Editorial Board

Acknowledgments

This project is the labor of many people, including some who labored diligently behind the scenes. Among those to whom I am greatly indebted for their 'behind-the-scenes' assistance are Pam Howell and Carole Girimont (first edition) and Pam Howell (second edition) for document processing and editing assistance; Mike Sanford, Pat Hope, and Jane Medley (first edition) and Hope Johnson (second edition) for assistance with the images, and Marsha Capinera for compiling the list of contributors. Ron Cave, Andrei Sourakov, and Lyle Buss helped greatly by supplying numerous photographs for the second edition.

Howard Frank deserves special mention for his editing acumen and assistance. Drion Boucias contributed the lengthy unattributed sections on insect pathology. The unattributed biographic sketches with last names beginning with A to J were contributed by Howard Frank. All other unattributed sections were contributed by John Capinera.

Preface

Some biologists have called this the 'Age of Insects.' Among animals, certainly the diversity of insects is unrivaled. Nearly one million species have been described to date, and some entomologists estimate that as the tropics are fully explored, we will find that there are actually more than three million insect species. The large number of insects is often attributed to the divergence of plants (angiosperms), which provide numerous hosts and places to feed, but if plant feeders are excluded from the tabulation the biodiversity of insects remains unrivaled. Virtually every environment has been exploited by these resilient organisms. Even if one dislikes insects, they are impossible to ignore, and a little knowledge about them could be indispensable should one have a 'close encounter' of an unpleasant kind.

Insects are remarkable biological organisms. They are small enough to escape the detailed scrutiny of most people, but I have yet to meet anyone whom, once provided the opportunity to examine insects closely (through a microscope) is not completely amazed by the detail and complexity of these exquisitely designed (by natural selection) beasties. They are fascinating in function as well as form. Insects are the only invertebrates to fly, they are disproportionately strong, and their ecological adaptability defies belief. For example, some insects produce their own version of anti-freeze, which allows them to be frozen solid yet to regain normal function upon thawing. Their sensory abilities are beyond human comprehension; a male insect can sometimes locate a female by her 'perfume' (pheromone) from several kilometers distance. Although not normally considered intelligent, insects display surprisingly complex behaviors, and altruistic social systems that could well serve as models for human societies.

Insects and their close relatives are important for many reasons besides their sheer diversity. Their effect on humans is profound. Insects are our chief competitor for food and fiber resources throughout the world. Annual crop losses of 10 to 15% are attributed to insects, with both pre-harvest and post-harvest losses considerably more at times. Insects also are the principal vector of many human, animal, and plant diseases, including viruses, mollicutes, bacteria, fungi, and nematodes. The ability to transmit diseases magnifies their effect, and makes it more difficult to manage injury. Over the course of human history, insect-transmitted disease has caused untold human suffering. For example, introduction of flea-transmitted bubonic plague to Europe centuries ago killed millions of people and caused severe disruption to western civilization. Though less dramatic, mosquito-transmitted malaria kills thousands annually throughout the world, and unlike plague, which is now mostly a historical footnote, the toll continues to mount.

Advances in technology, particularly the introduction of chemical insecticides, have done much to remove the threat of insect-related damage from the consciousness of most humans. Insecticides are applied preventatively to avoid pre- and post-harvest damage to crops, to our dwellings, and to our landscape. This is an oft-overlooked but remarkable achievement that has increased stability in the supply and price of resources, and in the lives of resource producers. No longer are people faced with starvation or economic ruin due to the ravages of insects; in almost all parts of the world, the ready availability of insecticides can be used to prevent massive insect population outbreaks. However, we realize increasingly that this approach is not without its own set of health, environmental and economic costs, and alleviating dependency on insecticides, or making alternatives to insecticides more readily available, has assumed greater priority.

We are faced with an interesting dichotomy. There is a wealth of information about insects, but it is known mostly to 'insect scientists' (entomologists). The public (non-entomologists or 99.99% of all people) has little knowledge about insects, and poor access to vital information about these important organisms. So this encyclopedia is presented to bridge the gap – to better enable those with a need to know to find fundamental information provided by more than 450 experts in the field of entomology. We provide a broad overview of insects and their close relatives, including taxonomy, behavior, ecology, physiology, history, and management. Importantly, we provide critical links to the entomological literature, much of which presently is unavailable for search electronically. The contributors are distinguished entomologists from around the world. They hope that the availability of this encyclopedia will help others to reap the benefits of centuries of discovery, and to discover the wonders that make the study of insects so compelling. It was constructed with college and university students in mind, but others may find it a handy reference.

John L. Capinera, Gainesville (Florida) April, 2008

Highlights of the Encyclopedia of Entomology

Major Taxa of Insects and Their Near Relatives

Alderflies and Dobsonflies (Megaloptera)
Angel Insects (Zoraptera)
Bark-Lice, Book-Lice, or Psocids (Psocoptera)
Beetles (Coleoptera)
Bristletails (Archeognatha)
Bugs (Hemiptera)
Butterflies and Moths (Lepidoptera)
Caddisflies (Trichoptera)
Centipedes (Chilopoda)
Chewing and Sucking Lice (Phthiraptera)
Cockroaches (Blattodea)
Diplurans (Diplura)
Dragonflies and Damselflies (Odonata)
Earwigs (Dermaptera)
Fleas (Siphonaptera)
Flies (Diptera)
Gladiators (Mantophasmatodea)
Grasshoppers, Katydids, and Crickets (Orthoptera)
Lacewings, Antlions, and Mantispids (Neuroptera)
Mayflies (Ephemeroptera)
Millipedes (Diplopoda)
Mites (Acari)
Pillbugs and Sowbugs, or Woodlice (Isopoda)
Praying Mantids (Mantodea)
Proturans (Protura)
Rock Crawlers (Grylloblattodea)
Scorpionflies (Mecoptera)
Scorpions (Scorpiones)
Sea Spiders (Pycnogonida)
Silverfish (Zygentoma)
Snakeflies (Raphidioptera)
Spiders (Araneae)
Springtails (Collembola)
Stick and Leaf Insects (Phasmida)
Stoneflies (Plecoptera)
Stylopids (Strepsiptera)
Symphylans (Symphyla)
Termites (Isoptera)
Thrips (Thysanoptera)
Ticks (Ixodida)
Wasps, Ants, Bees, and Sawflies (Hymenoptera)
Webspinners (Embiidina)

Other Groups

Anagrus Fairyflies (Hymenoptera: Mymaridae)
Ants (Hymenoptera: Formicidae)
Aphids (Hemiptera: Aphididae)
Apoid Wasps (Hymenoptera: Apoidea: Spheciformes)
Argasid (Soft) Ticks (Acari: Ixodida: Argasidae)
Assassin Bugs, Kissing Bugs and Others (Hemiptera: Reduviidae)
Bark Beetles, *Dendroctonus* spp. (Coleoptera: Curculionidae: Scolytinae)
Bees (Hymenoptera: Apoidea: Apiformes)
Bess Beetles (Coleoptera: Passalidae)
Biting Midges, *Culicoides* (Diptera: Ceratopogonidae)
Black Flies (Diptera: Simuliidae)
Blister Beetles (Coleoptera: Meloidae)
Bulb Mites, *Rhizoglyphus* (Acari: Acaridae)
Burnet Moth Biology (Lepidoptera: Zygaenidae)
Brush-Footed Butterflies (Lepidoptera: Nymphalidae)
Butterflies (Lepidoptera: Rhopalocera)
Carpenter Bees (Hymenoptera: Apidae: Xylocopinae)
Carrion Beetles (Coleoptera: Silphidae)
Cicadas (Hemiptera: Cicadoidea)
Clearwing Moths (Lepidoptera: Sesiidae)

Stink Bugs (Hemiptera: Pentatomidae), Emphasizing Economic Importance
Tachinid Flies (Diptera: Tachinidae)
Tent Caterpillars, *Malacosoma* spp. (Lepidoptera: Lasiocampidae)
Tiger Beetles (Coleoptera: Carabidae: Collyrinae and Cicindelinae)
Termites (Isoptera) in South America
Tiphiid Wasps (Hymenoptera: Tiphiidae)
Treehoppers (Hemiptera: Membracidae)
Underwing Moths –*Catocala* (Lepidoptera: Noctuidae)
Velvet Ants (Hymenoptera: Mutillidae)
Water Penny Beetles (Coleoptera: Psephenidae)
Weevils, Billbugs, Bark Beetles, and Others (Coleoptera: Curculionoidea)
Weta (Orthoptera: Anostostomatidae, Rhaphidophoridae)
Whiteflies (Hemiptera: Aleyrodidae)

Aster Leafhopper, *Macrosteles quadrilineatus* Forbes (Hemiptera: Cicadellidae)
Australian Sheep Blowfly, *Lucilia cuprina* Wiedemann (Diptera: Calliphoridae)
Banana Weevil, *Cosmopolites sordidus* (Germar) (Coleoptera: Curculionidae)
Bed Bugs (Hemiptera: Cimicidae: *Cimex* spp.)
Bee Louse, Bee Fly, or Braulid, *Braula coeca* Nitzsch (Diptera: Braulidae)
Beet Armyworm, *Spodoptera exigua* (Hübner) (Lepidoptera: Noctuidae)
Bertha Armyworm, *Mamestra configurata* Walker (Lepidoptera: Noctuidae)
Black Cutworm, *Agrotis ipsilon* (Hufnagel) (Lepidoptera: Noctuidae)
Black Fig Fly, *Silba adipata* McAlpine (Diptera: Lonchaeidae)
Bogong moth, *Agrotis infusa* (Boisduval) (Lepidoptera: Noctuidae)
Boll Weevil, *Anthonomus grandis* Boheman (Coleoptera: Curculionidae)
Brown Citrus Aphid, *Toxoptera citricida* (Kirkaldy) (Hemiptera: Aphididae)
Cabbage Aphid, *Brevicoryne brassicae* (L.) (Hemiptera: Aphididae)
Cabbage Maggot or Cabbage Root Fly, *Delia radicum* (Linnaeus) (Diptera: Anthomyiidae)
Cabbage Looper, *Trichoplusia ni* (Hübner) (Lepidoptera Noctuidae)
Cabbageworm, *Pieris rapae* (Linnaeus) (Lepidoptera: Pieridae)
Cactus Moth, *Cactoblastis cactorum* (Berg) (Lepidoptera: Pyralidae)
Cape Honey Bees, *Apis mellifera capensis* Escholtz
Cassava Mealybug, *Phenacoccus manihoti* Matile-Ferrero (Hemiptera: Pseudococcidae)
Chilli Thrips, *Scirtothrips dorsalis* Hood (Thysanoptera: Thripidae)
Chinch Bug, *Blissus leucopterus* (Say) (Hemiptera: Blissidae)
Cluster Fly, *Pollenia rudis* (Fabricius) and *P. pseudorudis* Rognes (Diptera: Calliphoridae)
Coconut Mite, *Aceria guerreronis* (Acari: Eriophyidae)
Coffee Berry Borer, *Hypthenemus hampei* (Ferrari) (Coleoptera: Curculionidae: Scolytinae)
Colorado Potato Beetle, *Leptinotarsa decemlineata* (Say) (Coleoptera: Chrysomelidae)
Corn Delphacid, *Peregrinus maidis* (Ashmead) (Hemiptera: Delphacidae)
Corn Earworm, *Helicoverpa zea* (Boddie) (Lepidoptera: Noctuidae)
Corn Leaf Aphid, *Rhopalosiphum maidis* (Fitch) (Hemiptera: Aphididae)
Corn Leafhopper, *Dalbulus maidis* (Delong And Wolcott) (Hemiptera: Cicadellidae)
Cotton Leafworm, *Spodoptera littoralis* (Boisduval)
Crapemyrtle Aphid *Sarucallis kahawaluokalani* (Kirkaldy) (Hemiptera: Aphididae)
Date Palm Stem Borer, *Pseudophilus testaceus* Gah. (= *Jebusea hammershmidti* Reiche) (Coleoptera: Cerambycidae)
Diamondback Moth, *Plutella xylostella* (Linnaeus) (Lepidoptera: Plutellidae)
Diaprepes Root Weevil, *Diaprepes abbreviatus* (L.) (Coleoptera: Curculionidae)

Differential Grasshopper, *Melanoplus differentialis* (Thomas) (Orthoptera: Acrididae)
Douglas-Fir Beetle, *Dendroctonus pseudotsugae pseudotsugae* Hopkins (Coleoptera: Curculionidae, Scolytinae)
Driver Ants (*Dorylus* Subgenus *Anomma*) (Hymenoptera: Formicidae)
Dubas Bug (Old World Date Bug), *Ommatissus binotatus* (Hemiptera: Tropiduchidae)
Eastern Lubber Grasshopper, *Romalea microptera* (Beauvois) (Orthoptera: Acrididae)
Elm Leaf Beetle, *Xanthogaleruca* (= *Pyrrhalta*) *luteola* (Müller) (Coleoptera: Chrysomelidae)
Eri Silkworm, *Philosamia ricini* (Lepidoptera: Saturniidae)
Eurasian Spruce Bark Beetle, *Ips typographus* Linnaeus (Coleoptera: Curculionidae, Scolytinae)
European Cherry Fruit Fly *Rhagoletis cerasi* (Linnaeus) (Diptera: Tephritidae)
European Corn Borer, *Ostrinia nubilalis* (Hübner) (Lepidoptera: Pyralidae)
European Earwig, *Forficula auricularia* Linnaeus (Dermaptera: Forficulidae)
Face Fly, *Musca autumnalis* De Geer (Diptera: Muscidae)
Fall Armyworm, *Spodoptera frugiperda* (J.E. Smith) (Lepidoptera: Noctuidae)
Formosan Subterranean Termite, *Coptotermes formosanus* Shiraki (Isoptera: Rhinotermitidae)
Fruit Stalk Borer, *Oryectes elegans* Prell (Coleoptera: Scarabaeidae)
Gamagrass Leafhopper *Dalbulus quinquenotatus* Delong & Nault (Hemiptera: Cicadellidae)
Glassy-Winged Sharpshooter, *Homalodisca vitripennis* (Hemiptera: Cicadellidae)
Grape Phylloxera, *Daktulosphaira vitifoliae* (Fitch) (Hemiptera: Aphidoidea: Phylloxeridae)
Grapevine Leafhopper Complex (Hemiptera: Cicadellidae) in Cyprus
Greater Date Moth, *Arenipses sabella* Hmps (Lepidoptera: Pyralidae)
Greenhouse Whitefly, *Trialeurodes vaporariorum* (Westwood) (Hemiptera: Aleyrodidae)
Green Peach Aphid, *Myzus persicae* (Sulzer) (Hemiptera: Aphididae)
Gypsy Moth, *Lymantria dispar* Linnaeus (Lepidoptera: Lymantriidae)
Harlequin Bug, *Murgantia histrionica* (Hahn) (Hemiptera: Pentatomidae)
Hazelnut and Walnut Twig Borer, *Oberea linearis* Linnaeus (Coleoptera: Cerambycidae)
Hessian Fly, *Mayetiola destructor* (Say) (Diptera: Cecidomyiidae)
Honey Bee, *Apis mellifera* Linnaeus (Hymenoptera: Apidae)
Horn Fly, *Haematobia irritans* (L.) (Diptera: Muscidae)
House Fly, *Musca domestica* L. (Diptera: Muscidae)
Human Botfly, *Dermatobia hominis* (Linneaus, Jr.) (Diptera: Oestridae)
Japanese Beetle, *Popillia japonica* Newman (Coleoptera: Scarabaeidae)
Jewel Wasp, *Nasonia vitripennis* (Walker) (Hymenoptera: Pteromalidae)
Khapra Beetle, *Trogoderma granarium* Everts (Coleoptera: Dermestidae)
Large Milkweed Bug, *Oncopeltus fasciatus* (Dallas) (Hemiptera: Lygaeidae)
Large Cabbage White Butterfly, *Pieris brassicae* (Linnaeus) (Lepidoptera: Pieridae)
Larger Grain Borer, *Prostephanus truncatus* (Horn) (Coleoptera: Bostrichidae)
Leaf-Cutting Ants (Formicidae: Myrmicinae: Attini)
Lesser Date Moth, *Batrachedra amydraula* Meyrick (Lepidoptera: Cosmopterygidae)
Lettuce Root Aphid, *Pemphigus bursarius* (Linnaeus) (Hemiptera: Aphididae)
Locust Borer, *Megacyllene robiniae* (Forster) (Coleoptera: Cerambycidae)

Roundheaded Pine Beetle, *Dendroctonus adjunctus* Blandford (Coleoptera: Curculionidae, Scolytinae)
Seedcorn Maggot or Bean Seed Fly, *Delia platura* (Meigen) (Diptera: Anthomyiidae)
Silkworm, *Bombyx mori* (Linnaeus) (Lepidoptera: Saturniidae)
Silverleaf Whitefly, *Bemisia argentifolii* Bellows and Perring (Hemiptera: Aleyrodidae)
Small Green Stink Bug, *Piezodorus guildinii* (Westwood) (Hemiptera: Heteroptera: Pentatomidae)
Small Hive Beetle, *Aethina tumida* Murray (Nitidulidae: Coleoptera)
Small Honey Ant, *Prenolepis imparis* (Say) (Hymenoptera: Formicidae)
Small Rice Stink Bug, *Oebalus poecilus* (Dallas) (Hemiptera: Heteroptera: Pentatomidae)
Southern Green Stink Bug, *Nezara viridula* (L.) (Hemiptera: Heteroptera: Pentatomidae)
Soybean Aphid, *Aphis glycines* Matsumura (Hemiptera: Aphididae)
Spined Soldier Bug, *Podisus maculiventris* (Say) (Hemiptera: Pentatomidae)
Spotted Cucumber Beetle or Southern Corn Rootworm, *Diabrotica undecimpunctata* Mannerheim (Coleoptera: Chrysomelidae)
Spruce Budworms, *Choristoneura* Lederer (Lepidoptera: Tortricidae)
Squash Bug, *Anasa tristis* (DeGeer) (Hemiptera: Coreidae)
Squash Vine Borer, *Melittia cucurbitae* (Harris) (Lepidoptera: Sesiidaae)
Stable Fly, *Stomoxys calcitrans* (Linnaeus) (Diptera: Muscidae)
Sweetpotato and Silverleaf Whiteflies, *Bemisia* spp. (Hemiptera: Aleyrodidae)
Sweetpotato Flea Beetle, *Chaetocnema confinis* Crotch (Coleoptera: Chrysomelidae Alticinae)
Sweetpotato Weevil, *Cylas formicarius* (Fabricius) (Coleoptera: Brentidae)
Taiga Tick, *Ixodes persulcatus* Schulze (Acari: Ixodida: Ixodidae)
Tarnished Plant Bug, *Lygus lineolaris* Palisot de Beauvois (Hemiptera: Miridae)
Taro Caterpillar or Rice Cutworm, *Spodoptera litura* (Fabricius)
Tent Caterpillars, *Malacosoma* spp. (Lepidoptera: Lasiocampidae)
Termites (Isoptera) in South America
Timarcha Latreille (Coleoptera: Chrysomelidae, Chrysomelinae)
Tomato Hornworm, *Manduca quinquemaculata* (Haworth) and Tobacco Hornworm, *Manduca sexta* (Linnaeus) (Lepidoptera: Sphingidae)
Tracheal Mite, *Acarapis woodi* Rennie (Acarina: Tarsonemidae)
Tsetse Flies, *Glossina* spp. (Diptera: Glossinidae)
Turnip Aphid, *Lipaphis erysimi* (Kaltenbach) (Hemiptera: Aphididae)
Turnip Root Maggot, *Delia floralis* (Fallen) (Diptera: Anthomyiidae)
Twospotted Spider Mite, *Tetranychus urticae* Koch (Acari: Tetranychidae)
Two-Spotted Stink Bug, *Perillus bioculatus* (Fabricius) (Hemiptera: Pentatomidae)
Twostriped Grasshopper, *Melanoplus bivittatus* (Say) (Orthoptera: Acrididae)
Varroa Mite, *Varroa destructor* Anderson & Truemann (Acari: Varroidae)
Variegated Cutworm, *Peridroma saucia* (Hübner) (Lepidoptera: Noctuidae)
Vegetable Leafminer, *Liriomyza sativae* Blanchard (Diptera: Agromyzidae)
Viburnum Leaf Beetle, *Pyrrhalta viburni* (Paykull) (Coleoptera: Chrysomelidae)
Vine Mealybug, *Planococcus ficus* Signoret (Hemiptera: Pseudococcidae)
Western Balsam Bark Beetle, *Dryocoetes confusus* Swain (Coleoptera: Curculionidae, Scolytinae)
Western Corn Rootworm, *Diabrotica virgifera virgifera* Leconte (Coleoptera: Chrysomelidae)
Western Grapeleaf Skeletonizer, *Harrisina brillians* Barnes & McDunnough (Lepidoptera: Zyganeidae)

A

Abafi-Aigner, Lajos (Ludwig Aigner)

George Hangay
Narrabeen, New South Wales, Australia

Ludwig Aigner was born on the 11 February 1840 at Nagyjécsa, Torontál Shire, Transylvania, Hungary, now Romania. His family moved to Temesvár, a large town in Transylvania, where he received a formal education in commerce and begun his career as a book merchant. His family was of ethnic German stock and young Ludwig only learned Hungarian when, in 1858, they moved to Pozsony (now Bratislava and in the Slovak Republic), a large town with predominantly Hungarian inhabitants. From here he soon moved on to Pest (now Budapest) and in 1863, as it was the custom in those years, he wandered all over Austria and Germany. He completed his studies in Köln and Stuttgart before returning to Pest. He always had an interest in entomology and he became a keen amateur lepidopterologist. However, besides entomology, he had a great variety of other interests too, especially in the field of publishing, writing, historical research as well as aspirations in business. He found success in publishing and in establishing a popular bookshop. In 1870 he was initiated as a Freemason and eventually he rose to the highest positions in the Order. For 12 years he has worked on an extensive monograph of the history of Freemasonry. He used his Hungarian pen name "Abafi" in a hyphenated form with his original family name: Abafi-Aigner and changed his German Christian name "Ludwig" to the Hungarian equivalent "Lajos." However, despite his successes in publication and writing his business begun to decline in the 1880s and within a few years he faced financial difficulties, which ultimately led to the closure of his famous bookshop. Disillusioned, he discontinued most of his business activities, and from 1890 he devoted all his time and energy to lepidopterology. In 1895, he published the results of his studies in the *Természetrajzi Füzetek* (Notebooks of Natural History), the journal of the National Museum's Natural History Department and he was one of the authors of *Fauna Regni Hungariae* (Catalogue of Hungary's Fauna). He resurrected *Rovartani Lapok* (Entomological Papers), which was established in 1884 but ceased to exist in 1886. His treatment of the butterfly fauna of Hungary won the coveted Bugát Prize. Based on this work he published *Butterflies of Hungary* in 1907. The book was (and probably still is) one of the most popular entomological publications in Hungary. It has inspired countless young entomologists and made the name of Abafi-Aigner well known to every naturalist in the country. He passed away on the 19 June 1909.

Abaxial Surface

The lower surface of a leaf (contrast with adaxial surface).

Abbott, John

John Abbott was born in London in 1751. In England, he was given drawing lessons and, through his drawing instructor, was introduced to Dru Drury, a collector of insects who had been president of the Linnean Society. These two encounters encouraged him to collect insects and draw them, but his father was training him to be an attorney. Finding legal paperwork not to his liking, he emigrated to Virginia in 1773. After 2 years in Virginia, he relocated to Georgia, where he served as a private in the Third Georgia Continental Battalion during the Revolutionary War. For his military service he received several hundred acres of land, and worked as a planter and schoolmaster. In Virginia he had collected American insects and bird skins, and drew and painted insects and birds. Some of the specimens and paintings were shipped to England for sale. Some of the paintings, after sale, adorned books on birds, insects, and spiders written by various authors, not necessarily with acknowledgment to Abbott. In all, Abbott produced over 3,000 drawings of a quality that was very high for that time. Some of the insect illustrations included not only adults, but also larvae and the plants on which they fed, and even observational notes. He died about 1840.

Abbott' s Formula

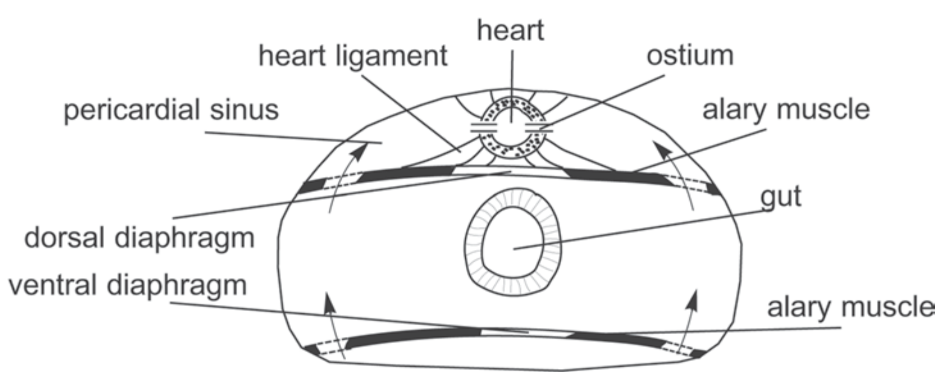
A mathematical technique commonly used to assess mortality in insecticide trials when there is need to correct for a change (decrease) in the background population density (i.e., in the check or control plots). The formula is:

% corrected control = 100 × (% alive in the check % alive in the treatment)/(% alive in the treatment)

Abdomen

The posterior of the three main body divisions of an insect (Fig. 1).

