

DSA

Digital subtraction angiography uses a fluoroscopically acquired digital 'mask' image without contrast which is then subtracted from subsequent frames obtained following contrast injection.

Time-consuming, invasive X-ray technique for visualisation of the vascular tree.

▶ Cerebral Aneurysms

Duct Disease, Breast

Luis Pina
ljpina@unav.es

Synonyms

Comedomastitis; Duct ectasia; Mastitis obliterans; Periductal mastitis; Plasma cell mastitis; Secretory disease; Varicocele of the breast; Varicocele tumor

Definition

The term "duct disease" includes duct ectasia and periductal mastitis. Both processes may occur independently or, more frequently, in combination. Duct ectasia is defined as the dilatation of the subareolar ducts, usually measuring 1–5 mm. Periductal mastitis is an inflammatory infiltrate surrounding the ducts (1–3).

Pathology

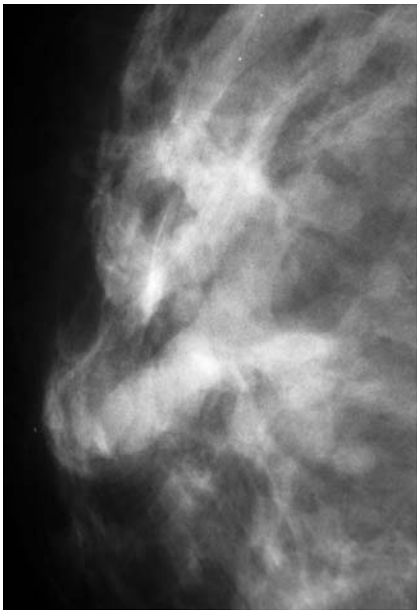
Dilated, thick-walled ducts with thick secretions are seen in the gross specimen (1). On microscopic examination, a leakage of ducts with release of lipid-rich material in the adjacent stroma in seen, inducing periductal inflammation, fibrosis, and fat necrosis. The periductal inflammation may be predominantly composed of plasma cells. Some authors believe that dilatation of the ducts is the primary event, whereas others believe it is secondary to periductal inflammation (1–3).

Clinical Findings

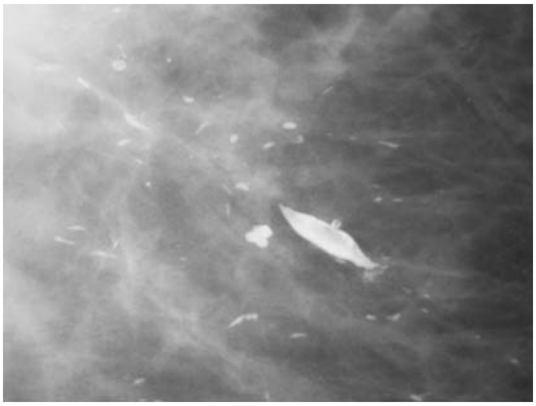
Duct ectasia is found in perimenopausal or postmenopausal women. Microscopically it has been described in up to 40% of autopsies (1).

The first symptom of duct ectasia is spontaneous and intermittent ▶nipple discharge from several ducts. This fluid may be off-white, creamy, brown, gray, or green, and also can be bloody (2). Sometimes the secretions are as thick as toothpaste. The patient usually describes subareolar tenderness. Nipple retraction and a hard retroareolar mass may be found, mimicking breast cancer. Abscess formation and mammary duct fistula can complicate this condition. Cigarette smoking is associated with these complications (2).

Duct disease is a benign condition and does not increase the risk of developing breast cancer.



Duct Disease, Breast. Figure 1 Duct ectasia is seen on mammography as dilated tubular structures underneath the nipple. Mediolateral oblique view (detail).



Duct Disease, Breast. Figure 2 Characteristic ▶secretory calcifications. The particles are coarse, dense, smooth-bordered, and pointing toward the nipple.

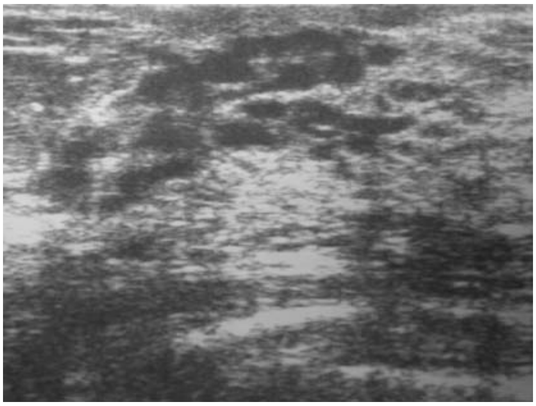
Imaging

Mammography: Duct ectasia is seen as one or more tubular structures oriented to the nipple (Fig. 1). If the periductal inflammation and fibrosis are predominant, the lesion may be seen as an ill-delimited mass, similar to breast carcinoma (4) (Fig. 2).

Galactography is not indicated for bilateral or pluriorifical nipple discharge. Rarely, the nipple discharge may be unilateral and uniorificial, and galactography is performed. In these cases, a dilated galactophoric tree is seen.

Characteristic calcifications may be found in intraductal, intramural, or periductal locations (5). These calcifications are typically coarse and elongated, pointing toward the nipple (Fig. 2). Other calcifications may be round or elongated with central radiolucency. Most of these calcifications are easily recognized as benign, especially if they are bilateral. However, sometimes the calcifications are very small and similar to the suspicious microcalcifications of intraductal carcinoma. In these cases, a biopsy is warranted (5) (Fig. 3).

Ultrasound: Duct ectasia is seen as fluid-filled tubular structures underneath the nipple (Fig. 3). If a palpable mass is found in the retroareolar space due to



Duct Disease, Breast. Figure 3 **Ultrasonography shows subareolar dilated ducts. Ductal ectasia.**

inflammation and fibrosis, ultrasonography may detect an irregular hypoechoic mass. In these cases, a biopsy is recommended. The characteristic calcifications are not usually seen on ultrasonography (4).

Magnetic resonance: The periductal inflammation may be responsible for the enhancement after paramagnetic contrast administration.

Nuclear Medicine

There are no indications for nuclear medicine in the diagnosis of duct disease.

Diagnosis

Most ductal ectasias are asymptomatic and are discovered on routine mammographic or ultrasonographic exams. If nipple discharge is absent, there is no need for further diagnostic procedures. However, if the ectasia is palpable or there is nipple discharge, the secretion may be analyzed. The combination of a retroareolar palpable mass and nipple retraction is suspicious, and a biopsy is recommended. The typical calcifications found on mammography are pathognomonic. However, in an initial stage the calcifications may be tiny and simulate breast cancer, especially intraductal carcinoma. In these cases, a biopsy should be performed.

Duct Ectasia

►Duct Disease, Breast

Duct of Santorini

The duct of Santorini is usually the accessory duct of the pancreas that atrophies once the dorsal and ventral glands fuse and once the main duct of Wirsung becomes patent. It is connected to the minor papilla.

►Congenital Malformations, Bile Ducts

Ductal Carcinoma In Situ

Malignant lesion located in the ductal component and characterized by the fact that the malignant cells do not trespass the basal line of the epithelium.

►Breast Conserving Therapy

Ductal Intra-Epithelial Neoplasia (DIN) Type 1c to 3

►Carcinoma, Ductal, *In Situ*, Breast

Ducts

15-20 tubular structures in the breast lined with epithelium which convey secretions from the breast lobules to the nipple.

►Carcinoma Breast, Imaging Mammography, Secondary Signs

Duodenal Atresia

A congenital abnormality in which there has been failure or canalization of the duodenum in embryological development resulting in complete duodenal obstruction.
▶GI Tract, Paediatric, Congenital Malformations

Duodenal Ulcer

▶Ulcers, Peptic

Duplication Cyst

Duplication of the gastrointestinal tract may occur at any level from the tongue to the anus. It corresponds to a duplicated segment of the gastrointestinal tract. The duplication may or may not communicate with the gastrointestinal tract. It can be round (and cystic) or tubular. At the level of the duodenum, the duplication may communicate with the pancreatic duct.
▶Congenital Malformations, Bile Ducts
▶GI Tract, Paediatric, Congenital Malformations

Duplication of bile ducts

Presence of additional bile ducts. In case of duplication of the common bile duct, both branches may enter into the duodenum or one may empty into the stomach while the other enters into the duodenum. Cases of duplication of the common hepatic and cystic ducts containing ectopic gastric mucosa have been reported.
▶Congenital Malformations, Liver and Biliary Tract

Duplications and Triplications (Kidney, Ureter, Bladder and Urethra) of the Urinary Tract

Increase in number of the ureter, the urethra, the bladder or the kidneys, respectively the pelvo-caliceal system. This embryologically induced condition may lead to impaired urinary drainage, VUR and potentially dysplasia of affected (renal) parenchyma.
▶Urinary Tract

Dural-Based Tumors

Dural-based tumors are benign or malignant tumors involving the dura. Enhanced magnetic resonance imaging is the modality of choice for their diagnosis.
▶Neoplasms, Extraaxial, Brain

DXA

▶Dual-energy X-ray absorptiometry

Dynamic Contrast-enhanced MR Imaging

Dynamic contrast-enhanced MR imaging is performed after the administration of intravenous contrast medium to access vascular characteristics of tumors and normal tissues. T1-shortening from contrast agent is considered a measure of tissue perfusion, capillary permeability, and volume of extracellular space.
▶Neoplasms, Salivary Glands

Dynamic Magnetic Resonance Imaging

MRI technique with very short acquisition time to assess displacement.
▶Incontinence, Urinary

Dysphagia

Difficulty swallowing. The term is properly used to describe some degree of obstruction after swallowing, but the term is used so loosely by physicians, that the radiologist has to ascertain from the patient the precise nature of the complaint to which the term dysphagia has been applied.

Synonyms

BPD; Chronic lung disease of prematurity; CLD

Definitions

►Bronchopulmonary dysplasia (BPD) is defined as a chronic lung disease which occurs in premature infants. due to treatment with oxygen and positive pressure ventilation. Pulmonary immaturity, oxygen toxicity, formation of oxygen radicals, volutrauma, and barotrauma as well as additional factors such as pulmonary inflammation contribute to pulmonary damage. BPD is infrequent in infants of more than 1,200 g birth weight and with greater than 30 weeks gestation. Gentler ventilation techniques, antenatal glucocorticoid therapy, and surfactant treatment have minimized severe lung injury in larger and more mature infants (1).

Pathology/Histopathology

Before the surfactant treatment era, airway injury, inflammation, and parenchymal fibrosis were the prominent findings in BPD. Four stages of BPD were identified representing acute lung injury, exudative bronchiolitis, proliferative bronchiolitis, and obliterative fibroproliferative bronchiolitis. Necrotizing bronchiolitis occurs as a result of edema, inflammatory exudate, and necrosis of epithelial cells. Inflammatory cells, exudate, and cellular debris obstruct the terminal airways. Activation and fibroblast proliferation results in peribronchial fibrosis and obliterative fibroproliferative bronchiolitis. Structural changes in the pulmonary arteries were similar to those seen in hypertensive vascular disease and include intimal proliferation, medial hyperplasia, and adventitial thickening (2).

In recent years, due to improved management and treatment, the lungs of infants with BPD showed less fibrosis and more uniform inflation. The large and small airways were remarkably free of epithelial metaplasia, smooth muscle hypertrophy, and fibrosis (3). However, alveoli were found to be less numerous and larger, indicating an interference with septation, despite an increase in elastic tissue that is proportionate to the severity of the respiratory disease before death. Some specimens also had shown decreased pulmonary microvasculature development.

Clinical Presentation

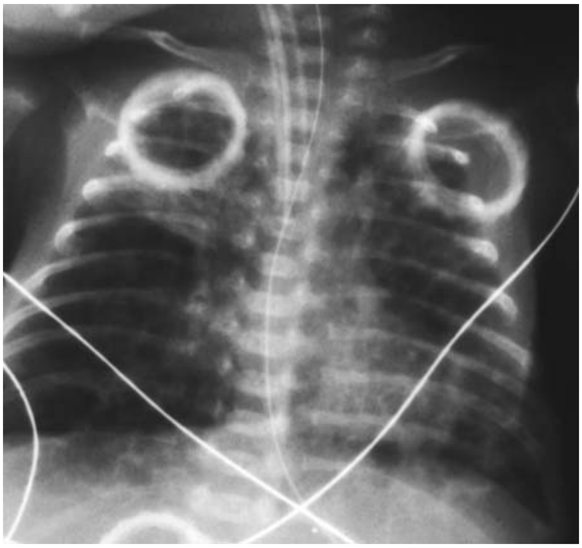
Infants with BPD present with tachypnea, tachycardia, intercostal retractions, nasal flaring, expiratory stridor, poor weight gain, right ventricular hypertrophy, and pulmonary hypertension. A June 2000 National Institute of Child Health and Human Development/National Heart, Lung, and Blood Institute Workshop proposed a severity-based definition of BPD for infants <32 weeks gestational age. Mild BPD was defined as a need for supplemental oxygen (O_2) for 28 days but not at 36 weeks postmenstrual age (PMA) or discharge, moderate BPD as O_2 for 28 days plus treatment with <30% O_2 at 36 weeks PMA, and severe BPD as O_2 for 28 days plus 30% O_2 and/or positive pressure at 36 weeks' PMA (4). Especially during the first two years of life, children with BPD suffer from lung dysfunction, airway hyperactivity, pulmonary hyperaeration, and recurrent respiratory tract infections. The disease may be complicated by right ventricular hypertrophy or pulmonary hypertension. However, in many children the pulmonary function improves over the years with continuing growth and healing of the airways.

Imaging

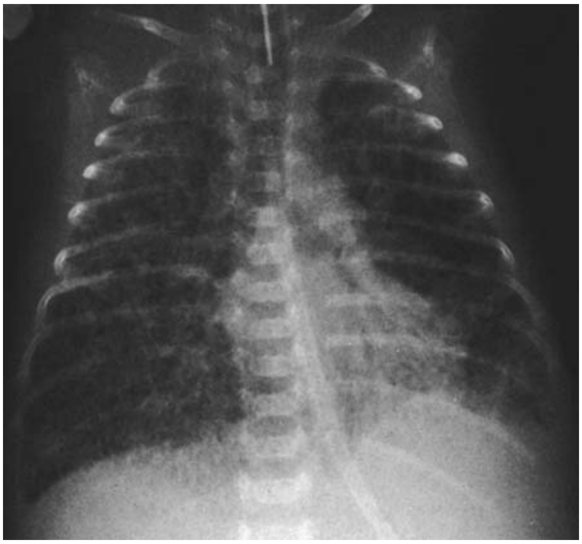
Imaging of pulmonary diseases in premature infants on intensive care units is based on chest radiography. In recent years, high-resolution computed tomography (HRCT) has been performed for better characterization of pulmonary changes due to BPD, and especially for the evaluation of pulmonary changes as late sequelae (5).

Nuclear Medicine

Scintigraphy is rarely used in infants with BPD. Ventilation and perfusion scans demonstrate a ventilation perfusion mismatch and air trapping with delayed nuclide washout, especially in bullous areas.



Dysplasia, Bronchopulmonary. Figure 1 Severe bronchopulmonary dysplasia. A coarse reticular pattern associated with pseudocysts (bubbles) especially in the lung bases is demonstrated. Atelectasis in the right upper lobe is also visible.



Dysplasia, Bronchopulmonary. Figure 2 Bronchopulmonary dysplasia with hyperinflated lungs, a fine reticular pattern and atelectatic areas in the left lower lobe.

Diagnosis

In 1967, Northway and associates first described four different stages of severity (6). Stage I (2–3 days after birth) is similar to uncomplicated respiratory distress syndrome with fine granular opacities and accentuation of the air bronchograms. In stage II of BPD (4–10 days), nearly complete opacification of the lungs is evident. Chest radiographs in stage III BPD (10–20 days) show small round cystic lucencies alternating with regions of irregular opacity. Stage IV BPD (beyond 1 month) demonstrates further enlargement of lucent regions alternating with thin strands of increased opacity, representing ►bubbly lungs (2).

The typical radiographic findings with grossly coarse reticular patterns associated with large pseudocysts (bubbles) especially in the lung bases (Fig. 1), are less commonly seen in recent years, due to the changed treatment regimen of respiratory distress syndrome in premature infants. Nowadays, BPD appears typically with a finer reticular pattern, localized hyperlucent areas and generalized hyperaeration (Fig. 2) (5). On HRCT images the late sequelae of bronchopulmonary dysplasia are well-identified, including multifocal areas of hyperaeration, well-defined linear opacities, and triangular subpleural opacities with an external base and an internal apex, vascular attenuation with reduced bronchoarterial diameter ratios, bronchial wall thickening without bronchiectasis and bullae or pneumatoceles (2, 5). The radiological differential diagnosis of BPD includes Wilson-Mikity syndrome, congenital pulmonary lymphangiectasia, neonatal tuberculosis, cystic fibrosis, and Hamman–Rich syndrome.

Synonym

Osteochondrodysplasia

Definition

Skeletal dysplasias are genetic connective tissue disorders affecting skeletal development. They become apparent by the abnormal growth, shape, and composition of bone.

Pathology/Histopathology

Skeletal dysplasias are a heterogeneous group of disorders characterized by systematic development disorders of ossification (1–4).

In recent years, the genetic defect of several dysplasias was discovered. For many conditions the pathogenesis still remains unknown.

Skeletal dysplasias can be divided into osteodysplasias and chondrodysplasias: Osteodysplasias are subgrouped into osteopenic and sclerosing bone dysplasias. The most widely used classification is the International Nomenclature of Constitutional Disorders of Bone. Genetic bone disorders are classified into families of disorders in an attempt to incorporate clinical, radiodiagnostic, and morphological features together with the genetic background (5).

Clinical Presentation

Skeletal dysplasias are a highly heterogenic group comprising more than 200 disorders (1). In general, the appearance is a disproportionate short stature below the mean height of age.

The incidence is about 2–5:10,000 births (6). The inheritance pattern is variable. The most common dysplasias are achondroplasia, osteogenesis imperfecta (OI), and thanatophoric dysplasia.

Achondroplasia

With an incidence of 1:20,000 live births, achondroplasia is the most common osteochondrodysplasia.

Most patients are of normal intelligence and have a normal life expectancy.

The typical features are

- Short stature.
- Hyperkyphosis and lordosis.
- Short limbs.
- Y-shaped growth plates.
- Trident hand with persistent space between the long and ring fingers.
- Short pedicles, which can lead to spinal stenosis.
- Short femoral neck; metaphyseal flaring; dysplastic ileum; narrow sacroiliac groove; and flat-roofed acetabula.
- Prominent calvarial bones in contrast to small cranial base and facial bones.
- Limited elbow extension.
- Genu varum.

Osteogenesis Imperfecta

OI occurs in 1:20,000 to 1:60,000 of live births.

OI results from a defect of type I collagen production that leads to congenital osteopenia with increased bone fragility.

The Sillence classification differentiates four subtypes with different clinical manifestations and different inheritance patterns.

The common feature is a micromelic (short-limbed) dwarfism of variable degree. Bone fragility may cause perinatal death or severe deformities into adulthood.

Common radiological hallmarks include: (Fig. 1)

- Generalized osteoporosis.
- Spinal abnormalities with scoliosis and platyspondyly.
- Deformation of long bones depending on the severity of OI (from overtubulated bone with thin cortex to thickened shortened bone with multiple fractures).
- Hyperplastic callus formation.
- A so-called wormian aspect of skull bone.

An important differential diagnosis in a child with multiple fractures is child abuse.

Thanatophoric dysplasia

Thanatophoric dysplasia is nearly always lethal in the prenatal period.

Typical findings are curved or straight short femurs, symmetric micromelia, narrow thorax with short ribs, and a protuberant abdomen.

Polyhydramnion can be observed.

Dysplasias, Skeletal. Figure 1 Babygram shows a reduced bone density, a thinning of cortical bone, and severe deformation of long bones.

Imaging

The radiologic evaluation plays an essential part in establishing the diagnosis.

If the radiologic and clinical identification of a syndrome is not conclusive, further molecular and genetic testing is necessary.

The primary aim of the radiologic work-up is to find out which regions of the skeleton are predominantly affected.

Cardinal information is obtained by analysis of the long bones, the hands, the pelvis, and the spine. Further skeletal imaging—for example, of the skull, feet, and flat bones—is of additional relevance.

The analysis of long bones takes into account their length and shape and determines whether the changes manifest themselves in the epiphyses, metaphyses, or diaphyses. Bone density must be assessed, because increased or decreased bone density is sometimes the clue to specific diagnosis.

Some radiographic features are highly specific for certain pathologies. Examples are the radiographic images of the pelvis of achondroplasia or the hypoplastic scapulae and nonossified thoracic pedicles in campomelic dysplasia.

Timing of ossification should be evaluated because sometimes it gives a diagnostic clue: some dysplasias, for example, achondrogenesis or atelosteogenesis, show a delayed or retarded ossification of skeletal elements. The skeletal survey should be done before puberty to be able to evaluate the growth plate. In many dysplasias specific diagnosis after closure of growth plates is difficult and in certain cases a specific diagnosis cannot be reached.

The radiographic evaluation should include:

- Anteroposterior (AP) and lateral view of the skull and the entire spine.
- AP view of the thorax.
- AP view of the pelvis.
- AP view of the left hand.
- AP view of the long bones (in cases of symmetry it can be limited to one side).
- Lateral view of knee (patella).
- In neonates and children younger than 6 months with suspicion of skeletal dysplasia, a babygram (AP and lateral views of the entire body) is sufficient.

Magnetic resonance imaging (MRI) is used to display associated pathologies of the brain, the brain stem, and the spine.

Myelopathy of the cervicomedullary cord secondary to stenosis of the foramen magnum is best evaluated by MRI.

Helical computed tomography (CT) with multiplanar and three-dimensional reconstructions is useful to show the morphology of complex deformities and allows surgical planning.

Antenatal ultrasound: Prenatal ultrasonography can identify most fetuses with skeletal dysplasia by identification of short limbs and other skeletal and nonskeletal anomalies. The finding of a short femur length (relative to gestational age) on routine prenatal sonographs should alert the examiner and lead to a systematic evaluation of the entire skeleton.

Pathologic ossification and shape of long bones, for example, bowing and angulation of the femur, can be detected by 15–18 weeks' gestation and distinguishes fetuses with skeletal dysplasia from growth-restricted fetuses. Additionally, callus formation in cases of antenatal fractures, thorax hypoplasia, spinal deformities such as platyspondylia, hand deformities, craniofacial malformation, and other associated anomalies can be visualized by ultrasound.

Bone mineral densitometry (BMD) measurements with dual-energy X-ray absorptiometry (DEXA) of the lumbar spine (children >1 year) and femoral neck (children >6 years) or qualitative CT (QCT) of the lumbar spine in children older than 4 years are accepted techniques with which to confirm osteoporosis in patients with OI.

Nuclear Medicine

Nuclear medicine is not used as a routine method in the evaluation of skeletal dysplasia.

Diagnosis

Because there is a high diversity in clinical and morphological features, the diagnosis of skeletal dysplasia can be very difficult. Typically the diagnosis is based on clinical hallmarks in combination with radiologic and morphologic studies. Biochemical or DNA analysis supports the diagnosis when the gene or the defective gene product is known.

A complete clinical assessment should include the following tests (5):

- Complete personal and family history with pedigree analysis.
- Physical examination with anthropometric measurements of height, weight, head circumference, upper-to-lower segment ratios, sitting height, and arm spans.
- Radiologic work-up.

If not conclusive, the following should be included:

- Biochemical studies to analyze protein defects.
- DNA studies.

Additionally histopathologic evaluation of specimens of chondroosseous tissues can help lead to the correct diagnosis. This requires bone biopsy and it should always be performed if the patient undergoes surgical intervention, for example, because of fracture stabilization.

Dysplastic Nodule, Hepatic

The term dysplastic nodule replaces older terms like adenomatous hyperplasia and macroregenerative nodule and refers to a nodular region of hepatocytes with dysplasia but without definite malignancy, which represent an intermediate step in the pathway of hepatocarcinogenesis in cirrhosis. Dysplastic nodules are considered neoplastic, premalignant nodules. At ultrasound US and unenhanced computed tomography CT it is difficult to distinguish these nodules from regenerative nodules or small hepatocellular carcinomas (HCCs). The signal characteristics at magnetic resonance MR allow to differentiate these nodules from HCC. Usually dysplastic nodules are hyperintense on T1-weighted and hypointense on T2-weighted sequences. Dysplastic nodules may be siderotic, appearing in these cases as hypointense both on T1 and T2-weighted images. The enhancement behaviour at contrast US, CT and MR studies is the most important imaging feature in the differential diagnosis of dysplastic nodule and HCC. The latter is typically hypervascular and shows marked enhancement in the arterial phase, while dysplastic nodules have a prevalent portal blood supply and do not show arterial enhancement. Sometimes a nodule-within-a-nodule appearance may be noted on MR images; this finding consists of one or more hyperintense internal foci within a low signal intensity nodule on T2-weighted images and represents HCC foci developing within a dysplastic nodule. This pattern is particularly evident if a focus of HCC originates within a siderotic regenerative nodule. The central nodule usually also shows enhancement during the arterial phase at dynamic study.

Synonyms

Extracorporeal membrane oxygenation

Definition

Extracorporeal membrane oxygenation (ECMO) is an extracorporeal therapy used in severe respiratory insufficiency that cannot be treated by conventional techniques.

Embryology and Pathogenesis

ECMO depends on the various underlying diseases that necessitate this invasive therapy. The principle of ECMO is to substitute the diseased lung (and partially also heart function). Venous blood is pumped through a filter that uses a membrane for CO_2 elimination and blood oxygenation; this blood is then retuned to the body. Two major approaches are used: (1) Venous ECMO (vv), in which blood is drained from and then infused back into a large vein (i.e., inferior and superior cava vein); (2) Arteriovenous (av) ECMO, in which blood is drained from the right ventricle and infused into the thoracic aorta usually *via* a carotid catheter (this approach additionally allows support of the circulatory system). This therapy needs anticoagulation, putting patients on ECMO at a high risk of hemorrhage.

Clinical Presentation

Severe respiratory and eventually combined cardiac and multiorgan system failure (MOSF) not treatable by conventional means as the common presentation of a variety of congenital or acquired diseases [e.g., diaphragmatic hernia, meconium aspiration syndrome or other severe respiratory distress syndrome (RDS) of various origin, multi-organ system failure multi-organ system failure (MOSF) or severe cardiac conditions, where ECMO may be used as bridging to and after cardiac or thoracic surgery]. Detailed ECMO indications and contraindications vary between different centers and are usually established clinically.

Imaging

There are many imaging methods used in ECMO—most of the imaging needs to be performed at the patients' bedside, as it is difficult and dangerous to transport these critically ill patients to the imaging suite. The *role of imaging* includes:

First, pre-ECMO assessment of disease (see specific chapters and entries); additionally, a detailed assessment of the heart (by echocardiography) and the brain is essential, as well as assessment of potential contraindications (cerebral hemorrhage, brain death, etc.). Subsequently, image-guided catheter placement at onset of ECMO (proper position of the catheter tip) is advocated. Finally, monitoring during ECMO (particularly in case of complications) as well as post-ECMO assessment of potential sequelae are heavily based on imaging.

Imaging Modalities

In *pre-ECMO assessment* mostly *plain film* and *ultrasound* (US) are used [patients are usually too sick to be brought to a computed tomography (CT) or magnetic resonance imaging (MRI) suite]. However, sometimes a *CT* (assessment of the lung or in cerebral hemorrhage) or *MRI* study (hypoxic-ischemic encephalopathy) may become necessary. At *ECMO onset*, US or plain film (and fluoroscopy) studies are used for catheter placement. *Monitoring during ECMO* is mostly performed using plain film and US—in rare cases a CT may become necessary, although bringing the patient on ECMO to the CT suite is quite complicated. *After ECMO* the entire range of imaging modalities may be used, as indicated by the child's specific condition; most commonly US (brain, heart, abdominal parenchymal organs, vessels), plain film (chest, skeletal queries), CT of the chest, and brain MRI are performed for post-ECMO follow-up.

Typical Imaging Findings

Pre-ECMO Assessment

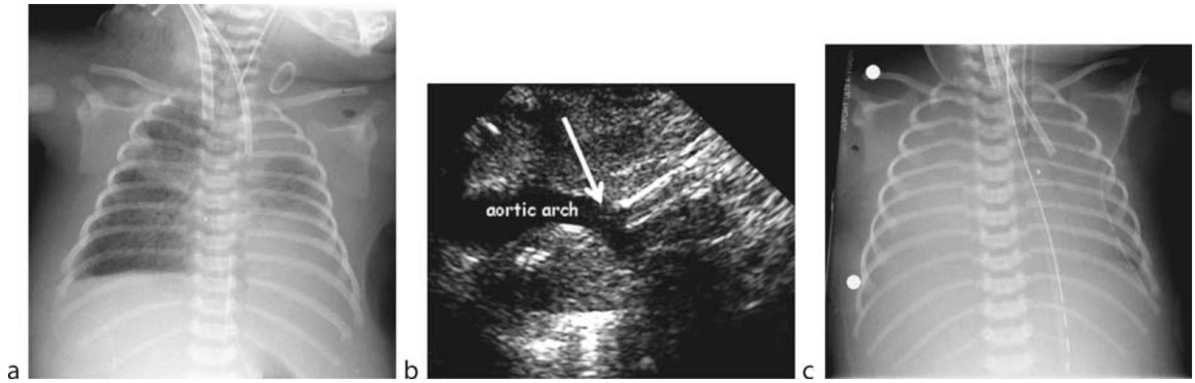
Imaging findings depend on the actual disease, which is usually infant RDS, meconium aspiration syndrome, MOSF (e.g., in severe septicemia), severe cardiac malformation, diaphragmatic hernia and other severe treatable lung malformations, inhalation or aspiration of severely toxic agents with consecutive severe RDS, acute chest syndrome in sickle cell disease, posttransplantation (heart and/or lung) problems. Here, primary diagnosis usually relies on imaging as an essential part of the diagnostic work-up. Furthermore, pre-ECMO assessment for potential ECMO contraindications is necessary and may reveal cerebral hemorrhage, severe brain edema or hypoxic-ischemic encephalopathy, or significant variation of cerebral vessel anatomy with hypoplastic communicant arteries obviating av-ECMO, as does brain death. Finally, a thorough assessment of the patient's cardiac situation is mandatory.

At the Beginning of ECMO

Catheter positioning is one of the most crucial aspects; the catheter tips should be in the aortic arch (arterial line) and in the right atrium (venous line) for av-ECMO, and in the distal inferior cava vein and the right atrium or superior cava vein for vv-ECMO. It is performed differently in various sites. Some centers only measure distances from a chest X-ray and insert the tubes blinded with a postinterventional film to check for and document the position of the catheter tip (Fig. 1a). Some centers use US, which allows for real-time guidance during the procedure and for position correction after having started the extracorporeal circulation (Fig. 1b). The latter may be important, as the consecutive reduction of respirator settings leads to a higher position of the diaphragm, which may cause catheter malposition. For this procedure, the catheters are not fixed initially, but only after repositioning and final adjustment after having started ECMO. Some centers use fluoroscopy to properly position the tips of the large catheters.

Monitoring on ECMO

Most centers have a strict imaging monitoring protocol, which heavily relies on plain film (chest) and US (brain morphology and perfusion, cardiac function, abdominal organ size and perfusion, catheter position and catheter thrombosis or obstruction, other vascular or perfusion disturbances, pleural hemorrhage or effusions, etc.). The appearance of the lung and chest on plain films depends on the underlying condition and the amount of residual mechanical ventilation for respiratory support. Often the



ECMO (Neonate, Pediatric) Imaging. Figure 1 **Early imaging in ECMO (a) Chest plain film for catheter positioning at ECMO onset. (b) Sonographically guided catheter positioning of ECMO cannula. The tip of the arterial line (=>, inserted *via* right carotid artery) just reaches the aortic arch. (c) Chest film during ECMO, in the phase of a "resting lung." Note the "white out" of the lung, due to reduced air content (not to be mistaken for pleural effusion), as well as the ECMO lines in place.**

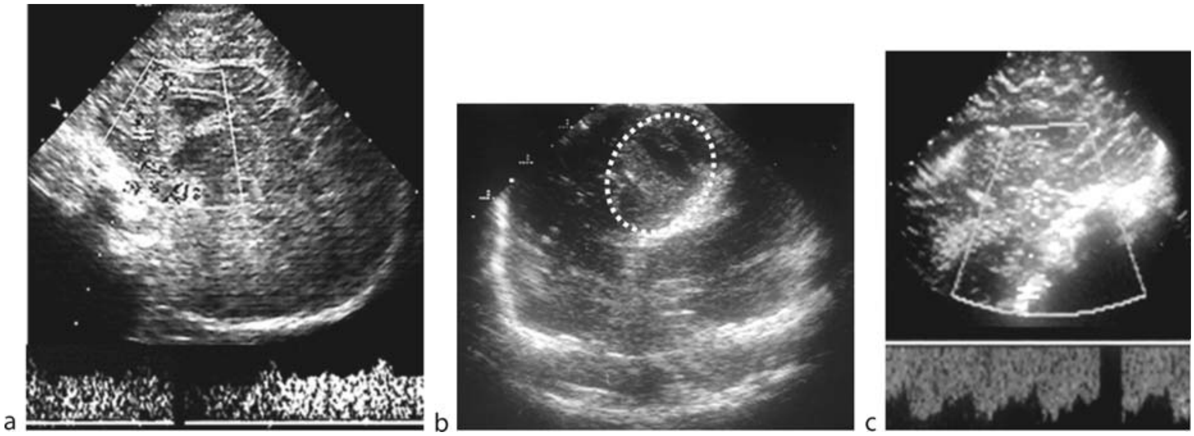
lung is virtually put at rest in the early ECMO stages, with hardly any ventilation left. During this "white out" of the lung, hardly any air is left in the lungs, thus creating a soft tissue or fluid-like appearance of the thorax without a visible ventilated lung (Fig. 1c). Later on (when the pulmonary condition improves) or in milder conditions (with an expected short ECMO time of only a few days and avoiding complete lung collapse), high PEEP is applied and high-frequency oscillation or positive pressure ventilation is reassumed, and a better air content of the lung can be seen, with some signs of overinflation, dystelectasis, or structural damage (influenced by the initially underlying condition). During this stage surfactant can be used to support lung recruitment; this can potentially create chest film abnormalities (i.e., in cases of maldistribution). Other lung complications may be noticed during this phase such as pneumothorax, pleural effusion, lung hemorrhage, or edema (e.g., in cardiac insufficiency). Another important aspect in following up patients on ECMO is to regularly check catheter and tube position, as malpositioning or perforation may create a disastrous situation, particularly with the increased risk of hemorrhage (impaired coagulation caused by heparin necessary for performing the extracorporeal circulation).

Typical US findings and tasks during ECMO include: Regular evaluation of the catheter tip position with assessment of possible catheter obstruction, obstruction of corresponding vessels with consecutive congestion, thrombosis, or suboptimal blood flow caused, for example, by malposition of the arterial line in the descending aorta, thus potentially creating hypoperfusion of the supraaortal branches, particularly to the brain and to the coronary arteries. Other sequelae may be caused by venous obstruction such as hypoperfusion or congestion of abdominal organs, renal vein thrombosis, or the commonly observed widening of the cerebrospinal fluid spaces (particularly extracerebral). On arterial Doppler sonography a high diastolic flow may be observed, with little pulsatile undulation (depending on the flow of the ECMO machine) in av-ECMO that should not be mistaken for brain edema or hyperperfusion (Fig. 2a). Furthermore, various complications such as (brain) hemorrhage and other (abdominal organ) pathology (e.g., organomegaly, ascites, infarction, hyper- and hypoperfusion, secondary phenomena in septicemia such as abscess formation etc.) may become visible. Finally, postoperative complications need to be addressed in patients who have been operated on with ECMO and remain on ECMO postoperatively (e.g., after correction of cardiac malformations or diaphragmatic hernia), such as hemorrhage, pleural and pericardial effusion, posthypoxic necrotizing enterocolitis, or bowel perforation.

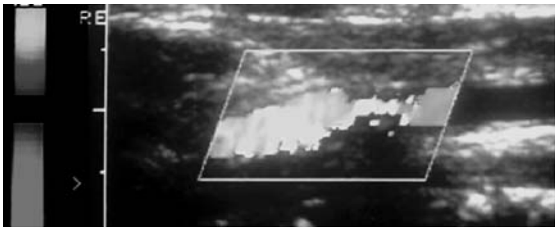
MRI is hardly applicable in neonates and children on ECMO, as the pump and devices are generally incompatible with the magnet. However, even if difficult, CT may be indicated during ECMO, usually for queries regarding the chest and lungs or in sonographically insufficiently assessable suspected cerebral hemorrhage (Fig. 2b).

Imaging After ECMO

Imaging after ECMO should not be neglected, including monitoring of lung development (chest films, chest CT), assessment of the development of potentially affected parenchymal abdominal organs such as the kidney or the liver (US, scintigraphy, MRI), assessment of cerebral



ECMO (Neonate, Pediatric) Imaging. Figure 2 Cerebral US on ECMO (a) Brain duplex Doppler of a newborn on av-ECMO (anterior cerebral artery): note the high diastolic flow velocity due to the ECMO roller pump, with only short systolic flow spikes at normal peak systolic flow velocity still visible. (b) Severe intracranial parenchymal hemorrhage (O) in an infant on av-ECMO for severe RDS after oil inhalation. (c) Additional vertebral steel phenomenon on DDS: reversed flow direction with ECMO-typical flow profile in the (basilar and) vertebral artery due to carotid obstruction by the ECMO cannula.



ECMO (Neonate, Pediatric) Imaging. Figure 3 Carotid artery stenosis after av-ECMO. Note the short, narrow concentric stricture at the site of the recanalization procedure, with some aliasing on color Doppler sonography.

outcome (potential hydrocephalus, cerebral atrophy, or hypoxic brain damage) using US and MRI, and assessment of potential vascular complications (stenosis, thrombosis, and occlusion; usually at the site of the catheter). This is performed primarily with US, particularly in vessels that have been recanalized surgically at catheter removal (Fig. 3). In some of these cases, CT or MR angiography or even digital subtraction angiography (DSA) may become necessary for further detailed evaluation of vascular anatomy before deciding on therapy options.

Diagnosis

Imaging diagnosis and diagnostic features depend on the underlying organ, symptom, or condition, as well as on the imaging modality.

ECMO Cannula

An extracorporeal circulation life support technique that replaces ventilation for conditions not treatable by conservative respiration therapy; large catheters are used to drain the blood from the venous system and reinfuse oxygenated blood.

ECST

European Carotid Surgery Trial.

►Stent, Carotid Artery

Ectopic Kidney

Malposition of the kidney by embryological reasons; these kidneys often are hypo-dysplastic, associated with other genito-urinary tract malformations or dysfunctions, and may be found in the pelvis and mid-abdomen, but even rarely in a thoracic position.

▶Urinary Tract

Ectopic Pancreas

Ectopic pancreas is defined as pancreatic tissue in ectopic anatomical locations, lacking contact with the normal pancreas. Ectopic pancreatic tissue possesses its own ductal system and blood supply.

▶Congenital Anomalies of the Pancreas

Ectopic Pregnancy

Clinically and on imaging, bleeding due to ectopic pregnancy that is most commonly located within the fallopian tube or ovary may be similar to ruptured follicle cysts with hemoperitoneum. A positive pregnancy test allows the definitive diagnosis of ectopic pregnancy.

▶Cyst, Follicular, Ovarium

▶Fetal Imaging

Ectopic Thymus

Aberrant thymic tissue arising from remnants of the thymopharyngeal duct due to migrational defects during thymic embryogenesis.

▶Congenital Malformations, Thymus

Edema

The presence of an abnormal accumulation of fluid in the intercellular spaces of the breast, which may be due to inflammation, vascular or lymphatic obstruction or treatment such as radiotherapy.

▶Carcinoma Breast, Imaging Mammography, Secondary Signs

Embolization, Portal Vein

University Klinik Hamburg-Eppendorf, Hamberg, Germany
krupski@uke.uni-hamburg.de

Synonyms

Liver regeneration, liver hypertrophy, and induced liver growth are used to describe the restoration of destroyed; Lost or removed liver parenchyma; and liver growth following portal vein embolization (PVE)

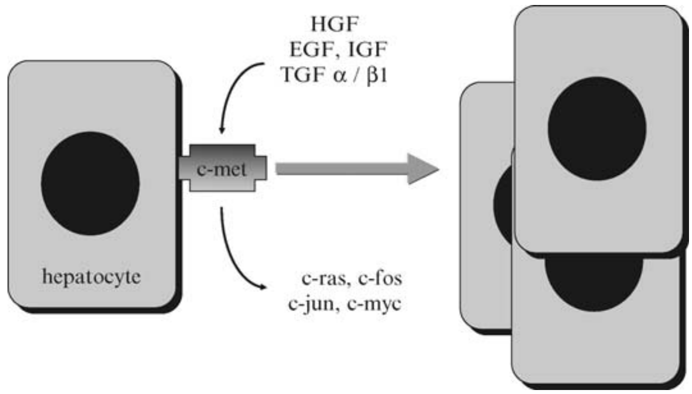
Definitions

Liver regeneration summarizes both enlargement of a formerly smaller entire liver or liver lobe as well as hepatic cellular and mitochondrial mRNA replication followed by cell division induced by elevated levels of hepatocyte growth factor (HGF).

Pathology/Histopathology

Liver regeneration is a complex process initiated by an increase in portal venous blood pressure. LaBreque and colleagues characterized HGF as the primary cellular signal with secretion from hepatocytes. HGF binds to the c-met receptor (1) at the hepatocyte membrane and causes mitochondrial and nuclear mRNA transcription as well as replication of mitochondria and entire hepatocytes. Apart from HGF, other growth factors include IGF, EGF, and TGF α/β. Proto-oncogenes are also affiliated to c-met regulation and interaction. Fig 1 gives an impression of the interactions of HGF and other growth factors, as well as oncogene products with the hepatocyte c-met receptor.

As result, liver cells divide, and the remaining liver regenerates within 3–6 months. The early volume changes are visible and measurable at 3–4 weeks after PVE; therefore, they do not represent true cell replication but cellular swelling and interstitial edema associated with intercurrent portal hypertension. Nevertheless, the amount



Embolization, Portal Vein. Figure 1 (a, b) Axial multidetector-row computed tomographic image of a 59-year-old man presenting with a Klatskin tumor, bismuth type Iia, proposed for extended right liver lobe resection 3 weeks after percutaneous portal vein embolization of segments IV–VIII (a). The left lateral lobe already looks ballooned. Three months after liver resection, the remaining left lateral lobe has gathered marked size and is almost as large as an entire liver (b).

of early volume increase can be interpreted as an indicator of adequate regeneration induction.

Mitochondria replicate much faster than hepatocytes—within 1–2 weeks. Parallel to this, the liver functional reserve improves markedly, which might be why safe resection can be performed almost 8 weeks after embolization and why PVE enables liver resection in moderate cirrhosis, preventing feared postoperative liver failure.

Potential interactions of proto-oncogenes and excretion of growth factors in a patient with a known tumor always suggests potential collateral tumor growth stimulation. To date, although discussion is ongoing on this topic, there is no clear evidence for tumor growth stimulation (2) after PVE.

Clinical Presentation

Surgical removal remains the method of choice for curative treatment of primary and secondary liver malignancies. Clear resection margins (R0 resection) are the key to cure in liver surgery for metastatic disease. This means extended liver resection in almost 50% of patients (3, 4). To prevent postoperative liver failure, an increase in the future liver remnant and improvement of postoperative liver function are necessary in up to one-third of all patients proposed for extended resection. By definite disruption of the portal venous flow to the right liver lobe using either embolization fluids, particles, coils, combinations of these, or, as formerly done, surgical ligation of the portal venous stem, regeneration of the remaining liver parenchyma is induced, resulting in volume increase and functional reserve improvement (5, 6). After 4–8 weeks, extended hepatic resection is possible, as indicated by volume increase on computed tomographic (CT) volumetry of the future liver remnant.

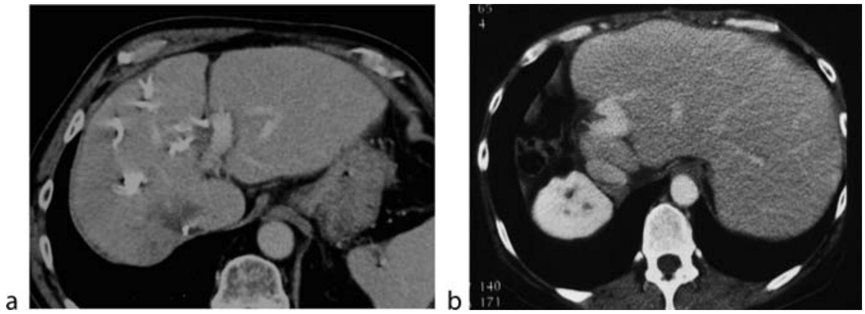
This two-stage hepatectomy approach facilitates resectability in primarily nonresectable patients. Today this procedure is routinely used in the surgical treatment of central hilar bile duct tumors (Klatskin tumors) as well as in surgery for extended hepatic metastases. In addition, by enhancing the functional reserve (7), PVE can enable resection of hepatocellular carcinoma in cirrhotic liver patients or extended resection in hepatic parenchymal damage associated with chemotherapy (particularly oxaliplatin).

Following PVE, No Specific Signs and Symptoms are Evident.

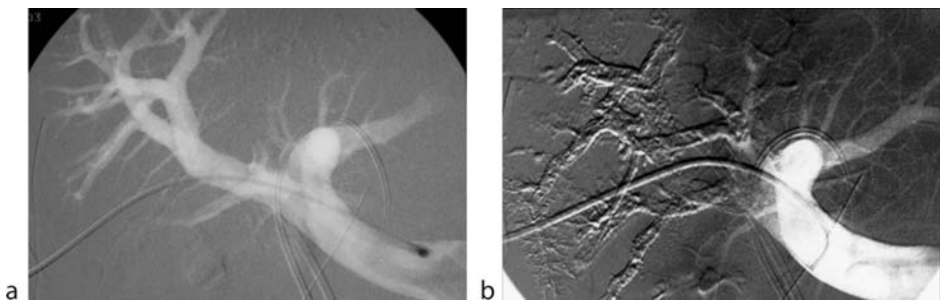
To prevent tumor growth and spread during liver regeneration and while awaiting resection, particularly in patients with rapidly growing tumor, adjuvant chemotherapy can be performed safely beginning 2 weeks after PVE. This intervals must be adhered to assure adequate regenerative response (which otherwise can be suppressed by antiproliferative drugs or antimetabolites). For chemotherapy, CPT-11 or 5-FU/FA can be used, whereas oxaliplatin should be avoided because of its hepatotoxicity.

Imaging

The regeneration itself cannot be imaged, but liver volume changes (Fig. 2a, b) may be measured using cross-sectional magnetic resonance imaging (MRI) and CT images. CT and MRI volumetry can be performed manually by marking the liver lobe with a variable region of interest and summating the marked areas, or automatically



Embolization, Portal Vein. Figure 2 (a, b) Percutaneous direct portogram before (a) and directly after embolization of segments IV–VIII using a mixture of cyanoacrylate and lipiodol.



Embolization, Portal Vein. Figure 3 Direct portogram after embolization of segments V–VIII. Segment IV provides two major branches (*, ◦) and a few small branches.

using segmentation software (e.g., MeVis, Bremen, Germany) that calculates liver volumes after locating segmental anatomy based on portal venous ramification.

Interventional Radiological Treatment

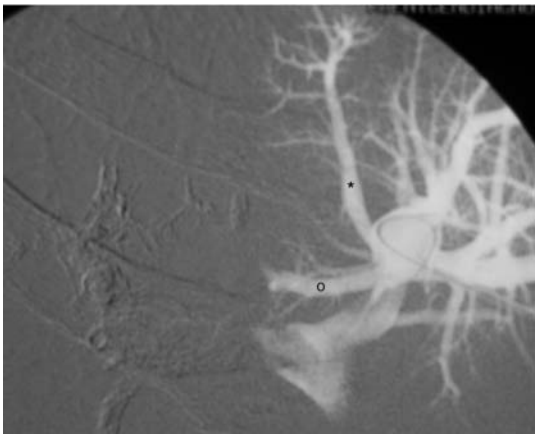
Before PVE is begun, adequate biliary drainage is obligatory, with a resulting serum bilirubin level at least below 4 mg/dL. Endoscopic or, particularly, multiple percutaneous external drains must be employed in central hilar tumors.

Percutaneous PVE is state-of-the-art for inducing liver regeneration (5). Depending on the indication, one can choose entire right lobar embolization, including segment IV, before extended right resections for maximal regenerative response or limited right lobe embolization in patients with impaired liver function before minor hepatic resections (such as in cirrhotic liver).

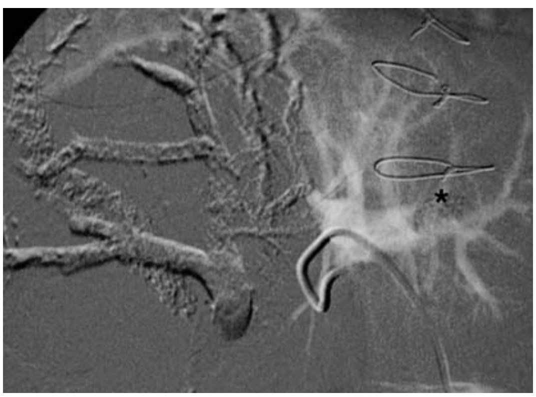
An intercostal right-sided puncture comparable with the PTC procedure or a subxiphoidal puncture will give access to the portal venous system. Thereafter, the portal venous system is embolized branch by branch until only the left lateral or left lobe remains perfused.

Both access site and embolization technique or embolization material vary widely among experienced centers, indicating that there is neither a best technique nor a best embolization material. In Japan, right-sided access and pure ethanol as embolization material is preferred, whereas in Europe (6), left-sided ultrasound-guided access and a mixture of cyanoacrylate and lipiodol as embolization material is most frequently used (Fig. 3a, b). The latter technique has three advantages when compared with ethanol and right-sided access: no double-balloon occlusion catheter has to be used; the postintervention clinical course is less eventful (after ethanol use, transaminases will increase up to 1,000 U/L and more because of adjacent liver parenchyma necrosis, contributing to necessary hospitalization time of 2–3 days; on the other hand, in more than 90% of cases patients can be discharged on the day after a procedure using histoacryl-lipiodol embolization); and costs are lower.

Segment IV is technically important and therefore has to be mentioned. Compared with simple right-sided embolization, extended right embolization including segment IV will result in significantly higher resulting volumes of the prospective liver remnant. Unfortunately, regarding the portal venous anatomy, segment IV embolization is rather difficult. In approximately two-thirds of patients, two or more larger portal branches can be seen deriving from the recess of Rex (Fig. 4). The branches to segments II and III are very close, bearing the risk of accidental dislodgement



Embolization, Portal Vein. Figure 4



Embolization, Portal Vein. Figure 5 Dislodged embolization material (cyanoacrylate and lipiodol) within the segment II portal vein branch, resulting in a peripheral hypoperfusion.

of embolization material. Therefore, superselective and safe cannulation of these branches is obligatory, often necessitating several SIM-1, Cobra-1 or -2, or even custom-shaped guiding catheters for cannulation attempts. If only subtotal embolization of segment IV can be achieved without overembolization hazard, it is worthwhile to await liver regeneration and perform a second percutaneous embolization in a two-stage procedure within a 4-week interval.

Overall complication rates are low and include dislodgement of embolization material (Fig. 5), hemorrhage (subcapsular), and insufficient regeneration.

Embolization, Transcatheter Embolization

Transcatheter embolization consists in selective occlusion of a systemic or pulmonary vessel through an open-ended catheter using coils, particles or other embolization agents. Embolization is indicated to treat various clinical conditions, including hemorrhage, vascular malformations, AVM or tumors.

►Pulmonary Arteriovenous Malformations

Emphysema and Bulla

HANS-ULRICH KAUCZOR
German Cancer Research Center, Heidelberg, Germany
hu.kauczor@dkfz-heidelberg.de

Synonyms

Alpha-1-antitrypsin deficiency; Bullous, bulla hyperinflation; Emphysema (centrilobular, panlobular, paraseptal)

Definition

Emphysema is defined histologically as a constant, irreversible, and abnormal enlargement of the alveolar spaces distal to the terminal bronchioles (3). It corresponds with destruction of the interstitium within the secondary pulmonary lobule and also the perilobular septae without any increase in soft tissue.

Pathology/Histopathology

According to the site of damage, emphysema may be classified as centrilobular, panlobular, or irregular. In centrilobular emphysema, the damage within the secondary lobule is pronounced along the axial interstitium, especially the respiratory bronchioles, while the peripheral compartment is less or not affected. In panlobular emphysema, the whole lobule is affected, with paraseptal emphysema being a type of panlobular emphysema with a special predilection for a subpleural location at the lung apices. An irregular or paracicatricial emphysema does not respect the normal anatomical architecture of the lung.

The development of emphysema is fostered by an imbalance between proteases and antiproteases. Alpha-1-antitrypsin, which is synthesized in the liver, is the most important pulmonary antiprotease. Its homozygous deficiency leads to panlobular emphysema, which has a basal predominance even in the absence of cigarette smoking. The latter is the single most important cause of emphysema due to an increased release of proteases and elastases, finally resulting in destruction of pulmonary tissue. Emphysema is commonly associated with chronic obstructive pulmonary disease (COPD), which also comprises chronic bronchitis. Emphysema without airway obstruction is infrequent.

A bulla is an air-filled, thin-walled space within the lung with a diameter >1 cm. Its wall is formed by pleura, connective tissue, or compressed lung parenchyma. Two types of bullous disease can be differentiated: bulla with COPD as a particular presentation of otherwise typical emphysema, or primary bulla without other parenchymal disease or airway obstruction.

Clinical Presentation

Cigarette smoking leading to chronic airflow limitation is the major determining factor in the development of emphysema and chronic bronchitis. The patients complain of productive cough and dyspnea. Airflow obstruction and emphysema regularly become apparent after the age of 50 years or after 20–30 pack-years of smoking. According to their presentation, patients with emphysema can be differentiated as "►pink puffers" or "►blue bloaters." Pink puffers, or type A patients, are usually thin and complain of severe dyspnea, but they are relatively well oxygenated without hypercapnia and do not suffer from right heart failure (cor pulmonale). Blue bloaters, or type B patients, suffer from severe hypoxemia and hypercapnia and have peripheral edema due to right heart failure but only mild dyspnea.

In emphysema, the thorax becomes fixed in an inspiratory position, the chest is barrel-shaped, thoracic kyphosis is increased, shoulders are raised, and the thorax moves en bloc together with contraction of the accessory respiratory muscles. Complications of emphysema are pulmonary arterial hypertension, right heart failure, recurrent exacerbations of COPD, and polycythemia secondary to hypoxemia.

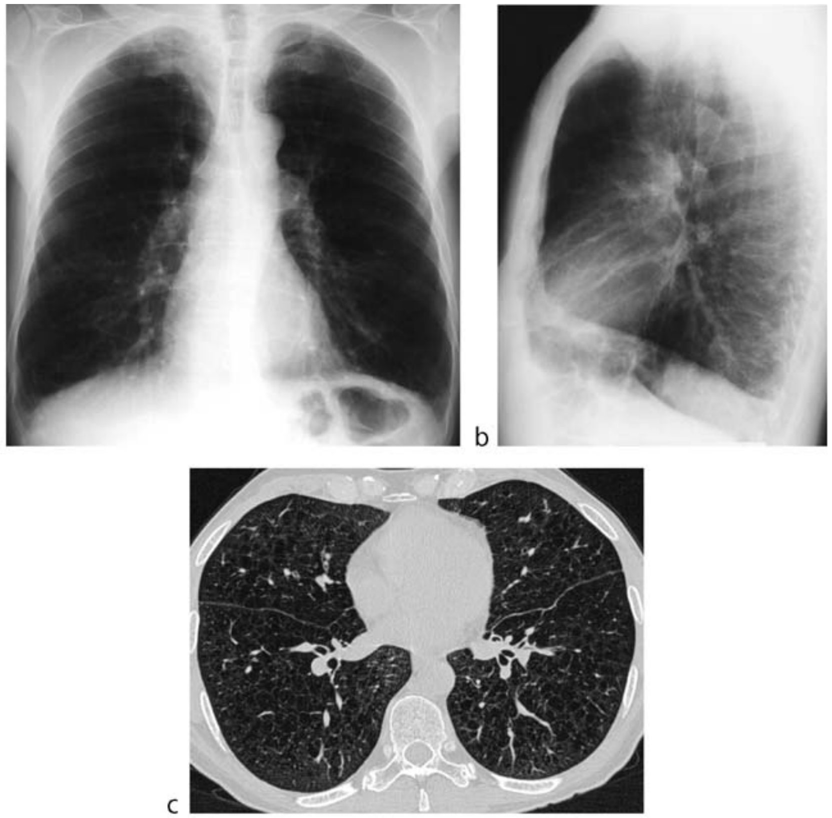
Primary bullous disease is characteristically asymptomatic with minimal abnormalities at pulmonary function tests, and it can be detected incidentally, such as at chest radiography.

Imaging

Chest Radiography

Chest radiography provides only indirect signs of hyperinflation, which leads to an increase in lung size that can be appreciated in all three orientations (Fig. 1). This increase in size, which is associated with a loss of attenuation, is best seen on the lateral view. The enlargement of the retrosternal space is a very good indicator. It is measured 3 cm below the angulus sterni as the distance between the posterior aspect of the sternum and the anterior aspect of the ascending aorta. More than 2.5 cm is indicative for hyperinflation and emphysema. On the anteroposterior view, two criteria can be applied: First, the enlargement of the intercostal spaces reflects the protrusion of the hyperinflated lung into these spaces. The distance between two ribs can be measured easily. Second, the position of the diaphragm is lowered and its shape flattened. In severe hyperinflation the diaphragm can even be inversed. The changes of the diaphragm are best appreciated by measuring the sternodiaphragmatic angle on the lateral view and the costodiaphragmatic angle on the anteroposterior view, with 90° and 40°, respectively, as thresholds indicating hyperinflation.

The loss of attenuation can be homogeneous or inhomogeneous, such as in localized emphysematous destruction and bulla formation (Fig. 1). Local hyperinflation can induce compression atelectasis of other lung areas. The emphysematous destruction of the pulmonary architecture results in a loss of vascular markings that is best appreciated in the lung periphery. The vascular rarefication and the decreased pulmonary blood volume further enhance the lower attenuation caused by hyperinflation. A nonhomogeneous distribution of emphysema or bullae is associated with displacement of vessels. Rarefication of vessels leads to a substantial reduction of



Emphysema and Bulla. Figure 1 Centrilobular emphysema. Chest radiograph postero-anterior (a) and lateral (b) views show hyperinflation with an enlarged retrosternal space and flattened diaphragm as well as a homogeneous loss of attenuation. Computed tomography (c) shows the typical appearance of centrilobular emphysema.

vascular cross-section, ultimately resulting in pulmonary hypertension with its typical radiographic signs: dilation of central pulmonary vessels and abrupt changes of the vascular calibers at the level of the lobar, segmental, or subsegmental branches. Subsequent changes affect the right heart with enlargement and signs of right heart failure, such as pleural effusion.

Bullae are identified as local, thin-walled, sharply delineated areas of avascularity (Fig. 2). They are better seen in the end-expiratory position. Evidence of diffuse emphysema may be present elsewhere in the lung.

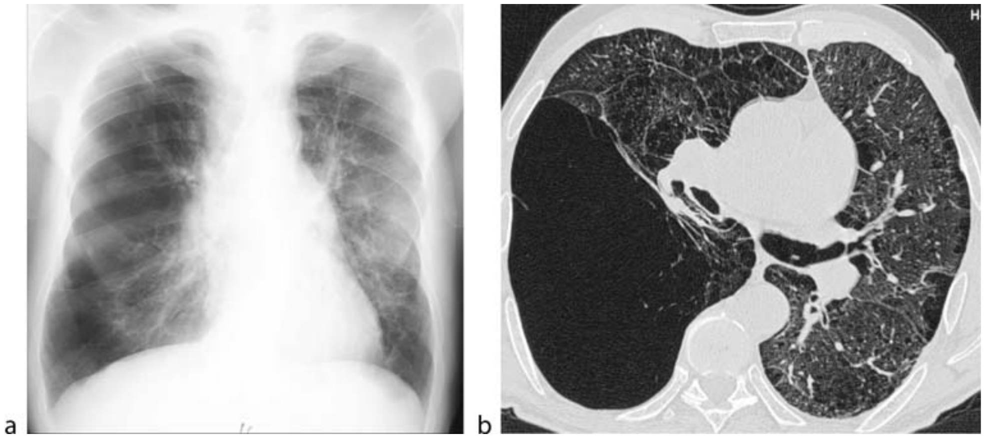
Additional Findings on CT

Computed tomography (CT) is capable of directly visualizing the enlargement of the alveolar space and the loss of the connective tissue by a decrease in visible structures and attenuation. Different types of emphysema can be categorized according to location of the low attenuation affecting the central areas of the secondary pulmonary lobule in centrilobular emphysema (Fig. 1) or the whole secondary lobule in panlobular emphysema. Special emphysema types such as paraseptal, paracicatricial, and lobar can also be differentiated (1). Emphysema typically does not show any walls. This is an important criterion for differentiation from other cystic patterns and bullae. Measurements of lung density on CT are generally accepted for quantitation of emphysema. With high-resolution CT, an upper threshold of –950 HU should be used, and the relative fraction of lung area or volume affected by emphysema – called emphysema or pixel index – can be calculated.

CT is much more sensitive than plain radiographs for identifying bulla, and can also reveal concomitant emphysema or compression of adjacent lung (Fig. 2). The latter might be used as an indication for surgical bullectomy.

Nuclear Medicine

Perfusion or ventilation scintigraphy plays only a minor role in the diagnosis of emphysema. On ventilation



Empyema. Figure 2 Bulla with emphysema. Chest radiograph (a) views show a large area of hyperlucency representing a bulla with compression of the adjacent lung. Computed tomography (b) also shows the large bulla on the right with compression of the adjacent lung and reveals emphysema of centrilobular and paraseptal type in both lungs.

scintigraphy using Technegas, emphysema is associated with a patchy and irregular distribution yielding hot spots and defects. Generally, the distribution of perfusion and ventilation is matched. When using xenon as a tracer for ventilation, single-breath examinations demonstrate a heterogeneous distribution, whereas scans after equilibrium and washout will show retention (trapping) of the tracer in emphysematous areas after a 3 min washout. Bullae are recognized as large perfusion and ventilation defects.

Diagnosis

Although emphysema is defined histologically, it is generally not diagnosed by biopsy and is only an additional finding at surgery for lung cancer. Thus imaging, especially CT, carries the most important role for the morphology-based diagnosis of emphysema (2).

Besides imaging, the diagnosis of emphysema is generally made from the results of lung function tests. A decrease of forced expiratory volume in 1 s (FEV1) indicates airway obstruction as it occurs in COPD and emphysema. A decrease in peak expiratory flow or of FEV1 expressed as a percentage of forced expiratory volume are additional helpful indicators of COPD and emphysema. Hyperinflation relates to an increase in residual volume followed by an increase in functional residual capacity and total lung capacity, which are associated with a decrease in vital capacity. The loss of alveolar surface area due to emphysematous destruction is best assessed by measuring the single-breath diffusion capacity, which will be markedly reduced in emphysema patients. As a result of alveolar hypoventilation and ventilation-perfusion matching, arterial blood gases are commonly disturbed, with hypoxemia frequently associated with hypercapnia (partial and global respiratory failure).

The diagnosis of bulla is usually made on chest radiography or CT.

Emphysematous Pyelonephritis

Severe complication of AP that appears in diabetic patients, in which gas is produced within renal tissue.

►Pyelonephritis, Acute

Empyema

The presence of gross pus in the pleural cavity; it consists of an effusion containing polymorphonuclear leukocytes and fibrin. The formation of an empyema can be divided into three phases: exudative (pus accumulation),

fibrinopurulent (fibrin deposition and loculation of pleural fluid) and organising (fibroblast proliferation, potentially lung entrapment by scarring).
▶Pleural Effusion
▶Pneumonia in Childhood

Empyema Necessitatis

TB pleural infection that penetrates the chest wall, creating a subcutaneous abscess.
▶Tuberculosis

Empyema, Gallbladder

Suppurative infection associated to cystic duct obstruction in which the gallbladder fills with purulent material.
▶Cholecystitis

En Plaque Meningiomas

En plaque meningiomas are a variant of primary neuraxial meningiomas, which may infiltrate both the dura and the bone cloaking the inner table of the skull.
▶Neoplasms, Extraaxial, Brain

Encephalitis

Encephalitis refers to any diffuse inflammatory process involving the brain that can be caused by a broad spectrum of agents. The most frequent virus responsible for acute viral encephalitis in adulthood is the herpes simplex virus type 1 (HSV-1) and in the neonatal period the herpes simplex virus type 2 (HSV-2). Viral encephalitides in immunocompromised patients are usually caused by human immunodeficiency virus (HIV) and cytomegalovirus (CMV).

Definition

Herpes viruses are a large group of double-stranded DNA viruses. Herpes simplex virus type 1 (HSV-1) is the causative agent in 95% of herpetic ▶encephalitis cases and the most common cause of fatal sporadic encephalitis.

Pathology/Histopathology

The gross appearance of the brain in adults with herpes encephalitis initially shows acute inflammation, congestion and/or hemorrhage, and softening. After approximately 2 weeks, these changes proceed to frank necrosis and liquefaction.

Clinical Presentation

Patients with HSV-1 encephalitis may present with fever, headache, nausea and vomiting, and neck stiffness with altered mental status (1).

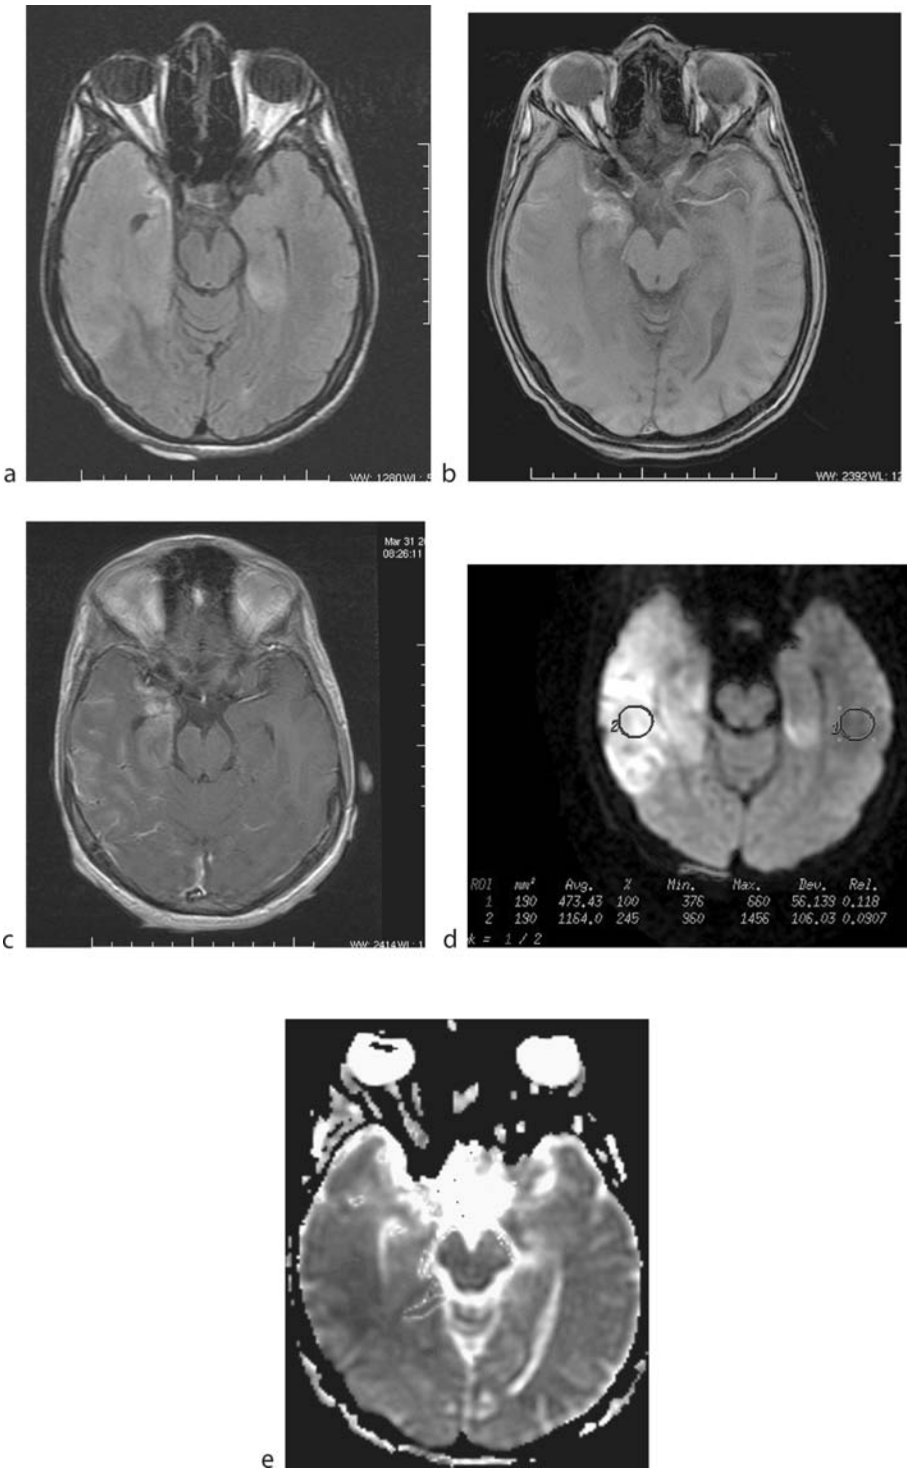
Imaging

Computed Tomography

Computed tomography (CT) images in the early stage of the disease are frequently normal, despite severe clinical manifestations. Hypodense lesions can be seen in the temporal lobes with or without involvement of the frontal lobes.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is more sensitive and demonstrates the early findings of edematous changes of HSV-1 encephalitis (Fig. 1) (2). These are an increased signal, particularly in the temporal and inferior frontal lobes on fluid attenuation inversion recovery (FLAIR) and T2-weighted images that may be seen as early as 48 h after the onset of symptoms. The signal abnormalities often extend into the contralateral temporal lobe, insular cortex, and cingulate gyri, sparing the basal ganglia (3).



Encephalitis, Herpes. Figure 1 HSV-1 Encephalitis. Axial FLAIR (a) image shows diffuse hyperintense signal with mass effect involving both the gray and white matter primarily in the right temporal lobe together with a small portion of the left temporal lobe. Axial, precontrast (b) T1-weighted image shows hyperintense signal at the anteromedial temporal lobe corresponding to hemorrhage. Mild hyperintensity is also seen along the lateral cortical sulci. There is also effacement of the sulci in the affected area. Postcontrast axial (c) T1-weighted image reveals gyriform enhancement of the right temporal lobe. DWI (d) demonstrates high signal in the affected region where ADC map (e) shows low signal compared to contralateral unaffected area, consistent with cytotoxic edema.

Although HSV-1 results in necrotizing and hemorrhagic encephalitis, frank blood is not commonly seen on imaging studies. Acute hemorrhage on MRI may appear as a focus of moderate to marked hypointensity on GRE images or on T2WI. The late sequelae of HSV-1 are atrophy, encephalomalacia, and dystrophic calcification (4). Two distinct types of diffusion-weighted imaging (DWI) findings have been noted: lesions similar to cytotoxic edema and lesions similar to vasogenic edema. The patients with the former type of lesions have fulminating disease and are in a poor clinical condition. Those with the latter represent early cases and they are in fairly good clinical condition (5). Magnetic resonance spectroscopy (MRS) shows elevated choline, low *N*-acetylaspartate levels, and the presence of lipids and lactate, reflecting necrosis.

Diagnosis

The mainstay in the diagnosis is the detection of HSV DNA in the cerebrospinal fluid by using polymerase chain reaction; however, false-negative results do occur.

Definition

Human immunodeficiency virus (HIV) belongs to the retrovirus family of RNA viruses (1). Its most common clinical manifestation is encephalopathy (28% of all AIDS autopsies).

Pathology/Histopathology

The virus is carried to the brain by macrophages and monocytes. The infection damages the blood–brain barrier and induces the production of cytokines. Initially, there is neuronal death leading to atrophy. Afterward, the virus causes astrogliosis, myelin pallor, and the presence of multinucleated cells (2). This gives rise to gradual demyelination and to perivascular nodules of microglial cells, monohistiocytes, and macrophages (1).

Clinical Presentation

The patient presents with progressive subcortical dementia.

Imaging

Computed Tomography

The most common finding is atrophy; however, computed tomography (CT) images are often normal.

Magnetic Resonance Imaging

The most common magnetic resonance imaging (MRI) findings are diffuse brain atrophy and widespread lesions in the periventricular white matter, predominantly the frontal lobes. The gray matter is generally spared and a mass effect is absent. Lesions usually do not enhance following contrast medium administration. The extent of disease roughly parallels the clinical deterioration. The lesions may reduce in size when treated (1, 2). Magnetic resonance spectroscopy (MRS) shows low *N*-acetylaspartate levels. Additionally, elevated levels of choline and myoinositol may be seen in these patients on short-echo time MRS. MRS abnormalities may be detected before the onset of encephalopathy and may be used to monitor the response to treatment (2).

Diagnosis

Clinical findings should guide the imaging studies. Demonstration of the typical imaging findings in an HIV-positive patient with neurological manifestations is very helpful for the diagnosis.

Encephalopathy of the Newborn

▶Cerebral Neonatal Disease (Neuro View)

Enchondroma

Enchondroma is a benign cartilage-forming tumor arising in the medullary portion of the affected bone.
▶Neoplasms, Bone, Benign

Endoluminal Therapy

Endoluminal therapy refers to treatments that occur from within a blood vessel without the need to open the vessel using conventional surgery.
▶Aneurysm, Aortic and Thoracic

Endometrial Carcinoma

▶Carcinoma, Endometrium Uteri

Endometrium

The endometrium is the central portion of the uterus and undergoes cyclic regeneration due to the hormonal influences of the menstrual cycle. The endometrium is thinnest at time of menstruation and gets thicker throughout the proliferative and secretary phase. After menopause, atrophy of the endometrial lining will occur.

Endoscopic Retrograde Cholangiopancreatography (ERCP)

ERCP is an endoscopical procedure that allows catheterization of the papilla of Vater and radiological evaluation of the biliary tree and pancreatic ducts by means of contrast medium injection. ERCP also offers the possibilities of prompt conversion into a therapeutical procedure such as papillotomy, stone extraction, and biliary and pancreatic stent placement over benign or malignant ductal strictures. The most important complication is the development of acute pancreatitis.
▶Biliary Anatomy

Endoscopic Ultrasound

EUS is the marriage of ultrasound and endoscopy, where ultrasound images of the gut wall and adjacent structures are obtained by passing an ultrasound probe into the gastro-intestinal tract.
▶Neoplasms, Gastroduodenal
▶Neoplasms Oesophagus

Endoscopy of the Oesophagus

Fibre endoscopic examination of the oesophageal mucosa. May also evaluate the distensibility of the oesophagus. It is possible to obtain biopsies during the procedure.
▶Diverticulum, Oesophagus

Endothelium

Endothelium is a single layer of endothelial cells that lines the heart, blood vascular and lymphatic channels.

▶Contrast Media, Ultrasound, Commercial Products

Enlargement of the Spleen

▶Splenomegaly

Enteric-Portal Drainage, Pancreatic

In pancreatic transplantation with enteric-portal drainage technique the arterial graft and the portal vein are anastomosed with the recipient's common iliac artery and superior mesenteric vein, respectively, whereas the exocrine pancreatic secretions are drained by an anastomosis between the donor's duodenum and a small bowel loop. In this technique the insulin is physiologically released in the portal venous system of the recipient.

▶Transplantation, Pancreatic

Enterocele

Descent of the peritoneal sac in between the rectum and the vagina down to the level of the perineum during defecation or Valsalva maneuver is called an enterocele. It may impress the posterior vaginal wall (grade II) and evert it to the outside across the introitus (grade III). An enterocele most often contains the sigmoid colon and mesosigmoid fat, but may also contain small bowel. It may persist after relaxation and need manual reposition.

▶Pelvic Floor Dysfunction, Anovectal Manifestation
▶Pelvic Floor Dysfunction, Genitourinary

Enteroclysis

Small bowel enema by duodenal intubation. The best method of contrast medium examinations. Several techniques exist, e.g., barium monocontrast, double contrast with barium and methylcellulose or air or guarin.

▶Malabsorption

Enterocolitis, Necrotizing

Definition

Necrotizing enterocolitis is due to alteration of the integrity of the intestinal mucosa as a result of ischaemia and hypoperfusion together with bacterial overgrowth. It is predominantly a disease of premature infants but can also occur in the term infant.

Pathology/Histopathology

The precise aetiology of necrotizing enterocolitis is uncertain and is thought to be multifactorial in origin. Ischaemia and hypoperfusion leading to mucosal damage which often extends through the bowel wall, together with bacterial invasion and inflammatory response are the most likely mechanisms of bowel wall necrosis. The distal ileum and proximal colon are most commonly affected. Bowel perforation occurs in 12–31% of patients. The bacteria involved include *Escherichia coli, Klebsiella and Clostridium*. However, frequently organisms are not isolated in these infants. The hypoperfusion may result from hypoxia-induced spasm of the bowel arterial supply. Other causes include stress, hypothermia and hyperviscosity, hypovolaemia, cardiac left-to-right shunting, decreased ventricular output, cardiopulmonary bypass for cardiac surgery, sepsis, dehydration, shock and cocaine abuse (1). Once ischaemia or hypoperfusion occurs ileus develops. After this initial period the bowel becomes active again and bloody diarrhoea may develop. At this stage there is loss of mucosal integrity and overgrowth of bacteria which leads to the formation of gas in the bowel wall and occasionally in the portal venous system. Pneumoperitoneum may develop following bowel perforation.

Clinical Presentation

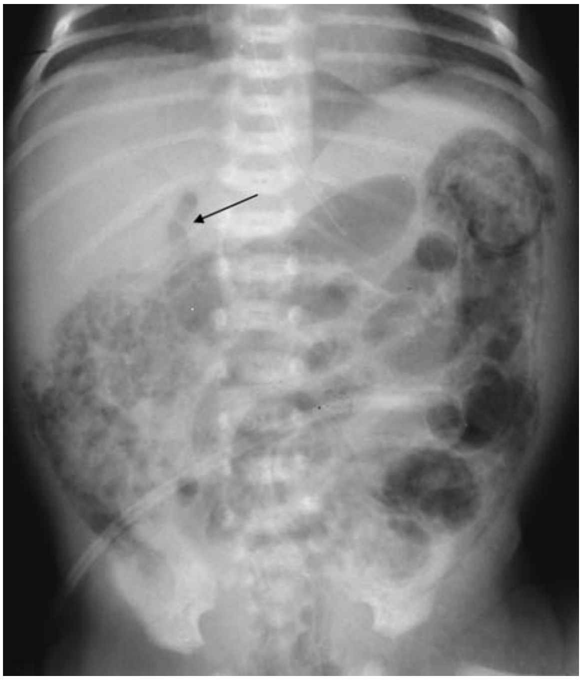
Clinically these infants have bile stained aspirates, abdominal distension, tenderness, bloody stools, hypotension and shock. Initial therapy involves nasogastric suction to decompress and rest the bowel and the use of broad spectrum antibiotics and intravenous nutrition. Treatment should be instituted once the diagnosis is suspected clinically without waiting for the development of specific radiological signs.

Imaging

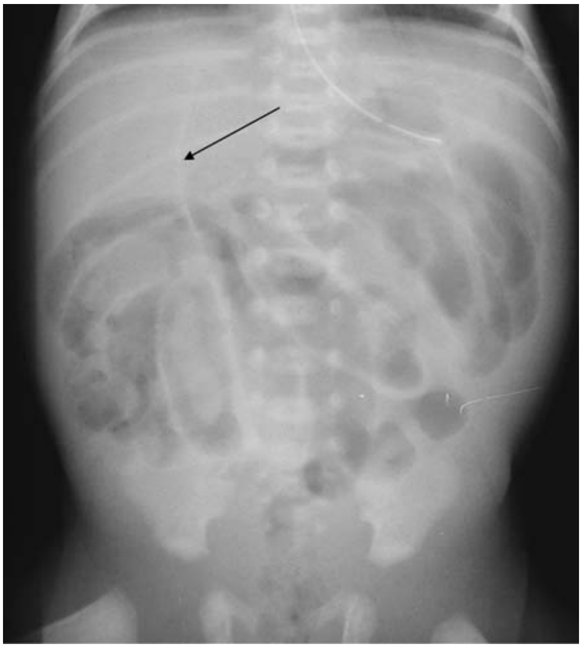
The role of imaging is to confirm the diagnosis and monitor its course. Anteroposterior and cross-table lateral radiographs are performed. A left lateral decubitus view involves unnecessary repositioning if the ill neonate and is less sensitive in the demonstration of free intraperitoneal air (2). The timing of serial radiographs is determined clinically. They are important to determine when to stop therapy and to determine if surgical intervention is required. The earliest and most common radiographic sign is bowel loop distension. This sign however is non-specific but should make one suspicious. Pneumatosis intestinalis is diagnostic (Fig. 1). However inter-observer variability in the diagnosis of pneumatosis is considerable. It maybe cystic (submucosal) or linear (intramuscular or subserosal) in nature. It tends to be an early rather than a late finding and maybe transient. It usually involves the colon or terminal ileum but may occur in other areas of the bowel. There is a poor correlation between the presence and extent of pneumatosis and the severity of the disease. In addition pneumatosis can sometimes be difficult to distinguish from faeces or meconium mixed with air in the bowel lumen.

Bowel wall thickening, a persistently isolated dilated bowel loop, ascites or portal venous gas may develop. Portal venous gas represents dissection of intramural pneumatosis into the lymphatics and mesenteric veins (Fig. 1). This may also be transient (2).

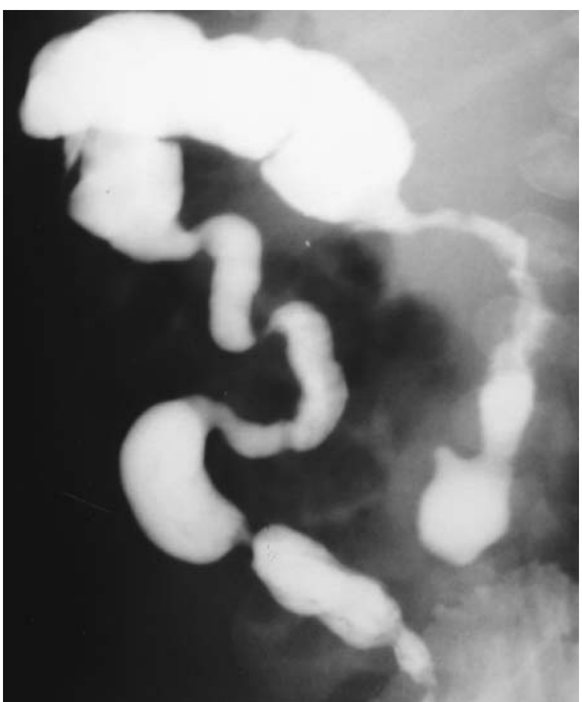
Ultrasonography is useful to detect intraperitoneal fluid and to guide paracentesis. The technique is also useful to detect gas in the portal venous system. Gas in the



Enterocolitis, Necrotizing. Figure 1 Premature infant with necrotizing enterocolitis. There is diffuse intramural air and portal venous gas (*arrow*). There is also lucency over the liver and central upper abdomen indicating perforation.



Enterocolitis, Necrotizing. Figure 2 Infant with necrotizing enterocolitis and bowel perforation. There is intramural air in the right flank and both sides of the bowel wall and the falciform ligament (*arrow*) are visible.



Enterocolitis, Necrotizing. Figure 3 Multiple colonic strictures following necrotizing enterocolitis.

bowel wall and abscess formation are also detected by sonography.

Colour Doppler ultrasound findings of absence of bowel wall perfusion has been shown to be more accurate than clinical examination and plain radiography findings in the prediction of necrosis in neonates with necrotizing enterocolitis and therefore may alter clinical staging and management (3).

The presence of a pneumoperitoneum is an absolute indication for surgical intervention and indicates full thickness bowel wall necrosis and perforation (Fig. 2). When there is a large amount of free air there maybe evidence of a central abdominal lucency, lucency over the liver with air outlining the falciform ligament (Fig. 2). Both sides of the bowel wall may also bee seen. Only 63% of infants with surgically proven perforation however, demonstrate a radiographically detectable pneumoperitoneum.

Other recognized indications for surgery are: clinical deterioration despite aggressive medical management, fixed dilated bowel loops, abdominal mass and ascites. When a neonate is too unwell to undergo surgery a percutaneous drain maybe placed with delayed resection of necrotic bowel.

Patients may go on to develop strictures at previously affected sites (Fig. 3). They maybe solitary or multiple, are usually short and of varying severity. They are suspected in infants with recurrent intermittent obstruction, acute obstruction, low-grade continuing rectal bleeding or constipation. When performing a contrast enema for diagnosis one must take great care to show continuity of the bowel lumen as short strictures maybe obscured by overlapping loops. Strictures may resolve spontaneously particularly if they occur after an acute episode of necrotizing enterocolitis. These latter areas of narrowing are not true fibrotic strictures but more likely areas of inflammatory narrowing.

Diagnosis

The clinical presentation in infants of bile stained aspirates, abdominal distension, tenderness, bloody stools together or in isolation, should make the clinician strongly suspicious of necrotizing enterocolitis and lead to the immediate introduction of medical therapy. The presence of dilated bowel loops together with bowel wall pneumatosis or portal venous air is diagnostic.

Enthesitis, Inflammatory Reaction of Tendon and Ligament Insertions

Enthesitis, inflammatory reaction of tendon and ligament insertions is seen in spondyloarthropathies, such as at the iliac crest, tuber ischiadicum, achilles tendon insertion, plantar fascia insertion, and so on, and comprises both destruction and bony proliferation. In magnetic resonance imaging, adjacent bone marrow edema and tendon attenuation, soft tissue edema, and contrast material enhancement in various degrees are present.

Epithelioid Hemangioendothelioma

▶Hepatic Sarcoma

Epithelioid Hemangioendothelioma, Hepatic

Rare primary hepatic malignancy of vascular origin developing exclusively in adults with a female predominance. This malignancy is typically solid formed of endothelial cells with an epithelioid appearance. Immunohistochemically, these tumoral cells are positive for endothelial markers and negative for epithelial ones. Microscopically, dendritic spindle cells associated with epithelioid round cells within myxoid and fibrous stroma can be seen. Fibrosis and calcifications are described in some cases. Macroscopically, this tumor is formed of multiple solid nodules of variable size located in a peripheral distribution forming large confluent masses composed of a fibrotic central core and a cellular hypervascular periphery. This tumor frequently induces fibrosis causing capsular retraction in the case of peripheral lesions; this capsular retraction is suggestive of epithelioid hemangioendothelioma. Tumoral growth tends to replace hepatic parenchyma and in the case of a protracted course a compensatory enlargement of the uninvolved liver parenchyma can be seen. Extrahepatic involvement includes the peripheral lymph nodes, mesentery, and in some cases the development of calcifications. Metastatic spreading is most commonly confined to the bones and soft tissues.

Synonym

Anemia

Definition

Anemia is defined as a low hemoglobin concentration: <13.5 g/dl for men and <11.5 g/dl for women.

Pathology/Histopathology

Anemia may be due to a reduced production (e.g., marrow failure, chronic disease) or an increased loss (e.g., iron deficiency, hemolysis) of erythrocytes.

Clinical Presentation

Fatigue, dyspnea, palpitations, headache, tinnitus, anorexia, dyspepsia, bowel disturbance, pallor, and retinal hemorrhages may occur in anemia. In severe anemia (hemoglobin <8 g/dl), hyperdynamic circulation and heart failure may be present.

Nuclear Medicine

Blood, Erythrocytes and Plasma Volume Determination

Radioactive ^{99m}Tc (short half-life)-labeled erythrocytes are suitable for blood volume determination. The marked erythrocytes must be reinjected within 2 h and the blood samples taken 30 min after injection. Should the erythrocyte kinetics be determined in addition, the labeling must be performed using the long-life ^{51}Cr.

After the radioactively labeled erythrocytes are injected, they distribute themselves in the blood volume. When a blood sample is taken, the concentration of radioactivity in the sample is the same as that in the patient's blood volume. The most important indication for determination of the erythrocyte and the blood volumes is the differential diagnosis of anemias.

Erythrocyte Kinetics

Erythrocytes have an average lifespan of 115 days. The average survival time and the main sequestration site of the mixed-age population can be determined with the patient's particular erythrocytes, following corresponding regulations for ^{51}Cr labeling (1 MBq, $Na_2{}^{51}CrO_2$ in ACD solution) and the measurement of the erythrocyte-bound chromium in the blood (2, 4). In addition, a standard sample is prepared. Blood samples are taken for two weeks without congestion in order to measure their radioactivity and compare them against the standards. From the standardized readings, the half-life of the erythrocyte-bound chromium in the blood is determined. The measured average half-life of the lifespan of the erythrocyte is smaller than the real erythrocyte half-life of 25–40 days; this is called apparent erythrocyte half-life.

The apparent half-life is found to be reduced to 5–20 days in patients with hemolytic anemia. The greatest reductions are seen with acquired autoimmune hemolytic anemia. Further indications are hereditary spherocytosis, nocturnal paroxysmal hemoglobinuria, infections, tumors, and rheumatic diseases; however, the lifespan alone is not pathognomonic.

The sequestration site of the erythrocytes is localized through the uptake measurements (constant measuring times) of the liver, spleen, and heart (as a measure for the blood pool). With acquired hemolytic anemia, the spleen is the main sequestration site. With a considered splenectomy, the contribution of the spleen to erythropoiesis must be taken into account (compare to ferrokinetic). With an intravascular hemolysis, no organ-specific sequestration site is observed. Hereditary spherocytosis (liver-spleen quotient >2) and hereditary nonspherocytic hemolytic anemia (increase from liver and spleen) show characteristic uptake patterns.

E

Iron Resorption

With the iron isotope ^{59}Fe it is possible to determine intestinal iron resorption (1, 3). Measurement of the whole-body retention from an orally applied $^{59}Fe^{2+}SO_4$ test dose (20 kBq, 2.8 mg) with vitamin C is the most common method. The interindividual (and very different) plasma iron clearance following intravenous injection cannot be applied for determining resorption.

Immediately after the oral application of $^{59}Fe^{2+}SO_4$, the first whole-body measurement is carried out to define the 100% value. Further measurements follow on the third and seventh days. The normal values are considerably varied (10–40%).

The differential diagnosis of iron deficiency anemia is influenced by the results of the iron resorption examination. Reduced iron resorption values point to a disease of the small intestine. Normal values for intestinal iron resorption provide no conclusions to the cause of a proven iron deficiency. If there is an increase in the intestinal iron resorption, the first line of thinking must be blood loss. Heavy blood loss during the examination time can simulate a normal result with an actually increased resorption.

For the diagnosis of hemochromatosis, no crucial significance can be attributed to determination of the intestinal iron resorption. The method promises a differential diagnostic gain for patients with hypersiderinemia and anemia. An increased intestinal iron resorption points to a bone marrow hyperplasia and increased ineffective erythropoiesis (that is, a sideroachrestic or sideroblastic anemia).

Diagnosis

In addition to the hemoglobin concentration, the mean cell volume (76–96 fl) must be determined to discriminate between microcytic, normocytic, and macrocytic anemias.

Esophageal Rupture (in Blunt Chest Trauma)

Esophageal rupture is usually due to penetrating trauma. Most patients with esophageal rupture have other significant associated thoracic injuries, which is usually followed by mediastinitis with high mortality (Boerhaave syndrome). Pneumomediastinum, left-sided pneumothorax and hemothorax without rib fractures are indirect signs on chest-X-ray or CT. The method of choice in suspected esophageal perforation is contrast esophagography with water-soluble contrast agents (90% sensitivity), if necessary with additional endoscopy.

Definition

Imaging of immediate, early, and late complications after surgical procedures of the esophagus has two goals: first, to detect morphological changes, such as leaks, stenoses, or extraesophageal lesions, and second, to evaluate the function of the upper gastrointestinal tract. Morphology and function may interfere in many symptomatic patients after esophageal surgery, and the radiologist has to integrate morphological and functional findings to explain symptoms and to support therapeutic decisions. Fluoroscopy with dynamic recording for the esophageal tube and computed tomography (CT) for extraesophageal complications are the standard tools in these clinical settings.

The diagnoses and surgical operations are numerous. The most common are the following:

- Gastroesophageal reflux disease—Laparoscopic fundoplication or modifications
- Achalasia—Dilatation
- Heller myotomy plus fundoplication
- Esophageal cancer—Total or partial esophagectomy
- Esophageal atresia—Immediate or delayed repair
- Benign tumor—Esophagomyotomy
- Diverticulum—Diverticulectomy.

Pathology/Histopathology

Complications associated with esophageal surgery are generally related to the type of operation performed and the extent of surgery. Complications can be roughly divided into technical complications and those associated with cardiopulmonary aberrations.

Early complications of esophageal surgery include:

- Gastroesophageal reflux
- Recurrent hernia, breakdown of fundoplication, telescope phenomenon
- Aspiration, neuromuscular affection of swallowing
- Anastomotic or staple-line leak
- Leak after dilatation
- Anastomotic edema
- Anastomotic narrowing
- Hypotony or atony of the esophagus or/and stomach
- Pneumothorax
- Mediastinal hematoma, abscess
- Empyema
- Vocal cord paresis
- Chylothorax
- Ischemia
- Extraesophageal injury.

Late complications may include:

- Stricture of anastomosis or after dilatation
- Gastroesophageal reflux and its sequelae
- Recurrent hernia, breakdown of fundoplication, telescope phenomenon
- Aspiration
- Recurrent carcinoma
- Fistula or leaks

Clinical Presentation

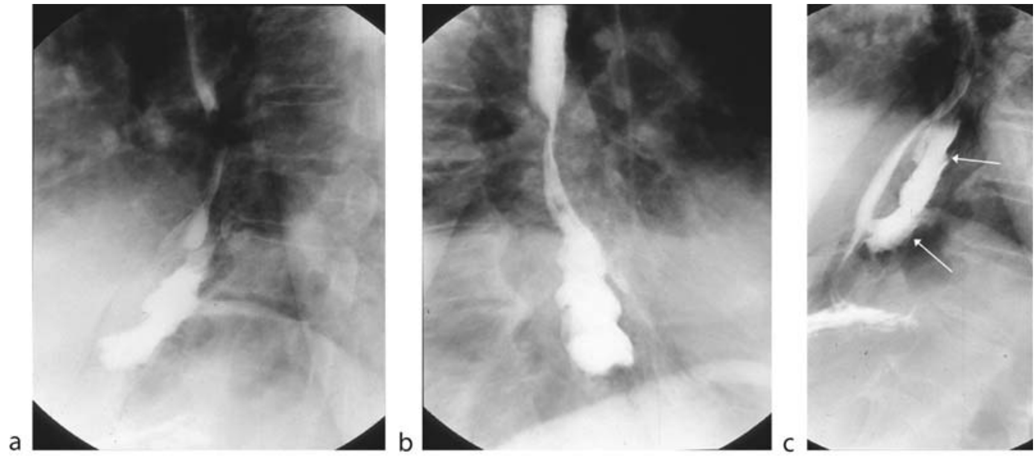
Immediate complications are usually managed during or just after the procedure. Perforation of the esophagus during dilatation is an indication for an urgent fluoroscopic work-up (Figs 1 and 2). Postoperative hemorrhage occurs with an incidence of 3–5% and requires urgent reexploration. For many early postoperative complications, radiologic imaging plays the key role in diagnosis.

If the patient aspirates, neuromuscular affection of swallowing can be detected by videofluoroscopy. Neuromuscular swallowing disorders are associated with longtime intubation and risk factors.

Anastomotic or staple-line leaks, conduit ischemia, or perforation due to dilatation are among the most feared postoperative and postintervention complications (Figs 1 and 2). The incidence and seriousness are highly variable, depending on the type of operation, the location of the anastomosis, the experience of the surgeon, and the degree of the complication. A cervical leak is less serious than a thoracic leak, and a small anastomotic leak is less serious than a dehiscence associated with conduit necrosis. Most leaks manifest within 10 days after surgery. The peak of clinical manifestation of anastomotic failure is between days 5 and 7 after surgery. Leaks may be detected at routine radiologic examination 5–7 days after surgery.

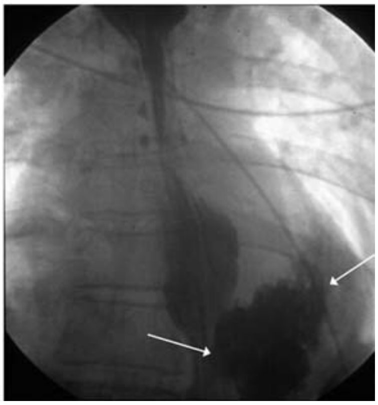
The clinical presentation of esophageal leaks can range from completely asymptomatic to all the signs of shock and even death. In some cases, the first signs of an intrathoracic anastomotic leak are chest pain, dyspnea, and the discovery of a pleural effusion on chest radiography or CT. Cervical anastomotic failure characteristically causes saliva effusion *via* drainage and is rarely accompanied by systemic signs of inflammation.

Hypotony or atony of the esophagus or stomach and delayed emptying of the esophageal substitute are typical



Esophagus, Postoperative. Figure 1 A 75-year-old man after removal of a stent, which was initially inserted endoscopically for treatment of an obstructing squamous cell carcinoma of the distal esophagus. A perforation of the esophagus was suspected. The patient was unstable, and radiologic investigation was limited by difficulties in the patient's positioning. (a, b) The first radiographic examination of the esophagus with water-soluble contrast material in the prone anteroposterior position and slightly rotated to the right side could not definitely reveal perforation. (c) Additional swallows in the strictly prone oblique position revealed a huge retroesophageal extravasation of contrast material (*arrows*).

a



b

Esophagus, Postoperative. Figure 2
A 45-year-old woman immediately after endoscopic pneumatic dilatation of the lower esophageal sphincter to treat idiopathic achalasia. The surgeon suspected esophageal injury, but the location was unclear, and attempts to locate the perforation site by endoscopy failed. In the operating theater, fluoroscopy was performed by the radiologist, using a catheter carefully introduced below the pharyngoesophageal sphincter. (a) Markedly dilated esophageal lumen of the cervical esophagus, which is characteristic for advanced achalasia. This must not be confused with perforation of the cervical esophagus. (b) Investigation of the lower esophagus revealed an extensive extravasation of contrast material arising from the lower esophagus (*arrows*). Therefore, a thoracic access for surgical repair was chosen.

functional findings of the dynamic radiological investigation. Postoperative motility disorders of the esophagus may lead to regurgitation and dysphagia for solid food and even liquids. After esophagectomy, up to 10% of patients will develop gastric emptying problems due to vagotomy and the anatomical rearrangement. A prophylactic pyloromyotomy or pyloroplasty (dilatation) is done routinely in most centers to avoid this disabling complication.

Uncommon extraesophageal complications, such as pneumothorax, mediastinal hematoma, abscess, empyema, chylothorax, and extraesophageal injury, are diagnosed or suggested by plain chest studies or CT. Ischemia of the gastric pull-up or the interposed colon leads to severe clinical signs of shock. Assuming ischemia, esophagogastroscopy is the appropriate diagnostic approach.

A common late complication of the postoperative esophagus is a stricture of the anastomosis or a restenosis after dilatation of a stenosis. Intermittent or constant dysphagia for solids or accumulated semisolid food (rice, potatoes, and noodles) is the typical clinical presentation.

Imaging

In the immediate period after surgery, pneumothorax, pleural effusion, mediastinal widening, or pneumomediastinum/subcutaneous emphysema on chest X-ray may be highly suggestive of esophageal perforation. To check the patency of an anastomosis and the absence of complications after surgery, a swallowing study is initially done. The use of low-osmolar or isoosmolar water-soluble contrast material is mandatory due to its rapid absorption from the mediastinum in cases of perforation and to avoid lung edema after aspiration. The examination must be performed in two perpendicular planes—in the majority of cases, in the left and right decubitus position. Small collections of extraluminal contrast material may be obscured by the esophagus in the frontal position (Fig. 1). If the examination is not properly done—the rotation of these unstable and critically ill patients is often challenging—a leak cannot be ruled out. Additionally, the investigation of the whole esophagus and the stomach, duodenum, and first loops of the jejunum in patients with complicated operations is important for demonstrating an obstruction, leak, or other possible complication distal to the anastomosis.

Dynamic recording of swallowing facilitates the detection of small perforations because of the possibility of observing the recorded swallow several times in slow motion. Motility disorders of the postoperative esophagus may be evaluated as well.

CT offers some advantages, including evaluation of the pleura, the mediastinum, and the aorta. It is often very difficult to localize the exact site of perforation on a CT scan; on the other hand, CT is excellent for detecting extravasation of contrast material.

Diagnosis

Neuromuscular affection of swallowing can be an early complication after esophageal surgery, especially after long periods of intubation and in patients with multiple comorbid diseases. A delayed swallowing reflex, pharyngeal weakness, and insufficient closure of the larynx are often found. For swallowing rehabilitation, a therapeutic videofluoroscopic study is helpful, in which the radiologist tries to discover which consistency and amount of contrast material shows the best results, combined with special maneuvers. This is done together with the speech and language pathologist.

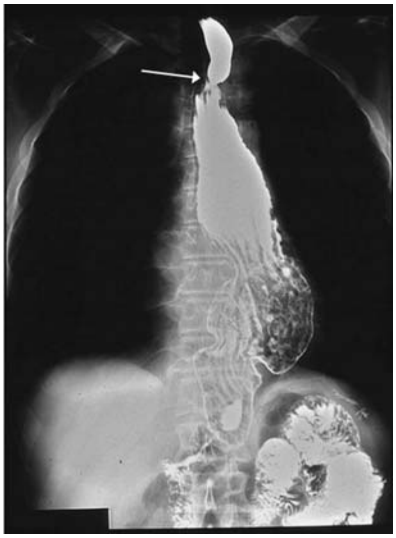
Leaks can be very subtle. Videofluoroscopy or digital series must precisely describe the amount of leakage in relation to the ingested volume of the bolus. If a patient can take only 5 mL per swallow, the extravasation of 20% of the bolus is relatively small, measuring 1 mL. If the patient is drinking constantly from a cup, an extravasation of 1 mL seems to demonstrate a small leakage with a good prognosis. After drinking 30 mL or even more contrast material, small leaks of some drops may lead to more or less symptomatic strictures. This example shows how function can be integrated in the evaluation of morphology, without direct visualization of the lesion characteristics. Only huge defects of the anastomosis of massive perforations present a visible disintegration of the gut itself.

Usually a leak after dilatation or other esophageal intervention leads to a severe problem that requires urgent exploration. If such clinical settings are questionable, the radiologic examination is performed in an often difficult situation. When radiography is doubtful, CT can establish extravasation of contrast material in most cases.

Anastomotic edema presents with markedly thickened mucosal folds. The passage of water-soluble contrast material can be hindered and restored completely some days later. Anastomotic narrowing based on technical complications cannot be differentiated from simple edema. However, a regression of edema can be demonstrated by a patent anastomosis in follow-up studies.

Hypotony or atony of the esophagus or stomach is often found in the early postoperative phase. If hyperperistalsis or aperistalsis is not combined with necrosis of the gut, such functional impairments have a good prognosis, but they can affect the patients for some months. It is important to report such findings to avoid numerous endoscopic controls. Vagal denervation may lead to gas bloat of the stomach.

Specific postoperative complications of antireflux procedures consist of recurring hernia and breakdown or malposition of the fundoplication. Esophageal obstruction occurs if the antireflux fundoplication is too tight; esophageal dilatation is usually required. In such cases delayed transit of contrast material through the esophagogastric junction can be detected. But this unspecific functional finding can be found in transient postoperative edema and esophageal motility disorders as well.



Esophagus, Postoperative. Figure 3
A 55-year-old man after subtotal esophageal resection and gastric tube reconstruction. Double-contrast examination 1 year after surgery showed a typical stenosis at the site of the anastomosis (*arrow*).

Pneumothorax, mediastinal hematoma, abscess, empyema, chylothorax, ischemia of bypass, and iatrogenic extraesophageal injury are relatively uncommon after esophageal surgery.

In cases of stricture of anastomosis or after dilatation, dynamic fluoroscopy of the esophagus can establish the degree and the length of the stenosis and the topographic relationship to the upper or lower aperture of the chest (Fig. 3).

Recurrent carcinoma can mimic a stricture and should be ruled out endoscopically. Late manifestation of a fistula or leak is rare after esophageal surgery. In the presence of an esophagotracheal fistula, laryngeal aspiration can make it difficult to document the penetration of contrast material from the esophagus into the trachea. Careful documentation in such cases is mandatory, and videofluoroscopy can be very helpful.

Definition

Facial nerve palsy (FNP) results from loss of function of the facial nerve. It is characterized by paralysis of the muscles of facial expression which may be associated with loss of other facial nerve functions such as lacrimation, salivation, sound dampening and loss of taste in the two anterior thirds of the tongue.

Pathology/Histopathology

►*Central facial nerve paralysis* (CFNP) results from supra-nuclear lesions and is usually part of a more striking neurological condition that includes symptoms and signs of long tract dysfunction. It results from any lesion affecting the motor tract, most commonly stroke, neoplasm, vascular malformation and infectious/inflammatory conditions (1).

Causes of ►*peripheral facial nerve palsy* (PFNP) include in decreasing order of frequency (Table 1): ►Bell's palsy (57% of cases), temporal bone trauma (17%), herpes zoster oticus (7%), other infectious/inflammatory conditions (4%), neurovascular conflicts (4%), congenital lesions (3%), brainstem lesions (1%) and other miscellaneous conditions (7%) (3).

Lesions involving the brainstem segment (nuclear level) include infarct, vascular malformations, demyelinating

Facial Nerve Palsy. Table 1 **Causes of facial nerve palsy (adapted from Roob G) (2)**

3) Neoplasm
Primary: Facial nerve schwannoma/neuroma, hemangioma, glomus faciale, cylindroma, hamartoma, epidermoid cyst, teratoma
Secondary: Metastasis (hematogenous or leptomeningeal carcinomatosis), perineural spread of parotid gland malignancies, direct invasion from adjacent tumours (meningioma, cholesteatoma, other temporal bone and skull base tumours)
4) ►Neurovascular Conflict (usually with facial dyskinesis)
Vascular loops (AICA, PICA, vertebral artery)
VB dolichoectasia
Aneurysm
5) Brainstem Lesions
Multiple sclerosis
Brainstem neoplasm: Glioma, metastasis
Vascular lesions: infarct, AVM, cavernous angioma
Rhombencephalitis
6) Congenital Lesions
Birth trauma (forceps delivery)
Mobius syndrome
Craniofacial malformations involving the 1st and 2nd branchial arches
7) Others
Paget's disease
Fibrous dysplasia
Ospeoptrosis
Melkersson-Rosenthal syndrome

disease, primary and secondary brainstem neoplasms and rhombencephalitis.

Bell's palsy, a condition for long considered idiopathic is now known to be a viral-induced neuronitis (4). Herpes simplex virus (HSV) is the most commonly implicated agent, thought to be in a dormant state in the geniculate ganglion, being reactivated by non-specific triggering events. The induced inflammatory response, leads to nerve compression against the rigid bony walls of the fallopian canal resulting in ischemia and axonal degeneration. Due to its reduced calibre and blood supply (transitional watershed zone between the vertebral and carotid artery systems), the labyrinthine segment and particularly the meatal portion of the nerve is most susceptible to injury.

Ramsay-Hunt syndrome or herpes zoster oticus is the second most common infectious inflammatory condition afflicting the facial nerve. This condition results from reactivation of a herpes zoster virus (HZV) lodged in the geniculate ganglion and is characterized by the presence of vesicular eruptions in the ear, face and neck.

Any acute or chronic bacterial infection of the middle ear and mastoid may lead to FNP. In the post-antibiotic era, necrotizing otitis externa became the leading cause of infectious facial palsy. It results from an opportunistic pseudomonas aeruginosa infection often afflicting diabetic and other immuno-compromised patients. The infection begins in the EAC and spreads to the parotid gland, temporal bone and posterior and central skull base. Facial nerve involvement occurs in 38% of cases secondary to spread of infection through the stylomastoid foramen or from direct involvement of the facial nerve canal at the tympanic or mastoid segments.

The widespread use of antibiotics decreased the incidence of FNP secondary to otitis media to 0.16% per year (1). The route of spread to the facial nerve is through small bony dehiscences of the fallopian canal, often seen in the tympanic segment. Facial nerve edema, granulation tissue or even intra-fallopian abscess may ensue and lead to acute FNP.

Lyme's disease, a spirochetal infection, is known to cause FNP in 10% of cases among which, 25% are bilateral (facial diplegia). Prior history of a thick bite is often elicited and associated findings of maculopapular rash, arthritis and meningitis, make the diagnosis straightforward.

HIV infection may course with FNP either due to a direct viral neuronitis or through secondary opportunistic infections.

Trauma is the second leading cause of FNP. It may be secondary to head trauma or to iatrogenic insult, during parotid or temporal bone surgery. Patients with blunt head trauma have a 5% incidence of temporal bone fractures. Longitudinal fractures, the most common, lead to FNP in 10–20% of cases. Facial nerve injury is usually at the level of the geniculate ganglion or tympanic segment and paralysis is typically delayed in onset and transient. Transverse fractures result in FNP in 30 to 50% of cases and paralysis tends to be immediate, complete and irreversible. The most frequent site of injury is the labyrinthine segment and results from nerve impingement or transection by a fractured fragment. Edema from traction and stretching of the nerve or intra-neural haematoma are other possible mechanisms of injury.

Facial nerve tumours are rare, responsible for only 6–10% of cases of FNP. They should be suspected whenever patients present with progressive, longstanding FNP, with ipsilateral recurrent episodes of paralysis or with associated facial twitches. Nevertheless, around 27% of cases present with sudden, acute FNP due to abrupt compromise of vascular supply from mass effect, mimicking Bell's palsy. Facial nerve schwannoma, the most common facial nerve neoplasm, is a benign slow growing tumour, composed of Schwann cells intermingled with a collageneous stroma. Haemangioma, the second most common, is usually small and hard to detect on imaging studies. They can both occur in any segment of the facial nerve, but are more common in the region of the geniculate ganglion (4, 5).

Other tumour histologies have been reported including facial nerve paraganglioma, choristoma, cylindroma, lipoma, teratoma and epidermoid cyst.

Secondary facial nerve involvement by neoplasm results either from direct invasion or from *perineural spread*. The latter is most often associated with parotid malignancies, prone to spread retrogradely along the nerve through the stylomastoid foramen and intratemporal segments. This type of spread is seen in 50% of patients with adenoid cystic carcinoma and early recognition is mandatory, as it should be treated along with the primary tumour (2, 4).

Any tumour of the temporal bone or arising from the posterior and central skull base may lead to FNP by direct extension. These include a variety of pathologic conditions originating within the intra- or extra-cranial compartments. Cholesteatoma, cholesterol granuloma, glomus jugulotympanic and endolymphatic sac neoplasms are among the most commonly implicated. The facial nerve may also be affected by metastatic disease and basilar meningitis (infectious, inflammatory or metastatic in nature).

Neurovascular conflict manifests by hemifacial spasm rather than FNP. This condition results from nerve impingement at the *root entry zone* by an adjacent vessel. The most frequent culprits are loops of the anterior and inferior cerebellar artery (AICA), posterior and inferior cerebellar artery (PICA) and vertebral artery. Vertebrobasilar dolichoectasia and aneurysms may also be implicated (4).

Several bony dysplasias, such as Paget's disease and fibrous dysplasia, may involve the temporal bone, lead to stenosis of the fallopian canal and subsequent FNP.

Clinical Presentation

Facial nerve paralysis manifests by effacement of facial skin folds, smooth forehead, widened palpebral fissure, lower lid sagging with tear dribbling and inferior displacement of the corner of the mouth with drooling of saliva. In the majority of cases, the condition is unilateral and the most obvious feature is facial asymmetry. In mild cases, FNP may only become apparent with voluntary movements. In chronic stages, a continuous diffuse contraction of the facial muscles (hyperkinesis) and facial spasms may ensue. Other facial nerve functions (lacrimation, acoustic reflex and taste sensation in the anterior tongue) may also be lost.

►*Hemifacial spasm* is characterized by intermittent, involuntary muscle twitches. It is usually secondary to lesions near the *root entry zone* (transitional zone between central and peripheral myelination), often neurovascular conflicts or compression by adjacent mass lesions (4, 5).

Clinical presentation depends on the site of facial nerve injury. Thorough neurological and ENT examinations can establish the topographic diagnosis of facial nerve lesions. Whereas patients with CFNP present with paralysis of the facial muscles sparing the forehead, patients with PFNP present with paralysis of all muscles of facial expression.

Associated deficits of cranial nerves V and VI, locate the lesion at the brainstem where their nuclei and fibres lie close together. The presence of vestibulo-cochlear dysfunction suggests a lesion in the CPA cistern or in the IAC where cranial nerves VII and VIII travel together within the same dural sheath. Lesions in these segments present with VIII nerve symptoms, (sensorineural hearing loss, tinnitus and vertigo), before facial nerve dysfunction can be detected due to higher vulnerability of the tightly packed, thinly myelinated fibres of the vestibulo-cochlear nerve to compression and ischemia.

Mass lesions in the geniculate ganglion and labyrinthine segment may remain clinically silent until growth into the middle cranial fossa, impinge upon the neighbouring trigeminal nerve or lead to Eustachian tube dysfunction. Tympanic segment tumours present with conductive hearing loss due to mechanical interference with the ossicular chain and by a MEC mass on otoscopy. Lesions in the mastoid segment present with sudden or gradual FNP, often mimicking Bell's palsy. Finally, tumours of the parotid segment present as parotid masses and are indistinguishable from other commoner pathologic entities of the parotid space.

Imaging

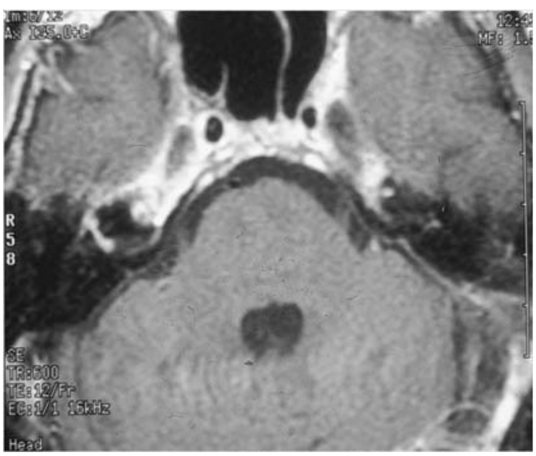
MR is the modality of choice to image patients with CFNP. Imaging is mandatory to determine the cause and to help planning treatment. In patients with PFNP the role of imaging is controversial as the majority of cases are due to Bell's palsy, usually a benign, self-limited disease, with 80% rate of functional recovery. The main arguments towards imaging include: depiction of prognostic criteria that would identify the 20% of Bell's palsy patients who will do poorly and would benefit from early functional rehabilitation (4, 5), and the early recognition of potentially treatable causes of PFNP other then Bell's palsy. Overall, imaging is mandatory in patients with atypical clinical presentations, with poor clinical prognostic signs and whenever surgical decompression is considered (4, 5).

'Atypical' clinical presentations do not follow the usual course of Bell's palsy and include: sub-acute, slowly progressive or recurrent episodes of PFNP, association with other cranial nerves deficits and presence of facial spasm or twitch. Imaging should also be performed when poor clinical prognostic signs are present such as prolonged course of paralysis, (beyond 3 months), high ►*House-Brackmann grade* from onset (above IV) and in the presence of signs of deinervation on electrophysiologic testing (1, 2).

Whereas the supra-nuclear, brainstem, cisternal, intra-canalicular and parotid segments of the facial nerve are best appreciated using MRI, the temporal bone segments are best evaluated with CT or a combination of CT and MRI (4, 5).

Clinical findings determine the best diagnostic imaging strategy. Patients with FNP and prior history of middle ear infection, temporal bone trauma, prior mastoid surgery or a visible mass on otoscopy should be evaluated primarily with high resolution CT (HRCT). CT is also used as an anatomic roadmap in patients selected for surgical treatment. MRI is the modality of choice in all other clinical presentations. Whenever *hemifacial spasm* or twitch is present CT or MR angiography should be used to rule out neurovascular conflict.

The imaging hallmark of inflammatory conditions is the presence of smooth linear enhancement, without focal mass, depicted on gadolinium-enhanced MRI studies. Enhancement of the intra-canalicular and labyrinthine segments of the nerve is the most typical feature of Bell's palsy (Fig. 1). Contrast-enhancement in other segments



Facial Nerve Palsy. Figure 1 Axial gadolinium-enhanced MR image through the pons shows linear, smooth, segmental enhancement along the intra-canalicular and labyrinthine segments of the facial nerve and enhancement of the geniculate ganglion in a patient with Bell's palsy.

of the nerve is of unclear significance as subtle enhancement can be seen along the tympanic and mastoid segments reflecting the presence of a rich perineural vascular plexus. CT has no role in the evaluation of inflammatory conditions of the facial nerve, except when surgery is considered.

Facial nerve enhancement is not a specific feature for Bell's palsy. It is seen in a variety of other inflammatory and neoplastic conditions. Perineural spread of malignancies along the facial nerve may be a potential pitfall, particularly in the absence of prior history of head and neck neoplasm.

In Ramsay-Hunt syndrome, contrast enhancement along the facial, trigeminal and acoustic nerves and within the membranous labyrinth makes the full-blown picture of this condition on MRI. There is arguable evidence that the facial nerve enhances to a further degree then that seen in Bell's palsy (4, 5).

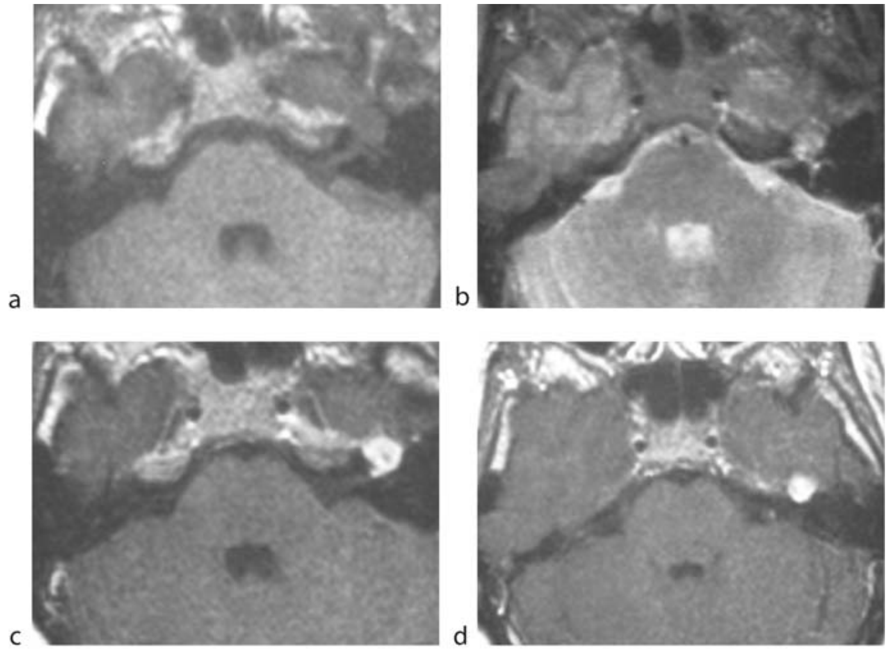
Infectious conditions of the MEC and EAC coursing with FNP can be adequately evaluated either with CT or MR. CT nicely demonstrates bone changes associated with chronic otitis media, cholesteatoma and necrotizing otitis externa and easily depicts dehiscence and erosion of the facial nerve canal. Contrast-enhanced MRI may be required, to determine the full extent of the inflammatory soft tissue, to detect cranial nerves involvement and access the extent of bone marrow involvement of the skull base.

CT is the modality of choice to assess post-traumatic and post-surgical PFNP. It nicely depicts disruption of the facial nerve canal. MR is reserved for cases of FNP unexplained by CT and may demonstrate FN haematoma (bright lesion on plain T1W images) or FN enhancement due to disruption of the blood–nerve barrier (4).

CT and MR are used complimentarily to achieve a full-blown picture of facial nerve neoplasms. On CT, schwannoma manifests as enlargement and remodelling of the fallopian canal in the segment(s) involved by tumour. It is well suited to determine the relationship between the tumour and other important structures of the MEC and with the petrous apex. On MRI, facial nerve schwannomas present as focal, eccentric, fusiform masses with well-defined margins along the course of the nerve. These tumours are iso-intense to brain on T1W, hyper-intense on T2W and show variable enhancement (Fig. 2).Neoplasms arising from the cisternal and intra-canalicular segments are indistinguishable from the commoner vestibular schwannomas, unless the tumour extends along the labyrinthine segment of the facial nerve (4).

Facial nerve hemangiomas are usually very small, often below the resolution of imaging studies. On CT,

F



Facial Nerve Palsy. Figure 2 Axial T1W (a), T2W (b), and gadolinium enhanced T1W MR images through the level of the midpons, show a mass in the geniculate fossa extending posteriorly into the middle ear cavity along the tympanic segment of the facial nerve and anteriorly into the middle cranial fossa. The lesion is iso-intense to grey matter on T1W images, heterogeneously hyper-intense on T2W images and enhances vividly on the post-contrast images. Diagnosis: facial nerve schwannoma of the geniculate ganglion and tympanic segment of the facial nerve.

ossifying hemangioma of the facial nerve presents as a lobulated soft tissue mass, with indistinct margins and intra-tumoral bony spicules. On MRI, this tumour tends to be ill-defined, heterogeneous in signal intensity, but otherwise non-specific.

MRI is the modality of choice to depict perineural spread of malignant tumours. It manifests as smooth or nodular thickening and enhancement along the facial nerve; obliteration of the stylomastoid foramen fat pad and atrophy of the muscles of facial expression due to chronic deinervation. PFNP may be the first clinical sign of a parotid malignancy. Therefore, no imaging study is complete without the inclusion of the parotid gland (Fig. 3).

The imaging hallmark of neurovascular conflict is the presence of a vessel crossing the facial nerve perpendicularly at the root entry zone, leading to displacement or indentation of the nerve (4, 5).

Diagnosis

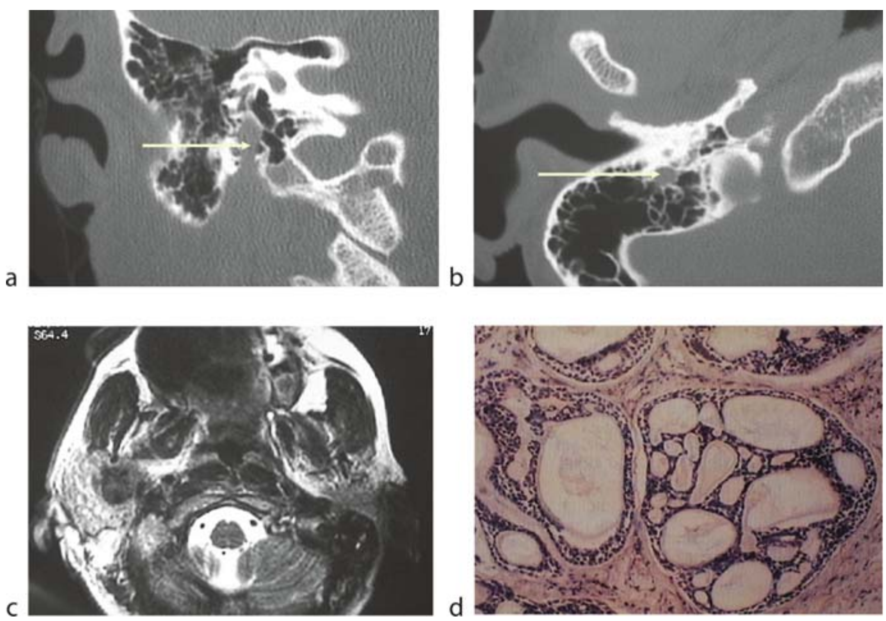
FNP is a clinical diagnosis, based upon signs and symptoms of loss of facial nerve functions. Topographic diagnosis requires a detailed clinical history, neurological and ENT examinations and helps to determine the probable site of nerve injury and to direct further diagnostic testing.

Serologic testing is an important aid in the diagnosis of PFNP secondary to diabetes mellitus, Lyme's disease, HIV, sarcoidosis, Guillain-Barré's syndrome and acute herpes and zoster infections. CSF sampling may also be helpful in cases of viral infection and basilar meningitis. Other diagnostic and prognostic testing includes electroneurography electromyography and evaluation of CN VIII function (audiogram, caloric testing and electronystagmogram).

Because most cases of facial nerve dysfunction are due to Bell's palsy, the major diagnostic challenge is the early recognition of potentially treatable causes aiming for function preservation or rehabilitation.

Interventional Radiological Treatment

Limited to pre-operative embolization of highly vascular lesions mainly facial nerve paragangliomas and glomus jugulo-tympanicum.



Facial Nerve Palsy. Figure 3 **Coronal (a) and axial (b) CT sections through the temporal bone in high resolution bone algorithm show abnormal enlargement and remodelling of the mastoid segment of the facial nerve (*white arrows*). (c) Axial T2W image through the parotid gland shows a mass lesion in the deep lobe of the parotid overlying the expected course of the facial nerve. The lesion is of low-signal intensity on this sequence a feature associated with parotid malignancies. (d) Photomicrograph of the pathologic specimen (hematoxilin and eosin stain; original magnification X 1000), shows multiple microcystic spaces lined by cuboidal epithelial cells with hyperchromatic nuclei, yielding an overall appearance of a Swiss cheese. These are typical features for adenoid cystic carcinoma (cribiform pattern). Diagnosis: Perineural spread of adenoid cystic carcinoma along the mastoid segment of the facial nerve in a patient presenting with peripheral FNP of unknown etiology.**

Fascioliasis

Hepatobiliary infection caused by flukes of the Trematoda (Fasciola hepatica, Fasciola gigantica), which are common parasites of cattle and sheep. Humans are incidental hosts. These two flukes cause similar diseases in patients, who become infected by ingesting contaminated watercress, raw fish, or raw cattle or sheep liver. The disease is characterized by an acute and a chronic phase that may last for years. From the duodenum, the cercaria and the immature flukes migrate through the bowel wall, the peritoneal cavity, and the Glisson capsule, reaching the bile ducts in which they will mature. Mature flukes migrate toward the larger bile ducts, causing hemorrhage, inflammation, necrosis, and subsequent fibrosis. This disease is reported worldwide, in particular in regions of sheep or cattle production. Clinically, patients may be asymptomatic or may present with fever, eosinophilia, and abdominal pain. US may show hypoechoic areas in the liver, corresponding to the burrow tracks of the larvae. CT shows millimetric lesions or tunnels with a radiating pattern in the liver parenchyma. These hypodense areas (corresponding to necrosis) show enhancing walls resembling abscess features and are mostly located in the periphery. After several months, these cavities decrease in size, and calcifications or granuloma formation can be observed. MR imaging provides findings similar to those in CT. Cholangiography may depict flukes in the biliary tree.

▶Cholangitis

FasL (CD95L)

Ligands of the respective receptors, which trimerize after binding, forming major regulators of apoptosis.

Femoroacetabular Impingement

Injury secondary to repetitive trauma of the femoral head upon the acetabulum. Cam-type impingment is characterized by lateral decentering of the femoral head resulting in contact with the acetabulum during flexion. This abnormality is commonly found in young, active patients. Pincer-type impingement is secondary to an abnormal acetabulum contacting the femoral head during normal hip movement. The acetabulum may be unusually deep (coxa profunda) or retroverted. Symptoms occurring in this patient population are of later onset. Both types of impingement lead to labral tears, cartilage abnormalities, and early osteoarthrosis of the hip. Adjacent marrow edema and cystic change is also found on MR imaging.
▶Fractures, Pelvis

Fetal Brain Abnormalities

CNS malformations and brain injury are the primary CNS abnormalities encountered in utero. Isolated ventriculomegaly is still a challenging clinical condition.
▶Fetal Neuroimaging

Fetal Brain MRI

MRI serves as a second imaging tool to confirm or correct ultrasound findings in utero. T1, T2, and diffusion images are routinely used to evaluate the brain parenchyma. Proton spectroscopy is still part of the clinical research protocol.

Synonyms

Intrauterine MRI; Prenatal MRI

Definition

Fetal magnetic resonance imaging (MRI) is a relatively new, nonionizing imaging modality in which ultrafast MRI sequences allow intrauterine examination of the fetus without the need for fetal sedation. Fetal MRI is advantageous compared to prenatal ultrasonography (US) because it is not obscured by overlying maternal bowel gas, pelvic bone structures, or obesity, is not influenced by the position of the fetus, and is less dependent on the investigator's skills (1, 2, 3).

Pathology/Histopathology

Fetal MRI allows the entire pregnancy to be evaluated, including maternal components, like the ovaries and uterus, as well as the placenta and umbilical cord. In addition, the complete fetus is examined from "tip to toe." If required, the birth canal can also be measured (MR pelvimetry). With progressing diagnostic experience and available data as well as continuous technical improvements (MRI hard- and software), the indications for fetal MRI continue to grow.

Fetal MRI is especially advantageous in the evaluation of the developing fetal central nervous system (CNS) (Figs 1 and 2). The CNS is the most frequently involved "organ" in congenital malformations (1:100 births). In addition, CNS malformations often have a significant impact on the quality of life. Moreover, spontaneous deliveries can be complicated by CNS pathologies and the primary adaptation of the neonate may be influenced. Fetal MRI is progressively applied in pathologies of the fetal thorax and abdomen (Figs 3 and 4); however, it is currently limited in the evaluation of the distal extremities in particular (Table 1).

Congenital lesions can be divided into (a) classic congenital malformations and (b) intrauterine acquired pathologies. In congenital malformations an erroneous development of the CNS has occurred, while in acquired pathologies, initially correctly developed structures have been injured. A significant overlap between both categories can be troublesome for differentiation. An early, minor ischemic event can, for example, result in a migrational disturbance indistinguishable from a primary malformation of cortical development. The most frequent malformations of the CNS include (1) disorders of neural tube closure, (2) disorders of sulcation and migration, and (3) disorders of diverticulation or brain cleavage (Table 1).

Disorders of Neural Tube Closure

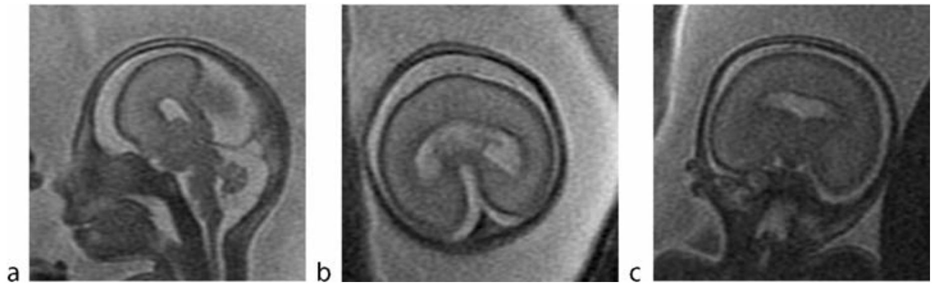
Chiari II Malformation: Chiari II malformation is a malformation of the rhombencephalic vesicle characterized by a too-small posterior fossa with coexisting and/or resulting mesencephalic and cerebellar anomalies including a downward displacement of the cerebellum, beaking of the tectal plate, embracement of the brain stem by the cerebellar hemispheres, and frequently a supratentorial hydrocephalus. Chiari II is almost always associated with spinal dysraphism.

Cephaloceles: Cephaloceles comprise varying degrees and/or combinations of protruding brain tissue and meninges through a skull defect. Cephaloceles may occur at multiple anatomical locations and are frequently associated with disorders of neuronal migration and sulcation or commissural malformations.

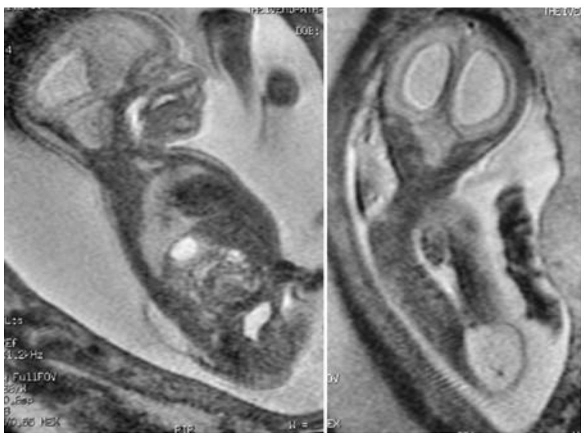
Dandy-Walker Malformation: Dandy-Walker malformation is characterized by cystic dilatation of the fourth ventricle associated with varying degrees of vermian hypoplasia. In 60% of patients additional CNS malformations are present. The posterior fossa is usually significantly enlarged.

Spinal Dysraphism: Due to a failure of neural tube closure, the meninges and a nonclosed neural tube (neural placode) protrude outside the open bony spinal canal in myelomeningoceles (MMC). MMC is always associated with Chiari II malformation.

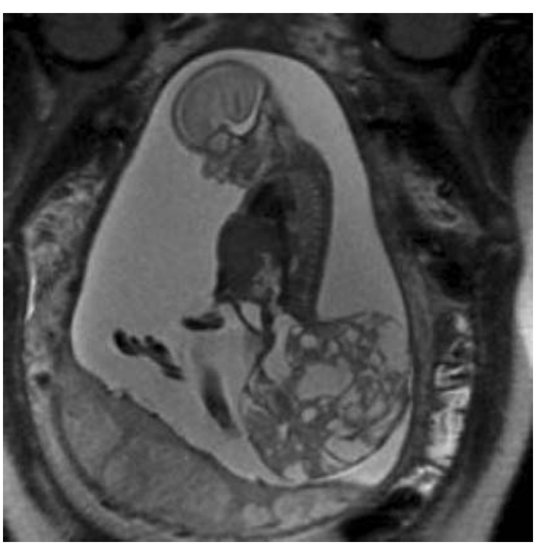
Commissural Malformation: The most frequently encountered commissural malformations are anomalies



Fetal Imaging. Figure 1 Sagittal, coronal, and axial fetal MRI. Semilobar holoprosencephaly in a fetus, 24th week of gestation.



Fetal Imaging. Figure 2 Sagittal and coronal fetal MRI. A lumbar meningomyelocele with an associated Chiari II malformation is seen. In addition, a thoracal diastematomyelia is seen. All findings were confirmed after birth.



Fetal Imaging. Figure 3 Sagittal fetal MRI. Large, multicystic, partially solid sacrococcygeal teratoma in a fetus, 25th week of gestation. No signs of fetal hydrops.

Fetal Imaging. Figure 4 Axial and coronal fetal MRI. A multicystic abdominal lymphangioma with multiple septa and fluid sedimentation levels is seen in a 22-week-old fetus.

of the corpus callosum. Agenesis may be partial or complete. Callosal anomalies are frequently associated with other CNS malformations.

Disorders of Sulcation and Migration

Pachygyria and Polymicrogyria: Pachygyria and polymicrogyria are disorders of neuronal migration and cortical organization. In pachygyria the cortex is thickened, while in polymicrogyria multiple small gyri are seen.

Lissencephaly: Lissencephaly results from an arrested neuronal migration and is characterized by a four-layer

cortex with a smooth surface. Bands of neurons are located within the white matter.

Schizencephaly: In schizencephaly, cerebral clefts extend from the brain surface to the ventricle. Most schizencephalies are lined by a malformed/disorganized cortex.

Disorders of Diverticulation or Brain Cleavage

Holoprosencephaly: Failure of the cleavage of the prosencephalon will result in a spectrum of malformations that are characterized by different degrees of fused cerebellar hemispheres. The most severe from is the alobar form, the mildest form is the lobar form.

Thoracal and Abdominal Malformations

Thoracal and abdominal malformations include a wide variety of pathologies such as hemangiomas, diaphragmatic hernias, omphaloceles, renal agenesis, cloacal malformations, hamartomas, etc. A complete list of lesions that can be diagnosed would outgrow this chapter.

Clinical Presentation

Most frequently, intrauterine CNS malformations are encountered on prenatal ultrasonography. Rarely will the mother experience any symptoms. The following description of presentation is consequently related to the child after birth.

Chiari II Malformation

Clinically, it is determined by the associated CNS malformations. The level and extent of spinal dysraphism result in varying degrees of paraplegia and bladder/bowel dysfunctions. The associated cerebral pathology, especially the hydrocephalus, determines the degree of psychomotor retardation.

Cephaloceles

Isolated cephaloceles may present with focal neurological deficits related to the affected functional centers. If associated migrational lesions are present, the child will present with seizures. Depending on the location, the cephalocele can be seen on gross inspection or can, for example, be "hidden" in the nasal cavity in the case of a frontobasal encephalocele.

F

Dandy-Walker Malformation

Depending on the degree of cystic dilatation of the fourth ventricle, the posterior fossa will be enlarged. Cognitive performance is frequently affected, and 35–50% of children will have normal intelligence. An associated hydrocephalus will result in macrocephaly.

Spinal Dysraphism

Defects of neural tube closure are easily identified on inspection. The neural placode is exposed to the skin surface and cerebrospinal fluid (CSF) leaks out. Frequently, the lower extremities are deformed and/or a hip luxation is present. In lipomeningomyeloceles a subcutaneous lipoma and a hairy tuft can be seen.

Commissural Malformation

Children may present with unspecific symptoms such as seizures, neurodevelopmental delay, microcephaly, hypothalamic–pituitary malfunction, or hypertelorism. Callosal dysgenesis is frequently an incidental finding on postnatal US.

Disorders of Sulcation and Migration

The degree, extent, and location of malformation determine the clinical presentation. Children may present with mental retardation, seizures, and focal neurological deficits. Disorders of migration can occur as part of a syndrome complex.

Disorders of Diverticulation or Brain Cleavage

In the severe forms of holoprosencephalies, a spectrum of symptoms have been described. Hypothalamic–pituitary dysfunction, seizures, mental retardation, dystonia, microcephaly as well as facial malformations such as cyclopia and fused metopic sutures can be encountered. The face may reflect the brain.

Thoracal and abdominal malformations are usually seen on gross inspection or present with clinical symptoms that are directly related to an impaired function of the affected anatomical regions.

Imaging

MRI relies mainly on T2-weighted single-shot fast spin-echo sequences (slice thickness 3–4 mm). T1-weighted gradient-echo sequences are added to rule out, for example, hemorrhages. Various additional sequences are currently progressively applied including diffusion-weighted sequences, magnetic resonance spectroscopy, as well as thick-slab, strongly T2-weighted sequences that provide a “fetographic” display.

Chiari II Malformation

Chiari II malformation is characterized by a small posterior fossa with herniation of cerebellar structures into the upper cervical spinal canal, deformation of the quadrigeminal plate, varying degrees of callosal dysgenesis, and supratentorial hydrocephalus. Rarely is an associated syringohydromyelia seen.

Cephaloceles

Cephaloceles are protrusions of the meninges and/or brain tissue through a skull defect. Most encephaloceles are occipital. The protruding brain tissue is usually dysplastic. Associated ventriculomegaly may be seen.

Dandy-Walker Malformation

Dandy-Walker malformation is characterized by cystic dilatation of the fourth ventricle, hypoplastic vermis that may be rotated upward, elevated torcula, and varying degrees of posterior fossa enlargement. The cerebellar hemispheres are usually laterally displaced. Associated ventriculomegaly may occur.

Spinal Dysraphism

In MMC a soft tissue defect in combination with a protruding neural placode through a wide open bony spinal canal is seen. The spinal cord is tethered, the dorsal and ventral nerve roots are usually stretched and appear along the ventral surface of the neural placode. Identification of the neural placode can be difficult as the neural placode is ventrally lined by T2-hyperintense CSF and dorsally by equally T2-hyperintense amniotic fluid.

Commissural Malformation

Callosal dysgenesis may be partial or complete. The corpus callosum develops in the following sequence: genu, truncus, splenium, and finally rostrum. If the truncus is missing, the splenium and rostrum will also fail to develop. In callosal agenesis the medial brain surface shows a radiating pattern of gyri and sulci. There is no cingulate gyrus. Both lateral ventricles show a parallel course on axial images, and a mild colpocephaly is frequently seen. On coronal images, the lateral ventricles have a trident shape, the third ventricle may extend interhemispherically. The hippocampi are malrotated.

Pachygyria and Polymicrogyria

In pachygyria the cerebral cortex is thickened, in polymicrogyria multiple small gyri are seen. Combinations of pachygyria and polymicrogyria may be seen.

Lissencephaly

Arrested neurons within the white matter are recognized as T2-hypointense bands that parallel the cerebral surface. In lissencephaly the overlying cortex is smooth, the sulci are shallow.

Schizencephaly

Clefts may extend from the cerebral surface until the lateral ventricles. The clefts are usually lined by thickened, polymicrogyric T2-hypointense cortex. The cleft may be closed (closed lip) or may open to the cerebral surface (open lip). The septum pellucidum is absent in 80% of the cases.

Holoprosencephaly

Depending on the severity of holoprosencephaly, different degrees of fusion of the cerebral hemispheres are seen. In the most severe cases a monoventricle is lined by a fused holosphere. In less severe cases, lobar holoprosencephaly, two hypoplastic frontal lobes are seen with hypoplastic frontal horns and a hypoplastic falx cerebri that extends frontally.

Thoracal and Abdominal Malformations

An exact delineation of the anatomy is essential to identify anatomical malformations. Functional information is very limited, and there are currently no routine intrauterine magnetic resonance angiography sequences available for examining cardiovascular malformations reliably.

Diagnosis

Fetal MRI serves as a second-line imaging tool in combination with prenatal US. Fetal MRI should be considered in complex (cerebral) malformations or pathologies, in those cases where US is limited due to, for example, adipositas or bowel gas and in those cases where the clinicians or parents desire a second imaging modality to confirm, correct, or complete sonographic findings. Diagnosis relies on the best spatial resolution that can be achieved with ultrafast MRI sequences in combination with sensitive phase array surface coils. The ultrafast sequences allow one to "picture freeze" the fetus while it is moving. Fetal MRI should be considered as an examination that evaluates the entire pregnancy, i.e., the uterus, placenta, umbilical cord, as well as the entire fetus. Imaging results should be evaluated by experienced radiologists who are familiar with the anatomy and pathology of fetuses and neonates. In addition, imaging findings should be discussed by an interdisciplinary team of specialists including pediatric (neuro-) radiologists, obstetricians, pediatricians, surgeons, and neonatologists.

Fetal Neuroimaging

NADINE J GIRARD, FREDERIQUE CHAPON, XAVIER COMBAZ
Department of Neuroradiology, Hopital Timone Adultes, France
nadine.girard@mail.ap-hm.fr

Definition

Fetal neuroimaging includes all the imaging methods for examining the fetal central nervous system (CNS). Ultrasound (US) is the main tool for routine examination of the fetal brain. Magnetic resonance imaging (MRI) can serve as a second imaging tool to confirm or correct ultrasound findings. Indications for fetal MRI have increased because of improvements in MR techniques with subsequent ability to detect subtle changes within the fetal brain. Computed tomography (CT) is not used routinely. However, multidetector CT permits helical acquisition with thin slices and volume-rendering reconstructions that may be helpful in assessing spine and cranial vault abnormalities.

Clinical Presentation

MRI is usually performed during the second half of gestation from 18 to 20 weeks onward because US can accurately diagnose severe ►brain abnormalities before that period of time and is hence usually sufficient for decision making. Moreover, MRI resolution is poor before 18 weeks.

Indications for ►fetal brain MRI are mainly based on abnormal US findings: Ventricular dilatation is the most frequent indication (40%), followed by suspicion of CNS malformation (31%) and brain injury (1). MRI is of paramount importance in evaluating ventriculomegaly because it has greater sensitivity for detecting associated brain lesions compared with US.

MRI is also performed after normal results of brain US in peculiar contexts: familial (familial history of genetic disorder involving CNS, such as X-linked hydrocephalus and tuberous sclerosis), maternal (coagulation disorders, infections, acute fetal/maternal events), fetal [twin-to-twin transfusion syndrome, fetuses presenting with extracerebral malformations that can be associated with brain lesions, intrauterine growth restriction (IUGR)).

Knowledge of the general rules of fetal maturation is extremely important. Indeed, anatomy and the effects of maturation on the MR signal change according to gestational age. Therefore, the MRI features of a definite pathology will change accordingly (2). Repetition of MR examination is thus necessary when early MR is not conclusive, resulting in illustration of the natural history of a definite pathology. Moreover, the image itself may be confusing because different pathologies can display similar images, especially in young fetuses from 20 to 25 weeks (1).

Imaging

Images are routinely obtained in the sagittal, coronal, and axial planes relative to the fetal head with both T1- and T2-weighted images. The development of fast imaging using multiple phased-array coils is of great benefit and results in good signal homogeneity without necessarily needing to sedate the mother.

T2-weighted single-shot sequences such as HASTE (half-Fourier single-shot turbo-spin echo) provide heavily

T2-weighted images with low-susceptibility weighting and are used to “freeze” the fetus. T2 images of true fast imaging with steady-state precession type (TRUE FISP) are highly accurate for evaluating the face and skull base and in depicting old hemorrhage, calcifications, and lipoma in young fetuses. Thin sections of 1–1.5 mm are obtained with three-dimensional TRUE FISP sequences, which are mainly used in evaluating the midline (i.e., partial corpus callosum agenesis and aqueduct stenosis).

T1-weighted images are required to look for signal changes from normal maturation as well as from hemorrhage, calcifications, leukomalacia, lipoma, and lesions seen in tuberous sclerosis. Gradient echo (GE) or turbo-spin echo (TSE) images can be performed; GE images give an excellent differentiation between the cortical ribbon, the white matter, and the ventricular walls.

Diffusion-weighted images are performed in the postnatal period to detect cytotoxic or vasogenic edema through anisotropic, trace, and apparent diffusion coefficient images. Diffusion-weighted images can show the normal maturation and the premyelinating white matter tracts in which signal changes are seen on diffusion-weighted images before T1- and T2-weighted images do. Therefore, minor abnormalities of the corpus callosum and white matter anomalies may be identified.

Images of the fetal brain are currently obtained with acceptable acquisition time on last-generation magnets: 20–40 sec for T2-weighted images, 45 sec for T1-weighted images, 1 min for three-dimensional T2-weighted images, and 30–50 s for diffusion-weighted images (Fig. 1).

Normal Development of Fetal Brain Anatomy

Developing brain anatomy is characterized by morphological and signal changes along with increasing gestational age (3).

Morphological changes consist of changes in ventricular shape, thickness of the germinal matrix, and volume of the subarachnoid spaces, along with the developing sulcation. From the agyric brain at 18–20 weeks, dramatic changes in sulcus formation can be seen at 24, 28–30, and 34–35 weeks, at which time the gyration appears almost complete. Development of the cerebellum is complex. MRI is able to show the appearance of the fissures of the cerebellum. The lateral ventricles and the subarachnoid space appear relatively enlarged in young fetuses, with a progressing decrease in size along with development of the cerebral mantle. However, the subarachnoid space can remain large throughout gestation, particularly in the parieto-occipital areas, which result from the evolving process of cavitations of the meninx primitiva.

Signal changes result from the maturation process, which includes high cell density, myelination gliosis (the multiplication of glial cells that precedes myelination), formation of myelin proper with accumulation of intracellular lipid myelin precursors, and decreased brain-tissue water content, mainly within the white matter. Signal changes are detected at 20 weeks within the posterior brainstem, germinal matrix, and white matter, in which intermediate layers of migrating cells are present until 30 weeks and give a typical multilayered pattern of the cerebral mantle. Transient intermediate layers within the white matter constitute an important hallmark, and their absence is highly suggestive of white matter damage. Basal ganglia also show similar signal changes, mostly related to high cell density, which are extremely conspicuous at 28–29 weeks and must not be mistaken with cytotoxic lesions. Signal changes are identified in the posterior limb of the internal capsule and optic tracts at 33 weeks as well as in the projecting fibers of the central area of the centrum semiovale at 35 weeks.

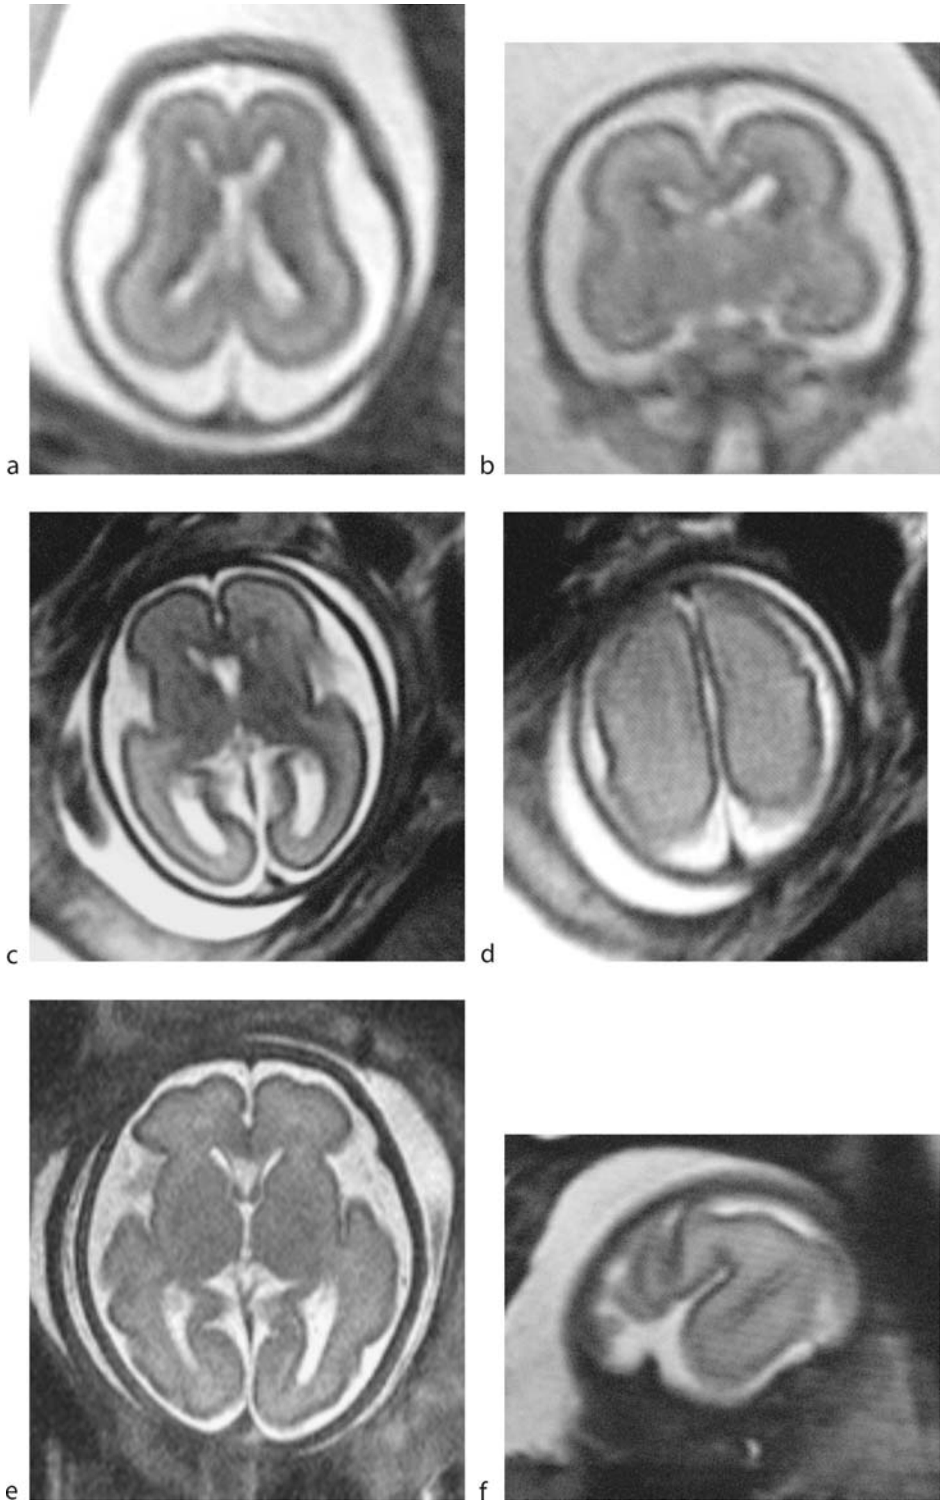
Diagnosis

CNS malformations and brain injury are the primary abnormalities encountered in utero (1, 2). Criteria for destruction of the brain include abnormal ventricular morphology (irregular ventricular wall), lack of brain layering, absence of maturation milestones and of normal signals, and the presence of abnormal signals. On the other hand, malformations are characterized by their specific morphological changes. However, these criteria may overlap, such as in cases of vascular malformation with brain damage.

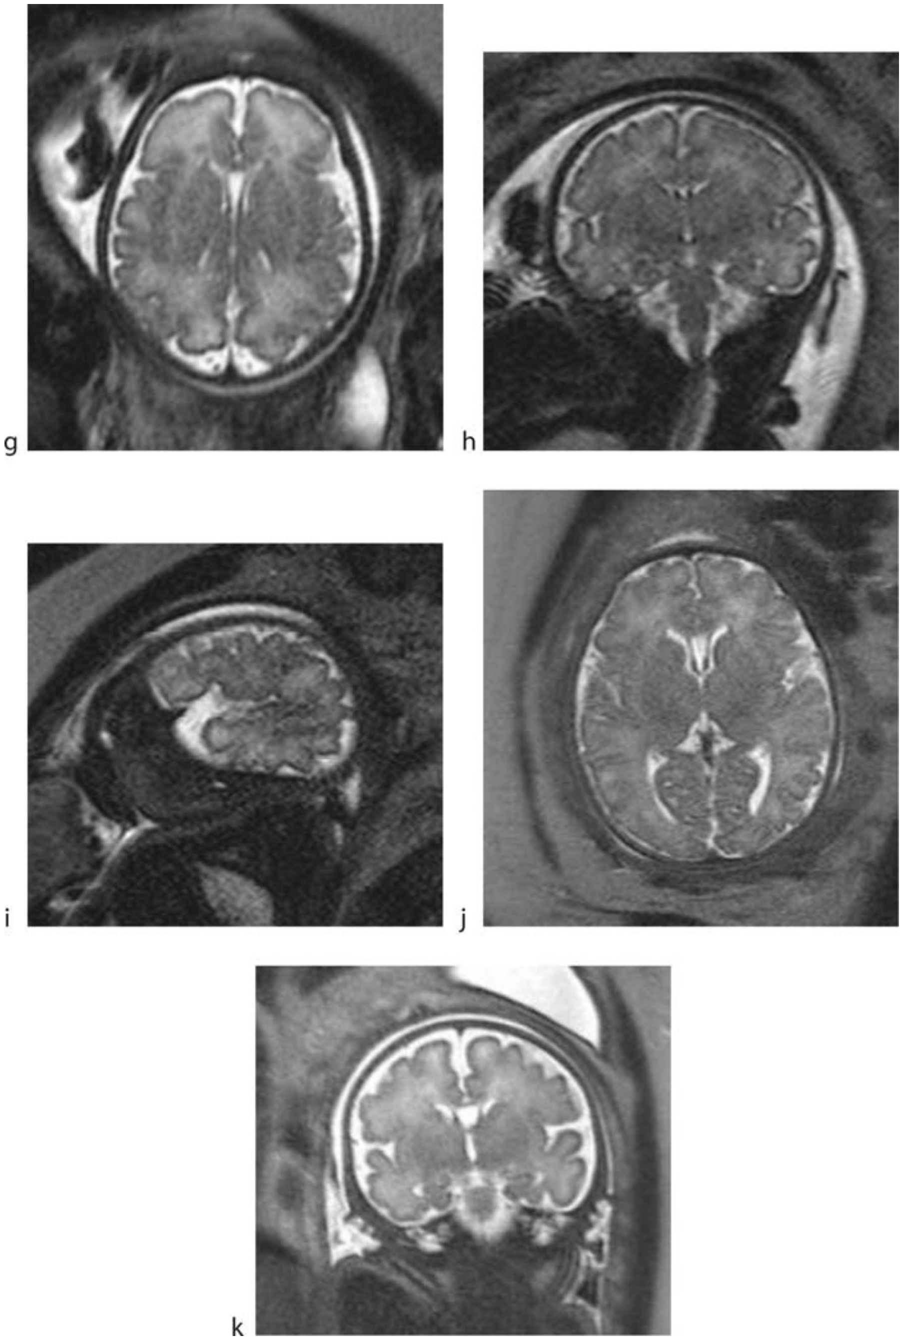
Numerous CNS malformations, from commissural to histogenetic disorders, can be seen in utero with limitations with regard to the accurate assessment of some malformations.

Corpus callosum agenesis (CCA) is the most frequent malformation (Fig. 2). Limitation is seen in cases of partial CCA associated with interhemispheric cyst, which, through its mass effect, can prevent detection of associated cortical malformations (especially micropolygyria) until after delivery and shunting. This condition increases the problem of prognosis in CCA, which is still debated.

Cerebral histogenetic disorders are rarely suspected on US and result from different types of pathogenic disorders: disturbances in cell proliferation (microlissencephalies), cell differentiation (focal cortical dysplasia), cell migration (heterotopia and lissencephalies, or agyria-pachygyria), and organization of the cortex [polymicrogyria (PMG)]. Absence of the multilayered pattern of the cerebral mantle, absence of the normal signal of the cortex, and an abnormal shape of the superficial cerebral hemisphere



Fetal Neuroimaging. Figure 1 **(continued)**



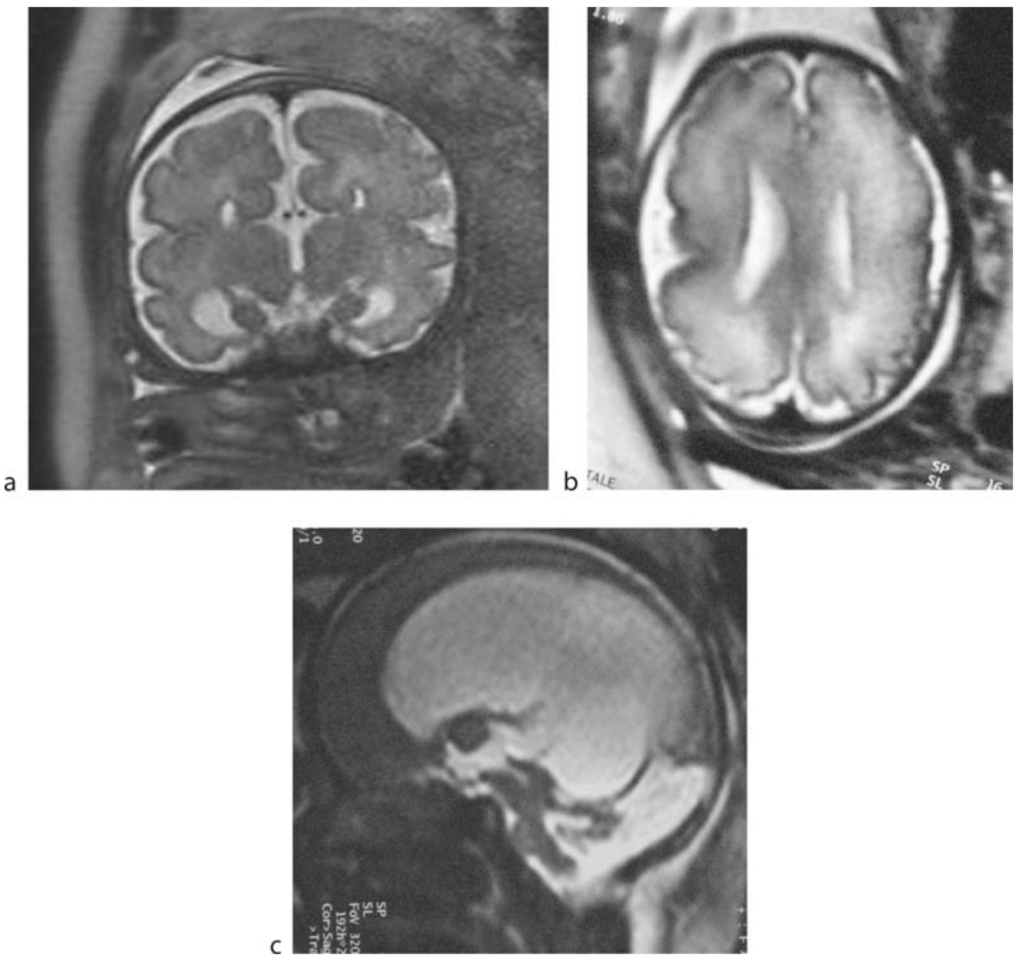
Fetal Neuroimaging. Figure 1 **Normal appearance of the fetal brain through T2 images at 20 (a), 24 (b), 28 (c), 32 (d, e), and 37 (f) weeks. The brain is agyric in young fetuses, with prominent lateral ventricles and subarachnoid spaces (a). The central sulcus is seen at the cerebral surface as a depression by 24 weeks (b). By 28 weeks, pre- and postcentral sulci are identified (c) while the superior temporal sulcus is achieved (c). By 32–33 weeks the superior frontal sulcus is depicted at the cerebral surface, while the lateral ventricles and subarachnoid spaces are not as large as in previous stages. Circumvoluted brain is seen at 37 weeks. The germinal matrix is thick in young fetuses and of low signal on T2 images. The cortical ribbon is also of low signal. Intermediate layers are seen within the white matter until 30 weeks, giving a multilayered appearance of the fetal brain. Basal ganglia are also of low signal intensity on T2 due to high cell density.**

are suggestive of a cortex/white matter abnormality. Microcephalies are usually diagnosed in the third trimester provided that the head circumference is three standard deviations below the mean.

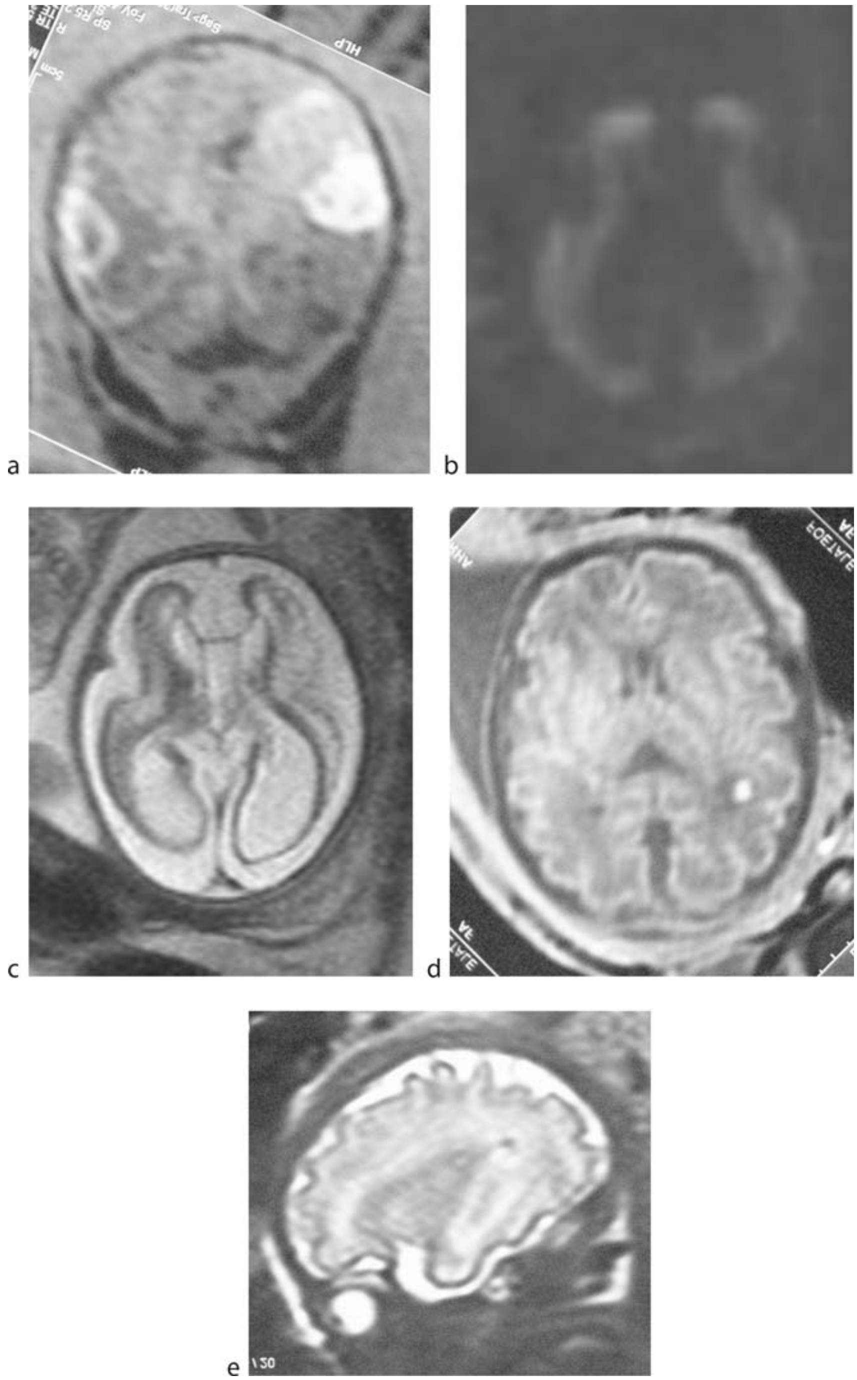
In posterior fossa malformations, MRI can detect whether the dural structures, especially the tentorium, are normally positioned. Cystic posterior fossa malformations as part of the Dandy–Walker continuum are characterized by an elevated tentorium and bulging of the parieto-occipital vault, whether or not the vermis is partially or totally absent. In contrast, a small posterior fossa is seen in Chiari type 2 malformation related to myelomeningocele. A normally positioned tentorium, usually within a posterior fossa of normal size, is seen in histogenetic disorders such as pontocerebellar hypoplasia, cerebellar dysplasia, rhombencephalosynapsis, and rhombencephaloschisis. Cerebellar hypoplasia is difficult to diagnose because development of the cerebellum is slow, with cellular migration continuing well after birth. Great difficulty is encountered in unilateral cases because the condition may be related to either malformation or a clastic origin. However, severe hypoplasias that have poor prognoses are easy to identify.

Brain injury may result from hypoxia, ischemia, congenital infection (especially toxoplasmosis and cytomegalovirus infection), malformation (cerebral vascular and cardiac malformations), inherited inborn error of metabolism, or tumors.

Different features are encountered in the fetal brain in response to injury. Chronic responses of the brain and the



Fetal Neuroimaging. Figure 2 Examples of malformations encountered in utero: corpus callosum agenesis (CCA) at week 31 (a), polymicrogyria (PMG) at week 31 (b), and cerebellar hypoplasia at 26 weeks (c). The corpus callosum is missing between the two cerebral hemispheres. Note the enlarged temporal horns and parallel course of the lateral ventricles, which are widely separated in CCA. In PMG the normal gyration is not identified, with areas of thickened and irregular cortex and enlarged subarachnoid spaces that overlie the cortical abnormality, especially in the right hemisphere. The case with severe cerebellar hypoplasia is associated with ventricular dilatation.



Fetal Neuroimaging. Figure 3 Examples of fetal brain injury: hemorrhage (a), necrosis and cytotoxic edema (b, c), and calcified abscess in toxoplasmosis (d, e). Hemorrhage: coronal T1 image at 34 weeks (a). Large areas of bright signal are seen bilaterally; brain hemorrhage is secondary to thrombocytopenia in this case. Necrosis and cytotoxic edema: axial diffusion (b) and T2 (c) images at 26 weeks in a twin-to-twin transfusion syndrome. Ventricular dilatation is associated with necrosis, seen as areas of bright signal on T2, especially in the left hemisphere with no identification of the normal low signal of the cortex. Cytotoxic lesion of the cortex is also identified as areas of bright signal on diffusion image in the frontal lobes. Toxoplasmosis: axial T1 (d) and parasagittal (e) images at 31 weeks. A nodule of bright signal on T1 and low signal on T2 is identified in the left periventricular area, corresponding to calcification. Note the slight low signal on the T1 image surrounding the bright nodule; this is due to edema.

combination of chronic and acute response are more commonly identified than acute response alone. Acute responses of the fetal brain include hemorrhage (intraventricular, in the germinal matrix, in the cerebral parenchyma, or in the subdural spaces), white matter damage (edema, leukomalacia), focal or diffuse infarction, and venous thrombosis (Fig. 3). Chronic responses of the fetal brain may manifest as ventricular dilatation, thickened or irregular germinal matrix or ventricular wall, white matter gliosis, loss of volume (atrophy), parenchymal cystic cavity (the most severe form being hydranencephaly), ependymal cyst, calcifications, malformations (especially of cortical development, such as PMG), and impaired myelination. Calcifications and cortical malformations are most likely seen in congenital infection, but not exclusively. White matter gliosis is not currently detected on conventional images but is seen at autopsy. Diffusion-weighted images and proton spectroscopy can help detect such cases (4, 5).

Ventriculomegaly may be caused by malformation, destruction of the brain, and, less commonly, by tumors, and is also seen in numerous syndromes in which it involves the frontal horns with a square, sharp shape of their walls. An apparent mechanism for ventricular dilatation is not always found in utero. The prognosis for ventriculomegaly in the fetus is variable. Findings indicative of a more favorable outcome include late diagnosis in the third trimester, slow evolution, a ventricle-hemisphere ratio of no more than 50% of normal and isolated ventriculomegaly. Isolated mild ventriculomegaly (whether unilateral or bilateral) is highly challenging because developmental delay ranges from 19% to 36%. The underlying mechanism of isolated ventriculomegaly can be related to fetal hypoxia (7%), early stages of benign external hydrocephalus (16%), and possible subtle changes of the white matter that are undetectable by conventional MRI.

Inborn errors of metabolism manifesting in utero are rare and extremely challenging in terms of diagnosis and prognostic significance. Metabolic diseases can be suspected because of IUGR, polyhydramnios, or brain malformation. CCA can be seen in pyruvate dehydrogenase deficiency, heterotopia in mitochondrial respiratory chain deficiency, and cortical abnormalities in Zellweger disease. Subependymal cysts are encountered in numerous diseases.

Definition

Fibrocystic disease has been a clinical problem for a long time, as it is reflected in the writings of Astley Cooper at the beginning of the nineteenth century. In fact, it is a confusing and inexact term. All clinicians have a concept of what fibrocystic disease is, but it is difficult to define and to differentiate from normal conditions of the breast. Fibrocystic disease is not a distinct entity but a heterogeneous group of abnormalities that include fibrosis, cysts, ▶apocrine metaplasia, ▶adenosis, and ▶hyperplasia (1, 2). Some of these abnormalities cannot be considered as pathologic conditions and do not increase the risk of the individual's developing breast cancer. However, other included conditions, such as some types of hyperplasia, may increase that risk. Nowadays fibrocystic disease is a term that should not be used anymore because it is confusing and does not reflect a real pathology or a risk of developing breast cancer. Fibrocystic disease is in fact a "nondisease."

Pathology/Histopathology

There is no specific pathology of fibrocystic disease. Fibrosis, cysts, apocrine metaplasia, adenosis, and hyperplasia compose the spectrum of fibrocystic disease.

Clinical Findings

Palpation of many normal breasts is difficult and unspecific, especially in young women. Firm, granular, or painful breasts at palpation, with cyclic changes, are frequently found in clinical practice and have for many years been described as "fibrocystic." But again, the term "fibrocystic disease" should not be routinely employed because in most cases it only describes the difficulty of studying these breasts, not a pathologic condition (1, 2).

Imaging

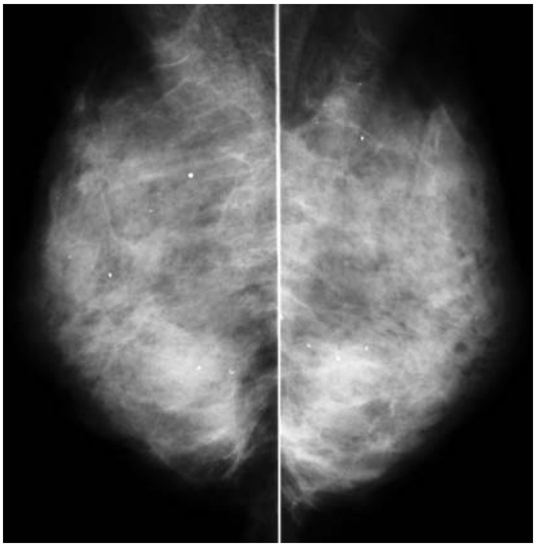
Mammography

The term "fibrocystic disease" should be avoided in mammographic reports, and it is not included in the American College of Radiology (ACR) breast imaging reporting and data system (BI-RADS) lexicon (3). In fact, the ambiguous significance of this term, prolifically used in other times, has made it difficult to standardize mammographic reports. This term has been used to describe dense breasts, usually with multiple round to oval masses, with well-delimited or obscured margins. Dense breasts were initially described as dysplastic by Wolfe. However, this term should also not be used because it is confusing. Nowadays, these types of breasts are classified as ACR class 4 (Fig. 1). The main problem of these breasts is the lower sensitivity to detect carcinoma compared with fatty breasts. Dense breast tissue reduces the sensitivity from 80% in fatty breasts (ACR class 1) to 30% (ACR class 4) (4).

It remains controversial whether dense breast have a higher risk to develop breast cancer than fatty ones. Some studies support this, but additional studies are needed (4).

Ultrasound

Ultrasound is the technique of choice to diagnose ▶breast cysts, a usual component of dense breasts (Fig. 2). It allows accurate characterization of a palpable mass, which is frequently found in these breasts, as cystic or solid. Moreover, ultrasonography may play a role in detecting breast cancers not seen on mammography. Nevertheless, supplemental use of ultrasonography in women with



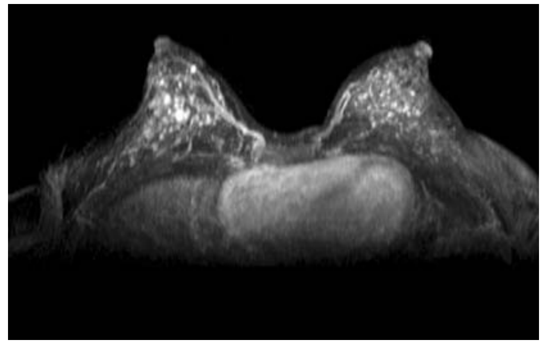
Fibrocystic Disease, Breast. Figure 1 Dense breasts (American College of Radiology class 4). Mediolateral oblique views.

Fibrocystic Disease, Breast. Figure 2 Ultrasonography of dense breasts. Multiple small cysts are seen.

asymptomatic dense breasts is still not accepted as a standard indication (5).

Magnetic Resonance Imaging

Magnetic resonance imaging should not be used to evaluate a breast lump in dense breasts. However, it plays an important role in determining the size of a breast cancer, especially in dense breasts, as well as determining possible multicentricity or bilaterality. Note that dense breasts may cause false positive results on magnetic resonance because the fibroglandular tissue may exhibit enhancement after paramagnetic contrast administration due to hormone stimulation (Fig. 3).



Fibrocystic Disease, Breast. Figure 3 Contrast-enhanced magnetic resonance imaging (Flash3D, MIP) in normal dense breasts. Multiple foci due to spontaneous hormone-induced enhancement are seen.

Nuclear Medicine

Nuclear medicine does not play a role in diagnosing fibrocystic disease. Rarely, dense breasts may uptake the radionuclide, causing false positive results on positron emission tomography scans.

Diagnosis

Cyclic breast pain not associated with a palpable abnormality is not an indication for imaging techniques. Most breast cancers do not present as pain, although in rare cases they may be painful. However, a breast lump always needs to be carefully studied. In spite of the lower sensitivity of mammography in dense breasts, it continues to be the first imaging tool used. If the palpable abnormality is mammographically benign, such as a lipoma, fibroadenolipoma, or an oil cyst, no further diagnostic procedures are required. However, if benignity cannot be ensured, or if the palpable lesion is not identified, an ultrasound exam is needed. Palpable cysts may be easily evacuated, but if a palpable lesion cannot be ensured as benign, a biopsy should be performed.

Fibrolamellar Carcinoma (FLHCC)

Rare malignant neoplasm of hepatocellular origin. In the past it was considered a variant of HCC, while it is now seen as an independent entity. Pathologically it is characterised by the presence of abundant fibrous tissue, which is distributed in bands or laminae. The central fibrous scar may show calcifications. Satellite nodules may also be present. This tumour occurs in younger patients, is not associated with hepatic cirrhosis and its histological features are less malignant than those of HCC. Most often it appears as a solitary, large, well-circumscribed mass with lobulated margins. Vascular invasion is rare, while lymphatic metastases are quite common.

Benign osseous tumors of the craniofacial region

Definitions

Fibro-osseous lesions (FOLs) of the face are quite rare and consist of lesions with osseous fibrous tissue instead of regular bone matrix. They represent a diverse group of pathologic conditions that includes developmental lesions and reactive or dysplastic diseases. FOLs share overlapping clinical, radiologic, and pathologic features that may lead to diagnostic confusion and possible misdiagnosis.

Because of their resemblances, FOLs are difficult to classify and terminology is unclear in some points. The WHO classification (second edition, 1992) reports three groups (1):

- ▶Fibrous dysplasia
- Benign fibro-osseous tumors: ▶cemento-ossifying fibroma, ▶osteoma, and osteoblastoma
- Cemento-ossifying dysplasia (reactive lesions) includes odontogenic lesions of the mandible: focal cemento-ossifying dysplasia, florid cemento-ossifying dysplasia, and gigantiform cementoma

The main differential diagnoses are ▶Paget's disease that often involves the face or the skull and giant cell tumors.

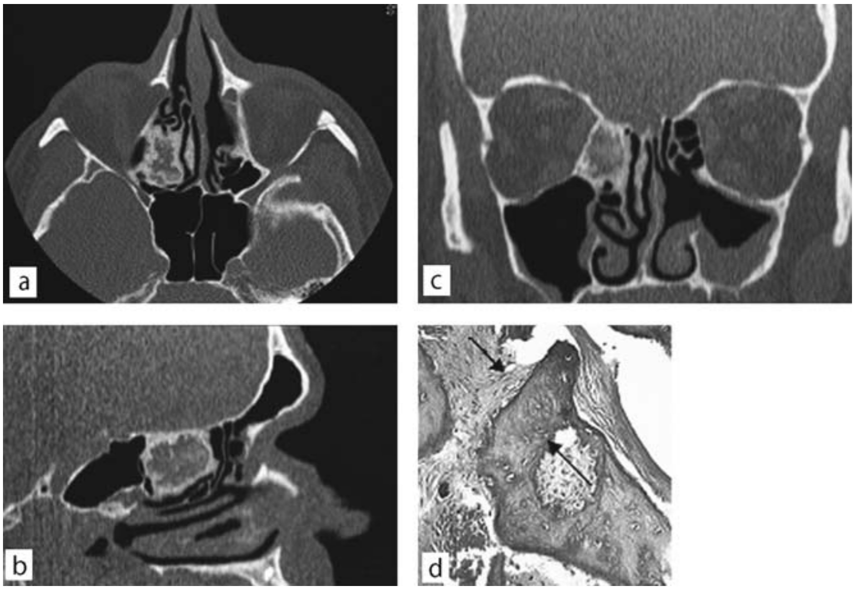
Pathology/Histopathology

Fibrous dysplasia is an uncommon benign bone disorder of unknown etiology in which normal medullary bone is replaced by fibrotic and osseous tissue. There are two variants of fibrous dysplasia (2): monostotic, which is more common (70%), and polyostotic (30%), which affects many bones and commonly the face.

McCune–Albright syndrome is characterized by polyostotic fibrous dysplasia, "cafe-au-lait" spots, and autonomous hyperfunction of various endocrine organs (precocious puberty). This is a rare disease that exclusively occurs in women. Lesions are usually diagnosed during the third decade of life. Fibrous dysplasia has two periods: an active growth phase until puberty and an adult quiescent phase.

Histopathologically, fibrous dysplasia (Fig. 1) shows irregular-shaped trabeculae of immature bone in a cellular fibrous stroma (3). The anarchic fibrous stroma has a variable cellularity. The bone component has mature and immature bone cells and anarchic trabeculae that are thinned, C- or S-shaped like "Chinese characters." Typically, the trabeculae are embedded in, and blend into, vascularized fibrous tissue lacking the osteoblastic rimming of normal bone.

There is a low but definite rate of malignant transformation (less than 1%) into osteosarcoma. For this reason radiation is generally felt to be contraindicated as a treatment modality for fibrous dysplasia.



Fibro-Osseous Lesions, Facial Skeleton. Figure1 Fibrous dysplasia: CT scans in (a) axial, (b) coronal, and (c) sagittal axes show an expansile mass of the right ethmoid. The cortices appear intact, the medullary space is composed of ossified and nonossified regions. Histology (d): irregularly shaped trabeculae of osteoid and immature bone, without osteoblastic rimming (arrows).

Cemento-ossifying fibroma belongs to the group of fibro-osseous tumors. Histologically, ossifying fibroma is a benign tumor composed of fibrous tissue with varying amounts of calcified tissue suggestive of bone and/or cement (Fig. 2). Most ossifying fibromas show some degree of bony trabeculae formation. Bone maturation is not achieved and fibrous tissue density is variable. Small hemorrhagic zones can be found, such as local inflammation with giant cells. The most similar entity to ossifying fibromas is fibrous dysplasia.

Juvenile ossifying fibroma is an aggressive variant with the ability to infiltrate. Histologically, juvenile ossifying fibroma arises from the periodontogenic ligament as the cemento-ossifying fibroma. It has a high cellularity.

Also from the fibro-osseous tumor group, osteomas are the most common benign osseous lesion of the sinuses. Although the etiology of these tumors is unknown, they occur most commonly in the frontoethmoid region.

Fitzgerald–Gardner syndrome is an autosomal-dominant disorder characterized by multiple facial osteomas, colic polyposis, and cutaneous lesions (fibromatosis, lipomatosis, leiomyoma). Histologically (3), these lesions are dense, well circumscribed, made of mature lamellar bone, sometimes with fibrous, hematopoietic, or fatty tissue components (Fig. 3).

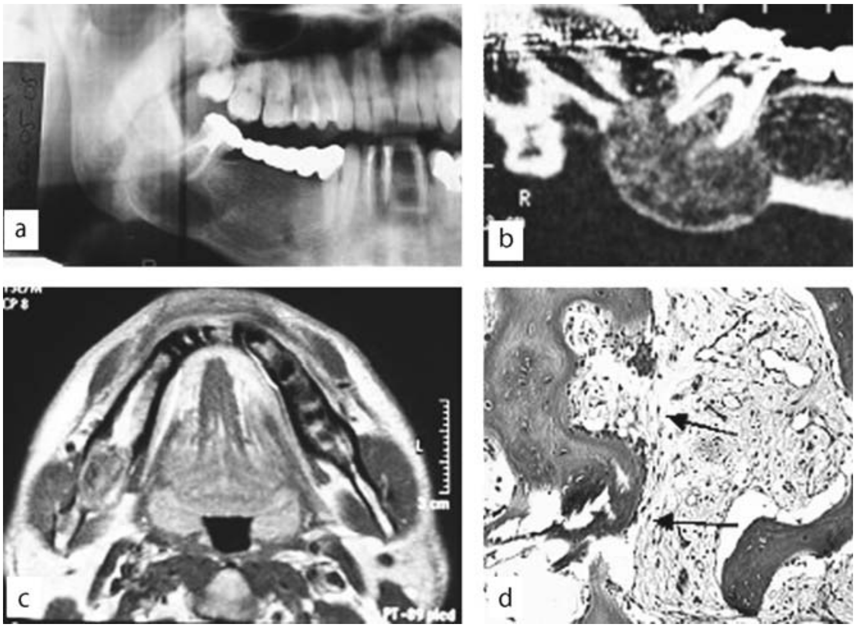
Osteoblastoma is a rare benign tumor of the face that occurs most commonly in young men (3). Histologically, osteoblastomas are characterized by osteoid trabeculation and loss of fibrovascular connection.

Cemento-ossifying dysplasias are part of the non-neoplastic fibro-osseous tumors of the WHO classification and are periodontogenic reactive lesions. These lesions occur exclusively in the mandible and the maxilla. Many authors do not consider these lesions as genuine facial fibro-osseous tumors.

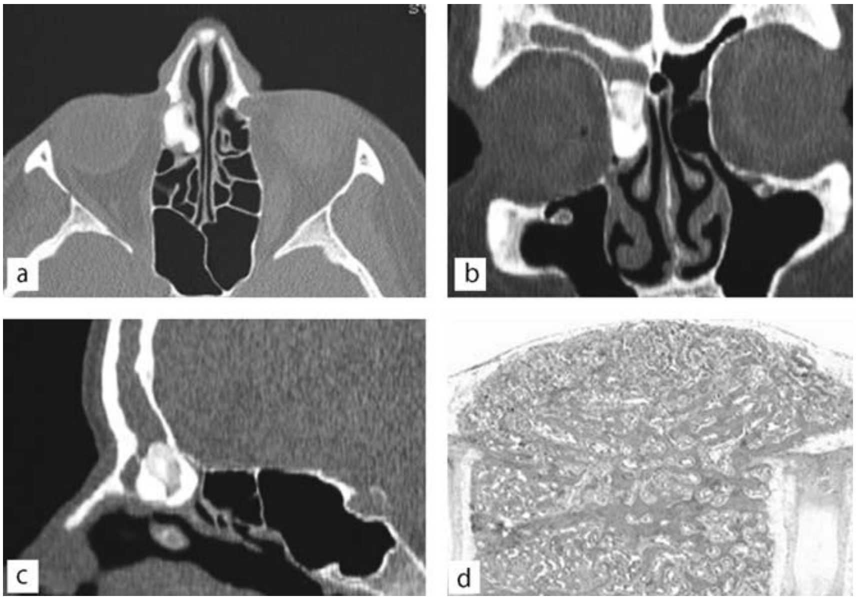
Clinical Presentation

Fibrous dysplasia presents with facial clinical symptoms such as pains (during active growth phase) and asymmetric deformations, but in adults the diagnosis is often made fortuitously from an x-ray study. Fibrous dysplasia is usually unilateral and most likely involves the frontal, ethmoid, sphenoid, and maxillary bones. Temporal, malar, parietal, occipital, and mandibular bone involvements are rare. Depending of the site of involvement, fibrous dysplasia can yield to headaches, nasal obstruction, mucoceles, and visual disorders (optic nerve compression).

Cherubism is considered as a variant of congenital fibrous dysplasia. It is an autosomal-dominant disorder. Extracranial skeletal involvement is rarely seen in hereditary and nonhereditary forms of the disorder. The mandible is the most severely affected craniofacial component. Bilateral swelling of the cheeks, mandibular enlargement, and maxillary spongious hypertrophy cause orbital manifestations and the tendency of the eyes to look



Fibro-Osseous Lesions, Facial Skeleton. Figure 2 Cemento-ossifying fibroma of the mandible. (a) Panoramic radiograph showing a well-circumscribed radiolucency with swelling at the cortices. (b) On sagittal CT scan the lesion is well limited, with high density and bony zones. (c) On axial T1-weighted post-Gd-DTPA MRI, we can see a significant enhancement correlated to the cemento-ossifying fibroma visualization. Histology (d): trabeculae of mature and immature bone in a fibrous stroma, with presence of osteoblastic rimming (→).



Fibro-Osseous Lesions, Facial Skeleton. Figure 3 Osteoma: (a) axial, (b) coronal, and (c) sagittal CT scans show an osteoma from the right anterior ethmoid cells. It looks like a well-circumscribed dense and calcified mass. For these patients, the osteoma obstructs the right frontal sinus. Histology (d): multiple packed levels of lamellar bone, without fibrous stroma, well circumscribed.

up to the sky. Thus, the pathognomic clinical feature resembles the appearance of "raised to heaven" Renaissance cherubs.

Cemento-ossifying fibromas are more common in women than in men and most often occur in the third and fourth decades of life. They are generally discovered incidentally on an x-ray or present as an asymptomatic mass without pain or swelling. The most common sites of occurrence are the mandible and the maxilla. They can also occur in the orbit and the paraorbital region. The juvenile form occurs most commonly in younger patients in the second decade of life and most likely involves the sinus and para-sinus regions (unifocal or plurifocal).

Osteomas are generally discovered incidentally on an x-ray or present with headache, facial deformation, or visual disorders. They often occur in men in the fifth decade of life but can occur at any age.

Osteoblastomas present with night pains and facial deformation, and teeth may be loosened.

Imaging

Computed tomography (CT) is now the key examination for the diagnosis of these lesions. The radiological appearance of fibrous dysplasia is variable (4). If predominantly fibrous, the lesion will appear radiolucent. If predominantly osseous, the lesion will appear radiodense. An equal mixture of the two will give the characteristic ground-glass appearance.

The radiological diagnosis should be evoked in cases of bone expansion with combined radiodense and radiolucent areas (Pagetoid variant, Fig. 1) or in cases of homogeneous radiodense bone expansion ("ground-glass expansion"). The pseudocystic variant is a radiolucent oval bone tumor with well-defined sclerotic contours.

Cortical bone is usually free of disease and can be deformed but not involved.

T1-weighted magnetic resonance imaging (MRI) reveals intermediate intensity and T2-weighted MRI reveals heterogeneous low intensity. Small hyperintense zones can be seen on T2-weighted images if cystic. Gadolinium enhancement is variable, sometimes intense.

The cemento-ossifying fibroma (Fig. 2) varies with the maturity of the lesion and with the amount of fibrous tissue. These lesions are sharply demarcated and unilocular. At the early stage, the immature lesion is radiolucent with rare calcifications. Later, the mature ossifying fibroma is radiopaque. CT scan shows a bone expansion surrounded by a dense contour. A dense center can be seen in some cases. T1-weighted MRI reveals intermediate intensity and T2-weighted MRI reveals low intensity. Gadolinium enhancement is moderate. The juvenile ossifying fibroma is very similar to ossifying fibromas. However, its aggressiveness yields to bone expansion with possible cortical ruptures without visible periosteal reaction. CT and MRI show calcification and osteoid trabeculation in the surrounding soft tissues. Ossifying fibromas can usually be surgically removed. Tumor recurrence after removal is low.

Radiologically, osteomas have regular contours. These are dense, osseous lesions developed in sinus cavities (Fig. 3). If large, osteomas can be heterogeneous.

For osteoblastomas, CT scans show a round lesion, well circumscribed with regular calcified contours. Osteoblastomas occur in the bone medullary. MRI findings are very similar to those of cemento-ossifying fibroma.

The radiological differential diagnoses are represented by Paget's disease and giant cell tumors.

Although the etiology of Paget's disease is unknown, it is characterized by an increased osteoclastic and osteoblastic activity yielding to the production of a dense and fragile osseous tissue. Paget's disease occurs most commonly in men after 50 years of age with a family history (3). Most often, this is a polyostotic disease (90%) with spinal, pelvic, and cephalic and femorotibial involvement. In cases of cephalic involvement, the most common sites of involvement are the skull vault, the mandible, and the maxilla. Cranial nerve disorders are reported in skull base involvement. Radiologically, the bone can appear flaky or thickened and dense with nonlinear cortical involvement associated with a poor corticomedullary differentiation. Well-circumscribed radiolucent zones can also be seen. T1-weighted and T2-weighted MRI reveal low-intensity zones of bony densification. Gadolinium enhancement is moderate. There is a 5–10% rate of malignant transformation into sarcoma for polyostotic disease. This rate is 2% for monostotic disease.

Giant cell tumors are rare benign lesions, locally aggressive (3). Histologically, these tumors show multinucleated giant cells, arising from osteoclasts, associated with mononucleated epithelial fusiform cells. These tumors most likely occur in the sphenoid, ethmoid, and temporal bone and present with pain and visual disorders. CT scans show lytic lesions, invading surrounding structures. MRI shows a T1 gadolinium enhancement in the early stage.

Nuclear Medicine

Bone scintigraphy is limited to the assessment of extension of the FOL. It is a useful examination for precisely identifying the extrafacial localizations in fibrous dysplasia and Paget's disease.

The role of PET CT has yet to be evaluated.

F

Diagnosis

FOLs of the face are difficult to diagnose. The radiological resemblance of these tumors requires a good knowledge of the clinical context. The pathologist should also correlate his results with clinicoradiological data for a reliable diagnosis.

In practice, diagnosis is mainly based on imaging; biopsy is very rare for facial lesions.

Fibrosarcoma

One of the malignant tumors having commonly low signal intensity of T2-weighting. May rarely be well circumscribed and mimic a benign tumor with decreased signal intensity on T2-weighting.

▶Neoplasms, Soft Tissues, Malignant
▶Hepatic Sarcoma
▶Neoplasms, Bone, Malignant

Fibrosarcoma, Hepatic

Rare primary malignancy of mesenchymal origin arising from fibroblasts. In some tumors, the development of cellular differentiation allows the presence of collagen. On gross examination, these lesions are grayish white and characterized by a local invasion or a hematogenous metastatic spreading. Clinical and imaging features are common to those of others hepatic sarcomas (leiomyosarcoma).

▶Hepatic Sarcoma

Fibrothecoma

Fibrothecomas are solid ovarian stromal tumors, which may contain dense calcifications or cystic degenerations. They typically occur in postmenopausal women. Due to hormonal effects, women may present with abnormal uterine bleeding.

ruediger.schulz-wendtland@idr.imed.uni-erlangen.de

According to the "Guidelines for Pathology—Addendum to the European Guidelines for Quality Assurance in Mammography Screening" and according to the recommendations of various pathology societies in Europe, fine-needle aspiration of breast tissue no longer constitutes a significant tool in the diagnostic work-up of breast lesions, because differential diagnosis, for example, lobular *in-situ* carcinoma (LCIS), low- or high-grade ductal *in-situ* carcinoma (DCIS) versus atypical ductal hyperplasia (ADH), is not possible on the basis of aspiration cytology. It has therefore been replaced by interventional methods, providing tissue for histologic assessment. However, two indications for fine-needle aspiration remain.

Indications

Painful cyst

In severely worried patients fearing malignant disease in spite of an unequivocal finding of a cyst (clinical findings, mammography, and ultrasound combined).

Technique

First, the most suitable access should be chosen, taking into account oncological/surgical considerations. Under sonographic guidance, the needle is advanced toward the cyst and pushed forward, until the tip of the needle is visualized within the cyst fluid. The containing liquid is aspirated to achieve complete drainage of the cyst.

Insufflation of the cyst with air and subsequent mammographic pneumocystography are now performed in particular cases only—a negative air contrast test might facilitate the identification of possible microcalcifications (Fig. 1a, b).

Definitions

Pulmonary arteriovenous malformations (PAVMs) are uncommon, abnormal, direct capillary-free communications between pulmonary arteries and pulmonary veins, which are most commonly congenital in nature (1). PAVM results in a ►right-to-left shunt with single or multiple enlarged feeding arteries and draining veins separated by a thin-walled bulbous-like or serpiginous vascular structure. The loss of normal filtering capillary bed leads to ►paradoxical systemic embolisms and to impairment of systemic blood oxygenation (2).

Pathology/Histopathology

Etiology

PAVMs are not a common clinical problem (1 PAVM in 5000 autopsies). Approximately 60–90% of the cases of PAVM are associated with hemorrhagic telangiectasia (HHT or Rendu–Osler–Weber syndrome). Conversely, approximately 15–35% of patients with HHT have PAVMs. With the onset of asymptomatic screening programmes in the USA and most European countries, a higher frequency of involvement has been estimated: at least 30% of HHT patients have PAVMs, 30% have hepatic involvement and 10% cerebral involvement.

Abnormal arteriovenous pulmonary communications have been described in a variety of acquired conditions: chronic hepatic disease, thoracic trauma, schistosomiasis, actinomycosis, Fanconi's syndrome, metastatic thyroid carcinoma, mitral stenosis, or congenital cyanotic heart disease after surgery (cavopulmonary anastomoses). We will discuss HHT predominantly as it relates to PAVMs.

HHT is a genetic disorder which is transmitted in an autosomal dominant pattern, and characterized by arteriovenous malformations (AVMs). This disease affects between 1 in 5000 and 1 in 8000 people in Europe and Japan, respectively. There are two classical types of HHT, type 1 and 2, caused by mutations in the endoglin (chromosome 9) and ALK-1 (chromosome 12) genes, respectively. HHT patients without detectable mutations in endoglin or ALK-1 have been recognised by the HHT genetic centres. Some of them are now known to have HHT–juvenile polyposis overlap syndrome caused by Smad4 mutations. More recently, a novel locus for HHT has been identified on chromosome 5.

Classification of PAVMs

A simple PAVM consists in single or multiple feeding arteries originating from a single segmental artery. Conversely, in complex PAVMs, feeding arteries always originate from two or more segmental arteries (3). Multiple lesions are highly suggestive of an association with HHT. Simple PAVMs usually account for 80–90% of PAVMs but simple and complex PAVMs are frequently seen in the same patient. The majority of PAVMs are located in the lower lobes. In some patients with simple and/or complex PAVMs, a diffuse pattern of PAVMs can be present. Diffuse PAVMs are defined as AVMs involving every subsegmental artery of at least one lobe. They occur in 5% of HHT patients. Bronchial artery hypertrophy or ►systemic supply to PAVM has been described in roughly 5% of PAVM.

Clinical Presentation

To permit a high degree of clinical suspicion of HHT, international consensus clinical criteria have been recently defined (The Curaçao Criteria): spontaneous recurrent epistaxis, mucocutaneous telangiectasia, visceral involvement and an affected first degree relative (4). The HHT diagnosis is definite if three of these criteria are present. It is possible or suspected if two criteria are present, and unlikely if fewer than two criteria are present (4).

Up to 55% of PAVMs are asymptomatic. Most of clinical manifestations can be attributed to right-to-left shunting. Dyspnoea is seen in almost all patients who have associated cyanosis, clubbing, easy fatigability or polycythemia. A concomitant involvement of the liver can induce a high-output cardiac failure. Haemoptysis and haemothorax occur in roughly 10% of patients. Mechanisms of haemoptysis are multiple: rupture of a PAVM into a bronchus, tracheobronchial telangiectases, pulmonary hypertension or bronchial artery supply to PAVM. PAVMs tend to increase in size. A progression of PAVM occurs frequently during the second and third trimesters of pregnancy. Pregnancy predisposes women to worsening of right-to-left shunt and to rupture of PAVMs leading to intrapleural and intrapulmonic haemorrhages.

Since patients with clinically silent PAVMs are still at risk of complications, screening of asymptomatic patients should be performed. Neurological complications in patients with untreated PAVMs are common and the incidence of stroke has been reported to be as high as 40% and that of brain abscess 20% with a mortality of up to 40%. The rate of neurological complications rises to 70% in diffuse PAVMs. These data illustrate the need for aggressive screening and treatment for PAVMs in patients with HHT.

Imaging

Screening imaging methods vary between centers but are based on non-invasive methods to detect the right-to-left shunt or to image the PAVMs.

Chest radiography: Diagnosis of PAVMs may be suspected on chest radiographs. The most common finding is a peripheral circumscribed, noncalcified oval or round lesion connected by blood vessels to the hilum (Fig. 1). However, chest radiography can be normal in 30% of patients with small PAVMs or with PAVMs superimposed on cardiac or diaphragmatic opacities.

►*Contrast echocardiography* (CE) is an excellent tool for detection of small right-to-left shunts. Diagnosis of PAVMs can be made with a high sensitivity (95%). But CE is not correlated with the size, location or number of PAVMs. Overdetection of clinically unimportant PAVMs not requiring embolization may limit the use of CE as the exclusive screening test for PAVM.

Pulmonary angiography: In some centers, a complete diagnostic pulmonary angiography is performed prior to embolotherapy. Selective injections in right and left pulmonary arteries in different projections permit to determine the best projection for occluding the PAVMs and measure the feeding pedicles which help to select the occlusion technique (3).

Computed tomography (CT): When CE is positive indicating a PAVM, thin section spiral chest CT should be performed to confirm the diagnosis and evaluate if treatment is necessary (5). The characteristic appearance of a PAVM on CT scans is the presence of a homogeneous, well-circumscribed, noncalcified nodule measuring up to several centimetres in diameter or the presence of a serpiginous mass connected with blood vessels. Spiral CT and multiplanar reconstructions allow easy identification of the feeding artery, aneurysm sac

Fistula, Arteriovenous, Pulmonary. Thirty-year old asymptomatic woman with hereditary hemorrhagic telangiectasia. Figure 1 Chest radiography demonstrates a round opacity along the left heart border. Connections with pulmonary vessels are not easily identified.

and efferent veins usually without contrast injection (Fig. 2). Multiplanar and three-dimensional reconstructions, potentially useful to obtain precise angioarchitecture of PAVMs before embolization, may replace diagnostic pulmonary angiography (5).

Magnetic resonance imaging (MRI) of PAVMs has been evaluated less than CT. Several techniques have been recently developed to improve sensitivity to flow. The use of gradient-refocused echo MRI technique or MR angiography with venous or arterial signal elimination or contrast injection has been reported with a high sensitivity. The obvious advantage of MRI over CT is the absence of radiation exposure but its main limitations include low sensitivity for detection of small PAVM, expense and limited availability.

Though non-invasive methods have rarely been compared, it seems that CE is the best initial screening tool in patients with suspected PAVMs due to its excellent sensitivity and availability. If the result is negative, the likelihood of significant PAVMs is low. The value of spiral CT in a screening algorithm is still considered low. Conversely, all patients with positive EC should be evaluated using spiral CT in order to identify PAVMs amenable to embolization. In addition, initial CT will be used as a baseline study that can be compared with postembolization examinations (5).

Fistula, Arteriovenous, Pulmonary. Figure 2 **Unenhanced spiral CT of the chest with sagittal reconstruction demonstrates the lingular feeding artery and the aneurysm sac. The draining vein of the PAVM lies anteriorly.**

Pulmonary Function Tests and Nuclear Medicine

Eighty to 100% of patients with PAVMs had either a PaO_2 <80mm Hg or a SaO_2 <97–98% on room air. Orthodeoxia is the laboratory correlate of platypnea. A decrease in PaO_2 or SaO_2 when going from the recumbent to the upright position is common in patients with PAVMs (most of PAVMs are located in the lower lobes). Oxygen saturation with the patient in upright posture is a better predictor of the presence or absence of PAVMs than the detection of hypoxemia but its sensitivity and specificity are too low (2).

The measurement of right-to-left shunt is performed using the 100% inspired oxygen breathing method, or less frequently using radionuclide scanning. A right-to-left shunt of more than 5% is considered abnormal.

Interventional Radiological Treatment

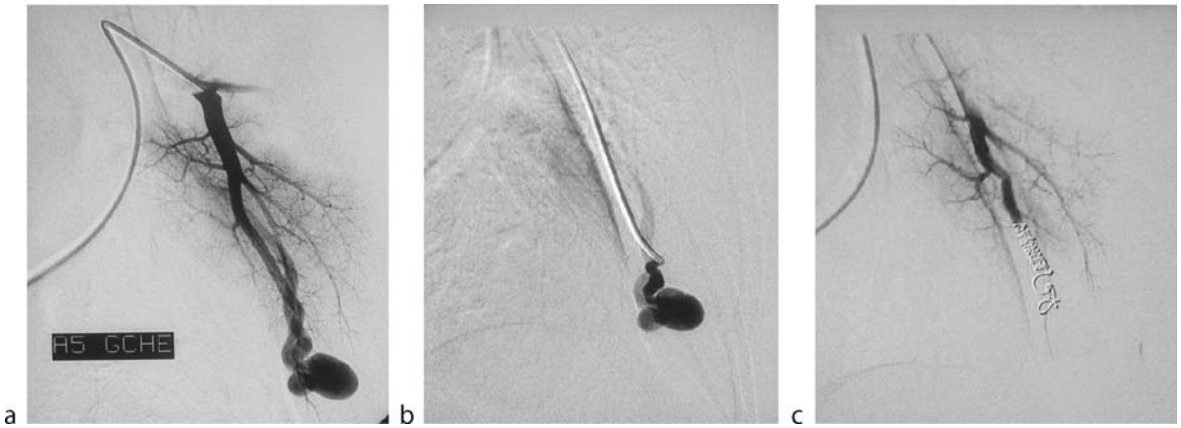
Medical treatments: These include prophylactic antibiotics to prevent septic embolisms at the time of dental and surgical procedures, medications for high-output heart failure and treatment of hemoptysis.

Surgical techniques: These include vascular ligations or parenchymal resection performed by thoracotomy or thoracoscopy. Properly performed in well-selected patients, surgery carries at least the same risks as any other thoracic surgery. Nowadays, indications for surgery are limited to high-flow PAVM with a short and large feeding artery.

Transcatheter embolization: The current preferred treatment for PAVMs consists of transcatheter embolization using coils or other intravascular devices. Permanent occlusion of PAVMs can be achieved in a vast majority of patients with minimal complications in experienced hands (1). Indications for treatment of PAVMs include prevention of thoracic hemorrhage, improvement of exercise intolerance and, most importantly, prevention of paradoxical embolism. It is usually considered that PAVMs with feeding arteries 3 mm or greater in diameter should be treated to prevent complications (1). In patients with diffuse PAVMs, multiple sessions are usually necessary to treat all the visible PAVMs.

Technique

Embolization is performed after an initial angiographic control (Fig. 3). Catheterization of the feeding pulmonary artery is performed and the catheter tip is positioned immediately proximal to the dilated venous portion. An arterial occlusion is then obtained using pushable coils or



Fistula, Arteriovenous, Pulmonary. Figure 3 **Angiography and transcatheter embolization in the same patient. (a) Selective angiography of the medial lingular artery reveals the PAVM with the feeding artery, the aneurysm sac and the draining vein. (b) The catheter is positioned in the feeding artery close to the aneurysmal sac of the PAVM before performing selective embolization. (c) After embolization using four coils, the control angiography demonstrates a complete occlusion of the PAVM.**

balloons. Nowadays, most groups favour the use of coils as the primary embolization agent (3).

Results

Long-term follow-up is indicated in all patients with PAVMs even after a successful therapy because of the risks of serial growth of small lesions and reperfusion of embolized PAVMs (1). The long-term clinical outcomes of embolization are successful in 96% of patients. During the follow-up, neurologic complications related to reperfused treated PAVMs have been reported. But the long-term morbidity of reperfused PAVMs is unknown. Repeat treatment is therefore indicated because of recanalization of previously embolized PAVMs or enlargement of untreated PAVMs. In one large study, follow-up with CT scan one or more years after embolization showed that 96% of treated PAVMs were either undetectable or reduced in size (5). CE and MR perfusion imaging are probably too sensitive and remain positive in the majority of patients even after successful occlusion of all angiographically visible PAVMs.

Complications

Complications following embolization of PAVMs are minor and self-limited, most of these only require symptomatic treatment (1). Pleuritic chest pain occurring in the first 24 h after embolization is the most frequent complication (13%). Pleural effusion has been reported in up to 12% of patients. Pulmonary infarction has been observed in 3% of patients. Air embolism during embolization occurs in up to 4% of patients who developed transient symptoms such as angina, bradycardia or perioral paresthesia.

Major complications such as paradoxical embolization of a device and stroke are extremely rare (1%). These migrations may require additional intervention using an intravascular retrieval device.

Pluridisciplinary Management

Embolization of PAVMs requires a specific expertise and should be performed by specially trained interventional radiologists only. Pluridisciplinary management of PAVMs in HHT is mandatory in order to apply the appropriate treatment and to fully educate the patients and their family about the diagnosis, its clinical implications and its hereditary nature.

Fistula, Hemodialysis

Geert Maleux
Department of Radiology, University Hospitals Leuven, Leuven, Belgium
geert.maleux@uz.kuleuven.ac.be

Definitions

A hemodialysis fistula is defined as a surgically created, direct communication in between an artery and a corresponding superficial vein allowing increased blood flow through the vein in order to provide luminal dilatation and thickening of the vein wall; it is also defined as "arterialisation of the vein". These postoperative changes will induce a flow rate between 200 ml/min and 450 ml/min over the fistula and the corresponding efferent vein, and subsequently will allow easy cannulation of the vein with large-bore needles to perform hemodialysis.

In accordance with the NKF-DOQI (National Kidney Foundation Dialysis Outcome Quality Initiative) guidelines, an autogenous arteriovenous fistula should be the first choice for vascular access because of good clinical performances with regard to patency and infection complications. Within the different types of autogenous arteriovenous fistulas, the radiocephalic fistula at the wrist, as firstly described by Brescia and Cimino in 1966, is the first choice, followed by a radiocephalic or brachiocephalic fistula at or near the elbow. The brachiocephalic fistula has some drawbacks as it might present a higher incidence of distal hand ischemia (steal syndrome), and finally because of potential risk of high output congestive heart failure. A brachiobasilic fistula is less popular as the deep location of the basilic vein makes cannulation more difficult, and therefore the basilic vein is often surgically relocated to a more superficial plane about one month after the fistula creation.

When placement of an autogenous fistula is not possible, a synthetic graft can be placed in between a suitable afferent artery and an efferent vein. Most commonly, polytetrafluoroethylene (PTFE) is used as graft material because of its good tolerance for repeated cannulation and better patency compared to other synthetic graft material. Although grafts can be placed in the forearm, they usually are inserted in the upper arm. In our practice a straight or, less frequently, a loop graft, is placed between the brachial artery and the axillary vein. Finally, when all upper extremity vessels have been exhausted, interposition grafts in the lower limb can be created, but owing to poor patient acceptance, increased incidence of infection (these grafts are mostly placed in the groin) and potential risk of lower extremity deep venous thrombosis, these graft locations are rarely chosen.

Pathology/Histopathology

Dysfunction of a previously well-functioning dialysis fistula is mostly due to the development of a stenosis or even occlusion at the surgically created fistula or, most commonly, at the efferent vein; a stenosis of the afferent artery is rare. Early, postoperative stenoses are mostly due to an error in surgical technique or judgment. Lately developed stenoses can be the result of a progressive anastomotic stenosis, secondary to intimal hyperplasia; other causes of late stenoses are focal fibrosis of the venous wall secondary to chronically high pressure in the venous circulation or to repeated traumatic needle punctures during hemodialysis. Finally, a central ►venous stenosis is nearly always the result of a previously placed indwelling dialysis catheter or central line. Rather rarely, an atherosclerotic stenosis of the afferent artery can be reason of problems during dialysis.

Other potential pathologies related to a dialysis fistula are infection, aneurysmal dilatation of the vein as a result of high pressure in a vein weakened by repeated cannulation, hand ischemia due to a steal phenomenon and hand edema or arm swelling caused by a venous outflow stenosis or occlusion. In case of hand edema, the venous occlusion is mostly located near the surgically created radiocephalic anastomosis; in case of arm swelling the occlusion will be found at the level of the central veins (axillary, subclavian or innominate vein).

Clinical Presentation

Dysfunction of a dialysis fistula, mostly owing to an underlying venous stenosis, can be diagnosed based on problems during or after a dialysis session: problems of cannulating the vein, high recirculation, increased venous pressure and longer bleeding time after withdrawal of the cannulation needles are classical, but late clinical signs in the course of access failure. Therefore, meticulous physical examination of the vascular access before, and flow measurements during each dialysis session are more sensitive to detect early access failure. A normally functioning arteriovenous fistula has a soft and easily compressible pulse with a low-pitched bruit, continuous with both systolic and diastolic components. In the presence of a venous stenosis, the bruit becomes more forcibly pulsatile and firm proximal to the stenosis, and potentially absent distal to the stenotic segment. Additionally, in case of a central venous stenosis, gross swelling of the entire arm is frequently seen.

Imaging

Digital Subtraction Angiography (DSA): DSA is still the gold standard for evaluating a dysfunctioning fistula. It is not more invasive than cannulation during a dialysis session and, if needed, can be followed immediately by a percutaneous intervention. However, DSA exposes the patient to ionizing radiation and administration of iodinated contrast medium. Although the patient is already in dialysis, the latter still can provoke further deterioration of the residual renal function and finally can induce an allergic reaction to iodine. Technically, a retrograde puncture of the brachial artery is preferred in case of a suspected stenosis of the surgical anastomosis; an antegrade puncture of the efferent vein is made in case of suspected distal outflow stenosis. In the latter case, the fistula itself still can be opacified when contrast is injected after placement of a tourniquet distal to the needle.

Duplex Ultrasound: Duplex ultrasound is a readily available, cheap and completely non-invasive imaging tool (1), but quality of examination largely depends on the operator's skills. Additionally, no clear evaluation can be made of the central veins, neither a complete angiographic mapping of the fistula can be obtained. Therefore, duplex ultrasound only can be used as a first step in the diagnostic work-up of a dysfunctioning dialysis fistula (Fig. 1).

MR Angiography: MR angiography is a relatively new imaging tool in the diagnosis of malfunctioning dialysis fistula, and currently three-dimensional, contrast-enhanced magnetic resonance (3D-Gd-MR) seems to provide most reliable information about the degree and location of stenoses compared to DSA (2). Additionally, MR angiography can provide an angiographic map of the entire fistula and efferent vein up to the superior vena cava, is non-invasive and lacks ionizing radiation and administration of nephrotoxic contrast media. The major drawback today is the fact that MR-guided percutaneous intervention is not yet clinically available.

CT angiography: CT angiography and in particular multi-detector CT (MDCT) is another new diagnostic tool to evaluate a malfunctioning dialysis fistula. Despite the use of ionizing radiation and the mandatory administration of iodinated contrast medium, MDCT has some unique advantages: it is a very fast and highly reliable examination providing a complete vascular map of the fistula (Fig. 2), correct evaluation of the degree of stenosis or of the extent of an aneurysm and MDCT will also depict potential signs of infection of a ►dialysis graft (3). Finally, in contrast to MR angiography, metallic clips, often located at the arteriovenous anastomosis, will not result in artefacts on CT angiography.

Diagnosis and Interventional Radiological Treatment

Stenosis of a malfunctioning dialysis fistula can occur at any point from the feeding artery to the superior vena

Fistula, Hemodialysis. Figure 2 3D-CT-reconstructions of the same brachiocephalic fistula demonstrating the same significant stenosis (arrows).

cava, but the arteriovenous anastomosis and the chronically cannulated venous segments are the most predominant areas of stenosis. The degree of stenosis has to be graded visually, or after comparison with the diameter of the vein proximally and distally to the stenosis. At least, in some rare, doubtful cases, pressure measurements using a pull-back technique can give a more definitive answer about the severity of the stenosis. Indications for treatment (according to the DOQI-guidelines) are: stenosis concomitant with clinical impairment or stenosis threatening access patency. Percutaneous dilatation technique is initiated by placement of a 6 French sheath antegradely or retrogradely in the efferent vein, depending on the location of the stenosis. After administration of 2500 U heparin, the stenosis is crossed by a (hydrophilic) guidewire and the dilatation balloon is placed over the stenosis. As venous stenoses are often very tight, high-pressure balloons with a burst ratio >25 atm are very helpful (4). Cutting balloons can be a valuable alternative to high-pressure balloons in patients presenting with very resistant stenoses. It is also advisable to choose a dilatation balloon with a nominal diameter 1 mm larger than the nominal diameter of the stenosed vein. Finally, a control angiography will show the post-dilatation result (Fig. 3). No stenosis or a residual stenosis of less than 30% is acceptable; if a residual stenosis of more than 30% is present, repeat and prolonged dilatation is mandatory. Persistent stenosis recoil after repeated dilatation is an indication for additional stent placement, especially in cases of central vein stenosis. Self-expandable stents are the preferred type of stent in a dialysis fistula and the nominal diameter should be 1 or 2 mm larger than the vein diameter. Recently, it is found that e-PTFE-covered stents have the potential to prolong the patency of dialysis grafts in case of venous outflow stenosis.

Long-term results of balloon dilatation to save a malfunctioning fistula show a primary patency of 51 and 35% for forearm and upper arm fistulas, respectively. After additional stent placement, the primary patency rates drop to 36 and 20% in the forearm and upper arm, respectively. Global secondary patency rates after both dilatation and/or stent placement can reach 85 and 82% for forearm and upper arm fistulae, respectively (5).

In conclusion, both dialysis fistulae and grafts are prone to stenose or even to occlude owing to both the artificial creation of a direct communication between artery and vein leading to "arterialisation of the vein" and to the repeated cannulation of the vein for each dialysis session. Nevertheless, several, reliable radiological tests are available today to evaluate the fistula and its afferent and efferent vessels; and finally, the interventional radiologist plays a major role in the maintenance of patency of a dialysis fistula and subsequently in the efficacy to dialyse a patient, resulting in a better quality of live and potentially in a longer survival of the dialysed patient.

Flail Chest

Life threatening condition of multiple rib fractures with paradox movement of the chest wall during respiration and respiratory failure. X-ray signs are serial fractures of at least five neighboring ribs or segmented fractures of at least two ribs. Fractures of the sternum and bilateral rib fractures can be indicative for a flail chest (see Fig. 1, Chest Trauma).

▶Chest Trauma

FLHCC

▶Fibrolamellar Carcinoma

FLT

Abbreviation for 3´-deoxy-3´-[18F]fluorothymidine, a radiopharmaceutical used for positron emission tomography. FLT is a substrate of the cellular thymidine kinase 1 (TK-1), which phosphorylates FLT to FLT-5-phosphate, a precursor of newly formed DNA during cell replication. Preclinical and first clinical studies showed a correlation between cellular FLT accumulation and other tests representing cell proliferation, giving evidence for the possible use of FLT as a proliferation marker.

▶Proliferation of Neoplasms

Fluid Collection, Pancreatic, Acute

Acute fluid collection occur early in the course of acute pancreatitis and it is located in or near the pancreas. It lacks a wall of granulation or fibrous tissue, which characterizes the pancreatic pseudocyst.

Definition

Fluorescence imaging describes the field of imaging technologies designed to visualize the spatial distribution of substances that emit fluorescence. These techniques incorporate a light source of appropriate wavelength that is used to excite the fluorochromes and a detection system that can perform spectral and spatial separation to differentiate and spatially resolve fluorescence emitted from the fluorescence substances. In its broader sense fluorescence imaging for biomedical applications includes fluorescence microscopy techniques, macroscopic fluorescence imaging of biological specimens and assays, for example in fluorescent gels or plates, and other tissue imaging.

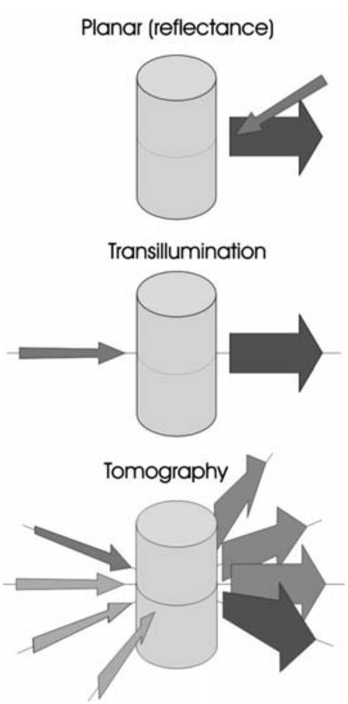
For medical imaging the term attains a narrower definition, that is: a modality that is used to *macroscopically* visualize intrinsic (endogenous) tissue fluorochromes (i.e., collagen, elastin, NADH), endogenously generated fluorescent reporters, that is fluorescent proteins or extrinsically administered fluorescent probes. The technique can be used for *in-vivo* or postmortem imaging on excised organs and it is generally applied for imaging of a field of view of millimeters to several centimeters and similarly, at depths of several millimeters to centimeters. This is in contrast to *in-vivo* fluorescence microscopy that is used for *microscopic* visualization of fluorochromes in tissues at small fields of view (millimeters) and depths of ~200–500 μm.

Fluorescence imaging encompasses several different implementations including photographic methods, advanced planar illumination methods, or tomography methods (1).

Imaging

Fluorescence imaging can be achieved with different implementation strategies, which correspondingly yield different performance characteristics.

The most common approach has been to use photographic methods, that is use a light source to illuminate tissue at a wavelength appropriate for fluorochrome excitation and use a highly sensitive digital camera, for example a charged coupled device (CCD) camera to detect fluorescence emitted back from tissues. A distinguishing feature therefore of this approach is that the light source and the detector reside on the same side of the tissue (see Fig. 1 top). The light source is typically a white light source that is appropriately filtered to select the appropriate wavelength or a laser source. Typically, the fluorescence image acquired is accompanied by a second image which is measured without the fluorescence filter to obtain a photograph of the tissue for image registration purposes (see Fig. 2). This intrinsic light image can also serve as a calibration measurement since it records the exact spatial distribution of the excitation light strength for later correction of excitation field inhomogeneities. This method is very simple and cost-efficient to implement and can be used for a multitude of applications, including intraoperative imaging, skin imaging, and small animal or specimen imaging to enhance the visual inspection and improve the specificity and the identification of disease borders. With appropriate adaptation this same principle of operation can be used with an endoscope, colposcope, in laparoscopy and other conventional optical imaging methods. The technology is well suited for imaging surface activity but its performance and quantification accuracy deteriorates for fluorescent activity coming from deeper in tissues. This is because the technique does not account for light propagation changes and attenuation as a function of depth and of tissue optical properties. The technique is also referred to as *fluorescence reflectance imaging* (FRI) or more accurately as *fluorescence epi-illumination imaging*.

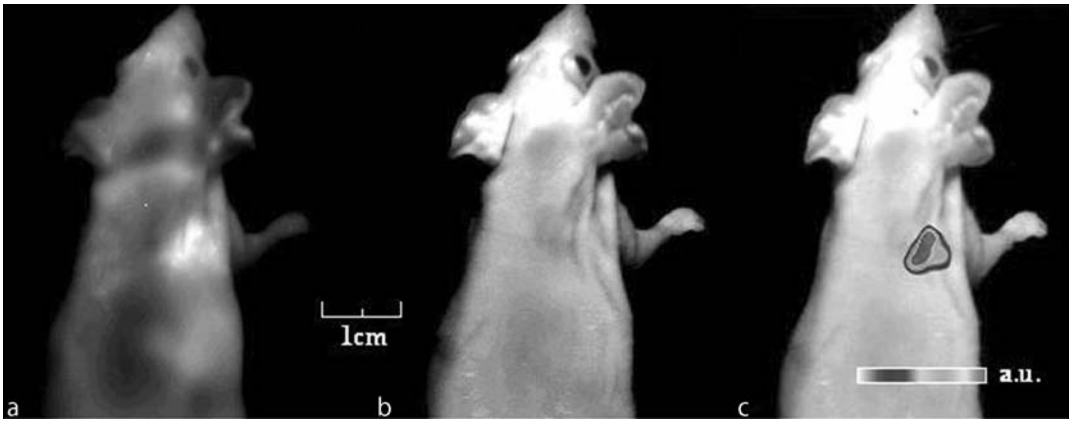


Fluorescence Imaging. Figure 1 Modes of fluorescence imaging.

An alternative fluorescence imaging method uses *transillumination* measurements (Fig. 1 middle). In this case tissue intersects the light beam and signals first propagate in the entire tissue before exciting on the other side and detected by the photon detector (typically also a camera). This approach is particularly interesting when light of near-infrared wavelengths is used. In this spectral region tissue yields low light attenuation and large penetration depths can be achieved (more than 4 cm in muscle and more than 10 cm in lung or breast tissues). Similarly to epi-illumination (reflectance) imaging, the signal recorded depends nonlinearly on activity depth and on optical properties and the method is therefore not well suited for quantitative measurements. Furthermore the resolution drops significantly as tissue thickness increases. The method in fluorescence imaging has found some application in dental or cardiac muscle imaging (invasively) and in small animal imaging.

Epi-illumination and transillumination fluorescence imaging, also referred to as “planar” imaging, offer an easily implemented and sensitive platform for *in-vivo* imaging. Conversely, the application is limited to qualitative observations due to the inability to resolve depth or account for the nonlinear dependence of light on depth and on optical properties.

A third imaging method that has been more recently developed is Fluorescence molecular tomography (FMT) (1). This technology can resolve and quantify fluorochromes deep in tissues through the use of tomographic principles. FMT is based on the general framework of reconstruction techniques that use diffuse light, developed since the early 1990’s (2, 3). These approaches employ mathematical models that describe the light propagation in tissue and technological advancements in photon sources and detection techniques for yielding three-dimensional tomography of entire tissues based on diffuse light. Similarly to transillumination most attention has



Fluorescence Imaging. Figure 2 **Example of fluorescence epi-illumination imaging of an HT1080 tumor implanted at the posterior upper thorax of a nude mouse. (a) A fluorescent image is obtained by a CCD camera by using appropriate band pass filters centred at the emission wavelength. (b) Image obtained at the excitation wavelength (intrinsic image) reveals the tissue surface with higher detail. (c) Superposition of the fluorescence image (after threshold) onto the intrinsic image. Fluorescence here is due to the intravenous injection of a fluorescent probes that is sensitive to major cathepsins and present in higher levels in the malignant tumor. (Image modified from Mol Imag 1(2):82–88 (2002).**

been focused on using light in the near-infrared due to the greater penetration depths that can be achieved.

FMT, similarly to other tomographic approaches that use diffuse photons, uses measurements at different projections around the boundary of the illuminated body as shown in Fig. 1 (bottom). It typically obtains measurements at both the excitation and emission wavelengths. It then effectively combines all measurements into an inversion scheme that in its general form takes into account the highly scattering nature of photon propagation and tissue optical heterogeneity and reconstructs fluorochrome distribution with significantly higher resolution and accuracy than the one achieved by planar methods. The resolution achieved in tomographic methods using diffuse photons strongly depends on the depth and overall tissue dimensions and on the tissue optical properties. It further depends on the characteristics of the illumination light employed. Therefore it is complex to define one resolution measure independently of the application. Generally, it has been observed in phantom measurements that submillimeter resolutions can be achieved for the small animal case and resolution worsens to several millimeters for larger tissues.

Originally, several tomographic approaches for *in-vivo* applications used fiber based technology and in some instances matching fluids to simplify experimental and theoretical approaches. More recently however attention has been shifted into developing high performance systems that offer noncontact illumination and using CCD camera measurements, in the absence of fibers and matching fluids, which allow for high spatial sampling of photon fields and experimental simplicity.

Multi-spectral Imaging

Fluorescence imaging can capitalize on the spectral differentiation of different fluorochromes to perform concurrent imaging of multiple targets. Multispectral imaging can be easily achieved using appropriate filters or monochromators although appropriate postprocessing spectral differentiation techniques may be required to reduce cross-talk between fluorochromes that have overlapping spectra. In some applications, multispectral imaging can be similarly used to differentiate specific extrinsically administered fluorescent probes or fluorescent proteins expressed by transgenic cells from background nonspecific tissue fluorescence, typically due to autofluorescence of elastins, collagen, NADH, and other intrinsic tissue fluorochromes. This latter application is more important for imaging application in the visible, since weak autofluorescence is generally observed in the near-infrared.

Optical Domains

There are three distinct domains that optical tomography of tissues operates in, that is the time-domain (TD), the frequency domain (FD), and the continuous wave (CW) domain. Each has distinct advantages and disadvantages and the selection of an appropriate technology largely depends on the specifics of the application. CW methods use light of constant intensity and require simple and low-cost instrumentation and generally yield good signal to noise performance compared to the other two methods.

Time-domain methods illuminate tissue with ultrafast photon pulses (femto-second to pico-second range) and resolve the arrival of photons as a function of time at different locations around the tissue boundary. Frequency domain technology uses light of modulated intensity at a frequency *f*, which establishes a photon wave of the same frequency in the diffuse medium. In contrast to CW methods, TD and FD methods can differentiate tissue absorption and scattering as well as fluorochrome lifetime. FD methods become more accurate when multiple modulation frequencies are used. They can be further used to improve resolution, for example using early-arriving photons.

In-vivo Applications

Fluorescence imaging can be used in combination with many developed or upcoming fluorescent probes to visualize a multitude of processes in tissues. Examples of imaging protease expression associated with various cancers and inflammation using activatable probes have been demonstrated with epi-illumination or tomographic methods. Imaging of cellular receptors using peptide-near-infrared dye conjugates has been also shown feasible in animal studies. Several other examples have been also demonstrated in applications ranging from imaging apoptosis using annexin-V-fluorochrome conjugates to imaging angiogenesis using fluorescent nanoparticles. Overall, with the increasing technical ability of fluorescence imaging and the growing list of available fluorescent probes and nanoparticles for *in-vivo* use the list of applications is expected to significantly grow.

Clinical Applicability

Much of the *in-vivo* demonstration of fluorescence imaging methods has been so far achieved using small animals. However feasibility to detect fluorochromes from human tissues has been demonstrated in the past for several applications, for example using epi-illumination (endoscopy) in skin, esophageal, cervical, lung, and other accessible epithelial cancers or using tomography through the entire human breast for breast cancer detection (4, 5). As adept new fluorescent probes propagate into the clinic, a significant number of these technologies can be adapted for human imaging, that is intraoperative imaging for tumor margin and metastasis identification, in several endoscopic applications or in the detection of breast cancer.

Diagnosis

Fluorescence molecular imaging is a novel imaging technology that has not been yet evolved as a standard diagnostic procedure. Nevertheless, significant progress has been achieved towards the validation of the technique in transgenic animal models that resemble human disease, for example in spontaneous or induced models of colon, lung, or breast cancer. At the clinical research level, autofluorescence colposcopy has also shown good performance in detecting cervical cancer (6). The following list summarizes areas where fluorescence imaging has strong potential to be used as a diagnostic method:

- Endoscopy
- Colposcopy
- Intraoperative imaging
- Laparoscopy
- Breast cancer
- Oral cancers
- Skin cancers
- Skin diseases (other)
- Arthritis
- Inflammation.

Foreign Bodies, Aspiration, Children (Chest View)

Gundula Staatz
Department of Radiology, Division of Pediatric Radiology, University of Erlangen-Nürnberg, Erlangen
gu.stz.uni-erlangen@t-online.de

Definitions

Aspiration of foreign bodies, such as peanuts, carrots or plastic toy pieces, occurs most often in children under the age of 4 years. The worst case is complete airway obstruction with total occlusion of the trachea above the carina. Partial obstruction occurs, when the trachea is partially occluded or when the foreign body obstructs bronchi distal the carina. The majority of foreign bodies lodge in the main bronchi with almost equal incidence on the right and left side.

Pathology/Histopathology

Food particles or organic materials may absorb water from bronchial secretions and tend to increase in size. Oil, salt and vegetable proteins irritate the mucosa, leading to oedema and formation of granulation tissue with subsequent narrowing of the bronchial lumen (1). Non-organic materials are usually inert to the bronchial mucosa, unless they remain in the tracheobronchial tree for a longer time and induce chronic inflammatory changes, such as ulcerations or epithelialisation (1).

Clinical Presentation

Children with foreign body aspiration usually present with the classical triad of choking, coughing and wheezing. Other symptoms are stridor, dyspnoea, haemoptysis or rarely pneumothorax. Crackles, decreased breath sounds in the affected lung and unequal chest expansion may be found on physical examination, but also normal findings are common. Besides acute symptoms of respiratory distress, recurrent pneumonia is observed as late sequelae, especially in patients who aspirated organic material (2).

Imaging

Chest radiography is usually the first imaging technique performed in children with suspected foreign body aspiration. Because most aspirated foreign bodies are radiolucent, the diagnosis is commonly based on indirect signs, such as ►obstructive emphysema, shifting of the mediastinum and unequal movement of the hemidiaphragms. Assessment by inspiratory and expiratory chest X-rays, lateral decubitus radiographs or with the use of fluoroscopy is often necessary additionally to plain chest radiographs. In some instances CT may provide additional information, because of its high sensitivity in demonstrating radiolucent foreign bodies. Low-dose MDCT and virtual bronchoscopy has shown good results in identifying the exact location of a foreign body before bronchoscopy and in ruling out a foreign body in patients with a low level of suspicion and normal or non-specific findings on chest radiography (3). MRI has been used for the diagnosis of peanut inhalation, however the high cost and the need for sedation prevents routine use of MRI in children with foreign body aspiration.

Nuclear Medicine

There are only a few studies dealing with scintigraphy in foreign body aspiration in children. In a European multicentre study many children with foreign body aspiration showed scintigraphic abnormalities 6 months after removal of the foreign body with persistent matched defects of perfusion and ventilation although the chest radiographs were considered normal (4).

Diagnosis

In children with partial airway obstruction, the plain chest X-ray during inspiration often reveals unremarkable findings. Expiratory films are more sensitive by demonstrating air-trapping with over distension of the affected lung distal to the obstruction (obstructive emphysema), deviation of the mediastinum to the contralateral side, a low ipsilateral hemidiaphragm and wide intercostal spaces (Fig. 1). In non-cooperative children lateral decubitus films may replace the inspiratory–expiratory films, showing failure of the affected lung to collapse. A valve-mechanism in foreign body aspiration is easily

Foreign Bodies, Aspiration, Children (Chest View). Figure 1 Chest radiograph of a 3-year-old infant with aspiration of a peanut into the left main bronchus. Hyperinflation of the left lung with shifting of the mediastinum to the contralateral side is visible.

recognised under fluoroscopy. The mediastinum shifts to the ipsilateral obstructed side during inspiration and to the contralateral side during expiration. Furthermore paradoxical movement of the hemidiaphragms is often visible (Fig. 2). A complete airway obstruction leads to a collapse of the lung distal to the obstruction or to segmental atelectasis. Occasionally a localised pneumothorax may develop peripheral to the collapsed lobe.

The foreign body may be exactly localised on MDCT and virtual bronchoscopy; additional CT findings are hyperaeration of the ipsilateral lung, atelectasis, infiltration and bronchiectasis (3). Chronic bronchitis, bronchiolitis obliterans and bronchiectasis as late sequelae of foreign body aspiration are accurately visualised by CT.

MRI with use of T1-weighted images is helpful for definitive diagnosis and location of peanut fragments in the lower airways because the fatty peanut material appears with a high signal-intensity surrounded by the low signal-intensity lung tissue (5).

Istanbul University, Department of Radiology, Istanbul, Turkey
ugurk9@istanbul.edu.tr

Synonyms

Gi Foreign Bodies; Foreign Bodies; Esophageal Foreign Bodies; Swallowed Foreign Bodies; Oropharyngeal Foreign Bodies; Rectal Foreign Bodies

Definition

Foreign bodies (FB) of the gastrointestinal (GI) tract are defined as any external object, introduced voluntarily or accidentally into the digestive system. Foreign bodies may be ingested, inserted into a body cavity, or deposited into the body by a traumatic or iatrogenic injury. In general, foreign bodies in the air and food passages are the sixth most common cause of accidental death in the United States (1). The ingestion of a FB is a relatively common GI emergency that causes significant morbidity. Fortunately, the vast majority of all swallowed objects pass through the GI tract without a problem. Only 1% of involuntary and generally unconsciously ingested FB will perforate the bowel and constitute abdominal emergencies whose diagnosis represents a challenge (2). Those that cause perforation are usually sharp, pointed, or elongated. They are usually fish bones, toothpicks, and chicken bones.

Foreign body ingestions are common in children and mentally handicapped adults. Although exact figures are unavailable, foreign body ingestion is very common among children. In the pediatric population, toddlers aged 2–3 years are most commonly affected because children in this age group are ambulatory and more orally explorative. While children younger than 6 months are rarely able to get a foreign object into the oropharynx, infants can ingest foreign bodies with the assistance of a sibling. Any child can swallow a foreign body; most incidents result in minor annoyance, but a few can lead to major catastrophe.

Pathology/Histopathology

The oropharynx is well-innervated, and patients can typically localize oropharyngeal foreign bodies. Scratches or abrasions to the mucosal surface of the oropharynx can create a foreign body sensation. Chronic foreign bodies or perforations can cause infections in surrounding soft tissues of the throat and neck.

Patients can usually localize foreign bodies in the upper esophagus but localize them poorly in the lower two-thirds of the structure. The esophagus has three areas of narrowing: the upper esophageal sphincter (UES), which consists of the cricopharyngeus muscle; the crossover of the aorta; and the lower esophageal sphincter (LES). These areas are where most esophageal foreign bodies become entrapped. Structural abnormalities of the esophagus, including strictures, webs, diverticula, and malignancies, increase the risk of foreign body entrapment, as do motor disturbances such as scleroderma, diffuse esophageal spasm, or achalasia (3).

Most foreign objects will pass through the pylorus, although on occasion, some objects may remain in the stomach for a long period. Once beyond the pyloric canal most objects, even sharply edged foreign bodies such as pieces of glass or nails, will pass without harm until the terminal ileum which is again a predilection site for obstruction. Ingested objects may occasionally remain fixed in the cecum, ascending colon, or sigmoid. Foreign bodies detected in the rectum have in most instances been introduced transanally.

Clinical Presentation

Nearly one-third of pediatric patients with esophageal foreign bodies are asymptomatic. Symptoms depend on the size, shape, and nature of the FB ingested. Large FB may cause obstruction whereas small and sharp objects may present with symptoms of esophageal irritation. Symptoms related to esophageal foreign bodies are choking, gagging, coughing, wheezing, dysphagia, dyspnea, fever, hematochezia, or neck, chest, or abdominal pain. Children with chronic esophageal foreign bodies may also present with poor feeding, irritability, fever, or stridor. Most children who have ingested a disk battery remain asymptomatic. Children with a battery lodged in the esophagus typically present with the above mentioned symptoms. Rashes following disk battery ingestion have also been reported and may be a manifestation of nickel hypersensitivity.

It is clear that thin, sharp objects carry a higher risk of perforation; and a safe policy is to treat the patient expectantly unless there are indications for a more aggressive approach. Large foreign bodies are not generally encountered in the small bowel in that rarely pass beyond the pylorus or the duodenojejunal flexure. A perforation of the peritoneal cavity can cause peritonitis whereas a retroperitoneal perforation, at the duodenojejunal flexure for example, can lead to the involvement of the psoas and the formation of an abscess. Nonetheless, the perforation of jejunal or ileal loop is a rare event (<1% of cases) and is usually caused by extremely pointed objects, such as fish bones, chicken bones, and toothpicks (3). Patients with a rectal foreign body may present with abdominal or rectal pain, pruritus, or bleeding.

Imaging

The relative difficulty in identifying a foreign body varies according to the type of object ingested and its radioopacity. Metal objects with a relatively high atomic weight are readily visible with plain film radiography in that they are intensely radiopaque regardless of their volume (Fig. 1). Radiopaque materials are glass of all types; most metallic objects (except aluminum); most animal bones and some fish bones; some foods; some soil fragments, sand, gravel, and mineral fragments; some medications and poisons (CHIPES: chloral hydrate, heavy metals, iodides, phenothiazines, enteric coated pills, solvents). Nonradiopaque materials at times may not be identifiable as they are composed of material with a relatively low atomic weight and therefore have intrinsically low radiopacity. Nonradiopaque materials are most foods and medicines; most fish bones; most wood, splinters, thorns of all types; most plastics; most aluminum objects (3).

Radiographs

Plain radiographs are indicated for every patient with a known or suspected foreign body in the oropharynx, esophagus, stomach, small and large intestine. Radiopaque objects are easily seen and localized on the radiograph. In cases of nonradiopaque foreign bodies, imaging studies rarely have any influence on management, except in delaying endoscopy or computed tomography (CT) scanning. In small children, a mouth-to-anus radiograph can be obtained. In older children and adults, plain films of the neck, chest, and abdomen should be obtained. A posteroanterior (PA) and lateral chest radiographs provide better localization for foreign bodies within the lumen of the esophagus (Fig. 2). The progress in the bowel, if needed, can be checked periodically with radiographs (Fig. 3).

a

b

Foreign Bodies, Gastrointestinal. Figure 3 The progress of migrated esophageal metallic stent (arrows) in GI tract. (a) Second day radiograph; stent in small bowels. (b) Third

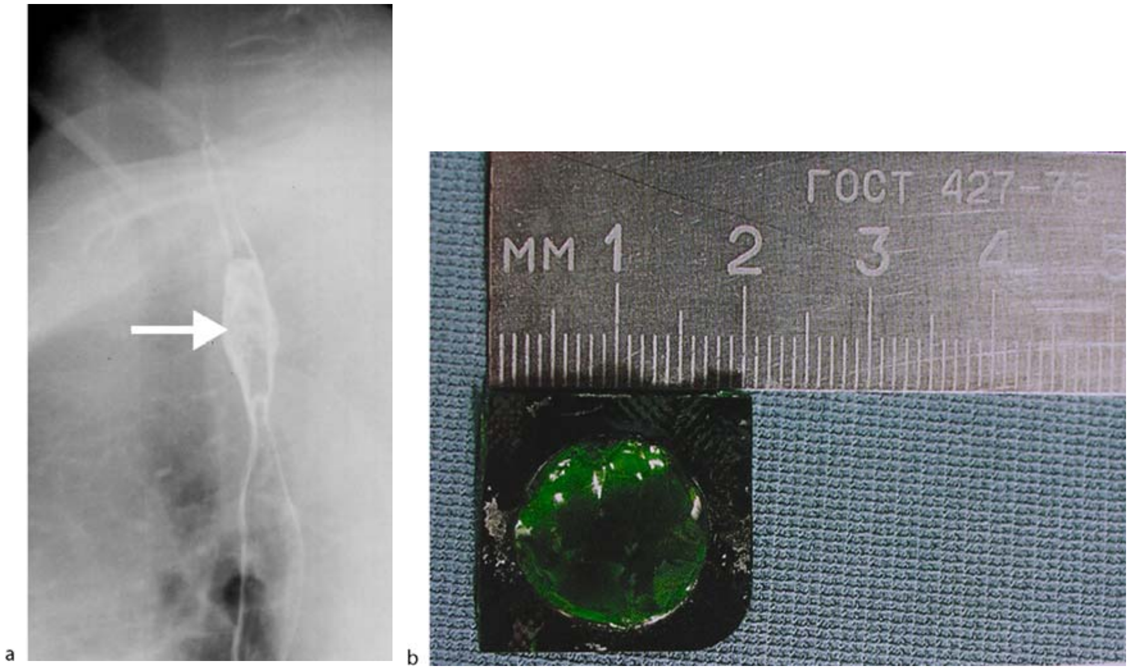
However, some foreign bodies such as small fish bones or pieces of plastic and wood are only faintly radiopaque and their detection may require CT. Indirect signs, visible on the plain radiograph are soft tissue swelling or air due to edema or hematoma.

Barium or Gastrografin Studies

Barium study may be indicated in cases of ingestion of nonopaque foreign bodies (Fig. 4), such as toothpicks or aluminum soda can tabs, although CT scanning is a much better imaging modality. A barium or gastrografin study, without cotton balls, can sometimes outline the foreign body, but, again, the yield is very low.

Barium swallow can be used for food impactions; however, most authorities believe that it adds nothing to the evaluation and delays definitive treatment. Contrast studies are not useful in detecting foreign bodies in the stomach or small intestine. Barium is contraindicated in cases in which esophageal perforation is suspected. Gastrografin may be used if a study is needed.

Esophagography should first be performed with hydrosoluble contrast medium to exclude perforation



Foreign Bodies, Gastrointestinal. Figure 4 **Swallowed pill with its plastic cover in upper thoracic esophagus. (a) Barium**

and can then be completed with a barium examination. The contrast medium may impregnate the surface of the foreign body and render it more conspicuous.

Computed Tomography Scanning

Recent technical developments have led CT to be used more frequently in emergency departments and have greatly enhanced CT's ability to accurately discriminate between those patients with a normal or abnormal abdomen, and to further characterize the etiology of the patient's abdominal pain. CT scanning is superior to plain radiographs for localization and identification of foreign bodies. It is now considered the imaging modality of choice to locate nonradiopaque foreign objects in the oropharynx, esophagus, stomach, small intestine, and large intestine. CT scanning is highly reliable in localizing foreign bodies in the esophagus. However, the application is probably unwarranted in every case of acute bone dysphagia, as only a minority of patients who sense foreign bodies after eating chicken or fish have a bone present.

Perforation of intestinal structures by ingested foreign bodies is a challenging diagnosis that should always be invocated in cases of acute abdominal symptoms. The definite diagnosis is based on the demonstration of the responsible foreign body that is optimally achieved by CT. It is also superior to other imaging modalities in demonstration of obstruction caused by a foreign body. Especially, the recent developments in CT (multidetector CT) technology made high-quality multiplanar reconstructions possible (Fig. 5). Conventional CT is able to detect the calcified content of ingested foreign body and the presence of very small quantities of extraluminal gas, but its performance is impaired by a limited spatial resolution, the discontinuity of the sections, and the very poor quality of multiplanar reconstructions (1).

Nuclear Medicine

Scintigraphy has a limited role in the assessment of GI tract foreign bodies.

Diagnosis

Diagnosis of GI tract FB is usually made on the basis radiological imaging. Endoscopic procedures may be required in cases with a history of FB ingestion and subtle radiological findings. Endoscopic procedures are also used for the purpose of treatment besides the diagnostic challenge. Early endoscopic removal from the stomach or

Foreign Bodies, Gastrointestinal. Figure 5 **Bezoar; multidetector CT findings. (a) Axial. (b) Coronal CT images demonstrated that heterogeneous and low-density**

duodenum is recommended to lessen the morbidity and cost to the health care system. In case of failure, rapid surgical removal of gastric FBs is wise.

Fractures, Bone, Childhood

Alan E. Oestreich
Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio, USA
Alan.Oestreich@cchmc.org

Synonym

Broken bones

Definition

A fracture is an acute break in the customary continuity of a bone or its growth cartilage or an acute disturbance of trabeculae, which will result in the formation of callus on follow-up imaging. ►Avulsion is the discontinuity of a bony or cartilaginous element by traction from muscle, tendon, or ligament. Epiphysiolysis is a Salter I fracture causing discontinuity solely through a physis, most notably through the proximal femoral physis (known as a slipped capital femoral epiphysis, or SCFE). In traumatic dislocations, a shift in relationship occurs between bones that usually articulate with each other so that the articulation is disturbed.

Epiphyseal fractures extend solely through secondary growth centers or their enchondrally-derived equivalents (such as tarsal, carpal, or sesamoid bones or apophyses). In traumatic ►plastic bowing (1), bones bend but do not break, but do not return to their preinjury shape.

Pathology/Histopathology

Bone is structure that offers support to the body; the characteristics that make it strong also leave it liable to fracture from various forces. Because children's bones are growing as well, their structure has further susceptibility to fracture. The callus of healing has a characteristic histologic pattern that changes through time and space. Typically at a break in a bone, the periosteal reaction begins to calcify at the greater distance from the fracture site and then proceeds inward toward the break under the lifted periosteum. Secondary growth centers, tarsal and carpal bones, and the sesamoids, including the patella, have no periosteum; their healing is by endosteal callus alone: without periosteum, one can have no periosteal reaction.

With SCFE, management is directed at stopping progression of the slip while hoping to avoid interruption of the blood supply (such interruption or impairment of blood supply would cause infarction/avascular necrosis). Chondrolysis of the growth cartilage of the head is sometimes a sequela of SCFE when one or more transphyseal orthopedic pins extend beyond the ossified head into its cartilage. Various epiphyses slip in scurvy in association with osteoporotic weakening of the bone adjacent to the physis.

Clinical Presentation

Pain, swelling, skin discoloration, and loss of function are primary signs of fracture. A child is a "good orthopedist" for about a day, immobilizing a fractured part, but then forgets, and thus casting is still necessary. Symptoms of acute dislocation at the elbow ("nursemaid's elbow") often vanish when positioned by a radiologic technologist for the 90° bent lateral view. Quite frequently after weeks of being in a cast, a child experiences stress fracture in a tarsal or nearby bone by enthusiastic reambulation when the bones are still demineralized from disuse osteoporosis. In acute plastic bowing of the forearm (1), the ability to pronate and supinate is lost; plastic bowing of the fibula occasionally prevents healing of an adjacent tibia fracture.

Repetitive trauma to the back of the ankle, such as from shoes resembling "pumps" of former days, may yield the pump bump (Haglund syndrome) of excessive prominence behind the posterior superior calcaneus, identifiable on plain radiographs as a soft-tissue prominence.

Imaging

Two orthogonal radiographic views at right angles should be obtained for evaluating fracture. At the hips, anteroposterior and frog-leg views are usually adequate instead and are especially pertinent in evaluation for SCFE.

Ultrasound can occasionally reveal occult fractures of cortex if clinical suspicion is high and radiographs unrevealing. Ultrasound may also show nasal bone fractures. Ultrasound is useful in newborns to evaluate for epiphysiolysis of the femur or humerus when those centers are still unossified (2).

Magnetic resonance imaging (MRI) can be helpful for revealing stress fractures of long bones when radiographs show only subtle callus or periosteal reaction, or when much of an elbow fracture traverses unossified cartilage. MRI of the elbow resolves whether a distal humerus fracture is Salter II or IV (3).

Computed tomography (CT) is potentially helpful for more fully describing certain fractures, particularly of the acetabulum about the hip and ►triplane fractures of the ankle.

When a proximal or midulna is fractured, it is important to show the elbow on two views to rule out associated radius dislocation (Monteggia fracture).

For acute shoulder injury, we recommend the "double-angled trauma oblique" (patient thorax 45° anterior oblique and X-ray beam angled 45° downward), which simultaneously shows glenoid or humeral fractures and possible dislocation. For sternal fracture or sternoclavicular dislocation, which may be difficult to show on plain images, ultrasound can reveal abnormality, but localized CT nicely defines the fractures or dislocations. Multislice CT can rapidly investigate for rib fractures. Tendon tears, including the Achilles, are evaluated well by ultrasound, looking for discontinuity, focal thinning, or hematoma.

In general, for pediatric musculoskeletal imaging, the radiation dose should be as low as reasonably achievable. If film, the images should be high speed. Digital imaging should be optimized for low doses as well. Follow-up bone radiographs need not be of as high resolution as initial diagnostic studies. For some indications, whole-body MRI may soon replace radiographic surveys.

Nuclear Medicine

Bone scanning is sensitive for acute, subacute, and chronic unhealed fractures and is especially helpful for occult fractures, such as in child abuse investigations, positive fat pad signs of fractures, possible pseudarthrosis fracture of orthopedic spinal fusions, sacrum fractures, and suspected stress fracture. Indeed, because in stress fractures no callus is visible on radiographs for 10 days after occurrence, bone scanning can speed the diagnosis as well as look for other sites of involvement. Increased activity compared with the usual physeal uptake may reveal subtle SCFE as well as unossified avulsion of a pelvis apophysis. "Painful normal variant" is a term used by Lawson for symptomatic ossification variants, such as bipartite patella or accessory navicular of the foot (4). High activity on bone may reveal true injury at those sites. Toddler fractures of tibia, fibula, or tarsal bones may be quite elusive on early radiographs but may be identified by localized activity on bone scanning.

Diagnosis

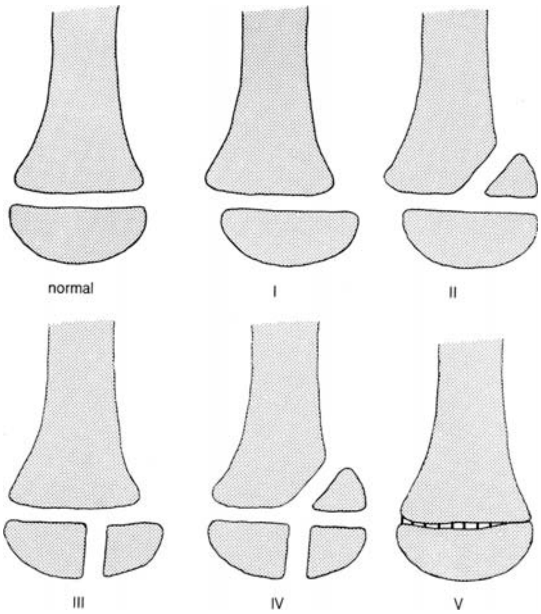
Fractures specific to childhood are the buckle (also called torus) fracture, traumatic plastic bowing (not a true fracture), toddler fracture, and metaphyseal corner fracture (of abuse, scurvy, and Menkes disease), as well as those fractures through the physis (Salter I–V, classically), including the stubbed toe (or, less commonly, finger) fracture, the Tillaux, the triplane, apophyseal avulsions, and SCFE.

The buckle, or torus, fracture (Fig. 1) appears as a bulge or bend on one or both sides of the normally monotonically curved cortex of a tubular bone (or occasionally a flat bone), most frequently near the wrist. In traumatic plastic bowing, one (or two) long bones bend from trauma but do not break, but also do not return to normal form, remaining bowed. The toddler fracture is a thin oblique or spiral fracture of the tibia or fibula (stress fractures of the toddler tarsal bones are also included in the term). The metaphyseal corner fracture is a Salter II fracture involving a corner of metaphysis plus the physis. Salter I epiphyseolysis goes exclusively through a physis, with a transverse shift of epiphysis relative to the metaphysis. Salter II goes through metaphysis plus epiphysis. Salter III goes through epiphysis plus physis, and Salter IV through epiphysis and metaphysis, crossing the physis. Salter V refers to the rare longitudinal crush of a physis (see Fig. 2). A stubbed toe or finger fracture is a Salter II of the dorsal distal phalanx beneath the nail bed (which has a good chance of being infected). Tillaux is a Salter III sagittal fracture of the distal tibia at a stage when the physis is partially fused. The triplane fracture of the ankle adds a coronal tibial metaphysis fracture to the Tillaux.

Avulsions are traction injuries of ossified, partially ossified, or only-cartilaginous apophyses. If they are only cartilaginous, ultrasound may indeed help diagnosis. When apophyses are at least in part ossified, their avulsion is seen by displacement from the customary position; on follow-up the size of ossification may increase considerably.

SCFE is recognized on plain images earlier on the frog-leg view by a (Klein's) line along the distal outer neck of the femur that does not intersect the capital epiphysis as it is continued upward. The physis also becomes less sharp than normal, and a "blush" of increased density in the neck may be seen, representing an attempt by the

Fractures, Bone, Childhood. Figure 1 **"Bunkbed" type buckle fracture of the metaphysis of the first metatarsal of a 4-year-old boy (such fractures often occur upon falling off an upper bunk). (a) The usual smooth curve of the lateral metaphysis and diametaphysis is disturbed by a buckle change in contour. (b) Three and 1/3 weeks later, endosteal and periosteal (*arrow*) callus is evident.**



Fractures, Bone, Childhood. Figure 2 **Schema of basic Salter (Harris) classification. (From Oestreich AE, Crawford AH (1985) Atlas of Pediatric Orthopedic Radiology. Thieme Verlag, Stuttgart, p 53)**

femur to strengthen itself against the deformity. The slipped *distal* femoral epiphysis of scurvy develops vigorous periosteal reaction. Idiopathic chondrolysis of the hip manifests by severe and rapid narrowing of the cartilage space between the femoral head and acetabular roof. However, in SCFE, that cartilage space may become narrow when the slip results in a portion of the head previously not designed to bear weight then becoming the uppermost part.

Stress fractures of bones without periosteum, such as the tarsals, manifest beginning 10 days after the event and only as endosteal callus, often in a linear or curved distribution. Tubular and other membranous-origin bone also show periosteal reaction after 10 days. For fracture of the calcaneus, check the Böhler angle of the two upper surfaces on the lateral image—it normally lies between 28 and 40°. After wrist trauma, be sure to check the lunate-capitate linear alignment on lateral images for possible perilunate dislocation (Fig. 3). Lateral bowing or displacement or obliteration of the fat stripe lateral to the scaphoid may well indicate fracture, especially when the anatomic snuff box is tender after trauma. Fractures of the body of the sacrum and of the sternum may require ultrasound, nuclear scintigraphy, CT, or MRI for identification.

Fractures, Bone, Childhood. Figure 3 Traumatic perilunate dislocation after a 16-year-old boy fell. Note especially that, abnormally, the proximal convex end of the capitate (*arrow*) does not fit into the distal concave end of the lunate (*arrowhead*). The scaphoid is also fractured across its waist.

Pelvic fractures: osseous disruption of the lower limb girdle comprised of the sacrum and the paired innominate bones.

Pathology/Histopathology

The bony pelvis is a complex osseous structure that provides weight-bearing support and protects the viscera within the pelvic cavity. Enormous stress is generally required to disrupt the osseous and ligamentous structures of the pelvis in patients with normal mineral density. Bone weakened by osteoporosis may be fractured by low-impact injuries such as falls.

Clinical Presentation

Stable Pelvic Fractures

Avulsion Fractures

Osseous disruptions at the sites of muscular insertions are termed avulsion fractures. These fractures occur most commonly at the ischial tuberosity, anterior superior iliac spine and anterior inferior iliac spine as a result of sudden, forceful contraction of the hamstrings, sartorius (Fig. 1) and rectus femorus respectively. Young athletes are most prone to these injuries and present with sudden, focal pain.

The avulsed fragments are variably displaced and usually associated with a focal hematoma and bone marrow edema. The integrity of the involved muscle belly

Fractures, Pelvis. Figure 1 AP radiograph of the pelvis demonstrates avulsion fracture of the left anterior superior iliac spine at attachment of sartorius.

and tendon may also be compromised. Sciatic nerve entrapment can occur in the setting of a healing hamstring avulsion fracture.

Sacral Fractures

Isolated acute sacral injuries most often occur after a direct impact from a fall. These fractures are generally oriented in the transverse plane and occur between the third or fourth sacral segment. The distal segment is usually displaced anteriorly. Injury to the lumbosacral plexus is an occasional complication.

Duvernay Fractures

Isolated fractures of the iliac wing are also known as Duvernay fractures. They most commonly occur as a result of direct trauma and seldom pose a diagnostic dilemma. Paralytic ileus and peritonism is not uncommon after this injury, usually due to irritation from a local hematoma.

Unilateral Pubic Rami Fractures

Unilateral pubic rami fractures are rare in high impact injuries. An additional occult bony or ligamentous disruption of the pelvic ring is usually present. Unilateral pubic rami fractures are characteristically associated with mild trauma in osteoporotic patients. Patients present with vague symptoms or inability to weight bear.

Unstable Pelvic Ring Fractures

Unstable pelvic fractures are defined as bony or ligamentous disruption in at least two points of the pelvic ring. These are generally high impact injuries associated with significant trauma to other organ systems. Critical injury to the cardiovascular or central nervous system is an important cause of morbidity and mortality in these patients. The presence and degree of these associated injuries affects the timing of imaging and management of pelvic trauma.

Young and Burgess classified these injuries by their mechanism of injury: lateral compression, AP compression, or vertical shear forces (5). This classification assists the surgeon in external fixation and aids in prognosis and identification of associated injuries.

Lateral Compression Injuries

Type I lateral compression injuries result from direct force on the ilium that internally rotates the ipsilateral hemipelvis causing an impaction injury to the ipsilateral sacrum. Horizontal or coronally orientated fractures of the pubic rami or pubic diastasis are found. Fracture of the ipsilateral sacrum and contralateral pubic rami is known as a bucket handle fracture. Type IIa injuries are similar to type I fractures but with additional disruption of the ipsilateral posterior sacroiliac ligaments. Twenty percent of patients suffer an oblique fracture of the iliac wing rather than a ligamentous injury (Type IIb).

Type III injuries result from internal rotation of the ipsilateral hemipelvis and external rotation of the contralateral hemipelvis. The ipsilateral hemipelvis is similar to a type II lateral compression injury. The contralateral hemipelvis injuries are characteristic of an AP compression injury. This constellation is known as a "windswept pelvis."

Anterior Compression Fractures

Anterior compression injuries result from a force in an anterior–posterior direction that result in external rotation of each hemipelvis. Type I injuries are characterized by diastasis of the pubic symphysis or fractures of the pubic rami. The pubic rami fractures are oriented in the sagittal plane in contradistinction to lateral compression injuries. The posterior ligaments remain intact. Type II AP compression injuries are similar to Type I fractures with additional disruption of the sacrospinous, sacrotuberous, and anterior sacroiliac ligaments. Avulsion fractures at the attachment sites of these ligaments or pubic symphyseal diastasis greater than 2.5 cm suggest this diagnosis.

Type III injuries include the posterior sacroiliac ligaments and result in complete diastasis of at least one SI joint. Sacral fractures are unusual but may occur. Posterior acetabular wall fractures are a common association.

Vertical Shear Fractures

Vertical shear injuries occur most commonly in patients who fall from a height. The classic injury is a Malgaigne fracture; vertical fractures through the sacral ala and ipsilateral pubic rami. However, various combinations of fractures can occur. The most characteristic feature of this very unstable injury is craniocaudal displacement of fracture fragments.

Complications

Internal hemorrhage is the most important local complication of pelvic trauma. Venous bleeding is most common and is effectively treated with fluid resuscitation and early external fixation. Arterial bleeding is frequently refractory to supportive care and percutaneous treatment becomes necessary.

Local organ injury also occurs in the setting of unstable pelvic fractures. Rectal and Lower urinary tract and rectal injuries occur in 2% and 10% of pelvic ring disruptions, respectively. Type II and III AP compression injuries are at highest risk for these injuries.

Acetabular Fractures

The most common mechanism for ▶acetabular fractures is motor vehicle accidents. These fractures are often associated with pelvic ring fractures, femoral head fractures, and ▶hip dislocations. The most widely used classification system for acetabular fractures is the Judet–Letournel system. This system describes basic injuries to the acetabulum as column, rim, and transverse fractures as elementary fractures (Table 1). Five additional combinations of these elementary fractures are described and are classified as associated injuries.

Column fractures are oriented in the coronal place through the acetabulum. Anterior and posterior column fractures disrupt the ileopectineal and ilioischial lines respectively. Wall fractures involve the lip of the acetabulum without extension into the adjacent columns. Transverse fractures are oriented in the transaxial plane through the anterior and posterior aspects of the acetabulum. They may be slightly oblique and detected as sagittally oriented fractures on transaxial images. Most acetabular fractures require surgery to maintain the congruency of the hip joint. The most common long-term complication is degenerative joint disease.

Fractures, Pelvis. Table 1 Letournel–Judet classification of acetabular fractures

Elementary fractures • Anterior wall • Anterior column • Posterior wall • Posterior column • Transverse
Associated • T-shaped • Anterior wall/column plus posterior hemitransverse • Transverse plus posterior • Posterior Column plus posterior wall • Both column

Hip Fractures

Minor trauma in a patient with osteoporosis is the characteristic clinical setting of most ▶hip fractures. Most hip fractures are subcapital fractures, occurring at the junction of the femoral head and neck. These injuries are intracapsular and often interrupt blood supply to the femoral head. The Garden classification system is a useful way of characterizing these fractures. Stage I is an incomplete impacted fracture occurring at the lateral femoral cortex. Stage II injuries are also impacted but extend completely through the femoral neck. Stage III fractures demonstrate distraction of fracture fragments along the lateral cortical margins. Some bony apposition is seen inferiorly and moderate rotation of fracture fragments is usually present. Stage IV fractures demonstrate no bony apposition. Instability and nonunion are more commonly found in high-grade injuries.

Other intracapsular fractures include transverse cervical and basicervical injuries. Extracapsular hip fractures include intertrochanteric and subtrochanteric fractures. These fractures are usually obliquely oriented and associated fractures of the lesser and greater trochanters are common. Pathologic fractures should be considered in the setting of isolated fractures of the trochanters or transversely oriented subtrochanteric injuries.

Hip fractures are a major source of morbidity and mortality in the elderly. Once bedridden, these patients are deconditioned and at increased risk for comorbid medical problems such as nosocomial infection and deep vein thrombosis. The risk of avascular necrosis often necessitates the placement of a hip prosthesis in intracapsular fractures.

Imaging

Radiographs

The AP radiograph demonstrates 60–70% of acute pelvic fractures in most series (2). The pelvic inlet view is obtained with 45° caudal angulation. It demonstrates anteroposterior displacement of fracture fragments characteristic of AP compression injuries. The pelvic outlet view is obtained at 45° cranial angulation and

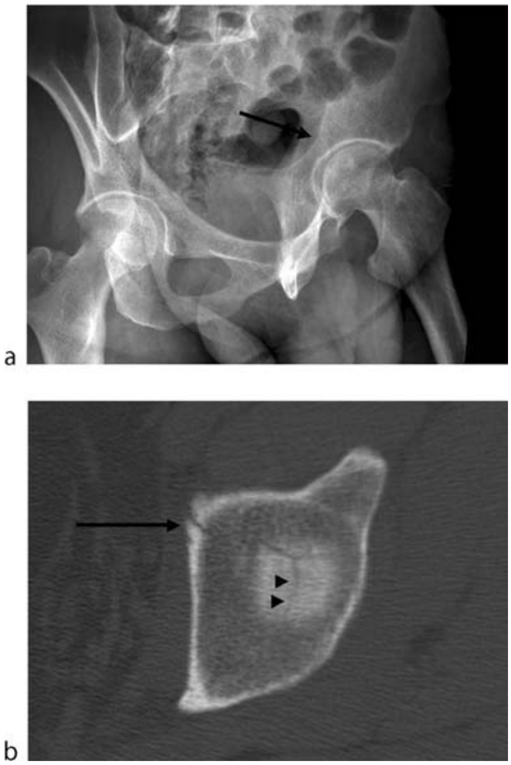
F

demonstrates craniocaudal displacement of fracture fragments characteristic of vertical shear injuries.

Judet views (45° obliques) are helpful to assess the integrity of the columns in acetabular injuries (Fig. 2). Radiographic sensitivity for acetabular fractures is around 70%. Transverse fractures of the sacrum and coccyx are best assessed on lateral views. While most hip fractures are seen on the AP film, lateral views of the hip increase sensitivity for detecting and help further characterize these fractures.

Computed Tomography

The advent of multislice CT technology has revolutionized the role of radiology in trauma. Most trauma centers obtain CT images of the pelvis in serious trauma as a matter of routine. Thin section axial images with coronal, sagittal, and 3D reformats allow excellent accuracy in identifying and characterizing pelvic fractures. Some authors report the addition of CT with multiplanar reformats can alter surgical management in 30% of acute pelvis fractures (1). Pseudoaneurysms or contrast extravasation on contrast enhanced CT is diagnostic of arterial injury and helps guide angiography. Sentinel hematoma can also help localize venous bleeding.



Fractures, Pelvis. Figure 2 (a) Judet view demonstrates a subtle acetabular fracture (*arrow*) that was not apparent on the AP radiograph of the pelvis. Subsequent CT (b) through the region of the superior acetabulum demonstrates an anterior column fracture that is oriented transversely (*arrow*) with a posterior hemitransverse component (*arrowheads*).

Radiographically occult pelvic fractures are accurately assessed on CT. In the setting of acetabular fractures, CT has a well-established role in the identification of impaction fractures of the femoral head and loose bodies within the joint. CT with multiplanar reformats improves accuracy in the acetabular fracture classification and increases diagnostic certainty.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is uncommonly used for evaluation of acute pelvic injury. This modality is too time-consuming for these unstable patients and CT is highly accurate is the assessment of acute bony injuries. MR imaging plays an important role in stable patients. It is the most sensitive modality for detecting occult fractures in the pelvis. These fractures present as low-signal linear defects on T1 and T2 images. Surrounding edema is the rule rather than the exception. Sometimes, however, only edema is shown and fracture lines are not visualized. Thus differential diagnosis may include infection and neoplasms, in these cases CT may be helpful.

MR imaging is useful in avulsion injuries as a method of assessing the integrity of the involved muscle and tendon. The actual fracture fragment may be inconspicuous.

MR is the primary imaging method for evaluating pelvic muscle strains and other soft-tissue injuries. Muscle strain is characterized by high-signal edema on fluid-sensitive sequences. In studies evaluating MR in the assessment of occult hip fractures, 40% of the exams diagnosed additional soft-tissue injuries (4).

Nuclear Medicine

Bone scintigraphy is useful in the setting of suspected occult pelvic fractures because of its excellent sensitivity. Weaknesses include its limited specificity and spatial resolution. These weaknesses and the time needed to image the patient limit the usefulness of scintigraphy in the acute trauma setting.

An acute fracture of the pelvis will be hot on all three phases of MDP bone scintigraphy. An acute fracture in the elderly osteoporotic patient may have a normal study in the initial 72 h. After a period of weeks, fracture uptake becomes more linear on scintigraphy and exhibits less activity on the flow and blood pool phases of the study. The delayed activity at a healing fracture site may persist for 2 to 3 years.

Diagnosis

The increased speed and accuracy of multidetector CT has made it the modality of choice for evaluation of pelvic trauma in most centers. AP radiographs are still useful in hemodynamically unstable patients or when timing of the CT is expected to be delayed. Unstable pelvic fractures can then undergo external fixation and excess bleeding prevented. AP radiographs should also be obtained in suspected hip dislocation to assist immediate reduction.

Radiographs remain the primary imaging modality in patients who suffer low-impact trauma and a hip or pelvis fracture is suspected. Often clinical suspicion persists despite negative radiographs. MR imaging or scintigraphy are very sensitive in detection of these occult fractures.

Intervention

Percutaneous embolization of arterial injury is an effective method of controlling blood loss in unstable pelvic ring fractures. Under what clinical circumstances and at what time that angiography should be performed is a matter of debate. Patients who do not respond to initial resuscitation or have widely diastased fracture fragments have been shown to have a high incidence of arterial injury. Extravasation of contrast or psuedoaneursyms seen on initial contrast enhanced pelvic CT is strong evidence of arterial injury and allows for preprocedure localization of the abnormality. Arterial injury is difficult to predict by the fracture pattern alone, and clinical factors are important in suggesting this diagnosis.

The obturator and pudendal arteries are most commonly injured in anterior disruptions. Posterior disruptions affect the superior gluteal artery most commonly. If an arterial abnormality is identified, subselective vessel catheterization and embolization is performed.

F

Definitions

Fracture: complete or incomplete break in the continuity of bone or cartilage.
Strain: muscular or tendinous injury.
Sprain: soft tissue injury of a ligament.

Pathology/Histopathology

Fractures usually result from a single episode in which excessive force is applied to normal bone. The pattern of osseous disruption depends on the force applied and the underlying mechanical properties of the bone. Most fractures are complete and are described in terms of the location, position, and orientation of fracture fragments. Partial fractures occur commonly in children and include greenstick, bending, and torus fractures.

Injury to the muscular, tendinous, and ligamentous structures is common in acute trauma. Muscular injury from direct impact usually manifests as intramuscular edema or hematoma. Trauma to ligaments and tendons is usually indirect, secondary to an acute distracting force. Mild trauma results in microtears and stretching of these structures. High-grade injuries are characterized by partial or full-thickness tears.

An acute fracture results in a bridging hematoma between fracture fragments. The initial inflammatory and reparative phases result in osseous resorption at the fracture margins. As this hematoma organizes, healing begins with the formation of endosteal and periosteal callus in a process that usually takes 4–16 weeks to complete. Remodeling occurs with replacement of woven with lamellar bone. Prompt healing is promoted by the stability of fracture fragments, close approximation of fragments, intact vascularity, and good nutrition (1).

Acute complications of fractures include neurovascular injury, hypotension, infection, and fat embolism syndrome. Chronic complications of extremity trauma are common and include venous thrombosis, infection, *nonunion*, *avascular necrosis, complex regional pain syndrome*, degenerative joint disease, and ► *myositis ossificans*.

Clinical Presentation

Shoulder

Acromioclavicular (AC) and glenohumeral dislocations are commonly sustained in athletic endeavors as a result of direct impact or falling on an outstretched arm. The normal width of the AC joint is highly variable but usually measures less than 5 mm. It is seldom wider than 3 mm in middle-aged and elderly patients. Disruption of the AC joint is characterized by unilateral widening of the AC joint or vertical displacement of the clavicle in relation to the acromion. Disruption of the coracoclavicular ligament occurs in high-grade AC joint dislocations and its identification may change surgical management (2). Avulsion fractures of the coracoid process, the conoid tubercle of the clavicle, or a coracoclavicular interval greater than 13 mm suggests disruption of this ligament.

The majority of glenohumeral dislocations are anterior and are classified as subcoracoid, subglenoid, subclavicular, and intrathoracic. The subcoracoid position of the humerus is most common and is usually obvious both clinically and on radiology studies. A subglenoid position results in luxatio erecta, persistent nonvoluntary abduction of the humerus. Anterior humeral dislocations are often associated with osseous impaction of the posterolateral humeral head and anteroinferior labral detachment. These lesions are known as Hill-Sachs and Bankart lesions, respectively. Fractures of greater tuberosity are associated with 15% of anterior dislocations. Injuries to the rotator cuff and the articular capsule are also associated with these dislocations. Recurrent dislocations are common in younger patients and those with associated soft tissue and osseous injury. Magnetic resonance imaging (MRI) is helpful for characterizing these abnormalities and assists in surgical planning.

Posterior dislocations usually occur secondary to muscle spasm during seizures. These injuries are difficult to diagnose both clinically and on standard radiographs. Axillary and transcapular radiographs or cross-sectional images are the most reliable methods in the identification of this injury. Reverse Hill-Sachs fractures, injury to the posterior labrum, and lesser tuberosity fractures are associated with posterior dislocations.

Humerus, Elbow, and Forearm

Fractures of the humeral neck most commonly occur in elderly patients with osteoporosis after minor trauma. The surgical neck is usually involved but additional fractures of greater and lesser tuberosity are frequently found. Most humeral neck fractures are minimally displaced as the fragments are held in apposition by partially intact periosteum, joint capsule, and rotator cuff tendons. These injuries are treated by supportive means. A fracture fragment distraction of greater than 1 cm or angulation of greater than 45° indicates high-grade injuries that may require surgical fixation. Fractures of the anatomic neck are less common, but result in disruption of blood supply with high rates of ►avascular necrosis of the humeral head. Additional complications of trauma to this region include neurovascular injury and adhesive capsulitis.

Fractures of the humeral shaft occur in high-impact injuries, often in younger patients. Transverse, mid-diaphyseal fractures are most common. Spiral fractures may occur after throwing in healthy young patients. Radial nerve injury occurs in 5–10% of fractures of the humeral diaphysis.

Most fractures of the elbow occur in patients who fall on an outstretched hand. Radial head fractures are most common in adults. These fractures are often minimally displaced and identification of an elbow effusion or displacement of the supinator fat pad may aid in their identification. Imaging of the wrist should be performed in cases of severe comminution of the radial head to rule out a coexisting distal radioulnar joint disruption, an Essex-Lopresti injury. Fractures of the olecranon are the second most common elbow fractures in the adult. Oblique fractures may be subtle but prominence of the olecranon bursa and joint effusion are often present.

The most common elbow fractures in children are supracondylar, lateral condylar, and medial epicondylar in descending order of frequency. Supracondylar fractures may be associated with arterial injury and median nerve palsy. Additionally, suboptimal reduction of supracondylar fractures may result in loss of normal valgus angulation at the elbow. Avulsion fractures of the medial epicondyle may be subtle, especially when the fragment is trapped within the joint. Absence of the medial epicondyle is abnormal if the secondary center of ossification of the trochlea is present.

Transcondylar and intercondylar fractures usually occur as a result of falling on an outstretched hand, often in osteoporotic patients. Displacement and rotation of fracture fragments are common and usually dictate surgical repair. Undisplaced fractures of the lateral condyle are considered stable if they do not extend past the trochlear groove. Similar fractures of the medial condyle are considered stable if they do not extend past the capitellotrochlear sulcus.

Elbow dislocations are usually posterior and secondary to high-impact trauma or falling on an outstretched arm. Fractures of the coronoid process of the ulna and avulsion of the medial epicondyle are common associated injuries. Fractures of the lateral condyle, radius, olecranon, and capitellum are less frequent.

Numerous combinations of ulnar and radius fracture/ dislocations have been described (Table 1). These patterns of injuries underscore the need to image from the elbow to the wrist in the setting of forearm trauma. Surgical reduction is considered in even mildly angulated fractures to preserve an adequate range of motion. Rotational deformity may be subtle on imaging and results in significant impairment.

Wrist and Hand

Most wrist injuries result from a fall on an outstretched hand. Distal radius fractures occur most commonly in patients with osteoporosis. The most common injury is Colles' fracture, which results in dorsal angulation of the distal fragment. The majority of Colles' fractures are intra-articular and a step of greater than 2 mm is an indication for surgical reduction. Closed reduction should attempt to restore the anatomic 15° of ulnar and 10° of dorsal angulation of the distal radial articular surface. Approximately 50% of wrist injuries are associated with triangular fibrocartilage tears and ulnar styloid fractures.

Scaphoid fractures are often radiographically occult and repeat radiography or advanced imaging techniques are often required for correct diagnosis (3). Fractures of the scaphoid are important because of the high risk for ►nonunion and avascular necrosis. These complications occur more commonly in proximal fractures of the scaphoid because of the distal entry points of the nutrient arteries. Ligamentous injuries to the carpus and fractures of the radial styloid, capitate, and triquetrum are associated with scaphoid trauma.

Ligamentous disruption of the scapholunate and radio-scaphoid ligament results in scapholunate dissociation. Indirect signs of this injury on radiographs include widening of the scapholunate interval, rotary subluxation of the scaphoid, and an increased volar tilt of the scaphoid on lateral views. Lunotriquetral and triangular fibrocartilage tears are also common ligamentous injuries of the carpus. Diagnosis of these ligament tears is confirmed on arthrography or MRI.

The most common dislocation in the wrist is a dorsal perilunate dislocation in which the lunate continues to articulate with the radius, but the remainder of the carpus is dislocated dorsally. The majority of these dislocations are associated with a scaphoid waist fracture. Lunate dislocations are usually volar and the remainder of the carpus aligns with the radius in a normal position.

Fractures, Peripheral Skeleton. Table 1 Common eponyms for extremity fractures

Arcuate	Fracture of fibular apex associated with posterolateral corner injury
Bony Bankart	Anteroinferior fracture of the glenoid labrum
Barton	Fracture of dorsal rim of radius and dorsal dislocation of carpus
Bennett's	Intra-articular fracture involving the base of the first metacarpal
Boxer's	Fracture of distal fifth metacarpal
Chauffeur's	Fracture of the radial styloid
Chopart	Fracture-dislocation through talonavicular and calcaneocuboid
Colles'	Transverse fracture of distal radius with dorsal angulation of distal fragment
Essex-Lopresti	Comminuted fracture of the proximal radius and disruption of the distal radioulnar joint
Galeazzi's	Fracture of the radius with disruption of the distal radioulnar joint
Hill-Sachs	Impaction fracture of the posterolateral aspect of humeral head
Jones	Transverse fracture at the base of the 5th metatarsal
Lisfranc	Fracture/dislocation involving ligaments between first metatarsal and middle cuneiform
Maisonneuve	Fracture of the proximal fibula associated with ankle injury
Monteggia	Fracture of the ulnar shaft and dislocation of the proximal radius
Nightstick	Isolated ulnar fracture secondary to direct trauma
Rolando	Comminuted fracture of base of the first metacarpal
Segond	Posterolateral flake avulsion fracture of the proximal tibia epiphysis associated with anterior cruciate ligament tears
Smith's	Transverse fracture of the distal radius with volar angulation of distal fragment
Tillaux fracture	Salter 3 fracture of anterolateral aspect of the distal tibial epiphysis

F

The hand is the most common location of skeletal trauma. The majority of these injuries occur in the phalanges and metacarpals and are due to direct trauma. Injuries to the ulnar collateral ligament of the first digit are important for the radiologist. An MR image can help diagnose a Stenner lesion in these patients where the ulnar collateral ligament is found above the adjacent aponeurosis. The presence of this lesion is an indication for surgery.

Femur, Knee, and Lower Leg

Fractures around the knee are uncommon and usually occur from high-impact trauma. Supracondylar fractures are frequently transverse. Hip fractures and dislocations are associated with this injury, and imaging of the entire femur should be performed. Intercondylar fractures are often comminuted and best characterized by multiplanar computed tomography (CT). Popliteal artery injuries are associated with distal femoral fractures.

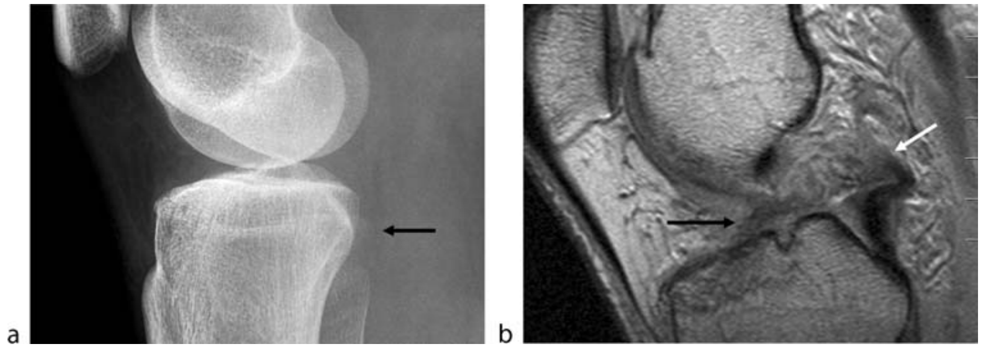
Acute injuries to the knee usually involve the ligaments and menisci and are best assessed with MRI. Several fractures of the knee may herald an important soft tissue injury. Segond fractures are a flake avulsion fracture along the posterior lateral tibial epiphysis. These injuries are associated with anterior cruciate ligament and meniscal pathology. In addition, avulsion fractures of the tibial spines and impaction fractures of the lateral condylar sulcus are other osseous findings in anterior cruciate ligament injury. Fractures of the apex of the fibula are important. These may represent avulsion fractures of the arcuate ligament and are the only radiographic evidence of a posterolateral corner injury (Fig. 1). These injuries involve the posterolateral joint capsule, the popliteal tendon, and the cruciate ligaments. These unstable injuries result in accelerated degenerative change and are an indication for urgent orthopedic referral.

Tibial plateau fractures usually occur in older patients with acute injuries, usually twisting injuries in falls but also in direct trauma. Valgus stress is common and 80% of fractures involve the lateral tibial plateau. These fractures may be radiographically occult with the only clue being a lipohemarthrosis. The coexistence of internal derangement in 70–90% of cases makes MRI well suited to their evaluation. Indications for fracture repair include distraction of fracture fragments of greater than 5 mm or depression greater than 10 mm.

Ankle and Foot

Supination-adduction injuries result from an acute varus stress on the foot when weight bearing on the outside of the foot. The initial injury is to the lateral ligaments of the ankle, most commonly the anterior talofibular and calcaneofibular ligaments. Loss of lateral stability results in lateral translation of the tibia on the talus. The shearing forces can lead to an oblique or vertical fracture of the medial malleolus.

Supination-external rotation of the ankle results from inward rotation of the leg while weight bearing on the outside of the foot. The initial injury is disruption of the anteroinferior tibiofibular ligament (AITF). Continued inward rotation of the tibia (external rotation of the planted foot) results in a spiral fracture of the fibula at the level of the ankle mortise followed by disruption of the posteroinferior tibiofibular ligament (PITF). After these injuries, continued force results in tear of the deltoid ligaments. This final stage of injury is unstable. Deltoid ligament injuries may be subtle and stress views are warranted in the setting of a spiral fracture of the fibula at



Fractures, Peripheral Skeleton. Figure 1 **Coned in lateral view of the knee (a) demonstrates an arcuate fracture (*arrow*) through the apex of the fibula, usually associated with posterolateral corner injury. A sagittal proton density MR (b) demonstrates disruption of the ACL (*black arrow*) and PCL (*white arrow*) in the same patient who suffered a total knee dislocation.**

the level of the syndesmosis and soft tissue swelling over the medial malleolus.

Pronation-external rotation occurs when inward rotation of the tibia takes place while weight bearing on the instep of the foot. This force initially places the deltoid ligament under tension and results in a ligamentous sprain or avulsion fracture. Continued motion results in disruption of the AITF ligament and rupture of the interosseous membrane. Fracture of the fibula 10 cm above the mortise usually follows, although fracture of the proximal fibula, a Maisonneuve fracture, may also occur in this setting. Finally, continued rotation results in a posterior malleolar injury at the level of the PITF attachment. Proximal fibular fractures should be sought in the setting of widening of the medial joint space or widening of the distal tibiofibular syndesmoses over 5.5 mm. These injuries may be subtle or temporarily reduce and the only clue to a proximal fibular fracture is medial malleolar swelling and an isolated posterior malleolus fracture.

Pronation-abduction injuries result from a valgus stress on the ankle while weight bearing on the instep of the foot. The initial injury results in a deltoid ligamentous injury or avulsion fracture. The second stage of the injury is disruption of the distal tibiofibular syndesmosis, which may be accompanied by an avulsion fracture of the posterior malleolus. Continued force results in a characteristic oblique fibular fracture above the ankle mortise. The interosseous membrane remains intact.

The calcaneus is the most commonly fractured tarsal bone. Compression fractures of the calcaneus occur in the setting of axial loading and are frequently associated with vertebral compression fractures. Fracture extension into the posterior subtalar facet and depression of this joint should be carefully assessed. Entrapment of the flexor hallicus longus and peroneal tendons may also occur (1). Two common locations for avulsion fractures of the calcaneus include the anterior process and anterolateral aspect of the calcaneus at the attachments of the bifurcate ligament and extensor digitorum brevis muscles, respectively. These injuries are the most commonly seen fractures on ankle radiographs and should be sought on anteroposterior (AP) radiographs.

Osteochondral injuries are the most common fracture of the talus. They are often radiographically occult and are best assessed with cross-sectional imaging. Fractures of the talar neck are predisposed to avascular necrosis. Osteochondral injuries are also common in the tarsal navicular bone.

The most important injury involving the cuneiforms is the Lisfranc fracture-dislocation. The first and second metatarsals are aligned with the medial and middle cuneiforms, respectively. Disruption of this alignment suggests a ligamentous injury. Associated dislocations may follow a homologous (second through fifth metatarsals laterally displaced) or divergent (additional medial displacement of the first metatarsal) pattern. Fractures of the metatarsals and phalanges are common and are often the result of direct trauma.

Imaging

Radiographs

Plain radiographs are sufficient for evaluation of most extremity fractures. As a rule of thumb, two orthogonal views and an oblique view are considered the minimum necessary to assess for the presence or absence of a fracture. Fractures are most commonly seen on radiographs as an abnormal line of radiolucency. Cortical irregularity or disruption is another important sign. Increased sclerosis with bone is found in compression fractures. Joint effusion and displacement of fascial planes are important secondary signs.

Ultrasound

Ultrasound is an excellent modality in acute trauma for assessing the integrity of ligaments and tendons. It is most commonly used in the assessment of the integrity of the rotator cuff and the Achilles and patellar tendons. It also is useful in characterizing hematomas and other muscle injuries and for the detection of nonradiopaque foreign bodies (4).

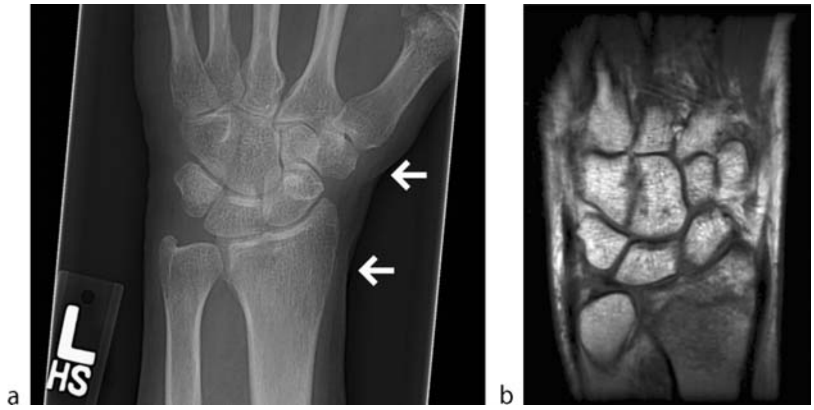
Computed Tomography

Osseous injury to the extremity is well evaluated by CT. Imaging characteristics of fractures are similar to those in radiography and include abnormal linear lucency, cortical discontinuity, and increased sclerosis. The increased use of multidetector CT (MDCT) with isotropic voxels and advanced PACS systems allows for visualization of fracture fragments in any plane. Therefore, despite inferior spatial resolution compared with radiography, MDCT is better able to fully characterize complex osseous injuries.

MDCT is also able to evaluate the soft tissues in acute trauma. Hematomas demonstrate increased density. Small amounts of air, foreign bodies, and effusions are also frequently found. Tendinous and ligamentous injuries are visualized as focal discontinuity or entrapment within fracture fragments (1).

Magnetic Resonance Imaging

MRI is very sensitive and specific in the identification of osseous trauma. Linear fracture lines are hypointense on T1- and T2-weighted sequences. This low signal abnormality is invariably surrounded by high T2-weighted bone



Fractures, Peripheral Skeleton. Figure 2 AP radiograph (a) of the wrist demonstrates no abnormality despite pain (*arrows* placed by technologist) along the radial aspect of the wrist after a fall. A T1-weighted coronal MR of the wrist (b) demonstrates a low signal fracture line in the distal radius.

edema. Enhancement adjacent to the fracture line and periosteum is also noted. Soft tissue trauma to ligaments, tendons, and muscles is also depicted well on MR images. Focal discontinuity and high T2-weighted signal within these structures are the most common signs of injury.

Nuclear Medicine

Bone scintigraphy is useful in the setting of suspected occult fractures because of its excellent sensitivity. Weaknesses include its limited specificity and spatial resolution. These weaknesses and the time needed to image the patient limit the usefulness of scintigraphy in the acute trauma setting.

An acute fracture will be hot on all three phases of MDP bone scintigraphy. An acute fracture in the elderly osteoporotic patient may appear normal in the initial 72 h. After a period of weeks, fracture uptake becomes more linear on scintigraphy and exhibits less activity on the flow and blood pool phases of the study. The delayed activity at a healing fracture site may persist for 2–3 years.

Diagnosis

Most extremity fractures are adequately assessed by radiography. MDCT provides additional information regarding the position of fracture fragments and is helpful in preoperative planning in complex injuries. Occasionally, extremity fractures may be occult on plain radiographs, especially in regions such as the scaphoid and hip. In these cases, scintigraphy, CT, or MRI may be performed to diagnose these injuries (Fig. 2).

Fractures, Stress

David Malfair
UCSF, San Francisco, USA
dmalfair@hotmail.com

Synonyms and Definitions

Stress fracture: Injury that occurs secondary to repetitive stress over a period of time. Stress fractures can be further classified as fatigue and insufficiency fractures.

Fatigue fracture: Injury that occurs in normal bones of healthy subjects secondary to an abnormal repetitive stress.

Insufficiency fracture: Injury that occurs when normal repetitive stress is placed on abnormal bone with decreased elasticity.

Pathology/Histopathology

Bone must be strong enough to withstand both acute and repetitive forces. Repetitive stress above a certain threshold induces a reparative response in bone. This remodeling response is initially resorptive in nature with decreased mineral density before an overall increase in cortical thickness and medullary bone strength. During this early reparative phase, bone is more susceptible to trauma. Cyclic forces of sufficient magnitude and periodicity may create microfractures of cancellous bone at this time. With continued activity, the repetitive stress overwhelms the healing response and progresses to macroscopic stress fractures.

This mechanism of injury is similar for both fatigue fractures and insufficiency fractures. In fatigue fractures, the force is large enough to overwhelm the normal healing response of bone. In insufficiency fractures, the bone lacks the strength, elasticity, and capacity for healing to respond to a normal repetitive force.

Clinical Presentation

Epidemiology

Fatigue fractures generally occur in athletes who initiate an intensive training program or change an existing regimen. Females are more prone to stress fractures than men in studies of army recruits (4). Patients with small body-mass index (BMI) ratio and deconditioned athletes are also at higher risk. No racial predilection has been shown.

The majority of fatigue fractures occur in the lower extremity. Runners and new army recruits suffer from the highest incidence of lower extremity fatigue fractures. Upper extremity fatigue fractures are more unusual and tend to occur in specialized athletes (Table 1).

Insufficiency fractures occur in patients with abnormal bone. Risk factors include osteoporosis, rheumatoid arthritis, and renal osteodystrophy. Iatrogenic factors such as radiation and medications such as corticosteroids are other common etiologies. Insufficiency fractures most commonly occur in the pelvic ring and lower extremity.

History

Fatigue fractures can be difficult to diagnose and a delay in appropriate management is not uncommon. In almost every instance, there is an increase in the level of physical activity. The onset of symptoms is gradual over several weeks. Most stress fractures occur between 2 to 8 weeks after increased exercise. Pain is the most common symptom. It occurs with activity and is relieved with rest. With continued activity discomfort is more severe, occurs more quickly and persists at rest. Local tenderness and edema are often noted on exam.

Patients with insufficiency fractures often present with nonspecific pain or difficulty in mobilization. Comorbidities such as arthritis, cancer, medications can also cloud the clinical diagnosis. These fractures are often discovered incidentally on imaging techniques.

Fractures, Stress. Table 1 Common stress fractures and related sports activities

Coracoid of scapula	Trapshooting
Distal humerus	Pitching

Location

Stress fractures occur in almost any bone due to a variety of activities. (Table 1) Several of the most common sites deserve special attention.

Pars Interarticularis

► *Spondylolysis* refers to a spectrum of abnormalities involving the pars interarticularis and occurs with a prevalence of 6%. Stress fractures are the most common etiology of spondylolysis. These injuries usually occur in childhood, most frequently in Caucasian males. The incidence is increased with certain activities such as gymnastics, diving, and weightlifting. Ninety percent of these injuries occur at the L5 vertebral level with most of the remainder found at L4. The majority of patients are asymptomatic. Some patients present with nonspecific low back pain exacerbated by activity. Frequently, individuals with stress fractures of the pars interarticularis progress to complete fracture and nonunion. The non-united pars defect is known as a spondylolytic defect. A minority of patients with spondylolysis will progress to spondylolysthesis, anterior translation of the vertebral body secondary to bilateral pars defects.

Pelvis

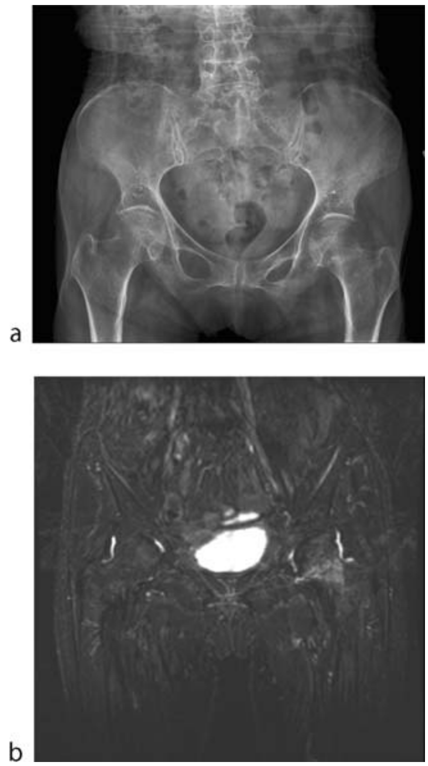
Insufficiency fractures are most commonly found in the pelvis. Women with osteoporosis or radiation treatment are most at risk. Fatigue fractures can also occur in the pelvis in military recruits and female runners. The majority of stress injuries involving the pelvic ring occur in the sacrum and pubic rami. Stress fractures of the sacrum demonstrate a parallel orientation to the sacroiliac joint. They are often bilateral and frequently associated with additional stress fractures in the proximal femora and pubic rami. Delay in diagnosis is common due to insensitivity of radiographs and presentation with nonspecific groin and or back pain.

Proximal Femur

Stress fractures of the femoral neck can be classified as tensile or compressive. The compressive stress fractures occur in the medial aspect of the femoral neck, involving the compressive trabeculae. These injuries are usually stable and are treated conservatively (Fig. 1). Tensile stress fractures occur at the midpoint of the lateral aspect of the femoral neck and are generally treated with internal fixation. Delay in diagnosis or treatment of these fractures can frequently lead to avascular necrosis of the femoral head, nonunion, or varus deformity. Some authors advocate conservative treatment for small or very proximal tensile stress fractures.

Tibia

Stress injuries have many manifestations in the tibia and usually occur in runners or military recruits. Stress fractures most commonly involve the posterior aspect of the proximal tibia. ►Shin splints are defined as a stress reaction of the periosteum of the posteromedial aspect of the tibia. Stress fractures may also occur in the medial aspect of the middiaphysis of the tibia. These types of fractures are treated with conservative management. Atypical stress fractures of the tibia include longitudinal stress fractures and anterior stress fractures of the tibia (Fig. 2). These rare but important subset of tibia fractures are difficult to treat and may progress to complete fracture.



Fractures, Stress. Figure 1 AP radiograph (a) of the pelvis demonstrates subtle sclerosis over left femoral neck. Coronal STIR MR image (b) shows extensive low signal stress fracture through the medial femoral neck surrounded by high signal edema. The severity of this stress injury necessitated percutaneous pinning.

Fractures, Stress. Figure 2 Lateral radiograph of the tibia demonstrates horizontal lucency in the anterior cortex of the tibial diaphysis diagnostic of a stress fracture.

Imaging

Radiography

Overall, the sensitivity of plain films is poor, calculated at 30% in most series. Plain films examination is usually within normal limits with the onset of symptoms. Findings are first seen 2–3 weeks after onset of symptoms (3). The earliest radiographic finding of a cortical stress fracture is diminished radiodensity termed the gray cortex. More commonly, stress fractures are discovered as a transverse/oblique lucency of the cortex with subtle fluffy periosteal reaction. Increased new bone formation may preclude visualization of the fracture and simulate an osteoid osteoma or infection. Stress fractures in cancellous bone are more likely to present with focal sclerosis representing condensation of trabeculae. With healing, sclerosis becomes more prominent in stress fractures of all locations.

Computed Tomography

The evolution of multislice CT with improved spatial resolution and higher quality reformations has increased the accuracy of this modality in the identification and characterization of stress fractures. CT demonstrates excellent sensitivity and specificity for cortical stress fractures. Early stress injuries are characterized by small resorption cavities and osteopenia in the cortex. More advanced stress fractures demonstrate a linear lucency. Periosteal and endosteal bony proliferation is characteristically seen in healing lesions. CT is insensitive for medullary stress injuries, which present as focal areas of sclerosis.

MR

MR is a highly accurate imaging method in the assessment of stress injuries. An early stress response demonstrates high T2-weighted signal within the medullary cavity or cortex. Progression to a stress fracture results in the characteristic appearance of a low signal intensity, transverse linear band on T1- and T2-weighted images. Bone edema surrounding the fracture line demonstrates indistinct margins. Periosteal edema is best identified on STIR sequences and may be the only sign of certain stress injury.

Nuclear Medicine

Bone scintigraphy demonstrates excellent sensitivity but limited specificity in detecting stress fractures. These injuries demonstrate increased activity on the blood flow and blood pool images with increased uptake on the delayed phase. Single photon emission CT (SPECT) increases sensitivity and allows three-dimensional localization of stress fractures.

Diagnosis

In patients with characteristic findings on radiographs and consistent clinical presentation, a stress fracture may be confidently diagnosed. If the radiographs are normal or atypical, MR or bone scintigraphy is recommended. MR imaging is favored by many authors because of its increased specificity and ability to diagnose other soft-tissue ailments (2). CT is increasingly helpful to problem solve and further characterize abnormalities found on MR and nuclear medicine studies.

The imaging differential for stress fractures includes osteoid osteomas, infection, Ewing's sarcoma, and pathological fractures. These entities are best differentiated clinically. The linear lucency of a stress fracture can be differentiated from the oval nidus of an osteoid osteoma on MR and CT imaging. Infection usually demonstrates more widespread uptake on delayed bone scan compared to the focal uptake of a stress fracture. A healing stress fracture can exhibit some features of Ewing's sarcoma. Lack of necrosis, indistinct margins of edema and visualized fracture line on MR favor a diagnosis of stress fracture. In oncology patients, an injury may represent a pathological fracture through a metastasis or an insufficiency fracture from radiation or osteoporosis. T1-weighted MR images are most helpful in demonstrating a low signal mass in the bone marrow of a pathologic fracture (1). The presence of endosteal scalloping and marked muscle edema supports the diagnosis of a pathologic fracture. Sometimes MRI may not show the fracture line but only edema, in particular in the pelvis/sacrum in postmenopausal females with osteoporosis and chronic back pain, and thus a tumor may be suspected. In these cases thin section CT may be useful to show the fracture line and reveal the diagnosis. Alternatively, in difficult cases, interval follow-up studies may also be useful.

Fulminant Hepatitis

Submassive to massive hepatic necrosis progressing from onset of symptoms to hepatic encephalopathy within 2 to 3 weeks is called fulminant hepatitis or fulminant hepatic failure. A course extending up to 3 months is called hepatic subfulminant failure. It is quite rare. The most common causes are fulminant viral hepatitis, drug toxicity (acetaminophen, isoniazid, antidepressant), chemical toxicity (mycotoxins of the mushroom *Amanita phalloides*), ischemia or shock. The necrosis may involve the entire liver or only random areas. A lobe may be spared or patchy necrotic areas may be dispersed throughout the liver. Within a week from the onset of necrosis, hepatocellular regeneration occurs. The evolution is variable and depends on the age of the patient and the previous status of the liver. The clinical scenario is dominated by jaundice, encephalopathy, coagulopathy and bleeding, renal failure, cardiovascular failure.
▶Hepatitis

Functional Cysts

An ovarian cysts is a sac filled with fluid or a semisolid material within an ovary. Functional ovarian cysts are the most common type of cysts in the ovary. The represent physiologic, not-disease-related cysts and occur as a normal process of ovulation usually disappearing within 8–12 weeks without treatment. Women who are past menopause almost never have functional ovarian cysts.

Functional Magnetic Resonance Imaging

An MRI technique that is used to visualize neuronal activity indirectly during the performance of specific tasks, using the blood oxygenation level dependent contrast.

Functional Renal Imaging

Michel Claudon, Damien Mandry
Department of Radiology, Childrens Hospital, Nancy University Hospital, Vandoeuvre les Nancy, France
m.claudon@chu-nancy.fr

Definition

Functional imaging is intended not only to depict anatomy and morphological anomalies but also to evaluate organ function. It is possible to

- Perform a visual observation
- Calculate some semiquantitative parameters
- Calculate absolute values.

Renal function involves at least two successive physiological processes: glomerular filtration (which depends on the number of nephrons and on blood perfusion) and reabsorption/secretion in the tubules. The functional unit of the kidney is the nephron; each kidney contains about 1.2 million nephrons.

Renal functional imaging has developed for a few reasons. First, the kidney is a paired and symmetric organ. Thus, visual comparison from one side to the other is easy. Second, due to recent technical improvements, the kidneys can be studied with high temporal and spatial resolution, allowing evaluation of blood perfusion, for instance. Other methods have failed to precisely determine renal function; indeed, they are based on the glomerular clearance of a substance, usually creatinine or inulin. However, because performing this measurement is constraining, creatinine clearance (Cl_{Cr}) is usually roughly estimated by the Cockroft and Gault formula:

$$\left(Cl_{Cr} = \frac{(140 - age) \times BM \times GF}{P_{Cr}} \right),$$

where BM is the body mass (kg), GF is a gender correction factor (male:1.23, female:1.04), and Pcr is the plasmatic creatinine rate (μmol/L). For many reasons, this value is underestimated in the elderly, and what is more troublesome is that this value remains normal until at least 50% of the nephrons are inefficient, leading to late diagnosis of renal insufficiency. What emphasizes the role of imaging is that nonspecific contrast media can be used as glomerular filtration rate (GFR) tracers.

Renal Anatomy and Physiology

Two layers compose the renal parenchyma. The cortex, containing the glomerulus, is the more external one and is comprised of the glomerulus, the proximal and distal convoluted tubules, and the beginning of the collecting ducts. Renal blood flow (RBF) represents about 25% of the cardiac blood flow, corresponding to 1.2 L/min. Eighty percent of this RBF is filtrated in the cortex through the glomerulus to form the primary urine, explaining the vascular phase depicted in imaging with high temporal resolution.

The internal layer corresponds to the medulla, which is constituted by the loops of Henle and the distal parts of the collecting ducts. Urine concentration increases as it advances through this layer.

Ultrasonography

Since the development of contrast media, the possibilities of ultrasonography (US) in functional imaging have improved and add to the Doppler techniques that have been used for years in renal imaging. These contrast media are purely intravascular; this means they have no interstitial diffusion and are not filtered through the glomerulus. Therefore, they cannot be used to measure the GFR. But this method allows evaluation of renal perfusion, including regional blood volume and flow, in different pathologic conditions such as renal artery stenosis and chronic obstruction. However, absolute quantification remains complicated because of the numerous parameters and adjustments, and exploration is still limited to a single slice or to a small volume.

Nuclear Medicine

Nuclear medicine (1) remains the reference method for quantifying the GFR or evaluating split function. Different tracers are available, allowing evaluation of the different processes leading to urine formation. First, the most widely used tracer of GFR is DTPA labeled with ^{99m}Tc; 51Cr-EDTA is another GFR tracer, but because of the low energy of the emitted photons, it can be detected only in blood and urine samples. Second, tracers excreted by the tubules help measure RBF because RBF is the ratio between clearance, which is measured, and extraction fraction, which is known. These tracers involve analogs of the hippuric acid—paraaminohippuric acid, orthoiodohipuric acid—labeled with ^{123}I or ^{131}I, which are filtrated by the glomerulus (about 20%), secreted by the tubules (80%), and labeled with mercaptoacetyltriglycine (MAG3). DMSA labeled with ^{99m}Tc is used to measure renal volume by making images in different planes 3 h after the injection, as it is not excreted. This radiopharmaceutical is also useful for measuring split function because the ratio of activity measured in each kidney, after correction for background activity, corresponds to split function.

Dynamic imaging protocols usually involve different phases: acquisition of 60 one-second images to observe the vascular phase, and follow-up of the medullar concentration and excretion during 20–45 min, sensitized by injection of furosemide. Renal perfusion is calculated from the vascular phase by dividing either the upslope of the kidney by that of the aorta (Kirchner index) or the area under the curves (Hilson index). After the vascular peak, activity continues to increase until a peak preceding excretion. From this second part of the curve, split function can also be achieved. Indeed, if correction for background activity and for each kidney volume is applied, it can be derived from the ratio either of the area under the curve or the upslope between 1 and 3 min after injection. Another method is based on the Patlak-Rutland method and is described in the section on computed tomography (CT).

Absolute quantification of the GFR is better achieved by analyzing consecutive blood and urine samples.

Iodinated Contrast Media and Gadolinium Chelates

After intravenous injection, these clinically available contrast media, known as nonspecific agents, have an unrestricted interstitial diffusion and are freely filtered through the glomerulus without secretion or reabsorption by the tubule. Thus, they are suitable for measuring the GFR. Indeed, some authors have used these contrast media to measure GFR by measuring their concentration in blood and urine samples in the same way as measuring

F

clearance of inulin or creatinine. GFR (mL/min) can then be calculated: $GFR = U_t \times V_t/(S_{t-1} + S_t)$, where t is the time of the collected sample, V_t is the urine flow rate (mL/min), and U_t and S_t are, respectively, the urine and serum concentrations of the contrast medium.

Intravenous Urography

Intravenous urography was the first renal functional imaging technique, but it provides only some basic physiological data that add to morphologic data.

Abdominal X-rays are performed before and at various times after intravenous injection of an iodinated contrast medium (usually at the end of injection and at 4, 8, 12, and 20 min).

Two phases of interest about kidneys are distinguished:

1. Nephrographic: This phrase begins with the arrival of the contrast medium in the cortex (vascular nephrogram), which lasts only a few seconds, followed by the concentration of the contrast medium in the medulla, which reaches its maximum between 5 and 10 min after injection in normal kidneys before wash-out.
2. Urographic: This phase begins about 2 min after injection, when the contrast medium is excreted in the renal calyces and pelvis.

Functional evaluation is therefore limited to a visual appreciation of a delayed nephrogram and/or urogram, without any specificity (renal artery stenosis, chronic obstruction).

Computed Tomography

Since the advent of multislice CT and the possibility to repeat the same acquisition in a very short time, the role of intravenous urography has considerably diminished. Indeed, the same observations can be made with CT, and the renal parenchyma can be directly studied (2).

CT also allows quantitative studies because the attenuation of X-ray beams is well correlated with concentration of the contrast medium. Thus, a Patlak-derived method is based on a two-compartmental model. The y-axis corresponds to the comparison between the evolution of the attenuation in regions of interest placed in the aorta (A) and in the kidney (K) ($K(t)/A(t)$), when a normalized time is on the x-axis $\left(\int_0^t A(t)/A(t)\right)$ (3). The clearance corresponds to the slope of this line, and the fractional vascular volume corresponds to the y-axis intercept.

However, two major drawbacks limit the use of this technique on a routine basis. First, the use of iodinated contrast media may worsen a preexisting renal insufficiency, but this risk is reduced by the small amount of contrast medium injected and the use of nonionic low osmolar contrast media. Second, these measurements are associated with a high radiation dose because of the numerous acquisitions required.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) seems to be the most challenging technique for nuclear medicine in renal functional imaging, becoming a one-stop-shop examination by combining this new approach with the high spatial resolution of morphologic imaging provided by MRI (Fig. 1) (4). In fact, it allows achievement of numerous functional parameters, including renal blood volume and flow, GFR, and tubular function (5).

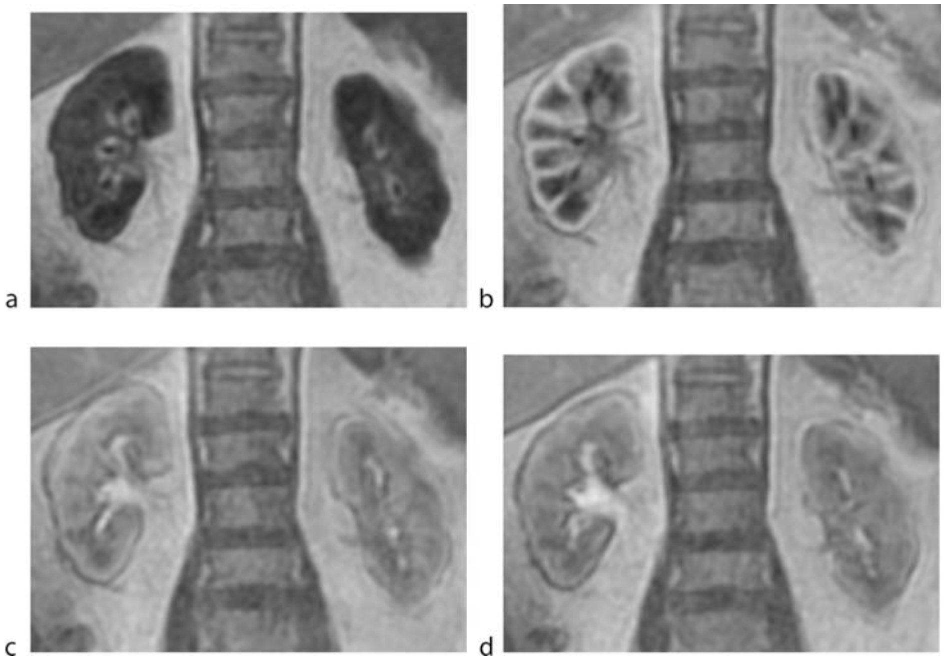
But routine use of MRI is limited by some difficulties. Some are common to all imaging techniques regarding kidneys: their intraabdominal situation results in respiratory motions between two acquisitions in breath-hold or if the acquisition lasts too long, and motion artifacts created by digestive peristalsis. Therefore, many research teams are working on these problems. Other difficulties are specific to MRI: the relationship between signal intensity and the concentration of the contrast medium is very complicated because it depends on the properties of the tissue (T1, T2) and of the contrast medium (relaxivities r1 and r2), which also vary with the temperature and composition of the organ or with the sequence used. Thus, conversion of signal intensities into concentrations based on phantom studies is preferable.

Renal Blood Volume and Flow

Evaluation of renal perfusion is particularly interesting in renal artery stenosis, in diseases with renal microvasculopathy, or in estimation of effects of treatment.

Blood flow in the renal arteries can be measured as in any other artery by using a cine-phase contrast sequence with no contrast agent, but the accuracy of this method is decreased because the vessels are small, and because their course is not a straight line, a partial-volume effect is induced. Signs of renal artery stenosis observed with this method are similar to those noted with Doppler ultrasonography: an early systolic peak decreases in moderate stenosis, and there is a delay in time to maximum systole. Arterial spin labeling is another method without contrast media, but the *in vivo* accuracy of this technique has yet to be demonstrated.

Perfusion parameters can also be evaluated using methods with contrast agents; this is known as dynamic contrast-enhanced imaging. This requires a bolus



Functional Renal Imaging. Figure 1 **Characteristic MR images before (a) and after intra-venous injection of a gadolinium chelate showing the vascular nephrogram (end of vascular phase, b), the nephrogram (urine concentration in the medulla, c) and the urogram (urine excretion in the calyces and pelvis, d). These are similar with CT.**

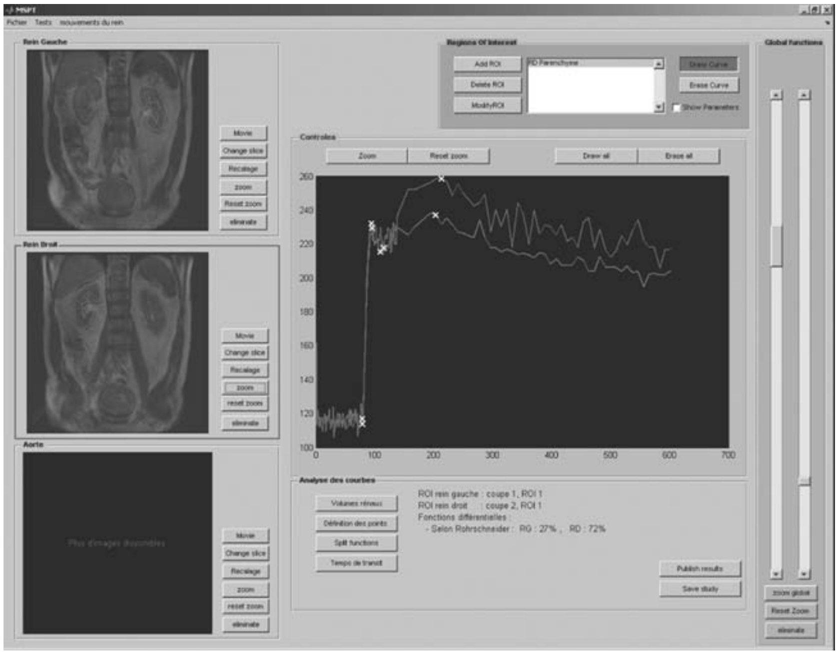
injection and a high temporal resolution, preferably below 1.5 sec, which can be achieved with fast acquisition techniques.

Signal–time curves are derived from regions of interest placed in the aorta and kidney. Various mathematic models have been evaluated; the choice of the appropriate one depends on the contrast agent used. Indeed, clinically available gadolinium compounds have an unlimited interstitial diffusion and are freely filtered through the glomerulus, theoretically requiring resort to a three-compartment model—notwithstanding that this third compartment, representing less than 10% of renal parenchyma, is usually neglected.

Other gadolinium chelates, known as rapid-clearance blood pool agents, have a higher molecular weight that limits their interstitial diffusion without compromising their glomerular filtration; thus, use of a two-compartmental model is possible without making any assumption. Moreover, conversion of signal intensities into concentration is easier because lower doses of gadolinium are injected thanks to their properties. With these gadolinium chelates, T1-weighted sequences are used, such as fast gradient echo with spoiler. T2-weighted sequences are used with ultrasmall particles of iron oxides (USPIO), which have no interstitial diffusion and are not excreted by the kidney. Thus, the central volume principle of Stewart and Hamilton can be applied: RBF = RBV$\times$ MTT, where RBF is the renal blood flow (mL/min/100 g), RBV is the renal blood volume, and MTT is the mean transit time. This is the way cerebral perfusion is evaluated.

Glomerular Filtration Rate

Evaluating or measuring GFR requires injecting a contrast medium that is excreted by the kidney. Semiquantitative approaches based on T1-weighted sequences have shown similar results to renal scintigraphy for parameters measured on signal–time curves, such as vascular upslope, time to peak, and area under the curve. Rohrschneider et al demonstrated that similar results could be obtained between dynamic T1-weighted contrast-enhanced MRI and scintigraphy in measuring split function in normal and pathologic conditions (Fig. 2) (6). Parenchymal signal–time curves begin with a vascular upslope corresponding to the arrival of the contrast medium in the vessels and the glomerulus, followed by a brief decrease and then by a second upslope corresponding to glomerular filtration and tubular function, until a peak preceding excretion. Once again, these curves can be converted into concentration–time curves thanks to phantom studies, allowing calculation of the GFR in the same way as is done with CT. However, accurate conversion of



Functional Renal Imaging. Figure 2 Screen capture from dedicated software designed to analyze split renal function using Rohrschneider's technique (From Grenier N, Basseau F, Ries M et al (2003) Functional MRI of the kidney. Abdom Imaging 28:164–175). ROIs are placed on the right (middle row) and left (upper row) kidneys. T (to be suppressed) Signs of nephropathy are more marked on the latter with decreased volume of parenchyma and sinus lipomatosis. Area under each curve during concentration upslope is calculated, and split renal function calculated by taken into account the ROI surface. In that case, area under the curve from the left kidney ROI (lower curve) is much smaller than that of the curve form the right-kidney ROI (upper curve), whereas time-to-peak are similar; indeed, left kidney participates only for 27% of the whole renal function. (Courtesy Pr Felblinger, IADI, INSERM Region Lorraine Universite de Nancy 1, Nancy, France)

signal intensities into gadolinium concentration remains a challenge. Thus, it would be preferable to work on 1/T1 measurements that are better correlated with the concentration than T1, but sequences that are fast enough are not yet available.

Functional Ventilation MRI

MRI technique for the assessment of lung ventilation with use of inhaled contrast aerosols, oxygen, hyper-polarised noble gases (Helium-3, Xenon-129), and fluorinated gases (sulphur-hexafluoride).

►Cystic Fibrosis

Fundoplication

This antireflux procedure is indicated in the surgical treatment of gastroesophageal reflux. The fundus is wrapped posteriorly around the distal esophagus and lower esophageal sphincter. The fundus is sutured anteriorly, making a complete 360° wrap (Nissen fundoplication) or incomplete 270° wrap (Toupet fundoplication) that lies below the level of the diaphragm.

▶Stomach and Duodenum in Adults Postoperative

Fungal, Abscess, Hepatic

Fungal abscesses are most often caused by Candida albicans, and they occur in immunocompromised individuals. They are a manifestation of disseminated fungal disease. Microabscesses often also involve the spleen. Hepatic abscesses caused by Cryptococcus infection and Aspergillus species have also been reported. Hepatic fungal microabscesses in immunosuppressed patients have a miliary distribution and appear as multiple small, often subcentimetric, lesions scattered throughout the liver. At US, four patterns of hepatosplenic candidiasis have been described. The US appearance of hepatic candidiasis in the initial phase is pathognomonic: the "wheel-within-a-wheel" sign consists in a central hypoechoic nidus of necrosis containing fungi surrounded by a hyperechoic zone represented by inflammatory cells and an outer hypoechoic halo corresponding to fibrosis. The second pattern has a "bull's-eye" appearance, due to the presence of a central echogenic area surrounded by a hypoechoic rim. The third pattern is the most commonly encountered at US and consists of uniformly hypoechoic nodules; however, it is the least specific. After therapy the lesions tend to decrease in size and increase in echogenicity, leading to the fourth pattern which consists of echogenic foci with variable degrees of posterior acoustic shadowing. At CT, fungal abscesses appear as multiple small, round lesions distributed in both lobes with low density on unenhanced and enhanced scans, but are better visualized after contrast material administration. These microabscesses usually show central enhancement, although peripheral enhancement may occur. At MRI, fungal abscesses show variable signal intensity. The untreated nodules are minimally hypointense on T1-weighted images before and after administration of contrast material and hyperintense on T2-weighted images. Treated lesions appear mildly hyperintense both on T1- and T2-weighted images and show contrast enhancement. A dark ring is usually seen around these lesions with all sequences.

Synonyms

Biliary lithiasis; Biliary stones

Definition

Solid particles that form from bile.

Pathology and Histopathology

Gallstones are a relatively common disorder. Women are more frequently affected than men. The prevalence increases with age in both sexes. There are two types of gallstones: cholesterol stones and pigment stones. About 80% of gallstones are mainly composed of cholesterol, with only a small percentage being pure cholesterol. Cholesterol stones often contain alternating layers of cholesterol crystals and mucin glycoproteins. The main component of pigment stones is calcium bilirubinate. Pigment stones are divided into black and brown stones. Black pigment stones consist of polymers of bilirubin, with large amounts of mucin glycoproteins, are hard and are more common in patients with cirrhosis or chronic hemolytic conditions. Brown pigment stones are made up of calcium salts of unconjugated bilirubin, with variable amounts of protein and cholesterol, and are friable; they primarily originate within the intrahepatic bile ducts and are usually associated with infection. They often occur in

Asians (1). Cholesterol is virtually insoluble in aqueous solutions, but in bile it is made soluble by association with bile salts and phospholipids forming mixed micelles and vesicles. The pathogenesis of biliary stones is principally related to supersaturation of bile constituents. Stone formation most often results from increased biliary cholesterol concentration, but may also be due to decreased bile acid synthesis or a combination of both mechanisms (2). Gallbladder dysmotility probably plays a role, too. These factors may be aggravated by a genetic predisposition, diet, and an inactive lifestyle. Additional risk factors for cholelithiasis include obesity, diabetes, use of oral contraceptives, ileal disease, use of certain medications, and total parenteral nutrition (3).

In the majority of the cases, stones develop in the gallbladder (cholelithiasis); afterwards they can migrate into the bile duct. These bile duct stones are called secondary stones. However, more likely they cause bile stasis, which promotes their growth and the formation of additional primary bile duct stones. Biliary stones are also considered to be primary in the rare setting of gallbladder agenesis and in the case of bile duct stones that are diagnosed many years after cholecystectomy.

Gallstones can be of any size and number. Small stones are more likely to migrate and cause symptoms. Extremely tiny sand-like stones form the so-called ►biliary sludge.

The most common complication of cholelithiasis is acute cholecystitis, which occurs when a stone obstructs the cystic duct. Further complications of cholelithiasis include choledocholithiasis, acute pancreatitis, duodenitis, biliary fistula, gallstone ileus, and ►Mirizzi syndrome. Cholelithiasis is found in about two thirds of patients with gallbladder carcinoma and is frequently associated with chronic cholecystitis, suggesting that chronic irritation is a causative factor.

Clinical Aspects

Most patients with gallstones are asymptomatic. Typical symptoms include recurrent right upper quadrant or epigastric pain which can radiate to the angle of the scapula and the right shoulder. Biliary pain generally lasts several hours and is triggered by food intake. Sometimes the pain gets chronic. Patients with acute cholecystitis present with severe abdominal pain, nausea, vomiting, fever, and leukocytosis. Less commonly, gallstones migrate in the common bile duct and may cause pain, cholestasis, and cholangitis. A severe complication of gallstones is acute pancreatitis, due to obstruction of the main pancreatic duct. Sludge and microscopic stones may also cause acute pancreatitis (2).

Patients with intrahepatic stones generally have a prolonged history of recurrent complaints of abdominal pain, fever, chills, and jaundice (1).

Imaging

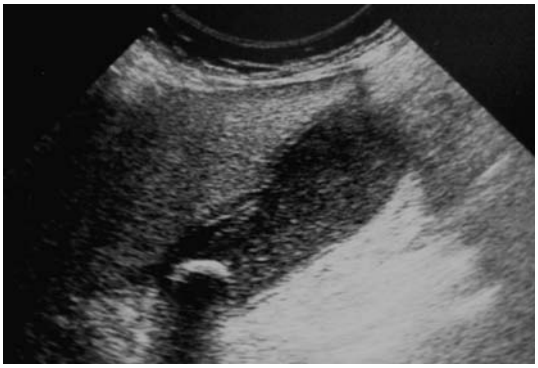
Gallbladder Stones

Plain radiography does not represent a useful tool in detecting gallstones, because only 15–20% are visible on plain radiographs, due to their calcium content. Oral cholecystography has been the only diagnostic tool for gallbladder lithiasis for decades. Currently, oral cholecystography is obsolete, while ultrasonography (US) is the method most often used to detect cholelithiasis and associated complications, such as acute cholecystitis (2, 3).

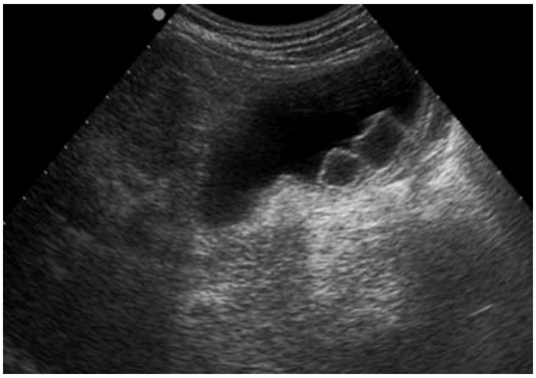
Oral cholecystography has a sensitivity close to that of US in detecting gallbladder stones and is even superior in determining the number and size of stones, which appear as filling defects within the opacified gallbladder; it is able to demonstrate cystic duct patency and to provide information about gallbladder contractility, evaluated after a fatty meal. However, US has the advantage of allowing adjacent organs to be explored, providing visualization of the gallbladder and its content, also when it is excluded on the cholecystograph, and being noninvasive. US also allows a functional evaluation of the contractility of the gallbladder after a fatty meal. The nonvisualization of the gallbladder on oral cholecystography may be due to absorption of contrast material through an inflamed gallbladder wall or due to obstruction of the cystic duct. Nevertheless, a normal gallbladder may fail to be visualized in the case of gastric outlet obstruction or poor absorption of the oral contrast agent by the gut (2).

Noninvasive US is the method of choice for the detection of gallstones, providing high sensitivity and accuracy (>95%). US is able to detect stones larger than 1–2 mm in diameter. Typically, gallstones appear as highly echogenic masses with a hypereflective echo from the anterior surface and a marked posterior acoustic shadowing. Usually, the mobility of gallstones can be demonstrated by repositioning the patient, although they may occasionally be adherent to the wall of the gallbladder. The presence of posterior acoustic shadowing is very specific because nonshadowing structures rarely represent gallstones. The finding of the so-called wall-echo-shadow triad is characteristic of a contracted gallbladder filled with stones. The wall of the gallbladder, next to the transducer, is echogenic; below this a thin, anechoic line of bile may be visible; finally, there is a highly echogenic line representing the surface of superficial stones with associated posterior shadowing. The deeper stones and the deeper gallbladder wall are not visible, being obscured by the acoustic shadow (3). In addition, US can rule out other causes of right upper quadrant pain, can show associated bile duct dilatation, suggesting the presence of common bile duct stones, and can demonstrate signs of acute cholecystitis. US can also detect ▶biliary sludge in the gallbladder, which appears as hypoechoic material usually without acoustic shadowing, forming a layer in the dependent portion of the gallbladder and shifting slowly with positioning (Figs. 1–2) (2).

Computed tomography (CT), endoscopic retrograde cholangiopancreatography (ERCP), and magnetic resonance cholangiopancreatography (MRCP) play a minor role in the primary detection of gallbladder stones. Nevertheless, in studies performed for other reasons cholelithiasis is a common finding. Furthermore, these examinations may be necessary in the assessment of complications such as acute cholecystitis, pancreatitis, choledocholithiasis, and biliary obstruction (3).



Gallstones. Figure 1 Gallbladder stone, sludge, and cholecystitis. Ultrasound demonstrates a large stone in the infundibulum typically appearing as a highly echogenic mass with a hypereflective echo from the anterior surface and a marked posterior acoustic shadowing. Biliary sludge appears as hypoechoic layer without acoustic shadowing. Inflamed gallbladder wall is thickened and shows a multilayered aspect.



Gallstones. Figure 2 Cholesterol gallstones. At ultrasound, cholesterol stones in the gallbladder appear hypoechoic without posterior shadowing.

Extrahepatic Bile Duct Stones

The recognition of choledochal calculi before and after cholecystectomy for cholelithiasis is a crucial clinical issue. Common bile duct stones can be demonstrated at US, but this technique has low sensitivity. US can demonstrate dilatation of the common bile duct which may suggest choledocholithiasis; however, in patients after cholecystectomy, the biliary duct caliber is not a useful predictor of bile duct lithiasis since the diameter of the extrahepatic duct can rise up to 10 mm overtaking the reservoir function of the former gallbladder (Fig. 3). ERCP allows identification of choledochal stones, appearing as mobile, round, and filling defects, with high accuracy and offers the possibility of interventional removal of calculi. Nevertheless, ERCP is an invasive technique with a relatively high incidence of complications; currently, this procedure is performed solely with an interventional purpose. Purely diagnostic ERCP should be avoided by using less invasive diagnostic imaging modalities, such as MRCP, unenhanced spiral CT, or CT cholangiography with intravenously or orally administered contrast agents. Among these, MRCP is evolving as the most accepted technique, because it is noninvasive, without need for administration of contrast material, and generally provides excellent image quality. The sensitivity of MRCP in the diagnosis of choledocholithiasis is more than 90%. According to numerous studies, the diagnostic accuracy of MRCP for the evaluation of choledocholithiasis is comparable to that of ERCP (1, 3–5).

US has low sensitivity and specificity in demonstrating stones in the main bile duct, since the normal caliber

Gallstones. Figure 3 Extrahepatic bile duct stone. Ultrasound is able to detect very small calculi (few millimeters). Small stone (arrow) obstructing the main bile duct, which appears dilated above the level of blockage.

and the presence of meteorism may limit the display of the extrahepatic bile tract.

Spiral CT may be an adequate diagnostic alternative to MRCP in patients in whom MR is contraindicated. Unenhanced thin-section scans may demonstrate choledochal stones, especially if they are calcified. However, the sensitivity of this technique is limited by the high frequency of false-negative results in the case of stones which are isoattenuating to bile. CT cholangiography seems to be as sensitive as MRCP in depicting choledocholithiasis. The high attenuation of bile achieved with cholangiographic contrast agents increases the detection of stones, which appear as filling defects. The maximum intensity projection (MIP) algorithm is routinely used both for MRCP and for CT cholangiography. A limitation of CT cholangiography is the insufficient opacification of bile ducts that may occur in patients with elevated bilirubin levels or liver insufficiency (in general a contraindication for the application of cholangiographic contrast agents) (4).

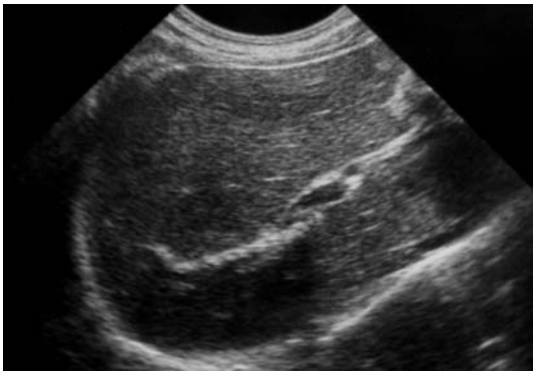
A possible source of false-positive results at MRCP is the presence of intraductal air, which may be abundant in patients with biliary-enteric anastomoses or after ERCP. On MR images, air is hypointense and may mimic stones on MR cholangiograms acquired in a coronal or oblique plane. In these cases, axial images can solve the diagnostic problem because air is located in nondependent portions of the bile duct, whereas calculi tend to be located in dependent positions. CT in the axial acquisition plane offers advantages in such cases because the negative attenuation of air differs clearly from that of stones. Some limitations are common to both CT cholangiography and MR cholangiography. For example, filling defects such as sludge may be the source of false-positive interpretations and affect the specificity of both techniques (1, 4).

Intrahepatic Bile Duct Stones

US has a limited role in the evaluation of the intrahepatic biliary tree, which can only be visualized when dilated. Intrahepatic calculi may be visualized as strongly hyperechoic lesions with or without shadowing (Fig. 4).

Intrahepatic stones can be depicted on unenhanced CT, but the detection rate is not sufficient because pigmented stones are sometimes not sufficiently hyperattenuating to be visible on CT. Therefore, MRCP is currently the most suitable noninvasive modality in diagnosing intrahepatic biliary stones.

In particular, MRCP seems to be superior to ERCP. Opacification of peripheral intrahepatic bile ducts with ERCP may be difficult in patients with intrahepatic calculi because of the common association of severe ductal strictures. Forced injection of contrast material may be required, but this increases the risk of cholangitis. In addition, an air block may also be a factor in patients with intraductal air hindering adequate contrast injection. In contrast, MRCP is able to depict the entire biliary tract and is very accurate in the identification of intrahepatic stones and associated biliary strictures. MRCP can also detect other associated abnormalities, such as perihepatic biloma or free fluid in the perihepatic spaces. Furthermore, a study of the liver parenchyma with an adequate MR protocol can be performed in the same MRCP session in order to identify malignant processes that can be associated with intrahepatic stone disease (1). Percutaneous transhepatic cholangiography (PTC), performed by injecting contrast material after percutaneous catheterization of an intrahepatic bile duct, allows a good depiction of peripheral bile ducts, but it is an invasive procedure and is used in most centers only as an interventional procedure.



Gallstones. Figure 4 Intrahepatic bile duct stones. Ultrasound shows a line of strongly hyperechoic spots, corresponding to small stones impacted in the intrahepatic bile ducts.

Nuclear Medicine

Cholescintigraphy, performed with 99m-technetium-labeled iminodiacetic acid, which is excreted into the bile, has a high sensitivity and specificity for acute cholecystitis, but it cannot provide anatomical information and cannot identify gallstones (2). Since the diagnosis of acute cholecystitis in general combines clinical and US findings, nuclear medicine studies are no longer necessary.

Interventional Radiology

Cholecystectomy is the standard treatment for gallbladder stones; nevertheless, in selected cases interventional radiology may be useful in the management of cholelithiasis. Several interventional procedures have been developed for the treatment of gallbladder stones. Among these, percutaneous cholecystostomy and percutaneous contact dissolution currently play a clinical role. Percutaneous cholecystostomy is usually performed in acute cholecystitis in patients at high surgical risk in order to obtain decompression of the gallbladder. Stone extraction may also be performed. US or fluoroscopy after orally administered contrast medium allows visualization of the gallbladder and guides the procedure (3). Cholesterol gallstones can be rapidly dissolved by direct instillation of solvents into the gallbladder through a transhepatic percutaneous catheter. Even if this procedure is usually performed under US guidance, severe complications including death due to systemic effects of the solvent agent are described (2).

Currently, ERCP should be performed only as an interventional procedure for removing common bile duct stones previously detected with noninvasive imaging techniques, mainly MRCP. The first interventional step is papillotomy or sphincterotomy, to widen the opening of the common bile duct into the duodenum by means of an electrocautery cutting instrument inserted into the papilla. Stones can subsequently be removed with balloons or baskets. Sphincterotomy may be complicated with perforation, pancreatitis (ca. 5%), cholangitis, and bleeding. Complications in sphincterotomy are particularly frequent if the common bile duct is not dilated. ERCP is often unsuccessful in removing stones larger than 2 cm in diameter from the common bile duct (2).

Radiological interventions also play a role in the treatment of intrahepatic stones, particularly in patients with clinical manifestations of cholangitis. After percutaneous drainage, stones can be removed by means of a small-caliber endoscope or using baskets under fluoroscopy guidance (1).

In complicated cases, rendezvous maneuvers combining radiological and endoscopic techniques can be helpful.

Diagnosis

US is the method of choice in the diagnosis of cholelithiasis and its associated complications, particularly acute cholecystitis (2, 3). However, among noninvasive techniques, MRCP is gaining wide acceptance and is becoming the modality of choice in the diagnosis of choledocholithiasis (4, 5). Furthermore, MRCP is currently the most suitable modality in diagnosing intrahepatic biliary stones (1).

Therefore, even if ERCP has been the standard of reference for the detection of common bile duct stones, this invasive procedure should currently be performed solely with an interventional purpose.

jm-bruel@chu-montpellie fr

The radiology of the gastrointestinal (GI) tract is a part of gastrointestinal and abdominal radiology, which is one of the recognized subspecialty areas of radiology where the advances have been and are the greatest and fastest. These advances concern both the diagnostic and the interventional imaging, and give GI imaging a profound impact on patient management.

In diagnostic imaging, gastrointestinal imaging has been focused for many years on barium studies, performing a highly precise, but indirect evaluation, by moulding (single contrast studies) or coating (double contrast studies) the endoluminal patterns of the bowel wall. Nowadays, if barium studies remain essential for evaluating the function of GI tract, the cross-sectional imaging techniques depict both the GI structures and the digestive tract surroundings; the improvement of 3D techniques results in the virtual endoscopy. In these conditions, the pattern approach of GI imaging has been greatly altered from an indirect analysis (filling defect and narrowing of the digestive lumen, projection of the lumen out of the GI wall, deformation of the lumen, increasing of well-defined peridigestive spaces…) to a direct evaluation of the segments of the alimentary tract (digestive lumen, GI wall itself and the peridigestive fat, vessels, lymph nodes, and organs).

Interventional imaging techniques become pivotal in current clinical conditions: pathological or microbiological studies after image-guided biopsy or sampling, drainage of peridigestive abscesses, digestive stenting.

Through the neck, chest, and abdomen, GI tract includes, in a cranio-caudal way:

- Pharynx and oesophagus
- Stomach and duodenum
- Small bowel including jejunum and ileum
- Colon and rectum

The GI tract surroundings are a main part of the anatomy of the digestive tract, especially within the peritoneal cavity where peritoneal reflections, ligaments, recesses, and mesenteries are basic to an understanding of the GI tract anatomy, inflammatory and neoplastic changes, and the spread and localization of the disease.

Imaging of the Gastrointestinal Tract: A Pattern Approach

The *location and gross morphology* of GI tract segments depend on the normal anatomy and variants. They may be altered by congenital (malrotation, duplication cysts, Meckel's diverticulum) or acquired abnormalities (hernias, bowel obstruction, postoperative appearance of the gut).

The main imaging pattern of GI tract abnormality is the *bowel wall thickening*. The criteria of this thickening need to be analyzed carefully: number, location, transition zones with the normal bowel wall, pattern of attenuation, degree of thickening, symmetric versus asymmetric thickening, focal versus segmental or diffuse involvement, ulcers, and perienteric abnormalities. A focal thickening may expand within the lumen or out of the bowel wall. A filling defect may be caused either by a lesion of the gastrointestinal wall expanding into the lumen or by an intraluminal structure.

A *local defect of the bowel wall* communicating with the lumen could affect only the inner layers of the bowel wall, or spread through all the layers within the mesenteric fat, the peritoneal cavity, or an adjacent organ. These defects may be demonstrated by their content: gas, or positive contrast after opacification either by barium or iodinated contrast media. Such defects could be related to a diverticulum or pseudodiverticulum, an ulcer, a perforation, a sinus tract, or a fistula.

Perienteric abnormalities concern the mesenteric fat, the ligaments and reflections of the peritoneum, the peritoneal cavity and its recesses, the mesenteric lymph nodes. These inflammatory or neoplastic abnormalities may be in reaction to a digestive tract lesion or related to a primitive disease of the peritoneum or mesenteries structures.

Esophageal and gastrointestinal motility disorders may be related to inefficient hypermotility, contractions and spasm, stasis and distention, aperistalsis. Distension may affect bowel loops proximally to an obstruction or be related to a loss of digestive wall contractility (localised ileus and intestinal pseudoobstruction). Abnormal contraction may cause a pseudoneoplastic thickening of the GI wall on nondynamic cross-sectional imaging, and is better evaluated by barium series. Esophageal and gastrointestinal motility disorders concern the swallowing disorders, the oesophageal motility disorders, the gastroesophageal reflux, the GI tract distension, the colorectal function disorders.

Gastroschisis

A congenital defect of the abdominal wall musculature allowing abdominal contents to herniate outside the abdomen with no peritoneal covering.

▶GI Tract, Paediatric, Congenital Malformations

Gated-SPECT

Gated-single photon emission computed tomography (SPECT) is a technique in which the electrocardiographic signal is used as a trigger during image acquisition, giving the option to provide data with respect to global ejection fraction and regional wall motion and thickening in addition to perfusion images. The combination of these results gives the clinician better information for optimal risk stratification.

▶Ischemic Heart Disease, Nuclear Medicine

Gaucher Disease

Lysosomal storage disease caused by lack of the enzyme glucocerebrosidase. Glucocerebrosides accumulate in the spleen. Hepatosplenomegaly is usually present, and splenic nodules are described (hyperechoic or hypoechoic).

▶Congenital Malformations, Splenic
▶Diffuse Infiltrative Disease, Hepatic

Gelatinous Carcinoma

▶Carcinoma, Other, Invasive, Breast

Gene Delivery System

▶Local Drug and Gene Delivery with Microbubbles

Gene-delivery System

A gene-delivery system consists of microbubble contrast agents usually with a lipid shell, containing genes in the form of oligodendronucleotides. After local destruction of the microbubbles, the gene fragments are incorporated into the nuclear DNA of the cells. Instead of genes, antisense molecules can be used to block the activity of endogenous genes. The transport of the nucleotides into the cells is facilitated by sonoporation, an effect causing the transient formation of micropores in the capillary vessels.

▶Contrast Media, Ultrasound, New Clinical Development

Gene Therapy

Gene therapy can be defined as the transfer of defined genetic material to specific target cells of a patient for preventing, altering, or treating of diseases.

Definitions

Nonneoplastic abnormalities of the male and female genital tract which are not caused by chromosomal conditions.

Pathology

Male Genital Organs

Cryptorchidism. At birth, undescended testes are found in 3% of term infants and in 33% of preterm newborns weighing less than 2,500 g. Testicular migration can stop anywhere along the course from the retroperitoneum to the scrotum. Cryptorchidism is thought to be caused by a disturbance of local factors or an anomaly of the hypothalamic-pituitary-testis axis. About 90% of undescended testes are located in the inguinal canal, with the remaining 10% located in the abdomen. An undescended testis has an increased risk of malignancy and can lead to infertility. Cryptorchidism may be bilateral in about 10% of cases. Very rarely, the missing testis is ectopic and can be found in the perineum, in the contralateral hemiscrotum, or at the base of the penis.

Acute scrotum is secondary to several causes: torsion of the testis, torsion of a testicular appendage, orchitis and epididymitis, idiopathic scrotal edema, and incarcerated hernia.

Torsion of the testis is caused by the testis and the spermatic cord twisting on their axis, causing obstruction of blood flow. Two types are known: intravaginal torsion, most common in adolescents, and extravaginal torsion which is observed in newborns and usually occurs *in utero*. In most cases, intravaginal torsion is associated with an abnormal development of the tunica vaginalis which completely surrounds the testis, epididymis, and caudal part of the spermatic cord (so that there is no posterior attachment to the scrotum) allowing the testis to twist within.

Intravaginal torsion requires surgical detorsion within 6 h of onset of symptoms: after 12–24 h only 20% of testes recover, whereas after 24 h the testis is unsalvageable in most cases. Extravaginal torsion *in utero* usually leads to a necrotic or atrophic testis.

The testicular appendages (appendix testis and appendix epididymis) are remnants of mesonephric tubules. Both appendices are pedunculated and may twist, especially in prepubertal boys.

Acute *orchiepidydimitis* is commonly secondary to infections caused by *Escherichia coli*, and—in sexually active boys—by *Chlamydia trachomatis* and *Neisseria gonorrhoeae*. More rarely, bladder outlet obstruction or genitourinary malformations (ectopic ureter ending in the vas deferens or seminal vesicles) may cause urine reflux leading to orchiepidydimitis.

Idiopathic scrotal edema is characterized by enlargement and thickening of the wall of one of both hemiscrota. Its cause is unclear.

Inguinal incarcerated hernia may compress the spermatic cord and cause infarction of the testis.

Varicocele is the dilatation of the veins of the pampiniform plexus of the testis. Varicocele can be idiopathic—usually on the left side—or secondary to increased intra-abdominal pressure by a retroperitoneal mass. Most varicoceles in adolescents are idiopathic and are usually caused by incompetent valves in the internal spermatic vein causing blood reflux in the pampiniform plexus. Varicocele may cause ipsilateral hypotrophy of the testis and infertility.

Rare conditions. Cystic dysplasia of the rete testis is a rare abnormality often associated with ipsilateral agenesis of the kidney. This malformation is due to a developmental defect of the mesonephric duct which is the cause of both the dilation of the testicular rete testis and renal agenesis. *Cysts of the seminal vesicles* represent another very rare malformation whose etiology is caused by an abnormal development of the mesonephric or wolffian duct, which can be associated with abnormal development of the ipsilateral upper urinary tract.

Female Genital Organs

Embryology. Two pairs of genital ducts develop in both sexes: the mesonephric or wolffian ducts, which connect the mesonephros to the cloaca, and the paramesonephric or müllerian ducts. The ureteric bud originates at 5 weeks of gestational age and reaches the metanephros inducing its differentiation into the kidney. The müllerian ducts are lateral to the mesonephric ducts, develop at 6 weeks' gestational age and at about 7–8 weeks fuse to form the uterovaginal canal that reaches the urogenital sinus at the müllerian tubercle. The urogenital sinus develops from the separation of the cloaca into the urogenital sinus and rectum. At the same time the vagina proliferates and subsequently undergoes canalization, becoming patent (hymen excluded) at about 22 weeks of gestation. Graaf's follicles first appear in the seventh month of gestation. The feminization of both fetal internal and external genitalia is largely a nonhormonal process. As the genital system develops in association with the urinary system, up to 50% of females with abnormalities of the genital tract are also affected by urinary abnormalities (1).

Uterovaginal Malformations

Uterovaginal anomalies can be classified into three groups according to faulty embryological steps.

Müllerian agenesis. The *Mayer–Rokitansky–Küster–Hauser syndrome* (MRKHS) is a condition caused by a developmental defect of the caudal portion of the müllerian duct. Type A (typical form) is characterized by no vagina or uterus and normal external genitalia; the fallopian tubes, ovaries, and kidneys are normal. In type B (more rare), the uterus may be normal except for the lack of a conduit to the *introitus*, or may be rudimentary with aplasia of one or both uterine horns, or asymmetrical horns; however, any of the lateral or vertical fusion abnormalities may be seen. The fallopian tubes are hypoplastic or absent. Absent or streak ovaries, or inguinal hernias containing an ovary, have been reported. Associated malformations are found in the upper urinary tract, skeletal system, and spina. The karyotype is normal.

Disorders of lateral fusion. Failed unilateral development of a müllerian duct causes a unicornis uterus with or without a rudimentary horn uterus. Complete failure of fusion of the müllerian ducts results in a didelphys uterus, whereas partial failure results in a bicornuate or in a bicornis bicollis uterus. Failure of resorption of the midline septum results in a septate uterus.

Disorders of vertical fusion. The interruption of fusion can occur at any level and may be multiple; high transverse vaginal septa are more common, whereas middle and low transverse septa are rarer. Imperforated hymen is not a disorder of vertical fusion and it is caused by the persistence of the central epithelial cells of the urogenital diaphragm; it is not associated with other abnormalities.

From a practical point of view, it is preferable to consider vaginal anomalies according to the presence or absence of obstruction, as the association between anomalies of vertical and lateral fusion is frequent. Obstructive vaginal anomalies are: imperforated hymen, transverse vaginal septum, obstruction of a rudimentary horn, atresia of the uterine cervix, and vagina. Nonobstructive vaginal anomalies are: longitudinal vaginal septum and incomplete transverse vaginal septum (2, 3).

Nonneoplastic Ovarian Masses

Cysts. Follicular cysts account for about 70% of ovarian masses in children. In newborns they are a consequence of maternal hormonal stimulation *in utero*. In postmenarchal girls, cysts are caused by a Graafian follicle which

G

continues to grow after a failed ovulation or when a corpus luteum does not involute after ovulation: they often have a complete involution within a few menstrual cycles.

Ovarian torsion. Ovary torsion may occur in an adnexum containing a cyst (typically in newborns) or a tumor. In young girls it usually occurs in a normal ovary.

Disorders of Puberty

Precocious puberty. It is defined as the development of secondary sexual characteristics (breast tissue, pubic and axillary hair, external genitalia, and menses) before 8 years of age. Most cases are the result of idiopathic activation of the hypothalamic-pituitary-gonadal axis (central or true isosexual precocity), or increased estrogen levels with low gonadotropin levels, in most cases caused by an autonomous follicular cyst (peripheral pseudosexual precocity), or increased level of androgens (premature adrenarche). The remaining cases are the result of hypothalamic or pituitary gland lesions and adrenal or ovarian tumors.

Amenorrhea. Primary amenorrhea is defined as the failure of menstruation by 16 years of age, or no thelarche nor adrenarche by 14 years of age, or no menarche more than 3 years after adrenarche and thelarche. The causes include hypothalamic and pituitary lesions, androgen-producing tumors, and abnormalities of the ovary (gonadal dysgenesis, polycystic ovary), the uterus (absence or hypoplasia), or the vagina (imperforate hymen, atresia) (2, 3).

Clinical Presentation

Male Genital Organs

Acute scrotum is a condition characterized by scrotal swelling and acute pain. Torsion of the testis, torsion of a testicular appendage, idiopathic scrotal edema, and orchitis and epididymitis show very similar clinical features. However, these conditions require a very different treatment: immediate surgery is needed for testicular torsion, whereas medical treatment is usually adequate for orchitis and epididymitis, torsion of testicular appendages, and idiopathic scrotal edema. The differentiation between these conditions on the basis of clinical findings only may be extremely difficult: therefore, ultrasound (US) with color Doppler sonography (CDS) is mandatory.

Small *varicoceles* can be detected only by palpation, whereas large varicoceles appear as multiple serpiginous structures in the hemiscrotum. A varicocele may become more evident during erect position or Valsalva's maneuver.

Rare conditions. Cystic dysplasia of rete testis may cause an asymptomatic scrotal mass, whereas a cyst of the seminal vesicles usually presents in adulthood with oligozoospermia, hemospermia, and urinary complaints.

Female Genital Organs

Uterovaginal malformations. Patients with MRKHS have normal external genitalia and secondary sexual development and present with primary amenorrhea or cyclic lower abdominal pain. Neonates with vaginal obstruction may present with a palpable pelvic or abdominal mass caused by the accumulation of secretions secondary to maternal hormone stimulation, whereas adolescent girls present with amenorrhea, recurrent lower abdominal pain, or a lower abdominal mass. Most patients with uterine anomalies present with amenorrhea, dysmenorrhea, or hematometra; after the second decade of life, infertility and abortion are common.

Ovarian cysts and ovarian torsion. Lower abdominal pain is a common finding; in a few cases a large cyst may cause excessive estrogen production and be responsible for precocious puberty. Up to 30% of cysts may undergo torsion. Acute abdominal pain is the main symptom in young girls, whereas in newborns torsion may be asymptomatic. Usually, neonatal ovarian cysts are initially detected during pregnancy by routine US and can twist *in utero*.

Imaging

Male Genital Organs

US is the primary imaging method for evaluating the scrotum and its content. The association with CDS studies allows the evaluation of both morphology and perfusion. Scrotal US is performed with a high-frequency linear array transducer (10 MHz and above) to maximize resolution of the scrotal contents. To improve the sensitivity a dedicated CDS setting (high frequency is necessary) is mandatory.

Female Genital Organs

Transabdominal US is the study of choice for girls with suspected anomalies of the genital tract. The urinary bladder should be distended to serve as an acoustic window, but not overfilled: overfilling may compress the uterus modifying the uterine shape and thus the fundus/cervix ratio. US is usually performed with 5–7-MHz sector transducer, although 3.5 MHz can be used in large patients. In newborns, high-resolution linear probes (10 MHz and above) are also very useful. Scans of the uterus and vagina are obtained in both the sagittal and transverse planes, and then the transducer should be angled to obtain views of all axes of both ovaries. Instillation of fluid into the bladder and rectum can help in detecting absence of the vagina and uterus.

MRI should be performed in cases of congenital malformations to define further the anatomy of the anomaly. MRI examinations should include axial, sagittal, and coronal T1- and T2-weighted sequences using phased array or surface coils to allow the highest resolution possible. Fat saturation sequences are useful in highlighting the anatomic structures.

Diagnosis

Male Genital Organs

Normal findings. On US, the testis is seen as ovoid-shaped and with a medium and uniform echogenicity. Echogenicity tends to increase with age until puberty; at puberty a slightly nonhomogeneous echogenicity can be observed sometimes. The hilum of the testis appears as a linear echogenic structure along the superoinferior axis. The epididymis lies on the upper pole of the testis, it is triangular, and its echogenicity is similar to that of the testis. With current US equipment, flow within testicular arteries is seen in virtually all testes. The normal epididymis shows minimal flow with CDS.

Cryptorchidism. US is the diagnostic tool of choice to detect a nonpalpable testis lying in the inguinal canal (sensitivity about 90%, specificity 100%). The undescended testis may appear hypotrophic in comparison with the contralateral testis. US is restricted to detecting testes located in the abdomen. MRI can be performed in such cases, but usually it is not performed as it requires sedation or anesthesia, and a surgical approach is necessary anyway.

Acute scrotum. In intravaginal testicular torsion, the US examination may show an abnormally enlarged and twisted testicular cord and the testis, which is suspended in the scrotum like "a clapper in a bell." US findings differ in relation to the duration of torsion. After the very first hours from the onset of torsion, on gray-scale US the testicular structure appears normal. After 4–6 h, edema causes testicular swelling and the testis appears hypoechoic. After 24 h, the testicular structure becomes heterogeneous because of hemorrhage and ischemia. Other common findings are an abnormal orientation of the testis within the scrotum, an enlarged epididymis, reactive hydroceles, and scrotal wall thickening. At the onset, an acute torsion can be easily confirmed with CDS if blood low is detected in the contralateral asymptomatic testis and absent in the painful testis. Partial torsion may cause reduced flow in comparison with the asymptomatic testis. Reactive hyperemia—mimicking epididymo-orchitis—may be observed in cases of spontaneous detorsion: however, the combination of spontaneously resolved pain and hyperemia should suggest the right diagnosis. Sometimes the differential diagnosis is not so evident and caution is recommended before excluding torsion. In inveterate torsion (more than 24 h), typical findings on CDS are hyperemia of the scrotal wall and paratesticular tissues with absent testicular flow. In extravaginal torsion, US findings range from an enlarged heterogeneous testis–in cases of recent torsion—to a minimally enlarged or normal sized testis with peripheral echogenicity due to calcifications in the tunica albuginea. Scrotal wall thickening and hydroceles are not uncommon. On CDS, flow is absent.

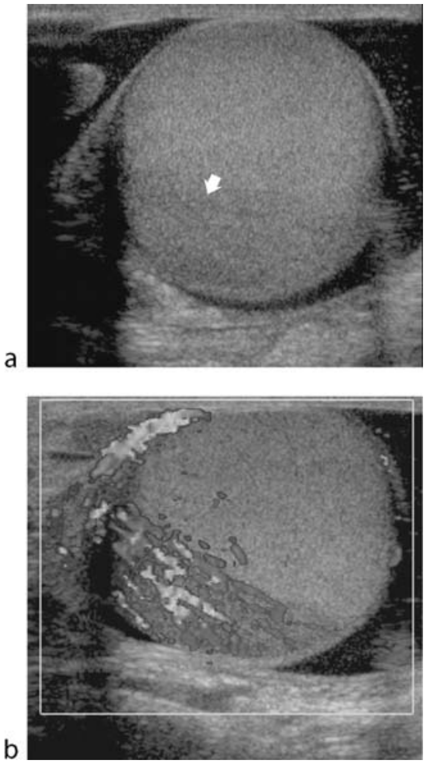
On US, a twisted testicular appendage, when detectable, appears as a small hypoechoic or hyperechoic mass close to the superior aspect of the testis or epididymis. Epididymal and testicular hypoechogenicity with enlargement, hydroceles, and scrotal wall thickening are commonly associated. CDS imaging often shows epididymal hyperemia and the avascular torsed appendage. Associated testis hyperemia is not uncommon. The differential diagnosis with epydydimo-orchitis may be difficult. Twisted appendages may eventually calcify and break free to become scrotoliths.

On US, epididymitis is characterized by an enlarged hypoechoic or hyperechoic epididymis with increased blood flow. Testicular involvement, which occurs in about 20% of cases, appears as increased size and reduced echogenicity. Rarely, secondary focal orchitis can be observed: focal lesions appear as hypoechoic areas close to the inflamed epididymis (Fig. 1).

In idiopathic scrotal edema there is thickening and often hyperemia of the scrotal wall with a normal testis and epididymis (4).

Varicocele. On US, it is characterized by tortuous and enlarged veins of the pampiniform plexus (range: 3–4 to 7 mm; normal maximum size of an individual vein: 2 mm in prepubertal boys, 3 mm in adolescents). The enlarged veins increase in size during Valsalva's maneuver or in erect position. CDS shows blood reflux into the pampiniform plexus very well; the US probe should also be placed on the ipsilateral groin with the patient standing erect in order to precisely assess blood reflux in the distal spermatic vein. Phleboliths may develop in long-standing varicoceles; ipsilateral testicular hypotrophy is not uncommon.