► Abdomen of Hexapods

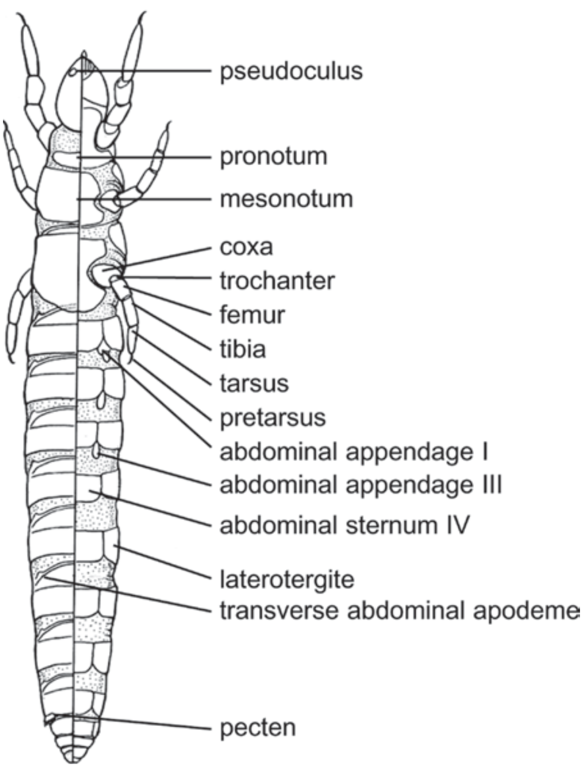


Abdomen, Figure 1 **Cross section of an insect abdomen, showing components of the insect circulatory system and direction of hemolymph flow (adapted from Evans, Insect biology).**

Abdomen of Hexapods

SEVERIANO F. GAYUBO
Universidad de Salmanca, Salamanca, Spain

The abdomen constitutes the caudal tagma in the hexapods and is usually larger than the other two, the head and the thorax. This region is also referred to as a visceral area because it houses the visceral organs. Its form can vary depending on the group, and even on the species. The maximum number of observed segments is 11, although certain authorities consider a twelfth segment that in fact corresponds to a telsonic caudal region. In general, the number of segments decreases from the preimaginal phases to the adult stage, especially in those holometabolous insects in which the last segments of the adults are formed from imaginal discs during pupation. In the groups considered most primitive, the number of abdominal segments is usually greater, as occurs in the Protura with 11 segments (Figs. 2–5). An exception is the Collembola, which only possess six. In addition, it is necessary to keep in mind that, in certain cases, the total number of visible segments does not coincide with what a particular individual actually possesses, since some segments remain "invisible" upon being telescoped, particularly those of the posterior region of the abdomen.



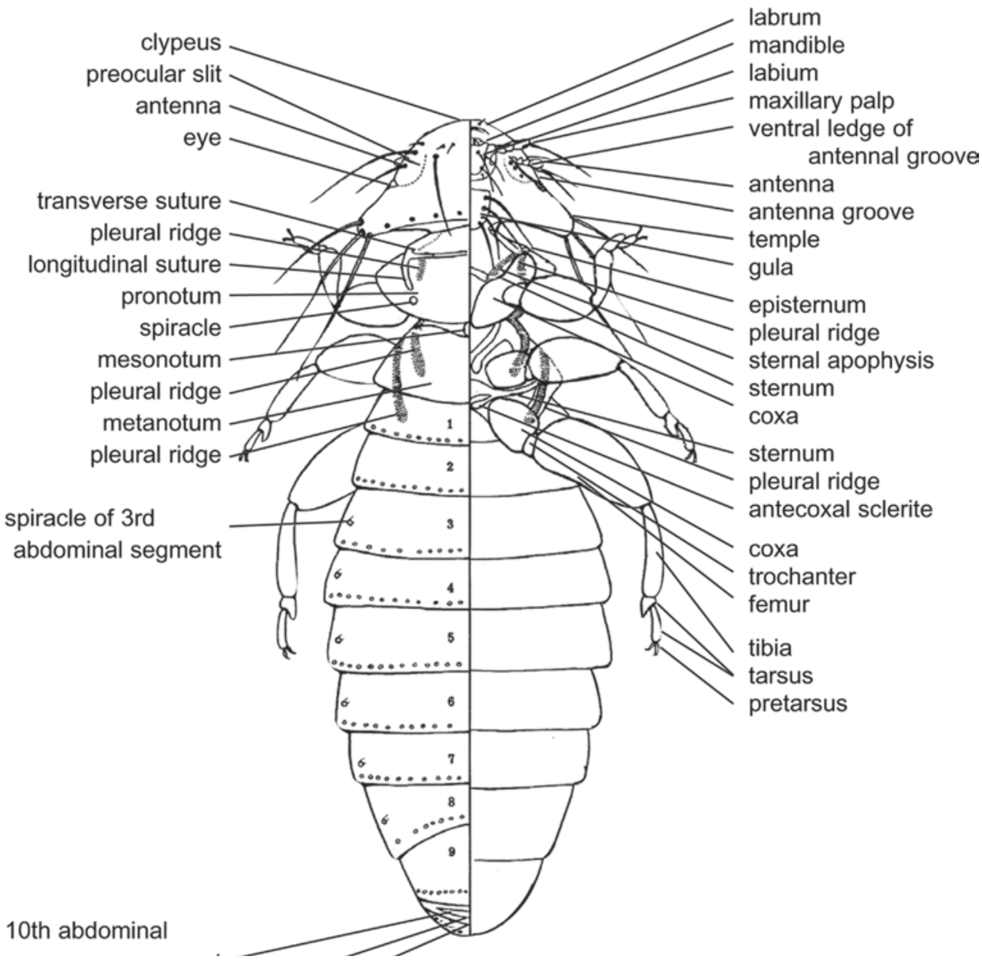
Abdomen of Hexapods, Figure 2 Diagram of a proturan (Protura) showing abdominal segments and appendages: dorsal view (left), ventral view (right).

According to Bitsch, a generalized abdominal segment would be limited anteriorly by a presegmentary domain, separated from the segmentary domain proper (of greater size) by a suture that begins an internal crest named the costa or antecosta. This crest anteriorly delimits an acrotergite or precosta in the tergal part and a presternite in the sternal part. In this idealized model, the muscles would be inserted in successive antecostas. No known structure is homologous to the thoracic furca.

The presence of the gonopore (double in Ephemeroptera) in segments VIII and IX (in VII in the case of Ephemeroptera), and fundamentally of the external structures related to reproduction (the genitalia), produce important modifications in those segments. Considering the presence of these genitalia, three regions of the abdomen are recognized: an anterior (pregenital or visceral region that includes the first eight segments), median (genital region, eighth and ninth segments), and caudal regions (postgenital region, tenth and eleventh segments plus the telsonic region).

The Pregenital Region

In the most generalized condition, the first abdominal segments conserve their basic structure, being easily distinguished from the thoracic segments. Nevertheless, the most frequent condition is that which produces morphological modifications that affect the thoracic-abdominal union. These modifications usually consist of reductions that affect the sternal region and involve a greater or lesser desclerotization of different structures and their

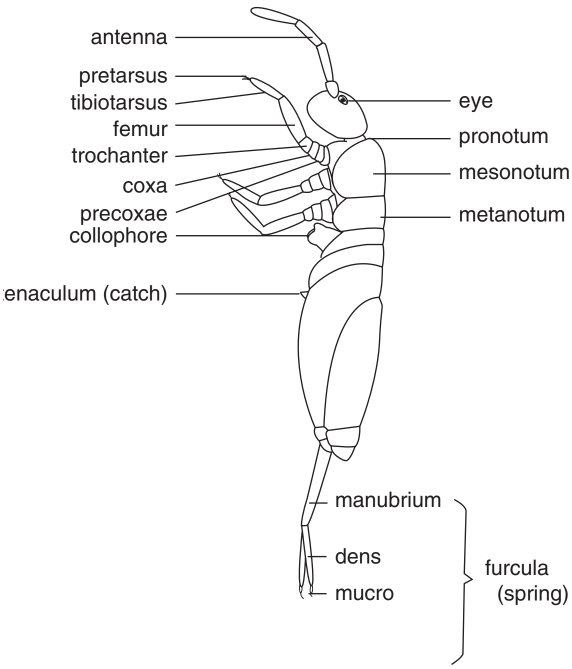


Abdomen of Hexapods, Figure 3 **Diagram of chewing louse (Mallophaga) showing abdominal segments, including numbering of segments: dorsal view (left), ventral view (right).**

incorporation to the metathorax. In this sense, the case of the Hymenoptera, Apocrita stands out, in which a narrowing is produced between the second and the third abdominal segments, which incorporate the thorax and is named the propodeum. The rest of the abdominal segments are called the gaster or metasoma. The region formed by the propodeum and the thorax constitutes the mesosoma. The narrowing allows a great amplitude of movements of the metasoma, which permits stinging in the capture of prey in aculeates. In some groups, like Formicidae and Sphecidae (Aculeata), one or two segments of the metasoma form a narrower zone called the petiole.

In the pregenital region, several appendicular structures can be found. Thus, three pairs of highly modified appendages exist in Collembola. In Archaeognatha, very developed coxites are differentiated, above which are inserted styli in a median position and the exsertile vesicles in the most internal position.

The styli are elongated pieces, articulated in their base above the external face of the coxite. They are unisegmentary and lack muscles inserted in their base, often presenting an apical spine. Taking into account their position and their embryonic development, the styli are considered by the majority of authorities as vestigial appendages, and more concretely as reduced telepodites. The exsertile vesicles are considered internal coxal formations (internal coxalia of some authorities).



Abdomen of Hexapods, Figure 4 Diagram of springtail (Collembola) showing furcular appendage at tip of abdomen.

In Pterygota the abdominal appendages remain restricted to the larval forms (Lepidoptera and Hymenoptera, Tenthredinoidea), although rough appendicular pairs already exist in the polypodous type of embryos. These abdominal appendages are named "false legs" or "prolegs" and are retractile, conical and membranous projections, with a circular planta that bears a crown, usually with hooks, to adhere to the substrate.

The Genital Region

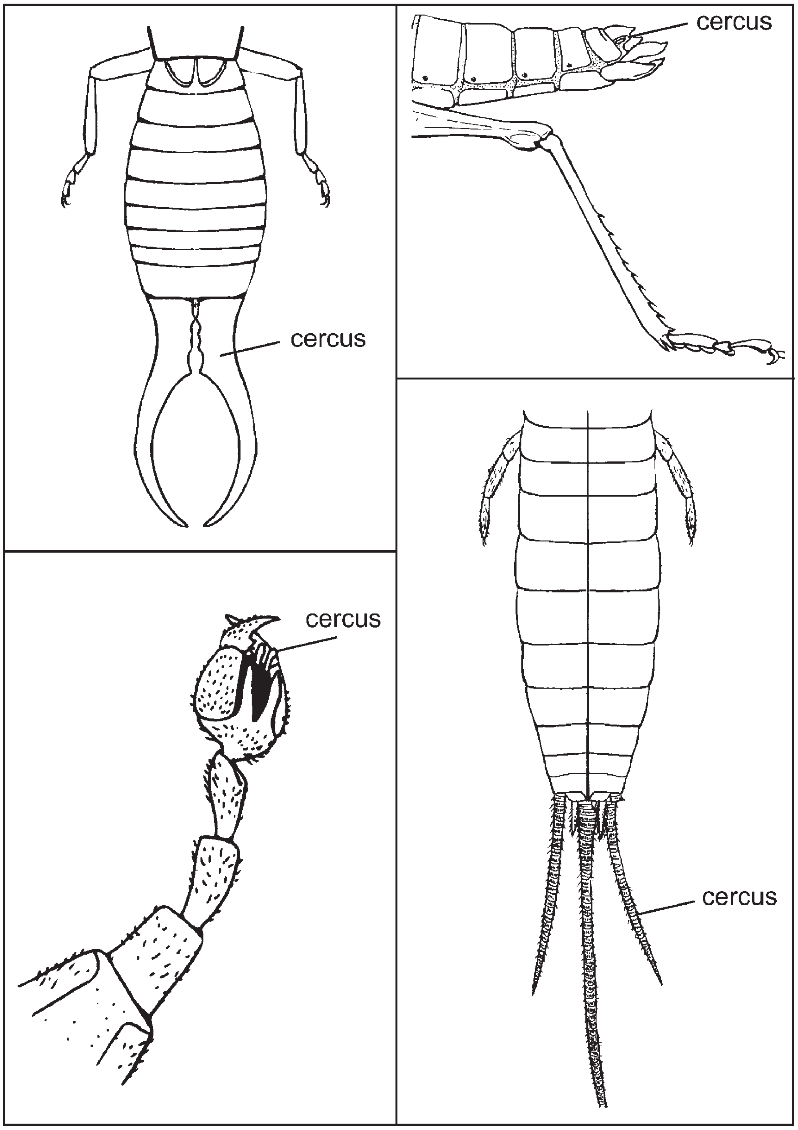
The transformations that affect the eighth and ninth abdominal segments are a consequence of the development of special external structures that in the case of the male serve in the transfer of sperm, and in the case of the female allow for oviposition. These structures together are known by the name genitalia.

The origin of the genitalia is controversial, although the majority of authorities accept that, at least in part, it is of appendicular origin. In this sense, it is clear that in the Archaeognatha the eighth and ninth segments are basically similar in males and females and their structures are homologous to those already indicated for the pregenital segments. Taking into account this relationship, the genitalia of Archaeognatha are considered primitive, and therefore fundamental to interpret the genitalia of Pterygota.

In the eighth segment of the Archaeognatha, the basal part of the appendicular structure is named first gonocoxa or gonocoxite and bears the first gonostylus; in the ninth is found the second gonocoxa with its corresponding stylus. In both segments (at times in the eighth, always in the ninth) formations homologous to the exsertile vesicles appear, which are called gonapophyses (parameters in the males and gonapophysis proper in the females). The fundamental difference between both sexes lies in the presence in the males of a phallic structure.

The female genitalia in the Pterygota constitute the ovipositor. The gonocoxites are incorporated into the lateral wall of the genital segments in a complete manner in the eighth segment, forming the first valvifer. In the ninth segment the basal part is incorporated into the lateral wall, originating the second valvifer, while the rest is extended, forming the third pair of valves (dorsal or lateral valves of some authorities), which are not homologous in Archaeognatha. The other two pairs of valves are the ventral valves, corresponding to the eighth segment, and the internal valves, corresponding to the ninth segment. These two pairs of valves are homologous to the gonapophysis of Archaeognatha. In the case of the generalized type of ovipositor like that of Orthoptera, these three pairs of valves are linked through the length of their course, forming in their interior a canal for oviposition.

Among the sclerites that are situated in the base of the valves (in addition to the valvifers already mentioned) are found the intervalves (intervalvulae of the authorities) by way of elongated transverse formations, one in the base of the valves of the eighth segment and another in the base of the valves of the ninth segment. The typical ovipositor



Abdomen of Hexapods, Figure 5 **Comparative development of cerci on earwig (Dermaptera, top left); grasshopper (Orthoptera, top right); scorpion fly (Mecoptera, lower left); silverfish (Zygentoma).**

that was just described can experience modifications according to the functions that it carries out; one of the most drastic is found in Hymenoptera, Aculeata, where it is transformed into a sting that serves the females as an attacking organ, either to capture prey or as a defense. On the other hand, the process of oviposition can be carried out through other, different structures, as occurs in the females of certain Diptera. In that case, the last segments are retractile and the intersegmental zones are highly developed, in such a way that they can become telescoped, forming oviposition tubes; this type of "ovipositor" is named the ovicauda. Not being homologous to the genitalia, many authorities call it terminalia.

The masculine genitalia present great morphological variability, which together with their taxonomic importance, have been the object of an infinity of descriptions, many of them without truly anatomical criteria. This has originated the use of very varied terminologies that have done nothing but complicate its study and impede the establishment of homologies even in the same group, creating in this way a great nomenclatorial chaos.

In the males, in addition to the genitalia proper, other structures (processes, lobes, etc). exist that intervene in functions other than those strictly related to the transfer of sperm; among the most common is the grasping of the female during mating. It has already been mentioned that the majority of authorities consider that the interpretation of the genitalia of Pterygota should be made by homology with the basic condition that is found in Archaeognatha. In this group, the phallic complex is formed by a median organ, the phallus or penis, and a pair of segmented pieces named parameres, that in the case of maximum development can exist in the eighth and ninth segments. The parameres correspond to the gonapophysis of the females (although the term gonapophysis is utilized indistinctly for both sexes by some authorities).

Many morphological models have been proposed to describe the male genitalia of Pterygota. The most complete, since it gathers and discusses early data, is that proposed by Bitsch. According to this author, what together forms the copulatory organ (phallus or penis) and the structures associated with the parameres (considered in the sense expressed by the Archaeognatha) is named the phallic complex.

The aedeagus is a sclerotized tube, situated above a largely membranous phallobase, although in more complex cases the phallobase presents an internal fold that remains membranous (endotheca) while the external part is sclerotized (phallotheca or theca). The aedeagus presents an invagination that forms a more or less developed internal chamber (the endophallus), which communicates with the gonopore at its base and in the other extreme communicates with the exterior through the phallotreme. In counter-proposition to the endophallus, the part formed by the external walls of the phallobase and the aedeagus forms the ectophallus. The phallic complex can present variable development, even being able to cause the aedeagus to disappear, or on the contrary, increase in complexity, developing spines and other types of processes named flagellum, virga or pseudovirga over the internal walls of the endophallus. When the endotheca and the endophallus are evaginated, the genitalia are converted into authentic intromittent organs.

The primitive position of the male genitalia can be displaced through different types of turns; one of the most showy cases is that which occurs in some Hymenoptera, Symphyta that present the condition called strophandric, which is characterized by a 180° rotation of the genitalia. Rotations have also been observed in males of Diptera.

The postgenital region, as was mentioned in the beginning of this section, comprises the tenth and eleventh segments plus the telsonic region. The tenth segment has been detected in Protura, Diplura, Archaoegnatha, Thysanura (Zygentoma), Ephemeroptera, Plecoptera, and some Orthoptera. The morphology of this segment is basically similar to the pregenital segments, although with certain frequency it can form a ring when the tergum and sternum unite, or the sternal region can be membranous. In embryonic forms, a pair of appendicular outlines is seen above this segment. In certain holometabolous insects, structures of uncertain meaning appear, such as the socii of some Hymenoptera.

The eleventh segment is recognized in the majority of embryonic phases of hexapods. In Archaeognatha and Thysanura it forms an annular structure from whose dorsal part is differentiated a long and narrow process called filum terminale, while from the lateroventral position are differentiated the cerci that in the adults possess numerous divisions. In the Pterygotes, the eleventh segment is formed by the epiproct (tergal region) and the paraprocts (in the lateroventral position); in the more primitive groups exist cerci (whose length and number of divisions are variable) situated in the membranous zones that exist between the epiproct and the paraprocts. The telsonic, asegmentary region constitutes the perianal membrane or periproct.

Abdominal Pumping

Contraction of the muscles associated with the abdomen can result in collapse and expansion of the air sacs. This forces relatively large volumes of air in and out of the insect through the spiracles, promoting ventilation. This is called active ventilation, in contrast with the more normal gas exchange mechanism of insects, diffusion or passive ventilation. To a small degree, abdominal pumping also promotes gas exchange through the trachea, but the trachea is quite resistant to change in shape. Abdominal pumping is more important for larger insects such as locusts, which display abdominal pumping almost continuously, but especially when active. In these insects air is sucked in through some spiracles and pumped out through others.

► Active Ventilation

Abiotic Disease

A disease caused by factors other than pathogens (e.g., weather or nutrition).

Abiotic Factors

Factors, usually expressed as factors affecting mortality, characterized by the absence of life. Abiotic factors include temperature, humidity, pH, and other physical and chemical influences.

Abnormality

In insect pathology, deviation from the normal; a malformation or teratology; a state of disease.

Abrocomophagidae

A family of chewing lice (order Phthiraptera).

► Chewing and Sucking Lice

Absolute Methods of Sampling

Techniques used to sample insect populations that provide an estimate per unit of area (e.g., per square meter, per leaf or per plant). Types of absolute methods include unit of habitat, recapture, and removal trapping. (contrast with relative methods of sampling).

► Sampling Arthropods

Acanaloniidae

A family of insects in the superfamily Fulgoroidae (order Hemiptera). They sometimes are called planthoppers.

► Bugs

Acanthmetropodidae

A family of mayflies (order Ephemeroptera).

► Mayflies

Acanthopteroctetidae

A family of moths (order Lepidoptera). They commonly are known as archaic sun moths.

► Archaic Sun Moths
► Butterflies and Moths

Acanthosomatidae

A family of bugs (order Hemiptera).
► Bugs

Acaricide

A pesticide applied to manage mite populations. An acaricide is also called a miticide.
► Acaricides or Miticides

Acaricides or Miticides

MARJORIE A. HOY
University of Florida, Gainesville, FL, USA

An acaricide or miticide is a pesticide that provides economic control of pest mites and ticks. Mites and ticks are collectively called either acari or acarina. Some products can act as insecticides or fungicides as well as acaricides.

An acaricide is a pesticide used to kill mites and ticks (Table 1). Always check with state and federal authorities to be sure products containing these active ingredients are registered for use. Always read labels carefully and follow the directions completely.

The toxicity of an acaricide is determined by a dose-response curve or a concentration-response curve. Such curves are obtained by exposing test mites or insects to increasing concentrations or doses of the pesticide and recording the resulting mortality after a given time interval. One estimate of toxicity used is the term LD_{50} (which is the dose required to kill 50% of the test population). The LC_{50} is the concentration required to kill 50% of the test population. If the dose is introduced through the insect's mouth it is an oral LD_{50}, if it is introduced through the skin or integument it is a dermal LD_{50}, and if it is introduced through the respiratory system it is the inhalation LD_{50}. A measured dose is applied to an arthropod by inserting a measured amount of toxicant into the gut or by applying a measured amount to the integument. The lower the LD_{50} or LC_{50}, the more toxic the poison.

An LC_{50} is obtained when a mite is exposed to a particular *concentration* of toxicant but the actual amount of toxicant the individual experiences is not determined. For example, if the pesticide is applied to foliage and the mite walks about on the foliage, the actual amount of toxicant the mite is exposed to depends on the activity of the mite, the amount taken up through the integument or by feeding.

Figure 6 shows a concentration-response curve in parts per million (ppm) for the acaricide Omite (propargite) exhibited by adult females from colonies of the Pacific spider mite *Tetranychus pacificus*. The concentration required to kill 50% of the individuals is the LC_{50}. The two types of F1 females (produced by crossing Chapla males and Bidart females, and vise versa) respond similarly and their concentration-response curves are about midway between those of the resistant (Bidart) and susceptible (Chapla) colonies, which indicates that resistance may involve a semidominant mode of inheritance. The term mode of inheritance describes how the trait is inherited; for example, the resistance can be determined by a single major dominant (only one copy of the gene is required for the mite to express the resistance) or recessive (two copies of the gene are required) gene. Or, the resistance can be a quantitative trait determined by multiple genes of equal and additive effect. In this example, the propargite resistance may be determined a single semidominant gene with modifying genes, but additional tests are required to resolve whether more than one gene actually contributes to this resistance.

Acaricide Classification

Pesticides are classified in several ways, including: (i) their mode of entry into the target pest, (ii) chemical structure, or (iii) source.

Acaricides or Miticides, Table 1 Acaricides (miticides) currently or recently available for general and restricted use to control mites and ticks*

Name** (chemical type) Some trade names	General Use (GU)*** Restricted Use (RU)	Potential use
Abamectin (avermectin B1a; produced from the bacterium Streptomyces avermitilis) Affirm, Agri-Mek, Avid, vertimec, Zephyr	GU, Class IV (practically nontoxic)	Also an insecticide; affects nervous system and paralyzes insects or mites; used in citrus, pears, nut tree crops
Amitraz (triazapentadiene) Acarac, Mitac, Ovidrex,Triatox,Topline	GU, Class III (slightly toxic)	Used in pears, cotton, and on cattle, and hogs to control insects, ticks and mites
Azadirachtin (tetranortriterpenoid extracted from the Neem tree) Align, Azatin, Turplex	GU, Class IV	Azadirachtin is similar to insect hormones called ecdysones, which control metamorphosis; also may serve as a feeding deterrent; used to control insects and mites on food, greenhouse crops, ornamentals and turf
Bifenazate (carbazate) **Floramite**	Class IV	Mites on greenhouse, shadehouse, nursery, field, field, landscape and interiorscape ornamentals, not registered in USA for use on food
Bifenthrin (pyrethroid) Talstar, Brigade, Capture	RU, Class II (moderately toxic)	Insecticide and acaricide that affects the nervous system and causes paralysis; used on greenhouse ornamentals and cotton
Carbaryl (carbamate) Adios, Bugmaser, Crunch, Dicarbam on formulation Hexavin, Karbaspray, Septene Sevin, Tornadao, Thinsec	GU, Class I, II or III, depending	General use pesticide to control insects on citrus, fruits, cotton, forests, lawns, nuts, ornamentals, shade trees, poultry, livestock and pets. Also works as a mollusccide and acaricide
Chlorobenzilate (chlorinated hydrocarbon) Acaraben, Akar, Benzilan, Folbex	RU, Class III, may cause tumors in mice	Used for mite control on citrus and in beehives; also kills ticks; use cancelled in USA
Chlorfenapyr (pyrrole) Pylon, Pyramite, Pirate	Class I	Used to control spider mites, broad ites, budmites, cyclamen mite, rust mites and some insects.
Cinnamon oil (cinnamaldehyde) Cinnamite	Exempt from registration under FIFRA	Broad spectrum miticide/ insecticide/fungicide controls or repels pests; could be phytotoxic in some cases; used in ornamentals, shade or nursery trees, vegetables, herbs and spices
Citronella oil	Exempt from FIFRA	Repels insects and ticks
Demeton-S-Methyl (organophosphate) Meta-Systox, Azotox, Duratox, Mifatox	No longer registered for use in USA; Class I, highly toxic	Systemic and contact insecticide and acaricide, widely used against diverse pests

Acaricides or Miticides, Table 1 **(Continued)**

Name** (chemical type) Some trade names	General Use (GU)*** Restricted Use (RU)	Potential use
Dicofol (organochlorine) Acarin, Difol, Kelthane, Mitigan	GU, Class II or III, depending on formulation	Miticide used on fruits, vegetables, ornamentals and field crops
Dicrotophos (organophosphate) Bidrin, Carbicron, Dicron, Ektafos	RU	Contact systemic pesticide and acaricide used to control sucking, boring and chewing pests on coffee, cotton, rice, pecans; used to control ticks on cattle
Dienochlor (organochlorine) Pentac, often formulated with other pesticides	GU, Class III	Contact material used for plant-feeding mites on ornamental shrubs and trees outdoors and in greenhouses; disrupts egg laying of female mites; use cancelled in USA
Dinocap (dinitrophenyl) Arathane, Caprane, Dicap, Dikar Karathane, Mildane	GU, Class III	Used as a fungicide and as an acaricide for ticks and mites; use cancelled in USA
Disulfoton (organophosphate) Disyston, Disystox, Dithiodemeton, Dithiosystox, Solvigram, Solvirex	RU, Class I, highly toxic	Systemic insecticide and acaricide used to control sucking insects/mites on cotton, tobacco, sugar beets, cole crops, corn, peanuts, wheat, grains, ornamentals, potatoes
Endosulfan (chlorinated hydrocarbon) Afidan, Cyclodan, Endocide, Hexasulfan, Phaser, Thiodan, Thionex	RU, Class I	Contact insecticide and acaricide used to control many pests on tea, coffee, fruits, vegetables, grains
Ethion (organophosphate) Acithion, Ethanox, Ethiol, Nialate, Tafethion, Vegfru Foxmite	GU, Class II	Insecticide and acaricide used on wide variety of food, fiber and ornamentals, including greenhouse crops, citrus, lawns and turf
Eucalyptus oil	Exempt from FIFRA	Repels mites; repels fleas and mosquitoes
Fenamiphos (organophosphate) Nemacur, Phenamiphos, Bay 68138	RU, Class I	A nematicide that has some activity against sucking insects and spider mites
Fenbutatin oxide (organotin) Vendex	RU	Miticide used on perennial fruits, eggplant and ornamentals
Fenitrothion (organophosphate) Accothion, Cyfen, Dicofen, Fenstan, Folithion, Mep, Metathion, Micromite Pestroy, Sumithion, Verthion	GU	Acaricide and insecticide effective gainst a wide array of pests

Acaricides or Miticides, Table 1 (Continued)

Name** (chemical type) Some trade names	General Use (GU)*** Restricted Use (RU)	Potential use
Formothion (organophosphate) Aflix, Anthio, Sandoz S-6900	RU, Class II	Systemic and contact insecticide and acaricide, used against spider mites on tree fruits, vines, olives, hops, cereals, sugar cane, rice
Hexythiazox (ovicide, growth regulator) Savey	Class III	Ovicide/miticide effective against spider mites on tree fruits, christmas trees, strawberries, hops, peppermint, caneberries
Lambda cyhalothrin (pyrethroid) Charge, Excaliber, Granade, Hallmark, Icon, Karate, Matador, Saber, Sentinel	RU, Class II	Insecticide and acaricide used to control a variety of pests in cotton, cereals, hops, ornamentals, potatoes, vegetables; controls ticks
Lindane (organochlorine) Agrocide, Benesan, Benexane, BHC, Gammex, Gexane, HCH, Isotox, Kwell, Lindafor, Lintox, Lorexane, Steward	RU, Class II Most uses cancelled in USA because of potential to cause cancer	Insecticide and fumigant; used in lotions, creams and shampoos for control of lice and mites (scabies) in humans
Methamidophos (organophosphate) Monitor, Nitofol, Tamaron, Swipe Patrole, Tamanox	RU, Class I	Systemic, residual insecticide/acaricide/avicide with contact and stomach action, used to control chewing and sucking insects and mites in many crops outside the USA
Methidathion (organosphosphate) Somonic, Supracide, Suprathion	RU, Class I	Insecticide and acaricide with stomach and contact action used to control a variety of insects and mites in many crops
Methomyl (carbamate) Acinate, Agrinate, Lannate, Lanox, Nudrin, NuBait	RU, Class I	Broad spectrum insecticide and an acaricide to control ticks, acts as a contact and systemic pesticide
Mevinphos (organophosphate) Fosdrin, Gesfid, Meniphos, Menite, Mevinox, Mevinphos, Phosdrin, Phosfene	RU, Class I	Insecticide and acaricide effective against a broad spectrum of pests, including mites and ticks; use cancelled in greenhouses
Monocrotophos (organophosphate) Azodrin, Bilobran, Monocil 40, Monocron, Nuvacron, Plantdrin	RU, registration in USA withdrawn in 1988	Systemic and contact insecticide and acaricide
Naled (organophosphate) Bromex, Dibrom, Lucanal	GU, Class I	Contact and somach insecticide and acaricide, used against mites in greenhouses
Oxamyl (carbamate)	RU, Class I granular form is banned in USA	Insecticide/acaricide/nematacide that controls a broad spectrum of mites, ticks and roundworms on field crops, vegetables, fruits, ornamentals

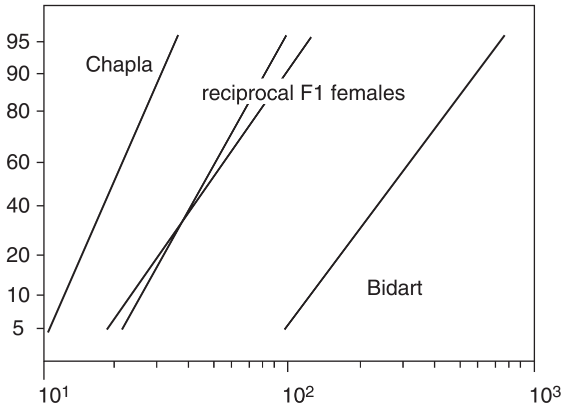
Acaricides or Miticides, Table 1 **(Continued)**

Name** (chemical type) Some trade names	General Use (GU)*** Restricted Use (RU)	Potential use
Neem oil Trilogy		Broad spectrum fungicide and acaricide in citrus, deciduous fruits and nuts, vegetables, grains
Permethrin (pyrethroid) Ambush, Cellutec, Dragnet, Ectiban, Indothrin, Kafil, Kestrel, Pounce, Pramex, Zamlin, Torpedo	Class II or III, depending on formulation RU in agriculture because of adverse effects on aquatic organisms	Broad spectrum used on nut, fruit, vegetable, cotton, ornamentals, mushrooms, potatoes, cereals, in greenhouses, home gardens, on domestic animals
Petroleum oils (refined petroleum distillate) Sunspray and others	Class IV	Kills by contact a wide range of mite and insects; complete coverage is essential; may act as a feeding or oviposition deterrent. Phytotoxicity can occur if plants are stressed, especially by lack of water; some plant cultivars are more susceptible than others. Used as dormant and as foliar sprays.
Phorate (organophosphate) Agrimet, Geomet, Granutox, Phorate Rampart, Thimenox, Thimet, Vegfru	RU, Class I	Insecticide and acaricide used on pests, including mites, in forests, root and field crops, ornamentals and bulbs
Phosalone (organophosphate)	GU, No longer for sale in USA due to carcinogenic effects	Broad spectrum insecticide/ acaricide used on deciduous trees, vegetables, cotton.
Phosmet (organophosphate)	GU, Class II, some tolerances in foods changed in 1994 by EPA	Broad spectrum insecticide, used to control insect and mites on apples, ornamentals, vines; is used in some dog collars.
Propargite (organosulfide) Comite, Omite	GU	Acaricide used in many crops but not USA
Rosemary oil (rosemary essential oil) Hexacide	Meets requirements of USDA National Organic Program Exempt from FIFRA	Broad spectrum contact insecticide/miticide used in fruits, nuts, vegetables. Could be phytotoxic on some cultivars.
Soybean oil (essential oil)	Low acute toxicity to humans, generally recognized as safe	
Spinosad (macrocyclic lactone) Conserve		Broad spectrum insecticide and miticide used on ornamentals and in greenhouses.
Sulfur (sulfur) Cosan, Hexasul, Sulflox, Thiolux	GU, Check label for restrictions	Fungicide and acaricide; used to control plant diseases, gall mites, spider mites, used widely in food and feed crops, ornamentals, turf and residential sites; a fertilizer or soil amendment, mixing with oil can cause phytotoxicity

Acaricides or Miticides, Table 1 (Continued)

Name** (chemical type) Some trade names	General Use (GU)*** Restricted Use (RU)	Potential use
Triforine (piperazine derivative)	RU, Class I	Fungicide used on almonds, apples, asparagus, berries, cheeries, hops, ornamentals, peaches, rose; also controls spider mites
Wintergreen oil (contains methyl salicylate)	Exempt from FIFRA	Used to control mites (Varroa) in honey bees; causes contact mortality and reduced fecundity when mites feed on syrup

* The list is based on chemicals currently registered in the USA, which can change as new information regarding environmental impact and human health effects become available. Inclusion in this list does not necessarily indicate that the products are effective acaricides; application methods and resistance levels in individual mite populations can affect efficacy.
**Most have a variety of trade or other names, as well as different formulations, which can affect their toxicity.
***Restricted Use (RU) means that pesticides may be purchased and used only by certified applicators. Check with specific state regulations for local restrictions.



Acaricides or Miticides, Figure 6 **This is a concentration-response curve showing the responses of a colony of *Tetranychus pacificus* resistant (Bidart) and susceptible (Chapla) to propargite (Omite). The mortality of adult females at different concentrations has been transformed into a straight line. The concentration-responses of the reciprocal F1 females in crosses between the susceptible and resistant populations are intermediate and similar.**

Mode of Entry

A pesticide can enter and kill mites as stomach poisons, contact poisons, and or as fumigants. A systemic acaricide is absorbed into a plant or animal and protects that plant or animal from pests after the pesticide is translocated throughout the plant or animal.

Chemical Structure

Pesticides are classified as organic or inorganic. Inorganic pesticides do not contain the element carbon (but include arsenic, mercury, zinc, sulfur, boron, or fluorine). Most inorganic pesticides have been replaced by organic pesticides.

Source

Organic pesticides include botanicals (natural organic pesticides) produced by plants (such as natural pyrethrums, nicotine, rotenone, essential oils such as those from the neem tree, soybean oil). Essential oils are any volatile oil that gives distinctive odor or flavor to a plant, flower or fruit, such as lavender oil, rosemary oil, or citrus oil. Essential oils have been registered as pesticides since 1947 and at least 24 different ones are available in registered products. These are used as repellants, feeding depressants, insecticides, and miticides. Botanicals have relatively high LD50 values to mammals, so usually are considered safe to humans. Some newer pesticides are derived from microbes, such as avermectin or spinosad.

Synthetic organic pesticides are commonly used in pest management programs and can be separated into groups based on their chemistry. The main groups are: chlorinated hydrocarbons (such as DDT and chlordane, which are banned from use in most parts of the world), organophosphates (such as malathion, parathion, azinphosmethyl), carbamates (carbaryl, propoxur), pyrethroids (permethrin, fenvalerate),and a variety of newer products with very different chemistries including nicitinoids, pyrroles, carbazates, and pyridazinones.

Insecticides as Acaricides

Many insecticides have acaricidal properties. Sometimes an insecticide is more effective as an insecticide than as an acaricide (lower concentrations are required to kill the insect than are required to kill the mite species). Some products are more toxic (often for unknown reasons) to mites than to insects. We think that mites have the same fundamental physiological responses to toxic chemicals as insects, although mite physiology and responses to pesticides have been studied less often. Different mite species appear to respond differently to different products, which could be due to behavioral differences (feeding behavior, location on plant, activity levels), differences in cuticle thickness, differences in detoxification rates, or other biochemical, morphological or behavioral factors. Different formulations also can influence toxicity to different species of both insects and mites.

Many insecticides are effective acaricides (or at least they were before resistance to them developed). For example, many OPs (such as azinphosmethyl, parathion, ethion, dimethoate) were toxic to spider mites until resistance to these products developed. Likewise, carbamates, formamides, and many pyrethroids have both insecticidal and acaricidal properties. Other products have both fungicidal and acaricidal properties. The reasons as to why these products are effective on particular taxonomic groups are generally unknown.

Acaricide Types

Pesticide registrations change frequently so some of the materials listed here may be obsolete. Always check with state and federal authorities to be sure products containing these active ingredients are registered for use. Always read labels carefully and follow the directions completely.

Chlorinated Hydrocarbons

Dienochlor (Trade name = Pentac) is a chlorinated hydrocarbon acaricide with long residual activity. It has been used in greenhouses and on outdoor ornamentals. Pentac cannot be used on food crops and has short residual activity when used outdoors. It has a rapid effect on mites, stopping their feeding within hours. Endosulfan and DDT have also been used as acaricides (as well as insecticides).

Essential Oils

Soybean oil was first registered in 1959 for use as an insecticide and miticide. Three products currently are registered to control mites on fruit trees, vegetables and a variety of ornamentals. Soybean oil is not phytotoxic under most conditions. Many of these oils are approved for organic farming.

Inorganics

Sulfur is a good acaricide and fungicide, although it can be phytotoxic (cause plant injury), especially if plants are not well watered during hot weather. Sulfur is probably the oldest known acaricide. Sulfur (dusts, wettable p owders and flowable formulations) are usually highly effective acaricides for spider mites and rust mites, with two known exceptions.

Spider mites in California vineyards (*Tetranychus pacificus* and *Eotetranychus willamettei*) developed resistance to sulfur, probably because sulfur was applied up to 20 times a season over many years to control powdery mildew. After a number of years, these spider mites became pests because they were no longer controlled by the sulfur which had been applied to control powdery mildew. A number of years later, a predatory mite called *Metaseiulus occidentalis* was demonstrated to have developed a resistance to sulfur. The resistance to sulfur in this natural enemy of spider mites is based on a single major dominant gene; once the predator became resistant to sulfur it became an effective predator of spider mites in San Joaquin Valley vineyards in California.

The resistance to sulfur in *M. occidentalis* is unusual; even very high rates of sulfur are non-toxic to the resistant populations. Interestingly, populations of this predator collected from nearby almond orchards in California are susceptible to sulfur, indicating that populations are subjected to local selection and evolution. No genetic analyses have been conducted on the resistance to sulfur in the spider mites, so their mode of inheritance to sulfur resistance remains unknown. The biochemical mechanism of resistance is unknown for both spider mites and their predators.

Petroleum Oils

Petroleum oils are excellent insecticides/acaricides/fungicides for integrated mite management programs and have been used in pest management programs for over 100 years.

Different types of petroleum oils are used with different molecular weights. Most oils used are distillations of petroleum, although some oils derived from plants (sesame, almond, citrus) are used.

Crude petroleum oil is a complex mixture of hydrocarbons with both straight chain and ring molecules. Crude oil is separated into a range of products by distillation and refining. The lightest fractions include gasoline, kerosene, diesel and jet fuel. As these lighter fractions distill or boil, they are separated into different fractions. Spray oils are derived from the lighter lubricating oil fraction and distill at a temperature range of 600 to 900°C.

Currently used petroleum oils in the USA are narrow-range oils and have had the waxes, sulfur, and nitrogen compounds removed. Labels on sprays usually describe the degree to which the sulfur compounds have been removed and the percentage of active oil. The sulfur compounds are likely to cause phytotoxic effects, so the degree of removal of these compounds (called the UR rating) is an important piece of information on the label and commonly is greater than 92%. The composition of oil should be greater than 60%.

Since the mid-1960s, narrow-range horticultural oils have been used both as dormant or summer oil sprays. These highly refined and narrow range petroleum oils rarely cause phytotoxicity and increasingly are used for controlling both insect and mite pests on deciduous trees, citrus, and ornamental trees and shrubs. Oils have a wide range of activity against scales, mites, psyllids, mealybugs, whiteflies, leafhoppers, and eggs of mites, aphids and some Lepidoptera. Heavier dormant sprays are used to control overwintering pests in deciduous trees and vines. Summer oils are used to control pests during the growing season.

Oil kills mites and their eggs by contact. The toxicity appears to be due to suffocation of the pest, although it may also be due to chemical effects. Oils block spiracles, reducing the availability of oxygen and suffocation occurs within 24 h. Penetration and corrosion of tracheae, damage to muscles and nerves may also contribute to the toxicity of oils. Oils are sometimes a repellent to pests. Once the oil dries it is no longer toxic to most natural enemies; thus the very short residual activity of oil makes it a useful material for integrated mite management programs, although it also means that there is no residual toxicity to the pests.

No resistance to oils has been reported in pest arthropods, including mites, perhaps because oils have a relatively short residual activity. Oils are easy to apply, relatively inexpensive, and safe to handle. They are relatively harmless to vertebrates, dissipate quickly after spraying, and leave little or no residue on crops. Oils man be used by organic farmers.

A disadvantage to petroleum oils is that they have little residual activity and kill only upon contact, so thorough and precise coverage is necessary to achieve effective control. Phytotoxicity can occur even with these narrow-range oils, especially if plants are weakened or under moisture stress. Thus, applications should not be made during droughts, or periods of very high temperatures. Some varieties of plants are more susceptible to phytotoxicity than others, so caution should be taken when using oils for the first time on a particular crop or cultivar. Oils are not compatible with sulfur or some other pesticides, causing serious phytotoxicity problems.

Organosulfurs

Tetradifon (Tedion) and propargite (Omite, Komite) are organosulfurs. These products contain sulfur as a central atom with two phenyl rings. Tedion is particularly toxic to mites, but has very low toxicity to insects. Organosulfurs are often ovicidal as well as toxic to active stages. Propargite was used for many years (more than 20) and appeared to some to be immune to the development of resistance in spider mite populations. However, propargite resistance has now developed in many populations of spider mites around the world. Propargite is less toxic to beneficial phytoseiid predators than to pest spider mites, and thus could be used in integrated mite management programs, although at high concentrations it also is toxic to phytoseiid predators.

Organotins

Cyhexatin (Plictran) and fenbutatin-oxide (Vendex) are examples of tin compounds that are primarily acaricides and fungicides. Plictran (cyhexatin) was introduced in 1967 and was widely used for many years before resistance developed in spider mites. Some people had assumed that the organotins were immune to resistance problems. The organotins were useful products because they were more toxic to spider mites than to phytoseiids and thus were very useful in integrated mite management programs. Fenbutatin-oxide (Vendex) is another organotin. These products were taken off the market in the USA due to concerns about safety.

Insecticides with Acaricidal Activity

Organophosphorus Pesticides

The organophosphates (pesticides that include phosphorus) are derived from phosphoric acid and are the most toxic of all pesticides to vertebrates. They are, in fact, related to nerve gases by structure and mode of action. Organophosphorus pesticides (OPs) are less persistent in the environment than the organochlorines such as DDT.

Organophosphorus pesticides (such as azinphosmethyl, parathion, ethion, demeton, dimethoate) function by inhibiting important enzymes (cholinesterases) in the nervous system. Acetylcholine is the chemical signal that is carried across synapses (where the electrical signal is transmitted across a gap to a muscle or another neuron. After the electrical signal (nerve impulse) has been conducted across the gap by acetylcholine, the cholinesterase enzyme removes the acetylcholine so the circuit won't be kept on. When OPs poison an organism, the OP attaches to the cholinesterase so it cannot remove the acetylcholine. The circuits then remain on because acetylcholine accumulates. This gives rise to rapid twitching of the voluntary muscles and to paralysis, which is can be lethal if it persists in the vertebrate respiratory system.

Not all OPs are highly toxic to vertebrates; if the phosphorus is modified by esterification (adding oxygen, carbon, sulfur and nitrogen), six different classes of OPs can be produced. Some of these are relatively safe to vertebrates, such as malathion. The use of most OPs is being eliminated in the USA due to the Food Quality Protection Act.

Carbamates

Carbamates (aldicarb, carbofuran, methomyl, propoxur) are derivatives of carbamic acid. The mode of action of carbamates is to inhibit cholinesterase. The carbamates were introduced in the 1950s. Carbaryl (Sevin) is one of the most popular products available to home gardeners for controlling a variety of insect pests and has low mammalian oral and dermal toxicity. Methomyl (Lannate) and aldicarb (Temik) are examples of other carbamates.

Sevin is well known to induce outbreaks of spider mites after applications are made to control other pests. The outbreaks are due to two factors; (i) Sevin kills phytoseiid predators and other natural enemies of spider mites, and (ii) it stimulates reproduction of spider mites, a process called hormoligosis. Even very low doses of Sevin appears to act like a hormone to stimulate reproduction of the two-spotted spider mite *Tetranychus urticae*. It is likely that the use of carbamates also will be eliminated or greatly reduced in the USA due to the Food Quality Protection Act.

Formamides

Formamides include chlorodimeform (Galecron or Fundal), amitraz, and formetanate (Carzol). These products are effective against the eggs of Lepidoptera and also against most stages of mites and ticks. The mode of action of these products is unclear, but thought to be due to the inhibition of monoamine oxidase, which results in the accumulation of compounds called biogenic amines.

Pyrethroids

Many of the pyrethroids have acaricidal activity. Some (such as bioresmethrin, fenpropathrin and bifenthrin) are considered effective acaricides. Unfortunately, pyrethroids usually are very toxic to beneficial arthropods, including phytoseiid predators. These detrimental effects can be very long lasting because the residues persist a long time. Few have been found useful for integrated mite management programs for this reason. Laboratory selection of phytoseiids (*Amblyseius fallacis, Metaseiulus occidentalis, Typhlodromus pyri*) for resistance to two pyrethroid insecticides has been successful. The pyrethroid-resistant strains were developed for use in apple pest management programs using both laboratory and field selection methods.

Pyrroles

Pyridaben is a novel pyrrole pesticide that works as a mitochondrial electron transport inhibitor to block cellular respiration, causing pests to become uncoordinated and die. Can be used on both insects and mites.

Other Acaricides

Azadirachtin

This is a triterpenoid extracted from the seeds of the neem tree *Azadirachta indica*. Extracts include a combination of compounds, the proportion of which vary from tree to tree. Such variability in this natural product makes it difficult to predict the precise effect of the product when extracted by local people. Commercial products may be more consistent in their effect because they have been tested to confirm their quality and are blended to achieve a consistent product. Azadirachtin blocks the action of the molting hormone ecdysone.

Avermectin

Avermectin is a natural product containing a macrocyclic lactone glycoside that is a fermentation product of *Streptomyces avermitilus*, which was isolated from soil. Avermectin is actually a mixture of two homologs, both of which have biological activity. Avermectin has insecticidal and acaricidal properties and is closely related to ivermectin, which kills nematodes.

At appropriate rates, abamectin is less toxic to beneficial phytoseiids than to spider mites; it paralyzes active spider mite stages, but is not toxic to eggs. Avermectin has translaminar activity (meaning it is taken up by the plant tissue and subsequently by spider mites feeding on the plant tissues), but has a short residual toxicity to phytoseiids.

Resistance to this product has been reported in some populations of spider mites. A resistant strain of *M. occidentalis* was obtained after laboratory selection, suggesting that resistance mechanisms may be present in field populations.

The mode of action of avermectin involves blocking the neurotransmitter gamma-aminobutyric acid (GABA) at the neuromuscular junction. Mites that are exposed to abamectin become paralyzed and, although they do not die immediately, the paralyzed mites do stop feeding.

Clofentezine and Hexythiazox

These are very interesting growth regulators of mites; they kill eggs (ovicides) of spider mites, but not the active stages of spider mites. The products have different chemistries, but both are nontoxic to phytoseiid mite eggs or active stages! In fact, the phytoseiid mite *Metaseiulus occidentalis* can be fed a diet consisting solely of spider mite eggs that have been killed with these products and the predator females reproduce and their progeny develop normally. This selectivity makes the products particularly useful for integrated mite management programs because predators can be maintained while suppressing spider mite populations. Unfortunately, resistance to these products has developed in spider mite populations in several locations around the world, including Europe and Australia.

Tebufenpyrad

This is a phenoxypyrazole and has been evaluated under the trade name Pyranica in Australia, where it was shown to be useful in integrated mite management programs in apples because it is selective (relatively nontoxic) to phytoseiid predators.

Acaricides and Fungicides

Benomyl is a carbamate that has been used primarily as a fungicide, but also has acaricidal properties. Benomyl is interesting because it acts as a sterilant of phytoseiid predators. Adult phytoseiid females treated with benomyl survive, but they do not deposit eggs. This product apparently disrupts spindle fiber formation in cells and interferes in the synthesis of DNA, resulting in females that are unable to reproduce.

Resistance in Mites

Resistance to pesticides is an increasingly serious problem around the world. Resistance to one or more pesticides has been documented in more than 440 species of insects and mites. Spider mite and tick species have readily developed resistance to all classes of pesticides.

Resistance is a decreased response of a population of animal to a pesticide or control agent as a result of their application. It is an evolutionary or genetic response to selection. Tolerance is an innate ability to survive a given toxicant dose without prior exposure and evolutionary change. Cross resistance is a genetic response to selection with compound A that generates resistance to both compound A and other compounds (B and C). Multiple resistance is resistance to different compounds due to the coexistence of different resistance mechanisms in the same individuals. Multiple resistances usually are generated by sequential or simultaneous selection by more than one type of pesticide.

Methods for Evaluating Resistance

There are a variety of methods available for assessing resistance to pesticides in mites. The test method chosen will depend upon the goals of the researcher. Each method has strengths and weaknesses.

Resistance is a genetically-determined change in the ability to tolerate a pesticide. Therefore, one must have at least two different populations to test – one that is putatively resistant and one that exhibits the normal, wild type response. Unless these two populations can be compared under identical laboratory conditions, it is difficult to document resistance because historical data are of questionable value in assessing whether a population is resistant. This is because it is very difficult to conduct identical bioassays in two different laboratories, even when attempts are made to use the same methods. Small differences in techniques can result in very large differences in toxicity data. For example, spider mites tested on smooth leaves may respond very differently than spider mites tested on the same plant species but on a variety with hairy leaves. Small differences in formulations and temperature also influence responses of mites to pesticides. Small differences in age or feeding status also influence toxicity responses. Most conclusions about resistance should be based on comparative data obtained by the same researcher under identical conditions.

The apparent failure of a product to control a mite population under field conditions is NOT adequate evidence for resistance. Field failure is a reason to investigate further, but field failures can occur for a variety of reasons that have nothing to do with resistance. Failures could occur because the pesticide applicator may have mixed the product improperly, coverage may have been inadequate, the pH of the water used to mix the pesticide could have altered the toxicity of the product, and the product could have been old or degraded due to improper storage.

Slide Dip Bioassays

Slide dip bioassays of adult female spider mites and phytoseiids have been proposed as a standard method for assessing resistance or tolerance. This method involves placing adult female on their backs on to double-sided sticky tape applied to glass microscope slides and dipping the slides into a specific pesticide concentration. This method has the virtue of being relatively rapid and easy to conduct. However, measuring toxicity to adult females after 24 or 48 h is not an appropriate assay for many pesticide types (for example ovicides, growth regulators). Also, the results probably bear little relation to the field toxicity of the product. It is very likely that many products are much more toxic to the mites using this assay than they would be under field conditions, where mites can feed and move around and coverage is rarely complete, so this method may give no information about whether the resistance level induced is relevant to field concentrations used.

Leaf Dip or Leaf Spray Bioassays

Leaf dip or leaf spray bioassays involve placing mites on leaf disks, which are then sprayed or dipped into a specific concentration of pesticide. This type of bioassay provides an exposure that is more similar that the mites would experience under field conditions and it is possible to measure survival, fecundity, and ability to successfully develop on pesticide residues.

Whole Plant Bioassays

This approach, which involves spraying the entire plant, is very realistic, unless the plants (and pesticide residues) are not exposed to sunlight or rain.

Field Tests

Field trials are the most realistic method for assessing resistance, but it can be difficult to determine why the predators or spider mites died (did other tolerant predators fly in and eliminate the pest?). If adequately replicated over time and space, field trials provide very relevant information. The relevance of application method (high or low volume), coverage, and droplet size can be assessed. Unfortunately, field trials are the most expensive to carry out so the methods described above are often used to save time and funds.