Other conditions. On US, cystic dysplasia of the rete testis is characterized by multiple tubular and cystic dilatations of the rete testis, often associated with absence of the ipsilateral kidney. On US, cysts of the seminal vesicles may be variable in size and, not unlike cystic dysplasia of the rete testis, ipsilateral kidney agenesis is often present.



Genital Tract. Figure 1 **Focal orchitis. (a) Enlarged testis with a hypoechoic area inside (*thick white arrow*). (b) Color Doppler sonography: hyperemia of the involved area.**

Female Genital Organs

US Findings

Normal uterus, vagina, and ovaries: The normal neonatal uterus is a tubular structure with the anteroposterior diameter of the cervix equal or slightly greater that of the fundus. The mean length is 3.4 cm, (range 2.3–4.6 cm), the mean fundal width 1.2 cm (range 0.8–2.1 cm), and the mean cervical width 1.4 cm (range 0.8–2.2 cm). The endometrial lining is often echogenic. In infants the uterus regresses in size, with the width of the fundus equal or slightly smaller than that of the cervix. From infancy until about 7 years of age, uterine length and width do not change: the length range is from 2.5 to 3.5 cm, whereas fundus and cervical width is from 0.5 to 1 cm. The endometrial canal is usually not visualized. After 7 years of age, the uterus increases in length and width, with the corpus growing more than the cervix. Finally, at puberty the uterus becomes pear-shaped with the fundus larger than the cervix; after puberty it measures 5 to 8 cm in length, 1.5 to 3 cm in maximum anteroposterior diameter, and 3.5 cm in width. The endometrial lining is seen and varies according to the phases of the menstrual cycle. The vagina appears as a tubular structure with a hypoechoic wall (5).

Ovarian size is determined by assessment of the volume according to the formula $V = 1/2\ length \times width \times depth$. Volume is slightly grater than 1 cm^3 for the first year of life and 0.67 cm^3 for the second year. The mean ovarian volume is less than or equal to 1 cm^3 in girls under 6 years of age, and then it starts increasing. In prepubertal girls (6–10 years), volume ranges from 1.2 to 2.3 cm^3, in premenarchal girls from 2 to 4 cm^3. In postmenarchal girls, the volume averages 8 cm^3 (range 2.5–20 cm^3). Normal microcystic follicles are easily seen from birth to 12 years of age (3).

Congenital anomalies of the uterus and vagina: At US, patients with MRKHS shows absence of the vagina and an absent or small uterus. Unilateral kidney anomalies can be observed in 50% of cases.

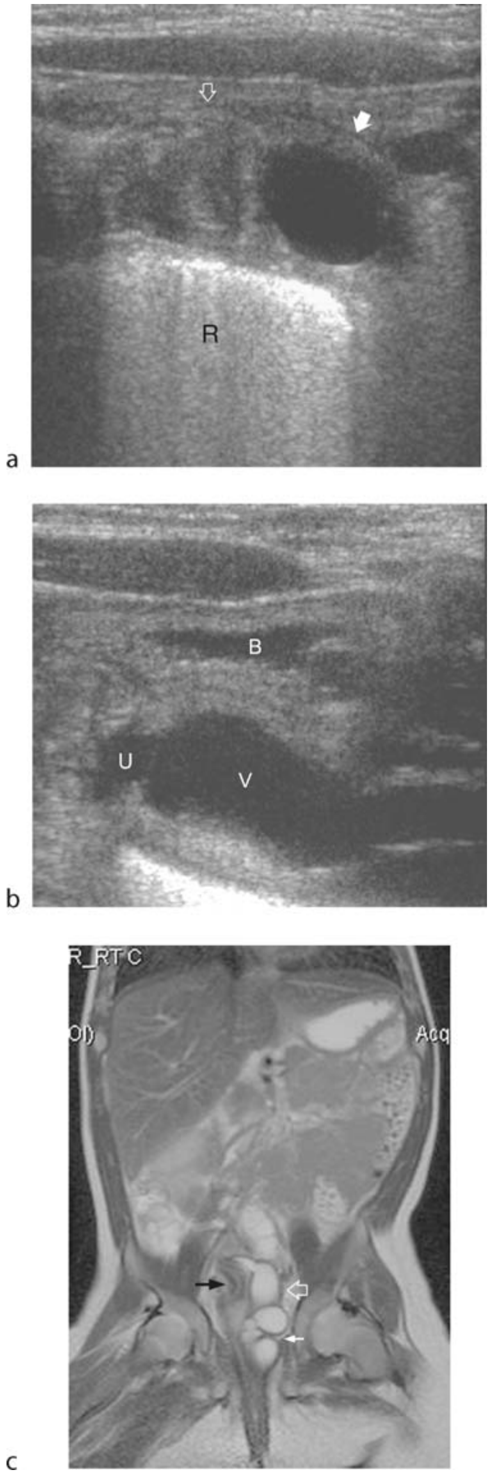
The diagnosis of unicornis uterus can be suggested when there are two horns of different size or when the uterus appears small and laterally located on US images. The US findings of a didelphys uterus are two divergent horns with a deep fundal cleft, two endometrial stripes, two cervices, and two vaginas (Fig. 2); the bicornuate shows two horns, one cervix, and one vagina. The septate uterus presents with two closely apposed endometrial canals surrounded by a common myometrial layer.

The US findings of hydrocolpos or hematocolpos are those of a tubular, fluid-filled midline mass representing the dilated vagina between the bladder and the rectum; the uterine cavity may (hydro- or hematometrocolpos) or may not be distended. Debris can be demonstrated in the fluid.

Precocious puberty. The role of US in this condition is to evaluate the size of the uterus and ovaries, and to differentiate between the fundus and cervix. A fundo-cervical ratio (fundus larger than cervix) greater than 2 with an echogenic endometrium suggests estrogens stimulation. Uterine and bilateral ovarian enlargement are typical of true isosexual precocity, whereas unilateral ovarian enlargement with a stimulated uterus is indicative of pseudosexual precocity. Follicles smaller than 9 mm are not a reliable indicator of precocious puberty. In pseudoisosexual precocity caused by an autonomous follicular cyst, US can demonstrate a unilateral follicular ovarian cyst, which is characterized by the daughter-cyst sign (presence of follicles within the main cyst) (3).

The uterus and ovaries maintain the small prepubertal appearance in cases of adrenarche.

Ovarian cysts and ovarian torsion. Size is the main criterion with which to differentiate a physiological follicle from a pathological cyst, with cysts larger than 3 cm considered pathological. US findings are different, according to the presence or absence of hemorrhage. Non-hemorrhagic cysts appear as a unilocular, thin-walled, and anechoic mass with posterior acoustic enhancement. Hemorrhagic cysts have similar findings when there is



Genital Tract. Figure 2 Uterus didelphys with distal vaginal atresia of one vagina and secondary distension. (a) Transverse section. fresh blood, whereas a complex heterogeneous appearance can be observed when clotting occurs (Fig. 3). Finally, the cyst again becomes anechoic with clot lysis.

A torsed ovary usually appears markedly enlarged. The only US finding relatively specific for torsion is the observation of multiple, small (7 to 12 mm in size), peripherally located cysts caused by vascular congestion and transudation of fluid into the follicles (plum-cake sign). The presence or the absence of blood flow on CDS does not exclude or confirm torsion.

In newborns, an ovarian cyst usually appears as an anechoic, easily mobile, thin-walled mass with posterior acoustic enhancement. Occasionally, it may be located far from the pelvis and its side in the abdomen does not determine from which ovary it originates, unless the opposite ovary can be also visualized. A fluid–fluid level is a frequent finding in a torsed ovary, and it is caused by hemorrhage within the cyst. Cysts smaller than 3 cm are considered follicles stimulated by maternal hormones.

Genitourinary Tract

Marie-France Bellin
Service de Radiologie, Hôpital Paul Brousse,
Villejnif, France
marie-france.bellin@pbr.ap-hop-paris.fr

Imaging of the genitourinary (GU) tract is evolving rapidly and, in the past few years, remarkable advances have been made that have modified diagnostic strategies. For decades, intravenous urography (IVU) was the primary means of evaluation of the upper urologic tract. It has now almost completely been replaced by modern cross-sectional imaging techniques: ultrasonography (US), computed tomography (CT), and magnetic resonance imaging (MRI). Few patients with urinary symptoms escape diagnostic imaging and most undergo multiple examinations.

US is frequently used as the first-line imaging modality; the use of US contrast agents for GU imaging is highly promising, but has been less thoroughly studied than in the liver. The application of CT to GU imaging has literally exploded and technical advances, particularly multidetector row CT, have had a major impact on the evaluation of retroperitoneal disorders. With increased speed and quality, CT has made major inroads into vascular imaging and CT urography is developing rapidly. MRI provides unique soft-tissue contrast, and allows for effective evaluation of a wide range of renal and vascular disorders, as well as bladder and prostate cancers. The lack of exposure to ionizing radiation and the safety profile of MR contrast agents are especially attractive for children, women of childbearing age and patients with renal insufficiency. MR urography using heavily T_2-weighted pulse sequences or gadolinium-enhanced T_1-weighted sequences has shown potential to detect, localize, and characterize collecting-system abnormalities. Functional MRI of the kidney is also making rapid progress. The promise of tomorrow's technology is better, faster, safer, and more cost-effective imaging of the GU tract.

Imaging of the GU tract is oriented toward symptoms and disease entities rather than imaging modalities. Thus the radiologist needs to know the main targets of each particular disease, and the respective advantages and limitations of all modalities. It is not enough for the radiologist today to understand technique and interpretation for accurate diagnosis, one must also have some understanding of the basic principles of physiology and the disease process, including pathologic aspects, genetics, as well as treatment options.

Schematically, six major anatomic areas with their different frequencies of involvement, functional aspects, and pathologies are usually defined: kidney, ureter, bladder, urethra, prostate, and scrotum.

Standard anatomic structures and their variants can be visualized by all the different cross-sectional imaging modalities, each with its proper advantages and limitations reflecting its respective intrinsic properties. The accurate analysis of imaging findings includes determination of the size, number, morphology, localization, and extension of pathologic abnormalities. Assessment of their vascularization is crucial not only for their characterization but also for evaluating treatment efficacy. US, CT, and MRI can be used for this evaluation. Functional imaging is mainly based on MRI.

Kidney diseases can be divided into several major groups: acquired renal cystic disease, acute pyelonephritis, acute renal colic, acute renal insufficiency, acute renal obstruction, acute tubular necrosis, anatomic variants of the GU tract, benign solid tumors of the kidney, chronic pyelonephritis, chronic renal insufficiency, chronic renal obstruction, complications of renal transplantation, functional imaging of the kidney (CM structure), glomerulonephritis, hypertension, lymphomatous involvement of the GU tract, medullary sponge kidney, normal transplanted kidney, polycystic kidney disease, renal abscess, renal arteriovenous fistula, renal artery aneurysm, renal artery stenosis, renal cell carcinoma, renal cysts, renal infarction, renal papillary necrosis, renal pseudotumor, renal vein thrombosis, retroperitoneal fibrosis, trauma of the GU tract, urinary incontinence, urinary stone disease, urinary tuberculosis, and urothelial tumors of the kidney and ureter.

Ureteral diseases can be divided into several major groups: acute renal colic, acute renal obstruction, anatomic variants of the GU tract, lymphomatous involvement of the GU tract, retroperitoneal fibrosis, trauma of the GU tract, ureterocele, ureteropelvic junction syndrome, urinary stone disease, urinary tuberculosis, urothelial tumors of the kidney and ureter, and vesicoureteral reflux.

Bladder diseases can be divided into several major groups: anatomic variants of the GU tract, cystitis, lymphomatous involvement of the GU tract, neurogenic bladder, tumors of the bladder, urethra and/or urachus, urinary incontinence, urinary stone disease, urinary tuberculosis, and vesicoureteral reflux.

Urethral diseases can be divided into several major groups: anatomic variants of the GU tract, stenosis of the urethra, trauma of the GU tract, urinary incontinence, and urinary tuberculosis.

Genito-Urinary Tract

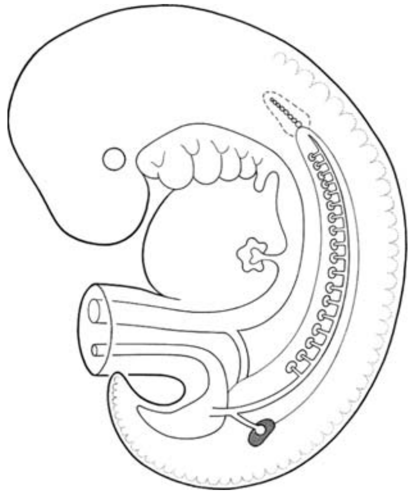
richard.fotter@meduni-graz.at

Definition

Normal anatomy of the urinary tract may include some more or less frequent variations; the clear differentiation of a "variant" from a "malformation" is difficult and can often only be made in the individual case with regard to the clinical development of the affected urinary tract.

Embryology

The embryologic development of the mesodermal kidney is complex with three successive stages: the pronephros, the mesonephros, and the final metanephros (Fig. 1). The kidneys develop in the pelvic cavity and migrate during the first trimester before they eventually take their normal position in the retroperitoneal space of the upper abdomen, with a simultaneous rotation of the renal pelvis, which eventually in a normal kidney points in an anterior-medial direction. The kidney is initially supplied by sacral branches of the aorta, and during its assent into the abdominal cavity the kidneys acquire successively higher branches with regression of the earlier, more caudal vessels. The differentiation of the renal tissue depends on proper contact between the metanephric tissue and the ureteric bud. Disturbance of this development may lead to variety of variants, dysplasia, and malformations (Table 1). The development of the lower urinary tract and the bladder is also complex and involves both the urinary and the genital tract, with formation of a primary cloaca which eventually differentiates into the urinary bladder (by septation and separation of vagina and rectum), the ureter (from the arising ureteric bud), the urethra, and the genitalia (maturation of the organs arising from the Wolffian and the Müllerian duct) (Fig. 2). Disturbance of this complex development may lead to a number of variants and malformations (Table 2).



Genito-Urinary Tract: Anatomy and Variants. Figure 1 Kidney development—pronephros, mesonephros, metanephros (from Benz-Bohm (2001) In: Fotter R (ed) Pediatric Uroradiology. Springer, Berlin-Heidelberg, p 44, Figure 2.1).

G

Clinical Presentation

Normal anatomy and usual variants do not cause any clinical symptoms.

Imaging

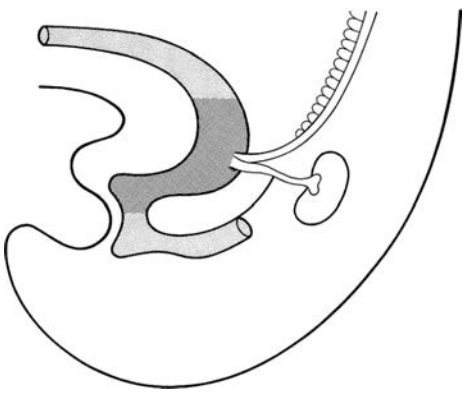
All imaging modalities may be applied to visualize the urinary tract.

Radiological anatomy: Anatomically, the kidney consists of the outer cortex, the inner medulla, and the centrally positioned collecting system, with the major supplying and draining vessels running close to the collecting system (Fig. 3a). Kidney position (in relation to other abdominal structures) as well as renal shape, histology, and function change with age; as the kidneys are less protected by the ribs in infancy, they are at higher risk for traumatic injury. These are reflected in age-dependent contrast dynamics and in different tissue appearances on various imaging modalities, particularly on ultrasound (US) (Fig. 3b and c). Physiologically, there is a marked lobar architecture in the infant (persistent fetal lobulation). The kidney usually has three groups of calices (upper, middle, lower), potentially with compound papillae (two papilla draining together into one calyx) particularly in the polar region (these are prone to intrarenal reflux). Usually, there is one main renal artery and renal vein, with the left renal vein crossing in front of the aorta. From this main artery, segmental arteries divide, along with segmental branches, into the arcuate arteries. Furthermore, there is a capsular supply with potential anastomoses between peripheral intralobular arteries and the capsular vessels deriving from the suprarenal, renal, and genital arteries. On US the neonatal kidney is initially quite echogenic, with a marked differentiation between

Genito-Urinary Tract: Anatomy and Variants. Table 1 List of most important kidney variants and "malformations"

Type	Comments, remarks, subtypes
Position and Rotation anomalies*	malrotation, malposition/renal ectopia (abdominal, thoracic)
Renal agenesis*	bilateral agenesis is lethal
Fusion anomalies*	horseshoe kidney (pre-aortal isthmus), crossed fused renal ectopia
Variations of renal vessels*	unusual course, e.g. retro-aortal (left) renal vein persisting or additional/accessory arteries and/or veins
Ureteral variations*	retro-/circumcaval ureter, ureteral folds, ureter fissus
Duplex (triplex) kidney*	caused by two (three) ureteric buds, with the lower ureter draining the upper renal moiety (usually obstructive), and the higher and more laterally inserting ureter (often refluxing) draining the lower moiety
Calyceal abnormalities*	calyceal diverticula, tertiary calyx, megacalicosis
other collecting system abnormalities	bifid collecting system ("incomplete duplication")

* some of these entities may cause symptoms and sequalae and thus may be also considered more a malformation and not just a variant (see *Urinary tract, Entry: Congenital malformations, genito-urinary tract*)



Genito-Urinary Tract: Anatomy and Variants. Figure 2 Development of the lower urinary tract—schematic diagram of the urogenital sinus (from Benz-Bohm (2001) In: Fotter R (ed) Pediatric Uroradiology. Springer, Berlin-Heidelberg, p 44, Figure 2.2).

Genito-Urinary Tract: Anatomy and Variants. Table 2 Most important lower urinary tract variants and malformations

Duplications of bladder, ureter, urethra, ureter fissus*
Megaureter (refluxing and/or dysplastic and/or obstructive)*
Persisting urachus, urachus cyst/-diverticula*
Diverticulum*
Bladder septations*
Megacystis*

There may be numerous associated anomalies of the genital tract (see *Urinary tract, Entry: Congenital malformations, genito-urinary tract*)
*Many of these entities may cause symptoms and sequelae and thus may also be considered as a malformation and not just a variant

the medulla and cortex, which decreases during growth (Table 3).

The renal pelvis varies in size and can be located predominantly intra- or extrarenally, and consecutively the shape of the ureteropelvic junction may vary. In early childhood, some mild tortuosity and elongation of the ureter with widening of the mid-ureter, short kinks, and intraluminal mucosal folds of the proximal ureter are common as a persistent fetal characteristic in the infant. Ureters in children may be highly mobile, and they may be difficult to visualize. The ureter courses down through the bladder muscular wall and then submucosally to its orifice, which usually is to the end/in the corner of the trigonum.

The urinary bladder is divided into a vertex, body, and the fundus, with the trigonum being the posterior aspect of the bladder base. This triangular space is formed by the two ureteral ostia superior-laterally and by the internal urethral meatus inferiorly to the midline. In infants, an incompletely filled bladder may occasionally show a transient herniation of the inferior lateral wall, which then appears like "bladder ears" that disappear when the bladder is full. The fetal urachus arising from the bladder roof coursing toward the umbilicus usually closes around birth and may still be visible in early childhood as a fibrous remnant—failure of this involution may lead to a persisting duct or cysts. Bladder capacity varies with age (Table 4). As the infant's bladder reaches up into the abdomen, there is a higher risk of intraperitoneal bladder rupture in any kind of trauma or nonaccidental injury. Only after 6 years does the bladder begin to be located more and more in the greater pelvis, and it only becomes a purely pelvic organ after puberty. The bladder neck is the poorly delineated junction between the bladder and the urethra at the level of the internal urethral sphincter.

The urethra differs with gender. The male urethra is divided into a posterior and anterior segment, with the prostatic urethra extending from the bladder neck to the urogenital diaphragm. This posterior urethra has a number of anatomical landmarks, e.g., veromontanum, physiologic (semi-)circular folds that may mimic mild posterior ureteral valves, thin anterior wall mucosa folds at the level of the veromontanum called "incisura," the prostate utricle, and numerous openings of prostatic ducts to the wall of the posterior urethra with potential reflux into these (Fig. 4). A final incision is caused circumferentially by the urogenital diaphragm, followed by the membranous part of the anterior and inferior urethra. Important landmarks are the Cowper glands, which may appear as contrast medium-filled structures in projection at the beginning of the membranous urethra. Accumulation of contrast material may be seen physiologically at the glans penis in uncircumcised infants on

voiding cystourethrography (VCUG) studies. The female urethra is much shorter, has a large variation in its normal appearance—depending on the degree of relaxation of the external sphincter and the muscles of the pelvic floor during inspection or voiding. This as well as some reflux of contrast material into the vagina during VCUG is a frequent finding without significance.

The definition of and differentiation between variant, anomaly, or malformation are difficult and cannot be made on the basis of clinical significance only; therefore,

most of the variants are described in the entry "Malformation, Congenital, Urinary Tract, Childhood" except for those mentioned earlier.

Imaging modalities: Usually the urinary tract is imaged by US and VCUG; rarely, intravenous urography (IVU) can be performed. On US, a comprehensive study should be performed in a well-hydrated child with full bladder and must include postvoid reassessment. Renal size and bladder capacity should always be assessed using weight-correlated growth charts (Table 3). Standard protocols for performing VCUG and IVU in infants and children exist, with IVU only being recommended in infants older than 4-6 weeks due to the neonatally immature kidney function. In the pediatric age group, (multidetector spiral) computed tomography (CT) is performed only for trauma and complicated stone disease as well as for tumors, applying age-adapted low-dose protocols with weight-related amounts of contrast medium and size or age-adapted delay timing. Additionally, magnetic resonance (MR) urography is becoming a comprehensive imaging tool for most parts of the pediatric urinary tract, with an excellent demonstration of the kidney parenchyma, the collecting system and ureters, the bladder, all surrounding soft tissue structures, and the major vessels; only visualization and evaluation of the urethra may be difficult. New approaches using dynamic diuretic contrast-enhanced MR techniques also allow for functional evaluation. It should be noted that sufficient distension of the collecting and draining system (achievable by proper hydration and administration of diuretic drugs) as well as (often) some sedation—in younger children and infants—is essential for good-quality examinations.

Genito-Urinary Tract: Anatomy and Variants. Table 4 Graph and equations for assessing age related changes of normal bladder capacity in childhood

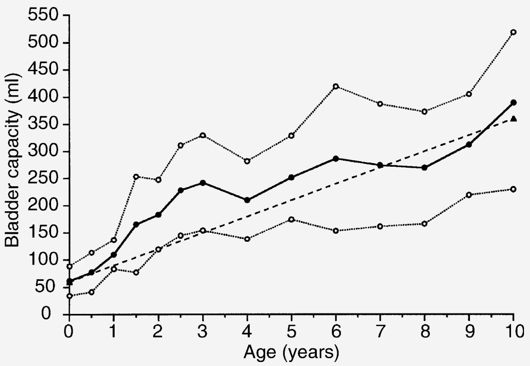
Bladder capacity (BC)

BC (mL) = (Age in years+2) × 30

BC (mL) = (30 × age in years) + 60 (both formulas are identical)

Bladder capacity in children with myelodysplasia

BC (mL) = (24.5 × age in years) + 62



From Ring E, Riccabona M, Fotter R (2001) In: Fotter R (ed) Pediatric Uroradiology, Springer, Berlin-Heidelberg, pp 413–420, Table 26.14, p 419, Figure 26.8, p 419

Bladder capacity (mean ± 1 SD) during childhood. The dotted line represents the formula-derived estimation of BC. Data obtained from Zerin et al. (1993)

Comment: The above-mentioned formula seems to underestimate mean BC during the first few years of life. This may reflect the normal development of BC but could be influenced by bladder training to reach continence. Children with myelodysplasia seem to have a BC? 20–25% less than neurologically intact children (Palmer et al. 1997).

Gestational Trophoblastic Disease

Gestational trophoblastic disease comprises a spectrum of lesions originating from the placental trophoblast. Classic hydatidiform moles are characterized by a diffuse trophoblastic hyperplasia with abundant, villous edema. Macroscopically it looks like a bunch of grapes. Molar pregnancies can invade into the uterine myometrium. Clinically, beta HCG is elevated mimicking pregnancy. The lack of fetal activity and the presence of a hyperechoic polycystic mass within the uterine cavity on US establish the diagnosis.

Synonyms

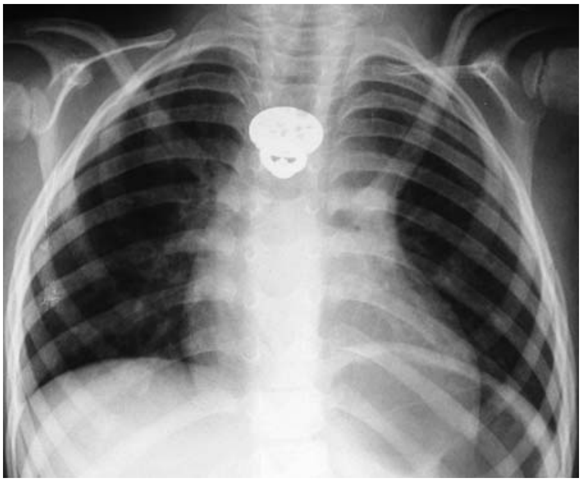
Foreign body (FB); Foreign object; Ingested foreign body; Oesophageal foreign body

Definition

An ingested object in the gastrointestinal (GI) tract.

Pathology/Histopathology

Children of all ages may ingest foreign bodies (FBs) either because they are very young, or by accident, or occasionally intentionally. Children with neurological impairment may be at increased risk. Most ingested objects are radio-opaque and the most common objects include coins, batteries, very small toys or components of toys, nails, pins, beads, marbles, pen tops, etc. Most of these objects pass through the entire GI tract uneventfully but some objects will get stuck at either a physiological narrowing in the gut or will become embedded in the wall of the gut. The main physiological points of obstruction are the cricopharyngeus muscle, aortic knuckle (Fig. 1) and the gastro-oesophageal junction. The ileocaecal valve may also present a point of obstruction. If a patient has had previous surgery to the oesophagus, or elsewhere in the GI tract, the level of the anastamosis may also be a point of hold-up. An FB that becomes impacted may cause erosion of the gut wall at any point along the GI tract. This may occur within 24–48 h, or even sooner in some cases. Of particular concern are lithium batteries which may erode the oesophageal wall in 12 h and therefore need to be removed promptly. The inflammation caused by a lithium battery in the oesophagus may subsequently cause a stricture. Also of recent concern are small, battery-sized magnets found in children's toys and electrical goods. If only one magnet is swallowed it can be allowed to pass through the gut uneventfully but if two are swallowed they may come to lie in adjacent loops of bowel and then become 'fixed' by their magnetic attraction to one another, eventually perforating the bowel wall (1). In this situation they should be removed promptly by laparotomy. FBs may erode through the oesophageal wall leading to an inflammatory response with subsequent granuloma formation. Fistulas have been reported as a complication of this. An FB lodged longer than 24 h poses a greater risk of oesophageal perforation, mediastinal abscess formation, and airway narrowing (2). The method of removal of the object, if it is in the oesophagus, will be determined as much by the history as by the findings on imaging.



GI Tract, Pediatric, Foreign Bodies. Figure 1 **AP chest radiograph showing a radio-opaque ►foreign body lodged at the level of the aortic knuckle.**

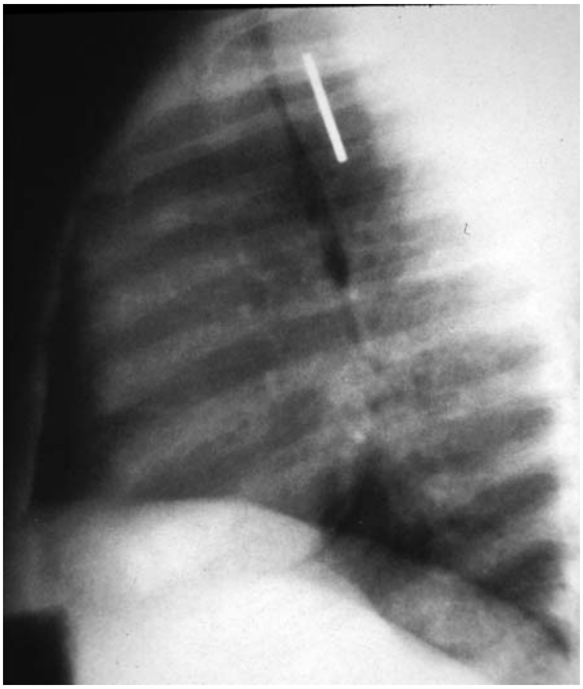
Clinical Presentation

The most common age for FB ingestion is in toddlers and young children with the vast majority of patients being under 5 years. Most patients will present to an emergency department and the carer will usually give a history of what they believe has been swallowed. When an object has been swallowed without the carer being aware the presentation may be significantly delayed. Most foreign bodies that are stuck in the oesophagus will lead to dysphagia but some may lead to stridor. Other symptoms may include drooling, gagging, vomiting, retrosternal pain, haemoptysis and acute respiratory distress. When the young or non-verbal patient is experiencing dysphagia he may suddenly express a preference for liquids and liquid or soft foods and this may provide a clue to the underlying pathology of a foreign body. Occasionally a FB may get stuck very high in the oesophagus or in the hypopharynx and may alternatively present with chronic respiratory distress, recurrent pneumonia (due to over-spill of foods into the airway) or, rarely, failure to thrive. Sometimes an ingested FB may be an incidental finding on a chest or abdominal radiograph performed for another reason.

Imaging

No imaging of any kind is necessary in the majority of cases. If the object is believed clinically to be stuck in the oesophagus, imaging is recommended and if the ingested object is radio-opaque its position can be determined by a chest X-ray (AP and lateral views) with a slightly extended field to include the cervical region. If it is non radio-opaque either a contrast study or endoscopy can be performed. Endoscopy is usually preferable as the object can then also be removed. If the patient is believed to have ingested, a battery imaging should always be performed because of the risk of erosion and this will then also require a supine abdominal X-ray. If there is clinical concern regarding associated mediastinitis or paraoesophageal abscess CT may be required.

On an AP chest X-ray, an object stuck at the thoracic inlet will be projected in the midline at the level of the clavicles, and will usually appear en face i.e. as a complete disc. A coin stuck in the trachea at this level will usually appear to be on edge, i.e., sagittally orientated due to the configuration of the cartilaginous rings in the trachea (Fig. 2). Objects stuck in the oesophagus at the aortic arch will lie at the impression of the aortic arch and objects stuck at the gastro-oesophageal junction will be seen approximately 3 vertebral bodies above the gastric air bubble in the midline.



GI tract, Pediatric, Foreign Bodies. Figure 2 Lateral chest radiograph showing a coin in the oesophagus. Note the air-filled trachea anteriorly and that the coin is lying in a coronal plane and is therefore seen edgeways on this lateral view. These two features locate it to the oesophagus.

Nuclear Medicine

No role to play.

Diagnosis

By imaging as above, primarily plain films, rarely by (pre- or post-endoscopy) contrast study, CT or MRI for complication such as mediastinitis.

Interventional Radiological Treatment

Fluoroscopic balloon catheter extraction of the foreign body is performed in some centres and involves passing a deflated Foley catheter beyond the FB under fluoroscopic guidance with the patient in a head down position on a steeply tilted fluoroscopy table. Once the balloon part of the catheter is past, the FB is then inflated and the whole catheter is slowly withdrawn thereby pulling the FB out ahead of it (3). This technique has recently been criticised by some operators due to the risk of aspiration of the FB as it exits the pharynx and is therefore not so widely practised. Endoscopic removal of oesophageal FBs is now the treatment of choice in many centres.

malrotation (with or without volvulus); Oesophageal atresia; Omphalocele; Rectal atresia; Stenosis; Tracheo–oesophageal fistula.

Definition

Congenital malformations of the gastrointestinal (GI) tract are those, which have developed in utero. They may be genetically determined, due to a developmental 'accident' or have been acquired in utero secondary to an insult such as ischaemia. Some of these conditions are now detected on antenatal ultrasound scanning but if not they usually present in the first few hours of life, and occasionally later.

Pathology/Histopathology

Congenital malformations of the GI tract arise from a wide spectrum of abnormalities and the pathology/histopathology is specific to the type of malformation.

Clinical Presentation

Oesophageal atresia (OA) is discussed in the section on 'Oesophageal disease, childhood'.

Duodenal atresia is sometimes detected antenatally on ultrasound as fluid can be seen in a distended stomach and proximal duodenum. As the atresia is usually at or below the level of the ampulla of Vater (insertion of the common bile duct) the infant will present after birth with vomiting or severe reflux which is characteristically bile stained. The abdomen will be distended and no gas or fluid will pass beyond the atresia. Duodenal stenosis will present in a similar way depending on the severity of the stenosis, although in these patients some gas and fluid will pass on through the rest of the GI tract.

Jejunal atresia presents in a similar way to duodenal atresia as above, although the abdomen may be more dilated and the vomiting less pronounced. The vomitus will still be bile stained.

Malrotation is the abnormal positioning and fixation of the midgut within the abdomen after it is withdrawn back into the abdomen during the tenth week of embryological life. It is discussed in greater detail in the section on 'GI tract, paediatric, specific problems'.

Ileal atresia: The neonate will present with obstruction, and usually associated vomiting which will be bile stained. The patient may fail to pass meconium in the first 24 h of life.

Colonic and rectal atresia: The infant will not pass meconium in the first 24 h of life and the abdomen will become increasingly distended.

Anorectal malformation: The first check at birth may show that the anus is not present and/or male infants may pass bits of meconium per urethra and females may show meconium on the labia or vaginal introitus.

Duplications of the intestine may occur anywhere along the GI tract but are most common in the small bowel, and may be cystic or tubular. Cystic duplications are more common and do not usually communicate with the lumen of the bowel. Tubular duplications usually communicate with the lumen. Either of these may present incidentally but often present as an abdominal mass and are at risk of bleeding, ulceration, and perforation if they contain gastric mucosa.

Omphalocele is persistence of the herniation of the abdominal contents into the umbilical cord. It is frequently detected antenatally but will otherwise be immediately visible at birth. It has a high association with small bowel malrotation and volvulus.

Gastroschisis: This abdominal wall defect will present at birth with a non-midline defect of the abdominal musculature (more common on the right) and this allow the extrusion of the abdominal viscera without involving the umbilical cord. It may or may not be detected antenatally.

Meckel's diverticulum: This is a small bowel diverticulum that often contains gastric mucosa. Clinical presentation may be with bleeding, anaemia, abdominal pain, or perforation.

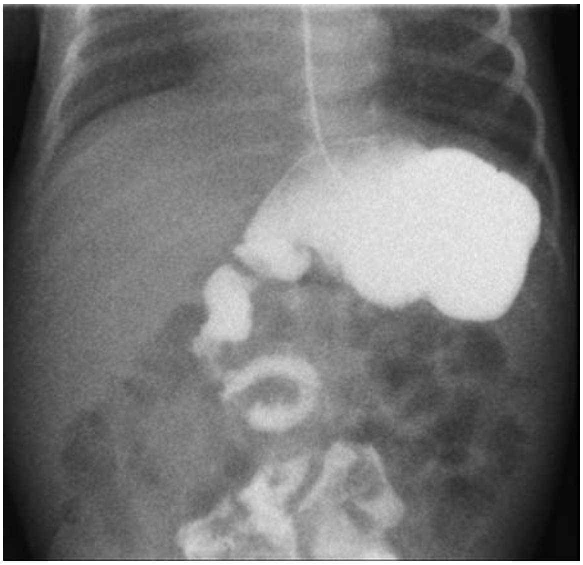
Imaging

Oesophageal atresia (OA): See the section on 'Oesophageal disease, childhood'.

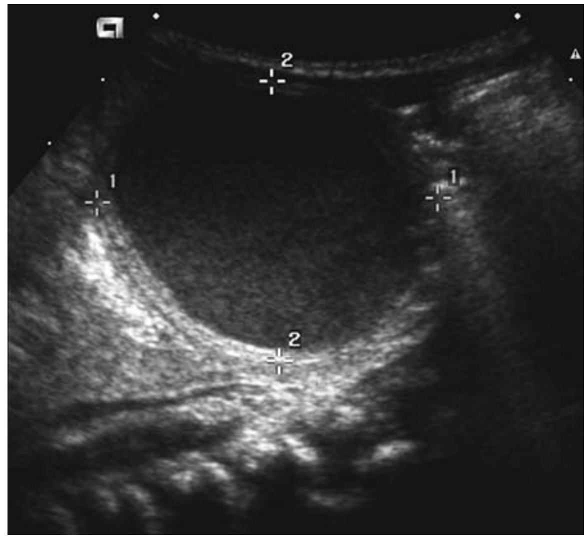
Duodenal atresia: The characteristic X-ray appearance is that of a distended gas filled stomach and a proximal duodenum; the so-called 'double bubble' sign. This may have been detected antenatally on ultrasound examination. A water soluble contrast study will show hold-up of contrast in the 2nd part of the duodenum. The remainder of the abdomen will be gasless in complete duodenal atresia. Imaging is not always necessary and some centres proceed straight to surgery on the basis of the abdominal X-ray.

Jejunal atresia may have a similar appearance to duodenal atresia on abdominal X-ray although further gas filled distended loops are usually seen (see Fig. 1 entry: Occlusion, bowel, childhood). A contrast study may or may not be necessary, but if an upper GI series is performed, then it will show several dilated loops of bowel with no contrast or air distally.

Malrotation: The normal position of the duodenal jejunal flexure is to the left of left pedicle of the superimposed vertebral body (2). The DJ flexure should also be at the height of the pylorus, thereby completing



GI Tract, Paediatric, Congenital Malformations. Figure 1 Malrotation on an upper GI series. The DJ flexure is too low and is too medial. The jejunum then loops to the right and inferiorly. This patient is not volved. See (Fig. 4) in the section on 'GI tract, paediatric, specific problems'.



GI Tract, Paediatric, Congenital Malformations. Figure 2 Ultrasound showing a duplication cyst of the bowel. Note the visible layers of the bowel wall.

the normal 'C' shape of the duodenum. If the layout of the bowel does not fulfil these two criteria on an upper GI series then malrotation must be suspected (Fig. 1). Ultrasound may be useful in demonstrating the normal relative positions of the SMA and SMV, with the SMV normally lying to the right of the SMA. If this relationship is reversed malrotation may be present. See the section on 'GI tract, paediatric, specific problems' for malrotation with acute volvulus.

Ileal atresia: The plain abdominal film will show multiple dilated loops of gas filled bowel. A contrast enema will demonstrate a microcolon and if contrast refluxes into the distal ileum it may be possible to show the exact position of the most distal atresia, this being the limit to which contrast will pass. There may be several atresias higher in the ileum or jejunum that will therefore not be demonstrated by contrast enema.

Colonic and rectal atresia: If the infant has failed to pass meconium a contrast enema may be performed. This will demonstrate an abrupt ending of the lower part of the large bowel and the exact level will determine if this is colonic or rectal. Imaging may also be performed by abdominal radiograph in conjunction with ultrasound, saline being instilled in the rectum; this technique is particularly useful for the lower anomalies including anal atresia.

Anorectal malformation: Imaging is usually by loopogram and micturating cystogram for high anomalies and by abdominal radiograph, possibly augmented by ultrasound for low anomalies. Please see the relevant section.

Duplications of the intestine: Ultrasound is the first investigation of choice and this may show one or several cystic structures closely related to the bowel. Typically the lining of a duplication cyst shows three layers of mucosa consistent with bowel wall although this is not always demonstrated (Fig. 2). The cysts may contain debris and may therefore be either anechoic or of mixed echogenicity. Tubular duplications may be detected on ultrasound but may also be shown on a contrast study. Cystic duplications may appear as filling defects on a contrast study.

Omphalocele does not usually require any immediate imaging and the infant will proceed directly to surgery although due to the high incidence of malrotation and UGI may be requested prior to surgery or soon after.

Gastroschisis: Imaging is not usually required.

Meckel's diverticulum: Nuclear scintigraphy remains the mainstay of imaging (technetium-99 m) with an area of increased uptake being identified in the lower abdomen (3). Occasionally a Meckel's diverticulum can be shown on contrast studies as a filling defect in the distal small bowel but this is unreliable. Ultrasound may also be used and can detect the diverticulum if it becomes obstructed and is therefore distended by fluid, in which case care must be taken to differentiate it from an obstructed appendix. It is a helpful adjunct in centres without ready access to nuclear medicine facilities.

Nuclear Medicine

Nuclear medicine has a limited role in the assessment of congenital malformations of the GI tract. It may be used in the search for a Meckel's diverticulum (technetium-99 m) and occasionally for ectopic gastric mucosa in duplications elsewhere in the GI tract.

Diagnosis

The diagnosis in all of these conditions is usually either made clinically or on the basis of the imaging as outlined above as these are all structural abnormalities. Subsequent histopathology of resected specimens may demonstrate bowel layers in a duplication cyst and gastric mucosa in a Meckel's diverticulum.

Interventional Radiological Treatment

A significant complication of oesophageal atresia repair is stricture formation and image guided balloon dilatation is the preferred technique for dilatation of these strictures.

Synonyms

Hypertrophic pyloric stenosis (HPS); Intussusception; Malrotation; Midgut volvulus; Pyloric stenosis; Small bowel volvulus

Definition

Intussusception is the prolapsing and invagination (or "telescoping") of a length of bowel, the "intussusceptum," into an adjacent segment, the "intussuscipiens." Four types of intussusception are described: ileocolic, ileo-ileocolic, colocolic, and ileoileal. Ileocolic is the most frequent and occurs in 90% of the cases.

HPS is the idiopathic hypertrophy and hyperplasia of circular muscle fibers of pylorus with proximal extension into gastric antrum. HPS may be inherited as a dominant polygenic trait and has an increased incidence in firstborn boys. It is considered an acquired rather than congenital condition.

Malrotation is the abnormal positioning and fixation of the midgut within the abdomen after it is withdrawn back into the abdomen during the tenth week of the embryological life. As a result twisting (or "►volvulus") of the midgut (third part of duodenum and beyond) can occur around the vascular pedicle of the superior mesenteric artery and superior mesenteric vein. This volvulus and compromise of the arterial and venous supply to the gut results in ischemia. The infant will present with bile stained vomiting due to the duodenal obstruction. The small bowel twists in a corkscrew pattern and depending on the degree of volving vascular compromise may ensue eventually resulting in necrosis, perforation, and gangrene.

Pathology/Histopathology

Intussusceptions most symptomatic intussusceptions in children arise in the ileum and are due to mucosal oedema and lymphoid hyperplasia of Peyer's patches following viral gastroenteritis or upper respiratory tract infection. These are termed "idiopathic intussusceptions" and occur predominantly at the ileocaecal valve (95%). In a small proportion of cases (5%) a "lead point" may initiate the intussusception. Typical lead points include a Meckel's diverticulum, polyps, duplication cysts, suture granulomas, appendiceal inflammation, Henoch Schonlein purpura, and occasionally inspissated meconium. Symptomatic ileocolic and ileo-ileocolic intussusceptions are generally idiopathic, rather than secondary to a lead point.

HPS is due to hypertrophy of the circular muscle layer in the pylorus eventually leading to a functional stenosis/gastric outlet obstruction. Histological examination shows that the muscle layer is deficient in the quantity of a variety of nerve terminals, and it is postulated that this abnormal innervation leads to the failure of relaxation of the pyloric muscle and increased synthesis of growth factors that lead to hypertrophy and hyperplasia resulting in obstruction (1). Prostaglandin E_2 has been reported in association with the development of HPS. Prostaglandin E_2 generation in the gastric mucosa and its concentration in the gastric secretions of patients with HPS have been reported to be significantly greater than in normal controls.

Prostaglandin E_1 and E_2 induce proliferation of the gastric mucosa and are related to muscle contraction in the human gastrointestinal tract. Prostaglandin drug therapy may have a similar effect.

Volvulus: During embryological life (6 to 10 weeks) the midgut is contained outside the fetal abdomen by a physiological umbilical herniation. The mid gut is then withdrawn back into the fetal abdomen at approximately week 10 and in this process normally undergoes physiological rotation so that the small bowel comes to lie centrally and the large bowel to lie peripherally. If this process does not happen correctly the bowel is described as malrotated or nonrotated and the bowel is not properly fixed by its mesentery. This poor fixation allows the small bowel to twist on its mesentery resulting in volvulus and vascular compromise. The caecum lies inferior to the pylorus and is fixed to the posterior abdominal wall by peritoneal bands (Ladd's bands) that pass over the duodenum and may cause obstruction in addition to the risk of volvulus.

Clinical Presentation

Idiopathic intussusception most commonly occurs between the ages of 3 and 9 months (40%) with a range between 3 months and 2 years. Seventy five percent of the cases are in children under 2 years of age, and in children older than 2 years a cause for a secondary lead point should be sought either at the time of the acute presentation or in the recovery period. Idiopathic intussusception is more common in boys (male:female = 2:1). The incidence of idiopathic intussusception is reported to be seasonal, being commonest in the late spring and the autumn. The clinical diagnosis of ileocolic and ileo-ileocolic intussusception can be difficult and there may be a delay in making the diagnosis. The classical clinical triad is of abdominal pain, red current jelly stool, and a palpable abdominal mass but these combined findings are only present in less than 50% of children with the condition. The child will typically draw up his legs to the abdomen during bouts of colic and this may be associated with facial pallor and the passage of red current jelly stools. Clinical examination of the abdomen is often difficult in a distressed child. The child may be shocked and peripherally shut down at the time of presentation. However, conversely, some children may be pain free at the time of presentation with only a history of bloody stools to suggest the diagnosis.

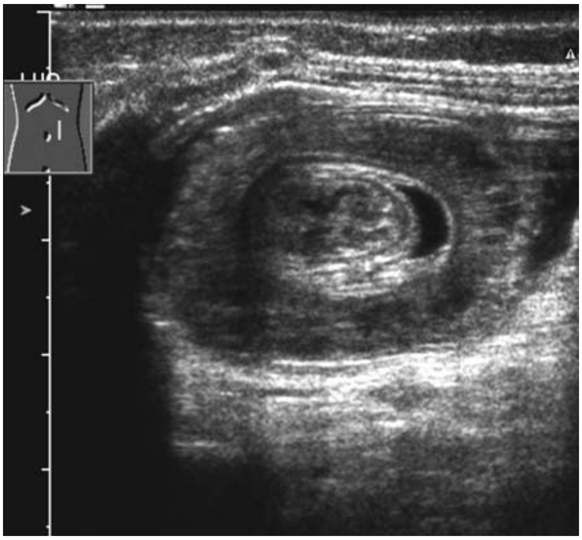
Infants with HPS usually present 2–8 weeks after birth (but may present in the first week) with classic "projectile" nonbilious vomiting, regurgitation, difficulty in feeding and, if severe, weight loss. There is sometimes a history of progression over a period of several weeks after birth (15–20%). Clear, or milky, nasogastric aspirates >10 mL are often present (92% sensitive, 86% specific). HPS occurs mainly in males but is also seen in females with an incidence of 3 cases per 1000 (male:female = 4–5:1) and sometimes with a positive family history. On examination there may be a palpable mass in the epigastrium, sometimes described as "olive-shaped", (80% sensitive in experienced hands, 14% false positive) and this combined with the clinical presentation may be enough to reassure the surgeon to proceed to operation without the need for further imaging.

Malrotation with volvulus usually presents within the first few days of life; there may be delayed presentation in chronic volvulus with only partial compromise to the intestine and its blood supply resulting in a protein loosing enteropathy. The cardinal sign is bilious vomiting or nasogastric aspirates indicating obstruction of the duodenum beyond the ampulla of Vater. If the volvulus has been present for some time (more than 12–24 h) the infant may present in shock and with sepsis from bowel ischemia or infarction.

Imaging

Intussusception: The abdominal radiograph has traditionally been the first investigation in children presenting with suspected intussusception. The most frequent plain film findings are those of reduced large bowel gas and the presence of a mass. However, the AXR is unreliable in confirming or refuting the presence of an intussusception and further imaging is always required. Ultrasound is the investigation of choice (2). If intussusception is suspected clinically ultrasound may be used as the first line investigation. A linear high-frequency transducer is used and whilst the whole abdomen should be scanned the intussusception is most frequently demonstrated in the right flank. Other common sites for demonstration of the intussusception are the left flank and the epigastrium. The intussusceptum is usually seen as a 3–5 cm diameter soft tissue concentric mass in transverse section (Fig. 1), and a sausage-like mass in longitudinal section. The characteristic appearances are of the circular wall of the intussuscipiens, and the central echogenic mucosa of the intussusceptum, with the appearance on transverse scans of the eccentric, semilunar, hyperechoic mesenteric fat that is pulled with vessels and lymph nodes into the intussusception by the intussusceptum: the "crescent and donut" sign.

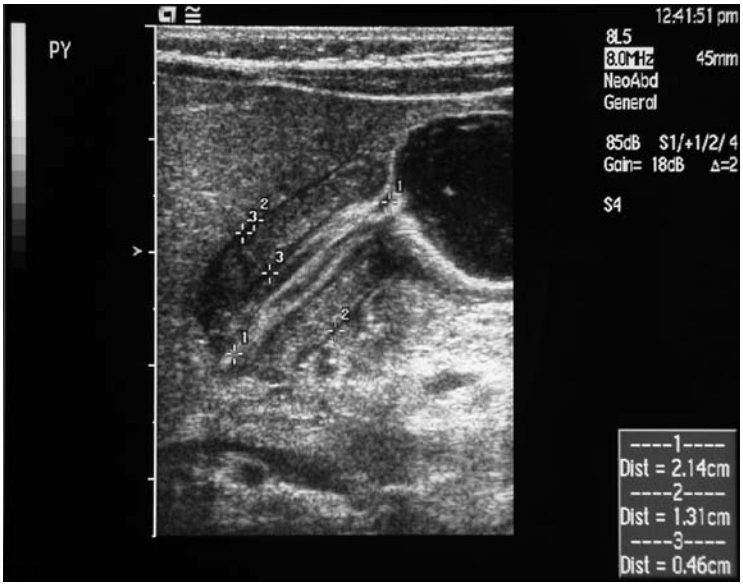
HPS: If imaging is required ultrasound is the modality of choice. Barium studies are no longer appropriate as the first line investigation. A linear high-frequency transducer is used and is placed slightly obliquely on the epigastrium with the patient supine. The hypertrophied pylorus is identified in longitudinal section as a tubular structure with echogenic mucosa seen centrally with the thickened muscle layer encasing it. The double-track sign of the echogenic mucosa and the echo poor fluid trapped between the fold of mucosa is typical in HPS but may also be seen in pyloric spasm and should not be considered pathognomic (3). In transverse section the hypertrophied pylorus appears as a midechogenic donut. The pyloric canal is elongated (>12 mm) and there is persistent spasm of the pyloric canal with little if any fluid passing into the duodenum, with a hyperperistalsing stomach (4). There is persistent thickening of the circular muscle in the elongated canal (>4 mm) which is fixed in the spasm (Fig. 2). It is important to distinguish HPS from pyloric spasm which can have a similar appearance and therefore the ultrasound examination must be continued over a reasonable period of time to see if the pylorus relaxes and opens. If doubt still remains the patient should be re-examined after a delay. A pyloric web would not be expected to result in such a degree of muscle hypertrophy but must be included in the differential diagnosis.



GI Tract, Pediatric, Specific Problems. Figure 1 Ultrasound performed with a high-frequency linear transducer showing the characteristic donut appearance of an intussusception in transverse section.

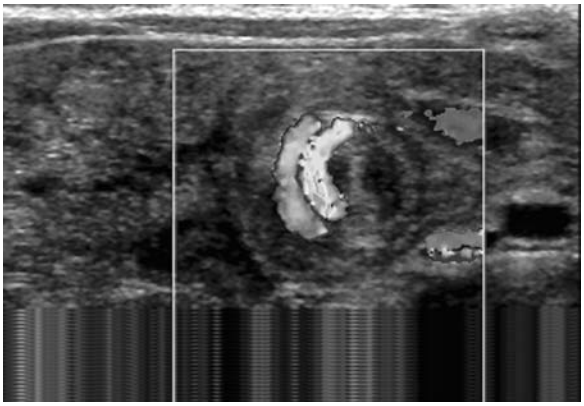
Volvulus: An infant with bilious vomiting requires immediate investigation. The abdominal radiograph may show a high gastrointestinal obstruction but equally may be nonspecific. The bowel gas pattern will partly be determined by the duration of the volvulus and whether the volvulus is intermittent. The presence of free air within the abdomen is a poor prognostic sign implying that perforation has already occurred.

An upper gastrointestinal series is the investigation of choice in most centers but ultrasound can elegantly demonstrate the volved bowel which is identified by a whirlpool appearance of the twisted small bowel and an absence of color flow on Doppler (Fig. 3). For the upper GI series either barium or water-soluble contrast can be used although water-soluble contrast is preferred in the neonate. In this particular clinical situation it is helpful to start with the patient in a right lateral position as the contrast is instilled so that it immediately passes into the



GI Tract, Pediatric, Specific Problems. Figure 2 Ultrasound appearances in ▶hypertrophic pyloric stenosis. The muscle layer is thickened and the pylorus is elongated.

duodenum. The child can then, quickly, be positioned supine so that the position of the DJ flexure can be accurately assessed without excess contrast in the stomach obscuring the DJ flexure. In normality the DJ flexure should lie to the left (5), of the superimposed pedicle of the vertebral body and the height of the DJ flexure should be at approximately the level of the pylorus thereby completing the normal "C" shape of the duodenum. An acute volvulus will show a spiralling or corkscrew appearance of the upper small bowel, typically from the third or fourth part of the duodenum and including the upper jejunum (Fig. 4). If the volvulus is especially tight there may be a complete obstruction at the level of the duodenum and in this case it is difficult to distinguish malrotation with volvulus from other causes of duodenal obstruction, such as a duodenal web (6), but volvulus must be presumed till proven otherwise. Emergency surgery is required before the bowel becomes ischemic or infarcts.



GI Tract, Pediatric, Specific Problems. Figure 3 CDS demonstrating the "whirl pool sign" in a baby with acute volvulus (Courtesy of M. Riccabona, Graz).

Ultrasound can be used to demonstrate the relationship between the superior mesenteric artery and the superior mesenteric vein which is often reversed in malrotation. However, most centers find that whilst this may be helpful as an adjunct it is not secure enough to exclude the diagnosis of malrotation (7) and an upper GI series is still required.

Nuclear Medicine

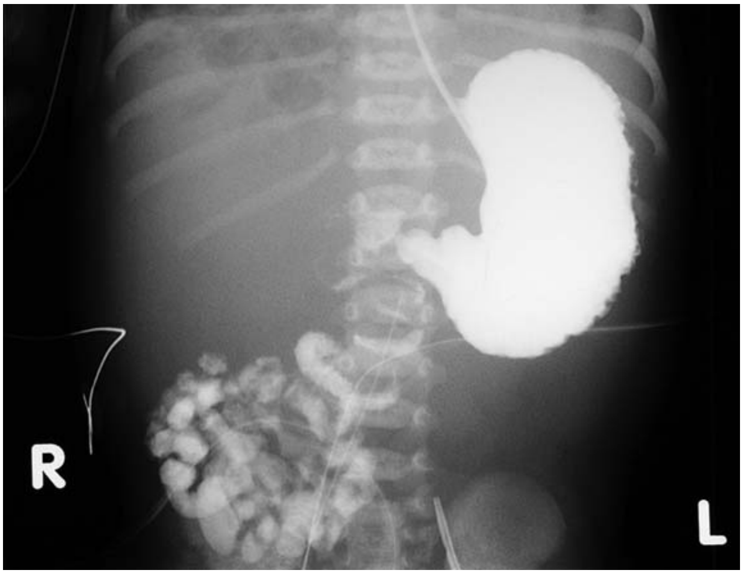
Not applicable to any of these entities.

Diagnosis

The diagnosis of intussusception is made by ultrasound as described above, rarely an enema may be performed for confirming the diagnosis before reduction, or it may be incidentally be picked up by an abdominal CT performed for unclear abdominal symptoms.

Diagnostic criteria of HPS are detailed above.

The diagnosis of volvulus is sometimes made by plain film and surgery, sometimes by US, or an upper GI series



GI Tract, Pediatric, Specific Problems. Figure 4 An upper GI series in a neonate with malrotation and volvulus. Note the spiral, or corkscrew, of contrast in the volved small intestine. The duodenojejunal flexure lies medial to the left pedicle of the superimposed vertebral body and most of the small bowel lies to the right side of the abdomen.

may be performed. Asymptomatic malrotation is diagnosed by an upper GI series and confirmed at surgery, US can only offer indirect signs and neither prove nor rule out malrotation unless there is an acute volvulus.

Interventional Radiological Treatment

Nonsurgical reduction is the treatment of choice in ileocolic intussusception. Barium or water-soluble contrast media have been used for the hydrostatic reduction of intussusception in the past but these techniques have largely been replaced by the use of the ►air enema under fluoroscopic guidance, or ultrasound guided hydrostatic or air reduction (8). The fluoroscopic guided air enema is currently the most universal procedure but as experience grows ultrasound guided reduction is likely to become the method of choice, avoiding the need to use ionizing radiation. The principle of reduction is to raise the intraluminal pressure in the distal colon to push the intussusceptum retrogradely along the colon, thereby reducing the intussusception, until it is completely resolved, usually through the ileocaecal valve. Complete reduction is achieved when either air or contrast media flood back into multiple loops of terminal ileum. Success rates of between 70% and 90% are reported. Pneumatic reduction can occasionally be successful in ileo-ileal intussusception but this is more commonly treated by surgery; but note that ileo-ileal intussusceptions often resolve spontaneously without treatment.

GI Tract, Pediatric, Specific Problems. Figure 5 Air enema shows the soft tissue filling defect of the intussusception in the mid abdomen outlined by air that has been introduced per rectum.

The procedure is performed by passing a catheter per rectum and insufflating the bowel under fluoroscopic or ultrasound guidance. Air will outline the intussusceptum as a "mass" and it will then be seen to pass retrogradely back along the colon as the air pressure is maintained (Fig. 5). Initially pressures of typically 80 mm of mercury (equivalent) are used, rising to a maximum of 120 mm of mercury. A risk of the procedure is of bowel perforation. This may be due to the bowel already being perforated but the perforation being undetected until the air is introduced, or be secondary to the bowel being ischemic and fragile, and perforating under the pressure of air being used to insufflate the bowel. The risk of perforation is approximately 1% overall (2), but is higher in patients presenting late. Hence air reduction should only be attempted in centers with pediatric surgery available.

No interventional approaches are available in HPS and malrotation with volvulus.

Definitions

Glomerular diseases are classified as primary and secondary. Primary glomerulopathies are those disorders that affect glomerular structure, function, or both in the absence of a multisystem disorder. The clinical manifestations are predominately the consequence of the glomerular lesion, and lead to a variety of clinical syndromes.

The terms glomerulonephritis, glomerulopathy, and glomerular disease are usually used interchangeably to denote glomerular injury, although some authors reserve the former term for injury with evidence of inflammation such as leukocyte infiltration, antibody deposition, and complement activation.

Pathology/Histopathology

The glomerular tuft is composed of four major components: the endothelial cells, the podocytes, the mesangium, and the capillary loop basement membrane. The capillary wall carries a net negative charge, and acts as both a charge-selective and size-selective filter. The filtration of albumin, a negatively charged molecule, is restricted to a greater extent than is the filtration of neutral molecules of an equivalent size. In patients with glomerulonephritis, the negative charge of the glomerular capillary wall is lost resulting in enhanced filtration of negatively charged molecules. ▶Proteinuria is often the first indication of glomerular disease.

Antibody-mediated and cellular immune responses have been implicated in the pathogenesis of the majority of glomerulonephritis. Final diagnosis of the different forms is based on findings at renal biopsy. In particular, minimal change disease is characterized at electron microscopy by diffuse effacement of the podocyte foot processes. At light microscopy, the appearance of glomeruli, tubules, and interstitium is normal. No immune deposits are detected.

Membranous glomerulonephritis is an antibody-mediated disease in which the immune complexes localize to the subepithelial aspect of the capillary loop. Focal segmental glomerulosclerosis presents with capillary loop collapse, hyaline and lipid deposition and often adhesion to Bowman's capsule. The remainder of the glomerular tuft is normal in appearance. Ultrastructurally, the glomeruli show effacement of podocyte foot processes. Poststreptococcal glomerulonephritis is the most common form of acute postinfectious glomerulonephritis and occurs following a skin or pharyngeal infection with Group A beta-hemolytic streptococci. These glomerulonephritis are immune complex mediated. The glomeruli show diffuse mesangial proliferation and endocapillary proliferation accompanied by infiltration of neutrophils and mononuclear inflammatory cells. The main pathologic finding in rapidly progressive glomerulonephritis is fibrinoid necrosis. Extensive crescent formation is present in at least 50% of glomeruli. IgA nephropathy is an antibody-mediated glomerular disease in which the immune deposits localize to the mesangium. Membranoproliferative glomerulonephritis presents with proliferation of mesangial and endothelial cells and expansion of the mesangial matrix, thickening of the peripheral capillary walls by subendothelial immune deposits and mesangial interposition beneath the endothelium.

Clinical Presentation

Several clinical syndromes related to glomerulonephritis have been described. Nephrotic syndrome consists of massive proteinuria, hypoalbuminemia with edema, lipiduria, and hyperlipidemia. Acute nephritis, or nephritic syndrome, consists of the abrupt onset of hematuria, proteinuria, ▶azotemia, and hypertension. Rapidly progressive glomerulonephritis is characterized by features of nephritis and progressive renal insufficiency. Although much overlap exists, glomerular diseases may be classified by their predominant clinical manifestations. Indeed, minimal change disease, membranous glomerulonephritis, and focal segmental sclerosis often present clinically as a nephrotic syndrome, while acute postinfectious glomerulonephritis and rapidly progressive glomerulonephritis usually present as a nephritic syndrome. IgA nephropathy and membranoproliferative glomerulonephritis can present both clinical manifestations.

Virtually all forms of acute glomerulonephritis can progress to chronic glomerulonephritis. This condition is characterized by irreversible and progressive glomerular and tubulointerstitial fibrosis, ultimately leading to a reduction in the ▶glomerular filtration rate, increased ▶serum creatinine, and progressive ▶renal failure.

Imaging

Urography and angiography are not indicated to evaluate glomerular disease, but they have been used in the past in these patients as well to rule out obstruction and renal artery stenosis. In patients with acute glomerulonephritis and slight to moderate decrease in glomerular filtration rate renal size is normal or symmetrically increased. Enhancement is normal, or slightly reduced. Angiography shows no significant changes. Severe and rapidly progressive forms of acute glomerulonephritis present with markedly reduced enhancement. Opacification of small peripheral intrarenal vessels is reduced at angiography, and the nephrographic phase is poor.

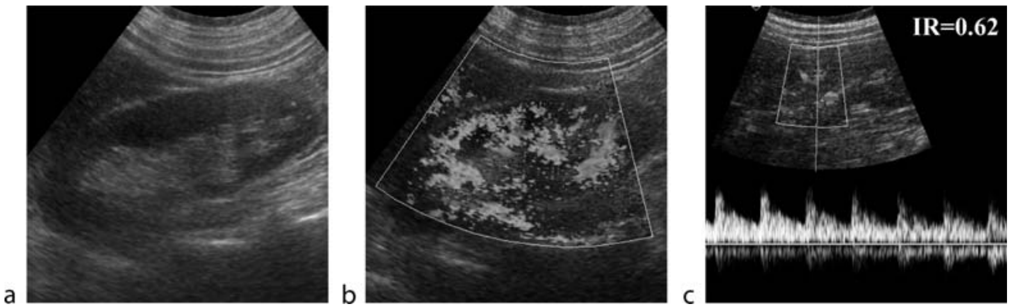
In chronic glomerulonephritis, renal size is usually reduced. Angiography demonstrates reduced opacification of peripheral branches, delayed wash out of the interlobar arteries, and heterogeneous appearance of the nephrographic phase.

Color Doppler US is the imaging modality of choice in patients with renal disease; however, in patients with glomerulonephritis no specific features are found. In acute glomerulonephritis, the kidneys appear normal or with a variety of pathologic changes that can be observed also in patients with other renal pathologies. The most typical appearance is diffusely increased echogenicity of both kidneys. Renal sinus may appear inhomogeneous at US for fibrosis, atrophy and loss of adipose tissue with a progressive reduction of the differentiation between the renal sinus and the renal parenchyma.

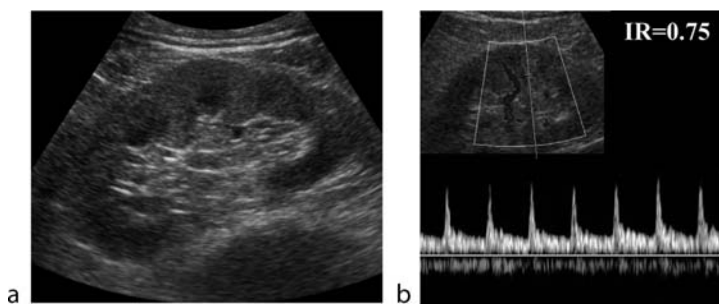
In glomerulonephritides with a prevalent mesangial matrix and basement membrane involvement, such as IgA nephropathy, minimal change disease, membranous glomerulonephritis, cortical echogenicity is usually normal (Fig. 1a). Positive correlation has been observed between renal enlargement and extent of glomerular hypercellularity and crescent formation, and between cortical echogenicity and severity of glomerular sclerosis, crescent formation, interstitial inflammatory cell infiltration, tubular atrophy and interstitial fibrosis (1). Renal cortical echogenicity is closely related to histologically measured average glomerular diameters, which is increased in glomerulonephritis (2), but in the clinical practice quantification of the US signal intensity does not provide useful information. Increased cortical echogenicity is more common in patients with advanced disease and associated vascular or tubulointerstitial involvement such as rapidly progressive glomerulonephritis, and diabetic glomerulosclerosis (Fig. 2a). As results from anatomical correlation studies, most patients with acute glomerulonephritis present with normal appearance of the renal vasculature at color Doppler US (Fig. 1b). Waveform Doppler analysis can be useful to differentiate acute glomerular from acute tubulointerstitial nephropathies. Indeed, renal RI is usually normal in glomerulonephritis (Fig. 1c) except for rapidly progressive and proliferative forms (Fig. 2b) in which RI may be increased (3). RIs are significantly correlated to the amount of pathologic changes in arteriolosclerosis, glomerular sclerosis, edema and interstitial fibrosis. These findings are nonspecific, and RIs analysis does not distinguish different forms of renal medical disorders.

In chronic glomerulonephritis the kidneys usually appear small, with reduced vascularity, and high RI at Doppler interrogation of the parenchymal vessels (Fig. 3). These changes reflect the anatomical changes of the kidney in which the process has involved also the tubulointerstitial compartment.

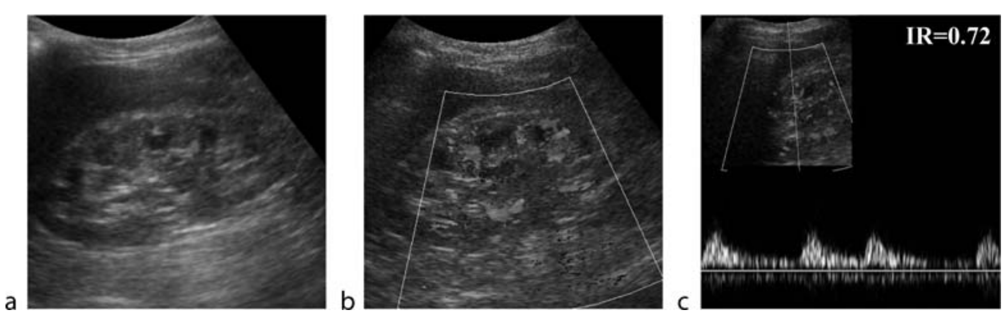
CT is not suited to patients with glomerulonephritis because no clinically useful information is obtained and iodinated contrast agents are nephrotoxic.



Glomerulonephritis. Figure 1 IgA nephropathy. Kidneys (a) present normal morphological appearance at US. Color Doppler US (b) shows normal vascularization of the renal parenchyma. Normal resistive index (RI) values of 0.62 (c) are recorded at duplex Doppler interrogation of the parenchymal vessels.



Glomerulonephritis. Figure 2 Rapidly progressive glomerulonephritis. Kidneys reveal a slight increase in cortical echogenicity (a) with an increased cortico-medullary differentiation and at duplex Doppler interrogation (b) increased resistive index (RI) values of 0.75 are recorded.



Glomerulonephritis. Figure 3 Chronic glomerulonephritis. Increased cortical echogenicity and cortico-medullary differentiation (a) Renal length is reduced. Color Doppler US (b) shows reduced vascularization of the renal parenchyma. Duplex Doppler interrogation (c) shows increased resistive index (RI) value of 0.72.

Magnetic Resonance Imaging (MRI) is under investigation in animal models to evaluate nephropathies by imaging the macrophages that migrate in the site of renal damage (4). Although these results are promising, however, their value must be demonstrated in human native and transplanted kidneys. Macrophages are usually virtually absent in normal kidneys; however, migration into renal tissues occurs frequently in specific nephropathies such as acute proliferative types of glomerulonephritis, renal graft rejection, and in nonspecific conditions such as hydronephrosis. The macrophagic activity may vary, depending on the type of renal disease and its severity; in glomerulonephritis it predominates in the cortex, whereas in interstitial nephritis or hydronephrosis it is diffused in all kidney compartments. Ultra-small superparamagnetic iron oxide (▶USPIO) particles are taken up by phagocytic cells, and could be used as a magnetic resonance contrast agent for exploration of the mononuclear phagocytic activity. Recent experimental studies have demonstrated that USPIO enhanced MRI could have a role in evaluation and differentiation of nephropathies in rat and, in particular, to differentiate glomerular versus interstitial macrophagic infiltration. Since in glomerulonephritis macrophages migrate selectively in the glomeruli, T2*-weighted gradient-echo sequences obtained 24 h after USPIO administration show a significant decrease in signal intensity of the renal cortex, whereas in other nephropathies signal intensity decreases in all renal compartments. Moreover, a strong correlation was observed between the degree of signal intensity variation and the estimate of glomerular damage which may have important implications in clinical practice for the follow-up of patients.

Nuclear Medicine

Radionuclide assessment of GFR is the standard criterion for measuring renal function. However, because it is expensive and not widely available, serum creatinine concentration and creatinine clearance are commonly used. Gallium-67 citrate has an affinity for inflammatory lesions and, clinically, has been used to detect and monitor inflammation. In particular, gallium scan may be useful for evaluation of active or acute lesions and to predict response to therapy in patients with lupus nephritis (5).

Diagnosis

Diagnosis of glomerulonephritis is based on clinics and laboratory findings and usually requires renal biopsy. Imaging findings are not specific, but can provide useful additional information in selected cases and guide biopsy.

Glycogen Storage Diseases

Glycogen storage diseases are inherited metabolic disorders, characterized by glycogen accumulation in tissues. More than 12 glycogen storage diseases are discussed in the literature and most of them have an autosomal recessive transmission. The most common ones include von Gierke disease (glycogen storage disease type Ia), Pompe disease (glycogen storage disease type II), Cori disease (glycogen storage disease type III). Liver and muscles are the most commonly and seriously affected tissues. In type I glycogen storage disease, liver and kidneys are the most severely involved organs. Long-term complications include short stature, hyperuricemia, renal insufficiency, and hepatic adenoma. The most frequent US findings are hepatomegaly, hyperechogenicity of the liver, enlarged kidneys. On CT scans, glycogen deposition results in increased hepatic parenchyma density, whereas fatty infiltration causes a decrease in density. Ultimately, the density of the liver depends on the relative amounts of each component. Biphasic contrast-enhanced CT is mandatory in order to detect and characterize hepatocellular adenomas. Glycogen is characterized by high signal intensity on T1-weighted MR images. Imaging findings are not specific neither sensitive. Biochemical assay for enzyme activity allows the definitive diagnosis.

Synonyms

Gouty arthritis; King's foot; Podagra; Primary gout; Secondary gout; Tophi

Definition

Gout is a monosodium urate crystal-induced arthritis that results from a systemic metabolic disease. Other typical characteristics include an increased uric acid pool, hyperuricemia, acute (episodic) and chronic arthritis, and deposits of monosodium urate crystals in connective tissue (tophi) and kidneys (1). The classic presentation of gout is podagra or pain in the first metatarsophalangeal joint.

Pathology/Histopathology

Homo sapiens possess a mutated uricase gene, which results in the inactivation of the enzyme. Excess urate leads to extracellular deposition of urate crystals and, since urate solubility decreases with lower temperatures, the deposition favors peripheral joints. Gout then follows when the inflammatory response is triggered.

The difference between uric acid production and disposal determines the total-body pool. The latter is the result of xanthine oxidase on purine bases (dietary purines, nucleic acids of senescent cells, and metabolic turnover of cellular purine nucleotides). Most urate is eliminated by urinary excretion, whereas approximately one-third is eliminated by bacterial degradation in the gut.

Approximately 10% of patients have an overproduction of urate and the vast majority has a reduced clearance of filtered urate despite normal renal function. Both hyperuricemia and idiopathic gout are associated with obesity and hypertriglyceridemia. Other risk factors include: exposure to lead, a high dietary intake of purine rich foods (red meat, liver, and fish), medications which impair renal excretion (aspirin, diuretics, levodopa, and cyclosporine), diabetes, kidney disease, family history, age, and gender.

Neutrophils play an important role in acute inflammation in gout. They ingest monosodium urate crystals and then release leukotrienes, interleukin-1, and glycoproteins which amplify neutrophil infiltration. Activated neutrophils produce superoxide and release lysosomal enzymes that induce pain, vasodilation, and vascular permeability and contribute to chronic articular destruction and tissue necrosis. Gout develops in less than 5% of individuals with hyperuricemia. Differences in protein modulators between gouty and non-gouty individuals account for the variability in inflammatory response to urate crystals.

Clinical Presentation

One of the oldest known diseases, gout was first described more than 2,000 years ago. In the past, it was often called “the disease of kings” because it was associated with the wealthy who overindulged in food and drink. Today, it affects approximately 0.5–0.7% of men and approximately 0.1% of women (2). The incidence in families with individuals with gout ranges from 6 to 80%. Gout most often occurs in middle-aged men and postmenopausal women.

The most frequent early manifestation of gout is fulminating arthritis affecting only one joint (75% of the initial attacks), often the metatarsophalangeal joint of the first toe (50%, called podagra), but the tarsal joint, ankle, heel, knee, wrist, and elbow (in descending order of frequency) can also be affected. The first episode frequently begins at night with intense pain and swelling. The joint rapidly becomes warm, red, and tender with a clinical appearance that is similar to cellulites. The initial attacks spontaneously subside with complete recovery within hours for mild attacks and days for severe attacks. The patient then reenters an asymptomatic phase (“intercritical” or “interval” gout) (2). Very severe attacks may be associated with fever, leukocytosis, and an increased erythrocyte sedimentation rate (2). Polyarticular acute gout may be seen in hypertensive male patients with an ethanol abuse problem or postmenopausal women. Inflamed Heberden’s or Bouchard’s nodes may be a first manifestation of gouty arthritis (1).

Repeated acute attacks cause chronic nonsymmetric synovitis in a portion of gouty patients. This condition may be confused with ►rheumatoid arthritis. Less frequently, these attacks will be the only manifestations and even less frequently, inflamed or noninflamed periarticular tophaceous deposits without chronic synovitis are the only manifestation (1).

Imaging

Early findings in gout are limited to soft tissue modifications, typically an asymmetrical swelling around the affected joint. Edema of the surrounding soft tissue may be present. After repeated episodes, a cloudy area of increased opacity may be seen on plain film radiographs. The first bony changes usually appear in the first metatarsophalangeal joint and occur during the intermediate phase. These cystic changes are located outside the joint or in the juxta-articular area and are described as punched-out lytic lesions that can progress becoming sclerotic with an increase in size. Fractures can be present in severe cases. Hallmark findings in the later stages are numerous interosseous tophi and severe symptomatic joint space narrowing. Marked deformities, subluxation, and calcification in soft tissue may also be present. Sometimes, in earlier stages or less progressive disease only degenerative changes of the first metatarsophalangeal joint may be found (Fig. 1).

Computed tomography is useful for the visualization of findings that cannot be clearly visualized on plain film radiology.

Magnetic resonance (MR) imaging is not routinely used as an imaging examination of gout. It may be a useful

Gout. Figure 1 Anteroposterior radiographs of the hands and feet of an 84-year-old woman presenting with pain and swelling of the first finger of the left hand and the second and fifth fingers of the right hand. Peripheral erosion of the distal interphalangeal joint of the first digit of the left hand and the second and fifth digits of the right hand can be observed. Subchondral cysts and thickening of the periarticular soft tissue are also present. A reduction of the joint space of the metatarsophalangeal joint of the first toe associated with calcification of the articular cartilage and a partially calcified bursitis can be observed. Erosive changes of the medial surface of the metatarsal head are also visualized.

imaging technique for the differentiation of a gouty tophus from an infectious or neoplastic process (3). On MR images, gouty tophi can sometimes present as tumor-like lesions both in the bones and the soft tissues, and without a clinical history it may be difficult to separate these entities.

Nuclear Medicine

Nuclear medicine studies can be a useful tool for confirming the presence of the disease when a suspicion arises and for measuring the extent of gouty arthritis. The characteristic findings in a triple-phase bone scan include increased activity seen in the affected area in all three phases.

Diagnosis

Gout should be suspected in cases of severe inflammatory arthritis with a sudden onset, especially if only a single joint of a lower extremity is affected and if there is a history of repeated attacks with asymptomatic periods in between (1). Suspicion of gout can be confirmed by needle aspiration of the tophaceous deposits, if present, or the synovial fluid of acutely or chronically inflamed joints. The effusion may have an abnormal appearance due to the presence of leukocytes (cloudy) and large amounts of crystals (thick pasty or chalky) (2). Negatively birefringent, needle-shaped sodium urate crystals under polarized light microscopy confirm the diagnosis. The leukocyte count can range from 500 to over 50,000 depending on the acuteness of the inflammation (2). Cell culture and gram staining procedures should always be performed to evaluate the presence of an infection. The underlying metabolic disease can be evaluated by arthrocentesis of the first metatarsophalangeal joint and knees, which often present crystals even between gout attacks.

Serum uric acid levels can be normal but are almost always elevated at some point of the disease. Analysis of the uric acid content of a 24-h urine collection can indicate an elevated excretion (>800 mg/24 h) suggesting overproduction. Elevated urinary uric acid excretion, a risk factor for renal stones, indicates allopurinol as treatment rather than uricosuric drug therapy.

Other pathologies that must be considered in the differential diagnosis of gout include: ▶pseudogout, ▶acute rheumatic fever (▶Rheumatic Fever, Acute), rheumatoid arthritis, traumatic arthritis, ▶osteoarthritis, ▶pyogenic arthritis, sarcoid arthritis, ▶cellulitis, bursitis, tendinitis, and thrombophlebitis (2). Many of these conditions can coexist with gout.

Synonyms

Medical subject headings (MeSH)

- Male breast enlargement
- Breast enlargement, male
- Enlargement, male breast

Definition

Nonneoplastic enlargement of the male breast, characterized by hyperplasia of ductal and stromal elements.

Physiological gynecomastia is normally observed in newborns, adolescents, and aging males, that is, in periods of hormonal instability. Thus, gynecomastia can affect approximately 30% of healthy men, as shown in autopsy studies (1).

In contrast, enlargement of the breast almost entirely due to fat deposition is termed pseudogynecomastia or adiposomastia.

Pathology/Histopathology

Histologically, the normal male breast contains subareolar ducts comparable to those in prepubertal girls. Due to hormonal stimulation, these ducts can increase in number, elongate, and branch. Proliferation of epithelial and myoepithelial elements appears, causing increased vascularity and cellularity of the surrounding stroma, with edema being a common component. Because lobule formation is very rare in men, fibroadenoma or cysts seldom develop.

Gynecomastia is not only associated with endogenous hormonal instability, but also with exogenous factors influencing hormonal levels, such as hepatic and renal disease, thyroid dysfunction, hormone-producing tumors, and numerous drugs (e.g., cardiac glycosides, diuretics, antacids, antiretroviral therapy for HIV, marijuana, anabolics).

Whether gynecomastia is a risk factor for male breast cancer is unclear, although it has been reported in association with male breast cancer.

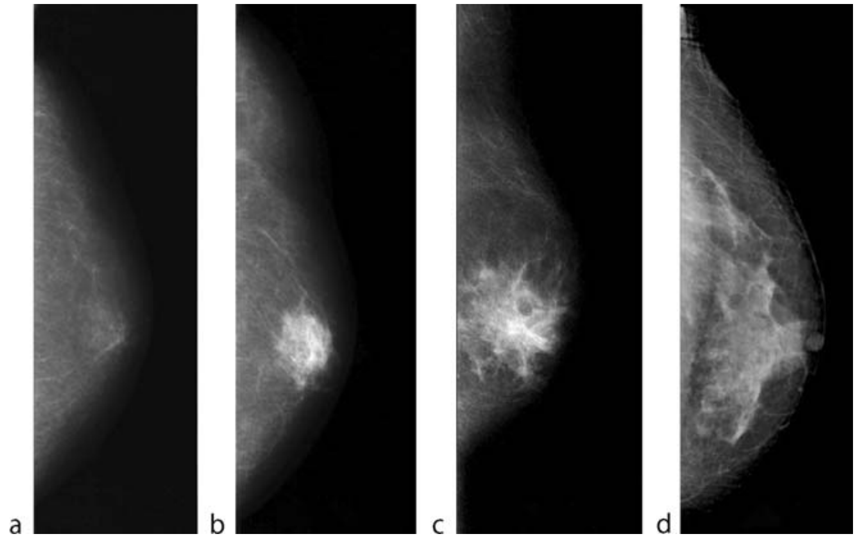
Clinical Presentation

Gynecomastia has a range of manifestations. The condition can occurs bilaterally or unilaterally as a diffuse thickening or a disk-like formation under the nipple. Associated pain, tenderness, and soreness are common complaints. Axillary nodal enlargement may occur despite the benign etiology.

Imaging

Mammography

In gynecomastia, stimulated subareolar ducts and periductal fibrous tissue appear as triangular areas of more or less water-dense tissue radiating form behind the nipple into the periphery of the breast. Right behind the nipple, ducts and periductal fibrosis appear as nearly homogeneous as they are packed closely. The size of the water-dense tissue equals the degree of stimulation and is most prominent in the proliferative phase (2).



Gynecomastia. Figure 1(a–d) Mammographic imaging of male breast enlargement (cc views). (a) Adiposomastia, i.e., fatty tissue only. (b) Gynecomastia nodularis, that is, convex margins of water-dense region behind nipple. (c) Gynecomastia dendritica; that is, serrated margins of water-dense region behind nipple. (d) Gynecomastia diffusa; i.e., concave margins, widely spread water-dense tissue.

Enlargement of the male breast lacking prominent water density in the subareolar region is a sign of adiposomastia or so-called pseudogynecomastia (Fig. 1a).

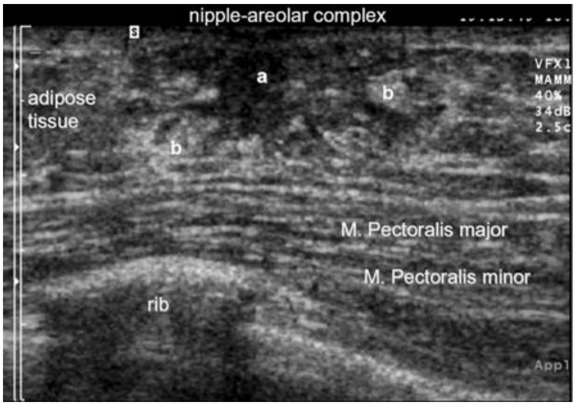
Mammographically, three different types of true gynecomastia can be distinguished:

- Gynecomastia nodularis with convex margins, which makes it difficult to clearly distinguish between gynecomastia and subareolar masses (Fig. 1b).
- Gynecomastia dendritica with serrated margins, especially prominent in the deep margins, caused by widely diverging ducts with insatuated fatty tissue (Fig. 1c).
- Gynecomastia diffusa, displaying mostly concave margins, comparable to the distribution of regular female breast tissue (Fig. 1d).

Ultrasound

The sonographic appearance of gynecomastia varies depending on the proliferative activity.

The typical appearance of proliferative-phase gynecomastia is dominated by stimulated, hypoechoic, and markedly enlarged subareolar ducts. These individual ducts are poorly defined and cannot be demonstrated sonographically as separate structures, but appear mass-like, which makes it difficult to distinguish them from nodular masses. Proliferating gynecomastia can display angular margins and a branch pattern and sometimes microlobulation. An increased metabolic activity is often associated with visibly increased color flow.



Gynecomastia. Figure 2 B-mode sonography 10 MHz (Siemens, Sonoline Elegra®) of mixed-phase gynecomastia; prominent hypoechoic ducts (a) embedded in hyperechoic dense fibrous tissue (b).

The quiescent phase of gynecomastia is dominated by hyperechoic periductal stromal fibrosis; residual small ducts might be seen.

A third, mixed phase reflects the presence of both prominent hypoechoic ducts and markedly hyperechoic dense periductal fibrosis (3), (compare Fig. 2).

Multimodal Diagnosis

The combination of clinical findings, mammography, and breast ultrasound improves the diagnostic confidence. Nevertheless, a normal imaging evaluation should never overrule a strongly suspicious finding on physical examination.

Diagnosis

Physiological gynecomastia, diagnosed by the patient's history including illness, medication, nutrition, and drug abuse, does not require imaging testing. When an underlying etiology for breast enlargement cannot be identified from history and physical examination, imaging is warranted to exclude primary or metastatic breast cancer or paraneoplastic estrogen production.

The imaging modality should be chosen in accordance to the patient's age. In boys and young men, the method of first choice should be ultrasound. In older men mammography is recommended, applying the same standards as for women. So far, there is no place for other imaging techniques in the diagnosis of clinical findings of the male breast.

Minimal invasive biopsy, i.e., core needle biopsy, can help in the diagnosis in cases of nodular gynecomastia, where malignancy cannot be excluded after clinical and imaging examinations.

Synonyms

Anomalies of cortical development; Disorders of neuronal migration

Definition

Spectrum of inherited or acquired congenital malformations characterized by a disruption of the normal architecture of the cerebral cortex.

Pathology and Histopathology

Cortical development results from a complex, programmed sequence of neuronal *proliferation*, *migration*, and cortical *organization* (1–3). Sulcation refers to the infolding of the cerebral surface resulting in multiple, complex branching sulci. The pattern and complexity of the cerebral sulci is tightly related to cortical development.

Subependymal germinal matrix cells begin to *proliferate* into premigratory neurons by the 7th week of gestation. Within the following weeks, these neurons start to *migrate* toward the cortical plate along radial glial cell processes that extend from the germinal matrix to the surface of the brain. Once these neurons have reached the cortical plate, *organization* processes will result in a complex layering of the neurons. The architecture and width of the cortical layers varies between functionally differing cortices.

Cortical malformations or gyration disorders result from a disturbance of the sequence of neuronal proliferation, migration and cortical organization. The etiology is manifold and includes genetic disorders, metabolic diseases, infections, ischemic, or hemorrhagic injuries to the germinal matrix or radial glial fibers or toxic substances ingested by the mother as well as exposure of the fetus to radiation. The timing of interaction with cortical development is essential and may determine severity and extent of cortical malformation.

Anomalies of cortical development can be divided into (A) neuronal migration anomalies and (B) cortical organization anomalies. Neuronal migration anomalies include (a) generalized lissencephalies (Type I and II) and generalized heterotopias as well as (b) focal/multifocal partial lissencephalies and focal/multifocal subependymal/subcortical heterotopias. Cortical organization anomalies include (a) generalized polymicrogyria and (b) focal/multifocal polymicrogyria, schizencephalies and focal cortical dysplasia (FCD) without or with balloon cells (1–3).

In Type I lissencephaly areas of agyria (absence of gyri) and pachygyria (broad gyri with thickened cortex) may coexist. The cortex is composed of a thin outer layer of neurons, an underlying "cell sparse zone" and an inner thick layer of arrested neurons. On gross inspection, the brain surface appears smooth. In Type II lissencephaly, a thickened cortex with shallow sulci is seen in combination with a characteristic irregular white–gray matter junction (cobblestone appearance). Type II lissencephaly is frequently seen in Walker–Warburg syndrome and Fukuyama's congenital muscular dystrophy.

Heterotopias are collections of normal neurons in abnormal anatomical locations, that is, distant to the cerebral cortex. Heterotopias result from an arrest of neuronal migration along the glial fiber tracts. This may result from infections, ischemia, hemorrhage, or may be genetically determined (X-linked band heterotopia).

In cortical organization anomalies (cortical dysplasias) like polymicrogyria the migrating neurons reach the cortex but the intracortical arrangement is disturbed resulting in multiple small gyri. The width of the cortex may be normal or widened. In FCD, a localized cortical dyslamination occurs. Neurons are frequently enlarged and malorientated throughout both the gray and white matter. In FCD Type II (Taylor), balloon cells accompany the enlarged neurons. The cortex is frequently thickened.

Schizencephaly refers to a cerebral cleft that extends from the brain surface to the ventricular system. The cleft is lined by dysplastic gray matter. The cleft walls may be separated by cerebrospinal fluid (open lip schizencephaly) or adhere to each other (closed lip schizencephaly). The etiology is the focus of ongoing investigation.

Clinical Presentation

Children with lissencephaly are usually severely disabled with psycho-motor retardation. Initial hypotonia frequently evolves into spasticity. Refractory seizures may develop at a very early age. Microcephaly is frequent. In focal heterotopias and in cortical organization anomalies, especially in focal cortical dysplasia, severe therapy refractory seizures may interfere with normal development. In schizencephaly, focal neurological deficits may accompany seizures. The degree of mental retardation is related to the extent of cerebral clefting/malformation. Vision may be limited because of a coexisting hypoplasia of the optic nerves and absence of the septi pellucidi in schizencephaly (1–3).

Imaging

Triplanar MRI combining T1, T2, and FLAIR sequences is essential in evaluating disorders of cortical development. High resolution, thin sliced T2-weighted images are especially helpful in delineating cortical anatomy. FLAIR images may be helpful due to its high lesion conspicuity (e.g., gliosis). Contrast injection is rarely necessary as in disorders of cortical development the blood brain barrier is intact (1–3). Functional MRI techniques like diffusion weighted imaging can be helpful.

Neuronal Migration Anomalies

Lissencephaly

Type I: Also known as agyria–pachygyria complex (Fig. 1a), the brain surface is smooth with shallow sulci. The cortex is significantly thickened with a characteristic T2-hypointense thin outer layer that is separated from a wide deeper layer of arrested neurons by a T2-hyperintense "cell-sparse zone." The junction zone between the deeper layer of neurons and the adjacent white matter is smooth. On axial images, the brain resembles the figure "eight." The sylvian fissures are wide open and vertically orientated. The ventricular system is enlarged.

Type II: The cortex is thickened (pachygyric) with shallow sulci. The gray–white matter interface displays a characteristic irregular junction zone resembling "cobblestones." Hypomyelination of the white matter and hydrocephalus may be observed.

Heterotopia

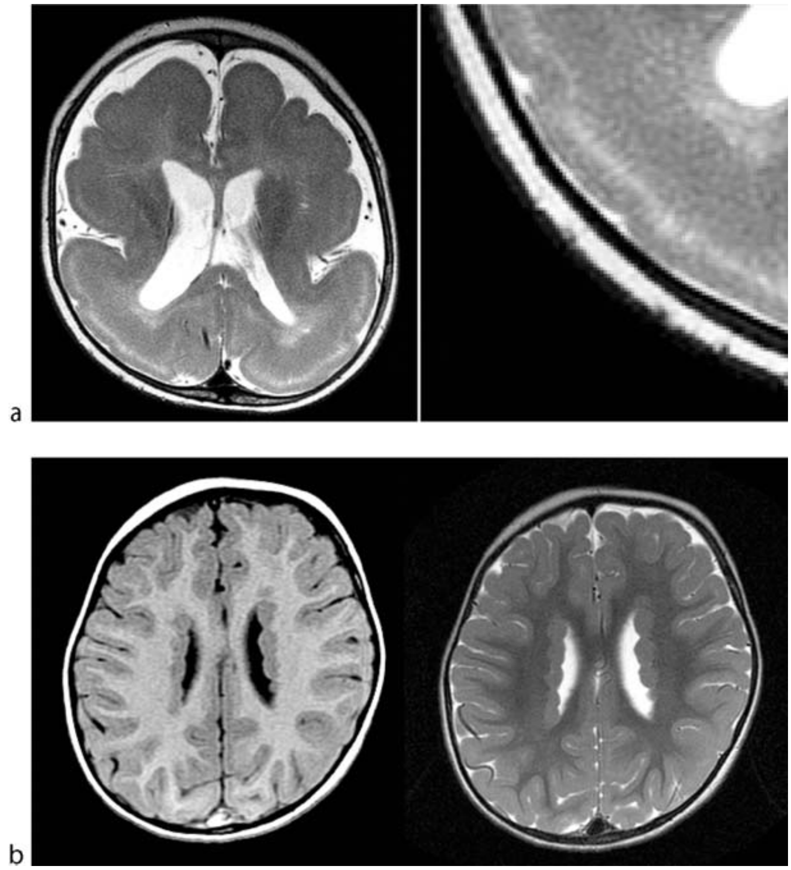
Generalized heterotopia: This is also known as band heterotopia, laminar heterotopia, or double cortex. The ectopically located neurons are arranged in bands that parallel the surface of the brain or the ventricular contour (Fig. 1b). The width of these bands may vary. The ectopic neurons are T1/T2-isointense with gray matter or cortex. In X-linked band heterotopia, the bands of neurons are usually symmetrically arranged within the white matter of the cerebral hemispheres. The overlying cortical ribbon may be normal or pachygyric.

Focal/multifocal heterotopia: Focal collections of heterotopic neurons may be located anywhere between the cerebral cortex and ventricular system. They are accordingly described as subcortical or subependymal/periventricular heterotopias. On MRI, these focal heterotopias are isointense with the cortex on all imaging sequences. According to their histology, the blood brain barrier is intact and no adjacent white matter edema occurs.

Cortical Organization Anomalies

Generalized Polymicrogyria

Polymicrogyria is characterized by multiple small gyri. The gyri may be too small to be detected on routine imaging or may mimic pachygyria. Thin slices with a



Gyration Disorders, Cerebral. Figure 1 (a) Axial T2-FSE MRI. Type II lissencephaly with a T2-hypointense thin outer layer that is separated from a wide deeper layer of arrested neurons by a T2-hyperintense "cell-sparse zone." The junction zone between the deeper layer of neurons and the adjacent white matter is smooth. The sylvian fissures are wide open and vertically orientated, the ventricular system is enlarged. (b) Axial T1-SE and T2-FSE MRI. Symmetrical, subependymal heterotopia. The heterotopic collection of neurons is isointense to the cortex and result in an undulated lateral border of the ventricles.

good signal-to-noise ratio and a good gray–white matter differentiation are mandatory (Fig. 2a). Symmetrical, bilateral polymicrogyria can be seen in syndromes (e.g., Aicardi) as well as in metabolic diseases (e.g., Zellweger). In addition, polymicrogyria may be seen in congenital cytomegalovirus infection. Depending on the underlying etiology, MRI may reveal additional focal lesions.

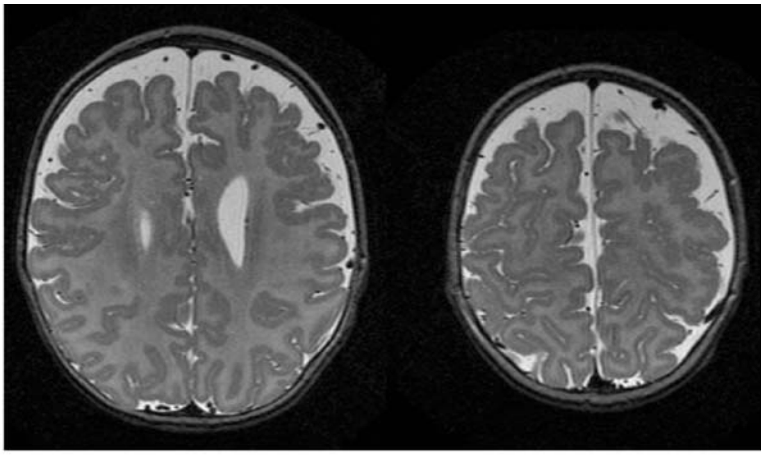
Focal Cortical Dysplasia

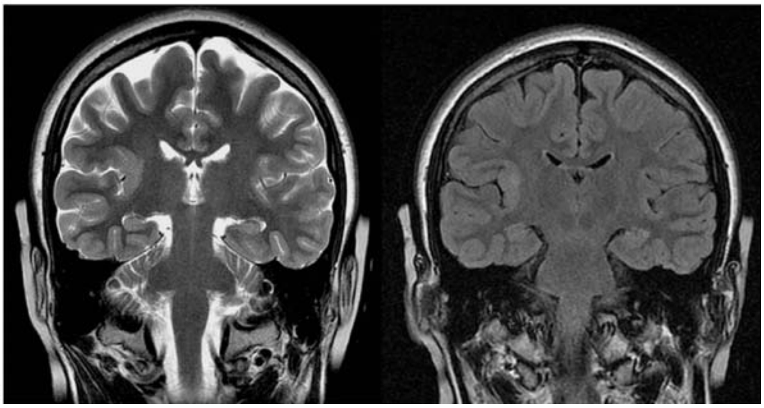
Focal cortical dysplasia refers to a localized cortical organization anomaly in which the cortex is dyslaminated. In focal cortical dysplasia the involved cortex may have a variable appearance. Pachygyria and polymicrogyria may be seen (Fig. 2b). The dysplastic cortex is usually isointense to normal gray matter. Calcification may occur.

In focal cortical dysplasia Type II (Taylor), the balloon cells may increase the signal intensity of the dysplastic cortex on T2-weighted images. The adjacent white matter may show a T2- and FLAIR hyperintense streak extending into the subependymal region.

Schizencephaly

Closed lip schizencephaly can be identified by the dysplastic gray matter lining the cleft. Open lip schizencephalies are easier to recognize as the opening cerebral cleft is filled with T2-hyperintense cerebrospinal fluid. The clefts connect the ventricles directly with the subarachnoid space. Gray matter may extend to the subependymal zone, mimicking subependymal heterotopia. In closed lip schizencephaly a dimple or focal outpouching of the ventricular wall is frequently identified. Prominent pial





Gyration Disorders, Cerebral. Figure 2 (a) Axial, high resolution (0.8 mm slice thickness) T2-FSE MRI. Asymmetrical, multifocal polymicrogyria (left > right) of both frontal and central cortices. The multiple small, tightly packed gyri efface the sulcal pattern of the affected areas. (b) Coronal T2-FSE and FLAIR MRI. Focal cortical dysplasia with a pachygyric insular cortex. No additional lesions were seen. The signal intensity of the affected cortex is isointense to the normal cortex.

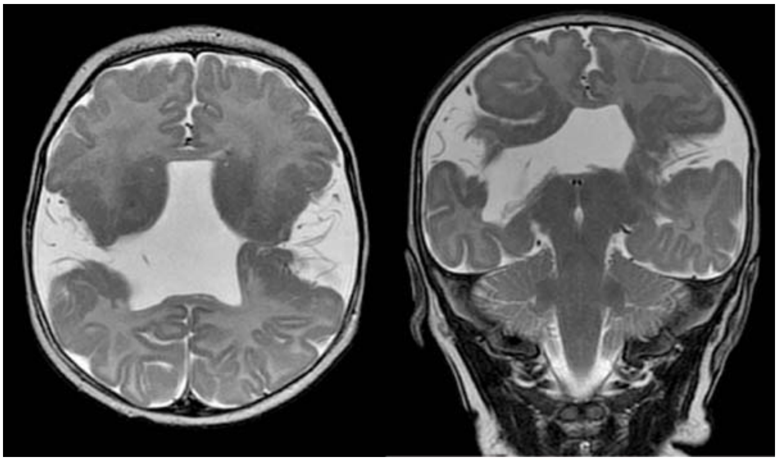
vessels are seen along the lateral opening of the cleft. Schizencephaly may be bilateral and the perisylvian area is most frequently affected (Fig. 3). The septum pellucidum is absent in up to 80% of cases, the optic nerves may be hypoplastic.

Nuclear Medicine

Nuclear medicine studies may be helpful to identify small areas of cortical dysplasia. Between seizure activities these lesions are usually hypometabolic/hypoperfused while they may be hypermetabolic/hyperperfused during seizure activity or shortly thereafter (2). PET and SPECT studies are nonspecific and suffer from a limited spatial resolution; the high lesion conspicuity is however very helpful in guiding imaging studies with a high spatial resolution like MRI. Nuclear medicine studies show you where to look; MRI uses this information for highly detailed focused studies.

Diagnosis

Diagnosis relies on a proper neurological examination and electro-encephalography (EEG). High resolution MRI examinations should identify underlying disorders of cortical development. A thorough knowledge about neuronal proliferation, migration, and cortical organization is mandatory to identify and understand the encountered lesions. However, in many cases of refractory seizures no morphological correlate is seen. In those cases, functional MRI techniques including diffusion weighted sequences, perfusion weighted sequences,



Gyration Disorders, Cerebral. Figure 3 **Axial and coronal T2-FSE MRI. Right sided open lip schizencephaly in combination with a left sided closed lip schizencephaly. The septum pellucidum is missing, the ventricles appear "box-shaped." Prominent pial vessels are seen within the lateral aspects of the clefts. Both clefts are within the perisylvian region. The clefts are lined by a dysplastic, pachygyric-polymicrogyric cortex.**

MR-spectroscopy and functional MRI (fMRI) with simultaneous EEG-monitoring inside the MRI-scanner should be considered. The simultaneous EEG–MRI–fMRI examination combines the strengths of each individual modality: excellent resolution in time (EEG), high resolution in space (MRI), and event related functional information. These combined examinations are however not yet widely available and time consuming.

HADD

Lynne Steinbach
Department of Radiology, University of California, San Francisco, USA
lynne.steinbach@radiology.ucsf.edu

Synonyms

Calcific tendinitis; Calcific tendinosis; Calcium hydroxyapatite deposition disease; Hydroxyapatite rheumatism; Peritendinitis and bursitis; Peritendinitis calcarea

Definitions

Calcium hydroxyapatite deposition disease (HADD) is characterized by periarticular calcifications, usually in tendons near their osseous attachments. Bursae, ligaments and peritendinous tissues may also be affected. This disorder is usually monoarticular and most commonly presents between the ages of 40 and 70 years. Although the etiology is not known, it is thought to be related to either repetitive microtrauma that results in necrotic tissue that takes up the HADD crystals or to a metabolic disorder.

Rarely, HADD can present with intra-articular deposition of crystals, producing an acute arthritis. A milky white effusion may be seen on radiographs. There is also a controversial form of arthropathy that has been called "chronic apatite arthropathy," "apatite-associated destructive arthropathy" (AADA), or "idiopathic destructive arthropathy." It is not known whether this is caused by HADD, but some believe that there is an association. This disorder is common in elderly patients, mostly women (90%) in their seventies. It has a predilection for large joints, including shoulders, hips, and knees. The patients present with joint swelling, reduced range of movement, instability, and loss of function of the affected joint but relatively mild pain and little evidence of inflammation. Large, "cool" synovial effusions are often hemorrhagic and noninflammatory. Radiographically, one sees a rapidly progressive course with evidence of accelerated osteoarthritis, extensive bone destruction, and intra-articular osteochondral bodies.

Pathology/Histopathology

Deposition of hydroxyapatite crystals in fibrous connective tissues, in a typically granular way, can cause an inflammatory synovitis and tendonitis; this may be associated with necrosis and loss of fibrous structure. The deposits appear milky or cheesy in consistency and are chalk-like in quality.

Clinical Presentation

Almost half of the patients present with pain, erythema, swelling, and limitation of motion of the neighboring joint. This is thought to result from rupture of a calcific deposit into an adjacent soft tissue space or bursa causing an acute, self-limited inflammatory reaction. Phagocytosis of hydroxyapatite crystals by neutrophils and macrophages results in the release of lysosomal enzymes and other inflammatory mediators. This is known as acute

►calcific periarthritis. Clinically, HADD can also be accompanied by fever and mimic an infection. A characteristic that distinguishes HADD from infection is that the ESR and leukocyte count are normal.

Treatment is often symptomatic with most symptoms subsiding in less than 2–3 weeks. Nonsteroidal antiinflammatory medication (NSAID) is the treatment of choice. Local corticosteroid injections and oral or parenteral steroids can be used for those who do not tolerate NSAIDs. Symptomatic deposits can also be removed surgically as well as by image-guided needle puncture, aspiration and lavage, and steroid injection if symptoms do not resolve quickly.

Imaging

HADD initially presents on *radiographs* and *CT* as a thin, cloud-like, poorly defined clump of calcification in periarticular soft tissues such as tendons, ligaments, bursas, or synovium. With time, the calcifications become more dense and homogeneous with sharp definition. Deposits may remain static over the years. They can also enlarge, change shape, or disappear. Rarely, the crystal can deposit in the joint. The calcification of HADD is difficult to identify on *MRI* due to the low signal intensity of the calcification and often presents with an aggressive appearance on MRI with marrow and soft tissue edema that simulates infection, injury, or neoplasm. HADD may cause bone erosion (1).

Nuclear Medicine

Skeletal scintigraphy may show increased radiotracer uptake in or around the joints, but these findings are not specific.

Diagnosis

Imaging characteristics and typical diagnostic features of HADD may vary from joint to joint. The most typical and common affected site is the shoulder joint.

Shoulder

The shoulder accounts for 60% of cases of acute calcific periarthritis (2). Periarticular calcifications in one or both shoulders occur in up to 7.5% of adults. Calcifications can be seen in any of the rotator cuff tendons, with the supraspinatus tendon being the most common tendon in the body for HADD deposition. This calcification can be seen near the greater tuberosity on the AP external rotation views of the shoulder. Calcifications of the infraspinatus and teres minor tendons are best seen in profile on internal rotation AP views, lateral to the humeral head (Fig. 1). Subscapularis tendons calcification occurs close to the lesser tuberosity of the humerus. HADD is also seen in the origin of the long head of the biceps above the glenoid fossa, and below the coracoid at the origin of the short head of the biceps and coracobrachialis tendons. Calcification adjacent to the inferior margin of the glenoid indicates HADD at the origin of the triceps tendon. Subacromial subdeltoid bursa calcification appears as a teardrop-shaped radiodense area below the acromion and deltoid muscle. The pectoralis major tendon calcifications are seen along the anterior aspect of the humeral shaft.

Hip

The hip is the second most common site to see HADD. The calcifications usually collect in the gluteus medius tendon near the greater trochanter (Fig. 2) or at the acetabulum. Further down, calcifications are commonly seen at the gluteus maximus attachment along the posterolateral femoral shaft of the femur, best seen on the frog-leg view. Calcifications can also be observed at other tendinous attachments along the femur, including the iliopsoas tendon attachment to the lesser trochanter, and at the hamstring origins along the ischium.

Elbow

HADD is seen in flexor and extensor tendon attachments adjacent to the epicondyles as well as in the collateral

HADD. Figure 1 HADD is identified in the region of the infraspinatus tendon on this AP radiograph of the left shoulder taken in internal rotation (*arrow*).

HADD. Figure 2 Calcification consistent with HADD is seen adjacent to the greater trochanter on this AP view of the left hip (*arrow*).

HADD. Figure 3 Just below the pisiform is a homogenous calcification consistent with HADD in the flexor carpi ulnaris tendon on this lateral view of the wrist (*arrow*).

ligaments. It may also be seen at the triceps, brachialis, and biceps tendon attachments on the olecranon, ulnar, and radial tuberosities, respectively. Olecranon bursal calcification has also been described.

Wrist and Hand

Calcifications of tendons and ligaments of the wrist and hand are seen with the wrist involved more frequently than the hand. The most common site of deposition is in the flexor carpi ulnaris tendon near its attachment to the pisiform (Fig. 3). HADD can lead to carpal tunnel syndrome. Calcifications are also common around the metacarpophalangeal and interphalangeal joints.

Knee

In the knee, HADD tends to occur near tendon attachments. Calcifications are most common adjacent to the femoral condyles, fibular head, and prepatellar region. The popliteus tendon and lateral collateral ligament are sites of involvement with HADD that have been recently described in the literature (3).

Ankle and Foot

Calcific deposits may occasionally be identified in the ankle and foot. HADD has been described in the tendons of the flexor hallucis longus and brevis, and the peroneal tendons. In the first metatarsophalangeal joint, hydroxyapatite pseudopodagra as this HADD is known, occurs predominantly in young, premenopausal women. Unlike most other locations, HADD is more common in young, premenopausal women in this latter site (4).

Spine

HADD in the tendon of the longus coli muscle and tendon was first described by Hartley in 1964 (5). This muscle originates from the anterior surfaces of the upper three thoracic and lower three cervical vertebral bodies and inserts into the anterior tubercle of the atlas and the second, third, and fourth cervical vertebrae. The calcification has a predilection for the superolateral portion of the muscle. Patients present with sudden onset of severe pain in the neck and throat exacerbated by swallowing and head movement. Radiographs and CT demonstrate calcification anterior to the upper cervical spine, particularly C2. Soft-tissue swelling accompanies an acute episode and may extend to the thoracic area. A differential diagnosis for calcification in this region includes an ossicle beneath the anterior arch of C1, a calcified stylohyoid ligament, and a horizontal fracture of the anterior arch of C1. Calcifications can also occur elsewhere in the spine including the ligamentum flavum, infraoccipital region, and interspinous bursae, around the odontoid process and in the apophyseal joints.

Differential Diagnosis

A very characteristic homogeneous, cloud-like appearance distinguishes HADD from most other disorders. Finding the calcifications in the specific sites favored by HADD without an underlying disorder should separate this entity from others in the differential diagnosis. HADD should not be confused with the more linear and diffuse CPPD crystal calcifications described in this article. Gouty tophi are more faintly calcified and are associated with elevated urate levels. Heterotopic bone and myositis ossificans has a trabecular pattern with a cortical rim, which can be distinguished from HADD and CPPD calcifications. ►Tumoral calcinosis, either primary idiopathic or secondary to renal disease, may mimic HADD if in small amounts. One would look for a metabolic disorder in the latter to try to distinguish this. Collagen vascular disease such as scleroderma or dermatomyositis can also produce calcifications that mimic HADD. These calcifications are usually more widespread, can involve the subcutaneous tissues, and have a known underlying disease to go along with them. Periarticular metastatic calcification may also be seen with metastatic calcification due to sarcoidosis, hypervitaminosis D, hypoparathyroidism, and milk-alkali syndrome.

Haemangioma and Haemangioendothelioma in Childhood

Johan G. Blickman[1], Dewi Ashi[2]
[1]Department of Radiology, UMC, Nijmegen, Netherlands
[2]Department of Radiology, Faculty of Medicine, University of Indonesia, Cipto Mangunkusumo General Hospital, Salemba, Jakarta Pusat, Indonesia
j.blickman@rad.umcn.nl

Definition

Hemangioma is a benign vascular tumor with endothelial proliferation. This tumor typically shows a rapid proliferative stage followed by a slower involutional stage. It is the most common benign soft tissue tumor in infancy, occurring in approximately 10% of full-term babies. The female-to-male ratio is 3:1.

Hemangioendothelioma is a benign vascular tumor that occurs in the liver in young infants. It undergoes a rapid proliferative phase and regression. It is the third most common hepatic tumor in children after hepatoblastoma and hepatocellular carcinoma. It may be isolated or diffusely involve the liver. Approximately 85% of affected patients present by 6 months of age, and 50% of patients also have cutaneous hemangiomas. The tumor has a 2:1 female predilection.

Pathology/Histopathology

In hemangioma the tissue reveals proliferating endothelial cells and may also contain other elements such as fat, smooth muscle tissue, myxoid stroma, hemosiderin, thrombus, and even bone.

Infantile hemangioendothelioma manifests as a mesenchymal tumor composed of a connecting network of predominantly small diameter vascular channels lined by endothelial cells. Unlike hemangiomas that contain larger blood-filled spaces with endothelial cell lining, infantile hemangioendothelioma is not an obviously vascular tumor at gross examination of the cut surface. Areas of varying degrees of hemorrhage, necrosis, calcification, thrombosis, or fibrosis are often present in large tumors.

Two types of infantile hemangioendothelioma based on tumor size and vascularity exist: Type I lesions are often calcified and consist of multiple small vascular channels with an immature endothelial cell lining and a fibrous stromal separation containing bile ductules between the channels. Type II lesions have a more disorganized appearance, with an endothelial cell lining and no stromal bile ductules.

Clinical Presentation

Hemangioma

The clinical presentation of hemangioma depends on the depth, location, and stage of evolution. The typical appearance is a slightly raised bluish-red plaque that resembles the surface of a strawberry. Visceral hemangiomas occurring in the liver can present with jaundice, while visceral hemangiomas located in the intestines can result in bloody stool. Hemangiomas located in the airway can produce stridor or dyspnea.

Syndromes associated with hemangioma include *Klippel–Trenaunay syndrome*, characterized by limb hypertrophy with subcutaneous hemangiomas; *Kasabac–Merritt syndrome,* the association of hemangiomas with disseminated intravascular coagulation; and *PHACE syndrome* (posterior fossa abnormalities, hemangioma of the face, arterial abnormalities, coarctation of the aorta, cardiac defects, and eye abnormalities), which may involve extensive facial lesions.

Multiple cutaneous hemangiomas are associated with concomitant visceral lesions.

Hemangioendothelioma

The clinical presentation of hemangioendothelioma may include a palpable abdominal mass, hepatomegaly, diffuse abdominal distention, and congestive heart failure due to secondary arteriovenous (AV) shunting (less common than in giant hemangioma or AV malformation). These tumors are usually benign, but malignant sarcomas have been reported to arise in existing hemangioendotheliomas.

Imaging

Hemangioma: Plain films may show increased soft tissue density and, rarely, skeletal abnormality. Ultrasound during the proliferative phase shows a variably echogenic mass (Fig. 1). Doppler sonography has shown high vessel density (>5 vessels/cm^2) and peak arterial Doppler shift (>2 kHz) in hemangiomas, which is useful in distinguishing hemangiomas from other vascular malformations.

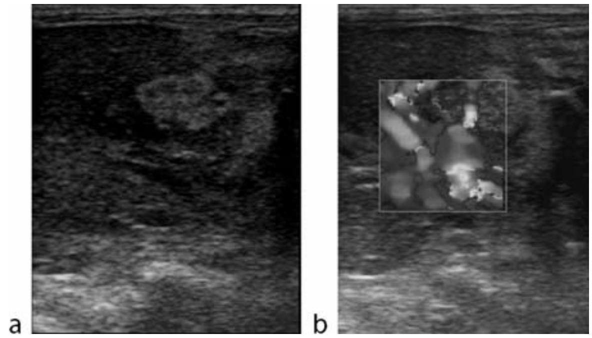
In the involutional phase, the lesion decreases in size and has a reduced number of vessels.

Computed tomography (CT) and magnetic resonance imaging (MRI) in the proliferative phase demonstrate a homogeneous mass with an intense, persistent, and usually lobular enhancement pattern. Involuting hemangiomas are more heterogeneous with less enhancement.

MRI often demonstrates heterogeneous intermediate signal intensity on T1-weighted images. On T2-weighted images, high signal intensity is seen with a flow void in and around the mass. Hemorrhage or fat deposition is seen as high signal intensity on T1- and T2-weighted images.

Angiography reveals a well-circumscribed mass with intense, persistent tissue staining in a lobular pattern and enlargement of feeding arteries. Angiography is required only if endovascular intervention is contemplated.

Hemangioendothelioma: Plain abdominal radiography may show hepatomegaly and a nonspecific mass effect in the upper abdomen, with displacement of intestinal structures and occasional calcifications within the mass.



Haemangioma and Haemangioendothelioma in Childhood. Figure 1 **Doppler ultrasound shows a highly vascularized lesion in the liver. (cited from Fletcher, 2004)**

The appearance of hemangioendothelioma on ultrasound is variable and nonspecific. It may be either hyperechoic or hypoechoic. Most of the tumors have well-defined borders toward the surrounding liver parenchyma. The caliber of the aorta may abruptly decrease below the level of the celiac axis because of increased hepatic arterial flow secondary to intrahepatic AV shunting.

CT shows a well-defined homogeneous or heterogeneous mass, hypoattenuating relative to the normal liver parenchyma. In about 40% of cases there may be calcifications. The postcontrast enhancement pattern resembles that of an adult giant hemangioma (peripheral enhancement in the early phase and central enhancement in the delayed phase). In larger tumors this central enhancement may not occur because of fibrosis, hemorrhage, or necrosis.

On MRI, low signal intensity on T1-weighted images and high signal intensity on T2-weighted images are seen. Flow voids may be observed on T2-weighted images in a tumor with AV shunting and high blood flow. The presence of hemorrhage, necrosis, and fibrosis make the tumor appear heterogeneous both on T1- and T2-weighted images. Postcontrast enhancement is similar to that on CT (Figs 2 and 3).

Angiography is performed only if embolization is considered either as definitive therapy or as a temporizing method prior to transplantation. Characteristically, there is prolonged pooling of contrast within the mass. Internal AV shunting with large draining veins may be seen.

Nuclear Medicine

Hemangioma: Radiolabeled red cell scintigraphy.

Hemangioendothelioma: Nonspecific, early uptake may be seen. Blood pool studies may show increased activity.

Diagnosis

Most hemangiomas are recognized clinically and do not require imaging. Imaging is required for atypical soft tissue masses, for deep hemangiomas with normal overlying skin, and for evaluation of deep extension of obvious hemangiomas. It is also required for hemangiomas that compromise important structures (subglottic hemangioma, periorbital lesions) or that cause high-output cardiac failure or thrombocytopenia (Kasabach–Merritt syndrome).

Differential diagnosis (Fig. 4):

Vascular malformation:

- Abnormal size and/or number of vascular structures
- Usually manifests as cutaneous birthmarks
- No regression.

The clinical manifestations of infantile hemangioendothelioma are variable. The tumor may be asymptomatic and discovered incidentally, but more often the tumor is large and manifests as hepatomegaly, abdominal distention, and/or a palpable upper abdominal mass. High-output failure and platelet consumption due to significant AV shunting can be present. Hematologic abnormality may be seen, including anemia and thrombocytopenia. The serum -fetoprotein level is usually normal, in contrast to hepatoblastoma. Ultrasound shows one or more solid masses with high flow in color Doppler. MRI shows a well-defined mass with an enhancement pattern resembling that of adult giant hemangioma.

Differential diagnosis:

Hepatoblastoma:

- α fetoprotein level is elevated.

Definition

Hepatic hemangiomas are benign, vascular tumors of the liver.

Epidemiology

The prevalence of hemangiomas ranges from 1% to 2% in the general population, the tumor being typically discovered incidentally during evaluation of nonspecific abdominal complaints. The prevalence of hemangiomas has been overestimated in autopsy series (from 2% to as high as 20%), because of overrepresentation of elderly patients with comorbid illnesses. The majority of hemangiomas are small (<4 cm). Liver nodes greater than 4 cm in size are defined cavernous hemangiomas. The reported female:male gender ratios range from 1.6:1 to 6:1.

Pathogenesis

The pathogenesis of hemangioma is unknown. Congenital hamartoma is a likely candidate. A pathogenic role of sex hormones has been postulated, because of consistent female predominance in larger tumors, and tumor enlargement/recurrence in hysterectomized women under estrogen replacement therapy and in patients with a long use of oral contraceptives. Cavernous hemangiomas may have accelerated growth during pregnancy and often display estrogen receptors. However, tumor growth was also induced or influenced by such drugs as metaclopramide.

Pathology and Histopathology

Macroscopically, the tumors are ovoid, soft, reddish-purple or blue masses separated from the surrounding parenchyma by a fibrous pseudocapsule. Varying degrees of fibrosis, hyalinization, calcification, thrombosis, and shrinking are seen. Extensive fibrosis and hyalinization, with narrowing or obliteration of vessels, are typical for sclerosed hemangiomas. Microscopically, hemangiomas are vascular abnormalities characterized by multiple blood-filled sinusoidal spaces and vascular lakes lined by endothelial cells. Vascular channels are separated by a fibrous tissue. They are fed by hepatic artery branches and their internal circulation is slow. Blood vessels and arteriovenous shunting may be seen in large septa. The tumor seems to grow by ectasia rather than by hyperplasia or hypertrophy.

Clinical Presentation

The most common clinical presentation of a hemangioma is an incidental finding on hepatic imaging and the majority of patients will have a single tumor node. A few patients may present with isolated diffuse hemangiomatosis in association with Rendu-Osler-Weber's disease or skeletal hemangiomatosis. Cavernous hemangiomas are typically silent, benign clinically and rarely expanding or symptomatic tumors. The few patients with symptoms complain one of the following: abdominal swelling, abdominal pain, early satiety, anorexia, abdominal mass, and hepatomegaly. There seems to be no correlation between symptoms and number of tumors, as well. Atypical hemangiomas exist that form arteriovenous shunts causing severe symptoms including heart failure. Other unusual clinical presentations of an hepatic hemangioma include hemobilia, inflammatory pseudotumor caused by recurrent intranodal thrombosis, caval thrombosis, portal hypertension, and torsion of a pedunculated tumor.

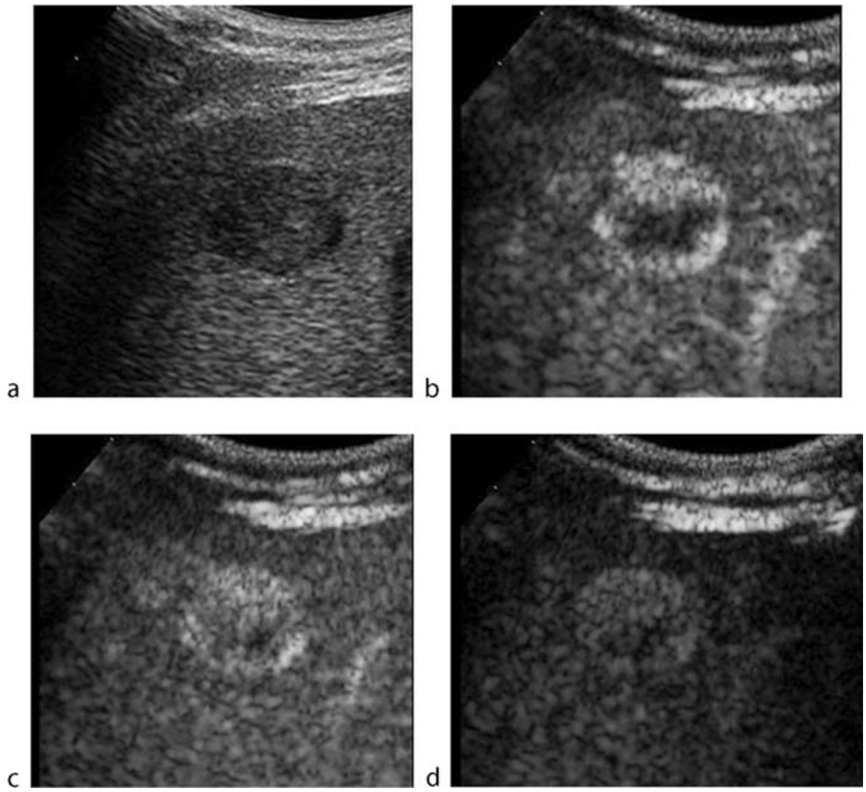
Imaging

Ultrasound and Contrast-Enhanced Ultrasound

The most common ultrasound (US) appearance of hemangioma is that of a sharply demarcated lesion with uniformly increased echogenicity relative to normal liver. This pattern is observed in about 70% of hemangiomas detected by US. The remaining cases show atypical US patterns, and appear either as hypoechoic lesions with a hyperechoic border or as lesions with heterogeneous internal structure. Heterogeneity is commonly observed in large hemangiomas. While there are no vascular patterns that can be used to reliably diagnose hemangioma with conventional color or power Doppler US, early clinical experience with US contrast agents has suggested that contrast-enhanced ultrasound (CEUS) can provide useful information (1, 2). Most liver hemangiomas (78–93%) show peripheral nodular enhancement during the early phase of the contrast-enhanced study, with progressive centripetal fill-in (Fig. 1)(1, 2). Diffuse contrast enhancement with homogeneous fill-in or persistent hypoechoic appearance due to absent contrast enhancement can be observed in small, high-flow hemangiomas or thrombosed hemangiomas, respectively (1).

Computed Tomography

The standard spiral computed tomography (CT) protocol for suspected hemangioma includes baseline and contrast-enhanced scanning in the arterial, the portal venous, and the delayed phase. Most hemangiomas are hypoattenuating on baseline scans, show peripheral nodular enhancement of vascular attenuation on arterial and portal phase imaging, and are hyperattenuating with possible central hypoattenuation or isoattenuation to vascular space in the delayed phase (Fig. 2). This pattern has a sensitivity of 67–86% and a specificity of 99–100% for the diagnosis of hemangioma. Atypical CT features are observed in hemangiomas with either high flow or very



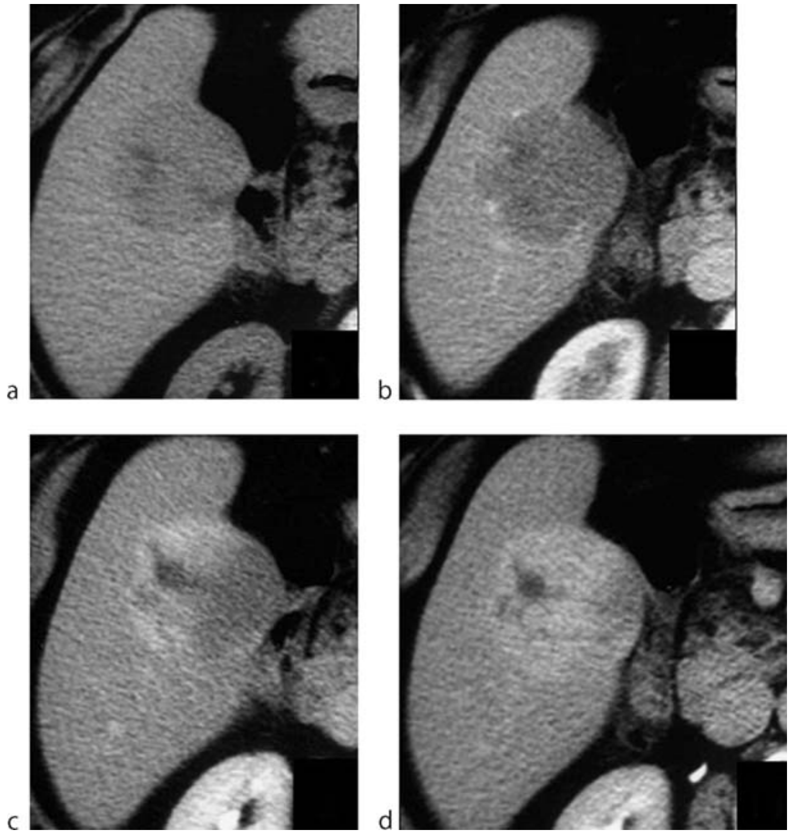
Haemangioma, Hepatic. Figure 1 **Typical hemangioma at contrast-enhanced US. Baseline US (a) shows a hypoechoic, well-defined lesion in the right liver. In the arterial phase (b) (25 sec after SonoVue injection), the lesion shows peripheral globular enhancement while in the portal venous (c) and delayed phases (d) (60 sec and 120 sec after SonoVue injection, respectively) a progressive but incomplete centripetal fill-in is observed.**

slow flow. High-flow hemangiomas show rapid filling after contrast administration, resulting in homogeneous enhancement during the hepatic arterial or portal venous phase (3). This feature is relatively common in small hemangiomas. Differentiation of high-flow hemangioma from hypervascular malignant tumors may be difficult, and relies on attenuation equivalent to that of the aorta during all phases of CT imaging, including the delayed phase. Very slow-flow hemangiomas appear either as nonenhancing lesions or as lesions with weak peripheral enhancement without centripetal progression. These features may be related to thrombosis or abundant fibrosis, and mimic a hypovascular malignant tumor.

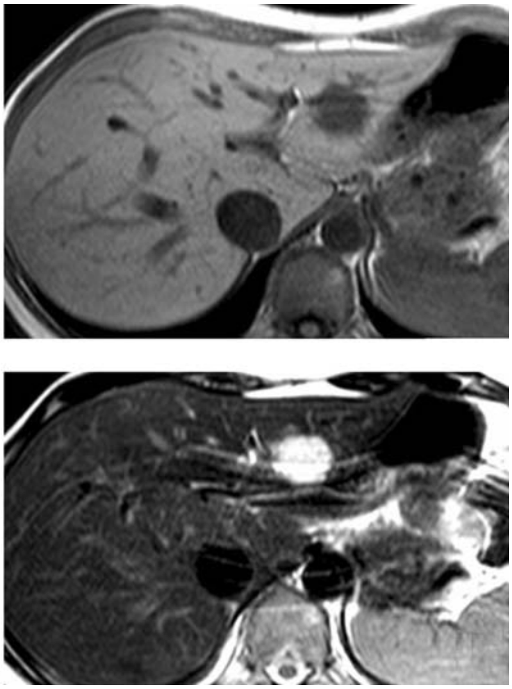
Magnetic Resonance Imaging

Magnetic resonance (MR) imaging protocol for characterizing suspected hemangioma includes gradient-echo T1-weighted sequences, fast spin-echo T2-weighted sequences with short and long (>200 msec) echo times, and serial dynamic gadolinium-enhanced gradient-echo T1-weighted sequences. Hemangioma appears as a homogeneous focal lesion with smooth, well-defined margins. The lesion is hypointense to liver parenchyma on T1-weighted MR images and strongly hyperintense to liver parenchyma on T2-weighted MR images (Fig. 3). The high signal intensity on heavily T2-weighted (long echo time) MR images gives to hemangiomas a consistent "light-bulb" pattern with 100% sensitivity and 92% diagnostic specificity. Dynamic contrast-enhanced MR imaging shows quite a typical perfusion pattern in hemangioma, that is, peripheral nodular enhancement in the early phase with centripetal progression to uniform or almost uniform enhancement during the portal venous and the delayed phase. Such a characteristic enhancement pattern has a sensitivity of 77–91% and a specificity of 100% for the diagnosis of hemangioma (4). However, very small (<1.5 cm), high-flow hemangiomas frequently

H



Haemangioma, Hepatic. Figure 2 Typical hemangioma at multiphase contrast-enhanced spiral CT. On unenhanced CT scan (a) the lesion is hypodense with well-defined margins. A peripheral, globular enhancement of the lesion that progress centrally is observed during the arterial (b) and portal venous (c) phase. Delayed scan (d) shows hemangioma almost completely filled with contrast material.



a

b

Haemangioma, Hepatic. Figure 3 Typical hemangioma at MR. T1-weighted MR image (a) shows hepatic hemangioma in the left lobe as a well-defined hypointense mass. Conversely, on the T2-weighted fast spin-echo MR image (b) the lesion appears markedly hyperintense.

exhibit an hypervascular pattern, with uniform enhancement in the arterial phase, that may persist in the portal venous and delayed phases (4). In these cases, diagnostic assessment may be difficult, and requires careful analysis of baseline and contrast-enhanced images. Hemangioma shows a peculiar feature after the injection of reticulo-endothelial system-targeted MR agents, that is lesion hyperintensity on T1-weighted postcontrast MR images. This is due to the T1 effect of superparamagnetic iron oxide particles trapped within the slow-flow vascular channels of the lesion.

Nuclear Medicine

^{99m}Tc-pertechnetate-labeled red blood cell scintigraphy is a relatively specific examination for characterizing hemangioma. Using this method, there is a decreased activity on early dynamic images and increased activity on delayed blood pool images. Comparison between ^{99m}Tc-pertechnetate-labeled red blood cell single-photon emission CT (SPECT) and MR imaging has shown that MR imaging had higher sensitivity and specificity than SPECT, especially for lesions smaller than 2 cm in diameter.

Diagnosis

The recommended diagnostic work-up for suspected hemangioma is dependent on the clinical scenario. If an hemangioma with typical US features is incidentally detected in a patient with neither history of malignancy nor chronic liver disease, no additional investigation may be required. It has been shown that in this clinical setting the risk of misinterpreting a malignant tumor for an hemangioma is negligible (0.5%). Conversely, in incidental lesions with atypical US features for hepatic hemangioma, further diagnostic work-up is recommended. Additional investigation is also mandatory—regardless of the US features—for any lesion detected in a patient at increased risk for malignancy. MR imaging is currently the most accurate technique for diagnostic confirmation of suspected hemangioma. Despite promising results obtained in recent investigations, contrast-enhanced US is at an early stage of clinical application. On the other hand, spiral CT has limitations in achieving a reliable diagnosis of small lesions, especially in the setting of liver cirrhosis. High-flow hemangiomas that enhance homogeneously in arterial phase CT scans may not be confidently distinguished from small hypervascular hepatocellular carcinoma. Because MR imaging has greater sensitivity to small differences in contrast enhancement and because several fast MR sequences can be used to track the passage of a small, tight bolus of contrast material, MR images may show the characteristic enhancement patterns of hemangioma and hepatocellular carcinoma better than CT images. In addition, MR imaging—besides the information provided by the dynamic gadolinium-enhanced study—can offer improved capability in lesion characterization through the analysis of lesion signal intensity on baseline sequences, especially heavily T2-weighted sequences. In the setting of cirrhosis, diagnosis of hemangiomas should meet strict CT or MR imaging criteria whereas percutaneous biopsy can be used to solve uncertain diagnosis.

Halo Sign

A rim of ground glass opacity surrounding the circumference of a nodule or mass in CT. It is pathologically based on intraparenchymal hemorrhage around the lesion. It is seen in invasive aspergillosis but also in other infections (candidiasis, herpes, CMV, etc.), in malignoma (adenocarcinoma, broncho-alveolar carcinoma, Kaposi sarcoma, metastases), Wegener's granulomatosis or other processes.

▶Nodules, Pulmonary, Solitary

Hamartoma

Tumor-like nonneoplastic overgrowth of tissue of disordered structure.

▶Lymphangioma

Hamartoma, Biliary

This entity also named microhamartoma or von Meyenburgh complex is a benign malformation of intrahepatic bile ducts. Histologically characterized by a focal disarray of dilated tortuous bile ducts, set in a dense fibrocollagenous stroma. Macroscopically these malformations are multiple millimetric grayish nodules. They are frequently associated with congenital hepatic fibrosis and polycystic liver disease but their pathogenesis remain unknown.

▶Congenital Malformations, Liver and Biliary Tract

Hampton Hump

Pleural-based shallow consolidation in the form of a truncated cone with the base against the pleural surface

▶Thromboembolic Pulmonary Arterial Diseases

Hampton's Line

A radiolucent line that separates barium in the ulcer crater from barium in the gastric lumen, created by the undermining of mucosa with minimal edema. It is considered one of the pathognomonic features of benign ulcer.

▶Ulcer Peptic

Hand Held Gamma Probe Detectors

Gamma probe detectors are imaging detectors. A wide range of probe systems are available with different detector materials, detector sizes, and collimation. They are used for preoperative and intraoperative detection of SLNs.

▶Sentinel Node, Scintigraphy

Hand–foot Syndrome

Infarction of small tubular bones in hands and/or feet in early childhood sickle cell anemia.

▶Osteonecrosis in Childhood

Harmonic Imaging

Ultrasound maging approach in which the non-linear harmonic components of the echoes from microbubble contrast agents is detected.

▶Specific Imaging Techniques (Contrast Media, Ultrasound)

Hashimoto's Thyroiditis

Hashimoto's thyroiditis is an autoimmune disease presenting as a chronic lymphocytic inflammation of the thyroid gland.

Head and Neck

Alfredo Blandino, Ignazio Pandolfo
Department of Radiological Science, University of Messina, Italy
ablandino@unime.it

The introduction of the newer imaging modalities such as computed tomography (CT), magnetic resonance (MR), and ultrasonography has dramatically changed the way imaging methods are used to diagnose diseases of the head and neck region.

In particular, the latest advances in the field of CT (multislice CT with the introduction of the isotropic pixel) and consequent improvements in the postprocessing of the images (three-dimensional imaging, VRT, SSD, and virtual endoscopy) has led to the increased quality and quantity of the diagnostic information in certain anatomic areas such as the paranasal sinuses, larynx, and temporal bone (Wang 2001, Rodt 2002).

On the other hand, progress in the field of MRI with the introduction of thin sections, high-resolution imaging, and fast T1- and T2-weighted sequences has made MRI the procedure of choice in the study of some anatomic regions of the head and neck, particularly in the suprahyoid area. Moreover, improvements in the gradient echo and fast spin-echo T2-weighted techniques have meant that MRI may now be used to evaluate the membranous labyrinth and its fluid content, structures never seen before (Casselman 2002).

The goal of providing anatomic information that accurately maps a lesion is met very well by all these imaging methods.

Recently, the areas of new investigation have involved metabolic and functional imaging techniques that may be more successful than cross-sectional imaging in the diagnosis as well as in the follow-up of neoplastic diseases (Shah 2003). These techniques include dynamic contrast-enhanced MR imaging for evaluating soft tissue masses and cervical lymph nodes, the use of ultrasmall superparamagnetic iron oxide contrast agents, and functional techniques such as *in vivo* and *in vitro* MR spectroscopy of head and neck cancer and lymph nodes and apparent diffusion coefficient mapping of parotid glands (Star-Lack 2000, Mack 2002, Sumi 2002).

Positron emission tomography (PET) and thallium-201 single photon emission tomography (Tl-201 SPECT) are other innovative techniques that may be helpful in providing functional and metabolic information about abnormalities of the head and neck region, with the aim not only of differentiating between benign and malignant diseases but also of providing information that helps assess the response to nonsurgical organ preservation treatment protocols (Fischbein 1999, Hanasono 1999, Mukherji 2000).

From the anatomic point of view, the head and neck region is encompassed between the skull base and the inlet of the mediastinum. The skull and its contents, in fact, are usually considered as pertaining to the field of neuroradiology. All of the remaining anatomic structures except the cervical spine and vessels (which are dealt with by neuroradiology and vascular radiology, respectively) are usually covered by head and neck radiology. The base of the skull represents the boundary between the head and skull contents and is generally considered under the scope of head and neck radiology.

From the topographic point of view, we can distinguish the face, which is located anteriorly and superiorly, and the neck, which runs more posteriorly from the base of the skull to the inlet of the mediastinum. The face includes the:

1. Orbits and their contents
2. Nose and paranasal sinuses
3. Oral cavity with the oral tongue
4. Jaws and temporomandibular joint
5. Salivary glands

The neck is composed of muscles, fat, vessels, nerves, lymphatic tissue, fascial planes, and a visceral compartment, including the aerodigestive tract (pharynx and larynx) and the thyroid and parathyroid glands.

After a brief description of the neck anatomy, we will consider key points of the several anatomic components of the head and neck with a short summary of their most frequent abnormalities.

Finally, lymphatic metastasis and perineural spread are two typical means by which malignancy spreads in the head and neck region and should be considered separately.

Anatomy of the Neck

Muscles and Triangles (Som 2003)

The most important anatomic landmark of the neck is the sternocleidomastoid muscle, which runs in the lateral neck, from the mastoid process to the sternum and clavicle. In its oblique course, the muscle divides the neck into anterior and posterior triangles.

The anterior triangle is limited posteriorly by the sternocleidomastoid muscle and anteriorly by the anterior belly of the omohyoid muscle. Its superior boundary is traditionally considered to be the undersurface of the body of the mandible.

Another fundamental anatomic structure is the hyoid bone, which divides the anterior triangle into suprahyoid and infrahyoid compartments.

In the anterior and more superficial part of the neck, close to the midline on each side, there are two triangles called muscular triangles that containing the infrahyoid strap muscles (thyrohyoid muscle and sternohyoid muscle). The strap muscles are very superficial and cover the thyroid gland and the thyroid cartilage.

Finally, the posterior triangle, encompassed between the sternocleidomastoid muscle anteriorly and the trapezius muscle posteriorly, is divided by the inferior belly of the omohyoid muscle into a larger occipital triangle and a smaller one, called the subclavian triangle.

The Fascia and Spaces of the Neck (Som 2003)

Classically, the neck is divided into spaces delimited by fasciae, which may limit to a varying extent the spread of infection and neoplastic diseases. The fasciae of the neck are traditionally classified as superficial cervical fascia (SCF) and deep cervical fascia (DCF). The SCF covers the face and neck and lies on the platysma and mimic muscles.

The DCF, conversely, is characterized by a more complex structure and is divided into three layers: the superficial layer of the DCF (SLDCF), the middle layer of the DCF (MLDCF), and the deep layer of the DCF (DLDCF). The SLDCF represents an outer layer that completely encircles the neck. The MLDCF, with its deep division, covers the surface of the esophagus and pharynx and at this level is termed "visceral fascia." Ventrally, the DLDCF covers the anterior surface of the cervical vertebrae. This fascia is termed prevertebral fascia and is divided into two layers, which are separated by a thin connective plane and are fused at the level of the fourth thoracic vertebra.

For this reason, this virtual space is a potential route for the spread of infection into the mediastinum and is known as the "danger space."

Finally, the expansion of the three layers of the DCF contributes to the formation of the carotid sheath, an anatomic compartment containing the internal carotid artery and part of the external carotid artery; the jugular vein; cranial nerves IX, X, XI, and XII; and lymph nodes.

According to most authors, the suprahyoid part of the carotid sheath can be considered part of the parapharyngeal space (the retrostyloid compartment).

The Lymphatic System of the Neck

The lymphatic system of the head and neck consists of lymphatic tissue associated with the mucosa, forming the Waldeyer's ring, and of about 300 lymph nodes embedded in fat tissue. The traditionally used classification for identifying the lymph nodes was that of the French anatomist Rouvière. More recently, the Rouvière system was replaced by a simpler system based on levels.

Base of the Skull

The base of the skull can be divided into three regions: anterior, posterior, and central. The anterior skull base consists of the roof of the orbits, the cribriform plate of the ethmoid bone, the frontal sinus, and the lesser wing of the sphenoid; this topic is covered in the section on paranasal cavities.

The posterior skull base is the temporal bone, and this topic is covered in the section on temporal bone.

The central skull base is formed of the sphenoid bone with a smaller contribution from the basioocciput. Since the foramina of the sphenoid bone open in the bordering soft tissue, the latter must be considered an integral part of the skull base (Curtin 2003). The most important extracranial soft tissues are the pterygolopalatine fossa and the masticator space, whereas the cavernous sinus and Meckel's cave are the landmarks of the intracranial soft tissue bordering the skull base.

In general, lesions of the central skull base can be divided into three categories:

- Intracranial lesions involving the skull base (this topic will be covered separately).
- Primary or secondary osseous lesions.
- Extracranial lesions involving the skull base (this topic will be covered separately).

Globes and Orbits

The orbits are two recesses containing the globes, lacrimal glands, muscles, blood vessels, nerves, and adipose and connective tissue.

For descriptive purposes, the orbit has been divided into the extraperiosteal, subperiosteal, extraconal, conal, and intraconal spaces (Mafee 1995). The intraconal space is separated from the other spaces by the rectum muscles and their intermuscular septa and contains the optic nerve.

The subdivision of the orbit into different spaces has great value both for radiological diagnosis as well as for surgical planning, as some lesions have a predilection for a specific space.

CT and MRI are the two most common techniques used for imaging this complex anatomic region.

CT is the technique of choice for bony details, for detecting calcification, and for evaluating foreign, especially metallic, bodies in or around the globe and orbit (Lakits 1999). The radiation dose to the lens is one of the major disadvantages of CT.

Conversely, MRI, because of its ability to detect different soft tissues and fluids, has become the method of choice for imaging eye disorders.

From a schematic point of view, it is possible to distinguish ocular from orbital diseases.
Ocular diseases include:

- Congenital ocular diseases
- Ocular detachments
- Retinoblastoma
- Persistent hyperplastic primary vitreous

Orbital diseases include:

- Congenital diseases
- Inflammatory and granulomatous
- Benign and malignant tumours
- Trauma
- Optic nerve diseases

Teeth, Mandible, Maxilla, and Temporomandibolar Joint (TMJ)

Panoramic radiography still remains the basic X-ray evaluation of the mandible--maxillary region, giving a survey of the entire mandible, the maxilla (including the lower part of the nasal cavity and maxillary sinuses), and the teeth. This single examination can be supplemented by other techniques such as intraoral radiography, CT, and MRI.

CT has become an important diagnostic tool in the assessment of this anatomic region, especially with the development of a dental reformatting program (i.e., the Dentascan) (Au-Yeung 2001, Gahleitner 2003).

Dental caries and periodontal disease are generally evaluated with panoramic and intraoral radiographs, whereas space-occupying lesions of the mandible and maxilla are better studied using CT and, rarely, MRI.

It should be remarked that despite the application of all the radiological methods, a definitive diagnosis of space-occupying masses is difficult to obtain, and surgical and histological examination are mandatory. The most important features that should be considered in order to obtain a tentative radiological diagnosis are (1) the location of the lesion within the mandible or the maxilla, (2) the size, shape, and demarcation of the lesion, (3) the relationship of the lesion to the adjacent tooth structures, and (4) the degree of lucency and the presence of intralesional calciossification. The analysis of these criteria forms the basis for the final radiological diagnosis.

It should also be stressed that the dental reformatting program has opened up new horizons in the field of dental implants and has introduced a new era of cooperation between the radiologist and the dentist or oral surgeon (Mupparapu 2004).

Moreover, the ability of MR imaging to visualize soft tissue structures in and around the temporomandibular joint (TMJ) make this the primary imaging technique for most clinical presentations, especially for internal derangement related to displacement of disk (Rudisch 2001).
Teeth, mandible, and maxillary diseases include:

- Caries and periodontal diseases
- Benign and malignant odontogenic and nonodontogenic tumours
- Trauma
- Infectious diseases
- Fibro-osseous lesions

TMJ disease includes:

- Internal derangement of the TMJ
- Tumours and tumour-like conditions
- Trauma

The Nose and Paranasal Sinuses

The paranasal sinuses include the frontal, ethmoid, sphenoid, and maxillary sinuses. They are air-filled cavities that develop in the facial bones and in the base of the skull.

From the embryological point of view, all of the sinuses originate as evaginations of the nasal fossae. The paranasal sinuses contribute to humidifying and warming the inspired air, to improving the resonance of the voice, to increasing the olfactory area, and to absorbing shock to the face and head in trauma.

The nasal fossa is divided by the turbinates (superior, middle, and inferior) into three distinct air passages, called the superior, middle, and inferior meati.

The posterior ethmoid cells and the sphenoid sinus drain into the superior meatus. Into the middle meatus drain the frontal sinus (*via* the frontal recess), the maxillary sinus (*via* the maxillary ostium and infundibulum), and the anterior ethmoid cells. Finally, the inferior meatus receives the nasolacrimal duct.

An understanding of the anatomy of the lateral wall of the nasal fossa and particularly of the osteomeatal unity (middle turbinatus, bullae ethmoidalis, infundibulum, ostia, and uncinate process) is the key for guiding functional endoscopic surgery in chronic inflammatory rhinosinusal diseases (Harnsberger 1990).

For this reason, CT study has become the most requested imaging procedure for examining the paranasal sinuses. High-resolution CT with three-dimensional and SSD reconstruction is also the first-line evaluation in traumatic and congenital lesions of the face and paranasal sinuses.

Finally, both CT and MRI can be used to evaluate benign and malignant lesions of the nose and paranasal sinuses in order to study local extension, with particular regard to involvement of some critical areas such as the pterygoid fossa or orbit (Som 2003).

Diseases of the nose and paranasal sinuses include:

- Congenital diseases
- Chronic inflammatory diseases
- Granulomatosis
- Benign and malignant diseases
- Trauma

Oral Cavity

The oral cavity is the most ventral portion of the aerodigestive tract, separated from the oropharynx by the anterior tonsillar pillar and the soft palate. The oral cavity includes the mobile or anterior two-thirds of the tongue, the hard palate, the flour of the mouth, the lips, and the gingivobuccal and buccomasseteric regions, including the retromolar trigone. The base of the tongue and soft palate belong to the oropharynx.

The primary reason for imaging the oral cavity is to evaluate and stage squamous cell carcinomas, which account for 90–95% of all malignant neoplasms of this head and neck region. Alterations of normal anatomy or abnormal regions of density on CT or signal intensity on MR are the key features in the diagnosis (Sigal 1996). Smoking and alcohol use are considered the most relevant risk factors for developing the carcinoma, which arises more frequently in the lips.

Congenital, vascular, and inflammatory lesions are by far the most frequent pathologies among the benign disorders.

Diseases of the oral cavity include:

- Congenital diseases
- Inflammatory diseases
- Benign and malignant tumours

Salivary Glands

The salivary glands are divided into major and minor salivary glands. The paired parotid, submandibular and sublingual glands are referred to as the major salivary glands. The minor salivary glands are clusters of salivary tissue present throughout the submucosa of the oral cavity, particularly concentrated in the buccal, labial, palatal, and lingual regions, but also found in the paranasal sinuses, pharynx, and upper respiratory tract.

Major and minor salivary glands produce the saliva, a clear, viscid fluid that moistens the mouth, lubricates food, and converts starch into maltose with the enzyme ptyalin.

Imaging studies of major salivary glands have evolved from conventional X-ray to sialography, ultrasound, radionuclide studies, contrast-enhanced CT, and MRI.

Despite the diagnostic effectiveness of all of these techniques, we must take into account the fundamental role still played by fine-needle aspiration in the diagnostic approach to benign and malignant lesions of the parotid and submandibular glands.

Stones of the submandibular or parotid ducts causing obstruction and salivary colic pain are a frequent disease. Acute and chronic infections, autoimmune disease (such as Sjogren's syndrome), and benign and malignant tumours are the others common salivary gland diseases.

Salivary gland diseases include:

- Benign and malignant lesions
- Acute and chronic inflammations
- Salivary stones

Pharynx

The pharynx is a musculomembranous tube extending from the skull base to the level of the caudal cricoid cartilage; anatomically it has been subdivided into three sections: cranially, the nasopharynx, which extends from the skull base to the hard palate; at an intermediate level, the oropharynx, which extends from the hard palate to the level of hyoid bone; and caudally, the hypopharynx, which extends from the hyoid bone to the caudal cricoid cartilage (Mukherji 2003).

Nasopharynx

The nasopharynx, the most cranial cavity of the pharynx, is roughly tubular or cuboidal in shape. The roof is formed by the floor of the sphenoid sinus and upper clivus; inferiorly the nasopharynx is continuous with the oropharynx at the level of the soft palate, and anteriorly it communicates with the choanae, through which it is continuous with the nasal cavities. Posteriorly this airway space is limited by the lower clivus and upper cervical spine along with the prevertebral musculature.

Very important superficial anatomic landmarks of the nasopharynx are the torus tubarius, the Eustachian tube orifices, and the lateral pharyngeal recesses (i.e., the fossa of Rosenmuller).

H

The submucosa contains minor salivary glands as well as a prominent lymphoid component, the most important of which are the adenoids or nasopharyngeal tonsils, situated in the roof of the nasopharynx.

Oropharynx

The oropharynx is posterior to the oral cavity and originates at the level of the soft palate. It includes the tongue base, the soft palate, the palatine tonsils and the pharyngeal constrictor muscles.

The palatine tonsils reach maximal size at puberty, whereas the lingual tonsils lie at the tongue base.

Hypopharynx

The hypopharynx will be described in the sections dealing with the larynx.

Carcinomas accounts for the vast majority of malignant diseases of the nasopharynx and oropharynx. Tobacco and alcohol use as well as prior irradiation, poor oral hygiene, and Epstein–Barr virus infection are the most important epidemiological factors in the development of upper aerodigestive tract cancers (Mendenhall 1994).

CT and MRI provide images with noteworthy information and striking anatomic details, which are very helpful in evaluating the presence and extension of neoplastic disease.

Anatomically closely correlated to the upper pharynx are some spaces and fossae that can be secondarily involved in neoplastic and infectious diseases but can also be the primary source of pathologic process.

The parapharyngeal space is a predominantly fat-filled space with an inverted pyramid shape that extends from the base of the skull to the level of the greater cornu of the hyoid bone. This space is subdivided into an anterior, or prestyloid, and a posterior, or retrostyloid, compartment, which is also known as the carotid space.

The masticator space is situated lateral to the parapharyngeal space and contains the masticator muscles and the upper part of the mandible. It is generally affected by vasculogenic tumours and inflammatory lesions.

The pterygopalatine and infratemporal fossa are two important crossway regions, containing vascular, nervous, and muscular structures.

The pathology of the rhinopharynx and oropharynx and related spaces includes

- Benign and malignant tumours
- Infections
- Primary and secondary lesions of the parapharyngeal space

Temporal Bone

Temporal bone consists of five parts: the squamous, mastoid, petrous, and tympanic portions and the styloid process.

The petrous and mastoid portions are the most important parts of the temporal bone because of their significant role in head and neck diseases. The petrous bone represents the posterior part of the base of the skull and contains the outer, middle, and inner ear. The outer ear consists of the external auditory canal, which is separated from the middle ear by the tympanic membrane. The tympanic cavity communicates with the nasopharynx by means of the Eustachian tubes and is crossed by the ossicular chain. In the middle ear is also part of the course of the facial nerve.

More laterally, the petrous bone contains the inner ear, which consists of the bony labyrinth (vestibule, semicircular canals, and cochlea) containing the membranous labyrinth (cochlear duct, vestibular sense organs, and endolymphatic duct and sac). The space between the bony and membranous labyrinth is filled by a small amount of fluid (perilympha), and the membranous labyrinth is filled by the endolympha.

In the more lateral part of the petrous bone runs the internal auditory canal, which contains cranial nerves VII and VIII, the intermediary nerve, and the internal auditory artery.

The diagnostic imaging technique and the algorithmic approach to temporal bone diseases depend on the symptom complex and clinical presentation (Swartz 1998). High-resolution CT is the method of choice when detection of the finest bony details is necessary, as in the suspicion of chronic otomastoiditis, in trauma, in otosclerosis, and in evaluation of postsurgical middle ear.

But in adult patients complaining of retrocochlear sensorineural hearing loss, contrast-enhanced MRI is mandatory to detect an acoustic tumour.

Vertigo should be studied both with CT and MRI. In the presence of peripheral facial nerve palsy, both CT and MRI can be employed, and the choice is related to clinical presentation.

Diseases of the temporal bone include

- Congenital conditions
- Trauma
- Acute and chronic inflammatory diseases
- Benign and malignant tumours
- Otosclerosis and dysplasias
- Facial nerve palsy

Larynx and Hypopharynx

Larynx

The larynx is a very complex structure composed of cartilage, fibrous membranes, ligaments, mucosa, fat, and muscles (Hermans 2001).

The laryngeal framework consists of the epiglottis, thyroid, cricoid, and arytenoid cartilages. The thyroid cartilage is suspended from the hyoid bone by the thyrohyoid membrane. The thyroid and cricoid cartilages are connected by the cricothyroid membrane. The epiglottis and arytenoids are connected by the aryepiglottic folds, which contain the aryepiglottic muscles and quadrangular membrane.

The muscles of the larynx can be divided into intrinsic and extrinsic. The intrinsic muscles connect the different cartilages and enable their coordinated movements. All of the intrinsic muscles except the posterior cricoarytenoid are adductor muscles (closing).

The larynx can be subdivided from cranial to caudal into three regions: supraglottis, glottis, and subglottis. The supraglottis region includes the epiglottis, the aryepiglottic folds, the false vocal cords, the ventricle, and the upper part of the arytenoids. The glottis includes the true vocal cords, the anterior and posterior commissure, and the lower part of arytenoids. The subglottis region includes the lower part of the cricoid.

The three main functions of the larynx are:

- Protection of the airway during deglutition, by constricting the supraglottis and glottis structures
- Provision of the overpressure of the air in the lungs
- Production of the voice due to passive vibration of the true vocal cords and modulation of the air column

The main role of diagnostic imaging of the larynx is to supply additional information to establish pretherapeutic staging and correct treatment of laryngeal cancer (radiation therapy versus surgery or total laryngectomy versus conservative surgery). The paralaryngeal space and cartilages are the critical areas in defining the pretreatment planning. Both state-of-the-art CT and MRI can give all the information needed by the surgeon, but most authors prefer CT as the first-line technique because it is more available and shorter in duration, resulting in less motion degradation of the images. Moreover, multislice CT gives high-quality coronal and sagittal reconstruction images and enables dynamic study during phonation.

Hypopharynx

The hypopharynx is the lower part of the pharynx and extends from the level of the hyoid bone to the inferior margin of the cricoid. The hypopharynx can be divided into three subsites: the pyriform sinus (paired), the posterior hypopharyngeal wall, and the postcricoid region.

The pyriform sinuses are grooves created by the impression of the larynx on the anterior wall of the pharynx. The aryepiglottic folds separate the pyriform sinus from the laryngeal lumen. The apex of the pyriform sinus is located at the level of the cricoarytenoid joint.

The posterior wall of the hypopharynx is continuous with the posterior wall of the oropharynx, is 6–7 mm high, and laterally is in direct continuity with the pyriform sinuses.

The postcricoid region extends from the level of the arytenoid cartilages to the lower border of the cricoid and is composed of the mucosa covering the posterior aspect of the cricoid cartilage.

Over 90% of hypopharyngeal carcinomas are squamous cell carcinomas. In 80–90% of cases, the hypopharyngeal carcinoma originates in the pyriform sinus, whereas tumours of the posterior wall and retrocricoid area are rarer. About 75% of the patients have lymph node metastasis at the time of the initial diagnosis.

Submucosal diffusion and invasion of the laryngeal framework are very frequent events and are well detected by CT as well as by MRI.

Diseases of the larynx and hypopharynx include:

- Laryngeal and hypopharyngeal carcinoma
- Inflammatory disease
- Benign tumours
- Laryngeal trauma

Thyroid and Parathyroid Glands

The thyroid gland has two lobes connected by an isthmus and is situated anteriorly to the first three tracheal rings; each lobe has a superior and inferior pole. The size of the gland varies with patient age, gender, and weight. It is generally situated in the neck above the level of the clavicle, but sometimes, extension in the superior mediastinum can occur.

The thyroid gland synthesizes hormones that play a fundamental role in regulating several metabolic functions, including lipid catabolism, cardiac rate and output, and skeletal growth.

Cross-sectional imaging, mainly ultrasound but also CT and MR imaging, provides anatomic and morphologic information, which needs to be integrated with functional information obtained using nuclear medicine (Loevener 2003).

The number of parathyroid glands range from 1 to 12, although most individuals (about 80%) have four. In 75% of patients, the upper parathyroid gland lies posterior to the middle one-third of the thyroid gland, whereas the most common anatomic location of the lower parathyroid glands is lateral to the lower pole of the thyroid gland.

Imaging of the parathyroid glands basically focuses on detecting adenomas in patients with primary hyperparathyroidism, and the role of imaging is debated regarding the primary method to be used to recognize such adenomas (Loevener 2003). Not infrequently, surgical exploration of the neck is requested to discover the diseased gland in patients with clinical signs of primary hyperparathyroidism.

Moreover, the close anatomic relationship with the thyroid gland can be the cause for accidental removal of the glands during thyroid surgery.

Diseases of the thyroid and parathyroid glands include:

- Congenital thyroid anomalies
- Autoimmune diseases
- Thyroid goiter
- Benign and malignant lesions of the thyroid and parathyroid gland

Lymphadenopathies

The detection of metastatic nodal disease is a critical event because it is one of the greatest prognosticators in the natural history of head and neck cancer. In fact, in patients with upper aerodigestive tract tumours, survival is reduced by nearly 50% in the presence of metastatic disease at the time of diagnosis.

Unfortunately, the imaging diagnosis suffers from lack of specificity because a wide variety of diseases may cause confusion and/or mimic metastatic nodal involvement. These include bacterial and viral diseases, lymphomatous, tuberculosis, and other granulomatosis diseases such as sarcoidosis.

However, only gross metastatic disease can be identified because microscopic neoplastic deposits escape current detection methods. Nevertheless, it is possible that in the near future, the newer diagnostic modalities like MR spectroscopy, PET, and thallium-201 SPECT might improve the specificity and sensitivity in the diagnosis of nodal metastasis (Star-Lack 2000, Hanasono 1999).

The current diagnostic criteria of lymphadenopathy are based on the following:

1. Size evaluation
2. Morphology evaluation
3. Central necrosis
4. Extranodal tumour extension

Congenital Neck Lesions

There is a wide range of congenital neck lesions that must be considered in the differential diagnosis with lymphadenopathies. They include anomalies of the branchial apparatus, vascular and lymphatic lesions, and thyroid anomalies (Som PM 2003).

Perineural Spreading

Perineural spreading is due to macroscopic neoplastic diffusion along the neural sheath and is a highly typical event in head and neck malignancies (Parker 1991, Chong 1996). The perineural spread can occur in a retrograde or anterograde direction and is characterized by relevant therapeutic and prognostic implications. Virtually any head and neck malignancy (squamous cell carcinoma, adenoid-cystic carcinoma, lymphoma, melanoma, etc.) may spread along the perineural route. The trigeminal and facial nerves are the most common routes of perineural spread.

Head and Neck Cancer

Malignant or benignant cellular growth caused by abnormal and uncontrolled cell division at level of head and neck.

▶Carcinoma, Hypopharynx
▶Neoplasms, Benign and Malignant, Larynx

Head, Injury

▶Trauma, Head, Accidental

Heartburn

A burning retrosternal sensation associated with reflux of gastric acid into the oesophagus.

▶Reflux, Gastroesphageal in Adults

Helicobacter Pylori

A bacillus that colonizes the stomach and predisposes to peptic ulceration both by acid hypersecretion and by compromising mucosal defense mechanisms.

▶Ulcers, Peptic

Hemangioma

Vascular malformation, benign. Several types depend on pathology—venous, capillary, arterial, or combination.

▶Neoplasms, Bone, Benign
▶Neoplasms, Soft Tissues, Benign

Hemangiomas

Benign tumors or malformations of mature vessels.

▶Breast, Benign Tumours

Hematoma

Collection of extravasated blood in a traumatic tear or surgical cavity.

▶Trauma, Breast

Hematoma, Epidural

►Trauma, Head, Accidental

Hematoma, Hepatic

Hepatic hematoma is an encapsulated, intraparenchymal blood collection. It is usually located between the capsule of the liver and the parenchyma in the anterolateral aspect of right lobe; however, a hematoma can exist anywhere within the liver parenchyma. Hematoma of the liver usually results from trauma and is caused by bleeding into a tissue laceration. Iatrogenic causes, such as percutaneous needle biopsy, interventional radiology procedures involving catheters or wires, and biliary lithotripsy, are often involved. Hepatic hematomas arising from spontaneous bleeding are rare. Hepatic hematoma appears as a well-defined, round (intraparenchymal hematomas), or curvilinear (subcapsular hematomas) mass.

The Ultrasound Appearance of Hepatic Hematoma Changes with Time. It is usually hyperechoic in the acute phase, whereas it appears inhomogeneously hypoechoic, with internal echoes due to septation and debris, in a more chronic stage.

In an acute or subacute setting, computed tomography (CT) features of hematoma are hyperdense areas on baseline CT scan not enhanced after contrast medium administration, whereas chronic hematoma is hypoattenuating on the precontrast scan and can display rim enhancement following intravenous contrast medium administration.

The magnetic resonance characteristics of hepatic hematoma depend mainly on the age of the hemorrhagic lesion. Acute hematoma shows an intermediate signal intensity on T1-weighted images and a low signal intensity on T2-weighted images due to the high-intracellular concentration of deoxyhemoglobin in red blood cells, whereas subacute hepatic hematoma, because of the presence of extracellular methemoglobin, appears as a heterogeneous mass with pathognomonic high signal intensity on T1-weighted images and intermediate signal intensity on T2-weighted images.
►Trauma Hepatobiliary

Hematoma, Subdural

►Trauma, Head, Accidental

Hematomyelia

Hemorragic collection inside traumatized spinal cord, best visible on GRE T2* MR images some hours after trauma, normally at the site of impact.
►Spinal Trauma

Hematopoiesis Disorders in Childhood

Johan G. Blickman[1], Dewi Ashi[2]

Definition

►Leukemia is a malignant proliferation of white blood cells. Responsible for 35% of pediatric oncological disease, it is divided into acute lymphatic leukemia (►ALL; 85%) and acute myeloid leukemia (►AML; 15%). ALL is slightly more common in males than females, with a peak incidence at 3 years of age. There is no difference in incidence of AML between males and females.

Pathology/Histopathology

Laboratory findings are immature leukemic blast cells and pancytopenia.

Clinical Presentation

The clinical presentation includes anemia, lethargy, dyspnea, anorexia, fever, bone pain, hepatosplenomegaly, and petechiae and epistaxis due to thrombocytopenia.

Imaging

Plain radiographic findings include the following:

Skeletal: Metaphyseal lucent band, local rarefied lesions, general osteoporosis. Periosteal bone formation may simulate a primary bone tumor. A soft tissue mass or

Hematopoiesis Disorders in Childhood. Figure 1 **Multiple hypodense lesions are visible on both spleen and liver.**

chloroma is a rare presentation. Spinal involvement may produce vertebral collapse.

Chest: Mediastinal enlargement due to hilar lymphadenopathy (10% of patients)

Abdomen: May reveal a sentinel loop of dilated terminal ileum in patients with neutropenic colitis, as the disease most often affects the cecum (typhlitis).

Ultrasound (US) may demonstrate a thickened bowel wall and small bowel, as well as hepatosplenomegaly with heterogeneous echogenicity due to infiltration of leukemic cells. Infiltration of the kidney usually consists of diffuse involvement that distorts the calyceal system, associated with focal hypoechoic areas. Testicular involvement may show hypoechoic diffuse or localized focal lesions.

Computed tomography (CT) shows hepatosplenomegaly with low attenuation lesions and periportal hypodense lesions that do not enhance after contrast injection. Renal images on CT are similar to those seen on US (Fig. 1).

Magnetic resonance imaging (MRI) can detect bone marrow infiltration as a patchy or diffuse decrease in signal in fatty marrow. Leptomeningeal disease shows as mass lesions.

Nuclear Medicine

Nuclear medicine techniques are used to rule out nonleukemic disorders in patients who complain of bone pain. These are not used for patients who have already been diagnosed with leukemia.

Diagnosis

The diagnosis of leukemia is made not on imaging modalities but on laboratory findings such as peripheral blood and bone marrow aspiration.

The *differential diagnosis* includes Langerhans cell histiocytosis, infection, and malignant lymphoma.

H

Hematopoietic Bone Marrow

Differential diagnosis of hematopoietic bone marrow and malignant disease may be difficult. Usually, a higher amount of hematopoietic bone marrow is found in younger patients, but reconversion of bone marrow from fatty marrow, in particular after chemotherapy, is not infrequent.

▶Myeloproliferative Disorders

Hematuria

Whether it be microscopic or gross should be further investigated. It may or may not be accompanied by pain. Painful hematuria can be caused by a number of disorders including infections and stones in the urinary tract. Painless hematuria can also be due to a large number of causes, including cancer.

▶Neoplasms, Bladder

Hemifacial Microsomia

Hemifacial microsomia is the second most common facial birth defect after cleft lip and palate; it is characterised by facial asymmetry with unilateral hypoplasia of the face. Zygoma and the lateral maxilla, in the upper face, and mandible, in the lower face, are most affected; the nose and columella deviate toward the hypoplastic side.

Anomalies of mouth (micro- or macrostomia), ears, eyes and central nervous system and/or plagiocephaly may coexist.

▶Congenital Malformations, Nose and Paranasal Sinus

Hemifacial Spasm/Hyperkinesia

Unilateral, intermittent, involuntary muscle twitches in the facial nerve territory. It is more prevalent in women and most commonly results from nerve compression at the root entry zone.

▶Facial Nerve Palsy

Hemihypertropy

Abnormal enlargement of one side of the body.

▶Neoplasms, Kidney, Childhood

Hemobilia

Hemobilia is a hemorrhage in the biliary tree due to an abnormal communication between the high-pressure hepatic artery system and the lower-pressure biliary tree. Causes include liver trauma (blunt or penetrating), iatrogenic injuries (percutaneous liver biopsy, bile duct interventions, intraarterial procedures), liver and bile duct tumors, aneurysms or pseudoaneurysms of the hepatic artery, infectious cholangitis, and gallstones. Hemobilia may be asymptomatic or give rise to biliary colic or obstruction if clot formation occurs in the bile duct. Most bleedings in the biliary tree are characterized by occult blood loss, but hypotension and shock are rarely observed. The computed tomography scan findings are often characteristic, with intrahepatic artery pseudoaneurysm formation. The diagnosis is usually confirmed by selective hepatic arteriography, and if a bleeding point is found, embolization may be considered.

▶Trauma Hepatobiliary

Hemochromatosis

Hereditary hemochromatosis (also called primary or idiopathic hemochromatosis) is an autosomal recessive disease characterized by an anomalous increase in iron absorption from the gastrointestinal tract. This excess of iron accumulates within the parenchymal cells of the liver, pancreas, endocrine glands, heart, skin, and joints. If left untreated, it leads to cellular damage and organ dysfunction. In patients with advanced disease, liver cirrhosis develops. At ultrasound (US), iron deposits in the liver do not determine specific findings. At computed tomography (CT), a diffuse homogeneous hyperdensity of the liver parenchyma can be appreciated on unenhanced scans. Biphasic contrast-enhanced CT study is required for the detection of hepatocellular carcinoma. A decrease of signal intensity of liver parenchyma is observed on T2-weighted magnetic resonance (MR) images. Since several studies have suggested that MR may enable an accurate quantification of hepatic iron concentration, it may be used in assessing the response to treatment in patients with hemochromatosis, avoiding the risks inherent in percutaneous liver biopsy.

▶Diffuse Infiltrative Diseases, Hepatic

Hemochromatosis, Arthropathy

Typically degenerative morphology, showing subchondral cyst formation, sclerosis, and thinning of cartilage. Chondrocalcinosis involving both fibrous and hyaline cartilage is frequently seen, particularly in the large joints. The distribution is characteristic with selective degenerative changes of the second and third metacarpophalangeal joints while abnormalities in the intercarpal joints are variable and the interphalangeal joints are spared.

Synonyms

Acquired or secondary hemochromatosis; Hereditary or genetic hemochromatosis; Iron overload

Definitions

Hemochromatosis is a condition of iron overload which results in parenchymal tissue damage (1). In European descendents, the disorder is most often hereditary (primary) hemochromatosis. Acquired (secondary) hemochromatosis occurs in a variety of chronic anemias that are caused by ineffective erythropoiesis (for example, thalassemia major or sideroblastic anemia), as the result of multiple transfusions or as the result of one of the following less frequent conditions: chronic oral iron ingestion (in absence of iron deficiency), African (Bantu) hemochromatosis, porphyria cutanea tarda, portacaval shunt, juvenile hemochromatosis, neonatal hemochromatosis, and congenital atransferrinemia. In acquired iron-loading disorders, massive iron deposits in parenchymal tissues can lead to the same clinical and pathologic features as in hemochromatosis.

Pathology/Histopathology

Hereditary or genetic hemochromatosis is an autosomal recessive disease most often caused by inheritance of a mutant HFE gene. The HFE gene is tightly linked to the HLA-A locus on chromosome 6p and encodes a 343-amino-acid complex class-1-type molecule that is structurally related to MHC class I proteins. Two missense mutations have been identified: C282Y resulting in a substitution of cysteine at position 282 with tyrosine and H63D resulting in a substitution of histidine at position 3 with aspartate. Hereditary hemochromatosis not associated with this mutation is termed non-HFE-related hemochromatosis (juvenile hemochromatosis, a rare disorder effecting males and females equally, is the most common example). Other forms of hemochromatosis are known to have a genetic basis which must still be defined (2).

Only the normal (wild type) HFE protein forms a normal complex with β_2-microglobulin and transferring therefore the mutant HFE protein remains trapped intracellularly, reducing transferring receptor mediated iron uptake by the crypt cells of the intestines. This upregulates the divalent metal transporter (DMT-1) on the brush border of the villous cells, leading to an inappropriate increase of intestinal iron absorption (1).

Hemochromatosis is a common genetic disease and is most common among northern European populations where approximately 1 in 10 persons are heterozygous carriers and 0.3 to 0.5% are homozygotes. Disease expression is variable and influenced by several factors including dietary iron intake and blood loss (menstruation and blood donation). The clinical expression of the disease is 5 to 10 times more frequent in men than in women.

The inappropriately high intestinal absorption of iron steadily increases from birth. While the normal content of iron is approximately 3–4 g, in advanced disease, the body may contain 20 g or more of iron that is deposited mainly in parenchymal cells of the liver, pancreas, and heart. Iron may be increased 50- to 100-fold in the liver and pancreas and 5- to 25-fold in the heart (1). Iron deposition in the pituitary causes hypogonadotropic hypogonadism in both men and women. Tissue injury may result from disruption of iron-laden lysosomes, from lipid peroxidation of subcellular organelles by excess iron, or from stimulation of collagen synthesis by activated stellate cells.

Clinical Presentation

Most individuals with hemochromatosis are asymptomatic. Initial symptoms include weakness, lassitude, weight loss, change in skin color, abdominal pain, loss of libido, and symptoms of diabetes mellitus (1). Hepatomegaly, suntan-like hyperpigmentation of exposed and nonexposed areas of the skin, spider angiomas, splenomegaly, arthropathy, ascites, atrial, or ventricular arrhythmias, congestive heart failure, loss of body hair, testicular atrophy, and jaundice are prominent in advanced disease. In non-treated advanced cases, the skin may become slate gray, and hepatosplenomegaly, ascites, pleural effusion, and arthritis can develop. The arthritis may affect any joint but usually involves the second and third metacarpophalangeal joints, knees, and hips. These joints may be deformed with or without inflammatory signs.

The liver is usually the first organ to be affected, and hepatomegaly is present in more than 95% of symptomatic patients (1). Hepatic enlargement may exist in the absence of symptoms or of abnormal liver function tests. Hepatocellular carcinoma develops in approximately 30% of patients with cirrhosis, and it is the most common cause of death in treated patients. Excessive skin pigmentation is present in over 90% of symptomatic patients at the time of diagnosis. Diabetes mellitus occurs in approximately 65% of patients and is more likely to develop in those with a family history of diabetes. Arthropathy is present in 20–70% of patients and may be the presenting feature (3). It usually starts in the metacarpophalangeal joints, but the wrists, knees, and hips may also be affected. Cardiac involvement is the presenting manifestation in approximately 15% of patients. The most common manifestation is congestive heart failure, which occurs in approximately 10% of young adults with the disease, especially those with juvenile hemochromatosis. Hypogonadism occurs in both sexes and may antedate other clinical features. Manifestations include loss of libido, impotence,

Hemochromatosis, Skeletal. Figure 1 Digital radiographs of the hands, knees, and feet of a 73-year-old woman with symptomatic diffuse arthralgia. Antero-posterior and oblique projections of the hands show a reduction of the articular space of the metacarpophalangeal and proximal and distal interphalangeal joints. Bilateral periarticular calcification, especially of the metacarpophalangeal joints and the triangular cartilage of the wrist requiring a differential diagnosis with ►calcium pyrophosphate dehydrate crystals deposition disease. Erosion is not observed. The osteochondral degenerative disease is associated with calcification of the menisci and hyaline cartilage of the knee. At the feet bilateral thickening and partial calcification of the plantar aponeurosis and of the first metatarsophalangeal bursa as well as bilateral calcified tendinopathy are present.

amenorrhea, testicular atrophy, gynecomastia, and sparse body hair.

The primary treatment is the removal of excess iron from the system by phlebotomy (500mL of whole blood once a week).

Imaging

Radiologic manifestations of hemochromatosis arthropathy are identical to degenerative osteoarthritis and chondrocalcinosis (4). Approximately half of the patients with hemochromatosis have radiographic evidence of osteoarthritis and 30% of chondrocalcinosis even in the absence of osteoarthritis (4). Other radiological features include cystic changes of the subchondral bones (typically of 1–5 mm and appear in the metacarpal heads), loss of articular cartilage with concentric narrowing of the joint space, diffuse demineralization, hypertrophic bone proliferation, and calcification of the synovium (3) (Fig. 1). Joint lesions will improve in 30% of the cases with therapy, but 20% will worsen symptomatically. Destructive arthropathy is an unusual finding (3).

Hemochromatosis, Skeletal. Figure 2 Multiplanar magnetic resonance study with SE, GE, and FSE sequences of a 30-year-old man with knee pain (predominately right). A hypointense signal in the T1 and T2 sequences is located predominately in Hoffa's fat pad at the margins of the hyaline cartilage of the femoral trochlea. The cartilage shows signs of erosion and fissures indicating an advanced stage of degeneration.

The onset of arthropathy favors the second and third metacarpophalangeal joints while the other metacarpophalangeal joints and proximal interphalangeal joints are involved less frequently and to a lesser extent (4). The carpal joints, larger joints and the spine may also be involved and show changes similar to those seen in the hand (4).

Differential diagnosis of hemochromatosis arthropathy of the hand includes calcium pyrophosphate dehydrate crystals deposition disease, ►degenerative joint disease and rheumatoid arthritis (4). Hemochromatosis arthropathy is more widespread and presents characteristic beak-like osteophytes of the metacarpal heads (4). Degenerative joint disease is more extensive in the interphalangeal joints and less severe in the metacarpophalangeal joints (4). While rheumatoid arthritis presents predominately erosive changes (4).

The excess iron in the liver parenchyma results in an attenuation in CT ("white liver" in unenhanced scans with a density above 70 HU) (4). The sensitivity varies with the amount of excess iron and reaches 100% with a fivefold increase (4). Similar results are obtained with magnetic resonance imaging using spin-echo sequences. The excess iron in other affected organs can also be seen with these imaging modalities.

A loss of signal intensity may be seen in the articular cartilage in T1- and T2-weighted magnetic resonance images of involved joints. This may be due to the presence of excess iron in the cartilage, synovium and/or synovial fluid (4) (Fig. 2).

Nuclear Medicine

Nuclear medicine techniques have limited use in this disease.

Diagnosis

Diagnosis of hemochromatosis is supported by the association of hepatomegaly, skin pigmentation, diabetes mellitus, heart disease, arthritis, and hypoganodism (1). Early diagnosis before permanent organ damage occurs is important because it increases the life expectancy from

2 years to that of a normal individual. A detailed family history can play a key role in diagnosis. Laboratory tests should exclude the possibility that the iron deposition is due to a hematological disease. Total-body iron store increase, especially parenchymal iron concentrations, should be assessed (see Table 1). Genetic testing for the two known mutations is negative in approximately 10% of the cases, indicating the presence of other, not yet identified, mutations.

The characteristic radiological features of hemochromatosis suggest that imaging techniques, especially computed tomography and magnetic resonance imaging, can be diagnostic but their elevated cost exclude their use for screening.