Accessory Cell

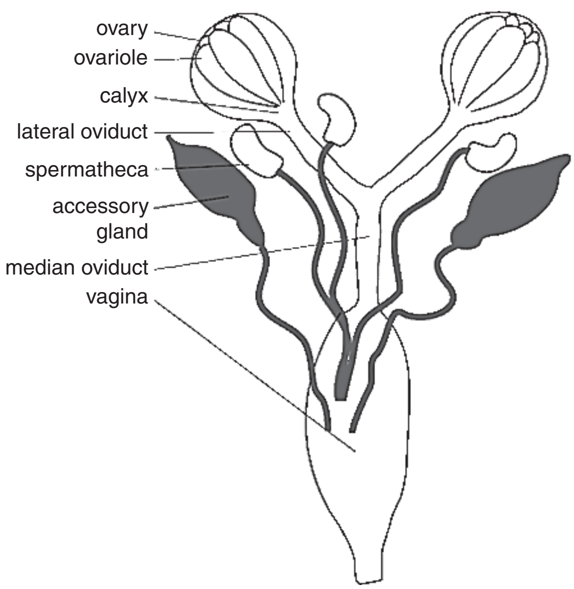
A wing cell not normally present in the taxon.

Accessory Circulatory Organ

Although the dorsal vessel (heart) is normally considered to be the organ responsible for blood circulation in insects, sometimes small sac-like structures are located at the base of appendages (antennae, legs, wings). These structures are capable of contractions independent of the dorsal vessel, and assist in circulation. This is also called "accessory pulsatile organ."

Accessory Gland

A gland associated with the male or female reproductive system, and producing substances associated with the sperm or eggs, respectively (Fig. 7). Male accessory glands produce such substances to



Accessory Gland, Figure 7 **Diagram of the female reproductive system, as found in *Rhagoletis* (Diptera) (adapted from Chapman, The insects: structure and function).**

facilitate sperm transfer, as a barrier to further insemination, as a means of altering female behavior, and as a means of providing nutrition to the female. Females produce substances for packaging their eggs, adhering them to a substrate, and providing a protective coating over the eggs.

Accessory Vein

An extra branch of a longitudinal vein. Such veins normally are designated by a subscript of "a."

► Wings of Insects

Accessory Hearts

Pulsatile, sac-like organs that assist in circulation of the hemolymph into appendages such as the antennae, wings, and legs.

Accidental Host

A host in which the pathogenic microorganism (or parasite) is not commonly found.

Accidental Species

Species that occur with a low degree of consistency in a community type. Such species are not useful for community definition.

Acclimation

The adaptation of an organism' s physiological responses to existing environmental conditions. A nearly equivalent term is "acclimatization," though acclimation may be a more rapid or laboratory-based phenomenon, whereas acclimatization is a long term, field-based phenomenon.

Accuracy

A measure of the closeness of an estimate to the true mean or variance of a population.

► Sampling Arthropods

Acephalous

The condition of lacking an apparent head. This term is usually applied to certain flies and wasps that lack a well-defined head.

Acerentomidae

A family of proturans (order Protura).

► Proturans

Acetylcholine

The synaptic transmitter substance found in the insect central nervous system. When released into the synaptic cleft, it is bound to a receptor, depolarizing the postsynaptic membrane and stimulating nervous excitation.

Acetylcholine Esterase

An enzyme that breaks down acetylcholine after it is released into the synaptic cleft of insect neurons. Interference with acetyl choline esterase, as by exposure to some insecticides, results in prolonged stimulation of the nerves.

Achilidae

A family of insects in the superfamily Fulgoroidae (order Hemiptera). They sometimes are called planthoppers.

► Bugs

Aclerididae

A family of insects in the superfamily Coccoidae (order Hemiptera).

► Bugs

Acoustical Communication in Heteroptera (Hemiptera: Heteroptera)

MARTA GOULA
University of Barcelona, Barcelona, Spain

Acoustic signaling is found in many hemipteran families. It serves a variety of purposes, particularly defensive behavior such as repelling potential predators and signaling alarm or distress, but also for species spacing within a particular habitat, reproduction, and coordination of group actions. Vibratory signals for reproductive purposes may be produced by males and/or females, leading to aggregation to mate attraction, courtship and copulation. Non-receptive females may sing to reject copulation (male-deterring stridulation), as in the subfamily Triatominae (Reduviidae) and in Pentatomidae (e.g., *Nezara viridula*).

The vibratory signals produced by many insect species cannot be heard by the human ear because the sounds are low frequency and generally transmitted by mechanical vibrations through the substrate, and not by the air. The study of acoustical communication has greatly progressed in accordance with improvement of recording and analyzing equipment, including the necessary computer software.

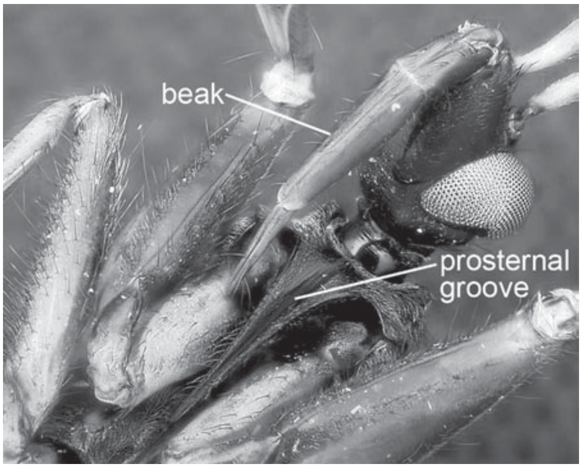
Production of Vibrational Signals and Songs

Vibrational signals and songs are produced by stridulation (stridulatory device, stridulatory organs), by body vibration, or by a simple tymbal mechanism. Stridulation occurs widely in Heteroptera, and is the act of producing sound or vibration by rubbing together certain body parts. The first systematic survey of sound-producing devices in the Heteroptera was that of Handlirsh in 1900. To stridulate, usually both a movable and a stationary portion are needed. The movable part is called the plectrum or scraper. The stationary portion may be called the stridulitrum, file, strigil (strigile, strigilis) or lima (pl., limae). The stridulitrum is typically striated or finely tuberculated, and the plectrum is a structure with a well-defined lip or ridge, tubercles, or provided with spines.

Different parts of the body may be involved to function as the stridulatory device. The forewing edge is most commonly used as a stridulitrum (file), while the hind femur is the most usual structure used as a plectrum (scraper). Other stridulitrum may be located in the head, associated with the mouth (labium, maxillary plate), the thorax (propleurum, metapleuron, prosternal groove), the wings (metathoracic wing vein, hypocostal lamina or articulatory sclerite, underside of clavus), the legs (forecoxa, mesotrochanter, tibia, femora), and the abdomen (sternum, the connexival margin, posterior margin of the pygophore). There are also a variety of locations for the plectrum or scraper: the rostrum, the legs (forecoxal cavity, coxal peg, hind tibia, and fore-, middle or hind femur) or the abdomen. Some stridulatory devices are present in several families, whereas others are only known from a few genera or even a single species.

Examples of stridulation devices are that of the Corixidae (spinose area inside the front femur against the clypeus, genitalia against abdomen segments), Scutelleridae (wart-like, toothed tubercles in the hind tibia against the femur), Reduviidae (tip of the labium against a cross-striated furrow (Fig. 8) in the prosternal groove), some Pentatomoidea and Lygaeiodea (dorsal abdominal files against teeth on the under-sides of the hindwings), some Miridae, Lygaeidae, Largidae and Alydidae (hind femur against forewing edge) and some other Pentatomoidea (tubercles on the hind femora against strigose regions on abdominal sterna).

Morphological differences in the stridulatory device may, in some cases, be related to differences in the songs emitted by either males or females, as



Acoustical Communication in Heteroptera (Hemiptera: Heteroptera), Figure 8 The stridulatory apparatus in Reduviidae: the tip of the labium is rubbed against a cross-striated furrow in the prosternal groove.

occurs in the burrower bugs (Fig. 9) *Scaptocoris castanea* and *S. carvalhoi*. In *S. castanea*, males have a longer stridulitrum than females. However, in *S. carvalhoi* the stridulitrum length does not differ between sexes. Instead, in *S. carvalhoi* the male stridulitrum has more teeth than in the female stridulitrum. There are no intersexual differences for this latter morphological trait in *S. castanea*.

Differences in the stridulatory apparatus may be related to interspecific differences, with a specific diagnostic value. In the genus *Triatoma* (Reduviidae), it is possible to distinguish between *T. guazy* and *T. jurbergi* at any nymph stage or in the adults by studying the stridulatory sulcus (stridulitrum). As *T. jurbergi* is naturally infected with *Trypanosoma cruzi*, the causal protozoan of Chagas disease (American trypanosomiasis), identification of specimens along their whole life cycle is of great medical importance.

In other instances, morphological differences in the stridulatory device do not cause differences in their song patterns. For example, in Reduviidae of the subfamily Triatominae, individuals of the same species have stridulatory grooves with different inter-ridge distances, though the frequency spectra and repetition rates are similar.

A tymbal is formed by abdominal tergal plates fused together and which vibrate over a hollow chamber within the abdomen. The tymbal is activated by muscular contractions and produces body vibrations that are low frequency. Tymbals have been found in Piesmatidae, Pentatomidae, Acanthosomatidae, Cydnidae, Lygaeidae, Coreidae and possibly Reduviidae, and similar vibration-producing mechanisms have been found in Plataspidae and Rhopalidae. Differences exist about precise abdominal parts and muscle contraction mechanisms among the tymbals of different families. For example, the description of the *N. viridula* tymbal follows: The first and second abdominal tergites are fused into a forward-backward movable tymbal-like plate that is loosely fixed, anterior and posterior, to the thorax and to the third abdominal tergum, by a chitinous membrane, and more firmly, laterally, to the pleurites. Longitudinal and lateral compressor muscles contract synchronously and in phase with these vibratory waves.

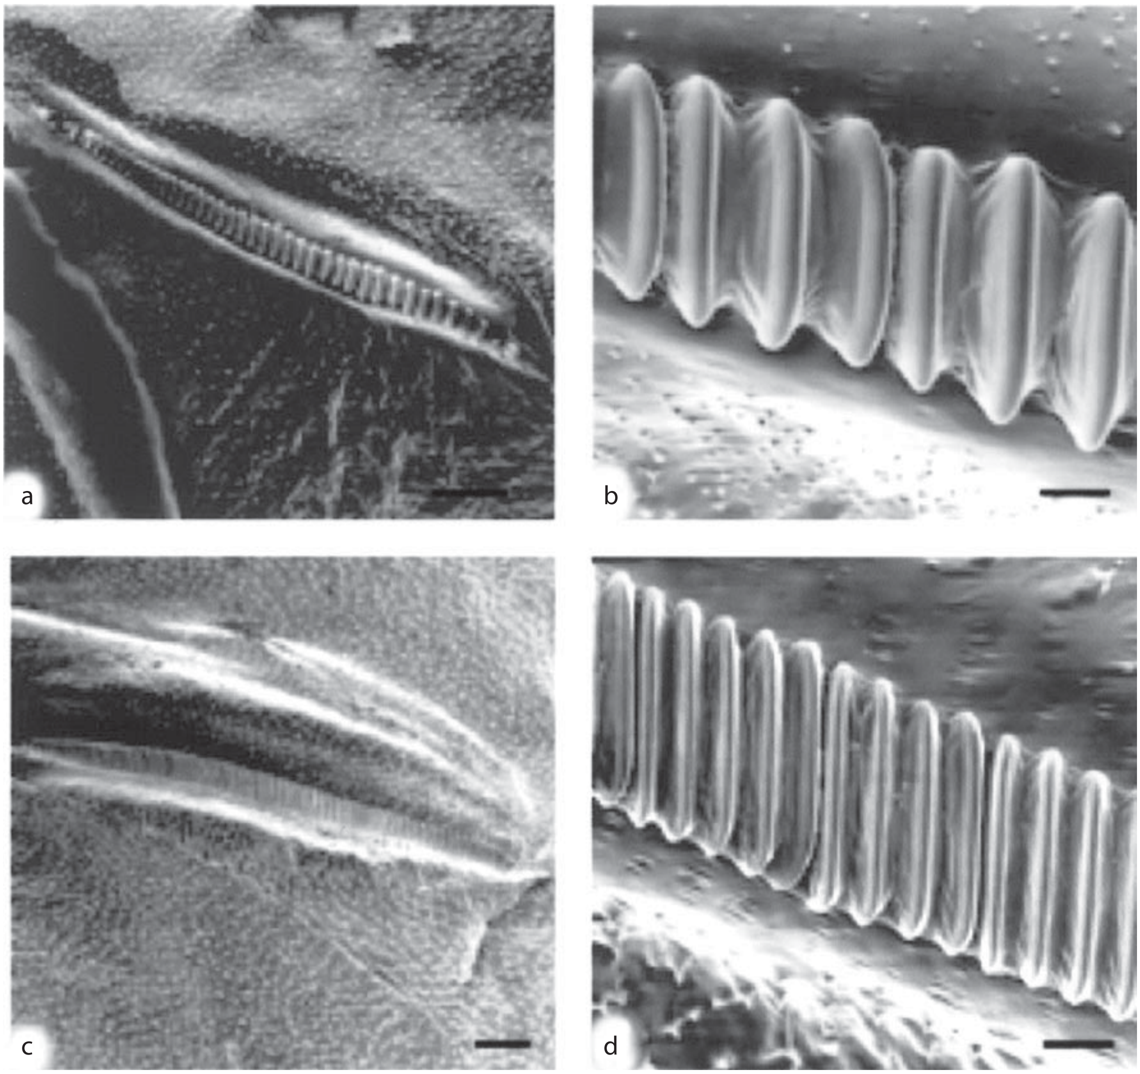
All Heteroptera species investigated so far emit low frequency narrow-band signals by body vibration, and/or broadband signals produced by stridulation. For example, in Cydnidae and Pentatomidae, vibratory mechanisms produce a low frequency vibration (around 100 Hz), and the stridulatory vibration extends up to 10 kHz.

Reception of Vibrational Signals and Songs

Although sound production is found quite widely in Heteroptera, it is not common to find structures specialized for sound reception. Sound reception in Heteroptera is possible due to the presence of either scolopophorous organs or tympanal organs.

Scolopophorous organs are mechanoceptors, and they occur widely in insects. They are composed of sensory sensilla (scolopodia), which may be arranged in groups, and are distally attached to a membrane in the body wall or to the body wall itself. Scolopophorous organs may be located in antennae (Johnston's organ), legs (subgenual organ, joint chordotonal organ), thoracic pleura, or abdominal terga.

Legs are the site of sensory organs that detect vibratory signals with highest sensitivity. For example, at the dorsal side of each leg of *N. viridula* there are four scolopodial organs: femoral, tibial, tarsopretarsal and subgenual organs. The receptor neurons may be low frequency (most sensitive between 50 and 100 Hz) or high frequency sensitive (there are two types: middle frequency neurons being sensitive around 200 Hz, and higher frequency



Acoustical Communication in Heteroptera (Hemiptera: Heteroptera), Figure 9 Interspecific differences in the stridulatory devices found in females of the burrower bugs *Scaptocoris castanea* and *S. carvalhoi* (Hemiptera: Cydnidae). Images a and b are *S. castanea*; images c and d are *S. carvalhoi*. Images a and c show the stridulitrum in the postcubital vein of the hind wings (scale bar = 100 μ); images b and d show the central section of the stridulitrum, showing details of the teeth (scale bar = 10 μ) (adapted from Čokl et al (2006) Physiol Entomol 31:371–381).

neurons sensitive around 700–1000 Hz). Also, the Johnston's organ of *N. viridula* has several vibratory sensitive organs which respond in the frequency range between 30 and 100 Hz. When standing on its host plant, the male of *N. viridula*, by different combinations of legs and antennae, may compare the vibratory signals on two branches of the host plant, and choose the best one in order to locate the singing female. The most probable mechanism underlying resolution of direction by vibratory cues (vibratory directionality) may be time-of-arrival differences (perception of vibratory signals by two different receptors in the insect). For example, when legs of the receptor bug are separated by 2 cm, a time-of-arrival difference between 0.125 and 0.250 ms is created, very close to that found in scorpions, where vibrational directionality is well known. Reduviidae also receive vibratory signals via legs and antennae. Fewer data are available on leg vibratory receptor organs in other land bug species. Among land bugs, no sensory organs for airborne sound have been found.

Tympanal organs have been found in the mesothorax of the Corixidae, and are in contact with the physical gill air bubble. They are able to catch airborne sounds, and to respond to stridulation frequencies produced by conspecific bugs.

Transmission of Vibratory Signals and Songs

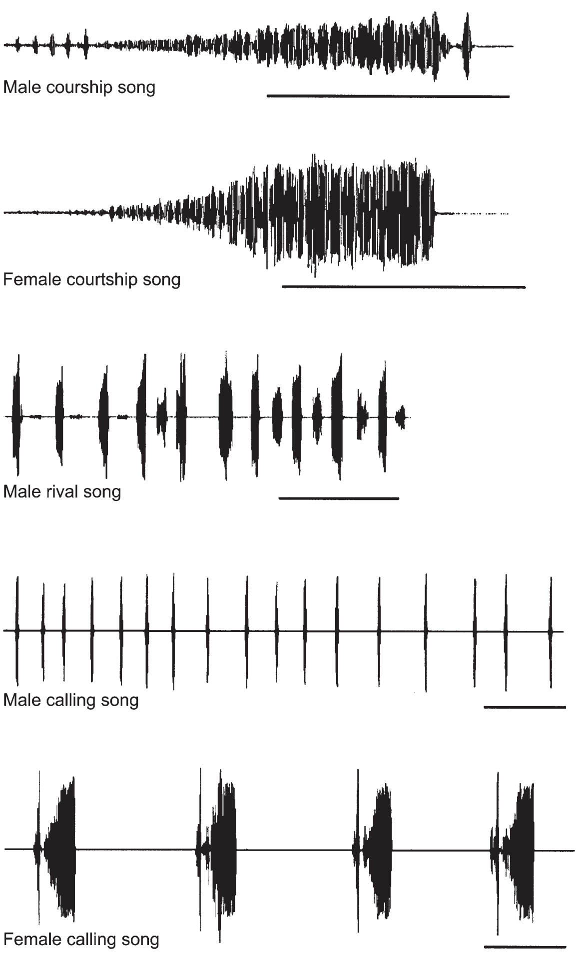
Independent of their mode of production, vibrational signals may be transmitted by the substrate (substrate-borne vibrations) or by the air (airborne vibrations). The signals may travel a short or long distance, or travel at a low or high speed. Low-frequency components are more suitable for longer-range communication through plants. Low frequency signals travel longer distances, but slowly; high frequency signals travel shorter distances, but quickly. Long-range vibratory songs are associated with pre-mating calling and vibrational orientation, and close-range vibratory songs are associated with courting rivalry and repelling.

Substrate-borne vibrations are less costly to the emitter. Also, substrate-borne vibrations are more far-reaching signals for intraspecific communication and not easily perceived by a potential predator or parasitoid. Usual substrates to transmit vibrational signals are plants or soil.

The characteristics of plants as transmission media for insect-produced vibrations have been described, and in many respects they determine signal production and the mode of reception. Depending on the physical properties of the host plant, the vibratory signals are transmitted effectively or not. Vibrations can be transmitted all along the stem, but the physical properties of a plant (e.g., elasticity, water content) affect resonance of insect vibrations. For transmission through plants, insects commonly emit broadbanded-mixed stridulatory and vibratory signals. Higher-frequency signals produced by stridulation are less relevant for long-distance communication through plants. However, narrow-band and low frequency songs are efficient in long-distance communication when well tuned to the resonant spectra of their host plants. The vibrational pulse reflects when attaining both the root area and top of the plant, and reflected waves travel up and down the stem several times. Reflections change the patterns of the input signal. Abiotic factors (temperature, rain, wind) may significantly modify plant resonance, masking insect vibratory signals and thus the effectiveness of the signal. Plant-borne vibrations seem to be important in the success of group-living, herbivorous insects for locating and remaining in a group of conspecifics, for locating food resources, and to avoid predation. Also, small insects that are not able to emit airborne sounds efficiently at low frequencies in many cases communicate with vibratory signals transmitted through plants.

In the stink bug *Nezara viridula* (Pentatomidae) (Figs. 10 and 11), a species which has become a model for all Pentatomorpha in relationship to acoustical communication, its vibratory signals were recorded and described first as airborne sound. However, further investigations showed that their most important mode of transmission is as substrate-borne vibrations. In *N. viridula*, a male could perceive a female calling in a *Cyperus* stem 2 m away from him, mechanically coupled only by roots and the surrounding earth. Below the leg of the singing bug, the intensity of signals was about 4 mm s^{-1}. On the bottom of the same stem (a distance of 80 cm) it decreased to around 3 mm s^{-1}, and at the place of the receiving bug, 200 cm away, it was approximately 0.5 mm s^{-1}.

When transmitted through the soil, signals travel a shorter distance and are more attenuated than when transmitted through a plant stem. For example, in *Scaptocoris* species (Cydnidae) the velocity of soil transmitted signals varied between 1.5 and 12.9 ms^{-1} at a distance of 0.5 cm.



Acoustical Communication in Heteroptera (Hemiptera: Heteroptera), Figure 10 Oscillograms of songs emitted by males and females of the southern green stink bug, *Nezara viridula* (Pentatomidae) (adapted from Čokl, Virant-Doberlet (2003) Annu Rev Entomol 48: 29–50).

Acoustic Characteristics of Vibrational Signals

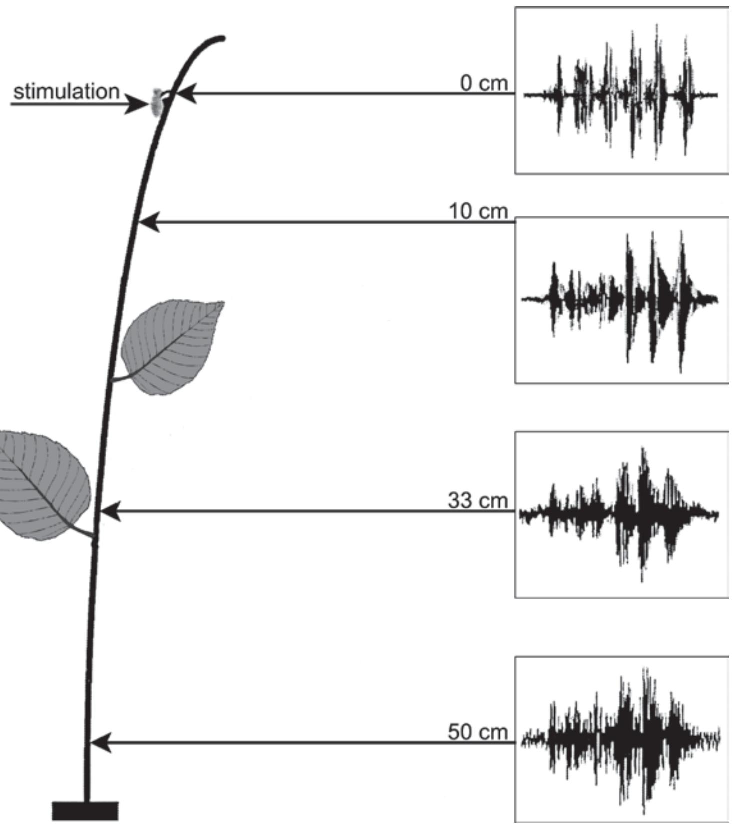
A vibrational signal may be characterized by its temporal (pulse train duration, repetition times, inter-pulse intervals) (Fig. 12) and spectral characteristics (dominant frequency). All of these characteristics may be measured by the receptor insect, who may modify its behavior in response to the message. The dominant frequency of signals produced by the vibratory mechanism lies between 50 and 200 Hz in most Heteroptera. Between species, songs differ in their time structure and amplitude modulation of their units. On the other hand, spectrally and temporally different pulse trains trigger the same male behavior in *N. viridula*.

In *Rhodnius prolixus* (Reduviidae), the male-deterring call has a main carrier frequency of about 1500 Hz, and the disturbance stridulation has a main carrier frequency of about 2200 Hz. In *Rhinocoris iracundus* (Reduviidae), low-frequency components of carrier frequency below 200 Hz are exchanged with frequency-modulated stridulatory components whose dominant frequency lies between 1 and 2 kHz. In *Triatoma infestans* (Reduviidae), distress songs have a peak of frequency between 700 and 800 Hz, although in other reduviids the carrier frequency may reach about 2000 Hz.

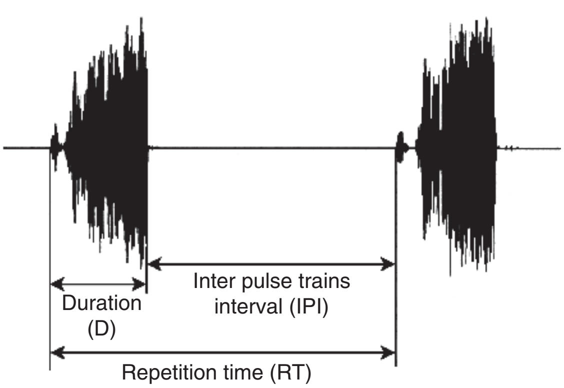
In *N. viridula*, dominant frequencies between 80 and 150 Hz were found in songs either as airborne sounds, or substrate or body vibrations. Body vibrations are around 100 Hz, and lie close to the range of best frequency sensitivity of low frequency receptor cells.

Specificity and Variability of Vibratory Signals

Sounds, especially those involved in the reproductive process (attraction, courtship, copulation),



Acoustical Communication in Heteroptera (Hemiptera: Heteroptera), Figure 11 **Laser vibrometer recordings taken from a plant fed upon by *Nezara viridula* showing the pattern of recordings at various distances (in cm) from the point of stimulation (adapted from Miklas et al (2001) J Insect Behav 14: 313–332).**



Acoustical Communication in Heteroptera (Hemiptera: Heteroptera), Figure 12 **Temporal parameters of a vibratory signal (adapted from Miklas et al (2003) Behav Process 61: 131–142).**

can be very complex and highly species-specific, and may be used as taxonomic characters of land bugs. In contrast, signals are much less specific when they provide information about enemies, rival mates, or serve as distress (disturbance or alarm) signals.

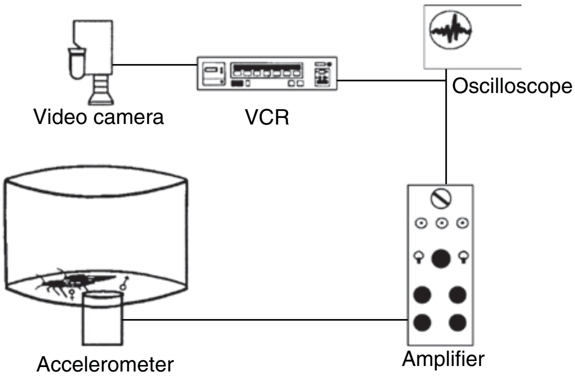
Females of *N. viridula* sing to trigger the male approach, and to evoke emission of the male courtship song. Females coming from populations of different geographic origin emit different calling songs, which can be differentiated by males. Females of *N. viridula* may emit a song that rejects copulatory attempts of males and stops their courting, and this is also known in the reduviid *Rhodnius prolixus*. The courtship songs of both males and females in different populations are not markedly different, but the calling songs may differ in some features and may be the source of reproductive isolation among populations. *Nezara viridula* produces four different species and sex-specific songs, and two of them play a vital role in mate location. There is song variability within populations (inter-individual variability). To assess those differences, the temporal song (pulse train duration, repetition times, inter-pulse intervals) and spectral song characteristics (dominant frequency) may be measured. Males usually show a preference for the females of their own population, although they may recognize females from other populations as potential partners.