Definitions

The hemoglobinopathies are a group of diseases resulting from molecular abnormalities of hemoglobin and associated with anemia and characteristic abnormalities of the skeleton.

Thalassemia is a genetically determined disorder of hemoglobin synthesis resulting in chronic hemolytic anemia, and also inadequate production or total absence of normal alpha or beta globin chains. Thalassemia may exist in a homozygous form, called thalassemia major, or a heterozygous form, termed thalassemia minor. Thalassemia intermedia represents a poorly defined intermediate variety of the disease.

Sickle cell disease is a term that describes all conditions characterized by the presence of S hemoglobin (Hb S).The presence of sickle cell erythrocytes is a hereditary transmitted as a Mendelian dominant. In the genetic analysis of families with the sickle cell trait, both parents must transmit the sickling character for an offspring to show the clinical picture of the sickle cell anemia (homozygous due to S-S hemoglobin). If one parent has normal A hemoglobin and the other S hemoglobin, the offspring will show the sickled trait (S-A hemoglobin) but not anemia. Hemoglobin S in combination with abnormal hemoglobin C (sickle cell S-C disease), a less severe form. The combination of hemoglobin S-thalassemia rarely occurs (1, 2).

Pathology/Histopathology

The hypoxia of anemia represents a stimulus for increased erythropoiesis and bone marrow hyperplasia, through the action of the hormone erythropoietin (1). In infants all bones are involved, whereas in older children and adults only bone with active marrow are affected (2). Erythropoiesis also occurs at extra-medullary sites, most commonly resulting in a paraspinal mass but occasionally affecting organs containing pluripotential stem cells.

A hypertransfusion regimen reduces the extent of marrow expansion. However, iron overload and hyperuricemia are potential consequences of repeated blood transfusions. High serum iron levels are associated with abnormalities of the synovium and articular cartilage.

In sickle cell anemia, precipitating factors that promote deoxygenation of red blood cells enhance sickling and responsible for the painful crises. The formation of the rigid sickled red cell is due to polymerization of the abnormal hemoglobin. These changes result in increased viscosity and stasis. Ischemia is the clinical (as well as radiologic and pathologic) consequence of these cellular characteristics. The bone marrow is a prime target of ischemia and infarction because of high oxygen utilization. Pain and tenderness frequently are related to infarction of bone marrow. In patients with sickle cell trait, painful crises usually are not apparent unless the patient is exposed to an atmosphere low in oxygen (1, 2).

Other skeletal abnormalities of the hemoglobinopathies are; vascular occlusion, bone infarction, epiphyseal osteonecrosis, growth disturbances, generalized osteoporosis and fractures, osteomyelitis, and septic arthritis (3).

Hemoglobinopathies, Skeletal Manifestations. Figure 1 Anteroposterior plain film of hand shows decreased bone density, round small radiolucent areas on both first and fourth metacarpal bone. There is loss of cortical concavity on first metacarpal bone.

Imaging

Skeletal Manifestations of Untreated Thalassemia

Radiographic features of thalassemia derive from erythroid hyperplasia of bone marrow, more marked than in other hereditary anemias. Medullary spaces are widened, resulting in the thinning of cortices by pressure atrophy. Many trabeculae are resorbed and those remaining are coarsened, which may result in the appearance of "cob-webbing" in the pelvis. Skeletal manifestations are rare before 6 months of age and seen after end of first year of life. Initially both the axial and the appendicular skeleton are altered, but as the patient reaches puberty, the appendicular skeletal changes diminish, owing the normal regression of the marrow from the peripheral skeleton (1, 2).

The earliest changes are in the small bones of the hands and feet. Marrow expansion also causes a loss of the normal concave outline of long bones. These changes are most commonly seen in the humerus and femur, the tubular bones in the hands and feet (Figs 1 and 2).

Hemoglobinopathies, Skeletal Manifestations. Figure 2 Anteroposterior plain film of hand, demonstrating a coarse trabeculations due to bone marrow expansion on the carpal bones.

In severe cases, the femur may develop a flask-like shape. Widening of the metaphyses and epiphyses resembles an Erlenmeyer flask (3).

Skull changes consist of the widening of diploic spaces and displacement and thinning of the outer table (Fig. 3). The diploic trabeculae orient themselves perpendicularly to the tables, producing the radial pattern called "hair-standing-on-end" (Fig 4). The frontal bones reveal the earliest and most severe changes, and the inferior aspect of the occiput is usually unaltered. Overgrowth of marrow in the frontal, temporal, and facial bones consistently impedes pneumatization of paranasal and mastoid sinuses (4) (Fig. 5). Maxillary alterations can produce lateral displacement of the orbits, leading to hypertelorism, malocclusion of the jaws, and displacement of dental structures, resulting in "rodent facies." These changes are unusual in other anemias.

There is an initial increase in the height-to-width ratio of the vertebral bodies, in untreated thalassemic patients. The vertebrae may eventually become biconcave and lose height, secondary to multiple compression fractures. Rarely, central squared-off vertebral depressions or H vertebrae, characteristic of sickle cell anemia, are noted in thalassemia major. A "bone-within-bone" appearance occurs in the spine and ribs (Fig. 6). Generalized osteoporosis and osteopenia are features of thalassemia. Growth retardation and premature fusion of growth plates in the tubular bones occur commonly, and is in part, due to the disease process but may also result from desferrioxamine (DFX) therapy. On plain radiographs, obliteration of the epiphyseal line is usually asymmetrical resulting in both growth retardation and deformity. Shortening and deformity of the extremity may be apparent. In the humerus, varus deformity is characteristic (1, 3).

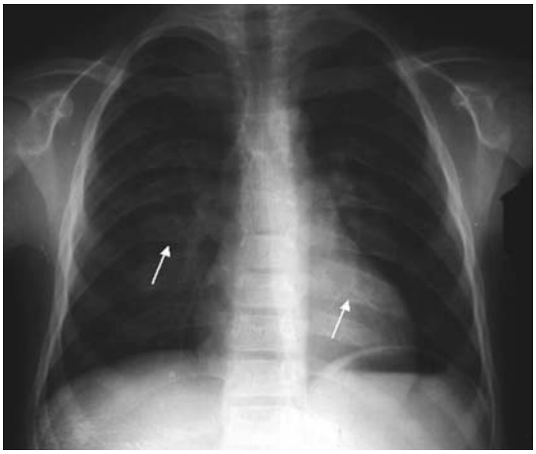
Hemoglobinopathies, Skeletal Manifestations. Figure 4 Hair-standing-on-end appearance in an untreated thalassemic patient.

Skeletal Changes Secondary to Hypertransfusion (Crystal Deposition) and Iron-Chelation Therapy

Iron overload and hyperuricemia are potential consequences of repeated blood transfusions. Secondary hemochromatosis resulting from repeated transfusions. Articular abnormalities are seen less frequently, and affect the large joints more commonly than primary hemochromatosis. Radiological features include symmetrical loss of articular space, cystic lesions, collapse and flattening of the subchondral bone, and osteophyte formation (3). Calcium pyrophosphate dihydrate crystal deposition may lead to chondrocalcinosis (1).

Initially, iron-chelation therapy was first used to reduce iron overload in hypertransfused thalassemic patients. Over the following years a new pattern of skeletal changes emerged. The radiological changes were attributed to the effect of DFX on the growth plates of young thalassemic patients. Although, the exact mechanism of production of the skeletal lesions remains unclear, a common pattern of dysplastic changes affecting the spine and long bones, as

Hemoglobinopathies, Skeletal Manifestations. Figure 5 In an untreated thalassemic patient, resulting in obliteration of maxillary sinuses due to bone marrow expansion.



Hemoglobinopathies, Skeletal Manifestations. Figure 6 Chest radiograph of untreated thalassemic patient, demonstrating bone-within-bone appearance (*white arrows*).

well as growth retardation, has been observed even with optimal transfusion regimens (3).

Repeated hypertransfusion can result in hemosiderosis. Iron deposition occurs at bone marrow, other solid organs, and breast tissue. Iron deposition is evident as areas of reduced signal intensity on spin-echo sequences both on T1-weighted and T2-weighted sequences on MRI (1, 3) (Fig. 7).

Extra-Skeletal Manifestations of Thalassemia

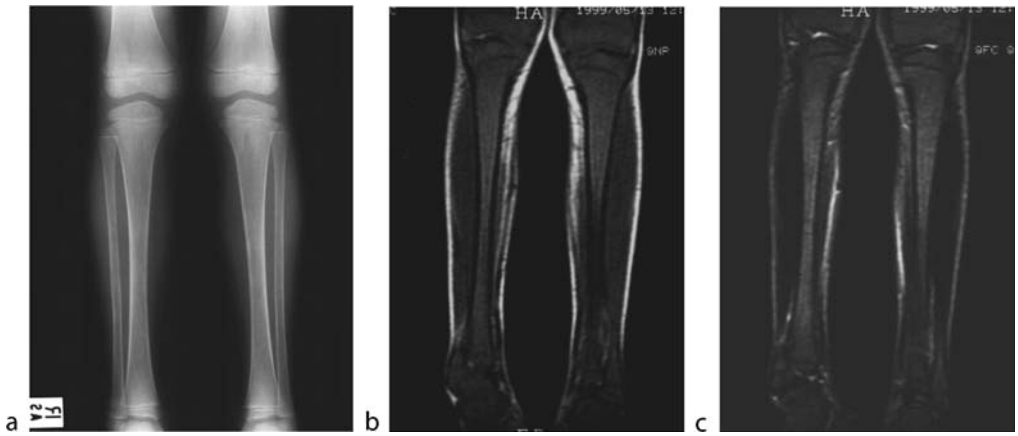
Extra-medullary hematopoiesis occasionally arises in organs containing pluripotential stem cells. The marrow has accelerated activity, extraosseous herniation of medullary tissue is observed. Posterior paravertebral mediastinal masses, representing sites of extra-medullary hematopoiesis, result from extraosseous extensions of medullary tissue derived from vertebral bodies and ribs (1, 3) (Fig. 8).

Skeletal Manifestations of Sickle Cell Anemia

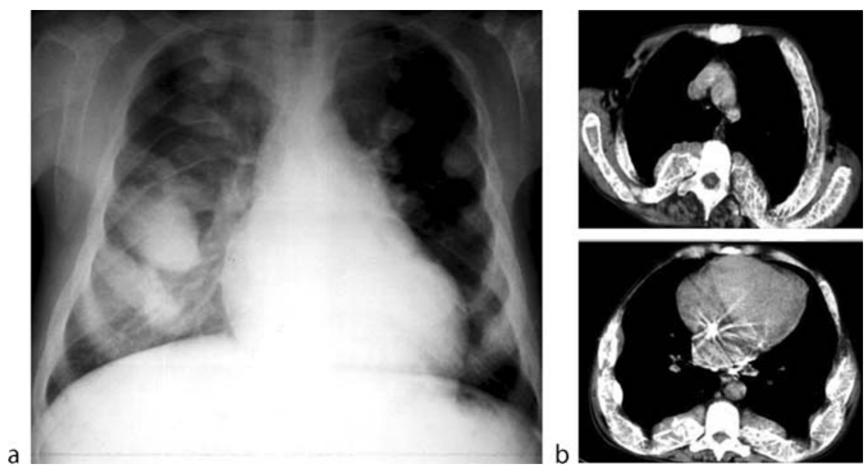
The presence of a chronic hemolytic anemia results in bone marrow hyperplasia. Sickle cell anemia is most likely to produce marrow hyperplasia and deossification; the variants are more often associated with bone infarction. In the spine, a step-like end-plate depression is frequently present (Fig. 9). Although this has been considered pathognomonic of sickle cell anemia, it may also appear in Gaucher disease, thalassemia major and congenital hereditary spherocytosis (2).

Marrow hyperplasia produces widening of the medullary cavities and rarefaction of remaining trabeculae in the spongiosa and cortex. In the skull, diffuse widening of the diploic space is associated with thinning of inner and outer tables of the skull. Focal radiolucent areas simulate metastasis or myeloma. Radial trabeculation causing a “hair-on-end” appearance may be seen, but not as commonly as with thalassemia. Mandibular involvement is common. Increased radiolucency and a coarsened trabecular pattern are characteristic. The base of the occiput is spared (1). Osteoporosis in the long bones tends to disappear in adolescence. The flat bones, especially ribs, will also present a thickened trabecular pattern with a cortical narrowing. There may be rib notching, “bone-within-bone” and a “spatula” appearance (2).

The major orthopedic complications of the sickle cell disease are bone infarct, osteomyelitis, and avascular necrosis of the femoral and humeral heads. Osteonecrosis is the sequela of the sickling phenomenon in which sequestration of cells occurs. In infants and children, bone infarcts most frequently occur in the diaphyseal portions of small tubular bones; in adult in the metaphyseal and subchondral portions of long bones. In children, osteonecrosis may involve the small tubular bones of the hand and feet, leading to the “hand-foot” syndrome or dactylitis. Infraction is often preceded by a painful soft-tissue swelling of finger or toe, then within 10 days, varying degrees of periostitis. Focal osteosclerosis is also seen. The findings resemble those of osteomyelitis. Infarction of vertebral bodies also occur, and massive infarction may cause collapse of the centra and has been



Hemoglobinopathies, Skeletal Manifestations. Figure 7 Fourteen years thalassemic patient, received by iron-chelation therapy showed no abnormality on plain radiography of both cruris (a), MRI showed decreased signal intensity on both T1-weighted and T2-weighted coronal images due to iron deposition on bone marrow (b).



Hemoglobinopathies, Skeletal Manifestations. Figure 8 Chest radiograph of untreated thalassemic patient, demonstrating expansion at the costochondral junction (a), chest CT showed expansion and coarse trabeculation on both costae and bilateral scapulas. There is also soft-tissue density at bilateral paravertebral area (b) (extra-medullary hematopoiesis).

termed the “fish vertebral” sign. Occasionally in older children, infarction of the capital femoral epiphysis leads to an appearance simulating that of Legg-Calvé-Perthes disease. In children with sickle cell anemia, the distal femur is a common site for acute long-bone diaphyseal infarcts.

Pathologic fractures are often a complication in patients with sickle cell anemia, perhaps because of the thin cortices due to marrow hyperplasia. Underlying factors could also be bone infarcts and/or osteomyelitis.

Patients of sickle cell anemia are prone to bacterial infection. The ischemic zones are appropriate foci for the settling of organism during the bacteremia. Bone and joint infections in sickle cell anemia are caused by salmonellae in over 50% of cases. Staphylococci represent a second common cause of osteomyelitis in sickle cell anemia. Osteomyelitis in most frequent in the long tubular bones. Roentgenographic changes are usually those of periostitis, with single or double layering of periosteal new bone reaction, and may progress to bone destruction with massive involucrum formation. Septic arthritis complicating sickle cell anemia is less frequent than osteomyelitis. Joint effusions in sickle cell anemia that are not associated with infection are relatively

Hemoglobinopathies, Skeletal Manifestations. Figure 9 Anteroposterior (a) and lateral (b) radiography of lumbar vertebrae showed increased density, step-like end-plate depression on vertebral bodies.

common. These effusions, which most frequently involve the knee and elbow, are associated with clinical manifestations of crises and presumably relate to synovial ischemia (1, 2).

Hemoperitoneum

Hemoperitoneum consists of the presence of blood in the peritoneum, usually resulting from abdominal trauma with laceration of liver, spleen, or other intraabdominal organs. Intraaddominal spontaneous bleeding caused by coagulation disorders and ulcer or neoplasm perforation is rare. Intraperitoneal blood tends to collect in the pouch of Douglas. However, smaller quantities of blood may commonly be contained in the right subhepatic and the right paracolic space and may provide an indication for the origin of the bleeding. In abdominal trauma patients, hemoperitoneum represents an important prognostic factor, and a timely diagnosis is mandatory.

Because diagnostic peritoneal lavage and ultrasound (US) are simple, inexpensive, and sensitive investigations for the detection of hemoperitoneum, they are widely employed for the first-line abdominal evaluation in trauma patients. Hemoperitoneum is commonly the only indication of injury on US, and it appears as a hypoechoic–anechoic collection located in the subhepatic space or in the pouch of Douglas. On unenhanced computed tomography scans, acute hemoperitoneum appears as a intraperitoneal fluid collection homogeneously or heterogeneously hyperattenuating.

jean-pierre.pelage@apr.ap-hop-paris.fr

Definitions

Hemoptysis is the expectoration of blood or blood-stained sputum from the lungs or airways (bronchi, larynx, trachea). The word hemoptysis comes from the greek "haima" meaning blood and "ptysis" which means spitting. When blood originates from outside the respiratory tract, the spitting is commonly described as pseudohemoptysis. For instance, differentiating between hemoptysis and hematemesis is an integral part of diagnosis.

Hemoptysis may be either self-limiting or recurrent. Hemoptysis can range from small quantities of bloody sputum to life-threatening amounts of blood. Classifying hemoptysis as mild or massive is somewhat arbitrary since it is difficult to accurately quantify the amount of blood. Thus, massive hemoptysis is variably defined as hemoptysis exceeding 200–600 mL within a period of 24 h or less. Massive hemoptysis, encountered in approximately 10% of cases, is a medical emergency since the reported mortality rate can be as high as 75%. Mild hemoptysis must be carefully investigated to prevent recurrence that could be life-threatening. In addition, in patients with already compromised lung function, even a small amount of blood in the bronchial tree may lead to acute airway obstruction and asphyxiation.

Pathology/Histopathology

Blood traversing the lungs can originate from low pressure and low resistance ▶pulmonary arteries accounting for 99% of the cardiac output and high pressure and high resistance ▶bronchial arteries accounting for 1% of the cardiac output. The pulmonary arteries supply exclusively the pulmonary capillary bed whereas the bronchial arteries provide the nutritive blood supply to the airways, the lymph nodes, visceral pleura and other portions of the mediastinum. There are normal anastomoses between both circulations but any abnormal process creating obstruction, compression of pulmonary artery branches or destruction of the pulmonary capillary bed may induce a compensatory development of these anastomoses. Thus, despite the quantitatively smaller contribution of the bronchial circulation to the normal pulmonary blood flow, the bronchial arteries are generally a more important source of bleeding than the pulmonary circulation (90% versus 10% approximatively) in lung disease. In addition to being perfused at a high pressure, the bronchial arteries supply blood to lesions within the airways and may become hyperplastic and tortuous, potentially causing massive hemoptysis. In the presence of pleural thickening, non-bronchial systemic arteries may develop through the pleural surface and become enlarged as a result of the inflammatory pulmonary process.

Clinical Presentation

There are many underlying disorders that can cause hemoptysis. In the past, tuberculosis, bronchiectasis and lung abscess accounted for 90% of cases. Recent reports suggest that nowadays the most common causes of hemoptysis are airway diseases including bronchitis in long-term smoking patients with or without bronchiectasis, which may account for up to 30% of cases and neoplasms. Pulmonary parenchymal diseases including infection (tuberculosis, aspergilloma and lung abscess) and inflammatory disorders, pulmonary vascular disorders (pulmonary embolism, pulmonary arteriovenous malformations, etc) may also cause hemoptysis. Immunologic lung disease, pulmonary hemorrhage in patients undergoing chemotherapy or bone marrow transplant and acquired cardiac disease are usually not amenable to interventional radiological treatment because specific treatments should be applied. Depending upon the study, up to 30% of patients with hemoptysis have no cause identified even after careful evaluation. These patients are classified as having idiopathic hemoptysis.

In patients presenting with hemoptysis, the initial approach is dictated by the clinical presentation. In case of massive hemoptysis and severe functional decompensation, the first priorities are to maintain the airway, optimize oxygenation and stabilize the hemodynamic status. The major question to be answered is whether or not the patient should be intubated for better gas exchange, suctioning and protection from sudden cardiorespiratory arrest. Once stabilization is accomplished, diagnostic (i.e. determine the site and cause of bleeding) and therapeutic interventions should be promptly performed because recurrent bleeding occurs unpredictably. History and physical examination are helpful in diagnosing some etiologies of hemoptysis. The precise timing and nature of the further evaluation are dictated by the suspected underlying pathologic process and the clinical condition of the patient.

Arteriography and embolization should be used immediately for both diagnosis and therapy in those patients who continue to bleed despite vasoconstrictive drugs and endobronchial therapy. Bronchial artery embolization should be attempted when bleeding is refractory to medical therapy, and surgery may be needed in severe hemorrhage. Emergent surgical intervention should be considered in operative candidates with unilateral or localized bleeding when embolization is not available or not feasible, when bleeding continues despite embolization or when bleeding is associated with persistent respiratory compromise.

Imaging

Diagnostic studies for hemoptysis include chest radiography, bronchoscopy and spiral computed tomography (CT) of the chest. Bronchoscopy and chest radiography have been considered the primary methods for the diagnosis and localization of hemoptysis. More recently, many researchers currently suggest that spiral CT should be performed prior to bronchoscopy particularly in case of massive hemoptysis. Arteriography has both a diagnostic, by demonstrating occasionally the site and the cause of bleeding, and a therapeutic value with selective embolization of bronchial or non-bronchial systemic arteries.

Chest Radiography

A good quality chest radiography should always be obtained. Localized pulmonary infiltration or condensation, atelectasis, cavitation, mass or signs of chronic bronchitis or bronchiectasis may indicate the source of bleeding. However, hemoptysis may occur from an area that appears normal by routine chest radiography.

Bronchoscopy

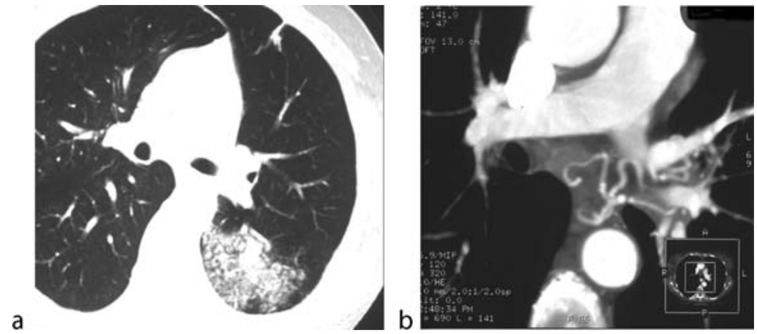
Fiberoptic bronchoscopy performed early in the evaluation, while the patient is actively bleeding, provides an important yield for lateralizing the bleeding side, localizing the specific site and identifying the cause of the bleeding. Identification of the bleeding site requires visualization of regions with continued fresh bleeding. Small volume lavage may sometimes help suggest the bleeding site. Flexible bronchoscopy can be performed at the bedside at the time of intensive care unit admission. In those patients with lateralized or localized persistent bleeding, immediate control of the airway may be obtained during the procedure with topical therapy, endobronchial tamponade or unilateral intubation of the nonbleeding lung. If the bleeding cannot be localized because the rate of hemorrhage makes it impossible to visualize the airway, emergent rigid bronchoscopy or emergent arteriography is indicated depending on their availability.

Spiral CT

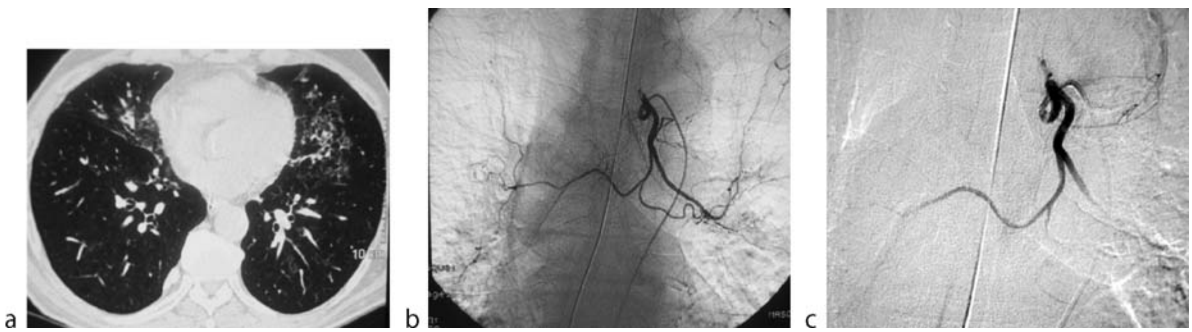
Over the past 5 years, early use of multi-detector row computed tomography (MDCT) has been advocated to help localize the bleeding site as well as the cause of hemoptysis. CT may also serve as a guide for other diagnostic or therapeutic procedures such as bronchoscopy or transcatheter embolization. MDCT allows rapid scanning throughout the thorax, multiplanar reconstructions without loss of z-axis information owing to near isotropic voxel size and acquisition of various three-dimensional images. Analysis of both lung parenchyma and visualization of the bronchial and non-bronchial systemic feeder vessels and pulmonary artery branches can be achieved simultaneously when iodinated-contrast material is administered (Fig. 1). Multiplanar (parallel to the axis of the bronchial arteries) and maximum intensity projection reconstructions are helpful to identify the origin and course of the bronchial and non-bronchial enlarged systemic arteries (Fig. 1). The sensitivity and accuracy of MDCT in the depiction of ►non-bronchial arteries is as high as 80% and may be particularly helpful before embolization. Multiple parenchymal abnormalities are consistent with direct or indirect signs of bleeding. These include ground-glass opacities, consolidation, atelectasia, etc. MDCT may identify the cause of bleeding by demonstrating bronchiectasis, aspergillosis, lung abscess or neoplasm (Figs. 1 and 2).

Arteriography

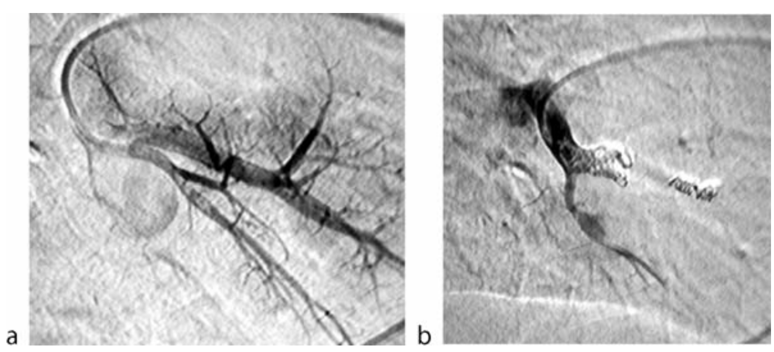
Arteriography has been a major addition to the diagnostic and therapeutic armamentarium for the management of hemoptysis. Since the majority of massive bleeds arise from the bronchial circulation, bronchial arteriography has a higher yield than pulmonary angiography. The pulmonary arterial circulation is the source of bleeding in fewer than 10% of patients with hemoptysis. When the pulmonary arterial circulation is involved, the most common underlying conditions are necrotizing pneumonia, tumoral ulceration, Rasmussen's aneurysms (due to tuberculosis) or iatrogenic pulmonary artery tear, as occurs with perforation from Swan–Ganz catheters (Fig. 3). Systemic arteriography is performed with a digital substraction technique by using a transfemoral approach and with the Seldinger technique. The most commonly used catheters to select the bronchial arteries are Cobra, Mikaelson, Simmons or Judkins right catheters. The usual angiographic criteria for arteries causing hemoptysis include



Hemoptysis. Figure 1 (a), MDCT (lung window settings) in a patient with massive hemoptysis demonstrates parenchymal consolidation of left lung base. (b) MDCT with iodinated-contrast administration in the same patient shows enlarged and tortuous bronchial arteries.



Hemoptysis. Figure 2 (a) MDCT (lung window settings) in a patient with hemoptysis demonstrates bilateral bronchiectasis. (b) Systemic arteriography in the same patient shows an enlarged and tortuous right–left bronchial artery. (c) Arteriogram obtained after selective embolization using 500–700 μm tris-acryl microspheres shows distal devascularization.



Hemoptysis. Figure 3 (a) Pulmonary angiogram (lingular branch) performed in a patient with massive hemoptysis after the use of a Swan–Ganz catheter shows a large extravasation of contrast material consistent with a pseudoaneurysm. (b) Angiogram obtained after selective embolization of two subsegmental pulmonary artery branches with coils shows satisfactory devascularization.

enlarged and tortuous bronchial or non-bronchial arteries, neovascularity or hypervascularity, antegrade or retrograde shunting to the pulmonary artery, extravasation of contrast material or bronchial artery aneurysm (Fig. 2). Both bronchial and non-bronchial transpleural systemic arteries may be causing hemoptysis and should be investigated. Non-bronchial arteries frequently involved in hemoptysis or recurrent bleeding include intercostal, inferior phrenic, subclavian, axillary and internal mammary arteries. There is also a high incidence of bleeding from non-bronchial systemic collateral vessels among patients who have undergone a previous bronchial artery embolization procedure. Therefore, persistence of bleeding after a technically good embolization suggests an origin other than those previously occluded. Bronchial arteries of anomalous origin or non-bronchial arteries initially not evaluated or missed and the pulmonary circulation should then be studied (Fig. 3).

Interventional Radiological Treatment

Jacques Remy and coworkers reported for the first time successful bronchial artery embolization in four patients with massive or repeated hemoptysis in 1973. Remy et al subsequently reported a study of 104 patients presenting either with massive or repeated hemoptysis treated with bronchial artery embolization using gelatin sponge pledgets. In 90% of cases, the source of hemoptysis is the bronchial circulation. However, non-bronchial systemic arteries can be a significant source of massive hemoptysis and a cause of recurrence after successful bronchial artery embolization. Knowledge of the bronchial artery anatomy, together with an understanding of the pathophysiologic features of massive hemoptysis, are essential for planning and performing arterial embolization in affected patients. According to Cauldwell et al, the bronchial arteries originate with a few exceptions from the proximal portion of the descending thoracic aorta. The right bronchial artery arises from the lateral or dorsolateral aspect of the aorta, most frequently in a common trunk with an intercostal artery (intercostobronchial artery). The left bronchial artery usually originates from the anterior aspect of the thoracic aorta or the concavity of the aortic arch. A left–right bronchial artery may also be seen (Fig. 2). Radiologists should be alerted to the possible presence of anomalous bronchial arteries, especially when significant bronchial artery supply to areas of abnormal pulmonary parenchyma is not demonstrated at a catheter search or aortography of the descending aorta. Thus, bronchial arteries of anomalous origin may arise from the convex surface of the aortic arch or from the supra-aortic arteries. Non-bronchial systemic circulation of the lung and the arteries of the pulmonary ligament may also cause hemoptysis.

Various embolization materials have been used to perform bronchial artery embolization. The use of resorbable pledgets of gelatin sponge, non-spherical (larger than 355 μm) or spherical polyvinyl alcohol particles (larger than 700–900 μm), tris-acryl gelatin microspheres (larger than 500–700 μm), acrylic glue and steel-coils are recommended (Fig. 2).

Coils are usually the most common embolization agents to perform embolization of pulmonary artery branches (Fig. 3).

Results Associated with Embolization

Technical failure of attempted embolization can be observed in about 10–20% of cases because of catheterization failure, catheter instability or visualization of dangerous branches such as the anterior spinal artery. Embolization is able to achieve an immediate control of hemoptysis in 70–95% of cases, confirming that systemic circulation is the primary source of bleeding in hemoptysis. Regarding mid-term and long-term results, embolization is sometimes considered as a palliative treatment with a relapse of bleeding occurring in up to 30% of patients. However, recurrence is influenced by the etiology of hemoptysis. For instance, in patients with aspergilloma or cystic fibrosis, the recurrence rate is higher than in patients with tuberculosis or bronchitis. Complications are rare in experienced hands but major complications have already been reported. Spinal cord injury related to invisible anastomotic connections between the bronchial circulation and the anterior spinal artery have been reported. Careful analysis of the angiographic images particularly to identify a spinal artery when injecting into a right intercostobronchial artery and the systematic use of microcatheters may reduce the rate of this complication. Subintimal dissection of the aorta and transient thoracic pain have also been reported in several studies.

Synonyms

Germinal matrix hemorrhage; Subependymal hemorrhage

Definition

Rupture of arterial or venous vessels with extravasation of blood into the germinal matrix, brain parenchyma, ventricular system, or subarachnoid space.

Pathology and Histopathology

Intracranial hemorrhage is one of the most common causes of acute focal neurological symptoms (e.g., seizures). Multiple factors including location, extension and etiology determine morbidity and mortality. Germinal matrix hemorrhages (GMH) are the most frequent intracranial hemorrhages in premature and term neonates though it is rare in the term infants (1, 2). The germinal matrix is a highly perfused transient zone along the lateral ventricles composed of postmitotic, premigratory cells. These cells migrate toward the cortical plate along radial glial cell processes that extend to the surface of the brain. The thickness of the germinal matrix correlates with gestational age; the germinal matrix regresses as cells migrate. The germinal matrix is in a close anatomical relation to the subependymal deep venous system. GMH results from rupture of the fragile venous capillaries in and along the germinal matrix. Hemorrhage may compress neighboring, initially patent veins with can thrombose on follow-up. Larger hemorrhages may compromise the venous drainage of the adjacent white matter with resulting venous ischemia of the hemispheric white matter and/or intraparenchymal hemorrhage. The relationship between GMH and prematurity is well known and has been confirmed by many autopsy studies. Many other factors have also been considered including coagulation disorders, hypercarbia, hypernatremia, hyperosmolarity, and metabolic acidosis. GMH occur postnatally in the vast majority of cases supporting the theory that hemorrhages are associated with phases of neonatal distress.

Less frequently, intracranial hemorrhages may occur due to neonatal tumors, intracerebral arteriovenous malformations (e.g., vein of Galen malformation), trauma, dural sinus thrombosis, or coagulation disorders. Subarachnoidal, subdural, and epidural hematomas may result from a traumatic birth.

Clinical Presentation

Small GMH may be asymptomatic. Larger GMH present with various combinations and degrees of impaired consciousness, hypotonia, seizures, increased irritability, poor feeding, and respiratory insufficiency or even coma. A rapid drop in hematocrit may signal massive intraventricular bleeding. A complicating posthemorrhagic hydrocephalus should be suspected if signs of increased intracranial pressure become apparent. The increased intracranial pressure may lead to a bulging of the fontanelle in combination with an increase of the head circumference. In most severe cases a compression of the brain stem leads to loss of pupil and oculomotor reflexes, decerebrate posture, and respiratory arrest. Venous infarctions may result in varying focal neurological deficits depending on the involved functional center.

Imaging

GMH are classified into three grades. Grade I: subependymal hemorrhage limited to the GM, grade II: intraventricular hemorrhage in which less than 50% of the ventricular volume is affected, and grade III: intraventricular hemorrhage in which more than 50% of the ventricular volume is affected. In previous classifications, a grade IV hemorrhage was defined as a GMH with extension into the adjacent cerebral hemispheres. This kind of neonatal hemorrhage is nowadays classified as "hemorrhagic venous infarction." This descriptive terminology takes the etiology better into account (3).

On imaging, the location and size of the hemorrhages should be described. Hemorrhages are typically described as small (<1 cm in diameter), medium (>1 cm, <2 cm in diameter), or large (>2 cm in diameter). In addition, the degree of complicating hydrocephalus should be estimated. Serial measurements of the diameter of the anterior horns of the lateral ventricles at the level of the foramen Monroi can be used to determine the evolution of a hydrocephalus on follow-up.

Ultrasonography (US) uses the anterior fontanelle as an acoustic window to perform high resolution imaging of the brain in neonates and babies. Typically, coronal and sagittal images covering the brain from anterior to posterior and left to right are acquired. Additional acoustic windows include the posterior and temporal fontanelle. Suboccipital views through the foramen magnum are used to image the posterior fossa. In addition, power Doppler US is used to assess patency of the major arterial and venous intracranial vessels. The profile of the arterial blood flow may give important information about the intracranial pressure and degree of brain swelling.

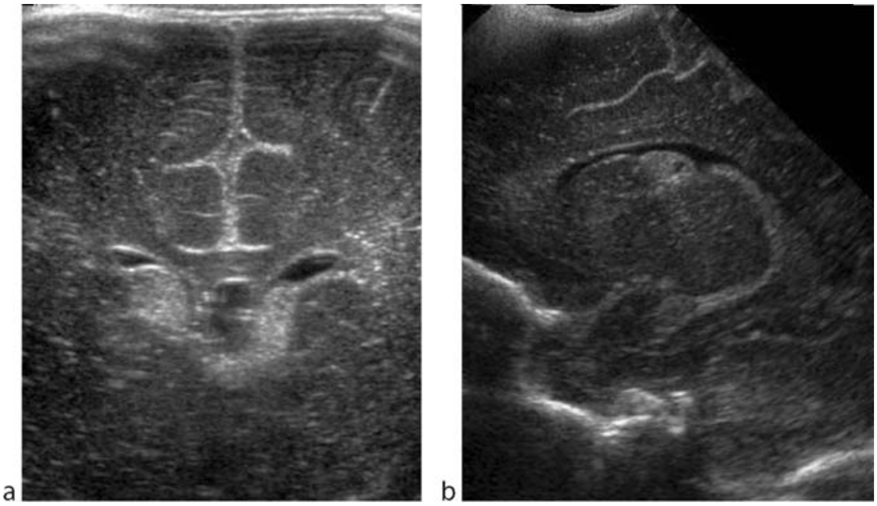
US has become the primary modality to examine the neonatal brain because it is a high resolution imaging modality, lacks ionizing radiation, can be performed at the bed side is widely available and is relatively cheap. In addition, serial examinations can easily be performed giving us the fourth dimension of time in the evaluation of cerebral pathologies.

In the acute and subacute phases GMH are hyperechoic (Fig. 1). On follow-up, hemorrhages become isoechoic and finally hypoechoic in the chronic phase. This process parallels the spontaneous evolution and resorption of hemorrhages. Finally, small hypoechoic cysts may be the sole remnant of GMH. In the case of an intraventricular extension (grade II and III), blood clots can be seen within the ventricles (Fig. 2). In addition, a hyperechoic lining of the ventricles can be seen, most probably reflecting a reactive chemical ependymal inflammation in reaction to the intraventricular blood products. In rare cases, an enlarged hyperechoic choroid plexus may indicate extension of the hemorrhage into the choroid plexus. Small grade I hemorrhages are typically seen at the foramen of Monro (Fig. 1), larger hemorrhages may be seen anywhere along the germinal matrix.

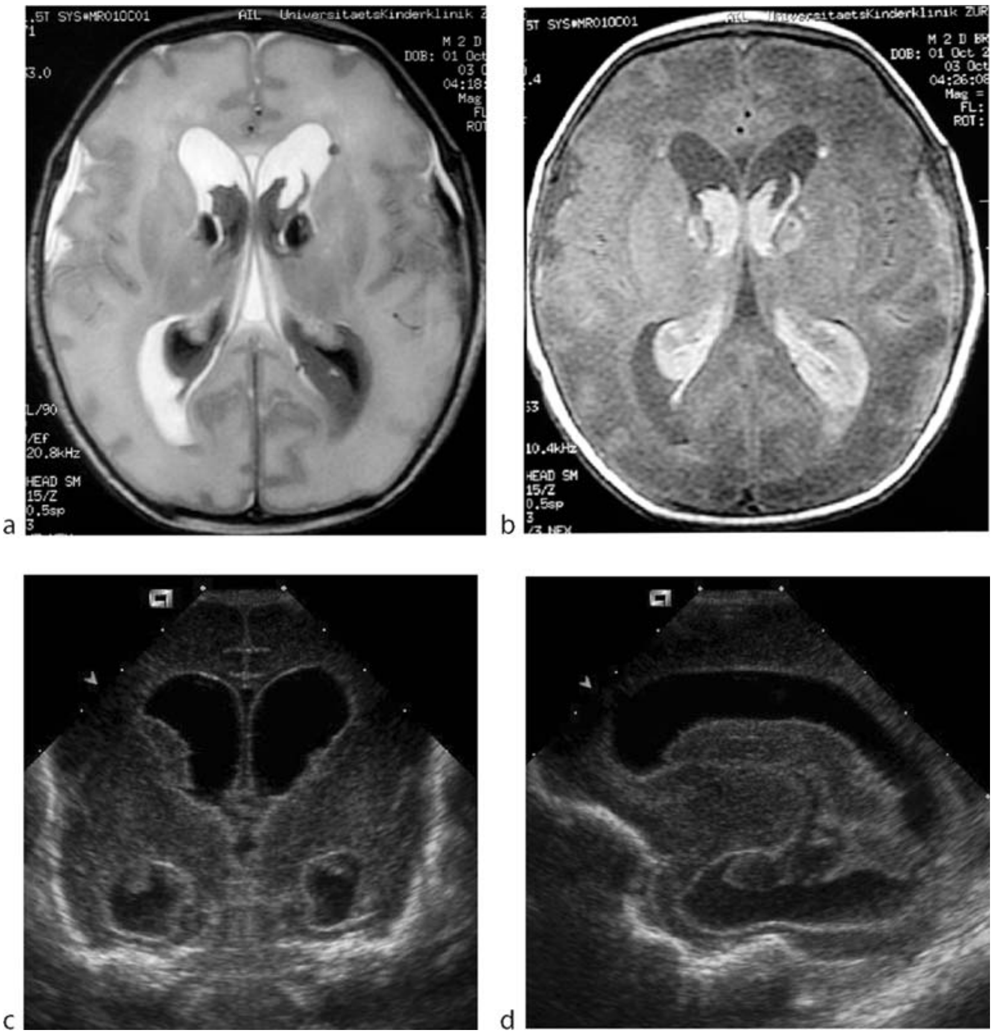
Venous infarction is characterized by a fan shaped hyperechonic injury of the cerebral white matter (Fig. 3). This signal change matches the course and distribution of the intramedullary veins that converge and drain into the subependymal, deep venous system. Two-third of the cerebral white matter drains into the deep venous system while the superficial one-third drains into the superficial venous system. Consequently, venous ischemia involves predominantly the periventricular white matter as GMH compromises drainage into the deep venous system. On US a corresponding signal alteration of the deep, periventricular white matter is seen. Venous ischemia is frequently complicated by hemorrhages on follow-up examination. Color Doppler sonography may be able to demonstrate compression or thrombosis of the subependymal veins. Follow-up examinations will show a progressive, hypoechoic cystic resorption of the infarcted brain.

Complicating hydrocephalus is easily identified by US. Follow-up examinations are necessary to monitor ventricular dilatation and to determine if a ventricle drainage should be considered. Duplex Doppler of the intracranial vessels during anterior fontanelle compression has been reported as a useful indicator of altered cranial compliance in infants with hydrocephalus and may be helpful in predicting the need for shunt placement (5). The addition of views of the thoracolumbar spine may identify an echogenic subarachnoid space due to the presence of high protein and red blood cell contents. This may help identify which infants are likely to benefit from lumbar puncture for therapy for progressive ventricular dilatation (6).

H



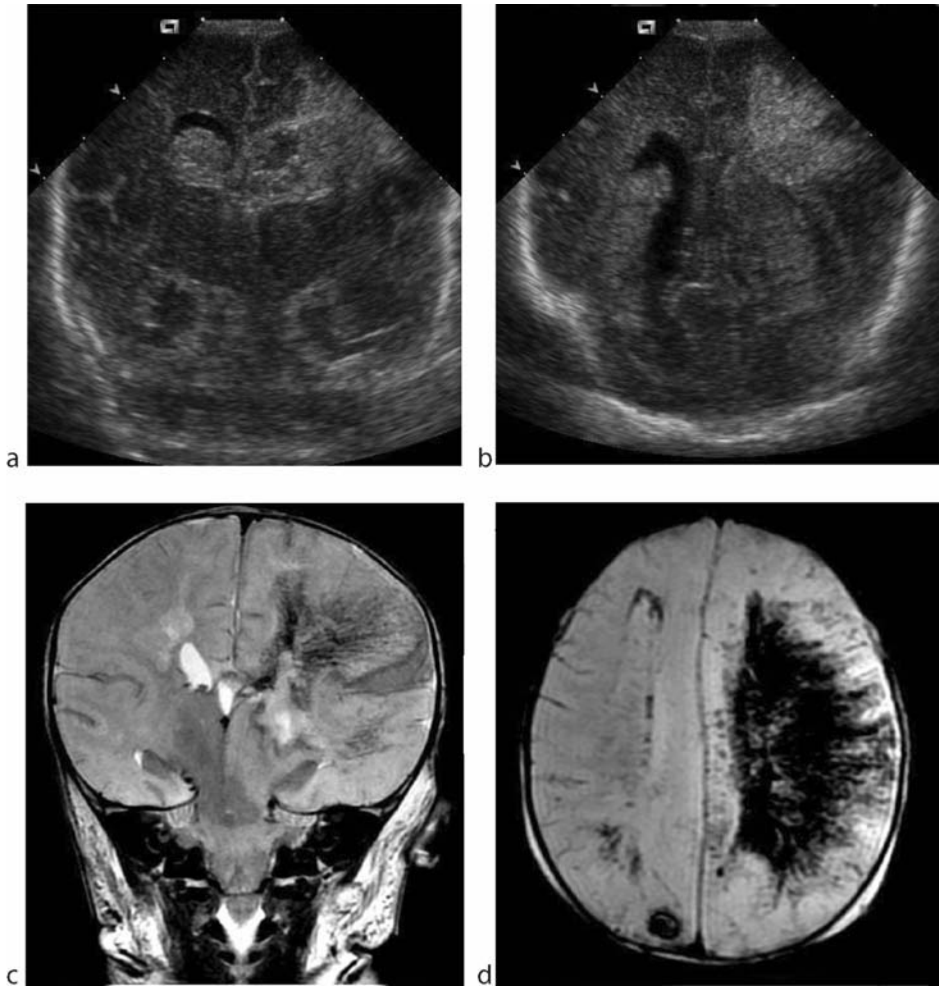
Hemorrhage, Intracranial, Neonates (Neuro View). Figure 1 Four weeks old premature girl (31 weeks of gestation). Coronal (a) and sagittal (b) ultrasonography reveal a bilateral hyperechoic grade I germinal matrix hemorrhage near the foramen Monroi. No ventricular dilatation is seen.



Hemorrhage, Intracranial, Neonates (Neuro View). Figure 2 **Three days old premature boy (29 weeks of gestation) axial T2-weighted (a) and T1-weighted (b) MRI show a bilateral T2-hypointense and T1-hyperintense grade III hemorrhage. A mild hydrocephalus is seen. One week later coronal (c) and sagittal (d) ultrasonography reveal a partial resorption of the hemorrhage, the hydrocephalus is however slightly progressive.**

Computer tomography (CT) is sensitive for identifying GMH and their complications. Hyperacute hemorrhages are isodense to normal brain tissue. Progressive blood clot retraction increases hemorrhage density during the acute and early subacute phases, while progressive red blood cell lysis during the late subacute phase will decrease the attenuation of the hematoma. Progressive resorption in the chronic phase will result in a hypodense, cyst filled with cerebrospinal fluid (CSF) (4). Several studies have shown that US is as sensitive as CT in the diagnosis of GMH. Major disadvantage of CT is the use of ionizing radiation and the need to transport the neonate to a CT-suite. CT is indicated in those cases where the findings on US do not explain neurological symptoms. In addition, CT should be considered in suspected pathology within the posterior fossa (brainstem and cerebellum). Finally, in cases where the acoustic windows are too small for an adequate evaluation of the cranial vault, CT should be considered.

Magnetic resonance imaging (MRI) is widely accepted as the most sensitive imaging modality for intracranial hemorrhage and its sequelae. T2*-weighted sequences, that are exquisitely sensitive for blood products, are especially helpful (Fig. 3). In the hyperacute stage the hemorrhage is T1-iso or hypointense and T2-hyperintense; in the acute stage T1-iso or hypointense and T2-hypointense (Fig. 3), in the early subacute stage T1-hyperintense and T2-hypointense, in the late subacute stage T1 and T2-hyperintense and finally in the chronic phase T1-hypointense and T2-centrally hyperintense surrounded



Hemorrhage, Intracranial, Neonates (Neuro View). Figure 3 **Five days old premature boy (28 weeks of gestation) coronal (a, b) ultrasonography shows a hemorrhagic venous ischemia within the left hemisphere next to a bilateral GMH. Follow-up coronal T2-weighted (c) and axial T2*-weighted (d) MRI confirms the fan shaped hypointense venous hemorrhagic infarction of the left hemisphere. The degree of hemorrhage is better seen on T2*-weighted images. The GMH is already partially resolved.**

by a rim of hypointensity (hemosiderin) (4). Similar to CT, MRI should be considered in cases where US does not explain neurological symptoms. Major disadvantage of MRI is the complexity of examining a neonate inside the MRI scanner and the limited availability.

Diagnosis

Clinically, GMH should be suspected and ruled out in preterm and term neonates who present with seizures, altered consciousness, bulging fontanelle, progressive head circumference, or other acute focal neurological deficit. GMH is easily identified on US, CT, or MRI. Imaging should identify secondary complications including hydrocephalus and hemorrhagic venous infarction. US remains the primary imaging modality of choice. CT and MRI should be considered if US-findings do not explain neurology. CT and MRI are indicated in neonatal hemorrhages other than GMH.

Hemorrhagic Functional Cysts

Bleeding may complicate corpus luteum cysts. Bleeding into the cyst or rupture within the peritoneal cavity manifests as acute abdominal pain and is the leading cause of gynecologic emergencies.

▶Cyst, Follicular, Ovarium

Hemosiderosis

In transfusional iron overload, iron is deposited in the reticulo-endothelial cells of the liver, spleen, and bone marrow. At ultrasound, iron deposits in the liver do not determine specific findings. At computed tomography, a diffuse homogeneous hyperdensity of the liver parenchyma can be appreciated on unenhanced scans. Biphasic contrast-enhanced CT study is required for the detection of hepatocellular carcinoma. A decrease of signal intensity of liver parenchyma is observed on T2-weighted magnetic resonance images. A splenic involvement is also present.

▶Diffuse Infiltrative Diseases, Hepatic

Hemothorax

Pleural effusion predominantly contains blood. It is frequently found in patients with lacerations or tears of intercostal vessels, lung, diaphragm, mediastinum, large vessels, and heart. Hemothorax due to lung contusion and venous lesions tends to be self-limiting, while it is often massive when due to lung laceration or mediastinal and arterial lesions. Pleural fluid of more than 200–300 mL can be detected on the "supine" radiograph. The diagnosis of acute hemothorax is generally based on ultrasound or CT. A rare differential diagnosis is chylothorax due to rupture of the thoracic duct.

Synonyms

Hepatic benign tumor in children; Liver tumors in infancy; Pediatric neoplasms of the liver

Definition

Benign hepatic neoplasms of childhood include a variety of lesions that are predominantly of mesenchymal origin. Most lesions present as a right upper quadrant palpable mass or with abdominal distension. Many of the lesions are initially asymptomatic and may be an incidental finding on cross-sectional imaging. Benign lesions include cavernous hemangioma, ►infantile hemangioendothelioma, ►mesenchymal hamartoma, focal nodular hyperplasia, ►nodular regenerative hyperplasia, and hepatocellular adenoma. The distribution and incidence of lesions differ from adults.

Pathology and Histopathology

Cavernous Hemangioma

Children are less frequently involved than adults, the exact incidence is however unknown. In children, hemangiomas frequently resolve spontaneously. Lesions are often small (<2 cm), single, red-purple, and spongy. Microscopically, hemangiomas are composed of well-marginated, dilated, large vascular channels lined by a thin layer of endothelial cells. Fibrosis, thrombosis, and calcifications may be present. Occasionally, cardiac failure results from arteriovenous shunting in large hemangiomas. Multiple lesions are considered a part of the syndrome of systemic hemangiomatosis.

Infantile Hemangioendothelioma

Most common liver tumor in the first year of life. Benign, single, multifocal, or diffuse infiltrating lesion composed of thin vascular channels lined by endothelial cells. The lesion is nonencapsulated well circumscribed, soft, and spongy with occasionally areas of hemorrhage, fibrosis, and dystrophic calcifications. Spontaneous regression has been reported. Congestive heart failure may occur. Histologically it is considered a variant of cavernous hemangioma. Differentiation between these two lesions is difficult. In hemangioendothelioma, the size of the vascular spaces is smaller (i.e., capillary) compared with hemangiomas.

Mesenchymal Hamartoma

Benign, usually multicystic mesenchymal lesion originating from primitive connective tissue in the portal tracts. It accounts for 22% of the benign liver tumors in children with a male predominance. The lesion is composed of loose mesenchymal tissue containing small bile ducts, cystic remnants of portal triads and cysts filled with serous fluid. About 80% of the lesions are seen in children younger than 2 years.

Focal Nodular Hyperplasia

Circumscribed, usually asymptomatic lesion of epithelial origin. Histologically, the lesion consists of hyperplastic hepatocytes with small bile ducts and intralesional arteries and veins. The lesion is sharply demarcated from the surrounding liver. A central fibrous scar or septa with prominent vessels can be observed. The lesion is usually firm and irregular. Focal nodular hyperplasia is rare in children compared to adults occurring most frequently between 6–10 years.

Nodular Regenerative Hyperplasia

Benign proliferation of hepatocellular nodules. Histologically, the nodules are composed of hyperplastic hepatocytes. Cause is unknown, it is associated with a variety of systemic diseases including myelo-lymphoproliferative diseases, metabolic diseases and cardiovascular diseases. There is usually no preexisting liver cirrhosis (1–4).

Hepatocellular Adenoma

Rarely diagnosed in children. Adenomas are primarily seen in teenage girls taking oral contraceptives. Usually, adenomas are solitary well-circumscribed lesions, partially or completely encapsulated and composed of sheets of hepatocytes. Tumor hemorrhage and rupture present with acute abdominal pain.

Clinical Presentation

Cavernous Hemangioma

Cavernous hemangiomas are usually asymptomatic and often diagnosed incidentally on ultrasound (US)

H

examinations. Large lesions may present as asymptomatic palpable masses or with congestive heart failure secondary to arteriovenous shunting within the tumor. Rarely tumor rupture with hemoperitoneum occurs. ►Kasabach–Merrit syndrome may occur. Hemangiomas may be discovered in the prenatal period because of hemorrhage into the amniotic fluid causing severe anemia and congestive heart failure or hydrops fetalis. Alpha fetoprotein may be highly elevated in preterm infants with hemangiomas.

Infantile Hemangioendothelioma

Clinical presentation strictly depends on the size of the lesions. Presenting symptoms include hepatomegaly, abdominal enlargement, or congestive heart failure due to multiple arteriovenous shunts within the tumor. Associated hemangiomas of the skin are reported in 20% of cases. The systemic administration of steroids, interferon alpha, and vincristine may reduce size and number of lesions.

Mesenchymal Hamartoma

Mesenchymal hamartomas are usually asymptomatic lesions presenting with an enlarging abdomen. The lesion may grow slowly over months or enlarge rapidly over a period of days due to intralesional accumulation of serum. The large size of the lesion may result in respiratory distress or compression of the inferior caval vein. Transformation into malignant sarcomas have been reported and surgical resection is recommended.

Focal Nodular Hyperplasia

Most children are asymptomatic, lesions can be found incidentally on cross-sectional imaging for another condition. Less than 10% of children may complain of episodic abdominal pain, vomiting, or diarrhea.

Nodular Regenerative Hyperplasia

Children are usually asymptomatic, the lesion is frequently misdiagnosed as focal nodular hyperplasia or metastatic disease. Hepatomegaly, abdominal mass, or portal hypertension are infrequently diagnosed. Malignant transformation into hepatocellular carcinoma has been reported (1–4).

Hepatocellular Adenoma

Most adenomas are asymptomatic. Episodic or acute abdominal pain is usually related to a hemorrhage within the adenoma.

Imaging

Cavernous Hemangioma

US: Hemangiomas are hyperechoic, well-circumscribed solid lesions. Large hemangiomas may show a central hypoechoity due to necrosis or fibrosis. The vascular etiology is confirmed by Doppler US.

Computed tomography (CT): Hemangiomas are typically hypodense with an irregular peripheral enhancement and progressive filling-in on delayed scans. In larger lesions, the necrotic or fibrotic center will show a limited enhancement. Calcifications may be seen.

Magnetic resonance imaging (MR): Hemangiomas are T1-hypointense and strongly T2-hyperintense (light-bulb). Dynamic contrast-enhanced sequences show an enhancement pattern similar to the CT enhancement.

Infantile Hemangioendothelioma

US: Findings are nonspecific. Lesions can be hypo-, hyper-, or mixed hypo-hyperechoic. Doppler US will confirm the vascular nature of the lesion. Lesions are usually well defined.

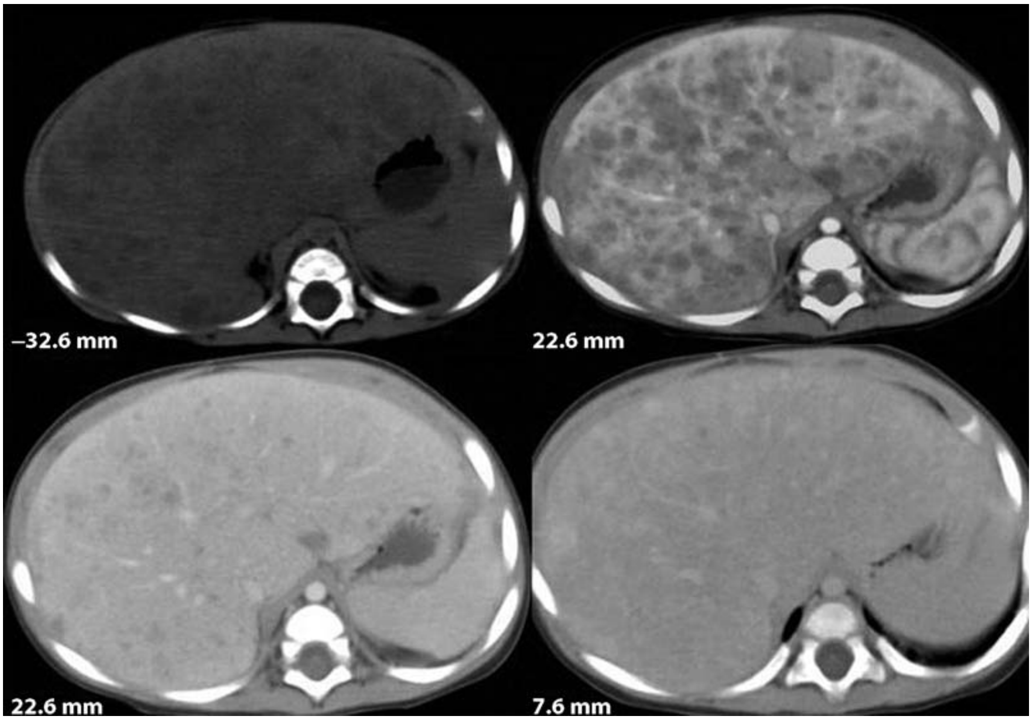
CT: Hemangioendotheliomas display the same hypodense pattern as hemangiomas; a progressive centripetal enhancement is observed with a delayed wash out and decrease of the attenuation values within the periphery of the lesion (Fig. 1). Central nonenhancing areas correspond to necrotic or hemorrhagic areas.

MR: Lesions are T1-hypointense and T2-hyperintense (Fig. 2). The peripheral areas are usually less T2-hyperintense than the central components. After contrast injection, a peripheral enhancement with subsequent centrifugal fill-in is seen with a prolonged and homogeneous enhancement on late phase images.

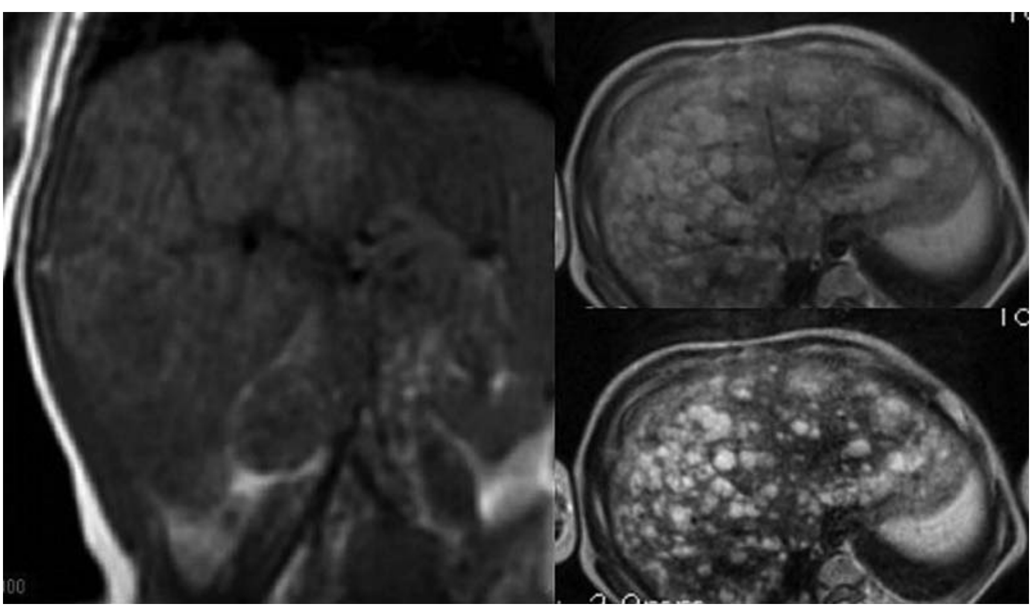
Mesenchymal Hamartoma

US: Appearance is variable and nonspecific. The solid mass may be hyperechoic while the cysts are hypoechoic. Occasionally, echogenic material is seen within the cyst secondary to hemorrhage.

CT: Hamartomas are homo- or heterogeneous hypodense with possible calcifications. After contrast injection, a strong peripheral enhancement is seen, the center of the lesion is usually less enhancing (Fig. 3). On delayed images, a washout of the periphery in combination with a progressive enhancement of the center reverses the contrast enhancement pattern.



Hepatic Pediatric Tumors, Benign. Figure 1 CT scans show a diffuse involvement of both hepatic lobes in a patient with infantile hemangioendothelioma. Basal scan (*up left*) displays multiple hypodense nodules with a progressive centripetal enhancement in the arterial (*up right*) and venous (*down left*) phases. Delayed scan (*down right*) shows a delayed wash out of the lesions.



Hepatic Pediatric Tumors, Benign. Figure 2 Infantile hemangioendothelioma (same case of Fig. 1). Coronal T1-weighted image (*left*) shows multiple hypointense nodules. Increasing the echo time nodules appear progressively hyperintense on axial T2-weighted images (echo time 50 up right and echo time 100 down right).

Hepatic Pediatric Tumors, Benign. Figure 3 **Mesenchymal hamartoma. US shows an hepatic hyperechoic solid mass (*left*); the same lesion appears homogeneously hypodense on basal CT scan (*middle*). After contrast administration peripheral enhancement with a less-enhancing center is shown on CT (*right*).**

MR: MR appearance depends on whether the hamartoma is predominantly mesenchymal (stromal) or cystic. Stromal lesions are T1- and T2-hypointense while the cystic types are T1-hypo- and T2-hyperintense. Cystic types may show a variable T1-hyperintensity according to its proteinaceous contain.

Focal Nodular Hyperplasia

US: Hypo-, iso-, or hyperechoic, well-circumscribed lesions. A central scar with small bile ducts can be seen in about one-third of the cases.
CT: Lesions are often difficult to identify on precontrast scans. After the injection of contrast media, an early enhancement with rapid washout is observed. The central scar may have a delayed, persisting enhancement.
MR: Lesions are homogeneous isointense to normal liver, the central scar may be T1-hypo-, and T2-hyperintense. Contrast enhancement is similar to CT.

Nodular Regenerative Hyperplasia

US: Nodules may be hyper-, iso-, or hypoechoic mimicking metastatic disease. The liver may be enlarged. Intralesional hemorrhages have been described.
CT: Lesions are hypodense without a significative enhancement.
MR: Nodules may be T1- and T2- hypo-, or hyperintense. Signal and enhancement pattern is nonspecific (1–4).

Hepatocellular Adenoma

US: Adenomas may be hypo-, iso-, or hyperechoic focal lesions. A peripheral hypoechoic rim is occasionally seen.
CT: Hypodense, homogeneously enhancing focal lesion with occasionally hemorrhagic components. On delayed images, the adenoma is usually isodense.
MR: T1-hypo- and T2-hyperintense lesions. Fat inclusions as well as hemorrhages may alter the signal intensities. Contrast enhancement is similar to CT.

Nuclear Medicine

Cavernous Hemangioma and Infantile Hemangioendothelioma

^{99m}Tc labeled sulfur colloid scans are usually unrevealing or nonspecific, although by means of blood pool studies an increased activity corresponding to the hypervascularity may be seen. Conversely SPECT (single photon emission tomography) scans using ^{99m}Tc labeled red blood cells show a typical early blush of this lesions.

Focal Nodular Hyperplasia and Nodular Regenerative Hyperplasia

^{99m}Tc labeled sulfur colloid scans are helpful as the majority of lesions show an uptake of tracer by the Kuppfer's cells within the nodules.

Diagnosis

Cavernous Hemangioma and Infantile Hemangioendothelioma

Differential diagnosis includes metastatic neuroblastoma and regenerative nodules in case of multiple lesions or hepatoblastoma in case of a solitary lesion. The peripheral nodular enhancement after contrast medium administration and filling in on delayed scans is characteristic for hemangioma and hemangioendothelioma. The persistent and markedly elevated alpha-fetoprotein levels in case of hepatoblastoma help to differentiate.

Mesenchymal Hamartoma

Differentiation from cystic sarcomas can be difficult for large hamartomas. Solid hamartomas may show vascular enhancement patterns mimicking other mesenchymal derived masses such as hemangioma and hemangioendothelioma.

Focal Nodular Hyperplasia and Nodular Regenerative Hyperplasia

Most lesions are discovered as a palpable mass and/or hepatomegaly. Imaging, especially enhancement pattern may suggest correct diagnosis. Biomarkers are not yet available.

Hepatocellular Adenoma

Hepatocellular adenoma should be suspected in teenage girls taking oral contraceptives who present with acute abdominal pain (hemorrhage within the adenoma) in combination with a focal finding on imaging.

Synonyms

Pediatric hepatic neoplasms; pediatric liver tumors

Definition

Primary hepatic neoplasms are rare in children. Less than 2% of all childhood tumors originate within the liver, 64% of the primary liver tumors are malignant. Hepatic tumors are the third most common abdominal malignancies after Wilms' tumor and neuroblastoma.

Pathology and Histopathology

Hepatoblastoma

►Hepatoblastoma is the most frequently occurring primary hepatic malignancy of childhood. The median age of diagnosis is 1 year. An increased risk for hepatoblastomas is known in Beckwith–Wiedemann syndrome, hemihypertrophy, fetal alcohol syndrome, Gardner's syndrome. The majority of hepatoblastomas are solitary solid tumors. Hepatoblastomas can also be multicentric, diffuse, or multicystic. The tumor is usually coarsely nodular or lobulated may be diffuse infiltrative and tends to be hypervascularized. Areas of necrosis, hemorrhage and calcifications are frequently present. Thrombosis of the porto-venous system may occur (1–3).

Hepatocellular Carcinoma

HCC is the second most common primary hepatic malignancy in children. HCC has two age peaks: 2–4 years and 12–14 years. HCC is associated with biliary atresia, familial polyposis, hereditary ►tyrosinemia, ►Byler's disease, neonatal hemochromatosis and chronic hepatitis B infection. The association with cirrhosis is less common than in adults although also in children, HCC is frequently seen in conjunction with preexisting liver disease. HCCs are single or multicentric solid masses, with or without tumor capsule. Areas of central necrosis and hemorrhage are frequent. Invasion of the porto-venous system may occur. Fibrolamellar HCC is a histologic variant of HCC with a more favorable survival rate (2–3).

►Undifferentiated Embryonal Sarcoma

Highly malignant hepatic tumor occurrs throughout the entire pediatric age group but most frequently in older children. They represent the malignant form of mesenchymal hamartoma. Tumors are typically large on presentation, can be solid and/or cystic, are usually well defined and hypovascular. A pseudocapsule of dense fibrous connective tissue may separate the lesion from normal liver tissue. Hemorrhage and necrosis are frequently seen.

Rhabdomyosarcoma of the Biliary Tree

►Rhabdomyosarcoma of the biliary tree and gallbladder is rare (>1% of all rhabdomyosarcomas) and affects

H

almost exclusively children under 5 years. The tumor typically extends along the biliary tree with resulting obstruction of the biliary ducts (jaundice). Infiltration of the porta hepatis is frequent. Metastatic spreading may involve the liver, lungs, peritoneal cavity, and retroperitoneal lymph nodes (1–3).

Hepatic Metastases

Virtually any malignant neoplasm may metastasize into the liver. The most common abdominal tumors that metastasize into the liver are neuroblastoma, Wilms' tumor, and rhabdomyosarcoma. Depending on the histology of the primary tumor, liver metastases have different characteristics. The liver may show multiple small, subcapsular located lesions without significant enlargement or may have multiple large lesions with resulting hepatomegaly.

Clinical Presentation

Hepatoblastoma

The majority of children present with an enlarging abdomen and a palpable nontender hepatic mass. In advanced stages of disease, anorexia, weight loss, nausea, vomiting, and abdominal discomfort may occur. Jaundice is seen only in a minority of children or in advanced stages. Symptoms of an acute abdomen may result from tumor rupture. The production of cytokines may result in an extramedullary hematopoiesis. In addition, paraneoplastic syndromes including precocious puberty, hypercalcemia and hypoglycemia occur. Serum alpha-fetoprotein is elevated in 75–96% of patients. Survival is determined by tumor resectability.

Hepatocellular Carcinoma

Children with a HCC usually present with an enlarging abdomen and a palpable hepatic mass. Symptoms include abdominal pain, discomfort and less frequently, fever, nausea, weight loss, and jaundice. Alpha-fetoprotein is elevated in 40–50% of children. Prognosis is poor with low survival rates. Treatment is surgical resection or liver transplantation. Chemotherapy has limited value.

Undifferentiated Embryonal Sarcoma

In the majority of children, presenting clinical symptoms is an abdominal mass with or without abdominal pain. Fever and jaundice may occur. Serum alpha-fetoprotein is rarely elevated. In half of cases, extramedullary hematopoiesis is seen. About 15% of children survive if radical surgical resection is achieved.

Rhabdomyosarcoma of the Biliary Tree

Symptoms are related to the close relation between tumor and biliary tree in which biliary obstruction results in jaundice (60–80% of children). Fever, abdominal distension, nausea, and vomiting occur. Bilirubin and alkaline phosphatase are usually elevated. Surgical resection and/or chemotherapy are treatment options; the proximity to the porta hepatis usually prevents radical surgery.

Hepatic Metastases

Abdominal distension due to a hepatomegaly and a progressive hepatic failure is the leading sign. Paraneoplastic symptoms are related to the histology of the primary tumor. In patients younger than 4 weeks, severe hepatomegaly may result in hypoventilation.

Imaging

Hepatoblastoma

Ultrasound (US): The solid tumor component is heterogeneous hyperechoic while the necrotic areas are hypoechoic or anechoic. Intratumoral hemorrhages and calcifications appear hyperechoic. Color Doppler US may show infiltration or compression of the hepatic venous vessels.

Computed tomography (CT): Hepatoblastomas are usually hypodense, well marginated with heterogeneous contrast enhancement that is slightly less accentuated compared to normal liver. A peripheral enhancing rim or septa may be evident in the delayed phases. Calcifications appear hyperdense, while areas of necrosis are hypodense and do not enhance. Tumor thrombus within the portovenous system is evident as filling defects.

Magnetic resonance imaging (MR): T1-hypo-, T2-heterogeneous hyperintense with a moderate, inhomogeneous contrast enhancement. Calcifications and hemorrhages are easily identified. To rule out tumor thrombus or cavernous transformation of the portovenous system, MR angiography is recommended.

Hepatocellular Carcinoma

US: HCC mimic hepatoblastoma, calcifications are less frequent. Doppler US may show intratumoral arteriovenous shunting as well as tumor thrombus within the porto-venous vessels.

CT: Typically hypodense, infrequently isodense with a strong, heterogeneous enhancement. Calcifications are seen in 10% of children. The presence of arterial-portal shunts may prolong enhancement of unaffected liver lobes and portal vein enhancement.

MR: T1-hypo- and T2-hyperintense with central areas of T1-hyperintensity corresponding to intralesional hemorrhages or fat inclusions. Contrast enhancement is similar to CT. A fibrous pseudocapsule may be seen.

Undifferentiated Embryonal Sarcoma

Typically, this neoplasm appears solid on US while cystic on CT and MR.

US: Iso- or hyperechoic solid tumor with small anechoic multiseptated cystic areas. The variable echogenity depends on the prevalence of myxoid, solid, necrotic, or hemorrhagic components and calcium depositions.

CT: Hypodense on CT mimicking a cystic nature. Intralesional septa as well as a peripheral pseudocapsule may enhance. Intralesional hemorrhages are hyperdense.

MR: T1-hypo- and T2-hyperintense with an enhancement pattern similar to CT. Intralesional hemorrhages appear T1-hyperintense.

Rhabdomyosarcoma of the Biliary Tree

US: Rhabdomyosarcomas are typically hyperechoic. Depending on the size and rate of growth, cystic degeneration and hemorrhage will result in a heterogeneous hypoechoic appearance. The presence of portal venous displacement without thrombosis is common.

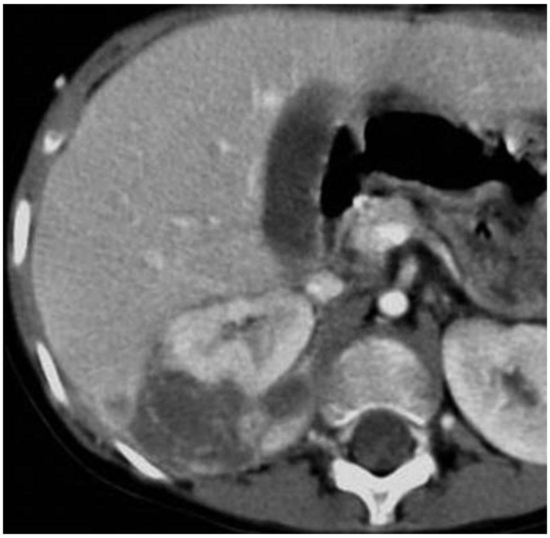
CT: Inhomogeneous hypodense mass with a variable contrast enhancement. An enhancing peripheral pseudocapsule is seen in some cases. A grape-like tumor cluster may be revealed.

MR: T1-hypo- and T2-hyperintense, contrast enhancement is usually intense but inhomogeneous. MR cholangiography (MRCP) is useful to depict the biliary tree showing the presence of filling defects related to the ductal tumor.

Hepatic Metastases

US: Most metastases are hypoechoic, multiple and located within the periphery of the liver. Presentation depends on the nature of the primary tumor. Hyperechoic metastases may be calcified or hemorrhagic. A diffuse involvement, e.g., neuroblastoma may simulate a large heterogeneous mass.

CT: Variable appearance. Most frequently, metastases appear as hypodense lesions on pre- and postcontrast scans. Calcifications are evident in neuroblastoma. In rare cases, liver metastases can be isodense or may have a target-like aspect with a central hypodensity (necrosis) in combination with an enhancing peripheral rim (Fig. 1). Hepatic involvement in lymphoma is characterized by a poorly defined, low attenuation mass with irregular margins.



Hepatic, Pediatric Tumors, Malignant. Figure 1 CT image displays the presence of a small metastasis with target-like aspect in the VI hepatic segment in a child with right suprarenal neuroblastoma.

MR: Signal intensities of liver metastases are related to the signal intensities of the primary tumor. Most frequently, lesions are T1-hypo- and T2-hyperintense (Fig. 2). In case of lymphoma, MR shows areas associated to T1 and T2 relaxation times equal to those of the spleen (1–4).

Nuclear Medicine

Hepatoblastoma

^{99m}Tc sulfur colloid liver scintigraphy shows prominent early tracer uptake at the site of the tumor persisting into the venous phase. Delayed images typically demonstrate a photopenic defect because the Kupffer's cells are replaced by tumor cells. Photopenic defects also correlate to foci of necrosis. Lesion must be at least 2 cm to be detected by planar scintigraphy. Smaller lesions can be detected by single photon emission computed tomography (SPECT).

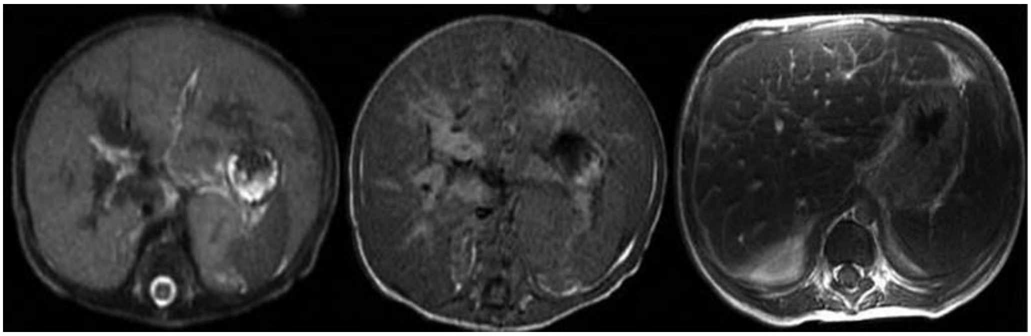
Rhabdomyosarcoma of the Biliary Tree

Scintigraphy using gallium or tallium may be employed to assess the metastatic spreading especially in case of skeletal involvement.

Hepatic Metastases

Radionuclide liver scans will show multiple photopenic areas or a generalized decrease of the liver activity. Sensitivity of nuclear medicine is lower than US, CT, or MR.

H



Hepatic, Pediatric Tumors, Malignant. Figure 2 Boy, 4 days old, axial T2-FSE (*left*) and T1-SE MR images (*middle*). Follow-up axial T2-FSE (*right*). Severe hepatomegaly due to diffuse liver metastasis in suprarenal left-sided neuroblastoma. Follow-up imaging 10 months later shows a spontaneous regression of the metastases and primary tumor.

Diagnosis

Hepatoblastoma

Large, inhomogeneous hepatic masses in child less than 5 years and elevated serum alpha-fetoprotein indicate hepatoblastoma. Imaging features are similar to those of HCC, the absence of an underlying chronic liver disease may help to differentiate hepatoblastoma from HCC.

Hepatocellular Carcinoma

The presence of liver cirrhosis increases the likelihood of HCC although the differentiation from regenerating nodules may be difficult. Serum alpha-fetoprotein is frequently elevated.

Undifferentiated Embryonal Sarcoma

Differentiation from hepatoblastoma or HCC can be difficult. The differential appearance on US versus CT and MR may help establish diagnosis. The lesion should be differentiated from benign mesenchymal hamartoma.

Rhabdomyosarcoma of the Biliary Tree

Biliary duct dilatation in combination with a small tumor in a central location is suggestive for rhabdomyosarcoma of the biliary tree. Initially, clinical symptoms are often misdiagnosed as infectious hepatitis. The US aspect of a solid hilar mass within the porta hepatis surrounded by a hypoechoic area (intraluminal rhabdomyosarcoma) may be mistaken for a choledochal cyst.

Hepatic Metastases

Clinical history and a known history of malignant disease help diagnose hepatic metastases. In addition, the multiplicity, location, enhancement pattern, and size will help diagnose metastases.

Definition

Hepatic sarcomas are primary malignancies originating from the different types of mesenchymal supportive tissue of the liver. Hepatic sarcomas, with the exception of angiosarcoma and the undifferentiated embryonal sarcoma (found in children and also in adults), are particularly rare.

Pathology and Histopathology

Angiosarcoma, Hepatic

Primary malignancy of the liver occurs in adults (60–70 years mean age) with a relevant male predominance, arising from vascular endothelial cells of the liver. This form, although rare (2% of all primary liver tumors), represents the most common primary mesenchymal malignancy of the liver. Tumor onset seems to be related to chronic exposure to toxic agents such as inorganic arsenic, and vinyl chloride, or to long-term irradiation with thorium oxide (thorotrast) used in the past (1930–1940) as angiographic contrast medium. In some cases, association with hemochromatosis, von Recklingausen's disease, alcoholic cirrhosis, and anabolic steroids intake has been described. However, most of these tumors occur in the absence of known risk factors. On gross examination, four forms have been described: multifocal nodules, large solitary masses, mixed patterns of a dominant mass with nodules, and, rarely, a diffusely infiltrating micronodular tumor. Tumor size may vary from a few millimeters to several centimeters. The presence of internal hemorrhage determines the red-brown appearance of the nodules. Larger tumors are usually ill defined, not capsulated, with a sponge appearance and may contain cystic areas with blood debris filling. This tumor is composed of malignant endothelial spindle-shaped cells organized to form vessels that may range from abortive or cavernous forms to structured, frequently dilated sinusoids. Neoplastic cells develop along vascular channels forming solid nodules or cavitary spaces. Fibrosis and hemosiderin are frequently encountered in the solid portions of the tumor. In cases of thorotrast-induced sarcomas, particles of this substance may be found inside neoplastic cells. Liver cell hyperplasia with dilatation of the sinusoids and increased fibrosis leading to portal hypertension are typical early stages of tumor growth. Early metastatic spreading to the lungs and spleen is common (1).

Epithelioid Hemangioendothelioma, Hepatic

It is a rare primary hepatic malignancy of vascular origin developing exclusively in adults (with a peak in the third to fourth decade of life), with a female predominance. It was originally described as a soft tissue tumor, but recently (1982) it has been recognized as a distinct entity reported exclusively at the level of the liver and lungs. This tumor also should not be confused with the benign infantile hemangioendothelioma occurring in pediatric patients. At the present time, the etiology and pathogenesis of this tumor remain unclear and no risk factors have emerged. This malignancy is typically solid, consisting of endothelial cells with an epithelioid appearance. Immunohistochemically, these tumoral cells are positive for endothelial markers and negative for epithelial ones. Microscopically, dendritic spindle cells associated to epithelioid round cells within myxoid and fibrous stroma can be seen. Fibrosis and calcifications are described in some cases. Tumoral cells tend to invade small vessels (sinusoids, small branches of the Hepatic and portal veins). Macroscopically, two forms have been described: a multifocal nodular pattern of infiltration in the early stages that increases in size and coalesces forming a diffuse pattern. Large lesions are composed of multiple solid nodules of variable size located in a peripheral subcapsular region forming large (more than 4 cm) confluent masses with a fibrotic central core and a cellular hypervascular periphery. An avascular rim may be seen around the lesion due to the presence of tumoral compression and obliteration onto sinusoids and tributaries of the portal and Hepatic veins. Neoplastic cells invasion of these venous vessels may also occur. Intratumoral calcifications, necrosis, and hemorrhage are common findings. This tumor frequently induces fibrosis causing capsular retraction in the case of peripheral lesions; this capsular retraction is suggestive of ►epithelioid hemangioendothelioma. Tumoral growth tends to replace hepatic parenchyma and in the case of a protracted course, a compensatory enlargement of the uninvolved liver parenchyma can be seen. Extrahepatic involvement includes the peripheral lymph nodes and mesentery with the development of calcifications in some cases. Metastatic spreading is most commonly confined to the bones and soft tissues (2, 3).

Leiomyosarcoma, Hepatic

Although very rare, this primary mesenchymal tumor of the liver shows a slightly higher incidence with respect to other sarcomas such as ►malignant fibrous histiocytoma and ►fibrosarcoma. Most frequently, this tumor occurs in adult patients (mean age 40–60 years). This is a very rare pediatric hepatic malignancy occurring mostly in immunocompromised patients. Some cases have been described in HIV-infected children or in hepatic allografts in pediatric liver recipients. Gender predilection has not been described. The lesions are composed of large spindle cells immunohistochemically positive to smooth muscle proteins. The distinction between primary ►hepatic leiomyoma and ►leiomyosarcoma is not always easy because the histological criteria for malignancy are not well defined. Usually, differentiation between benign and malignant tumors of the smooth muscle is made considering some factors such as tumor size, cellularity, nuclear atypia, number of mitoses, and presence of necrosis. In addition, the mitotic rate, if more than ten mitoses for HPF, is considered the most reliable factor for predicting prognosis. Macroscopically, this sarcoma appears as large, solid, solitary masses located in a normal noncirrhotic liver. The lesions are often polylobulated containing a variable amount of internal hemorrhage or necrosis (4).

Histiocytoma Fibrous Malignant, Hepatic

Rare sarcomatous neoplasm most commonly affects limbs and rarely the abdominal organs such as the stomach, intestine, peritoneal wall, pancreas, and liver. The number of described cases have increased since 1970 when this tumor was definitively classified as a separate pathologic and nosologic entity. This tumor occurs mostly in elderly patients, without gender prevalence. Histologically, it appears as sarcomatous changes in normal components of the mesenchymal stroma resembling a reticulosarcoma. Macroscopically, it is a rapidly growing bulky mass with polylobulated shapes.

Clinical Presentation

Angiosarcoma, Hepatic

This tumor is very aggressive and consequently associated with a poor prognosis (median survival after diagnosis is 1 year). The surgical approach may play a role only in cases of lesions confined to one hepatic lobe without metastases. The clinical presentation is nonspecific including weight loss, weakness, abdominal pain, hepatomegaly, and intraperitoneal bleeding. Thrombocytopenia, disseminated intravascular coagulation, and hemolytic anemia have been described. The pathogenesis of all these hematologic abnormalities is probably related to the traumatism created inside the poorly organized tumoral vessels (1).

Epithelioid Hemangioendothelioma, Hepatic

The clinical course is related to a highly variable malignant potential, which is intermediate between that of benign endothelial tumors (hemangioma) and malignant angiosarcoma with a median patient survival of 5–10 years after diagnosis. Clinical signs and symptoms are not specific such as jaundice, upper quadrant pain, and liver failure. In rare cases, associated hemoperitoneum and Budd-Chiari syndrome have been described. It may happen also that this tumor is incidentally discovered (2, 3).

Leiomyosarcoma, Hepatic

The clinical presentation is not specific. A variable range of signs and symptoms such as abdominal pain, hepatomegaly, jaundice, and liver failure may occur. In some cases, daughter nodules and large tumoral lesions rupture may develop. Metastases are mainly hematogenous and the biological behavior of the tumor determines the precocity of the metastatic spreading (4).

Histiocytoma Fibrous Malignant, Hepatic

Symptoms are mainly due to compression of this large, rapidly growing mass on the neighboring organs.

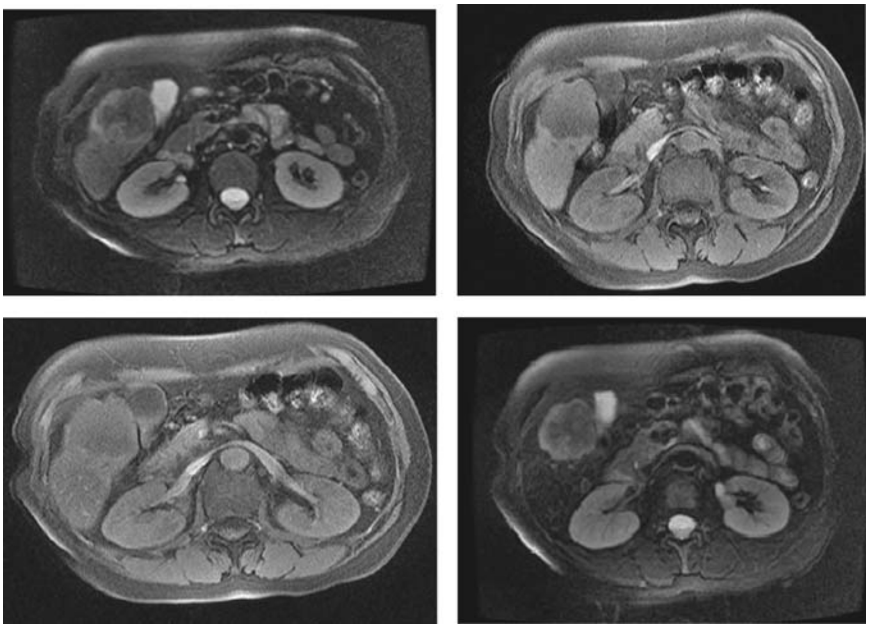
Imaging

Angiosarcoma, Hepatic

Ultrasound (US) shows sarcomatous nodules as hyperechoic masses (that can be either single or multiple) with an inhomogeneous echo structure in the case of internal areas of hemorrhage and necrosis. Computed tomography (CT) depicts hepatic angiosarcoma on unenhanced scans as a hypodense area with unshaped borders, in some cases containing foci of higher attenuation due to fresh hemorrhage or areas of lower attenuation (near water density) related to old hemorrhage. In cases of thorotrast-induced tumors, neoplastic nodules as well as involved lymph nodes and the spleen show an inhomogeneous hyperdensity due to thorotrast storage. The enhancement pattern is similar to that of cavernous hemangiomas (angiosarcoma may also contain cavernous vessels) with peripheral enhancement followed by progressive centripetal opacification (Fig. 1). Therefore, these areas of enhancement frequently show a lower attenuation than the aorta and bizarre shapes or peripheral ring-shaped enhancement. Magnetic resonance (MR) features of angiosarcoma resemble those of hemangiomas. The presence in both of blood-filled vascular spaces determines the high signal intensity on T2-weighted images. After gadolinium injection, a peripheral centripetal enhancement may be seen (Fig. 2). In some cases, the presence of proteinaceous material shows an inhomogeneous signal intensity on T2-weighted images, while hypointense areas suggest the presence of hemosiderin, fibrous solid portions, or fresh hemorrhage. High signal intensity areas on T1-weighted images suggest subacute hemorrhage.

The main role of angiography in the case of hepatic angiosarcoma is interventional with a palliative purpose by means of intratumoral injection of chemotherapeutic agents or chemoembolization. Angiography may also depict the hypervascular nature of this lesion showing the presence of a peripheral spot, late in the arterial phase, with

Hepatic Sarcoma. Figure 1 **Angiosarcoma. Enhanced CT scans show a large focal liver lesion with hyperdense areas predominantly at the periphery of the mass; a progressive, but incomplete centripetal fill in with contrast medium is observed during the portal venous (*middle*) and delayed phases (*right*).**



Hepatic Sarcoma. Figure 2 **MR: T2-weighted image of the same lesion (*up left*). The nodule appears slightly hyperintense. On dynamic acquisition the lesion shows a progressive, persistent, peripheral enhancement without the discontinuous and globular pattern typical of hemangiomas (*up right, down left*).Delayed T2-weighted image obtained 10 min after RES targeted contrast medium administration shows the hyperintensity of the lesion respect to the surrounding parenchyma demonstrating the absence of mature reticulo endothelial cells content (*down right*).**

intralesional accumulation of contrast material from the mid arterial phase to the late venous phase. The presence of the described peripheral spot should help to distinguish hepatic angiosarcomas from hemangiomas (1).

Epithelioid Hemangioendothelioma, Hepatic

The pathologic anatomy of epithelioid hemangioendothelioma explains its appearance on diagnostic images. US depicts multiple well-defined solid coalescing nodules forming large confluent masses, predominantly hypoechoic; although in some cases iso- or hyperechoic nodules have been described associated with a hypoechoic peripheral rim or central area. In addition, in regions of massive involvement a diffusely heterogeneous echo texture may appear.

Unenhanced CT scans depict tumoral conspicuity well as a hypodense area with associated calcifications in some cases. The hypodense pattern is mostly due to the presence of the myxoid stroma. Enhanced scans may show a target appearance of the lesions due to the presence of a central unenhancing area associated with a hypervascular hyperdense peripheral proliferating rim surrounded by an unenhanced area due to the avascular outer zone if present. In the late venous phase the lesion tends to become isodense. The absence of the avascular outer zone determines the isodensity of the peripheral vascular rim with respect to the enhancing normal surrounding hepatic parenchyma and makes it difficult to delineate the tumoral contours (Fig. 3). Other findings include capsular retraction (although the liver capsula is not usually affected) and compensatory hypertrophy of the unaffected liver segments.

MR features are similar of those of CT. Both T1- and T2-weighted images, especially after gadolinium enhancement, show concentric changes of signal corresponding to regions of different histology. The overall signal tends to be low on T1-weighted images and heterogeneously high on T2-weighted images. Delayed phases after gadolinium administration may show a peripheral wash out which is useful for characterization. On delayed images acquired after hepatobiliary contrast medium administration, these lesions appear hypointense. Central areas of reduced signal may correspond to coagulation, necrosis, hemorrhage, or calcifications (2, 3).

Leiomyosarcoma, Hepatic

US usually depicts a large mass with a variable echo pattern according to the presence of central necrosis and hemorrhage. Satellite nodules may also be seen. Unenhanced CT shows hypodense, homogeneous masses without calcifications. Heterogeneous peripheral enhancement due to viable tissue may be observed after contrast medium administration.

The MR signal is not characteristic. Usually, these lesions appear hypointense both on T1- and T2-weighted images. Gadolinium administration shows a peripheral rim of enhancement similar to that shown by CT (4).

Histiocytoma Fibrous Malignant, Hepatic

The US pattern is extremely variable, ranging from hypo- to hyperechoic patterns. In some cases, calcifications may be present and may be depicted on unenhanced CT scans. CT has an important role in tumoral staging and presurgical planning. CT depicts the tumor as a hypodense lesion, in some cases heterogeneous for the presence of areas of internal necrosis. Well-vascularized areas (usually peripheral) tend to enhance after contrast medium administration.

Hepatic Sarcoma. Figure 3 Hepithelioid hemangioendothelioma.Basal CT scans obtained at two different levels in the same patient show the presence of two uniformly hypodense lesions (*up left*) in the right lobe. A peripheral enhancement is progressively appreciated after contrast administration, delineating a central unenhancing area (*up right, down left*). The hypodense outer zone is shown in the major lesion on delayed phase (*down right*).

Diagnosis

Angiosarcoma, Hepatic

The differential diagnosis must include large hemangiomas, even though both angiosarcoma and hemangioma are composed of blood-filled vessels or cavernous spaces explaining their common features on CT and MR images. A differential criterion is the centripetal enhancement after contrast medium administration that in the case of hemangiomas is denser and typically globular. Angiosarcomas with central hemorrhage or necrosis show an incomplete opacification after contrast medium administration simulating large hemangiomas, which commonly do not fill in completely with contrast material. Some authors believe that it is extremely difficult to distinguish hepatic sarcomas from other hypervascular tumors of the liver such as hypervascular metastases (neuroendocrine tumors) or hepatocellular carcinoma. In addition, these lesions may demonstrate internal hemorrhage and heterogeneity associated with an early and heterogeneous enhancement. The presence of a delayed enhancement in the case of angiosarcoma helps to differentiate it from hepatocellular carcinoma. The presence of splenic involvement and hematologic disorders associated with the absence of background cirrhosis and alpha fetoprotein elevation may also help to diversify it from hepatocellular carcinoma (1).

Epithelioid Hemangioendothelioma, Hepatic

The multiple concentric rim pattern may suggest the feature of one abscess, although the clinical setting allows the diagnosis to be made.

MR hyperintensity of the lesion on T2-weighted images is similar to other malignancies but not as intense as the characteristic high signal of hepatic hemangiomas.

Multiple confluent peripheral solid masses, associated with capsular retraction depicted by the different diagnostic imaging techniques (US, CT, MR), are suggestive of epithelioid hemangioendothelioma.

Leiomyosarcoma, Hepatic

Imaging features of leiomyosarcoma are not peculiar, resembling those of other hepatic mesenchymal malignancies, so that a definitive diagnosis is achieved by means of histology.

Histiocytoma Fibrous Malignant, Hepatic

The imaging pattern resembles that of other hepatic sarcomas. The presence of calcifications may help to differentiate it from leiomyosarcoma.

Synonym

Diffuse inflammatory disease of the liver

H

Definition

Hepatitis is any disease featuring diffuse inflammation of the liver, characterized by partial or extensive necrosis involving all hepatic lobules. Acute hepatitis is a diffuse inflammation of the liver usually due to hepatotropic viruses and causing necrosis and acute inflammatory infiltrates. In chronic hepatitis, the hepatic inflammation and necrosis continue for at least 6 months. ►Fulminant hepatitis is characterized by submassive to massive hepatic necrosis, progressing from onset of symptoms to hepatic failure within 2 to 3 weeks.

Pathology and Histopathology

Acute Hepatitis

Various possible viral agents may cause acute hepatitis. Unless otherwise, the specified term "viral hepatitis" is reserved for infections that are caused by a group of viruses which shows a particular affinity for the liver. The main hepatotropic viruses are hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis D virus (HDV), also called delta agent (which requires the presence of the hepatitis B virus), and hepatitis E virus (HEV). A vast array of other viruses may also produce hepatitis, including cytomegalovirus, Epstein-Barr virus (EBV, the agent responsible for mononucleosis), herpes viruses, yellow fever virus, rubella virus, Coxsackie virus, and adenovirus. Nonviral infectious acute hepatitis may be related to severe bacterial infections and amoebic infection. ►Toxic hepatitis usually has an acute onset and it can be due to drugs, hepatotoxic substances such as fungal toxins and alcohol. The morphologic changes in acute viral hepatitis and in drug-related hepatitis are virtually the same. Grossly, the liver is enlarged and more or less green depending on the degree of jaundice. Histologically, the major findings are necrosis of isolated or clustered hepatocytes, diffuse liver cell injury, reactive changes in Kupffer cells and sinusoidal lining cells, consisting in hypertrophy and hyperplasia, inflammatory infiltrate in portal tracts, hepatocytic regeneration during the recovery phase. In more severe acute inflammation, confluent necrosis may lead to bridging necrosis connecting portal-to-portal, central-to-portal, or central-to-central regions of adjacent lobules.

Fulminant Hepatitis

Submassive to massive hepatic necrosis progressing from onset of symptoms to hepatic encephalopathy within 2 to 3 weeks is called fulminant hepatitis or fulminant hepatic failure. The most common causes are fulminant viral hepatitis, drug toxicity (acetaminophen, isoniazid, antidepressant), chemical toxicity (mycotoxins of the mushroom *Amanita phalloides*), ischemia or shock.

Chronic Hepatitis

Chronic hepatitis is a process present for at least 6 months and has a number of different causes, including viral hepatitis (HBV, which leads to chronicization in more than 90% of infected neonates and in 5% of adults, of whom one-fourth progress to cirrhosis; HCV, with a risk of chronicization greater than 50% of infected patients, of whom half progresses to cirrhosis; superinfection by HDV in patients infected by HBV, whose outcome is a more severe chronic hepatitis), chronic alcoholism, drugs (isoniazid, alpha-methyldopa, methotrexate), autoimmunity, metabolic disorders (Wilson's disease and hemochromatosis), alpha 1-antitrypsin deficiency. Chronic hepatitis is classified, on the basis of the extent of inflammation, in chronic persistent hepatitis (in which inflammation is confined to the portal tracts), chronic active hepatitis (in which inflammation spreads from the portal tracts into the parenchyma and surrounds regions of necrotic hepatocytes), chronic lobular hepatitis (in which persistent inflammation is confined to the lobule). Most histological features are common to all forms of chronic hepatitis. In the mildest forms of chronic hepatitis, the inflammatory infiltrate is limited to the portal tracts; this consists of lymphocytes, macrophages, and occasional plasma cells. Liver architecture is usually preserved. The histological mark of progressive disease is the so-called "piecemeal necrosis," consisting of necrosis of hepatocytes of the lining plate associated to spilling of chronic inflammatory infiltrate out of the portal tracts. Lobular inflammation with focal hepatocellular necrosis may be present. Bridging necrosis may connect adjacent portal–portal, central–central, and portal–central zones. Continued loss of hepatocytes results in fibrous septum formation, which, accompanied by hepatocellular regeneration, results in cirrhosis. Some histological features are specific of chronic hepatitis of different etiology. In chronic HCV hepatitis, lymphoid aggregates in portal tracts and mild fatty change are seen in about one-half of cases and bile duct damage is observed in most cases. "Ground glass" hepatocytes are sometimes present in chronic HBV hepatitis.

Clinical Aspects

Acute Hepatitis

The symptoms of acute hepatitis are considerably variable. Sometimes acute hepatitis is completely asymptomatic. Children usually show mild symptoms. The early stage is characterized by aspecific manifestations such as weakness, low fever, nausea, loss of appetite, changes in taste perception, headache. This syndrome is followed by the jaundice phase, in which the scleral and cutaneous jaundice is associated to dark urine and light-colored stools. Weakness may last for weeks during the recovery phase.

Fulminant Hepatitis

The clinical scenario is dominated by jaundice, encephalopathy, coagulopathy and bleeding, renal failure, cardiovascular failure. The evolution is variable and depends on the age of the patient and the previous status of the liver.

Chronic Hepatitis

Many patients with chronic hepatitis have no symptoms. The most common manifestations are weakness, muscles, and joints pains. Mild right-upper-quadrant discomfort may occur. Jaundice may appear in the later stages of chronic hepatitis.

Imaging

Imaging has a limited role in the diagnosis of hepatitis, especially in acute hepatitis. It may be helpful in the evaluation of chronic hepatitis, especially in assessing complications. Probably the most important role of imaging in suspected hepatitis is to help exclude the presence of other hepatic diseases, such as cholestasis, diffuse metastatic disease, and cirrhosis (1).

Acute Hepatitis

Specific sonographic signs of acute hepatitis have not been described. Ultrasound (US) is performed in order to exclude biliary obstruction in patients with jaundice, but does not allow a definite diagnosis of acute hepatitis. Usually the liver is uniformly enlarged and the hepatic margins are regular. In the large majority of cases, the echo structure does not show any modification. Sometimes, US demonstrates a diffuse decrease in parenchymal echogenicity, which causes a relative increase in the echogenicity of the portal vein walls ("starry night" pattern) (1–3). Transient changes in morphology and motility of gallbladder may occur in acute hepatitis. In early stages, the gallbladder may be contracted with thickened wall whereas in advanced stages it may be enlarged with normal wall and shows a reduced response to cholecystokinetic stimula (4). Enlarged inflammatory periportal, hilar, and coeliac lymph nodes may be present (Fig. 1).

In acute hepatitis, the computed tomographic (CT) findings are aspecific and inconstant and may vary from normal liver to hepatomegaly with homogeneous parenchymal hypodensity, to diffuse inhomogeneity with alternating hypodense and hyperdense areas. Periportal edema may be appreciable as a hypodense halo along intrahepatic portal vessels. This CT sign is called "periportal tracking" and can involve both minor and major branches, sometimes being visible also around the inferior vena cava. The use of contrast media allows a better depiction of the periportal tracking, which becomes more

Hepatitis. Figure 1 US scan of porta hepatis: enlarged lymph nodes of the porta hepatis and of the coeliac trunk may be demonstrated. These inflammatory lymphadenopathies have an elongated morphology.

easily distinguishable from the vessel lumen during the portal-venous phase. Sometimes in the early stage, multiple-regenerating nodules may be detected.

Fulminant hepatitis is characterized by the presence of multiple confluent necrotic areas. Necrosis appears as a hypodense area with a hyperdense border due to concomitant fibrosis and regeneration. After contrast medium administration, necrosis remains unenhanced whereas fibrosis and regenerative nodules show variable contrast enhancement.

On magnetic resonance (MR) images acute inflammation of the liver determines a specific increase of T1 and T2 relaxation times, due to the increased content in water protons. Nevertheless, variations of signal intensity are rarely appreciable. On T2-weighted images, it is sometimes depicted a hyperintense band along the portal vessels, related to inflammatory phenomena with edema. A common finding is the presence of inflammed enlarged lymph nodes (5).

Chronic Hepatitis

In patients with chronic hepatitis, imaging studies are used to evaluate the development of cirrhosis and ascites and to exclude hepatocellular carcinoma. US does not show peculiar findings in chronic hepatitis. The liver is usually increased in size and has regular margins. The echo structure may be normal or have a coarsened texture and increased parenchymal echogenicity, when fibrotic or fibrosteatotic phenomena are associated. This causes portal vein radicles to be less conspicuous. The appearance of the liver is essentially identical to that seen with diffuse fatty change. In some cases, the sonographic appearance is indistinguishable from cirrhosis. Enlarged lymph nodes of the porta hepatis and of the coeliac trunk may be demonstrated. These inflammatory lymphadenopathies have an elongated morphology and a central hyperechoic line may be depicted (1–3). In patients with chronic hepatitis, the CT and MR imaging features resemble those of early-stage liver cirrhosis.

In chronic active hepatitis, the "periportal tracking," appearing as a hypodense band on CT and hyperintense band on T2-weighted MR images may be depicted, due to inflammation and edema. Geographic zones of reduced density at CT and increased signal intensity on T2-weighted MR scans correspond to edema and indicate active disease (3, 5) (Fig. 2).

Hepatitis. Figure 2 Coronal MR scan of the liver, true-FISP sequence: ►nonalcoholic steatohepatitis (NASH), also called nonalcoholic fatty liver disease (NAFLD) is a liver inflammation with fatty degeneration not due to abuse of alcohol. This condition is more common in women and it is associated with obesity, diabetes mellitus type II, and insulin resistance as in this patient. Liver is enlarged. In this out-of-phase condition, liver has low signal for high grade of steatosis.

Diagnosis

In acute hepatitis, the diagnosis is done on the basis of clinical and laboratory data. The laboratory data allows establishing the presence of liver inflammation and its cause. In chronic hepatitis, biopsy is needed in order to assess the stage and the grade of the disease. Laboratory data provide information about the cause of the disease and the degree of liver function impairment. HCV-related hepatitis is suspected when serum aminotransferases are elevated and anti-HCV is present in serum (indicative of past and current infection). The diagnosis is confirmed by the finding of HCV RNA in serum (indicative of active viral replication). In HBV infection, HBsAg is a marker of acute and chronic disease; HBeAg and HBV-DNA indicate active viral replication. Anti-HBs is indicative of serum immunity after vaccination, anti-HBc IgG is marker of past or recent HBV contact whereas anti-HBc IgM is a marker of acute infection if the titer is high and chronic infection if the titer is low.

Hepato-Biliary Malformations

▶Congenital Malformations, Liver and Biliary Tract

Hepatobiliary System

CARLO BARTOLOZZI
Division of Diagnostic and Interventional Radiology,
University of Pisa, Pisa, Italy
bartolozzi@med.unipi.it

Recent advances in imaging techniques have determined a radical change in the radiological approach to the diagnosis and treatment of hepatobiliary, pancreatic, and splenic diseases. Particularly, improvements in ultrasound (US), computed tomography (CT), magnetic resonance (MR), and nuclear medicine allow an accurate noninvasive evaluation of parenchymal, vascular, and biliary structures.

This section presents an overview of the hepatobiliary system (liver, pancreas, spleen), providing an accurate description of the anatomy (normal and radiological) and pathology, emphasizing the most relevant diagnostic tools. Special emphasis has been put on focal and diffuse disease detection and characterization, which may enable definitive diagnosis without the need for histological specimens. Pediatric diseases and congenital malformations are covered separately. Finally, radiological interventional procedures and organ transplantation imaging are discussed.

The liver enables multiple vital functions (metabolic, storage, and digestive) that are reflected in its peculiar complex anatomy (**Anatomy, Normal and Radiological, Biliary System**) consisting of parenchyma, biliary ducts, and a double vascular supply. The liver occupies much of the right hypochondrial region of the abdomen. It has two major surfaces, a superior or diaphragmatic surface and an inferior or visceral one. It can be divided in two different ways, by external lobation and by segmentation. The classical anatomic subdivision into four externally defined lobes is based on approximately H-shaped indentations on the visceral surface. In contrast, the internal lobation and segmentation are based on the branching pattern of the portal vein, hepatic artery, and hepatic ducts, with the major hepatic veins occupying and helping to demarcate the planes between the lobes and segments.

The choice of the most appropriate liver imaging approach, tailored on the clinical request, is mandatory as it is now possible to electively depict the hepatic parenchyma or vascular and biliary anatomy.

Since the introduction of fast imaging and new contrast agents an extremely accurate evaluation of liver parenchyma has been obtained. Cross-sectional imaging techniques, including US, CT, and MR, are well-established modalities enabling diagnosis of focal and diffuse liver disease in most cases. The use of contrast agents increases both sensitivity and specificity of liver lesion detection and characterization.

Extracellular contrast agents are largely employed in CT and MR (vascular interstitial agents) and, recently, in US (blood pool agents), increasing lesion detection and providing crucial additional information about the dynamic contrast behavior for lesion characterization. However, the vascular pattern may not be specific for each focal lesion, and the diagnostic accuracy of dynamic phase imaging alone can be unsatisfactory. Therefore, the advent of novel MR contrast agents with liver-specific properties may increase tissue characterization, enabling an accurate evaluation both of diffuse and focal liver disease.

Diffuse liver diseases comprise many different pathological conditions, including metabolic disorders, infections, and chronic toxic injury. Imaging techniques are increasingly becoming involved in the study of such affections. Because several diffuse liver diseases predispose to the development of primary hepatic neoplasms, the aim of imaging is to characterize some of these conditions and to detect neoplasms at an early stage.

Particularly, hepatitis (**Hepatitis**) and hepatic cirrhosis (**Cirrhosis, Hepatic**) have a high prevalence, representing a major health problem. In such conditions, as well as in several rare diffuse infiltrative diseases of the liver (**Diffuse Infiltrative Diseases, Hepatic**), imaging techniques are largely employed to screen for neoplastic changes.

Finally, structural and morphological changes induced by several diffuse liver diseases, such as fatty infiltration (**Steatosis, Hepatic**) and diffuse infiltrative disease, especially in cases of heterogeneous distribution, must be distinguished from tumors.

However, imaging techniques are used mainly for differentiating benign and malignant focal liver lesions. Benign lesions are currently classified according to their cellular origin into hepatocellular, cholangiocellular, and mesenchymal types. Benign proliferation of hepatocytes leads to hepatic adenoma (**Adenoma, Hepatic**) and focal nodular hyperplasia (**Hyperplasia, Focal, Nodular Hepatic**). Hepatic hemangioma (**Hemangioma, Hepatic**) is the most common benign tumor affecting the liver and develops from endothelial cells. Hepatic cysts and cystic like lesions (**Cystic-like Lesions, Hepatic; Abdominal**) are of congenital or developmental origin arising from biliary epithelial cells in most cases. Finally, other rare benign lesions may originate from mesenchymal tissue (**Lipomatous Tumors, Hepatic**), and biliary duct epithelium such as biliary cystoadenoma (**Neoplasms, Bile Duct**).

Most benign tumors are incidental findings and do not produce clinical symptoms. They must be diagnosed noninvasively and differentiated from malignancies. However, because of the possibility of malignant degeneration, as in the case of hepatic adenoma, the benign tumors must also be differentiated from one another. Benign focal liver lesions include inflammatory/infectious diseases (**Hydatid Disease; Abscess, Hepatic**) and traumatic lesions such as hepatic hematoma and biloma (**Trauma, Hepatobiliary**).

The liver is an important organ from an oncologic perspective. Primary hepatic neoplasms are common, especially in the presence of several diffuse liver diseases. Histologically, primary hepatic malignancies can be divided on the basis of their origin from hepatocytes (**Hepatocellular Carcinoma**), bile duct epithelium (**Neoplasms, Bile Duct**), and mesenchymal tissue (**Lymphoma, Hepatic; Sarcoma, Hepatic; Lipomatous Tumors, Hepatic**). Hepatocellular carcinoma is the most common primary malignancy of the liver, representing the main complication of chronic hepatitis and cirrhosis. Because surgical and percutaneous procedures (**Interventional Hepatic Tumors, Procedures**) are well-established therapeutic options for hepatocellular carcinoma treatment, early diagnosis is a crucial point, nowadays possible for radiologists.

The liver provides fertile soil for metastases (**Metastases, Hepatic**), not only due to its dual blood supply from both the systemic and splanchnic circulation, but also for sinusoid vascular architecture and a rich biochemical environment favoring rapid growth of metastatic cells. It is the most common site of metastases from a variety of cancers, particularly gastrointestinal tumors. The radiologist's challenge in liver malignancies is not only diagnosis and staging but also treatment (**Interventional Radiological Procedures, Hepatic**) and evaluation of the response to therapy.

Moreover, the assessment of the vascular branches' course and segmental and subsegmental anatomy has become of utmost importance, particularly because of the increasing necessity of accurate localization of liver lesions and preoperative demarcation of resection planes.

Volumetric techniques, such as CT and MR, implemented by three-dimensional reformation allow investigation of the variability in anatomic relationships between external landmarks and hepatic vascular structures, clarifying segmental and subsegmental anatomy and offering the possibility to obtain images at the peak of vascular enhancement. This allows precise depiction of hepatic vessels and generation of angiographic images, particularly useful in the imaging of focal liver lesions as well as in pre- and posttransplant liver imaging evaluation (**Transplantation, Hepatic**) and in **Vascular Disorder Hepatic** assessment.

Vascular imaging with Doppler US has expanded the role of US to permit rapid assessment of vessel patency and blood flow direction, allowing not only a morphologic but also a dynamic and functional approach, particularly useful for portal vein evaluation in **Portal Hypertension**.

Vascular hepatic disorders (**Vascular Disorders, Hepatic**), representing a miscellaneous group of pathological conditions affecting the visceral vessels, can be accurately depicted by means of CT and MR technologies, allowing angiographic applications and restricting angiography to a therapeutic role.

Diagnosis of biliary affections, especially several benign conditions affecting the gallbladder (**Gallstone; Cholecystosis; Cholecystitis**), represents an everyday challenge for radiology. US is routinely employed for the first assessment of such diseases, while CT may be used to implement the role of US, especially when evaluation of the distal portion of the biliary duct is required or to assess the tumoral spreading in cases of malignancy (**Gallbladder Tumors**). However, when a more accurate evaluation of the biliary tree is required (**Cholangitis; Occlusion, Bile Ducts**), cholangiographic techniques must be employed. Since the advent of MR cholangiography, an accurate evaluation of the biliary branches can be obtained noninvasively, while direct cholangiography (transhepatic or retrograde) is used for treatment only.

Pediatric conditions (**Pediatric Tumors, Hepatic, Benign; Pediatric Tumors, Hepatic, Malignant**) and congenital malformations (**Congenital Malformations, Liver and Biliary Tract**) are covered separately.

The pancreas is a gland consisting of two different components: The exocrine pancreas secretes digestive enzymes (amylase, lipase, etc.), which are collected in the pancreatic ductal tree and, *via* the main pancreatic ducts of Wirsung and Santorini, flow into the duodenum. The endocrine pancreatic insulae produce various hormonal substances (insulin, glucagon, gastrin, VIP, etc.), which are released in the portal venous system.

The pancreas is located in the retroperitoneum. Its deep position, posteriorly to the stomach and intestinal loops, has in the past limited its radiological explorability; it was possible to obtain only indirect signs of pancreatic disease with conventional radiology. The advent of tomographic techniques has permitted direct visualization of the gland, and consequently, imaging has assumed a fundamental role in diagnosis, staging, and pre- and posttherapeutic evaluation of pancreatic disorders. Nowadays, the radiologist has a complete and detailed view of the normal anatomy of the pancreas and its ductal and vascular systems, and can thus easily identify congenital abnormalities (**Congenital Abnormalities, Pancreatic**) and precisely define postsurgical anatomy in patients having pancreas transplantation.

US usually represents the first examination performed when a pancreatic disease is suspected. The sonographic study of the pancreas has some limitations because of its anatomic location; particularly, the pancreatic tail can be difficult to visualize. Nevertheless, it often displays indirect signs of pancreatic disease, such as dilatation of biliary and pancreatic ducts, abdominal fluid collections, ascitis, peritoneal carcinosis, and hepatic metastases.

Doppler US can integrate the US exam; a recent application of Doppler US is the follow-up of the transplanted pancreas. Thanks to the possibility of assessing the patency of vascular anastomoses and of identifying abnormalities in parenchymal vascularization, abdominal US and Doppler US enable correct assessment of the transplanted pancreas and therefore represent an effective diagnostic technique for first recognition of parenchymal and vascular complications (**Transplantation, Pancreatic**).

US contrast media have been employed in experimental studies in the evaluation of focal pancreatic lesions. The usefulness of contrast-enhanced US in demonstrating pancreatic malignancies is still not evident. However, indirect signs of pancreatic cancer, such as ductal dilatation and vascular involvement, seem to become clearer after contrast administration.

Spiral CT is the standard imaging modality for evaluating the pancreatic gland because it allows visualization of the entire organ and accurate assessment of the relationships with adjacent anatomic structures. Furthermore, the use of iodinate contrast medium allows study of the pancreas in different phases of contrast distribution; this is crucial in characterizing focal lesions and evaluating the vascular structures, especially in malignancies (**Carcinoma, Pancreatic**; **Cystic Neoplasms, Pancreatic; Islet Cells Tumors, Pancreatic**). Image processing can improve depiction of the vessels and, in cases of neoplastic disease, increase the accuracy of assessing the vascular involvement. CT represents the imaging technique of choice for the detection of pancreatic neoplasms and for local and distant staging; furthermore, on the basis of CT findings it is possible to establish the resectability of the lesion.

In transplanted patients, the CT examination, performed in selective arterial, pancreatic, and venous phases, enables detailed visualisation of the transplanted pancreas, including the anastomoses for exocrine pancreatic drainage and those of the afferent and efferent vessels, thus allowing accurate identification of possible complications.

In acute inflammatory disease of the pancreas (**Pancreatitis, Acute**), CT allows complete visualization of the pancreas and retroperitoneum, thus demonstrating the typical pancreatic findings, fluid collections, and possible complications. CT is also used to assess the severity and estimate the prognosis of acute pancreatitis, by means of the well-established CT criteria.

In the early stage of chronic pancreatitis (**Pancreatitis, Chronic**), the diagnosis is based mainly on clinical and laboratory data, due to the absence of the typical morphologic changes detectable by means of imaging. In advanced disease, imaging plays a key role in diagnosis, demonstrating characteristic findings (calcifications, ductal dilatation, etc). The major limitation of imaging modalities concerns differentiation of focal chronic pancreatitis and cancer. In general, differentiation between cancer and focal pancreatitis is difficult with a single imaging modality and may sometimes require the use of contrast-enhanced CT, MR, positron emission tomography (PET) imaging, and, in selected cases, histological evaluation.

Technical advances in MR have promoted the application of this technique in the study of the pancreas; in fact, MR is able to provide a paramount view of the pancreatic region, including the parenchyma, the ductal system, and the vascular structures. Hence, a comprehensive assessment of most pancreatic diseases can be achieved with a single examination.

Unenhanced MR sequences provide additional information about the pancreatic parenchyma and pancreatic lesions with respect to CT examination, for example in characterization of cystic lesions.

The current major areas of investigation are dynamic contrast-enhanced imaging techniques, use of tissue-specific contrast agents, and magnetic resonance cholangiopancreatography (MRCP).

The use of contrast media, both vascular interstitial (gadolinium chelates) and tissue specific (Mn-DPDP), can improve the depiction and the characterization of focal lesions.

Mn-DPDP contrast-enhanced MR has proven to be very helpful in the detection of small tumors, thanks to the very little uptake of the agent into tumors with respect to normal parenchyma, which results in a reliable increase of pancreas-tumor contrast, thus improving the detectability of neoplastic lesions.

Mn-DPDP may also improve the staging of pancreatic cancer by increasing the sensitivity of MR imaging in detecting liver metastases during the same examination.

The pancreatic ductal system can be visualized with high diagnostic accuracy either by means of heavily T2-weighted scans, which highlight the signal intensity from static fluids, o by using hepatobiliary contrast media. MRCP allows depiction of pancreatic ductal tree abnormalities with an accuracy similar to that of endoscopic retrograde cholangiopancreatography (ERCP).

The MRCP sequences can also be applied to perform pharmacodynamic studies; for instance, it is possible to evaluate the pancreatic ductal system after intravenous secretin administration to enhance the delineation of the main pancreatic duct and its side branches, and to obtain additional information concerning signal voids and strictures.

Locoregional vessels can be accurately assessed in the same session by using MR angiography techniques and image reformations.

Finally, nuclear medicine, by using somatostatin receptor analog, may be useful in evaluating pancreatic endocrine tumors.

The spleen is formed by reticular and lymphatic tissue and is the largest lymphatic organ. It is located in the left hypochondriac region of the abdominal cavity between the fundus of the stomach and the diaphragm. The spleen has two main functions: It represents an important site for the immunological response, and it is the principal site of destruction of senescent erythrocytes or abnormal blood elements. During fetal life, the spleen also works as a hematopoietic organ.

The spleen is an uncommon site of primary disease; however, it is secondarily involved in various different pathological conditions.

Modern imaging modalities such as US, CT, and MR offer an easy examination of the spleen and show high sensitivity in demonstrating focal or diffuse abnormalities, but low specificity in characterizing the different diseases. US and CT are screening modalities for the spleen, while MR is performed for problem solving in selected clinical settings. Use of organ-specific contrast agents, such as superparamagnetic iron oxide particles, represents a promising tool to improve the detection of splenic disorders.

Currently, splenic angiography is not used as a diagnostic tool and is almost exclusively performed for interventional procedures, while conventional nuclear medicine techniques have been widely replaced by radiological modalities. However, the advent of PET imaging seems to improve splenic lesion detection, particularly in malignancies.

Enlargement of the spleen (**Splenomegaly**) is the most common, but quite nonspecific, manifestation of disease in this organ, including hematologic, neoplastic, infectious, and immunologic disorders, as well as storage diseases and portal hypertension.

Focal splenic lesions are uncommon. The most frequent are cysts; both benign and malignant primary tumors are rare. Benign neoplasms (**Neoplasms, Splenic, Benign**) include hemangiomas, hamartomas, and lymphangiomas, while lymphoma and hemangiosarcoma represent the most common primary splenic malignancies (**Neoplasms, Splenic, Malignant**). Splenic metastases are usually correlated with widespread malignant disease.

The spleen is the most frequently injured organ in cases of blunt abdominal trauma. US and CT are able to accurately depict direct and indirect signs of traumatic splenic injuries (**Trauma, Splenic**).

The spleen may be a target for various infectious agents that can lead to formation of splenic abscesses (**Spleen, Infections, Disease; Hydatid Disease, Abdominal**).

The most common congenital anomalies (**Congenital Abnormalities, Splenic**) of the spleen are accessory spleens, lobulations, and notches (**Splenic Anomalies**).

Hepatoblastoma

It is the most common primary hepatic malignancy in children and represents the most frequent malignant tumor in pediatric patients after neuroblastoma and Wilms' tumor. This tumor originates from hepatocytes but may also contain mesenchymal elements. Hepatoblastoma frequently presents as a large mass, mostly located in the right hepatic lobe but multicentric, diffuse, and multicystic lesions can also be seen. These tumors are frequently hypervascular with neovascularity and encased vessels.

Synonyms

HCC; Primary malignant hepatocellular tumour

Definition

Hepatocellular carcinoma (HCC) is a primary malignant neoplasm that originates from hepatocytes.

Pathology/Histopathology

HCC is a common malignancy worldwide, with an estimated incidence of up to 1,000,000 new cases per year.

The highest incidence rates are found in sub-Saharian Africa and the Far East. Areas of low incidence include North America and Northern Europe, while Mediterranean countries have an intermediate to high incidence. The geographic distribution of HCC is related to the etiology of the disease: in Western countries and in the Far East, most cases occur in patients with liver cirrhosis, mainly due to hepatitis B or C virus infection and alcohol abuse (1). Cirrhosis is a premalignant condition: the development of HCC represents a common long-term complication of cirrhosis. HCC may rarely occur in non-cirrhotic livers.

On gross pathology, HCC may show three different patterns: in the nodular form, most commonly associated with liver cirrhosis, it presents as single or multiple nodular lesions, with or without a capsule. The true fibrous capsule may be surrounded by the so-called 'pseudocapsule', which consists in compressed liver tissue at the periphery of the nodule, containing small vessels and bile ducts. The massive form, most frequently encountered in non-cirrhotic livers, appears as an infiltrative mass. The diffuse form is quite rare and consists in a miliary infiltration of the liver parenchyma (1).

From a histologic point of view, there are four different types of HCC: the most frequent variant is the trabecular type. The other forms are the pseudo-glandular type, the solid type, the scirrhous or sclerosing type. On the basis of Edmondson and Steiner' s classification these tumours can be described as well differentiated, moderately differentiated, poorly differentiated, or undifferentiated (anaplastic). Occasionally the malignant liver cells may contain glycogen or fat.

The large majority of overt HCC have an arterial blood supply. Only a few, well-differentiated HCCs have a portal blood supply. Haemorrhage and necrosis may occur in advanced HCC (1).

A tendency to grow into the portal veins, producing tumour thrombi, is a peculiar feature of HCC. Satellite or 'daughter' lesions located near the main tumour represent intrahepatic metastases developed *via* the portal branches. Lymphatic metastases are not common; they usually involve hepatic hilar lymph nodes. Extrahepatic haematogenous metastases, usually associated with advanced-stage tumours, are most commonly encountered in lung, followed by bone and adrenal gland (2).

Different types of hepatocellular nodules can be found in the cirrhotic liver: regenerative nodule, low-grade and high-grade dysplastic nodule, HCC. A stepwise carcinogenesis for HCC has been proposed in which these lesions represent the sequence of events. Dysplastic nodules are considered premalignant nodules. Foci of HCC can be found in dysplastic nodules (3). According to the *de novo* pathway, a single cell or a group of hepatocytes may give rise to a focus of HCC (3).

In the progression from regenerative nodule to overt HCC, there is a reduction in portal blood supply and development of new arterial anomalous vessels, called non-triadal arteries, which become the dominant blood supply in overt HCC lesions.

►Fibrolamellar carcinoma (FLHCC) is a rare malignant neoplasm of hepatocellular origin. In the past, it was considered a variant of HCC, whereas it is now seen as an independent entity. Pathologically, it is characterized by the presence of abundant fibrous tissue. The central fibrous scar may show faint calcifications. Satellite nodules may also be present. This tumour occurs in younger patients, is not associated with hepatic cirrhosis and its histological features are less malignant than those of HCC. Most often, it appears as a solitary, large, well-circumscribed mass with lobulated margins (1, 2). Vascular invasion is rare, whereas lymphatic metastases are quite common (3).

Clinical Presentation

HCC is usually poorly symptomatic until it has reached an advanced stage.

In the low and intermediate-incidence geographic areas the tumour typically develops as a complication of a long-standing cirrhosis in elderly patients (>50–60 years). Symptoms due to a small tumour are indistinguishable from those of the underlying liver disease. The most common manifestations are right hypochondrial or epigastric pain, weight loss, ascitis, hepatic failure, jaundice.

In the high-incidence geographical areas the tumour often develops in absence of cirrhosis in younger individuals (<40 years); when the patients become symptomatic, the neoplasm has already a large size. The most common manifestations are severe, often diffuse abdominal pain, weakness, weight loss, lack of appetite, constipation.

Rarely HCC may present with acute abdomen due to haemoperitoneum caused by the rupture of the tumoral mass. Late symptoms can be due to extra-abdominal metastases, mainly bone and pulmonary lesions. In patients without cirrhosis or other underlying liver disease, HCC is usually diagnosed at a very advanced stage (3). FLHCC usually becomes symptomatic when the tumoural mass has reached a large size, causing palpable mass, abdominal pain, nausea.

Imaging

Ultrasound

At ultrasound (US) the small, classical, nodular type HCC appears as a well demarcated round lesion. The demonstration of a hypoechoic halo can be due to the presence of the fibrous capsule or the so-called 'pseudocapsule' (compressed liver tissue at the periphery of the nodule); the capsule is more often seen in larger tumours. The infiltrative nodular HCC shows irregular and poorly demarcated margins, without a peripheric halo. Most commonly, HCC has a hypoechoic pattern, but it may also be hyperechoic. A minority of lesions have an isoechoic pattern, frequently with a peripheral hypoechoic halo. Small HCC usually have a homogeneous appearance, whereas large HCC often show a heterogeneous echostructure due to internal mosaic architecture, characterized by components of different echogenicity separated by thin septa. Spontaneous massive necrosis may be present in large HCC lesions and is shown as an internal hypoanechoic area. The infiltrative type HCC is depicted as an uneven area with ill-defined margins. In the diffuse form, a large part of the parenchyma is replaced by tumoural tissue. At US, the rare diffuse type appears as multiple small hypoechoic nodules scattered throughout the liver (4).

At colour Doppler and power Doppler studies, HCC usually shows intratumoral vascular signals, due to its hypervascularity. The two characteristic findings of HCC are the 'basket pattern', which is a fine blood-flow network surrounding the tumour, and the 'vessel within the tumour', which is the presence of vessels flowing into the nodule and branching within it. These findings are almost always depicted in large HCC lesions, more rarely in small nodules. On Doppler, spectral analysis of intratumoral vessels an arterial waveform with high resistive indices is demonstrated (4).

At contrast-enhanced US HCC appears hyperenhancing in the arterial phase, hypoenhancing or isoenhancing in the portal phase and hypoenhancing in the delayed phase. Necrotic phenomena, when present, are appreciable as non-enhancing intratumoral areas.

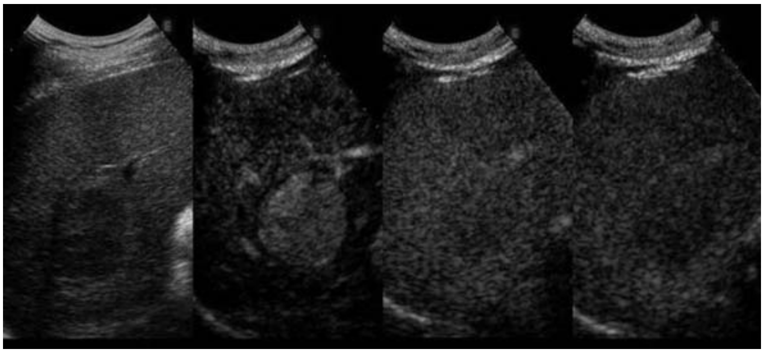
US associated to Doppler studies are also very useful in evaluating thrombosis of the main portal veins. As patients with cirrhosis are at high risk of developing portal thrombosis, a differential diagnosis between neoplastic and non-neoplastic thrombosis is required. At conventional US portal thrombosis is depicted as echoic material within the portal veins, which obliterates partially or completely the vascular lumen. Malignant thrombosis appears as solid mass in a portal vessel often in contiguity with the main tumour; Doppler study may show the presence of arterial flow within the neoplastic thrombus (4), while US contrast, agents may demonstrate a clear enhancement in the arterial phase (Fig. 1).

FLHCC appears as a large solitary mass, with clear margins and iso- or hyperechoic pattern. A central hyperechoic scar with microcalcifications may be detected (4).

Computed Tomography

The majority of HCC lesions are hypervascular tumours. Therefore, the best vascular phase to depict HCC is the arterial phase. The use of a spiral scanner is mandatory to perform a complete covering of the hepatic parenchyma during the arterial phase. The standardized computed tomography (CT) protocol for the study of patients with known or suspected HCC consists in unenhanced acquisition followed by dual-phase contrast-enhanced examination, in which an arterial phase and a portal-venous phase are obtained. Delayed phase images may also be useful, particularly to evaluate the presence of a capsule (2).

On unenhanced scans, HCC usually appears isodense or slightly hypodense; in the case of severe fatty metamorphosis, CT shows areas of negative attenuation values. When



Hepatocellular Carcinoma. Figure 1 US. A hypoechoic nodule in a cirrhotic liver is appreciable at US examination. Contrast-enhanced US shows strong enhancement in the arterial phase and wash out in the following phases. This pattern is typical of HCC.

the degree of fat deposition differs among internal portions of the tumour, the characteristic mosaic architecture is visualized. Spontaneous necrosis is shown as a clear isodense area within the tumour. Deposition of haemosiderin may occur in regenerative and dysplastic nodules, resulting in increased attenuation on precontrast scans.

Classical nodular type HCC appears as a sharply demarcated lesion which may or may not be encapsulated. The capsule is more often seen in larger tumours and is depicted as a peripheral rim that is hypodense on unenhanced and arterial-phase images and hyperdense on delayed phase.

The infiltrative type HCC is characterized by an irregular and indistinct tumour-non-tumour boundary and is demonstrated as an uneven area with unclear margins.

In the diffuse form there is a massive involvement of a large part of the hepatic parenchyma. This type is characterized by numerous small hypodense nodules diffusely distributed in the liver (2).

The large majority of overt HCC lesions are fed from the hepatic artery. These lesions show homogeneous or inhomogeneous contrast-enhancement during the arterial phase, thus appearing markedly hyperdense. Therefore, even small nodules can be depicted. Early-stage HCCs with immature vasculature fail to enhance and cannot be distinguished on the arterial phase.

Almost no overt HCC tumours are fed by the portal vein, so the lesions show wash out in the portal-venous phase and appear as hypodense defects. Early-stage HCCs maintain a portal blood supply, so they appear slightly hypodense or even isodense in the portal-venous phase, being hardly detectable (Fig. 2) (2).

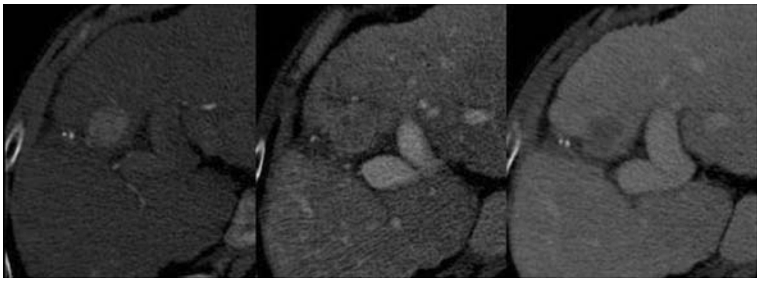
CT is an ideal technique for the staging of HCC, because it allows a reliable assessment of number, size, location and features of the nodules, tumoural vascular invasion, extrahepatic metastases. Satellite lesions are hypervascular like the main tumour and appear as tiny foci of enhancement in the arterial phase. Tumour thrombi in the main portal branches appear as solid masses within the vessel with a marked hypervascularity in the arterial phase (2).

FLHCC usually appears as a solitary, large mass, with well-defined and lobulated margins (2).

Magnetic Resonance

HCC demonstrates variable signal intensities on magnetic resonance (MR) images.

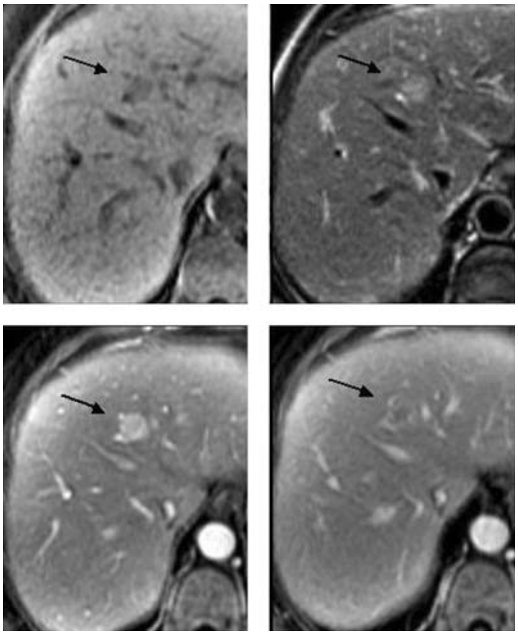
On unenhanced T1-weighted scans nodular HCC is usually seen as a well-defined mass showing a moderate hypointensity. Patterns of isointensity are often observed in well-differentiated HCC. Hyperintensity on T1-weighted images may be due to fatty metamorphosis, haemorrhagic necrosis, glycogen or copper deposition. Fat and glycogen are more common in well-differentiated HCC. On unenhanced T2-weighted scans nodular HCC usually shows moderate hyperintensity. The high intensity on T2-weighted images correlates with the degree of malignancy: well-differentiated lesions may appear isointense, while regenerative nodules are never hyperintense; dysplastic nodules and early HCCs show similar MR features, although the latter may be hyperintense, while dysplastic nodules are almost never hyperintense on T2-weighted images (3). Using T2-weighted scans HCC nodules are depicted more evidently than with T1-weighted scans, due to the higher contrast between the tumour and the surrounding parenchyma (1). HCC may arise within a high-grade dysplastic nodule. These lesions have a nodule-within-a-nodule appearance on MR images, consisting of one or more hyperintense internal foci within a low signal intensity nodule on T2-weighted images (3). The tumour capsule is more likely to be seen on T1-weighted images, detected as a thin hypointense rim. T2-weighted images delineate a single hypointense rim or a double ring with inner hypointensity, corresponding to the fibrous capsule, and outer hyperintensity, corresponding to the pseudocapsule. The typical mosaic pattern of large HCC lesions is well demonstrated on MR: intratumoral hypointense septa are detected on T1-weighted scans, while inhomogeneity is seen on T2-weighted scans (1).



Hepatocellular Carcinoma. Figure 2 **CT. Classical nodular HCC has a clear enhancement in arterial phase and wash out in the portal-venous and delayed phases. The capsule is optimally depicted on delayed phase as a peripheral hyperdense rim.**

Dynamic study after bolus administration of gadolinium-chelates using fast T1-weighted sequences can demonstrate the typical arterial supply of overt HCC. The enhancement in the early arterial phase may show different patterns: peripheral, central, mixed, complete or absent. More often, the arterial enhancement appears inhomogeneous. A nodule-within-nodule pattern can be observed. A minority of HCC nodules, usually well differentiated, do not show any arterial enhancement. Tumour enhancement decreases in the middle phase leading to isointensity. The pseudocapsule shows delayed enhancement. This is due to the large extracellular spaces of the capsular region, which include vascular lakes within the compressed liver parenchyma (Fig. 3) (1).

Hepatobiliary contrast agents pass from blood through the hepatobiliary system with partial excretion through the kidneys and bile ducts. Many of them can be used both as vascular contrast agents in dynamic studies and as hepato-specific agents in delayed T1-weighted scans. In the hepatobiliary phase, the normally functioning parenchyma shows a clear enhancement. Lesions that do not have hepatobiliary function, such as non-hepatocellular lesions or undifferentiated hepatocellular lesions, fail to enhance, appearing as clearly contrasted defects. The conspicuity and the detection rate of lesions are increased. The degree of tumour enhancement of HCC correlates with its histologic differentiation and preservation of hepatobiliary function. Therefore, HCC may become hyperintense, hypointense or isointense, depending on the amount of uptake relative to the surrounding parenchyma, which correlates with its differentiation. Cirrhotic livers show a decreased uptake of hepatobiliary agents in comparison with normal livers, due to a decreased hepato-biliary function (1).



Hepatocellular Carcinoma. Figure 3 MR. Classical nodular HCC (*arrows*) appears moderately hypointense on unenhanced T1-weighted scans and moderately hyperintense on unenhanced T2-weighted scans.Dynamic study after bolus administration of gadolinium-chelates using fast T1-weighted sequences demonstrates the typical enhancement in the arterial phase with wash out in the following phases. The pseudocapsule shows delayed enhancement.

RES-targeted agents consist of suspensions of iron particles, which are removed directly from the blood by the reticuloendothelial cells of the liver and spleen. The presence of iron particles, captured in the Kupffer cells of the normal liver, produces a significant signal loss on T2-weighted images during the hepato-specific phase. Focal lesions usually do not contain Kupffer cells, thus-appearing hyperintense in the hepato-specific phase. Lesion demarcation and visualization are improved and the detection rate is increased. HCC usually cannot adsorb these agents because Kupffer cells are lacking, but this is variable and depends on the grade of the tumours (1).

FLHCC appears as a solitary capsulated mass with well-defined lobulated margins. In general tumours are iso- or hypointense on T1-weighted scans and iso- or hyperintense on T2-weighted scans. Typically, the scar has low signal intensity both on T1 and T2-weighted images (1).

Diagnosis

The detection of a nodule at US in a cirrhotic patient should raise the suspicion of HCC. In case the nodule is less than 1 cm in size the recommended protocol is to repeat US every three months; lack of growth over a period of more than 1–2 years suggests the nodule is not a HCC. If the nodule size ranges from 1 to 2 cm, the finding should be investigated with two dynamic imaging techniques (CT, MR, contrast US); the coincident demonstration of the typical enhancement pattern (hypervascular nodule with washout in the portal-venous phase) at two modalities allows the diagnosis of HCC; otherwise, biopsy of the nodule is recommended. For nodules above 2 cm in size, imaging techniques are usually able to establish a confident diagnosis without needing confirmation with a positive biopsy. In cirrhotic livers, a nodule greater than 2 cm showing the typical features of HCC (hypervascular nodule with washout in the portal-venous phase) at one dynamic imaging technique (US, CT, or MR) and/or with a concomitant increase of alpha fetoprotein serum level above 200 ng/mL must be considered a HCC and should not be biopsied. The EASL conference recommended that the diagnosis of HCC can be made in nodules greater then 2 cm in cirrhotic livers by demonstrating characteristic arterial vascularization on two dynamic imaging modalities (5, 6).

Interventional Radiology

Several interventional radiologic procedures, including percutaneous and intraarterial techniques, can be employed in treatment of HCC. Percutaneous treatments are considered a curative treatment for small HCC in patients who cannot undergo resection or in patients listed for transplantation. Percutaneous ethanol injection (PEI) is the most commonly used technique in nodules up to 3 cm in size, while radiofrequency (RF) ablation represents a valid alternative and its efficacy is clearly superior to that of PEI in larger lesions (7). Trans-arterial chemoembolization (TACE) is widely performed for palliative treatment of large/multifocal vascularized HCC. The best candidates are patients who have preserved liver function and without vascular invasion or extrahepatic disease.

Single large HCC tumours can be profitably treated with the combination of TACE and PEI. Treatment response is usually evaluated by dual-phase spiral CT or dynamic MR 1 month after the procedure. On CT, the necrotic lesion obtained after ablative treatments appears as a hypodense non-enhancing area. On MR, the ablated tissue shows slight hyperintensity on T1-weighted images and strong hypointensity on T2-images, while viable tumoural tissue maintains a clear hyperintensity on T2-weighted scans. Both on dual-phase spiral CT and dynamic MR, residual viable neoplastic tissue can be easily demonstrated as enhancing areas in the arterial phase within or at the periphery of the treated nodule. On CT, lesions treated with TACE appear as highly hyperdense areas, due to the retention of lipiodol; this may not allow a confident interpretation of contrast-enhanced images. On the contrary, MR signal intensity is minimally influenced by the presence of iodized oil, so areas of enhancing tissue can be easily recognised. Contrast-enhanced ultrasonography might become a real-time alternative to assess therapeutic response (7).

Synonyms

Abdominal wall defects; Fascial weakness and defects

Definition

The protrusion of a viscus through an orifice or a defect in the wall of a cavity in which it is confined is defined as a hernia.

Pathology

Hernias may occur in several locations in the abdomen. They may contain bowel, omentum, bladder, and, on occasion, other abdominal organs such as liver and gall bladder. Generally, the herniation occurs through openings or potential spaces that already exist. However, weaknesses may occur in muscle tissue or fascia, encouraging the passage of a viscus. Muscle weakness may occur with wasting or previous surgery. Occasionally, hernias may be secondary to trauma. As the development of each of the abdominal hernias may be unique to its location, they are discussed under the respective subheading. The two most common sites of herniation in the abdomen are the diaphragm and inguinal areas.

Clinical Presentation

The clinical presentation depends on the location and type of hernia. Complications of a hernia, such as obstruction, may be the first clinical presentation in a significant number.

Hiatal Hernia

The oesophageal hiatal hernia is the most common. In this hernia, a portion of the stomach herniates through the oesophageal hiatus. Though often considered synonymous with reflux, there is really very poor correlation between a hiatal hernia and reflux oesophagitis. The function of the lower oesophageal sphincter and the presence of reflux are the factors that produce symptoms and cause complications. There are two types of hiatus hernia. The sliding hiatus hernia is the more common type. In this hernia, the gastro-oesophageal junction is displaced more than 1 cm above the diaphragmatic hiatus. Small hiatal hernias often reduce in the upright position. The para-oesophageal hiatus hernia is the less common type. It represents about 1% of the total diaphragmatic hernias. Here the gastro-oesophageal junction remains in the normal location but a portion of the stomach, usually the fundus, herniates above the diaphragm. If the hernia is large, the herniated stomach can volvulate and become strangulated. These patients will experience severe pain. If there is no strangulation present, which is most often, the patient may complain of intermittent symptoms of proximal obstruction (vomiting), or early satiety. The hernia may include stomach or omentum. When there is gross ascites present, the hernia may include fluid.

Bochdalek Hernia

If the embryonic pleuroperitoneal canal persists, a defect is present in the diaphragm, and herniation can occur through this opening. This defect is the foramen of Bochdalek. The secondary effects of a Bochdalek hernia depend on its size. The larger hernias are often seen in the neonatal period and can contain omentum, spleen, kidney, and retroperitoneal fat. It is usually seen as a posterior lateral mass above the left hemidiaphragm. When present in the neonatal period, the infant may have an ipsilateral hypoplastic lung and respiratory distress. These hernias are more often seen on the left. This is presumably because of the protective effect of the liver on the right, though herniation can also occur through the pleuroperitoneal canal on the right. Bochdalek hernias when seen in the adult are usually small.

Morgagni Hernia

This is the least common type of diaphragmatic hernia. It is due to a defect in the para-sternal portion of the diaphragm and is invariably right-sided. It may contain omentum, transverse colon, or liver. It is usually seen as a right-sided asymptomatic cardiophrenic angle mass. Most often, it is asymptomatic but like most hernias it can obstruct.

Traumatic Hernia

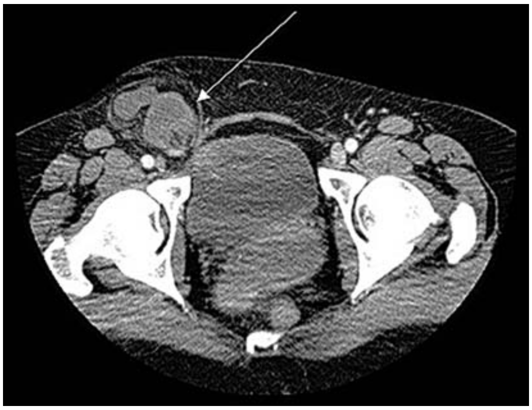
Rupture of the hemidiaphragm allows herniation of abdominal contents through the tear. The tear that is usually in the central or posterior aspect of the diaphragm may follow penetrating injury or blunt thoracoabdominal trauma. Again, the left side is affected in over 90% of cases as the liver dissipates the traumatic forces and protects the right hemidiaphragm. Traumatic hernia is suspected when gas-filled loops of bowel or stomach are seen in left lower thorax following severe trauma. The left lobe of the liver may herniate, in addition to the stomach, small bowel, colon, kidney and spleen. The contour of the left hemidiaphragm may also be indistinct or elevated on radiographs.

Inguinal Hernia

In inguinal hernias, bowel, omentum or bladder may herniate into the inguinal canal. This may present as a scrotal or labial mass. In the majority, the hernia contains bowel. The hernia may reduce spontaneously or can often be reduced manually. When it cannot be reduced, it is said to be incarcerated. Incarcerated hernias can strangulate (Fig. 1). Inguinal hernias are often asymptomatic but may cause obstruction (1). The hernias may be classified as direct or indirect (2). The inferior epigastric artery gives off the cremasteric artery at the deep inguinal ring. The hernia passing lateral to the artery (that is through the deep ring) is an indirect hernia and that passing medial to the artery is a direct hernia.

Umbilical Hernias

In infants, they result from an abdominal wall defect at the umbilicus. Umbilical hernias may be seen in up to 20% of newborns. They are more evident with prematurity and in situations associated with raised intra-abdominal pressure. Almost all hernias have a fascial defect of 5 mm or less closer by the first year of life. Larger hernias close over a longer period of time. In adults, they may occur through the umbilical cicatrix or through the linea alba either just above or below the umbilicus. Ten percent of adults with umbilical hernias have a history of childhood umbilical hernia. Other associated causes are ascites associated with congestive heart failure, nephrosis or cirrhosis. They may also occur with multiparity, obesity, intra-abdominal malignant tumours, and advanced age. Most of the patients with umbilical hernias are women in a ratio of 3:1 women to men. The aetiology of a weak umbilical cicatrix is not clear. It may be related to an abnormality of decussation of the aponeurotic fibres in the midline. The hernial contents in adults and infants are similar. They may contain omentum or small bowel. In adults, the hernia may also contain metastatic deposits or be the site of collateral pathways in portal hypertension.



Hernia, Abdominal and Inguinal. Figure 1 Inguinal hernia causing obstruction. Dilated bowel within hernia shown by arrow.

Exomphalos (Omphalocele) and Gastroschisis

These two herniations are often confused. An omphalocele is a congenital defect of the abdominal wall in which there is herniation of abdominal viscera into the base of the umbilical cord. The viscera is covered by a translucent avascular membrane made up mostly of peritoneum on the inside and amniotic membrane on the outside. The umbilical cord inserts into the sac with the vessels running radially within its wall. The sac may contain a single loop of bowel, or the entire liver and numerous other viscera. They are differentiated from umbilical hernias by the size of the fascial defect. In umbilical hernias, the defect is always small and is usually less than 4 cm in diameter. The abdominal musculature is usually well developed. The omphalocele likely represents persistence of a portion of the extra-embryonic coelom and failure of the intestine to return into the abdominal cavity.

In gastroschisis, the defect in the abdominal wall is in the extra-umbilical location and there is therefore an absence of a membraneous sac. There are other differences as well. This includes (a) the herniated intestine is covered by a thick gelatinous material and is foreshortened, (b) the umbilicus is situated to the left of the herniated bowel and separated from the fascial defect by a bridge of skin, (c) the abdominal cavity is well developed in contrast to an omphalocele and the midgut is invariably malrotated with the caecum being located on the left side of the abdomen and (d) other congenital abnormalities are evident.

Obturator Hernias

These hernias pass through the obturator foramen in the pelvic bone. They have been found to be the cause of between 0.4% and 0.8% of mechanical obstruction. There is a preponderance in females with the ratio being 5 or 6 to 1. Therefore, males are affected in only 15% of these hernias. The greater incidence in women is related to the anatomic differences in the obturator foramen. In women, the foramen is smaller and more triangular yet its transverse diameter is greater. Pregnancy has also been incriminated. Most of these hernias occur in the seventh to eighth decades of life. In addition to aging, the other predisposing factors are chronic lung disease, associated with wasting and emaciation. The protective layer of fat around the obturator foramen is lost in these patients, predisposing to herniation. Bilateral obturator hernias are rare. It tends to be more common on the left in men and on the right in women. The hernia usually contains small intestine, in most instances, the ileum. Rarely a Richter-type hernia occurs. Occasionally the sac is empty. It may also contain omentum, appendix and fallopian tubes.

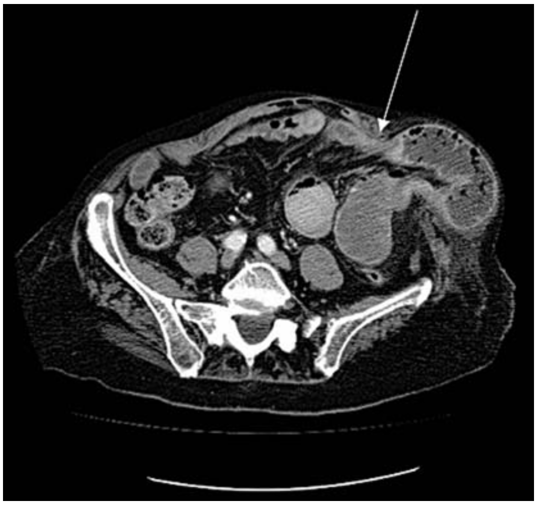
The obturator canal is a fibro-osseous structure about 2 to 3 cm in length. It passes downward and obliquely ends in the obturator region of the thigh. It readily admits the tip of a finger but its walls are firm and unyielding. Therefore, strangulation occurs easily.

Perineal Hernias

Perineal hernias are protrusions of abdominal contents through the fascia and muscles that form the pelvic floor. Perineal hernias can affect any part of the pelvic floor. There is a weakness between the iliococcygeus and pubococcygeus muscles and many hernias pass through this gap. Perineal hernias can be subdivided into anterior and posterior, based on their relationship of the transverse perineal muscle. Anterior perineal hernias may be evident in the labia majora where they are known as labial or pudendal hernias. Anterior perineal hernias almost never occur in men. Posterior perineal hernias occur in both men and women but with far greater frequency in women.

Spigelian Hernias

These are rare and seen in males and females equally. Persons of any age may be affected. Predisposing conditions include obesity, increased abdominal pressure brought on by episodes of coughing or sudden lifting of a heavy weight. Aging is also a predisposing factor as most spigelian hernias occur in elderly individuals. These hernias are protrusions through the linea semilunaris (3), a line that marks the outer border of the rectus muscle and extends from the tip of the ninth costal cartilage to the pubic tubercle. This line has also been described as the point of division of the internal oblique into anterior and posterior layers to enclose the rectus muscle. A spigelian hernia has also been defined as a spontaneous abdominal defect situated lateral to the rectus muscle, with the protrusion passing through the spigelian fascia, which is limited laterally by the muscular fibres of the internal oblique and medially by the insertion of external oblique aponeurosis to form the anterior rectus sheath. Most of these hernias are small in size but be up to 14 cm in diameter. They may contain omentum or bowel. The neck is often narrow and the hernial ring rigid, therefore, incarceration and strangulation (Fig. 2) are the very present dangers.



Hernia, Abdominal and Inguinal. Figure 2 **CT of Spigelian hernia with obstruction. The distal limb is collapsed (arrow).**

Lumbar hernias

They are defects of the parietal abdominal wall that can occur anywhere in the lumbar region. The area is bounded above by the 12th rib, below by the iliac crest, behind by the erector spinae muscle and vertebral column and anteriorly by a line from the 12th rib straight downward to the iliac crest. They are also known as Petit hernias.

Incisional Hernias

This hernia develops in the scar of a surgical incision. The defect in the fascia varies in size, but may be as large as 12 to 15 cm. The hernia itself may be extremely large despite of a small fascial defect. Incisional hernias usually contain omentum and small bowel. Rarely, the hernia may contain other viscera. The only covering is skin and subcutaneous tissue. They occur in 1% to 14% of patients who have had transparietal abdominal operations. Incisional hernias do not usually cause serious problems.

Imaging

Imaging of hernias includes plain films, barium studies, ultrasound, CT and MRI. The imaging modality used depends on the location of the hernia.

Diagnosis

Hiatal hernia on chest radiographs, are seen as an air fluid level, or a mass, in the immediate supra-diaphragmatic retrocardiac area. The hernia can be confirmed with a barium swallow or CT. On CT, there is a usual widening of the oesophageal hiatus in the diaphragm and the hernia is seen above it (Fig. 3). The upper limit of a normal hiatal opening is 1.5 cm and when a hernia is present, it is often widened to 3–4 cm. This is easily measured on a CT scan.

A Morgagni hernia may be distinguished from partial eventration by demonstrating the diaphragmatic defect on coronal magnetic resonance imaging (MRI) or CT.

Inguinal hernias can be difficult to diagnose in obese patients on clinical examination. They are easily seen with multidetector CT (MDCT), especially if it is the cause of an obstruction.

Traumatic hernias may be diagnosed by an upper or lower barium study of the bowel but MDCT with coronal and sagittal reconstruction, or, sometimes ultrasound, is often more useful. Diagnosis of a traumatic hernia may be delayed because these patients often have associated thoracic and abdominal injuries that may obscure the clinical and radiographic findings. The diagnosis is therefore often made later with symptoms caused by intestinal obstruction and strangulation, or compression of the left lung. These symptoms include pain, vomiting, fever, dyspnea and cough.

All the others are best seen on MDCT, but MRI is also useful in the diagnosis of obturator, perineal, incisional, sciatic hernias. Ultrasound may also diagnose ‘lumps’ that turn out to be hernias.

Bochdalek hernia; Congenital diaphragmatic hernia (CDH); Hiatus hernia; Morgagni hernia; Para-oesophageal hernia; Sliding hernia; Traumatic hernia

Definition

A ►hiatus hernia is the herniation of part of the stomach through the diaphragmatic hiatus into the chest. If the part of the stomach that has herniated lies alongside the lower oesophagus but the main body of the stomach remains below the diaphragm, and therefore the gastro-oesophageal junction also remains below the diaphragm, it is termed a para-oesophageal hernia. This type of hernia is uncommon in children unless they have had surgery such as a Nissen’s fundoplication. If the cardia of the stomach has moved cranially though the diaphragm such that the diaphragmatic hiatus forms a waist around the upper part of the stomach and the GOJ is within the chest this is termed a sliding hiatus hernia. The sliding type is more common in children, particularly in infants.

Other defects in the diaphragm result in either a Bochdalek or a ▶Morgagni hernia, and these are not related to herniation of the oesophagus. These may be large defects of the diaphragm that allow herniation of bowel and/or abdominal organs into the chest. These are termed ▶congenital diaphragmatic hernias (CDH) as opposed to a 'hiatus' hernia. A Morgagni hernia is secondary to an anteromedial parasternal defect of the diaphragm. The Morgagni hernia lies anterior and in a central location, with herniated structures more commonly seen on the right, it usually presents in older children and is usually small. The herniated structures may include liver, omental fat, or part of the transverse colon. A ▶Bochdalek hernia is a posterolateral defect of the diaphragm and results in a posteriorly located herniation. It is left sided, more commonly seen in newborns and infants, and is usually large. It accounts for 90% of congenital diaphragmatic hernias and may contain part of the bowel, spleen, left lobe of liver, kidney or part of the pancreas. Herniation can also occur following trauma.

Pathology/Histopathology

In infants a hiatal hernia is thought to occur secondary to immaturity of the lower oesophageal sphincter (LES) and reflux may also occur as a result of this. In older children it is due to the LES sliding through the diaphragmatic hiatus as a result of incompetence of the phrenicoesophageal membrane. Morgagni and Bochdalek hernias are secondary to maldevelopments of the diaphragm. These congenital diaphragmatic hernias may allow herniation of abdominal structures such as bowel and solid organs of the upper abdomen into the chest can result in hypoplasia of the lung on the affected side. This hypoplasia is characterised by a reduction in cross-sectional area of the pulmonary vasculature. The lungs have a reduced alveolar capillary membrane for gas exchange, which may be further decreased by surfactant dysfunction. In addition to parenchymal disease, there may be increased muscularisation of the intra-acinar pulmonary arteries.

Traumatic hernias through the diaphragm are usually following blunt trauma to the abdomen with an associated sudden rise in intra-abdominal pressure causing abdominal contents to push up into the chest, usually secondary to a rupture of the diaphragm rather than passing through an existing hiatus.

Clinical Presentation

The child with a hiatal hernia may present with reflux and intermittent vomiting, with repeated chest infections (1) or with epigastric pain. However, vomiting and reflux are very common in infancy and the incidence of hiatus hernia is low, typically only 0.5% of children undergoing UGI (2, 3) so the imaging of the vomiting but otherwise healthy infant may not be justified. Sometimes a hernia may be an incidental finding on an upper GI series performed for another reason. Hiatal hernias are more common in children who have undergone a Nissen's fundoplication, in which case they may be either para-oesophageal or of the rolling type.

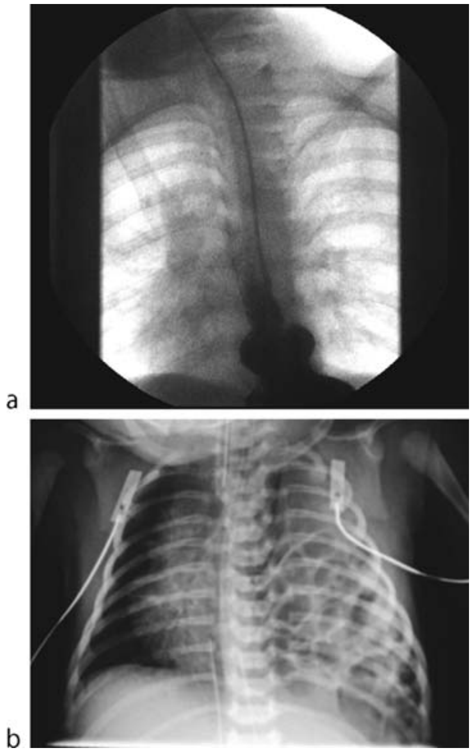
Children with significant congenital diaphragmatic hernias usually present with cyanosis and respiratory distress in the first minutes or hours of life, although a later presentation is possible in the first few months of life. Only rarely do patients present outside infancy. Congenital diaphragmatic hernias may also be detected in utero, either on a routine antenatal ultrasound or if the mother presents with poly-hydramnios.

Traumatic hernias may present acutely at the time of injury but may present months or years later. They may be detected incidentally with bowel, liver or spleen being shown on an incidental chest X-ray; or may present with discomfort or obstruction from compromised bowel or solid organs in the chest. If a large volume of the chest is filled with abdominal contents the patient will present with dyspnoea.

Imaging

Sometimes indirect signs of particularly large hiatal hernias that contain air may be detected on chest radiographs as a radiolucent viscus seen behind the cardiac silhouette. The definite and detailed imaging diagnosis of a hiatus hernia is achieved by an upper gastrointestinal series and barium is used. In a sliding hiatus hernia gastric folds will be seen extending up through the diaphragmatic hiatus (Fig. 1a); in a rolling hernia, part of the cardia will be demonstrated as an outpouching parallel to the lower oesophagus but in continuity with the remainder of the stomach that is below the diaphragm.

Imaging for congenital diaphragmatic hernias may be initiated in the antenatal period on the basis of an antenatal ultrasound which may demonstrate bowel loops peristalsing in the chest. Other antenatal sonographic findings include poly-hydramnios, an absent or intrathoracic stomach bubble, and mediastinal and cardiac shift away from the side of the herniation. Ultrasound will also show which organs may have herniated into the chest. This antenatal work-up allows plans to be made expectantly for the management of the child at the time of delivery. Both 3D ultrasound and MRI may also be used in the antenatal period to give an estimation of lung



Hernia, Diaphragm, Congenital. Figure 1 (a) An upper GI series in a child with persistent vomiting show a small hiatus hernia above the diaphragm and associated reflux. (b) Chest radiograph of a newborn infant with congenital diaphragmatic hernia showing gas filled loops of bowel in the left hemithorax and mediastinal shift to the right.

volume and are potential predictors of pulmonary hypoplasia and postnatal outcome.

A chest X-ray taken shortly after birth will classically show cyst-like structures in the left hemithorax representing the herniated bowel in the chest (Fig. 1b). If the chest X-ray is taken very early after birth the loops of bowel may still be exclusively fluid filled and will appear as a radiopaque mass. There will be a reduced number of bowel loops in the abdomen which will be relatively gasless; additionally the liver and/or spleen may be in the chest.

Subsequent imaging of CDH is by ultrasound and MRI or CT, which will demonstrate the extent of the hernia and what its contents are.

Traumatic hernias are usually imaged in the acute situation by CT, but ultrasound and MRI may also be used.

Nuclear Medicine

No role in this condition.

Diagnosis

Achieved by imaging as described above.

Interventional Radiological Treatment

No role in this condition.

Department of Neuroradiology, University of L'Aquila, Italy
massimo.gallucci@cc.univaq.it

Synonyms

Hernia nuclei pulposi; Lumbar or cervical disk hernia; Protruded or extruded intervertebral disk; Ruptured intervertebral disk

Definitions

Intervertebral ▶disk herniation and other ▶degenerative disk changes can be grouped under a broader category of degenerative spinal manifestations that also include pathologic changes affecting the vertebral body (spondylosis) as well as the articular processes and associated ligaments (spondylarthrosis); these are discussed in detail elsewhere. Disk herniation has been separated from these other spinal degenerative changes because of the specific diagnostic and therapeutic interests involving this condition. Degenerative disk changes affect the disk itself as well as the adjacent end plates and are due to trauma, normal aging, and chronic overload. The difference between changes due to normal aging on the one hand and true pathologic changes on the other hand is confusing, and the separation is often arbitrary.

Pathology/Histopathology

Three main pathogenetic mechanisms are involved in degenerative disk disease:

1. Acute trauma leading to spinal instability with alterations in spinal alignment and anatomy, which may accelerate degenerative changes.
2. Chronic static and dynamic overload, causing chronic traumatisms. The integrity of the spinal curves is also involved in the process because loss of alignment decreases the load-absorbing function of these curves. L5 and S1 are maximally involved by overload. For this reason, lumbar disk herniation is located between the L4 and S1 levels in 90% of cases, at L3–L4 in 7%, and at L1–L3 in only 3% of cases.
3. Decreased permeability of the end plates, leading to loss of function of disk fibroblasts and chondrocytes, with subsequent alteration of the keratin/chondroitin sulfate ratio. Matrix degeneration determines the loss of water in the nucleus pulposus and the consequent rigidity.

Degenerative changes of the annulus fibrosus may result in two lesions: (i) breakdown of bridges among annular fibers, with annular weakness and diffuse or focal bulging, or (ii) radial tears of the annular fibers, producing herniation of the nucleus through the annulus. ►Fissures can progress to more severe disruption and consequent herniations. Herniated material may include nucleus, cartilage, fragmented bone, or annular tissue. Dehydration and progression of annular fissures can result in dramatic destruction of the disk, with collapse of the disk space and gas formation (1).

Natural history: Unequivocal and generally applied treatment protocols do not exist, but long-term follow-up results of surgically and nonsurgically treated patients indicate that after 5–10 years, the success rate is similar. After 1 year, a good clinical outcome is registered in up to 95% of untreated patients. Up to 63% of disk herniations may show a spontaneous volume reduction on magnetic resonance imaging follow-up 6–12 months after the diagnosis (2). The causes of spontaneous reduction of herniated disk material are shrinkage due to dehydration, fragmentation, and phagocytosis of the material.

Classification: The most accepted nomenclature for disk herniation was published in 2001 (3) (Fig. 1):

1. ►Bulging disk: A disk in which the contour of the outer annulus extends in the axial plane beyond the edges of the disk space, over greater than 50% of the circumference of the disk and usually less than 3 mm beyond the edges of the vertebral body.
2. Asymmetric bulge: a bulging more evident in one section of the periphery of the disk, but not so focal as to be characterized as a protrusion.
3. Disk herniation: Localized displacement of disk material beyond the normal margins of the intervertebral disk space.

Disk herniation may take the form of protrusion or extrusion:

1. ►Protruded disk: A herniated disk in which the greatest distance, in any plane, between the edges of the disk material beyond the disk space is less than the distance between the edges at the base in the same plane.
2. Contained disk herniation: Displaced disk tissue that is wholly within an outer perimeter of uninterrupted outer annulus or capsule.
3. ►Extruded disk herniation: A herniated disk in which any one distance between the edges of the disk material beyond the disk space is greater than the distance between the edges of the base in the same plane.
4. Migrated disk: A herniated disk in which a portion of extruded disk material is displaced away from the tear in the outer annulus through which it has extruded.
5. Sequester or free fragment: A fragment of disk that has separated from the disk of origin and has no continuous bridge of disk tissue to the disk of origin.

Relative to the axial plane the herniation may be (i) central, (ii) right-left central, (iii) right-left subarticular, (iv) right–left foraminal, and (v) right-left extraforaminal (Fig. 2).

Clinical Presentation

Disk herniation can present clinical symptoms by two mechanisms: diskogenic pain and compression of nervous structures. In the first condition, local pain is due to stimulation of receptors in the outer annulus fibrosus *via* the recurrent spinal nerve of Luschka.

The second condition is more complex and depends on the level and location of the herniation, its extension, and its relationship with neural structures. In the case of herniation located at the cervical or dorsal levels, compression of the spinal cord can occur, with abnormal reflexes and progressive disturbance of gait and micturition. More commonly, disk herniations can compress nerve roots, causing radicular pain that also depends on the release of inflammatory molecules causing chemical radiculitis. In late stages, sensory or motor deficits are also possible.

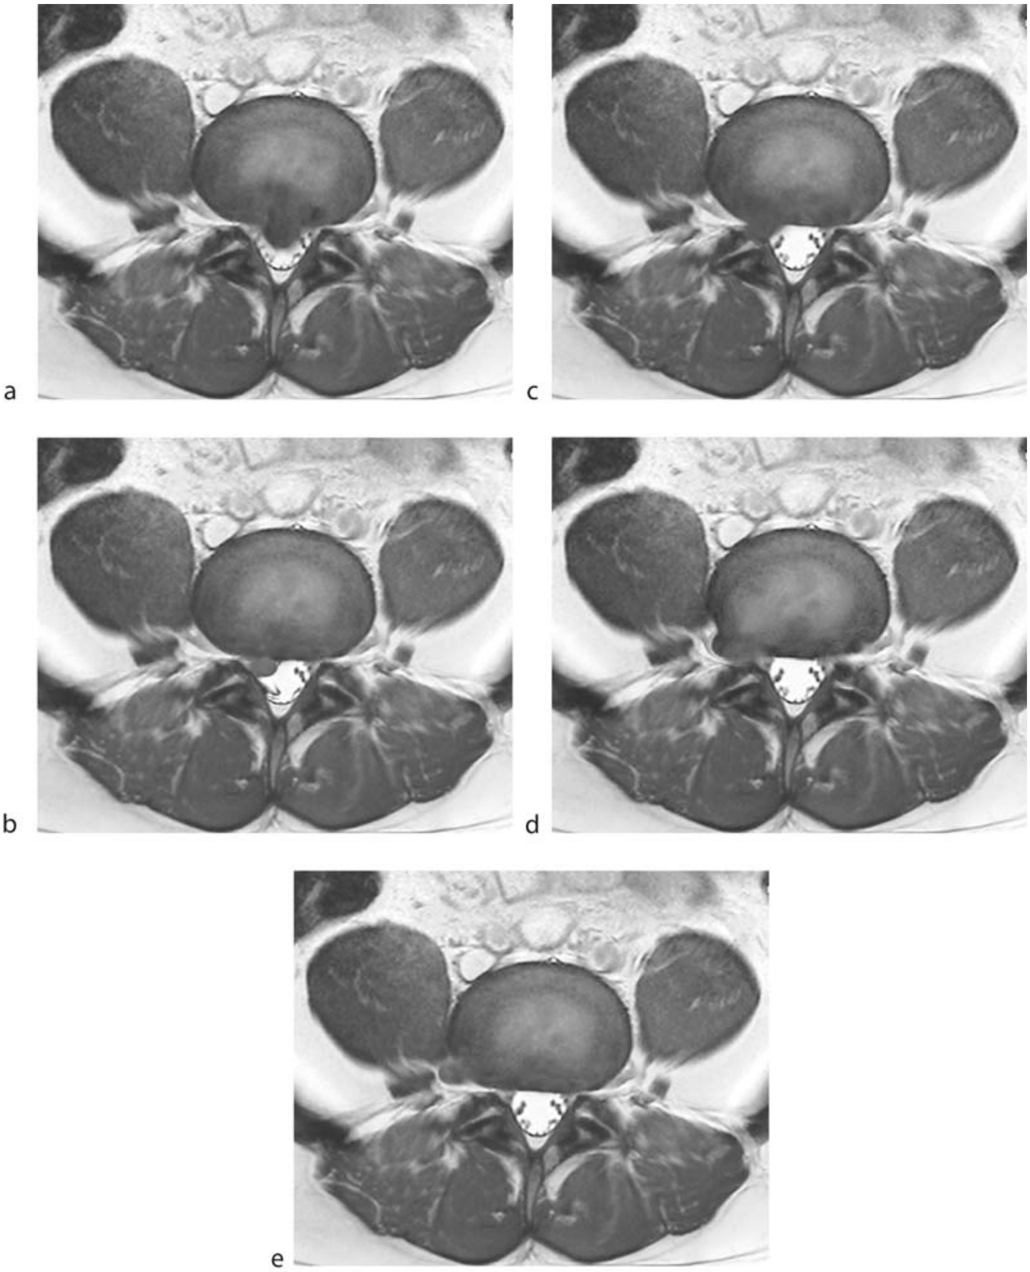
Imaging

Conventional radiographs of the spine are useful to diagnose degenerative disk disease and exclude other causes of pain. In acute disk herniation, plain films can be normal, especially in young patients. When disk herniation is associated with degenerative changes, the most evident sign is reduction of the intervertebral space due to loss of disk height. Sclerosis of the end plates is common. Radiography is limited by the inability to directly visualize the disk and the herniation. This is possible with diskography, which is invasive and is now used only in selected cases to confirm the diskogenic origin of pain.

X-ray myelography shows deformations of the dural sac and root sleeves caused by disk herniations and other lesions. The examination is accurate for demonstrating

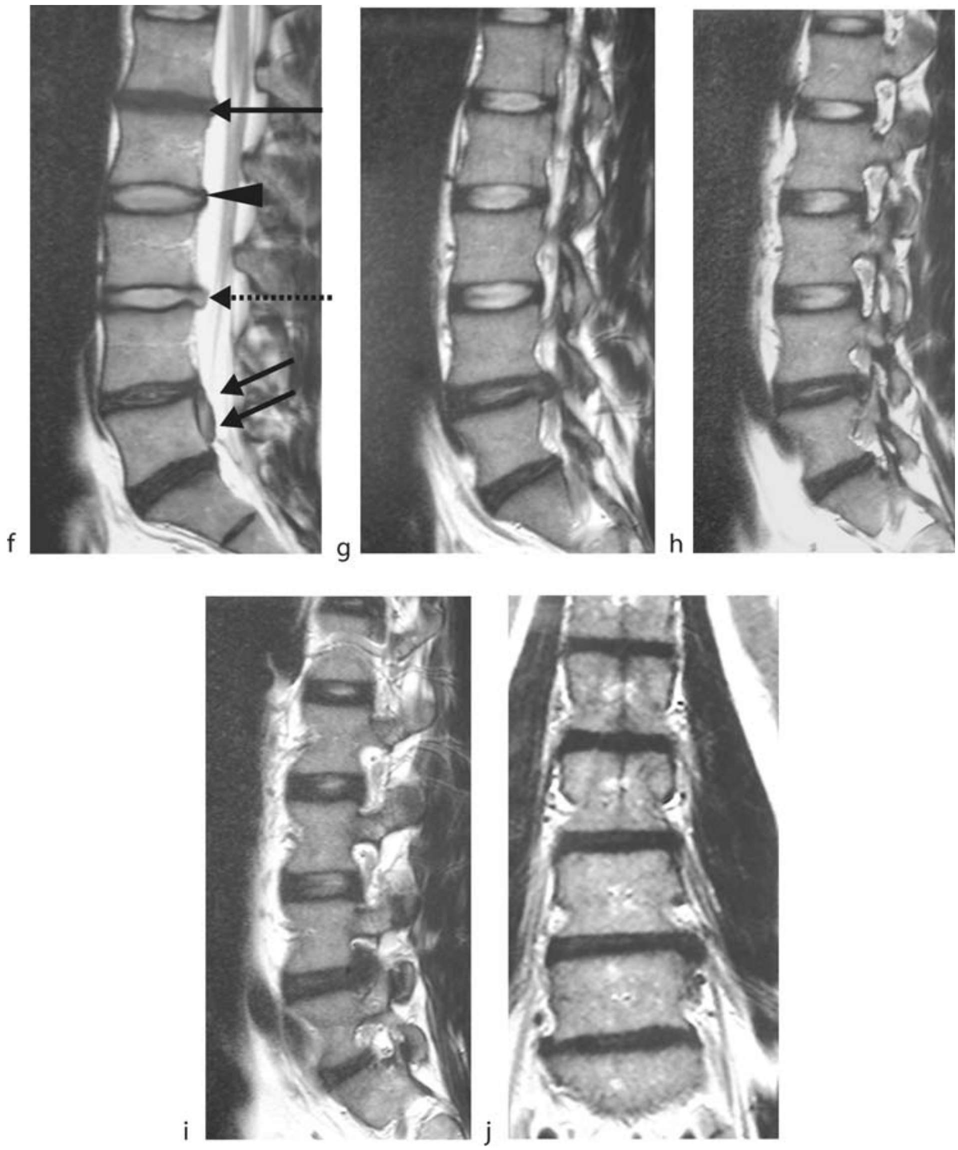


Hernia, Disk, Intervertebral. Figure 2 (continued)

root compression, but it is invasive and rarely used at present.

Computed tomography (CT) allows the differential diagnosis between bulging and herniation, evaluation of dimensions and location of the herniated disk, and detection of free fragments. The disk is hypodense, and the nucleus pulposus cannot be exactly identified. CT allows easy identification of calcified herniations and associated spondylotic changes and can determine stenoses of the foramina, the lateral recesses, and the vertebral canal. CT sensitivity can be improved by combining CT and myelography (myelo-CT).

Magnetic resonance imaging (MRI) is the technique used most often for evaluating disk herniation. The examination should comprise sagittal T1- and T2-weighted sequences and axial T1- and/or T2-weighted sequences. MRI myelographic images may help to clarify root compression, and intravenous gadolinium injection may be useful when postoperative scarring obscures recurrent disk herniation.



Hernia, Disk, Intervertebral. Figure 2 **Location of lumbar disk extrusions relative to axial plane. Central (a axial, f sagittal). Right-central (f) (b axial, g sagittal). Subarticular (c axial, h sagittal). Intraforaminal (d axial, i sagittal). Extraforaminal (e axial, j coronal). (e) Various kinds of disk degenerative diseases with central location: bulging of dehydrated disk (*black arrow*), protrusion (*black arrowhead*), extrusion (*dotted arrow*), extrusion with free fragment (*double arrow*). Note: Simulation with Adobe Photoshop 6.**

Disk degeneration is evident as loss of disk height and signal intensity on all sequences due to dehydration of the nucleus pulposus. The presence of a radial tear of the annulus is demonstrated by a band of high signal intensity on T2-weighted images, sometimes showing enhancement on T1-weighted postgadolinium images.

MRI is more sensitive than CT for detecting disk herniation at all levels and is preferred over CT thanks to the superior multiplanar imaging and the intrinsic better soft-tissue contrast. The herniation is usually associated with disk degeneration, and its signal is usually low but is higher than that for the rest of the disk. Acute herniations can be hyperintense on T2-weighted fast spin-echo images. The hyperintensity of the herniated fragment is thought to be due to the high hydration of the nucleus compared with the annulus (1). A hyperintense signal has been reported in up to 80% of sequestered disks.

At cervical and thoracic levels, the diagnosis of disk herniation can be more difficult than at the lumbar spine because these herniations are usually smaller.

Gradient-echo (GRE) sequences can be useful because there is little epidural fat at this level, while the epidural venous plexus is well represented. This venous structure has high signal on GRE sequences; therefore, small herniations can be seen.

Diagnosis

MRI is the optimal diagnostic tool, comparable in sensitivity to myelo-CT, for diagnosing disk herniation. The principle of disk herniation diagnosis is the same with CT and MRI. The herniation is seen as a focal contour abnormality along the posterior disk margin with a soft-tissue mass displacing the epidural fat and, sometimes, the thecal sac and the nerve roots. The herniation is usually contiguous with the rest of the disk.

MRI can be used for follow-up of untreated disk herniation. Spontaneous reduction or disappearance of the herniation is frequently possible. The main predictive MRI signs are hyperintense signal of the herniation on T2-weighted images and enhancement after gadolinium administration. In our experience, free fragments regress spontaneously by 6 months in 100% of cases, while extruded and T2-weighted hyperintense disk herniations regress spontaneously in 80% (4).

The high sensitivity of MRI in detecting even very mild changes of the disk anatomy may sometimes lead to overinterpretation of the findings, giving pathologic meaning to paraphysiological features and vice versa. Abnormal MRI findings are not in themselves necessarily pathologic, nor do they necessarily constitute an indication for surgery or other invasive treatment; they always need to be compared with the clinical evaluation, with treatment tailored to the individual patient.

Interventional Radiological Treatment

The first techniques employed were chemonucleolysis and aspiration diskectomy, both presently done only rarely. A widely performed intervention is intraforaminal/epidural steroid injections, but the success rate is only 40–60% after 6 months. Newer procedures are annuloplasty in bulging disks, percutaneous laser disk decompression, and intradiskal ozone injections, and the reader is referred to separate essays dealing with operative and nonoperative therapeutic procedures (5).

Synonyms

Gastro-oesophageal reflux; GERD/GORD; Hiatus hernia

Definition

►Hiatus hernia is defined as loss of the intra-abdominal portion of the oesophagus, with the gastro-oesophageal junction coming to lie above the diaphragmatic hiatus.

►Gastro-oesophageal reflux disease (GERD) is defined as an abnormal frequency of reflux of gastric acid into the oesophagus. GERD has become one of the most common gastrointestinal complaints in industrialized nations, but for the majority of people it is only a minor inconvenience. For a minority it may become a major health problem, and its complications of stricture, choking and adenocarcinoma may be fatal. Since 1980, advances in understanding of the underlying mechanisms of reflux and its control have allowed a more rational approach to treatment of the symptoms. However, elimination of the disease requires modification of the life style choices that usually, but not always, underline the disease and this is much more difficult to achieve. Hiatus hernia and gastro-oesophageal reflux are commonly, but not necessarily, associated.

Pathology

Anatomy

There is normally about 2.5 cm of intra-abdominal oesophagus which includes most of the 3–4 cm long lower oesophageal sphincter (▶LES). With respiration the sphincter slides up and down within the diaphragmatic hiatus, but gastric rugal folds are not seen above the hiatus. If they are, then a hiatus hernia is present. The stages of sliding hiatus hernia development range being present on inspiration only with abdominal compression, present at all phases of respiration with the patient lying down, or finally may be present with the patient erect in all phases of respiration in which case the oesophagus may also be shortened.

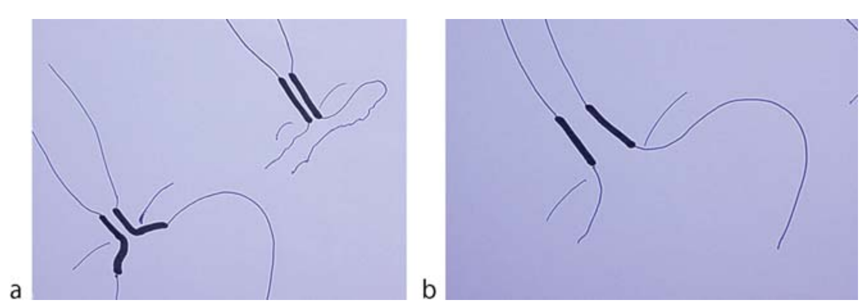
In some older patients with long standing hiatus hernia more of the stomach rolls up into the chest until the stomach is largely intra-thoracic. In this case the fundus usually remains inferiorly in the chest while the greater curve of the body rotates superiorly and the antrum passes down through the diaphragmatic hiatus anterior and to the right of the lower oesophagus.

Physiology and Pathogenesis

In the 1960s, reflux was thought to be controlled by the intra-abdominal portion of the oesophagus which acted as a flutter valve. The key breakthrough in understanding came from the laboratory of Wylie J Dodds who was working with the Dent sleeve, a multi-channel catheter whose long separate compartments allowed measurement of pressure over a length rather than at a fixed point. This allowed the lower oesophageal sphincter pressure (▶LESP) to be measured even if it slid up and down with respiration. Multiple such measuring stations along the catheter as well as pH measuring points allowed the observation in normal subjects that the lower oesophageal sphincter undergoes transient collapse of pressure from its normal of about 40 mm Hg to zero with swallowing, but that in addition, transient inappropriate total collapses of sphincter pressure occurred two or three times a night. These spontaneous inappropriate collapses of sphincter pressure may be accompanied by acid reflux and a drop in pH that recovers with swallowing while the subject is in light REM sleep. It was soon established that individuals with reflux disease have dozens of such LESP collapses every night, and during the daytime. If the stomach is full when these occur then there is frequent acid reflux. In normal subjects, there are usually less than three or four such episodes of LESP collapse in 24 h, and they are more frequent in the day than at night and last for less than 5 min. It seemed therefore that the acid reflux disease was due to a neuromuscular abnormality of frequent LES relaxations.

However, subsequent work has shown that there is more to reflux than simply the LES pressure. The competence of the sphincter is dependant on position, pressure and length. An intra-abdominal position of the LES bolsters effective sphincter pressure, as intra-abdominal pressure is applied equally to stomach and to the LES, and contraction of the gastric sling fibres maintains the acute angle between stomach and oesophagus. When the abdominal oesophagus is short, as in the presence of a sliding hiatus hernia, intra-abdominal pressure is applied mainly to the stomach, and LESP is more readily overcome. Pressure and length are related in that the longer the sphincter, the lower the pressure required to maintain competence, and conversely a shorter sphincter needs a higher pressure for competence.

Thus it is highly relevant that overdistension of the stomach opens the lower part of the contiguous sphincter causing shortening (Fig. 1), and this shortening of the sphincter can be demonstrated to initiate a transient collapse of sphincter pressure, more in hiatus hernia patients than in those with a long segment of intra-abdominal oesophagus.



Hernia, Hiatus in Adults. Figure 1 (a) Diagram illustrates a normally closed LES with the stomach empty, and shows how as the fundus distends the sphincter is partially taken up, with opening of the lower portion. This shortens the effective sphincter, and precipitates episodes of transient LESP collapse. (b) This shows the final stage with a permanently defective sphincter that is lax and open, and has migrated up into the chest with some shortening of the oesophagus.

This suggests that shortening of the sphincter is the key in determining frequency of collapse and subsequent reflux. Even in normal individuals, overeating has been shown to shorten the LES sufficiently to cause intermittent LES collapse and gastro-oesphageal reflux. In addition instillation of fat into the gastric antrum causes tonic contraction of the pylorus and delayed gastric emptying in dogs and humans, prolonging fundal distension.

The present understanding can therefore be summarized, as described by DeMeester and Karilas (1, 2). Overeating and delayed gastric emptying (the latter enhanced by fat in the diet), cause prolonged fundal distension with opening of the lower end of the LES shortening its effective length. This leads to repetitive LESP collapse, reflux with mucosal inflammation, and the many symptoms of GERD. Reflux is more likely to occur when the stomach is full and the lower end of the sphincter is distended, which explains the common experience that night heartburn is exacerbated by going to bed shortly after eating.

In the majority of patients reflux is due to frequent inappropriate sphincter relaxations. In a minority of patients (perhaps 10%) prolonged reflux with no relief of the underlying causes will lead to a permanently defective sphincter which is defined as a pressure less than 6 mm Hg, a length of less than 2 cm, and in intra-abdominal length of less than 1 cm. It is part of the role of the radiologist to identify these patients and distinguish them from those with early GERD with or without complications.

Upper Sphincter

If acid is dripped experimentally into the oesophagus while the pressure of the sphincter at the cricopharyngeus is being measured, an abrupt increase in pressure will be observed. If the acid is instilled into the lower sphincter the reflex pressure increase is modest, but if into the upper oesophagus, it is a greater increase. The reason for this is unknown, but it may serve to protect the airway and larynx to some extent when the oesophagus floods with acid, though this is not totally successful and laryngeal oedema and symptoms are seen in severe reflux disease. Repeated reflux leads to a chronic increase in cricopharyngeal sphincter pressure and to thickening of the muscle. This is associated with restriction in the degree of relaxation of the sphincter in some patients with sometimes a permanent posterior bar remaining throughout the swallow. These bars occasionally act as a functional stricture causing dysphagia, and may make endoscopy difficult. However, if a small cannula is passed through the cricopharyngeus under direct vision with an endoscope, the endoscope can then easily be passed into the oesophagus over the cannula which acts as a guide wire, indicating that this is no true fibrous stricture, but merely a bar of hypertrophied non-relaxing muscle.

The increased tone of the sphincter leads to delayed opening of the sphincter, and to premature contraction at the end of the swallow so that a little barium at the tail end of the bolus is trapped above the closing sphincter. Sometimes the increased pressure caused in the pharynx leads to transient herniation of mucosa posteriorly through the small triangular defect between the horizontal and oblique fibres of the cricopharyngeus as a brief transient mini ►Zenker's diverticulum. This little herniation is a reliable radiological sign of gastro-oesophageal reflux disease (Fig. 2). In a small number of patients, the herniation slowly enlarges and becomes permanent, and such patients may present in later life with regurgitation of food swallowed some hours previously, that has been trapped in a Zenker's diverticulum. As with the bar described above, endoscopy may be difficult in these patients as the endoscope tends to pass posteriorly into the diverticulum. As with the bars, a cannula can be used to intubate the cricopharyngeus in patients with a large Zenker's diverticulum, and this may best be done with radiographic guidance as the guide wire often preferentially enters the diverticulum rather than the lumen and this is not always easy to detect endoscopically.

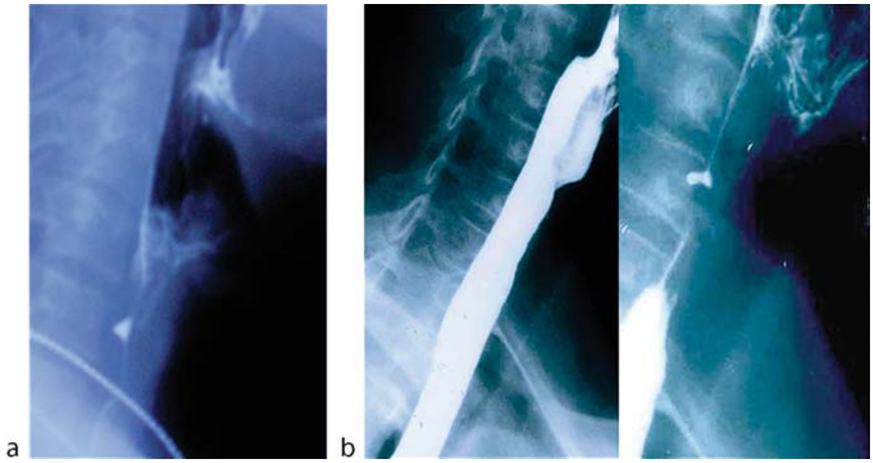
The ►Gastric Inlet Patch (Gip)

An island of ectopic gastric mucosa is present at the upper end of the oesophagus in from 0.3% to 5% of subjects, with a figure of 2.4 in one prospective radiological study. The patch, a salmon pink area of mucosa just below the cricopharyngeus, is best seen during slow withdrawal of the endoscope through the upper oesophagus. Its detection on barium study requires views of the well-distended upper oesophagus in two projections which explains why it is rarely seen unless specifically looked for. It is usually asymptomatic, but may contain parietal cells and produce acid, undergo dysplasia, cause strictures or webs, and invasive adenocarcinoma. With acid production it may cause sleep disturbance with coughing and globus.

When patients have pharyngeal, laryngeal or respiratory symptoms of GERD but no apparent hiatus hernia or detectable reflux, an acid producing gastric inlet patch will occasionally be the cause.

Oesophageal Motility

There are five types of oesophageal contractions that may be recognized by the radiologist. Peristaltic contractions may be primary (initiated by swallowing) or secondary (initiated either spontaneously in mid oesophagus or by mid oesophageal distension). Non-peristaltic contractions may be of low amplitude and not obliterate the lumen (less than 25 mm Hg pressure) and are called tertiary contractions by radiologists. Sometimes these



Hernia, Hiatus in Adults. Figure 2 **(a) This shows the most common cricopharyngeal abnormality seen in patients with GERD. There is slight premature contraction of the upper sphincter which traps a few drops of barium from the tail of the swallowed bolus. (b) This shows how, although the posterior wall of the sphincter is smooth when it is distended, the premature contraction is producing increased pressure which transiently forces some mucosa through Killian's dehiscence, producing a momentary Zenker's diverticulum that is only present for less than a second. This is not an uncommon finding in patients with GERD and ►globus.**

H

non-peristaltic contractions are of high amplitude and completely obliterate the lumen either segmentally, or as corkscrew (Presby) oesophagus. In some conditions such as nutcracker oesophagus and diffuse spasm, these high amplitude non-peristaltic contractions may reach 600 mm Hg, and be associated with severe chest pain, mimicking a myocardial infarct. Much more commonly, non-cardiac chest pain that mimics an infarct is due to gastro-oesophageal reflux disease. The final type of oesophageal contraction is called the feline oesophagus and is often observed radiologically and occasionally endoscopically, usually as a transient transverse fine ridging of the oesophageal mucosa that occurs immediately after an episode of reflux. It may be thought of as an oesophageal shiver, and is almost certainly caused by a transient contraction of the longitudinally orientated muscularis mucosae in response to contact with acid.

Assessment of the Relationship Between Oesophageal Motility and Gastro-Oesophageal Reflux

The most frequent motility disorder associated with GERD is ineffective primary and secondary peristalsis, at least as measured by manometry (It has for many years been obvious to radiologists that far more common are the low amplitude non-peristaltic tertiary contractions, of such low amplitude that they may not be noticeable on manometry.). However only a minority, 30–40% of patients with reflux disease, have impaired peristalsis and it is more common in advanced GERD such as those with associated respiratory symptoms, oesophagitis and ►Barrett's oesophagus. Disappointingly, most studies have shown that optimal medical control of reflux does not produce improvement in peristaltic amplitude, and nor does fundoplication. Barium video fluoroscopy has been shown to be excellent in ruling out ineffective primary peristalsis, (and thus in excluding achalasia and scleroderma).

Oesophageal peristalsis may be defective as part of a primary motility disorder, but may also deteriorate secondary to long standing GERD. In patients with heartburn the most important primary disorder to detect is scleroderma which is an uncommon but not rare cause of GERD. Its particular significance is that because of the lack of propulsive power in the oesophagus, these patients do very badly with fundoplication surgery which is contraindicated. The weakest part of the normal stripping wave is around the level of the aortic arch where the striated muscle of the upper portion blends with the smooth muscle of the lower oesophagus. In the earliest stage therefore of scleroderma, or of diminished motility secondary to reflux, examination of a single swallow of barium will reveal that the primary wave is inefficient at the level of the arch leaving some barium behind at this point, a phenomenon called proximal escape. By the time scleroderma presents with reflux symptoms however, the motility disorder has progressed and the radiologist will see that the peristalsis that starts in the pharynx fades out around the arch of the aorta, and that there is no visible peristalsis in the lower two thirds of the oesophagus. Whenever severely diminished peristalsis is seen in the oesophagus in a patient with reflux, especially if the oesophagus is more distensible than usual, enquiry should be made for Raynaud's phenomenon and the possibility of scleroderma should be mentioned in the report. In patients with chest pain in whom reflux is being assessed, occasionally vigorous achalasia, diffuse spasm and rarely nutcracker oesophagus will be encountered. Assessment of oesophageal motility is therefore a necessary part of the examination in suspected reflux disease and it is best carried out with the patient prone oblique making single swallows of barium at least 30 sec apart. Many patients routinely double swallow, and the second swallow interrupts and aborts the first primary wave, so it is essential that the leading edge of the peristaltic wave (the upper end of the barium bolus) be kept at the bottom of the screen so that any second peristalsis coming down from above can be detected, and the result of those swallows discarded.

Any cause of severe oesophagitis will impair peristalsis including Herpes, Candida, Cytomegalovirus and irradiation. In most of these motility may recover with healing, though less foten following radiation because of fibrosis.

Effect on Lower Oesophageal Sphincter Pressure and Cardia

There is usually an acute angle between the intra-abdominal portion of the oesophagus and the stomach. In the presence of a lax taken up sphincter this acute angle is lost, as it is when a hiatus hernia is present. It may sometimes be possible to assess the length of the sphincter, especially in those patients with severe reflux, when it may be apparent that between the barium in the lower oesophagus, and the barium in the hernia, there are only a few millimetres of closed lumen. In more advanced disease the LES is permanently wide open with continual free reflux. In some patients with hiatus hernia, one of the rugal folds may have at its upper end a swelling, looking like a polyp and usually called a sentinel fold. Herlinger has shown that these swellings at the top of a rugal fold are usually oedema, but in a minority of cases (4/23 in one series) the finding was due to a small gastric adenocarcinoma. For this reason, the finding of one of these nodules at the oesophagogastric junction should always lead to endoscopy for biopsy, although endoscopists do not always find a correlating nodule—oedema is a reversible finding.

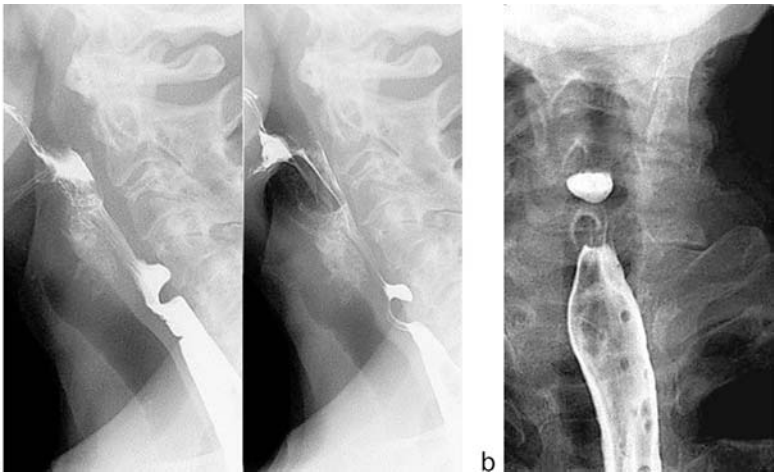
Effect of Gastric Emptying Changes

There is an association between GERD and impaired gastric emptying. It is not clear whether this is usually cause and effect or merely an association. If gastric emptying is impaired, gastro-oesophageal reflux will often follow, and respond to treatment of the cause (Fig. 3). Gastric emptying is impaired in diabetes and by a high fat meal. This is difficult to assess on barium examination, but will be implied if there are gastric distention, food residue in the stomach, poor antral peristalsis and poor flow of barium to the duodenum. Obesity, diabetes and high-fat diet are commonly associated and are associated with GERD.

Mucosal Damage

Acid reflux leads to oesophagitis though only a minority of patients with symptomatic GERD have endoscopic evidence

a



b

Hernia, Hiatus in Adults. Figure 3 (a) This patient with GERD shows a cricopharyngeal bar due to incomplete relaxation of the upper sphincter, and a slightly later stage in the progression to Zenker's diverticulum. Barium persists for a while in the herniated mucosa (b).

of oesophagitis, which has been graded endoscopically into four stages, under the Los Angeles classification. Grade 1 is a mucosal break <5 mm in length, and grade 4 a mucosal break >75% of the circumference of the oesophagus. This classification is not helpful radiologically as it does not distinguish between erythema and ulceration. The two earliest stages which are loss of the vessel pattern due to oedema, and linear erythema are not detectable on barium meal study. Once there is a mucosal break with surface white slough endoscopically, this is potentially detectable as barium adheres to the slough and a small linear irregular longitudinal barium shadow may be seen. This is reliable when it is seen, and especially when there are multiple such linear ulcers with oedema such that longitudinal folds do not efface with distension. However there is no published correlation between the endoscopic grading and the barium finding. It is sufficient to say that good quality double contrast barium studies can often demonstrate moderate and severe ulcerative oesophagitis, and are useless in showing mild or minimal reflux oesophagitis.

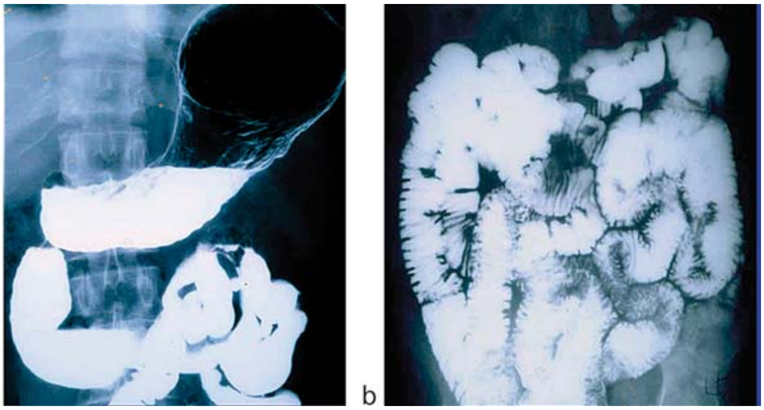
Strictures, Rings and Pseudo-Diverticulosis

A peptic stricture does occur with long standing oesphagitis but is not the most common cause of dysphagia in reflux disease. Much more common is the Schatzki ring which is a short ring narrowing at the gastro-oesophageal mucosal junction (Fig. 4). The ring is only apparent when the oesophagus above and the hiatus hernia below are distended more than the ring itself. A symptomatic ring (causing meat bolus dysphagia for example) may have a calibre of 12 or even 15 mm, so that good distention is essential to demonstrate the ring and this may not always be achievable with erect double contrast views. The prone oblique view with a deeply held inspiration as the barium bolus passes through the LES is the best view with liquid swallows. If the history is of dysphagia, and the liquid swallows are normal, a solid marshmallow bolus should be given for the patient to swallow, unchewed, with a few sips of barium. This will often reveal the presence of a Schatzki ring missed on the liquid study. One half of a standard large North American or European marshmallow, kept fresh in a sealed container, is suitable. Alternatively, if the consistency of the local marshmallow is unsatisfactory, as it is for example in Australia (it is too soft and squeezes out into a long string that can not show a mild stricture) a recipe for a home mode gelatin barium bolus has been published). Ott et al. have shown that properly conducted barium studies are more sensitive than endoscopy in detecting Schatzki rings. Longer peptic strictures are usually obvious, but when mild or long can be overlooked, and any suspicion should be confirmed with a solid bolus. In patients with long standing chronic oesophagitis, and mild stricturing, pseudo-diverticula may form due to enlargement of goblet cells, and produce a striking appearance of multiple small barium collection alongside the margins of the thickened oesophageal wall. Oesophageal pseudo-diverticulosis is easily missed at endoscopy although its clinical relevance is uncertain. The pseudo-diverticula can be at, above or below the strictures, and may even rarely occur without strictures. They are often associated with candida colonization.

Barrett's Oesophagus and Adenocarcinoma

Prolonged gastro-oesophageal reflux may lead to a change in the lower oesophageal mucosa whereby the squamous epithelium becomes replaced by a fundic type of gastric mucosa in which dysplasia is prone to occur, followed in some cases by the development of adenocarcinoma. Most

a b

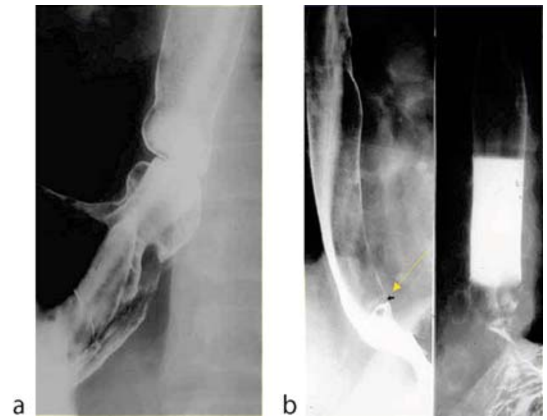


Hernia, Hiatus in Adults. Figure 4 (a) This 27 year old medical student presented with heartburn, and the image shows retained food in the stomach due to delayed gastric emptying. This is due to the severe duodenal and jejunal changes from Coeliac disease. (b). His heartburn resolved on gluten free diet as his gastric emptying returned to normal.

often the gastric metaplasia is limited to the lower oesophagus as short fingers of salmon coloured mucosa spreading up from the gastro-oesophageal junction, and carcinoma in this short segment Barrett's is uncommon, but can occur. Sometimes the zone of transition may spread most of the way up the oesophagus. This new gastric mucosa in the oesophagus is immune to oesophagitis, and remains smooth on barium study, though sometimes with a velvety surface of small polygonal islands resembling areae gastricae—rarely seen but permitting a definitive diagnosis when they are noticed.

The finger like projections can occasionally be seen on good double contrast views but this is unreliable. Oesophagitis in such patients occurs in the lower end of the remaining squamous mucosa. Therefore, the finding of a segment of smooth oesophagus above the gastro-oesophageal junction (as defined by the cessation of rugal folds), above which the changes of oesophagitis can be seen, such as ulceration, spasm or scarring, allows a confident diagnosis of Barrett's oesophagus at barium meal study. Only a minority of patients with Barrett's can be diagnosed in this way. The gastric mucosa in the lower oesophagus is however liable to undergo peptic ulceration, with a substantial discrete ulcer of some depth and with defined margins. Such a discrete ulcer does not occur in peptic oesophagitis, and the differential diagnosis is rather of ulcerated squamous carcinoma, or a discrete ulcer from unusual infection such as cytomegalovirus or herpes. Finally, the oesophagus in long segment Barrett's tends to be more distensible than usual, and there is usually a permanently defective sphincter with a hiatus hernia and free reflux. The high risk patient in whom endoscopy may be recommended, even when Barrett's oesophagus can not be diagnosed radiologically, are middle aged men, overweight, with a long history of reflux whose heartburn symptoms may have typically diminished in recent years, and who have a lax sphincter and rather distensible oesophagus (Fig. 5).

Dysphagia from cancer may be the presenting symptom in these patients, as the heartburn often diminishes as the gastric mucosa extends up the oesophagus. The cancers may arise at the cardia or anywhere in the metaplastic gastric mucosa. Cancer is less common in short segment Barrett's but does occur.



Hernia, Hiatus in Adults. Figure 5 (a) A prone oblique film on deep inspiration as the patient swallowed showed this Schatzki ring above a hiatus hernia, which was not visible on the erect double contrast views. (b) This patient has a minimal Schatzki ring (*arrow*), barely detectable on the erect double contrast views, but nevertheless it is sufficient to obstruct a half large marshmallow, support a column of barium and reproduce the patient's symptoms of Dysphagia.

Hiatus Hernia and Short Oesophagus

Hiatus hernia often accompanies GERD, but is neither necessary nor sufficient for its diagnosis. It is more readily seen with abdominal pressure, i.e. prone, and therefore a small hiatus hernia may be reported from a barium meal study when it is not apparent endoscopically. A hiatus hernia is most significant when the gastro-oesophageal junction is permanently above the hiatus, as this may indicate oesophageal shortening. This is critical in advanced disease in which surgery may be considered, since if the intra-abdominal position of the LES cannot be restored without undue tension, a different operation will be required (4). However there is disagreement on how common this is, and how reliably it may be recognized by the radiologist. Some surgeons find that 23% of patients requiring surgery for GERD have a ►short oesophagus and require some form of Collis gastroplasty (3). Other surgeons regard this as rare, occurring in less than 5% of surgical patients. In some elderly patients, although the GE junction may be well above the hiatus with the patient erect, the oesophagus is elongated and tortuous and the LES can readily be pulled down at surgery. In other cases the oesophagus is straight and a high GE junction probably does mean a short oesophagus with irreducible hernia (Fig. 6). The radiologist must recognize the position of the gastro-oesophageal junction and report when the oesophagus appears to be short, while acknowledging that this does not necessarily mean that a gastroplasty will be needed at operation. The radiologist examining the patient erect is in a good position, with the double contrast films, to identify the position of the gastro-oesophageal junction by identifying the top of the rugal folds, and thus alert the surgeon to the potential problem.

Most patients with sliding hiatus hernia do not have a short oesophagus, and the hernia is often only present when the patient is horizontal, and when the stomach is

Hernia, Hiatus in Adults. Figure 6 **This patient with very mild bolus Dysphagia has a mild stricture from peptic oesophagitis. The erect double contrast view of the gastro-oesophageal junction also shows that there is a hiatus hernia with the patient in the erect position, (the *arrow* indicates the top of a gastric rugal fold), and this appearance suggests that there may well be a short oesophagus. The surgeon should be alerted to the likelihood that a Collis gastroplasty may be required instead of a routine fundoplication.**

distended. In old age a hiatus hernia may enlarge progressively. In this case the enlargement may occur with the LES always above the hiatus, or instead the lateral part of the fundus and greater curve of the body may roll up into the thorax through the lax diaphragmatic hiatus, and lie above the LES. This is very rarely associated with volvulus and necrosis, and many of these patients are too frail for surgery for what are often quite minor symptoms. Some surgeons grade hiatus hernias into four types, and if your surgeon does, then it will be helpful to indicate the type in the report. Type I is the common sliding hernia. In Type II the GE junction remains at or below the hiatus with superior herniation of the gastric fundus. Type III has features of both Types I and II, and is more common than II. Type IV is used to describe herniation of most or all of the stomach into the chest usually with rotation of the greater curve of the body up above the fundus.

Heterotaxia Syndrome or Situs Ambiguous

This syndrome implies a disordered organ arrangement in the chest and/or abdomen. The anatomy is unpredictable. The visceral malformation is associated with indeterminate atrial arrangement. Asplenia is associated with right isomerism or bilateral right-sidedness. Polysplenia is associated with left isomerism or bilateral left-sidedness.

▶Congenital Malformations, Splenic

Heterotaxia Syndromes, Ambiguous Situs Abdomen

▶Congenital Malformations, Splenic

Heterotopia

Heterotopia gray matter in an abnormal location, between the germinal matrix and the final destination, the cortex.

▶Congenital Malformations, Cerebrum

Hiatal Hernia

▶Reflux, Gastroesophageal in Adults

Hiatus Hernia

Herniation of part of the stomach upwards through the diaphragmatic hiatus and into the chest; ‘sliding’ and ‘rolling’ types are described.

▶Hernia, Hiatus in Adults

▶Hernia, Diaphragm, Congenital

▶Reflux, Gastroesophageal in Adults

Hibernoma

Benign mesenchymal tumor developing from vestiges or fat storage organs. These tumors, originating from both brown and white fat tissues, are considered a variant of lipoma. Hibernomas are usually capsulated, highly vascularized with a slow growth. Imaging features show inhomogeneous masses with relatively well-defined margins.

▶Lipomatous Neoplasms, Hepatic

HIE

▶Hypoxic-Ischaemic Encephalopathy

High ARM

ARM where the blind pouch ends above the sling of the hypotrophic puborectalis muscle. There can be associated rectobulbar fistulas in males or rectovaginal fistulas in females.

▶Anorectal Malformation

High Osmolality Contrast Media

A high osmolality contrast medium is a water-soluble imaging contrast agent that has osmolality (a measure of the number of particles in solution) much higher than human blood. For radiographic iodinated contrast media, this is typically around four times the osmolality of human blood. Certain adverse effects of contrast media are attributed, at least in part, to elevated osmolality. See also iso-osmolality contrast media and low osmolality contrast media.

▶Adverse Reactions, Iodinated Contrast Media, Acute Renal

High Pressure Balloon

Balloon catheter with nominal burst ratio of more than 25 atm.

▶Fistula, Hemodialysis

High-Resolution MR Imaging

High-resolution MR imaging using a small surface coil (e.g., a 47-mm microscopy coil) offers images with high signal-to-noise ratios of the superficial organs and tissues.

▶Neoplasms, Salivary Glands

Hilgenreiner Lines

Horizontal and vertical lines constructed on frontal radiographs of the hips for evaluation of possible dysplasia, subluxation, or dislocation.

▶Dysplasia, Hip, Developmental

Hilum

The normal lymph node contains fat-filled hilum, through which almost all vessels enter the lymph node. The hilum is depicted by sonography and CT as an echogenic central structure and a fat-density structure, respectively, and is identified by T1-weighted MR imaging as a hyperintense area. The presence of intact hilum on sonographic, CT, and MR images is a hallmark of the normal lymph node.

▶Lymphadenopathies, Head and Neck

Hip Dislocation

Most commonly occurs posteriorly in the setting of major trauma with resultant posterior displacement and internal rotation of the femur. Diaphyseal fractures of the femoral shaft are not infrequently seen and may obscure the clinical diagnosis of hip dislocation sciatic nerve injury occurs in 10% of these injuries. Posterior labral tears and posterior acetabular fractures are commonly associated. Compression fractures of the femoral head may also occur, usually on its inferomedial aspect. Approximately 10% of hip dislocations are anterior. Impaction fractures of the superolateral femoral head and fractures of the anterior acetabular rim are associated with these injuries. Hip dislocations are best assessed by CT after urgent reduction. MR is also useful in assessing the integrity of the labrum and the cartilage.

Synonym

Developmental dysplasia of the hip (DDH)

Definition

Developmental dysplasia of the hip (DDH) is defined as a deformity of the acetabulum of varying degree in which the femoral head may be located correctly or displaced in relation to the acetabulum.

Pathology/Histopathology

For its correct development the acetabulum needs a sufficient pressure of the femoral head. DDH develops *in utero* if the contact between the femoral head and the acetabulum is too loose. Different factors have been discussed concerning the development of DDH (1): mechanical reasons can be responsible for DDH if intrauterine space is limited, such as in oligohydramnios. DDH is more frequent in primiparous mothers. Increased levels of estrogens have been shown to cause a delayed maturation of collagen and therefore present a functional factor for the development of DDH. Genetic factors are reported to contribute to the development of DDH. Furthermore, environmental factors may contribute to the development of DDH; in particular, the way newborns are held by their mothers is different in various cultural settings and is reported to influence the risk of DDH.

In the majority of cases, DDH develops in the late phase of pregnancy based on the risk factors described earlier but without underlying disease. In a minority of cases, DDH develops in the early phase of pregnancy due to an underlying neuromuscular disorder such as spina bifida or arthrogryposis multiplex.

Clinical Presentation

The incidence of DDH is reported to be in the range of 2–6 newborns per 1,000. It is 4–8 times more frequent in females than in males (1). The clinical presentation varies greatly and ranges from near normal findings that are found on screening examinations to complete dislocation of the hip.

DDH should be diagnosed as early as possible. Clinical diagnosis is mainly based on specific tests including the Ortolani's and Barlow's maneuver, but sonography is more accurate. In some centers sonography is used as a routine screening for DDH in newborns, or sonography is routinely performed in newborns at risk (2). Radiography becomes most useful from the age of 3–6 months, when the relevant structures of the acetabulum and femoral head are sufficiently ossified.

Imaging

Sonography

Sonography plays a major role in DDH in the newborn and infant. The technique of hip joint sonography for diagnosing DDH was described by Graf in the early 1980s (2). Within the sonographic examination, the acetabular angle and the acetabular coverage are measured by a standardized technique and can be compared to age-related reference values. Based on this comparison, four grades of hip dysplasia have been defined. Sonography is reported to detect one-third more pathologic cases than clinical examination alone. Though sonography is most useful in very young age groups, sonographic methods have also been described in patients older than 2 years, with the intention of preventing patients from radiation exposure (2).

Radiography

Radiography is most useful from the age of 3–6 months, when the ossification of the relevant joint structures is sufficient. In patients younger than 6 weeks, radiography shows no changes of DDH (1). Usually, anteroposterior views of the pelvis are obtained, with optional frog-leg views or, in older patients, faux-profile views.

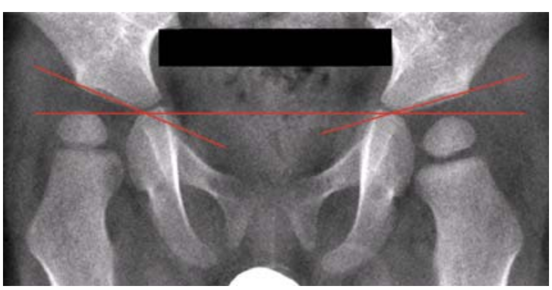
There are typical measurements indicating deformity of the acetabulum, the proximal femur, and the relationship between both structures. These include the acetabular index (AI), the center-edge (CE) angle, and the percentage of coverage of the femoral head (1, 3). The acetabular index is the angle of the acetabular roof to the Hilgenreiner's line, a line through the two triradiate cartilages (Fig. 1). The CE angle is the angle between the center of the femoral head on one hand and a line perpendicular to a line through both femoral head centers on the other hand. It is used in older children in whom the femoral heads are completely ossified. The percentage of coverage of the femoral head is measured using three lines perpendicular to the Hilgenreiner's line and cutting the medial and lateral aspects of the femoral head and the lateral corner of the acetabulum. Dividing the distances between these lines leads to the percentage of coverage of the femoral head.

The frog-leg view projection is used for determining antetorsion and the center-collum-diaphysis angle. Faux-profile projections serve for measuring the vertical-center-anterior angle.

All these and further measurements indicate whether and to what degree there is a deformity of the acetabulum or the proximal femur (3). These results can be compared with age-related normal values.

Computed Tomography

Computed tomography can be performed as an additional method to measure the anterior and posterior acetabular sector angle in patients being evaluated for surgical correction (3).



Hip Dysplasia. Figure 1 Anteroposterior radiograph of the pelvis. *Lines* indicate the measurement of the acetabular index, which is pathologically high on the right side and indicates the presence of developmental dysplasia of the hip.

Nuclear Medicine

Nuclear medicine does not play a role in the diagnosis of DDH.

Diagnosis

A complete evaluation includes a physical examination and either a sonographic or radiographic examination. Whether sonographic or radiographic imaging is used depends mostly on the patient's age. Diagnosis can usually be made very accurately on the basis of measurements performed with both methods.

Hip Dysplasia

Abnormal growth or development of the acetabulum, femoral head, and associated ligaments and soft tissues.

▶Congenital Malformations of the Musculoskeletal System

Hip, Dysplasia, Developmental

Alan E. Oestreich
Cincinnati Children's Hospital, Medical Center,
Cincinnati, , Ohio, USA
Alan.Oestreich@cchmc.org

Synonym

Formerly known as "congenital hip dislocation"

Definitions

Abnormal configuration, motion, or position of the hip apparent in the first days of life or discovered on follow-up later in childhood. The location of the femoral head with respect to the acetabulum, the steepness of the roof of the acetabulum, the shape of the outer corner of the roof, and abnormal clinical (or sonographic) testing for subluxability of the hip are major features at presentation. The findings may either ameliorate or progress if not treated.

Pathology/Histopathology

The anatomy of hip bone and cartilage on ultrasound images closely follows what is seen on gross dissection at autopsy. In dislocations, one question is interposition of the fatty pulvinar between the acetabulum and femoral head, which may prevent reduction.

Clinical Presentation

A hip click, asymmetric buttocks, and eventually an abnormal gait are signs of developmental dysplasia of the hip. Asymmetry will not be found, however, in bilateral disease.

Neuromuscular weakness, especially of the hip abductors, is typically a risk for acquired dislocation/ ►subluxation of valgus hips, a different entity from developmental dysplasia of the hip.

Imaging

Until about 3 months of age in girls, perhaps somewhat later in male infants, evaluation for the usual developmental dysplasia of the hip is by ultrasound. A coronal approach from the side is used, with evaluation and any angle measurements from images that simulate the frontal radiographs, but also show cartilage as separate from other soft-tissue structures. Subluxability (resembling the Barlow test) may be dynamically viewed while imaged by ultrasound.

In infancy, plain films for developmental dysplasia usually require only one frontal image, thus sparing the radiation of a second (frog leg) view. A straight pelvis (nonoblique) position should be sought. A computed tomography (CT) reconstructed image could also be used if available. Magnetic resonance imaging (MRI) is generally not needed, but nicely shows any trapped pulvinar (also evident on CT) in irreducible dislocation, as well as the musculotendinous structures of the region.

In preparation for corrective surgery for hip dislocation, a three-dimensional rotatable presentation from CT slices may help to guide the surgeon.

H

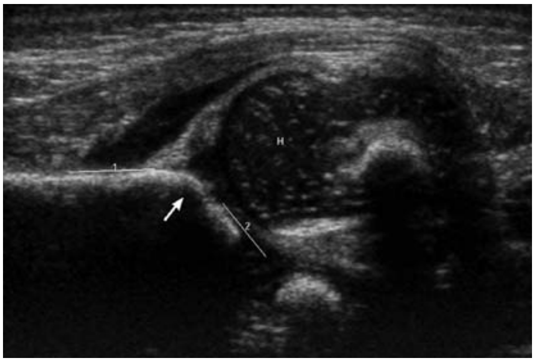
Diagnosis

Before the femoral head ossifies, ultrasound is the preferred imaging modality. A subluxed or dislocated femoral head is not 50% covered by the cartilage of the acetabular roof. The cartilaginous head is indeed well visualized early in infancy on ultrasound (including the channels of blood vessels within it). The ultrasound findings are graded according to Graf (1), in part using the α-angle between the extension of the vertical lateral edge of the ilium and the acetabular roof line (see Table 1). Normal, or Graf I, has an α-angle of at least 60°, and a well-formed lateral margin of the acetabular roof. In Graf I and most cases of Graf II, the femoral head is seen to be at least 50% covered by the roof. In Graf II (Fig. 1), the α-angle lies between 50 and 59°, and the

Hip, Dysplasia, Developmental. Table 1 ►Graf classification

Graf	Sonographic type	Acetabular outer corner	α-angle (degrees)
I	Mature	Sharp or slightly rounded	>60
IIA	Immature hip <3 months of age	Rounded	50–60
IIB	Immature hip >3 months of age	Rounded	50–60
IIC	Dysplasia, stable	Rounded	43–49
IID	Dysplasia, unstable (decentering)	Rounded or slightly flattened	43–49
III	subluxed (eccentric)	Flattened	<43
IV	Dislocated	Deformed	Not measurable

Modified from Keats TE, Sistrom C (2001) Atlas of Radiologic Measurement. 7th edn. Mosby, St. Louis, p 216.
In I–IIC, cartilage roof of acetabulum covers the femoral head
In IID, cartilage roof is displaced upward
In III, cartilage roof is displaced, either devoid of echoes or echogenic
In IV, cartilage rood is trapped between femoral head and ilium.



Hip, Dysplasia, Developmental. Figure 1 **Example of a Graf II hip in a 9-day-old infant. The head (H) of the femur is 50% covered; the α-angle (between lines 1 and 2) is 53˚, and the outer corner of the acetabulum (*arrow*) is more rounded than angular (we presume the head is 50% covered).**

Hip, Dysplasia, Developmental. Figure 2 **A 15-month-old girl with left developmental dysplasia of the hip leading to subluxation. The Shenton line (*dots*) on the left is disturbed, as is the "outside Shenton" curve (*dashes*), which is normal on the right in comparison (From Oestreich AE, Crawford AH (1985) Atlas of Pediatric Orthopedic Radiology. Thieme Verlag, Stuttgart, p 184).**

lateral roof is rounded. This is an immature hip. In Graf III, the angle is between 43 and 49˚ and the head is subluxed whereas in Graf IV the hip is dislocated and the angle is below 43˚. As the hip is subluxed, one looks for a trapped pulvinar between the head and acetabulum. During ultrasound visualization of the hip, subluxability can be dynamically demonstrated.

The ►Hilgenreiner horizontal line on plain images connects the lowest ossified points of the two acetabular roofs; the Hilgenreiner vertical line perpendicular to it is constructed at the lateral corner of the roof. The proximal femoral shaft should be at least partly medial to the vertical line on the anteroposterior (AP) image. The acetabular angle is constructed between the horizontal line and the line connecting the lowest and outermost points of the roof. The higher the angle, especially above 45˚, the more dysplastic the acetabulum. In some cases of complete dislocation, no acetabular roof has formed at all.

After the femoral head ossifies, the ossification tends to be greater on the nondysplastic hip in unilateral disease. The femoral head is displaced lateral to the vertical line in subluxation or dislocation. The inner curve of the femoral neck should be able to be smoothly continued to the lower surface of the superior pubic bone, the normal Shenton line (Fig. 2). An "outer Shenton" line is also present in normal cases on AP, with the curve of the lateral surface of the neck of the femur continuing with the lateral outer curve of the iliac bone (Fig. 2).

The acetabular angle is relatively low in Down syndrome, achondroplasia, Rubinstein–Taybi syndrome, and often in long-standing neuromuscular disease.

Hip dislocation in early infancy is also a manifestation of several dysostoses/dysplasias, including Larsen syndrome (knees are also dislocated at birth) and geroderma osteodysplastica congenita (osteoporosis, Walt Disney dwarf facies) (2).

Hip Fractures

Minor trauma in a patient with osteoporosis is the characteristic clinical setting of most hip fractures. Most injuries are subcapital fractures, occurring at the junction of the femoral head and neck. These injuries are intracapsular and often interrupt blood supply to the femoral head. Other intracapsular fractures include transverse cervical and basicervical injuries. Extracapsular hip fractures include intertrochanteric and subtrochanteric fractures. These fractures are usually obliquely oriented and associated fractures of the lesser and greater trochanters are common. Pathologic fractures should be considered in the setting of isolated fractures of the trochanters or transversely oriented subtrochanteric injuries.

HiornM@gosh.nhs.uk

Synonyms

Aganglionosis of the colon; Chronic intestinal pseudo obstruction; Congenital megacolon. Related disorders include Hypoperistalsis syndrome; Hypoganglionosis; Neuronal intestinal dysplasia (NID); Total colonic aganglionosis; Ultra short segment Hirschsprung's disease

Definition

This group of disorders is known collectively as the dysganglionoses and they are all characterised by abnormalities in innervation of the bowel. ►Hirschsprung's disease is defined as ►aganglionosis of part or, occasionally, the entire large bowel. The most distal part of the rectum is always affected but the proximal extent of the disease is variable.

Hirschsprung's disease is a dominantly inherited multigenic disorder with incomplete penetrance and variable expressivity. Of the genes identified so far, the RET proto-oncogene is the major susceptibility gene and accounts for most cases.

Pathology/Histopathology

Hirschsprung's disease is characterised histologically as the congenital absence or deficiency of the ganglion cells in the myenteric and submucosal plexuses (1) of the rectum and the distal, non-dilated part of the colon, together with a hyperplasia of cholinergic nerve fibres in the circular muscle layer, muscularis mucosae and mucosa with a high activity of acetylcholinesterase.

Hypoganglionosis is described histologically as a variable length of gut with abnormal numbers of ganglion cells. It is believed to be the primary cause of intestinal pseudo-obstruction and may represent a forme-fruste of Hirschsprung's disease.

Hyperganglionosis is described as having two distinct patterns: ganglioneuromas (nodular proliferations of ganglion cells often associated with multiple endocrine neoplasia type 2B and not seen in children) and NID. NID is a controversial entity but a consistently described feature is of increased density of the submucosal ganglia (2).

Chronic intestinal pseudo-obstruction is a rare clinical condition also known as chronic adynamic ileus, pseudo Hirschsprung's disease and adynamic bowel syndrome. ►Megacystis-microcolon-intestinal hypoperistalsis syndrome is the most severe form of chronic intestinal pseudo-obstruction. Histologically abnormalities are either seen in the myenteric plexus with an associated visceral myopathy, or show argyrophobic cells or argyrophilic cells on silver stains.

Clinical Presentation

Hirschsprung's disease is the most common cause of neonatal obstruction of the colon and accounts for 33% of all neonatal obstructions. Overall there is an incidence of approximately 1 in 5,000 to 1 in 8,000 live births. Occurrence is usually sporadic but it is reported to be familial in 4%. In classic Hirschsprung's disease and in 'ultra short segment disease' there is a male to female ratio of 3:1 and in total colonic aganglionosis the ratio is 1.8:1.

The absence of the intramural ganglion cells interferes with normal relaxation and peristalsis of the bowel wall and the internal anal sphincter. The abnormally innervated segment of colon becomes hypertonic and behaves as a functional stenosis leading to partial or complete colonic obstruction. Immediately proximal to the aganglionic segment the intestine becomes markedly dilated with faeces and gas. Presentation is most common in the full term infant during the first six weeks of life (70–80%) and is extremely rare in premature infants. Failure to pass meconium in the first 24 h of life is common and Hirschsprung's disease must be considered in the differential diagnosis until proven otherwise. However, in some cases obstruction may not be the predominant feature and the infant may present with diarrhoea or an enterocolitis. In a small proportion of cases presentation will be delayed until the child is older and presents with intractable constipation.

Hyper- and hypoganglionosis will also present a similar and overlapping clinical picture and need to be considered in the differential diagnosis until histology is available.

Chronic intestinal pseudo obstruction (also known as chronic adynamic ileus, pseudo Hirschsprung's disease and adynamic bowel syndrome) tends to be more severe in cases with an earlier presentation. In the neonatal period, symptoms include failure to pass meconium, abdominal distension or bilious vomiting. Constipation may subsequently develop. In older children presentation may be abrupt or slowly progressive. Urinary tract involvement occurs in up to 50% of patients.

H

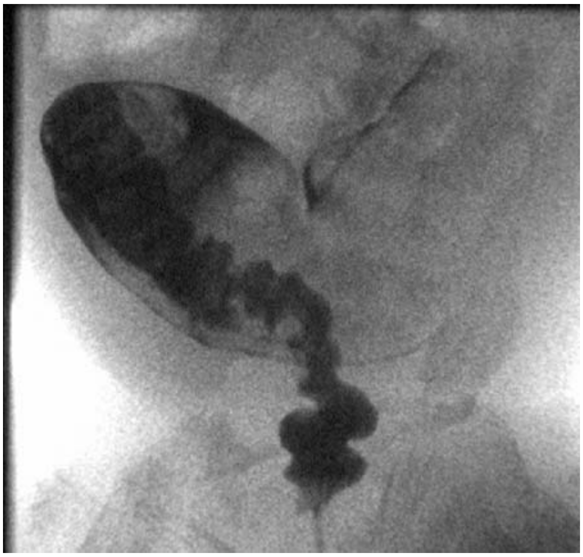
Imaging

After Hirschsprung's disease is suspected clinically, a water-soluble contrast enema should be performed. If the patient is beyond the neonatal period dilute barium can be used (3). The imaging should begin with the patient in a lateral position to best demonstrate the rectum and sigmoid and their relative sizes. The classic appearance is that of a short segment of normal appearing distal rectum with a 'transition zone' (an abrupt increase of calibre of the rectum or sigmoid colon) to distended gas and stool filled colon (Figs. 1 and 2). The recto-sigmoid index may be used to assess the comparative size of the rectum and sigmoid: the rectum is normally of larger diameter than the sigmoid and if this relationship is reversed an abnormality of bowel innervation is likely.

The affected part of the bowel is the distal part that is of small calibre. However it is frequently the case that the transition zone may not be so clearly demarcated as the colon proximal to the aganglionic section may be not be entirely normal but may be hypoganglionic and in these cases there may only be subtle cone-shaped tapering towards the rectum. In the neonate, the distal (affected) rectum may show a serrated (or 'saw-tooth') appearance representing abnormal (spastic) contractions.

Enterocolitis may be a complication of Hirschsprung's disease and presents with abdominal pain and profound, often bloody, diarrhoea. The enema findings are those of spasm, mucosal oedema, cobblestoning and ulceration and are indistinguishable from the appearances of any other acute colitis.

Imaging in megacystis-microcolon-intestinal hypoperistalsis syndrome usually shows a very large volume bladder on ultrasound that may empty poorly and a microcolon on the first contrast enema at birth.



Hirschsprung Disease and Related Disorders. Figure 1 Contrast enema in an infant in a lateral position showing a normal calibre rectum and then an abrupt change in calibre to a grossly distended sigmoid colon that is filled with stool.

Hirschsprung Disease and Related Disorders. Figure 2 Contrast enema in a neonate showing a dilated, air filled, sigmoid loop and an abrupt change of calibre at the recto–sigmoid junction.

Nuclear Medicine

It has no role to play in these conditions

Diagnosis

The diagnosis is confirmed by biopsy. It is usually the case that a suction biopsy is performed initially. If this shows ganglion cells the diagnosis of Hirschsprung's disease is excluded, but if no ganglion cells are identified a full thickness biopsy is then performed for full histological assessment. Hirschsprung's disease is characterised by congenital absence or deficiency of the ganglion cells in the myenteric and submucosal plexuses of the rectum and the distal, non-dilated part of the colon, together with a hyperplasia of cholinergic nerve fibres in the circular muscle layer, muscularis mucosae and mucosa with a high activity of acetylcholinesterase. Therefore Hirschsprung's disease is a histological and not an imaging diagnosis.

Interventional Radiological Treatment

It is not applicable.

Hydatid Disease, Abdominal

Riccardo Lencioni, Chiara Franchini
Department of Diagnostic and Interventional
Radiology, University of Pisa, Pisa, Italy
lencioni@med.unipi.it

Definition

Hydatid disease is a zoonosis produced by the larval stage of the *Echinococcus* tapeworm.

Pathology and Histopathology

Echinococcus granulosus and *Echinococcus multilocularis* are the two most common causes of hydatid disease. The most frequently encountered type in humans is *E. granulosus* and is commonly seen in the great grazing regions of the world (the Mediterranean region, Africa, South America, the Middle East, Australia, and New Zealand). *E. multilocularis* is less common but more invasive, mimicking a malignancy.

The definitive host is usually a dog but may be some other carnivore. The adult worm of the parasite lives in the proximal small bowel of the definitive host and releases eggs which are excreted in the feces. Sheep are the most common intermediate hosts. They are infected grazing on contaminated ground. Humans may become intermediate hosts through contact with a definitive host (usually a domesticated dog) or ingestion of contaminated water or vegetables. The egg loses its layer in the duodenum and an embryo, called oncosphere, is released. The embryo passes through the intestinal wall into the portal circulation and reaches the liver, where it may die or develop into a cyst. The right lobe is the most frequently involved portion of the liver (1, 2). In humans, hydatid disease involves the liver in approximately 75% of cases.

The hydatid cyst has three layers: the outer layer, or pericyst, is composed of modified host cells that form a fibrous protective zone; the middle laminated membrane is acellular and allows the passage of nutrients; the rupture of the laminated membrane predisposes to infection; the inner germinal layer produces the scolices (the larval stage of the parasite) and the laminated membrane. The middle and the inner layers form the true wall of the cyst, called endocyst. Daughter vesicles are small spheres that contain the protoscolices and are formed from an outpouching of the germinal layer. Scolices and vesicles form a white sediment known as hydatid sand. Daughter cysts may grow through the wall of the mother cyst, particularly in bone disease. The thickness of these layers depends on the tissue in which the cyst is located. The layers tend to be thick in the liver, less developed in muscle, absent in bone, and sometimes visible in the brain. Peripheral calcifications are common in both viable and nonviable cysts. Cyst fluid is clear or pale yellow, has a neutral pH, and contains sodium chloride, proteins, glucose, ions, lipids, and polysaccharides. The fluid is antigenic and may also contain scolices and hooklets (1–3).

Complications of hydatid cysts include local complications and hematogenous dissemination.

Local complications comprise cyst rupture, cyst infection, exophytic growth, transdiaphragmatic thoracic involvement, perforation into hollow viscera, peritoneal seeding, biliary communication, portal vein involvement, abdominal wall invasion. Intrahepatic complications are cyst rupture and infection. Rupture is usually a step of the natural history of hepatic hydatid cysts. There are three different types of cyst rupture; contained rupture involves the endocyst, while the pericyst remains intact; communicating rupture implies passage of the cyst contents into the biliary radicles incorporated into the pericyst; direct rupture, usually complicating superficially located cysts, involves both the pericyst and endocyst, allowing free spillage of hydatid material. Infection occurs only after rupture of both the pericyst and endocyst (communicating and direct rupture), which allows bacteria to pass easily into the cyst. Exophytic growth usually occurs through the bare area of the liver and the gastrohepatic ligament. Transdiaphragmatic migration usually occurs *via* the bare area of the liver. The involvement varies from simple adherence to the diaphragm to rupture into the pleural cavity, seeding in the pulmonary parenchyma, and chronic bronchial fistula. Spontaneous rupture of the cyst into hollow viscera is an extremely rare complication. Peritoneal seeding is almost always secondary to hepatic disease and is usually related to previous surgery, but sometimes it occurs spontaneously. Hydatid cysts communicate with the biliary tree *via* small biliary radicles incorporated into the pericyst. However, frank rupture into the biliary tree may occur. Compression of the portal vein and thrombosis is a rare event. Cysts may invade the abdominal wall, usually passing through a small orifice.

The most common sites of hematogenous dissemination are the lungs, involved in about 15% of cases in humans. Other possible anatomic locations are spleen, brain, bone, kidneys.

Involvement of the spleen is quite uncommon and isolated splenic involvement is even more uncommon. In some series, the spleen is the third most common location of hydatid disease after the liver and lungs. Splenic involvement may be due to hematogenous dissemination or intraperitoneal spread from a ruptured liver cyst. Splenic hydatid cysts are usually solitary (1).

In rare cases, retroperitoneal localization has been described. Hydatid disease of the pancreas is extremely rare and is usually associated to other localizations. The pancreas may also be involved in acute inflammation secondary to liver hydatid disease when intracystic debris is eliminated through the biliary tree (1).

E. multilocularis is responsible for the rare multilocular or alveolar form of hydatid disease. Definitive hosts are foxes and, less commonly, cats and dogs. Humans are infected either by direct contact with a definitive host or indirectly by ingestion of contaminated water or vegetables. This type of *Echinococcus* produces multilocular cysts which grow by exogenous proliferation. The cyst wall is composed of an inner germinal layer, a syncytial tegument, and an outer acellular laminated layer. These lesions show a strong tendency to develop central liquefactive necrosis, which may be surrounded by vital vesicles. The liver is the most commonly involved organ (3).

Clinical Presentation

Echinococcal lesions are often asymptomatic for many years and are discovered incidentally on imaging examinations. When symptomatic, hepatic hydatid cysts classically produce upper abdominal pain and hepatomegaly. In case of ruptured cyst, the passage of the cyst contents into the blood circulation can produce anaphylaxia due to the antigenic nature of the cyst fluid, although cyst rupture may be clinically silent. Infection usually manifests as a hepatic abscess.

Direct rupture into hollow viscera may present with hydatidemesis or hydatidorrhea.

If the rupture is followed by biliary communication, with subsequent biliary obstruction and cholangitis, jaundice, fever, and chills may occur.

The most frequent clinical manifestations of splenic involvement are abdominal pain, splenomegaly, and fever (1).

Imaging

E. granulosus Cysts

Hydatid cysts have been classified into four types on the basis of their appearance, reflecting the natural history of echinococcal disease (4).

Type I cyst appears as a simple cyst without internal architecture.

At ultrasound (US) it appears as an anechoic lesion with regular margins, and may contain hydatid sand and tiny septa. Rolling the patient during the examination disperses the sand and creates a “falling snowflakes” pattern, consisting in small fluctuant echoes. At computed tomography (CT), a type I hydatid cyst appears as a well-defined lesion, with a water-like density. The cyst wall and, when visible, the septa, usually show contrast enhancement after contrast medium injection. Magnetic resonance (MR) images show similar features to those of a simple liver cyst, including hypointensity on T1-weighted images and marked hyperintensity on T2-weighted images. A hypointense rim, particularly evident on T2-weighted scans, may be appreciable. This finding corresponds to the pericyst which is rich in collagen (1–3).

Type II cyst is a lesion containing daughter cysts and matrix, also referred to as multivescicular hydatid cyst.

Type II lesions have a US appearance that is generally specific and diagnostic of echinococcal disease. US is the most sensitive modality for the detection of membranes, septa, and hydatid sand. Daughter cysts are seen inside the mother cyst. Floating membranes or vesicles may also be seen in the cyst. Detachment of the endocyst from the pericyst is probably related to decreasing intracystic pressure, degeneration, host response, trauma, or response to therapy. When most of the cyst is filled with matrix, it may appear as an echogenic lesion mimicking a solid mass. At CT, viable daughter cysts have a consistently lower density than that of mother cyst. This finding is useful in differentiating multivescicular hydatid cyst from various septated cystic lesions. On the basis of CT appearance, multivescicular hydatid cysts have been classified into three types. Type IIA lesions contain small round daughter cysts at the periphery. Type IIB lesions contain larger, irregularly shaped daughter cysts that occupy almost the entire volume of the mother cyst. The high-attenuation fluid that surrounds the daughter cysts gives the appearance of septa, and creates a “rosette” appearance. Type IIC lesions, representing the degeneration of old cysts filled with matrix, appear as relatively high-attenuation round or oval masses with scattered calcifications and occasional daughter cysts. The hydatid matrix appears hypointense on T1-weighted MR images and markedly hyperintense on T2-weighted MR images; daughter cysts may appear hypointense or isointense relative to the maternal matrix both on T1- and T2-weighted images. The “snake sign” represents the presence of floating parasitic membranes within the cysts. These membranes have low signal intensity both in T1- and T2-weighted scans (1–3).

Type III cysts represent dead cysts with total calcification (Figs. 1–3).

At US, they demonstrate strong posterior acoustic shadowing. At CT, they appear as round, completely calcified lesions. At MR, they manifest as hypointense areas in all sequences (1–3).

Type IV cysts represent complicated hydatid lesions.

Intrahepatic complications of hydatid cysts include cyst rupture and infection and may occur in both type I and type II cysts. Rupture occurs in 50–90% of cases in the natural history of hepatic hydatid cyst, being due to the degeneration of parasitic membranes as a result of age, therapy, or host defense response. Sometimes it may be related to minor trauma. Rupture of a hydatid cyst may be contained, communicating, or direct. Contained ruptures involve the endocyst, while the pericyst remains intact. In these cases, endocyst detachment is seen at US, CT, and MR as undulating floating membranes within the cyst. The parasitic membranes appear as hypointense linear images on T2-weighted MR scans. In communicating rupture, the cyst content passes into the biliary radicles. In these cases, the cyst has a higher echogenicity than in contained rupture. US can demonstrate the presence of hydatid sand in the biliary channels. Direct rupture involves both the pericyst and endocyst, with

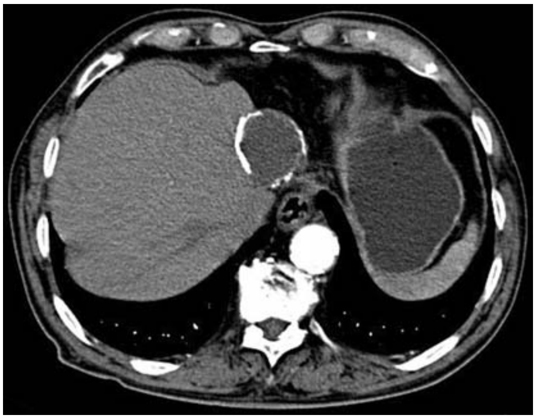
Hydatid Disease, Abdominal. Figure 3 Hydatid cyst of the liver (type III) same case of Fig 1. Enhanced CT portal-venous phase. The cyst dose not show any contrast enchancement both in the arterial and portal-venous phase.



Hydatid Disease, Abdominal. Figure 2 Hydatid cyst of the liver (type III) same case of Fig 1. Enhanced CT arterial phase. The cyst does not show any contrast enhancement both in the arterial and portal-venous phase.

consequent leakage of hydatid material into the peritoneal cavity, pleural cavity, hollow viscera, abdominal wall. Direct rupture is more frequent in superficially located lesions. In communicating and direct ruptures, the cyst empties and may became smaller and less spherical; US, CT, and MR may demonstrate a cyst wall fissure and leakage of the cyst contents.

Infection may complicate communicating and direct rupture, which allows the passage of bacteria into the cyst. US and CT findings are similar to those in other hepatic abscesses. US findings that suggest infection include a solid appearance, mixed echogenicity with solid and fluid components, internal echogenic foci, air–fluid or fluid–fluid levels, poor delimitation. All these US findings are nonspecific and may be observed in uninfected ruptured cysts. CT is the standard modality in the study of infected cysts. Infected cysts usually have ill-defined margins. After contrast administration, the typical hyperdense peripheral rim of abscesses is depicted. Patchy enhancing areas, corresponding to inflammatory changes, near the lesion may occasionally be seen. CT also most clearly depicts gas or air–fluid levels within the cyst (1–3).

In case of transdiaphragmatic migration of hydatid disease from the liver, chest radiography may show pleural effusion, elevation of the diaphragm, lung consolidation, or laminated atelectasis at the lung base. US can confirm the presence of hepatic hydatid disease and demonstrate pleural effusion. CT is very useful in demonstrating migration of hydatid disease and assessing the thoracic component. MR, thanks to the possibility of obtaining sagittal and coronal scans, allows an optimal depiction of the diaphragmatic defect and of the migration of the cyst through the diaphragm, giving an accurate presurgical evaluation. Rarely the cyst may perforate into hollow viscera. CT may demonstrate the presence of orally administered contrast material inside the cyst cavity. Changing the patient position may demonstrate filling or emptying of the cyst cavity. Barium study can be used to depict the fistula between the cyst and the hollow viscus. CT is the modality of choice in identifying peritoneal localization because it allows imaging of the whole abdomen and pelvis. Cysts may be multiple and located anywhere in the peritoneal cavity. In some cases they may occupy the entire peritoneal cavity, simulating a multiloculated mass. This condition is called encysted peritoneal hydatidosis. Communication of ruptured hydatid cyst with the biliary tree may be suspected on the basis of both direct and indirect imaging signs. Direct visualization of the cyst wall defect or of a communication between the cyst and a biliary radicle is possible with US and CT, especially in cases of wide communication. The presence of hydatid material in the biliary branches may sometimes be observed; in these instances, US demonstrates anechoic or echoic material filling the biliary radicles or the main bile duct, while CT depicts hyperdense material within the biliary tree. Endoscopic retrograde cholangiopancreatography and percutaneous transhepatic cholangiography can demonstrate the communication in more detail.

Indirect signs of biliary communication include increased echogenicity at US and fluid levels and signal intensity changes at MR imaging. An air–fluid level within the cyst may indicate infection, as well as rupture into the biliary tree or into a hollow viscus or development of a bronchopleural fistula. A fat–fluid level within the cyst has also been described as an indirect sign of biliary communication. Dilatation of the biliary tree may be the only, but aspecific imaging sign of hydatid cyst communicating with the biliary tree. Compression of the portal vein occurs rarely and may lead to thrombosis followed by cavernous transformation. Doppler US, CT, and MR can demonstrate the lack of flow in the portal vein and the presence of multiple small vessels with venous flow at the hepatic hilum, indicating portal cavernomatosis. Hydatid cysts may invade the abdominal wall. Imaging reveals a cystic mass within the abdominal wall that is similar to and in communication with the hepatic component of the hydatid cyst (1).

Splenic hydatid cysts have imaging features which are very similar to those of hepatic hydatid cysts. Any type of hydatid cyst can be seen in the spleen. Cyst wall calcification may occur and is better depicted at CT than at radiography or US. Splenic echinococcal lesions are usually solitary (1, 2).

Information about the appearance and location of hydatid cysts of the pancreas is inadequate due to their rarity (2). US and CT show a cystic lesion of the pancreas which may or not have some characteristics of hydatid cysts. Dilatation of the pancreatic duct due to compression may be associated.

E. multilocularis Cysts

At US, the typical presentation of echinococcal *multilocularis* is the so called "hailstorm" pattern, characterized by multiple echogenic nodules with indistinct margins. Larger lesions with central liquefactive necrosis have a hypoechoic structure, with some internal echoes and present irregular hyperechoic margins. CT demonstrates multiple irregular, ill-defined lesions which are usually hypodense. At MR, these lesions appear hyperintense on T2-weighted scans. This pattern may mimic either metastases or pyogenic abscesses. However, the enhancement after administration of contrast medium is absent or minimal. In advanced stages, the lesions are larger and irregularly shaped, and present central hypodensity with irregular tiny calcifications, corresponding to liquefactive necrosis. Hilar infiltration is a common event, resulting in biliary obstruction with dilatation of the intrahepatic bile ducts and invasion of the portal and hepatic veins, with subsequent atrophy of the affected liver segments due to hypoperfusion (3).

Interventional Radiology

Although previously thought to be contraindicated, percutaneous drainage of uncomplicated hydatid cysts is gaining wider acceptance as an effective and safe alternative to surgery. Generally, percutaneous drainage is combined with instillation of a sclerosing scolicidal agent after pretreatment with mebendazole (5).

Diagnosis

Echinococcal lesions are often asymptomatic for many years and are discovered incidentally on imaging examinations. Clinical data, imaging findings, and serology usually give useful and complementary information on the nature of the cyst and allow a definite diagnosis. Biochemical analysis usually demonstrates eosinophilia, while serologic tests for the parasite are positive in only 25% of patients.

However, hydatid disease in the pancreas may be a disturbing diagnostic problem and must be distinguished from cystic neoplasms. Usually the definite diagnosis is achieved at surgery.

Imaging is also a useful tool in monitoring treatment response.

Synonyms

(Dilating)uropathy; Hydronephrosis; Nephro-ureteral dilatation; Pyeloectasia

Definition

The term ▶hydronephrosis (HN) was derived from earlier times in imaging, when any detectable dilatation of the renal collecting system was considered a potential obstructive and dilative uropathy. With the improved resolution of modern ultrasound (US) techniques, 'physiological' distension of the normal renal calyces and pelvis as well as of the ureter became visible and we learned that this phenomenon does exist without any pathological meaning. Though often done, describing such a renal unit as a hydronephrotic kidney and ureter may be misleading, as this condition may still represent a physiological transient phenomenon mostly without clinical implications. Various grading and scoring suggestions have been introduced. The most commonly used grading system of HN in paediatrics has been derived from the Society for Fetal Urology (SFU), after birth applicable only to neonates and infants (Fig. 1). This grading scale is defined as follows:

- HN 0 = no collecting system visible
- HN I = just the renal pelvis with an axial diameter less than 5–7 mm visible
- HN II = axial renal pelvis diameter less than 5/7–10 mm, some non-dilated calyces with normal forniceal shape visible
- HN III = marked dilatation of the renal calyces and pelvis larger than 10 mm with loss of forniceal and papillar differentiation without parenchymal narrowing
- HN IV = gross dilatation of the collecting system with narrowing of the parenchyma
- In some places HN V is used additionally to communicate an extreme HN with only a membrane-like residuum of the renal parenchyma

Embryology

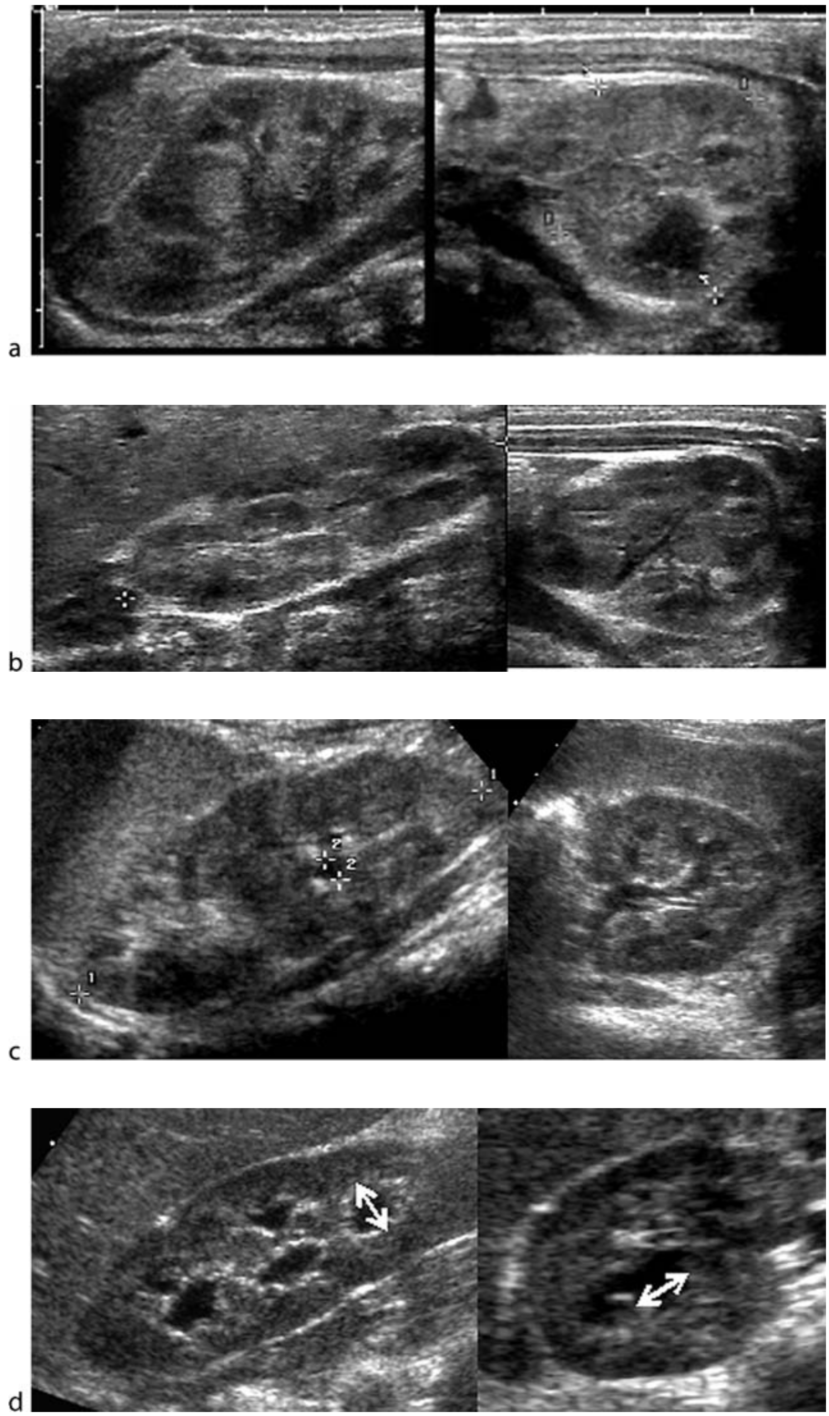
Embryology varies with the underlying disease.

Clinical Presentation

HN itself has no typical clinical presentation: clinical symptoms depend on degree of HN, patient age, potential underlying causes (e.g. secondary HN in tumour conditions), whether HN is uni- or bilateral, and additional complications such as urinary tract infection.

Imaging

HN is usually detected during foetal US, in screening situations, or—far less commonly—in a focussed US examination of the urinary tract or the abdomen based on clinical symptoms. The degree of dilatation may vary with patient hydration and bladder filling, therefore a standardised assessment is recommended. As a variety of conditions can lead to some degree of dilatation, the purpose of imaging is not only to detect HN, but also to help to differentiate the various entities such as physiological distension due to diuresis or (neonatal) system laxity, reactive laxity in infection, refluxing uropathy with consecutive dilatation of the ureter and renal pelvis, or obstructive uropathy due to an obstruction at any level of the urinary tract. Finally, non-obstructive and non-refluxive, purely dilative uropathy with macro-/mega-/hydrocalyces, calyceal diverticula or just a physiologically

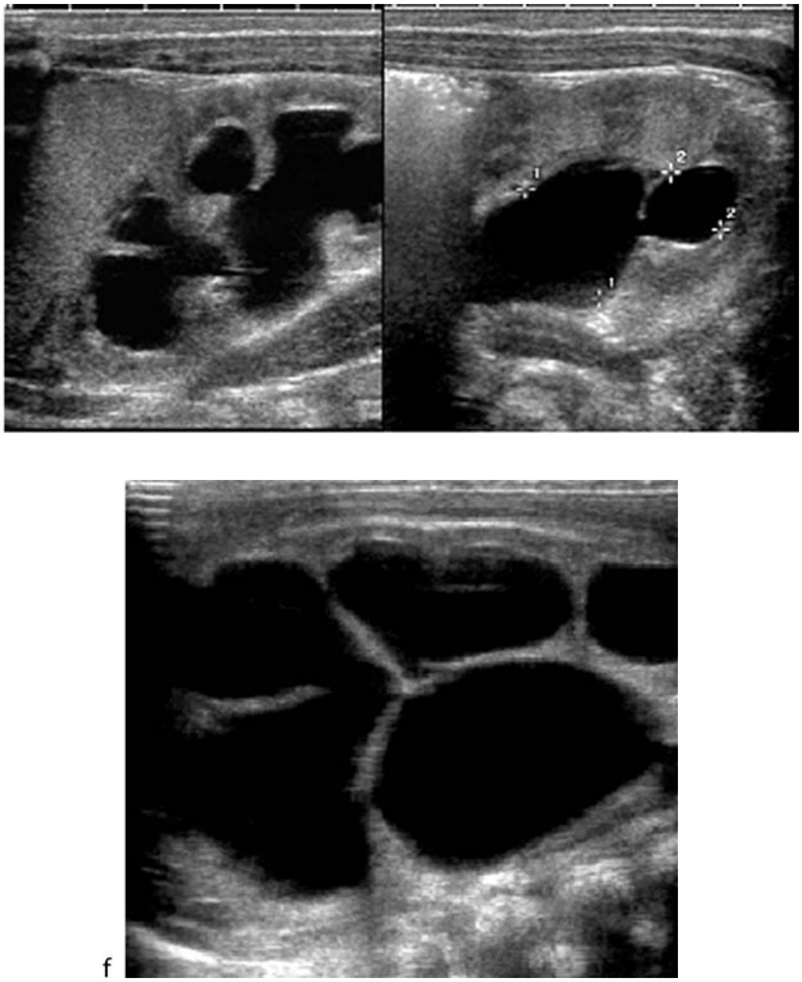


Hydronephrosis in Childhood. Figure 1 (continued)

ectatic renal pelvis should be considered. Standardised imaging algorithms may be helpful for a thorough and economic work-up of these babies with particularly prenatally diagnosed HN (Table 1).

Imaging Modalities

Basically, ultrasound (US) in a standardised fashion and a well-hydrated child is the primary imaging tool. It allows for adequate initial assessment of dilatation of the ureter, e



f

Hydronephrosis in Childhood. Figure 1 **Neonatal grading of hydronephrosis on US, adapted according to the 'SFU' grading system, in longitudinal (left) and axial (right) display. HN 0˚ = no visualization of any fluid within the collecting system HN 1˚ = only renal pelvis filled with fluid and thus visible HN 2˚ = some calyces visible, but normal shape of calyces and normal parenchyma HN 3˚ = dilated calyces (⇔) with flattened fornices, rounded papillas, without parenchymal narrowing HN 4˚ = gross dilatation of the entire collecting system (++) with narrowing of the parenchyma HN 5˚ = extreme dilatation of the distorted collecting system with only a residual rim of parenchyma (only used in a few centres to describe a monstrous HN 4˚).**

the renal pelvis and the calyces with simultaneous comprehensive assessment of the renal parenchyma, and for follow-up. The use of extended US criteria based on indirect signs such as bladder wall morphology, changing degree of calyceal dilatation, thickened urothelium (▶urothelial sign), parenchymal structure analysis or calyceal shape, or of colour Doppler sonography (i.e. accessory renal vessel causing uretero-pelvic junction obstruction, retrocaval ureter, etc.) often allows to narrow the differential diagnosis and to set up the consecutive imaging pathway (Fig. 2). Note that age-dependent normal values for renal size and age-dependent appearance of the renal parenchyma should be considered, as well as correlation of the findings with the state of hydration and bladder filling (see entry 'Urinary Tract, Anatomy'). A post-void evaluation may help to differentiate various conditions and should be part of any compulsory urinary tract US examination. Depending on the initial findings and the suspected diagnosis, only US follow-up (in low-degree HN without any other clinical symptoms, e.g. in screening conditions or after foetal US), a thorough work-up for vesico-ureteric reflux (VCUG and/or echo-enhanced cystosonography, as well as radionuclide cystography and renal scintigraphy—see entry 'VUR'),

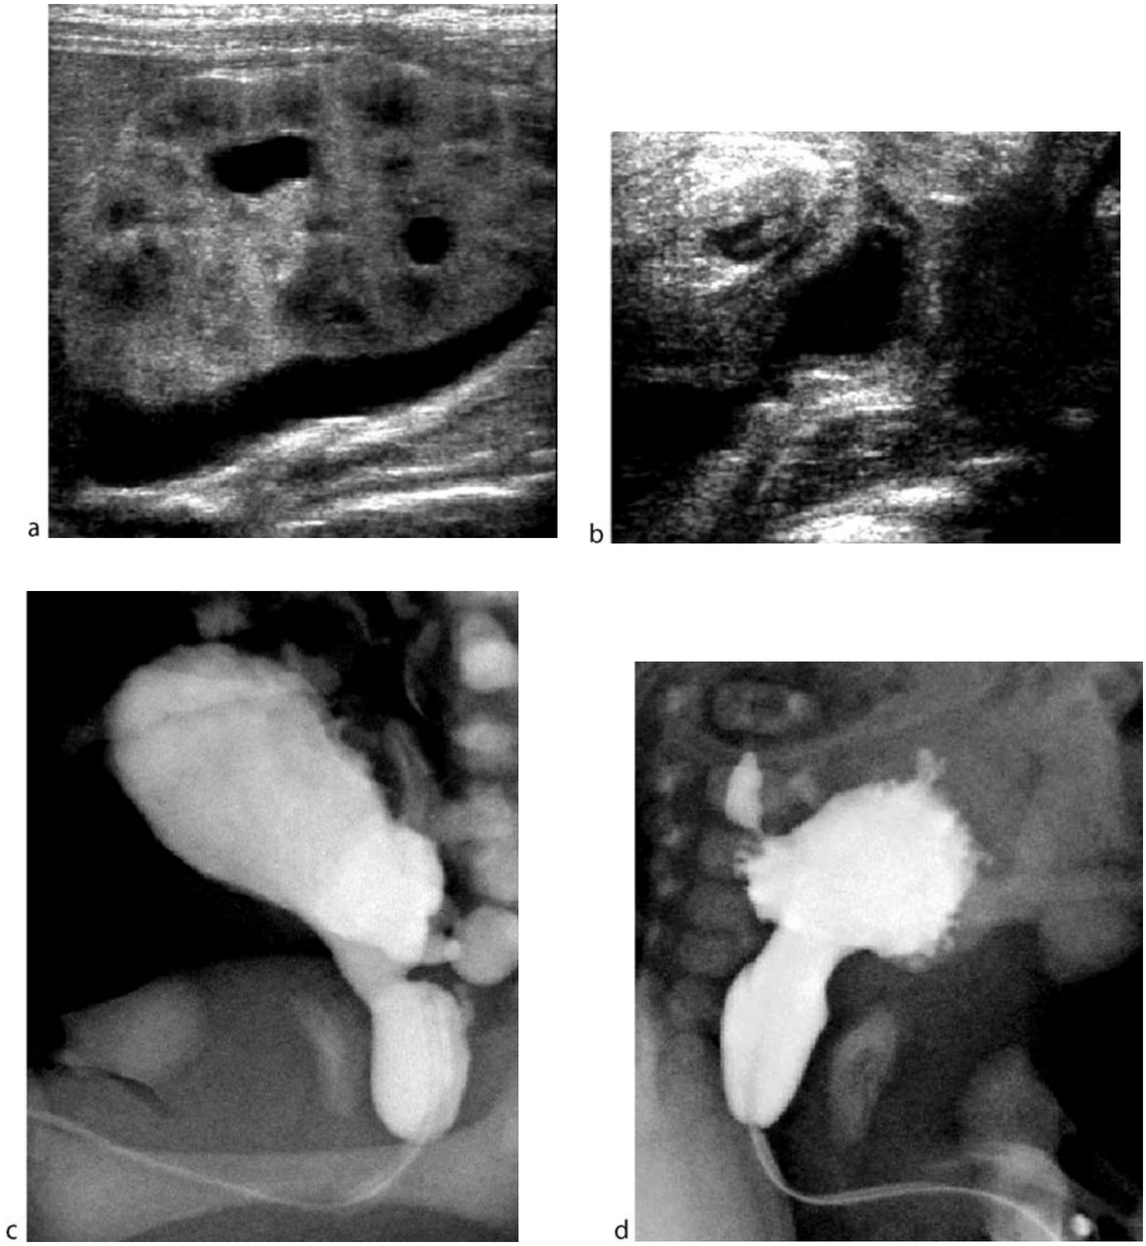
US of the right kidney at the level of the renal pelvis: note the thickened pelvic wall known as the 'urothelial sign' (marked ++ in the axial view) that is reported in urinary tract infection and ▶obstructing or refluxing uropathy.

or an imaging protocol for the assessment of obstructive uropathy (see entry 'Obstructive Uropathy', using diuretic renography and MR-urography/IVU) will become indicated.

Imaging Algorithms (Table 1)

As the knowledge on pathogenesis and physiological development of various conditions is constantly deepening, the imaging algorithms for working-up neonates and



Hydronephrosis in Childhood. Figure 3 **Imaging findings in PUV–US (a and b) and VCUG (c and d). (a) Longitudinal US section of the right kidney with perirenal urinoma (due to intra-uterine calyceal rupture) shows mild dilatation of the collecting system with some parenchymal inhomogeneity as well as a parenchymal cyst as a sign for dysplasia. (b) Perineal US (sagittal plane) demonstrates a posterior urethral valve (PUV) in the same neonate; note the thickening of the bladder wall with some irregularity of the inner urinary bladder wall contour. (c and d) VCUG demonstrates PUV with bladder diverticula and VUR on spot films in lateral (c) and anterior–posterior projection (d).**

infants with HN are constantly undergoing changes—however, at present, usually US follow-up is recommended in low-degree HN; VCUG or echo-enhanced urosonography is suggested for mid-grade HN (for differentiation of refluxing versus obstructive uropathy), and an additional diuretic renal scintigraphy or diuretic MR-urography (or IVU, if MR-urography is unavailable) are suggested for cases with persisting high-grade HN or deterioration of mid-grade HN. There is one additional aspect that needs to be considered: Neonatal boys with huge bladders, bladder wall thickening and particularly gross HN may suffer from ►posterior urethral valves; furthermore the 'Prune belly syndrome' should be considered. In these conditions early imaging and intervention (US, VCUG, cystostomy or/and nephrostomy) may become indicated during the earlier days of life for obstructive renal insufficiency (Fig. 3).

Diagnosis

Diagnostic features depend on the underlying cause and HN grade. Diagnosis is made based on imaging that depicts dilatation of the collecting urinary system. On MRU, scintigraphy and IVU, missing or delayed contrast excretion and delayed drainage of the contrast material or radiotracer indicate significant obstruction. In severe unilateral acute obstruction DDS may exhibit asymmetrically elevated resistive indices of the affected kidney.

Hydrops, Gallbladder

This condition, also called "mucocele of the gallbladder," is characterized by the massive distension (more than 5 cm in the transverse section) of the gallbladder lumen as a result of prolonged obstruction of the cystic duct usually caused by an impacted stone. The distended gallbladder contains clear mucus (white bile) produced by the mucosal epithelial cells. This condition may be either asymptomatic or symptomatic with right upper quadrant discomfort or pain. A palpable mass is usually appreciable in the right upper quadrant. US shows an enlarged gallbladder of biconvex shape with an anechoic content, although sludge or stones can be present. The gallbladder wall usually shows a normal thickness.

Hyperparathyroidism

Thomas M. Link
Clinical Director MQIR, Department of Radiology, San Francisco, USA
tmlink@radiology.ucsf.edu

Synonyms and Definitions

▶Primary hyperparathyroidism is due to an increased secretion of parathyroid hormone (PTH) induced by overactive parathyroid glands. In ▶secondary hyperparathyroidism, a metabolic disorder such as kidney failure with decreased calcium levels in the blood leads to increased PTH levels. ▶Tertiary hyperparathyroidism is defined as an autonomous production of PTH by the parathyroid glands, which was originally induced by a metabolic disorder with secondary hyperparathyroidism. ▶Renal osteodystrophy due to chronic renal failure encompasses a bone disease that is characterized by secondary hyperparathyroidism, osteomalacia, and osteoporosis.

Pathology/Histopathology

PTH maintains appropriate serum calcium concentrations, regulates bone metabolism, and is essential for bone remodeling. It affects osteoclasts and osteoblasts, but osteoclastic activity is more pronounced with pathological serum concentrations of PTH. As bone is resorbed, fibrous tissue replaces it; microfractures and hemorrhage may occur, and subsequent growth of fibrous tissue may cause ►brown tumors.

Primary hyperparathyroidism is due to an adenoma of the parathyroid gland in 50–80% of cases, to diffuse hyperplasia in 10–40%, and to multiple adenomas in 10%. Rarely, it is due to a carcinoma of the parathyroid gland. The differential diagnosis should always include multiple endocrine neoplasia (types I or IIA).

Secondary hyperparathyroidism is caused by chronic hypocalcemia, either due to chronic renal failure or intestinal malabsorption. Chronic renal failure is accompanied by other changes with elevated phosphate levels and reduced renal production of 1,25-dihydroxycholecalciferol or vitamin D3. Alkaline phosphatase is frequently increased. In patients on long-term hemodialysis, an accumulation of aluminum prevents mineralization of osteoid. All of this may lead to osteopenia, osteomalacia, and insufficiency fractures. Renal osteodystrophy is a complex disease that has features of secondary hyperparathyroidism, osteomalacia, and osteoporosis but also a varying degree of osteosclerosis. Bone resorption goes along with fibrous replacement of the bone marrow, and brown tumors may develop if osteoclastic activity is substantial. Osteosclerosis is also a typical finding and may be due to the anabolic activity of PTH, an increase in woven bone, or accompanying oxalate deposition. In addition, certain proteins such as beta-2-microglobulin are no longer eliminated by the kidneys, resulting in deposition of amyloid.

Tertiary hyperparathyroidism develops in patients with chronic secondary hyperparathyroidism with stimulated growth of the parathyroid glands, causing an autonomous adenoma. This goes along with hypercalcemia and inability to control osteomalacia despite vitamin D therapy.

Clinical Presentation

Primary hyperparathyroidism typically presents with hypercalcemia after routine laboratory testing. Symptomatic bone disease is found in 10–25% of the patients, and one of the earliest findings may be nonspecific back pain. Other important clinical findings include nephrolithiasis (in 10–20%), pancreatitis, and peptic ulcer disease as well as neuromuscular, neuropsychiatric, and cardiovascular disease.

In secondary hyperparathyroidism features of renal failure are usually present, and bone and joint pain may develop; this pain is usually vague and commonly located in the lower back, hips, knees, and legs. More severe pain may be due to insufficiency fractures or to periarticular deposition of hydroxyapatite, which typically occurs with marked hyperphosphatemia. In addition, muscular weakness or bowing deformities of the weight-bearing long bones may be found.

Imaging

Conventional Radiographs

Conventional radiography is the standard imaging procedure in the diagnosis of bone changes induced by hyperparathyroidism. In primary hyperparathyroidism radiographs of the hands may show subperiosteal resorption, in particular at the tufts of the distal phalanges and the radial side of the middle phalanges II and III. These findings are pathognomic (Fig. 1). Other typical findings include resorption of the lamina dura around the teeth, the distal clavicle, and the sacroiliac joints with widening of the joint spaces. Resorptive changes at the sternoclavicular and acromioclavicular joints, the symphysis, and the ribs are also demonstrated. In skull radiographs, a salt-and-pepper appearance is described that consists of intermingled areas of decreased density with small sclerotic areas (1).

Radiographs of the skeleton may show osteopenia, which may be generalized or asymmetric. Fine trabeculations are lost, and the bone structure may appear coarse or thickened. In later stages a ground-glass pattern may be found. However, it should be noted that on conventional radiographs bone loss must be in the order of more than 30% in order to be diagnosed. In addition to subperiosteal resorption, intracortical, endosteal, subligamentous, and subtendinous bone resorption may be found in hyperparathyroidism.

In more advanced disease, brown tumors are demonstrated, which are well-circumscribed lytic lesions of bone due to focal osteoclastic resorption and subsequent fibrous replacement. These lesions may be single or multiple, with expansion of the overlying bone. Typical locations are the pelvis and femur, clavicle, ribs, and mandible. After treatment of the hyperparathyroidism, these tumors usually calcify.

Calcium pyrophosphate deposition disease (CPPD) may also be observed with calcification of the menisci of the knee and triangular fibrocartilage. It is more common in primary than in secondary hyperparathyroidism.

Findings in secondary hyperparathyroidism are very similar to those in primary hyperparathyroidism. In a previous study by Mayet et al that analyzed radiographic findings in patients with secondary hyperparathyroidism, pathological changes were found in hand radiographs of 56% of the patients, in 45% at the acromioclavicular joints, in 31% at the shoulders, and in 27% at the pelvis (2).

Hyperparathyroidism. Figure 1 **Hand radiograph in an adolescent with end-stage renal failure and resorptive bony changes at the diaphyses, in particular of the middle and proximal phalanges II and III at the radial aspect (*arrows* in a). In addition, a brown tumor (*arrow* in b) and widening of the growth plates (*asterisk* in b) are demonstrated, the latter being a finding consistent with rickets.**

In renal osteodystrophy additional features of osteomalacia and sclerotic bony changes are shown. These sclerotic changes occur in approximately 20% of patients and may be found at the spine, pelvis, ribs, and extremities, more frequently at the metaphyses and sometimes at the epiphyses, which may mimic aseptic necrosis of the bone. One of the most typical findings is the rugger-jersey spine with bands of increased bone density adjacent to the endplates.

Extraosseous calcification is also a characteristic finding in secondary hyperparathyroidism, in particular in long-standing disease. These calcifications include tumoral calcifications around the joints (hip, shoulder, and knee), with or without bony erosion, vascular, corneal, subcutaneous, and visceral calcifications. More rare findings include periosteal reactions around the metatarsals, femora, and pelvis.

Osteomalacia may sometimes be predominant in patients with renal osteodystrophy with Looser zones and pathologic fractures, bone deformities, and osteopenia. In children, typical changes of the growth plate with widening and disorganization as well as irregularities of the metaphyseal margins may be found; these findings are consistent with rickets (3).

In patients on long-term hemodialysis, additional findings are shown that may be due to aluminum intoxication or deposition of amyloid: (i) Aluminum intoxication may cause osteomalacia and rickets with insufficiency fractures, and (ii) amyloid depositions may be found in the bone appearing as lytic, sharply demarcated, juxta-articular lesions. In addition, (iii) destructive spondylarthropathies, (iv) osteonecrosis, (v) articular rheumatologic manifestations, and (vi) tendonitis and tendon rupture as well as (vii) an increased incidence of musculoskeletal infections may be found (3).

DXA and QCT

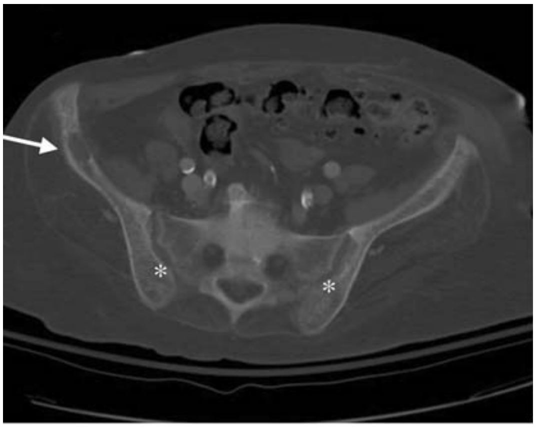
Dual X-ray absorptiometry (DXA) and quantitative computed tomography (QCT) are used to assess loss of bone mass and are more sensitive to these changes than conventional radiographs. However, loss of bone mineral density (BMD) is a nonspecific finding for hyperparathyroidism. Also note that due to sclerotic bony changes in renal osteodystrophy, BMD may be falsely increased and not correctly reflect actual fracture risk.

CT

Findings that may be better visualized with computed tomography (CT) than with conventional radiography are brown tumors and insufficiency fractures, particularly of the pelvis. Erosive changes of the sacroiliac joints may also be better characterized with CT imaging. The axial CT image of the pelvis presented in Fig. 2 shows, in addition to a brown tumor in the right iliac wing and erosive changes of the sacroiliac joints, a coarse, ground-glass-like trabecular bone structure. Soft tissue calcifications are also better depicted with CT, and extensive Schmorl's nodes may be well visualized.

MRI

Magnetic resonance imaging (MRI) is useful to detect insufficiency fractures or reactions. It also may show



Hyperparathyroidism. Figure 2 Computed tomography of the pelvis in a patient with secondary hyperparathyroidism shows resorptive changes at both SI joints (*asterisk*) and a brown tumor within the right iliac bone (*arrow*).

osteonecrosis and slipped capital femoral epiphyses. More important, however, is that in the absence of conventional radiographs and CT images, MRI findings may be confused with those found in neoplastic disease such as diffuse nonspecific bone marrow changes, brown tumors, and tumorlike metastatic calcifications. The MR signal in these latter calcifications may be variable, and contrast enhancement may also be found. Fig. 3 shows metastatic calcifications in the second digit of the left hand in a patient with secondary hyperparathyroidism, which were interpreted as tumors at first, as they show contrast enhancement in the coronal fat-saturated T1-weighted images, but the conventional radiograph clearly shows the extensive soft tissue calcifications. Brown tumors can sometimes show intraosseous and extraosseous components with cystic changes, which can easily be mistaken for primary bone tumors or metastatic disease in the absence of findings indicating end-stage renal disease.

Skeletal scintigraphy may present pathological findings that may help in differentiating hyperparathyroidism from malignant disease in the presence of increased

Hyperparathyroidism. Figure 3 Coronal T1-weighted magnetic resonance imaging without (a) and with contrast enhancement and fat saturation (b) of the left hand, showing partially enhancing tumorlike lesions with low signal intensity areas (*arrows*) at the second digit. Radiograph of the left hand (c) clearly shows calcifications at the second and fifth digits (*arrows*).

calcium levels. Typical findings include increased uptake of technetium throughout the skeleton; sometimes a so-called super-scan is found. Typically increased uptake is most apparent at the axial skeleton, the calvarium, the mandible, the long bones, and the sternum. In secondary hyperparathyroidism due to renal failure, kidney and bladder may not be well visualized on technetium scans.

Diagnosis

To diagnose primary or secondary hyperparathyroidism, the history and clinical findings are extremely important (4). Increased calcium levels in primary hyperparathyroidism and a history of end-stage renal failure in secondary hyperparathyroidism are key findings required to correctly assess imaging findings. Although pathology on conventional radiographs and CT images is usually fairly straightforward, it may be more difficult to interpret this pathology on MR studies.

The differential diagnosis of intracortical bone resorption includes hyperthyroidism and acromegaly, while subchondral resorptions and deformities may be similar to those found in inflammatory arthropathies (rheumatoid and psoriasis arthritis), osteonecrosis, and chondrocalcinosis. Resorptions at the sacroiliac joints may sometimes appear as in ankylosing spondylitis. Brown tumors can be difficult to differentiate from primary or secondary bone tumors. Bony sclerosis is also found in myelofibrosis, mastocytosis, Paget's disease, neoplastic disorders, and sarcoidosis, and after radiation therapy. Soft-tissue calcifications have to be differentiated from calcium–pyrophosphate deposition disease.

Synonym

Benign prostatic hypertrophy

Definition

Benign prostatic hypertrophy (BPH) is a noncancerous enlargement of the prostate gland that may restrict the flow of urine from the bladder consisting of nodular hypertrophy of the fibrous, muscular, and glandular tissue within transition zone and periurethral areas.

Epidemiology

Thirty million men worldwide have symptoms related to benign enlargement of the prostate. BPH is first detectable around the fourth decade of life (1). The prevalence of BPH is only 8% in males in their 40s (2). According to the National Institutes of Health (NIH), BPH affects more than 50% of men over age 60 and as many as 90% of men over the age of 70.

Pathophysiology

The cause of BPH of the prostate gland is unknown. It is possible that the condition is associated with hormonal changes that occur as men age. The testes produce the hormone testosterone, which is converted to dihydrotestosterone and estradiol. High levels of dihydrotestosterone, a testosterone derivative involved in prostate growth, may accumulate and cause hyperplasia. How and why levels of dihydrotestosterone increase remains a subject of research (3, 4). BPH is a proliferative process of the cellular elements of the prostate (i.e. an enlarged prostate). BPH involves both the stromal and epithelial elements of the prostate arising in the periurethral and transition zones of the prostate gland (for the distribution of BPH, see Table 1). The pathogenesis of BPH is still largely unresolved, but multiple partially overlapping and complementary theories have been proposed, all of which seem to be

operative at least to some extent. At the moment two theories are hypothesized, namely the neoplastic and hormonal theory. The first theory assumes that the enlargement is a benign neoplasm. The latter theory, hypothesize that with advancing years, the balance between androgenic and estrogenic stimulation of the prostate is deregulated. As aging occurs, estrogenic stimulation becomes more active with concomitant decline in androgenic activity. Hypertrophic changes first commence in the region of the inner group of prostatic glands in the lateral lobes of the prostate. Progressive enlargement causes indentations of the urethra and atrophy of the outer glands with compression of the stroma to form a false capsule around the enlarging fibroadenomyoma. The enlarged prostate will therefore have a true and false capsule with the main blood supply, between these two capsules. The hypertrophied tissue is relative avascular. The prostate grows in two different ways. In one type of growth, cells multiply around the urethra and compress it. Which may result in that the bladder becomes hypertrophied with trabeculation (Fig. 1), sacculation, and, occasionally, diverticulum formation. The second type of growth is middle lobe prostate growth in which cells grow into the urethra and the bladder outlet area. Castrated males do not develop BPH.

Symptoms

Many symptoms of BPH stem from obstruction of the urethra and gradual loss of bladder function, which results in incomplete emptying of the bladder. Common symptoms of BPH include hematuria (caused by straining to void), dribbling after voiding, frequent urination (nocturia), feeling that the bladder has not emptied completely after urination, weak urine stream, leakage of urine, and sudden urgent need to urinate (5). Acute urinary retention can result from holding urine for a long time in severe cases of BPH (6). Acute urinary retention causes severe pain and discomfort. Catheterization may be necessary to drain urine from the bladder and obtain relief.

Diagnostic Tests and Imaging Techniques in Benign Prostatic Hypertrophy

Digital rectal examination—This examination gives a general idea of the size and condition of the prostate gland.

Prostate-specific antigen—A prostate-specific antigen (PSA) test can be taken to rule out cancer as a cause of urinary symptoms. However, much remains unknown about the interpretation of PSA levels, the test's ability to discriminate cancer from benign prostate conditions, and the best course of action following a finding of elevated PSA.

Urine flow study—A reduced flow often suggests BPH (7).

Cystoscopy—This examination allows to identify the location and degree of the obstruction and determine the size of the gland.

Transrectal ultrasound—Transrectal ultrasound (TRUS) is useful for determining prostate size in patients with lower urinary tract symptoms. TRUS can assess the prostate anatomy, zonal anatomy, and internal changes (Fig. 2). Prostatic volume can easily be assessed with TRUS. Generally, TRUS is not indicated for the initial evaluation of BPH. Imaging of the prostate using TRUS is recommended in selective patients. Ruling out prostate cancer in patients with elevated PSA (>4 ng/mL) is a strong indication to proceed imaging studies and TRUS-guided biopsies.

Computed tomography—With computed tomography (CT), BPH appears as a homogeneous-enhancing area with well-defined borders (Fig. 3). CT has no

Hyperplasia, Benign, Prostate. Figure 2 Transrectal ultrasound image of the prostate in the axial plane in a 64-year-old patient. In the central gland, two large benign prostatic hyperplasia nodules are present (white arrows).

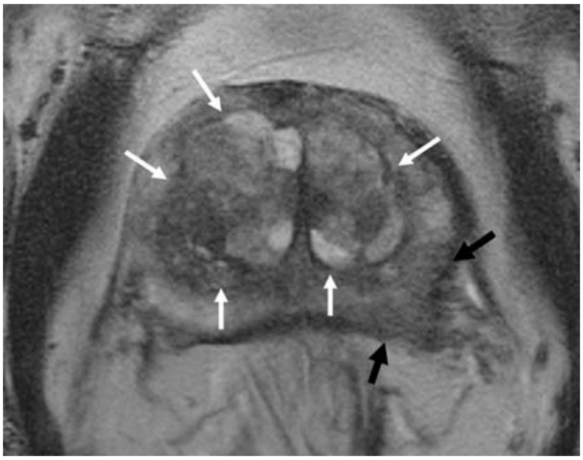
Hyperplasia, Benign, Prostate. Figure 3 Axial CT plane after intravenous contrast agent demonstrates homogeneous enhancing benign prostatic hyperplasia nodules in the central gland of the prostate (white arrows).

place in the evaluation of BPH because of low intraprostatic tissue contrast/resolution, which consequently does not allow the evaluation of the ratio of glandular to stromal tissue in the prostate. Prostate volumes can be estimated with this imaging modality. However, this imaging method is costly and has limited availability.

Magnetic resonance imaging—Magnetic resonance (MR) imaging allows high intraprostatic tissue contrast/resolution, which can be used to estimate prostate volume and glandular to stromal ratio. MR imaging has high accuracy for determining the histologic type (8). BPH nodules appear as nodular heterogeneous (iso- to high) signal intensities lesions with a small rim of low signal intensity in the central gland (9) (Fig. 4).

Positron emission tomography—Positron emission tomography (PET), using $[^{11}C]$acetate, has been reported to be of clinical relevance for the diagnosis of prostate cancer (10). Normal prostate tissue or BPH can show enhanced accumulation of $[^{11}C]$acetate, especially in younger men. Preliminary results indicate that careful interpretation of $[^{11}C]$acetate PET images of prostate cancer is necessary because of the standardized uptake value (SUV) and the early-to-late activity ratio of the SUV for the normal prostate and for BPH overlap significantly with those for prostate cancer (11).

Currently, indication for the treatment in BPH patients is based on subjective measurements of symptoms. Thus, imaging does not play a major role in the evaluation of such patients. However, the primary imaging investigation of choice is TRUS of the prostate, which may be performed either by an urologist or by a radiologist, depending on the local availability of expertise. Also TRUS is a noninvasive, cost-efficient, quick and easily available modality.



Hyperplasia, Benign, Prostate. Figure 4 T2-weighted transverse plane of the prostate in a 63-year-old male. In the central gland of the prostate, two large benign prostatic hyperplasia nodules with low to high signal intensities are present (white arrows). Note the low signal intensity area in the left peripheral zone representing prostate carcinoma (black arrow).

International Prostate Symptom Score—Alternative to imaging modalities, the International Prostate Symptom Score (IPSS) was introduced. This score was developed to quantify and validate responses to the questions asked. A set of seven questions has been adopted worldwide and yields reproducible and quantifiable information, regarding symptoms and response to treatment. Each question allows the patient to choose one of six answers indicating increasing severity of symptoms on a scale of 0–5; the total score ranges from 0 to 35. Questions concern incomplete emptying, frequency, intermittency, urgency, weak stream, straining, and nocturia. The eighth question is known as the bother score and pertains to the patient's perceived quality of life (QOL). Scores can range from 0 (delighted) to 6 (terrible). After calculating the total score for all eight questions, patients are classified as 0–7 (mildly symptomatic), 8–19 (moderately symptomatic), or 20–35 (severely symptomatic).

Treatment

Patients with (mild) symptoms are initially treated with medical therapy. Management with hormone substitutes emerged from the discovery of a congenital form of pseudohermaphroditism secondary to dihydrotestosterone deficiency. This deficiency produced a hypoplastic prostate. Type II 5-alpha reductase is an enzyme responsible for the conversion of testosterone to dihydrotestosterone. The 5-alpha reductase inhibitors block the conversion of testosterone to dihydrotestosterone, causing lower intraprostatic levels of dihydrotestosterone. This leads to inhibition of prostatic growth, apoptosis, and involution. Transurethral resection of the prostate (TURP) has long been the most common method by which obstructing prostate tissue is removed through the urethra. The indications for surgical intervention include acute urinary retention, failed voiding trials, recurrent gross hematuria, urinary tract infection, and renal insufficiency secondary to obstruction. TURP has a significant risk of morbidity (18%) and mortality (0.23%). Prostatic stents are flexible devices that can expand when put in place to improve the flow of urine past the prostate. However, their use has been associated with encrustation, pain, incontinence, and overgrowth of tissue through the stent, possibly making their removal quite difficult. Their full role and long-term effects are not fully known yet. Radical prostatectomy is now reserved for patients with very large prostates, patients with concomitant bladder stones or bladder diverticula, and patients who cannot be positioned for transurethral surgery.

Hyperplasia, Breast

Luis Pina
Department of Radiology, Clínica Universitaria de Navarra, Spain
ljpina@unav.es

Definition

Hyperplasia is the proliferation of epithelial cells lining the wall of ducts and lobules. It may involve the ducts (ductal hyperplasia) or the lobules (lobular hyperplasia). Three categories of ductal hyperplasia have been reported: ►mild ductal hyperplasia, moderate or florid ductal hyperplasia, and atypical ductal hyperplasia (1).

Pathology/Histopathology

Hyperplasia shows no specific features on gross examination (2). Mild ductal hyperplasia consists of a proliferation of more than two but less than four cell layers between basement layer and lumen, without cellular atypia (1). Moderate or florid ductal hyperplasia is defined as an intraductal epithelial proliferation greater than four cell layers, usually enough to distend the ductule and bridge the lumen. Some cellular atypia is seen (1).

Atypical ductal hyperplasia is characterized by the proliferation of evenly distributed monomorphic cells with ovoid to round nuclei. Structures such as micropapillae, arcades, bridges, and others may be found, mimicking ductal carcinoma *in situ*. Differentiating between the two entities may be difficult. The criteria used include the involvement of only one duct or a size equal or less than 2 mm. Nevertheless, an important variability may be found between pathologists (1, 2).

►Atypical lobular hyperplasia is composed of cells similar to those found in lobular carcinoma *in situ*. The differentiation may be difficult. If less than half of the acini are filled, distorted, or distended by the proliferation, the lesion is considered atypical lobular hyperplasia. If there are luminal spaces free of cells and if different types of cells are intermixed, the lesion is also considered atypical lobular hyperplasia instead of lobular carcinoma *in situ* (1).

Clinical Findings

Hyperplasia can affect females at virtually any age, although most women are between 35 and 60 years of age (1).

Hyperplasia is an alteration associated with no specific clinical features. Most cases are microscopic in dimension and thus nonpalpable and asymptomatic (2). However, hyperplasia may be associated with other coexisting lesions, such as radial scar-complex sclerosing lesion, pseudoangiomatous stromal hyperplasia, papilloma, sclerosing adenosis, and duct ectasia. The clinical findings may be due to the accompanying lesion and present as pain, nipple discharge, or a palpable mass, usually referred to as breast thickening.

Mild hyperplasia does not increase the risk of developing breast cancer. Moderate or florid hyperplasia carries a small risk (relative risk about 1.5). However, atypical ductal hyperplasia and atypical lobular hyperplasia are well-recognized risk factors for breast cancer, with a fourfold and even tenfold increased risk if there is a marked family history (1). It is controversial whether ductal hyperplasia may evolve into atypical ductal hyperplasia or low nuclear-grade ductal carcinoma *in situ*.

Imaging

Mammography

There are no characteristic findings on mammography to diagnose hyperplasia. The diagnosis is made based on biopsy of suspicious calcifications, masses, or architectural distortions (Figs. 1, 2 & 3), but the former are the most frequent (3). The calcifications associated with ductal hyperplasia, atypical ductal hyperplasia, and low nuclear-grade ductal carcinoma *in situ* are similar, being usually round, punctate, or irregular. No linear calcifications are found due to the lack of necrotic debris.

Ultrasound

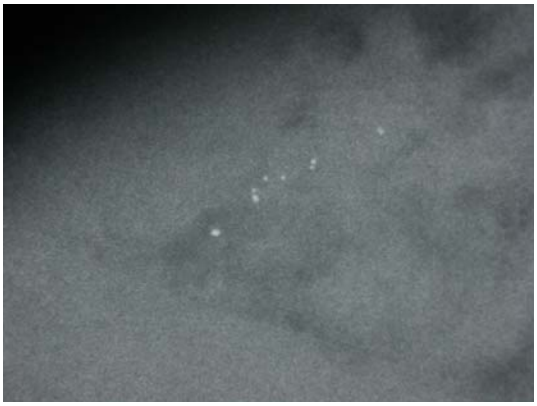
There are no conclusive ultrasonographic features for diagnosing hyperplasia. If hyperplasia is associated with other lesions, the ultrasonographic appearance is usually that of the accompanying alteration (3).

Magnetic Resonance

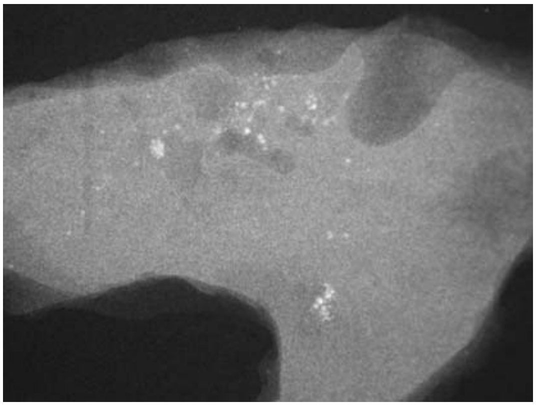
Both atypical ductal hyperplasia and atypical lobular hyperplasia may enhance after paramagnetic contrast administration.

Nuclear Medicine

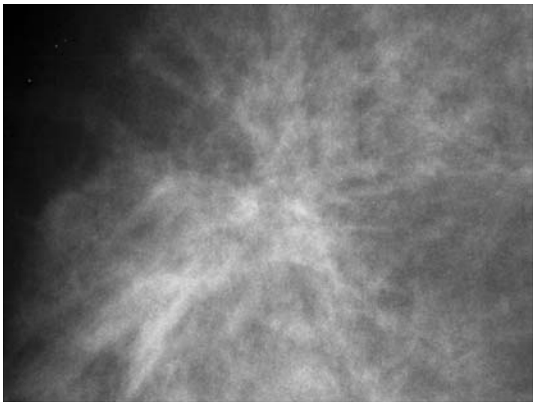
Nuclear medicine does not play a role in the diagnosis of hyperplasia.



Hyperplasia, Breast. Figure 1 Round calcifications in a linear distribution. Pathology: florid ductal hyperplasia.



Hyperplasia, Breast. Figure 2 Surgical specimen of calcifications of intermediate concern, rounded and flaky. Pathology: atypical ductal hyperplasia.



Hyperplasia, Breast. Figure 3 Architectural distortion. The lesion was a complex sclerosing lesion with atypical ductal hyperplasia. In this case, the complex sclerosing lesion was the cause for the mammographic image, and the atypical hyperplasia was not visible.

Diagnosis

Hyperplasia is a histopathologic term, usually diagnosed as the result of biopsy of nonpalpable lesions such as breast calcifications. The widespread use of mammography and percutaneous biopsy techniques has led to a increasing number of cases. The management after percutaneous breast biopsy is important. A result of atypical ductal hyperplasia at 14-gauge core biopsy underestimates carcinoma in 20–50% of cases (4, 5). Vacuum-assisted devices decrease this underestimation, but underestimation persists in up to 38% of cases (4, 5). Even the complete removal of the mammographic lesion does not ensure the absence of carcinoma. Thus, a diagnosis of atypical ductal hyperplasia at percutaneous biopsy warrants surgical excision. Atypical lobular hyperplasia at percutaneous biopsy is also an indication for surgical excision. However, mild or ►moderate ductal hyperplasia diagnosed at core needle biopsy does not need further intervention.

Hyperplasia, Focal, Nodular Hepatic

Riccardo Lencioni, Marzio Perri
Department of Diagnostic and Interventional Radiology University of Pisa, Pisa, Italy
lencioni@med.unipi.it

Definition

Focal nodular hyperplasia (FNH) of the liver is a completely benign lesion characterized by nodular hyperplasia of hepatic parenchyma around a central scar containing an anomalous artery.

Epidemiology

FNH is the second most common benign tumor of the liver, with an estimated prevalence of 0.4–0.8% in unselected autopsy series. The tumor has a female:male ratio of between 2 and 26:1 and the average age at presentation is between the ages of 35 and 50 years.

Pathogenesis

FNH appears to be the result of a hyperplastic response of the hepatic parenchyma to an arterial lesion and/or portal venous ischemia. A congenital vascular malformation is suggested by the presence of a central fibrous scar containing abundant arteries with spider-like malformations and the association with other vascular abnormalities such as hepatic hemangioma and hereditary hemorrhagic telangiectasia. The finding of unbalanced expression of angiopoietin1 and angiopoietin2 genes coupled with expression of angiopoietin1 protein by the endothelial cells of dystrophic vessels, suggests a role of angiopoietin genes in FNH. Clonality studies and overexpression of important genes, involved in cell omeostasis such as Bcl-2 and transforming growth-factor alpha, support the important role for hepatocellular proliferation, in FNH. Conversely, the role of oral contraceptives in FNH is disputed. Their use has been associated with increase in size and vascularity of FNH nodes and tumor regression was observed after drug withdrawal.

Pathology and Histopathology

Macroscopically, the vast majority of the patients have a single, pale tan to light brown lesion causing a central scar radiating into the liver tissue. FNH may present with classical and nonclassical forms. The latter include telangiectatic, mixed hyperplastic/adenomatous, with cytologic atypia and multiple FNH syndrome forms. Eighty percent of the patients present with the classical form, which is characterized by abnormal nodular architecture, malformed-appearing vessels, and bile duct proliferation. The majority of classical forms contain one to three macroscopic scars. Microscopically, classical FNH lesion shows nodular hyperplastic parenchyma, the nodules being completely or incompletely surrounded by fibrous septa. The central scar contains malformed vessels of various caliber, mostly large and tortuous arteries showing intimal or muscular fibrohyperplasia. Dense bile ductular proliferation accompanies the vascular structures both in the central scars and in the radiating septa with histologic cholestasis. A mild degree of macrovascular steatosis is often present. Nonclassical forms of FNH show atypical histology and bile ductular proliferation, but lack either nodular architecture or malformed vessels.

Clinical Presentation

FNH is usually an incidental finding but a few patients may have symptoms as a palpable mass or hepatomegaly. Liver chemistry is usually unaltered. In a few patients, FNH may cause slight elevations in serum GGTP levels. Serum tumor markers AFP, Ca 19.9, and CEA are invariably negative.

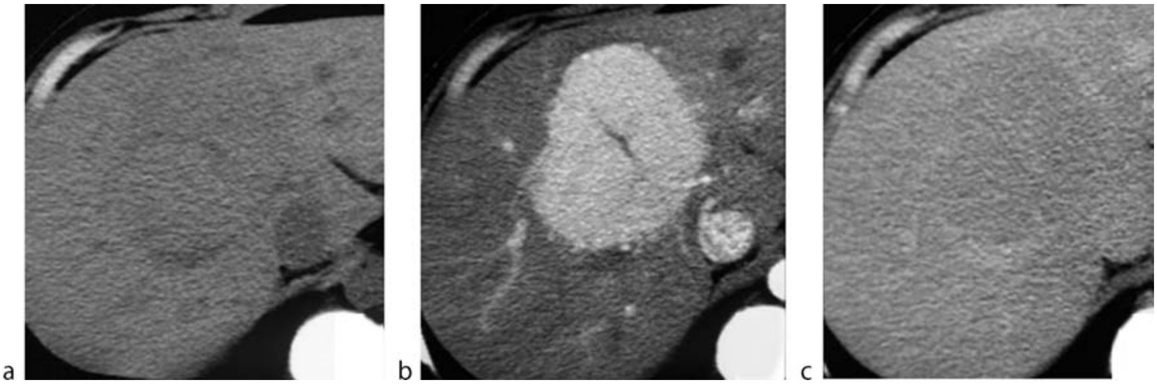
Imaging

Ultrasound and Contrast-Enhanced Ultrasound

FNH may have variable ultrasound (US) features. It usually appears as a round mass that is slightly hypoechoic or slightly hyperechoic with respect to liver parenchyma. Some lesions may be isoechoic to liver and be detected only because of vascular displacement. The lesion is frequently homogeneous. In fact, the detection of the central scar at baseline US is uncommon. Typical findings at color or power Doppler US include the presence of a central feeding artery with a stellate or spoke-wheel pattern determined by vessels running into radiating fibrous septa originating from the central scar. Doppler spectral analysis can show an intralesional pulsatile waveform with high diastolic flow and low resistive index (1). The specificity of US in the diagnosis of FNH has improved following the introduction of US contrast agents. At contrast-enhanced ultrasound (CEUS), FNH shows central vascular supply with centrifugal filling in the early arterial phase, followed by homogeneous enhancement in the late arterial phase. In the portal phase the lesion remains hyperechoic relative normal liver tissue, and becomes isoechoic in the late phase. This pattern has been observed in 85–100% of FNH (2). The central scar becomes detectable as a hypoechoic area in the portal phase of the contrast-enhanced study.

Computed Tomography

FNH is usually isoattenuating or slightly hypoattenuating to surrounding liver at baseline computed tomography (CT) scanning. The detection rate of the central scar, that appears as a hypoattenuating structure, is related to the size of the lesion. It may be identified in 35% of lesions



Hyperplasia, Focal, Nodular Hepatic. Figure 1 Typical FNH on multiphasic spiral-CT. On unenhanced CT scan (a) a slightly hypodense nodule is depicted. At the dynamic enhanced-CT study the nodule shows homogeneous enhancement except for the central scar in the arterial phase (b) becoming isoattenuating with the surrounding liver in the portal venous phase (c).

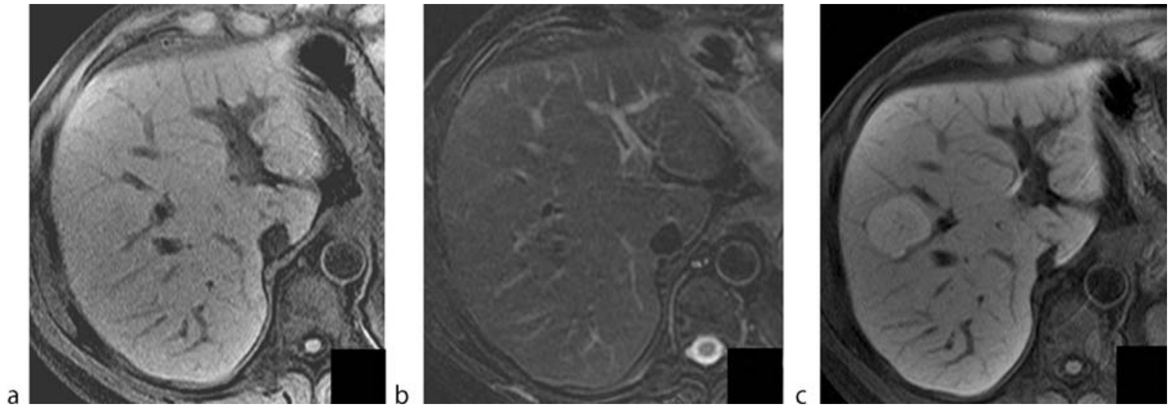
smaller than 3 cm in diameter and in 65% of those exceeding 3 cm (3). FNH shows strong homogeneous enhancement during the arterial phase of the contrast-enhanced CT study. The central scar is typically hypoattenuating during the arterial phase. In the portal venous and delayed phases, FNH becomes isoattenuating to the hepatic parenchyma (Fig. 1). On delayed images, the central scar may become hyperattenuating because of contrast distribution within its fibrous stroma.

Magnetic Resonance

Magnetic resonance (MR) imaging is the most accurate imaging method to characterize FNH. Owing to the affinity of its cells with normal hepatocytes, FNH is usually slightly hypointense or isointense with respect to normal liver parenchyma on T1-weighted images and slightly hyperintense or isointense on T2-weighted images (4). The hallmark of the lesion, the central stellate scar, is usually depicted because of its hypointensity on T1-weighted images and hyperintensity on T2-weighted images, reflecting its pathologic substratum of a vascularized connective tissue (4). At baseline MR imaging, however, the mentioned typical features, that are, homogeneous structure, isointensity to liver, and presence of the central scar, are observed in only 20–25% of the cases. Diagnostic confirmation requires a contrast-enhanced MR study. This is usually performed through serial dynamic imaging following the administration of a Gadolinium chelate (5). FNH shows strong, homogeneous enhancement in the arterial phase sparing the central scar, while it becomes isointense to liver parenchyma in the portal venous and delayed phases. The central scar may show contrast uptake in the delayed phase owing to the interstitial distribution of the contrast agent. These features have a specificity of more than 95% for the diagnosis of FNH (5). However, even with the administration of Gadolinium chelates, the central scar may not be detectable as many as 22% of the FNHs, including 80% of those smaller than 3 cm (5). Liver-specific MR contrast agent provides an alternate strategy to diagnose FNH. Owing to the affinity of its cells with the hepatocytes, FNH takes up hepatocyte-targeted agents, like normal parenchyma. These agents are then trapped within the lesion, since FNH is unable to effectively eliminate the compound *via* biliary excretion. Hence, it appears hyperintense to normal parenchyma on T1-weighted images (Fig. 2). Also, the central scar, that does not take up the hepatocyte-targeted agent—becomes well delineated in up to 90% of cases. This approach may enable diagnosis of 90% of the FNHs with atypical features at the baseline and conventional contrast-enhanced dynamic study (5). The diagnosis of FNH has also been achieved with the use of RES-targeted agents. Because of its rich Kupffer cell population, FNH takes up iron oxide particles, and shows marked signal intensity decrease on T2-weighted images. The central scar is usually well delineated on postcontrast images as it does not contain RES cells and therefore keeps a high signal intensity.

Nuclear Medicine

^{99m}Tc sulfur colloid scintigraphy has long been used to characterize FNH. In fact, up to 80% of these lesions show uptake owing to their Kupffer cell population. Unfortunately, the uptake of sulfur colloid is not highly specific. In one series, sulfur colloid studies were diagnostic in only about 20% of FNHs.



Hyperplasia, Focal, Nodular Hepatic. Figure 2 Focal nodular hyperplasia after Mn-DPDP. On baseline T1 (a) and T2-weighted (b) images the hepatic nodule is not clearly appreciable. Conversely, on the delayed T1-weighted image after Mn-DPDP administration (c) a hyperintense, well-defined lesion is depicted in the right hepatic lobe.

Diagnosis

FNH is usually incidentally detected. Diagnostic confirmation can rely solely on imaging findings, when the typical features are detected in the proper clinical setting. CT can be used to characterize lesions of medium-to-large size, but has limitations in the diagnosis of small lesions. Although promising results have been recently reported with the use of CEUS, MR imaging is the most accurate technique to diagnose FNH. MR imaging, by means of liver-specific contrast agents, enhances the informations provided by the baseline and dynamic gadolinium-enhanced study, improving the capability in lesion characterization, especially in case of small lesions. The use of percutaneous biopsy should be restricted to cases with questionable findings. In patients with atypical FNH, a scoring system has been proposed to categorize lesions into definite FNH, possible FNH, and negative for FNH.

Definition

Individuals with a systolic blood pressure (BP) of 140 mmHg or more or a diastolic BP of 90 mmHg or more have to be considered as hypertensive. A systolic BP of 120–139 mmHg or a diastolic BP of 80–89 mmHg has recently been defined as prehypertension, which indicates an increased risk for progression to hypertension (1).

Pathology/Pathophysiology

Hypertension can be classified as either essential or secondary. Essential hypertension is the term used when no specific medical cause can be found to explain a patient's condition. Secondary hypertension means that the high BP is secondary to other conditions, such as kidney disease or hormone-producing tumors.

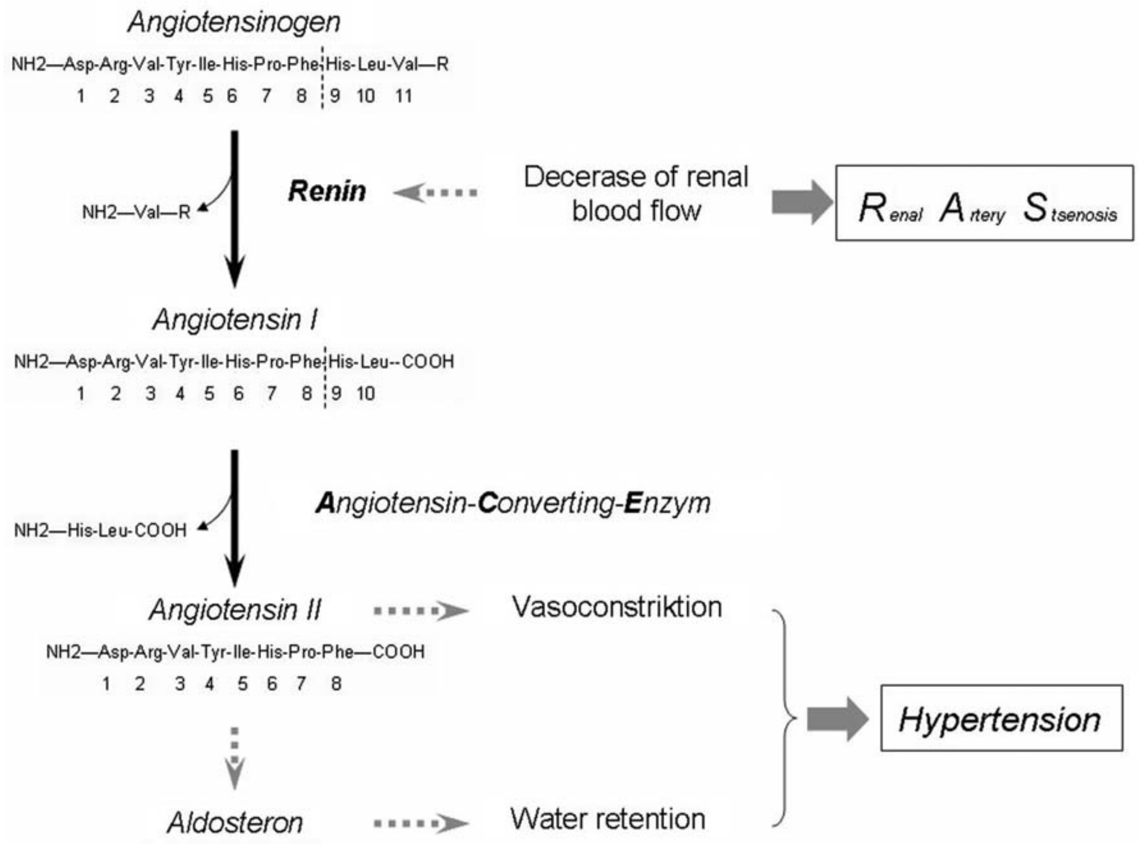
Renovascular hypertension (RVH) is one of the most frequent types of secondary hypertension. It results from stenosis of the main renal artery or one of its major branches. The true prevalence of RVH is unknown but it may account for 1–5% of all cases in hypertensive adults. The pathophysiology of hypertension in renal artery stenosis (RAS) was first described by Goldblatt. Reduction of arterial perfusion pressure in the stenosed kidney leads to activation of the renin-angiotensin-aldosterone system (RAA) causing systemic angiotensin II-dependent vasoconstriction and aldosterone-mediated volume expansion (Fig. 1). Local RAA activation, arterial wall remodeling, and oxidative stress are responsible for maintaining the hypertension. These local paracrine and structural changes may also contribute directly to renal injury (2). In the majority of cases, RVH is caused by either atherosclerotic RAS or fibromuscular dysplasia (FMD). Atherosclerosis accounts for 70–90% of cases of RAS and usually involves the ostium and proximal one-third of the main renal artery (Fig. 2). FMD is a collection of vascular diseases that affects the intima, media, and adventitia of the middle and distal portion of the main renal artery and its major branches. It is responsible for 10–30% of cases of RAS (Fig. 3). Neurofibromatosis, Takayasu's arteritis, and radiation are rare causes of RVH.

Imaging

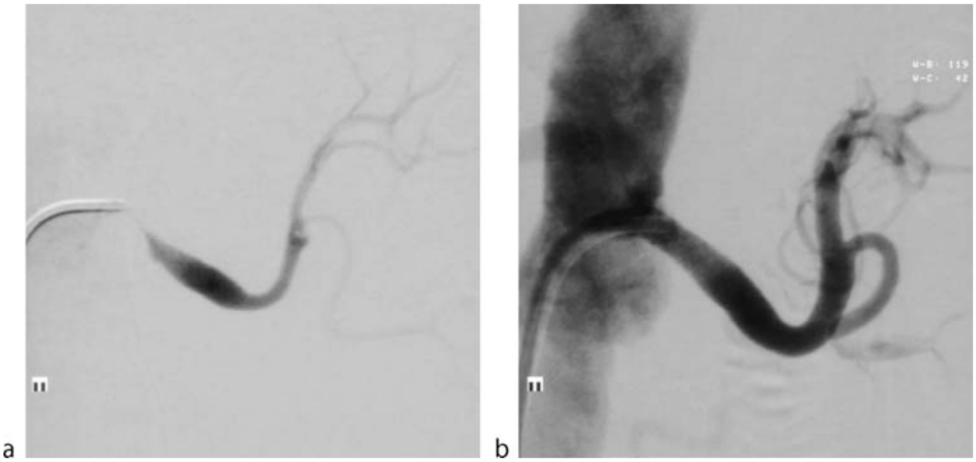
Intra-arterial digital subtraction angiography (*IA-DSA*) is traditionally regarded as the 'gold standard' in assessing renal artery anatomy. Due to its high spatial resolution, DSA is particularly useful in the early detection of FMD, in the diagnosis of intrarenal branch artery stenoses, and in kidneys with complex anatomy, including multiple accessory arteries. Disadvantages of this technique include significant interobserver variation in assessing the degree of stenosis, the absence of functional information, and the risks of contrast agent nephropathy and cholesterol emboli syndrome. Contrast arteriography is used routinely before angioplasty or surgical intervention.

Ultrasonography can be used to measure renal size and detects renal asymmetry that may be due to RAS. Importantly, kidneys less than 7 cm long are unlikely to benefit from revascularization procedures. Color-coded Doppler ultrasonography can identify RAS using either peak systolic velocity in a stenosis or by poststenotic flow phenomena. Velocities of 180–200 cm/sec at the point of maximum stenosis are widely used as the cut-off point to establish at least 50% stenosis. However, this test is unsuccessful in about 10–20% of the examinations. RASs can be detected indirectly by measuring acceleration and the waveform in intrarenal arteries distal to a stenosis. Combining direct and indirect measurements may increase the diagnostic yield. The reported sensitivity and specificity of color-coded Doppler ultrasonography for diagnosis of RAS ranges from 80 to 90% in the hands of experienced investigators. A recent meta-analysis showed that the accuracy is significantly lower than that of contrast-enhanced magnetic resonance angiography (CE-MRA) and multidetector computed tomography angiography (MD-CTA). It has been proposed to use the resistance index calculated from the Doppler spectrum as a predictor of therapeutic outcome. However, there are conflicting data about the value of this parameter.

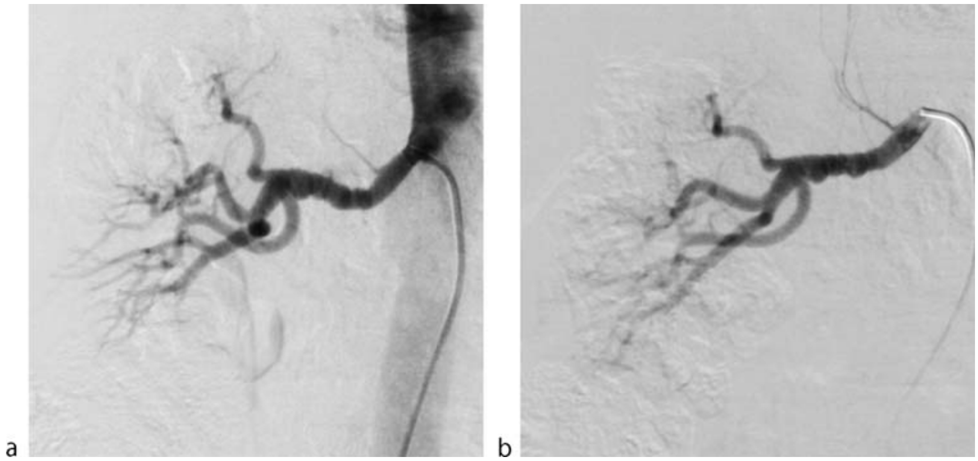
Three-dimensional *CE-MRA* is widely accepted to be the best MR imaging technique for investigation of narrowed renal arteries. CE-MRA is typically performed using a spoiled gradient echo sequence acquiring the entire 3D data set in 20–30 sec with a spatial resolution of $1.5 \times 1.5 \times 1.5$ mm^3 or better. To get information of the dynamics of blood flow, time-resolved MRA such as multiphasic MRA or time-resolved imaging of contrast kinetics has been proposed. Although these techniques are valuable for the detection of delayed flow, they suffer from relatively poor spatial resolution. Besides anatomical abnormalities, MR imaging can determine the functional significance of narrowed renal arteries. Multiple functional parameters such as renal perfusion, glomerular



Hypertension, Arterial. Figure 1 Classic Goldblatt mechanism. A stenosis of the renal artery leads to the formation of renin *via* a reduction in renal circulation. This renin is released *via* the renal vein into the systemic circulation. It converts angiotensinogen into angiotensin I. This occurs after the splitting of two amino acids to angiotensin II by angiotensin-converting enzyme. Angiotensin II leads to constriction of peripheral resistance vessels and to water retention *via* the release of aldosterone. Together they cause systemic arterial hypertension (according to: Uder M, Humke U (2005) Endovascular Therapy of Renal artery stenosis—Where do we stand today? Cardio Vasc Intervent Radiol 28:139–47).



Hypertension, Arterial. Figure 2 High-grade atherosclerotic stenosis of the ostium of the left main renal artery in a 53-year-old man who had severe hypertension before and after deployment of a balloon-expandable stent (according to: Uder M, Humke U (2005) Endovascular Therapy of Renal artery stenosis—Where do we stand today? Cardio Vasc Intervent Radiol 28:139–47).



Hypertension, Arterial. Figure 3 **Fibromuscular dysplasia of the renal artery in a 43-year-old man with severe hypertension. (a) Typical changes in the distal main artery. (b) After PTA with a 6-mm balloon catheter, irregularities of the vessel still appear. However, the patient became normotonic within 3 days, because the web-like stenoses were torn apart (according to: Uder M, Humke U (2005) Endovascular Therapy of Renal artery stenosis—Where do we stand today? Cardio Vasc Intervent Radiol 28:139–47).**

filtration rate (GFR), tubular concentration, and transit and oxygenation can be assessed using MRI. Although there are promising results with the new techniques, today they are not yet used in clinical routine.

With the introduction of multidetector row (MD) scanners, *CTA* has become an alternative for evaluation of renal arteries. Sixty-four-row scanners can cover the abdominal aorta and its side branches in a few seconds with submillimeter *z*-axis resolution, which allows near-isotropic imaging. To provide sufficient vessel-to-background contrast, 80–150 mL of 300–400 mg I/mL nonionic contrast medium is needed. Injection speeds range from 2–6 mL/sec. CTA data sets have to be acquired in breath-hold with individualized timing of contrast material bolus. The spatial resolution of MD-CTA is superior to that of CE-MRA, and has reached $0.6 \times 0.6 \times 0.6\ m^3$.

The method has been successfully used for the assessment of atherosclerotic RAS. Broad experience in patients with FMD is still missing. CTA is as accurate as MRA but has the disadvantage of radiation dose and radio-contrast volume.

Nuclear Medicine

Captopril renography is a functional test used to detect the angiotensin II dependence of GFR. In patients with activation of the RAA system, the preadministration of 25–50 mg oral captopril delays the uptake of tracer, reduces peak uptake, prolongs parenchymal transit, and slows excretion. The result of the test can be affected by factors such as volume depletion, concurrent medication, underlying renal dysfunction, and bilateral RAS. Therefore careful preparation of the patient is mandatory. It is widely used as a screening test for RAS, but in reality it provides little additional information than an assessment of plasma creatinine level 3–5 days after introducing the drug. However, its most useful role is probably in predicting the benefit from revascularization of a stenosed kidney. Most data are from studies of patients with RAS due to FMD, and there are few available data from patients with atherosclerotic RAS.

Diagnosis

The low prevalence of renovascular disease in patients with arterial hypertension makes universal screening for RAS in all hypertensive patients inappropriate. Therefore, imaging studies should be limited to groups with a higher clinical index of suspicion. Clinical indicators for RVH are abrupt onset of hypertension before age 30 or after age 55, accelerated or malignant hypertension, hypertension refractory to multiple drugs, hypertension in the presence of diffuse atherosclerosis, presence of a systolic/diastolic epigastric bruit, hypertension with unexplained renal insufficiency, azotemia induced by an ACE inhibitor or angiotensin receptor blocker, asymmetry of kidney size, and flash pulmonary edema. In these patients a secondary screening is mandatory to exclude RAS. Although there is no general consensus on which is the best imaging method, for the initial screening noninvasive methods such as ultrasound, MRA or CTA, or scintigraphy are widely preferred. A meta-analysis showed the superiority of both CTA and MRA over both captopril renography and ultrasonography for noninvasive detection of RAS (3). In contrast, a recent prospective multicenter comparative study including more than 400 patients casts doubts on the usefulness of CTA and MRA in patients with suspected RAS (4). The study showed that neither CTA nor MRA were able to rule out RAS in patients with a high pretest probability of the disorder.

A major problem with RAS is determining whether such lesions are functionally significant. Based on animal experiments, a reduction of lumen diameter of 70% is seen as relevant. In newer studies motivated by an analogous conclusion for the evaluation of stenoses of the coronary arteries or the leg vessels, stenosis of the renal artery of more than 50% has already been used as cut-off for hemodynamical significance. However, for stenoses between 50 and 70%, data that persuasively demonstrate their relevance are missing. An angiographically proven stenosis is highly suggestive of being hemodynamically effective, if collateral vessels become visible or when arterial phase, parenchymogram, and excretion into the collecting system are delayed in comparison to the contralateral side.

For stenoses based on a fibromuscular dysplasia, proof of the typical changes in the presence of renal insufficiency or hypertension is sufficient as a treatment indication. Estimation of the angiographic stenosis grade does not play a role here, because the web-like stenoses cannot be reliably evaluated angiographically for their relevance to renal blood flow.

Interventional Radiological Treatment

Many studies show that removal of hemodynamically relevant stenoses of the renal artery can lead to an improvement in or cure of arterial hypertension (5). The success of the treatment is not dependent solely on the degree of the stenosis but also on its etiology, on the age of the patient, and the duration of hypertension, for instance. Treatment of stenoses in fibromuscular dysplasia shows cure of the hypertension in 40% of patients and improvement in 51% of patients, with cumulative success rates up to 90% over 10 years. The results for atherosclerotic RAS are less favorable. An improvement of hypertension by PTA or stenting of the renal artery can be reached in a maximum of two-third of patients. In total, 30–50% of the treated patients get a relapse of hypertension within short to midterm follow-up. Three randomized controlled trials showed no benefit of PTA over antihypertensive medication in terms of changes in BP. However, meta-analyses of 210 patients from the randomized trials showed a moderate but significant advantage for the angioplasty as opposed to pure pharmacological therapy in change of both systolic and diastolic BP. However, the value of angioplasty or stenting in RAS for treating arterial hypertension cannot yet be definitely rated with the available data.

Angioplasty has become the primary treatment for fibromuscular dysplasia of the renal arteries, with a technical success in nearly all patients and excellent long-term results. In approximately 10–20% of the patients, the procedure has to be repeated due to a relapse of hypertension by restenoses.

Atherosclerotic RAS does not respond as well to PTA therapy as do dysplastic stenoses. In atherosclerotic stenoses distant to the aortic wall, PTA is the first treatment option, with success rates of 70–90%. Stents should only be used if angioplasty fails. In ostial stenoses secondary to aortic plaque, a stent is needed to achieve technical success in most cases. Of the stented patients, 20% were faced with a restenosis within 6–12 months, whereby the risk increases with smaller stent diameters.

The endovascular therapy of atherosclerotic renal artery stenoses is afflicted by a complication rate of 5–36% with periprocedural deaths reported in less than 2% of cases. Most frequently observed complications are hematoma formation and puncture trauma. Cholesterol embolism was identified as a main reason for the loss of kidney function after angioplasty and stent placement.

Hypertension, Pulmonary

Edwin J. R. van Beek
Department of Radiology, Carver College of Medicine, C-751 GH, Iowa City, USA
edwin-vanbeek@uiowa.edu

Definition

Pulmonary hypertension is defined as a mean pulmonary arterial pressure of greater than 25 mm Hg causing excessive loading of the right heart. The etiology of pulmonary hypertension is manifold. It may be caused at the precapillary level (pulmonary arterial obstruction, such as chronic thromboembolic pulmonary embolism), capillary level (often labeled as idiopathic) and postcapillary level (usually due to left heart diseases, such as mitral valve stenosis or insufficiency). The most important differentiation should be focused on eliminating thromboembolic disease and shunts, as these are treatable through medication, interventional radiological procedures or surgery (1).

Pathology/Histopathology

Due to the heterogeneity of this group of disorders, the pathology and histopathology may differ considerably. A classification of pulmonary hypertension has been widely adopted, and the main causes are presented in the Table 1.

Several of the main types are

1. Precapillary pulmonary hypertension, with its main cause of (recurrent) pulmonary embolism.

H

Hypertension, Pulmonary. Table 1 The revised World Health Organization classification of pulmonary hypertension

Group I Pulmonary arterial hypertension
Idiopathic (primary)
Familial
Related conditions: collagen vascular disease, congenital systemic-to-pulmonary shunts, portal hypertension, HIV infection, Drugs and toxins (e.g., anorexigens, rapeseed oil, L-tryptophan, methamphetamine, and cocaine); other conditions: thyroid disorders, glycogen storage disease, Gaucher's disease, hereditary hemorrhagic telangiectasia, hemoglobinopathies, myeloproliferative disorders, splenectomy
Associated with significant venous or capillary involvement
Pulmonary veno-occlusive disease
Pulmonary-capillary hemangiomatosis
Persistent pulmonary hypertension of the newborn
Group II Pulmonary venous hypertension
Left-sided atrial or ventricular hear disease
Left-sided valvular heart disease
Group III Pulmonary hypertension associated with hypoxemia
Chronic obstructive pulmonary disease
Interstitial lung disease
Sleep-disordered breathing
Alveolar hypoventilation disorders
Chronic exposure to high altitudes
Developmental abnormalities
Group IV Pulmonary hypertension due to chronic thrombotic disease, embolic disease, or both
Thromboembolic obstruction of proximal pulmonary arteries
Thromboembolic obstruction of distal pulmonary arteries
Pulmonary embolism (tumor, parasites, foreign material)
Group V Miscellaneous
Sarcoidosis, pulmonary Langerhans'—cell histiocytosis, lymphangiomatosis, compression of pulmonary vessels (adenopathy, tumor, fibrosing mediastinitis)

Source: Simonneau G, Galie N, Rubin LJ et al (2004) Clinical classification of pulmonary hypertension. J Am Coll Cardiol 43:5S–12S

2. Capillary pulmonary hypertension, which includes media hyperplasia and the so-called idiopathic forms of pulmonary hypertension.
3. Postcapillary pulmonary hypertension, which is related to diseases that give rise to pulmonary venous hypertension. These may be primarily associated with pulmonary venous occlusive disease or with cardiac disorders, including mitral valve regurgitation, left-to-right shunts and increased back-up pressures in the presence of left-sided heart failure.

In all instances, pulmonary hypertension will increase the preload as well as the after-load on the right ventricle. Given sufficient time, the heart will respond by developing right ventricular hypertrophy (cor pulmonale), while the central pulmonary arteries will become dilated (a main pulmonary artery diameter of >3 cm should be considered pathological).

Hypertension, Pulmonary. Figure 1 PA chest radiography, demonstrating enlargement of the right heart with double contour due to enlargement of right atrium and large central pulmonary arteries.

Clinical Presentation

The clinical presentation of pulmonary hypertension depends on the underlying etiology. Gradual onset of symptoms is typical, and these often consist of (a combination of) progressive shortness of breath, palpitations, and episodes of syncope. Most patients will demonstrate a gradual decline in walking distance or inability to perform exercise. Acute presentation is rare, occurring in 5% of cases, whereas the vast majority will have experienced symptoms in excess of 6 months following onset of symptoms (2).

With progressive pulmonary hypertension, the right heart will ultimately fail and right heart failure signs and symptoms will develop, including pitting edema, ascites, raised jugular vein pressure, tachycardia, enlarged pulsating liver, loud P2 sound and/or pansystolic murmur, right ventricular heave and pleural effusions. Sudden death may occur.

Imaging

Chest radiography will help distinguish disorders that may mimic symptoms, such as pneumonia, tuberculosis, and heart failure. In patients with established pulmonary hypertension, the heart configuration and the main pulmonary arteries are usually (but not always!) enlarged (Fig. 1). Vascular pruning may be evident, resulting in hyperlucent areas in the lungs.

Right heart catheterization is currently the reference method for measurements of pressures, pressure gradients and combination with stress tests helps to assess the potential response to treatment.

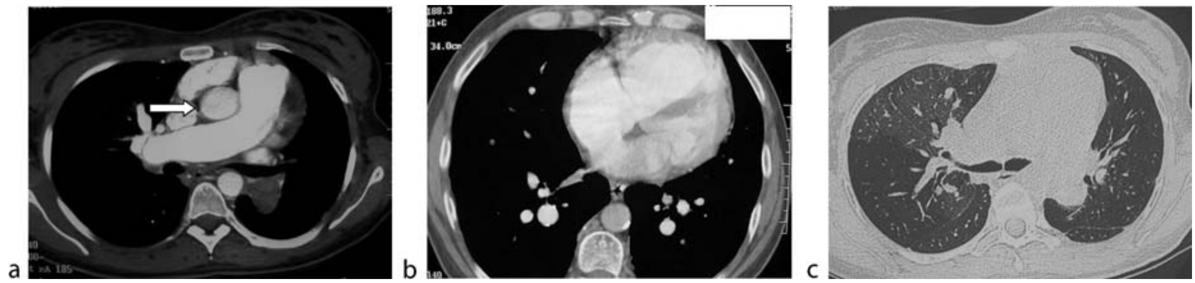
Echocardiography will reveal right ventricular overload, consisting of right ventricular hypertrophy, wall motion abnormalities, bowing of the interventricular septum to the left and tricuspid valve regurgitation. Echocardiography is capable of giving an estimate of the pulmonary artery pressure.

CT pulmonary angiography is a very useful technology for the comprehensive assessment of the pulmonary vascular system, and is also capable of evaluating the consequences of pulmonary hypertension, such as right heart dilatation and hypertrophy, bronchial artery hypertrophy and perfusion anomalies (Fig. 2).

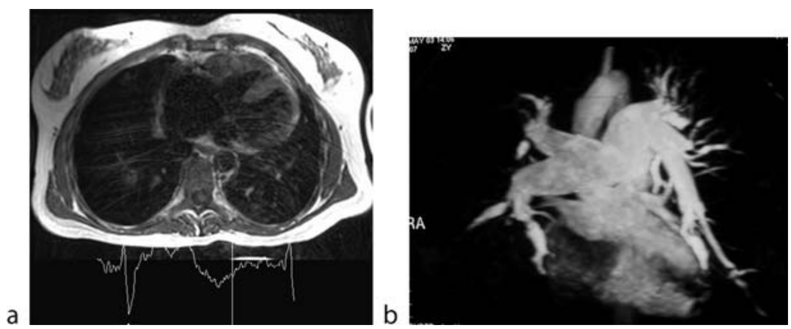
Magnetic resonance imaging (MRI) has many different techniques, which may be employed for the diagnosis of pulmonary hypertension and its etiologies. These techniques include vascular assessment, including MR perfusion and MR angiography, quantification of blood flow across the pulmonary valve and anatomical and cine imaging of the heart (Fig. 3). Although it is currently not possible to determine the exact measurement of pulmonary arterial pressure, MRI is a useful test to give an overall impression of the severity of the disease and may help to determine the precise etiology of pulmonary hypertension (3).

Nuclear Medicine

Traditionally, perfusion (-ventilation) lung scintigraphy was the main diagnostic test for pulmonary vascular



Hypertension, Pulmonary. Figure 2 CT findings in pulmonary hypertension. (a) Pulmonary artery dilatation (notice the size of the corresponding aorta, *arrow*). (b) Right ventricular hypertrophy, as demonstrated by anterior wall thickening (compare this to the left ventricular wall). (c) Mosaic perfusion, as indicated by areas of high attenuation (this is where the lung is receiving increased/shunted blood flow) versus areas of low attenuation which are hypoperfused.



Hypertension, Pulmonary. Figure 3 MRI findings in pulmonary hypertension. (a) Patient with ventricular septal defect and Eisenmenger syndrome. Notice the high septal defect, the distended right atrium and the right ventricular hypertrophy. The perfusion scintigram of this patient is demonstrated in Figure 5. (b) Patient with chronic thromboembolic pulmonary hypertension. Notice large central pulmonary arteries, multiple caliber changes in the segmental branches, consistent with webs and stenoses after recanalization of pulmonary emboli.

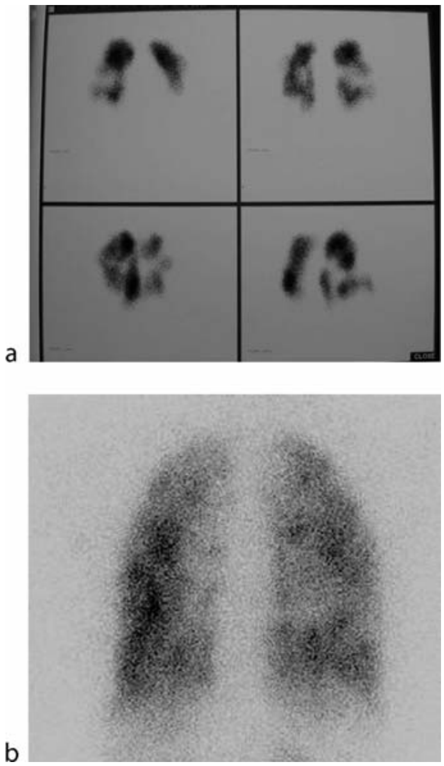
disease. With the advent of CT and MRI, this technology has been largely omitted from the diagnostic work-up. Nevertheless, perfusion scintigraphy is still considered a useful adjunct to assess the severity of pulmonary hypertension and to monitor disease progression and response to therapy. Furthermore, it is exquisitely sensitive to the development or presence of left-to-right shunts and capable of determining the actual severity of these shunts (Fig. 4).

Diagnosis

The diagnosis of pulmonary hypertension is often delayed due to the insidious onset of symptoms. Once the diagnosis is considered, chest radiography and ECG findings will be abnormal in 80% of patients (2). Echocardiography is a first line investigation, and will raise further suspicion of increased pressures and may demonstrate right ventricular dysfunction. The final diagnosis will be made by right heart catheterization, while non-invasive tools, such as perfusion scintigraphy, CT and MRI will assist in determining the etiology and extent of the disease process. These tools are also increasingly being developed to help monitoring disease progression and response to treatment.

Interventional Radiological Treatment

There is an, albeit limited, role for interventional radiological treatment. First, inferior vena cava filters may be inserted in patients who undergo surgical corrections. Second, left-to-right shunts may be treated through



Hypertension, Pulmonary. Figure 4 Perfusion scintigraphic findings in different etiologies of pulmonary hypertension. (a) Patient with chronic thromboembolic pulmonary hypertension. Notice that there are multiple wedge-shaped defects, similar to that seen in acute pulmonary embolism. (b) Patient with ventricular septal defect, Eisenmenger syndrome, and right-to-left shunt. The lungs show inhomogeneous tracer uptake, with photopenic central hilar areas due to pulmonary artery dilatation. Notice that the kidneys are visible; quantification of the shunt can be performed by calculating the actual uptake as a percentage of the total injected dose.

invasive radiological procedures, including coil occlusion of arteriovenous fistulas and placement of umbrellas to cover patent foramen ovale, persistent ductus arteriosus, or small ventricular septal defects.

Synonyms

Renovascular disease; Renovascular hypertension

Definitions

►*Renovascular disease* (RVD) is a complex entity involving renal arterial lesions, renal disease, and hypertension. The relationships between these three entities are variable from patient to patient and difficult to assess, but their severity and their association increase the patient's cardiovascular and renal risks.

►*Renovascular hypertension* (RVH) is a reversible cause of hypertension secondary to a decrease in renal perfusion pressure, which activates the renin–angiotensin system and leads to the release of renin and the production of angiotensin II (angiotensin II increases sodium reabsorption and induces postglomerular and systemic arterial vasoconstriction, causing renovascular hypertension). The prevalence of RVH is around 1% among hypertensive patients.

►*Renal artery stenosis* (RAS) is the main cause of RVH, but small-vessel intrarenal vascular disease can also be responsible for it. Its prevalence is unknown. Only the stenoses that reduce the internal diameter by >60% produce a significant decrease in renal blood flow. They can be atherosclerotic (90% of cases) or dysplastic (fibromuscular dysplasia, 10% of cases), ostial or not, and be located on main or accessory arteries. Small-vessel intrarenal vascular lesions are almost exclusively atherosclerotic.

The relationship between hypertension and RAS is also difficult to assess, the best test being the reversibility of hypertension after revascularization. In fact, the majority of patients with atherosclerotic RAS and hypertension have essential hypertension as suggested by the absence of benefit of revascularization.

Atherosclerotic, or ischemic, nephropathy is a complex entity. It is an important cause of end-stage renal failure (ESRF), causing up to 14% of ESRF over the age of 50 years. It is a consequence of the association of multiple factors, including decreased renal blood flow (secondary to bilateral RAS or to unilateral stenosis plus contralateral occlusion or to unilateral stenosis in a solitary kidney), intrarenal atherosclerotic arterial disease, atheroembolism, diabetes, increased oxidative stress, medullary hypoxia, endothelial dysfunction, inflammatory response, and proteinuria. This multiplicity of causal factors explains the great heterogeneity of renal damage. There are several arguments in favor of nonischemic factors being responsible for ▶atherosclerotic nephropathy: (i) the presence of atheroembolic disease and focal segmental glomerulosclerosis at histology; (ii) a variable functional response to revascularization, with evolutive processes independent of a reduction of renal blood flow; and (iii) the possible observation of patients with two equal-sized kidneys, unilateral RAS, and impaired renal function, or of patients with severe bilateral RAS and relatively preserved renal function.

Characteristics

Clinical distinction between renovascular and essential hypertension is difficult and based on classical criteria such as, among others, the onset of hypertension before or after the age of 50 years, the absence of a family history of essential hypertension, an abdominal bruit, duration of hypertension of less than 1 year, hypokalemia, and decreased renal function (Table 1).

Atherosclerotic RAS is the most common cause of RAS. The prevalence increases with age, particularly in patients with diabetes, aorto-iliac occlusive disease, coronary artery disease, or hypertension. Progression of the degree of stenosis occurs in approximately 51% of renal arteries 5 years after diagnosis, and 3–16% of renal arteries progress toward occlusion. But in many cases, these arterial lesions are never detected because they are asymptomatic. Most of these stenoses are located at the ostium of the renal arteries and are in fact perirenal aortic plaques extending into the ostia.

Hypertension, Renal. Table 1 Clinical features suggestive of atherosclerotic renal artery stenosis

1. Hypertension
• Abrupt onset before the age of 50 year or after the age of 55 year
• Accelerated or malignant hypertension
• Refractory to treatment with ≥3 drugs
2. Renal abnormalities
• Progressive or otherwise unexplained renal insufficiency in the setting of hypertension in elderly patients
• Abrupt rise in serum creatinine after ACE inhibition
• Low grade proteinuria and unremarkable urinary sediment
• Significant discrepancy in size between the two kidneys
• Unexplained hypokalemia
3. Other findings
• Abdominal or flank bruit
• The presence of various atherosclerotic manifestations and/or abdominal aortic aneurysm
• Unexplained left ventricular hypertrophy
• Flash pulmonary edema
• Severe retinopathy

Fibromuscular dysplasia (FMD) is the second cause of RAS, occurring preferentially in females between 15 and 50 years of age. It is usually located more distally than atherosclerotic RAS, on the distal two-thirds of the renal artery and its branches, and may affect the intima, media (90% of cases), or adventitia. Depending on its type, FMD is characterized by long or short (diaphragm-like) stenoses and aneurysmal dilatations. Intimal and periarterial FMD are commonly associated with progressive dissection and thrombosis, whereas medial FMD progresses in 30% of patients and is rarely associated with dissection or thrombosis.

When atherosclerotic disease progresses unilaterally, the size of the ipsilateral kidney, its cortical thickness, and its blood flow decrease, whereas the serum creatinine concentration and glomerular filtration rate remain normal because of compensatory changes within the contralateral kidney. When the disease progresses bilaterally, both kidneys present with progressive shrinkage and cortical thinning and irregularities. Usually, serum creatinine concentration increases and GFR decreases when more than 50% of renal mass is lost. Renal atrophy develops in approximately 21% of patients with RAS of more than 60%.

The radiological imaging techniques available today have to reach four objectives: (i) to detect and characterize the RAS in terms of nature and anatomical and hemodynamic severity, (ii) to assess the anatomical consequences of the RAS on the artery itself and on the renal parenchyma, (iii) to assess the functional and cellular consequences of the RAS on the kidney, and (iv) to identify criteria of associated renal impairment related to RVD.

Because the cardiovascular risk mainly depends on the degree of hypertension, improving blood pressure control has been a major task. Today, we know that medical treatment can achieve this control without renal revascularization in many cases. Therefore, management of these patients does not always require, as before, an early diagnosis of RAS, even though recent improvements in radiological techniques allow an accurate diagnosis of RAS noninvasively.

Imaging of RAS

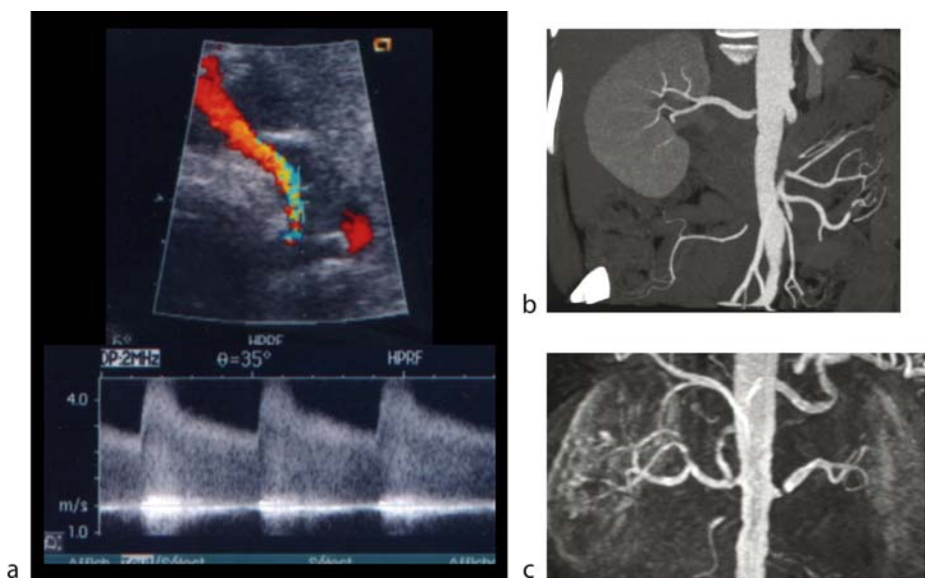
Intraarterial digital subtraction angiography is considered the gold standard for diagnosing RAS, but it is limited now to characterizing the stenosis before transluminal angioplasty during the same procedure.

Doppler ultrasound has gained a major place in the detection of RAS. The examination includes measurement of both kidneys, spectral sampling of two or three interlobar or segmental arteries of each kidney, and spectral sampling of both renal arteries. Diagnosis is based on direct proximal criteria (Fig. 1a) using both focal changes of color related to acceleration (aliasing) and turbulence (perivascular artifact) and spectral waveform changes at the site of stenosis (spectral broadening and increased velocity). Once detected, stenoses are considered significant (≥60%) when the renoaortic velocity ratio (RAR) is higher than 3.5 and/or when the peak systolic velocity is ≥180 cm/sec. Intrarenal wave forms may present changes distally to severe (>75%) RAS: slowed systolic acceleration, defined by an acceleration time of systolic peak >0.07 sec and a decreased resistive index (RI). Ultrasound contrast agents may improve the feasibility of the test in patients with a high body mass index or with decreased renal function.

Multislice computed tomography (CT) angiography provides high-resolution images of renal arteries with 1 mm (or less) slice thickness. Using an 80–100 mL bolus of iodinated contrast agent and maximum intensity projections (MIP) of reformatted slices, delineation of the true lumen and its separation from calcification are enhanced. Drawbacks of CT angiography are the ionizing radiation and the need for iodinated contrast media, a problem when renal function is impaired. Sensitivity (92%) and specificity (99%) in detecting significant stenoses are high. FMD stenoses, which are more distal than atherosclerotic stenoses, can also be better characterized using multislice CT (Fig. 1b).

Magnetic resonance (MR) angiography has moved from flow-enhanced (time-of-flight or phase-contrast) sequences to 3D breath-hold T1-weighted and contrast-enhanced acquisitions (Fig. 1c). Fluoroscopic guidance of arrival of the bolus in the aorta improves the reproducibility of the technique. Parallel acquisition techniques allow improved spatial resolution without increasing the acquisition time and yield an isotropic resolution of 1 mm^3 in a single breath-hold. These improvements are responsible for an improved grading of stenoses, which has the same interobserver variability as conventional angiography, and better detection of accessory arteries. Its performance is excellent, with sensitivity and specificity for diagnosis of significant RAS of 88–100% and 71–99%, respectively.

Comparison of techniques: A recent meta-analysis compared the validity of CT angiography, MR angiography, and ultrasound for diagnosing RAS in patients suspected of having RVH. Receiver-operating characteristic curves found that CTA and gadolinium-enhanced 3D MR angiography were significantly better than the other diagnostic tests and seemed to be preferred in patients referred for evaluation of RVH.



Hypertension, Renal. Figure 1 Diagnosis of renal artery stenosis. (a) Color flow sonography showing an aliasing phenomenon on the proximal segment of right renal artery and flow changes evocative for significant stenosis: severe spectral broadening and increased peak systolic velocity around 5 m/sec. (b) CT angiography showing an ostial stenosis of the right renal artery. (c) MR angiography showing a post-ostial stenosis of the left renal artery.

Anatomic and Hemodynamic Consequences of RAS

Detection of RAS further requires evaluating the severity of narrowing and its consequences on renal flow, renal parenchyma, and renal function, to improve the interobserver variability and to define predictive factors of improvement after revascularization.

Renal Anatomy changes

The *renal anatomy* changes when the renal blood flow is significantly decreased. Two parameters have been proposed to evaluate this effect in RAS:

- *Measurement of renal length*: To be significant, a length difference of 1 cm should be considered, attesting to a hemodynamically significant RAS (Fig. 2a). If the renal length is <8 cm, revascularization is contraindicated because the patient is less likely to get benefit from it.
- *Measurement of cortical thickness and cortical area*: A threshold of 8 mm for cortical thickness and 800 mm^2 for cortical area allows one to distinguish control kidneys from poststenotic kidneys. Its prognostic value has still to be evaluated.

Renal Arterial Flow Below the Stenosis

3D phase-contrast MR sequences, with flow encoding in the three directions, is sensitive to flow velocity, and velocity–time curves can be obtained. It is possible to separate normal velocity–time curves and abnormal curves evocative for moderate or high grade stenoses (Fig. 2b). This combined approach has revealed the best interobserver variability and almost perfect intermodality agreement with digital subtraction angiography. A renal flow index—renal flow (mL/min) divided by renal volume (cm^3)—less than 1.5 mL/min/cm^3 seems predictive of a successful outcome of revascularization.

Intrarenal Hemodynamics

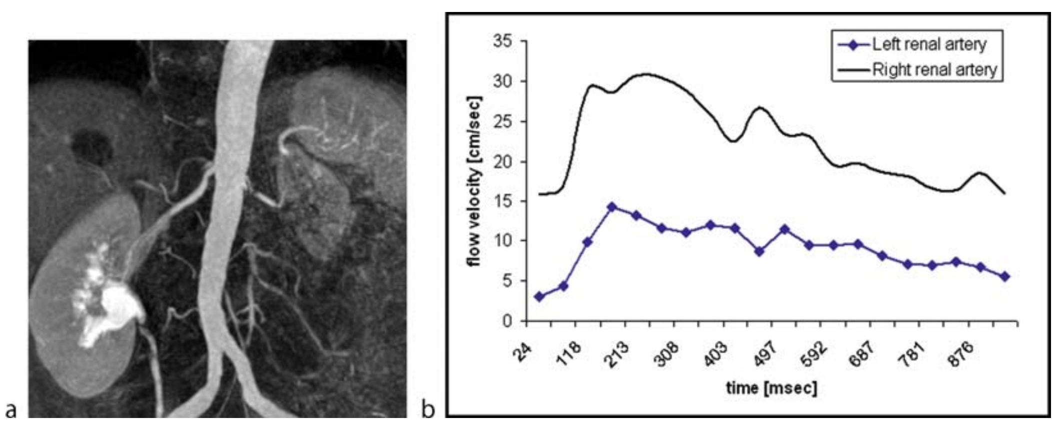
By sampling distal intrarenal vessels with Doppler ultrasound, two types of flow curve changes can be observed: A decreased RI is related to a compensatory vasodilatation due to severe RAS upstream, but an increased RI is compatible, in this context, with the diagnosis of atherosclerotic nephropathy. Radermacher et al showed that an RI > 0.8 was associated with a poor prognosis in patients with RAS shown by an absence of improvement of hypertension, renal function or kidney survival after revascularization.

H

Consequences of RAS on Renal Function

Glomerular Filtration

Baseline semiquantitative evaluation or quantification of glomerular filtration is neither sensitive nor specific enough to detect renal dysfunction due to RAS. Blockade of the renin–angiotensin system by angiotensin-converting enzyme (ACE) inhibitors, such as captopril, is mandatory for this purpose. Administration of ACE inhibitors decreases the vasoconstrictor-stimulating effect of angiotensin II, which produces a drop in glomerular filtration on the side of the stenosis. A positive test, defined as a functional change induced by the ACE inhibitor, demonstrates the diagnosis of "functional stenoses" producing renovascular hypertension, which means a real link between



Hypertension, Renal. Figure 2 Anatomical and hemodynamical consequences of renal artery stenosis. (a) MR Angiography shows a left renal astery stenosis showing a decreased of size of the kidney. Hypertension, Renal. Figure 3 Functional renal consequences of renal artery stenosis. (a) Positive captopril MAG3-Tc99 scintigraphy obtained in a patient with stenosis of the left renal artery: the baseline study shows symmetrical elimination of the tracer (right of the image). After captopril (*left* of the image), there is an accumulation of the tracer within the left kidney whereas it remains unchanged in the right. (b, c) Dynamic Gd-enhanced MR imaging of the kidneys before (a) and after (b) captopril administration in the same patient (from *top-to-bottom* then *left-to-right*): before captopril, the tubular phase with low signal intensity within medulla (*arrows*) and excretion of contrast medium within renal collecting system (*double arrows*) are symmetrical. After captopril, the right kidney shows a normal tubular phase (*arrow*) and normal excretion (*double arrow*) whereas tubular phase is delayed on the left but then enhances with time, extending within the cortex and providing a complete low signal intensity of the left kidney; this effect is related to a severe retention of the contrast agent within the entire left kidney induced by captopril.

RAS and hypertension. This test has traditionally been coupled with scintigraphy but more recently with dynamic MR imaging (Fig. 3).

Renal Perfusion

Absolute quantification of parenchymal perfusion can be assessed with diffusible (as gadolinium chelates) or purely intravascular contrast agents (as iron oxide particles). A 50% decrease in cortical perfusion (from 400 to 200 mL/min/100 g) has been observed below tight (80%) stenoses. However, its potential role in prognosis has not been demonstrated to date.

▶Congenital malformations, Thyroid, and Functional Disorders
▶Thyroid Autoimmune Diseases

Hypertrophic Arthropathy, Secondary

Secondary hypertrophic arthropathy is one of the more common and specific paraneoplastic diseases that may present as an oligoarthritis or polyarthritis of the distal joints with clubbing, painful periostitis of the distal long bones, and noninflammatory synovial effusions. Linear ossification of the distal long bones separated by a radiolucent zone from the underlying cortex can be seen in radiographs. Usually acromegaly induced bone changes are not as painful and linear ossifications along the bones are not found.

Definition

Hypertrophic osteoarthropathy is characterized by ▶periostitis, arthritis, and bilateral clubbing of the digits on the hands and feet. Hypertrophic osteoarthropathy may be divided into primary and secondary forms. ▶Primary hypertrophic osteoarthropathy can be hereditary or idiopathic and is very rare (3–5% of all cases of hypertrophic osteoarthropathy). ▶Secondary hypertrophic osteoarthropathy is often associated with intrathoracic neoplastic or inflammatory conditions.

Pathology/Histopathology

Periostitis with new periosteal deposition of bone is the hallmark of the disease. While the new surface is rough in primary hypertrophic osteoarthropathy, it has a more linear appearance in secondary hypertrophic osteoarthropathy (Fig. 1). In histologic cross sections, the delineation between the old and new periosteal bone is less distinct in primary compared to secondary hypertrophic osteoarthropathy, where the new bone is often less dense than the original cortex. However, if secondary hypertrophic osteoarthropathy has a longer history, e.g. in congenital cyanotic heart disease, the findings are more similar to that of primary hypertrophic osteoarthropathy. As in primary hypertrophic osteoarthropathy, osteolysis of the digits can also be found.

Hypertrophic, Osteoarthropathy. Figure 1 Radiograph of the right distal tibia and fibula in an anteroposterior and lateral view. The patient suffered from lung cancer and severe, burning pain in both distal legs. The periosteal appositions (white ▶) have a linear appearance typically found in secondary hypertrophic osteoarthropathy. (Courtesy of Prof. Thomas M. Link, San Francisco.)

Articular inflammation with joint effusion is found more commonly in secondary than in primary hypertrophic osteoarthropathy. The synovial membrane presents with a mild cellular hyperplasia and a thickening of the subsynovial blood vessels. The synovial fluid is viscous and noninflammatory.

The ▶clubbed digits are not a result of the periostitis, but due to an internal soft tissue edema with collagen and fiber deposition. Arterio-venous anastomosis can develop in the nail bed. Thickening of vessel walls is seen with a lymphocyte infiltration. In electron microscopy, Weibel–Palade bodies and Golgi complexes can be found indicating cellular damage.

Clinical Presentation

Hypertrophic osteoarthropathy is a syndrome characterized by digital clubbing, arthritis, periostitis, swelling and thickening of the skin of distal extremities and the head (pachydermia), as well as local nervous dysfunctions like hyperhidrosis (1). Digital clubbing was first described by

Hippocrates in the 5th century BC (2). A first description of hypertrophic osteoarthropathy was given by Friedreich in 1868. Primary hypertrophic osteoarthropathy is a hereditary autosomal dominant disease with variable penetrance. It affects males about seven times more often, is more severe in males, and is more common in African Americans than in Caucasians. The onset of primary hypertrophic osteoarthropathy is typically during adolescence. The disease often starts with enlargement of the hands and feet, producing a paw-like appearance. Digital clubbing is a frequent, though not invariable feature of hypertrophic osteoarthropathy. Its presence should not be equated with the syndrome, as several other disorders show clubbing without any other features of hypertrophic osteoarthropathy. Coarsening of the skin of the face and scalp, known as cutis verticis gyrata, may be observed as well as seborrheic dermatitis and palmoplantar hyperhidrosis. The clinical manifestation patterns are variable, ranging from the full syndrome (periostitis, pachydermia, and cutis verticis gyrata) or a partial expression (no involvement of the head) to a "forme fruste" (pachydermia without periostitis) (3). Primary hypertrophic osteoarthropathy usually shows a progression of about 10 years, when it arrests spontaneously. The life expectancy is normal, but disabling can occur if the axial skeleton is involved with stiffness, kyphosis, and neurological manifestations as spinal nerve roots get compressed by new bone formations.

In 1890, Bamberger and Marie independently described secondary hypertrophic osteoarthropathy as a syndrome of digital clubbing and periostitis in patients suffering from chronic heart and lung diseases (4, 5). Secondary hypertrophic osteoarthropathy shows an even distribution between males and females with no racial preference. Life expectancy is not changed by secondary hypertrophic osteoarthropathy, but it is often limited by the underlying disease. Symptoms are somewhat different from primary hypertrophic osteoarthropathy. In secondary hypertrophic osteoarthropathy, the periostitis is often associated with a deep, burning pain. Arthritis is more frequent (up to 40% of patients) and can mimic symptoms of rheumatoid arthritis when affecting small joints. Cutis verticis gyrata is observed much less frequently. However, with a long duration of secondary hypertrophic osteoarthropathy, like in congenital cyanotic heart disease, symptoms and findings can fully correlate with those observed in primary hypertrophic osteoarthropathy.

Imaging

Periostitis is the characteristic feature of the disease (6). Bones most affected are tibia, fibula, radius, and ulna. Periosteal appositions usually start developing at the distal end of the diaphysis. In case of primary hypertrophic osteoarthropathy, the periosteal appositions extend to the epiphyseal regions and appear irregular and exuberant. The cranium and pelvis can be affected as well. In more advanced stages, osteolysis can appear at the distal phalanges and ossification of ligaments can be observed. Joint capsules, menisci, and discs can also ossify. Synostosis can develop, particularly between carpal and tarsal bones, as well as at the symphysis pubis. In an advanced stage of primary hypertrophic osteoarthropathy, synovialitis may affect joints causing limited motion due to periosteal appositions near the joint.

In secondary hypertrophic osteoarthropathy, the appositions are linear thin lines separated from the cortical bone. They also can have an "onion-skin"-like appearance, but are usually not as irregular as in primary hypertrophic osteoarthropathy. In a later stage of the disease, the new periosteal bone fuses with the original cortex. The epiphysis is usually not involved. Besides the tibia, fibula, radius, and ulna, periosteal appositions can also appear at the femur, humerus, metacarpalia, metatarsalia, and the phalanges. Rarely an involvement of the scapula, the clavicle, rips, spine, or skull is found. As in rheumatoid arthritis, joint effusion can be found as well as osteoporosis near the joint. In contrast to arthritis, no joint space narrowing or erosive bony lesions are seen. The digital clubbing leads to radiographically evident soft tissue swelling.

Nuclear Medicine

Radionuclide bone scanning using technetium Tc99m polyphosphate can reveal the disease in an early stage, where plain films are still negative. It shows increased uptake of the tracer in the cortex of diaphysis and metaphysis. In primary hypertrophic osteoarthropathy, the epiphysis is also involved. The activity usually increases bilaterally in a linear fashion. Clubbed digits and associated synovitis can both show increased activity, particularly in an early phase of the scan.

Diagnosis and Differential Diagnosis

Differential diagnosis between primary and secondary hypertrophic osteoarthropathy can be achieved based on radiographic findings (irregular, with epiphyseal involvement in primary hypertrophic osteoarthropathy), clinical presentation (e.g. painful periostitis in secondary hypertrophic osteoarthropathy), and the patient's family history (positive in 1/3 cases of primary hypertrophic osteoarthropathy).