In *Tritoma infestans*, stridulation songs differ in their syllable durations, repetition rate and main carrier frequency, depending on the song function. Differences come from rubbing their rostrum (scraper) at different speeds on the prosternal file. Also in *Rhodnius prolixus*, the different frequency between deterrent and disturbing signals can be explained on the basis of a different rubbing velocity by the proboscis against the prosternal stridulatory organ (Fig. 13).

In *Scaptocoris carvalhoi* and *S. castanea* (Cydnidae), two sympatric burrower bugs, high individual variation of the dominant frequency was observed in both male and female emissions (Fig. 14).

Vibratory Signaling in the Families of Heteroptera

Vibratory signaling has been reported in several Dipsocoromorpha and Leptodomorpha, but has been better studied in the following families: Veliidae (Gerromorpha), Nepidae, Corixidae, Notonectidae (Nepomorpha), Reduviidae, Miridae, Tingidae, Nabidae (Cimicomorpha), Aradidae, Acanthosomatidae, Cydnidae, Pentatomidae, Scutelleridae, Tessaratomidae, Thaumastellidae, Colobathristidae, Lygaeidae, Piesmatidae, Largidae, Alydidae, Coreidae, Rhopalidae (Pentatomorpha) (Figs. 15 and 16). Selected examples follow:



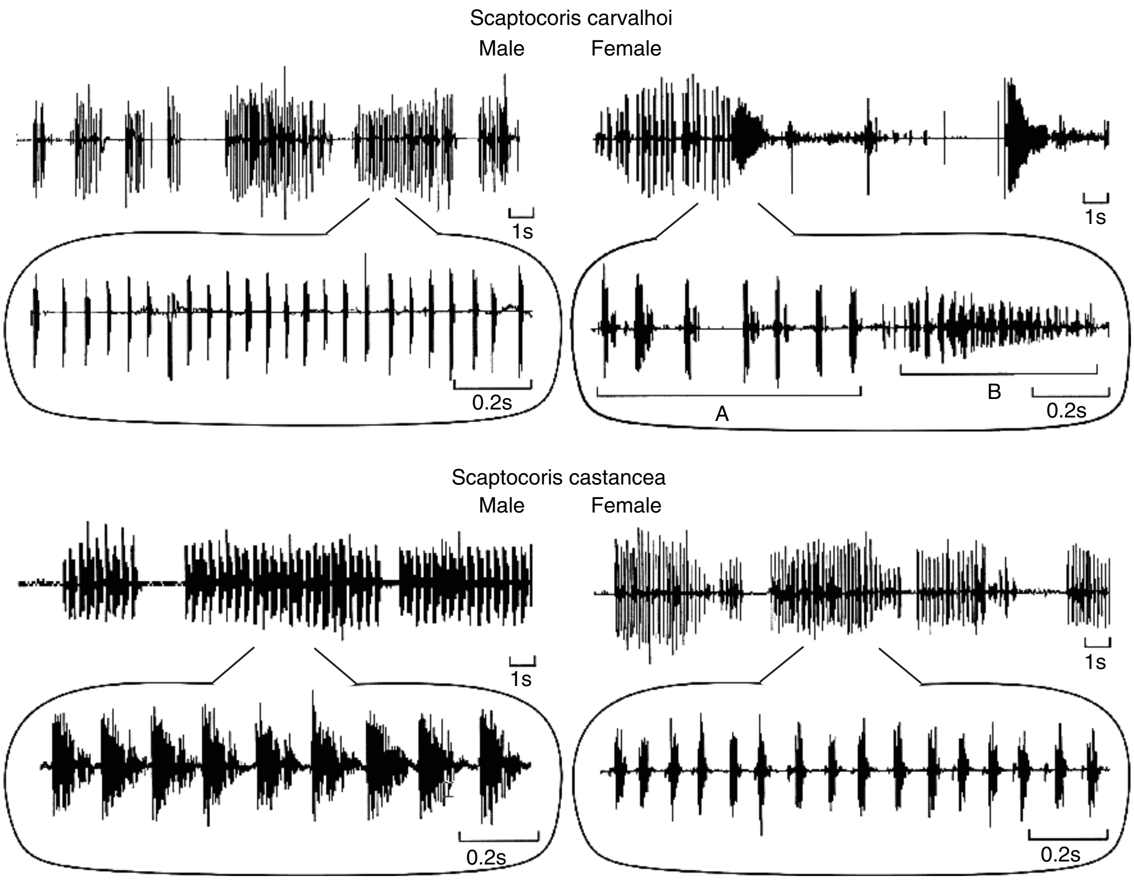
Acoustical Communication in Heteroptera (Hemiptera: Heteroptera), Figure 13 **Experimental setup used to study substrate-borne signals produced by stridulation in *Rhodnius prolixus* (Hemiptera: Reduviidae). The accelerometer generated a signal with voltage proportional to the instantaneous acceleration of the moving object, electrical signals were amplified and monitored by an oscilloscope, then this information was stored in the sound track of a videotape. Also, the behavior of the bugs was simultaneously videotaped (adapted from Manrique, Schilman (2000) Acta Trop 77:271–278).**

Corixidae

In Corixidae, males or both sexes use species-specific sound for mate attraction and in courtship. The sounds are produced by stridulation, i.e., rubbing together specially modified parts of the body, or the partner's body.

Notonectidae

In Notonectidae, males produce species-specific courtship sounds by rubbing roughened parts of their front tibiae and femora against a special stridulatory region at the base of the rostrum (Fig. 17). In genus *Buenoa*, the sound can be heard at a distance of several meters. While next to the female, but before clasping her, the sound pattern can change.

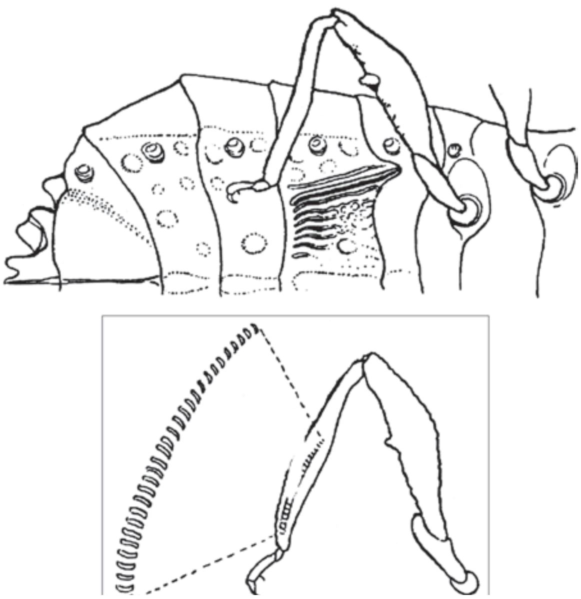


Acoustical Communication in Heteroptera (Hemiptera: Heteroptera), Figure 14 Vibratory emissions of male and female burrower bugs *Scaptocoris carvalhoi* (above) and *S. castanea* (below) (Hemiptera: Cydnidae). A and B designate the two types of female song found in *S. carvalhoi*. Time scales are marked below oscillograms (adapted from Čokl et al. (2006) Physiol Entomol 31:371–381).

Reduviidae

Distress (disturbance or alarm) signals in Reduviidae may be produced either as nymphs or adults (males and/or females). In *Panstrongylus rufotuberculatus* (Reduviidae), stridulation occurs only under conditions of extreme provocation. Its sound is audible by the human ear, which is unusual among stridulating Triatominae, and is similar to the sound of sandpaper scraping wood. The tip of the rostrum is rubbed along the transversely ridged prosternal groove with an anterior-posterior movement; the return stroke (posterior-anterior) is silent. Stridulation lasts for about 5 min, although the insect remains immobile when held for a longer time. In a silent environment, the sound is audible at about 1 m away. A disturbance call has been described in the following triatomine species: *Dipetalogaster maxima*, *Triatoma infestans*, *T. guasayana*, *T. sordida*, *Panstrongylus megistus* and *Rhodnius prolixus*.

In the spined assassin bug, *Sinea diadema*, agonistic interactions between adult females may be resolved by stridulation in 33% of the cases. Stridulating individuals retreated more often than their non-stridulating opponents, indicating that stridulation may be a startle mechanism employed by temporarily disadvantaged individuals to escape from encounters. Together with other signs, stridulations provide information on the identity and relative fitness of the opponent.

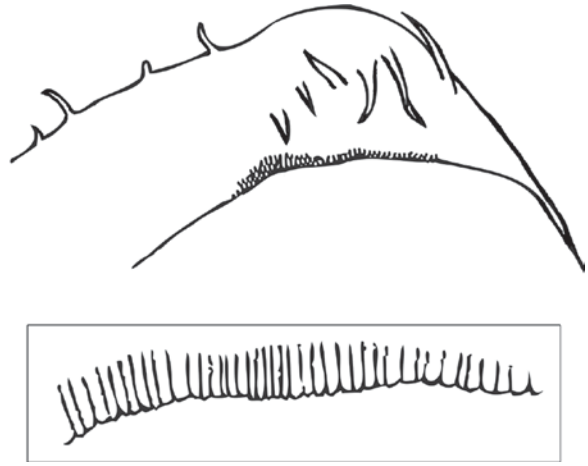


Acoustical Communication in Heteroptera (Hemiptera: Heteroptera), Figure 15 ***Artabanus lativentris*** **(Hemiptera: Aradidae): (above) ventral view of abdomen, with file (stridulitrum), (below) hind leg with detail of scraper (plectrum) in the interior surface of the hind tibia (adapted from Schuh and Slater 1995 True bugs of the world (Hemiptera-Heteroptera): classification and natural history. Cornell University Press, Ithaca, NY, 335 pp).**

The acoustic repertoire of the ambush bug, *Phymata crassipes*, is quite large and may be displayed by females, males or nymphs. Its vibrational songs may be emitted in response to, and alternating with, calls from conspecifics, or even human speech or whistle. Sound emission is related to disturbance, interaction with other males and females, or courtship. Signals are produced by locomotory, stridulatory and/or vibratory mechanisms. Airborne signals directly or indirectly stimulate vibrational receptors. Bugs within a group respond to each other only via substrate, even in close proximity.

Miridae

Although a stridulatory device has been described in several tribes and subfamilies, the functions of acoustical communication in Miridae are still unknown.



Acoustical Communication in Heteroptera (Hemiptera: Heteroptera), Figure 16 ***Phyllomorpha laciniata*** **(Hemiptera: Coreidae): (above) dorsal view of pronotum with scraper (plectrum) at its margin, (below) detail of spines of scraper (adapted from Moulet 1995 Faune de France 81).**

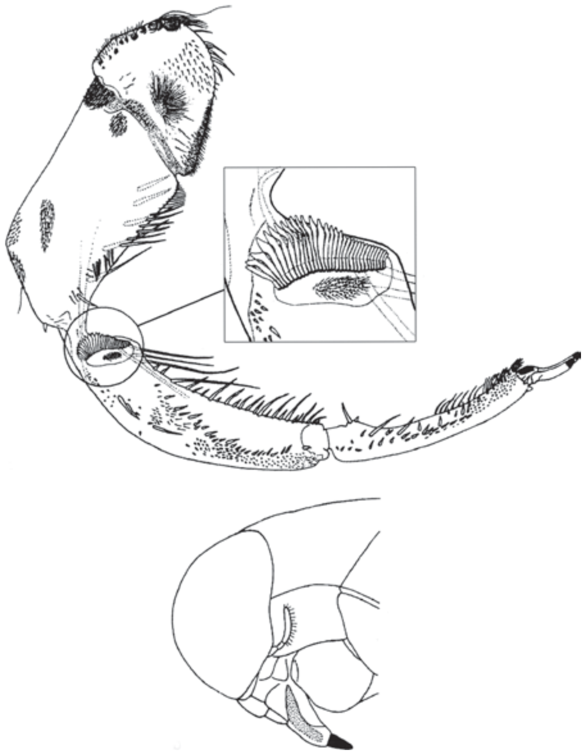
Tingidae

In the tingid *Corythuca hewitti*, vibrational signaling during group movements may occur as groups of nymphs are attended by a female. It has been reported that a disturbance of the leaf where *C. hewitti* aggregated caused feeding to stop and dispersal by the bugs, with occasional stopping of the bugs to vibrate the abdomen in a vertical plane, a behavior followed by conspecifics.

Cydnidae

In cydnids, the low species and sex specificity of pure stridulatory signals indicates that these vibratory emissions may play a role in disturbance (defensive) behavior, as in *Tritomegas bicolor*. Stridulatory signals are also related to aggregation or some other unspecific behavioral context. Cydnid bugs engage in rival singing and also distress (disturbance or alarm) signals, either as nymphs or adults (males and/or females).

Courtship, acceptance and rivalry songs show higher specificity and in most cases are



Acoustical Communication in Heteroptera (Hemiptera: Heteroptera), Figure 17 **Male *Anisops megalops* (Hemiptera: Notonectidae): (above) foreleg with detail of scraper (plectrum) in the interior surface of the fore-tibia, (below) lateral view of the head with file (stridulitrum) on the labium (adapted from Schuh and Slater 1995 True bugs of the world (Hemiptera-Heteroptera): classification and natural history. Cornell University Press, Ithaca, NY, 335 pp).**

produced by low frequency body vibration and/or by stridulation. *Tritomegas bicolor* produces courtship, mating, and male rivalry calls by stridulation and body vibration. In *Sehirus luctuosus*, the male's courtship call is produced by body vibration, giving a drumming song. Two types of species-specific male courtship songs, produced by stridulatory and vibratory mechanisms, have been described. The first type triggers female response, a species-specific agreement song. The second type stimulates pair formation.

In the group-living species of genus *Scaptocoris*, the absence of low frequency components of the emitted signals and the uniformity of songs indicate that calling and courtship may be mediated by signals of other modalities. The lack of low frequency signals may be explained by the direct contact of the bug with soil, which mechanically prevents free vibration of the abdomen.

Pentatomidae

Pentatomid bugs engage in rival singing. For example, *Nezara viridula* and *Rhapigaster nebulosa* may alternate rival songs until one or both stop singing, and in *P. lituratus*, males perform rival singing. Vibrational directionality has been demonstrated in host or prey searching in the predatory stink bug *Podisus maculiventris*.

The general pattern of singing during pre-mating behavior is similar for all Pentatomoidea. Calling starts with the emission of the female calling song, which triggers males to respond with calling and courtship songs, activates them to walk on the plant, and enables directional movement toward the female. Alternation of male and female songs may result in more or less complex duets, as is the case in *N. viridula*. *Nezara viridula* vibrates its body as part of intersex communications (courtship, directional cue for locating the mate, mate recognition), which implies that substrate-borne signals are highly species-specific. The female song causes the male to walk, to respond with the calling and courtship songs, and to approach the source of the song with characteristic search behavior. In contrast, females show no reaction to vibratory stimulation and no vibrational directionality.

Acoustic Aposematism (Clicking) by Caterpillars

Adult Lepidoptera are well known to perceive sound, such as the ultrasonic cries of insectivorous bats. Some even produce sounds that are used for social communication. Less well known is the sound production and reception of larvae. Some caterpillars employ vibrational signals with ants (e.g., Lycaenidae and Riodinidae), communicate about space with conspecifics (e.g., Gracillariidae), or detect insect predators or parasitoids (e.g., Noctuoidea and Gracillariidae). However, "clicking" sounds are an audible sound produced by caterpillars of silk moth (Saturniidae) and hawk moth (Sphingidae). This noise has also been described as "squeaking" or "crackling," and originates with the mandibles. Defensive sounds are usually categorized as startle or warning behaviors; startle sounds warn a potential predator, causing momentary hesitation and escape of the potential prey, whereas warning sounds alert a potential predator that it is inadvisable to attack. Associated with the clicking sound is regurgitation behavior, and both actions follow disturbance of the larva. Regurgitant usually is adverse to predators, and is a widespread defensive behavior among insects. Thus, clicking is thought to warn potential predators of an unpleasant experience if predation is attempted, but it is also possible that clicks function as startle sounds, allowing escape. This latter explanation seems unlikely, however, as caterpillars usually move very slowly, so escape is not very likely.

Acoustic Communication in Insects

ALLEN SANBORN
Barry University, Miami Shores, FL, USA

Sound is used by a wide variety of insects for diverse purposes. It is difficult to evolve an acoustic communication system. There must be modifications to produce sound, transmit the sound in the environment and modify the sound to specific biological purposes, as well as the evolution of structures that will receive and decipher the signals. Arthropods are one of only two major groups of animals (along with the vertebrates) that have evolved acoustic communication and insects are the primary group of arthropods to exhibit acoustic behavior. At least ten orders of insects possess species that produce acoustic signals.

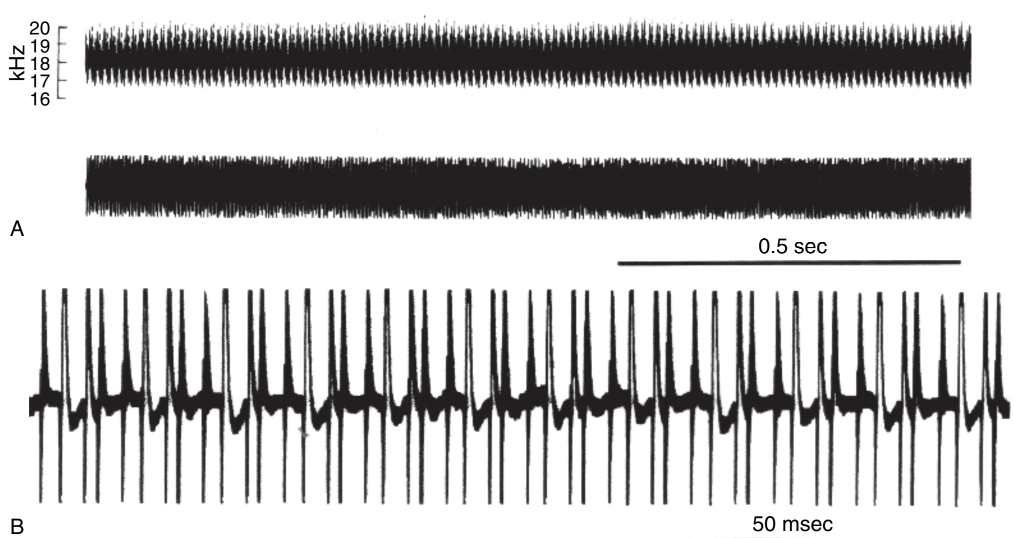
Sound

Sound is generated by causing the repeated compression and rarefaction of an elastic medium. The waves of compression produced will then travel through the medium to the receptor or target. The medium can be air, water or a substrate – so sound also encompasses vibrations. As the sound energy travels through the environment, it is modified by various interactions with the components of that environment. In addition, sound waves are reflected as they move through any environment. This bending of sound waves can initiate interactions among the waves. The signal begins to deteriorate as a result of these wave interactions and with the variations in the signal initiated due to temperature and humidity. Acoustic energy is also lost as it is absorbed by structures in the environment and as a result of spherical spreading from the sound source. The loss of signal integrity due to these environmental interactions is termed the excess attenuation of the signal. The amount of excess attenuation varies with the habitat and the original signal properties.

To complicate matters, the small size of insects requires that they use high frequencies (Fig. 18) to transfer energy efficiently to the signal. This will limit the range of a given signal because higher frequencies attenuate more rapidly in the environment. To use lower frequencies, insects must modify their bodies or behaviors to increase the efficiency of sound production. For example, tree crickets (Gryllidae) create a baffle by inserting their body in a leaf to decrease the acoustic short circuiting of a small dipole sound source, mole crickets (Gryllotalpidae) dig burrows which act as loudspeakers that amplify and direct their calls skyward, and the hollow abdomen of male cicadas (Cicadidae) acts as a resonating structure to amplify the acoustic signals produced by the tymbals.

The sound producing systems of insects are generally vibrating structures. These structures are necessary because muscles cannot contract rapidly enough to produce high frequency sounds. The sound generating structures vibrate multiple times for each muscle contraction, so the sound producing systems act as frequency multipliers. Once the vibrations are initiated, the sound can be modified by attached resonant structures.

There are many different schemes that can be employed to describe insect calls. The variety of sound production mechanisms has led to a variety of terminologies. No one terminology has been successful in describing the different sound production mechanisms or phylogenetic relationships of insects. When sounds are recorded and analyzed in any acoustic work, each analysis of acoustic signals in



Acoustic Communication in Insects, Figure 18 **Acoustic signal produced by the cicada *Beameria venosa* (Uhler). (a) Sonogram of calling song illustrating energy distribution of the call. Middle trace is an oscillogram illustrating the temporal pattern of the call. (b) Expanded oscillogram to show individual sound pulses within the call.**

insects should provide a detailed description of the terminology used to describe the signals, and illustration of the terminology on any oscillogram or sonogram in the work.

Sound Production

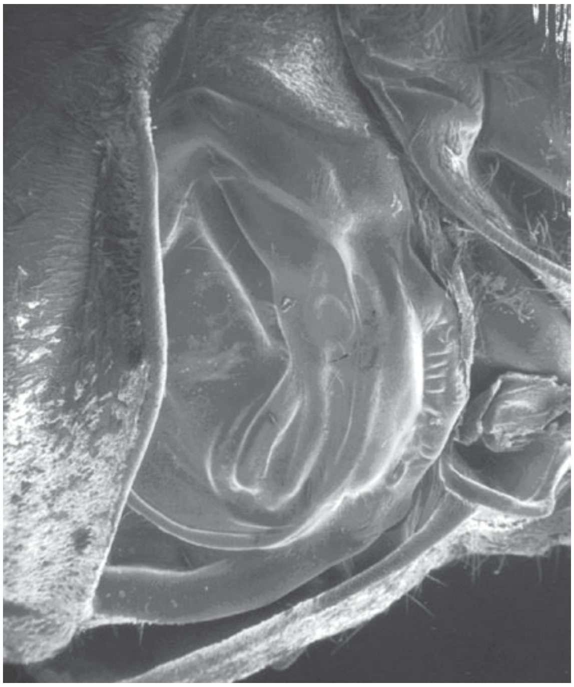
There are several different types of sound production mechanisms that have evolved in insects. The relatively low muscle contraction frequency means that additional structures had to evolve in order to produce the high frequency sounds that small body size will require to generate acoustic signals efficiently.

The primary mechanism used by insects to produce sound is a stridulatory apparatus. The chitinous exoskeleton and jointed appendages of insects are preadapted for modification into stridulatory apparati. Each stridulatory apparatus is composed of a file and plectrum or scraper. The file is generally a row of small cuticular teeth that is rubbed against a ridge or blade (the plectrum) on some other body part (Fig. 19). The teeth are bent as they catch on the plectrum and pop forward as they release from the plectrum. The release causes the teeth to vibrate alternately compressing and expanding air molecules producing sound. In general, these vibrations will occur in a single plane, resulting in a dipole being formed that produces an asymmetrical sound field at close range. The joints and exoskeleton of insects have permitted stridulatory apparati to evolve in many locations on the body. There are file and scrapers found between antennal segments (Phasmatodea), separate mouthparts (Orthoptera), head and thorax (Coleoptera), abdominal segments (Hymenoptera), wings and thorax (Lepidoptera, Hemiptera), body parts and legs (Hemiptera, Orthoptera), legs and wings (Orthoptera, Lepidoptera, Coleoptera), legs and legs (Thysanoptera, Hemiptera), between wings (Orthoptera), and between segments on the genitalia (Lepidoptera, Hemiptera). A tymbal organ is a specialized sound production organ. It is a ribbed, chitinous membrane attached to a tymbal

Acoustic Communication in Insects, Figure 19 **Stridulatory apparatus of the cicada *Tettigades undata* Torres. The file (illustrated) is located on the mesothorax in this group of cicadas. The plectrum is located on the tegmina. Sound pulses are produced as the tegmina is rubbed over the series of mesothoracic ridges.**

muscle (Fig. 20). The tymbal buckles as the tymbal muscle contracts. Sound pulses are produced when the tymbal buckles, when individual ribs buckle and potentially when the tymbal returns to its relaxed position. The unbuckling of the tymbal is assisted by the resilin within the tymbal. The resonant frequency of the tymbal determines the frequency of the sound pulses produced. Additional structures such as the opercula, tymbal covers, various muscles and the abdominal air sacs can modify the sound produced. The abdominal air sacs can become rather large as in the bladder cicada *Cystosoma saundersii* Westwood whose abdomen is so large, to resonate at a low frequency, that the male has difficulty flying. The tymbal is a common organ in the Hemiptera and acts as the ultrasonic pulse generator in the Lepidoptera.

Percussion is another mechanism of sound production used by insects. Crepitation, a clicking sound produced by the wings, is another percussion mechanism in insects. The wings are clapped together or banged on the substrate to produce a sound pulse in some Hemiptera. It is relatively rare for airborne signals which are generally produced as a by-product of flight. The wings may strike each other or the legs



Acoustic Communication in Insects, Figure 20
Tymbal organ of the cicada *Beameria venosa* (Uhler). The internally attached tymbal muscle buckles the tymbal to produce a sound pulse.

during flight-producing sound pulses as in the acridid grasshoppers (Orthoptera). However, specialized percussive sound production systems have evolved. A castanet is found on the costal margin of the tegmina in some moths (Lepidoptera) which produces a pure tone when struck. The acridid grasshopper *Paratylotropidia brunneri* Scudder can snap their mandibles together to generate sound. Percussion has been observed in Hemiptera, Isoptera, Plecoptera, Lepidoptera, and Orthoptera.

Tremulation is the vibration of unspecialized body parts to generate sound. The abdomen is often moved dorso-ventrally or laterally to send vibrations through the legs to the substrate. This mechanism has been well studied in the lacewings (Neuroptera). Wing vibrations can also be used to send information over short distances. This type of signal is produced by members of the Diptera (flies and mosquitoes) and Hymenoptera.

The expulsion of tracheal air is the final and relatively rare mechanism of insect sound production in insects. This method of sound production has been described in a number of insects, most notably the Madagascan hissing cockroach (*Gromphadorhina portentosa* [Schaum]), the Death's Head hawk moth (*Acherontia atropos* [L.]) and some African Sphingids (Lepidoptera).