Other differential diagnoses to consider are ►thyroid acropachy, ►venous stasis, hypervitaminosis A, infantile cortical hyperostosis, acromegaly, and endosteal hyperostosis. In thyroid acropachy, pretibial myxedema and a

H

Hypertrophic, Osteoarthropathy. Figure 2 Radiograph of the right distal tibia and fibula in an anteroposterior and lateral view. The patient suffered from venous stasis with ulceration in both lower limbs. The periosteal appositions are more pronounced in the fibula (white ▶). They have an irregular appearance and are not separated from the original cortex. (Courtesy of Prof. Thomas M. Link, San Francisco.)

Hypertrophic, Osteoarthropathy. Figure 3 Radiograph of the right distal tibia and fibula in a lateral and anteroposterior view of a 59-year-old patient with pachydermoperiostitis. Multiple regions of periosteal reaction are identified involving the diaphysis, metadiaphysis, metaphysis, and epiphysis of the tibia and fibula. (Courtesy of Prof. Kenneth E. Sack, San Francisco.)

history of thyroid dysfunction are present; the typical speculated periosteal appositions have a predilection for small tubular bones. Venous stasis shows a predilection for the lower extremity with signs of phlebolitis, soft tissue swelling, and ulceration. The periosteal appositions have an undulated osseous contour and cortical thickening appears as the appositions are not well separated from the original cortex (Fig 2). In hypervitaminosis A, soft tissue nodules may be present with epiphyseal deformities. Infantile cortical hyperostosis is characterized by cranial destructions and skeletal deformities. A differentiation from acromegaly is clinically possible. In endosteal hyperostosis, digital clubbing is not evident. Other diseases, like fibrous dysplasia, Paget's disease, fluorosis, diffuse idiopathic skeletal hyperostosis are usually easily differentiated from hypertrophic osteoarthropathy (Fig. 3).

Synonyms

Birth asphyxia; Hypoxic-ischaemic encephalopathy; Neonatal; Perinatal; Seizures

Definitions

Perinatal hypoxic-ischaemic (HI) brain injury is defined here as an injury arising from a lack of blood and oxygen, birth asphyxia, occurring during labour or delivery. There may be a clear sentinel event such as a cord prolapse or uterine rupture that precedes signs of foetal distress detected as abnormalities in foetal heart rate seen on cardiotocograph with or without meconium stained liquor. These signs are usually accompanied by a low cord pH < 7.1. The diagnosis of ▶hypoxic-ischaemic encephalopathy is made when such neonates require resuscitation at birth, having low Apgar scores <5 at 1 min and often <5 at 5 min, and then develop abnormal neurological signs such as seizures, abnormal tone, irritability and poor feeding. The pattern of injury sustained in the brain depends on the length and nature of the hypoxic-ischaemic insult.

Aetiology

Following a significant HI event to the brain there is a period of primary energy failure, which initiates a cascade of reactions leading to secondary energy or mitochondrial failure. These reactions include increased glutamate, NMDA receptor activation, intracellular calcium accumulation, free radical formation and mitochondrial failure. Cellular swelling is followed by necrosis and is associated with acute changes on diffusion weighted imaging with a decreased apparent diffusion coefficient (ADC). In some regions of the brain, cells will die from apoptosis. In acute HI, tissues with a high metabolic rate are most susceptible to injury. In the neonatal brain this involves all areas that are actively myelinating, e.g. corticospinal tracts, basal ganglia and thalami (BGT), hippocampal region, brainstem. White matter is often relatively spared if there is an isolated acute event but will show secondary atrophy in the presence of severe BGT injury. The dentate nucleus of the cerebellum is considered to be very susceptible to hypoxic-ischaemic injury but the cerebellum rarely demonstrates abnormal MR signal intensity acutely.

Middle cerebral artery infarction may occur as the result of spasm or embolus. There is an increased incidence of thrombophilic disorders in neonates with perinatal infarction. Factor V Leiden has been associated with more extensive infarction and poorer outcomes. The cause of focal haemorrhagic lesions is often not ascertained.

Clinical Presentation

Neonates with global HI brain injury may present with a full encephalopathy; altered tone, poor feeding and altered conscious level with or without seizures. With focal injuries the only presenting feature may be seizures. Neonates may require assisted ventilation because of respiratory depression secondary to the injury or to anti-convulsant medication administered to control seizures. An early EEG recording is useful for assessing the severity of the insult and will relate to the likelihood of abnormal outcome: the presence of depressed background activity is more worrying than the presence of seizures. The incidence of hypoxic-ischaemic encephalopathy is approximately 1.66/1,000 in the UK.

In infants with marked basal ganglia lesions feeding remains difficult for weeks or months. Infants with mainly ►white matter lesions usually have no feeding problems and neurologically may examine quite normally. The white matter, however, atrophies and they develop a secondary microcephaly.

Imaging

MR imaging is the modality of choice for assessing the brain in infants with suspected perinatal brain injury at term. Ultrasound is complimentary but needs to be performed serially for at least the first week to detect lesions. It may still be difficult to identify peripheral infarction and subtle but clinically significant basal ganglia lesions. CT is unable to detect many lesions within the basal ganglia and thalami, to determine their severity or to visualise the signal intensity within the posterior limb of the internal capsule. It may add little to a good cranial ultrasound. Optimal MR imaging can identify the pattern of injury in great detail providing information that can then be used to predict outcome. The timing is important whilst early imaging may be required so that decisions about continuing intensive care can be made the severity of injury may not be obvious unless diffusion weighted sequences are used. The ideal imaging window is from 1–4 weeks.

An optimum MR examination should include T1 and T2 weighted images in the transverse plane and T1 weighted images in sagittal plane should be obtained. Sequences may need to be adapted to the neonatal brain with its higher water content and longer T1 and T2 values. Diffusion weighted imaging should be used in the first week from delivery as it may identify areas of ischaemia that are not yet obvious on conventional imaging. T1 transverse images are the most useful for assessing the posterior limb of the internal capsule (PLIC) (1).

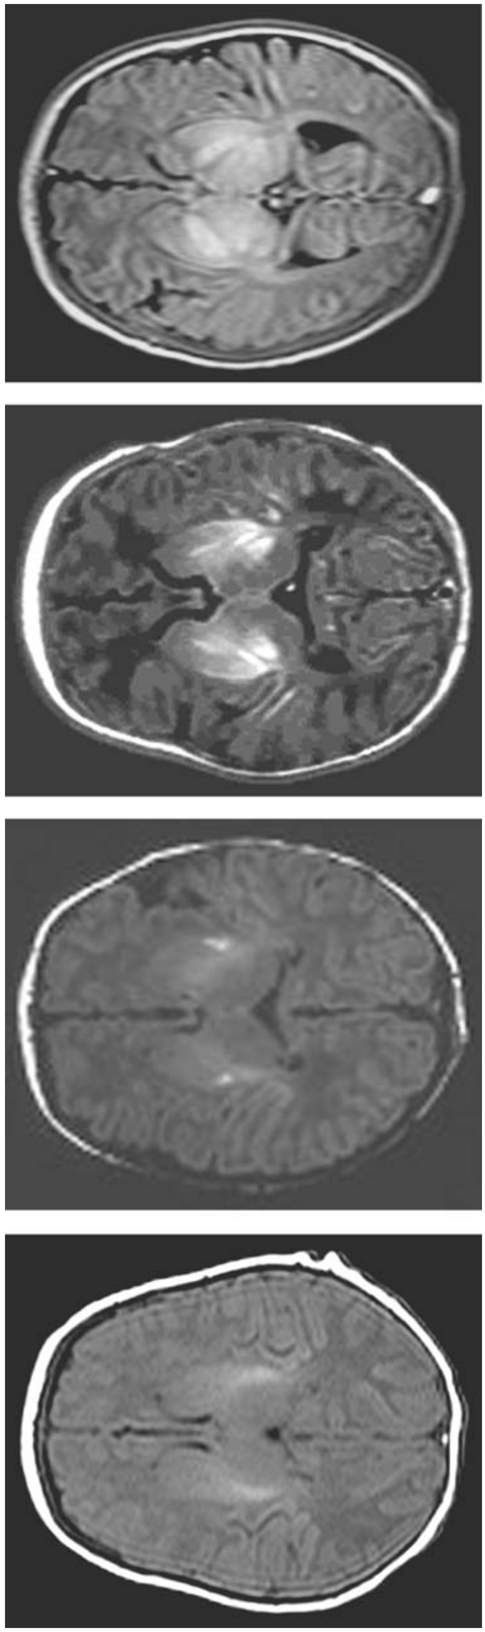
There is not usually any need for contrast. A venogram is helpful in delineating associated thrombosis from subdural haemorrhage within the major sinuses. By the time most neonates are imaged, haemorrhage is evident on conventional T1 and T2 weighted sequences. It is usually necessary to sedate neonates for MR examination; anaesthesia however is not justified. Feeding and wrapping neonates can occasionally produce a natural sleep for long enough to image.

H

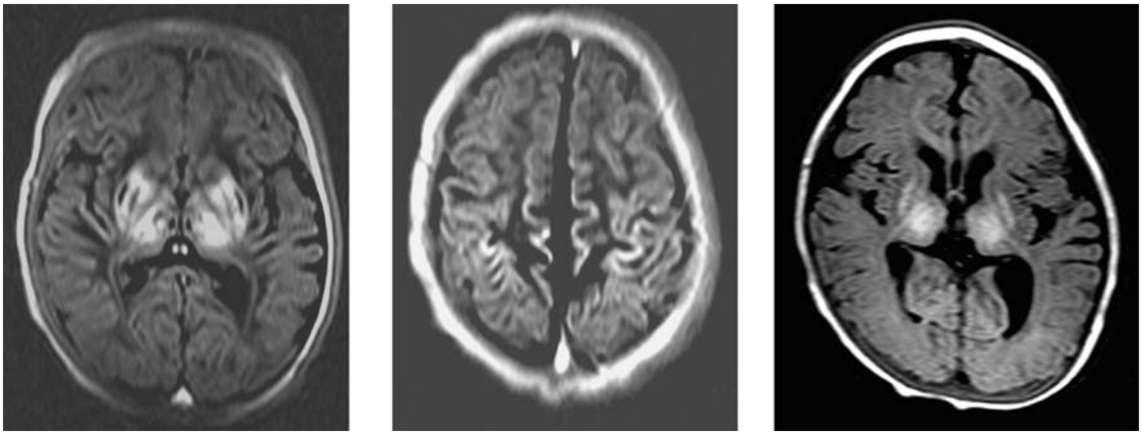
Imaging Patterns in HIE

A brain with a clinically significant HI injury will show abnormalities on MR imaging but expertise is required in interpretation. If the MR images are normal or show mild changes only in a neonate who is encephalopathic or having on going seizures then an alternative diagnosis is likely. These neonates always warrant a full metabolic screen as certain metabolic disorders may coexist or masquerade as hypoxic-ischemic encephalopathy (HIE) e.g. non-ketotic hyperglycinaemia.

The most common sites of injury in the neonate with HI injury are the basal ganglia and thalami. The severity of these lesions can be graded as mild, moderate or severe (Fig. 1) (2). They are related to the development of cerebral palsy. The intervening PLIC is normally partly myelinated in the term neonate but in BGT injury it loses its normal signal intensity. This single sign can be used to predict an abnormal motor outcome (1). In association with lesions within the BGT there may be abnormalities within the cortex, usually around the central sulcus, insula and interhemispheric fissure. The subcortical white matter adjacent to these areas of "cortical highlighting" develops a long T1 and long T2 consistent with ischaemic change (Fig. 2) . This tissue usually atrophies and appears gliotic at follow up after 1 year of age. The medial temporal lobe may also show obvious cortical and subcortical abnormalities. In infants with severe BGT lesions WM that initially has a normal appearance develops a long T1 and long T2 over the first month of life. It subsequently atrophies resulting in poor head growth and a secondary microcephaly.



Hypoxic, Ischaemic Brain Injury. Figure 1 Classification of basal ganglia and thalamic lesions. T1 weighted images showing a normal appearance, mild, moderate and severe basal ganglia lesions in neonates presenting with hypoxic-ischaemic encephalopathy.



Hypoxic, Ischaemic Brain Injury. Figure 2 Cortical and subcortical WM abnormalities. Infant with established severe basal ganglia lesions showing cystic breakdown and some atrophy. There is abnormal cortical highlighting along the interhemispheric fissure and the central sulcus. There is abnormal low signal intensity in the subcortical white matter. At 5 months of age there is persisting abnormal signal intensity with the atrophied basal ganglia and thalami and white matter atrophy.

H

In approximately 40% of infants with a global HI injury there is additional more significant WM injury involving periventricular and deep white matter (Fig. 3). Occasionally infants with signs of HIE show only white matter involvement with no BGT lesions. This can be graded as mild, moderate or severe (3). These infants do not develop cerebral palsy unless the WM involvement is very extensive. They do however develop cognitive impairment the severity of which is related to the severity of white matter abnormality. Severe WM injury may be associated with haemorrhage. On later imaging the findings can be identical to late findings in periventricular leucomalacia.

Infants with early seizures, but no encephalopathy, usually show focal infarction or haemorrhagic lesions. The infarction is usually in the region of the middle cerebral artery more often on the left side. If extensive there is involvement of hemisphere, BGT and PLIC. This combination of three sites predicts later hemiplegia (Fig. 4) (4, 5). Infants with extensive middle cerebral artery infarction may have a genetic disorder such as Factor V Leiden. Focal haemorrhage may occur at any site within the brain and be seen in association with apparent germinal matrix involvement or subdural haemorrhage (Fig. 5). There may be additional non-haemorrhagic WM abnormalities.

Prediction of Outcome

1. ►Basal ganglia and thalamic lesions are associated with later motor impairments in the form of cerebral palsy.
2. The signal intensity within the posterior limb of the internal capsule is a good predictor of abnormal motor outcome.
3. White matter lesions are associated with cognitive impairments. Motor impairments are only seen with very extensive WM injury.

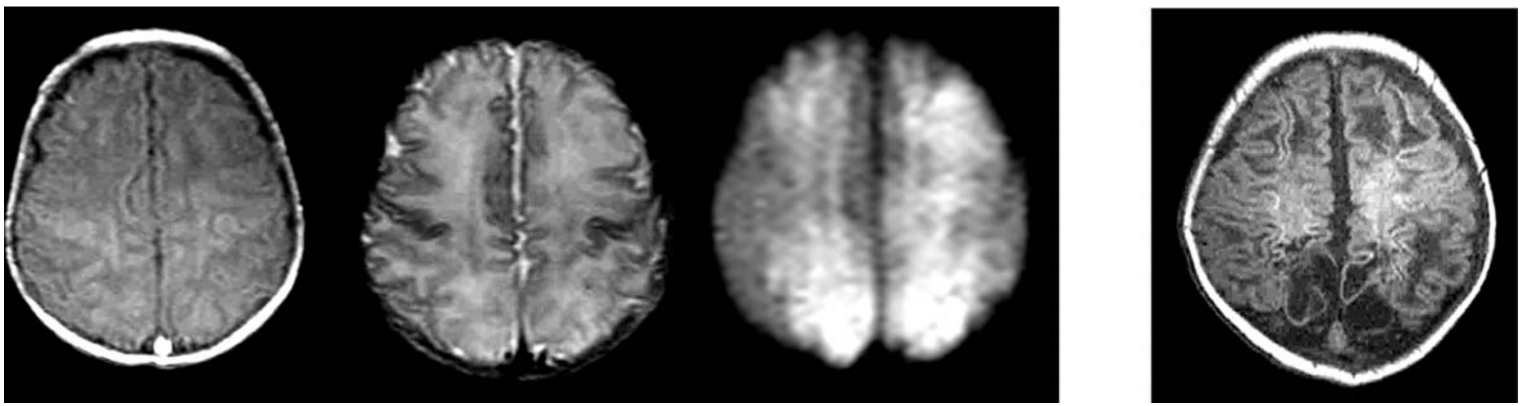
Infants with only mild basal ganglia and thalamic lesions and a normal PLIC (Fig. 1) may have a normal outcome. They may however have transient abnormalities in tone during the first year with some delay in motor milestones. They may occasionally develop a tremor in early childhood. Imaging later in childhood may be unremarkable.

Infants with moderate BGT lesions have an abnormal SI in the PLIC (Fig. 2). They usually maintain their head circumference because they have no additional WM atrophy. They show a dystonic or athetoid form of cerebral palsy. They may or may not gain independent walking. Imaging later in childhood may show atrophy of the lateral lentiform, with focal areas of long T1 and long T2 within the posterior aspect of the putamen and the lateral thalami.

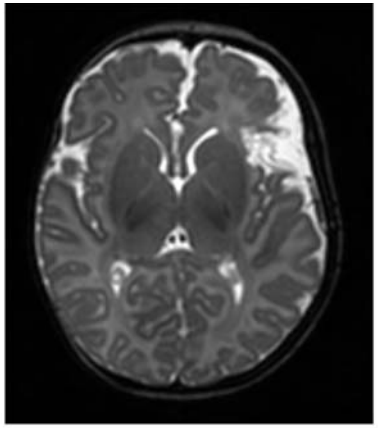
Infants with severe BGT show involvement of caudate head, lentiform nuclei and thalami with abnormal signal intensity within the PLIC. The BGT atrophy sometimes with associated cystic change. There is associated secondary WM atrophy and poor head growth (Fig. 1). These infants develop severe forms of spastic cerebral palsy. They often show little development and may develop life threatening chest infections secondary to aspiration. Seizures may develop later in infancy and may be difficult to control.

Infants with severe BGT and severe early WM lesions have a similar poor developmental outcome (Fig. 3).

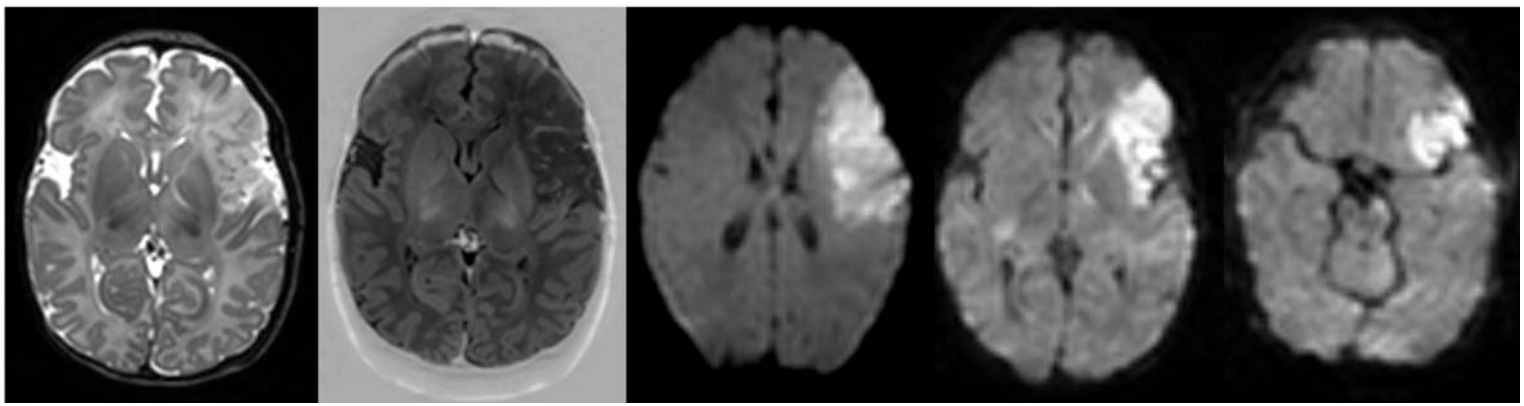
Infants with only WM involvement develop secondary microcephaly and cognitive impairments (Fig. 4). There is usually only mild motor impairment unless the WM injury is extensive with or without additional



Hypoxic, Ischaemic Brain Injury. Figure 3 White matter infarction in a neonate presenting with HIE. Aged 5 days. There is some loss of grey white matter differentiation on the conventional scans, most obvious on the T2 weighted images. Diffusion weighted imaging show widespread abnormal signal intensity consistent with restricted diffusion and impending infarction. At 3 weeks of age there has been extensive infarction of the white matter (*right*). This may have been difficult to predict with T1 weighted images alone.

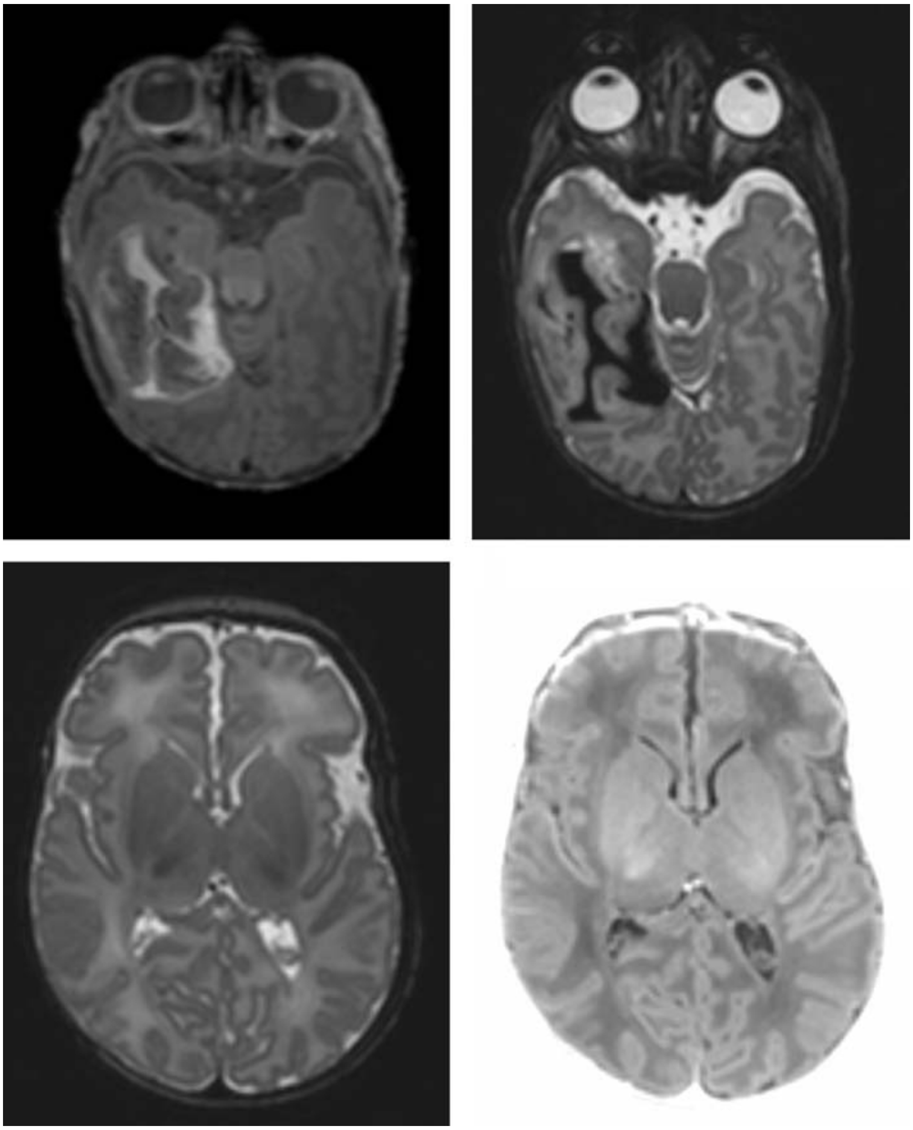


a



b

Hypoxic, Ischaemic Brain Injury. Figure 4 Middle cerebral artery infarction. (a) T2 weighted image showing small infarct in frontal lobe on left. There is a symmetrical appearance to the BGT and PLIC. This infant would be very unlikely to develop a motor impairment. (b) Left middle cerebral artery infarct at 5 days from delivery. There is a symmetrical appearance to the myelinated part of the PLIC. However there is some abnormal signal intensity within the more anterio part of the PLIC and the anterior internal on all sequences. There is additional abnormal signal intensity within the brainstem on the diffusion tensor images. This combination would put this infant at increased risk of a later hemiplegia.



Hypoxic, Ischaemic Brain Injury. Figure 5 **Focal haemorrhage Term born neonate presenting with seizures. There is a large haemorrhage involving the right temporal lobe. The appearances of the BGT and posterior limb of the internal capsule are symmetrical and within normal limits. This child is highly unlikely to develop any motor impairment.**

haemorrhage. Motor impairment in these severe cases usually takes the form of a diplegic cerebral palsy (3).

Focal infarction or haemorrhage site of lesions determines outcome (Fig. 5). White matter lesions or haemorrhagic lesions that do not involve the corticospinal tracts particularly the PLIC usually show a normal motor outcome (Fig. 5).

Hysterosalpingography

HSG is an X-ray technique to visualize the inside of the uterus and tubes after administration of contrast agent into the endometrial cavity. It provides a morphological assessment of the endometrium cavity and supplies information regarding tubal patency. Typically, the question of müllerian duct anomaly arises during HSG examination if the typical trigone configuration of the cavity is not demonstrated. Because only the internal contour of the uterus can be assessed and the outer contour remains unclear, the characterization of uterine anomalies is somehow difficult, especially in the common case of differentiation between bicornuate and septate uterus.

Synonym

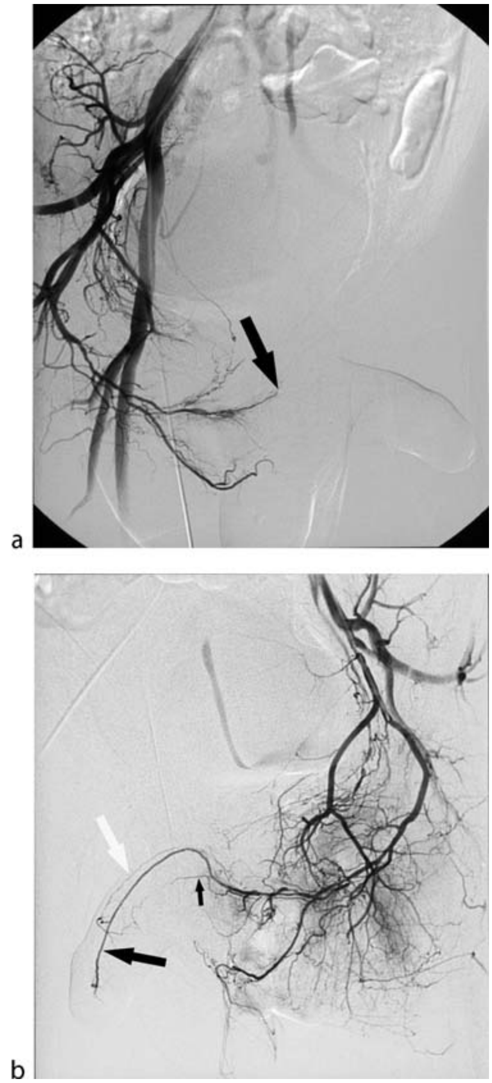
Erectile dysfunction (ED); Impotentia coeundi

Definition

Impotence is defined as "male erectile dysfunction, that is, the inability to achieve or maintain an erection sufficient for satisfactory sexual performance" (1).

Imaging

Prescription of a PDE-5-inhibitor is the recommended primary treatment in most men, irrespective of the etiology. Therefore, imaging studies in the field of erectile dysfunction will rarely influence the treatment of these patients. Imaging in the field of erectile dysfunction is warranted in men with a presumed vasculogenic erectile disorder that may be amenable to surgical or interventional treatment. A Doppler ultrasound examination of the penile arteries after pharmacologically inducing an erection (intracavernosal injection of prostaglandin E1, e.g., 10 μg Alprostadil) is the preferred technique to assess an arteriogenic ED (depending on peak systolic arterial flow rates). Moreover, a veno-occlusive ED can be suspected when high end-diastolic arterial flow rates are recorded. The index of vascular resistance (RI) can be calculated and adds further information when considering a veno-occlusive ED. Several investigator and patient dependent factors make this examination subject to artifacts. Patient's anxiety and a cold and busy examination room are not helpful to facilitate relaxation of smooth muscle cells within the corpus cavernosum after pharmacostimulation.



Impotence. Figure 1 (a) Selective arteriography of the anterior trunk of the right internal hypogastric artery depicting an occlusion of the right common penile artery (**black arrow**). (b) Selective arteriography of the left internal pudendal artery depicting normal dorsal penile (**fat black arrow**) and cavernosal artery (small black arrow). The right dorsal penile artery is filled through collaterals from the left side (**white arrow**) (With courtesy of the department of radiology, University Hospital Zurich, Switzerland.).

Impotence. Figure 2 (a and b) Cavernosography depicting early venous outflow in superficial dorsal and pelvic veins.

Selective penile arteriography is advisable before planning surgery when Doppler ultrasound examination results are abnormal (Fig. 1a, b). Arteriography offers the best anatomical information concerning the pelvic arterial inflow. Additionally, a dynamic infusion cavernosometry and cavernosography can help to confirm the diagnosis of a veno-occlusive ED (Fig. 2a, b). However, the clinical consequences and diagnostic yield of this study, in the light of color Doppler flow studies, remain limited.

Accidental clinical findings; Incidentalomas; Lesions of unknown etiology; Unexpected clinical findings

Definitions

►Incidental findings are defined as observations of potential clinical significance made unexpectedly in healthy subjects or in patients recruited to research that are unrelated to the purpose or variables of a study. Clinically significant incidental findings in research, such as that of a tumor or arteriovenous malformation (Fig. 1), are distinguished from discovery of significant findings in clinical situations because they are not prompted by a complaint or an individual's medical history. This entry will focus on the complex issues surrounding the discovery of incidental findings primarily in the domain of neuroimaging research in which tens of thousands of human subjects are scanned each year as healthy volunteers.

A decade of empirical work on incidental findings in brain imaging, genomics, and other areas of research has yielded new knowledge about the frequency, investigator responsibility, and risks and benefits of disclosure. Early guidance on how such unexpected findings might be handled, especially given the variation in clinical significance with which they occur, is offered by the genetics literature. The 1999 National Bioethics Advisory Commission (NBAC) and the 2004 *Working Group on Reporting Genetic Results of NIH's National Heart Lung and Blood Institute*, for example, recommended that research results should be given to subjects if (a) the findings are scientifically valid and confirmed, (b) the findings have significant implications for the subject's health, and (c) a course of action to ameliorate or treat the concerns is readily available. However, the genetics guidelines and discussion address, as intended, data that might predict a health condition rather than reveal the presence of a potentially clinically significant medical condition.

Characteristics

Although case reports and retrospective studies of incidental findings in clinical medicine have been published in the past with some frequency, there were only a few reports of incidental neuroradiological findings in healthy control subjects recruited to brain imaging for research purposes until recently. Early data suggest anomalies in as many as 18–20% of research subjects (1). In 2–8% of the subjects, findings were clinically significant and required clinical evaluation with various degrees of urgency, from routine to immediate, depending on the nature of the finding. In another retrospective study, three of four findings in adults aged 18–59 years were found to require urgent referral (e.g., arteriovenous malformations, extra-axial lesions) (2). In the same study, incidental findings were discovered in 47% of older adults (≥60 years), although most required only routine follow-up such as for nonspecific white matter lesions. In

The image is displayed in radiological convention. (Courtesy of the Richard M. Lucas MRI Center, Stanford University.)

another study based on a sample of ultra healthy air force pilots, incidence was only a fraction of a percent (3). In a study of 225 pediatric subjects, incidental findings were found in 21%. In 5% of the cohort, the findings were clinically significant (4).

Management

Protocols

Wide variability exists in the way that incidental findings are handled. One group worked for more than a year to develop practical guidelines for managing incidental findings. This group of leaders in neuroscience, bioethics, policy, and law reached consensus that investigators engaged in brain imaging research must anticipate incidental findings in their experimental protocols and establish a pathway for handling them (5). A majority of this group felt that an individual with medical training should review any suspicious brain finding. If there is sufficient reason to think that the finding may be significant, the principal investigator or designate should inform the subject or the subject's surrogate in the case of children or subjects with limited decisional capacity. A minority of the group felt that given continuing uncertainty about true incidence and risks of ►false positive findings, subjects should be given the option to decline to be told (i.e., right to not know). In addition, they maintained that investigators should have the option not to pursue findings beyond clearly articulating a management plan both to the Institutional Review Board (IRB) and to participants when obtaining informed consent (see also "Disclosure" below). Principal investigators bear primary responsibility for handling all findings in their research and for managing them appropriately.

A variable element in research protocols is the extent and immediacy of the involvement of medically trained staff. Physicians may be involved as principal investigators of a study, as collaborators, or as ad hoc consultants. One obvious impact of physician involvement in a research protocol is in the cost of conducting the research. Another is in the accessibility of medically trained personnel. Beyond the issues of cost and availability is the level of responsibility of a clinician in a research setting. A limited clinical relationship is established that may confer responsibility beyond the researcher–subject relationship when a clinician provides a clinical read of a research scan even for the sole purpose of assessing whether a clinical work-up is mandated, and even with the inherent limitations of the scan given research acquisition parameters.

Disclosure

One of the greatest risks to participants, just as to patients in the clinical setting, is the communication of a suspicious finding that ultimately has no clinical significance. The major consequences involve personal and psychological cost, financial cost, and cost to privacy.

1. Psychological cost: Awaiting clinical work-up for a finding detected in the context of research participation may cause significant anxiety for an individual who, by all measures, is asymptomatic and has contributed altruistically to the research enterprise.

   While mortality of follow-up tests such as routine MRI or CT scans is certainly slight, morbidity may be greater with the administration of contrast or the use of radiation. For certain types of findings (e.g., vascular malformation or tumors) further more risky diagnostic tests such as angiography or biopsy might be indicated. Anxiety may be exacerbated for patients for whom MRI is contraindicated because of claustrophobia.
2. Financial cost: The financial cost of clinical follow-up of an incidental finding is borne by the participant or a third party insurance carrier since such coverage is not a usual part of the funding for research. This is different at a small number of imaging centers in the United States, such as at the National Institutes of Health, where every research subject is required to be a patient and undergoes a complete clinical examination before being entered into a protocol.
3. Cost to privacy: Discovery and follow-up of an incidental finding may have implications for a participant's future medical insurability, even if the result is negative, and possibly to employability in cases where fitness is partly assessed by medical history.

Subject Selection

Challenges to subject selection arise in designing research protocols when incidental findings are a possibility. These include proper inclusion/exclusion criteria based on the risk of incidental findings occurring, subjects' ability to obtain follow-up health care, researchers' ability to track or contact subjects for follow up, and the inclusion of populations that may be vulnerable. Ethical considerations play an important role when thinking about special populations such as pediatric subjects, pregnant subjects, and subjects with limited access to health care and health insurance.

Good neuroimaging studies providing baseline images of "normal" pediatric brains in various developmental stages are lacking and make predictions about the possible clinical significance of a pediatric incidental finding particularly difficult.

Involvement of subjects such as university students and employees of imaging laboratories must be carefully considered given risks to privacy, such as the discovery of an incidental finding and other broader ethics risks such as the possibility of coercion in recruitment. The sense of subjects' rights in research, such as that of the right to withdraw, maybe also be compromised in a setting in which a power relationship exists.

In the case of adults with diminished decision-making capacity, it is important to clarify who is empowered to make research decisions for the participant. Inclusion of disadvantaged or disenfranchised subjects who do not have ready access to health care, either through a lack of insurance or the availability of medical facilities, is essential to much research involving mental illness and addiction disorders. Protocols should have a safety net for these subjects and for the real costs that may directly stem from the discovery of a finding requiring work up. Requiring contact information is justifiable because of potential for the discovery of life-saving information.

Overall, ensuring the protection of human subjects in neuroimaging, and trust in and integrity of the scientific process are of paramount importance.

catherine.roy@chru-strasbourg.fr

Definition

Dysfunction of the bladder, caused by various abnormalities, is a rather common clinical symptom, especially in women. ▶Incontinence, Urinary is defined as any involuntary urine loss that is a social or a hygienic problem. Stress urinary incontinence is defined as urine loss during daily or physical activities that increase abdominal pressure (in the absence of detrusor contraction or overdistended bladder). Perineal descent, cystoceles, and prolapses are often associated with urinary incontinence. Cystoptosis corresponds to the descent of any part of the bladder below the horizontal line drawn at the inferior edge of the pubic bone symphysis. When the neck and the bladder base fall, the result is cervicocystoptosis. When, rarely, the isolated neck falls, it is called cervicoptosis.

Pathology

Urinary incontinence requires integrity of both the nervous system and overall pelvic anatomical support structures, including muscular and fascial components. If the intravesical pressure exceeds the intraurethral pressure, incontinence results. Alternatively, it has been suggested that urethral compression against the endopelvic fascia and vagina is responsible for closure, as stated in the "hammock theory" (1). The most important risk factor for urinary incontinence is obstetric injury first with vaginal delivery, second with prolonged labor, and then forceps delivery. The mechanism of urinary incontinence in pregnancy remains unclear, but it may be due to a combination of endocrine and mechanical factors. Less common causes of urinary incontinence include urethral diverticula, overflow incontinence secondary to pharmacologic or neurologic causes, and very rarely in women bladder outlet obstruction.

Urinary incontinence is divided into two main etiologic groups (1).

Urge Urinary Incontinence (or Vesical Incontinence)

Urge incontinence is the involuntary loss of urine associated with an abrupt and strong desire to void. It is the occurrence of involuntary contractions during filling or provoked by coughing or postural changes which the patient is unable to inhibit. The diagnosis is made by urodynamic testing. The role of imaging techniques is limited to searching for a rare cause such as a morphologic abnormality, an adjacent pathology, or a neurological disease.

Stress Urinary Incontinence (or Urethral Incontinence)

Stress Urinary incontinence is defined as urine loss during current daily or physical activities that increase abdominal pressure (in the absence of detrusor contraction or overdistended bladder). It may result from two distinct mechanisms: hypermobility of the bladder neck in 75% of cases (HBN) or intrinsic sphincter deficiency (ISD) in the others 25% of cases.

- With HBN, the basic anatomy and function of the bladder neck and urethra are intact. It is primarily caused by weakened pelvic floor support caused by denervation, musculofascial defects, or both secondary to aging, obesity, pregnancy, and vaginal delivery. The bladder neck and proximal urethra descend below their normal pelvic positions during straining, owing to weak musculofascial bladder and urethra attachments to the pelvic wall. When this normal anatomic position is altered, the urethra is no longer able to respond to the increase in abdominal pressure.
- In the case of ISD, the urethral sphincter is defective. It is unable to generate adequate urethral pressure to collapse the urethral lumen, and the bladder neck remains open even at rest. The bladder neck and urethra are well supported in their pelvic position. ISD can be caused by sympathetic nerve injury (surgery, trauma) or by degenerative processes (myelodysplasia, spinal cord lesions at the conus medullaris). Indeed, in most cases, it remains idiopathic.

Clinical presentation

It occurs in 38% of women over the age of 60 years and 59% of women after 75 years. The problem is seen even in the young, occurring episodically in as many as 45% of women over 18 years of age. The initial and essential step for the diagnosis of Urinary incontinence is a clinical examination and urodynamic testing with voiding speed evaluation. Voiding speed, the simplest urodynamic study, is performed particularly on patients with no obvious neurological lesion or those who may have an obstructed bladder outlet.

Imaging

Over the past decade, the most widely used imaging studies were voiding bead chain cystourethrograms and dynamic retrograde urethrograms, in addition to the minimally invasive colpocystodefecography, developed by Bethoux in France (2), and transabdominal ultrasound. These studies are designed to analyze and quantify the mechanisms of incontinence, whereas transabdominal ultrasound is used to assess overall urinary status and postvoiding bladder volume. Alternative advanced ultrasound techniques and ▶magnetic resonance imaging (MRI) are now emerging as new tools for imaging pelviperineal defects.

Ultrasound: Ultrasound offers major advantages over X-rays for imaging the bladder and urethra. It provides good soft-tissue morphologic analysis of the urethrovesical junction and dynamic bladder neck imaging with quantified movements. Examinations are easy, relatively quick (10–15 min), and inexpensive. Evaluation is limited, however, to the anterior pelvic compartment, and requires operators to have experience and knowledge of urodynamics (3).

Three different approaches to ultrasound are available today: external ultrasound (transabdominal, perineal, and introital); endosonography (transvaginal and transrectal); and endoluminal (intraurethral) sonography. Transabdominal ultrasound gives an overall evaluation of the urinary tract, but misses the perineal floor.

In perineal scanning, a narrow curved array linear probe (3–5 MHz) or a common sectorial vaginal or transrectal probe (5–7.5 MHz) is applied to the perineum, whereas for introital sonography only the second one can be used, placed under the distal part of the urethra at the introïtus. Image quality depends partly on the probe's proximity to the target area, meaning that endosonography produces the clearest images. However, route choice requires a compromise between image quality and degree of interference in normal lower urinary tract function. Probe placement in endosonography displaces the bladder neck and compresses the urethra. Dynamic studies can consequently be limited, inhibiting normal voiding. Thus, perineal or introïtal US seems to be the pertinent technique using a common endoluminal probe. The sagittal plane is used to obtain a cross-sectional view through the bladder and urethra. The best image quality is obtained with a bladder filled with approximately 300 mL of urine (Fig. 1). Evaluation is first performed at rest in lateral decubitus with knee flexion and in standing position. Dynamic studies are then carried out during pelvic floor contraction and maximum straining in each position.

The normal aspect is a closed bladder neck in all positions or situations (Fig. 2). Correct identification of

I

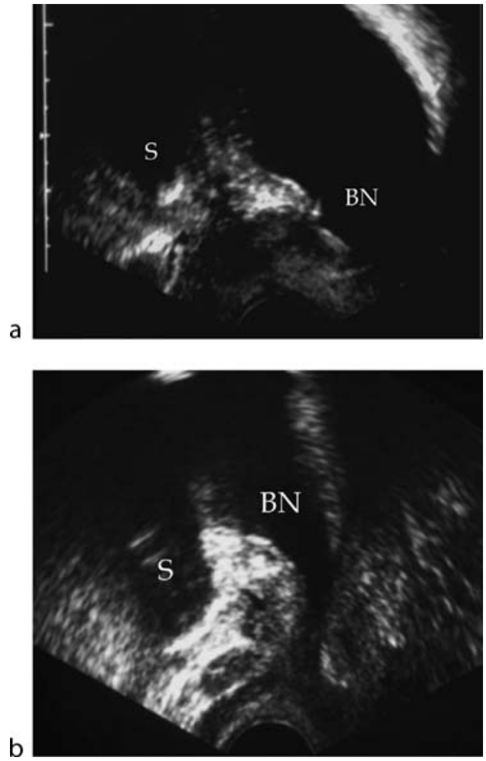
The bladder neck (BN) is clearly above the reference line. It is closed. The urethra has a hypoechoic pattern. (S): symphysis pubic bone.**

the bladder neck, which should remain closed, can be problematic with external techniques. In certain orientations, notably a strict sagittal view, an anechoic posterior shadow artifact caused by the urethra's fibrous normal component hides the bladder neck. This is easily avoided by tilting the probe slightly.

The long axis of the symphysis and the lower border of the symphysis pubic bone are used as fixed landmarks. The position of the bladder neck and displacements are calculated using a horizontal line as reference perpendicular to the axis of the symphysis (Fig. 1). At rest, the normal position of the bladder neck is above or at the level of the reference line and the angle is around 50°.

The diagnosis of HBN (Fig. 2) can be made with a displacement up to 1 cm associated or not with a low position of the bladder neck at rest under the reference line.

Isolated ISD is suggested by bladder neck funneling or a clearly opened urethra at rest and vesicalization of the urethra or opened urethra with voiding during maximum straining (Fig. 2). However, the position of the bladder inside the pelvic cavity remains within normal limits.In the recommendations of the First International Consultation on Incontinence held in Monaco in 1998 (4), bladder neck and pelvic floor ultrasound were considered only as a complementary investigational imaging technique in the evaluation of female incontinence and pelvic floor disorders and not as diagnostic for stress Urinary incontinence. They also recommended that only residual urine measurement by transabdominal ultrasound should be included in the routine initial evaluation of incontinent patients. However, ultrasound evaluation of the bladder neck can help to document the pelvic floor anatomy and discover mixed



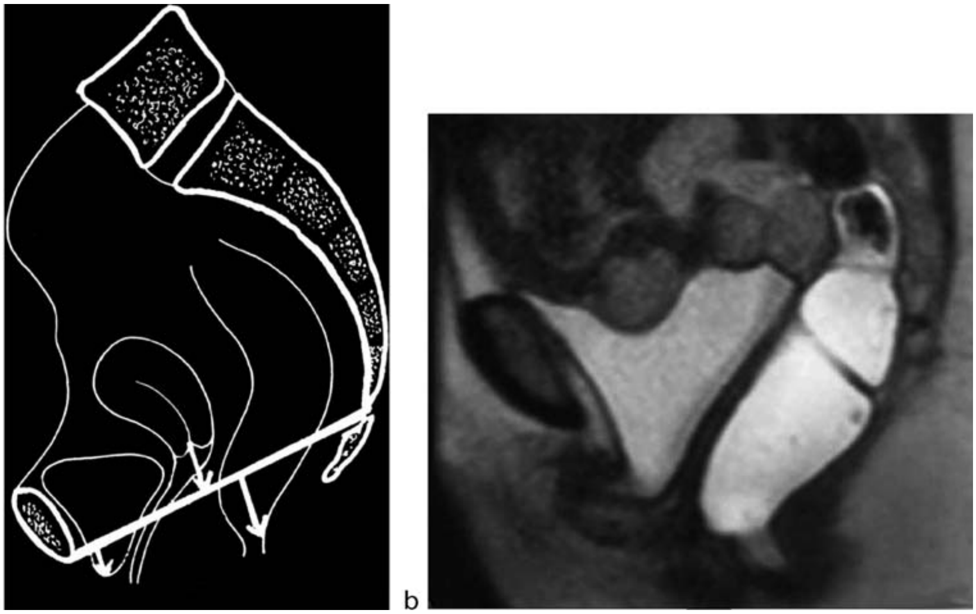
Incontinence, Urinary. Figure 2 ►***Perineal ultrasound technique*****. Sagittal view. Lateral decubitus. (a) Hypermobility of bladder neck (HBN). Maximum straining. The bladder neck is under the reference line. It appears slightly funneled. The urethra has moved down and horizontally. Cystocele is associated with enlargment of the angle between the urethra and bladder base. (b) Rest. Intrinsic sphincter insufficiency (ISD). The bladder neck (BN) is opened at rest with a clear funneled aspect. It is located at the level of the inferior border of the symphysis pubic bone (S). There was no abnormal displacement during straining.**

abnormalities, which is a rather common finding. Ultrasound can also be used to evaluate postsurgical slings or other medical devices and complications.

Magnetic Resonance Imaging

Pelvic floor weakness is a global abnormality, affecting all three compartments. Noninvasive dynamic imaging of the whole pelvic cavity may also be possible.

Morphologic analysis of muscles is made by T1-weighted spin-echo imaging, whereas T2-weighted fast spin-echo imaging is used for pelvic organs. Highly detailed morphologic evaluation of soft tissues, especially the urethra and bladder neck, is provided by addition of an endoluminal coil, located endovaginally or endorectally. This may be used in combination with a phased array multicoil to assess the



Incontinence, urinary. Figure 3 ***MRI. Sagittal view*. (a) Drawing of reference line. The pubococcygeal line is commonly used. Note the associated posterior descent.**

entire pelvic cavity. Fast T2-weighted imaging allows dynamic imaging of the mobility of pelvic floor structures during straining, without any kind of opacification except for the rectum filled with 120 cc of sonographic gel to obtain homogeneous hypersignal inside. Imaging is performed sagittally, to assess displacement, and coronally, to assess levator ani muscles curves. Pelvic prolapse can be imaged in all three compartments simultaneously. Dynamic MRI is used to determine the frequency of associated urinary, genital, and anorectal abnormalities in women with pelvic floor dysfunction.

Pelvic organ descent is measured in relation to a reference line drawn from the inferior border of the symphysis pubic bone to the last coccygeal joint (pubococcygeal or pubosacral lines) on a sagittal plane (Fig. 3). At rest, the normal bladder neck is located between 1 and 2 cm above the reference line or at its level. During straining, the bladder neck goes back and down but remains at the level or slightly below the line. While not as accurate as ultrasound in finding tiny details on the bladder neck or urethra during movement, dynamic MRI can demonstrate an open or funneled bladder neck (Fig. 3). Endoluminal MRI demonstrates the characteristic "target" appearance of the urethra. It is useful in identifying urethral abnormalities (including diverticula) and periurethral tissues (congenital abnormalities, fistulae, tumors).

Indirect Imaging

CARMEL T. CHAN, SANJIV SAM GAMBHIR
Department of Radiology, Molecular Imaging Program at Stanford (MIPS) and Bio-X Program, Stanford University School of Medicine, Stanford, USA
carmelc@stanford.edu
sgambhir@stanford.edu

Definition

Indirect imaging refers to imaging a process or molecular target indirectly. For example, if one is imaging a protein target and using that information to infer location(s), activity, or numbers of a different molecular target, which would be considered indirect imaging. The target is often considered a surrogate for the true target of interest. The indirect imaging approach is in distinction to direct imaging in which the target of interest is directly imaged.

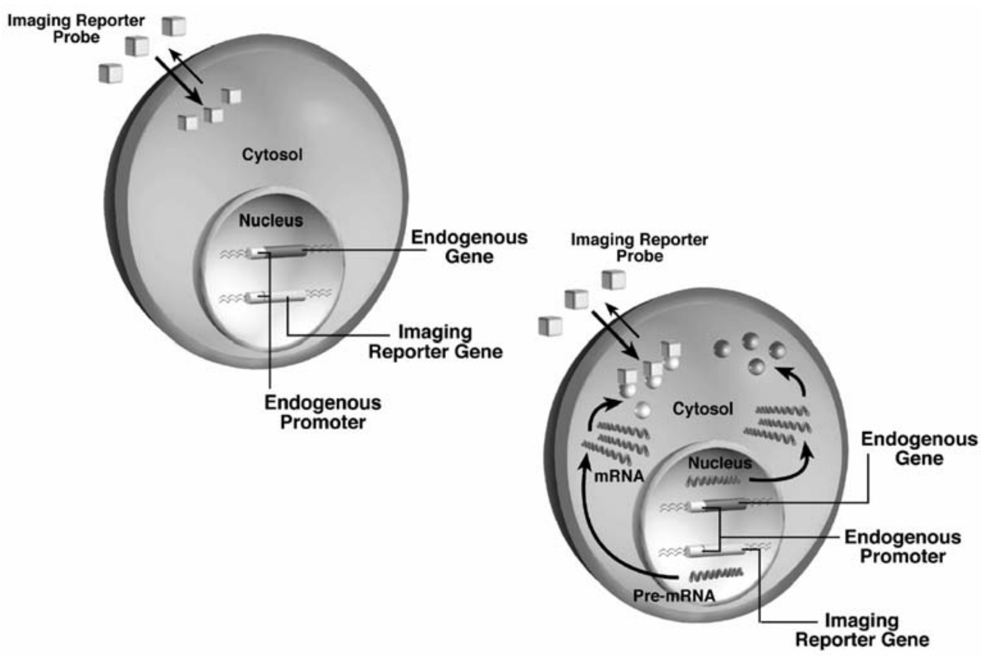
Imaging

Indirect imaging is useful when production of an imaging probe specific for a target of interest is difficult/impossible, or when the target of interest is present in relatively low amount and cannot be imaged directly using standard techniques such as labeled antibodies and ligands. For the latter, higher levels of imaging signal per unit level of target and probe interaction can be achieved with indirect imaging through different signal amplification strategies that will be described below (1). Indirect imaging can be accomplished by both radiolabeled probes and optical probes in conjugation with micropositron emission tomography (microPET), bioluminescence/fluorescence imaging respectively, as well as magnetic resonance imaging (MRI). As in the case for direct imaging, a time delay between injection of the probe and imaging is required for clearance of untrapped/unbound probes and enhancement of signal to background ratios, since the scanner cannot distinguish the parent tracer from the bound or metabolized tracer.

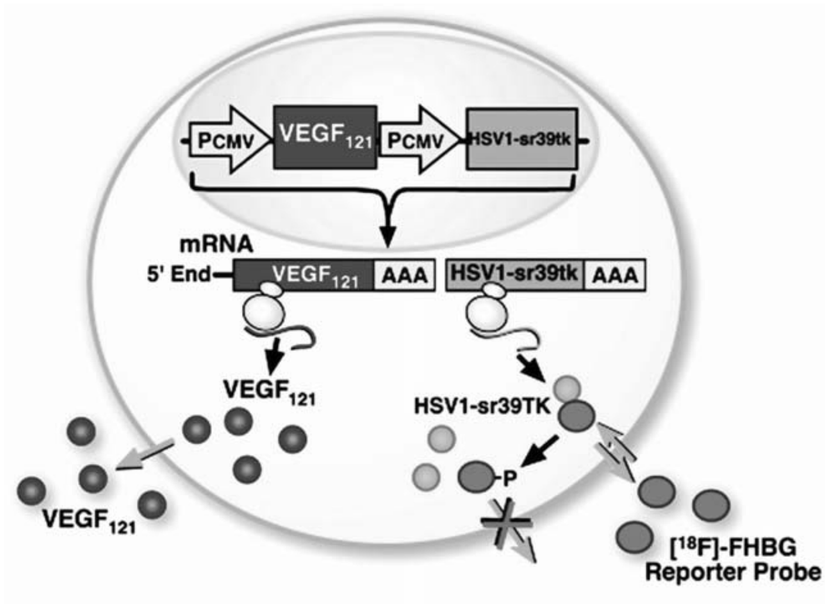
Applications Indirect Imaging

Indirect Imaging of Endogenous Gene Expression

In order to monitor endogenous gene expression noninvasively, one would need to develop specific probes that will recognize the gene product(s). For example, labeled antibodies or ligands are needed to detect cell surface proteins and those secreted into the extracellular space whereas another set of probes that can penetrate the cells will be needed to image intracellular targets. Ideally, specific probes can be made to allow direct imaging of targets of interest (See Applications of Direct Imaging in "Direct Imaging".). However, when such probes are not readily available, the expression of an endogenous gene can still be imaged indirectly by fusing the promoter of that gene to drive the expression an imaging reporter gene (Fig. 1). In order to study the regulation of vascular endothelial growth factor (VEGF) noninvasively during wound healing in skin, the express of VEGF protein was indirectly imaged using the Firefly Luciferase (FL) (2, 3)



Indirect Imaging. Figure 1 Concept of indirect imaging to monitor endogenous gene expression. An endogenous promoter is fused to an imaging reporter gene of interest. Transcription of the endogenous gene and imaging reporter genes are regulated by the same endogenous promoter. Expression of the endogenous gene can then be indirectly inferred from that of the imaging reporter gene.



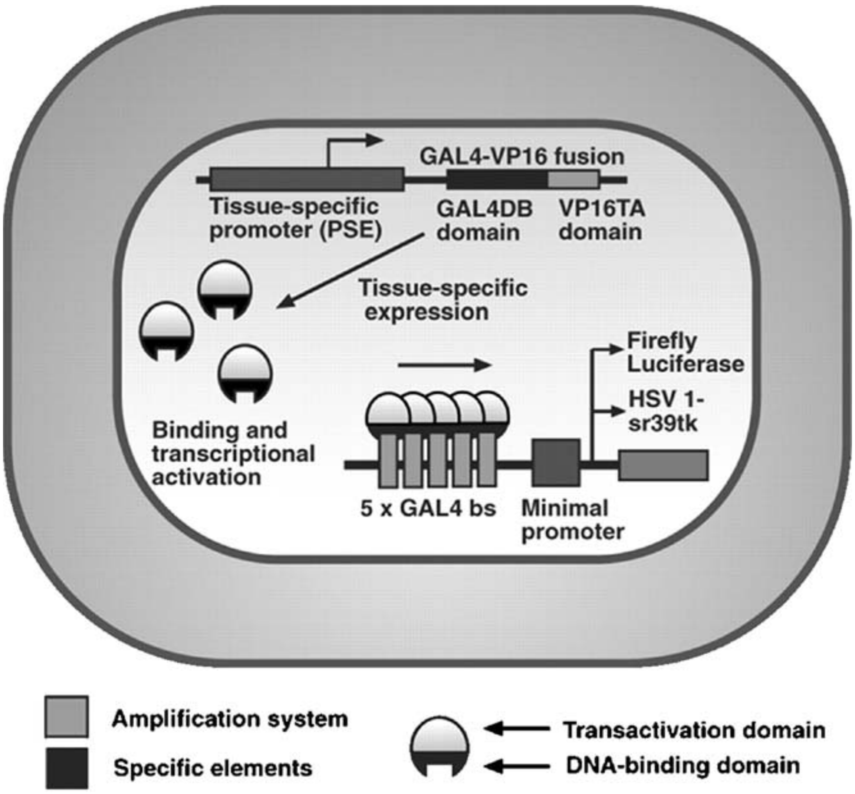
Indirect Imaging. Figure 2 Schematic diagram for indirect imaging of vascular endothelial growth factor (VEGF) expression in a rat myocardium infarction model. An adenovirus carry the gene cassettes expressing the therapeutic $VEGF_{121}$ and HSV1-sr39tk reporter gene was used to infect the rat myocardium. The production of VEGF protein was indirectly imaged by microPET using HSV1-sr39tk as the reporter gene and [^{18}F]-FHBG as the substrate. Reproduced with permission from Wu JC et al (2004) Circulation 110:685–691.

as the optical reporter gene for bioluminescence imaging. The kinetics of VEGF production in the ischemic rat myocardium infected with an adenovirus carrying both VEGF and the Herpes Simplex Virus Type 1 thymidine kinase (HSV-tk) was indirectly imaged by microPET using the HSV-Tk as the reporter gene (1) (Fig. 2). The promoter activity of the prostate-specific antigen (PSA) in a prostate cancer xenograft models was also indirectly imaged using the same approach, in which FL and the mutant HSV-TK (HSV1-sr39tk) were used the reporter gene for optical bioluminescence and microPET imaging respectively. To noninvasively determine the influence of protein diets on endogenous albumin gene expression, a transgenic mouse model in which the endogenous albumin promoter was used to drive the expression of the Mutant HSV-TK reporter gene was utilized. The expression of the albumin gene was indirectly monitored from HSV-tk activity, using microPET in conjunction with 9-[4-[^{18}F]fluoro-3-(hydroxymethyl) butyl]guanine (FHBG) as the HSV-TK substrate. Even though endogenous promoters are highly specific for the genes of interest, they are relatively weak compared to other constitutively active viral promoters such as the cytomegalovirus (CMV) promoter. As a result, direct fusion of an endogenous promoter to the reporter gene(s) often leads to very low levels of reporter mRNA/protein and hence low sensitivity for imaging in living subjects. To circumvent this issue of high specificity but poor sensitivity, the two-step transcriptional amplification (TSTA) system was developed to monitor transcription of a weak/endogenous promoter noninvasively in living animals. The TSTA system is based on the use of a weak/ tissue-specific promoter to drive the expression of a strong transcriptional activator (effector), which in turns binds to a strong promoter (e.g. CMV) that drives the expression of the reporter gene (Fig. 3). A bidirectional TSTA system has also been developed that allows simultaneous amplification of two different reporter genes driven by the same promoter, as well as possible replacement of one of the reporter gene with a therapeutic gene of interest. Most recently, transgenic mice models utilizing TSTA system have also been developed to image the tissue-specific and temporal regulation of the PSA promoter and VEGF promoter activity using FL as the reporter gene.

Indirect Imaging of Protein–Protein Interactions

Protein–protein interactions play an important role in all aspects of cell function, including biosynthesis and degradation of macromolecules (DNA, RNA, and proteins), as well as cellular responses to proliferation, differentiation, survival and apoptosis signals. Despite of the rapid increase in number of molecularly targeted agents, the technologies available for studying protein–protein have been limited to *in vitro* analyses such as co-

I



Indirect Imaging. Figure 3 **Schematic diagram for indirect imaging of endogenous promoter activity using the two-step transcriptional amplification (TSTA) system. In the first step, the expression of the GAL4-VP16 transactivator is driven by a tissue-specific promoter (e.g., PSE). In the second step, GAL4-VP16 transactivator binds to the GAL4 response elements in a minimal promoter to drive the expression of reporter genes (either *fl* or HSV1-sr39tk), leads to reporter protein, which in turn leads to a detectable signal in the presence of the appropriate reporter probe (D-Luciferin for FL and FHBG for HSV-sr39tk). The TSTA system thus allows amplification of the imaging signals without sacrificing tissue specificity. Reproduced with permission from Iyer M et al (2001) PNAS 25:14595–14600).**

immunoprecipitation (co-I.P.)/western blotting and cell binding and cytotoxicity assays, which are labor intensive and invasive in nature. To overcome limitations in studying protein–protein interactions intact cells in their native environment, the split Renilla Luciferase (RL)–Protein-Fragment-Assisted-Complementation (SRL–PFAC) technology and other split reporter protein strategies were developed and validated for noninvasive, indirect imaging of protein–protein interactions, both in cell culture and in living animals (4). The SRL–PFAC is based on the complementation of N-terminal (amino acids (aa) 1–229) and C-terminal fragments (aa 230–311) of full length RL mediated by two interacting proteins. As proof-of-principle, interaction between the transcription factors MyoD and Id was imaged noninvasively in tumor cells, both in cell culture and in living animals. The SRL–PFAC has also been adapted to monitor homodimerization of HSV1-TK (5) as well as rapamycin-mediated interaction between mTOR kinase and immunophilin FKBP12. In addition to the split RL, split firefly luciferase, split β-galactosidase and split β-lactamase PFAC have also been developed to monitor protein–protein interactions and protein translocation in intact cells. Advantages of using split enzyme fragment-assisted-complementation technologies for indirect imaging of protein–protein interactions include signal amplification through the enzymatic reaction in the presence of the substrates, the ability to study protein–protein interactions in intact cells in their native environment and repetitively image the same animal for dynamic monitoring of protein–protein interaction in response to therapies. See "Protein–Protein Interactions, Applications." for a more detailed description of molecular imaging of protein–protein interactions.

Indirect Imaging of Pharmacokinetics and Pharmacodynamics of Drug Treatment

Indirect imaging has also been utilized to monitor the pharmacokinetics and pharmacodynamics of drug treatment. For example, contrast enhanced ^{1}H MRI and functional magnetic resonance spectroscopy (fMRS) have been used to indirectly monitor the release of the antimetabolite fludarabine monophosphate and gadolinium (Gd)-DTPA from an interstitial liposome depot in rats, respectively (6). The effect of tamoxifen in a murine breast cancer xenograft model in rats was indirectly imaged by dynamic contrast-enhanced MRI to monitor vascular permeability (7). Most recently, the stomach acidity (pH) in rats treated with different nitroxide compounds were monitored using low-field electron paramagnetic resonance techniques that can be extended for monitoring of drug pharmacology and different biological processes such as wound healing and tumor acidosis (8). Indirect imaging has also been used for evaluation of the pharmacodynamics of response to therapy. Heat shock protein 90 (HSP90) is involved in protein folding and is overexpressed in cancer cells. 17-allylamino-demethoxy geldanamycin (17-AAG) is a HSP90 inhibitor known to degrade HSP90 client proteins such as HER2. The efficacy of 17-AAG in a mouse tumor xenograft models was determined using cell-surface HER2 receptor as a surrogate marker (9). The expression of cell-surface HER2 before and after treatment with 17-AAG was determined by microPET imaging. 17-AAG was found to decrease the level of cell-surface HER2. However, since 17-AAG inhibits the chaperone activity of HSP90 and subsequently lead to degradation of multiple client proteins, down-regulation of cell-surface HER2 alone may not be the sole determinant for response to 17-AAG treatment.

Indirect Imaging Tumor Grades and Responses to Treatment Using Radiolabeled Metabolic Tracers and MRI Contrast Agents

Chemotherapy and radiation treatment can lead to decrease in tumor size, proliferation as well as metabolism and these events can be imaged indirectly using metabolic tracers (10). For example, ^{18}F-2-fluoro-2-deoxyglucose [^{18}F-FDG] is a biochemical mimic of glucose that can be transported into the cells by the glucose transporter and phosphorylated by hexokinase and retained inside the metabolically (glycolytic) active cells. FDG can be considered a direct imaging technique if one is interested in determining glucose transporter levels and/or hexokinase activity, but if instead FDG uptake/accumulation is being used to infer levels of other proteins or a cellular process than this should be considered indirect imaging. FDG has been used for diagnosis, staging and evaluation of response to chemotherapy in different cancers in human. Another metabolic tracer that has been used for cancer imaging is 3′-deoxy-3′-[^{18}F] fluorothymidine (FLT). FLT is transported into cells by the nucleoside transporter and subsequently phosphorylated by human thymidine kinase, which is upregulated before and after DNA proliferation. FLT has also been used as a marker for cell proliferation in staging as well as evaluation of response to chemotherapy in tumor xenograft models as well as in human clinical trials. In addition to being indirect imaging agents for evaluation of a drug/treatment that is targeted to an upstream or downstream effects of proliferation, FLT and FDG can also be used for direct imaging for mammalian thymidine kinase activity and hexokinase activity respectively. In addition to PET, MRI has also been used for screening, staging of tumor grades and responses to treatment in conjunction with different contrast agents such as gadolinium and superparamagnetic iron oxide particles.

Induratio Penis Plastica (IPP)

▶Peyronie's Disease

Indurative Mastopathy

▶Radial Scar, Breast

Infantile Choriocarcinoma

Rare tumor developing from the mother's placenta and spreading to the child. Hypervascularized lesion with infant anemia. Usually rapid tumor progression with deathly outcome. High levels of beta-HCG are diagnostic.
▶Hepatic Pediatric Tumors, Malignant

Infantile Cortical Hyperostosis

▶Caffey Disease

Infantile Hemangioendothelioma, Hepatic

Variant of cavernous hemangioma. Lesion presents often in the first 6 months of life and the majority of the patients are less than 1 month of age. Infantile hemangioendothelioma is most commonly a diffuse alteration with typical histological findings. The vascular channels in hemangioendothelioma are thinner compared to the vascular channels in hemangioma.

Synonyms

Infarct; Ischemic necrosis; Necrotic area

Definition

Renal infarction is defined as a coagulated necrotic area of renal parenchyma that results from renal arterial occlusion.

Pathology/Histopathology

The loss of blood supply results in a wedge-shaped area of coagulative necrosis that affects mostly the renal cortex but can extend into the medulla. It produces a pale area of ischemic renal tissue. Some blood supply from capsular vessels is responsible for the presence of a viable subcapsular band of cortex. The size of parenchymal loss depends on both the distribution of the occluded artery and the development of collateral arterial supply arising from the pelvicalyceal arterial network and transcapsular perforating arteries. After several weeks the infarcted parenchyma starts to shrink and will leave a cortical scar.

Renal infarction can result from various causes including embolism mechanism in patients with cardiovascular diseases, renal artery spontaneous dissection, vasculitis, shock, and trauma. In renal transplant, it is mostly due to renal arterial branch injuries occurring during surgery including kidney removal in donor and transplantation.

Clinical Presentation

Acute renal infarction produces acute symptoms including sudden onset of flank pain and tenderness or upper abdominal pain, fever, hypertension, hematuria, proteinuria and leukocytosis. Patient also can be asymptomatic.

Imaging

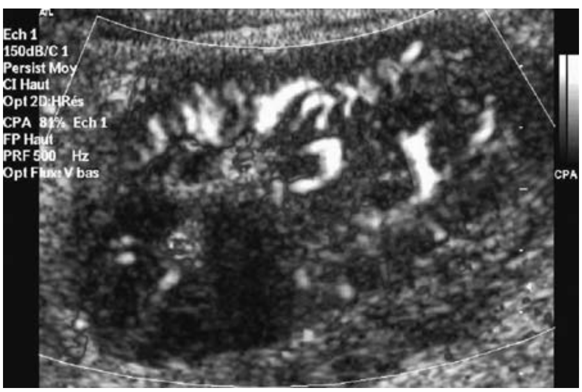
Color-Doppler Ultrasound

At color-Doppler ultrasound (CDUS), segmental infarct appears as hypoechoic area with complete loss of Doppler signals showing color flow defects with sharp edges (1) (Fig. 1). Appropriate settings (low pulse repetition frequency, PRF and optimal gain) are mandatory to obtain optimal sensitivity of the technique. Although CDUS is a valuable method in the detection of renal allograft necrosis, it is less accurate for the diagnosis of perfusion defects in native kidneys because of their deeper location. Perfusion assessment at the level of the upper and lower poles is limited by the direction of the vessels perpendicular to the US beam. The diagnosis of small perfusion defects in native and transplanted kidneys also remains difficult despite the improvement of the Doppler technique, particularly in small hypoperfused kidneys.

Ultrasound contrast agents are helpful to improve the performance of CDUS in case of technical problems and/or the small infarct size. When the renal function is compromised, they provide critical information without any renal toxicity even at the bedside of the patients. Postcontrast studies using nonlinear gray-scale imaging provide the highest resolution and sensitivity in the detection of cortical defects at an early arterial phase following contrast injection (2, 3) (Fig. 2). In renal transplants, contrast-enhanced US plays a critical role to differentiate ischemia due to medical complications, such as acute tubular necrosis and acute rejection, from true infarction.

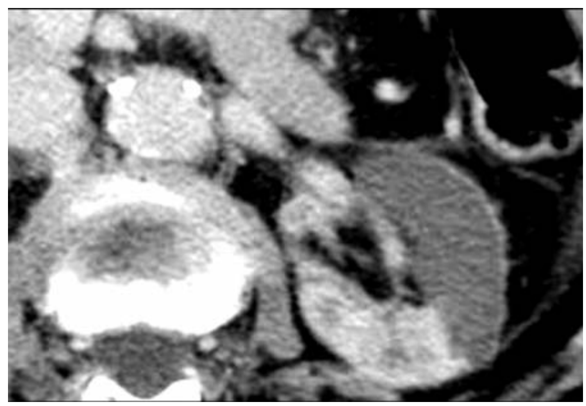
CT and MRI

►Contrast-enhanced CT remains the gold standard in the diagnosis of renal infarction. It easily demonstrates the presence of a perfusion defect, as a wedge-shaped nonenhancing area triangular in shape and cortically based, typically associated with a subcapsular enhanced rim of cortex supplied by capsular arteries (called "rim sign") (4) (Fig. 3). Such a cortical rim helps differentiate defects of ischemic origin from hypoattenuating infiltrative lesions such as acute pyelonephritis. Focal renal swelling can also be seen at an acute phase. Follow-up CT examinations show progressive reduction of the size of the cortical defect that lead to a cortical scare after several months (Fig. 4).



Infarction, Renal. Figure 1 **Power Doppler US of a renal infarction. Longitudinal scan of the left kidney shows hypoechoic area of the upper pole with loss of color Doppler signal.**

Infarction, Renal. Figure 2 **Contrast-enhanced gray-scale US of a renal infarction. Transverse scan following contrast injection shows a wedge-shaped nonenhancing area related to arterial perfusion defect.**



Infarction, Renal. Figure 3 **Acute segmental infarction of the left kidney. Contrast-enhanced CT scan shows the presence of a large wedge-shaped nonenhancing perfusion defect associated with a subcapsular enhanced rim of cortex.**

Infarction, Renal. Figure 4 **Follow-up CT scan 6 months after infarction of the left kidney. Segmental infarction has lead to a cortical scare.**

Infarction, Renal. Figure 5 Multifocal cortical infarction after renal transplantation. Contrast-enhanced MR imaging shows multiple perfusion defects. Note the presence of a typical rim sign at lower pole.

Gadolinium-enhanced MR imaging, especially in patients with critical renal failure, is also a modality of choice particularly when early accurate diagnosis is clinically required. The infarcted area exhibits a slight increase in signal intensity on T2-weighted images and is hypointense on T1-weighted images (5). Postcontrast features are similar to that of CT findings (Fig. 5).

Nuclear Medicine

Scintigraphy is of limited value in the diagnosis of renal of renal infarction. It can however demonstrate a focal loss of tracer uptake corresponding to the region of parenchymal infarction.

Diagnosis

Clinical history and findings are often confusing since it can mimic acute pyelonephritis or renal colic. While CDUS can strongly suggest the diagnosis at initial screening, accurate diagnosis relies on contrast-enhanced cross-sectional techniques (CT or MRI) or even contrast-enhanced US in skill hands.

Infarction, Spleen

Splenic infarction is a relatively rare disease. It is the result of arterial or venous compromise and is associated with a heterogeneous group of diseases, including embolic and autologic disorders, splenic vascular diseases, and anatomic abnormalities. Splenic infarction may be segmental or global, involving the entire organ.

▶Spleen, Infectious Diseases

Infected Necrosis, Pancreatic

Pancreatic necrosis is a diffuse or focal area of nonviable pancreatic parenchyma, which is typically associated to acute pancreatitis with peripancreatic fat necrosis. Secondary infection of the pancreatic necrosis is a possible complications and leads to clinical findings of infection. Distinction between sterile and infected necrosis is critical, since development of infection increases the mortality risk. Often cultures obtained by needle aspiration are necessary and surgical drainage is needed.

Cerebral infections; Immunsuppression

Definition

► Opportunistic infections are infections caused by organisms that usually do not affect persons with a healthy immune system, but can affect people with a poorly functioning immune system.

Pathology/Histopathology

Viral Infections

Cytomegalovirus

Cytomegalovirus (CMV) is the member of the herpesvirus family, the infection in adults is a result of the reativation of a latent infection. Small microglial nodules and inclusion-bearing cytomegalic cells are widely distributed in the cortex, basal ganglia, brain stem, and cerebellum in CMV diffuse micronodular encephalitis (1).

Progressive Multifocal Leukoencephalopathy

► Progressive multifocal leukoencephalopathy (PML) is a subacute opportunistic infection caused by JC *Polyomavirus* (JCV) with increased incidence due to the acquired immunodeficiency syndrome (AIDS) epidemic (0.7–11% of HIV patients will develop PML during the course of their illness) (2). The histopathological hallmark of PML is demyelination with enlarged oligodendroglial nuclei and bizzare astrocytes. The disease is usually multifocal, and the lesions may occur in any location in the white matter.

Fungal Infections

Cryptococcosis

Approximately 5–10% of patients with AIDS develop CNS ► cryptococcosis caused by *Cryptococcus neoformans.* The infection is a result of a newly acquired infection with hematogenous dissemination of the infection from the lung to the CNS. Cryptococcal meningitis is the most common manifestation, where the subarachnoid spaces are thickened and filled with multiple organisms and their material. From the subarachnoid space, cryptococcus extends along the Virchow-Robin perivascular spaces into the basal ganglia, thalami, midbrain, and cerebellum. The Virchow-Robin spaces become dilated. With disease progression, dilated perivascular spaces become confluent and cystic lesions develop called "gelatinous pseudocysts." Cryptococcoma is the only parenchymal form of the cryptococcal CNS infection. The lesions result from the direct invasion of the brain by the fungus with the development of a granulomatous reaction.

I

Aspergillosis

Aspergillusis accounts for 18–28% of all fungal brain abscesses, and it is the most common CNS complication following bone marrow transplantation. Meningitis, abscess or granuloma, vascular invasion with thrombosis and infarction, and hemorrhage and aneurysm formation are manifestations of cerebral ► aspergillosis. Pathologically, hyphal elements invade cerebral vessels, resulting in thrombosis and infarctions. Sterile infarctions become septic when the fungus erodes the wall of the vessel with extension into the brain parenchyma with inflammatory reactions and necrosis.

Parasitic Infections

Toxoplasmosis

Cerebral ► toxoplasmosis results from infection by an intracellular protozoan, *Toxoplasma gondii.*

After the acute infection, the latent form, called encysted bradyzoites, remains in the tissues until a decline in immunity. Rupture of the cysts releases the free tachyzoite, which causes acute illness. In AIDS patients, toxoplasma causes necrotizing encephalitis.

Clinical Presentation

Viral Infections

Cytomegalovirus

In immunocompromised patients, CMV can produce a variety of clinical syndromes. Five distinct neurological syndromes due to the CMV infection have been described: retinitis, myelitis/polyradiculopathy, diffuse micronodular encephalitis, ventriculoencephalitis, and mononeuritis multiplex.

Progressive Multifocal Leukoencephalopathy

Pyramidal signs, gait disturbances, hemiparesis, extrapyramidal and cerebellar signs, sensory deficits, cognitive dysfunctions are parts of the "multifocal" clinical picture of PML. Without treatment, the prognosis for PML is usually poor, with death occurring after 2.5 to 4 months. Only a small number of cases will have a more benign clinical course (only 7 to 9% of patients demonstrate prolonged survival without therapy). Recent studies have shown clinical and radiological improvements in patients with PML who underwent highly active antiretroviral therapy (HAART).

Fungal Infections

Aspergillosis

Clinical presentation of cerebral aspergillosis includes fever, alterations of mental status, seizures, depression. In some cases stroke-like symptoms will develop.

Parasitic Infections

Toxoplasmosis

The clinical symptoms in cerebral toxoplasmosis are nonspecific; usually patients have fever, seizures, headaches, or altered mental status.

Imaging

Viral Infections

Cytomegalovirus

The most common imaging findings in patients with CMV encephalitis are: cortical atrophy, periventricular enhancement, and diffuse white matter abnormalities. Generalized atrophy is the most commonly reported CT abnomality, but it is a nonspecific finding. Periventricular enhancement is also not diagnostic; it has been described in cases of lymphoma, toxoplasmosis, and other infections. Rarely, cerebral mass lesions due to CMV or choroids plexitis were observed.

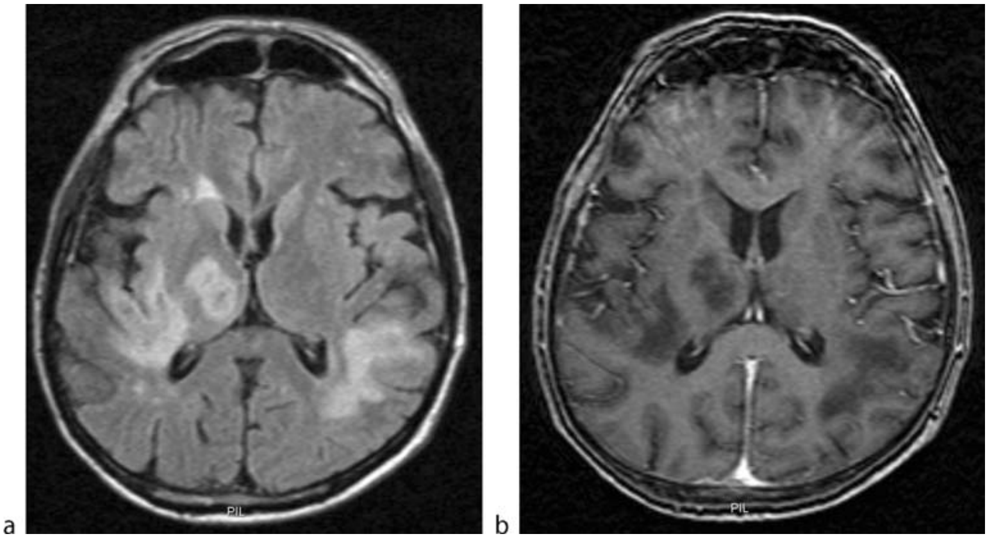
Progressive Multifocal Leukoencephalopathy

The findings on MR imaging correlate very well with macroscopic changes. PML lesions are patchy, scalloped, high signal intensity lesions on T2-WI MR images located in the white matter with extension along the white fibers (2). Subcortical arcuate fibers are involved, mass effect is mild or absent, and peripheral, faint enhancement is a rare feature. On T1-WI images, the PML lesions are marked hypointense (Fig. 1).

Fungal Infections

Cryptococcosis

In cases of cryptococcal meningitis CT scans rarely show meningeal enhancement, whereas enhanced T1-WI MR



Infection, Opportunistic, Brain. Figure 1 PML in an 35-year-old male HIV positive patient. On axial fluid-attenuated inversion-recovery (FLAIR) MR image (a) high signal intensity lesions located bilateral in the white matter, without involvement of the subcortical fibers are observed. The lesions are hypointense on T2-WI MR image (not shown) and do not show enhancement on postcontrast images (b). Mass effect is also not present.

images may demonstrate meningeal disease. Dilated perivascular spaces will be recognized on MR images as multiple, bilateral, small round- or oval-shaped lesions, located usually in the basal ganglia, which show high signal on T2-WI images, and have signal slightly higher than the CSF on T1-WI MR images. Enhancement is not present. Gelatinous cysts do not differ from the dilated Virchow-Robin spaces on MR images. Enhancement and mass effect are also absent. On CT, cryptococcomas are hypodense with high signal on T2-WI images, and low signal on T1-WI MR images. On enhanced images, the lesions usually demonstrate a ring-like or nodular enhancement, and cannot be distinguished from granulomas of other origin.

Aspergillosis

On MR imaging, brain lesions in aspergillosis usually have low signal centrally or peripherally on T2-WI images, probably due to accumulation of fungi containing iron, magnesium, and manganese, as well as blood breakdown products (Fig. 2). Contrast enhancement is rarely present, depending on the severity of the immunocompetence (3).

Parasitic Infections

Toxoplasmosis

On nonenhanced CT scans, toxoplasma lesions are hypodense with edema and mass effect. Solid, nodular- or ring-enhancing lesions are typically observed on postcontrast scans. On T1-WI MR images, toxoplasma lesions have iso-to-low signal centrally. Signal intensity on T2-WI images depends on the stage of the lesion, which could be iso, hypo, or hyperintense (4). Enhanced T1-WI images reveal ring or nodular enhancement. Approximately 10 days after the initiation of therapy, a decrease in the number and size of the lesions with reduction in edema and mass effect should be observed on follow-up MR examinations (Fig. 3). Calcifications are often seen in healed foci. The MR spectroscopic pattern of toxoplasma lesions is nonspecific, consistent with anaerobic inflammation within the abscess.

Nuclear Medicine

Viral Infections

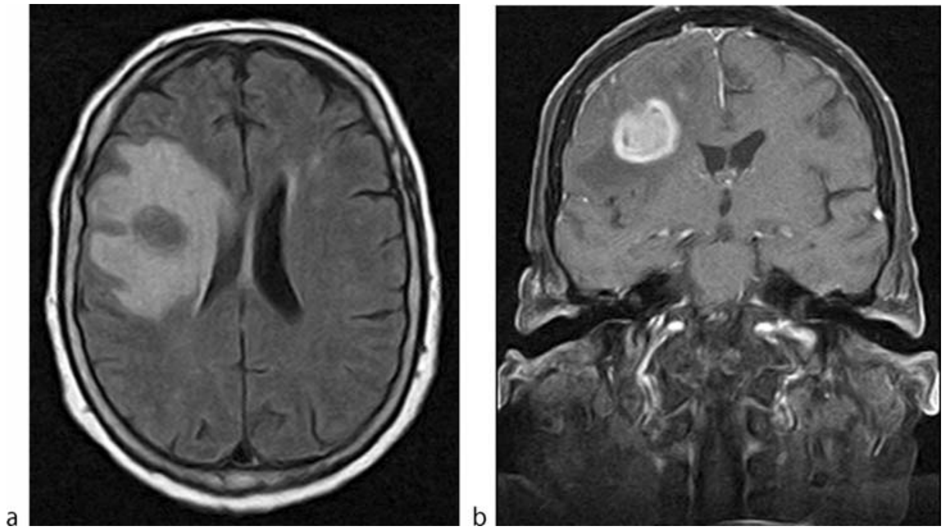
Progressive Multifocal Leukoencephalopathy

Patients with PML had two different patterns on thalium and gallium scans: patients with positive gallium and negative thallium scans, and a second group with negative thallium and gallium scans. Demyelination and destruction explain negative thallium and gallium scans. Positive gallium and negative thallium scans may be a result of coexisting pathology.

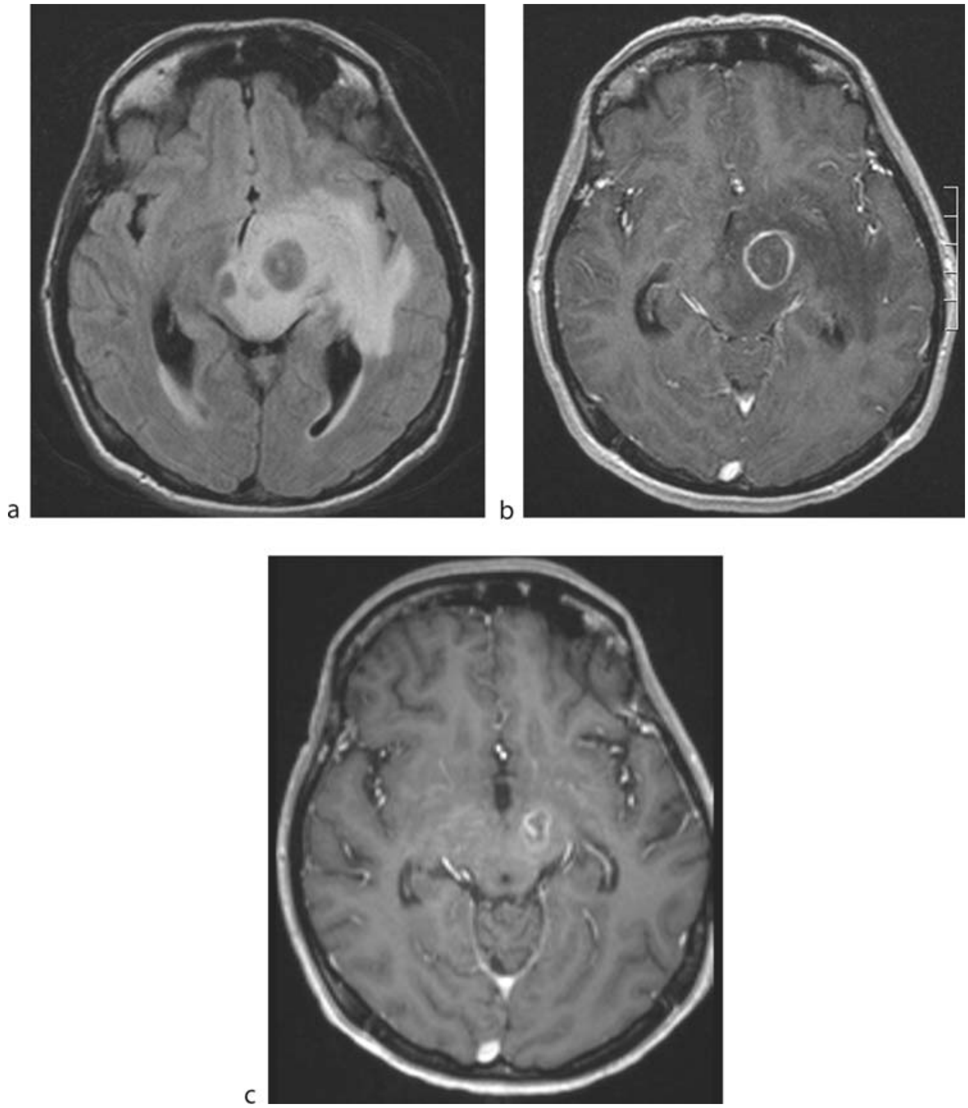
Parasitic Infections

Toxoplasmosis

Based on conventional MR imaging, cerebral toxoplasmosis cannot be distinguished from primary cerebral lymphoma.



Infection, Opportunistic, Brain. Figure 2 Cerebral aspergillosis in a female patient 2 months after bone marrow transplantation. Low signal intensity lesion with extensive perifocal edema located in the white matter of the right frontal lobe is shown on axial FLAIR MR image. (a) Marked enhancement of the lesion is demonstrated on coronal postcontrast T1-weighted MR image with fat suppression (b).



Infection, Opportunistic, Brain. Figure 3 Cerebral toxoplasmosis in an AIDS patient. On axial FLAIR MR image (a) hypointense lesion with perifocal edema located in the left basal ganglia region is hown. On axial postcontrast T1-weighted MR image (b) ring-like enhancement of the lesion is demonstrated. Decrease in size and enhancement is shown on follow-up MR examination (c) 1 month after the initiation of antitoxoplasmosis treatment.

The use of Thallium-201 (^{201}TI) brain SPECT in AIDS patients has been proven to be very helpful in distingushing toxoplasmosis from lymphoma (Ruiz). Positive ^{201}TI brain SPECT is suggesstive of CNS lymphoma, and negative uptake suggests infection in AIDS patients.

The potential use of F-18 fluorodeoxyglucose (FDG)-positron emission tomography (PET) in differentiating lymphoma from toxoplasmosis in AIDS patients has been also examined (5). The standardized uptake values (SUVs) over cerebral lesions were much higher in lymphomas than in toxoplasma lesions.

Diagnosis

Viral Infections

Cytomegalovirus

The infection of the CNS due to CMV is difficult to diagnose while the patient is alive because the virus is difficult to culture from cerebrospinal fluid (CSF). The recent development of the polymerase chain reaction (PCR) technique has allowed isolation of CMV based on the presence of DNA within the CSF.

Progressive Multifocal Leukoencephalopathy

A rapid onset of symptoms in an HIV positive patient with multifocal clinical picture, typical MR imaging findings, and positive JCV PCR in CSF are sufficient evidence for clinical diagnosis of PML. However, a negative result of JCV DNA PCR of the CSF does not rule out PML.

Fungal Infections

Aspergillosis

Because of the high mortality rate of 85–100% early suspicion of aspergillosis is essential. The diagnosis is usually based on a combination of clinical findings in a patient with risk factors and isolation of the microorganism, radiological data, serological detection of antibodies or antigens, or histopathological evidence of invasion.

Parasitic Infections

Toxoplasmosis

Differentiation between lymphoma and toxoplasmosis in AIDS patients remains a diagnostic dilemma. The combination of a neuroradiological examination, a compatible radionuclide study (^{201}TI SPECT, PET), and CSF analysis (Epstein–Barr virus DNA) is a current approach in those patients.

Infection, Soft Tissue

Catherine M Phan, Thomas M Link
Hôpital de Bicêtre, Service de Radiologie BROCA, Le Kremlin-Bicêtre, France
catherine.phan@bct.aphp.fr

Synonyms

Infectious myositis; Infection of skeletal muscle; Primary muscle abscess; Pyomyositis

Definition

Soft tissue infections can develop separately, but frequently they are associated with musculoskeletal infections involving joints and bones. Infection is often considered as a therapeutic emergency requiring the radiologist's assessment of the presence or absence of infectious disease and its extent. Soft tissue infections can be focal (▶abscess) or diffuse (▶cellulitis) and are subdivided according to the compartment involved. The specific entities discussed are cellulitis, pyomyositis, abscess, ▶necrotizing fasciitis, tenosynovitis, and septic bursitis. They could be the primary event (cellulitis, muscle abscess) possibly leading to infective periostitis, osteitis, and osteomyelitis, or the consequence of spread of infection from adjacent structures (spondylodiskitis, osteomyelitis, and arthritis).

Pathophysiology

Soft tissue infections cause considerable morbidity with variable degrees of severity. Predisposing factors are open fracture, foreign bodies, and prosthetic material, as well as impaired immunity affecting drug abusers, diabetics, patients with immunodeficiency virus or leukemia, and patients taking immunosuppressive medication. Patients with human immunodeficiency virus infection are susceptible to bacterial and fungal infections (1). They are predisposed to osteomyelitis, septic arthritis, and pyomyositis.

Isolated soft tissue infections are less common than those involving bone and joint at the same time. The principal routes by which soft tissue can be contaminated are hematogenous spread of infection, spread from a contiguous source of infection, direct implantation, and postoperative infection (2). Isolated soft tissue infections arise from direct implantation (skin breaches, penetrating wounds, foreign bodies, decubitus ulcers, open fracture, and surgery) and less frequently from hematogenous spread from distant sites of infection. Human bites (*Staphylococcus aureus, Bacillus fusiformis*) and animal bites (*Pasteurella multocida, S. aureus*, and *Staphylococcus epidermidis*) are also common causes of infection from direct implantation. Infection could extend to adjacent soft tissue by progressing from osteomyelitis to osteitis to periostitis or from the vertebral body endplate to the disk to the closest adjacent vertebral body to soft tissue (subligamentous, paraspinous phlegmon, or abscess) in the case of spondylodiskitis.

Pyomyositis consists of a primary muscle abscess, and is prevalent in tropical countries, in immunocompromised patients, and in drug abusers. Bacteria, mycobacteria, fungi, viruses, and parasitic agents may be responsible.

Clinical Presentation

Clinical features of soft tissue infection are not specific to the compartment involved and initially include pain, rigor, fever, and soft tissue enlargement.

Clinical diagnosis is based on the appearance of lesions, degree of pain, and systemic toxicity. Knowledge of the organisms involved does not always help define the tissue depth of disease, but aids in choosing antimicrobial therapy.

Cellulitis represents acute, febrile, and diffuse inflammation of subcutaneous fat and skin. Stiffness may precede visible signs of skin involvement or lymphangitis by 24 h. Tender regional lymphadenitis often develops. The involved area may show blistering and local necrosis. Desquamation may occur on recovery.

Myositis—Muscular Abscess

Nonspecific clinical features of myositis are fever, localized myalgia and stiffness, swelling, and tenderness. In certain instances, it is the anatomic location rather than the morphologic characteristics of the lesion or the etiologic infecting agent that distinguishes the particular type of infection. Clinical manifestations of psoas abscess include fever, lower abdominal or back pain, or pain referred to the hip or knee.

Necrotizing fasciitis **(NF)** usually afflicts patients with impaired immunity. It is characterized by rapidly extensive infection of superficial and deep soft tissue. The overlying skin is classically warm, indurated with a mottled appearance and purple patches. Crepitus due to superficial fascial emphysema is rarely palpable. Extreme pain followed by anesthesia suggests the diagnosis. At the late stages, there is local coagulopathy and thrombosis of the blood vessels with necrosis of the deep soft tissues. NF is differentiated from the other soft tissue infections by a rapid progression to multisystem failure and death without early recognition and treatment.

Imaging

Conventional Radiographs

In the case of a suspected musculoskeletal infection, plain radiographs (XR) are normal until soft tissue infections are advanced; however, they allow assessment of associated bony destruction or joint erosion. They are of little value, showing a nonspecific thickening of soft tissue. They can reveal the presence of gas in subcutaneous fascial planes (necrotizing fasciitis) or in muscle (a minority of muscle abscess). The presence of subcutaneous gas on a radiograph does not necessarily indicate a clostridial infection, because *Escherichia coli, Peptostreptococcus* species, and *Bacteroides* species may produce gas under appropriate conditions.

Ultrasonography

Ultrasonography (US) is an important modality for evaluation of musculoskeletal infections especially in children because it is nonionizing and very sensitive for fluid collection and joint effusions (3). It allows detection of clinically occult collections providing guidance for diagnostic aspiration and could change the management of patients with initially diagnosed cellulitis. It should be performed in conjunction with radiography and could help to differentiate abscess from necrotic or cystic tumors, hematoma, and joint fluid. With the development of high-frequency and color Doppler sonography, US remains an accessible and inexpensive technique for studying infectious tenosynovitis and bursitis.

Computed Tomography

Computed tomography (CT) provides high spatial resolution and allows a precise visualization of the anatomic structures involved by infection. After contrast medium administration, enhancement of abscess walls, internal septa, and inflammation of deep fascia are well visualized. CT may also be used to guide interventional procedures to drain abscesses.

MRI

Magnetic resonance (MR) imaging is the ideal technique for assessing the soft tissue abnormalities produced by infectious processes. On MR images, soft tissue alterations consist of signal intensity changes that reflect the increased water content of the inflammatory soft tissues. These changes are nonspecific; however, they are helpful in detecting the presence and extent of the infection, which is suspected clinically on the basis of physical and laboratory findings and predefined by other imaging studies.

Intravenously administered gadolinium allows differentiation of an abscess from cellulitis or phlegmon in the soft tissues, or an abscess from bone marrow edema in the marrow space; Gadolinium also increases the visualization of sinus tracts and sequestra, and plays an important role in the diagnosis of fascia abnormalities in necrotizing fasciitis, if readily available at an early stage.

Diagnosis

Cellulitis

The diagnosis is usually clinical, but imaging excludes underlying abscess formation or other complication. *Plain radiographs* depict nonspecific findings: soft tissue swelling, displacement of fat planes, and the presence or absence of radiolucent gas foci (streaks, bubbles by gas-forming organisms) and radiopaque foreign bodies (needle, tips).

US typically shows edema as diffuse thickening of skin and subcutaneous fat, dissected by a reticular pattern of anechoic strands (Fig. 1a) with progressive transition to normal tissue. CT provides similar information with a precise depiction of the infectious focus and the presence of gas (Fig. 1b). MR findings show diffuse areas of low signal intensity on T1-weighted and high signal intensity on T2-weighted images, with a reticulated pattern in the subcutaneous fat and skin thickening without abnormality of deep fascial planes. The signal intensity in the same pathological areas is increased by gadolinium contrast.

Abscess

Abscesses, even sizeable ones, are difficult to discern on plain radiographs, but their visualization is facilitated by signs such as periosteal reaction or joint effusions. US detects abscesses as a fluid collection, totally or partially anechoic with well-marginated hyperechoic rim in the acute and subacute phases (Fig. 2). Echogenicity can vary by the presence of internal debris, hemorrhage, or septum. The abscess content could be hyperechoic, isoechoic, or appears as diffuse homogeneous low-level echoes, mimicking a solid mass. Color Doppler imaging, dynamic compression of the fluid collection, and motion of the purulent material within the collection may help differentiate echogenic fluid from a solid tumor or hematoma.

CT and MRI are the best imaging modalities for the extent of abscess formation. On CT scans, abscess walls and internal septa typically enhance after contrast administration (Fig. 3).

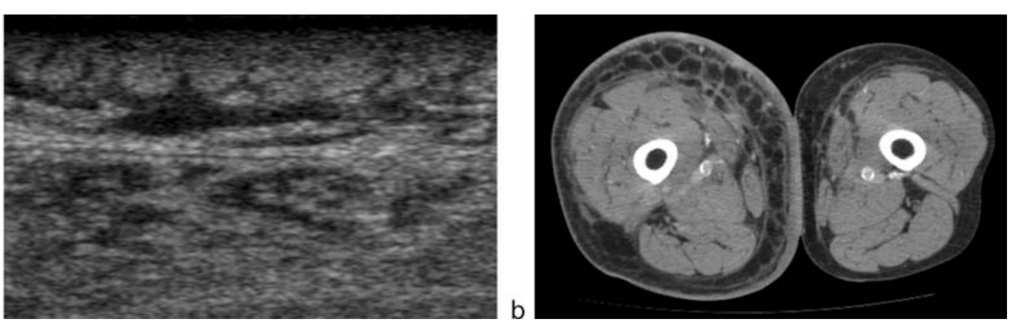
On MR scans, muscle abscesses are fluid-filled cavities that are bright on T2-weighted images, with a rim that shows postcontrast enhancement (Fig. 4). Such a pattern is typical for an abscess, but it may be seen in other entities including ischemic foci in muscle and necrotic soft tissue tumors.

Infectious Myositis—Pyomyositis

MR findings are not specific in pyomyositis. There is diffuse muscle enlargement with intermediate signal intensity on T1-weighted images, and diffuse high signal intensity on T2-weighted images sometimes with abscesses (4). The precise diagnosis is made after aspiration or biopsy and the culture of the abnormal muscle.

Necrotizing Fasciitis

CT and MRI are used to distinguish cellulitis from necrotizing fasciitis (Fig. 5) (1). With necrotizing fasciitis, the abnormalities are seen in the subcutaneous fat, as for cellulitis, with an extension in the deep fasciae between muscles and into muscles. The abnormalities are best demonstrated with MRI on short T1 inversion recovery (STIR) images. Muscle involvement is not required for making the diagnosis of necrotizing fasciitis but fascial involvement is. Linear high signal intensity is seen in both superficial and deep fasciae representing the fascial necrosis. The associated muscle involvement, when present, is seen as areas of high signal intensity within the muscles on T2-weighted or STIR images with or without hyperintense fluid collections from abscesses. Postcontrast T1-weighted images show linear enhancement of the fascia, focal enhancement of the affected muscles, and peripheral enhancement of the abscesses. Contrast administration is not necessary for making the diagnosis of necrotizing fasciitis. During the surgical debridement,



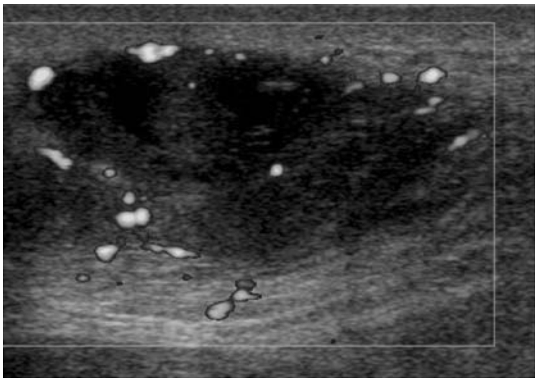
a b

Infection, Soft Tissue. Figure 1 Infectious cellulitis of the right thigh. Ultrasonography (a) shows diffuse thickening of the skin and subcutaneous tissues characterized by a reticular pattern of anechoic strands. The CT image (b) also demonstrates findings of cellulitis (e.g., skin thickening, stranding of the subcutaneous fat, and blurring of the fat).

tissue biopsies are performed to obtain proper cultures for microorganisms.

Septic Tenosynovitis/Septic Bursitis

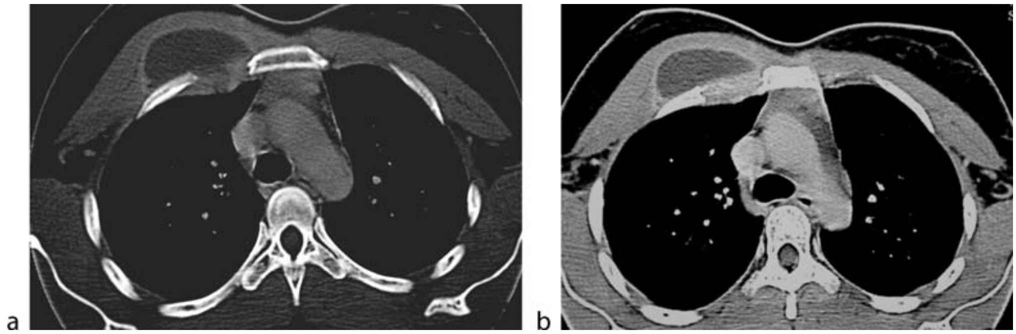
Septic or aseptic causes of tenosynovitis and bursitis cannot be distinguished by imaging features. They are often described with adjacent cellulitis. Septic cases result from tuberculosis or usually from penetrating trauma. The most common pathogen is *S. aureus* or *Staphylococcus pyogenes* (2). US findings for septic tenosynovitis are accumulation of fluid within the tendon sheath, tendon enlargement compared with the contralateral size, and hyperemia seen with Doppler. US may help to exclude other diagnoses such as septic arthritis, cellulitis, or foreign bodies. Septic bursitis most frequently involves the olecranon or prepatellar bursa. US demonstrates a fluid collection within the bursa with possible thickened wall, hyperemia in the walls, and debris or septae within the collection. Fluid surrounding a tendon or within a bursa is well depicted with US and will be seen as low signal intensity on T1-weighted and high signal intensity on T2-weighted images, with enhancement of the synovial lining after intravenous injection of gadolinium contrast.



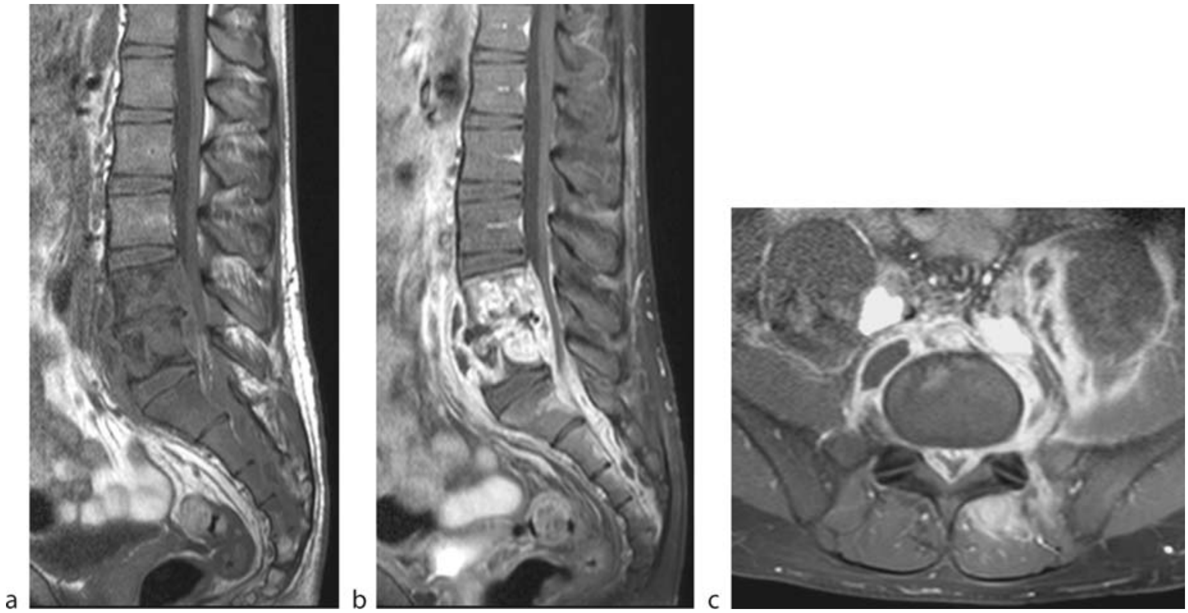
Infection, Soft Tissue. Figure 2 Fifty-year-old diabetic woman with erythema, edema, and firm mass on the thigh. Transverse sonogram with 7.5-MHz linear-array transducer shows well-defined, subcutaneous, anechoic mass with few internal echoes. Thick, hyperemic rim of the soft tissue abscess is seen at the periphery with color Doppler sonogram. *Staphylococcus* was cultured from abscess fluid after aspiration.

Diabetic Foot Infection

Foot disease in diabetics is a common problem and results frequently in one or more of the following: vascular disease, infection, and neuroarthropathy. Infection in diabetics is usually related to a soft tissue injury, followed by cellulitis; the infection may remain limited to the soft tissues or extend to the bones and the joints. CT scans and XR offer useful bony anatomic information, in particular for sequestrum. However, soft tissue details are limited and sensitivity and specificity for determining infection are low, especially in the early stages of infection. MRI remains the optimal imaging modality for soft tissue infection. Combined indium-111-labeled leukocyte technetium phosphate bone scintigraphy is the radionuclide procedure of choice for determining infection in neuropathic joints. Soft tissue ulcerations account for more than 90% of diabetic pedal osteomyelitis cases. They usually occur under pressure areas of the foot, such as the plantar soft tissues beneath or adjacent to the first and fifth metatarsal heads, the calcaneal tuberosity, the distal phalanges, and the malleoli. Ulcers can be identified on MRI as soft tissue defects of low signal intensity on both T1-weighted and T2-weighted images. Findings that suggest infection instead of diabetic neuropathy include osteomyelitis with bone marrow areas of low signal on T1-weighted and high signal on T2-weighted or STIR images associated with soft tissue ulcer or sinus tract overlying the abnormal bone and located as



Infection, Soft Tissue. Figure 3 Chest wall tuberculosis arising from costochondral infection in a 65-year-old woman with active pulmonary tuberculosis. Thoracic axial CT images (a, b) show a soft tissue lesion of homogeneous low density in the right chest wall with a rim enhancement by iodine contrast. Aspirated fluid revealed *Mycobacterium tuberculosis*.



Infection, Soft Tissue. Figure 4 **MRI depicts well a paraspinal and subligamentous abscess associated with lumbar spondylodiskitis in a 29-year-old North African man. T1 sagittal image (a) shows abnormal, low signal in two adjacent vertebral bodies with endplate destruction. There are soft tissue masses extending anteriorly and posteriorly to the vertebral bodies. Fat-saturated T1 sagittal (b) and axial (c) contrast-enhanced axial images show the anterior subligamentous, epidural, and paraspinal abscesses.**

previously described. Abnormalities suggesting diabetic neuroarthropathy are joint misalignment and destruction and fragmentation of bone at the intertarsal and tarsometatarsal joints.

Foreign Bodies

Foreign bodies are most often wood, thorns, or glass. Their sites of predilection are the feet and hands. Foreign bodies in the soft tissue create an inflammatory reaction and may lead to the occurrence of an abscess, a sinus tract, or osteomyelitis. The identification of particles of glass or wood is difficult and can be done using XR combined with US or CT. On MR images, foreign bodies usually have a linear form with low signal intensity on all sequences surrounded by high signal intensity on T2-weighted images corresponding to granulation tissue, cellulitis, or abscess.

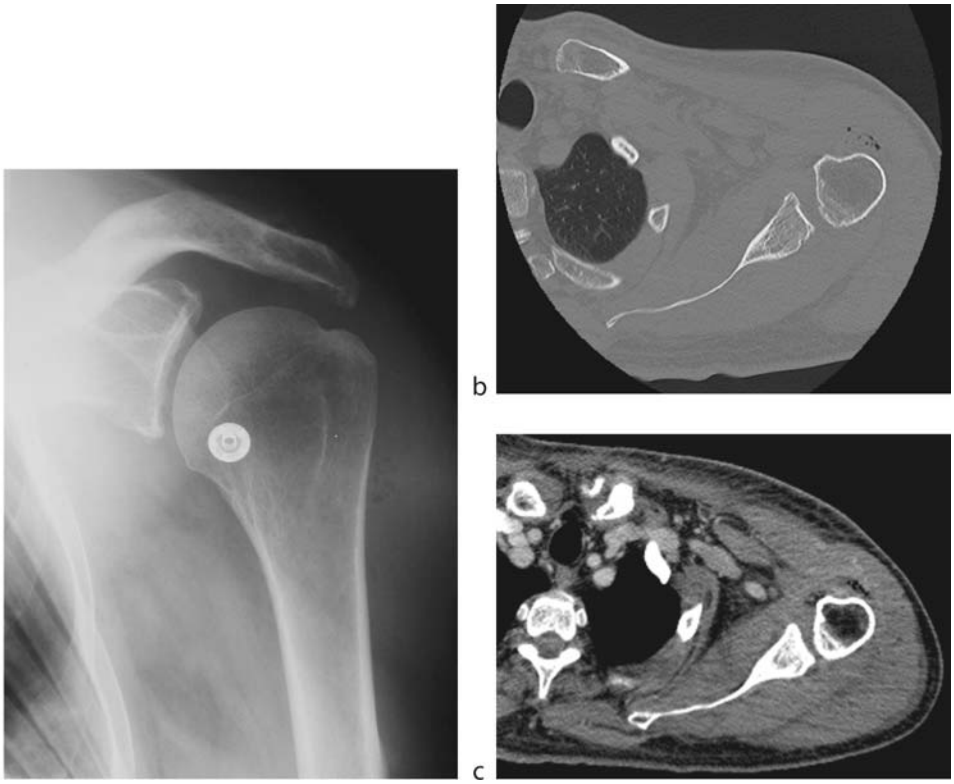
Nuclear Medicine

Nuclear medicine plays an important role in the assessment of periprosthetic infection and osteomyelitis in children, including early detection of infectious disease, differentiation of osteomyelitis from cellulitis, and identification of renewed activity in cases of chronic osteomyelitis. However, radionuclide studies are currently less widely used in the evaluation of infectious diseases due to the development of CT and MRI. Three main radionuclide studies including technetium phosphate bone scintigraphy, indium-111-labeled leukocyte scintigraphy, and fluorodeoxyglucose-PET (FDG-PET) can be performed for diagnosing soft tissue or bony infection (5).

Technetium phosphate bone scintigraphy with three phases is commonly used if bone infection is suspected: serial images are obtained at the angiographic phase (first minute just after intravenous technetium compound bolus), a postinjection image is obtained at the blood pool phase (end of the first minute), and further images are obtained at a delayed phase (2 or 3 h later). Osteomyelitis shows increased accumulation of the radionuclide within the bone during all three phases. In the case of cellulitis, early scans show increased uptake of soft tissue corresponding to hyperemia and later scans are normal.

Indium-111-labeled leukocyte scintigraphy based on leukocyte accumulation within the abscess is more sensitive in detecting peripheral than axial disease, and soft tissue infections than bone infections and chronic ones.

FDG-PET with CT has the advantage of high-resolution anatomical depiction of infectious sites, higher sensitivity in the uptake, and reliable diagnosis of axial infection compared to other radiotracers tested (gallium, radio-labeled serum albumin, thymidine) (5) (6). FDG-PET may be limited in differentiating between malignant and infectious processes as well as in postoperative patients.



Infectious Diseases. Figure 5 Anterioposterior radiograph (a) of the left shoulder demonstrates gas bubbles in the deep soft tissue in a splenectomized, diabetic, 80-year-old man. CT scan (b) obtained after ultrasonography confirms gas bubbles under the deep fascia of the deltoid, and shows an abscess within the deltoid associated with fluid collection and thickening of subcutaneous fat. After iodine injection (c), typical enhancement of the fascia associated with abscess in the deltoid muscle are well depicted suggesting the diagnosis of an early necrotizing fasciitis, which was surgically confirmed.

In 1969 the US federal government's principal spokesperson on matters of public health, Surgeon General William H. Stewart, testified to the US Congress: "The time has come to close the book on infectious diseases." In fact, infections are still the most frequent diseases, and prospects of improving the situation in the near future are dismal. According to the World Health Organization, infections account for about one-third of all deaths worldwide, second only to cardiovascular diseases (Table 1).

Additionally, within the last 30 years a plethora of new and reemerging infections were recognized and face

Infectious Diseases. Table 1 Deaths by cause worldwide, estimates for 2002 (Source: The World Health Report 2003)

Cause	Number of deaths	%
Total deaths	57,027,000	
Cardiovascular diseases	16,655,000	29.2
Infectious diseases	14,967,000	26.3
Neoplasms	7,254,000	12.8
Injuries	5,188,000	9.1
Respiratory diseases	3,696,000	6.5
Perinatal diseases	2,464,000	4.3
Digestive diseases	1,963,000	3.4
All other causes	4,840,000	9.2

mankind with almost insurmountable problems. Not only are new epidemics like AIDS and SARS of significant concern, but the resurgence of diseases like malaria and tuberculosis are also ominous developments. At the same time, the underdeveloped world has to bear the brunt; in these areas of the world—with poor sanitation, overcrowding, uncontrolled urbanization, poverty, and little or no access to medical care—infectious diseases continue to cause significant morbidity and mortality. So as long as this part of the world cannot provide its inhabitants with the basic needs of clean water, sufficient and healthy food, shelter, and adequate medical care, the fight against infections can never be won.

In contrast, in developed countries, mortality from infectious diseases has been reduced significantly by improvements in sanitation, widespread vaccination, and access to medical care. However, new problems have evolved. So-called infections of leisure or diseases that complicate exposure to vacation climates, pets, recreational activities, and exotic cuisine pose problems of diagnosing and adequately treating these infections. Also, we have to pay a high price for medical progress: organ transplantation, invasive surgery, implantation of prosthetic devices, and immunosuppressive therapies have prolonged survival for some diseases but also resulted in compromised immunity and render previously normal individuals susceptible to microbes formerly considered to be pure saprophytes.

Even more intriguing is the steadily increasing resistance of bacteria, fungi, and viruses against anti-infective agents. The stunning success of the pharmaceutical industry in the western world in creating new antibiotics over the past four decades has caused the society and the scientific community to become complacent about the potential of bacterial resistance. Despite the warning in renowned textbooks that "it requires but a moment's reflection to realize that the substitution of a prescription for a broad-spectrum antibiotic or a quick injection of penicillin for the systematic collection of facts and thoughtful consideration of diagnostic possibilities is a fallacious, unwise, and dangerous practice....They should never be prescribed as placebos, antipyretics, or substitutes for diagnosis" (1), the misuse and overuse of these originally termed "miracle drugs" became more or less general practice and finally led to the situation that is described as the postantimicrobial era. The increasing frequency of drug resistance has been attributed to combinations of microbial characteristics, selective pressures of antimicrobial use, and societal and technologic changes that enhance the transmission of drug-resistant microorganisms. Antimicrobial resistance is resulting in increased morbidity, mortality, and health-care costs. In fact, this problem is dramatic not only because microorganisms "invent" new mechanisms of drug resistance but also because most pharmaceutical companies withdraw from research on new antiinfectives because their profit margin is too small in the long run.

The relationship between the human host and the microbial world represents the interaction of two very complex systems. Microbial forms are ubiquitous on the Earth's surface, on plants, and in water and constitute more than half of our planet's biomass. Bacteria and archaea, the two domains of the prokaryotic world, were the first forms of life to appear on Earth about 3.8 billion years ago. They were the absolute sovereigns of the world for about 1 billion years and created the global geochemical cycles that allowed other forms of life to develop. It is obvious that in the course of their long records, bacteria developed an abundant variety of metabolic capabilities that allowed them to survive even under unfavorable conditions. Bacteria acquired knowledge of how to maximize the plasticity of their genomes, constantly acquiring new genetic information and mutating or rearranging existing genes. These ever-changing capabilities enable bacteria to colonize all the niches the Earth provides. When warm-blooded animals and humans appeared on the evolutionary scene, of course bacteria immediately took advantage of these new niches for colonization. Taking into consideration that the human body is an almost infinite source of nutrients and offers shelter under constant temperature and humidity conditions, humans are an optimal habitat for continuous colonization, creating a biosphere of their own. Colonization begins when the primarily germ-free fetus leaves the protective amniotic sac. Within a very short period, the normal flora is constituted, forming a dense bacterial covering mainly of the skin, the oropharynx, and the intestinal and vaginal tracts. In fact, reduced to pure numbers, the human body consists of 10% mammalian cells and at least 90% prokaryotic cells, which form our normal flora. The human host is also surrounded by an abundant number of environmental microorganisms, some of which may interact transiently with the human body. Therefore, it is clear that the ability of bacteria to grow and damage human tissue has an effect on human evolution.

Under normal conditions, this microbe–human interaction is in equilibrium based on the microbes' capability to harm and the host's defense system. This equilibrium is just one aspect of the human–microbe interaction. At the other end of the scale is the ultimate damage by microorganisms: death. However, infection and disease, like everything else in life, are continuous processes. Nevertheless, as with other complex continuous processes, it is convenient and, perhaps because of the limitations of our imagination, necessary to describe and define the dynamics of an infection as a sequence of more or less discrete steps.

In scientific terms, "infection" is defined as the process of microorganisms that are capable of causing disease to occupy and multiply in a particular area of the human body. An infection that produces symptoms is called an infectious disease. Thus, infection does not inevitably result in disease. Because common speech usually associates the term "infection" with disease, it seems rational to replace the scientific meaning by the term "colonization" because its understanding is more neutral. This proposal seems justified with regard to the fact that microorganisms forming the body's normal flora, which are usually regarded as noninfecting or benign, nevertheless may cause infectious disease depending on the immune status of the host involved. Healthy people colonized with obvious pathogens, such as *Salmonella typhi*, are called asymptomatic carriers, but they may serve as sources of infectious diseases when they transmit their "bug" to other people. Another example is the asymptomatic carriage of highly antibiotic-resistant bacteria, like methicillin-resistant *Staphylococcus aureus* (MRSA), which is a much feared and epidemically spreading hospital pathogen.

Although a specific infectious disease will not occur in the absence of the causative organism, the mere presence of the organism in the body does not invariably lead to clinical illness. Indeed, the production of symptoms in humans by many microorganisms is the exception rather than the rule. The occurrence of disease depends on the contributions of both host and pathogen to this process that is based on a microbe's ability to cause damage as a function of the host's immune response. In fact, the host may experience damage during the state of colonization by a given microorganism, the damage being part of a continuum spanning from "none" to "significant." Progressive damage that results from the host's inability to contain or eliminate the inflicting microorganism may lead to disease or death. However, damage may be mediated not only by the pathogen but also by the host's immune response (e.g., aberrant immune responses such as those associated with rheumatic fever or poststreptococcal glomerulonephritis). In this respect, damage is an inclusive term that encompasses cell, tissue, and organ damage. Damage at the cellular level includes necrosis, apoptosis, and malignant transformation. Damage at the organ and tissue levels includes granulomatous inflammation, fibrosis resulting from chronic inflammation, and tumor.

The transition from colonization to an infectious disease is defined by characteristic symptoms that have been well known since antiquity: fever (calor), pain (dolor), inflammation (rubor), swelling (tumor), and impaired function (functio laesa), of which fever has been recognized as a cardinal manifestation of disease. However, in clinical practice the variability of the disorders attributable to infection of humans by microorganisms is so variable that generalizations about them are difficult. The clinical manifestations of infection can duplicate those of diseases of any other etiology. It is obvious that the presence of one, several, or all of the so-called characteristic features of infection does not constitute proof of the microbial origin of illness in a given patient. Conversely, serious, even fatal, infectious disease may exist in the absence of fever or other signs and symptoms.

Nevertheless, the majority of acute infectious diseases are accompanied by fever, and its occurrence accounts for a large proportion of visits to physicians worldwide. In evaluating patients with elevated body temperature it is important to distinguish between disorders that lead to hyperthermia—an imbalance between heat-generating and heat-dissipating mechanisms—and fever, defined as a controlled elevation of body temperature in response to a control setpoint change in the hypothalamus mediated by endogenous pyrogens. But even when hyperthermia is excluded, a wide variety of diseases causing fever have to be considered: Besides infection, other causes include inflammatory, immune, granulomatous, neoplastic, vascular, and metabolic disorders; trauma; and tissue infarction.

This diagnostic dilemma is best exemplified with the case of sepsis, the most severe and life-threatening form of a febrile state. The clinical situation of a physician confronted with a patient in whom sepsis is suspected is best described using the statement of the US Supreme Court Justice P. Stewart: "I can't define obscenity, but I know it when I see it." However, in contrast to this theoretical problem, modern medicine needs clear definitions to provide a sound basis for diagnostic and therapeutic approaches in critically ill patients.

In the late 1980s and early 1990s it was recognized that the original definition of sepsis by Schottmüller (continuous or intermittent release of pathogenic microorganisms into the bloodstream from a focus within the body, leading to subjective and objective signs of disease) focusing on bacteria recovered from blood cultures was far too narrow because a variety of overlapping clinical conditions may mimic an acute infectious process and be equally catastrophic. Progress in medical knowledge and expanding therapeutic modalities made clear that the clinical picture of sepsis falls within a more general inflammatory response of the organism, which is triggered not only by localized or generalized infection but also by trauma, thermal injury, or sterile inflammatory processes such as acute pancreatitis.

This was the background for a consensus conference of the American College of Chest Physicians and the Society of Critical Medicine, leading to the concept of systemic inflammatory response syndrome, or SIRS (2), which was updated in 2001 (3). The term "sepsis" is now divided into four different disease entities:

- SIRS
- Sepsis
- Severe sepsis
- Septic shock

The common denominator is the occurrence of a systemic inflammation, and differentiation is based on the fact that signs of systemic inflammation can and do occur in the absence of infection among patients with a variety of disease states in which clinical manifestations are protean and even distinct biochemical features (such as interleukin 6, procalcitonin, or C-reactive protein) are not consistently present.

The distinction of infectious from noninfectious SIRS is based on the definition of infection as "a pathological process caused by invasion of normally sterile tissue or fluid or body cavity by pathogenic or potentially pathogenic micro-organisms" (3). However, as mentioned earlier, this definition does not encompass the so-called toxi-infections that may be induced by members of the normal body flora (enterocolitis by *Clostridium difficile* enterotoxin). Because of these limitations, the systemic response to infection is designated "sepsis," which includes a wide set of diagnostic criteria. Besides general parameters such as fever, tachycardia, tachypnea, and altered mental status, the criteria include a set of inflammatory, hemodynamic, and tissue perfusion parameters. Again, it is emphasized that in clinical reality, none of these findings is specific for sepsis.

This example illustrates how the definition of a certain infection may change over time depending on our ever-increasing knowledge in pathophysiology and the ongoing improvement and progress in diagnostic methods or single diagnostic parameters. Similar to the complexity in the diagnosis of sepsis, an increasing number of patients present with nonspecific signs of infection, especially immunocompromised patients or patients in intensive care units. In these patients a single diagnostic step almost never suffices to unequivocally confirm the diagnosis of an infection. It is always the combination of different tests, the interpretation of which with respect to the clinical picture should enable the clinician to establish a diagnosis.

Diagnostic procedures are usually divided into laboratory and imaging studies. Laboratory tests obtained in patients with suspected infectious diseases fall into three categories: (i) those that assess the degree and severity of the inflammatory response to infection, (ii) those that help determine the site and complication of organ involvement by the process, and (iii) those that are employed to determine the etiology of the infectious agent, either by culture or histology or by a specific immune response. In addition, imaging technologies are categorized into traditional and conventional techniques (such as X-ray and ultrasound), more advanced techniques (such as computed tomography and magnetic resonance imaging), and finally, specific nuclear imaging techniques. In contrast to the first two methodologies, the latter techniques allow, for the first time, detection of infection-related abnormalities based on physiological or biochemical tissue changes. A dazzling array of changes within the different body compartments can be visualized by diagnostic imaging, including features of the following—probably incomplete—list:

Central Nervous System

- Intracerebral abscess
  - i. Ring-enhancing mass
  - ii. Vasogenic edema
  - iii. Mass effect
  - iv. Hypodense area
- Cerebritis
- Encephalitis
- Subdural abscess
- Epidural abscess
- Calcification
- Ventricular compression
- Sulcal effacement
- Midline shift
- Granulomatous disease
- Cysticercosis
- Toxoplasmosis
- Mycotic aneurysma
- Postinfectious vasculitis
- White matter disease

Spine

- Osteomyelitis
- Discitis
- Intervertebral discitis

- Bone erosion
- End-plate erosion
- Sclerosis
- Pott's disease

Head and neck

- Sinusitis
  i. Mucosal thickening
  ii. Sinus opacification
- Periorbital infection
- Mastoiditis
- Soft tissue neck infection

Chest

- Pneumonia
- Necrotizing pneumonia
- Bronchopneumonia
- Aspiration pneumonia
- Localized empyema
- Pulmonary emboli
- Lung abscess
- Atypical pneumonia
- Interstitial inflammation
- Interstitial infiltrate
- Pneumocystis jiroveci pneumonia (PCP)
- Fungal pneumonia
- Aspergillosis
- Tuberculosis
- Parapneumonic effusion
- Pleural thickening
- Pleural effusion
- Lobar consolidation
- Segmental consolidation
- Apical fibrosis
- Air–Crescent sign
- Halo sign
- Diffuse pulmonary infiltrate
- Pulmonary nodules
- Cavitation
- Ground-glass attenuation
- Mediastinitis
- Adenopathy

Abdomen

- Solid organ abscess
  i. Hepatic abscess
  ii. Splenic abscess
  iii. Pancreatic abscess
  iv. Renal abscess
- Perinephritic abscess
- Subphrenic abscess
- Peritoneal abscess
- Pyelophlebitis
- Appendicitis
- Cholecystitis
- Diverticulitis
- Inflammatory bowel disease
- Necrotic pancreatitis
- Gas formation
- Bowel wall thickening
  i. Colitis
  ii. Enteritis
- Gallbladder wall thickening
- Fistula

Soft tissue and osteoarticular infection

- Gas edema
- Gas formation
- Osteopenia
- Scalloping of the cortical bone
- Sequestration
- Periostal deviation
- Reactive bone formation
- Osteoblastic change
- Bone demineralization
- Periarticular soft-tissue swelling
- Widening of the joint space
- Vascular graft infection

General

- Whole body scan
- White blood cell scan
- Cellular labeling
- Antigranulocyte monoclonal antibodies
- Inflammatory response imaging
  i. Increased blood flow
  ii. Increased capillary permeability
  iii. Recruitment of white blood cells

Definitions

Rhinosinusitis is defined as the inflammation of the nasal cavity and the adjacent paranasal sinuses and is most often the result of a viral infection (typically a cold) that causes the mucous membrane of the nose to become inflamed, blocking the drainage from the sinuses into the nose and throat. It may develop as a result of nasal allergies or other conditions that obstruct the nasal passages. However, any factor that causes the mucous membrane to become inflamed may lead to ▶sinusitis. Bacteria and fungi are more likely to grow in sinuses that are unable to drain properly. Bacterial or fungal infections in the sinuses often cause more phlogosis and are more likely to last longer and worsen with time.

The terms acute, recurrent acute, subacute, and chronic rhinosinusitis have been used to define the illness by its duration (1).

Acute rhinosinusitis has a relatively rapid onset and is normally of 4 weeks duration or less and symptoms totally resolve. Resolution of symptoms usually occurs within 5 to 7 days, and patients usually recover without medical intervention.

Recurrent acute rhinosinusitis is defined as four or more episodes of acute disease within a 12-month period, with resolution of symptoms between each episode.

Subacute rhinosinusitis is basically a low-grade continuum of acute infection of more than 4 but less than 12-weeks duration.

Chronic rhinosinusitis is distinguished by symptoms that persist for 12 weeks or more or occurs more than four times a year with symptoms persisting for more than 20 days. The most frequent complications of inflammatory rhinosinusitis are ▶Polyps Nasal and cysts. Chronically obstructed sinus secretions can accumulate and a ▶mucocele can develop.

Pathology/Histopathology

Rhinosinusitis is inflammation or infection of the mucous membranes that line the inside of the nose and sinuses. The evoked completely reversible inflammatory changes in acute disease are swelling of the turbinates, thickening of mucosae in the nasal fossae and sinuses due to submucosal edema, and variable amount of sinus secretions. In acute sinusitis, fluid often collects in the sinus cavity, giving rise to an air-fluid level.

The chronic disease can result in an atrophic, sclerosing, or hypertrophic polypoid mucosa. These different mucosal alterations often coexist with one another and with areas of acute inflammations of either an allergic or an infectious etiology. The bony sinus walls surrounding a chronically infected sinus frequently become thickened and sclerotic with reactive new bone formations. Epithelial hyperplasia and mucosal infiltration of leukocytes are common features of chronic rhinosinusitis.

Nasal polyps are outgrowths of nasal mucosa made up of edema fluid with sparse fibrous cells, a few mucus glands and a surface epithelium invaded by some inflammatory cells. Inflammatory polyps may be present in the nose and/or paranasal sinuses. Polyps are gelatinous in appearance, rarely bleeding, mobile, and insensitive to manipulation. They have a characteristic gray color that allows to distinguish them from the normal pink nasal mucous membrane.

A ►retention cyst is a spherical mucoid-filled cyst that forms when a mucous gland of the sinus mucosa becomes obstructed; its walls are thus defined by the epithelium of a mucous gland and duct itself, not by the walls of the sinus. There is almost always air still surrounding the retention cyst, while bony expansion and remodeling of the sinus do not often occur.

A sinus mucocele is defined as a mucous collection of mucoid secretions lined by the mucus-secreting epithelium of a paranasal sinus. It occurs when a sinus ostium or a compartment of a septated sinus becomes obstructed, thus causing the sinus cavity to be mucous-filled and airless. The obstruction is often inflammatory in nature, but may also be due to tumor, trauma, or surgical manipulation. It is the most common expansile lesion of the paranasal sinuses and leads to outward expansion with bony remodeling. Initially, the bony structures remain intact, but with further expansion deossification may occur.

Clinical Presentations

In acute sinusitis, nasal congestion and discharge are almost always present. The discharge is typically thick and contains pus that is yellowish to yellow–green. Severe headache occurs and there is pain or pressure in specific areas in the face. The symptoms of recurrent acute and chronic sinusitis tend to be vague and generalized, last longer than 8 weeks, and occur throughout the year, even during nonallergic seasons. Nasal congestion and obstruction are common. Chronic cough, yellowish discharge, bad breath, and postnasal drip may occur. Sufferers do not usually experience facial pain unless the infection is in the frontal sinuses: in this case, it usually results in a dull, constant ache. Facial tenderness or pressure, however, may be present. Sinusitis complicated by the presence of polyps will not resolve until the polyps have been reduced in size, either medically or surgically. Signs and symptoms of a mucocele may last from a few days to years and are most often due to mass effect. A mucocele in the frontal sinuses typically leads to frontal headaches and inferolateral proptosis with diplopia. Additionally, a superomedial orbit mass may develop, and the voice may be nasal in quality. A mucocele in the ethmoidal sinuses frequently presents as lateral proptosis as well as nasal congestion. A mucocele in the maxillary sinuses causes upward displacement of the eye, a cheek mass, and nasal congestion. A mucocele in the sphenoid sinuses can lead to suboccipital headaches and visual loss.

Imaging

Conventional Sinus Radiographs

The plain radiographic examination for rhinosinusitis can include Caldwell (antero-posterior view), Waters (occipito-dental view), and lateral view. The Caldwell and Waters views best demonstrate the frontal and maxillary sinuses. The lateral view is the best choice for visualization of the sphenoid sinus and adenoidal tissue in children. Nevertheless, these views do not allow a good evaluation of ethmoidal cells (2, 3). Opacification, moderate-to severe mucosal thickening, or air-fluid levels in patients with persistent symptoms are generally considered suggestive of sinusitis. Such abnormalities are easily detected in maxillary and frontal sinuses by standard radiographs. Isolated polyps may be visualized by plain radiography but their precise localization often requires further imaging procedures. Although standard sinus radiographs are often considered useful in the diagnosis and monitoring of acute sinusitis, they are of limited value in the evaluation of chronic unremitting disease (2, 3). Low cost and small radiation dosage are advantages of this technique, and the possibility of portable examination can be helpful in the intensive care setting. The major drawback of plain radiography is its low sensitivity in the diagnosis of rhinosinusitis; in fact, interpretation of standard radiographs may be controversial: overlay of anatomical structures may mimic mucosal thickening or air-fluid levels and a hypoplastic sinus may be misinterpreted as pathologic opacification. Standard radiographs are inadequate for determination of the need for, or guidance of, endoscopic sinus surgery in both children and adults.

Computed Tomography

CT is currently the modality of choice for the evaluation of the regional anatomy of the nasal cavity and the paranasal sinuses (4). In contrast with plain radiographs, CT excellently demonstrates the anterior ethmoid cells, the upper two-thirds of the nasal cavity and the frontal recess. There is also strong evidence that CT is the gold standard for precise delineation of inflammatory sinus disease secondary to obstruction of the ostiomeatal complex. Axial views parallel to the hard palate can provide important anatomical data. Optimal demonstration of the anterior ethmoid sinuses and ostiomeatal channels requires CT imaging in coronal planes that, in addition, closely correlate with the surgical approach. Ideally, coronal and axial 1.5 mm slices are performed with a helicoidal CT scan, which allows for a 3D reconstruction. Highly contrasting densities identify air within the bony sinuses, fat within the orbit and soft tissues outlined by air in the nasal cavity.

The primary role of CT scans is to aid in the diagnosis and management of recurrent and chronic sinusitis, or to define the anatomy of the sinuses prior to surgery. The characteristics of chronic inflammatory disease on CT are mucoperiosteal thickening, soft tissue mass, and osteitis of the ethmoid bony architecture. Bony erosion is unusual and is more frequently associated with more invasive processes such as mucocele, polyposis, or a neoplastic lesion. The region most frequently involved with inflammatory disease is the middle meatus. Associated maxillary sinus mucoperiosteal disease and, to a lesser extent, frontal sinus disease are frequently found.

It is well known that sinusitis may originate from or be perpetuated by local factors predisposing to sinus ostial obstruction. Current surgical strategy aims to remove the causative disease and reestablish ventilation and mucus clearance. In this respect, coronal CT offers an optimal view of the components of the ostiomeatal complex and enables the detection of significant anatomical variants: Haller's cells, agger nasi cells, paradoxical curvature of the middle turbinate, bulla ethmoidalis, deformities of the uncinate process, or concha bullosa. In terms of preoperative assessment, coronal CT serves as an anatomical map for the surgeon and it has been demonstrated that it greatly improves the planning and the safety of functional endoscopic surgery.

CT scan is the preferred imaging technique for the diagnosis of polyps and the evaluation of the extent of polyposis. Solitary polyps can be detected by CT imaging, although they cannot be differentiated from mucous retention cysts as both entities are shown as homogeneous soft-tissue masses with smooth and outwardly convex borders (Fig. 1). However, this is of little consequence, as any treatment for these common benign entities is the same.

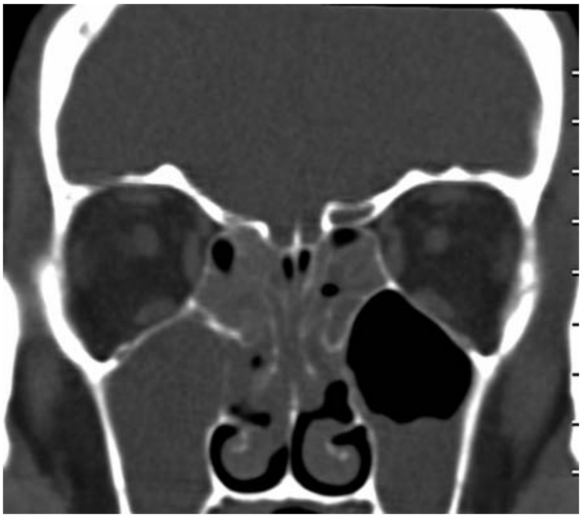
In more severe polyposis, the major CT features are polypoid masses associated with complete pansinus opacification and infundibular widening; bony changes assume a destructive appearance that, in more advanced cases, suggests malignant tumors or granulomas (Fig. 2).

The CT finding of an expanded, airless sinus cavity filled with secretions characterized by rather homogeneous mucoid attenuation is characteristic of a mucocele (Fig. 3).

Inflammation, Chronic, Nose, and Paranasal Sinus. Figure 1 Coronal (a) and axial (b) CT scans. In (a) there is a solitary retention cyst or polyp in the right maxillary sinus. In (b) there is a retention cyst or polyp in the left sphenoid sinus. The sinuses are otherwise normal.

Magnetic Resonance Imaging

MR provides better imaging of soft tissues than CT, but it is less suited to imaging the bony anatomy of this region, and more particularly that of the ostiomeatal complex (4, 5). Because bone and air yield similar signal intensities on MRI, resolution of bony structures is poor and it is difficult to perceive anatomical characteristics critical for the surgeon. Furthermore, in the patient with extensive inflammatory disease mainly involving the ethmoid sinuses, the signal intensity on T2-weighted images of



Inflammation, Chronic, Nose, and Paranasal Sinus. Figure 2 **Coronal CT scan shows diffuse pansinusitis with the evidence of mucosal thickening and polyposis. Bony changes with a destructive appearance are also evident.**

the pathologic process is indistinguishable from the appearance of the normal mucosa in the edematous phase of the nasal cycle. Although MRI has significant limitations in the definition of anatomy, it is extremely sensitive in evaluation of paranasal sinus mucosal disease in the frontal, maxillary, and sphenoid sinuses because the mucosa in these sinuses does not suffer the cyclic edema.

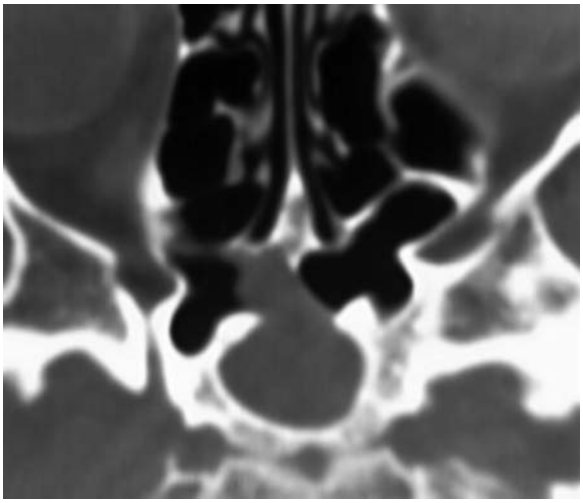
The etiology of certain disease processes and other sinus lesions may be better differentiated by MR. MR is often useful in the differential diagnosis between inflammatory diseases and malignant tumors. Bacterial and viral inflammations have high signal intensity on T2-weighted images, whereas neoplastic processes demonstrate an intermediate bright signal on T2-weighted images. Fungal concretions have very low signal intensity on T2-weighted images similar to that of air. MRI with Gadolinium contrast is useful for cases complicated by orbital or intracranial extension.

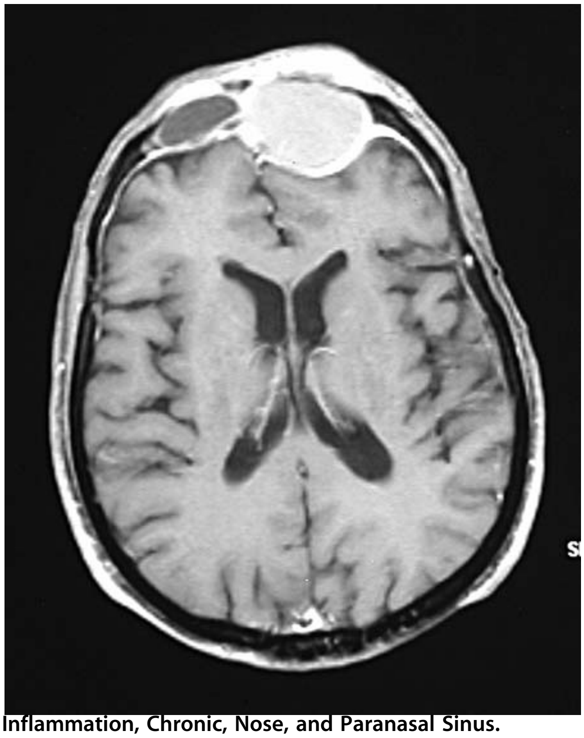
Nuclear Medicine

Nuclear medicine has a limited role in the assessment of rhinosinusitis. Rhinoscintigraphy may be a quick and reliable imaging method for evaluating the ciliary activity of nasal mucosa and the nasal mucociliary clearance function in patients with sinusitis.

Diagnosis

Clinical judgment with a careful history and physical examination should generally suffice in the diagnosis of uncomplicated acute or subacute rhinosinusitis. Therefore, in these cases confirmatory plain radiography, given its low sensitivity, is rarely necessary.





Inflammation, Chronic, Nose, and Paranasal Sinus. Figure 3 **Mucocele. Axial CT scan (a) shows an expanded airless sphenoid sinus cavity filled with fairly homogeneous mucoid attenuation secretions. The sinus walls are remodeled. Axial T1-weighted MR image (b) shows bilateral expansive frontal sinus masses. On the right side has low signal intensity, on the left one it is hyperintense due to the high protein content of the entrapped secretions.**

However, when symptoms are recurrent or refractory despite adequate treatment, further diagnostic evaluations may be indicated. In patients requiring confirmation of sinusitis, simple axial and coronal CT images can be adequate for screening purposes. In clinical practice, diagnosis of sinonasal polyposis is usually assessed by endoscopy but CT scan is frequently performed to help evaluate the disease.

Given the cost, the longer acquisition time, and the poor delineation of bony anatomy by MRI, it should only be used in rare cases of suspected sinonasal neoplasia, fungal sinusitis, or supposed intracranial or orbital complications of rhinosinusitis.

CT and MR should not be used in the initial diagnostic stages of patients with uncomplicated rhinosinusitis.

Definition

Acute renal insufficiency is the sudden rapid deterioration in renal function. There is no clearly defined set of biochemical criteria that characterize renal insufficiency. In some forms of renal insufficiency, known as renal failure, the renal function is insufficient to maintain homeostasis.

Pathology

The causes of acute renal insufficiency can be divided into three main categories: prerenal or functional causes, renal causes, and postrenal causes.

Prerenal causes constitute the most common causes of acute renal insufficiency and are associated with renal hypoperfusion. Such conditions include congestive heart failure, diuretic use, sepsis, dehydration due to gastrointestinal causes (diarrhea, vomiting), renal or respiratory loss, hemorrhage, burns, cirrhosis with ascites, and diabetic ketoacidosis. Renal artery stenosis, when treated by angiotensin-converting enzyme inhibitor, represents a rare but interesting model of functional cause of renal failure due to a decrease of the glomerular filtration pressure by an excessive vasodilatation of the postglomerular arteriole.

Renal causes may result from damage to any portion of the kidney: the tubule, the glomerulus, the blood supply, or the interstitium. Tubular nephropathy includes acute obstruction of the tubules mainly due to precipitation of urate in patients receiving chemotherapy or to precipitation of Bence Jones proteins, and acute tubular necrosis, which constitutes the most common renal cause of acute renal insufficiency. Acute tubular necrosis is due to two mechanisms: hypoperfusion of the kidney with decreased glomerular filtration and increased pressure in the tubules. The renal involvement is reversible with treatment of the cause. A large number of conditions are reported in relation to acute tubular necrosis, including burns, sepsis, snake bites, toxins, transfusion, incompatible transfusion, dehydration, peritonitis, and pancreatitis; some of these are the same as for functional renal failure, explaining why these two conditions may be associated and that their differential diagnosis is difficult.

The vascular nephropathy responsible for acute renal insufficiency includes acute renal vein thrombosis, renal artery occlusion, and disease of the intrarenal arteries, such as collagen vascular diseases (polyarteritis nodosa, Wegener's granulomatosis, and systemic lupus erythematous), scleroderma, and intravenous drug abuse.

Acute interstitial nephritis is underestimated in frequency, and diagnosis is difficult because it is not revealed by any clinical finding such as edema or hypertension and because the diuresis is preserved for a long time. It may occur in association with a variety of drugs, such as penicillin, sulfonamide derivatives, or nonsteroidal anti-inflammatory agents, or with a number of nonrenal infectious processes; it may be due to tumoral infiltration of the two kidneys in lymphoma, for instance; or it may arise in an idiopathic form. Glomerular damage constitutes less than 5% of acute renal insufficiency as a result of acute glomerulonephritis, drug toxicity, Goodpasture's syndrome, or systemic lupus erythematosus.

Postrenal causes refer to the onset of acute renal insufficiency due to acute obstruction. Although acute obstruction accounts for only 15% of acute renal insufficiency, it is the most commonly sought cause because it is the one most easily reversed under appropriate treatment.

Clinical Presentation

Uremia may result in symptoms related to a number of different organ systems including the gastrointestinal tract (nausea, vomiting), the cardiovascular system (hypertension, cardiac arrhythmias, pericarditis), the nervous system (personality changes, seizures, somnolence), and the hematopoietic system (anemia, bleeding diathesis). However, clinical findings are more often due to the cause of the acute renal failure and to the hydroelectrolytic changes than to the consequences of uremia.

Imaging

Ultrasound

Ultrasound (US) is the best available imaging study for patients with renal failure. It permits clinicians to know the size of the kidney as evaluated by its maximum length, which has become the standard parameter because it is simple and correlates well with renal volume. (The average renal length is 11 cm in adults.) US also allows measurement of the cortical thickness from the outer border of the medullary pyramids to the renal capsule (which normally measures about 10 mm) and analysis of the outline of the kidney, which may be rounded, lobulated, or dented.

US permits study of the cortical echogenicity, which is most often inferior to the liver echogenicity. Although the echogenicity of the renal cortex and liver may be the same in a minority of healthy subjects, a renal cortex more echogenic than the liver is clearly abnormal past the age of 6 months and indicates renal disease.

Corticomedullary differentiation must be analyzed. Prominently hypoechoic medullary pyramids usually indicate increased cortical echogenicity (Fig. 1), whereas

Insufficiency, Acute, Renal. Figure 1 Acute renal insufficiency due to glomerulopathy. The cortex of the kidney is hyperechoic, making the medulla appear very hypoechoic.

hyperechoic pyramids indicate medullary disease. But the main use of US is to seek dilated fluid-filled calyces in the renal sinus that may be differentiated from venous engorgement and peripelvic cysts.

US is an useful tool to differentiate acute from chronic renal insufficiency because in acute renal insufficiency, the kidneys have a normal size or are enlarged whereas in chronic insufficiency, they are more often decreased in size with decreased thickness of the renal cortex, which is considered the most sensitive finding. However, renal size is conserved or increased in glomerulopathy and diabetic nephropathy. Consequently, in the clinical context of renal insufficiency, normal kidney size does not affirm the acute character of the affliction, whereas a decrease in kidney size, as well as in the thickness of the cortex, rules it out.

The main task of US is to look for an obstruction. However, in the clinical setting of two native kidneys, acute obstructive renal failure is rare except in patients with bilateral iatrogenic postoperative obstruction. The lack of calyceal dilatation effectively rules out obstruction as a cause of acute renal failure. For diagnosing non-obstructive causes of acute renal insufficiency, US may provide limited but interesting information regarding the nature of the underlying renal disease and must be integrated to the clinical setting. Swelling of the renal cortex in conjunction with a history of an inciting event or the presence of granular casts in the urine indicates acute tubular necrosis, whereas enlarged, echogenic kidneys in conjunction with hematuria are indicative of nephritis. In a patient with nephrotic syndrome and acute renal failure, swollen, echogenic kidneys may instead indicate renal vein thrombosis, particularly if there is new-onset hematuria or the renal vein is prominent with luminal echoes. Unilateral cortical atrophy with hypertension and unremarkable urinary sediment should raise suspicion for renovascular disease.

Doppler

Doppler improves the sonographic assessment of renal dysfunction. In the setting of acute renal failure, its principal use is to demonstrate the patency of the renal arteries and veins and to look for thrombosis.

Arterial thrombosis may lead to acute renal failure in patients with a single kidney. In other cases, it may decompensate a chronic renal insufficiency in acute failure in patients with nephroangiosclerosis and severe atherosclerosis. Thrombosis of the renal artery occurs most commonly as a complication of severe atherosclerosis or transluminal angioplasty. The most common Doppler finding is absence of an intrarenal arterial signal. If there is incomplete occlusion or if collateral vessels are present, a severe tardus-parvus abnormality is detected. In some patients, US may demonstrate a proximal renal artery stump.

Thrombosis of the renal vein is usually caused by an underlying abnormality of hydration, the clotting system, or the kidney itself. In infants it is mainly due to dehydration, whereas in adults the most common cause is membranous glomerulonephritis. Color Doppler may image the renal vein thrombosis, and spectral analysis may show abnormality of the arterial wave with a shift in the anterograde frequency and reversal of flow during diastole.

The clinical role of Doppler for differentiating renal disease by the resistive index (RI) is more controversial. Classically, patients with isolated glomerular disease have normal RI values, whereas subjects with vascular or arterial disease have markedly elevated RI values. However, these data indicate rather a trend, and there is no cut off to differentiate disease in a given patient.

Computed Tomography

Computed tomography (CT) is not recommended for exploring the cause of renal insufficiency because such exploration needs intravenous contrast except for the search for a ureteral stone. However, it may sometimes be performed when the renal function is unknown or when dialysis is scheduled. Analysis of the CT nephrogram gives some information. When bilateral, global absence means a total lack of renal function; when unilateral, it is most often seen with blunt abdominal trauma with renal pedicle injury. Segmental absence is attributable to focal renal infarction (Fig. 2), most likely due to arterial emboli. Global persistence may be unilateral, caused by renal artery stenosis, renal vein thrombosis, urinary tract obstruction, systemic hypotension, intratubular obstruction, or abnormalities in tubular function. A striated nephrogram is caused by ureteric obstruction, acute pyelonephritis, contusion, renal vein

Insufficiency, Acute, Renal. Figure 2 Bilateral renal infarcts complicating a spontaneous dissection of the renal arteries

I

thrombosis, tubular obstruction, hypotension, or autosomal recessive polycystic disease. The rim pattern is most often associated with renal infarction and occasionally with acute tubular necrosis and renal vein thrombosis.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) has great potential in the noninvasive evaluation of important functional renal parameters such as glomerular filtration, renal perfusion, tubular concentration, renal diffusion, and the oxygenation state of the kidneys. To date, however, MRI is used more in research than in clinical practice.

Nuclear Medicine

Because the excretion of radiopharmaceuticals depends on renal function, they cannot be used to evaluate all patients with renal failure. This is particularly true concerning products excreted primarily by glomerular filtration (technetium). Products excreted by tubular secretion may demonstrate the kidneys even when renal dysfunction is relatively advanced. In clinical practice, radionuclide studies usually only help exclude arterial occlusion because images are difficult to interpret when renal function is markedly impaired.

Diagnosis

An acute renal insufficiency may be diagnosed in a clinical setting that makes obvious the cause of the renal failure, or it may be discovered by clinical findings of hyperuremia or by biochemical results. The goals of imaging are the following:

1. To differentiate acute renal failure from chronic failure
2. To understand the mechanism of the renal failure: functional, postobstructive, or due to nephropathy
3. To seek the cause of the nephropathy: tubular, glomerular, interstitial, or vascular

Most often, the diagnosis of the causes of the renal failure is obvious in the clinical context because several causes may be involved; for instance, in the clinical setting of shock, functional insufficiency and acute tubular necrosis may explain the renal failure and may be related. In the lack of clinical orientation, the imaging strategy is based on US rather than on Doppler. US is used to look for a dilatation of the calyces and seek for findings of chronic renal insufficiency by showing kidneys with decreased size. Doppler is used to look for a thrombosis of the renal artery or veins or a bilateral stenosis of the renal arteries. Other parameters, including kidney echogenicity and the RI, have only an orientation value and do not substitute for renal biopsy.

Definition

Chronic renal insufficiency is the gradual progressive loss of renal function. The renal dysfunction is attributable to the loss of functioning renal parenchyma and, as such, is irreversible. Consequently, in most cases, the process of chronic renal insufficiency results in the need for dialysis or renal transplantation

Pathology

The causes of chronic renal insufficiency may be divided into three main categories: prerenal causes, renal causes, and postrenal causes:

Prerenal chronic renal insufficiency is due to medical conditions that cause continuous hypoperfusion of the kidneys, leading to kidney atrophy (shrinking), loss of nephron function, and chronic renal failure. These conditions include poor cardiac function, chronic liver failure, and atherosclerosis of the renal arteries.

Renal chronic renal insufficiency may result from damage to any portion of the kidney: the gomerulus, the tubule, the blood supply, or the interstitium.

- The main cause of glomerulopathy that is responsible for renal failure is diabetes, and diabetic nephropathy is the most common cause of chronic renal failure in industrialized countries. It occurs as a result of glomerular hyperperfusion that leads to glomerular hypertension, which results in glomerular sclerosis. Other causes of secondary glomerulopathies include amyloidosis, systemic lupus erythematosus, or primary glomerulopathies when there is no extrarenal finding. Theoretically, glomerulopathies are slowly evolutive; however, in some cases the evolution to terminal renal failure may be fast, in particular in the context of HIV nephropathy.
- The tubulo-interstitial involvement in nephropathy may be due to drugs, infection, tumoral infiltration by lymphoma or leukemia, or precipitation of urate or calcium in the metabolic causes of nephropathies.
- The vascular nephropathies represent a cause of chronic renal failure increasing in frequency. The disease may be a

result of three mechanisms: nephrosclerosis due to hypertension which constitutes the second leading cause of chronic renal failure, distal renal infarct due to emboli, or ischemia of the kidneys by bilateral stenosis of the renal arteries.
- Constitutional diseases, such as polycystic disease or Alport's syndrome, are responsible for about 10–15% of cases of chronic renal failure.

Postrenal chronic renal insufficiency is due to obstruction of the normal flow of urine, leading to obstructive uropathy, progressively reduced renal blood flow, and glomerular filtration and damage to the nephrons. Abnormalities that may hamper urine flow and cause postrenal chronic renal insufficiency include bladder outlet obstruction due to an enlarged prostate gland or bladder stone, neurogenic bladder, kidney stones in both ureters, obstruction of the tubules, retroperitoneal fibrosis of any cause, and vesicoureteral reflux.

Clinical Presentation

Patients with mildly diminished renal reserve are asymptomatic, and renal dysfunction can be detected by laboratory testing. A patient with mild to moderate renal insufficiency may have only vague symptoms. Nocturia is noted, principally due to a failure to concentrate the urine during the night. Lassitude, fatigue, and decreased mental acuity are often the first manifestations of uremia. Neuromuscular features then follow including twitches, peripheral neuropathies, muscle cramps, and convulsions. Anorexia, nausea, vomiting, stomatitis, and an unpleasant taste in the mouth are almost uniformly present. The skin may appear yellow–brown and there are bony lesions of renal osteodystrophy. Malnutrition is very common. In advanced renal failure, gastrointestinal ulcerations and bleeding are common. Hypertension related to hypervolemia is present in 80% of patients, and cardiomyopathy and pericarditis are not rare.

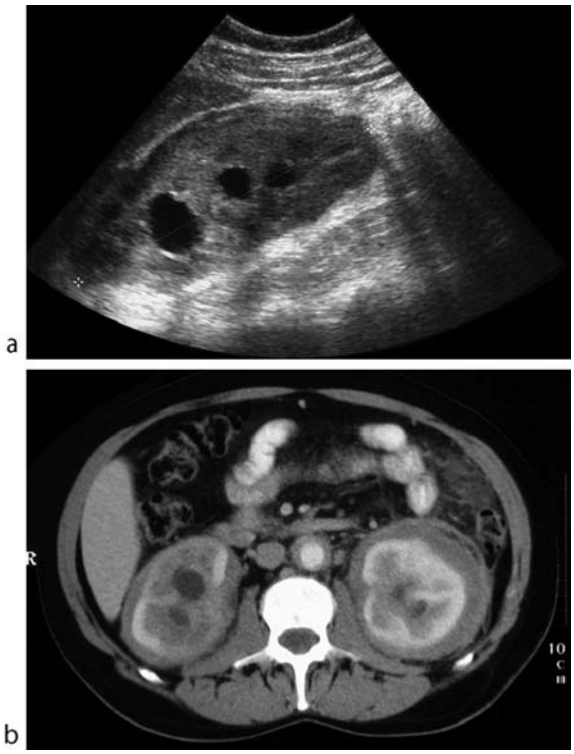
Imaging

Ultrasound

Ultrasound (US) is the best available imaging study for patients with renal failure. The size of the kidney can be evaluated using its maximum length, which has become the standard parameter because it is simple and correlates well with renal volume. Average renal length is 11 cm in adults. US also allows measurement of the cortical thickness from the outer border of the medullary pyramids to the renal capsule, which normally measures about 10 mm, and it allows analysis of the outline of the kidney that may be rounded, lobulated, or dented. The cortical echogenicity can be studied with US, which is most often inferior to the echogenicity of the liver. Although the echogenicity of the renal cortex and the liver is the same in minority of healthy subjects, a renal cortex more echogenic than the liver is clearly abnormal past the age of 6 months and indicates renal disease. The corticomedullary differentiation must be analyzed. Prominently hypoechoic medullary pyramids usually indicate increased cortical echogenicity, whereas hyperechoic pyramids indicate medullary disease and particularly medullary nephrocalcinosis for which the most common causes are medullary sponge kidney (Fig. 1), renal tubular acidosis type 1, and hypercalcemic states. With US, one can search for dilated fluid-filled calyces in the renal sinus (Fig. 2) that may be differentiated from venous engorgement and from peripelvic cysts.

US is a useful tool with which to differentiate acute from chronic renal insufficiency, since in acute renal insufficiency the kidneys have a normal size or are enlarged, whereas they are more often decreased in size

Insufficiency, Chronic, Renal. Figure 1 Medullary nephrocalcinosis due to medullary sponge kidney. (a) US shows hyperechoic renal pyramids without obvious shadowing; (b) CT at the excretory phase shows stasis of urine in the dilated distal collecting tubes.



Insufficiency, Chronic, Renal. Figure 2 **Bilateral perirenal fibrosis. (a) US shows dilatation of the calices; (b) CT clearly shows the perirenal fibrosis responsible for the obstruction.**

with a decreased renal cortex thickness that is considered the most sensitive finding. However, renal size is conserved or increased in glomerulopathy or in diabetic nephropathy. Consequently, in the clinical context of renal insufficiency, a decrease in the size of the kidney, as well as in the thickness of the cortex, may confirm chronic disease, although a normal-sized kidney does not rule it out.

US is mainly used to look for an obstruction. Chronic obstruction produces increasing dilatation of the ureter and the collecting system proximal to the obstruction lesion. The amount of dilatation varies from case to case. In general, the dilatation increases both with the duration of obstruction and as a direct function of the intraluminal pressure. The most severe dilatation therefore does not occur with very mild obstruction or with complete obstruction after which urine formation tends to cease, but rather at an intermediate state in which the degree of obstruction increases intraluminal pressure but does not cause immediate severe oliguria.

In chronic renal failure, the size of the kidney and the thickness of the cortex are most often decreased. A very thin cortex indicates severe, irreversible renal disease. However, enlarged, very echogenic kidneys suggest amyloidosis, HIV nephropathy, or nephritis. Normal-sized or moderately enlarged kidneys that are echogenic are suggestive of glomerulopathies, such as diabetic nephropathy, immunoglobulin A nephropathy, or membranous nephropathy. Renal size is preserved even in advanced diabetic nephropathy, often with only a modest increase in cortical echogenicity, an appearance that is distinctly unusual in advanced renal failure from other causes. Cortical irregularity with a history of multiple urinary tract infections suggests the diagnosis of chronic pyelonephritis, particularly if dilatation of the calyces is present. In the absence of such a history, cortical scarring could represent vascular disease with previous infarcts. In polycystic kidney disease, US easily shows a huge and bilateral renal enlargement due to numerous cysts of variable size.

Doppler

Doppler improves the sonographic assessment of renal dysfunction. In the setting of chronic renal failure without cause, the principal interest is to look for a stenosis of the renal arteries by showing an increased peak systolic frequency shift at stenosis and a poststenotic spectral broadening with a decrease of the resistive index within the intrarenal arteries.

The clinical role of Doppler for differentiating renal disease using the resistive index (RI) is controversial. Some studies suggest that an increased RI of the renal arteries is associated with the severity of systemic atherosclerosis and that the intrarenal vascular resistance differs depending on the underlying renal disease, with a greater increase in diabetic nephropathy than in chronic glomerulonephritis and nephrosclerosis. However, these data indicate a trend, and there is no cut-off for differentiating disease in a given patient.

Computed Tomography

Computed tomography (CT) is not recommended in the exploration of the cause of renal insufficiency, because such exploration needs intravenous contrast agents, except when searching for a ureteral stone. However, in cases where the renal function is not known or because dialysis is scheduled CT can be performed. The analysis of the CT nephrogram gives some information. A global absence when bilateral means a total lack of renal function. Segmental absence is attributable to focal renal infarction, most likely due to arterial emboli. Global persistence may be unilateral, caused by renal artery stenosis, renal vein thrombosis, or urinary tract obstruction, or due to systemic hypotension, intratubular obstruction, or abnormalities in tubular function. Striated nephrograms are caused by ureteric obstruction, acute pyelonephritis, contusion, renal vein thrombosis, tubular obstruction, hypotension, and autosomal recessive polycystic disease.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) has a great potential in the noninvasive evaluation of important functional renal parameters such as glomerular filtration, renal perfusion, tubular concentration, the oxygenation state of the kidneys, and renal diffusion. However, to date, the evaluation of these parameters is more in the field of research than in clinical practice. The main clinical interest of MRI in the daily clinical evaluation of patients with renal failure is to permit the morphological evaluation of the kidneys and the urinary tree after noniodinated contrast enhancement.

Nuclear Medicine

Because the excretion of radiopharmaceuticals depends on renal function, they cannot be used to evaluate all patients with renal failure. This is particularly true for products (Technetium) excreted primarily by glomerular filtration, whereas products excreted by tubular secretion may demonstrate the kidneys even when renal dysfunction is relatively advanced. In clinical practice, radionuclide studies usually only help exclude arterial occlusion, because images are difficult to interpret when renal function is markedly impaired.

Diagnosis

In most cases, the cause of the renal failure is known (diabetic nephropathy, uropathy, polycystic kidney disease) and the goals of imaging will be to look for an aggravating factor (obstacle, stenosis of the renal artery).

In some cases, the renal failure is discovered after clinical findings of hyperuremia or is more often revealed by biochemical test results. In these cases the goals of imaging are

- To differentiate acute renal failure from chronic failure;
- To seek the cause of the nephropathy: tubular, glomerular, interstitial, or vascular. This diagnostic step is crucial because (a) some diagnoses are obvious on imaging (polycystic kidney disease, bladder outlet obstruction), (b) in some cases it may be possible to treat the cause (surgery of a uropathy, dilatation of a stenosis of the renal artery), (c) the prognosis depends on the cause, (d) some renal diseases (glomerulopathy) may recur on the renal transplant;
- To look for factors worsening the renal failure (obstacle).

The imaging strategy is based on US. US will provide some clues of the cause of nephropathy, based on the size of the kidney, the presence of cysts, the outline of the kidneys, their symmetry, and the corticomedullary differentiation. In patients with a suspicion of vascular nephropathy, Doppler will look for findings of stenosis of the renal artery. Renal biopsy, often guided by imaging, is used to discover the cause of the renal failure when the size of the kidney is preserved and when the calyces are not dilated.

Synonyms

Temporomandibular arthropathy; Temporomandibular joint disorders

Definition

Internal derangement is caused by an abnormal movement and/or position of the disc. Naturally, the disc with its posterior attachment is located in closed-mouth position on the zenith of the condyle. During the opening of the mouth, the condyle and the disc slide on the tuberculum articulare. In joints presenting a disc displacement, the disc is located in front of the condyle. If the patient opens the mouth, the condyle might slide on the disc and consequently, the condyle–disc relation normalises during mouth opening (anterior disc displacement with reduction). This action is clinically associated with a click during opening and closing.

In other cases, the condyle might not slide on the disc during mouth opening (anterior disc displacement without reduction). Thus, the disc–condyle relation remains pathological in the opened-mouth position. Consequently, there is often a limitation of the mouth opening in combination with pain as the disc closes the condyle in its movement. However, many subjects present an anterior disc displacement without suffering from any clinical signs or symptoms (the data vary between 7% and 35%).

Anatomy

The main components of the temporomandibular joint (TMJ) are the head of the mandible, the tubercle, the mandibular fossa and the articular disc. The disc has a posterior attachment to the ligamentous apparatus (the superior and inferior strata of the bilaminar zone). The articular disc plays a major role in TMJ function. It consists of an avascular anterior part, which is composed of fibrocartilage and a vascularised posterior part. The anterior part includes an anterior band, an intermediary zone and a posterior band. Under physiological conditions, the biconcave disc separates the TMJ into two compartments, which coordinate rotational movements (lower portion) and translational movements (upper portion). The face of a clock can be used for describing the anatomical location of the disc in relation to the condyle with the head of the mandible in the middle. When the mouth is closed, the posterior attachment of the disc is located at a position between 11 and 12 o'clock in the sagittal plane (Fig. 1a) (3).

When the mouth is open, the disc is interposed between the head of the mandible and the tubercle in the sagittal plane (Fig. 1b). Portions of the articular disc are not infrequently located medial to the head of the mandible in the coronal plane (Fig. 2a–c).

The head of the mandible is homogeneously structured without bony attachments and/or conspicuous flat areas. Under physiological conditions there is (almost) no fluid within the joint.

Pathology/Histopathology

Internal Derangement (Sagittal View)

Partial anterior displacement is diagnosed if the posterior attachment of the disc is located at a position between 10 and 11 o'clock or if anterior displacement cannot be seen on all slices.

Complete anterior displacement is diagnosed if the posterior attachment of the disc cartilage is located at a position below 10 o'clock on all slices or if it has no contact with the condyle (Fig. 3a). Anterior displacement is the most common type of internal derangement. The distinction between partial and complete anterior displacement in the closed-mouth position has no clinical relevance. What is clinically important is whether the disc resumes its normal position relative to the condyle when patients open their mouths (anterior disc displacement with reposition) or whether the disc remains anterior to the condyle on mouth opening (anterior disc displacement without reposition, Fig. 3b). Whereas anterior disc displacement with reposition is often accompanied by clicking sounds on opening and closing the mouth, anterior disc displacement without reposition is char-

acterised by a limitation of mouth opening. Posterior disc displacement is relatively rare.

Internal Derangement (Coronal View)

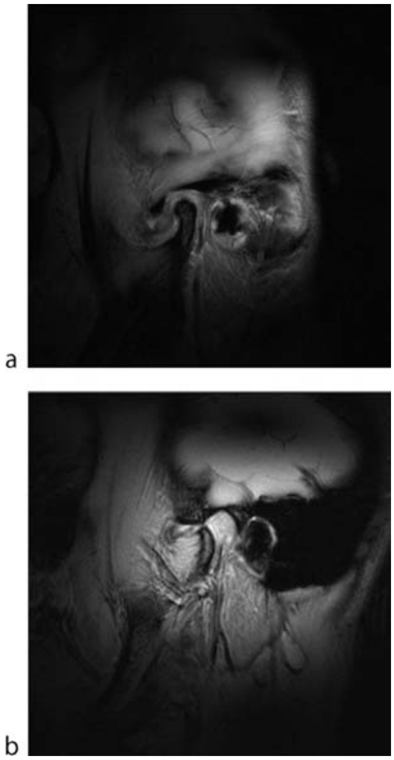
While there is an extensive literature on the pathology of internal derangement in the sagittal plane, very few studies have focused on the coronal view. Normal and abnormal disc positions in the coronal plane, for example, have not yet been sufficiently defined. A review of the literature shows that there is only one prospective study that describes disc positions in a population of symptom-free subjects (Fig. 2a–c) (5). Medial displacement of the disc on mouth opening has been described as a pathological condition in many publications but appears to be within the range of normal variation. By contrast, the absence of a medial orientation seems to be a pathological finding. In addition, the coronal view can help avoid false-negative results in patients evaluated for disc position in the sagittal plane. A further systematic scientific analysis of coronal disc positions (especially in association with the clinical presence of clicking sounds and unremarkable sagittal MR images) might in the future offer useful diagnostic information (Table 1).

Clinical Presentation and Examination

The main clinical symptom is unilateral arthrogenous pain and/or a limited mandibular range of motion. For the clinical examination of the stomatognathic system, standardised criteria should be used and applied by calibrated examiners to obtain a higher reliability (1). A basic distinction should be made between arthrogenic and myogenic changes, which is often difficult, especially in patients with limited mouth opening. The importance of this distinction and the associated difficulties are explainable when the proximity of the TMJ to the surrounding muscles is taken into consideration. Diagnosis is facilitated by detailed information about clinical findings and their diagnostic significance.

Functional disorders are multi-factorial in origin. For this reason, the approach to the patient should include an assessment of psychosocial factors, although arthrogenic disorders are less commonly associated with psychosocial findings than myogenic disorders. The research diagnostic criteria for temporomandibular disorders (RDC/TMD) (1) is an examination protocol that meets all relevant requirements and is used worldwide for the assessment of functional disorders.

The clinical examination for patients suffering from TMD (e.g. the RDC/TMD) includes palpation of muscles (e.g. the masseter and temporal muscles) and portions of the TMJ (e.g. the lateral and posterior poles of the condyle) and documentation of sites painful to palpation. In addition, the range of motion of the mandible is assessed by measuring (maximum) mouth opening as well as lateral and protrusive movements. An additional clinical item to be considered is the assessment of joint sounds since grinding sounds, for example, may be indicative of changes in the shape of the condyle. The fluctuating character of TMJ sounds, however, must be considered in the examination.



Internal Derangement, Temporomandibular Joint. Figure 3 MR image and schematic drawing of complete anterior disc displacement (a) without reposition (b). Sagittal T1-weighted FLASH 2D sequence with the mouth closed (a) and opened (b).

Imaging of the Temporomandibular Joint

As the clinical assessment of the TMJ condition is sometimes unreliable because of fluctuating joint sounds, psychosocial aspects and the overlap of muscular and arthrogenous findings, imaging of the TMJ is necessary in some cases.

Magnetic resonance imaging offers high soft-tissue contrast and is therefore ideally suited for visualising tumourous, inflammatory and degenerative conditions of the TMJ. CT and X-ray only show bony structure and have a role in trauma (2).

The critical structures of the TMJ, such as the posterior attachment of the disc are very small. In addition, the accuracy of MRI findings depends not only on image resolution and quality but also on the anatomical knowledge of the radiologist. The higher the image quality, the higher will be inter-rater reliability or in other words, the level of agreement between the examiners with regard to disc position (4). For this reason, high image resolution and a good signal-to-noise ratio are important. Further factors that make image acquisition difficult are the pain that most patients feel when opening their mouth and the movements of the mandible that are associated with swallowing. This limits the examination time and requires the use of magnetic resonance systems with a field strength of 1.5 T and bilateral surface coils. These surface coils should have a diameter not exceeding 10 cm and should be placed over the TMJ. When MRI is used for evaluating patients suspected of having internal derangement, a TMJ positioning device that can be adjusted steplessly to each patient should be used in order to achieve a maximal opening of the mouth. This helps minimise mandibular movements during imaging.

Magnetic Resonance Imaging Protocol

The advantages and disadvantages of the various types of sequences must be carefully considered in selecting the most appropriate sequences. Spin echo sequences offer high soft-tissue contrast but are associated with a long imaging time at a relatively low resolution. The

Internal Derangement, Temporomandibular Joint. Table 1 MRI protocol for diagnosing internal derangement

		TE (msec)	TR (msec)	Field of view	Matrix	Slice thickness (mm)	Acquisition time (min)
Coronal oblique	PD FLASH 2D	10.2	208	120×120	256×256	3	3.32
Sagittal oblique	PD FLASH 2D	10.2	208	120×120	256×256	3	3.32
Coronal oblique	T2 TSE	112	5290	120×120	256×256	3	3.41

advantages of gradient-echo sequences are a short imaging time, high resolution and small slices. Although these sequences offer less contrast, they are widely used for functional MRI. We use a modified FLASH 2D sequence. PD-weighted sequences have proved to be effective in diagnostic imaging of other joints. With a reduced flip angle, the modified FLASH 2D sequence allows us to obtain images similar to PD-weighted scans. This sequence makes it possible to delineate the head of the mandible, the disc and the dorsal ligamentous apparatus. For this reason, we use it in object-oriented coronal and sagittal planes in the closed-mouth and open-mouth positions. Cine mode MRI at different openings of the mouth is not required since it does not provide additional information of clinical relevance and offers images of poor quality. The protocol also includes a coronal T2-weighted sequence that is used for imaging joint effusion and bone oedema.

The administration of an intravenous contrast agent is not necessary when internal derangement is suspected but may be required for diagnostic imaging of patients with tumours. In these cases, a T1-weighted fat-saturated sequence should be used.

Joint Effusion

An abnormal fluid collection within the TMJ is always a pathological condition that is not necessarily accompanied by pain. By contrast, minimal amounts of fluid in the lateral and medial recesses serve as physiological conditions.

Joint Contour

The head of the mandible usually has a smooth surface. Arthrotic osteophytes of the head of the mandible may be indicative of degeneration. It should be noted, however, that healthy joints can also show minimal shape changes within the range of normal variation. Depending on their extent, these changes can cause deformation of the condyle. They must be distinguished from mutilating abnormalities of the TMJ, which can be a sign of arthritis especially in young patients and should not be diagnosed as arthrotic changes. The administration of a contrast agent is not necessary since contrast enhancement of the synovial membrane must be expected in the presence of such marked joint lesions. Instead, patients should be advised to consult a rheumatologist and undergo serological testing.

In addition, cartilage lesions are found in the TMJ as in other joints. Cortical or osteochondral defects with loose fragments can occur.

Under normal physiological conditions, the disc has a biconcave shape but often adopts a different shape in the course of disc displacement, for example, it becomes biconvex. In the late stage of disc degeneration it is no longer possible to delineate the contours of the disc.

Range of Motion

Range of motion in the anterior–posterior direction depends on mouth opening capacity and thus shows individual differences. Asymmetries, where one mandibular head moves further in the ventral direction than the other one, are pathological conditions. In healthy test subjects, the condyle not infrequently (in more than 40% of cases) slides over the tubercle. Hypomobility is a pathological condition that is associated with the limitation of mouth opening and is characterised by a limited range of motion of the condyle in relation to the tubercle. It is often accompanied by an asymmetric opening of the mouth and occurs together with anterior disc displacement without reduction.

Diagnosis

Anterior displacement: Posterior attachment is below 10 o'clock position in closed mouth,

With reposition: Disc is in the normal position on mouth opening,

Without reposition: Disc is in front of the condyle on mouth opening,

Posterior displacement (very rare): Posterior attachment is dorsal to 1 o'clock position in closed mouth,

Hypomobility: Limitation of mouth opening and is characterised by a limited range of motion of the condyle in relation to the tubercle,

Joint effusion: An abnormal fluid collection within the TMJ.

Synonyms

Diffuse parenchymal or interstitial lung disease from known causes or association

Definition

Many factors may produce diffuse predominantly interstitial infiltration of the lung. These entities comprise: hypersensitivity pneumonitis (HP), smoking-related interstitial lung disease, collagen vascular diseases, pulmonary vasculitis, drug toxicity, and radiation induced lung fibrosis.

Pathology/Histopathology

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis is an immunologically induced inflammatory disease of the lung parenchyma and terminal airways as a consequence of repeated inhalation of a variety of organic dusts and other agents in a sensitized host. The classic histopathology of HP features the triad of cellular bronchiolitis, a lymphoplasmocytic interstitial infiltrate, and poorly formed nonnecrotizing granulomas. However, pathologic features may vary with disease stage and a fibrotic pattern very similar to usual interstitial pneumonia (UIP) or nonspecific interstitial pneumonia (NSIP) is frequently seen in chronic, fibrotic HP.

Smoking-Related Interstitial Lung Disease

The increasing recognition that Langerhans cell histiocytosis (LCH), respiratory bronchiolitis-interstitial lung disease (RB-ILD), and desquamative interstitial pneumonia (DIP) form a spectrum of interstitial patterns in response to smoking-related lung injury has led to the proposal of the term “smoking-related interstitial lung disease" to cover these entities. The variety of interstitial lung diseases associated with cigarette smoking is wider than generally appreciated and these often coexist (1). Respiratory bronchiolitis (RB) is a histopathologic lesion, characterized by the presence of pigmented intraluminal macrophages within respiratory bronchioles, whereas RB-ILD disease occurs when RB is extensive enough to cause symptoms and physiologic evidence of interstitial lung disease. LCH in adults results from the accumulation of specific histiocytic cells known as Langerhans cells in the lung, and is strongly associated with cigarette smoking.

Collagen Vascular Diseases

The collagen vascular disorders can affect many parts of the lung: the pleura, alveoli, interstitium, vasculature, lymphatic tissue, or airways. Most of the parenchymal manifestations of collagen vascular diseases are similar to those found in lone idiopathic interstitial pneumonias (IIPs).

Pulmonary Vasculitis

Pulmonary vasculitis may occur in the context of a systemic vasculitis or may be associated with other underlying diseases such as collagen or drug induced lung diseases. Principally small-vessel primary vasculitis, which causes alveolar hemorrhage and/or inflammatory infiltrates more reminiscent of diffuse interstitial lung disease (2).

Miscellaneous Causes of Pulmonary Fibrosis

Drug Toxicity

Numerous agents including cytotoxic (such as bleomycin, methotrexate, and cyclophosphamide) and noncytotoxic drugs (such as nitrofurantoin, sulfasalazine, and amiodarone) have the potential to cause pulmonary toxicity damage. The spectrum of the abnormalities includes mainly diffuse alveolar damage (DAD), nonspecific interstitial pneumonia, organizing pneumonia (OP), eosinophilic pneumonia, and pulmonary hemorrhage (3). Granulomatosis-like reactions as well as pulmonary vasculitis may also be caused by drug toxicity.