In addition to the airborne signals produced by acoustic insects, it has now been shown that vibrational signals are also produced by sending information through the substrate. These vibrational signals are primarily produced by tremulation but also can be important in deciphering an airborne signal, particularly at close range to the sound source. Vibrational signals have been identified in members of the Neuroptera, Diptera, Hemiptera, Plecoptera, Coleoptera, Orthoptera, Mecoptera, Raphidioptera, Lepidoptera and Hymenoptera.

Sound Reception

A receptor for acoustic signals is necessary for a communication channel to exist. Because sound is produced by changing air pressure, a modified mechanoreceptor is needed to sense the acoustic information. The receptors can be classified as either a pressure detector or a particle detector. Pressure detectors are membranes that bend when pressure is unequal on the two sides of the detector. Particle detectors are long structures that move when impacted by many particles moving in the same direction. The movement of the particle detector alternately stretches and compresses sensory cells at the base of the organ.

The primary type of pressure receptor organ is a tympanum, which has evolved independently in at least eight orders of insects. Tympana are generally a thin membrane system stretched over a closed cavity. The tympanum bends away from the side of higher pressure setting up oscillations as the sound waves strike the membrane. Each tympanum has a resonant frequency based on its thickness, size and shape. The resonant frequency is generally tuned to the carrier frequencies of the communication channel to increase the efficiency of information transfer.

The tympana are associated with other mechanoreceptor organs to transduce the signal for the nervous system. As the tympana oscillate, vibrations are sent to various types of receptors, generally a specialized chordotonal organ called a scolopidial organ, which act as the input site to the central nervous system. There can be elaborate structures associated with the tympana to transduce energy into the central nervous systems such as the crista acoustica of the crickets and katydids (Orthoptera) and Müller's organ of locusts (Orthoptera), which provides frequency discriminating abilities. These pressure receptors are generally found in pairs, one on each side of the body. This provides an animal with a means to determine the direction from which the sound originated.

The sensory structures for vibrational signals are trichoid sensilla generally found on the feet or cerci or through specialized subgenual and metatarsal organs located in the legs. The subgenual organs are located just distal to the femoral-tibial joint in all six legs to promote detection and directional hearing. They are similar to tympana in that they are chordotonal organs but lack the tympanal membranes and tracheal air sacs of the tympanal system.

Particle receptors are generally specialized structures found in specific groups of insects. For example, female fruit flies (Diptera) sense the courtship signals produced by the male with a special antennal segment called an arista. Male mosquitoes and midges (Diptera) have plumose antennae which detect the species-specific wing beat frequencies produced by females. Johnston's organ is a more complex chordotonal organ found in the antennal pedicel of some Diptera and Hymenoptera which is stimulated by the vibration of the antennal flagella. The long bristles and antennae provide a mechanical advantage to the sensory cells increasing the sensitivity of the receptor.

Functions of Acoustic Signals

Sound has many potential benefits in that the signals can be used day or night, can be modified quickly, and can travel a significant distance even if conditions are not optimal for other signal pathways. However, sound is energetically costly to produce and advertises your position to potential predators as well as potential mates. Even with these potential problems, insects have evolved diverse functions for acoustic signals. Acoustic signals are used for a variety of purposes in insects including sexual signaling, courtship signals, aggression, social recruitment and defense.

A primary function of acoustic signals is as an intraspecific communication channel. Sounds are used to attract mates and to isolate species reproductively. Each species has a characteristic call that can prevent related species from cross mating. The calls produced by individual signalers can be compared by receivers providing the opportunity to select a mate who is producing a call that exhibits specific characteristics. This is particularly true when callers have congregated into localized areas, which is another function of acoustic signaling. Mates may be selected based on the number of calls, the temporal patterns, loudness, etc. The specific characteristics used by a given species are usually chosen based on their ability to demonstrate the viability of the caller. Duets between individuals (either intrasexual or intersexual) can also act as mechanisms to determine mate choice. The signals often change as potential mates approach. These courtship sounds are modified advertisement calls which provide further opportunities for mate assessment. Acoustic signals can also be used intraspecifically to space individuals in the environment, as aggression signals, or as competitive signals to jam the signal of a neighbor. Eusocial insects use acoustic signals as warnings, to recruit a defensive response within the colony, and to recruit foragers to specific food sources.

Predator deterrence is another significant function of acoustic signals. The loud sounds produced by many insects (e.g., cicadas [Hemiptera]), can startle a potential predator giving the insect a chance to escape. The percussion sounds produced by acridid grasshoppers (Orthoptera) are thought to be defensive displays. Sound production has evolved specifically for this anti-predator function in click beetles (Coleoptera). The acoustic systems that use air movement in the Death's Head moth (Lepidoptera), cockroaches (Blattodea) and grasshoppers (Orthoptera) also have anti-predator functions. Moths (Lepidoptera) have evolved a sound production system that is used to jam the ultrasonic signals of the bats that prey upon them. The arctiid moths emit ultrasonic pulses as bats approach which act to confuse the bat as to the exact location of its target. This gives the moth a chance to escape while the bat circles around for another attempt at capturing the insect. These pulses may also have an aposomatic function warning bats of a potentially distasteful meal.

Insects have also evolved specialized acoustic receptors as a means of avoiding predation. Bat-detectors have evolved independently in geometrid, noctuid and hawk moths (Lepidoptera), lacewings, (Neuroptera), praying mantises (Mantodea), beetles (Coleoptera), crickets, locusts and katydids (Orthoptera). These bat-detectors provide an early warning system for the insects that a bat is nearby giving the insect a chance to escape before the bat can sense an insect in the vicinity.

Acrididae

A family of grasshoppers (order Orthoptera). They commonly are known as shorthorned grasshoppers.

► Grasshoppers, Katydids and Crickets

Acriology

The study of grasshoppers, katydids, crickets and their relatives (Orthoptera). This is sometimes expanded to include the orders of insects related to Orthoptera (the Orthopteroids) such as cockroaches (Blattodea), mantids (Mantodea), stick insects (Phasmatodea), earwigs (Dermaptera), and gladiators (Mantophasmatodea).

► Classification
► Grasshoppers, Katydids and Crickets

Acrobat Ants (Hymenoptera: Formicidae)

A term applied to ants of the genus *Crematogaster*. Typically they are small, shiny brown or black, and possess a pedicel with two nodes. They elevate the gaster (tip of the abdomen) over the thorax or head when alarmed. Acrobat ants usually are found in association with wood or trees, including the tunnels of termites and wood boring beetles. They are omnivorous and tend aphids. Their bite can be painful.

► Ants (Hymenoptera: Formicidae)
► Ant-Plant Interactions

Acroceridae

A family of flies (order Diptera). They commonly are known as small-headed flies.

► Flies

Acrolepiidae

A family of moths (order Lepidoptera). They commonly are known as false diamondback moths.
► False Diamondback Moths
► Butterflies and Moths

Acrolophidae

A family of moths (order Lepidoptera). They commonly are known as tube moths.
► Tube Moths
► Butterflies and Moths

Acron

A preoral, unsegmented portion of the body, anterior to the first true body segment. This is also known as the prostomium.

Acrosternite

The narrow marginal region at the anterior edge of a sternite. It appears to be the posterior edge of the preceding sternite, and includes the intersegmental fold. It is found on the abdominal sterna, but absent from the thoracic sterna.

Action Threshold

A level of pest abundance that stimulates action to protect plants from serious damage.
► Economic Injury Level (EIL) and Economic Threshold (ET) Concepts in Pest Management

Active Dispersal

The redistribution of animals caused by their own actions such as flying or walking. The wings of insects allow active dispersal frequently (contrast with passive dispersal).

Active Ingredient (A.I.)

The toxic component of an formulated pesticide. It also is known as the toxicant.

Active Space

The area or space in which the concentration of pheromone (or other behavioral chemical) is at or above threshold concentration necessary to elicit a response from the receiver.

Active Ventilation

Although most gas exchange in insects occurs through diffusion (passive ventilation), in some cases it is inadequate to meet the oxygen needs of insects, particularly large or flying insects. Thus, muscular contractions acting via hydrostatic pressure (pressure on the hemolymph) compress the trachea and air sacs to force carbon dioxide out and allow more rapid intake of air. The exact mechanism varies among taxa, but usually involves contraction of the abdomen, and synchronization of opening and closing of the spiracles.
► Abdominal Pumping

Aculae

Small spines on the wing membrane of Lepidoptera.

Aculeus

This term has several meanings depending on the taxon of insects under consideration. In Hymenoptera, it is synonymous with the sting, an eversible hollow cylindrical structure at the tip of the abdomen used to deliver venom. Though derived from the ovipositor, it is not used to deliver eggs. Among Diptera, this term is sometimes used to refer to a pointed, sclerotized structure associated with the reproductive system in males. Among Lepidoptera, this term refers to hair-like structures on the body and wings of primitive moths; these also are known as microtrichia.

Acute

Of short duration, characterized by sharpness or severity.

Acute Bee Paralysis

A disease of honey bees caused by a picornavirus. Symptoms include trembling, sprawled appendages, and sometimes hairlessness (contrast with chronic bee paralysis).

Aculeate

Pertaining to the stinging Hymenoptera (suborder Aculeata), a group including the bees, ants, and many wasps.

► Wasps, Ants, Bees and Sawflies (Hymenoptera)

Acute Toxicity

The toxicity of a pesticide determined after 24 h. The toxicity resulting from a single dose or exposure.

► Insecticide Toxicity
► Insecticides

Adaptation

This term has at least two meanings: changes in the form or behavior of an organism during its life, and natural selection of organisms in evolutionary time. In entomology, usually the latter definition is intended.

Adaptation of Indigenous Insects to Introduced Crops

WENDELL. L. MORRILL
Montana State University, Bozeman, MT, USA

Host range expansion, or adaptation of insects to new crops, is a world-wide phenomenon that has been observed repeatedly and extensively. It is particularly well documented in North America, where forests and prairies consisting of indigenous plants were planted extensively to introduced cultivated crops only after European emigrants arrived in the eighteenth century. Although many new insect pests were also accidentally introduced from Europe into Canada and the United States, many species of native insects adapted to the new crops and became economically important pests (Table 2).

Prior to widespread introduction of cultivated crops, some species of native insects fed on a wide range of plants and therefore might be expected to accept the new crops readily. Although polyphagous insects such as grasshoppers (Orthoptera: Acrididae), wireworms (Coleoptera: Elateridae), and cutworms (Lepidoptera: Noctuidae) readily accepted corn, wheat and other crops, not all of the species within these groups became agricultural pests. For example, several hundred species of cutworms and grasshoppers are present, but only about a dozen species in each group have achieved regular pest status.

Other native insect species had a narrower host range, and therefore adapted to a more narrow range of crops, or perhaps only a single crop. In the south the boll weevil, *Anthonomus grandis grandis* Boheman (Coleoptera: Curcullionidae), originally fed on native plants in Mexico related to cultivated cotton, and dispersed northward into the new cotton belt of the southeastern United States as cotton was planted extensively. In the north, the wheat stem sawfly, *Cephus cinctus* Norton (Hymenoptera: Cephidae), fed on hollow-stemmed wild grasses, and within 10 years after tillage began in Alberta, wheat was damaged from

Adaptation of Indegenous Insects to introduced Crops, Table 2 **Examples of American insect pests that have adapted to introduced crops**

Insects with wide host ranges	Old host plant	New host plant
Apple maggot, *Rhagoletis pomonella* (Walsh) Diptera: Tephritidae	Hawthorne	Apple
Chinch bug, *Blissus leucopterus leucopterus* Heteroptera: Lygaeidae	Grasses	Corn
Western corn rootworm, *Diabrotica virgifera virgifera* LeConte Coleoptera: Chrysomelidae	Grasses	Corn
Western bean cutworm, *Loxagrotis albicosta* (Smith) Coleoptera: Chrysomelidae	Solanaceous weeds	Corn, beans
Colorado potato beetle, *Leptinotarsa decemlineata* (Say) Coleoptera: Chrysomeliodae	Buffalo burr	Potato
Carrot weevil, *Listronotus oregonensis* (LeConte) Coleoptera: Curculionidae	Umbelliferous weeds	Carrots, etc.
California red scale, *Aonidiella aurantii* (Maskell) Hemiptera: Diaspididae	Shrubs and trees	Citrus
Boll weevil, *Anthonomus grandis* Boheman Coleoptera: Curculionidae	Malvaceous weeds	Cotton
Insects with wide host ranges	**Old host plant**	**New host plant**
Sugar beet wireworm, *Limonius californicus* Coleoptera: Elateridae	Weeds, grasses	Field and vegetable crops
White grubs, *Phyllophaga* spp. Coleoptera: Scarabidae	Weeds, grasses	Field and vegetable crops
False chinch bug, *Nysius raphanus* Howard Hemiptera: Lygaeidae	Weeds, grasses	Field and vegetable crops
Tarnished plant bug, *Lygus lineolaris* (Palisot de Beauvois) Hemiptera: Miridae	Weeds, grasses	Field and vegetable crops
Army cutworm, *Euxoa auxiliaris* (Grote) Lepidoptera: Noctuidae	Weeds, grasses	Field and vegetable crops
Yellow striped armyworm, *Spodoptera ornithogalli* (Guenée) Lepidoptera: Noctuidae	Weeds, grasses	Field and vegetable crops
Redlegged grasshopper, *Melanoplus femurrubrum* (de Geer) Orthoptera: Acrididae	Weeds, grasses	Field and vegetable crops

the Canadian prairie provinces south into Montana and North Dakota. In the eastern United States the apple maggot, *Rhagoletis pomonella* (Walsh) (Diptera: Tep hritidae), expanded its host range to included newly introduced cultivated fruits, especially apples. The Colorado potato beetle, *Leptinotarsa decemlineata* Say (Coleoptera: Chrysomelidae) originally fed on solanaceous weeds in Mexico or the southwestern United States, and quickly spread across the United States on potatoes once it gained access to potato acreage. These are just a few examples of insects accepting new hosts, and the same phenomenon is well documented for important tropical crops such as sugarcane and cacao, and other crops, as they were introduced and cultivated in various locations around the world.

Some of the native insect populations originally occurred at low levels because their host plants were relatively sparse. Large acreage of new monocrop habitats therefore resulted in an abundant food supply, excellent survival, and eventually in pest population outbreaks. Also, the native environments were relatively stable, and supported a wide range of beneficial insects suppressed herbivorous insects. However, soil tillage within the agricultural environments produced highly disturbed systems, and pests with high fecundity were not effectively suppressed by predators and parasitoids.

America's native insects displayed considerable plasticity in acquiring new hosts. This trend has been noted everywhere agriculture is practiced, and we can expect the number of pests to increase with time, and especially with the area planted to each particular crop, as indigenous species adapt to imported host plants or crops are exposed to additional potential pests in new geographic areas. However, species accrual occurs most rapidly soon after plant introduction, and the number of species feeding on a plant (species richness) does not increase indefinitely, leveling off after less than 300 years if there is not an increase in crop acreage.

We can observe insects with both broad and narrow host selection behavior expanding their host range to include introduced crop plants. This is not surprising for generalist species, which feed broadly on many plants, but it is quite interesting when insects with a narrow host range adopt new hosts. In such cases the species with a narrow host range usually are pre-adapted to accept the foreign crops because they feed on plants in the same family as the introduced crop. North America possesses close relatives to nearly all the introduced crops among its indigenous flora, so it is not surprising that insects associated with the native plants would adapt to the introduced crops. The presence of secondary plant metabolites (allelochemicals) such as alkaloids, terpenoids, and cyanogenic glycosides often serves to keep non-adapted insects from feeding extensively on plants, but may serve as chemical cues or stimulants for insects that are adapted. Thus, insects that specialize on cruciferous weeds and crops are attracted to allylisothiocyanate, and insects that feed on cucurbitaceous weeds and crops are attracted to cucurbitacin.

Host selection behavior by insects is not a static situation, nor is it as simple as the single-chemical scenario presented above. It is constantly evolving in response to various biotic characteristics such as herbivory, and even to crop cultural practices. Some natural selection of insect strains may have occurred during the adaptation from native to introduced plants. In the northern Great Plains, wheat matures earlier in the season than wild grasses. Therefore, after a century, adult wheat stem sawflies are now active nearly a month earlier than previously, and now are more effective in utilizing wheat.

Changes in farming practices that have also impacted populations of native insect pests in croplands. Originally, horses were used for farming, and oats were needed for their feed. Later, the horses were replaced by tractors, and the need for oats was reduced. Oats are resistant to wheat stem sawflies, and when oats was eliminated from the cropping system, the vast acreages of wheat resulted in a population explosion of the sawflies. More recently, canola has been included in the Canadian Prairie Provinces, and populations of grass-feeding insects are somewhat disrupted by the presence of a non-host, cruciferous crop. Other water and soil conservation practices such as alternate-year summer fallow, strip cropping, and chemical fallow have affected the prevalence of both pest and beneficial insects.

Beneficial insect populations were also impacted by tillage and cultural practices, and changes in the chemical constituency of crop plants. Parasitoids have complex host searching behavior that begins with finding plant environments in which their hosts could occur. Therefore, it was necessary for the parasitoids to learn that the new crops could be sources of hosts. In the case of the wheat stem sawfly, only two of the known parasitoid species have currently adapted from wild grasses to wheat. Parasitoids may be more favored by one plant cultivar than another, or less favored by a crop than a similar weed. The availability of food for the adult parasitoid or predator, either nectar from blossoms or extra floral nectaries or pollen from blossoms, is often implicated in differential survival of beneficial insects among different plants.

Overall, adaption by herbivorous insects to new host plants is a dynamic and widespread phenomenon. Though sometimes it is difficult to determine whether it is the change in the constituency of the host plant that accounts for insect acceptance, or it is some other factor such as widespread host plant availability that accounts for insect abundance, it is clear that the relationship between insects and plants is not static, resulting in a continuing stream of new pest problems for crop plants.

Adaxial Surface

The upper surface of a leaf (contrast with abaxial surface).

Adeheterothripidae

A family of thrips (order Thysanoptera).

► Thrips

Adelgidae

A family of insects in the order Hemiptera. They sometimes are called pine and spruce aphids.

► Aphids
► Bugs

Adelidae

A family of moths (order Lepidoptera). They commonly are known as long horned fairy moths.

► Long horned Fairy Moths
► Butterflies and Moths

Adephaga

One of four suborders of beetles (Coleoptera), and one of two suborders that contain numerous and important beetles (the other is suborder Polyphaga). It is comprised of about nine families, the principal ones being Carabidae, Gyrinidae, and Dytiscidae. Nearly all groups are predatory, and many are aquatic.
► Beetles (Coleoptera)

Aderidae

A family of beetles (order Coleoptera). They commonly are known as antlike leaf beetles.
► Beetles

Adfrontal Areas

A pair of narrow oblique sclerites on the head of a caterpillar. The adfrontal areas border the front, which normally is triangular, so the adfrontal areas take on the shape of an inverted "V."
► Head of Hexapods

Adelphoparasitism

A type of hyperparasitism occurring in Hymenoptera: Aphelinidae in which the males are parasitoids of females of their own species (the females parasitize Hemiptera).

Adherence

The ability of a material such as a pesticide to stick to a surface.

Adipohemocyte

A type of hemocyte, ovoid in shape and likely secretory in function.
► Hemocytes of Insects: Their Morphology and Function

Adipokinetic Hormone (AKH)

A decapeptide hormone synthesized in neurosecretory cells of the corpora cardiaca and important in the regulation of lipid metabolism, and sometimes carbohydrate or proline metabolism and other physiological functions.

Adipokinetic and Hypertrehalosemic Neurohormones

GERD GÄDE, HEATHER G. MARCO
University of Cape Town, Rondebosch, Republic of South Africa

The adipokinetic hormones and hypertrehalosemic hormones of insects comprise a family of peptide hormones that primarily regulate the levels of energy metabolites, such as trehalose, diacylglycerol and proline that circulate in the hemolymph. These peptide hormones are products of neurosecretory neurons located in the corpora cardiaca, neuroendocrine glands attached to the brain. The structural organization of the insect corpora cardiaca is similar to the hypothalamus-neurohypophysis of the vertebrate endocrine system.

Historical Perspective

The existence of hypertrehalosemic hormones was discovered with the observation that injections of extracts of corpora cardiaca elevated the concentration of trehalose in the hemolymph of cockroaches (hypertrehalosemia). Unlike vertebrates that use glucose as the major blood carbohydrate, the hemolymph of insects generally contains the disaccharide trehalose, an α-1-1-gluco-glucoside, as its major circulating carbohydrate. In addition, the enzyme glycogen phosphorylase in the fat body of cockroaches was demonstrated to be activated when these insects were injected with an extract from the corpora cardiaca. Subsequently, studies in locusts showed that injections of corpora cardiaca extracts elevated hemolymph diacylglycerols, instead of trehalose, and this action was referred to as an adipokinetic or hyperlipemic effect. Injections of locust corpora cardiaca extracts into cockroaches produced the hypertrehalosemic response, and vice versa. Hence, it was likely that the adipokinetic hormone (AKH) of locusts and the hypertrehalosemic hormone (HrTH) of cockroaches were related, or identical, peptides.

The locust adipokinetic hormone was isolated and characterized first. It was obtained from the migratory locust, *Locusta migratoria*, and its primary structure consisted of ten amino acids. It was designated Locmi-AKH-I according to the newest nomenclature for naming insect neurohormones. The amino acid composition and sequence of Locmi-AKH-I had a remarkable similarity to a previously reported red pigment-concentrating hormone (Panbo-RPCH) obtained from the shrimp *Pandalus borealis* and later found in various crustaceans. It was shown that Locmi-AKH-I was also present in the desert locust, *Schistocerca gregaria*.

Subsequently, both *L. migratoria* and *S. gregaria* were shown to contain a second adipokinetic hormone (Locmi-AKH-II and Schgr-AKH-II, respectively) that differed from each other by the amino acids in position 6. The two locust AKH-IIs were octapeptides with sequences similar to those of Locmi-AKH-I and Panbo-RPCH. A third octapeptide AKH (Locmi-AKH-III) was also found in *L. migratoria* and a similar octapeptide (designated Phymo-AKH-III) occurs in pyrgomorphid and pamphagid grasshoppers, but an AKH-III is missing in *S. gregaria*. Subsequently, three research groups ultimately reported, in the same year, the presence of two octapeptides from the corpora cardiaca of the American cockroach, *Periplaneta americana*, that were structurally related to the locust AKHs and the crustacean RPCH. These two peptides were isolated on the basis of myotropic or heartbeat acceleration bioassays and are referred to as cardio acceleratory hormones (Peram-CAH-I and Peram-CAH-II), but they also produced hypertrehalosemia in the cockroach and represent the hypertrehalosemic hormones. These pioneering studies, along with numerous subsequent studies, demonstrated that there are, so far, about forty structurally related, but distinct, peptides with adipokinetic and hypertrehalosemic effects in the insects and one in crustacean (Table 3). The name adipokinetic hormone/red pigment-concentrating hormone (AKH/RPCH) family was coined for this general family of peptides, which likely encompasses the arthropods.

Chemistry of the AKH/RPCH Family

The members of the adipokinetic hormone/red pigment-concentrating hormone family share numerous structural features. They consist either of eight, nine or ten amino acids, depending on the insect species from which they are isolated. They are blocked by pyro-glutamate at the N-terminus and by an amide moiety at the C-terminus. Presumably, blocked termini prevent degradation of the neuropeptides by amino- and carboxypeptidase enzymes while circulating in the hemolymph. Aromatic amino acids, usually phenylalanine and tryptophan, always occupy positions 4 and 8, respectively, but aromatic amino acids can also occupy other positions. The peptides are usually neutral under physiological conditions, but a few have a negatively charged aspartate at position 7. Glycine is always present at position 9 as deduced from cDNA analysis of the precursor. The terminal glycine is converted to the amide moiety on the tryptophan in the octapeptides.

Adipokinetic and Hypertrehalosemic Neurohormones, Table 3 **Representative sequences of adipokinetic/hypertrehalosemic peptides from various insect orders**

Crustacea	Panbo-RPCH	*Pandalus*	pGlu	Leu	Asn	Phe	Ser	Pro	Gly	Trp	NH_2		

[a]Note that the peptide in certain orders is identical. For example: Peram-CAH-I and -II of the Blattodea, Blattidae is also present in Coleoptera (Leptinotarsa); Schgr-AKH-II of Orthoptera, Caelifera is present in Orthoptera, Ensifera and in Hymenoptera (***Xylocopa***, ***Bombus***); Grybi-AKH of Orthoptera, Ensifera is also present in Dermaptera, Neuroptera and Hymenoptera, etc.

[b]***Heliothis*** is revised to ***Helicoverpa.***

Some of the members of this peptide family have additional post-translational modifications besides the blocked termini. For example, two HrTH decapeptides are present in the corpora cardiaca of the stick insect, *Carausius morosus*; one of these decapeptides is glycosylated and has a unique C-glycosylation where the sugar is linked to the C-2 atom of the indole ring of tryptophan. Another unusual modification has been found in an AKH of the protea beetle, *Trichostetha fascicularis*: the corpora cardiaca contain two AKHs, one of which is an octapeptide with a phosphothreonine at position 6.

The relationships between individual AKH and HrTH peptides and insect species are complex. There are no clear rules concerning which peptide occurs in which order of insects. Several species within an order may share the same peptide and have other species-specific sequences, and the same peptide may be present in species of different orders. As described above, the two locust species, *S. gregaria* and *L. migratoria*, share an identical decapeptide (Locmi-AKH-I); each species possesses a second, unique octapeptide (Locmi-AKH-II; Schgr-AKH-II); and *L. migratoria* contains a third octapeptide (Locmi-AKH-III) that does not have a complement in *S. gregaria*. Cockroach species of the families Blattellidae and Blaberidae share a single hypertrehalosemic decapeptide hormone (Bladi-HrTH), whereas cockroaches of the family Blattidae contain two octapeptide hormones (Peram-CAH-I and -II). In addition, there is overlap between orders. Grybi-AKH is present in certain crickets and in species of Neuroptera, Dermaptera and Heteroptera. Peram-CAH-I and -II of the blattid cockroaches are also found in the Colorado potato beetle, *Leptinotarsa decemlineata*, and Peram-CAH-II is shared with the heteropteran bug, *Pyrrhocoris apterus*. Whereas Peram-CAH-I and -II mobilize glycogen from the fat body of the cockroach to increase hemolymph trehalose, the same or similar peptides increase hemolymph proline in beetles to serve as the major flight substrate.

Unlike the complex situation in insects, the crustaceans apparently possess only the single Panbo-RPCH peptide which has a chromatophorotropic effect. Panbo-RPCH has also been found in an insect species, the heteropteran stinkbug, *Nezara viridula*, where it has an adipokinetic effect.

Phylogenetic relationships of the HrTHs have been proposed for the cockroaches based on morphological, behavioral and physiological characters congruent with the distribution of the various structures of the HrTHs within the order.

Physiological Actions

The general physiological action of the adipokinetic and hypertrehalosemic hormones in insects is to elevate the hemolymph metabolites that are used by the muscles and other tissues as a source of energy, regardless of the nature of the metabolites. This is accomplished by stimulating the fat body, which is the hormone's target tissue, to convert its stores of triacylglycerides or glycogen to diacylglycerides or trehalose, respectively, or to synthesize proline. The diacylglycerides, trehalose or proline are released from the fat body to increase their respective levels in the hemolymph. The same peptides that elevate diacylglycerides in locusts elevate trehalose when administered to cockroaches, and vice versa, and the hormones of locusts and cockroaches elevate proline in the Colorado potato beetle. The decision as to whether lipid-, carbohydrate-, or proline-mobilizing pathways are activated is a species-related function of the enzyme composition in the fat body.

Muscular activity for animal locomotion can involve either long-term or short-term events. Long-term activities might entail sustained, non-emergency actions such as migration or persistent searching for food, mates or shelter. Short-term activities might consist of local searching activities but may also require immediate, brief, emergency responses such as evading attack by a predator or defending a breeding territory. Long-term events require a steady supply of energy metabolites, whereas short-term events may be brief but intense, and, if successful, they can be followed by a period of recovery to replenish exhausted metabolites.

The adipokinetic hormones are often involved in prolonged, constant muscular activity such as migration. This is characteristically true for the locusts whose migratory behavior has been described since biblical times. Migration is a sustained flight activity that uses muscular oxidation of fatty acids to produce energy, since fatty acids deliver more energy per mole than carbohydrates. However, carbohydrate serves as the major source of muscular energy during initial flight, and lipid becomes the major source for energy as flight persists and becomes sustained. Based on differing physiological effects, it is speculated that the three AKHs may exert different regulatory actions on metabolite mobilization and use during the different stages of migration. Locmi-AKH-II is likely to be the major carbohydrate-mobilizing hormone that provides trehalose for initial flight; Locmi-AKH-I is the major hormone responsible for fat mobilization during sustained flight and Locmi-AKH-III may be responsible for regulating energy metabolism during rest. Furthermore, during lipid mobilization, AKH performs several distinct but related actions. In the fat body, AKH activates lipase for triacylglyceride degradation; this is achieved by binding of the AKH to a G-protein coupled receptor at the cell membrane, activation of adenylate cyclase resulting in the second messenger cAMP which, in conjunction with Ca^{2+}, is responsible for lipase activation. In the hemolymph, AKH increases the lipid-carrying capacity of lipophorins (proteins) resulting in increased amounts of low-density lipophorin for shuttling lipids from the fat body to the muscles. At the flight muscle level, AKH increases the rate of lipid oxidation. Recent research on a number of terrestrial and aqueous heteropteran bugs that have various feeding patterns (plant sap sucking, predators, obligatory hematophagous), also established a lipid-based activity (flight and/or swimming) metabolism that is regulated by the respective AKHs of these insects.

By contrast, insects such as cockroaches, bees and flies use only carbohydrate (trehalose) as the primary source of energy for muscular activity and locomotion. These species do not migrate and lack the adipokinetic response, but they are faced with emergency situations of predator evasion, and in such cases, the hypertrehalosemic hormone mobilizes trehalose in response to the emergency. However, injections of hypertrehalosemic hormone show that significant elevation of the hemolymph trehalose may take as long as 10–30 min. This delay in elevating hemolymph carbohydrate is too long to significantly assist the insect in evading capture. Furthermore, the open circulatory system of insects does not efficiently direct circulating metabolites to the muscles in the manner of the closed circulatory system of vertebrate animals. Energy metabolites, such as trehalose, must constantly be maintained at high levels in the hemolymph to meet urgent, immediate demands. Hence, the role of the hypertrehalosemic hormone appears to be to replace depleted hemolymph trehalose and maintain it at high levels. Maintenance of high trehalose levels allows the insect to make quick responses to elude capture that may require only seconds, or at most, several minutes to conclude. If the insect is successful at escape, the hormone stimulates the degradation of fat body glycogen to restore the high trehalose levels by activating specifically the enzyme glycogen phosphorylase after the hormone has bound to a G-protein coupled receptor on the membrane of a fat cell and had activated a phospholipase C, resulting in the production of inositol trisphosphate and the release of Ca^{2+} from internal stores (influx of external Ca^{2+} is also activated by HrTH) which sets in motion a cascade of activation of kinases and, finally, glycogen phosphorylase. Removal of the hypertrehalosemic hormone does not affect the ability of such insects to be active for the short term (several minutes), but after exhaustion, lengthens their recovery time.

Tsetse flies and various beetle species fuel their flight metabolism by the partial oxidation of proline and the production of alanine. For continuous flight or replenishment of proline reserves in the fat body a unique system exists in these insects to synthesis proline: the respective AKHs activate a lipase in the fat body and the fatty acids that are liberated from triacylglyerols undergo β-oxidation, and the resulting acetyl CoA units are used in conjunction with alanine to synthesize proline. Alanine, which is derived from the partial oxidation of proline, is re-used for proline synthesis and can be viewed as a shuttle system for the transport of acetyl units.

Although the mobilization of energy for flight and other metabolically intense situations is likely the major function for the adipokinetic and hypertrehalosemic hormones, the hormones exhibit pleiotropic actions. The hypertrehalosemic hormones were isolated originally based on their cardioacceleratory action on the heart. This is a logical action for the hormone since elevated heartbeat rate would facilitate distribution of the energy metabolites throughout the body and assure their ready access to the muscles. In keeping with the stimulatory action of AKH on lipid degradation in locusts, lipid synthesis is inhibited by AKH. Other, less well characterized actions include: inhibition of RNA and protein synthesis related to vitellogenesis in locusts and crickets, and the stimulation in cockroaches of the oxidative capacity of mitochondria during fat body maturation, and of gene expression for a fat body cytochrome P450 related to lipid oxidation. These latter actions by the hormones may be equally important as their effects on mobilization of energy metabolites, but they are poorly elucidated because of insufficient research, and they cannot yet be placed into perspective as to their physiological significance. Other actions in which AKHs seem to be involved are an enhanced activation of the locust immune system and, possibly, in the activation of an antioxidant protection mechanism in potato beetles.

In summary, the adipokinetic-hypertrehalosemic-hyperprolinemic hormones constitute a family of peptides that are adapted to the individual biology of the insect species in which they are found. They display a unique relationship with their target tissue in that the hormone carries the endocrine message to the target tissue (fat body) to mobilize energy stores, but the target tissue determines which metabolic pathways are activated depending on the biology of the species. It is this biology that determines the nature of the muscular activity (prolonged–migration; brief–predator evasion) and its metabolic need for consuming carbohydrates, lipids or proline as a source of energy.

Adjuvants

Chemicals added to insecticides to improve their effectiveness. Examples of adjuvants include toxicity, stability, and adhesion.

► Insecticide Formulations

► Insecticides

Adoption Substance

A secretion presented by a social parasite that induces the host insects to accept the parasites as members of their colony.

► Social Insect Pheromones

Adult

The sexually mature stage of an animal. The adult is usually the winged stage in insects. With rare exceptions, the adult does not molt again.

► Metamorphosis

Adulticide

A pesticide used to kill adult insects. This term often is used to describe products used to kill adult mosquitoes. (contrast with larvicide)

► Insecticides

Adultoid Reproductive

In higher termites, a supplementary reproductive that in indistinguishable morphologically from the reproductive.

Adult Transport

A behavior in which social insects (usually ants) drag or carry their nestmates to a new location. This normally occurs during colony emigration.

Adventitious Veins

In some insects, additional wing veins are present which are neither secondary nor intercalary veins. They usually are the result of the lining up of cross veins.

► Wings of Insects

Adventive

An organism that has arrived in an area from elsewhere. It is not native, and likely arrived as an invader or accidental introduction. It is also known as nonindigenous.

► Invasive Species

Aedeagus

The intromittent (copulatory) organ of the male; the distal portion of the phallus. Sometimes referred to as the penis.

► Abdomen of Hexapods

Aenictopecheidae

A family of bugs (order Hemiptera).

► Bugs

Aeolothripidae

A family of thrips (order Thysanoptera). They commonly are known as broad-winged thrips or banded thrips.

► Thrips

Aepophilidae

A family of bugs (order Hemiptera). The sometimes are called marine bugs.

► Bugs

Aeshnidae

A family of dragonflies (order Odonata). They commonly are known as darners.

► Dragonflies and Damselflies

Aetalionid Treehoppers

Members of the family Aetalionidae (order Hemiptera).

► Bugs

Aerial Photography

In pest management, photographs taken by an airplane or satellite that are used to identify variations within fields/crops to help make management decisions.

Aeropile

The opening in the egg surface (chorion) through which air enters.

Aerosol

The air suspension of liquid or solid particles of small diameter. This is a common formulation for flying insects or for household use where no additional formulation or preparation is desired.

► Insecticides

► Insecticide Formulations

Aesthetic Injury Level

The level of pest abundance above which aesthetic, emotional, or sociological considerations require pest control actions. Economic considerations are not relevant.

► Economic Injury Level (EIL) and Economic Threshold (ET) Concepts in Pest Management

Aesthetic Pest

A pest which, through its presence or actions, is deemed objectionable and in need of elimination even though it causes no economic loss. The presence of some insects in homes or on ornamental plants are examples of aesthetic pests, though in the latter case if they inhibit the ability to market plants then the same insect can be come an economic pest.

► Economic Injury Level (EIL) and Economic Threshold (ET) Concepts in Pest Management

Aestivation

A state of inactivity or curtailment of normal activity during the summer months. Diapause

Aetalionidae

A family of insects in the order Hemiptera. They sometimes are called aetalionid treehoppers.

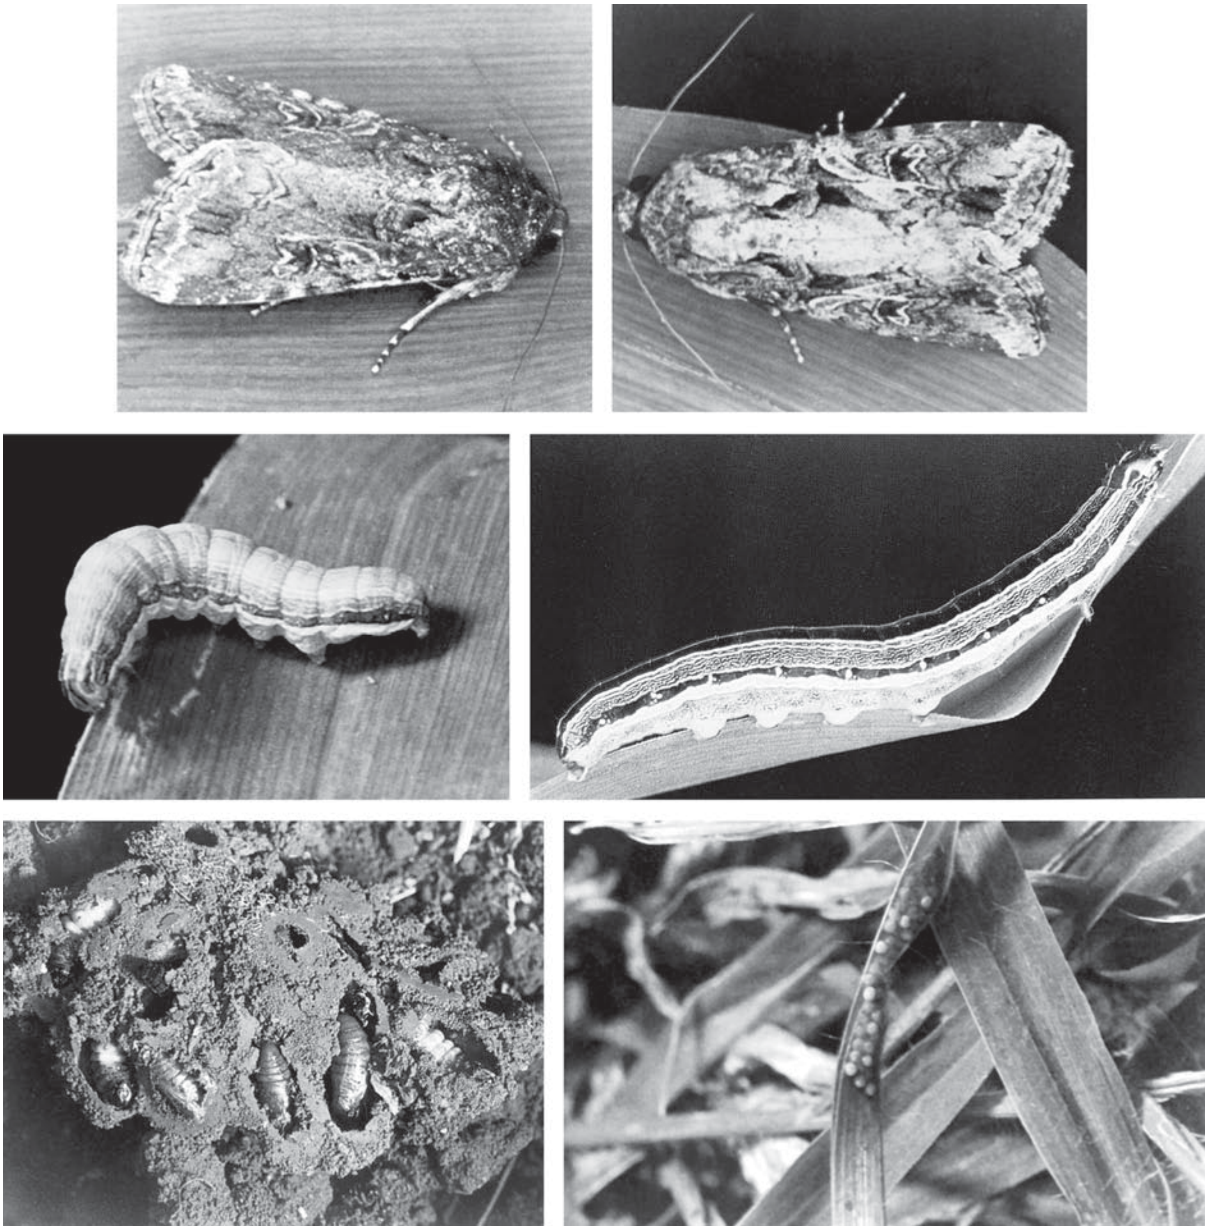
► Bugs

► Treehoppers

African Armyworm, *Spodoptera exempta* (Walker) (Lepidoptera: Noctuidae)

JOE C. B. KABISSA
Tanzania Cotton Lint and Seed Board, Dar Es Salaam, Tanzania

The African armyworm (Fig. 21) is a larva of a nocturnal moth, *Spodoptera exempta* (Walker). This species, although commonly referred to as the African armyworm, occurs rather widely in the grasslands of tropical and subtropical Africa and Asia. In Africa, where *S. exempta* is of major economic importance, its occurrence is confined to countries south of the Sahara: Tanzania, Kenya, Uganda, Ethiopia, Somalia, Malawi, Zimbabwe, Zambia and South Africa. Outside Africa, *S. exempta* has been reported from southwest Saudi Arabia in the republic of Yemen, southeast Asia, Australia, New Zealand and Hawaii.



African Armyworm, *Spodoptera exempta* (Walker) (Lepidoptera: Noctuidae), Figure 21 **African armyworm: top left, adult female, top right, adult male; middle left, solitary form of larva; middle right, gregarious form of larva; lower left, pupae in soil; lower right, eggs on foliage.**

During an armyworm outbreak, larvae of *S. exempta* march together in long columns, akin to army columns, in search of susceptible plant material. This is the basis for the name "armyworm." When susceptible plant material is found, it is often voraciously devoured to ground level. In typical armyworm outbreaks, larval density may exceed 1,000 per m^2 over areas covering tens or even hundreds of square km.

In Africa, *S. exempta* is adapted for survival on seasonal grasslands by combining a high intrinsic rate of increase with "migration" to places of rainfall where grasses are suitable for survival of its caterpillars. Because of its capability to move over long distances, hundreds and sometimes thousands of km across national boundaries freely, *S. exempta* is truly an international pest. Often times it appears sporadically and suddenly in dense outbreaks capable of causing extensive and enormous damage to susceptible rangeland grasses, cereal crops and sugarcane. Because of its ability to appear suddenly and then disappear equally suddenly, the African armyworm has sometimes been referred to by farmers as the "mystery worm." The scale of devastation to crops and pastures by armyworm is comparable only to that caused by locusts. Thus, the armyworm is greatly feared wherever it occurs.

Biology and Ecology

Adult moths of *S. exempta* have a wing span in the range of 20–37 mm. The forewings are characterized by an overall dull gray-brown appearance. The hind wings are whitish with dark veins. The two sexes can be distinguished by examining the number of bristles on the frenulum (the mechanism that couples the fore and hind wings during flight), which are single in the males and multiple in the females. A characteristic feature of the African armyworm is the presence of racquet-shaped scales at the tip of the abdomen of the males and black scales on the tip of the body of the females.

Females of *S. exempta* lay between 100 and 400 eggs per night in a mass covered by black scales from the tip of their abdomen. Eggs are small, 0.5 mm in diameter, whitish in color, but then turn black prior to hatching. Eggs are often laid on the lower side of leaves and hatch in about 2–4 days after oviposition. There are six larval instars extending over a larval period of between 14 and 22 days depending on the temperature and the host plant on which the larvae have been reared. Fully grown sixth instar larvae are often 25–35 mm long. Pupation occurs 2–3 cm below the soil surface. This process is often preceded by a sudden and synchronized disappearance of larvae that quickly burrow into the ground, particularly if soil conditions are moist enough.

Adults emerge within 7–12 days after pupation and can live up to 14 days if appropriately fed. In their lifetime, females can lay up to 1,000 eggs. *Spodoptera exempta* is not known to enter into any type of diapause. This probably explains why this species has to migrate soon after emergence.

Spodoptera exempta exhibits a phenomenon called polyphenism, or phase polymorphism (i.e., the occurrence in a population of two or more phenotypes due to exposure to different environmental conditions). For example, up until the third molt, all larvae of *S. exempta* remain green in body color. However, at this stage, depending on whether there are many larvae or just a few, they will turn black or remain in various shades of green or brown. If there are large numbers of larvae present as in a typical outbreak situation, larvae tend to be characteristically velvety black on top with pale lines on each side and greenish-yellow underside; this phenotype is called the gregarious phase. It is during this phase that *S. exempta* is most devastating to crops. Larvae in the gregarious phase tend to be very active and often march on the soil in one direction only looking for fresh food. They also feed high on the plant during the day.

However, if not crowded, the developing larvae remain one of the many shades of green, pink or brown color until they pupate. In contrast to black gregarious larvae, they are sluggish, living mostly at the bases of plants and are not as destructive to crops. Although their appearance is so different, they are the same insect and one may easily be converted into the other. Nevertheless, because moths derived from gregarious and solitary larvae exhibit the same level of readiness to fly, phase change in *S. exempta* is construed as being merely a stress phenomenon associated with crowding. It is unknown whether this aspect of phase polymorphism is of any evolutionary significance to *S. exempta*. In the case of locusts, it is thought that the solitary form is the one that enables the populations to persist at a low level during the dry season when there are no outbreaks occurring. It is worth speculating, in the case of *S. exempta*, that at such low densities, its populations continue to breed during the dry season in areas where grasses remain green, such as in the cool highland areas and, more especially, the coastal areas where it is hot and there are periodic showers during the dry season. This form may, therefore, be of some critical survival value for this pest.

Seasonal Movements and Armyworm Outbreaks

Upon emergence, adult moths of *S. exempta* are fully capable of movement from their breeding sites to new areas. Such flights can be very short, or very long, depending on whether they are carried in a downwind direction or not. Nevertheless, because they are one-way journeys, they cannot, therefore, be regarded as migration in its strict ethological sense – where there is invariably a return flight to breeding sites.

The question of how armyworm outbreaks start has baffled scientists and farmers alike for a long time. Because moths emerge over a period of up to 12 days, and can also fly off on "migration" at different times, they become widely dispersed and do not form swarms as occurs with locusts. Moreover, the moths are weak fliers and are often carried in a downwind direction. Thus, moths disperse in space and time downwind. For purposes of this narrative, an armyworm outbreak is simply described as the sudden appearance of larval infestations, often simultaneously on many farms in one region.

Two hypotheses, the continuity and the concentration hypotheses, have been put forward in order to explain how outbreaks begin during an armyworm season. The continuity hypothesis, which is based on biogeographical analyses of past outbreaks, proposes that much of the armyworm population is always at crowded, outbreak densities, and that the seasonal absence of reports represents not a real absence of outbreaks, but a temporary loss of contact with the main population in remote and perhaps uninhabited areas. This continuity implies that the first outbreaks to appear in East Africa are due to the migration of parent moths from the north at the end of the season. Although there is ample evidence of adult dispersal on the wind over distances up to several hundred km in a few successive nights, there is little evidence in support of a southward dispersal at the start of an armyworm outbreak in East Africa.

The concentration hypothesis, on the other hand, postulates that because of occasional capture of moths in traps during the off-season, as well as the finding of rare caterpillars after concerted searches, *S. exempta* persists during such times of year as uncrowded populations (the solitary phase, in which caterpillars remain green and unreported), and that the first outbreaks of the season are due to concentration of moths before the synchronized mating and egg laying.

Thus, there seem to be two types of armyworm outbreaks: primary and secondary outbreaks. During primary outbreaks, sources of outbreaks are the low density populations that survive and breed during dry seasons in green areas of the coast and the highlands. Secondary outbreaks occur downwind from the coast near the first highlands. During years of serious armyworm outbreaks, the first outbreaks often start in Tanzania, Zimbabwe and Malawi at about the beginning of the wet season in December, and are followed by a progression of outbreaks at about one generation time-intervals from Tanzania through Kenya, Uganda, Ethiopia, Somalia to the Yemen and from Zimbabwe to South Africa. Wind convergence plus localized weather and moth behavior provide the mechanism for transporting and concentrating moths emerging from primary outbreaks.

Flight mechanisms of *S. exempta* prior to outbreaks have been the subject of extensive studies. After drying and hardening their wings, moths first move up into the trees. Then, when they are ready, they fly up several hundreds of meters into the air, where if caught up by prevailing wind, are carried away downwind. When dawn arrives, the moths descend and hide on the ground in the grass, but at dusk they take off again. They will continue to do this for several days, either until they die, or until they come to an area where rain is falling. Rain causes the moth to descend to the ground. The winds coming out of the rainstorm have the effect of concentrating the moths, rather as though they were being swept together with a brush. This is the reason why armyworms occurring during outbreaks are not evenly distributed. Upon descent to the ground, moths tend to drink water if this is available, mate and then lay their eggs. At this stage dispersal will have come to an end.

In Africa, seasonal rains are brought by the meeting of large scale winds from the northeast and the southwest at the Inter-Tropical Convergence Zone (ITCZ). The position of the ITCZ moves with the sun across the tropical zone twice each year, from north to south between July and December and from south to north between January and June. The first outbreaks, designated as primary outbreaks in East Africa, usually occur in central Tanzania in November or December. Occasionally they occur further south, in Mbeya, Mtwara and Lindi regions of Tanzania. More rarely, they occur in southeastern Kenya.

Moths produced by these primary outbreaks are then carried by the wind towards the ITCZ, which has meanwhile moved north. The moths are thus concentrated in areas where the rains are just beginning, and so they breed and multiply yet again. If conditions are suitable, they will increase at an enormous rate. Although the first outbreaks are only a few hectares in extent, by February and March there may be outbreaks of hundreds of square km.

Thus, as the ITCZ takes the rains northwards, so the moths, carried by the prevailing wind, move with it, bringing new armyworm outbreaks, designated secondary outbreaks, to northern Tanzania, Kenya, Somalia, Ethiopia, Sudan and eventually Yemen. Armyworm outbreak seasons vary greatly in severity, extent and timing in each of these countries.

From September to November, there are seldom armyworm outbreaks in any part of eastern Africa. The armyworm seems to disappear during the dry season. But since they have no diapause, they must be living and breeding somewhere. It has now been established that they survive in quite low numbers along the coastal area, where some rain falls in every month of the year. When the rains begin again in central Tanzania, small numbers of moths migrate inland from the coast and it is these that cause the first outbreaks.

Economic Importance of Outbreaks of *S. exempta*

During armyworm outbreaks, feeding damage by *S. exempta* to cultivated and wild host plants is almost entirely restricted to the leaves, although when food is scarce, the young stems or flowers, particularly of wild grasses, may also be eaten up. The young larvae at first eat the upper and lower surface tissue of the leaves, which results in the skeletonization, or windowing, of the leaves. As a rule, armyworm larvae tend to prefer young plants and recently germinated crops, often defoliating them to ground level. It is estimated that two larvae can completely destroy a 10-day-old maize plant with 6–7 leaves and a single larva can consume 200 mg of dry mass of maize leaves in the course of the sixth instar.

Destruction of cereal crops such as maize, rice, wheat or sorghum often necessitates replanting of the entire affected crop. *S. exempta* larvae are most damaging to cultivated and wild host plants during outbreaks when gregarious bands of larvae travel together on the ground. Such armyworm outbreaks are often capable of causing total crop loss within hours at the local level. Thus, crop losses as a result of armyworm outbreaks can be potentially devastating to local and national economies as they occur in some of Africa's most impoverished economies. Losses are sometimes difficult to assess quantitatively because of hidden costs such as effects of forage destruction, damage to subsistence farms, the expense of additional seed and, most importantly, food aid from international donors.

Survey and Control

Circumstantial evidence from light and pheromone traps shows that long distance migrations occur between moth emergence and the next breeding areas which are in the vicinity of seasonal passages of low-level wind convergence such as Inter-tropical Convergence Zone or African Rift Convergence Zones. Furthermore, increasing levels of moth catches in light and pheromone traps have been found to be followed by increased probability of infestations of larvae occurring 2–4 weeks later at up to 200 km from the trap.

Because primary outbreaks of *S. exempta* originate from moths taken downwind from sources nearest the coasts of eastern Africa, and concentrate where heavy rains are falling, control of this pest involves accurately detecting primary outbreaks and eliminating them before the subsequent moths emerge and move downwind causing secondary outbreaks in another region or country. The major objective is to kill as many armyworms as possible on pasture or crops before subsequent moths emerge and move downwind. Normally, the largest and densest outbreaks are attacked first. This approach is referred to as "strategic control." However, because primary outbreaks often remain unnoticed until after secondary outbreaks have occurred, direct elimination of the latter becomes the main objective in multiple outbreak situations.