Radiation Induced Lung Fibrosis

Radiation effects on the lung are commonly seen within 6–8 weeks of starting treatment, and peak 3–4 months after completing treatment. After the early transient radiation, pneumonitis fibrosis progresses, consolidates, and contracts over the following months.

Clinical Presentation

Hypersensitivity Pneumonitis

The clinical features of HP are classically divided into three stages, based on the duration of the patient's symptoms: acute, subacute, and chronic. However, significant clinical and radiological overlap can often occur between these nominal phases.

Smoking-Related Interstitial Lung Disease

Patients with RB are usually asymptomatic whereas most patients with RB-ILD have mild symptoms that are not disabling. Cough and dyspnea are the most common presenting symptoms, though pneumothorax may be the presenting complaint in patients affected by LCH.

Collagen Vascular Diseases

The lung disease associated with collagen vascular disease may precede the clinical presentation of the collagen disease by 5 years or more. The pulmonary symptoms resemble mainly those of patients with other interstitial lung diseases.

Pulmonary Vasculitis

Wegener's Granulomatosis

At presentation, upper airway involvement with sinusitis and rhinitis is the most common clinical feature in patients affected by Wegener's granulomatosis. The pulmonary symptoms include hemoptysis, cough, chest pain, and dyspnea.

Churg-Strauss Syndrome

The diagnosis of Churg-Strauss syndrome is made in the presence of the following findings: (1) asthma, (2) eosinophilia greater than 10%, (3) neuropathy, (4) transient or migratory pulmonary opacities.

Microscopic Polyangitiis

A nongranulomatous necrotizing systemic vasculitis is usually responsible for the pulmonary–renal syndrome. Hence, important features that distinguish it clinically from any other vasculitis are the presence of glomerulonephritis and the frequency of pulmonary hemorrhage.

Miscellaneous Causes of Pulmonary Fibrosis

Drug Toxicity

Recognition of drug-induced lung disease can be difficult because the clinical manifestations are often nonspecific, and may be attributed to infection, radiation pneumonitis, or recurrence of the underlying disease.

Radiation Induced Lung Fibrosis

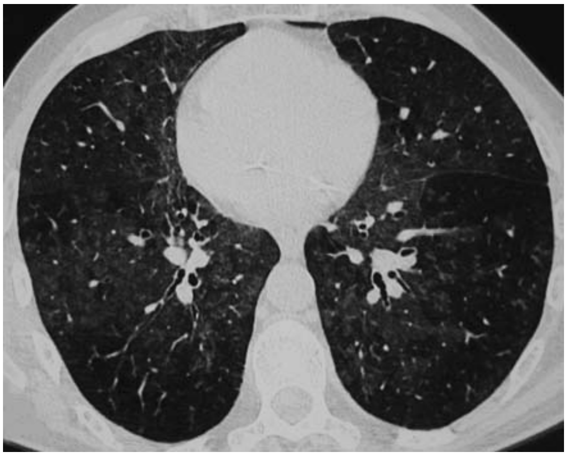
If any symptoms (dyspnea, cough, and fever) related to pulmonary irradiation occur, they are mainly seen in the acute phase. In chronic phase, if fibrosis is not severe and extensive, patients are usually asymptomatic.

Imaging

Hypersensitivity Pneumonitis

Chest radiography, in the acute or subacute phase, is often nonspecific; ground-glass opacification (GGO) or a nodular/reticulonodular pattern may be present. In chronic HP reticular opacities and volume loss occur.

A variety of high resolution computed tomography (HRCT) patterns have been described in HP. GGOs, mosaic attenuation, nodules, and reticular abnormalities may all be found in acute or subacute or chronic forms of the disease since significant clinical and radiological overlap can often occur between these nominal phases. Diffuse or patchy GGO with a geographic distribution is the most common finding in the acute phase, although HRCT is rarely obtained at this stage. The nodules are the most distinctive HRCT feature, and they are often seen in the subacute stage; they are centrilobular, poorly defined, of GG attenuation in contrast to the nodules of most other inhalational diseases. A mosaic pattern, due to small airways involvement with expiratory air-trapping, provides supportive evidence for the diagnosis, especially when it occurs in association with GGOs and nodules (Fig. 1) (4). Findings of fibrosis, such as reticular opacities, honeycombing, and traction bronchiectasis are only present in the chronic phase; at this stage, the predominant mid-lung distribution of the abnormalities in association with areas of air-trapping may help to differentiate chronic HP from other fibrotic lung diseases such as nonspecific interstitial pneumonia and usual interstitial pneumonia.



Interstitial Lung Diseases, Known Causes or Association. Figure 1 Subacute hypersensitivity pneumonitis (farmer's lung). Inspiratory HRCT shows mosaic attenuation, with areas of poorly defined ground-glass nodular opacities superimposed on a background of decreased attenuation.

Smoking-Related Interstitial Lung Disease

It is unusual to be able to diagnose RB-ILD by chest radiography alone. The HRCT features of both RB and RB-ILD are essentially represented by hazy centrilobular nodules predominating in the upper lobes and small patches of GG attenuation; in RB-ILD these abnormalities are more widespread and often associated with a background of emphysema and bronchial wall thickening. Interlobular septal thickening due to interstitial fibrosis may be seen in RB-ILD, but is rarely a prominent feature. Knowledge of a smoking history is clearly important, and may help to distinguish RB/RB-ILD from subacute HP which is usually not associated with this habit. RB-ILD differs from DIP in that GG attenuation of RB-ILD is usually less extensive, patchier, and more poorly defined.

Chest radiography in LCH shows nodular, cystic, reticular, or reticulonodular lesions, almost invariably involving the middle and upper lung zones, and frequently sparing the costophrenic sulci. Pneumothorax is a recognized feature of Langerhans cell histiocytosis. The HRCT appearance is a cystic-nodular pattern involving mostly the upper lobes. Nodules are usually <5 mm in diameter, have a peribronchiolar and centrilobular distribution, and may cavitate. Cysts are usually <10 mm in diameter but may coalesce becoming >20mm and leading to bizarre-shaped spaces with a bilobed, clover-leaf, or branching appearance. Nodules and cysts can occur independently of each other, but in the majority of patients they are found concomitantly. Occasionally, patchy or diffuse GGOs may be seen, probably related to areas of RB and DIP (1).

Collagen Vascular Diseases

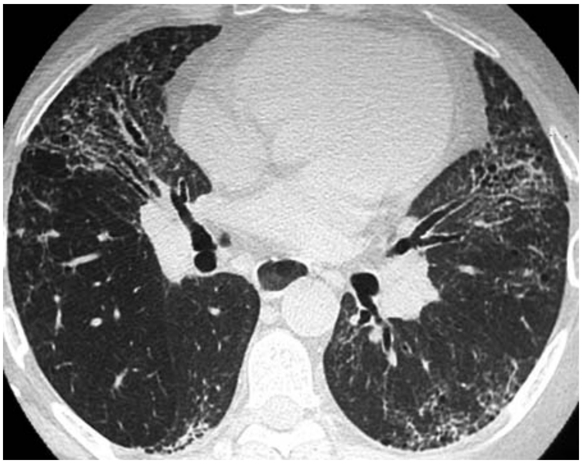
Rheumatoid Arthritis

The chest radiograph of a patient affected by RA is usually normal but may show hyperinflation, reticulonodular pattern, or pleural effusions. The "rheumatoid lung," interstitial inflammatory, and fibrotic pulmonary disease occur in a minority of patients; however; such term seems to be of little use as a descriptor, since lung biopsies show a wide range of abnormalities, including interstitial pneumonia, lymphoid hyperplasia, OP, and DAD, and HRCT more accurately reflects these changes than chest radiography. Although UIP and less frequently NSIP are the most frequent by encountered patterns, airway diseases including bronchiectasis and bronchiolectasis (even away from the fibrotic areas) and obliterative bronchiolitis (which causes a mosaic pattern) are not uncommon. It should be kept in mind that patients with rheumatoid arthritis often receive chronic drug therapy so that there may be coexistent drug-induced disease.

Systemic Sclerosis

As with other fibrosing lung diseases, the initial radiographic abnormalities may be subtle and consist of fine reticulation; as the disease progresses, the lower zone reticulation become coarser and more extensive.

The HRCT features of lung disease in patients with systemic sclerosis closely resemble those in patients with idiopathic nonspecific interstitial pneumonia. The finding of pulmonary arterial enlargement out of proportion to the severity of the lung fibrosis may indicate an independent vasculopathy akin to primary pulmonary hypertension. The presence of a dilated esophagus may also suggest of systemic sclerosis (Fig. 2).



Interstitial Lung Diseases, Known Causes or Association. Figure 2 A 55-year-old patient with systemic sclerosis. HRCT through the lung bases shows fine reticulation and ground-glass opacity with a patchy distribution, consistent with a nonspecific interstitial pneumonia (NSIP) pattern (note the esophageal dilatation).

Systemic Lupus Erythematosus

Pleuropulmonary involvement of some sort occurs in approximately one-half of patients with systemic lupus erythematosus (SLE). The most common radiographic findings (not usually coexistent) consist of pleural effusion, cardiovascular changes, elevation of the diaphragm associated with basal atelectasis, and parenchymal consolidations and/or GGO pattern. The latter may reflect infection, pulmonary hemorrhage, lymphoproliferative infiltrate, or rarely of acute lupus pneumonitis characterized histologically by changes of DAD; moreover, fibrotic interstitial lung disease (NSIP, UIP, and OP subtypes) is generally regarded as an unusual manifestation of SLE.

Polymyosistis/Dermatomyositis

Radiographic changes in the lungs usually consist of symmetric reticulonodular opacity; more acute cases may show areas of airspace opacity. The HRCT changes are consistent with the pathologic findings, and represent OP and/or NSIP. Bilateral multifocal consolidation tends to occur in the lower zones with a subpleural and bronchovascular predilection, usually accompanied by linear opacities or GGO. In time, a fine honeycombing pattern equivalent to usual interstitial pneumonia may develop.

Pulmonary Vasculitis

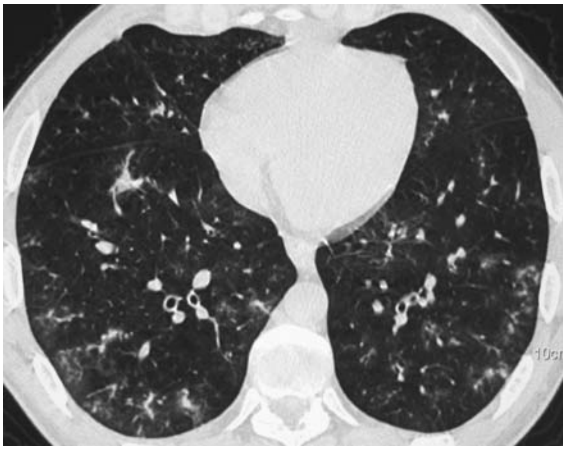
Wegener's Granulomatosis

Chest radiographs typically show bilateral, multiple rounded opacities which may cavitate. The CT findings, although variable, consist mainly of subpleural or peribronchovascular nodules or masses; central cavitation usually occurs in nodules measuring greater than 2 cm in diameter, and the walls of cavitated lesions are often thick and irregular. Predominant bilateral air-space consolidation due to pulmonary hemorrhage is an infrequent but serious complication. Bronchial abnormalities, including bronchiectasis and bronchial wall thickening, have been reported in about 40% of cases. Tracheal narrowing is an important and relatively common manifestation of Wegener's granulomatosis.

Churg-Strauss Syndrome

The main HRCT features of Churg-Strauss syndrome consist of air-space consolidation or GGOs, nodules, and septal lines: these findings reflect the presence of air-space eosinophilic infiltrates as well as OP, and interstitial edema (which may be secondary to cardiac dysfunction) (5). Airway changes, in particular bronchial wall thickening, may be ascribed to the underlying asthma (Fig. 3).

I



Interstitial Lung Diseases, Known Causes or Association. Figure 3 **A 28-year-old man with Churg-Strauss syndrome. HRCT shows patchy ground-glass attenuation and poorly defined nodules with a peripheral distribution. Areas of decreased attenuation and bronchial wall thickening are also present, reflecting the underlying asthma.**

Microscopic Polyangitiis

The HRCT findings are mostly related to ▶diffuse alveolar hemorrhage caused by capillaritis. Thus, consolidation as well as patchy GGO may be seen.

Miscellaneous Causes of Pulmonary Fibrosis

Drug Toxicity

The spectrum of abnormalities seen on HRCT in patients with drug-induced lung disease reflects the underlying histopathological findings including mainly DAD, NSIP, OP, eosinophilic pneumonia, and pulmonary hemorrhage (3). Some drugs can produce more than one pattern of histopathological involvement, and amiodarone toxicity is arguably the only condition in which CT can be used to make a definitive diagnosis by virtue of the high-attenuation values of amiodarone deposits in the lung.

Radiation Induced Lung Fibrosis

The earliest radiographic finding is a diffuse haze in the irradiated region with obscuration of vascular margins; scattered consolidations appear, and these areas may coalesce into a geometric area of pulmonary opacity. At this stage, CT findings are GGO and consolidation with a geographic distribution. With time the opacities become more linear or reticular and distort adjacent structures. 3D conformal radiotherapy can produce atypical findings, sometimes suggesting residual tumor or relapse.

Nuclear Medicine

Radiation Induced Lung Fibrosis

Fluoro-deoxyglucose positron emission tomography (FDG PET) imaging is more accurate than chest radiographs, and CT for distinguishing persistent or recurrent tumor from posttreatment scarring or fibrosis.

Diagnosis

Hypersensitivity Pneumonitis

Clinical and HRCT features often are characteristic enough to make the diagnosis. If the diagnosis remains equivocal, bronchoscopy may be helpful by demonstrating lymphocytosis on bronchoalveolar lavage or granulomas on transbronchial biopsy.

Smoking-Related Interstitial Lung Disease

A firm histological confirmation generally requires an open or thoracoscopic lung biopsy. However, the identification of Birbeck granules on electron microscopic evaluation of the cell pellet from a bronchoalveolar lavage can be diagnostic for LCH.

Collagen Vascular Diseases

Many of these diseases are characterized by the presence of a specific type of autoantibody, which may greatly assist specific diagnosis. Careful evaluation of the chest radiograph and CT can yield some useful clues to the presence of collagen vascular disease.

Pulmonary Vasculitis

Their diagnosis is based on clinical, radiographic, and histopathalogic findings. Although this group of diseases eludes a precise clinical or histological diagnosis, an increasing array of HRCT features can be used to corroborate pulmonary vasculitis as the dominant pathologic process.

Miscellaneous Causes of Pulmonary Fibrosis

Drug Toxicity

Diagnosis of drug-induced lung disease requires careful correlation of the history of drug exposure, compatible radiological findings, exclusion of alternative diagnoses, and improvement after withdrawal of offending agent.

Radiation Induced Lung Fibrosis

Radiological manifestations typically have a characteristic temporal relationship to the completion of therapy. Knowledge of this temporal relationship and an understanding of the expected patterns of radiation fibrosis associated with different radiation therapy techniques is needed to suggest a diagnosis of radiation induced lung fibrosis and to differentiate it from recurrent tumor or superimposed infection (6).

Synonyms

Diffuse interstitial lung disease from unknown causes; Diffuse parenchymal lung disease from unknown causes; Idiopathic interstitial lung diseases

Definition

The term "idiopathic interstitial lung diseases" is applied to a group of disorders with distinct histological and radiological appearances and without a known cause. These disorders essentially include sarcoidosis, ►lymphangioleiomyomatosis, ►pulmonary alveolar proteinosis, eosinophilic pneumonia, and idiopathic interstitial pneumonias (IIPs).

Idiopathic Interstitial Pneumonias

Pathology/Histopathology

The evolution of the classification of the IIPs over time has culminated in seven entities: idiopathic pulmonary fibrosis (IPF), corresponding to the pathology of usual interstitial pneumonia (UIP); nonspecific interstitial pneumonia (NSIP); desquamative interstitial pneumonia (DIP); respiratory bronchiolitis-associated interstitial lung disease (RBILD); cryptogenic organizing pneumonia (COP), formerly known as bronchiolitis obliterans organizing pneumonia; acute interstitial pneumonia (AIP); and lymphocytic interstitial pneumonia (LIP) (1).

The histological diagnosis of UIP is based on temporal and spatial heterogeneity of the fibrotic lesions (variegated appearance with scattered areas of normal lung, fibroblastic foci, honeycombing, etc.) with patchy involvement and normal lung adjacent to severely fibrotic lung. In contrast to UIP, the pathologic findings of NSIP are spatially and temporally uniform and consist primarily of interstitial inflammation or fibrosis. The main pathologic finding of COP consists of polypoid masses of granulation tissue within peripheral airways, extending into the alveoli and associated with interstitial and peribronchial cellular infiltration. Although DIP is currently classified as an IIP (1), its usual association with cigarette smoking has led it to be considered part of a spectrum of smoking-related lung diseases. DIP is characterized by spatially homogeneous thickening of alveolar septa, associated with intraalveolar accumulation of macrophages. AIP is a rapidly progressive form of interstitial pneumonia that is histologically identical to acute respiratory distress syndrome (ARDS). LIP occurs almost exclusively in patients who either have a connective tissue disorder (particularly Sjögren syndrome), immunodeficiency or Castleman disease. Though not usually idiopathic, it was included in the classification of IIPs (1) largely because it is important in the histological differential diagnosis of the IIPs. LIP is characterized by marked infiltration of the interstitial space by a monotonous sheet of lymphocytes.

Clinical Presentation

The most frequent presenting symptoms of patients affected by IIPs are progressive dyspnea, nonproductive cough, and (more commonly in COP) an influenza-like illness. Less common symptoms include nonspecific chest pain and constitutional symptoms such as weight loss and

I

fatigue, whereas patients with AIP and dyspnea progress rapidly to respiratory failure.

Imaging

Almost all patients affected by IIPs have abnormal chest radiographs characterized mostly by a variety of nonspecific patterns, most frequently a reticular pattern; however, consolidations and patchy abnormalities may predominate, especially in COP and AIP.

UIP. Abnormalities are predominantly basal, often patchy, with a strikingly peripheral distribution. The typical high-resolution computed tomography (HRCT) image is characterized by the presence of reticular opacities, within which are cystic airspaces (honeycombing), and traction bronchiectasis (Fig. 1). Ground-glass opacity (GGO) is usually present but is less extensive than the reticular pattern. Mediastinal adenopathy is a frequent accompaniment.

A rapid development of new areas of GGO and/or consolidation raises the possibility of an accelerated phase of the disease, an opportunistic infection, or pulmonary edema. Other complications include pneumothorax, pneumomediastinum, lung neoplasms, pulmonary hypertension, and cardiac failure.

NSIP. The CT features of NSIP consist mainly of GGO and reticular opacities involving the lower zones, with a peripheral and/or a peribronchovascular distribution. GGO occurs as an isolated finding in about one-third of patients but is more commonly associated with reticular abnormality or consolidation, which may represent foci of organizing pneumonia. Honeycombing, if present, is limited in extent compared with UIP.

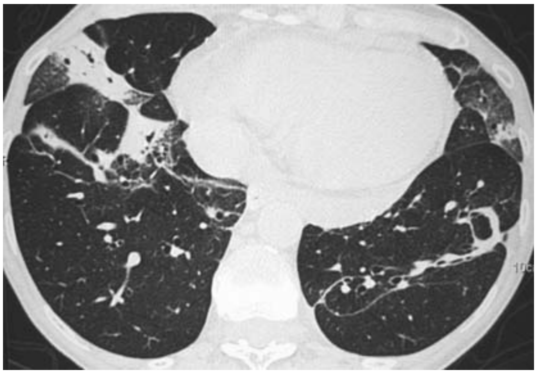
Even though no single feature or combination of CT features can be identified as being entirely specific for a histological diagnosis of NSIP, a summary of the CT findings, particularly the extent of the disease, is very important for the evaluation of patients with NSIP. There is a better correlation between response in terms of disease extent on CT than the absolute histopathological subtype of disease, presumably due to the global assessment of the lung provided by CT in contrast to the inherent sampling of lung biopsy (2).

COP. CT shows consolidations that are usually bilateral, patchy, asymmetric, peripheral, and migrating; the lower lung zones are more frequently affected (Fig. 2). GGOs are present in about 60% of cases (3). Other CT findings include small centrilobular nodules, irregular lines, and ill-defined perilobular densities. COP in its usual radiological manifestation may spontaneously resolve or respond to steroid therapy, but some cases associated with reticular opacities may progress to irreversible fibrosis. When considering the dominant feature of COP on CT – namely consolidation – other entities, such as infections, bronchioalveolar carcinoma, lymphoma, and vasculitis, should be excluded.

DIP. The main feature on CT is the presence of GGO, which is usually bilateral and symmetrical. The distribution is basal and peripheral. Small thin-walled cysts may occur within the areas of GGO, whereas signs indicating architectural distortion (irregular linear opacities, honeycombing) are seen in about one-third of cases.

AIP. The earliest CT appearances are bilateral and patchy GGOs, often associated with consolidation in the

Interstitial Lung Diseases, Unknown Etiology. Figure 1 A 63-year-old man with usual interstitial pneumonia. High-resolution computed tomography shows peripheral honeycomb lung destruction and reticular abnormality in the lower lobes.



Interstitial Lung Diseases, Unknown Etiology. Figure 2 A 52-year-old man with recurrent migratory consolidation due to cryptogenic organizing pneumonia. The consolidation has a predominant peribronchovascular distribution.

dependent lung. In surviving patients, CT shows a progressive change from GG attenuation to traction bronchiectasis, cystic lesions, and reticular opacities, predominantly in the nondependent lung.

Patients with AIP are more likely to have a symmetric bilateral distribution of the lesions with lower lung predominance compared with patients with ARDS (1). Other differential diagnoses include acute exacerbation of an underlying chronic idiopathic fibrosis or systemic disease (connective tissue diseases and vasculitis), infections, pulmonary edema, and pulmonary hemorrhage.

LIP. The concomitant presence of GGOs, poorly defined nodules (centrilobular or subpleural) and scattered thin-walled cysts can help differentiate LIP from other IIPs on HRCT but the range of CT appearances of the rare IIP is wide, and a confident HRCT diagnosis is unusual. Other common findings are lymphadenopathy and interlobular septal thickening.

Nuclear Medicine

To date, nuclear medicine techniques such as positron emission tomography (PET) and lung scanning have no well-documented clinical role in the diagnosis, management, or prognosis of most diffuse lung processes.

Diagnosis

HRCT assumes a central role in defining the morphologic pattern of the IIPs, particularly in distinguishing between UIP from the other IIPs. Because UIP has a worse prognosis than the other forms of IIPs, it is important to clearly separate those patients who have the pattern of UIP on HRCT from those with other patterns. However, the HRCT features of each IIP may not be characteristic, and there is overlapping as well as coexistence of these entities.

When the HRCT pattern is typical, UIP can be confidently diagnosed in more than half of cases. Nevertheless, a confident diagnosis of UIP on HRCT is not straightforward in about one-third of patients with biopsy-confirmed UIP; in such cases, the honeycombing is less pronounced and the GGO may predominate, resembling an HRCT appearance of NSIP.

In all the other cases of IIPs, surgical biopsy is usually warranted to secure a definite diagnosis.

Sarcoidosis

Pathology/Histopathology

Sarcoidosis is a systemic disease of unknown etiology characterized by noncaseating granulomatous inflammation. Although known to affect any organ system, the lungs and its associated lymph nodes are involved in 90% of patients. Pathologic findings in sarcoidosis consist of noncaseating granulomas with epithelioid cells and large, multinucleated giant cells. In the lungs, granulomas are predominantly distributed along lymphatic pathways, being characteristically found along bronchovascular bundles, interlobular septa, and pleura. Although granulomas may remain stable for a long time or resolve spontaneously (or in response to treatment), in a minority of cases a centripetal fibrosis tends to obliterate the granulomas, leading to an extensive interstitial fibrosis with destruction and distortion of the lung architecture.

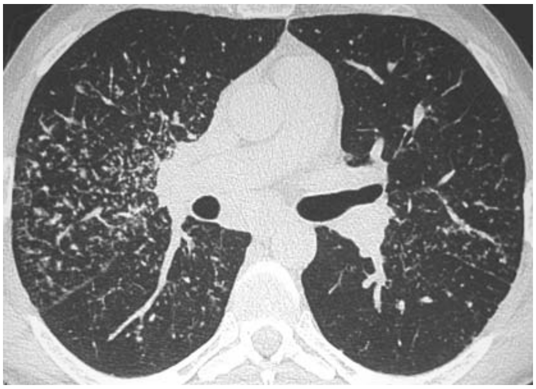
Clinical Presentation

Sarcoidosis most commonly presents between 20 and 40 years of age. Presentation as an incidental radiographic finding occurs in about 50% of cases. Respiratory illness, erythema nodosum, and ocular symptoms represent the other common presentations. Acute onset with erythema nodosum or asymptomatic bilateral hilar lymphadenopathy usually heralds a self-limiting course with spontaneous resolution, whereas insidious onset, especially with lung involvement or multiple extrapulmonary lesions, may be followed by progressive fibrosis of the lung and other organs (4). Sarcoidosis occurring in blacks is later in onset, is more likely to involve peripheral nodes, and to become chronic and disseminated; in general, the prognosis of sarcoidosis is worse in blacks than in whites. Although patients with sarcoidosis usually have a restrictive defect, an obstructive impairment can be surprisingly related to the extent of the reticular pattern depicted on HRCT or to small airway involvement and air trapping.

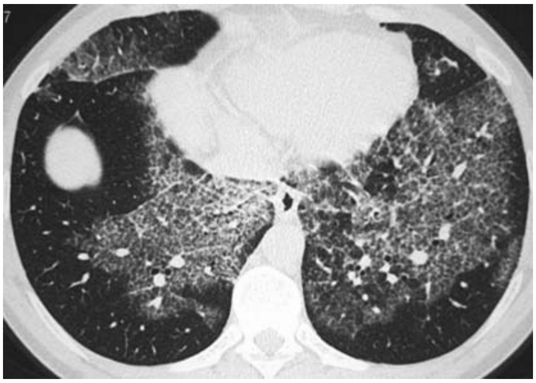
Imaging

Frequently, the diagnosis is first brought to attention by incidental findings on chest radiography, and staging of the disease is traditionally based on chest radiograph findings: stage O = no demonstrable abnormality; stage I = nodal enlargement only; stage II = nodal enlargement associated with parenchymal abnormality; stage III = pulmonary opacity not associated with node enlargement or evidence of fibrosis; stage IV = lung fibrosis (parenchymal distortion, lobar volume loss, etc.). Generally, the abnormalities on chest radiography mostly consist in hilar (typically symmetric) and mediastinal adenopathy, profuse bilateral small nodules, rounded or irregular, associated with linear and irregular opacities in the middle and upper zones. Symmetry is an important diagnostic feature of the hilar adenopathy associated with sarcoidosis because symmetric adenopathy is unusual in lymphoma, tuberculosis, and metastatic disease.

Hilar and mediastinal lymphadenopathy is seen more frequently on CT, which can also allow a more detailed analysis of nodal calcification. Because of their typical "perilymphatic" distribution, the nodules depicted on HRCT are clustered along the bronchovascular bundles, interlobular septa, interlobar fissures, adjacent to the costal pleural (sometimes mimicking small pleural plaques), and also in the centrilobular regions (Fig. 3) (5). Nodules tend to predominate in perihilar regions with relative sparing of the lung periphery and may be grouped unilaterally or bilaterally in small areas. Nodules of sarcoidosis typically measure 1–5 mm, but rarely, multiple ill-defined large nodules (ranging in diameter from 1 to 4 cm) can be observed on chest radiography. In approximately 10% of patients with sarcoidosis, a confluence of granulomas may cause compression of the alveoli and result in poorly defined bilateral parenchymal consolidations containing an air bronchogram; both parenchymal consolidations or large nodules can, although rarely, cavitate. Innumerable small interstitial granulomas (beyond the resolution of CT) may cause patchy GGOs on HRCT.



Interstitial Lung Diseases, Unknown Etiology. Figure 3 Sarcoidosis. High-resolution computed tomography shows small nodules along interlobular septa, pulmonary vessels, and visceral pleura (e.g., the left oblique fissure).



Interstitial Lung Diseases, Unknown Etiology. Figure 4 Pulmonary alveolar proteinosis. High-resolution computed tomography shows extensive bilateral ground-glass opacity with a geographic distribution and a fine reticular pattern with interlobular as well as intralobular septal thickening superimposed (crazy-paving pattern).

Although the parenchymal abnormalities are often reversible, pulmonary fibrosis occurs in approximately 20–25% of cases. Classic changes include linear opacities (radiating laterally from the hilum), fissural displacement, bronchovascular distortion (bronchiectasis), and honeycombing concentrated in the upper zones of the lungs. Finally, HRCT can also help demonstrate other specific complications (pulmonary hypertension, bronchial stenosis, etc.) and comorbidities (such as aspergilloma colonization of the cavities).

Nuclear Medicine

Only PET scanning with various markers has shown utility in detecting occult disease activity in patients affected by sarcoidosis.

Diagnosis

The definitive diagnosis of sarcoidosis requires clinical and imaging features compatible with the diagnosis, as well as confirmation of the presence of noncaseating granulomas. Laboratory investigations may show various nonspecific derangements such as high serum levels of angiotensin converting enzyme (ACE), hypercalcemia, and a decreased CD4:CD8 ratio in the blood serum. Chest radiography still plays an important role in diagnosis of sarcoidosis, while CT is superior for demonstrating subtle mediastinal lymphadenopathy and associated parenchymal involvement. Histological confirmation of the presence of granulomas is critical in the diagnosis of sarcoidosis; transbronchial biopsy has a high diagnostic yield because of the predominantly peribronchovascular distribution of the granulomas.

Interventional Hepatic Procedures

Riccardo Lencioni, Marzio Perri
Department of Diagnostic and Interventional Radiology University of Pisa, Pisa, Italy
lencioni@med.unipi.it

Several image-guided interventional procedures, including percutaneous and intra-arterial therapies, have been developed to treat primary and secondary liver malignancies. Percutaneous techniques of tumour ablation consist in the direct application of chemical agents (ethanol or acetic acid) or thermal agents, including heating (radiofrequency, laser and microwaves) and freezing (cryoablation) to a focal tumour (1). In intra-arterial therapies, chemotherapeutic and/or embolizing agents are delivered into the hepatic arterial system.

Techniques

Ethanol Injection

▶Percutaneous ethanol injection (PEI) has been the most widely used tumour ablation technique (2, 3). PEI induces local tumour necrosis as a result of cellular dehydratation, protein denaturation and chemical occlusion of tumour vessels. Since it allows a real-time control, US guidance is the best option for PEI administration enabling a faster procedure time, precise centring of the needle in the target, and continuous monitoring of the injection. Fine non-cutting needles, with either a single end hole or multiple side holes, are commonly used for PEI. PEI may be performed under local anaesthesia and patient hospitalization is not required. The treatment schedule typically includes four to eight session performed once or twice weekly. However, number of session and amount of ethanol to inject may vary according to the size of the lesion, intra-tumour ethanol distribution and patient's compliance.

Radiofrequency Ablation

Percutaneous ▶ radiofrequency (RF) ablation works on the principle that alternating current operated within the radiofrequency range can produce focal thermal injury in tissues (2, 3). The thermal damage caused by RF heating is dependent on both the tissue temperature and the duration of heating and when a 90–105°C temperature throughout the entire target volume is achieved and maintained for at lest 4–6 min, a large area of coagulative necrosis can be obtained. In RF ablation, the patient is part of a closed-loop circuit that includes an RF generator, an electrode needle, and a large dispersive electrode (ground pads). In each treatment session the electrode needle is placed within the liver tumour under US, CT or MR, guidance. Grounding is achieved by attaching large ground pads and the electrode is then attached to the RF generator. Since the dimension of RF thermal lesions is related not only to tissue-anatomic characteristics (heat conduction and heat lost *via* circulation) but also to technical elements (current intensity and size of the needle electrode), several technological improvements have been introduced in order to optimize RF results. Particularly, modified electrodes, such as cooled-tip electrode needles and expandable electrode with multiple retractable lateral-exit prongs on the tip, allow to obtain a larger volume necrosis and to make the procedure more effective. With any technology, each insertion lasts 10–20 min, since after this time the impedance rise induced by coagulative necrosis not allow further heat diffusion in the tumour. RF treatment may be performed by using local anaesthesia or conscious sedation.

Laser Ablation

▶Laser ablation uses laser light produced by a neodymium yttrium albuminium garnet (Nd:YAG; wavelength 1,064 nm) delivered through a quartz fibre optic with a diameter of 400 µm with diffuse light emission. Laser light is converted into heat in the target area with an ensuing coagulative necrosis, secondary degeneration and atrophy, and tumour shrinkage with minimal damage to surrounding structures. The dimension of the coagulative necrosis laser induced depends on laser power, laser irradiation time and the optical and thermal tissue characteristics (4).

Microwave Ablation

►Microwave ablation is an electromagnetic method of inducing tumour destruction by using devices with frequencies greater than or equal to 900 kHz (5). In microwave ablation a microwave generator and needle electrodes are employed. The microwave energy is transmitted *via* a flexible cable and delivered by the electrodes. Microwaves cause vibration and rotation of molecular dipoles, predominantly water, resulting in a thermal coagulation of tissues.

Cryoablation

►Cryotherapy is defined as local tumour destruction *in situ* by freezing. The resulting freeze process causes irreversible cellular damage and tissue necrosis is obtained (3–5). Different methods, including repeated freeze cycles, temporary hepatic inflow occlusion and multi-needle probe systems, have been developed to increase the size of cryolesion.

Transcatheter Arterial Embolization and Chemoembolization

►Transcatheter arterial embolization (TAE) consists in a temporary or permanent peripheral occlusion of the hepatic artery. It requires catheterization of the segmental hepatic artery supplying the liver tumour following by intra-arterial injection of embolic materials. ►Transcatheter arterial chemoembolization (TACE) combines peripheral occlusion and local deposition of chemotherapeutic agents, consisting in intra-hepatic arterial injection of chemotherapeutic agents followed by embolic agents. The anti-tumour effect depends on the synergy between the actions of chemotherapy and ischemia, since the occlusion of the tumour arterial supply advantageously follows the controlled infusion of the chemotherapeutic drug. TACE can be performed by using several different techniques, including conventional and segmental catheterism. Conventional TACE is performed by injecting an anticancer-in-oil emulsion followed by embolic material at the level of the proper hepatic artery while in segmental and subsegmental technique a micro-catheter is inserted into the more distal branches of the hepatic artery, and the drug as well as the embolic material are injected solely in the feeding artery of the tumour. This allows a more strong anticancer effect, sparing at the same time the non-cancerous liver parenchyma (3). A large variety of chemotherapeutic drugs and embolic agents have been used.

Clinical Applications

Radiological interventional procedures have been employed in the treatment of either primary or secondary unresectable hepatic malignancies. A robust evidence concerning the clinical value of these techniques is currently available for the use of ethanol injection, radiofrequency ablation and TACE. An appropriate use of each treatment technique can only be done when the therapeutic strategy is decided by a multidisciplinary team and is tailored to the individual patient and to the features of the disease (2, 3).

Ethanol Injection

PEI is cheap, easy to perform, repeatable and has been the most widely used ablation technique in HCC patients. It is a well-tolerated treatment, with a high anti-tumoural efficacy in small solitary, nodular-type HCC (3 cm or less). Since HCC nodules have a soft consistency and are surrounded by a firm cirrhotic liver, injected ethanol diffuses within tumour tissue easily and selectively, leading to complete tumour necrosis in a great number of small lesions (2). The injected ethanol does not always accomplish complete necrosis in HCC nodules because of its inhomogeneous distribution within the lesion, especially in the presence of intra-tumoural septa, and repeated treatment session are usually required. In hepatic metastases the hard consistency of the neoplastic tissue impairs an adequate diffusion of ethanol resulting in a poor tumour control.

Radiofrequency Ablation

RF ablation is an effective treatment both in primary and metastatic liver tumour and represents the most widely used method for percutaneous thermal ablation. RF ablation seems to be more effective than PEI in the treatment of small HCC. Particularly, RF can achieve a more effective local tumour control than PEI with fewer treatment sessions. However, despite RF may provide marginal anti-tumour benefits also in lesions larger than 3 cm in diameter, where PEI is unable to disrupt the intra-tumoural septa, the treatment of large HCC is still problematic (2). RF is also effective in the treatment of hepatic metastases and to date it represents a valuable option in unresectable, solitary and small hepatic metastases arising from colorectal adenocarcinoma (3, 4). Although more invasive than PEI, RF ablation is considered to be safe, with a relatively low complication rate. Particularly, RF treatment of lesion adjacent to the gallbladder or to the hepatic hilum as well as of lesions located along the surface of the liver is associated with a higher risk of complications.

Transcatheter Arterial Chemoembolization

TACE may be an effective method of controlling hepatic disease in many patients with liver-dominant neoplasms, such as HCC, colorectal metastases and neuroendocrine tumours (3). Particularly, TACE remains a valuable approach for HCCs in the intermediate stage.

Moreover, TACE can also be used as an adjuvant to other forms of therapy and, since the absence of tumour seeding risk, it represents the first therapeutic option in HCC patients waiting for liver transplantation.

TACE has also been proved to be effective in the treatment of hepatic metastases arising from neuroendocrine tumours and colorectal cancer.

Interventional Procedures

Procedures which treat disease states by open surgery or minimally invasive methods.

▶Aneurysm, Aortic and Thoracic

Intervertebral Disk Degeneration

Degenerative changes in the intervertebral disk usually begin with dehydration of the nucleus pulposus and annular tears. Dehydration is easily diagnosed on sagittal T2-weighted MR images as decreased signal of the disc. This can be accompanied by narrowing the intervertebral space due to the decreased height of the intervertebral disk, which may be seen on plain films, sagittal reformatted CT images and sagittal T2-weighted MR images. Other features of disk degeneration are vacuum phenomenon (the presence of the gas in the disk due to the production of the nitrogen during the degenerative process) and calcifications; both are excellently visible on CT examination, may be also seen on plain films and MR gradient-echo images. Degeneration of the intervertebral disk is often associated with disk bulging and may lead to disk herniation. On the other hand it is almost always combined with degenerative changes of the adjacent vertebral endplates and very often-with degeneration of the other structures of the disco-somatic unit.

▶Fetal Imaging

Intravascular Contrast Media

▶Contrast Media, MRI, Blood Pool Agents

Intravenous Urography

Recently nonionic contrast agents are administered intravenously, which are excreted by the kidney into the renal pelvis, ureters, bladder, and urethra (at miction). IVU is useful for the diagnosis of obstruction, trauma, tumors, congenital malformation, and infection. It can assess kidney function, intra- and extraluminal pathology, and differentiate stones from other abdominal calcifications. It can differentiate nonmalignant from malignant causes of obstruction, haematuria, and pain. Radio-opaque calculi projecting inside the collecting system, independent of the patient's position, can be less, equal or more opaque as surrounding contrast, while radiolucent calculi present as a filling defect. IVU confirms the diagnosis of acute stone obstruction also if KUB is inconclusive by assessing secondary signs of obstructing calculi: delayed excretion, persisting nephrographic effect, extravasations in spontaneous forniceal rupture, mild and local dilatation. After obtaining a KUB, 20 min post-contrast films are proposed in obstruction. In carefully conducted IVU, stones or other pathology can be assessed within the time of examination in the majority of cases using solely four images. The application of prone or slightly oblique standing projections, when necessary to opacify the collecting system to the level of obstruction, under fluoroscopic control, reduces the examination time and number of films. Rarely delayed films are required.

Iron Overload

Iron overload can be subdivided into two types: parenchymal cell iron deposition in hemochromatosis, cirrhosis, intravascular hemolysis, and iron deposition in cell of the reticulo-endothelial system, also called hemosiderosis, which is seen most commonly after multiple transfusions or in diseases with extravascular hemolysis. Iron deposition in hepatocytes causes cellular damage, while iron deposition in reticulo-endothelial cells (Kupffer cells in the liver) does not produce a significant organ dysfunction.

▶Diffuse Infiltrative Diseases, Hepatic
▶Hemochromatosis, Skeletal

Ischemia

In ischemia, oxygen deprivation is accompanied by an inadequate removal of metabolites due to reduced perfusion. During the ischemic condition, an imbalance occurs between oxygen supply and demand, which may manifest as anginal discomfort, deviation of the ST segment on electrocardiography, or impairment of the regional or global left ventricular function.

Synonyms

Acute upper extremity ischemia

Definition

Acute arterial insufficiency of the upper extremity

Pathology

Embolization is the most common cause of acute upper-limb ischemia. Embolization of the upper-limb arterial bed represents 15–32% of all peripheral emboli (3). The heart is the source of emboli in 90% of the cases. Other sources of emboli are shown in Table 1. The brachial artery is more frequently embolized (60%), followed by the axillary artery (23%), the subclavian artery (12%), and the forearm and digital arteries (5%). Iatrogenic trauma to the upper extremity arteries occurs during arterial cannulation for angiography or monitoring. Thrombosis of the brachial artery is common after arteriotomy for cardiac catherization (0.3–28%). Percutaneous brachial artery catheterization is more often complicated with local complications compared to femoral catheterization. Because of the collateral supply, many patients remain asymptomatic. Nevertheless immediate surgical intervention with thrombectomy is recommended because many initially asymptomatic patients develop symptoms of ischemia later. Axillary artery thrombosis complicates transaxillary arteriography in 0.8% of the patients. Immediate thrombectomy is required. Radial artery thrombosis occurs in 40% of the patients undergoing radial artery cannulation for monitoring, but ischemic symptoms develop in only 0.5%. Other iatrogenic injuries are encountered during blind placement of central venous catheters.

Non-iatrogenic arterial trauma of upper extremities is not rare. Of all arterial injuries in civilian experience, the axillary artery is injured in 5–9%, the brachial artery in 30%, and the forearm arteries in 7–20%. The causative agents are missiles or sharp objects. Other mechanisms include stretch injuries from falls or those occurring during shoulder dislocation. Brachial artery injury is a complication of fractures and dislocations of the elbow.

Clinical presentation: The presentation is similar to that of the lower extremity acute ischemia with pulseness, palor, pain, paresthesias, and paralysis. Usually it involves the hand and the fingers. Mild symptoms are not rare with the patient complaining of only a cold hand (1). The clinical picture of embolization maybe dramatic or symptoms may develop over the course of several hours. Physical examination is essential to access the level of obstruction.

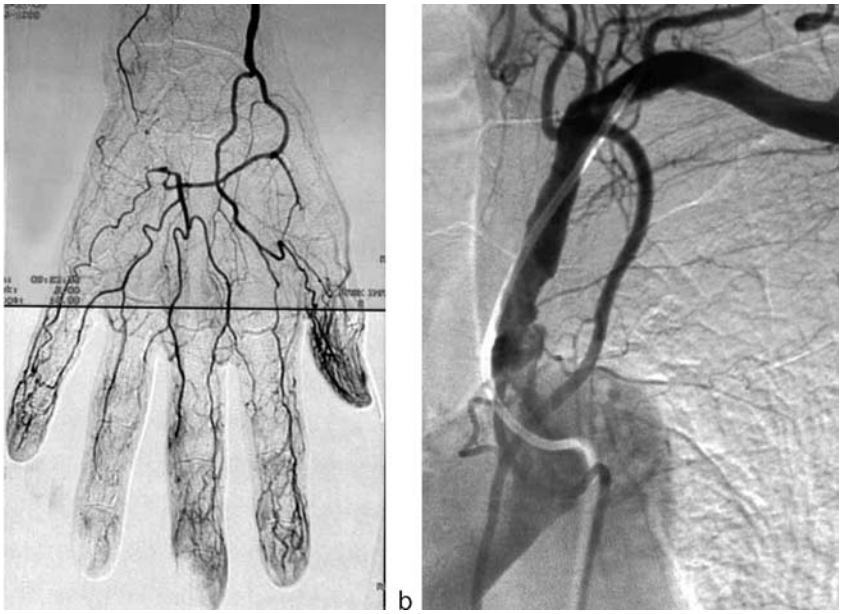
5. Aortic dissection



a b

Ischemia, Brachial. Figure 1 (a) Hand DSA in a patient with acute onset of left-hand ischemia depicts atherosclerotic disease of the hand arteries, absence of the ulnar artery and the deep palmar arch, and filling defects of the digital arteries suggestive of peripheral embolization. (b) Selective DSA of the left subclavian artery depicts ulcerated occlusive lesion of the left subclavian artery.

Imaging and Diagnosis

If embolization is suspected, color Doppler sonography or other noninvasive imaging modalities can evaluate large arteries, but may fail to provide detailed information on the hand arterial pathology. Angiography is recommended to rule out proximal arterial embolic source. Imaging from the arch to the digits should be performed. The proximal arteries should be evaluated for aneurysm containing thrombus or atherosclerotic lesions. With digital embolization, luminal defects are depicted in the involved vessels (Fig. 1). In non-iatrogenic trauma the diagnosis is obvious in the presence of active arterial hemorrhage, expanding hematoma, ischemia, or absence of pulses. Sometimes the patient has to go immediately to surgery. Imaging is mandatory to rule out subclinical vascular injury. Angiography is the recommended imaging modality as it can be used in the same session for interventional treatment. Findings include spasm, intimal flaps, thrombosis, laceration, frank exsanguination, and pseudoaneurysm.

Interventional treatment

Surgical exploration with thrombo-embolectomy is the treatment of choice for acute ischemia of the upper limb. Intra-arterial thrombolysis has promising results. When the source of emboli is a proximal ulcerated plaque, stent placement can be used as an alternative to surgical reconstruction. Following arterial trauma, extravasation or pseudoaneurysms can be treated by embolization.

Synonyms

Acute arterial occlusion; Acute ischemic limb

Definition

Acute leg ischemia is mainly a result of embolic disease either from the heart or from ulcerating atherosclerotic lesions that may induce thrombus formation and consecutive thrombus induction. It may also be of iatrogenic origin due to invasive studies or percutaneous interventions such as vascular recanalization.

True thrombosis may occur in the case of a thrombophilic state or due to physical rest such as long-distance flights or long car driving. If thrombosis occurs in an artery that allows sufficient collateral flow onto a preexisting lesion, a sufficient collateralization, symptoms may be less severe. Thus, diagnosis may be made late leading to the state of subacute or chronic thrombosis.

Pathology/Histopathology

Acute ischemia of a peripheral limb is caused by acute embolic embolization of clot material of mainly cardiac origin, acute thrombosis from preexisting arterial lesions, or, rarely, coagulation problems.

Clinical Presentation

In general, the duration of symptoms of up to 4 weeks is classified as acute, between 1 and 3 months as subacute, and longer than 3 months as chronic thrombosis of the artery. This classification is of practical importance since treatment – both surgically and percutaneously – is influenced by the age of the occlusion. A simple mechanical removal of the embolus/thrombus becomes more difficult the longer an occlusion exists.

Clinically, acute ischemia is classified into four different states: stage I, with mild symptoms and no tissue or nervous deficits representing acute limb threatening; stage IIa, with minimal sensory loss, no muscle weakness but inaudible arterial Doppler signals; stage IIb, with extended sensory loss, mild to moderate muscle weakness, and inaudible arterial signal; and stage III, with profound anesthesia of the limb, muscular paralysis, and inaudible venous and arterial signals (1).

Clinical examination, pulse status, and duplex sonography are valuable tools for making the diagnosis of an acute leg ischemia. The patient's history is important for analyzing potential risk factors such as arrhythmias or heart valve disease.

Imaging

Duplex sonography and angiography are the principle imaging modalities that are used to make the diagnosis. Magnetic resonance (MR) angiography and computed tomography (CT) angiography may play a role in the future, but the painful state and the acuteness of the event lead to agitation of the patient, preventing lengthy imaging protocols which require full cooperation.

Angiographic imaging is frequently required to analyze the extent and the location of thrombotic occlusions (Fig. 1a–f). An ipsilateral antegrade approach is recommended if the ipsilateral femoral pulse is present and normal. An antegrade puncture is preferred so as to continue with a percutaneous intervention if possible. A contralateral retrograde approach is performed if the ipsilateral femoral pulse is abnormal. The diagnostic catheter is introduced into the iliac artery *via* a cross-over maneuver if the proximal iliac artery is patent. If involvement of the common or profound femoral arteries is suspected, sonography or duplex sonography may be added as a simple diagnostic tool.

Hand injection of dye and a 4 to 5 F access are usually sufficient to establish the diagnosis.

To date, other imaging modalities such as MR angiography or CT angiography do not play a major role in the diagnosis of acute ischemia as the potential combination of the diagnostic and interventional procedure in one step favors direct transarterial imaging.

In the case of renal insufficiency or contrast media intolerance, carbon dioxide or MR contrast agents may be used as alternative contrast media for catheter-directed angiography. Carbon dioxide is, however, frequently very painful in acute ischemic limbs limiting the imaging quality by movement artifacts.

Nuclear Medicine

Nuclear medicine plays no particular role in the diagnosis of acute ischemia.

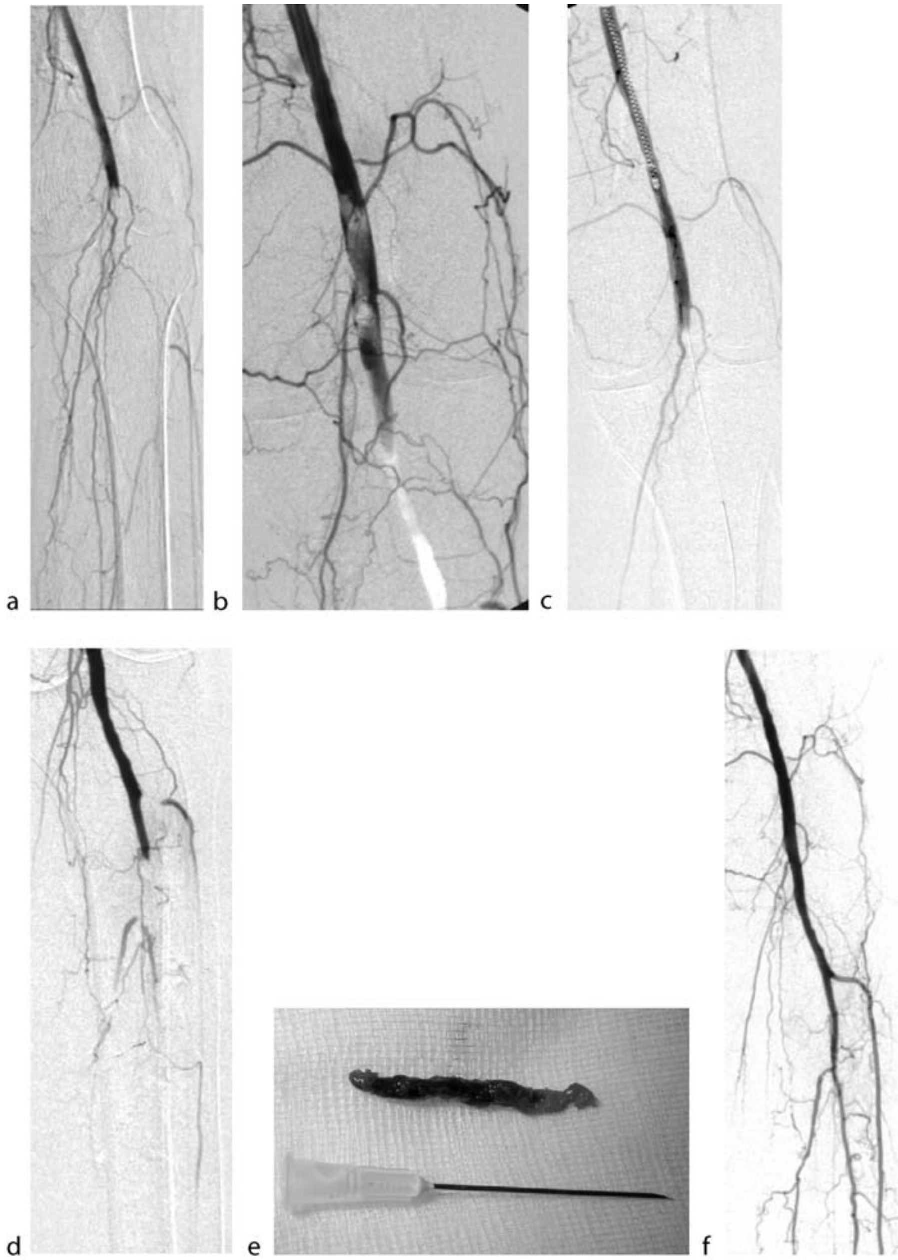
Diagnosis

Diagnosis based on the clinical and angiographic findings is usually easy to make. It is more difficult to detect the underlying source of acute occlusion, the extent of the thrombosed arterial segment, and the best appropriate therapeutic approach.

Interventional Radiological Treatment

According to the TASC document (1), treatment of acute ischemia depends on the clinical stage. In stage I and IIa, surgical treatment with open embolectomy or thrombectomy by use of Fogarty embolectomy balloons and its derivatives as well as thrombolysis by use of thrombolytic agents including rtPA and urokinase are accepted concepts. In stage IIb, Fogarty embolectomy is the treatment of choice, while thrombolysis is not recommended due to potential complications that may result from bleeding into revascularized tissue, resulting in a compartment syndrome. In early stage III, surgical thrombectomy may be tried; however, in advanced stage III cases, only amputation remains the principal option.

As usual, a correct diagnosis in time and rapid onset of treatment are mandatory for limb salvage and they need to be implemented in each center dealing with acute disease. It is, however, true that acute ischemic states are frequently overseen or neglected also by the patient. The



Ischemia, Brachial. Figure 1a–f Acute ischemia of the lower left leg. (a) Acute embolic occlusion of the poplietal artery at the level of the joint. (b) Aspiration fails to clear the popliteal artery but demasks a large thrombus. (c/d) After rotational thrombectomy by a Rotarex catheter, the popliteal lumen has ben reopened but there is still occulsion of the distal popliteal artery and the trifurcation. (e) Aspiration removes a larger clot from the distal popliteal artery. Trifurcation is now reperfused.

time factor is crucial for the success of a surgical approach as well as for percutaneous interventions.

To achieve a successful and enduring result, at least one lower limb artery or a major collateral has to be reopened down to the foot in order to establish a sufficient outflow situation and to avoid early rethrombosis. Follow-up medication is an important part of the treatment concept.

Thrombolysis has some drawbacks that prevent its widespread use in subacute and acute thrombosis and embolic disease. It is relatively time consuming and a rapid revascularization is rare. In particular, in advanced stages a treatment duration of up to 24 h may worsen the clinical situation with an unpredictable outcome. Local bleeding may occur at the entry site, complicating an adjunctive surgical approach – if required. Reduced clotting abilities after thrombolysis also interfere with surgery. Furthermore, the subset of patients with acute ischemia are frequently of older age and their comorbidities often contraindicate the use of thrombolytic agents.

Two different trials – the STILE and TOPAS trials – have advocated thrombolysis to be equivalent to surgery. The TOPAS trial found a limb salvage rate of 72% after 6 months for the urokinase group vs. 75% in the surgical group. The STILE trial found a similar outcome at 30 days for both treatments. Earnshaw et al., however, found that patients with a neurosensory deficit and acute ischemia had a significantly lower limb salvage rate (31%) compared to those treated by surgery (59%) (2). Berridge et al., performing an analysis of randomized data available on thrombolysis vs. surgery in acute ischemia, found no significant difference with regard to limb salvage for up to 1 year and with regard to overall survival, but found a significant increase in stroke rate, major hemorrhage, and distal embolization at 30 days in patients undergoing initial thrombolysis (Berridge).

Fogarty embolectomy *via* a femoral or popliteal approach is a quick method in the case of circumscribed thrombi, but it may become difficult in concomitant atherosclerotic stenoses or extensive thromboses including the lower limb arteries.

In older thrombi, wall adhesion of the occluding clots can complicate removal of clots by use of Fogarty embolectomy balloons and sometimes additional instruments are required.

Instruments for Mechanical Thrombectomy

Mechanical removal of thrombosis *via* a percutaneous approach is an old dream of interventional radiologists who – like surgeons – prefer a quick, elegant, and effective solution to the problem instead of going through lengthy procedures, which thrombolysis certainly can turn out to be. Many different mechanical devices were developed with enthusiasm, introduced into clinical practice, tested as insufficient and have disappeared from the market. The Kensey catheter is an early example of this not-too-small family of disappointed hopes.

In the meantime, however, some valid instruments and techniques are available which allow successful and relatively safe and timely removal of clot material.

They include:

- Manual aspiration
- Hydrodynamic thrombectomy
- Rotational thrombectomy
- Atherectomy
- Stent placement

In addition, a number of other devices or treatment options are under development and evaluation and their number is still growing.

Synonyms

Acute mesenteric arterial embolus (AMAE); Acute mesenteric arterial thrombosis (AMAT); Acute mesenteric infarction; Acute mesenteric ischemia; Acute mesenteric occlusive disease; Acute mesenteric venous thrombosis; Mesenteric vascular occlusion; Nonocclusive mesenteric ischemia (NOMI); Occlusive mesenteric arterial ischemia (OMAI)

Definitions

Acute mesenteric ischemia is the acute interruption of blood flow to the small or large intestine. The word "ischemia" means decrease in oxygen supply. Mesenteric ischemia is a condition in which the mesenteric arteries do not deliver enough blood and oxygen to the small and large intestines. This makes it difficult for the intestines to digest food and can cause segments of the intestine to die. "Occlusion of the mesenteric vessels is apt to be regarded as one of those conditions of which the diagnosis is impossible, the prognosis hopeless, and the treatment almost useless" (1). Antonio Beniviene first described mesenteric ischemia in the fifteenth century. It was studied more intensively in the mid-nineteenth century after case reports by Virchow and others.

Pathology/Histopathology

In practice, acute mesenteric ischemia (AMI) is divided into four different primary clinical entities: (1) acute mesenteric arterial embolus (AMAE), (2) acute mesenteric arterial thrombosis (AMAT), (3) nonocclusive mesenteric ischemia (NOMI), and (4) mesenteric venous thrombosis (MVT). Occlusive mesenteric arterial ischemia (OMAI) includes both AMAE and AMAT.

Typically, the celiac artery trunk (CAT) supplies the foregut, hepatobiliary system, and spleen; the superior mesenteric artery (SMA) supplies the midgut (i.e., small intestine and proximal mid-colon); and the inferior mesenteric artery (IMA) supplies the hindgut (i.e., distal colon and rectum). However, multiple anatomic variants are observed. Venous drainage is through the superior mesenteric vein (SMV), which joins the portal vein.

AMI arises primarily from problems in the SMA circulation or its venous outflow. Collateral circulation from the CA and IMA may allow sufficient perfusion if flow in the SMA is reduced because of occlusion, low-flow state (NOMI), or venous occlusion. The inferior mesenteric artery is seldom the site of lodgment of an embolus. Only small emboli can enter this vessel because of its smaller lumen. When lodgment occurs, the embolus lodges at the site of division of the inferior mesenteric artery into the left colic, sigmoidal, and superior hemorrhoidal arteries. In such instances, collateral flow from the middle colic and middle hemorrhoidal arteries (through the vascular arcades of the inferior mesenteric artery distal to the embolus) may sustain the perfusion of the left colon (2).

Insufficient blood perfusion to the small bowel and colon may result from arterial occlusion by embolus or thrombosis (AMAE or AMAT), thrombosis of the venous system (MVT), or nonocclusive processes such as vasospasm or low cardiac output (NOMI). Embolic phenomena account for approximately 50% of all cases, arterial thrombosis for about 25%, NOMI for roughly 20%, and MVT for less than 10% (3). Hemorrhagic infarction is the common pathologic pathway, whether the occlusion is arterial or venous.

Embolic AMI is usually caused by an embolus of cardiac origin. Typical causes include mural thrombi after myocardial infarction, atrial thrombi associated with mitral stenosis and atrial fibrillation, vegetative endocarditis, mycotic aneurysm, and thrombi formed at the site of atheromatous plaques within the aorta or at the sites of vascular aortic prosthetic grafts interposed between the heart and the origin of the SMA. Most often, emboli lodge about 6–8 cm beyond the SMA origin, at a narrowing near the emergence of the middle colic artery.

Damage to the affected bowel portion may range from reversible ischemia to transmural infarction with necrosis and perforation.

The mucosal barrier becomes disrupted as the ischemia persists, and bacteria, toxins, and vasoactive substances are released into the systemic circulation. This can cause death from septic shock, cardiac failure, or multisystem organ failure before bowel necrosis actually occurs. As hypoxic damage worsens, the bowel wall becomes edematous and cyanotic. Fluid is released into the peritoneal cavity, explaining the serosanguinous fluid sometimes recovered by diagnostic peritoneal lavage. Bowel necrosis can occur in 8–12 h from the onset of symptoms.

Thrombotic AMI is a late complication of preexisting visceral atherosclerosis. Symptoms do not develop until two of the three arteries (usually the CA and SMA) are stenosed or completely blocked (4, 5).

Clinical Presentation

Symptoms are initially nonspecific, before evidence of peritonitis is found (6–8). Thus, diagnosis and treatment are often delayed until the disease is far advanced; the key to diagnosis lies in a high index of suspicion. Patients with advanced ischemia present with diffuse peritonitis, shock, and severe metabolic derangements. The diagnosis will become obvious at the time of surgery. Often these patients cannot be salvaged; the mortality is reported to be between 70 and 90%. While the prognosis is grave for patients in whom the diagnosis is delayed until bowel infarction has already occurred, patients who receive the appropriate treatment in a timely manner are much more likely to recover. In the early stage of ischemia the patient complains of severe abdominal pain (due to vasospasm) in the absence of peritoneal findings. This scenario has been described by clinicians as "pain out of proportion to the physical findings." Symptoms often found are: severe abdominal pain out of proportion to physical examination findings, pain initially of a visceral nature and poorly localized, nausea, vomiting, diarrhea, gastrointestinal bleeding may be present.

Imaging

A flow-chart for the diagnosis and treatment of patients at risk of AMI is given in Fig. 1(9).

- Plain abdominal films (abnormal in 20–60% of cases)

Findings on plain films of the abdomen are often normal in the presence of AMI. However, plain films are warranted to exclude identifiable causes of abdominal pain such as perforated viscus with free intraperitoneal air. Therefore, all patients should have an upright and supine plain film of the abdomen in order to rule out visceral perforation or bowel obstruction.

Positive findings are usually late and nonspecific (ileus, small bowel obstruction, edematous/thickened bowel walls, and paucity of gas in the intestines). More specific signs, such as pneumatosis intestinalis—i.e., submucosal gas, thumbprinting of bowel wall, and portal vein gas—are late findings.

- Computed tomography scan

Computed tomography (CT) scan helps to evaluate AMI and to exclude other causes of abdominal pain. CT angiography has a sensitivity of 71–96% and a specificity of 92–94% (10). Although still not considered the gold standard compared with classic angiography, CT angiography is noninvasive, readily available, and the preferred modality for MVT (90% sensitivity). Moreover, with recent multidetector CT scanners, accuracy is expected to be much higher, close to 100%.

CT scan may also show pneumatosis intestinalis, portal vein gas, bowel wall, and/or mesenteric edema, abnormal gas patterns, thumbprinting, streaking of mesentery, and solid organ infarction. Bowel wall edema is the most common finding on CT scan. Arterial occlusion may show nonenhancement of the vessels (Fig. 2). MVT usually shows a thrombus in the SMV or portal vein. Finally, intraluminal thrombus in involved vessel is well detected (11).

- Angiography

This was the gold standard for diagnosis and presurgical planning and is often an important part of treatment. To promptly diagnose patients with true AMI, a low threshold for obtaining early angiographs should be adopted for patients at risk. Sensitivity is reported to be 88% for AMI. Nowadays, multidetector CT is equal or even more adequate in presenting vascular anatomy and surrounding tissue, such as in the bowel.

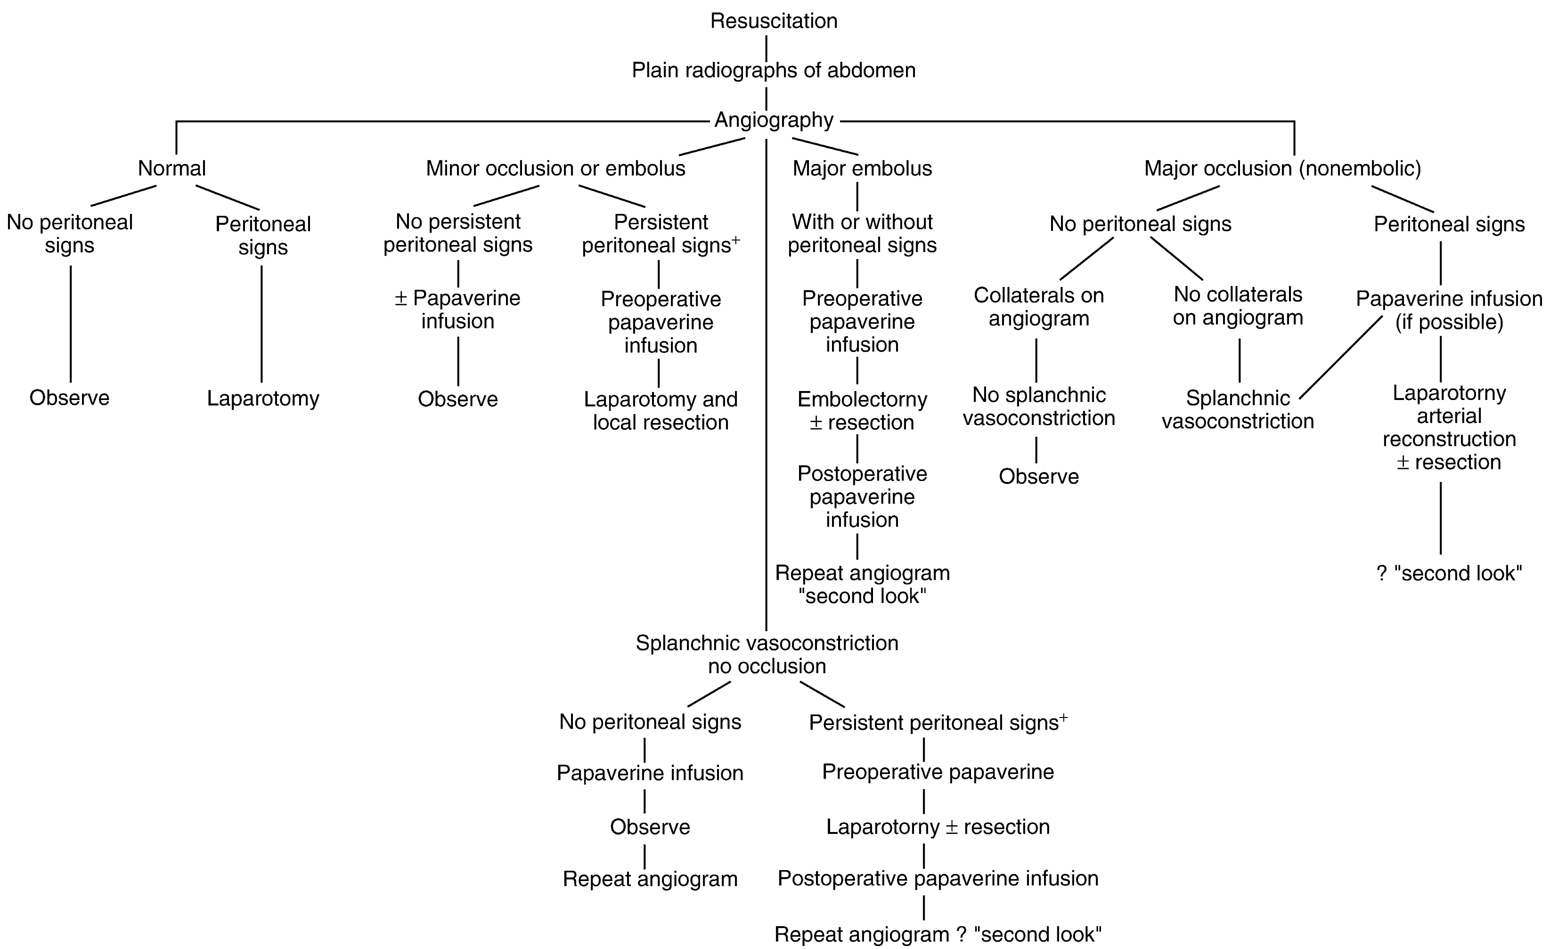
- Ultrasonography

Duplex sonography studies are highly specific (92–100%) but not as sensitive (70–89%) as angiography (12). The examination cannot detect clots beyond the proximal main vessels nor can it be used to diagnose NOMI. Ultrasound is considered a second-line study for AMI. It is often less useful in the presence of dilated fluid-filled loops of bowel.

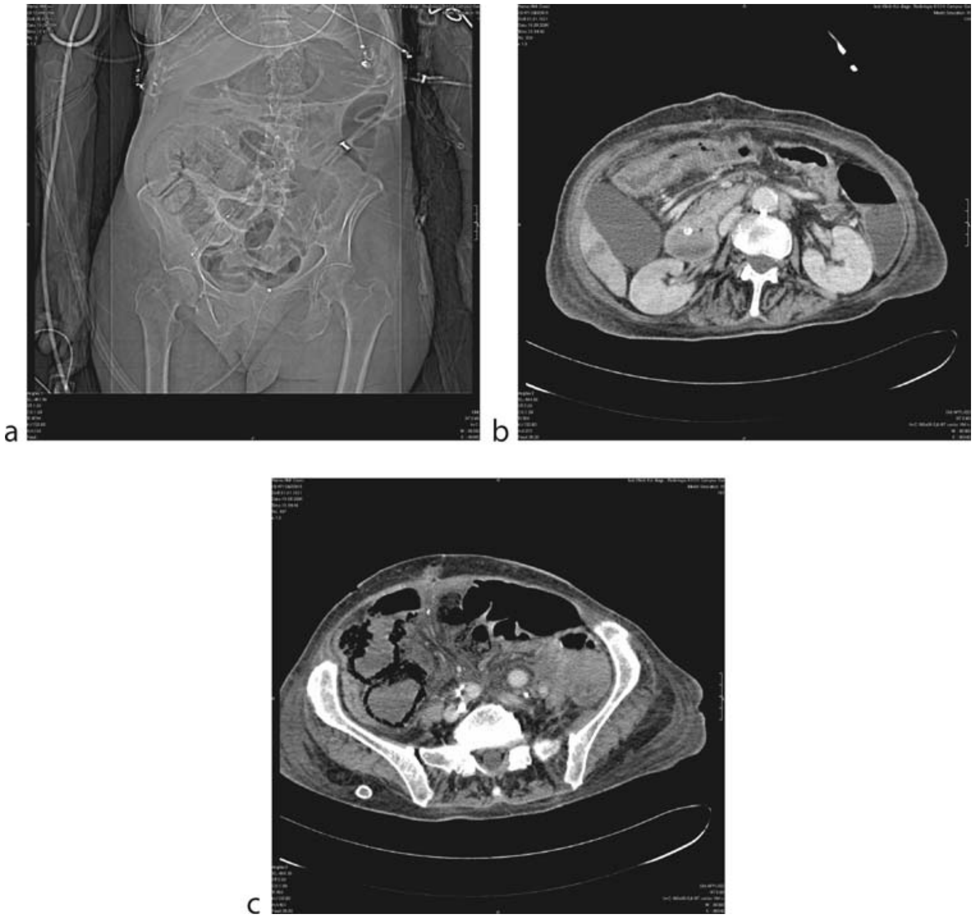
Some studies show that the usefulness of duplex scanning is similar to that of CT scanning if it is performed for MVT. It may show a thrombus or absent flow in the involved arteries or veins. Other possible findings include portal vein gas, biliary disease, free peritoneal fluid, thickened bowel wall, and intramural gas.

- Magnetic resonance imaging/magnetic resonance angiography

Magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA) provide findings similar to CT scan in AMI. Sensitivity of MRA is 100% and specificity is 91%. MRA is particularly effective for evaluating MVT; however, in emergency situations MR should not be the first choice.



Ischemia, Mesenteric, Acute. Figure 1 **A flow-chart for the diagnosis and treatment of patients at risk of AMI (modified from Oldenburg WA, Lau LL, Rodenberg TJ et al (2004) Acute mesenteric ischemia—A clinical review. Arch Int Med 164:1054–1062.**



Ischemia, Mesenteric, Acute. Figure 2 CT scan of a patient suffering from AMI. Celiac trunk is severely stenosed and SMA is partially occluded by calcified plaque material. On CT scout view, pneumatosis intestinalis is visible (a). The bowel is edematous and thickened (b), clear signs of pneumatosis intestinalis are often seen in advanced acute mesenteric ischemia (AMI) with gangrenous bowel proven by surgery (c).

Nuclear Medicine

It is not of importance for the diagnosis of AMI.

Diagnosis

Clinical sequelae in combination with typical imaging findings make the diagnosis clear.

Interventional Radiological Treatment

- Angiographically infused papaverine (Vasodilator therapy)

Catheter-directed papaverine infusion in the affected vessel following angiography is useful for all arterial forms of AMI. It relieves reactive vasospasm in occluded arterial vessels and is the only treatment for NOMI other than resection of gangrenous bowel.

After angiography, an infusion of 30 mg/h should be started, and the dose should be adjusted up to 60 mg/h for a clinical response. This is continued for at least 24 h for a maximum of 5 days. If the catheter slips into the aorta, significant hypotension can occur (13). Papaverine is incompatible with heparin (crystallization)

- Angiographically infused thrombolytics

Thrombolytics infused through the angiogram catheter can be a life-saving therapy for selected patients with embolic AMI (14).

Bleeding is the main complication. Thrombolytic administration is risky and should only be undertaken if peritonitis or other signs of bowel necrosis are absent. It must be started within 8 h of symptom onset. If symptoms do not improve within 4 h or if peritonitis develops, the perfusion should be stopped and surgery should be performed.

- Angioplasty after thrombolysis

A very select group of patients who have atherosclerotic plaques at the origin of the SMA after thrombolysis are eligible for angioplasty. Angioplasty can be technically difficult because of the anatomy of the SMA. The use of low-profile Monorail devices (0.014 or 0.0018 in. compatible) might enhance technical success rates. Restenosis rates are 20–50% (15).

- Heparin for MVT

Heparin anticoagulation is the main treatment for MVT. If no signs of bowel necrosis exist, the patient may not even need an operation. Heparin may increase the chance of bleeding complications. An avenue of study for possible future clinical trials may be the use of enoxaparin (Lovenox) or other low-molecular-weight heparins as a potential substitute for heparin in the treatment of MVT.

Heparin should be administered as a bolus of 80 U/kg, not to exceed 5,000 U, and then as an infusion at 18 U/kg/h until full conversion to oral warfarin. Appropriate monitoring of anticoagulation using activated partial thromboplastin time (aPTT) is mandatory.

Surgery

Thrombectomy/embolectomy, arterial bypass, and resection of necrotic bowel are typical procedures (16–18).

- Complications: Sepsis/septic shock, multiple system organ failure, death
- Mortality: 70–90% overall; from arterial embolism: 60–80%, from arterial thrombosis: 70–100%, from nonocclusive mesenteric ischemia: 40%, from mesenteric venous thrombosis: 25–30%

Ischemia, Mesenteric, Chronic

Stefan Müller-Hülsbeck
Department of Radiology, University Hospital Schleswig-Holstein, Kiel, Germany
muehue@rad.uni-kiel.de

Definitions

Chronic mesenteric ischemia (CMI), first described as “abdominal angina” by Councilman in 1894 (1), Goodman in 1918 (2) and as entity by Dunphy in 1936 (3), is a rare disorder that is often diagnosed late. CMI is a condition caused by narrowing of the arteries to the intestines. There are three main arteries to the intestines and, in general, two of them must be narrowed to cause symptoms.

Pathology/Histopathology

Because of the extensive collateral arterial network of the gut, chronic mesenteric ischemia is relatively uncommon. The incidence of CMI is estimated to be at 1 in 100,000 (4), although autopsy studies of an unselected population demonstrated mesenteric atherosclerosis in 35% to 70% of the cases (5). It is usually related to extensive mesenteric atherosclerosis. In more than 95% of patients, the cause of mesenteric ischemia is diffuse atherosclerotic disease, which decreases the flow of blood to the bowel. Symptoms of CMI arise when transient episodes of inadequate, usually postprandial blood flow in the mesenteric arteries are not able to assuage the physiological demand in the intestines. Stenoses in visceral arteries commonly are caused by atheroma, mainly in the proximal segments of the vessels. Fatty infiltration in the arterial wall results in stenosis or finally occlusion of one or more visceral arteries. As the atherosclerotic disease progresses, symptoms worsen. The number of involved arteries before symptoms occur is still debated. So, at least two vessels of the celiac trunk, the superior mesenteric artery and the inferior mesenteric artery, should be stenosed or occluded for the diagnosis of CMI with abdominal angina (6, 7). The presence of a stenosis in a single visceral vessel collateral flow may allow patients to be asymptomatic. Usually, all three major mesenteric arteries are occluded or narrowed.

The pathophysiologic mechanism by which ischemia produces pain is still not completely understood.

Chronic mesenteric ischemia is a rare diagnosis. No reports of the actual incidence have been published. Moawad searched 20 years of literature and found only 330 cases. Because many cases are not reported, the true prevalence could be much higher. Autopsy studies support this theory, with findings of stenosis in up to 30% of selected patients with a history of abdominal pain.

Clinical Presentation

Patients classically present with chronic postprandial pain, nausea, diarrhea and obvious weight loss, which often results in "food fear" in patients. CMI is caused by intermitting transient episodes of inadequate intestinal blood supply, usually concurring with the increased metabolic demand at digestion (7). As no sensitive and specific tests are available to diagnose CMI, accurate acquisition of medical history and exclusion of other conditioning gastrointestinal causes are essential (8). Patients with the diagnose of CMI are usually over 60-year-old. However, most patients do not present with "classic" symptomatology and are frequently misdiagnosed for other diseases. In some patients, if untreated, the narrowing in the arteries leads to clotting causing severe abdominal pain and death.

Imaging

- Ultrasound

Ultrasonography (US) uses sound waves to generate images of internal organs on a monitor. A special ultrasound (Doppler) of the celiac, superior mesenteric and inferior mesenteric arteries can help your doctor determine if there is decreased blood flow, which indicates a likelihood of chronic mesenteric ischemia.

Mesenteric duplex ultrasonography is a non-invasive method of analyzing flow through the vessels. Unfortunately, intraperitoneal gas, respiratory movements, obesity and any previous abdominal surgeries limit results.

Besides duplex sonography as an accurate non-invasive technique of detecting significant stenoses in mesenteric vessels (9), computed tomography angiography and magnetic resonance angiography have been established for pretreatment evaluation of the celiac artery and superior mesenteric artery. With duplex sonography as the easiest to perform screening and follow-up tool, intraarterial digital subtraction angiography (DSA) remains the most precise technique for the evaluation of the degree of the stenosis.

Based on currently available literature, MRI and computerized tomography (CT) should be performed as second step for diagnostic imaging; if anything remains open, DSA should be performed in order to start interventional treatment during the same session.

We currently perform multi-detector CT with 3D reformatting in all patients with suspected acute or chronic mesenteric ischemia. In our experience, CT has eliminated the need for additional imaging studies such as Doppler US or diagnostic angiography. However, further investigation is necessary to determine the scope of utility of multi-detector row CT in this clinical setting (10).

Nuclear Medicine

Not of importance for the diagnosis of AMI.

Diagnosis

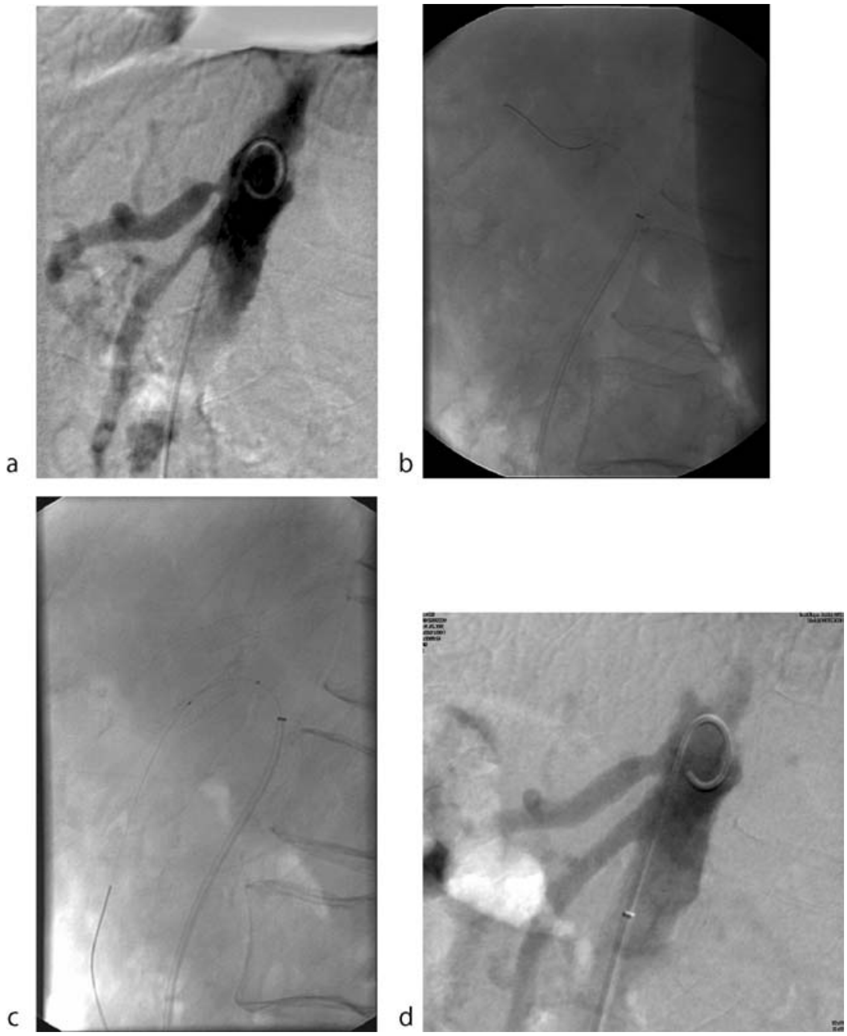
Clinical sequelae in combination with typical imaging findings makes the diagnosis clearer.

Interventional Radiological Treatment

Until the 1990s, open surgery was considered the treatment of choice; percutaneous transluminal angioplasty (PTA) was reserved for patients for whom surgery carried a high risk. Many surgical procedures have been described with various results. The blockage in the involved arteries is removed, and the arteries reconnected to the aorta. Alternatively, a bypass around the blockage, usually with a prosthetic plastic tube graft, is performed. Endarterectomy and aortovisceral bypass have been employed. Until today, surgical revascularisation has been the method of choice for treatment of patients with CMI (7). Surgical procedures such as endarterectomy and aortoceliac and aortomesenteric bypass grafting are associated with relatively high peri-operative major complications (15–33%) and mortality (0–17%) (11–13). Thus, there has been a demand for a less invasive technique. As an alternative method, PTA and stenting was established in the early 1980s. However, only few studies have been performed since then to prove the safety and durability of percutaneous angioplasty and stenting with results for periprocedural major complications of up to 25% and mortality of up to 13%, most of them with inhomogeneous collectives of both PTA and stenting in one study (6, 11–19).

More recently, balloon angioplasty has appeared to provide good results with a less invasive approach. In order to obtain good long-term results with acceptable recurrence rate, we gather minimal invasive PTA, and stent procedures should only be performed by experienced physicians.

Therefore, we recommend after diagnosing CMI to plan interdisciplinarily (gastroenterologist, surgeon and interventionalist/radiologist) the optimal therapeutic approach towards the management of the stenosed arteries for each affected individual. However, there are no definite recommendations for the planning of the right procedure, since only descriptive studies, blind experience and case reports and no type I data (i.e., randomized trials) or type II data (i.e., nonrandomized controlled trials) have been available so far (7, 12). In general, open vascular surgery was the method of choice for patients with CMI, whereas



Ischemia, Mesenteric, Chronic. Figure 1 (a) DSA presenting a severe stenosis involving the origin of the celiac artery and the superior mesenteric artery. (b) In order to treat symptoms of CMI in the 62-year-old patient stent placement was performed in the celiac artery (6 × 18 mm) and the superior mesenteric artery (5 × 18 mm) during the same approach, so-called rapid-exchange/monorail devices were used. (c) The fluoroscopic view shows unfolded stents in a proper position. (d) The final angiography reveals patent arteries, with a remaining light luminal narrowing of the celiac artery.

endovascular therapy with or without stent implacement was reserved for patients with multi-morbidity and at high operative risk. For surgical revascularization, excellent long-term patency ranges from 70 to 93% (mean 84%), but an overall perioperative morbidity rate of 29% and mortality rate of 7% gives rise to concern (12, 18). Endovascular therapy with a mean primary patency rate of 76%, at 15 months, a peri-inervent ional complication rate close to 0%, an initial technical success rate of 96% and a mean mortality rate of 4% seems to be effective as well (20; Fig. 1). Despite visceral PTA being a safe and effective alternative to open surgery, it still seems to offer inferior patency and durability rates (15). However, due to the absence of comparative trials of open revascularization versus endovascular therapy and due to different evaluation criteria with a tendency of referring multimorbid patients to endovascular therapy, it is undoubtedly problematic to easily compare those numbers.

It has to be ruled out that in case of median arcuate ligament syndrome, it should be treated in symptomatic cases by surgery (21). It is discussed that it arises from celiac plexus compression and consequently is not an indication for PTA or stent placement (12, 18, 19).

Unfortunately, there is no specific diagnostic test for CMI. A high index of suspicion should be maintained in patients with post-prandial pain and weight loss. If imaging presents in these patients focal stenoses, the very promising and safe technique of PTA and stent placement should be performed immediately as the initial treatment for patients with CMI.

Short Description

Ischemic heart disease (IHD) remains the leading cause of death in the Western world, and early detection of disease allows optimal therapeutic management. Consequently, substantial effort has been invested to develop techniques that can detect coronary artery disease (CAD).

Noninvasive coronary artery imaging challenges any diagnostic modality because the coronary arteries are small and tortuous, and they course in multiple planes around the heart, while cardiac contraction and respiration cause motion artifacts. Therefore, noninvasive coronary imaging requires high spatial and temporal resolution. In addition, anatomic coverage should be fast to allow scanning within one breath-hold. One of the most recent noninvasive coronary imaging modalities is multislice spiral computed tomography (CT) or multidetector row helical CT. The literature on four-slice CT and 16-slice CT as applied to the imaging of coronary arteries shows a progressive improvement in detecting coronary stenosis (1). The results of 64-slice-generation scanners show further improvement in diagnostic performance (2). CT of the coronary arteries promises to be the diagnostic modality in the clinical field for assessing the coronary lumen and wall. Preliminary experiences also show potential in assessing left ventricular function, volumes, and delayed-enhancement viability (3, 4).

Characteristics

CT Criteria for Eligibility

Coronary CT angiography (CTA) can be performed with reliable results in a selected patient population with sinus rhythm, heart rate below 70 bpm, and the ability to hold their breath for 20 s (16-slice CT technology) or for less than 12 s (64-slice CT technology). Patients with contraindications to intravenous iodinated contrast material should be excluded or treated accordingly. A high-calcium burden impairs the diagnostic accuracy and, in particular, reduces specificity, but sensitivity generally remains preserved.

CT Technology

Coronary CTA requires retrospective electrocardiographic gating of the image reconstruction. This allows a flexible approach to image reconstruction in virtually any phase of the cardiac cycle. Optimization of the reconstruction windows allows the generation of datasets with the least residual motion artifacts.

A high-temporal resolution of the CT scanner has been achieved by combining a fast gantry rotation speed (down to 330 ms for 64-slice CT) that provides a temporal resolution of half the rotation time (i.e., down to 165 ms for 64-slice CT). For angiographic contrast enhancement, a bolus of 80–100 mL contrast material with high-iodine concentration should be administered through an antecubital vein with a flow rate of 4–5 mL/s. The use of a saline bolus chaser administered after the main bolus of contrast material improves the vascular attenuation and allows a reduction in contrast volume.

The heart rate should be reduced below 70 bpm in order to preserve a diagnostic image quality. For this purpose, β-blockers can be administered before the scan (for instance, 100 mg of metoprolol 1 h in advance).

Routine reconstruction should be performed in the end-diastolic and end-systolic phases. Images should be reconstructed with thin slices and 50% overlap between the slices.

The reconstructed contiguous axial slices are stacked in a volume to generate a three-dimensional dataset from which any paraxial, coronal, sagittal, or oblique plane can be created. Other display modalities are useful for performing the evaluation, such as multiplanar reconstruction (MPR) or curved MPR, thin-slab maximum intensity projections (MIPs), and or volume rendering (VR).

Diagnostic Performance of Coronary CT Angiography

Initial results with four-slice CT were promising, and high sensitivity and specificity to detect IHD were reported. However, 20–30% of coronary segments had to be excluded from analysis due to nondiagnostic quality. Substantial improvement was achieved by the introduction of 16-slice scanners with submillimeter collimation as well as faster rotation times. Pooled analysis of available data (11 studies, 681 patients) has demonstrated a sensitivity of 88% with a specificity of 96%, with a concomitant increase in the number of assessable segments (5). For both, four-slice and 16-slice studies, vessel diameter thresholds for assessment were adopted (i.e., vessels of 1.5–2 mm or more).

Recently the diagnostic performance of the latest 64-slice CT scanner, with increased temporal (165 ms) and spatial (0.4 mm^3) resolution, was evaluated (2). Sensitivity and specificity for assessment of significant stenoses were 99 and 95%, respectively, with no exclusion of segments and with no threshold in vessel size for image evaluation (2).

Clinical Applications

Given the current literature and evidence, there are few clinical applications for coronary CTA. What can be said is based on speculation referring to validation series. The most important feature of coronary CTA is the high-negative predictive value, which indicates a reliable capability of ruling out the presence of significant IHD. Accordingly, CT should be used as a first-line imaging technique to exclude the presence or recurrence of IHD in eligible patients (Fig. 1).

The applications that appear to be feasible, based on current validation literature, are evaluation of patients with a low-pretest likelihood of the presence of a significant coronary stenosis (Figs. 2 and 3), evaluation of patients with recurrent angina, follow-up of proximal coronary stents (Fig. 4), follow-up of patients with previous coronary artery bypass graft (CABG; Fig. 5), and evaluation of coronary artery anomalies.

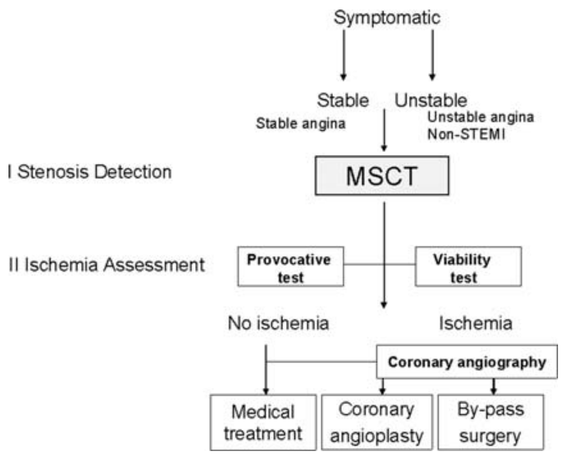
Coronary CTA can exclude the presence of significant coronary stenosis in patients with low-intermediate pretest probability because of the high-negative predictive value, and it may be properly used after an inconclusive stress test or in patients with atypical chest pain.

The high density of stent struts limits the reliability of in-stent lumens. However, preliminary data indicate that 16- and 64-slice CT scanners can detect in-stent restenosis. The presence of stent occlusion or in-stent restenosis may be assessed in proximal segments.

The assessment of CABG is reported as being reliable with CT. However, the presence of metallic surgical clips around arterial grafts, extensive atherosclerosis, and previous stenting of native coronary arteries are some of the limitations that have been encountered.

Coronary CTA can show coronary anomalies because of its three-dimensional and volumetric capabilities.

The introduction in clinical practice of 64-slice CT, and most probably the next generation of CT scanners with multiple tube-detector units, will allow the triage of acute chest pain. CT is the noninvasive gold standard for diagnosing pulmonary embolism and aortic dissection. The possibility to include the assessment of coronary arteries in a thoracic scan will provide a totally new approach in assessing acute chest pain.

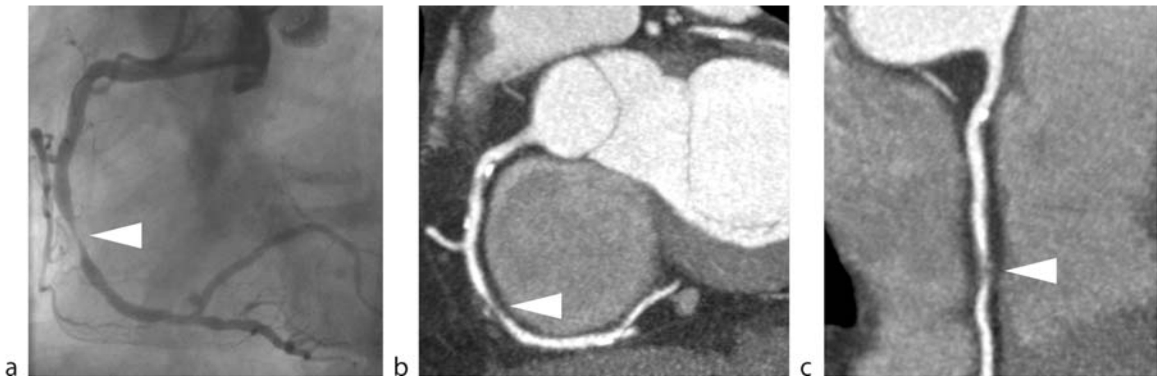


Ischemic Heart Disease, CT. Figure 1 Proposed diagnostic algorithm of suspected coronary ischemia. The first-line imaging modality could be computed tomography, providing two important pieces of information: detection of any atherosclerotic involvement of coronary arteries, and stratification of patients based on the presence of significant stenosis (>50% lumen reduction). The second stage would be evaluation of patients for stress ischemia. Provocative performance is likely to improve when patients are referred after tests that ensure the presence of significant coronary atherosclerosis. In the final stage, morphology and functional information are covered, and a decision for the need for conventional/interventional coronary angiography can be made.

Plaque Imaging with CT

The newer information available since the introduction of coronary CTA is coronary artery wall evaluation. CT can show the presence of plaques and their tissue features (i.e., predominantly calcified, mixed, or predominantly noncalcified). Regarding noncalcified plaque components, it has been suggested that the attenuation measured could indicate the predominant composition as fibrous or lipid.

Other important information that can be derived from CT is the extent of vessel wall remodeling. This information is of great value because the risk of acute coronary syndromes caused by plaque disruption and



Ischemic Heart Disease, CT. Figure 2 Diagnosis of a patient with stable angina. Conventional coronary angiography displays a significant stenosis (*arrowhead*) in the distal right coronary artery (a). Ischemic Heart Disease, CT. Figure 3 **Diagnosis of patient with atypical chest pain. Significant coronary artery stenosis (*arrowhead*) is detected by 64-slice computed tomography (a) and confirmed by conventional coronary angiography (b).**

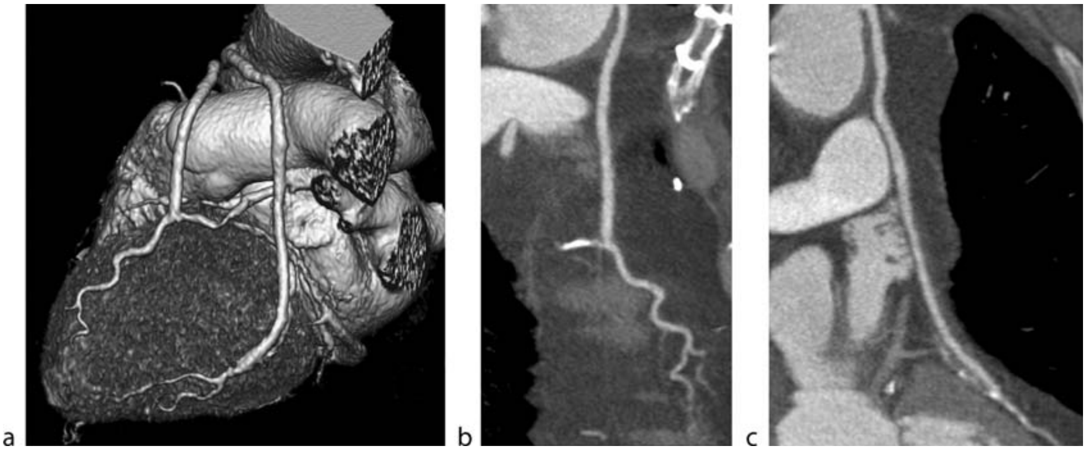
Ischemic Heart Disease, CT. Figure 4 **Follow-up of bifurcation stenting of the left main coronary artery using 64-slice computed tomography angiography. The volume-rendered image (a) shows the anatomical configuration of the left coronary artery and the stents. The curved multiplanar reconstructions along the vessels show the lumen in one single plane (b, c). A dedicated plane can be used to display the bifurcation of the stent, which is the main site of restenosis (d). The stent is patent in the proximal region (left main) and in the two main branches (left anterior descending [LAD] and circumflex [Cx]) as confirmed by the conventional coronary angiogram (e).**

thrombosis depends on plaque composition (i.e., non-calcified, predominantly lipid plaques with positive remodeling) rather than on stenosis severity. For this reason, reliable noninvasive assessment of plaque constitution could be important in risk stratification of patients with IHD.

Limitations

CT has several limitations in terms of spatial and temporal resolution and contrast-to-noise ratio, which are the reasons for the tight selection of patients for its clinical application. Coronary calcifications limit the



Ischemic Heart Disease, MRI. Figure 5 Follow-up of a coronary artery bypass graft using 64-slice computed tomography angiography. The volume-rendered image displays two venous bypass grafts (a). The first graft runs from the aorta to the first diagonal branch; the second graft runs from the aorta to the second marginal branch. The maximum intensity projections show that both grafts are patent (b, c).

reliability of the assessment of stenosis. Nonsinus heart rhythm, such as atrial fibrillation, prevents diagnostic coronary CTA. Heart rates >70 bpm result in progressively poorer image quality, and a drop out of assessable segments limits the diagnostic accuracy.

Coronary CTA is also a technique that requires highly specific and long training. For this reason it remains a severely operator-dependent modality.

The main concern, though, remains the radiation exposure associated with CT. The effective x-ray doses of 64-slice coronary CTA are reported to be 15.2 mSv and 21.4 m Sv for men and women, respectively, without prospective tube current modulation. This is to allow end-systolic reconstruction for diagnostic purposes. The application of prospective tube current modulation algorithms may reduce the x-ray dose down to 50% of the nominal one, depending on the heart rate.

Conclusion

Coronary CTA is at present the only clinical noninvasive modality for assessing the coronary arteries. The field of application is still restricted by technical limitations and the lack of large clinical trials. This information will become available soon as new generation scanners progressively extend the spectrum of indications.

Short Description

Magnetic resonance imaging (MRI) has emerged as a non-invasive cardiac imaging technique and plays an increasingly important role in the assessment of coronary artery disease (CAD). Its superb spatial and temporal resolution combined with excellent soft tissue contrast currently allows accurate assessment of cardiac morphology, global cardiac function, regional wall motion and the extent of myocardial infarction. Regional myocardial perfusion can be assessed by first-pass techniques using ultrafast T1-weighted sequences. MR coronary angiography has become feasible and high-resolution imaging with or without contrast-enhancement may allow for characterization of atherosclerotic plaque. Some of the techniques are currently used in clinical routine whereas others must be considered a field of active research (Fig. 1).

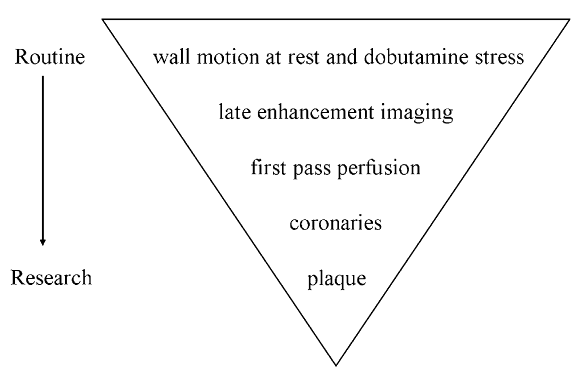
There are two common clinical scenarios in which MRI is frequently applied in patients with CAD:

1. To detect CAD and myocardial ischemia
2. To define the extent of myocardial infarction and to distinguish different causes of wall motion abnormalities including scar, myocardial stunning and myocardial hibernation

This review discusses the diagnostic accuracy and the impact of different MRI techniques on management of CAD patients.

Detection of Coronary Artery Disease and Myocardial Ischemia

Several non-invasive tests including stress ECG, stress echocardiography, nuclear techniques, cardiac computed tomography are used in clinical routine for the detection of CAD. However, due to limited sensitivity and specificity of all non-invasive techniques, the final diagnosis as well as the exclusion of CAD is established by catheter angiography in the majority of patients. MRI offers different morphologic and functional techniques including wall motion analysis at stress, first-pass stress perfusion, MR coronary angiography and coronary vessel wall imaging for the detection of CAD.



Ischemic Heart Disease, MRI. Figure 1 Status of different MR techniques for the assessment of ischemic heart disease.

Wall Motion Analysis at Stress

CAD may result in global or regional wall motion abnormalities of the left ventricle and lead to heart failure. The MR analysis of the global left ventricular function at rest, expressed as left ventricular ejection fraction, has impact on patient management and predicts patients' prognosis. Regional wall motion abnormalities are classified as hypo-, a- or dyskinesia of the left ventricular myocardium, but the different pathophysiological causes of wall motion abnormalities (scar, stunning, hibernation) cannot be differentiated by analysis of rest function.

The assessment of regional wall motion at pharmacological stress provides additional information to the rest examination. Low-dose dobutamine stress MRI can be used to assess myocardial viability. Dysfunctional myocardium that improves at low-dose dobutamine can be characterized as ischemic myocardium (hibernation), with a high probability of recovery of function after revascularization.

High-dose dobutamine stress MRI can identify myocardial ischemia non-invasively. The positive inotrope and chronotrope effects of dobutamine increase the myocardial oxygen demand and new or worsened wall motion abnormalities at stress are sensitive signs of hemodynamically significant CAD. High-dose dobutamine MRI can be performed with a standard dobutamine/atropine stress protocol, which was introduced for stress echocardiography. However, compared to stress echocardiography, detection of wall motion abnormalities by stress MRI provides a significantly higher accuracy for the diagnosis of significant CAD.

Stress Perfusion

Contrast enhanced first-pass myocardial perfusion imaging uses fast T1-weighted sequences during injection of a contrast bolus. The T1-shortening effect of the contrast agent results in a successive increase of the signal intensity in the right ventricle, the left ventricle and the myocardium. To be well suited for first pass imaging MR pulse sequences have to fulfil several, to some degree contradictory requirements. Most sequences provided for the assessment of myocardial first pass perfusion make use of a saturation-recovery pre-pulse to achieve heavily T1-weighted images followed by a fast data read out by means of gradient echo, echo planar imaging or steady-state free precession techniques. However, sequence optimization must be considered an area of active research and no general recommendations can be given.

Contrast dose varies between 0.025 and 0.15 mmol/kg of extra-cellular Gd-chelates in different studies. As different sequences are more or less sensitive to susceptibility artefacts, the optimum total amount of contrast depends on the applied MR sequence and on the employed post-processing methods. Myocardial first-pass perfusion studies can be analyzed in different ways including qualitative approaches, semi-quantitative methods and finally a fully quantitative analysis. Visual assessment is operator-dependent whereas semi-quantitative and quantitative methods are time consuming, and approved post-processing tools are not available for clinical applications.

Since the early 1990s, several groups have evaluated the diagnostic potential of first-pass perfusion MRI for the non-invasive detection of CAD against coronary angiography and nuclear techniques in a number of smaller studies. Although coronary angiography must be considered as an imperfect standard of reference, because a morphologic and a functional approach for the detection of significant stenoses are compared, the sensitivity and specificity of perfusion MRI ranged from 65 to 92% and from 76 to 100%, respectively.

However, large clinical trials defining the impact of first pass perfusion MR imaging onto patient management are still lacking, and a consensus on optimal imaging protocols and post-processing techniques has not been achieved so far. Therefore, MR first pass perfusion imaging must still be considered an area of active research, and the technique is not ready for clinical use.

MR Coronary Angiography

Invasive coronary artery angiography still serves as the gold standard for the diagnosis of CAD. However, limitations inherent to catheter coronary angiography include a major complication rate of approximately 0.3–1.1% considerable radiation exposure as well as excessive cost to the health care systems. These drawbacks have promoted alternative imaging strategies. With the development of ultrafast imaging sequences, magnetic resonance angiography of the coronary arteries (MRCA) has recently become possible.

Magnetic resonance angiography has replaced diagnostic catheter angiography for most vascular territories in clinical routine, but magnetic resonance coronary angiography is still an area of active research. The major challenges for MRCA include spatial resolution and coverage, compensation of cardiac and respiratory motion and signal-to-noise issues. Initial studies using two-dimensional (2D) time-of-flight MR angiography techniques suffered from poor through-plane resolution, but these shortcomings were compensated by the introduction of nearly isotropic fast three-dimensional (3D) techniques. Advantageous features of 3D imaging techniques are the acquisition of thinner slices, superior signal-to-noise ratio (SNR) and the total coverage of tortuous coronary arteries.

In order to prevent vessel blurring, compensation of cardiac motion using ECG triggering is mandatory. All data for image reconstruction are collected in an acquisition window of 80–150 msec in mid to late diastole where displacement of the coronaries is minimized. To suppress the effects of respiration MRCA scan can either be performed in a single breath-hold or using respiratory gating. For breath-hold MRCA the scan time must be adapted to the patients' breath-hold capabilities, limiting the number of slices and the spatial resolution. For free-breathing MRCA using the navigator approach can be performed with high spatial resolution, however, image quality may be reduced by navigator failure depending on the patients breathing pattern.

MRCA using standard 3D-gradient echo sequences leads to rather poor contrast between blood and myocardium. To overcome this limitation T2 preparation has been introduced to suppress myocardial signal. Recently, steady-state free precession sequences have become clinically available, improving contrast between blood and myocardial tissue. Another approach for improving the quality of 3D-MRCA is to use T1-shortening contrast agents. Extra-cellular contrast agents are of limited value because they only permit data acquisition directly after intravenous application during the first arterial pass of the agent. Recently, blood pool MR contrast agents have been introduced for MRCA, which are characterized by higher T1-relaxivities and an intravascular distribution. These new intravascular MR contrast agents have recently been shown to improve breath-hold and navigator MRCA.

Until now, only two larger studies have compared free-breathing MRCA with X-ray angiography and reported high sensitivities and specificities for the detection of relevant CAD. Nevertheless, approximately one third of all examinations were not assessable due to impaired image quality. It can be concluded that MRCA is still challenging and the technique is not ready for clinical use in CAD patients.

Plaque Imaging

All luminographic techniques including conventional, computed tomography and magnetic resonance angiography, frequently underestimate the true burden of atherosclerosis because early stage atherosclerotic plaques, which do not compromise the arterial lumen cannot be detected. However, these non-stenotic plaques are of great clinical interest, because about one third of all myocardial infarctions occur due to plaque rupture in a vascular segment without stenoses.

Furthermore, it is well established that the risk of an acute event mediated by plaque rupture is predicted by the composition of the plaque rather than the degree of luminal narrowing. Plaques with a large necrotic lipid core and a thin fibrous cap are associated with a high risk of rupture.

Due to its ability to distinguish different plaque components like lipids, the fibrous tissue, calcium and thrombi, high-resolution multi-contrast MRI is considered the most promising technique for imaging of the vessel wall. Recently, compounds that accumulate in atherosclerotic plaques or that bind to plaque components have shown promising results in animal studies.

Assessment of Myocardial Infarction and Myocardial Viability

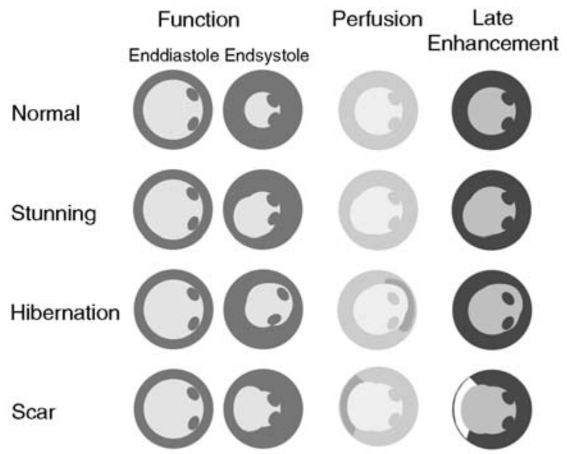
The concept of myocardial 'late enhancement' (LE) or 'delayed enhancement' in contrast-enhanced cardiac MRI is currently being established for the assessment of myocardial viability. Animal studies have demonstrated that myocardial areas accumulating extra-cellular gadolinium-based contrast agents in the equilibrium phase after intravenous administration reliably reflect irreversible myocardial damage after myocardial infarction.

For the detection of late enhancement inversion-recovery gradient echo sequences should be performed 10 to 20 min after injection of 0.1–0.2 mmol/kg Gd-based contrast. The inversion time (TI) has to be adjusted manually between 180 and about 300 msec to null the signal of normal myocardium. These sequences optimize the image contrast and allow a reliable differentiation between infarcted tissue and normal myocardium.

Cardiac MR combining contrast-enhanced imaging (ceMRI) and cine sequences has shown potential characterizing myocardial tissue in patients with ischemic heart disease. Regional myocardial wall motion abnormalities can be caused by irreversible (scar tissue) or reversible myocardial damage, the latter of which can be differentiated in myocardial hibernation and myocardial stunning. MRI allows the discrimination of myocardial infarction (dysfunction with hyper-enhancement), myocardial stunning (dysfunction, normal perfusion, no hyper-enhancement), myocardial hibernation (dysfunction, hypo-perfusion, no hyper-enhancement) and normal myocardium (normal function without hyper-enhancement (Fig. 2).

Acute Myocardial Infarction

Acute myocardial infarctions (MI) are characterized by a loss of the cell membrane integrity. Therefore, standard extra-cellular contrast agent can enter the space formerly occupied by the cells resulting in an increased fractional distribution volume. However, a dark zone in the centre of the enhancing area can frequently be detected in acute MI. Although, the great epicardial coronary arteries are patent after acute percutanenous coronary interventions (PCI) or thrombolysis, there might be areas without early contrast uptake, because the small vessels and capillaries are occluded. This no-reflow phenomenon for MR has been described more than 10 years ago and can now be visualized *in vivo* using MRI.

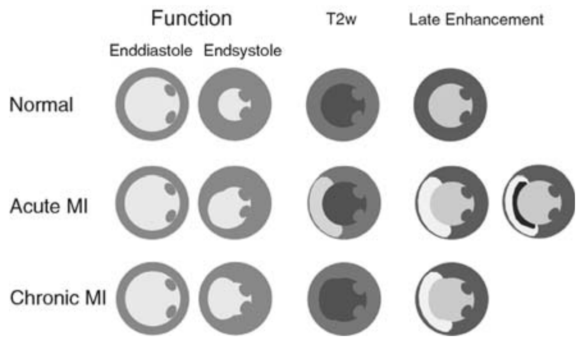


Ischemic Heart Disease, MRI. Figure 2 MR characterization of normal and dysfunctional myocardium.

Within the first week after acute MI wall motion abnormalities can either be caused by infarcted or stunned myocardium. Stunning is defined as dysfunctional but viable myocardium due to a temporary severe ischemia. The differentiation between stunned and infarcted segments in patients with recent myocardial infarction is clinically important and can easily be made by MRI because irreversible damaged myocardium shows late enhancement whereas stunned myocardium does not (Fig. 2). Based on this criterion, contrast-enhanced MR reliably distinguishes stunning from infarction and allows predicting the functional improvement of stunned myocardium.

The true extent of irreversible myocardial injury defined by MRI using the late enhancement approach is a strong predictor of patients' outcome. Furthermore, no-reflow areas detected within the area of late enhancement are an additional independent risk factor and are associated with an increased number of cardiac events and poor prognosis.

Acute myocardial infarction can reliably be distinguished from chronic scar tissue using T2-weighted images. While acute MI appears bright due to myocardial oedema, chronic MI is isointense to myocardium on



Ischemic Heart Disease, Nuclear Medicine. Figure 3 **MR appearance of acute and chronic myocardial infarction.**

T2-weighted images (Fig. 3). Additionally, chronic myocardial infarctions frequently show wall thinning due to scar formation, whereas in acute MI the end-diastolic wall thickness is not different from normal myocardium. Another criterion to distinguish acute and chronic myocardial infarctions is the no reflow phenomenon, which can only be detected within the first 4 to 6 weeks after an acute myocardial infarction.

Chronic Myocardial Infarction

Chronic myocardial infarctions show a homogenously increased signal intensity compared to normal myocardium 5 to 30 min after contrast injection (Fig. 3). Whereas the contrast agent is rapidly washed out from normal myocardium, the contrast agent accumulates in the increased interstitial space of non-viable myocardium. Additionally, the reduced perfusion of scar tissue results in a delayed wash out of the contrast agent. Chronic myocardial infarction shows homogenous enhancement after contrast application (Fig. 3).

In patients with a history of myocardial infarction, myocardial dysfunction can be caused by scar tissue or myocardial hibernation. Hibernation is defined as dysfunctional but viable myocardium due to chronic ischemia. The differentiation between hibernating and infarcted segments in patients with a history of myocardial infarction is clinically important and can easily be made by MRI because irreversible damaged myocardium shows late enhancement whereas hibernating myocardium does not.

This differentiation is clinically important because patients with hibernation benefit from re-vascularization whereas patients with scar tissue do not. The delayed enhancement technique has recently been introduced into clinical routine for the assessment of myocardial viability. Contrast-enhanced MRI can reliably discriminate between reversible (hibernation) and irreversible ischemic injury and predicts functional recovery after re-vascularization with high sensitivity and specificity.

Comparing MRI with positron emission tomography (PET) as the reference standard for the detection and quantification of myocardial scar tissue, several studies demonstrated a higher sensitivity of MRI for the detection of small scars, reflecting the higher spatial resolution of the LE images. Furthermore, MRI is superior defining the transmural extent of infarcted myocardium which is a strong predictor of functional recovery after revascularization. Analyzing regional contractility before and after revascularization, function improved in about 3/4 of segments without hyper-enhancement, whereas almost none of the segments with hyper-enhancement of more than 75% of the left ventricular wall showed a recovery of function.

However, although LE is very sensitive in detecting and localizing myocardial scarring, it is, on the other hand, not specific for ischemic damage. Pathologically controlled studies have shown that extra-cellular contrast agents accumulate not only in infarction scars, but generally in tissues with increased water content. Thus, the presence of LE has been described in myocardial areas of fibrosis, inflammation and edema where the extra-cellular volume is enlarged. Different entities of myocardial diseases or disorders are accompanied by fibrosis and acute or chronic inflammation and might, therefore, be diagnosed based on the pattern and localization of LE in contrast-enhanced MRI. Whereas myocardial infarctions always involve the sub-endocardial layer of the myocardium and the area of late enhancement is related to the territories of the coronary arteries, non-ischemic entities frequently show a more patchy and sub-epicardial distribution.

Definition

Many pathological conditions with respect to the coronary blood flow have been described. Hypoxia is the condition in which the oxygen supply is diminished despite an adequate perfusion of the myocardium. Anoxia is regarded as the absence of oxygen supply, whereas in ▶ischemia the oxygen deprivation is accompanied by inadequate removal of metabolites due to a reduced perfusion. During the ischemic condition an imbalance occurs between oxygen supply and demand, which may manifest as anginal discomfort, deviation of the ST segment on electrocardiography, or impairment of the regional or global left ventricular function. In the presence of coronary obstruction, an increase in myocardial oxygen requirement leads to a transitory imbalance or the so-called demand ischemia. This condition may be caused by exercise, tachycardia, or emotion and is responsible for most episodes of chronic stable angina. On the other hand, imbalance caused by a reduction of the oxygen supply related to increased vascular tone or the presence of thrombi is termed supply ischemia. This form of ischemia is responsible for episodes of unstable angina and myocardial infarction.

Nuclear medicine dedicated to imaging procedures of the heart using radiopharmaceuticals—so-called nuclear cardiology—has been an active clinical specialty for at least three decades. Major advances have occurred over the past years in both radiopharmaceutical development and instrumentation. Nuclear cardiology gives insight into many functional aspects of the heart and thus into risk stratification and prognosis (1). The clinical applications of nuclear cardiology include ▶*myocardial perfusion scintigraphy*, measurement of the left ventricular ejection fraction, assessment of myocardial viability, assessment of myocardial fatty acid metabolism, and assessment of receptor integrity.

Pathology/Histopathology

A strong correlation between ischemic heart disease and prognostic factors, such as smoking, hypertension, diabetes, and hypercholesterolemia has been established. Other contributory factors may be lack of exercise and physiological characteristics. These factors lead to initiation and progression of a process of reduction in the lumen of the coronary artery. This process is characterized by the formation of an atheroma affecting the intima, fibrin, and platelet deposition on the intima, hemorrhage under the intima, thrombosis, or a combination of these factors. The anterior descending coronary artery is especially vulnerable to atheroma, and sudden occlusion of this vessel is particularly dangerous. In myocardial infarction, there is usually an occlusion due either to a platelet thrombus or to rupture of an atheromatous plaque, which may result in subendocardial or transmural infarction. During an acute infarction an inflammatory reaction occurs, and if the epicardial surface is affected, it may lead to overlying pericarditis.

Clinical Presentation

▶*Angina pectoris* is the name for a clinical syndrome due to myocardial ischemia. The symptoms are commonly provoked by exertion, particularly out of doors, or by anxiety. It is usually experienced as a sense of oppression or tightness in the middle of the chest, and the patient commonly places his or her hand on the sternum. Angina pectoris is likely to be worse on a cold day or when walking against a wind or uphill and it commonly occurs after meals. In all of these circumstances, a greater coronary blood flow is demanded to fulfill the increased oxygen requirement. The pain is commonly accompanied by discomfort in the arms (most often the left), wrists, and hands. Angina may more rarely be epigastric or interscapular or may radiate to the neck and jaw. There may be accompanying breathlessness or even syncope.

Imaging

The acquisition and display of nuclear medicine images depends on detecting photons emitted during the decay process of a radionuclide. These radionuclides are intravenously administered to a patient and are either labeled to specific tracers or are unlabeled. The photons are detected with a scintillation (gamma) camera interfaced with a computer. The photomultiplier tubes translate the scintillations that occur in a large sodium iodide crystal into voltage pulses, which are finally measured as an electrical signal. The computer is a principal component of all nuclear imaging systems as it uses software containing reconstruction algorithms and functionality for quantifying static and dynamic images.

Over the past years, single photon emission computed tomography (SPECT) has been used more commonly in cardiovascular imaging. A series of planar images is acquired over a 180–360° arc around the patient's thorax, which gives the option of three-dimensional imaging of the heart. The transaxial images are reconstructed into short-axis and horizontal and vertical long-axis orientations. The overall result is an improvement in anatomical resolution and contrast in relation to planar imaging, but it requires more stringent quality control measures of the whole imaging device. Finally, by using the electrocardiogram (ECG) signal as a trigger for image acquisition, the so-called ▶*gated-SPECT* method, perfusion imaging is combined with functional imaging to reveal data with respect to perfusion, global ejection fraction, and regional wall motion and thickening. As a result, it provides the clinician better information with respect to risk stratification and prognosis.

Nuclear Medicine

Radiopharmaceuticals for Myocardial Perfusion Imaging

The regional distribution of myocardial perfusion can be visualized with radiopharmaceuticals that accumulate proportional to the regional blood flow. In 1874, Thallous chloride-201 (Tl-201) became available, which has the advantage of viability assessment in addition to perfusion evaluation. Over the past decade, however, Technetium-99m (^{99m}Tc)-labeled compounds became available. These latter radiopharmaceuticals have better imaging characteristics and novel biological properties. Although worldwide ^{99m}Tc-labeled compounds are most commonly used, combinations with both radiopharmaceuticals are still in use (2).

Thallium-201

Thallium-201 is a cyclotron-produced radiopharmaceutical that emits mercury X-rays at 69–83 keV and photons with an energy of 135, 165, and 167 keV. Its physical half-life is 74 h, but its biological half-life is 58 h. Because of the relative long half-life and the rather high whole body doses, only a small amount of radioactivity can be administered. The first-pass extraction fraction is approximately 85%, whereas the overall uptake is about 4% of the injected dose. The initial accumulation is proportional to the blood flow, and once it has entered the cell it continuously exchanges across the cell membrane. This process involves the Na^+, K^+-ATP-ase pump. Consequently, with one single injection, this radiopharmaceutical may provide images related not only to the initial blood flow but also to a redistribution process. The latter images reflect the distribution of the potassium pool and hence myocardial viability. A disadvantage of this compound is that because of this redistribution process, acquisition should start very shortly after administration, whereas the acquisition time is limited.

Technetium-99m-Labeled Compounds

Over the past years, a number of ^{99m}Tc-labeled compounds have been introduced in clinical practice. The most commonly used agent is ^{99m}Tc-sestamibi, a lipophilic monovalent cation, which later on came to be used for tumor scintigraphy. The production of these compounds is on site. The advantage of ^{99m}Tc over Tl-201 is the optimal energy of photons emitted, 140 keV, which can be easily detected by sodium iodide crystals in the gamma camera. Consequently, better image quality can be achieved using these compounds. The half-life of ^{99m}Tc is approximately 6 h, whereas the radiation exposure for patients is less than obtained with Tl-201. Because of the favorable dosimetry, up to 1,000 MBq of these agents can be administered per day.

The initial myocardial uptake is similar to Tl-201 and is proportional to the regional blood flow. In contrast to Tl-201, however, there is rapid accumulation in the liver as well as excretion into the biliary tract. Consequently, extracardiac activity may be observed, which may interfere especially with interpretation of the inferior wall. Uptake in the myocardium is by passive diffusion followed by binding to intracellular membranes. The myocardial distribution remains stable over time and can be imaged for several hours after administration. There is no significant redistribution. The most commonly used ^{99m}Tc-labeled compounds are ^{99m}Tc-sestamibi and ^{99m}Tc-tetrofosmin (3).

Stress-Rest Imaging Protocols

To assess myocardial perfusion, different study protocols have become available. The aim of these imaging protocols is to differentiate, on one hand, normal from abnormal perfusion studies. On the other hand, the aim is to differentiate persistent perfusion abnormalities from reversible ischemia and, in the case of the use of Tl-201, to assess the presence of viable tissue. In this respect, different protocols have become available over the past years (3).

Stress Protocols

To assess myocardial perfusion, different stress protocols are available. The choice of protocol depends on the condition, comorbidity, medication, abnormalities on ECG, and so on. In most nuclear cardiology centers, a stress test is followed by a rest study, but it has been stated that in the case of a normal stress study, the performance of a rest study is questionable.

Physical exercise: Several treadmill protocols exist. Endpoints for physical exercise are severe symptoms as dyspnea and angina, hypotension, exhaustion, and ST-segment depression on electrocardiography. During peak exercise, the radiopharmaceutical is administered intravenously in an antecubital line, after which time the patient is encouraged to exercise for another 1 or 2 min.

Pharmacological vasodilatation: If disabilities or contraindications to physical exercise exist, pharmacological alternatives are available. The most commonly used are adenosine infusion and dobutamine stress. Adenosine is a vasodilator with minimal side effects. The only contraindications are chronic obstructive pulmonary disease and AV block. Maximum dilatation is achieved after 4–4.5 min, at which time the radiopharmaceutical is administered, and the infusion continues for 1.5–2 min. Side effects include transient headache, abdominal discomfort, and nausea. The advantage of adenosine over other techniques is its rapid clearance and, consequently, the instantaneous reversibility of symptoms.

Dobutamine stress increases myocardial oxygen demand by increasing contractility, heart rate, and blood pressure. The increase in flow is comparable to that of physical exercise but less than that with adenosine. The infusion protocol takes about 15 min, with administration of the radiopharmaceutical in the 12th min. The most commonly reported side effects include ventricular ectopy, headache, dyspnea, paresthesia, and flushing; however, their reversibility is less rapid than in adenosine protocols.

One-day stress–rest study: Several study protocols can be used during a one-day stop-and-shop imaging strategy:

1. Tl-201 (100 MBq) injected at peak exercise, delayed imaging after 2–4 h to assess redistribution, followed by reinjection of Tl-201 (75 MBq) to assess the perfusion at rest.
2. ^{99m}Tc-labeled compounds (250–500 MBq) injected at rest, followed by a stress study 2 h later using 750–1,000 MBq of a ^{99m}Tc-labeled compound.
3. Dual isotope imaging, which is based on the injection of Tl-201 at rest and a ^{99m}Tc-labeled compound during stress.

Two-day stress-rest study: This is the most commonly used strategy. The major advantage over a one-day stress-rest study protocol is the fact that the amount of activity is comparable under both circumstances (500–1,000 MBq), revealing better image quality and the option of optimal gating during stress as well as rest. Although Tl-201 can be used in this protocol, the use of ^{99m}Tc-labeled compounds is advised because they give a better option of gating during both studies and, again, better image quality.

Interpretation of Images

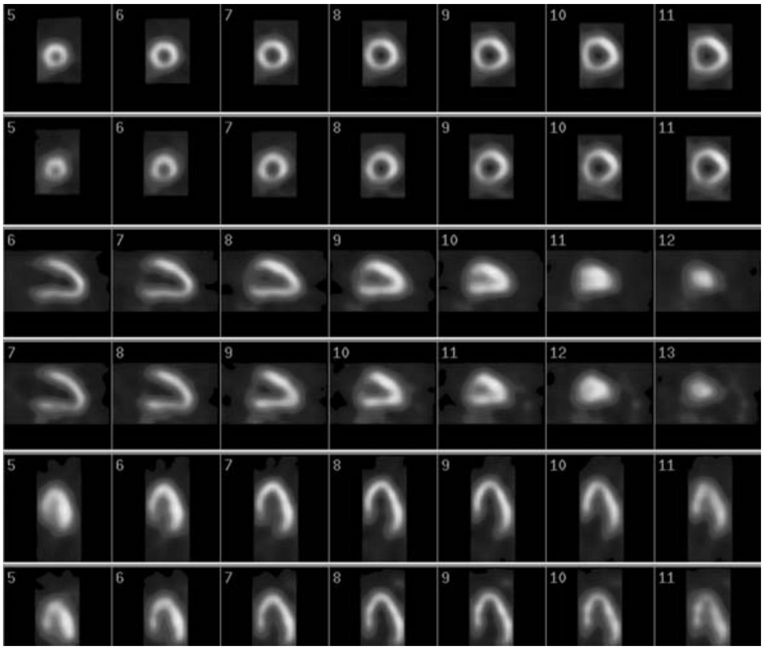
Myocardial perfusion studies are reconstructed and presented in short-axis and horizontal and vertical long-axis projections. The initial interpretation is visual, in which the heart is subdivided into segments (e.g., 9, 17, or 20 segments). For each segment, the perfusion is scored as normal (0), slightly to moderately diminished uptake (1), moderately to severely diminished uptake (2), or no uptake (3). It is important to assess the size of the left ventricle and the distribution pattern of the radiopharmaceutical, either homogeneous or irregular. An irregular pattern may indicate microangiopathy caused by diabetes or cardiomyopathy. The visual analysis is done for the stress as well as for the rest study, and the results are combined with a semiautomatic analysis method developed by Germano and Berman (4). This software package gives the option to measure the left ventricular ejection fraction, the regional wall motion, and wall thickening. Furthermore, a polar map, or bull's eye display is used to compare the stress–rest images semiautomatically. The purpose of this map is to generate one single image that encompasses the relative distribution of the radiopharmaceutical. Relative uptake on short-axis images is compressed to a color-coded concentric ring with the apical slice in the center and the basal slices on the periphery of the map. The combination of all data finally results in the following interpretations:

1. Normal intensity, homogeneous distribution, normal function of the myocardium (Fig. 1)
2. Defect in one or more segments, abnormal function in these segments, which may be indicative for infarction (Fig. 2)
3. Reversible defect, which is a defect present on initial stress images and no longer present on the resting or delayed images. This pattern indicates ischemia (Fig. 2). Functional abnormalities may be seen, which commonly correspond to the severity of the perfusion abnormalities.

It must be realized that artifacts may occur, leading to possible misinterpretation of the reconstructed images. Motion artifacts may show up as reversible defects, which can be assessed on the raw data images. A typical motion artifact is the so-called upward creep of the heart, which is caused while the patient recovers from stress and the heart consequently moves into the horizontal position. Other common artifacts are caused by attenuation. Acquisition is normally performed with the patient in the prone position, because in this position the overall attenuation by the camera table at one side is comparable with the attenuation of photons passing through the chest at the other side. When acquisition is done in the supine position, it may cause artifacts in the inferior wall. Attenuation by large and/or dense breast tissue will result in abnormalities in the anteroseptal region.

Diagnosis

Myocardial perfusion scintigraphy is an extremely sensitive and reliable method for the assessment of perfusion abnormalities and prognostic stratification (5, 6). Indications for perfusion scintigraphy are visualization of ischemia (site, extent, and severity), stratification of risk for cardiac death (low, intermediate, or high), identification of the culprit artery, determination of viability of dysfunctioning myocardium, and, in certain cases, recommendation for the type of therapy as medical, coronary artery bypass graft (CABG), or transplantation. In most of the studies published over the past year, myocardial perfusion



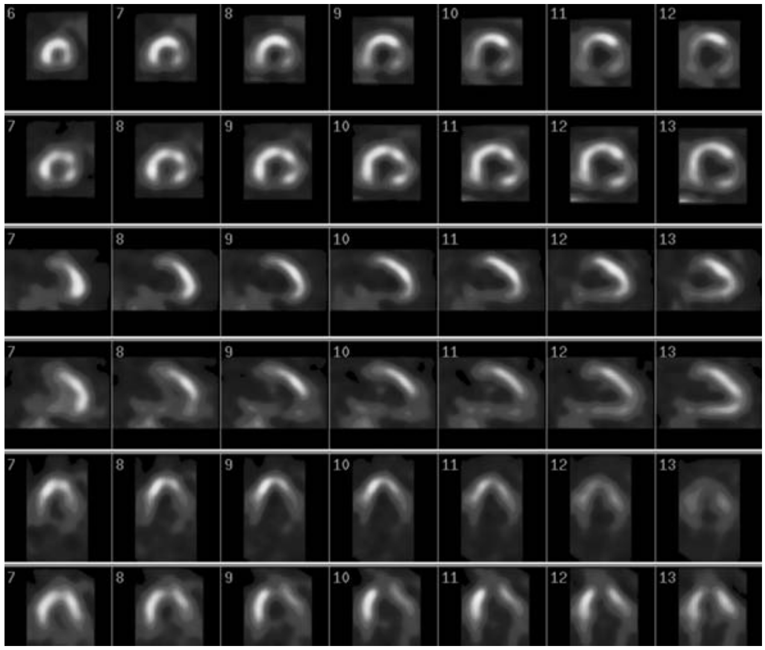
Ischemic Heart Disease, Nuclear Medicine. Figure 1 Standard short-axis and horizontal and vertical long-axis reconstructions of a stress–rest myocardial perfusion study with ^{99m}Tc-tetrofosmin. The first, third, and fifth rows demonstrate stress images, and the second, fourth, and sixth rows demonstrate rest images. A normal distribution pattern is seen without perfusion defects. This patient, who presented with atypical chest pain was categorized into the very-low-probability risk group for cardiac events.

scintigraphy has revealed a sensitivity and specificity of 80–100% and 80–90%, respectively, for detecting ischemia or infarction, whereas the negative predictive value is up to 99%. It has been concluded from these studies that gated-SPECT myocardial perfusion scintigraphy has significant incremental prognostic value regarding individual parameters such as age and gender, risk factors such as hypercholesterolemia and hypertension, and ECG changes. Following perfusion scintigraphy, patients can be stratified into the following risk groups for a major cardiac event:

1. Low risk (<1%)
   a. Normal or near normal perfusion
   b. Normal left ventricular ejection fraction with normal or near normal perfusion
2. Intermediate risk (<1% for cardiac death, but 1% for nonfatal myocardial infarction)
   a. Small perfusion defect (15% of left ventricle volume) with normal left ventricular ejection fraction and absence of nonperfusion markers of left ventricular decompensation with exercise
3. High risk (>3% for cardiac death)
   a. Severe left ventricular dysfunction at rest
   b. Severe left ventricular dysfunction with exercise
   c. Large stress-induced perfusion defect
   d. Moderate stress-induced perfusion defect with abnormal Tl-201 lung uptake
   e. Multiple moderate stress-induced perfusion defects
   f. Large fixed perfusion defect with left ventricular dilatation.

Low-risk patients can be followed medically, whereas high-risk patients are ideal candidates for revascularization. An intermediate-risk patient can be followed medically except for special circumstances such as intolerability of symptoms or other reasons.

In patients who do undergo interventions, follow-up is indicated based on the technique used, the presence of symptoms, the relative risk for subsequent problems, and, finally, the time that has passed since the intervention. For example, the time to assess for restenosis after percutaneous transluminal coronary angioplasty is approximately 3–6 months. The majority of restenoses occur by this time interval regardless of recurrent symptoms. In the published studies, nuclear perfusion imaging demonstrated a superior sensitivity of 87% and a specificity of 78% compared with 46 and 77%, respectively, for the treadmill test. Assessment of perfusion after CABG by gated-SPECT studies definitely provides better insight into the site and extent of ischemia compared with treadmill tests. To understand abnormalities seen on the scans, however, knowledge of pre-CABG anatomy, vessels that were bypassed, and operative reports should be



Ischemic Heart Disease, Nuclear Medicine. Figure 2 Myocardial perfusion scintigraphy with ^{99m}Tc-tetrofosmin in a patient with typical angina 1 year after myocardial infarction. The short axis and vertical long axis demonstrate persistent perfusion defects in the inferior and lateral wall in an enlarged left ventricle, consistent with myocardial infarction. Reversibility is seen in the septal and inferolateral wall, categorizing this patient into the high-risk group.

available, as these post-CABG scans may demonstrate a combination of nonrevascularized but diseased vessels, entrapped vessels, new disease, disease beyond anastomotic sites, or pathology of the grafts themselves.

Hibernation and Stunning

Hibernation refers to a condition of chronic sustained abnormal contraction due to chronic underperfusion in patients with coronary artery disease. In these patients, revascularization may cause recovery of function, even more than a year after intervention. In addition to this chronic underperfusion phenomenon, stunning is defined as repeated ischemic attacks, which may also result in chronic dysfunction with flow remaining normal or mildly reduced. The term "jeopardized myocardium" includes the entire spectrum ranging from stunning to hibernation. It is beyond the scope of this essay to describe in detail the principles and applications of jeopardized viable myocardium assessment. In summary, under such conditions glucose metabolism remains preserved in viable tissue. Regional glucose metabolism can be assessed with fluorodeoxyglucose (FDG), a radiolabeled glucose analog, and SPECT imaging. Dysfunctional segments with both preserved perfusion and glucose metabolism are thought to represent stunned myocardium, whereas segments with preserved glucose metabolism but reduced perfusion are considered hibernating myocardium. In contrast, segments with reduced perfusion and concordantly reduced FDG uptake are considered scar tissue. In this respect, myocardial perfusion studies performed at rest are a prerequisite for an optimal viability assessment and, consequently, for the prediction of functional recovery and long-term prognosis.

Definitions

Ischemic heart disease results from stenosis and/or occlusion of one or more coronary arteries. When ►myocardial perfusion is reduced, ischemia develops with resulting impairment of myocardial function. Reversible myocardial dysfunction due to transient and chronic ischemia is defined as stunned and hibernating myocardium, respectively (1). Irreversible myocardial dysfunction or myocardial infarction occurs when prolonged ischemia results in myocyte death (2).

Pathology/Histopathology

In ►myocardial stunning, myocardial function is temporarily impaired, which may result from reperfusion injury with generation of free radicals and calcium overload. With maintenance of normal perfusion, myocardial function returns to normal. In hibernating myocardium, a mixture of normal, atrophied, and hypertrophied myocytes is found. Prolonged hypoperfusion leads to reversible downregulation of myocardial function and to variable structural changes, ultimately including loss of myocytes.

Myocardial infarction is characterized by myocardial muscle necrosis. Acute or evolving myocardial infarction is characterized by infiltration of polymorphonuclear leukocytes (after 6 h) in addition to cell death. Acute myocardial necrosis can be recognized by the release of myocardial proteins in the blood (e.g., myoglobin, troponins T and I, creatine kinase) and by the loss of electrically functioning cardiac tissue (Q waves on electrocardiograms). Healed myocardial infarction is manifested as scar tissue without cellular infiltration and requires about 6 weeks or more to develop after the acute event (2).

Clinical Presentation

Ischemic heart disease remains one of the leading causes of morbidity and mortality. Angina pectoris is a typical symptom of ischemia. Dyspnea can occur as a result of extensive ischemic reversible myocardial dysfunction and is referred as "angina equivalent." Acute myocardial infarction is usually accompanied by typical chest pain, lasting for at least 20 min, but may also present without symptoms.

Ultrasound Imaging

Ischemia

Ischemia results in a sequence of events referred to as "the ischemic cascade": initially diastolic dysfunction, at a later stage systolic dysfunction, eventually followed by electrocardiographic changes, and finally by angina pectoris.

The initial diastolic abnormality is prolonged and delayed myocardial relaxation. This is apparent from decreased early left ventricular filling (E) and a decreased early atrial (A) to mitral filling ratio (or E/A) assessed by ►Doppler echocardiography. With worsening diastolic function, the left ventricular compliance is decreased and left ventricular filling becomes dependent on increased left atrial pressure, causing an increased E/A ratio. As the underlying impaired relaxation is masked and because the left ventricular filling pattern resembles the normal filling pattern, it is called pseudonormalization. Combining E peak velocity, which is dependent on both left atrial pressure and myocardial relaxation, with tissue Doppler-assessed early diastolic mitral annulus velocity (Ea), which is mainly dependent on myocardial relaxation, allows differentiation ("unmasking") of a normal from a pseudonormal signal. With ongoing decrease in compliance, the mitral filling pattern becomes restrictive (Fig. 1).

With prolonged ischemia, regional myocardial thickening and motion are decreased (less than 30% = hypokinesia, or absent = akinesia) or systolic outward motion occurs (dyskinesia). Regional wall motion of the left ventricle is assessed in 17 segments (American Heart Association) and analyzed in different views (apical and parasternal ultrasound windows). Each segment is assigned a wall motion score: normal: 1, hypokinesia: 2, akinesia: 3, and dyskinesia: 4. A wall motion score index is calculated as the sum of segmental scores divided by the number of segments. The segmental wall motion abnormalities in ischemia correspond to coronary perfusion territories. Left anterior descending artery disease results in abnormalities of the anterior, anteroseptal, and apical segments, while right coronary artery disease results in abnormalities of the inferior and basal posteroseptal

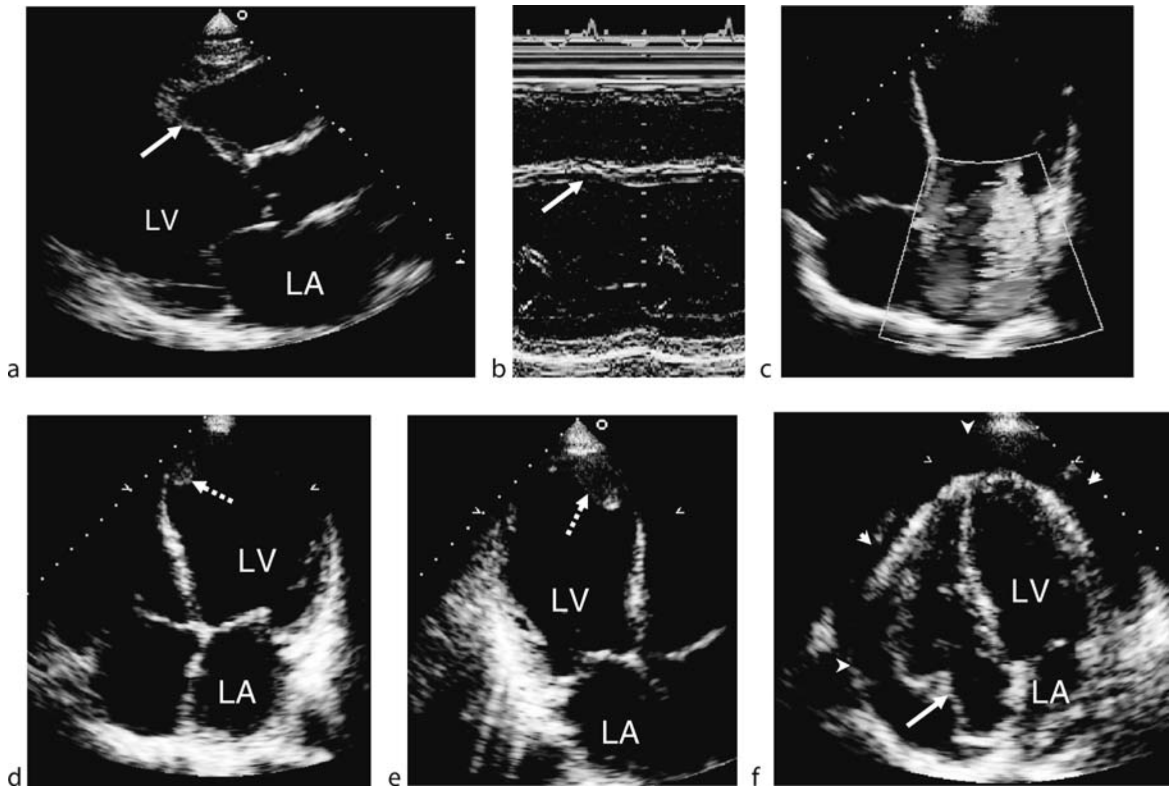
Ischemic Heart Disease, Ultrasound. segments. Circumflex artery disease affects motion of the lateral and posterior segments. These patterns of segmental dysfunction may vary depending on the coronary dominance pattern and the site of ►coronary artery disease.

Patients with ►coronary artery disease frequently have normal left ventricular function at rest. Diagnosis of coronary artery disease using stress echocardiography is based on the induction of a decreased myocardial oxygen supply/demand ratio resulting in new or worsening segmental systolic wall motion abnormalities. Depending on patient characteristics (capability of exercise) and echolab logistics, physical exercise (treadmill or bicycle) or pharmacological (inotropic stress: dobutamine; vasodilator stress: adenosine, dipyridamole) stress testing can be performed. Exercise echocardiography has a mean sensitivity and specificity of 84 and 82%, respectively, while dobutamine echocardiography has a mean sensitivity and specificity of 80 and 84%, respectively, to detect coronary artery disease (3). The accuracy of stress echocardiography is highly dependent on endocardial border definition. In the case of a suboptimal acoustic window, improved endocardial border delineation can be obtained by using ►Second harmonic imaging. and (optionally) administration of intravenous contrast agents to assess myocardial perfusion.

Besides diagnosis and assessment of the location and extent of myocardial ischemia, stress echocardiography is used for the preoperative risk evaluation in major noncardiac surgery and for the assessment of myocardial viability. Identification of dysfunctional but viable myocardium (as opposed to necrotic myocardium) has important prognostic value and is predictive of the recovery of function after revascularization. Indicators of myocardial viability include contractile reserve to inotropic stimulation (augmentation of regional myocardial function) and preserved myocardial thickness (>6 mm).

Myocardial Infarction

In the emergency department, echocardiography is essential in the bedside evaluation of a patient with chest pain (but a nondiagnostic electrocardiogram). In the acute phase of myocardial infarction, the affected myocardium is dysfunctional (akinetic, hypokinetic, or dyskinetic) but wall thickness is still preserved. Two-dimensional echocardiography has, in addition, prognostic implications and the amount of myocardial dysfunction allows estimation of the amount of myocardium at risk. If wall motion during chest pain is normal, the likelihood of acute myocardial infarction remains low. Echocardiography is also useful in detecting other causes of chest pain such as: pericarditis, pulmonary embolism, and aortic dissection.



Ischemic Necrosis. Figure 2 (a) Parasternal long-axis view and (b) ►M-mode echocardiogram. showing dilatation of the left ventricle and thin-walled infarcted anteroseptal wall (arrow). Note absence of thickening in infarcted myocardial wall. (c) Two-dimensional echocardiogram of ischemic mitral regurgitation, (d) apical four-chamber, and (e) three-chamber view showing mid and apicoseptal thin-walled aneurysm with intracavitary thrombus (dashed arrow). (f) Large pericardial effusion (arrowheads) with partial collapse of the right atrial wall (arrow). LA; left atrium, LV; left ventricle.

Besides assessment of left ventricular dysfunction, two-dimensional echocardiography with Doppler is the primary imaging technique for the initial evaluation of postmyocardial infarction complications: right ventricular involvement, free wall rupture, ventricular septal rupture, papillary muscle rupture causing acute flail mitral leaflet, pericardial effusion and tamponade, intraventricular thrombus, and false and true ventricular aneurysm (Fig. 2). Transesophageal imaging is often necessary to visualize mechanical complications such as muscular rupture.

After several weeks, myocardial infarction results in thinning and increased intensity of the involved segments. A nontransmural myocardial infarction may result in hypokinesia rather than akinesia. Expansion of the infarction zone, global left ventricular dilatation and distortion, together with segmental compensatory hypertrophy, is referred to as postinfarction remodeling. Due to left ventricular dilatation and/or ischemia, mitral regurgitation is often present in ischemic cardiomyopathy. Doppler interrogation of the mitral filling pattern helps guide therapy, including diuretics. Depressed left ventricular ejection fraction, mitral regurgitation, and restrictive mitral filling pattern are associated with a poor prognosis and cardiac death.

Islet Cells Transplantation

In pancreatic islet transplantation, pancreatic cells are taken from a donor and transferred into the recipient. In this procedure, islet is removed from pancreas of a deceased donor by means of specialized enzymes. A typical transplant requires about 1 million islets, equal to two donor organs. Because the islets are extremely fragile, transplantation occurs immediately after they are removed. The surgeon uses ultrasound to guide placement of a catheter through the upper abdomen and into the liver; the islets are then injected through the catheter into the liver. Then cells attach to new blood vessels and begin releasing insulin. Nowadays the procedure is still experimental and more research is needed to answer questions about how long the islets will survive and how often the transplantation procedure will be successful.

Neuroendocrine tumors of the pancreas

Definitions

Neuroendocrine tumors of the pancreas, or islet cell tumors, are rare pancreatic tumors. Among clinically functioning islet cell tumors of the pancreas, insulinoma is the most frequent; others, such as glucagonomas, VIPomas (tumors producing vasoactive intestinal peptide, VIP), somatostatinomas, PPomas (tumors producing pancreatic polypeptide), GFRomas (growth factor releasing hormone tumors), and others, are very rare. Some neuroendocrine tumors secrete more than one hormone, whereas approximately 15–20% of islet cell tumors do not secrete any hormones and are called nonsecreting tumors. They may be single or multiple and benign or malignant. Islet cell tumors may appear multiple, especially in case of multiple endocrine neoplasia (MEN), and are most often found in the pancreas. An extrapancreatic location is reported with a frequency of 10% for gastrinomas; extrapancreatic insulinomas are very rare. ▶Pancreatic carcinoid tumors, producing serotonin, are exceedingly rare. Patients with von Hippel–Lindau's disease are more prone to the development of tumors such as pheochromocytoma and neuroendocrine pancreatic tumors (1, 2).

Pathology/Histopathology

The most common islet cell tumor is insulinoma. About 70% are solitary adenomas, 10% are multiple adenomas, and 10% are carcinomas, whereas the remainder are a mixed group of diffuse hyperplasia of the islet and adenomas occurring in ectopic pancreatic tissue. Adenomas are usually encapsulated and histologically composed of cords of well-differentiated beta cells with typical granules. Malignant tumors show anaplasia; local invasion and spread to the local lymph nodes occur. Other islet cell tumors are similar in histology and differ in content of granules, which may be identified by means of immunohistochemistry (1, 2).

Clinical Presentation

Insulinomas are most common between the fifth and seventh decades of life. The typical clinical feature is hypoglycemia due to uncontrolled insulin secretion. Symptoms related to recurrent hypoglycemia are headache, slurred speech, psychological alterations, visual disturbances, confusion, and, eventually, coma and death. The body tries to compensate for the hypoglycemia by secreting catecholamines, which can result in tremulousness, diaphoresis, palpitations, cardiac arrhythmias, and irritability. Because symptoms due to hyperinsulinism develop early, insulinomas are usually <15 mm in size and solitary at the time of diagnosis; however, multiple tumors are found in 10% of cases, especially in patients with Wermer syndrome or MEN type I (1, 2).

Gastrinomas are the second most common hormone-secreting tumor of the pancreas. They occur more frequently in men than in women. In 30–50%, gastrinomas are associated with other disorders as a part of the

MEN I syndrome. Approximately 90% of all gastrinomas are found in the "gastrinoma triangle," an area limited by the junction of the cystic and common bile duct, the junction of the body and neck of the pancreas, and the second and third portions of the duodenum. Gastrinomas can also be found outside the pancreas, which has never been described for insulinomas. Approximately 60% of all gastrinomas are malignant. Gastric and/or duodenal ulcers develop in the majority of patients due to uncontrolled secretion of gastrin, which is called the Zollinger–Ellison syndrome. Patients with gastrinoma commonly complain about midgastric pain; and diarrhea and weight loss are present in at least 40% of patients. In approximately one-third of the patients, esophagitis is found (1, 2).

The glucagonoma syndrome is a combination of diabetes mellitus and necrolytic migratory erythema. Glucagonomas are single and slow-growing tumors, with metastatic spreading in more than 75% of cases at the time of the diagnosis, most commonly to the liver and the bones. Glucagonomas have been reported in patients suffering from MEN I. A fasting plasma level of glucagon of more than 1,000 ng/L establishes the diagnosis. An erythematous, raised, sometimes psoriatic, and ultimately crusted skin rash has been described in association with glucagonoma. The face, abdomen, perineum, and distal extremities are often the affected portions of the body. After resolution, the regions of acute eruption usually remain indurate and hyperpigmented. Others symptoms, such as glossitis, stomatitis, angular cheilitis, dystrophic nails, and hair thinning, have also been described. The diabetes is mostly mild or even asymptomatic and may manifest only as an abnormality on an oral glucose tolerance test. Weight loss, hypoaminoacidemia, anemia, and thromboembolic disease can also occur in association with this syndrome. Due to the unspecific and often very mild symptoms, these tumors usually are large at the time of diagnosis (1, 2).

Verner and Morrison described a syndrome of watery diarrhea, hypokalemia, hypochlorhydria, and renal failure in association with non-beta-cell tumors of the pancreatic islets. The clinical features are caused by the high levels of VIP secreted by the tumors. The typical manifestations of VIPoma include secretory diarrhea, profound weakness, hypokalemia, and hypochlorhydria. High plasma VIP levels in combination with a stool volume of least 1 L/day are indicative for a VIPoma. The majority of VIPomas are located in the pancreas. In contrast to insulinomas and gastrinomas, they grow to a considerable size before becoming clinically apparent. Although slow-growing, VIPomas usually are malignant and accompanied by metastases in approximately 60% of cases (1, 2).

Somatostatinomas are extremely rare endocrine tumors. The classic triad of somatostatinoma syndrome includes diabetes mellitus, steatorrhea, and cholelithiasis. These symptoms derive from the inhibitory actions of somatostatin, including inhibition of insulin release, pancreatic enzyme and bicarbonate secretion, and gallbladder motility. Like glucagonomas and VIPomas, somatostatinomas are usually single, large, and malignant (1, 2).

No specific syndrome has been associated with pancreatic polypeptide (PP)-secreting tumors. Possible clinical symptoms of PPomas include rash-like efflorescences, weight loss, jaundice, and abdominal pain. The lack of specific symptoms is the reason such tumors are often diagnosed at a stage when they have a mass effect (size >5 cm). The diagnosis can be established by measuring fasting circulation levels of PP (1, 2).

Nonsecreting islet cell tumors are often considerably large at the time of diagnosis compared to hormone-secreting tumors. Because of their mass effect, they cause symptoms such as abdominal pain, jaundice, bowel obstruction, and weight loss. In most cases, nonsecreting islet cell tumors are solitary lesions, being malignant in more than 80% (1, 2).

Imaging

On ultrasound (US), most of the endocrine pancreatic tumors appear as small, round, hypoechoic lesions compared with the pancreatic parenchyma. Larger tumors, which usually do not secrete any hormones and thus do not cause any symptoms at an early stage, may present with a heterogeneous pattern due to necrosis, calcifications, or hemorrhage. Invasion of the peripancreatic structures, hepatic and lymph nodes metastases, and peritoneal carcinosis are more common in nonsecreting malignant tumors. Due to the low specificity of US, other imaging techniques are a necessity in cases of any positive findings in the US examination. However, the use of harmonic imaging and US contrast agents may improve sensitivity. Endoscopic ultrasound (EUS) imaging of small islet cells tumors of the pancreas is more sensitive than transabdominal US. At intraoperative ultrasound (IOUS), the sonographic appearance of islet cell tumors is identical to that of transabdominal US. With high-frequency scanners, the sensitivity of IOUS is very high (3, 4).

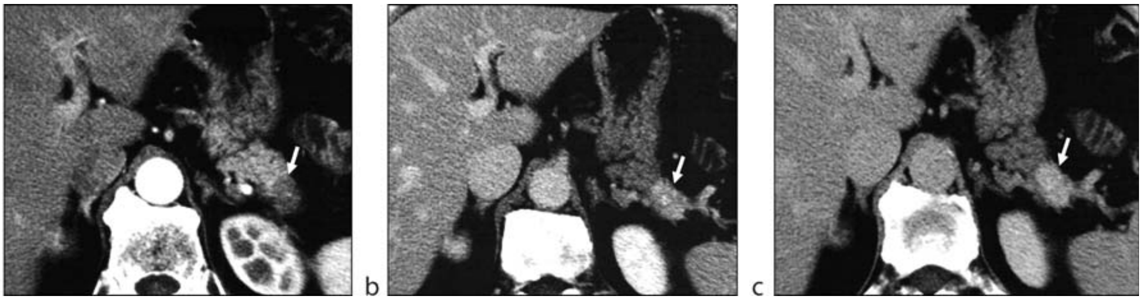
Computed tomography (CT) is widely used to identify and localize islet cell tumors. Single or multislice spiral CT scanners represent the standard equipment. The typical scanning protocol consists of several phases (at least three), including a precontrast phase for detecting hypodense lesions, cystic lesions or calcifications; early arterial and pancreatic phases for detecting hypervascular lesions; and a portal-venous phase for detecting hypovascular lesions, being isodense at the precontrast scan or arterial phase scan. In some cases, a further scan in the delayed phase may demonstrate a late enhancement, particularly in malignant tumors. For examination of the pancreas, slice thickness may vary between 1 and 3 mm. Typically, 120 mL of highly concentrated contrast agent is administered intravenously at an injection rate of 3–5 mL/sec. Additionally, the previous administration of 1,000 mL of water as a “negative” oral contrast as well as the administration of intravenous butyl scopolamine or glucagon may help detect small lesions in the pancreatic head and define their relationship with the duodenum. Islet cell tumors typically appear hyperdense compared with the surrounding tissue at the early arterial and pancreatic phases (Fig. 1). Large, mostly nonsecreting tumors may be centrally hypointense at the arterial and portal-venous phases due to a central necrosis. Sometimes, tumors can be detected even at the precontrast phase because of microcalcifications. Malignant islet cells tumors may require a scan in the delayed phase to demonstrate a late enhancement (Fig. 2). Rarely, an islet cell tumor may present as a cystic lesion. Without a specific clinical syndrome (and/or elevation of a specific hormone), the typical hyperdense appearance may be not sufficient for differentiating an islet cell tumor from other pancreatic lesions. The main advantage of CT is the possibility to stage malignant lesions by identifying local spread and distant metastases (3, 4).

At magnetic resonance (MR), islet cell tumors appear to be hypointense on T1-weighted images and hyperintense on heavily weighted T2-weighted images. Using intravenous gadolinium-DTPA may help differentiate hyperintense islet cell tumors from the normal-enhancing pancreatic tissue. The use of mangafodipir trisodium (MnDPDP) also may help to increase diagnostic sensitivity. Additionally, MR cholangiopancreatography (MRCP) can be used to depict an obstruction of the common bile duct or the main pancreatic duct as an indirect sign for a malignant tumor; however, it does not help differentiate islet cell tumors from other pancreatic neoplasms (3, 4).

Nuclear Medicine

Nuclear medicine is useful for tumor imaging and staging because neuroendocrine tumors express peptide hormone receptors on their membranes, and radiolabeled compounds can bind to such receptors. Over the last decade, a

Islet Cells Tumors, Pancreatic. Figure 1 Multidetector computed tomographic study of typical insulinoma of the pancreatic tail. The nodule (*arrows*) appears hyperdense in the early arterial (a) and pancreatic (b) phases, with wash-out and a hypodense appearance in the venous (c) and delayed (d) phases.



Islet Cells Tumors, Pancreatic. Figure 2 Multidetector computed tomographic study of malignant islet cells tumor of the pancreatic tail. The nodule (*arrows*) appears hypodense in the arterial phase (a) with a late enhancement in the venous (b) and delayed (c) phases.

somatostatin analog labeled with indium-111, ^{111}In-DTPA-D-Phe^1-octreotide, has been made available, exhibiting efficient uptake at tissues with high-density receptors for somatostatin. Scintigraphy with ^{111}In-DTPA-D-Phe^1-octreotide has been used for evaluating several types of cancer, especially neuroendocrine tumors, as well as medullar thyroid carcinomas, small cell lung cancer, and a certain fraction of breast cancers. In terms of diagnostic accuracy, scintigraphy with ^{111}In-DTPA-D-Phe^1-octreotide has shown satisfactory results only in the study of neuroendocrine tumors. Scintigraphic investigation envisages the intravenous administration of 111–148 MBq (3–4 mCi) of ^{111}In-DTPA-D-Phe^1-octreotide and "total body" acquisition after 4 and 24 h postinjection. Single photon emission computed tomography (SPECT) should be performed in all patients, preferably at 24 h. In some patients, a 48-h acquisition may be necessary to evaluate unclear accumulation in the abdomen. All images should be obtained with a large-field-of-view gamma camera equipped with a medium-energy parallel-hole collimator (3, 4).

Diagnosis

History taking, clinical examination, and laboratory tests are the basic tools to make up the diagnosis, especially in hormone-producing tumors causing typical symptoms.

Inactive endocrine tumors are generally at an advanced stage of disease at the time of their diagnosis because they become symptomatic only due to their mass effect or, in malignant cases, due to their metastases.

The role of imaging is to localize, demonstrate the extent of, and stage the lesion. Most islet cell tumors are easily identifiable by modern cross-sectional imaging techniques.

Juvenile aseptic bone necroses; Juvenile avascular necroses

Definitions

In principle, the same definition applies to juvenile osteonecrosis as is used for adult osteonecrosis. The prevalence of these osteonecroses is limited to childhood and adolescence. It is an avascular, ischemic necrosis found at the epiphyseal and subarticular region.

Pathology/Histopathology

The anatomy and histology of the articular and subarticular region are important for understanding the pathophysiology of osteonecrosis. The adult pattern of vascular supply usually becomes established at the age of 18 years with the closure of the endplate (1). The number of subchondral vessels (arterial vessels, capillaries, sinusoids, and venous vessels) at the base of the articular hyaline cartilage reaches their highest level with adolescence and decline by approximately 20% until the seventh decade of life. This vascular bed of the subchondral regions is very important for the nourishment of the base of the articular cartilage.

Special vascular supplies, different from adult vascularization, have a great impact on the development of osteonecrosis. For example, the growth plate represents an effective barrier preventing anastomoses between the femoral head and femoral neck.

Necrosis of the trabeculae and marrow is found histologically, which can lead to flattening and collapse of bones. In this case compression of trabeculae and intertrabecular detritus is observed. In the case of healing, viable bone is deposited on dead trabeculae with reconstitution of intertrabecular marrow.

Clinical Presentation

The clinical symptoms depend on the anatomic location of the osteonecrosis. One of the most important juvenile osteonecroses is Perthes' disease. The clinical manifestation is characterized by limping, pain and limitation of joint motion, particularly on abduction and internal rotation of the hip. Even atrophy of the soft tissues of the thigh, muscle spasm, and contractures can be found. The differential diagnosis can be acute irritable hip syndrome with transient synovitis, which is, however, a self-limiting disease. The cause of transient synovitis of the hip and the relationship to Perthes' disease are not clear. Patients with Freiberg's infarction may present with local pain, soft tissue swelling, and limitation of motion of the affected metatarsophalangeal joint. In Köhler's disease the foot may be held in a slight varus position and the patient walks on the outer side of the foot. Again, localized pain and swelling are the main clinical features.

Imaging

Basically, standard radiographs still have to be used in the diagnosis of juvenile osteonecrosis. Soft tissue swelling on the lateral side of articulation is characteristic. Every second patient may present with smallness of the femoral ossification nucleus in Perthes' disease. Lateral displacement and even flattening and sclerosis of the femoral ossification nucleus are further findings. Ultrasound can be used for the detection of a joint effusion and joint space widening, which is, however, unspecific and can be found in a variety of clinical conditions. Radiographs are not suitable for early diagnosis because in the initial stages usually no radiographic abnormalities are found. Due to its unbeatable sensitivity for bone marrow changes including visualization of necrotic tissue, magnetic resonance imaging ►(MRI) is the imaging modality of choice for early diagnosis (2) (Fig. 1a, b). Signal intensities of the femoral epiphysis in Perthes' disease are usually reduced on T1- and T2-weighted MR images (3). MRI may reveal findings consistent with transient bone marrow edema, which may be a precursor for Perthes' disease. Further findings are a thickening of both the femoral and acetabular articular cartilage with subsequent lateralization of the hip. In patients with Freiberg's infarction a serpentine region of lowered signal intensity can be found in the head of the second metatarsal bone on T1-weighted images, with surrounding bone marrow edema on T2-weighted sequences and an associated joint effusion. In Panner's disease a low-signal intensity demarcation of the capitulum humeri is characteristic on T1-weighted images with a hyperintense edema on short T1 inversion recovery (STIR) images representing bone marrow edema in early phases of the disease.

Nuclear Medicine

Reduction of blood flow appears as a "cold" spot on radionuclide studies in patients with osteonecrosis. Comparative studies with MRI using a dynamic gadolinium-enhanced subtraction technique and bone scintigraphy demonstrated good agreement between both techniques in the depiction of epiphyseal necrosis in Legg-Calvé-Perthes disease (4). MRI is nowadays widely accepted as a nonionizing substitute for bone scintigraphy, which is especially relevant in juvenile patients.

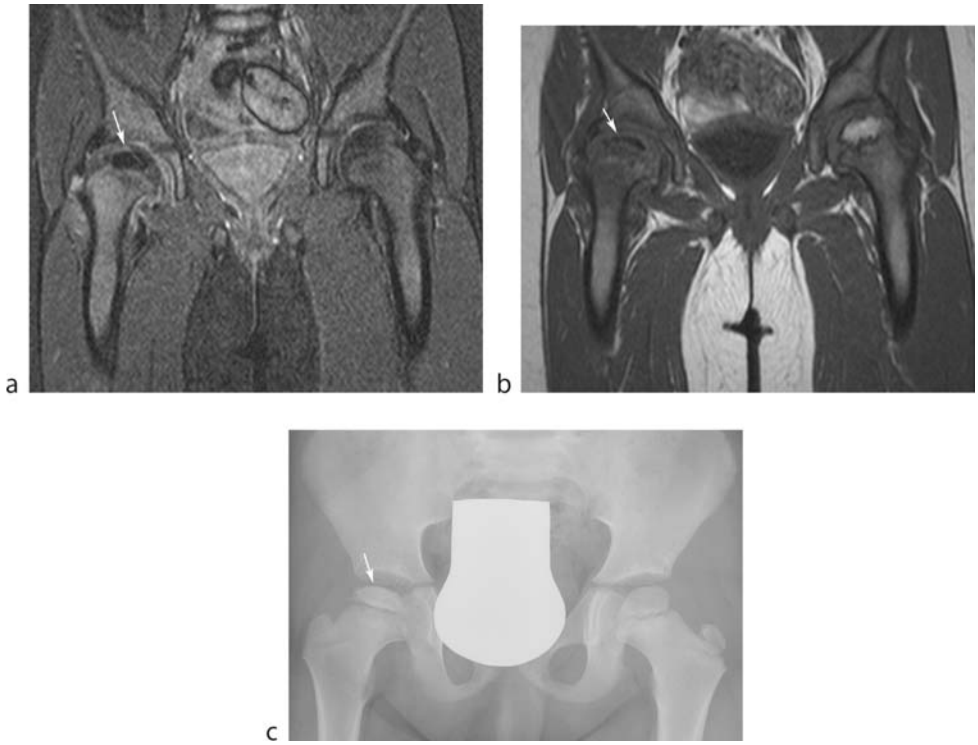
Diagnosis

The most common sites for juvenile osteonecrosis are the femoral head, the navicular bone, the head of the second metatarsal bone, and the capitulum of the humerus.

Legg-Calvé-Perthes disease affects children, particularly those between the ages of 4 and 8 years. The disorder is more frequent in boys than girls with a ratio of approximately 6:1. Bilateral abnormalities are detected in about 10–20% of cases. In cases in which both hips are involved, the two hips are usually affected sequentially, not simultaneously.

The early radiographic signs include soft tissue swelling due to an effusion, diminutive femoral head ossification center with lateral displacement, fissuring/fracture, flattening, and sclerosis (Fig. 1c).

The pathologic basis of the above-mentioned radiographic signs is osteonecrosis. Necrosis of the marrow and trabeculae is observed with a resulting collapse and compression of the trabeculae and flattening of the joint surface. Healing is characterized by revascularization of the marrow starting from the periosteal and ligamentum teres vessels. Reconstitution of intratrabecular marrow



Juvenile Osteonecroses. Figure 1 (a) Coronal MRI (STIR) demonstrates marked signal reduction of the right femoral head in ►Legg-Calvé-Perthes disease. (b) Coronal MRI (T1-SE) demonstrates marked signal reduction of the right femoral head in Legg-Calvé-Perthes disease. (c) Anteroposterior view of the pelvis shows flattening of the right femoral head with sclerosis in Legg-Calvé-Perthes disease in a 5-year-old girl.

and the trabeculae is almost always complete, but some degree of flattening of the head and shortening and broadening of the femoral neck is not unusual. The synovialis may show reactive inflammatory changes in the acute phase.

The etiology of the osteonecrosis is based on vascular insufficiency. The factors leading to the deficient blood supply have not been precisely identified. One explanation is the change of vascular supply in this age group. Before the age of 4 years, two groups of vessels are left (superior and inferior retinacular arteries). Between the ages of 4 and 7 years, the importance of the lateral epiphyseal vessels is established as the metaphyseal and fovea vessels decrease. After the age of 8 years, the importance of the ligamentum teres vessels increases again. The open growth plate prevents anastomosis between the vessels of the neck and the head. This vessel reorganization during the period of 4–7 years and possible failures in this reorganization do not explain the male prevalence of the disease. A second theory stresses the posttraumatic etiology. Direct repetitive compression leads to subchondral fractures. Traumatic synovitis with effusion could lead to compression of the adjacent vasculature with infarctions leading to osteonecrosis.

Finally, a genetic cause has been discussed. This genetic and developmental factor may lead to alterations in the blood vessels or (and) to a localized abnormal maturation of epiphyseal cartilage that is responsible for the delay in the skeletal maturation, which is also a very typical feature in Legg-Calvé-Perthes disease.

A better prognosis is observed in boys and younger patients, perhaps indicating that a longer elapsed time before skeletal maturity allows more extensive remodeling and healing of the femoral head.

Grading and classification systems try to stage the different disease phases, the extent, and the end result of the disease.

The four stages are characterized by: 1. epiphyseal irregularity, dislocation, and increased density, 2. epiphyseal fragmentation, 3. increasing homogeneity, and 4. normal ossification or deficient healing.

The extent of disease is graded according to Caterall in four groups:

Patients in groups 3 and 4 have a poorer prognosis, in general. It is, however, evident that no simple radiologic observation is indicative of a good or poor result, and that a combination of clinical and radiologic findings must be used for prognostic accuracy.

Besides standard radiographs, MRI is applied for early diagnosis and follow-up of the disease. With bone scintigraphy the reduced or missing uptake of the radioisotope in the head of the femur is indicative of the onset of the disease. The increasing radioisotope uptake parallels the healing process; however, bone scintigraphy has been largely replaced, as stated above.

As in the adult type of osteonecrosis, MRI is ideally fitted for the early detection and follow-up of Legg-Calvé-Perthes disease. The missing ionizing radiation is another important advantage of this modality. Moreover, it allows direct visualization of neighboring bone marrow changes. One important feature is thickening of cartilage and loss of containment of the femoral head within the acetabulum (5). Thickening and contrast enhancement of the synovial structures with effusion are other typical MRI findings.

In dislocations of the femoral head and slipped epiphysis, the ligamentum teres vessel and the retinaculum vessels may be torn, resulting in diminished blood flow.

Dislocation of the hip joint is a common complication of acetabular fractures, too. Osteonecrosis has been reported in as many as 10–20% of patients with hip dislocation. Reposition has to be done within 6 h after the trauma to minimize the risk of osteonecrosis development.

Freiberg's Disease

Women are predominantly affected by a factor of 5:1. Most commonly it is found in the age group of 13–18 years. Typically, the head of the second metatarsal bone is involved, but it may also be found in any other metatarsal heads. The disease is unilateral. MRI reveals a localized subchondral marrow edema with flattening of the cortical endplate and fragmentation. Radiographic abnormalities include subtle flattening, increased radiodensity, and cystic lucent areas. The process ends with deformity, defect healing, and collapse of the bone. Complete healing can be seen, even after many years (Fig. 2).

Juvenile Osteonecroses. Figure 2 Anteroposterior view of the right foot with flattening of the head of the second metatarsal bone (Freiberg's disease).

Juvenile Osteonecroses. Figure 3 Lateral view of the left foot with collapse of the navicular bone (Köhler's disease) in a 5-year-old boy.

Köhler's Disease

The relationship between Köhler's disease of the tarsal navicular bone and osteonecrosis has not been defined. Its etiology could go back to an altered ossification or a vascular insufficiency. It affects more boys than girls (5:1) and is found in the age between 3 and 7 years. Unilateral involvement is seen in 80% of all cases. In one-third of all cases an additional trauma can be elicited. Some authors believe it is not a disease at all, but only an altered sequence of tarsal ossification. The "disease" is self-limiting and reversible. The imaging findings are the same as those described in the other bones (Fig. 3).

Panner's Disease

It is a rare disease involving the capitulum of the humerus. It appears usually between the age of 5 and 10 years. Boys are almost exclusively affected. It may be found in patients with chronic trauma. Bilateral involvement is rare; it is most likely that, similar to Legg-Calvé-Perthes disease, a change in the vascularization because of maturation makes the capitulum especially vulnerable to mechanical trauma.

KUB

▶ Kidney, Ureter, Bladder Plain Film

Kulchitsky Cell

Or synonym *enteroendocrine cell* contains granules that may be either argentaffinic or argyrophilic. They are scattered throughout the digestive tract, are of several varieties and are believed to produce more than 20 gastrointestinal hormones and neurotransmitters.

▶ Neoplasms of the Chest in Childhood

Kyphoscoliosis

A curvature of the spine that is backward and lateral.

▶ Neurofibromatosis, Musculoskeletal Manifestations

Laceration, Hepatic

Hepatic lacerations represent the most common form of hepatic injury. These lesions can be single or multiple and tend to involve hepatic parenchymal areas contiguous to intrahepatic portal vascular branches and suprahepatic veins; in particular, typical lacerations are parallel to hepatic veins or the posterior segmental right branch of portal vein. The cause of injury is the "shaking" forces that operate near the central vascular structures.

A large range of severity must be distinguished in lacerative lesions of the liver, including small and superficial lesions of the hepatic capsule (capsule tears), lacerations involving the central portal triad (deep lacerations), and major deep lacerations extending between two margins of the organ (hepatic fracture). Hepatic lacerations can, occasionally, slightly increase in size within the first week, also becoming less sharply defined; however, they usually disappear within 4–6 months.

Hepatic laceration is a typical lesion appearing as a nonenhancing linear streaking area on contrast-enhanced computed tomography. Appearances on ultrasound of hepatic laceration change with time: it initially appears slightly echogenic, becoming hypoechoic or cystic after several days.

▶Trauma, Hepatobiliary

Laceration, Splenic

A splenic parenchymal lesion with a linear or branching appearance that may reach the splenic margins without completely traversing the parenchyma.

▶Trauma, Splenic

Lactating Adenoma

Benign tumor that occurs during pregnancy or the puerperal period. It is composed of compact aggregates of lobules with secretory hyperplasia.

▶Adenoma, Breast

Laennec's Cirrhosis

Hepatic cirrhosis in which increased connective tissue spreads out from the portal spaces compressing and distorting the lobules, causing impairment of liver function, and ultimately producing the typical hobnail liver.

▶Cirrhosis, Hepatic

Lamina Dura

The radiographic dense line that surrounds roots of erupted teeth and all of not yet erupted teeth is washed out in hyperparathyroidism and several other conditions, including Langerhans cell histiocytosis and local periapical infection.

▶Battered Child Syndrome

Laminectomy

▶Radicular Syndrome of the Spine, Surgical Therapy for

Langerhans Cell

Langerhans cell histiocystosis (LCH) contain granulomatous lesions containing characteristic Langerhans cells.

Definition

Inflammatory diseases of the larynx may be of infectious or noninfectious origin. Acute infections present with a sudden onset and develop symptoms like fever and respiratory distress. Chronic infections develop over a longer period and present with hoarseness and pain.

Acute infections of the larynx are predominately relatively harmless viral infections but hazardous infections like ►laryngotracheitis (croup), ►epiglottitis, and diphtheria must be taken into consideration, because the latter can be lethal especially for children. Angioneurotic edema causing inspiratory stridor affects adolescents and adults more commonly than children.

►Chronic laryngitis develops over weeks to month and the dominant symptoms are hoarseness and pain caused by exogen factors (cigarette smoking, occupational contact with toxic fumes, voice abuse, gastroesophageal reflux disease), granulomatous and fungal infections. Systemic diseases involving the larynx are rheumatoid arthritis, sarcoidosis, Wegener's granulomatosis, and ►amyloidosis. Radiation therapy induces inflammatory changes of the laryngeal mucosa and submucosal tissue, which usually decrease within the first 6 months after completion of the therapy but may persist for years.

Pathology and Histopathology

►*Acute unspecific laryngitis* is usually caused by viruses (rhinovirus, influenza and parainfluenza virus, coxsackie virus, adenovirus, and respiratory syncytial (RS) virus), which can be associated with group A streptococcus, *Staphylococcus*, hemophilus influenzae, or *Moraxella catarrhalis*. Less common causes are thermal, allergic, or chemical inhalative substances. Serous–mucous, purulent–catarrhal, or fibrinous–purulent inflammatory changes may be observed. Pseudomembranous-necrotizing inflammation is characteristic for diphtheria.

Laryngotracheitis or croup is an infection of the subglottic larynx in the age group of 3 months to 3 years and usually is caused by a parainfluenza virus (type 1), less common are RS virus and type A influenza virus. Rapid onset of inflammatory edema of the cricovocal membrane and cranial trachea cause severe airway narrowing. *Epiglottitis* or supraglottitis occurs in an older age group (2–4 years), but can also occur in the adult population and is commonly caused by hemophilus influenza type B (HIB). In the adult population, hemophilus parainfluenzae, *Streptococcus pneumoniae*, group A streptococcus, or *Staphylococcus aureus* is also common, but there is also a high rate of negative blood cultures. Epiglottitis causes inflammation and swelling of the epiglottis, vallecula, arytenoids, and aryepiglottic folds.

Angioneurotic edema is characterized by episodes of increased capillary permeability with extravasation of intravascular fluid and subsequent edema of the cutis or mucosa of the upper airways or gastrointestinal tract. Hereditary angioneurotic edema is caused by a C1-esterase inhibitor deficiency. Allergic edema is caused by drugs (amongst others angiotensin-converting enzyme inhibitors and ionic contrast material) and food.

Tuberculosis of the larynx is rare but gained increasing importance in immunocompromised patients. The larynx is most often infected through bronchogenic spread from active lung disease but may also be affected lymphogenic or hematogenous. Mucosal hyperemia and thickening, nodules and ulcerations can be found at laryngoscopy and deep biopsy is required to exclude carcinoma. Biopsy reveals acid-fast bacilli and cultures should be performed to confirm diagnosis.

Other granulomatous diseases include Wegener's granulomatosis, sarcoid, pemphigus, leprosy, and numerous mycotic infections. Wegener's granulomatosis is characterized by necrotizing granuloma affecting the upper respiratory tract, lung, and kidneys. Laryngeal involvement is rare, mucosa ulceration and bone destruction as well as glottic and subglottic stenosis can result. Sarcoid usually affects the supraglottis, less commonly the glottis and subglottis. It may present as an isolated submucosal mass, indistinguishable from tumor.

Rheumatoid arthritis can affect the cricoarytenoid and cricothyroid joints as well as other synovial joints in the body.

Relapsing perichondritis is a rare inflammatory disease of unknown etiology. The cartilages of the ear, nose, larynx, trachea, and joints can be affected. Initially, edematous soft tissue around the cartilage is found with progression to cartilage destruction and collapse.

Amyloidosis is not a single entity but rather a group of diseases characterized by the presence of extracellular deposition of amyloid in tissues. Less than 1% of all benign tumors in the larynx are amyloidomas. The supraglottic larynx is the most commonly involved region, amyloid deposits are located in the submucosa. Yellow-reddish tumorlike lesions with vitreous consistency can be found at inspection.

Gastroesophageal reflux disease (GERD)-related laryngitis or reflux laryngitis is common, but the prevalence varies considerably in the literature. The presence of gastric acid in the larynx can cause inflammation in the posterior larynx, especially in the interarytenoid region, aryepiglottic folds, and posterior cord area. In laryngoscopy, edema and erythema can be found as well as mucosal ulcerations in the posterior larynx.

Radiotherapy (RT) frequently induces edema and chronic inflammatory disease. Histologic findings are an acute inflammatory reaction with leukocytic infiltration, histiocyte formation, necrosis, and hemorrhage. Smaller vessels demonstrate detachment of the lining endothelial cells causing increased permeability resulting in interstitial edema. Deposition of collagenous fibers is found in the following 1–4 months, leading to sclerosis and hyalinosis of connective tissues. This inflammatory process eventually results in obstruction in the small arteries, veins, and lymphatics. By 8 months, there is advanced sclerosis, hyalinosis, and fragmentation of the collagen fibers. The formation of collateral capillary and lymphatic channels may reduce interstitial fluid.

Clinical Presentation

Acute unspecific laryngitis is characterized by dysphonia and dry cough. In advanced cases, pain and dysphagia may occur.

Laryngotracheitis has a gradual onset and typical symptoms are stridor and barking cough.

Epiglottitis or supraglottitis typically present with a sore throat and painful dysphagia/inability to swallow, along with stridor and dyspnoea. The onset is sudden with a rapid progression. Epiglottitis is a life-threatening condition because total airway obstruction may occur very rapidly.

Angioneurotic edema is characterized by recurrent edema of the face, respiratory, and gastrointestinal tract. The episodes occur spontaneous without concomitant symptoms and last for 2–3 days causing inspiratory stridor.

Tuberculosis present with dysphonia, dysphagia, and sore throat.

Wegener's granulomatosis, sarcoid, pemphigus, leprosy, mycotic infections and *rheumatoid arthritis* can present with hoarseness and dyspnoea but other organ manifestations usually cause the leading symptoms.

Relapsing perichondritis shows a prolonged course, increased subjective discomfort and typical pain on palpation.

Amyloidosis rarely affects the larynx. Symptoms are hoarseness and dyspnoea. *Gastroesophageal reflux disease* (GERD)-related laryngitis or reflux laryngitis present with chronic hoarseness, sore throat, chronic cough, dysphagia, or globus.

Radiotherapy (*RT*) frequently induces edema and mucositis leading to dyspnoea, dysphonia, and dysphagia. Delayed complications include soft tissue necrosis, osteochondronecrosis, fistula formation, pharyngeal motility dysfunction and strictures, and recurrent laryngeal nerve paralysis.

Imaging

Imaging is only occasionally performed in patients with inflammatory disease of the larynx, most patients are diagnosed clinically. Imaging may be done to exclude foreign bodies, recurrent tumor, and to localize the site of biopsy before performing laryngoscopy. Assessment of complications like abscess formation is another indication for cross-sectional imaging.

Conventional radiographs may be used in the diagnosis of laryngotracheitis (croup) or epiglottitis (supraglottitis).

CT and MRI are helpful to assess the submucosal extent of disease and to detect cartilage involvement. Imaging should be performed prior to biopsy in order to avoid misinterpretation of biopsy trauma and underlying disease.

High-resolution MRI is more sensitive to soft tissue changes than CT, but suffers from motion artefacts related to prolonged acquisition time. Fast gradient echo imaging can be performed in patients short of breath, but these patients are preferentially imaged with multislice spiral CT (MSCT) scanners.

The entire larynx can be examined with submillimeter collimation in less than 10 sec, minimizing motion artefacts and allowing phonation scans with MSCT.

Acute unspecific laryngitis is diagnosed clinically.

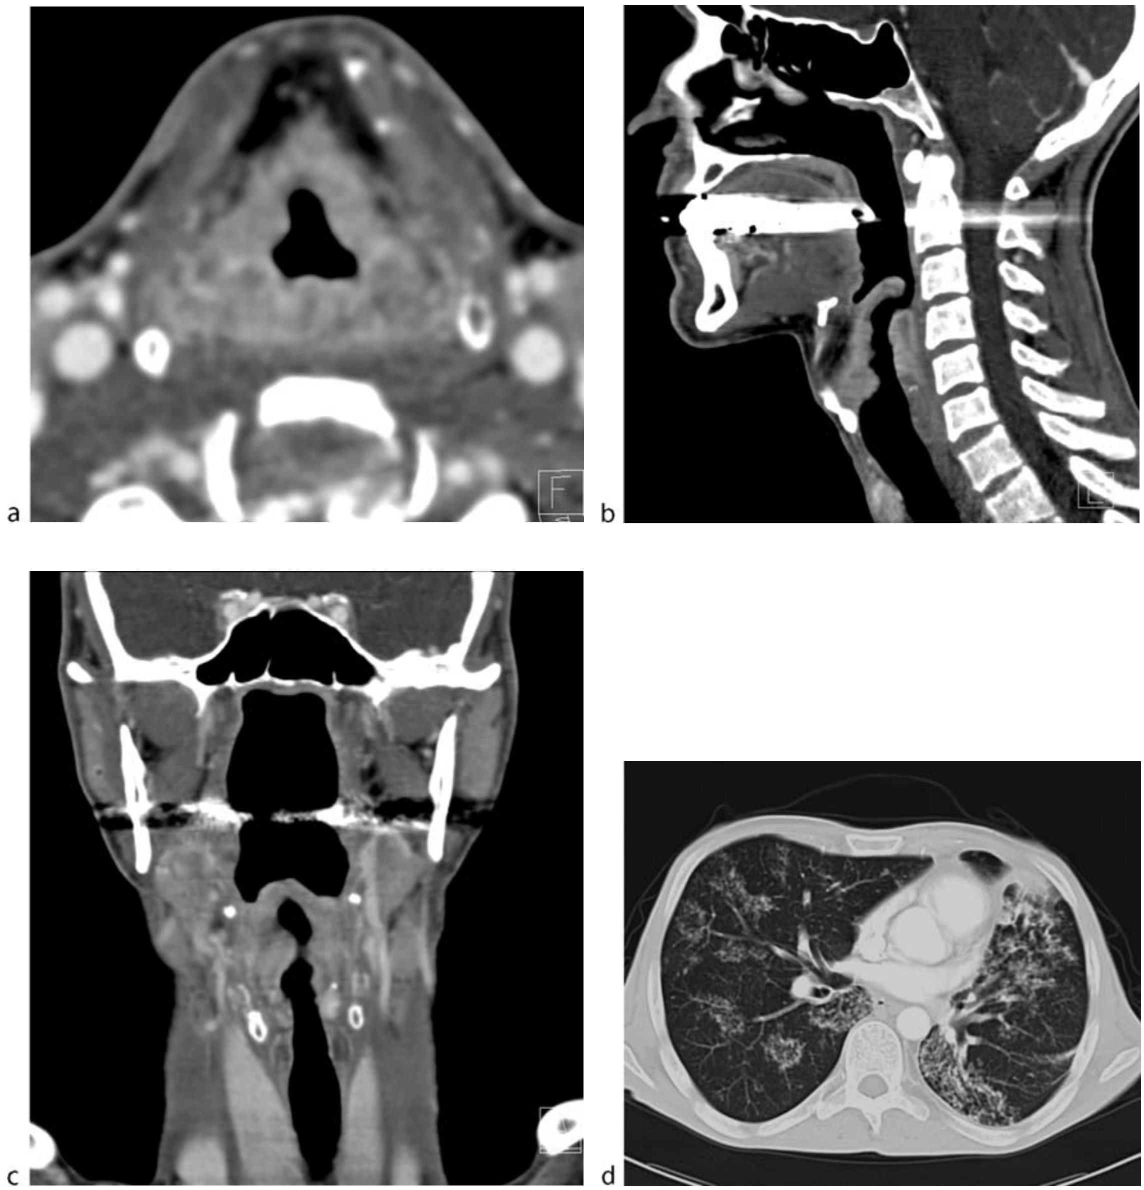
Laryngotracheitis causes mucosal swelling in the subglottic area and can be appreciated on a frontal radiograph as the “wine-bottle” or “steeple” sign. Paradoxical dilatation of the hypopharynx during inspiration should alert the clinician to the diagnosis.

Epiglottitis or supraglottitis is a life-threatening condition because total airway obstruction may occur very rapidly. Therefore the patient must never be out of an environment where emergency tracheostomy can be performed. If imaging is performed, thickening of the epiglottis and supraglottic larynx can be seen on lateral plain films. The thin curvilinear shape is lost ("thumb print sign"), the epiglottis bends into the enlarged aryepiglottic folds and the vallecula looses definition ("vallecula sign"). In severe cases, the arytenoids prominence may be swollen. CT or MRI can be employed in selected cases to exclude abscess formation.

Angioneurotic edema: CT or MRI demonstrates edema of the laryngeal mucosa.

Tuberculosis of the larynx: Imaging features are nonspecific and may be indistinguishable from squamous cell carcinoma. Diffuse or nodular soft tissue thickening with or without infiltration of the paraglottic and preepiglottic spaces and perichondritis can be found (1) (Fig. 1). Diffuse bilateral thickening without destruction of the laryngeal skeleton is common. The cricoarytenoid joint can be involved, causing fixation.

Wegener's granulomatosis, sarcoid, pemphigus leprosy, and mycotic infections: Radiographic findings in granulomatous disease are nonspecific soft tissue thickening and biopsy is required to establish the correct diagnosis.



Larynx, Inflammatory Diseases. Figure 1 ►**Laryngeal tuberculosis: diffuse bilateral thickening of the glottic and supraglottic larynx. (a) Axial section at the level of the false cords demonstrates nodular mucosal thickening with peripheral contrast enhancement. The extent of laryngeal involvement can be appreciated on sagittal (b) and coronal (c) images. Active pulmonary tuberculosis was present (d).**

L

Rheumatoid arthritis: On CT irregular sclerosis or erosion of the joints can be identified.

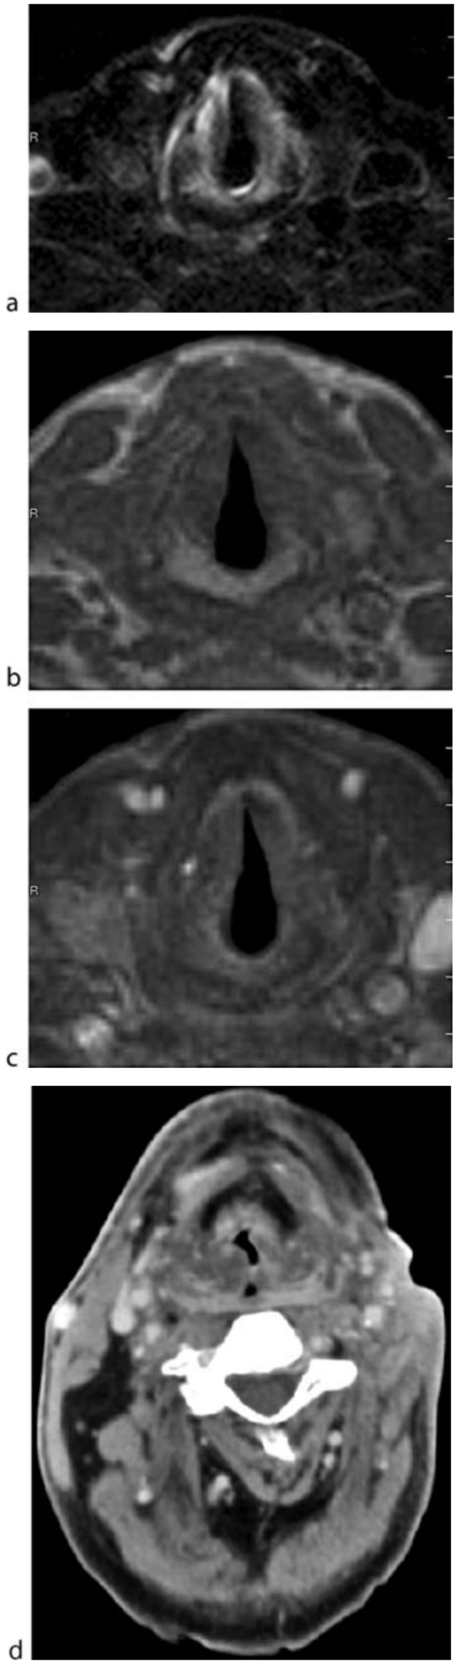
Relapsing perichondritis: Initially, edematous soft tissue around the cartilage is found with progression to cartilage destruction and collapse. Edema and inflammation can present with high signal intensity (SI) on T2-weighted images along the margins of the cartilage. Other imaging findings are cartilage expansion, sclerosis or destruction, and soft tissue calcification.

Amyloidosis: The supraglottic larynx is the most commonly involved region, amyloid deposits are submucosal. The lesions may appear as a well-defined homogeneous mass or diffuse soft tissue infiltration (Fig. 2). Although bone erosion has been described in skull base and spine lesions, cartilage or bone destructions are uncommon in the larynx. Although the amyloid itself does not enhance with contrast material administration, peripheral enhancement can be found with CT or MRI. Enhancement may be caused by the foreign body giant-cell reaction that is evoked by amyloid deposition. Calcification has been described and is best appreciated on high-resolution CT scans. Amyloidosis is isointense to muscle on T1-weighted images and can be hypointense (2) or iso- to slightly hyperintense on T2-weighted images. This may help to differentiate calcified focal amyloidoma from chondrosarcoma, which is markedly hyperintense on T2-weighted images (3).

Gastroesophageal reflux disease (GERD): Imaging findings are nonspecific, demonstrating edematous soft tissue swelling in the posterior larynx.

RT results in radiologic changes that involve both the exolaryngeal and endolaryngeal regions. In the larynx, RT

Larynx, Inflammatory Diseases. Figure 2 Amyloidosis in a patient with multiple myeloma. Extensive amyloid deposition in the supraglottic larynx.



Larynx, Inflammatory Diseases. Figure 3 (continued)

results in thickening of the epiglottis and is typically seen on CT and MRI within 3 months after RT (4). Almost all patients will show increased attenuation in the fat layers, thickening of the aryepiglottic folds and the false vocal cords (Fig. 3). Early changes at the glottic level include increased attenuation of the paraglottic fat planes, typically identified within 2 months following RT. Symmetric subglottic thickening occurs in about 80% of patients. Late changes at the glottic level include thickening of the anterior and posterior commissure. These changes occur within 7 and 14 months, respectively, and are irreversible (5). Unilateral paramedian position of the vocal cord, anteriomedial displacement of the arytenoids cartilage, ipsilateral dilatation of the pyriform sinus, laryngeal ventricle and vallecula, as well as thickening and anteromedial displacement of the aryepiglottic fold indicates recurrent laryngeal nerve paralysis. Soft tissue necrosis and chronic inflammatory disease most often observed within the first two years after RT can be focal and mimic recurrent tumor. Follow-up examinations or biopsy may be required for diagnosis.

Nuclear Medicine

Nuclear scans have a limited role in the assessment of inflammatory lesions of the larynx. Radionuclide bone scans in patients with rheumatoid and collagen vascular disease can be positive over affected joints as well as over the larynx and may be used for primary diagnosis as well as therapy follow-up.

Diagnosis

Diagnosis of inflammatory disease of the larynx is done clinically (including laryngoscopy) and imaging is rarely performed. MRI is more sensitive to inflammatory changes than CT due to better soft tissue resolution. The purpose of imaging is to exclude other causes of stridor such as foreign body aspiration or tumor and to diagnose complications like abscess formation. If abscess is suspected, CT-guided intervention can be performed in the same session. High-resolution CT is recommended in the diagnosis of perichondritis, demonstrating chondral sequestration.

Legg-Calvé-Perthes Disease

First described in 1910, it is an osteonecrosis of the femoral head occurring in young children (4–7 years). The juvenile vascular architecture with a tendency toward critical ischemia plays a major role in this disease.
▶Juvenile Osteonecroses

Leiomyoma, Hepatic

It is a very rare, well-circumscribed, smooth muscle tumor of the liver in some cases associated with human immunodeficiency virus infection. Hepatic leiomyoma does not show peculiar radiological features. On US, it appears as a solid hypoechoic lesion with internal echoes. Unenhanced CT depicts a hypodense lesion with an early peripheral or a delayed homogeneous enhancement. This lesion usually shows a low signal on T1-weighted images and high signal on T2-weighted images with an enhancement pattern that resembles that seen on CT scans.

Synonyms

Uterine fibroid; Myoma; Fibroma; Uterus myomatosus

Definition

Leiomyomas are the most common benign tumors of the uterus. They have been described in up to 40% of woman by the fifth decade of life and are the most common cause for uterine enlargement after pregnancy. Leiomyomas arise from the smooth muscle cells. Over 90% of leiomyomas are located in the corpus uteri and only about 5% are in the cervix. They can rapidly increase in size during pregnancy. After menopause, they normally regress in size and may calcify. A single lesion may be found, but leiomyomas are more commonly multiple and usually variable in size.

Pathology/Histopathology

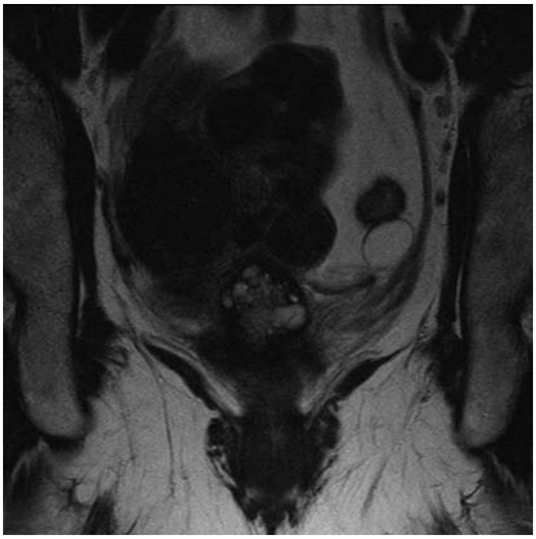
Leiomyomas present macropathologically as well-circumscribed tumors containing muscle and some parts of fibrous tissue. Leiomyomas have a pseudo capsule of areolar tissue. Rarely leiomyomas become cancerous (<0.1%). They are classified according to their location in relation to the uterine wall as intramural, submucosal, subserosal, or in the broad ligament. The intramural location is most commonly seen.

Clinical Presentation

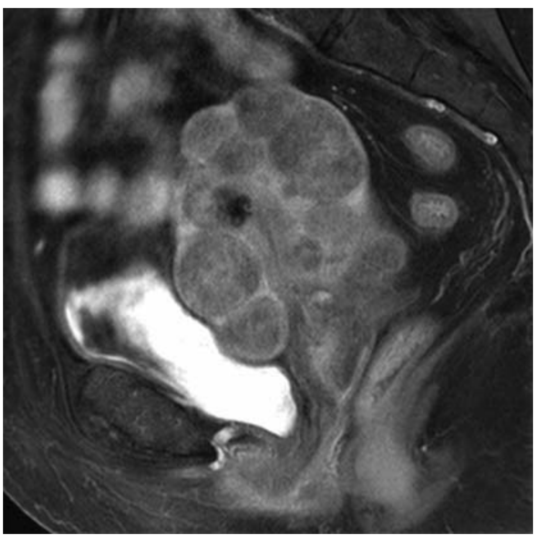
Symptoms usually come from pressure effects due to the large pelvic mass. Leiomyomas can result in pelvic pain, dysmenorrhea, and abnormal uterine bleeding. Submucosal leiomyomas in the uterine cavity can cause infertility, abortion, or hypermenorrhea. Intramural leiomyomas are also associated with infertility. The majority of women with fibroids (up to 80%) has no symptoms. They may grow during the pregnancy and decrease in size after menopause. Subserosal leiomyomas can grow exophytic from the uterus and may undergo a torsion and in this specific situation present as acute abdomen.

Imaging

Transvaginal-ultrasonography (TV-US) remains the primary imaging modality for clinically suspected leiomyomas and normally no further imaging techniques are required. MRI is indicated when sonography results are inconclusive. Sonography is especially limited, if the uterus is retroflexed, with a 20% amount of incorrect diagnosis. MRI is especially useful for diagnosing leiomyomas in patients undergoing work-up for infertility. Furthermore, it is possible to differentiate between leiomyomas and adenomyosis using MR imaging. Prior to myomectomy or embolization, MRI may also be useful to evaluate the location and precise size of leiomyomas. On MRI, leiomyomas present as well-circumscribed masses of similar or slightly low T1 and low T2 signal intensity



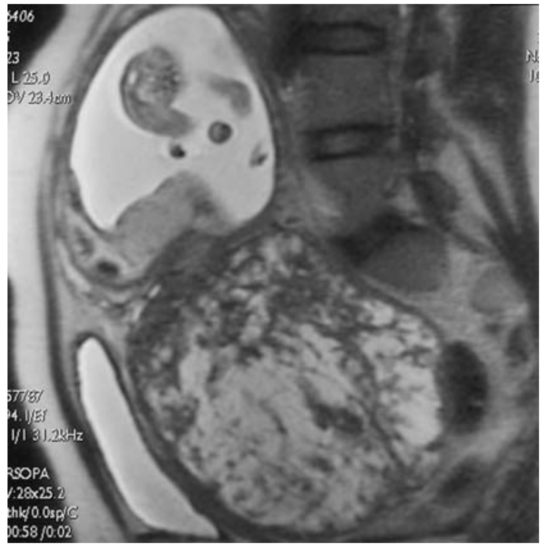
Leiomyoma, Uterus. Figure 1 **Coronal T2 weighted MR image of uterus with multiple low intense leiomyomas.**



Leiomyoma, Uterus. Figure 2 **Sagittal contrast enhanced MR image demonstrate the relative homogenous enhancement of the uterine myomas.**

relative to the myometrium (Fig. 1). They show as a diffuse homogeneous enhancement after intravenous gadolinium administration (Fig. 2). The enhancement is less pronounced than that of the adjacent normal myometrium. Degenerative leiomyomas present in MRI as inhomogeneous on T2 weighted images and often with areas of T2 weighted hyperintense signal alterations (Fig. 3).

CT is not the imaging technique of choice for searching leiomyomas, because the differentiation between leiomyomas as solid lobulated masses and the



Leiomyoma, Uterus. Figure 3 **Sagittal T2 weighted MRI in a pregnant woman demonstrates a large leiomyoma with necrosis.**

normal myometrium of the uterus is difficult on CT images. Signs like focal calcifications and irregular low-density areas in a mass are also suggestive for leiomyomas.

Diagnosis

Symptoms, pelvic exam, and imaging (TV-US and MRI) are the basis for diagnosing leiomyomas. They often present as incidental findings. In asymptomatic patient, further work-up is necessary as long as the leiomyomas show the classic features as described earlier. In symptomatic patients and in cases with indeterminate imaging findings (e.g., necrosis, strong contrast-enhancement, and increase in size) histological exploration is necessary.

Interventional Radiological Treatment

An interventional radiological treatment of uterine leiomyomas is possible with the embolization of the uterine artery (5).

Angiomyolipoma; Benign lipomatous tumors; Fatty tumors hepatic; Hibernoma; Lipoma; Liposarcoma; Malignant lipomatous tumors; Myelolipoma hepatic

Definition

Liver tumors (both benign and malignant) composed mainly or partially of adipocytes. The presence of mature adipocytes characterizes benign lesions. Benign hepatic tumors made up of fat include ▶lipoma, ▶hibernoma, and combined tumors such as angiomyolipoma (blood vessels, muscle, and fat), ▶myelolipoma (hematopoietic tissue and fat), angiomyelolipoma (blood vessels, hematopoietic tissue, and fat). The terms myelolipoma and angiomyelolipoma are suggested in the case of prominent hematopoietic foci.

Malignant forms include ▶liposarcoma with its histological subtypes.

Pathology And Histopathology

Lipoma, Hepatic

Hepatic lipomas are extremely rare, benign mesenchymal tumors composed of mature adipocytes. A variable amount of fat content is present in all liver tumors; however, pure lipomas are uniformly composed of fat, whereas the other lesions have fat mixed with other components such as blood vessels, muscles, or hematopoietic tissue (angiomyolipoma, myelolipoma, angiomyelolipoma). Therefore, these lipomatous combined tumors have intermediate imaging features. ▶Hepatic lipoma commonly occurs in a noncirrhotic liver and ranges from a few millimeters to more than 10 cm in diameter. Macroscopically, hepatic lipomas are usually solitary, yellowish masses, well circumscribed, and round. Histologically, they are composed of mature adipocytes with a variable degree of fibrous stroma.

The risk of malignant degeneration is not documented (1).

Angiomyolipoma, Hepatic

▶Hepatic angiomyolipoma is a very uncommon, benign mesenchymal tumor composed of a variable amount of fat, proliferating blood vessels, and muscle elements (smooth muscle with thick-walled blood vessels). This lesion has also been considered a hamartoma and its benign nature is confirmed by the DNA diploid pattern shown by flow cytometry. It can occur as a solitary mass or as multiple lesions in the case of tuberous sclerosis or Bourneville–Pringle syndrome. These tumors are well circumscribed, ranging in size, and predominantly occurring in women. When these tumors reach large sizes, intratumoral large vessels (called macroaneurysms) and areas of hemorrhage may appear.

Liposarcoma, Hepatic

Liposarcoma is a rare mesenchymal malignancy originating from lipoblasts, which is usually described in the retroperitoneum and extremities and only in very few cases in the liver. Liposarcomas account for 15% of all sarcomas and are most frequent in the fifth decade of life, although primary liposarcomas of the liver have also been described in children. Classification of liposarcomas into five major histological types (myxoid, round cell, well-differentiated, dedifferentiated, pleomorphic) reflects a combination of the two basic histological aspects of this tumor: the differentiation stage of lipoblasts and the overall degree of cellularity and cellular pleomorphism. This tumor, like other primary sarcomas of the liver, presents as an isolated, usually infiltrating, large mass developing in a noncirrhotic liver. Metastatic spread is mainly hematogenous.

Clinical Presentation

Lipoma, Hepatic

These lesions usually do not cause symptoms and are discovered incidentally. An association with any underlying disease has not been described (1).

Angiomyolipoma, Hepatic

Commonly hepatic angiomyolipomas do not produce symptoms and consequently are discovered incidentally. In some cases, they can reach large sizes showing an increased propensity for hemorrhage. However, unlike renal angiomyolipomas, no cases of rupture have been reported. In some cases, association with abdominal pain may result from intratumoral hemorrhage (1). When associated with the Bourneville–Pringle syndrome the lesions are generally multiple, progressive, and symptomatic.

Liposarcoma, Hepatic

Clinical symptoms are aspecific and may appear in the case of compression determined by large masses. Reported signs and symptoms include: abdominal pain, nausea, vomiting, abdominal distension, and weight loss. In some cases, massive ascites and pleural effusion have been described.

Imaging

Lipoma, Hepatic

Ultrasound (US) shows lipomas as homogeneous echogenic masses. Features of intrahepatic lipomas on computed tomography (CT) images include the presence of a well-marginated, homogeneous, low-density mass with attenuation values similar to those of subcutaneous fat (less than −20UH). Pure lipomas do not enhance after contrast medium administration, but a variable enhancement occurs in lesions containing angiomatous elements.

Magnetic resonance imaging (MR) presents intrahepatic lipomas as homogeneous, well-demarcated lesions with signal intensity equal to that of subcutaneous or retroperitoneal fat in all pulse sequences. On MRI, lipomas appear as masses with high signal intensity on T1-weighted images with only a slight signal increase on T2-weighted images. On fat-suppressed protocols the lesions appear hypointense; therefore, a distinction from other cases of hyperdensities on T1-weighted sequences such as areas of hemorrhage, copper overload, or peliotic changes is possible. MRI is also important in demonstrating the presence of a homogeneous fat content. These tumors do not show signal changes in contrast-enhanced sequences (1, 2).

Angiomyolipoma, Hepatic

This tumor usually presents as a combination of fat tissue and other tissue types. Imaging features of angiomyolipoma are related to the distribution and amount of fat and to the relative proportion of its three histological components. On US, typical lesions appear hyperechoic, making the differentiation from hemangiomas difficult. Frequently, they present a mixed hyper-hypoechoic pattern. In the case of very homogeneous predominantly lipomatous tumors, the presence of a posterior acoustic enhancement may be shown. All fat-containing tumors of the liver (angiomyolipoma, lipoma, myelolipoma), show common features on CT, related to the presence of fatty areas, typically hypodense on unenhanced scans. After contrast medium administration, both on CT and MR images, these lesions usually appear heterogeneously enhancing according to the soft tissue contrast uptake. Enhancement of the vascular components is clearly depicted, while the lipomatous areas show little or no enhancement.

MRI is the modality of choice for demonstrating the fatty nature of these lesions. Angiomyolipomas typically appear as well-circumscribed masses on MR images. On MRI, the high signal intensity on T1-weighted images and the hyper- to isointensity on T2-weighted images associated with a heterogeneous pattern is considered a specific feature. The hyperintensity is mostly related to the fat content, disappearing with fat-saturated sequences. In addition, MRI allows fatty areas to be distinguished from hemorrhage. This tumor is not capsulated, and therefore the peripheral rim depicted on MR images corresponds to surrounding compressed liver parenchyma. Atypical lesions without fat content show mixed signal with heterogeneous enhancement on MR imaging. When employing dynamic MRI or MR angiography, the large intratumoral vessels occurring in large angiomyolipomas are well depicted (2, 3).

Liposarcoma, Hepatic

Imaging findings are not specific and resemble those of other liver sarcomas. US usually shows a poorly defined, lobulated, infiltrating, echogenic tumor associated with shadowing. Internal hyperechoic and hypoechoic areas related to hemorrhage and necrosis have been described (4, 5).

CT features include the presence of a large solid mass containing hypodense foci due to the presence of fat, old hemorrhage, or necrosis. Contrast enhancement is limited, because of the poor vascularity of these lesions. On MR images, the lesions appear inhomogeneous reflecting the presence of areas with fat signal intensity.

Diagnosis

Lipoma, Hepatic

The imaging appearance of lipomas is characteristic, and consequently percutaneous biopsy or surgery is usually unnecessary. The differential diagnosis includes other neoplastic lesions of the liver with fatty degeneration, such as ▶angiomyolipoma, hepatic adenoma, or hepatocellular carcinoma. The overall structure of lipoma consisting of fat is revealed by means of specific MR sequences such as fat-suppressed or in-phase and out-of-phase techniques. Fatty hepatocellular carcinoma is usually discovered in cirrhotic patients and it shows a different behavior after contrast medium administration compared with lipoma. Fatty hepatocellular carcinoma is characterized by heterogeneous enhancement (both on CT and MRI) due to the absence of contrast uptake by the fatty areas (1, 2).

Angiomyolipoma, Hepatic

Successful imaging diagnosis relies on the identification of intratumoral fat, although it can be difficult to distinguish this tumor from other fat-containing hepatic tumors. The enhancement of the soft tissue on both CT and MR images after intravenous injection of contrast medium allows distinction between pure lipomas and angiomyolipomas. However, this criterion is not sufficient to allow a clear-cut distinction between angiomyolipoma and angiomyelolipoma. Early enhancement phases of both CT and MRI are helpful in differentiating between angiomyolipomas and fatty hepatocellular carcinoma. The enhancement of the vascularized fatty areas is typical of angiomyolipoma, while the areas of fatty change in hepatocellular carcinoma are almost avascular. The diagnosis of hepatic angiomyolipoma is easy when a fatty lesion is discovered in a patient with known tuberous sclerosis. Moreover, when the diagnosis of tuberous sclerosis is not known, other lesions, both benign and malignant containing areas of fatty density, may mimic angiomyolipoma. Seldom, hepatic angiomyolipomas do not contain fat and then the diagnosis remains unclear requiring fine-needle aspiration biopsy (2).

Liposarcoma, Hepatic

Primary liposarcoma of the liver, although extremely rare, must be considered in the differential diagnosis of a hepatic mass that develops in a noncirrhotic liver. Imaging features are not specific, resembling those of other sarcomas. The presence of fatty areas in the case of differentiated lesions is highly suggestive of liposarcoma. However, the final diagnosis is only possible on histological specimens (4).

Local Drug and Gene Delivery with Microbubbles

Peter Hauff
Global Drug Discovery, Bayer Schering Pharma AG, Berlin, Germany
peter.hauff@bayerhealthcare.com

Synonyms

Drug delivery system; Gene delivery system; Nonviral vector; Targeted delivery

Definition

Local drug or gene delivery with ultrasound comprises the transport of microbubbles containing bioactive substances, their ultrasound controlled release in the region of interest and ultrasound-induced enhancement of substance penetration (▶sonoporation) into the surrounding tissue or cells. It provides a technique for noninvasive ▶gene therapy and organ-specific ▶drug delivery.

Mode of Action

Ultrasound contrast agents (USCAs) for the delivery of bioactive substances such as drugs or genes consist of shell stabilized gas-filled microbubbles whereby the substances can be attached to the microbubble shell surface, or incorporated into the microbubble shell or lumen. A further approach is the coadministration of microbubbles and bioactive substances. Following injection, the substance-loaded microbubbles can be destroyed in the region of interest with ultrasound of a certain frequency and intensity. After intravenous injection, substance release can currently only be performed from microbubbles which are targeted passive in the region of interest (e.g., after phagocytosis) or passing through the ultrasound beam during blood circulation. However, a higher level of substance release may be achieved by using substance-loaded specific microbubbles (active targeting) which would lead to their higher target accumulation. The ultrasound-triggered substance release allows spatially and temporally controlled and precisely targeted therapies. In addition, ultrasound can promote and enhance released substance uptake by targeted tissues or cells, and this capability is called sonoporation. The ultrasound-induced sonoporation effect, which works as well without microbubbles, can be amplified by the additional use of microbubbles (1). Further advantages of this approach are seen for instance in the protection of encapsulated bioactive substances (e.g., protection of DNA from nucleases) within the blood; low level of invasiveness; ▶nonviral vector system for gene therapy and the possibility to visualize the breakup of the microbubbles on the screen of the ultrasound device through the color pixels that are produced when the bubbles are destroyed (SAE, stimulated acoustic emission effect) by using the color Doppler mode (Fig. 1).

Indication

Although local drug and gene delivery with ultrasound is currently at an experimental preclinical stage, researchers were able to demonstrate their feasibility *in vitro* and in animal models. In the majority of the published *in vivo* cases, the microbubbles have been tested for their use as nonviral ▶vector system for the genetic treatment of ischemic diseases, mainly by intramuscular injection, or of tumors after systemic administration. Most of the investigators used so-called marker genes for their feasibility studies, such as β-galactosidase and luciferase, in order to identify the optimum experimental settings. Only few investigations have been performed with microbubbles containing therapeutic agents. A successful genetic treatment of tumors could be shown more recently by using microbubbles containing the tumor suppressor gene *p16* (2). Another group was able to show *in vivo* the potential of microbubbles loaded with the

Smad7 gene as a useful therapeutic strategy for the prevention of renal fibrosis in association with hypertension. Finally, it could be shown already in humans that the coadministration of microbubbles and a fibrinolytic agent lead to a significant acceleration of thrombolysis by ultrasound treatment of the thrombus which is also referred to as "sonothrombolysis" (4) (Fig. 2).

Local Recurrence

The most frequent breast recurrence, which occurs either in the scar margins or near the place where the primary neoplasm was removed.

▶ Recurrent Neoplasms, Breast

LOCM

▶ Low Osmolality Contrast Media

Log-roll Test

Rolling a femur like a log on physical exam. Pain or resistance is elicited when the hip contains more than the normal minimal fluid.

▶ Transient Synovitis

Longitudinal Relaxation Time

Relates to the T1 time constant, which determines the rate at which excited protons return to equilibrium within the lattice.

▶ Contrast Media, MRI, Oral Agents

Looser's Zone

Radiolucent bands of unmineralized osteoid on radiographic images which are typical for osteomalacia.

▶ Osteomalacia

LORA

Late onset (LO) (>65 years) rheumatoid arthritis (RA) is frequently atypical concerning the affection of larger joints. It is said that LORA patients are more likely to go into remission. However, LORA can be as damaging as classical RA, and joint erosions are often observed at presentation. Disease compounded by age-associated factors may in fact have a worse prognosis later, rather than early, in life.

▶ Rheumatoid Arthritis

Low ARM

ARM where the rectum passes through a well-developed puborectalis muscle sling. The aboral ending is an anocutaneous fistula in males, whereas in females this is represented by an anocutaneous or anovestibular fistula.

▶ Anorectal Malformation

Low Osmolality Contrast Media (LOCM)

A low osmolality contrast medium is a water-soluble imaging contrast agent that has osmolality (a measure of the number of particles in solution) higher than human blood. For radiographic iodinated contrast media, this is typically twice the osmolality of human blood. See also high osmolality contrast media and iso-osmolality contrast media.

▶Radicular Syndrome of the Spine, Conservation Therapy for

Lumpectomy

Breast surgical technique that consists of the surgical removal of a tumor along with a small margin of the surrounding normal breast tissue.
▶Breast Conserving Therapy

Lung Abscess

Thick-walled cavity within the lung filled with pus.
▶Pneumonia in Childhood

Lung Contusion

Typically induced by blunt chest trauma and presents as edema and hemorrhage with intact histological structure of the lung. The corresponding patchy or confluent radio opacities develop within 6 h and start to decrease after 2–3 days with restitution after 3–10 days. CT is superior to chest X-ray in defining their extent. Infection and ARDS are life threatening complications of ▶lung contusion which are associated with progressive radio opacities after 48 h.
▶Chest Trauma

Lung Laceration

The local rupture of lung parenchyma with round or oval shaped accumulations of blood and air following direct perforation or indirect deceleration forces due to blunt trauma. On chest X-ray, areas of laceration are often masked by surrounding contusions. Pneumothorax and superinfection are quite frequent complications, whereas cerebral air embolism is rare. If uncomplicated, the corresponding radio opacities vanish after 3–7 weeks, sometimes with remaining scars (see Fig. 2, Page 000).
▶Chest Trauma

Lung Resection

▶Postoperative

Lung Scintigraphy

Refers to two different examinations: the ventilation (V) and the perfusion (Q) scan. Normal V/Q studies show homogeneous patterns of evenly matched ventilation (V) and perfusion (Q). Pulmonary diseases are frequently associated with scintigraphically detectable perturbations of the ventilation and/or perfusion. Two types of perturbations are differentiated: match defects that are typical for pulmonary embolism and mismatch defects that are commonly caused by nonembolic pulmonary diseases.

Benign and malignant nodes in the neck

Definition

The term lymphadenopathy indicates inflammatory, granulomatous, or neoplastic involvement of nodes with or without increasing the volume. The whole neck contains approximately 300 nodes. Several classification systems have been used for the regional categorization of the nodes in the neck. However, recent advances in CT and MR imaging have enabled the use of an image-based classification with the aid of anatomical landmarks that are identified on CT and MR images (1). This classification system categorizes the cervical nodes into seven groups; the nodes at levels I to VII. Supraclavicular, retropharyngeal, parotid, facial, occipital, postauricular, and the other superficial nodes are referred by their anatomic names. Metastasis to one or more of these nodes has not been reported to have a high impact on the patients' prognosis. However, such metastasis may influence the local control and surgical plan and should be carefully followed-up.

Pathology/Histopathology

Cervical lymph node metastases originate most frequently from squamous cell carcinomas of the mucosal lining of the upper aerodigestive tract and uncommonly originate from the salivary and thyroid glands and skin. Malignant melanoma of the head and neck skin is a possible origin of nodal metastasis in the neck. Nodal metastasis is considered to occur after cancer cells that had migrated into the lymphatic vessels travel *via* the afferent lymphatic vessels and settle into the nodal cortex; here, metastatic cancer cells continue to proliferate and form cancer foci in the node. Cancer growth in the nodes requires angiogenesis for the tumor blood supplies. Growing cancer cell foci gradually displace and destroy the surrounding nodal lymphatic tissues and may obliterate the nodal ▶hilum. Large cancer foci are frequently associated with liquefaction or coagulation necrosis (central nodal necrosis) and keratinization (cancer pearl).

Malignant lymphomas are classified into Hodgkin's and non-Hodgkin's lymphomas. Non-Hodgkin's lymphomas are subclassified into B-cell neoplasm (precursor B-cell neoplasm and peripheral B-cell neoplasm), and T-cell and natural killer (NK)-cell neoplasms (precursor T-cell neoplasm and peripheral T-cell and NK-cell neoplasm). Hodgkin's tumors are subclassified into five types (lymphocyte-rich, nodular sclerosis, mixed cellularity, lymphocyte depletion, and nodular lymphocyte-predominant). In the head and neck region, Hodgkin's lymphomas occur predominantly in the nodes, while about two-thirds of non-Hodgkin's lymphomas arise in the nodes.

The lymph nodes are also enlarged because of nodal abscesses secondary to bacterial (mycobacterial) infections or cat scratch disease in the head and neck region. Tuberculosis is a rare case but should be considered for differential diagnosis when enlargement of multiple lymph nodes is associated with irregular contrast medium enhancement on CT or MR images. Viral infections such as mononucleosis, herpes, cytomegalovirus, and HIV are common causes of single and multiple lymph node enlargements. Sarcoidosis, Castleman's disease, and Kimura's disease are also rare causes of enlargement of cervical lymph nodes.

Clinical Presentation

Metastatic nodes in patients with head and neck cancer are painless and firm masses in the neck. A single metastatic node will increase in size with the growth of metastatic cancer cells in the node. Further spread of metastatic cancer along the lymphatics may involve the down stream nodes, and may be eventually fixed to adjacent tissues. Nodal lymphomas are painless, single large or multiple small rubbery masses, are often bilateral, and are sometimes complicated with recurrent fevers. Inflammatory adenopathy such as bacterial adenitis and cat scratch disease presents as painful masses. Kimura's disease and sarcoidosis cause painless multiple masses in the neck, basically unilaterally in the former and bilaterally in the latter. Castleman's disease is usually associated with a solitary asymptomatic enlarged node.

In patients with head and neck cancer, the presence or absence of nodal metastasis is the most important predictive factor. Therefore, early detection of metastatic nodes and their effective differentiation of them from nonmetastatic nodes is a very critical step for the staging of patients with head and neck cancer and for planning treatment with surgery, radiotherapy, and chemotherapy.

Nodes at levels I and II of the neck receive lymphatic drainage from the anterior facial structures and skin, oral floor, and anterior oral cavity. Nodes at levels II–IV receive lymphatic drainage from the parotid and retropharyngeal regions and the nodes at level IB. The nodal chain at levels II–IV serves as a common pathway for all the lymphatics of the upper aerodigestive tract and neck. Thus, these drainage patterns result in different incidences of metastatic nodes at different levels of the neck. The incidence of adenopathy or enlarged nodes is higher in patients with pharyngeal cancer than in those with oral cancer. Metastasis from the oral cavity occurs predominantly to nodes at levels IB and IIA. Level IA is a common site for metastasis from cancers of the lower gingiva, oral floor, and tongue. Cancers of the oral floor and tongue can metastasize to nodes in levels III and IV, but metastatic nodes from other oral cancers are uncommon at this level. In contrast, laryngeal and esophageal cancers rarely metastasize to nodes at levels IA and IB. Levels VA, VB, and VI are uncommon sites for metastasis from head and neck cancers.

The sentinel node is the first node to receive lymphatic drainage from a primary cancer. The presence of metastatic cancer in the sentinel node indicates possible involvement of the downstream nodes in that chain. On the contrary, if the sentinel node does not contain cancer, the downstream nodes are not likely to harbor metastasis.

Imaging

Computed Tomography

CT imaging is most commonly used for screening metastatic nodes in patients with head and neck cancer, because CT provides excellent information about their location, size, and even internal architectures of the node.

Increase in size of the node, a rounder shape, and rim enhancement (central nodal necrosis) or irregular enhancement after contrast enhancement due to tumor necrosis are the hallmarks for the metastatic nodes. The minimal axial diameter is a better criterion than the maximal axial diameter (2). A minimal axial diameter of 10 mm has been reported to be the most effective size criterion. ►Nodal necrosis is considered a pathognomonic feature of metastatic nodes from head and neck squamous cell carcinomas. It occurs as cancer cells infiltrate into the medullary portion of the nodes and surpass the blood supply. Nodal necrosis has been reported to occur in 56–63% of metastatic nodes larger than 1.5 cm in diameter.

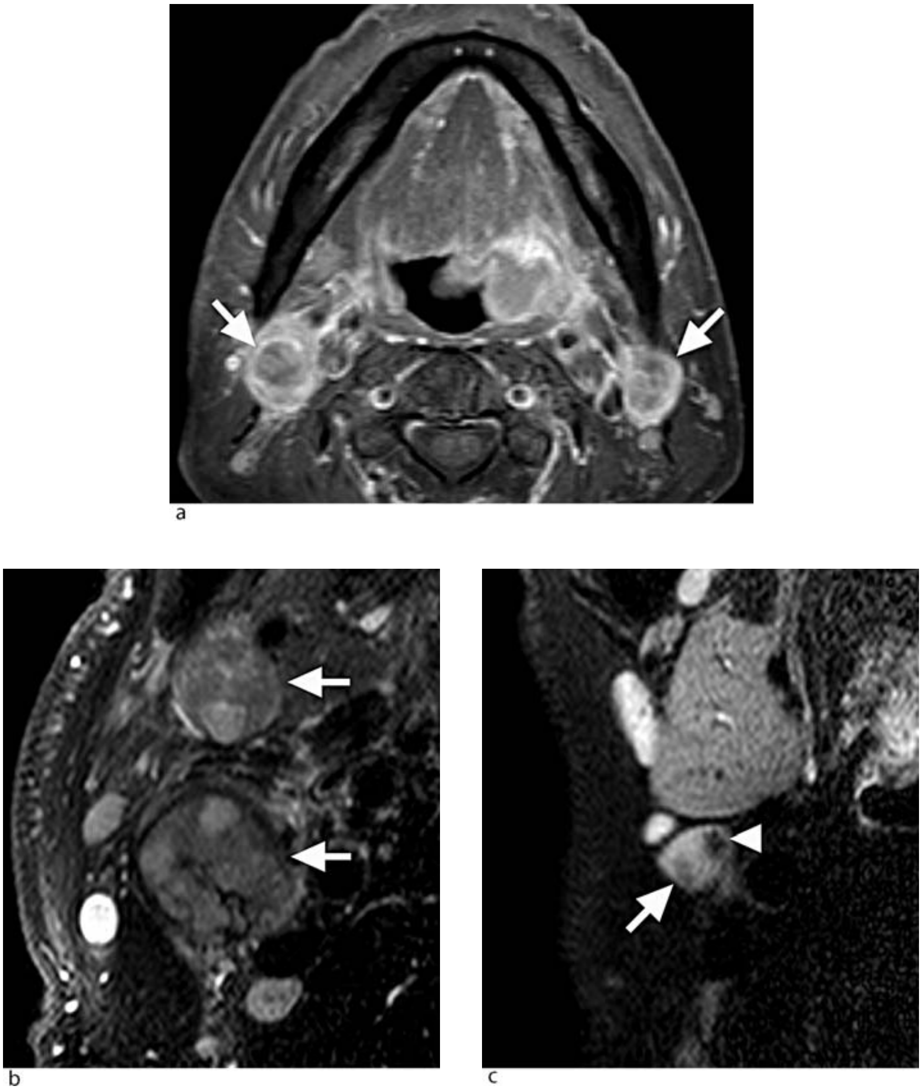
The general features of nodal lymphoma are multiple, bilateral, nonnecrotic enlarged nodes. However, nodal necrosis has been reported in 27% of non-Hodgkin's lymphomas (most commonly in the diffuse large cell lymphomas in the palatine tonsil).

Application of the multidetector-row CT can improve the diagnostic performance for the detection of malignant nodes in the neck. It allows displaying coronal, sagittal, axial, and paraxial images of the node without increasing the examination time. Therefore, the multidetector-row CT technique could permit more precise assessment of the topographical relationships of the node to vessels as well as the volumetric assessment of enlarged nodes in the neck.

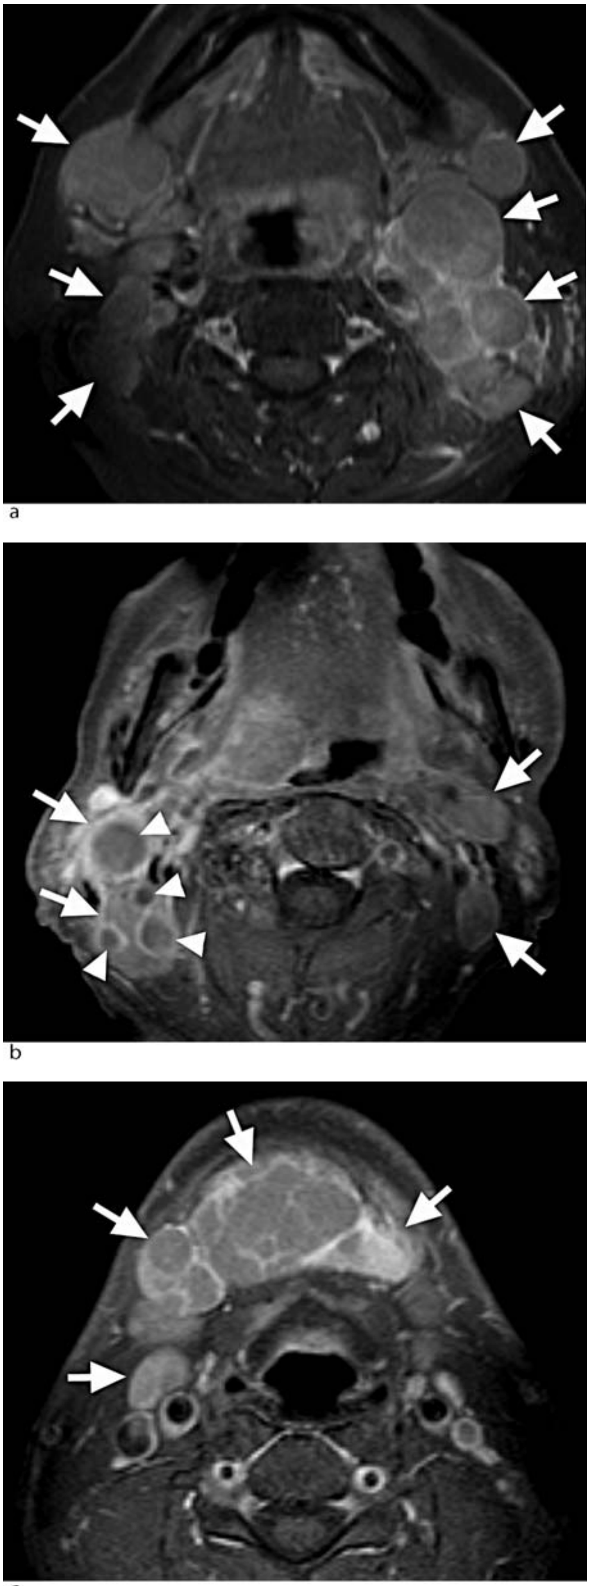
Magnetic Resonance Imaging

The performance of MR imaging in diagnosing metastatic nodes in the neck has not been highly ranked. However, recent advances in MR imaging technology have enabled fast, ►high-resolution MR imaging and functional imaging of the cervical nodes, thereby greatly improving the diagnostic ability. Lymph node metastases lead to drastic changes in the components and structure of the nodes and are associated with proliferation and necrosis of the cancer cells, angiogenesis, and obliteration of the hilar fat. Application of a small-sized surface coil allows the evaluation of the detailed architecture of metastatic nodes (Fig. 1), for example, liquefaction necrosis, cancer cell nests, keratinization, and extranodal spread. The combined use of some of these high-resolution MR features has greatly improved the diagnostic ability of MR imaging for the detection of metastatic cervical nodes (3).

In addition, the ►apparent diffusion coefficients (ADCs) obtained by ►diffusion-weighted MR imaging of lymphadenopathy may provide additional information that is distinct from the morphological features. Among metastatic nodes, nodal lymphomas and benign nodes, the ADCs are lowest in nodal lymphomas and highest in metastatic nodes. The presence of necrosis in the metastatic cancer increases the ADC levels of the lesion. In contrast, nodal lymphomas are usually displayed as nonnecrotic masses (Fig. 2). High cellularity in lymphomas leads to restricted water diffusion, which,



Lymphadenopathies, Head and Neck. Figure 1 **MR imaging of metastatic lymph nodes. Gadolinium-enhanced, fat-suppressed T1-weighted image (a), high-resolution, fat-suppressed T2-weighted image using a 47-mm microscopy coil (b, c) show cervical nodes (arrows) metastatic from squamous cell carcinomas of tonsil (a), oropharynx (b), and tongue (c). Metastatic nodes exhibit central nodal necrosis with rim enhancement (a), concomitant presence of cancer cell nests with intermediate to low signal intensity, and liquefaction necrosis with hyperintense signals (b), and hypointense keratinization areas (arrowhead) (c).**



Lymphadenopathies, Head and Neck. Figure 2 MR imaging of nodal lymphomas. Gadolinium-enhanced, fat-suppressed T1-weighted MR images of non-Hodgkin's lymphomas (arrows) (a, b), and Hodgkin's lymphoma (arrows) (c). Necrosis (arrowheads) may be associated with diffuse large B-cell lymphoma as in (b). Enhanced blood flow signals are characteristic features of Hodgkin's lymphomas as in (c).

in turn, results in low ADC levels. The ADC measurements could significantly and independently contribute to the discrimination of metastatic cervical nodes and nodal lymphomas (3).

Sonography

The evaluation of metastatic nodes by a high-resolution sonography is also based on the assessment of their internal architecture and determination of their size. Abnormalities in the metastatic nodes may be reflected by the increased parenchymal echogenicity or loss of hilar echogenicity. In addition, the recent development of Doppler sonography has highlighted the diagnostic significance of changes in the nodal blood flow while differentiating metastatic nodes from reactive nodes.

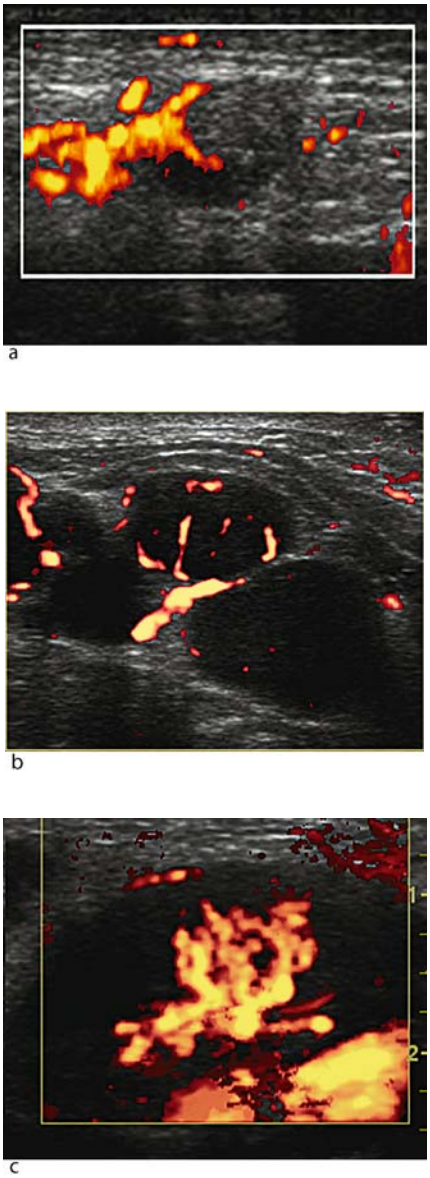
The minimal axial diameter is the most accurate size criterion. The best size criterion for metastatic nodes differed among the different neck levels; a recent report postulated that in the palpably N0 necks, a minimal axial diameter of 7 mm for level II and 6 mm for the other neck levels provide the optimal diagnostic ability (4).

Power Doppler sonography has a greater dynamic range than conventional color Doppler sonography, thus providing enhanced visualization of the microvascularity of the lymph nodes (Fig. 3). The detection of abnormal blood flow signals is considered important in differentiating metastatic nodes from reactive nodes. Nodal blood flow signals are usually classified as follows: (1) hilar (reactive), (2) parenchymal (metastatic), or (3) no blood flow signals (metastatic) (5).

Nodal lymphomas are usually displayed as round areas with a pseudocystic appearance and posterior acoustic enhancement. The sonographic features result from the uniform cellular arrangement in lymphomas. Hilum in lymphomas is narrowed or absent and may be associated with hilar blood flow signals; otherwise, lymphomas are poor in blood flow signals.

Nuclear Medicine

Lastly, we should comment on the recent advances in positron emission CT (PET) for the detection of metastatic nodes. PET with 2-[18F] fluoro-2-deoxy-D-glucose (FDG) could be used as another functional imaging modality for the detection of metastatic nodes. Malignant nodes have higher glucose utilization than



Lymphadenopathies, Head and Neck. Figure 3 **Sonographic imaging of lymphadenopathies. Power Doppler sonography shows changes in hilar echogenicity and blood flow signals in lymphadenopathy. Lost hilar echogenicity and hyperechoic tumor areas associated with displaced blood flow signals in metastatic node (a), homogeneously hypoechoic tumor associated with varying amounts of sparse blood flow signals in nodal lymphomas (b), and, rich vascularity radiating from hilar region in lymphadenitis (c).**

normal nodes. Accordingly, FDG-PET might detect metastatic nodes that are negative by the size criteria on MR imaging. However, metastatic nodes that contain large necrotic areas are negative by the FDG-PET criteria due to the low glycolytic activity of the necrotic material. The FDG-PET criteria have not been well established, and the poor accuracy of FDG-PET in the visual interpretation of a lesion is a frequent problem. Other disadvantages of FDG-PET are limited clinical availability, low spatial resolution, and high cost. Further studies are necessary to facilitate the clinical application of FDG-PET for head and neck imaging.

Diagnosis

In general, sonography performed better than CT in detecting benign and malignant lymphadenopathies, particularly for metastatic nodes in patients with head and neck squamous cell carcinomas (2). Nevertheless, the fact that sonographic examination requires considerably greater amount of time than CT may greatly diminish the value of sonography. In addition, sonography is not suitable for the detection of deep cervical nodes such as those in the retropharyngeal space. Fine-needle aspiration cytology has become the standard procedure in the diagnosis of lymphadenopathies in the neck. This technique could be performed more accurately under sonographic guidance. On the other hand, MR imaging with high tissue contrast can provide useful information regarding the changes in nodal structures and components in lymphadenopathy. Furthermore, some MR imaging techniques such as coronal short inversion time inversion recovery (STIR) turbo spin-echo imaging, allow rapid MR imaging for screening with high sensitivity and negative predictive value. Therefore, CT or rapid MR imaging should be the first choice for the diagnosis of cervical lymphadenopathy, and it may be reasonable to perform sonographic examination or functional (e.g., diffusion-weighted MR imaging) and high-resolution MR imaging using a small surface coil for the detailed study of suspected cervical nodes, following CT or MR screening.

Lymphadenopathy

Pinar Balci, MD
Dokuz Eylül University School of Medicine,
Department of Radiology, Izmir, Turkey
pinar.balci@den.edu.tr

Synonym

Adenomegaly

Definitions

Lymphadenopathy is the term used to indicate enlargement of lymph nodes. It involves swelling of one or more lymph nodes and is a recognized symptom of many diseases, including acute infection (bacterial or viral) or chronic infection (tuberculous lymphadenitis, cat-scratch disease). Lymphadenopathy may be tumoral (Hodgkin's lymphoma, non-Hodgkin's lymphoma, metastasis) or be of unknown etiology (sarcoidosis).

In the breast, subdermal and intramammary lymphatics anastomose at the subareolar plexus; their path is centrifugal toward the axillary, internal mammary, and intercostal chains. The axillary chains form the main drainage. The associated nodes are subdivided into six groups: external mammary, scapular, axillary, central, subclavicular, and interpectoral (Rotter). A small amount of the lymphatic flow from the breast crosses to the opposite side, and some passes to the upper abdominal nodes *via* diaphragmatic lymphatics. Furthermore, some lymph nodes may occur within the breast; these are intramammary lymph nodes. Although they may occur in any location within the breast, they are usually situated on the posterior half of the upper outer quadrant (1).

For surgical purposes, the lymph nodes in the axilla are divided into three levels according to their relationship with the pectoralis minor muscle. Nodes lying lateral to this muscle are termed level I, those deep to the pectoralis minor are level II, and those lying medial to it are level III. Additionally, a small percentage of breast cancers drain medially into the internal mammary chain. These nodes follow the internal mammary vessels and are usually present in the first three intercostal spaces.

The most common cause of axillary lymph node enlargement is nonspecific benign adenopathy (29%) (2). Causes of this change can include skin and nail infections or inflammatory processes in the arm, breast infections, or inflammation and breast surgery. It is generally known and accepted that involvement of regional nodes is an important prognostic parameter in breast cancer. A large number of nonmalignant diseases have been reported to cause axillary lymphadenopathy. These include tuberculosis, human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS), sarcoidosis, rheumatoid arthritis, psoriasis, and other collagen vascular diseases.

Although lymphadenopathy is the most common cause of axillary masses, other abnormalities, including epidermal cysts, silicone granuloma, abscesses, cysts, lipomas, primary breast carcinoma, and other benign breast tissue lesions, have been reported. Some lesions probably arise from accessory breast tissue in the axilla. Hence, the differential diagnosis of axillary masses should be similar to that for breast masses (3).

Pathology/Histopathology

Lymphatic capillaries drain close to 10% of all interstitial fluid back to the venous circulation. The lymph circulates first through capillaries, and then lymph vessels, converges toward the cysterna chili located between the T11 and L2 levels and then through the thoracic ducts, and then merges before draining into the venous angle between the internal left jugular vein and the left subclavian vein. Lymph nodes thus form barriers to the lymphatic drainage. Afferent lymphatics converge toward the outer nodal cortical surface before exiting the nodes *via* centrally located medullary sinuses. As such, they can be seen as barriers to the lymphatic extension of cancer cells. Additionally, nodes receive a specific blood supply *via* both arterial and venous branches (4).

Axillary lymphadenopathies play an important role in staging of tumor and metastasis of breast carcinoma in cases of breast masses, particularly in women. Clinically palpable lymph nodes of the axilla do not always indicate metastasis. In histopathologic examination, huge lymph nodes may be reactive; on the other hand, nonpalpable nodes may have metastasis microscopically, as in invasive lobular carcinoma. Of lymphoid tissue neoplasms, Hodgkin's and non-Hodgkin's malignant lymphomas and plasmocytic tumors are among the causes of axillary lymphadenopathies. Both primary and metastatic breast lymphoma may accompany such cases, or the breast may even be uninvolved. Lymphadenopathy may be due to systematic or regional skin and soft tissue non-neoplastic diseases. Miscellaneous systematic infections may occasionally lead to lymphadenopathy, with specific findings of infection or reactive hyperplasia. In addition, malignant tumors of tissues and organs may result in metastasis of axillary lymph nodes, as in malignant melanoma and lung and other organ malignant tumors.

The frequency with which a primary tumor is detected pathologically in the ipsilateral breast varies from 55 to 82%. Most cases in which lymphadenopathy is associated with a visible breast cancer represent metastatic breast disease. In those where there is no visible breast disease, causes include connective tissue disease (commonly rheumatoid arthritis), hematological malignancies, occult carcinomas, dermal infection, and benign reactive nodes.

Clinical Presentation

The first step in clinical examination of the breast is palpation of regional lymph nodes (axillary and supraclavicular nodes). In cases of palpable lymphadenopathy of superficial lymph node sites, the following features of such adenopathy must be taken into consideration:

- Site or sites of adenopathies
- Number of palpable ganglions
- Size of ganglions
- Consistency of adenopathy (tough as stone, soft as rubber, fluctuating): Although not a rule, adenopathies due to cancer metastasis frequently have a tough consistency; adenopathies due to lymphoma have a rubbery consistency; and adenopathies having pus are soft. Metastatic ganglions may also be painful. Although ganglions due to lymphoma are generally not painful, ganglions showing enlargement in a short time may be painful.
- Mobility: Enlarged ganglions having single localizations can be easily mobilized. On the other hand, lymphadenopathies showing package formations and adherent to surrounding tissue are likely to be immobile. In cases of tough and immobile lymphadenopathies, cancer metastasis is the strongest possibility.
- Condition of the skin over the lymphadenopathy: Erythema, warmth, and fistulization (in some cases) may indicate inflammatory adenopathies such as tuberculous adenitis.

Imaging

The normal mammographic pattern of lymph nodes is reniform or coffee-bean-shaped with a fatty hilum. The size of normal nodes is variable. If only the parenchyma excluding the fatty hilum of the small axis is determined, this measurement allows some correlation with the presence of malignant involvement (accuracy 70–80%). Lymphadenopathy on mammography underestimates the extent of disease as demonstrated by the current series. This may be partly due to the fact that most axillary nodes are not included in the oblique mammogram. In addition, a deposit that does not enlarge the node or replace the fatty hilum is unlikely to appear pathological even if it is included on the mammogram. When mammographic imaging of axilla is desired, this can be optimized using the axillary view. This view is performed using a small rectangular compression paddle over the axilla and angling the view 40°. Even with this optimized view, only about the lower half of level I can be imaged mammographically (1).

Sonographically, lymph nodes are also coffee-bean-shaped and smoothly marginated, with an echo-poor cortex and a central echogenic fatty hilum. Ultrasound, while able to accurately determine size and morphology, presents technical difficulties in imaging all axillary nodes, and small subcapsular metastatic deposits may not be visualized. Unlike mammography, ►sonography is capable of imaging the entire axilla. Conventional ultrasound has a high sensitivity for detecting enlarged lymph nodes, whereas its specificity is moderate. Tumor-associated alterations of intranodal angioarchitecture are not specific enough to allow reliable differential diagnosis of lymphadenopathy by color-coded Doppler ultrasound. Power Doppler ultrasound has improved the distinction among inflamed, reactive, and metastatic nodes (5).

Lymph node imaging has not played a significant role in staging of patients with breast cancer because of the inability of imaging to detect microscopic nodal metastases. Axillary dissection is more accurate in this situation. But to decrease the morbidity associated with axillary dissection, sentinel node sampling is increasingly being used as an alternative procedure for histopathologic staging. The technique involves injecting blue dye or isotope in the breast and locating the first node or nodes to which it travels, this node being the "sentinel node." This node is then removed. If it does not contain metastatic disease, no further axillary dissection is performed (1, 4).

►Magnetic resonance imaging (MRI) using gadolinium chelate as the contrast agent has a high positive predictive value for axillary nodal metastases. The use of ultrasmall particles of iron oxide (USPIO) as a so-called specific contrast agent is presently being investigated. USPIO accumulates in the reticuloendothelial system of normal lymph node tissue and causes a decrease of signal intensity on T2-weighted images by its ferromagnetic properties. In metastatic nodes, USPIO does not accumulate; therefore, signal intensity does not change. However, in the patient who presents with axillary adenopathy or supraclavicular adenopathy and occult carcinoma, MRI of the breast may be the diagnostic test of choice because of its high sensitivity and high negative predictive value. In women with axillary lymph node metastasis, breast MRI should be included as part of the work-up when conventional imaging and clinical breast examinations are negative. MRI has proved to be valuable in identifying the breast as the primary source, with localization ranging from 75 to 100%. Breast MRI can eliminate uncertainty about the primary site and offer the opportunity for optimal treatment (4).

Nuclear Medicine

Positron emission tomography (PET) using (fluorine 18) 2-deoxy-2-fluoro-D-glucose (FDG) may also be useful in assessing axillary lymph nodes. It is reported that the sensitivity, negative predictive value, specificity, and accuracy of PET are 95, 95, 66, and 77%, respectively.

Detection of small microscopic malignant foci in lymph node may not be possible with PET. But the major advantage of PET appears to be its capability to image distant metastases simultaneously. Thus, in selected patients its use may be cost-effective (1). However, FDG is not specific for tumor imaging; macrophages involved in inflammatory and infectious diseases can accumulate the tracer in large amounts as well, making the characterization of mediastinal nodes particularly challenging. In addition, lymph nodes involved with several types of tumors, such as bronchioloalveolar cell carcinoma and carcinoid tumor, are often false-negative with FDG-PET. False-negative outcomes may also arise in lymph nodes that are smaller than 1 cm or that contain micrometastases. In melanoma and breast cancer, for example, surgical sentinel node biopsy remains the method of choice for detecting metastatic spread in the draining lymph nodes. In fact, spatial resolution of PET is relatively low, compared with cross-sectional imaging, and deep foci of uptake are attenuated by the surrounding tissues. The implementation of PET-computed tomography (CT) fusion, either by computer coregistration or, more recently, by dedicated dual-modality scanners, have partly overcome these obstacles (4).

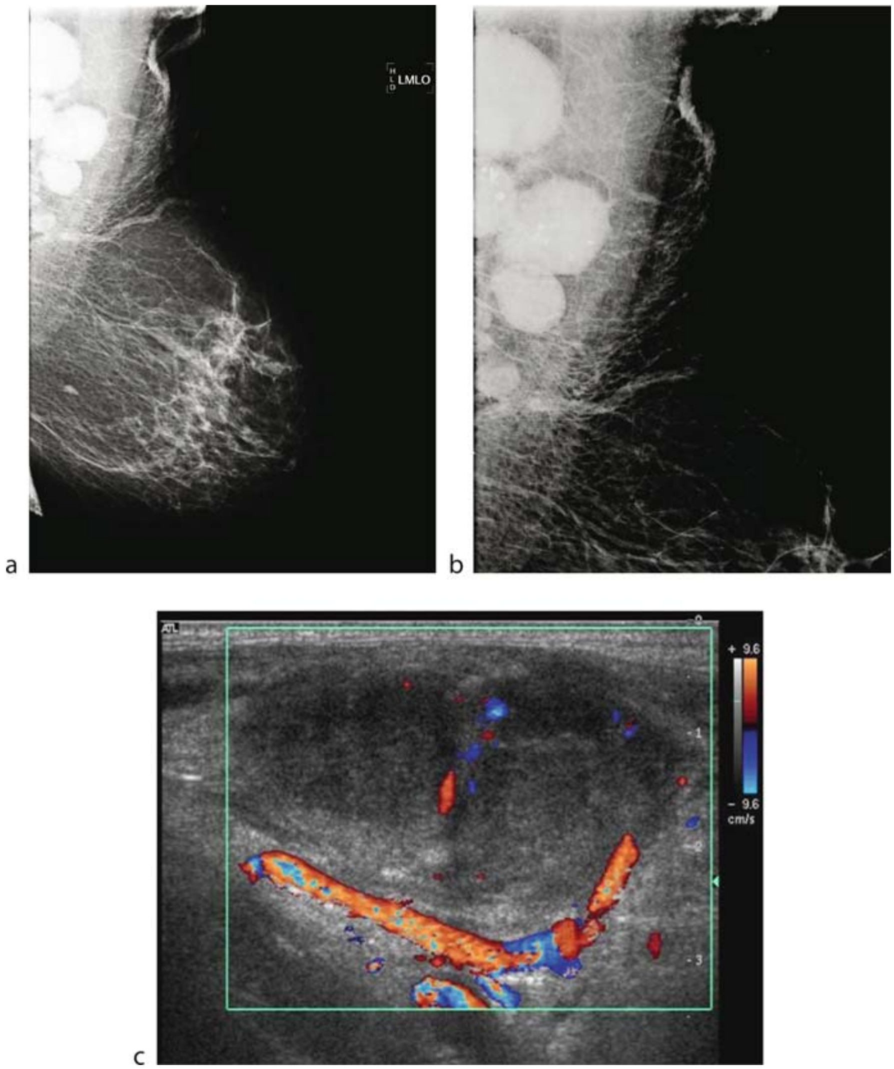
Diagnosis

Axillary lymph nodes are frequently visualized on routine *mammography* as a well-defined mass that is isodense or hypodense compared with breast parenchyma and contains a central fatty hilum(3). Oblique view mammography, now routine in breast cancer screening, permits visualization of the low anterior axilla. Normal axillary lymph nodes are frequently identified and are typically small and oval with a lucent center due to hilar fat. Enlarged but otherwise normal axillary lymph nodes may be seen in older patients due to fatty replacement of normal lymphoid parenchyma (6). Size is not significant because a large central fatty hilum may cause nodes to be >2.5 cm. Abnormality of axillary lymph nodes is suggested by an increase in nodal density and loss of the fatty hilum. Although nodal size and margins are variable in both benign and malignant lesions, a pattern of spiculated nodes has been reported to result from perinodal extension from a biologically aggressive carcinoma. Microcalcifications are commonly present in the primary breast carcinoma but are rarely seen in axillary node metastases. Axillary node calcifications are usually pleomorphic and faint. Similar calcifications may also be seen with metastatic ovarian and thyroid carcinoma. Coarse calcifications may be seen in granulomatous disease such as tuberculosis and fat necrosis (Fig. 1). Tuberculosis of the breast is rare, and tuberculous axillary lymphadenitis without evidence of tuberculous mastitis is even rarer. The HIV epidemic has resulted in a higher percentage of extrapulmonary tuberculosis, and more cases of tuberculous lymphadenitis can be expected because peripheral lymph node tuberculosis is one of the more common manifestations of extrapulmonary tuberculosis.

If silicone drains from breast augmentation prostheses into the axillary nodes, it may be observed as extremely dense. Mammographically, intramammary lymph nodes appear in the typical morphology of a lymph node (1, 3) and are recognized as typical morphology of lymph nodes in imaging modalities.

Sonographically, asymmetric thickening and focal lobulations in the cortex, partial or complete replacement of the echogenic fatty hilum, focal or diffuse decrease of echogenity within the nodal cortex, and marginal irregularity in some metastatic cases or increased transverse diameter of the lymph node parenchyma can occur. Overall size does not have clinical significance. Several series have reported *color Doppler ultrasound* (US) findings that indicated malignancy: displacement of hilar vessels, focal absence of perfusion, aberrant vessels, and subcapsular vessels. The longitudinal-transverse axis ratio and the presence of a peripheral versus central flow pattern were shown in recent publications on ►color Doppler US (Fig. 2) Different flow patterns can be depicted on US; metastatic nodes tend to show a more peripheral vasculature than benign or reactive nodes. The usual figures for accuracy and specificity range between 85 and 88%. However, inherent limitations of US are well known, including the poor accessibility of deeply located nodes, in contrast to the use of MRI or CT. Combining Doppler US with microbubble contrast agents could overcome this drawback, and contrast-enhanced US lymphography following the interstitial injection of submicron-diameter bubbles could even compete with isotope sentinel node detection, as suggested by a recent animal study (1, 4).

Lymph nodes located within the breast or lower axilla may be visualized on imaging studies of the breast. Unfortunately, imaging methods are often unable to differentiate inflammatory and neoplastic nodes.



Lymphadenopathy. Figure 1 (a) Mammogram in MLO position shows large lymph nodes with coarse calcifications due to tuberculosis lymphadenitis in the axillary region. Its magnification is seen in (b). (c) Doppler view of the same patient

Owing to their low invasiveness and availability, *cross-sectional imaging techniques* have gained widespread acceptance for lymph node imaging. However, whether with CT or MRI, criteria for lymph node metastases remain limited to size assessment. Maximum short axis diameters of normal-sized nodes usually do not exceed 1 cm. However, this value may vary depending on the node's location. Additional morphologic features suggestive of normal nodes include the presence of a fatty hilum, regular contours, and homogeneous signal or density on MRI and CT. Nevertheless, micrometastases, such as in breast cancer, are commonly reported in normal-sized nodes. Improving the spatial resolution of cross-sectional imaging and, especially, being able to identify morphologic alterations of either lymph node cortex and sinus could allow better distinction of the involved tumor and normal nodes. Several studies have assessed whether dynamic enhancement of lymph nodes following intravenous injection of extracellular contrast agents (gadolinium-based contrast agents on MRI) could improve the identification accuracy of nodal metastases. In contrast to extracellular contrast agents, iron oxide-based contrast agents reach lymph nodes indirectly (USPIO). Benign and reactive nodes share the presence of phagocytic or mononuclear cells in contrast to massively involved metastatic nodes, which fail to show a decreased signal intensity after USPIO injection: therefore, benign nodes can be distinguished from tumor-involved nodes regardless of size criteria. USPIO thus behave as "negative" contrast agents (4).

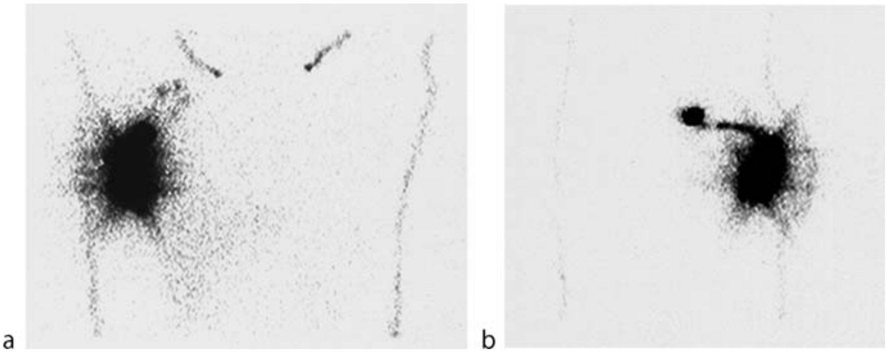
Lymphadenopathy. Figure 2 (a) Benign and malignant lymph nodes in the same image. B-mode scan shows loss of the echogenic fatty hilum, focal lobulations in the cortex, and diffuse decrease of echogenicity within the nodal cortex in metastatic lymph node on the right and a typical benign node on the left side of the figure. (b) Benign reactive lymph nodes on color Doppler ultrasound with smooth cortex, small size, and central vascularization. (c) Malignant lymph nodes on color Doppler ultrasound reflecting large size, loss of echogenic hilus, and peripheral

Lymphoscintigraphy has recently regained interest in oncology for the surgical evaluation of the sentinel node, which is defined as the first lymphatic relay in the drainage territory of a primary tumor and is thought to be the first site of metastases in cases of lymphatic spread. The technique has evolved with the use of patent blue dye and ^{99m}Tc-labeled nanocolloids, both of which make it easier to identify the sentinel node intraoperatively. As initially demonstrated for both melanoma and breast cancer, lymphoscintigraphy allows avoidance of unnecessary invasive lymph node dissection procedures by identifying the sentinel node with the guidance of a gamma probe intraoperatively. In addition, it warrants better nodal staging because skip metastases during lymph node extension of a cancer are rare. Based on several reports, the success rate of sentinel node resection exceeds 90%, and the overall accuracy exceeds 95% (4) (Fig. 3). This technique may help decrease the extent of axillary surgery and reduce the postoperative sequelae of axillary dissection, including lymphedema.

Indirect Interstitial CT and MR Lymphography

The concept of indirect interstitial CT and MR lymphography closely matches that of sentinel node mapping. Small-sized contrast agents injected intradermally can reach lymphatic vessels owing to the increased permeability of the fenestrated endothelial lining of distal lymphatic capillaries. Similarly to radio-isotopes, such agents then follow the lymphatic flow and progressively converge toward afferent nodes. However, the literature remains limited to animal studies, and clinical trials on humans still have to be conducted. Similar results can be obtained with MR following interstitial administration of iron-oxide-based contrast agents or macromolecular gadolinium-based contrast agents (4).



Lymphangioma. Figure 3 Sentinel lymph node imaging shows increased accumulation of tumor site and mapping of sentinel node. (a) Anterior view. (b) Lateral view.

Intervention

Female patients presenting with unilateral axillary masses and normal breast on physical examination can be a diagnostic and therapeutic challenge because there are many causes of axillary masses, including benign and malignant diseases. Mammographically detected enlarged axillary lymph nodes that show any abnormal radiological features or are clinically palpable merit further investigation, including biopsy (6). For those whose diagnosis of axillary adenopathy remains a mystery, fine-needle aspiration or excisional biopsy of the axillary node is necessary to determine the cause (3). Fine-needle aspiration biopsy is very useful in this setting. Although a negative diagnosis cannot definitely exclude malignant involvement, a possible diagnosis is quite reliable and can be used to influence treatment decisions (1).

Lymphangioleiomyomatosis

A rare idiopathic disease characterized by smooth muscle cell proliferation occurring both in the lungs and in the mediastinum and retroperitoneum. In the thorax it manifests as numerous lung cysts, recurrent pneumothorax, chylous effusion, and lymphadenopathy. Lymphangioleiomyomatosis predominantly affects the lungs of women of childbearing age and individuals affected by tuberous sclerosis. On chest radiography the unusual combination of a reticular pattern and hyperexpansion of the lungs is typical, and pneumothorax or pleural effusion are commonly present. Widespread cysts are the characteristic feature on computed tomography. They are multiple, thin-walled, and rounded; vessels are seen at the periphery of the cysts and generally are not displaced, as is often the case in centrilobular and bullous emphysema. The cysts do not show preferential distribution, unlike the cysts in Langerhans cell histiocytosis, which typically spare the costophrenic regions.

Synonym

Congenital lymphatic malformation

Definition

Lymphangiomas are uncommon hamartomatous congenital malformations of the lymphatic system that involve both the skin and subcutaneous tissues. Two major groups based on depth and size of abnormal lymph vessels are defined: Group I consists of lesions located superficially, and group II consists of lesions more deeply located (such as cavernous lymphangioma and ►cystic hygroma). The female-to-male ratio is equal. About 50% of lymphangiomas are seen at birth, and most are evident by the time the patient is 5 years old.

Pathology/Histopathology

Dilated lymph channels cause the papillary dermis to expand. These channels are more numerous in the upper dermis and often extend into the subcutis. These vessels contain smooth muscle. The lumen is filled with lymphatic fluid and often contains lymphocytes, red blood cells, and neutrophils.

Clinical Presentation

Lymphangiomas can occur anywhere in the skin and mucous membranes. The most common sites are the head and neck, followed by the proximal extremities, the buttocks, and the trunk. Sometimes they can be found in the bowel wall, pancreas, and mesentery.

Lymphangioma circumscriptum (group I) involves small clusters of vesicles measuring about 2–4 mm on the skin. These clear vesicles can vary from pink to red to black secondary to hemorrhage. This lesion can have a warty appearance and as a result can be confused with warts.

Cavernous lymphangiomas typically appear as subcutaneous nodules with a rubbery consistency. The overlying skin has no lesions or changes. The area of involvement varies, ranging from lesions smaller than 1 cm in diameter to larger lesions that involve an entire limb.

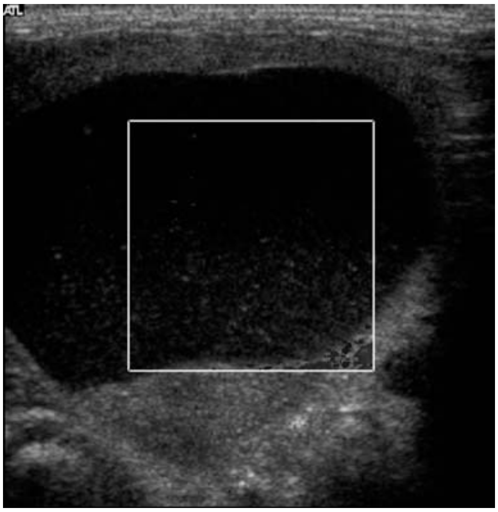
Cystic hygroma commonly occurs in the neck and parotid gland. It is a soft and translucent mass, with diameters larger than those of cavernous lymphangiomas.

Imaging

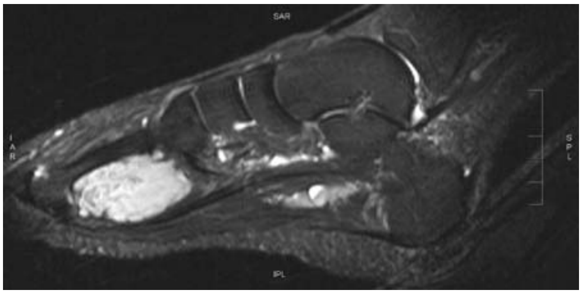
Plain films may show a large mass displacing adjacent structures.

Ultrasound (US) reveals an anechoic mass that is multilocular with fine septations. Sometimes the loculated space may be hypoechoic or hyperechoic depending on the chyle or blood content (Fig. 1).

Computed tomography (CT) also demonstrates septae and loculation. The attenuation value ranges from near fat to near water, depending on the fluid content. Postcontrast, the septa may enhance.



Lymphangioma. Figure 1 US shows hypoechoic mass without vascular flow.



Lymphangioma. Figure 2 On T2WI a hyperintense lesion is seen on the plantar side of the foot.

Magnetic resonance imaging (MRI) shows cyst characteristics ranging from fluid (hypointense on T1-weighted images) to fat (hyperintense on T2-weighted images; Fig. 2).

Nuclear Medicine

Nuclear medicine has no place in lymphangioma evaluation.

Diagnosis

The diagnosis of lymphangioma is based mainly on clinical history, physical examination, US, and conventional light microscopy.

US and CT can delineate septae and cysts. Both CT and MRI can define the extension of the lesion and involvement in surrounding tissues. If the lesions contain large cystic structures, they are treated with percutaneous sclerosing.

Immunohistochemical investigation for difficult cases is useful for differentiating between lymphangioma and hemangioma. Test results with factor VIII-related antigen are positive for hemangioma and negative for lymphangioma. Immunohistochemical studies for laminin show the typical multilayered basal lamina blood vessels in the case of hemangioma and discontinuous basal lamina in lymphangioma.

Lymphangioma

▶Cysts, Cerebral and Cervical, Childhood

Lymphangioma, Hepatic

Convolute of dilated lymphatic channels that may contain proteinaceous material or blood. Usually solitary hepatic lesion, if multiple lesions are seen in multiple organs the condition is referred to as lymphangiomatosis.

▶Hepatic Pediatric Tumors, Benign

Lymphangiomatosis, Splenic

Diffuse involvement of the spleen by multiple lymphangiomas. It can be part of a generalized multisystem syndrome involving the liver, bone, lung, and/or brain, and it presents during infancy, childhood, or adolescence.

▶Neoplasms, Splenic, Benign

Lymphedema

Lymphatic edema of the arm, which affects 10–20% of patients who have suffered some kind of axillary surgery, especially if the patient also underwent radiation therapy and/or the lymph nodes contained cancer cells. Early signs of lymphedema are a feeling of tightness, pain, heaviness, swelling, redness, and less movement or flexibility.

▶Breast Conserving Therapy

▶Lymphopoietic System, Diseases of the

Lymphoepithelial Cyst

Lymphoepithelial cyst of the pancreas is extremely rare. It is a well-defined cystic lesion lined by mature keratinizing squamous epithelium surrounded by a rim of lymphoid tissue. They present predominantly in middle-aged or elderly males with non-specific symptoms. At imaging lymphoepithelial cysts show mainly a cystic appearance, but they may contain some debris as a result of their keratin content. The differential diagnosis includes all cystic lesions, but particularly dermoid cysts.

Definition

Breast lymphoma is an uncommon haematologic malignancy of the breast, representing about 0.5% of all malignant lymphomas and 2% of extranodal lymphomas. In most cases, the breast is involved as part of disseminated extranodal disease, usually ►non-Hodgkin lymphoma and very rarely Hodgkin lymphoma. Primary lymphoma of the breast, with or without axillary nodal involvement, is unusual.

Pathology/Histopathology

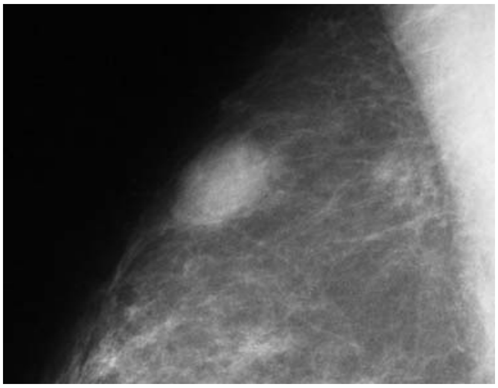
The majority of mammary lymphomas are of the ►B-cell type, with rare occurrences of T-cell lymphoma. Microscopically, they appear similar to extramammary lymphoma and consist of diffuse or focal (single or multiple) infiltration of the breast parenchyma with dense populations of lymphoma cells. They are fairly well circumscribed from the surrounding tissue, but usually show some marginal irregularities or indistinctness, because of their peripheral reactive lymphoid infiltrate. In contrast to primary breast carcinomas, however, they show no spiculations, since they do not elicit a desmoplastic reaction.

Clinical Presentation

Most breast lymphomas present as a rapidly growing painless palpable lump that is fairly mobile and relatively soft and elastic. Skin thickening, enlargement of the breast, and systemic symptoms such as fever, weight loss and night sweats may also be present. At the time of diagnosis, bilateral disease is present in about 10% of patients and enlarged axillary lymph nodes may be associated.

Mammography

The mammographic instance of breast lymphomas is non-specific and there is no correlation between the different subtypes of lymphoma and their mammographic features. Breast lymphomas can present as solitary or multiple, round or lobulated, fairly well-circumscribed nodules with smooth or indistinct borders, but without spiculations or calcifications (Fig. 1). In diffuse involvement, an asymmetric density with skin thickening and coarsening of the trabecular framework of the breast may be observed.



Lymphoma, Breast. Figure 1 Breast lymphoma presenting as an oval fairly well-circumscribed mass in the upeer outer quadrant. Note that no spiculations or calcifications are present.

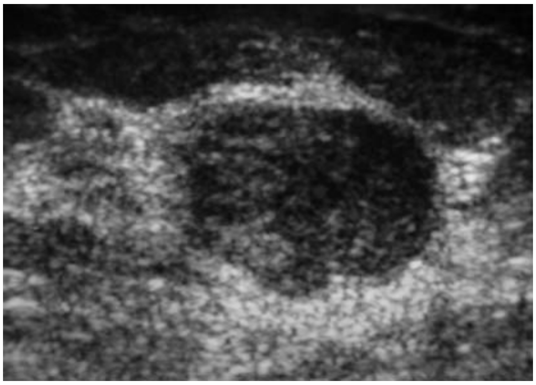
Axillary nodal involvement is mammographically indistinguishable from nodal metastases of primary breast carcinoma.

Sonography

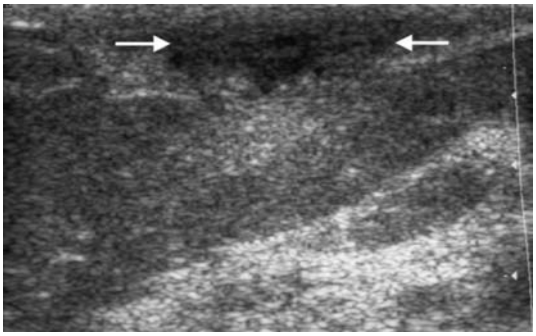
Breast lymphomas may be recognized as single or multiple, round or lobulated, heterogeneously hypoechoic masses with variable through-transmission and fairly well-circumscribed margins (Fig. 2). When there is peripheral reactive lymphoid infiltration, an ill-defined echogenic rim may surround the lesion. The skin may also be thickened and the lymphomatous tissue may show decreased echogenicity (Fig. 3).

Magnetic Resonance Mammography

The magnetic resonance instance of breast lymphoma is non-specific. On T1-weighted images, fairly well circumscribed hypointense masses that enhance rapidly, sometimes in a ringlike fashion, have been reported. On T2-weighted images, the masses may be ill defined or show a hyperintense halo. Magnetic resonance mammography can be helpful in determining the extent of involvement, but differentiation from primary breast carcinoma is not possible.



Lymphoma, Breast. Figure 2 Sonogram of a lobulated well-circumscribed heterogeneously hypoechoic breast lymphoma.



Lymphoma, Breast. Figure 3 Cutaneous B-cell lymphoma of the breast presenting as a lobulated fairly well-circumscribed hypoechoic mass adherent to the skin.

Nuclear Medicine

PET/CT scan may be useful to detect extramammary localizations of lymphoma and to distinguish between breast involvement in extranodal lymphoma or primary mammary lymphoma.

Diagnosis

Since most mammary lymphomas are part of a disseminated extranodal disease, any palpable abnormality in the breast in a patient with known lymphoma should raise the suspicion of mammary involvement. The diagnosis of primary breast carcinoma is limited to those patients without evidence of extramammary lymphoma at the time of diagnosis. Since the clinical and imaging presentation of both primary and secondary lymphoma are generally non-specific, the diagnosis should be obtained through cytological smear, core biopsy or excisional biopsy.

Lymphomas of the male genital tract; Lymphomas of the urinary tract

Definition

Lymphomas are tumors of the lymphatic tissue and account for 5% of all cancers. Although, lymphomas mainly involve lymphatic organs (lymph nodes, bone marrow, thymus, spleen, and mucosa-associated lymphoid tissue), they can also involve organs systems not containing lymphoid tissue. The most frequent extranodal localizations are digestive tract, skin, bone marrow, and head and neck. Genitourinary (GU) lymphomas represent 2 to 10% of all lymphomas. The GU tract may be affected either primarily or much more frequently secondarily in disseminated lymphomas or at recurrence.

Pathology/Histopathology

Most of lymphomas involving the GU tract are aggressive non-Hodgkin's lymphoma (mainly of B-cell origin), but low-grade lymphomas may be also seen. The appearance of a renal lesion in a patient followed up for a low-grade lymphoma suggests a transformation into a high-grade lymphoma. Usually, GU involvement is observed in patients with disseminated lymphoma, having other extranodal lesions. Primary renal lymphoma is a discussed entity, which has been reported in less than 0.7% of extranodal lymphoma series in the literature. Indeed, lymphoid tissue is not present in normal kidneys, and extrarenal lesions are frequently diagnosed at autopsy.

Clinical Presentation

Patients with lymphomas of the GU tract long remain asymptomatic and the diagnosis is usually made at CT. Clinical symptoms are usually nonspecific: pain, palpable mass, or less commonly, hematuria, edema, and hypertension. Serum creatinine level is increased in 10–40% of cases. In aggressive lymphomas, B symptoms such as night sweats, fever, or weight loss may be present.

Imaging

Urinary Lymphomas

Lymphomas of the urinary tract mainly involve kidneys, and may exhibit different patterns, depending on the mechanism of spread (1). The hematogenous spread usually results in tumor foci in the renal cortex, with progressive infiltration and formation of expansile masses displacing the collecting system, ultimately leading to complete replacement of kidney parenchyma. Infiltrative growth from retroperitoneal or perirenal preserve renal contours but invades kidney hilum and may compress excretory cavities.

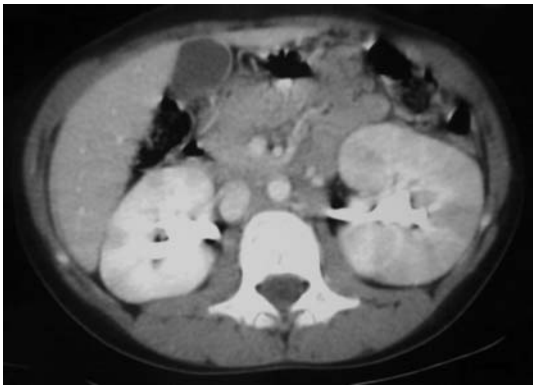
Masses/Nodules

Masses are one of the most common patterns of renal lymphomas. They consist of multiple *bilateral nodules* seen within kidney parenchyma, and usually reflect advanced disease in patients presenting for staging evaluation (Fig. 1). In some cases, lymphomas manifest as a *solitary tumor* simulating a renal cell carcinoma. Unique or multiple, lymphomatous nodules appear as round solid lesions in the renal parenchyma, hypoattenuating at CT, with little enhancement after contrast administration. At sonography, nodules appear hypoechoic with little vascularity. Nodules may displace calices and modify renal contours.

Contiguous Retroperitoneal Extension

Contiguous retroperitoneal involvement is also a common pattern, observed in 25–30% of patients (2). Initially, lymphoma is confined to retroperitoneal lymph nodes.

Lymphoma, Genito Urinary Tract. Figure 1 Contrast-enhanced CT examination in a patient with diffuse large B-cell lymphoma shows bilateral hypoattenuating nodules and retroperitoneal lymph nodes.



Lymphoma, Genito Urinary Tract. Figure 2 Contrast-enhanced CT examination in a young patient with lymphoblastic lymphoma shows lymphomatous infiltration of both kidneys, which causes nephromegaly and heterogeneous pattern of enhancement.

Then, lymph nodes grow up and typically result in a bulky retroperitoneal mass that invades the renal hilum, and secondarily spreads toward the parenchyma (Fig. 2). As a result, the renal collecting system may be obstructed, leading to renal failure. Before initiating therapy, placing a double-J ureteral catheter allows decreasing serum creatinine level and protecting kidneys from chemotherapy toxicity.

Infiltrative Disease

The infiltrative form of the disease is due to lymphomatous proliferation within the interstitium of the kidney. It is observed in 20% of patients, is almost always bilateral,

Lymphoma, Genito Urinary Tract. Figure 3 Contrast-enhanced CT examination in a patient with diffuse large B-cell lymphoma shows a large mass in the right retroperitoneum with extension into the right kidney. The heterogeneous pattern of enhancement in the kidneys suggests also an infiltrative pattern.

but may induce subtle changes, which may be misdiagnosed in the early stages of the disease. The main pattern of lymphomatous infiltration is enlarged kidneys with preserved contours (Fig. 3). Kidneys enhance only slightly after contrast injection due to impaired renal function. In some cases, contrast injection delineates more focal areas of infiltrations presenting as poorly defined hypoattenuating foci (3).

Perirenal Infiltration

Perirenal infiltration is rare in an isolated form without parenchymal involvement or retroperitoneal lymph nodes. It may appear as a thickening of the Gerota fascia, a renal sinus infiltration, or perirenal masses (2). The diagnosis may be difficult if the patient does not receive contrast material. However, after contrast, a sharp delineation between tumor and normal kidney is clearly seen since lesions usually enhance much less than normal kidney parenchyma. When present, this pattern is highly suggestive of lymphoma.

Excretory Cavities Involvement

Lymphomas involving the excretory cavities alone are very rare. They are more frequently seen at relapse than at initial diagnosis.

The diagnosis ureteral lymphomas can be made on a follow-up CT, or in a patient presenting with hydronephrosis. The typical pattern is a circumferential thickening of the ureteric wall, either segmental or total, sometimes associated with an infiltration of the surrounding fat.

Lymphomas involving the bladder are exceptional. They usually result from a contiguous pelvic extension in patients with aggressive lymphomas and bulky iliac lymph nodes or pelvic masses. They usually appear as a defect into the bladder resulting from the tumor bulging. Few reports of lymphoma involving the urethra have been published.

Genital Lymphomas

Genital lymphomas in male patients are mainly represented by testicle lymphoma. Lymphomas involving the prostate, the epididymis and the seminal vesicles are much less frequent.

Testicles

Primary testicular lymphomas are rare and represent 0.5–2% of all lymphomas. They are more frequently observed in elderly patients. Testicular lymphomas are usually aggressive lymphomas of diffuse large B-cell type. In the largest published series, the diagnosis was obtained by orchidectomy in 95% of cases, and the disease was at a localized stage in 79% of cases (4). Lesions are unilateral in 90% of cases, bilateral in 10%, and are best seen by sonography. Testicular lymphomas are hypoechoic relative to the surrounding parenchyma in about 95% of cases. The frequency of disseminated lymphomas in patients with testicular lymphomas depends on the examinations performed, and ranges between 13 and 66% in the literature. This kind of lymphoma is usually considered as a lymphoma having a pejorative outcome, with 50% extranodal relapse at 2 years, mainly in the central nervous system.

Prostate

Prostate lymphomas are very rare, and represent less than 0.1% of all lymphomas. They are usually diagnosed in elderly patients or on prostatectomy specimens. As opposed to prostate cancer, any part of the prostate may be involved. Clinical symptoms are the same as those seen in adenomas. Imaging studies detect a mass but the prostate specific antigen remains normal. Diagnosis relies on biopsy.

Lymphoma in Immunocompromised Patients

Immunocompromised patients may develop lymphoma more often than healthy subjects.

Acquired Immunodeficiency Syndrome

It is estimated that 10% of HIV positive patients will develop lymphoma. Lymphomas in AIDS patients are usually high-grade lymphomas (diffuse large B-cell lymphomas, B-cell immunoblastic lymphomas, and Burkitt lymphomas), presenting at stage IV with multiple extranodal lesions. Among these, kidney is frequently involved. The clinical course is more aggressive, and the disease is both more extensive and less responsive to chemotherapy than in general population.

Kidney Transplant Recipient

Lymphoma is a serious complication following solid organ transplantation. The risk for lymphoma during the first posttransplant year is 20- and 120-fold higher after kidney or heart transplantation, respectively, than that in the general population. Approximately 2% of renal transplant recipient will develop lymphoma. Whereas literature reports agree that the majority of lymphomas occur during the first few months after transplantation, little is known about the long-term risk for lymphoma development. Posttransplant non-Hodgkin lymphomas differ from lymphomas in the general population in histopathologic findings, higher extranodal involvement, a more aggressive clinical course, poorer response to conventional therapies, and poorer outcomes like AIDS-related lymphomas. The renal transplant itself may be involved, mainly in the nodular form.

Diagnosis

Apart from the testicular lymphoma, which is often localized, the diagnosis of lymphoma in general is evoked on a suggestive distribution of lesions at CT that is multiple lymph nodes associated with extranodal lesions. However, in patients with one renal nodule and sentinel retroperitoneal lymph nodes, the question of a renal cancer raises. The final diagnosis of lymphoma with appropriate subtyping is based on histopathology only. The progresses made in image-guided needle biopsy techniques and immunochemistry studies make possible to obtain a definite diagnosis of lymphoma in up to 93% of cases (5). This minimally invasive procedure is safe, easy to perform in the kidneys and reliable. In order to optimize tissue sampling and allow immunochemistry and cytogenetic studies, a coaxial technique is highly recommended. The use of large-cutting needles is possible since lesions are usually hypovascularized. Therefore, open surgery may be avoided as first diagnostic procedure in the management of patients with urinary lymphoma, and should now be fortuitous in case of an equivocal mass or a complication. In patients with testicular masses, the diagnostic approach still remains surgical biopsy or orchidectomy.

L

Synonyms

Hepatic lymphoproliferative disease

Definition

Hepatic lymphoma is considered to be primary when the malignancy is limited to the hepatic parenchyma and there is no evidence of further nodal or extranodal involvement. Hepatic involvement in patients with systemic lymphoma is defined as ►secondary hepatic lymphoma.

Pathology/Histopathology

Primary lymphoma of the liver, first documented in 1965, is extremely rare, representing only 0.4% of all extranodal lymphomas. However, the liver is often a secondary site of lymphomatous involvement, occurring in approximately half of the patients with non-Hodgkin's lymphoma and in 60% of patients with Hodgkin's disease at autopsy (1, 2).

►Primary hepatic lymphoma typically occurs during the fifth decade of life and has a male predominance. It is more common among immunocompromised patients, and a strong association has been identified with chronic hepatitis C.

▶AIDS-related lymphomas represent a nosological entity whose characteristic features resemble those of lymphomas seen in organ transplant recipients. Extranodal disease is more frequent, with marked predilection for the brain and the gastrointestinal tract. The liver is the second most common site of abdominal involvement after the bowel. AIDS-related lymphomas are highly aggressive tumors with poorly differentiated histological subtypes, most frequently non-Hodgkin's types, and are associated with a poor prognosis. Patients are typically diagnosed with advanced stages of disease (3).

The interrelationship between chronic hepatitis C and primary hepatic lymphoma remains unclear, although an increased incidence of hepatic lymphomas has been reported in patients affected by chronic hepatitis C. It has been documented that the hepatitis C virus may promote the clonal expansion of B-cells as occurs in associated cryoglobulinemia; additionally, viral cRNA has been detected within extrahepatic lymphoma tissue.

While Hodgkin's disease, non-Hodgkin's lymphoma, and various leukemias may secondarily involve the liver, virtually all primary hepatic lymphomas are non-Hodgkin's types. Most cases of primary lymphoma of the liver are of intermediate or high grade according to the classification of the working formulation for clinical usage. Diffuse large cell lymphoma is the most commonly encountered histological subtype, and most cases are B-cell lymphomas. The rare Hodgkin's lymphoma is generally of Reed–Stemberg cell type. Macroscopically the primary hepatic lymphoma usually occurs as a single large lobulated mass involving both hepatic lobes, and less often as multiple lesions. Conversely, Hodgkin's disease occurs more frequently as miliary lesions than masses. In both Hodgkin's and non-Hodgkin's lymphoma, initial involvement is seen in the portal areas, where the lymphoid tissue is mostly localized.

A few cases of primary hepatic mucosa-associated lymphoid tissue (MALT) lymphomas have been described in the literature. These lymphomas have a good prognosis and are low-grade B-cell lymphomas, occurring in a variety of extranodal sites but rarely as primary hepatic lymphomas. Different from other MALT lymphomas, these are not associated with autoimmune disorders. Typically, primary ▶hepatic MALT lymphomas appear as lymphoid infiltrates invading the liver in a serpiginous fashion, with nodular entrapment of normal liver (4).

Secondary hepatic involvement by malignant lymphoma (both Hodgkin's and non-Hodgkin's types) often appears diffusely infiltrative. Distinct nodular lesions are exceedingly uncommon in Hodgkin's disease but occur in half of the patients with non-Hodgkin's lymphoma. However, the nodule size is usually small, less than 1 cm (5).

Clinical Presentation

The most common early signs and symptoms are epigastric and right upper quadrant pain or discomfort and hepatomegaly without splenomegaly.

Fever, weight loss, and night sweats may be present. Jaundice and ascites are uncommon.

Liver function tests are usually normal except for elevated lactic dehydrogenase and alkaline phosphatase levels. Alpha-fetoprotein and carcinoembryonic antigen levels are invariably normal.

In immunocompromised patients the disease demonstrates an aggressive course.

Imaging

Ultrasound (US) displays primary liver lymphoma as a large hypoechoic mass, sometimes anechoic with a cystic-like appearance and typically with homogeneous echo structure and regular margins. In the diffuse forms, the echogenicity and architecture may be both normal and subverted.

Computed tomography (CT) findings of hepatic lymphoma consist of a large, lobulated, usually homogeneous, sharply marginated, solitary mass that is hypodense on nonenhanced scan and appears demarcated and lightly enhancing after contrast medium administration (Fig. 1). Low enhancement is due to tumoral hypovascularity. The degree of necrosis and the presence of calcifications can be variable. Typically, lymphomas do not infiltrate surrounding structures such as the vascular vessels, which are dislocated instead by mass effect (2).

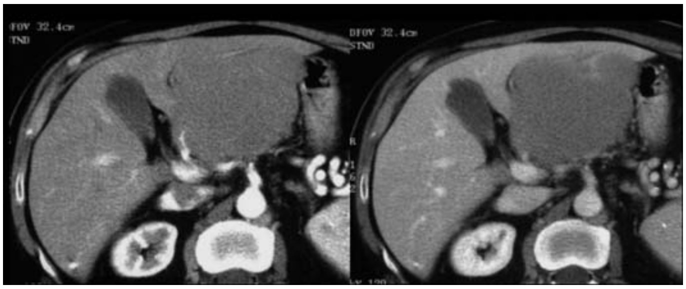
On magnetic resonance imaging (MR) the tumor usually appears homogeneously hypointense on T1-weighted images, isointense to the spleen in T2-weighted images (because of its rich cellularity), and minimally enhanced on early postgadolinium spoiled gradient echo images (Fig. 2).

AIDS-related lymphomas may show atypical imaging patterns such as a rim enhancement or an inhomogeneous appearance, simulating a complex mass.

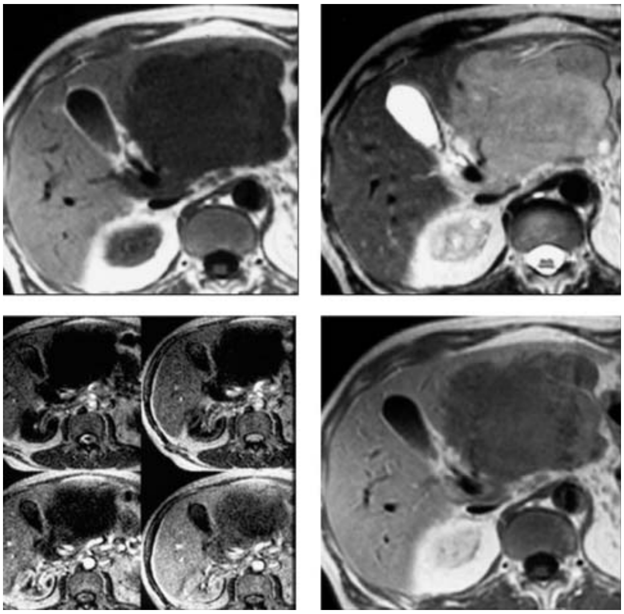
The appearance of primary liver lymphoma is in contrast to secondary involvement, which is diffusely infiltrative or micronodular (Fig. 3) in most cases and is frequently associated with the presence of retroperitoneal lymphadenopathy. When discrete lesions are present, they appear similar to those of primary hepatic lymphoma (5).

Nuclear Medicine

Imaging using radionuclide ^{67}Ga has proved useful for evaluating posttreatment lymphoma residual masses,



Lymphoma, Hepatic. Figure 1 **Primary hepatic lymphoma. Computed tomography scans shows a large mass involving most of the left hepatic lobe, causing compression but not infiltration of the surrounding structures (hepatic vessels). The lesion appears hypodense both in the arterial (*left*) and portal (*right*) venous phases.**



Lymphoma, Hepatic. Figure 2 **Magnetic resonance study of the same lesion of in Fig. 1: T1-weighted image shows a homogeneous hypointense mass (upper left). T2-weighted image at the same level shows hyperintensity of the mass that is almost isointense to fat (upper right). After Gd–DTPA administration, the nodule reveals moderate enhancement in the arterial phase (*lower left*), with a hypointense pattern in the delayed phase (*lower right*).**

although the presence of normal bowel mucosal uptake and a relatively poor spatial resolution reduce the diagnostic accuracy of this technique. Fluorodeoxyglucose positron emission tomography (FDG-PET) imaging is a tomographic technique that allows precise localization of active glucose metabolism, suggesting potential sites of active disease.

Diagnosis

Imaging features of primary liver lymphoma are not specific when using a single modality. On the contrary, the integration of findings obtained with different imaging techniques may suggest the diagnosis. In the differential diagnosis, a solitary metastasis must be considered; however, a unique large metastasis is very unusual in the absence of a known primary tumor. Classic hypervascular hepatocellular carcinoma, focal nodular hyperplasia, and hepatic hemangioma can be excluded by contrast-enhanced CT if the typical hypodensity of lymphoma is demonstrated. The combination of clinical history, liver findings, and the presence of other supportive findings such as retroperitoneal lymphadenopathy can lead to the correct differentiation between primary hepatic lymphoma and other liver diseases.

Lymphoma, Hepatic. Figure 3 Secondary lymphomatous hepatic involvement. Ultrasound image shows an aspecific pattern consisting of multiple hypoechoic nodular areas of infiltration of the liver parenchyma.

Finally, the appearance of a normal biliary tree and the absence of a late enhancement on dynamic MRI allows the diagnosis of cholangiocarcinoma to be ruled out (2).

Lymphoma, Pancreatic

Lymphoma (predominantly the non-Hodgkin B cell type) involves the pancreas secondarily in approximately 30% of patients with widespread disease. Primary lymphoma of the pancreas is uncommon, representing 1–5% of cases of extranodal lymphomas. The most common clinical findings are abdominal pain and weight loss. Although representing classic symptoms of nodal non-Hodgkin's lymphoma, fever and night sweats are rare in patients with primary pancreatic involvement. Jaundice represents an infrequent finding, even with large lesions involving the pancreatic head.

On sonography, primary ►pancreatic lymphoma usually appears as a homogeneous hypoechoic mass with enlarged peripancreatic lymph-nodes. At CT, pancreatic lymphoma generally appears as a larger, bulky tumor and is often seen as a homogeneous mass. Enhancement after administration of contrast medium is usually poor. Two distinct CT patterns have been described, including focal and circumscribed masses and diffuse enlargement of the gland. The diffuse infiltrating pattern may mimic the imaging findings of pancreatitis with gland enlargement and irregular infiltration of the peripancreatic fat. Dilatation of Wirsung's duct is usually mild. Encasement of the peripancreatic vessels may occur, but vascular obstruction is uncommon despite the presence of a large tumor, a helpful distinguishing feature from other malignant tumors. The presence of associated enlarged peripancreatic lymph nodes also favors the diagnosis of lymphoma. At MR examination, lymphoma appears as a low-signal-intensity homogeneous mass within the pancreas on T1-weighted images with poor enhancement after gadolinium administration. On T2-weighted images, the lesion shows a more heterogeneous appearance. Only mild pancreatic ductal dilatation is usually visible on MRCP. Despite the rarity of primary pancreatic lymphoma, it is important to differentiate this entity from adenocarcinoma as the management of these two conditions is different. If the imaging findings are suggestive of lymphoma, a definitive diagnosis must be achieved by percutaneous or endoscopic biopsy averting unnecessary surgery, because lymphomas are generally treated by chemotherapy.

Synonyms

Lymphedema; Lymph node metastasis

Definition

1. Lymphedema is defined as an increased accumulation of lymphatic fluid in the extravascular compartment.
2. Lymph node metastasis is defined as regional or distant lymphogenic spread of malignant solid tumors.

Pathology/Histopathology

1. Lymphedema may be due to an injury or insufficiency of lymph vessels, an increased venous pressure (e.g., deep vein thrombosis, right heart failure) or a decreased intravascular oncotic pressure (e.g., albumin deficiency).
2. Infiltration and/or destruction of lymph nodes by malignant solid tumor cells.

Clinical Presentation

1. Lymphedema initially presents with swelling of the legs which is often painful and extends above the legs in severe cases.
2. Lymph node metastasis may often show painless, hardened, and immobile lymph node enlargement.

Imaging

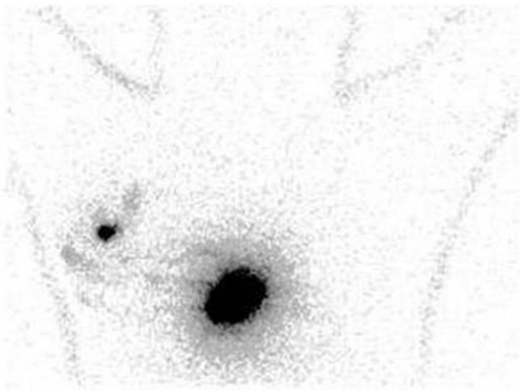
The procedure of lymphoscintigraphy using indirect interstitial injections offers advantages compared with the radiological procedures of lymphatic angiography and lymphadenography with contrast medium for the visualization of the lymphatic drainage system as well as the lymph node stations. Admittedly, the latter techniques stand out for their more detailed representation, but they are more complicated and more invasive, because the lymphatic vessels must be cannulated directly. The nodi lymphatici iliacae internae and mammariae internae are not amenable to radiological imaging but only to scintigraphic visualization after interstitial injection of the tracer in the surrounding connective tissue.

In the case of suspected lymph node metastasis, ultrasound and computed tomography or combined ^{18}F-FDG-PET-CT should be performed in order to determine the size, shape, and metabolic activity of the lymph nodes (cf. oncology).

Nuclear Medicine

Using lymphoscintigraphy, the first priority is to visualize the lymphatic drainage system in the surroundings of malignant tumors. In this way the possible metastasizing routes of the particular tumor can be determined (1, 2). As a rule, colloidal particles are used in lymphoscintigraphy, for example, denaturated albumin. Owing to their size, from 20 to 30 nm, these particles are removed *via* the lymphatic drainage system and retained and phagocyted in the reticuloendothelial system (RES) of the lymph nodes. The colloidal particles are labeled with 20–40 MBq ^{99m}Tc and injected intra- or subcutaneously, mostly in several smaller portions, into the surrounding tissue of the tumor. Direct injection into the tumor should be avoided so as not to risk a transfer of tumor cells into healthy tissues.

Acquisitions are performed immediately after injection in order to visualize the primary lymphatic routes. Preoperatively, it may be necessary to draw these routes on the skin of the patient. Static late acquisitions, mostly after several hours, serve to register the lymph node stations, whose knowledge is necessary for the surgical planning. The primary lymph node or the primary lymph node stations, which are a first filter station in the lymphatic drainage system of the tumor, are called the "sentinel lymph nodes" (SLNs). In patients with malignant melanoma, breast cancer, and tumors in the small pelvis—like the cervix, vagina, prostate, bladder, and rectum—for the preoperative visualization of the draining lymph vessels and the regional lymph nodes, the SLN should be visualized scintigraphically, because the surgical procedure of lymphadenectomy is particularly dependent on the histology of this lymph node (Fig. 1). The reliability of the detection of the SLN is further increased through the intraoperative application of a gamma detector. Therefore, unnecessary radical lymphadenectomies can be prevented. The targeted removal of the primary lymph node means that the therapeutic



Lymphopoietic system, diseases of the. Figure 1 ***Malignant melanoma*****. For improved localization, the body contours are delineated using a cobalt marker.**

perspectives remain preserved for many patients in an early tumor stage, despite the fact that lymphogenic metastatic spread has already occurred.

Lymphedema

Lymphoscintigraphy is also applied for the assessment of a primary or secondary lymphedema (3–5). In the case of an injury to the lymph vessels or a valve insufficiency, a diffuse outflow of lymphatic fluid occurs in the surrounding tissue ("dermal backflow"). As an indication of a proximal lymphatic vessel obstruction, collaterals between the distal lymphatic vessels can be detected. A subcutaneous injection of 20 to 40 MBq of a ^{99m}Tc-labeled microcolloid is made in the first or second interdigital space of the hands or feet. The removal of the tracer can be increased by mobilization of the extremities. During the first 2 h after the injection, planar scintigrams of the extremities are acquired and further acquisitions are made after an endurance test (e.g., 20 min climbing stairs).

Diagnosis

1. Lymphedema can be diagnosed by inspection and palpation. In order to determine the cause of the lymphedema, venous insufficiency, right heart failure, and albumin deficiency have to be excluded. An injury or insufficiency of lymph vessels can be determined by lymphoscintigraphy.
2. Lymph node metastasis is often diagnosed by inspection, palpation, and primarily morphologic imaging procedures. The exact anatomical position of the sentinal lymph node (SLN) can be determined using lymphoscintigraphy.

Magnetic Resonance Cholangiopancreatography

A noninvasive technique for the evaluation of the biliary tract. It is performed with the use of heavily T2-weighted images obtained with different pulse sequences without the injection of contrast medium that demonstrates stationary fluids, including bile and pancreatic secretions, as having high signal intensity whereas solid organs show a low signal intensity. This technique also allows the visualization of the pancreatic ducts generally after the administration of a secretive agent (secretin).

Magnetic Resonance Imaging, Activatable Imaging Agents

RALPH WEISSLEDER, ALEXANDER R. GUIMARAES
Center for Molecular Imaging Research, Massachusetts General Hospital, Charlestown, USA
weissleder@helix.mgh.harvard.edu

Magnetic resonance imaging (MRI) continues to be one of the diagnostic modalities of choice of producing noninvasive, high spatial resolution, multiplanar imaging of various disease states. It has recently become possible to expand MRI to obtain molecular information using genetic reporter systems (1) (see Chapter on genetic reporters). An alternative strategy has been to use targeted (see Chapter on targeted imaging agents) and activatable imaging agents. The different forms of activation strategies include: (i) imaging agents that change magnetic properties after specific enzymatic reactions (i.e., through cleavage of sugars or other molecules affecting water diffusion to paramagnetic metals [e.g., LacZ (2)]; (ii) imaging agents that amplify their signals due to oligomerization and protein binding [e.g., MPO (3)]; and (iii) nanoparticle-based magnetic relaxation switches (MRSW) capable of sensing DNA–DNA, protein–protein, and small molecule interactions (4).

Agents Based on Cleavage

Louie and Meade et al have recently demonstrated an example of a novel "smart" contrast probe that remains silent until activated by a specific transgene product (2). By using bacterial β-galactosidase (LacZ), because it is easily assayed, and not expressed in most mammals, they developed a contrast agent that was associated with a substrate for LacZ, galactopyranose. They covalently linked galactopyranose to a chelated paramagnetic Gd^{3+}, in a way that precluded access of water protons to the Gd^{3+} atom. This interaction with the LacZ substrate cleaved the galactopyranose, and thus allowed access of water protons to Gd^{3+} which shortened T1 and thus produced contrast. With intravenous mRNA to allow β-galactosidase activity within organisms, injection of this novel smart probe, produced visualization of those cells involved with LacZ activity. Using this technique, the authors measured an approximate 50% drop in T1, 100% increase in relaxivity with cleavage of the galactopyranose (2). Similar strategies have been employed using calcium activation, pH sensitive strategies, and through changes in viscosity through protein binding.

Agents Based on Oligomerization

Chen et al have recently synthesized an activatable paramagnetic MR imaging agent that targets the enzyme myeloperoxidase (MPO), which is an enzyme that is a marker of inflammation (3). This class of contrast imaging agents is highly sensitive to MPO activity, and have been shown to image *in vivo* sites of MPO activity that reflect inflammation. The imaging agent based on a covalent conjugate of Gd-DOTA and serotonin (3-(2-aminoethyl)-5-hydroxyindole). When the imaging agent was exposed to MPO, there was a resultant increase in molecular mass, and consequently increase in MR signal, with concomitant delayed clearance from tissue. Furthermore, MPO-mediated oxidation products bind to and cross-link with plasma proteins causing more local accumulation. The association with proteins also further contributes to the increase in MR signal due to R1 increase. The summation of these factors causes an approximate fivefold increase in R1, and thus increased contrast-to-noise (3).

MPO is implicated in multiple disease states including Alzheimer's disease, multiple sclerosis, lung cancer, and leukemia, and this class of agent, because of its capability of detecting sites of active inflammation in infection or injury, may lend further insight into these disease processes. One exciting possibility is in vulnerable plaque imaging, given the role that inflammation plays in atherosclerosis and plaque vulnerability. Furthermore, there is now an accumulating body of evidence that MPO plays a central role in this process, because MPO is found in high abundance in vulnerable plaques and in culprit lesions. Recent clinical trials have found that serum MPO levels predict cardiovascular risk in patients with acute coronary syndrome and chest pain. Furthermore, MPO-deficient humans appear to have decreased risk for cardiovascular diseases. Additional agents using this principle include dopa-DOTA and DPTA-bis-amide based agents.

Superparamagnetic-Based Activatable Reporter Systems

Magnetic nanoparticles (MNP) offer another means of achieving signal amplification through exploitation of their spatial arrangement. Through specific molecular interaction (e.g., DNA–DNA or small molecule–protein interactions) they can be induced to assemble into larger nanoassemblies and the superparamagnetic iron-oxide cores of the nanoparticles become more efficient at dephasing the spins of water protons, that is, at enhancing the spin–spin relaxation rate ($1/T_2$). Both dispersed (~40 nm) and clustered or nanoassembled state (~200 nm) remain in

M

solution and the conversion between the two states can be induced repeatedly (4). It has also been shown that this is a reversible process, and thus these nanoassemblies can be disassembled and returned to their original dispersed state by methods including heat, enzyme cleavage, pH alteration, and disulfide bond reduction (4). This reversibility provides a powerful medium of distinguishing subtle changes in the environment for which they are applied, and have thus been termed MRSW (4). This technology has been used to measure multiple different molecular reversible molecular interactions at extremely low contrast agent concentration (fM). Concentrations as low as 0.5 fM have been observed for DNA and proteins, whereas targets like viruses, with large, high multivalence, allow for detection of as few as five viral particles per 10 μL of herpes simplex virus-1 and adenovirus-5 (4).

We have exploited this observation and demonstrated MRSW assays are homogenous assays that can sense a wide variety of molecular interactions with high sensitivity and specificity with no sample preparation (Table 1). At the concentrations used (<20 μg Fe/mL) the nanoassemblies have not been noted to precipitate and are thus stable, and since these MNP are being used in clinical trials, there is a strong possibility of *in vivo* application in the near future.

Magnetic Resonance Imaging, Genetic Reporter Systems

Ralph Weissleder, Alexander R. Guimaraes
Center for Molecular Imaging Research, Massachusetts General Hospital, Charlestown, USA
weissleder@helix.mgh.harvard.edu

Magnetic resonance imaging (MRI) continues to be the diagnostic modality of choice of producing noninvasive, high spatial resolution, multiplanar imaging of various disease states. Only recently have technological advances in MRI systems and molecular biologic techniques advanced to such a degree to allow imaging of gene expression, *in vivo* (1). Imaging of gene expression using MRI may be achieved by two approaches: (i) imaging of introduced reporters or enzymes, which bind or metabolize (super) paramagnetic substrates; or (ii) imaging of a unique spectroscopic signature (2).

MR Imaging Strategies

Imaging gene expression by the use of receptors expressed on the cell surface, can be achieved by endocytotic internalization of supraparamagnetic nanoparticles (e.g., MION) (1). Tumor cells have a higher rate of endocytosis than normal cells and thus can be labeled selectively. For example, the human transferrin receptor (TfR) is expressed at higher levels on a variety of tumor cell types and can be imaged using transferrin (Tf) bound supramagnetic particles. Further, a genetically engineered form of the human transferrin receptor (ETR), lacking the negative feed back mechanism that results in the down-regulation of endogenous TfR expression, was expressed in 9L glioma tumors (1). At 24 h after perfusion of supraparamagnetic Tf particles into tumor-bearing mice, ETR tumors *in vivo* showed considerably enhanced MR signal intensity as compared to the same tumors lacking the ETR. HSV-based amplicon vectors have also been used to deliver ETR as a reporter, the expression of which can be probed with a dextran cross-linked iron-oxide (CLIO)Tf superparamagnetic nanoparticles, with ETR gene expression correlating with expression of therapeutic genes carried by the same amplicon. Thus, MRI of ETR expression can serve as a surrogate for measuring therapeutic transgene expression.

Another related example of the above is the use of ferritin transgenes. Following transfection of a metalloprotein from the ferritin family, into specific host tissues, the protein is made superparamagnetic as the cell sequesters endogenous iron from the organism. In this approach, the cells construct the MRI contrast agent *in situ* using genetic instructions introduced by the vector. No exogenous metal-complexed contrast agent is required, thereby simplifying intracellular delivery.

An alternative method with further amplification (and hence sensitivity) is the use of metabolically biotinylated reporter proteins (BAP) on the cell surface and imaging this with detectable versions of (strept)avidin (e.g., CLIO-streptavidin). One model recombinant reporter protein incorporates the prokaryotic *Propionibacterium shermanii* 1.3S transcarboxylase domain (PSTCD) biotin acceptor peptide (BAP) between an N-terminal signal sequence and the PDGF receptor transmembrane domain (TM). Western blot analysis of cell homogenates, immunocytochemistry of nonpermeablized cells and FACS analysis demonstrated that this BAP-TM reporter protein is efficiently biotinylated by endogenous biotin ligase in mammalian cells with the biotin displayed on the cell surface. Magnetic resonance (MR) imaging of subcutaneous tumors *in vivo* showed a significant difference in T2 values of BAP-TM-reporter-expressing tumors over control tumors following intravascular injection of streptavidin-CLIO. This BAP-TM reporter can allow noninvasive real time imaging of any cell type transduced to express it in culture and *in vivo,* and should be compatible with use in humans since (strept)avidin-biotin interactions are being used in clinical trials. In our hands it also represents the most efficient reporter gene developed so far.

Another way to monitor gene expression *in vivo* by MRI is to use biocatalysts to generate MR probes *in situ*. Several enzymatic systems have come forth based on single enzymes, such as tyrosinase, to catalyze the conversion of low-relaxivity substrates into high-relaxivity products. Tyrosinase, an enzyme normally involved in melanogenesis, has a remarkably high metal-binding capacity (up to 35% by weight), particularly of iron, that results in the high signal intensity in melanomas on T1-weighted images. Tyrosinase catalyzes two major reactions that occur primarily in lysosomes or premelanosomes: (i) the hydroxylation of L-tyrosine with the formation of L-DOPA (3,4-dehydroxy-L-phenylalanine) and (ii) the subsequent oxidation of DOPA with the formation of DOPA quinone. Several COOH-terminally truncated mutant forms of tyrosinase were engineered based on the hypothesis that in the absence of sorting signals, tyrosinase would not be sequestered exclusively in lysosomes/premelanosomes and tyrosinase-generated quinones could then cause toxicity to tumor cells. The expression efficiency, enzyme activity, and toxicity of these mutant tyrosinases were compared in several transformed cell lines. The mutant tyrosinases were able to convert certain model prodrugs into cytotoxic agents with resultant cell death and antiproliferative effects. Thus, tyrosinase mutants can serve for both antitumor gene therapy, as well as imaging marker gene expression.

The use of novel MRI contrast agents that can indicate reporter gene expression for commonly used marker enzymes, like β-galactosidase, offer the promise of *in vivo* mapping of gene expression in transgenic animals. One approach is the use of paramagnetic chelates that have the capacity to change their magnetic properties upon enzymatic hydrolysis (3). A paramagnetic galactopyranose chelator substrate for β-galactosidase has been developed based on the observation that the relaxivity of chelated gadolinium can be modulated by conjugating into β-galactose *via* a spacer. The removal of β-galactose from the paramagnetic conjugate by β-galactosidase mediated hydrolysis results in an increase in relaxivity by about 40%, which is detectable by MR imaging. This phenomenon has been used to image β-galactosidase activity in Xenopus laevis embryo (3).

Other recent examples of imaging transgene expression include the utililzation HeLa cells, transfected to express a truncated form of the $H2K^K$ antigen, $tH2K^K$. When exposed to $tH2K^K$ antibodies conjugated to a superparamagnetic iron-oxide particle and imaged with MRI, there was a marked decrease in the $tH2K^K$ expressing cells (4).

MR Spectroscopy

MR spectroscopy (MRS) shares the same principle as MRI. In MRS, the signal obtained from a single element is further separated into its different chemical forms. It is thus possible to define a spectrum of nuclear magnetic resonance signals, in which the several chemical forms of an element give peaks in specific positions and thus offer the potential to measure gene expression. MRS has been used for quantitative noninvasive imaging of tumors (5). Animals bearing tumors expressing the cDNA encoding for cytosine deaminase from yeast (yCD) were treated with nontoxic 5-fluorocytosine (5-FC) prodrug. The yCD catalyzed conversion of 5-FC to the chemotherapeutic agent 5-fluorouracil (5-FU) was quantitated *in vivo* using 19F MRS. This study demonstrated the local conversion of 5-FC to 5-FU, validating the concept of localized chemotherapy by enzyme prodrug activation. The ability of MRS to follow prodrug conversion dynamically and to distinguish between individual metabolites is a significant advantage over PET methods, which would require measurement of plasma metabolite levels.

Gemacitabine (dFdCyd) is a cytotoxic deoxycytidine (dCyd) analog that has demonstrated significant antitumor activity in a variety of human tumor models. dFdCyd is converted to an active metabolite by phosphorylation to a triphosphate derivative, dFdCTP, which is then incorporated into DNA. This reaction is catalyzed by a rate-limiting enzyme, deoxycytidine kinase (dCK). 19F MRS has been recently used to detect increased incorporation of dFdCTP in human colon carcinoma xenografts in mice infected with a retroviral vector containing the dCK gene. This finding has potential clinical relevance in dCK gene-directed therapy through enhancing cytotoxic effects of dFdCyd chemotherapy and allows use of 19F MRS as a noninvasive tool to determine efficacy of prodrug conversion.

Recent advances in the development of magnetic nanoparticles and their use in cell tracking heralds high potential for MRI in the future. Magnetic nanoparticles have been used to track and recover as few as 100 cells after a specific population of cells was specifically labeled and followed using MRI. Also, magnetic nanosensors (see Chapter—activatable imaging agents) have recently been developed with the capacity to detect specific DNA or mRNA sequences. Following hybridization of superparamagnetic nanoparticles bound to DNA to cellular nucleotide sequences, these probes exert sensitive and reversible effects on spin–spin relaxation of water protons.

Magnetic Resonance Imaging, Molecular MR Imaging

Ralph Weissleder, Alexander R. Guimaraes
Center for Molecular Imaging Research, Massachusetts General Hospital, Charlestown, USA
weissleder@helix.mgh.harvard.edu

Magnetic resonance imaging (MRI) is a noninvasive, multiplanar imaging modality based on the manipulation of the inherent nuclear magnetic moment of endogenous nuclei (most commonly ^1H in H_2O) within subjects, or after exogenous administration of agents which alter the natural relaxation mechanisms of these nuclei. By exposing nuclei to a static magnetic field, and within that static field, perturbing a steady-state equilibrium with time and space varying magnetic fields, one can obtain images with exquisite spatial resolution and soft-tissue contrast of disease states such as cancer, stroke, neurodegenerative diseases, autoimmune diseases, and trauma. After perturbation, all nuclei relax by two unique and codependent relaxation mechanisms: T1 (spin–lattice relaxation), and T2 (spin–spin relaxation). By exploiting these relaxation mechanisms, contrast agents and pulse sequence algorithms can be designed to further specify the imaging patterns of many diseases. This can be achieved by spectroscopic methods, the use of unique pulse sequence strategies [e.g., diffusion-weighted imaging

M

(DWI), functional MRI (fMRI)], MR detectable reporter transgenes (see Chapter on genetic reporter systems), activatable MR imaging agents (see Chapter on activable reporter systems), or targeted MR imaging agents (see Chapter on targeted imaging agents). Molecular MR imaging aims to provide detailed, specific molecular and cellular information in diagnostic imaging studies.

Intrinsic MR Contrast Mechanisms

Magnetic Resonance Spectroscopy

Magnetic resonance spectroscopy (MRS) has been used for some time to analyze the metabolic properties of cells and tissues in organs and in living systems. Multiple nuclei possess a nuclear magnetic moment, and can thus be probed using nuclear magnetic resonance. The nuclei most often investigated with MRS can be divided between their capability of being inherently monitored using extant MR technology (e.g., ^{1}H,^{31}P, and ^{23}Na), or by whether they need to be exogenously administered (e.g., ^{19}F, ^{13}C,^{7}Li). Either through single-voxel localized techniques (e.g., STEAM, PRESS), or through multiphase encoding spectroscopic imaging, MRS has advanced the study of cellular and organ physiology, *in vivo* and *in vitro* in normal and diseased systems.

Using the administration of exogenous metabolites, MRS has shown the capability of monitoring and quantifying *in vivo* concentrations in many normal and diseased states. A few examples include the following: (i)^{19}F MRS has been used to rapidly monitor the pharmacokinetics of fluorinated chemotherapeutic agents (e.g., 5-flurouracil); (ii) ^{13}C label has been used on multiple carbon atoms of the glucose molecule to study metabolism in disease states such as cancer and cardiac; (iii) ^{7}Li is an uncommonly interrogated nucleus, but has been used to better understand and correlate the uptake and brain concentration of ^{7}Li to therapeutic efficacy in patients suffering from manic depression and other psychiatric illnesses routinely treated with lithium.

Although exogenously administered metabolites continue to be used, it is the endogenous nuclei, ^{1}H and ^{31}P, that have most impacted *in vivo* study of human disease (1). In summary, although inherently an insensitive technique, ^{31}P MRS has been used to study energy, phospholipids, and carbohydrate metabolism *in vivo* and *in vitro* noninvasively in human disease states including neuromuscular diseases (e.g., muscular dystrophy, neurologic diseases, psychiatric disease, hepatobiliary disease, and cardiovascular disease).

As ^{31}P MRS continues to evolve in development and application to many disease states, the application of ^{1}H MRS to human disease states has made a significant impact on extant, quotidian clinical care. The following metabolites in the ^{1}H MR spectrum have played a role in the study of disease states: (i) lactate—resonating at approximately 1.5 ppm, is a metabolic end-product of anaerobic glucose metabolism, and has been shown to correlate to degree of ischemia in neurologic and cardiovascular disease states, and has demonstrated a role in cancer prognosis, monitoring and therapeutic efficacy of anticancer medications that reduce intracellular pH[1]; (ii) N-acetyl aspartate—resonating at 2 ppm relative to tetramethylsilane (TMS), is only seen in functional neurons and easily quantified because of its relative isolation with the ^{1}H MR spectrum. Its loss has been correlated in many neurologic disease states (e.g., stroke, multiple sclerosis, cancer, and Alzheimer's disease); (iii) citrate, which resonates at approximately 2.3 ppm, although a normal intermediate within the Kreb's citric acid cycle, is not usually visualized within the ^{1}H MR spectrum of normal tissues, but has played an important role in prostate cancer, where it is thought to play a role as a carbon source for sperm and seminal fluid in distinguishing normal prostate gland from prostate gland involved with malignancy; (iv) creatine, which resonates at approximately 3.0 ppm, is a direct measure of cell energy viability, and its ^{1}H MRS quantification has been correlated to cell viability, and as such, is routinely used as an internal standard when quantifying other more specific markers of disease within the ^{1}H MR spectrum (i.e., choline and citrate)(1); (v) choline, which resonates at approximately 3.2 ppm, has been shown to be a sensitive and specific marker for cancer diagnosis and staging, has been shown to be elevated in cancers of the breast, prostate, colon, cervix and brain, as well as metastatic disease, and has been used in quantifying and distinguishing efficacy of treatment in chemo and radiation treatment strategies (1).

Diffusion-Weighted Imaging

A second intrinsic contrast mechanism in MRI exploits the dependency of water mobility on the directionality of the extracellular matrix, molecular viscosity and membrane permeability to probe water diffusion directly, and indirectly tissue cellularity in disease states (stroke, malignancy). Diffusion-weighted MR imaging (DWI) is performed by imparting two field gradients of equal strength, surrounding the 180° pulse of a spin echo sequence, which makes the MR signal intensity dependent on the phase shift imparted in water molecules. Varying the symmetric gradient strengths, thus probing different diffusion sensitivities, can facilitate calculation of the apparent diffusion coefficient (ADC) (2). Raw diffusion-weighted images are in routine clinical utility in the study of acute ischemic disease in humans. As a result of water mobility being impaired by areas of increased cellular density, it has been proposed that the ADC value is inversely related to cellularity of brain tumors.

Early results from using the ADC in both pre-clinical and clinical treatment trials in various malignancies (e.g., breast, brain) indicate that changes in the ADC may predict later changes in tumor volume, and may be an early surrogate marker of treatment efficacy (2). Preliminary results suggest with decreases in contrast enhancement were increases in water mobility as measured by increased ADC, which suggests tumor necrosis in both animal models and clinical trials. (2)

Contrast Agents

Gadolinium-Based Agents

This section provides a brief overview of commonly used MR contrast agents. See also chapters on targeted (MR-targeted imaging agents) and activatable (MR-activatable agents) for additional compounds. Targeted contrast agents characterize the extrinsic contrast mechanisms of MR molecular imaging. Those contrast agents that use Gd (III) can be categorized as low molecular weight or high molecular weight (macromolecular) contrast agents (3, 4). The low molecular weight contrast agents, which Gd(III) with a diethylenetriaminepentaacetic acid (DTPA) chelate is the most ubiquitous, have been used for molecular imaging because their chemical structure lends itself well to coupling with other molecules or targets (3). Gd-DTPA allows the evaluation of physiological parameters such as the status of the blood–brain barrier, perfusion, with mathematical modeling, tumor enhancement, and renal function. Because of the relative nonspecificity of Gd-DTPA, the relatively poor relaxivity, as well as short intravascular half-life, there has been increased interest in gadolinium-based macromolecular contrast agents to attach more Gd(III) groups to each molecule (3, 4).

Macromolecular contrast agents that use Gd(III) have been developed with varying protein based conjugates including the following: (i) albumin, which has been demonstrated to have long lived intravascular components, and as a result continues to be used both as a conjugate for other biomolecules, as well as a primary imaging agent for angiogenesis; (ii) avidin, which binds to streptavidin, the combination of which has been used as a prelabeling mechanism to bind to the biotin ligands; (iii) poly-L-lysine; (iv) polyamidoamine (PAMAM) dendrimers; and (v) direct conjugation to monoclonal antibodies (mab). Another approach that has been attempted to increase delivery of number of gadolinium groups to the target is by cross-linking liposomes labeled with a large concentration of gadolinium, thus increasing the relaxivity of the target. In all cases, the goal is to increase the contrast to noise after delivery of target to background. Although of significant preclinical and biomedical research interest, these strategies have not reached the clinical arena.

Superparamagnetic Magnetic Nanoparticles

An alternative contrast agent strategy is based on the superparamagnetic iron oxide containing nanoparticles [a.k.a magnetic nanoparticles (MNP)]. These materials typically consist of a 3–5 nm core of superparamagnetic iron-oxide and polymer coatings, to which biomolecules can be attached (5). Iron-oxide MNP have R2 relaxivities between 50 and 400 $(\text{mM sec})^{-1}$ and typically contain multiple thousands of iron atoms per nanoparticle. When clustered R2 relaxivities can reach as high as 300,000 $(\text{mM sec})^{-1}$ (5). Because these MNP are superparamagnetic their R2 relaxivity dominates over the R1 relaxivity and is thus most sensitive on T2- and T2*-weighted pulse sequences.

Historically, polymer-coated iron-oxide molecules have been used in the treatment of anemias, and because of the relaxivity properties multiple variants of iron-oxide MNP with polymer coating have been developed. The first iron-oxide MNP, because of size heterogeneity, were rapidly phagocytosed by macrophage, and served as excellent imaging agents for the liver and spleen, demonstrating good sensitivity for distinguishing metastases from normal liver and splenic parenchyma. By refining the chemical structure and making the molecule smaller (25–30 nm) and homogeneous in size (termed monodisperse—one crystal per nanoparticle), these MNP were found to have increased vascular half lives (>10 h in mice, and >24 h in humans) as well as lymphotrophic components (6).

Other derivatives of iron-oxide MNP involve iron-oxide crystals (3–10 nm in diameter) coated with lipid and polyethylene glycol (PEG), which can reduce binding of plasma proteins and phagocytosis and clearance by macrophage. The most ubiquitous, and widely clinically used MNP offer a superparamagnetic iron-oxide core with a dextran or dextran derivative coating (Feredex®, Resovist®, Combidex®, and ferumoxytol) (5). Depending on the size and surface characteristics of these surface coats, different clearance mechanisms exist (5, 7).

Clinical Applications of Molecular MR Imaging

Using these techniques, advances have been made in contrast agent development in clinical and preclinical

Magnetic Resonance Imaging, Molecular MR Imaging. Table 1 List of targeted and nonspecific MRI based contrast agents and their specific clinical or preclinical application

Disease	Imaging agent	Application
Cancer	Iron oxide (ferumoxide)	Liver cancer
	Iron oxide (ferumoxtran, ferumoxytol)	Nodal staging/angiogenesis
	Integrin a_vB_3	Angiogenesis
Infection	Iron oxide	Inflammation
Inflammatory diseases (e.g., arthritis)	Iron oxide	Inflammation
Neurological	Beta-amyloid targeted iron oxide	Alzheimer's disease
Thrombosis	Fibrin (Gd-labeled)	Acute/subacute thrombi
Atherosclerosis	Iron oxide (ferumoxtran)	Macrophages/inflammation
	Integrin a_vB_3/VCAM	Angiogenesis
	Gadofluorine	Lipid-rich plaques

models including earlier detection of disease, drug discovery and development, and biomedical research, including the elucidation of enzymatic and cellular events in inflammation, angiogenesis, apoptosis, stem cell trafficking, and atherosclerotic disease. Table 1 illustrates various targeted, and nonspecific MRI based contrast agents and their specific clinical or preclinical application (8). Although a detailed listing of all applications of MR molecular imaging is beyond the scope of this chapter, we highlight the application of MRI within cancer and atherosclerotic disease.

Molecular Imaging of Cancer

Cancer Staging

MR molecular imaging has made marked strides in cancer staging, in specific, lymph node metastases (6). As with cancer detection, extant imaging approaches rely on computed tomography (CT), conventional radiography, and MRI for cancer staging, and these imaging approaches, in their conventional form, lack the sensitivity and specificity to distinguish potential metastatic involvement of lymph nodes that are less than 1 cm. in short axis. In addition, small lymph nodes (<1 cm) remain beyond the detection threshold of this technique as well.

The development and clinical introduction of lymph node targeted MNP has been shown to significantly improve diagnostic accuracies of MR imaging for nodal staging in prostate cancer (6). Within this technique, images are performed before and 24 h after the administration of magnetic nanoparticles, in particular Ferumoxtran-10 [Combidex—Advanced Magnetics, Inc., Cambridge, MA]. Secondary to their iron-oxide core, T2*-weighted imaging is performed. There is reliable accumulation within normal lymph nodes, and the lack of contrast uptake, as determined by a lack of T2* decrease in signal, has been shown to correlate to the presence of metastatic deposits (6). Preliminary studies in patients with prostate cancer show that MNP are highly accurate reporters for detecting tumor burden even in clinically occult disease. This methodological approach has increased the sensitivity of MRI detection of metastatic involvement of lymph nodes from values as low as 43% to >90%, with specificities approaching 100% (6).

In later more recent work, Weissleder and Harisinghani have expanded upon this work to semiautomate data analysis routines in lymphotropic magnetic resonance imaging (LMRI). With this semiautomated approach, the combination of two variables was determined to increase the sensitivity and specificity of LMRI with MNP to 94.3% and 93.5%, respectively, with positive and negative predictive values 93.5% and 98%.

Although, gadolinium-based approaches have been applied to lymph node imaging, these have not reached clinical utility.

Angiogenesis Imaging

The imaging of neovascular content is currently one of the most intensely studied tumor pathways because of the rapid development of novel strategies to inhibit neovascular growth in cancer. Angiogenesis is a prominent feature of invasive cancers and is associated with adverse prognosis (9). Toward that end, recent increased interest has focused upon the rapid development and implementation of drugs to inhibit neovascular growth (angiogenesis inhibitors). Multiple variants of these inhibitors continue to be developed and are in various phases of ongoing clinical trials. Documentation of the degree of angiogenesis in primary and metastatic tumors is also important for treatment planning and assessing the efficacy of angiogenesis inhibitors, including low-dose cytostatic therapies.

Current biomarkers of angiogenesis include serum markers (e.g., VEGF, FGF), microvessel density (MVD) quantification, tissue markers (e.g., histologic staining for CD31, FVIII, Ulex lectin) and imaging (e.g., nuclear imaging, CT imaging with dynamic contrast or MR imaging). MVD is a correlative, surrogate marker of angiogenesis, and has been shown to be of prognostic significance in various malignant therapies. Concurrent with recent advances in the development of angiogenic inhibitors, has been technological improvements in imaging angiogenesis, so as to provide a noninvasive, surrogate marker of anti-angiogenic efficacy.

Imaging angiogenesis with MRI has been focused into three different arenas: (i) functional imaging using dynamic tracking of contrast administration; (ii) steady state blood volume determinations of neovascular density; and (iii) specific molecular markers of angiogenesis.

Functional dynamic contrast enhanced MRI (DCE-MRI) approaches rely on the "leaky" nature of angiogenic blood vessels associated with malignancy. By using a small contrast agent, dynamic imaging is used and with the aid of compartmental modeling, various parameters are derived including permeability surface area product (a.k.a Ktrans), and fractional plasma volume. DCE-MRI has been applied clinically to many cancer systems including breast, brain, prostate, and renal cell, with interesting results, but confounded by high variance.

By imaging primary neoplasms, before and following the administration of MNP, a parametric map of tumor blood volume can be calculated by the change in T2* within the primary neoplasm. By correlating tumor blood volume to known blood volume of muscle, one can derive a vascular volume fraction (VVF). We refer you to the original description of this technique for further elaboration of the mathematical details of the technique (10).

In animal models it has been shown to have high accuracy when compared to other surrogate markers of angiogenesis (e.g., microvessel density, radiolabeled blood volume measurements). In recent xenograft treatment trials, results suggested that VVF measurements are earlier and more reliable indicators of successful antiangiogenic treatment regimen than is tumor volume.

MR Molecular Imaging of Atherosclerosis

The noninvasive assessment and identification of high-risk atherosclerotic lesions and thus, those patients deemed "high-risk" for a cardiovascular, or cerebrovascular events, remains an important focus of clinical research. One goal of molecular imaging has been to provide functional information about those biologic processes specific to atherosclerosis (8), and the pathophysiology of vulnerable plaque including inflammation, apoptosis and angiogenesis.

Activated macrophages have been found to play a key role in the pathophysiology of atherosclerosis and their presence is specific for high-risk lesions. Imaging of macrophages may offer a window into separating and identifying those patients and plaques at high risk for disruption. Iron-oxide MNP accumulate within macrophages, have been found to accumulate within human atherosclerotic macrophages and are therefore preferentially found in macrophage-rich carotid plaques. After intravenous injection of magnetic nanoparticles, there was uptake and enhancement of carotid plaques on T2* sensitive gradient echo techniques as compared to baseline MRI. Histopathologic analyses of carotid endarterectomy specimens confirmed iron localized within these regions.

Specific targets have been exploited as well. An example is VCAM-1, which is a critical component of the leukocyte-endothelial adhesion cascade. By using this protein and binding to a CLIO—Cy5.5 backbone (a cross-linked iron-oxide nanoparticle that provides a platform for novel magneto-fluoro MR contrast agent development in animals), MRI and fluorescent imaging demonstrated high affinity for endothelial cells expressing VCAM-1 but low affinity for macrophages *in vitro* and *in vivo* in both neoplastic and atherosclerotic models. In addition to VCAM-1, the CLIO platform has been used to image selectively E-selectin in mouse xenograft models of Lewis lung carcinoma by attaching E-selectin-binding peptide to CLIO (Cy5.5) nanoparticle, as well as apoptosis through attachment of CLIO (Cy5.5) to Annexin V.

Magnetic Resonance Imaging, MR-Targeted Imaging Agents

Ralph Weissleder, Alexander R. Guimaraes
Center for Molecular Imaging Research, Massachusetts General Hospital, Charlestown, USA
weissleder@helix.mgh.harvard.edu

Exploiting T1 and T2 contrast mechanisms have dominated the design of novel magnetic resonance imaging (MRI) agents targeted for various clinical and preclinical molecular imaging applications. Multiple such targets have been exploited using paramagnetic [e.g., Gd (T1-based)] and superparamagnetic [e.g., iron oxide magnetic nanoparticles (MNP)]. For nontargeted MR contrast agents see Chapter (MRI—molecular imaging). Table 1 is a list of many targets for which imaging agents have been developed.

Paramagnetic-Targeted Imaging Agents

Targeted paramagnetic imaging agent strategies can be categorized based on the size of the molecule being developed. Examples of small molecule (<1,000 Da) approaches to contrast agent development include: (i) MnDPDP, which binds to a vitamin B6 analog, and is a commonly used hepatobiliary agent and (ii) MS-325, a small contrast Gd-based contrast agent that binds to

Magnetic Resonance Imaging, MR-Targeted Imaging Agents. Table 1 List of Various Targeted Imaging Agents, their respective sizes, and targets

Type	Size	Imaging agent	Targets
Paramagnetic (Gd)			
	Small molecule		
		MS-325	Albumin
		Mn-DPDP	Hepatocytes
	Peptides		
		Gd(DTPA)	Nonspecific
	Macromolecules		
		Mab	Antibodies
		Streptavidin	Biotin + antibodies
		Polylysine	Antibodies
		Dendrimers	Receptors (folate)
		MPEG-polylysine	
	Nanoparticles		
		Micelles	Cell internalization
		Liposomes	Cell internalization
		Nanoshells	Cell internalization
Superparamagnetic (MNP)			
	Nanoparticles		
		MION-36-antimyosin	Myosin
		CLIO-Tf, MION-Tf	TfR
		CLIO-Cy5.5-VHS	VCAM-1
		CLIO-Cy5.5-BCDSDSDITWDQLWDLMK	E-selectin
		CLIO-L-R-Cy.5.5	Cathepsin-B
		CLIO-Bombesin	GRPR
		CLIO-Cy5.5-RGD	AvB3
		CLIO-Cy5.5-YCAREPPTRTFAYWG	Muc-1
		CLIO-Mab	CD40 ligand
		CLIO-annexin	Phosphatidyl serine
		CLIO-Tat(FITC)	Cell labeling
		MION-46, MION-47, CLIO-Cy5.5	Macrophages
		CLIO-annexin	Annexin V

albumin, which increases its intravascular half-life, making it suitable for angiographic studies.

A number of targeted approaches using direct peptides bound to Gd-DTPA have been investigated but remain low in sensitivity (1).

Macromolecular contrast agents that use Gd(III) have also been developed for MR imaging using the following platforms: (i) albumin has a long lived intravascular component and as a result continues to be used both as a conjugate for other biomolecules, as well as a primary imaging agent for angiogenesis (1); (ii) avidin, which binds to streptavidin, the combination of which has been used as a prelabeling mechanism to bind to the biotin ligands (1); (iii) poly-L-lysine; (iv) polyamidoamine (PAMAM) dendrimers; and (iv) direct conjugation to monoclonal antibodies (mab). Specific examples of targeted gadolinium contrast agents using some of these approaches include a dendrimer (PAMAM) conjugated to Gd-DTPA which demonstrated affinity to the folate receptor in folate expressing ovarian tumor xenografts. In an alternative approach, breast cancer xenografts expressing HER-2/neu receptors were imaged with a two-step labeling protocol using biotinylated Herceptin mab and avidin-Gd-DTPA conjugates (1).

Nanoparticle-Based Targeted MR Imaging Agents

Nanoparticles with magnetic properties have been developed to further amplify MR signal (2). Nanoparticle imaging agents can be divided into those that are paramagnetic and those based on superparamagnetic agents.

Paramagnetic Magnetic Nanoparticle–Based Targeted Agents

Paramagnetic nanoparticles using Gd(III) have been developed using micelles liposomes, and nanoshells (1). These methods improve cell internalization and serve as an amplification strategy for targeted MR paramagnetic imaging contrast agent development. One example that has been targeted for angiogenesis imaging with a paramagnetic substrate is the $\alpha_v\beta_3$ ligand. This receptor integrin has been shown to be selective for angiogenic endothelium and tumor cells and was therefore chosen as a potential, specific marker for directed molecular target–specific agent development both for diagnostic imaging as well as therapeutic efforts, possibly. This has been exploited in a variety of different avenues including other MRI-targeted approaches either using antibodies conjugated to liposome nanoparticles sequestering Gd, or other direct antibody conjugations to nanoparticles. These approaches open up a novel means of addressing specific angiogenesis targets, and also demonstrate novel means of addressing the benefits of soft-tissue contrast, and superior spatial resolution inherent to MRI, while solving some of the inherent low sensitivity associated with MRI.

Magnetic Nanoparticles

An alternative approach for molecular targeting of contrast agents is based on superparamagnetic nanoparticles (MNP). This is an attractive platform for targeted agents for the following reasons: (i) the use of long-circulating nanoparticles improves the bioavailability of imaging ligands and avoids rapid renal clearance; (ii) nanoparticles can be used to attach small molecules in multivalent form, resulting in binding affinities that vastly surpass those of single molecules; and (iii) fluorescent nanoparticle platforms can be used as screening techniques to identify "binders."

Almost all *clinical* preparations to date have relied on dextran or carbohydrate derivatives as coating materials because of their prior use as a plasma expander and because of their affinity for iron oxides. The most widely used polymer-coated magnetic nanoparticles (Feridex, Resovist, Combidex, AMI-228/ferumoxytol) all contain dextran or dextran-derivatized coating. An important distinction between first generation polydisperse and second generation monodisperse preparations is the much longer half-life of the latter. For this reason, polydisperse materials are only useful for liver imaging, whereas monodisperse materials have a wider range of applications.

One of the earliest approaches at direct targeting includes direct conjugation of magnetic iron oxide nanoparticles (MNP) to monoclonal antibodies. These agents, however, demonstrated low sensitivity and specificity for the target. In order to make iron oxide MNP more target-specific, multiple strategies have been employed. By formation of Schiff bases between the amine of the biomolecule of attachment and aldehyde of the dextran coating of MNP, we devised a reproducible scheme based on earlier work by Molday to conjugate biomolecules to MNP's (3). Early examples include asialoglycoprotein receptors for liver imaging, antimyosin-labeled MNP for detection of myocardial infarcts, and labeled secretin for imaging of pancreatic acinar cells. More recent examples include conjugating MNP to the C2 domain of the protein synaptotagmin, which binds to phosphatidylserine, a protein present on the plasma membrane of apoptotic cells.

While second generation MNP are useful for lymph node and angiogenesis imaging, these materials have the disadvantage that the dextran coating is not tightly associated with the iron oxide core, yielding inefficient starting materials for targeted agents. An alternative approach for targeted synthesis using superparamagnetic MNP cross-links and aminates the dextran of dextran-coated MNP's to therefore provide an amino group for binding biomolecules. One experimental agent that has been used widely is amino-CLIO (cross-linked iron oxide). Each amino-CLIO bears approximately 40 amino groups for attachment of biomolecules, and is approximately 40–50 nm in size. An example targeted human endothelial cells, by using the F(ab)2 fragment of human E-selectin mab, conjugated to CLIO. The CLIO-based platform has been used to synthesize target-specific agents for specific receptors, enzymes, integrins, and specific cells. Using phage display technology and high-throughput screening approaches, this technology has been used to synthesize agents specific for targets such as E-selectin and activated macrophage specific agents.

One specific target that has been exploited is the VCAM-1, which is a critical component of the leukocyte-endothelial adhesion cascade. By using phage display, a specific sequence was found that showed high binding specificity for VCAM-1, while blocking leukocyte–endothelial interactions. By using this protein and binding to a CLIO—Cy5.5 backbone, MRI and fluorescent imaging demonstrated high affinity for endothelial cells expressing VCAM-1 but low affinity for macrophages *in vitro*. *In vivo*, this contrast agent successfully identified VCAM-1 expressing endothelial cells in a murine tumor necrosis factor-α induced inflammatory model and colocalized with VCAM-1 expressing cells in atherosclerotic lesions present in cholesterol-fed apolipoprotein E apo$E^{-/-}$ mice.

Utilizing the CLIO backbone has used other combined MRI and fluorescent imaging probes. In addition to VCAM-1, this technology has been used to image selectively E-selectin in mouse xenograft models of Lewis lung carcinoma by attaching E-selectin-binding peptide to CLIO (Cy5.5) nanoparticle, as well as apoptosis through attachment of CLIO (Cy5.5) to Annexin V.

Other nanoparticles used for imaging include methylmethacrylate, zeolite doped GdNaY nanoparticles, ferrofluids, and synthetic magnetic nanoparticles, which obviate the need for dextrans, having much tighter polymer coatings (a *sine qua non* for small molecule conjugation), and yet be biodegradable. This family of compounds offers a very promising platform for targeting applications in MR imaging, and because the synthetic polymer coatings are biodegradable, may be soon applicable to patients.

Cell-Targeted Imaging

To track cells *in vivo* and visualize by MRI, they must be tagged magnetically. Previous attempts at tagging cells with magnetic beads proved efficient for *in vitro* separation of cells, but because beads were recognized as foreign by macrophage and the reticuloendothelial system, they were rapidly eliminated from the blood when injected intravenously *in vivo*. Labeling lymphocytes with magnetic nanoparticles demonstrates a possible solution to this problem, but the low labeling efficiency exacerbates the inherently low sensitivity of MRI in cell trafficking studies as compared to fluorescence and nuclear medicine. Unmodified magnetic nanoparticles have been used at high concentrations *in vitro* to label monocytes, T-cells, glioma cells and macrophage, and oligodendrocyte progenitors.

Multiple methodological approaches have been used to induce internalization of MNP into nonphagocytic cells. In specific, by linking amino-CLIO to the human immunodeficiency virus (HIV) tat peptide, which contains a membrane translocating protein, Lewin et al, developed a cell labeling approach that internalized MNP with high specificity into hematopoietic and neural progenitor cells with very low concentration of MNP (10–30 pg) per cell (4). High spatial three-dimensional imaging demonstrated the heterogeneity of T-cell recruitment within this model, and more significantly, the data indicate that serial administration of CD8 + T-cells appear to home to different intratumoral locations, which suggested that dose division may enhance the potency of T-cell based immunopotentiation therapies clinically.

Other approaches that have been used for cell labeling and include the following: (i) dendritic cells using MD-100; (ii) genetically engineered anti-Her-2/neu directed NK cells; and (iii) labeled Sca1 + bone marrow cells with superparamagnetic iron oxide MNP (ferumoxides-poly-L-lysine complexes). In summary, these cell-based approaches offer an exciting potential to advance multiple areas of cell-based therapy including stem cell therapy, cell implantation therapy, and immunopotentiation therapies.

Although efficacious, these strategies often require high levels of receptor expression and illustrate the problem of sensitivity facing contrast agent design. In considering novel targeted agents, sensitivity is of utmost import and various techniques need to be considered to overcome these obstacles. Some of these include receptor overexpression, and the presence of activatable or "smart" agents (those agents that undergo a physiochemical process to "activate" their contrast mechanisms). Please refer to Chapter (MRI—genetic reporter systems), for a detailed discussion on various amplification strategies used for transgene expression imaging, that may also be used in the synthesis of targeted agents.

Magnetic Resonance Mammography

▶MR Mammography

Magnetization Transfer MRI

An MR-based technique which provides estimates of tissue integrity. MT-MRI is based on the interactions between protons in free fluid and protons bound to macromolecules. When off-resonance irradiation is applied, the magnetization of bound protons becomes saturated. Magnetization is then transferred from these protons to more mobile protons, which causes a reduction of the tissue signal. A low-MT ratio reflects a reduced capacity of macromolecules in tissue to exchange magnetization with surrounding water molecules, and is interpreted as an indication of damage to myelin and to other cellular structures, such as the axonal membranes.

Malabsorption

Günther Antes
Department of Radiology, Klinikum Kempton-Oberallgäu, Kempton, Germany
gantes@gmx.de

Synonyms

Malabsorption; Malassimilation; Maldigestion

Definition

Deficient delivery of nutrients into the body can be a result of malfunction at several levels. This results into the classification of *malabsorption*, ▶*maldigestion*, and ▶*malassimilation*. In clinical practice these three terms are applied liberally.

Pathology/Histopathology

The causes of malabsorption can be congenital or acquired (Table 1).

Malabsorption. Table 1 Classification of malabsorption

Malabsorption
▶Sprue (celiac disease)
Ischemia
Hypogammaglobulinemia
Radiation enteropathy
Lymphoma
Short bowel syndrome
Whipple's disease
Amyloidosis
Mastocytosis
Eosinophilic gastroenteritis
Parasitosis
Tropical sprue
Crohn's disease (extensive)
Maldigestion
Chronic pancreatitis
Pancreatic resection
Cholestasis
Ileal resection
Zollinger-Ellison syndrome
Lactose (disaccharidase) deficiency
Malassimilation
Lymphangiectasia
Abetalipoproteinemia
Bacterial overgrowth
Pseudoobstruction (idiopathic)
Systemic sclerosis
Diverticulosis
Obstructive lesions
Fistulae
Surgical blind loop
Immune deficiencies
Miscellaneous
Drugs
Alcohol
Gastric surgery
Endocrinopathy
Malnutrition

M

1. Malabsorption proper refers to a deficient intake and metabolism by the columnar cells that line the mucosa of the small intestine.
2. Maldigestion within the small bowel lumen may follow the deficient secretion of enzymes, especially those derived from the pancreas, or the diminished delivery of bile with its effect on the solubilization of fat. Maldigestion also can occur at the brush border of the epithelium where enzymes normally aid in the digestion of carbohydrates and peptides.
3. Malassimilation refers to malfunction in the transport of absorbed and metabolized nutrients from the intestinal mucosa into the body.

Other entities of malabsorption are bacterial overgrowth and miscellaneous causes.

Clinical Presentation and Diagnosis

The leading symptoms of malabsorption are chronic diarrhea and weight loss. The diagnosis of malabsorption is made clinically and not radiologically. However, imaging may play an important role.

Imaging

►Enteroclysis is the best contrast medium examination of the small bowel for the exploration of malabsorption. Terms like "*flocculation*" or others used in follow-up small intestinal examinations are often based on artifacts. However, even with proper technique, one can observe a reduction of the mucosal coating, which can be interpreted as a nonspecific sign of mucosal irritation or enteritis.

CT and MRI can be helpful in detecting causes of maldigestion like chronic pancreatitis, cholestasis, tumors, and Crohn's disease. Ultrasonography can detect changes of the intestinal wall e.g., Crohn's disease, amyloidosis, or lymphoma.

Nuclear Medicine

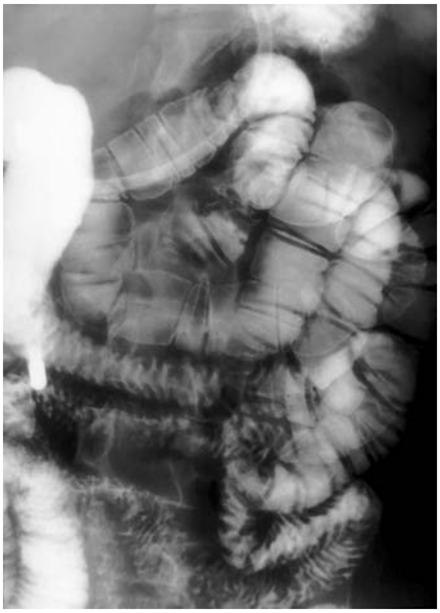
Scintigraphy plays no major role in the assessment of malabsorption, except in hormone producing tumors, e.g., Zollinger-Ellison syndrome (ZES) and carcinoid. There are two *in vivo* tests that can be applied. This is the ^{14}C-breath test for fat malabsorption and the vitamin B12 absorption test (Schilling test) to diagnose pernicious anemia and malabsorption syndrome.

Lactose Intolerance

Lactose intolerance is world wide the most common cause of malabsorption. In Europe, 10–15% and in many parts of the world over 95% of the population are unable to ferment and resorb lactose because of an enzyme deficiency in the small intestinal mucosa. In lactose intolerance, enteroclysis is usually normal. The same is true also for other intestinal allergies if the patient is asymptomatic at the time of the examination.

Sprue (Celiac Disease)

In a normal small bowel, the number of folds in the jejunum (≥5/2.5 cm) is greater than in the ileum. In sprue, there is a loss of folds in the duodenum and jejunum (Fig. 1). This is caused by the damage of the mucosa and deeper intestinal wall by the influence of gluten on the proximal small bowel. The lumen of the jejunum becomes more or less dilated and a reduction of contractions is observed. This leads to a regional hypoperistalsis. Thus, the jejunum resembles a colon like appearance ("colonization"). In the ileum, there is a resulting increase of folds combined with a regional hyperperistalsis. The ileum takes the form of a jejunum ("jejunization"). The process can be conceived as a



Malabsorption. Figure 1 Sprue. Typical fold pattern showing loss of valvulae conniventes and some dilatation in the jejunum ("colonization") and an increase of folds associated with an increase of contraction in the ileum ("jejunization").

compensatory response to the loss of mucosal surface in the jejunum.

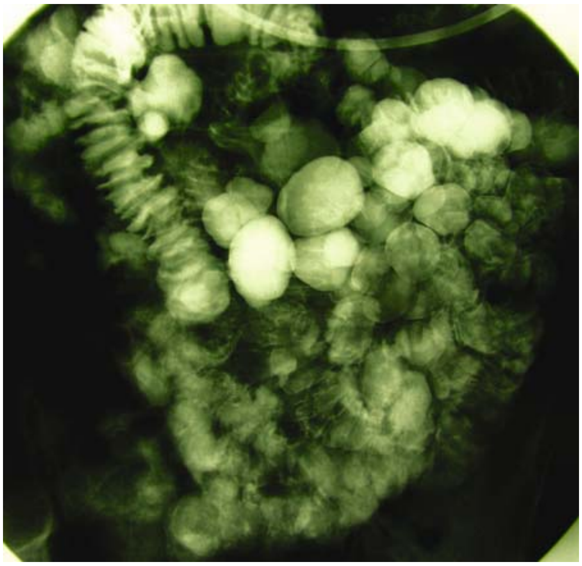
Complications of long standing celiac disease are lymphoma and adenocarcinoma and rarely ulcerative jejunoileitis.

Bacterial Overgrowth

An overgrowth of the normal flora of the small intestine by pathogenic bacteria can be caused by diverticula (Fig. 2), fistulae, strictures, postoperative changes, and in immune deficiencies, but also in disturbed motility, e.g., diabetic neuropathy, scleroderma or idiopathic intestinal pseudoobstruction. Apart from morphologic changes, a poor mucosal coating and early flocculation and fluid retention as signs of a nonspecific enteritis are often observed.

Short Bowel Syndrome

Up to 50% of the middle part of the small intestine can be removed without serious consequences. An intact duodenum, at least 50 cm of the jejunum, and the preserved colon are necessary for the survival without parenteral nutrition. In case of resection of the colon, 150 cm of small bowel has to be preserved.



Malabsorption. Figure 2 Bacterial overgrowth in diverticulosis. Apart from the multiple diverticula there are thickened folds and a reduced mucosal coating as a sign of a nonspecific enteritis.

Intestinal Lymphangiectasia and Protein Loosing Enteropathy

A primary and a secondary form exist. Primary lymphangiectasia is a congenital malformation of the lymphatics that manifests between birth and early adulthood. Secondary intestinal lymphangiectasia can be caused by several conditions that obstruct the lymph flow, such as retroperitoneal fibrosis, malignant infiltration of the retroperitoneum or severe congestive heart disease. As a result of both forms, the removal of nutrients from the intestine into the portal and systemic circulation is impaired leading to protein loosing enteropathy and malabsorption.

The radiological findings are nonspecific and include thickened and distorted folds with numerous small or larger nodules. The bowel wall may be thickened. Ultrasonography, CT, and MRI can detect lymphoma, tumors, and inflammatory conditions causing secondary lymphangiectasia.

Zollinger-Ellison Syndrome

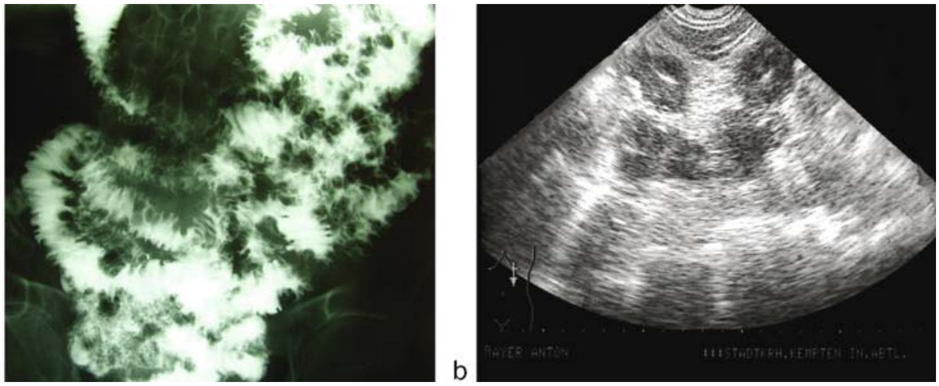
Gastrinomas are endocrine tumors secreting excessive amounts of gastrins that may cause ZES. This is characterized by severe ulcer disease in the stomach, duodenum and small bowel and watery diarrhea. This leads to protein loosing enteropathy, steatorrhea, and malabsorption. Gastrinomas are usually located in the pancreas or duodenum. More than 50% of the tumors are malignant and have set metastases in most cases at the time of detection. Gastrinomas may be part of the multiple endocrine neoplasia type I (MEN I) syndrome.

CT, MRI, angiography, and endoscopic ultrasonography help to detect gastrinomas. The somatostatin receptor scintigraphy with 111 indium octreotide is often the most sensitive test for detecting these lesions.

Amyloidosis

A primary and a secondary form exist. In primary amyloidosis, the gastrointestinal tract is involved in 70% of patients. Secondary amyloidosis is rarely associated with chronic inflammatory conditions such as rheumatoid arthritis, Crohn's disease, and familial Mediterranean fever. Radiological findings include nonspecific diffuse of localized nodular changes of the intestinal surface and wall thickening that can resemble Crohn's disease. This can be also seen on CT or ultrasonography (Fig. 3).

M



Malabsorption. Figure 3 Amyloidosis. (a) There is a thickening and distortion of the folds and intestinal wall. A nonpropulsive, pendular peristalsis can be observed that is caused by amyloid deposits in the vessel walls leading to a chronic ischemia and occult blood loss. (b) Ultrasonography shows the wall thickening.

Whipple's Disease

This disease is caused by the organism *Tropheryma whippelii*. The disease is characterized by fever, cachexia, malabsorption, and systemic manifestations. The radiologic findings include thickening of the small bowel folds and a diffuse micronodular pattern. CT may reveal lymph nodes in the mesentery and retroperitoneum.

Eosinophilic Gastroenteritis

Eosinophilic infiltration of the mucosa and intestinal wall may affect the entire GI-tract. Symptoms include malabsorption, especially protein loss, resulting in hypoalbuminemia. Radiologic findings may include thickening of small bowel folds and of the intestinal wall, simulating Crohn's disease, carcinoma, or lymphoma. The distribution may be regional or general.

Malabsorption

►Malabsorption

Malassez Epithelial Rests

The remaining cells of the root sheath in the periodontal ligament.

►Neoplasms, Odontogenic

Malassimilation

Malabsorption because of malfunction in the transport of absorbed nutrients.

►Malabsorption

Maldigestion

Malabsorption because of deficient secretion of enzymes.

►Malabsorption

Malignant Angioendotheliomatosis

Malignant Angioendothelimatosis is a rare pulmonary lymphoma characterized by proliferation of malignant

endothelial cells within small blood vessels with makroscopic appearance of pulmonary nodules. Its origin is usually within pulmonary arterial branches, and it is classically associated with pulmonary arterial hypertension.
▶ Neoplasms Pulmonary

Malignant Fibrous Histiocytoma

More prevalent aggressive tumor in older age groups, commonly in the thigh. May be associated with hemorrhage and variable signal intensities on MRI. Up to 20% is reported as having some radiographically evident soft tissue calcification.
▶ Neoplasms, Soft Tissues, Malignant

Malignant Lesions of the Nasopharynx

▶ Neoplasms, Nasopharynx

Malignant Mesenchymoma

▶ Neoplasms, Soft Tissue, Malignant

Malignant Oropharyngeal Tumors

Mammary Dysplasia

▶Fibrocystic Disease, Breast

Mammary Dystrophy

▶Fibrocystic Disease, Breast

Mandibulofacial Dysostosis

Mandibulofacial dysostosis, also known as Treacher Collins syndrome, is characterised by all or most of the following: hypoplastic or agenetic zygomatic arches, maxillary narrowing or overprojection, small mandible, broad or protruded nose, microstomia, anomalous development of eyelids and/or ears.

▶Congenital Malformations, Nose and Paranasal Sinus

Manubriosternal Junction

Synchondritis of the symphysis or manubriosternal junction is characterized by adjacent sclerosis and bony destruction. Symphyseal involvement is typically seen in ankylosing spondylitis. Sternal manifestations are seen in ankylosing spondylitis, psoriatic arthritis, and SAPHO syndrome.

▶Spondyloarthropathies, Seronegative

Marchiafava–Bignami Disease

Marchiafava–Bignami disease is a rare disorder associated with chronic alcohol abuse. First described by Italian pathologists performing autopsies in chronic alcoholics, the disease is characterized by cystic, layered necrosis and demyelination of the genu and body of the corpus callosum, with occasional splenial involvement. Clinically, patients present with cognitive impairment, gait disturbance, hypertonia, dysarthria, and signs of interhemispheric disconnection. Occasionally, the disease is fatal. MRI demonstrates signal changes in the corpus callosum without mass effect.

Synonyms

Benign and malignant ovarian tumors; Ovarian neoplasm

Definition

The ovaries consist of three functional and anatomical components that may give rise to tumors. They include the surface epithelium, germinal tissue, and ovarian stroma consisting of sex cord and mesenchymal cells. Epithelial neoplasms comprise up to 75% of ovarian tumors and 85% of ovarian malignancies (1).

Histopathology

Epithelial neoplasms are classified into benign, borderline, and malignant on the basis of histologic and clinical features (1). Dermoid cysts derive from germ cells and are the most common benign tumors in females younger than 45 years (2). ►Cystadenomas account for the majority of benign ovarian tumors in postmenopausal age.

Imaging

Differential Criteria for Benign and Malignant Lesions

Discrimination between benign and malignant ovarian tumors is one of the most important issues in ovarian imaging. Based on these findings, surgical management may be directly affected, including the adequate therapeutic approach, surgical technique, and need of subspecialty cooperation.

Sonography including endovaginal sonography and Doppler analysis is the primary imaging modality for assessing ovarian masses (1, 3). Contrast-enhanced computed tomography (CT) and particularly magnetic resonance imaging (MRI) are currently performed in indeterminate cases to further characterize lesions as benign or malignant (4).

In CT and MRI, fat is the pathognomonic finding in dermoids, and fibroids can be reliably diagnosed with MRI. For all other ovarian tumors, features suggesting that a lesion is benign include: lesion size less than 4 cm, entirely cystic architecture, wall thickness less than 3 mm, lack of internal structures, lack of ascites, lack of peritoneal disease or lymphadenopathy. Using these criteria preoperative characterization of ovarian lesions by MRI studies yields an accuracy of 91–95% (4).

Diagnosis

Differential Diagnoses of Ovarian Masses According to Imaging Features

Adnexal masses may be characterized according to their predominant morphologic appearance at imaging. As imaging findings often overlap, for differential diagnostic purposes neoplastic and nonneoplastic ovarian masses are included in the list. The latter can only be used as a general approach based on the most common appearance at imaging. If ovarian masses display a spectrum of imaging findings, they are enlisted in more than one category.

Completely cystic: Physiologic ovarian cyst, cystadenoma, hydrosalpinx, paraovarian cyst.

Cystic with proteinaceous or hemorrhagic contents: Cystadenoma, endometrioma, hydropyosalpinx.

Cystic with Septations: Cystadenoma, ►granulosa cell tumors, carcinoma.

Cystic with papillary excrescences or mural nodules: ►Borderline tumor, ovarian cancer, clear cell cancer, cystadenoma, dermoid.

Fat Containing: Dermoid, malignant teratoma.

Mixed Solid and Cystic: Carcinoma, tubo-ovarian abscess, cystadenofibroma, Brenner tumor.

Predominantly Cystic: Cystadenoma, tubo-ovarian abscess, cystic dermoid, carcinoma.

Solid with Necrosis: Metastases, ovarian cancer, dysgerminoma, sclerosing cell tumor of the ovary.

Predominantly Solid: Fibroma, dysgerminoma, lymphoma, metastases, ovarian cancer.

Solid with Calcifications: Fibroma, Brenner tumor, dysgerminoma, malignant teratoma.

Benign Ovarian Neoplasm

Benign ovarian neoplasms account for the majority (60–80%) of ovarian tumors. Although there is a large spectrum of ovarian tumors, the majority is encompassed by only a few different histologic types. In a larger series of benign ovarian lesions, 58% were teratomas, followed by 37% cystadenomas (25% serous and 12% mucinous), 4% fibromas/►fibrothecomas, and 1% Brenner tumors (2).

Benign Ovarian Teratomas: See cross-reference Benign Teratoma.

Cystadenoma

Cystadenomas are the most common type of cystic ovarian tumors. Cystadenomas account for 37–50% of benign ovarian tumors in the reproductive age. Their frequency increases with age, and after menopause cystadenomas account for up to 80% of the benign ovarian tumors. Cystadenomas are thin-walled, unilocular or multilocular cystic lesions filled with serous, mucinous, and sometimes hemorrhagic contents (1, 3) (Fig. 1). Rarely, small papillary projections may be found within the cyst walls.

Serous cystadenomas are bilateral in up to 20% of cases, whereas mucinous cystadenomas are bilateral in only 2–3% of cases. Mucinous cystadenomas may be filled with sticky gelatinous fluid and tend to be large (<10 cm) at the time of presentation. In contrast to serous