Monitoring possible sources of the moths that cause primary outbreaks has involved deployment of a network of light and pheromone traps, as well as ground searches for low-density larvae in the off-season in areas historically known to be sites of primary outbreaks. In addition, for all primary outbreak areas, rainfall stations must report on a weekly or daily basis the amount of rainfall during the first month of the rainy season. Recently, there have been attempts to introduce predictive models that integrate African Real Time Environmental Monitoring and Information System (ARTEMIS) and satellite imagery and synoptic weather data that has been applicable for detection and elimination of gregarious locusts. The major challenge associated with armyworm monitoring, forecasting and control in countries most ravaged by this pest is the inadequacy of funding for these operations.

Because elimination of all primary outbreaks is almost impossible to achieve, management strategies for *S. exempta* tend to focus more on suppression of secondary outbreaks. This approach has invariably been dependent on the application of pesticide sprays. To date, a series of low toxicity pesticides are often used (e.g., synthetic pyrethroids, carbamates and organophosphates). Previously, highly toxic, persistent and broad spectrum pesticides such as DDT, BHC, dieldrin and a series of others were used due to lack of alternative, safer products. However, due to the need for rapid intervention and coverage of fairly extensive areas during outbreaks, newer oil-based pesticides are being applied as ultra-low volume (ulv) formulations using hand held, battery driven applicators. Nevertheless, suppression tactics are only cost-effective when applied in a timely manner on farmland. Outbreaks occurring on uncultivated land often remain unchecked.

Unfortunately, control of armyworms by less toxic means has received far less attention than in the case of other international migratory pests such as locusts, which have been the targets for tests involving fungi, protozoa and even viruses.

Extensive studies in eastern Africa have confirmed that all life stages of the armyworm are subject to attack by a diversity of natural enemies. For example, up to 90% of armyworm caterpillars in the last instar can be killed by a nuclear polyhedrosis virus (NPV). Similarly, pupal and prepupal stages can be killed by a cytoplasmic virus. The only fungus known to attack armyworms during conditions of high humidity and temperature is *Normuraea rileyi*. Armyworms infected by this fungi typically climb to the top of grass blades where they die amidst masses of mycelia.

Armyworm larvae are also subject to parasitism by some 28 species of tachnid flies (Diptera: Tachinidae). In cases of parasitism from wasps (Hymenoptera), some 25 parasitoids have been isolated from eggs, larvae and pupae of *S. exempta*. Apart from attack by parasitoids, there are several arthropod predators that prey on armyworms, including ants (Hymenoptera: Formicidae) and beetles (Coleoptera), which often prey on eggs and early larval stages of *S. exempta*. To date, there has been no effort to study the potential of some of these natural enemies for commercialization. Armyworm outbreaks also attract flocks of avian predators, notably storks such as Marabou storks, white (European) storks and Abdim's storks. Occasionally, such assemblages of predators help to eliminate small primary or secondary outbreaks of *S. exempta*.

For the more foreseeable future, it is evident that preventive control of armyworms will continue to rely on diligent surveillance during recessions and, as outbreaks occur, intensified scouting will be necessary to locate and then eliminate pockets of solitary morphs before outbreaks.

African Honey Bee, Africanized Honey Bee, or Killer Bee, *Apis mellifera scutellata* Lepeletier (Hymenoptera: Apidae)

JAMIE ELLIS[1], AMANDA ELLIS[2]
[1]University of Florida, Gainesville, FL, USA
[2]Florida Department of Agriculture and Consumer Services, DPI, Gainesville, FL, USA

The African honey bee (*Apis mellifera scutellata* Lepeletier) is a subspecies (or race) of western honey bee (*A. mellifera* L.) that occurs naturally in sub-Saharan Africa but has been introduced into the Americas. More than 10 subspecies of western honey bees exist in Africa and all justifiably are called "African" honey bees. However, the term "African (Africanized) honey bee" refers exclusively to *A.m. scutellata* in the bee's introduced range (Fig. 22).

Subspecies of western honey bees are native to Europe and Africa but have been spread widely outside their native range due to their economic importance as pollinators and producers of honey. Initially, only European subspecies of honey bees (hereafter referred to as European bees) were introduced into the Americas, where they were found to be productive in temperate North America but less so in Central and South America where tropical/subtropical climates dominate. In response to the poor performance of European bees in Brazil, Warwick Kerr, a Brazilian scientist, traveled to southern Africa to screen African honey bee subspecies for productivity and viability. His visit resulted in the importation of *A.m. scutellata* into Brazil in the late 1950s.

Dr. Kerr hoped that through experimentation and selective breeding, the African bee could be made manageable and available for use by Brazilian beekeepers. As such, he initiated efforts to breed gentleness into the African stock while amplifying its many positive traits. The breeding effort was not carried to completion because the African bees swarmed accidentally, ending their initial quarantine. Following this, the bees began to spread throughout Brazil and into other parts of South America.

All subspecies of *Apis mellifera* can interbreed or hybridize. Consequently, African bee hybridization with European bees became frequent as African bees moved into areas previously occupied by European bees. It is this hybridization with

African Honey Bee, Africanized Honey Bee, or Killer Bee, *Apis mellifera scutellata* Lepeletier (Hymenoptera: Apidae), Figure 22 The natural distribution of *Apis mellifera scutellata* in Africa (modified from Hepburn HR, Radloff SE (1998) Honeybees of Africa. Springer-Verlag, Berlin, 370 pp), and its distribution in the Americas.

European honey bees that earned them the name "Africanized" honey bees. Traditionally, "African" and "Africanized" have been used interchangeably although the former really refers to the pure race and the latter to the hybrid.

The spread of African bees throughout South and Central America, fueled by rapid hybridization with European subspecies and the dominance of African alleles over European ones, occurred at a rate of 200–300 miles per year. Because their movement through South and Central America was rapid and largely unassisted by humans, African bees earned the reputation of being the most successful biologically invasive species of all time. In 1990, populations of African honey bees had saturated South and Central America and begun to move into the USA. As of 2006, African honey bees were established in the southernmost USA: Texas, California, New Mexico, Arizona, Oklahoma, Louisiana, Arkansas, Alabama, and Florida.

The spread of African bees in the U.S. continues, albeit at a much slower rate than what occurred throughout South and Central America. This slowed rate of territory expansion appears due to climatic limitations. African bees do not survive in temperate climates as well as European bees do. Therefore, they have failed to establish populations below about 32° latitude in the southern hemisphere. Although they have expanded beyond this parallel in the northern hemisphere, African bee expansion northward also appears limited climatically, being found only below about 34° latitude currently.

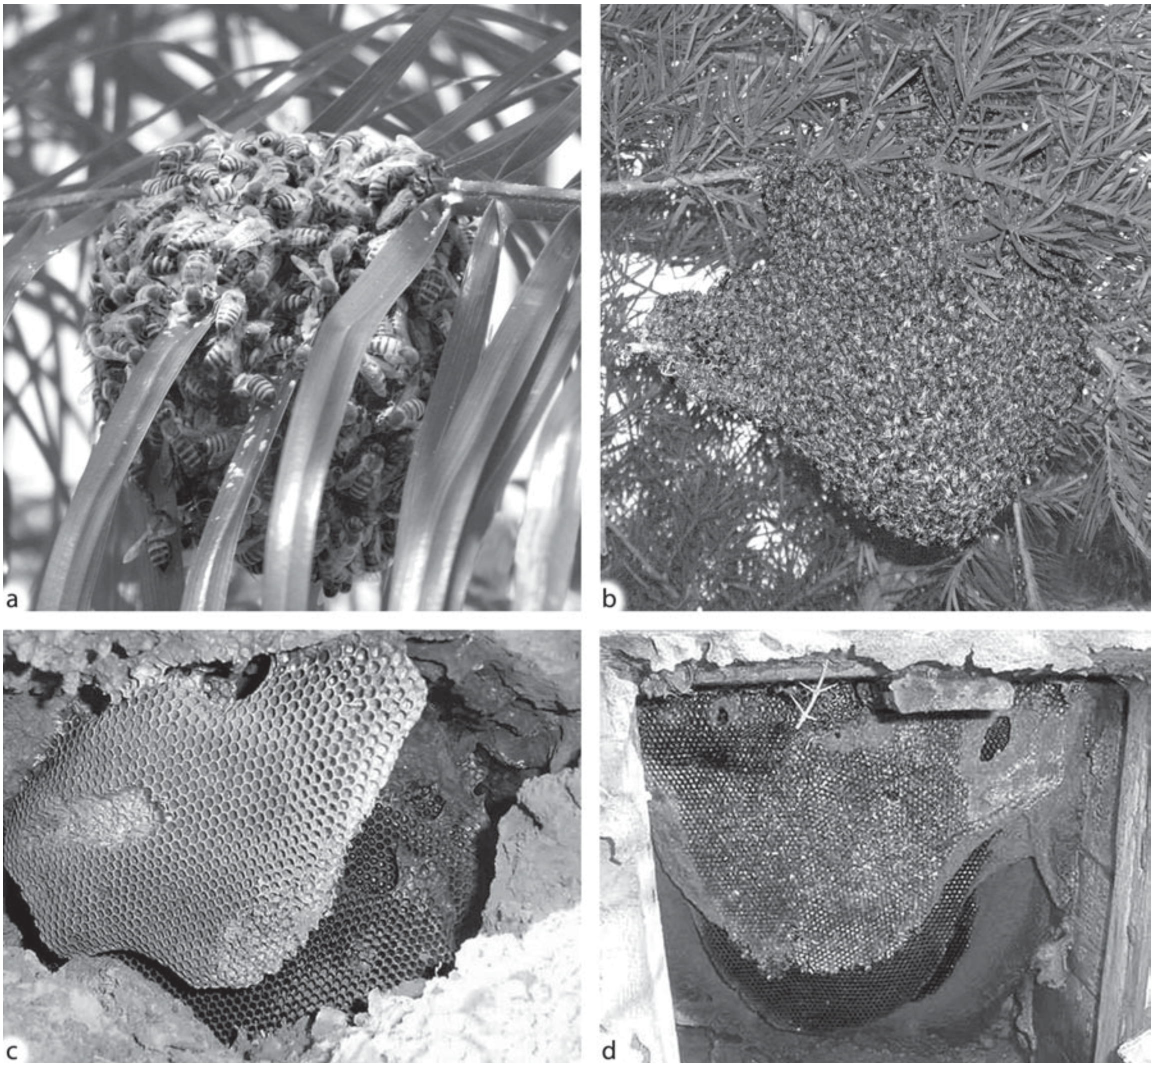
Description and Behavior

African honey bees cannot be distinguished from European honey bees easily, although they are slightly smaller than the various European races. Laboratory personnel use morphometric analyses to determine the likelihood that a given colony is Africanized or fully African. With honey bees, the measurement of wing venation patterns and the size and coloration of various body parts (morphometry) are important determinants of identification at the subspecific level. Morphometry has been used to differentiate honey bee races since the 1960s and remains the first round of identification when suspect colonies are discovered. Morphometric analyses were first used to differentiate Africanized and European honey bees in South America in 1978. A more rigorous identification is achieved by genetic analysis and often is necessary when the suspect bees are a hybrid between African bees and the European subspecies.

Other differences between African and European bees manifest themselves behaviorally. To the casual bystander, the primary identifying behavioral characteristic of Africanized bees is their heightened defensiveness compared to that of European subspecies. Selection pressures induced by man are, in part, responsible for this increased defensiveness. "Beekeeping" (management of honey bee colonies by humans) is more common in Europe, where the native honey bees have been bred for gentleness and ease of management. In contrast, "honey hunting" (near-complete destruction of hive to harvest contents) is more common in Africa, resulting in a bee that is more defensive of its nest. Other selection pressures that led to a heightened defensiveness in African bees include climatic stresses, resource availability, and predation by birds, mammals, and various reptiles. These selection pressures resulted in an African race of bee that can be 10 + times more defensive than any of the various European races of bee.

All honey bees readily defend their nests, and an attack usually means that the victim is too close to the nest. While European races of bees may attack a nest intruder with >10 bees, African bees may attack the same intruder with >1,000 bees. Further, African bees defend a larger radius around their nest and require lower levels of stimuli to initiate an attack. Because of these characteristics, African bees are capable of killing large mammals, including man. This defensiveness has earned them the nickname "killer" bee. It is important to note that their ability to kill humans has nothing to do with their size or the potency of their venom. African bees are smaller than European bees and probably deliver a comparatively smaller dose of venom to their victim than do European bees. Because both bees use the same type of venom, human deaths are a result of the number of stings they receive rather than an increased potency of African bee venom.

Another behavioral difference between African and European bees concerns colony level reproduction and nest abandonment. African honey bees swarm and abscond in greater frequencies than their European counterparts. Swarming, bee reproduction at the colony level, occurs when a single colony splits into two colonies, thus ensuring survival of the species. European colonies commonly swarm 1–3 times per year. African colonies may swarm >10 times per year. African swarms tend to be smaller than European ones, but the



African Honey Bee, Africanized Honey Bee, or Killer Bee, *Apis mellifera scutellata* Lepeletier (Hymenoptera: Apidae), Figure 23 (a) African bees swarm readily and nest in unusual locations, including (b) exposed on tree limbs, (c) within cavities in the soil, (d) within discarded furniture.

swarming bees are docile in both races. Regardless, African colonies reproduce in greater numbers than European colonies, quickly saturating an area with African bees. Further, African bees abscond frequently (completely abandon the nest) during times of dearth or repeated nest disturbance, while this behavior is atypical in European bees.

Another common difference between African and European honey bees is their choice of nest locations. African honey bees are less selective when considering a potential nesting site than are European bees. They will nest in a much smaller volume than European honey bees and have been found in water meter boxes, cement blocks, old tires, house eaves, barbecue grills, cavities in the ground, and hanging exposed from tree limbs, just to name a few places. One rarely finds European colonies in any of these locations because they prefer to nest in larger cavities like those provided by tree hollows, chimneys, etc. As one can imagine, humans inadvertently provide multiple nesting sites for African bees. Therein lies the primary reason African bees are encountered frequently by humans (Fig. 23).

A final behavioral curiosity of African bees concerns nest usurpation (or colony takeover) of European colonies. Small African swarms containing a queen often land on the outside infrastructure of a European colony (a wall, beekeeper-managed hive, etc.). As time passes, the worker bees in the African swarm begin to exchange food/pheromones with the European workers from the colony. This gradually ensures the adoption of the African bees into the European colony. Somewhere during this process, the European queen is lost (perhaps killed by the African bees – her fate remains uncertain at this point) and the African queen is introduced into the colony, thus becoming the reigning matriarch. European bees do not display this behavior but often fall victim to it, thus creating an African colony from a preexisting European one.

Other behavioral differences between African and European races exist and are worth discussing briefly. For example, African bees are more “flighty” than European bees, meaning that when a colony is disturbed, more of the bees leave the nest rather than remain in the hive. African bees use more propolis (a derivative of saps and resins collected from various trees/plants) than do European bees. Propolis is used to weather-proof the nest and has various antibiotic properties. African colonies produce proportionally more drones (male bees) than European bees. Their colonies grow faster and tend to be smaller than European colonies. Finally, they tend to store proportionately less food (honey) than European bees, likely a remnant of being native to an environment where food resources are available throughout the year.

Life Cycle and Genetic Dominance

Mating biology and developmental time play an important role in the success of African bee colonies in replacing European colonies in an area. For the most part, mating and developmental biology are similar for African and European bees, but key differences confer adaptive benefits to the former.

Virgin queens of all western honey bees emerge from peanut hull-shaped waxen cells. After a short time of further maturation, a virgin queen will leave the colony to mate with drones. All mating occurs in the air, with the fastest drones being the most successful suitors. Queens will mate multiple times over the course of 7–10 days and during this time they will mate with an average of 12–20 drones. Queen bees store semen in an organ called a spermatheca. African colonies produce more drones/colony so drone populations in an area tend to favor African bees. As such, virgin European queens are more likely to mate with African drones rather than European ones. Further, flight time and distances of mating flight from the colony tend to result in European queens encountering African drones more often than European drones, thus setting the stage for hybridization.

All honey bees undergo complete metamorphosis but the time from egg to adult varies by subspecies. The newly-mated queen bee oviposits in wax cells constructed by worker bees. Fertilized eggs result in female offspring, either workers or queens. If fed a diet rich in royal jelly, the female larva will develop into a queen, with the reciprocal true for the development of workers. Drones result from unfertilized eggs and consequently only inherit genetic material from their mother (they have no father).

Developmental time varies by caste member (see Table 4) and favor African honey bees because they generally develop faster than European bees. When bee colonies decide to make a new queen, newly emerged female larvae are fed royal jelly constantly. Because Africanized offspring, including queens, develop faster than European offspring, a queen having an African genotype is more likely to emerge earlier than a queen with a European genotype. The first queen to emerge kills all of her queen sisters that have not yet emerged from their cells. The Africanized virgin proceeds to mate in an area having higher densities of African drones. Over time, this results in the colony becoming more African with the European phenotype being replaced almost altogether. This process is exacerbated further due to the dominance of African genetic traits over European ones.

Finally, African bees are more resistant to many honey bee pests/pathogens than are European bees. Western honey bees face a myriad of pests and diseases, the most severe of which include varroa mites (*Varroa destructor*), tracheal mites (*Acarapis woodi*), small hive beetles (*Aethina tumida*), and American foulbrood (*Paenabacilis larvae*). These bee pests almost eliminated all wild colonies of European honey bees in North America. Because African bees are resistant to many of these pests/diseases, their survivorship in the wild is favored over that of European bees.

Public Risks

Due to their heightened defensive behavior, African honey bees can be a risk to humans. Children, the elderly, and handicapped individuals are at the highest risk of a deadly attack due to their inability or hampered ability to escape an attack. African honey bees are agitated by vibrations like those caused by power equipment, tractors, lawn mowers, etc. Further, their nesting habits often put them in close proximity to humans. Because of this, precautions should be taken in an area where Africanized honey bees have been established. These precautions are not suggested to make people fearful of honey bees but only to encourage caution and respect of honey bees. The precautions include remaining alert for honey bees flying into or out of an area (suggesting they are nesting nearby), staying away from a swarm or nest, and having wild colonies removed from places that humans frequent. The latter is perhaps the most important advice one can heed when dealing with African bees. In the USA, a large percentage of African bee attacks occur on people who know a nest is present but elect not to have it removed (or try to do it themselves).

If an attack occurs, remembering a few simple recommendations will increase one's chances of minimizing the effects and severity of the attack. If attacked, a victim should run away from the area using his shirt to cover his head and especially airways. Running through tall grass or small trees will help to disrupt the attacking bees. The victim should not stand and swat at the bees. The bees are defending their nest, and the victim needs to get away from that nest as quickly as possible. It is important that the victim get cover in a bee-proof vehicle or structure if either is available. One should not jump into the water or hide in bushes. The bees can remain defensive and in the area for some period of time, thus increasing the risk to the victim. If stung, the victim should remove the stinger quickly by scraping it rather than by pulling it. One should see a doctor immediately if breathing is affected.

Many African bee attacks can be prevented by limiting the number of nesting sites that are available to the bees. A homeowner, school worker, etc. can "bee proof" his or her property by eliminating possible nesting sites. This can be accomplished by removing any unnecessary debris from an area and closing off wall, chimney, electrical and plumbing-related gaps that are >30 mm using a small-mesh hardware cloth or caulking. This will limit bee access to potential nesting sites. Finally, one should check walls and eaves of structures regularly, looking for bee activity.

Drone	24	24

Managing African Bee Colonies

It is important to remember that African honey bees pollinate crops and produce honey just like other races of honey bees. Beekeepers in South Africa use African honey bees as the bee of choice in their operations. So, African bees can be managed efficiently and safely but the skills required to manage African bee colonies differ from those required to manage European bee colonies.

In general, the management of African bee colonies has been discouraged in the US while accepted in Central and South America. This may have to do with the public perception of honey bees, particularly African bees, in the USA and the robust legal system in place in the USA. On the other hand, beekeepers in Central and South America routinely use African bees in their operations with slight management modifications. In fact, some South American countries are among the leading honey producers in the world, due largely to the presence of African bees in the country.

Beekeepers in South and Central America utilize a number of management practices in order to keep African bees. First, they keep single bee colonies on individual hive stands rather than using one hive stand for multiple colonies. This limits the management activity to one colony at a time rather than aggravating other colonies while working only one.

Secondly, beekeepers in South and Central America use ample amounts of smoke when working African bee colonies. It is believed that smoke masks the alarm pheromone of the bees, thus lessening the defensive response of the colony. Most South and Central American beekeepers agree that copious amounts of smoke should be used when working African bee colonies. It is important to smoke the colonies well before any work is done, for once bees from a colony are agitated, smoke may fail to calm them down.

Beekeepers managing African bees wear appropriate protective gear. A typical beekeeper working an African colony would wear a full bee suit, boots, gloves, and a bee veil. Bee veils (protective headgear) are worn by almost all beekeepers worldwide. Traditionally, the veil mesh protecting the face is colored black to keep down the sun's glare. African bees (and most honey bees) attack dark colors so black-faced veils often get covered with bees. Consequently, beekeepers can use white-faced veils to keep the bees off of their veils. Beekeepers managing African colonies often tape their bee suits to their boots and gloves to limit the possibility of bee access.

Finally, some beekeepers in areas with African bees try to requeen African bee colonies with European queens. This is not a common practice in sub-Saharan Africa. Most African beekeepers in areas having African bees gladly use the bee in their operations, paying little attention to the bees' defensiveness.

Conclusion

The economic impact of African bees in an area can be substantial. Keepers of European bees often notice a decrease in resource availability for their bees because of the density of African bee colonies in an area, and thus the demand on the available resources is high. Furthermore, cities, municipalities, etc., often initiate eradication programs, with much futility. Finally, the loss of animal and human lives is a tragic occurrence, being beyond measurable cost.

African bees also may affect the environment negatively. Colony densities as high as 300 African bee colonies per square mile have been suggested. If true, African bees may have a substantial impact on the native flora and fauna in an area. While this impact often is not reported and largely is not understood, it could be significant considering the potential number of colonies and their need for resources. Thus, the world's most infamous honey bee is among nature's most enigmatic creatures.

African Horse Sickness Viruses

CYNTHIA C. LORD
University of Florida, Florida Medical Entomology Laboratory, Vero Beach, FL, USA

African horse sickness is a highly fatal, noncontagious disease of equines, particularly horses. The African horse sickness virus group consists of nine serotypes, in the genus *Orbivirus*, family Reoviridae. It is closely related to the bluetongue viruses, which cause disease in cattle and sheep. Infection with any of the serotypes of African horse sickness virus usually results in severe disease and high mortality in horses. Donkeys and mules generally exhibit less severe disease and lower mortality, while wild equids such as zebra generally show no signs of disease or mortality after infection. The serotypes are differentiated based on the host immune response, and there is some cross reaction between serotypes.

All nine serotypes are endemic to sub-Saharan Africa, and have caused serious epidemics when introduced outside this area. African horse sickness has had a significant impact on the history of some parts of Africa, as horses could not be used in exploration and farming. Outbreaks of African horse sickness have a significant economic impact, resulting from the direct loss of animals, the costs of control programs, and trade regulations and quarantines restricting movement of equines from infected areas.

The virus is transmitted by biting midges in the genus *Culicoides*. *Culicoides imicola* has been implicated in most outbreaks, while in endemic areas there may be several species of *Culicoides* midge involved in the transmission cycle. Most species of equines can develop viremias sufficiently high to infect midges. Some tick species have been shown to be able to become infected and transmit the virus in the laboratory, but the importance of this transmission route in nature is unknown.

In endemic areas, African horse sickness viruses circulate primarily between midges and zebra, and frequently multiple serotypes are present. Transmission rates can be very high. For example, in the Kruger National Park, South Africa, zebra foals typically are exposed to all nine serotypes by the time they are 1 year old.

The first outbreak outside the sub-Saharan zone began in 1959 in Saudi Arabia and Iran, spreading to involve Afghanistan, Pakistan, Syria, Lebanon, Jordan, Iraq, Turkey, Cyprus and parts of India before being controlled by vaccination campaigns and the loss of most susceptible horses by the end of 1961. Another outbreak occurred in North Africa in 1965, crossing into Spain in 1966. An outbreak of African horse sickness serotype 4 virus began in central Spain in 1987 and ultimately encompassed a large part of Spain, along with parts of Portugal and Morocco. This outbreak was the first recorded instance of an African horse sickness virus overwintering outside of Africa. African horse sickness cases occurred for four subsequent years in Spain, and it was not eradicated until 1990. The most likely route of introduction was via zebra imported from Namibia. Control and eradication of the virus was achieved only by extensive vaccination campaigns and slaughter of infected or exposed equines. It is estimated that 2,000 horses died and over 350,000 were vaccinated during this outbreak. In 1989, an outbreak of serotype 9 occurred in Saudi Arabia.

Spain was divided into African horse sickness-free and infected regions, in order to allow movement of horses for the 1992 Olympics held in Barcelona. No vaccination was allowed in the African horse sickness-free region, so that any transmission activity would be observed. Equine movement out of the infected region was prohibited.

A similar strategy is used in South Africa, with an African horse sickness-free zone in the Western Cape Province, based on historically low incidence of African horse sickness, and that *C. imicola* is rare. Surrounding this zone is a surveillance zone and a protection zone. No vaccination is allowed in the free and surveillance zones, and strict movement controls are in place for equines moving from other areas of the country. The zoning creates an area where animals can be held prior to exportation. In 1999, there was an outbreak of African horse sickness in the surveillance zone, opening debate about the effectiveness of the movement restrictions and the vector species involved. Currently, the zoning is still in place and there have not been further outbreaks in the African horse sickness-free zone.

Clinical signs of African horse sickness in horses generally begin with fever. There are three forms of African horse sickness disease in horses: pulmonary, cardiac, and febrile. The febrile form, often referred to as horse sickness fever, does not progress beyond fever and generally resolves. The pulmonary form begins with fever and progresses to respiratory difficulty, coughing and nasal discharge. Death is due to pulmonary edema and cardiac failure. The cardiac form also begins with fever, and subsequently edemas develop around the head, neck and chest. Death results from cardiac insufficiency and progressive pulmonary edema. Mortality rates can be as high as 95% in horses, although donkeys and mules are much less susceptible and mortality rates are much lower. Movement of donkeys may be important in the spread of these viruses outside the endemic area, as they are rarely clinically ill and so infected animals are not noticed. There is variation in virulence between the nine African horse sickness serotypes, along with differences between breeds of horse and individual immune responses to the virus.

Vaccines have been developed against these viruses, but due to the immunological differentiation between the serotypes, cross protection is not complete and full protection requires vaccination against each serotype. Routine vaccination of horses, against all serotypes, is practiced in endemic areas. Elsewhere, vaccination generally is not used routinely or is not allowed. In outbreak situations, the virus is first typed to determine the serotype involved, then vaccination is targeted against that serotype only.

Most countries restrict importation of equids from endemic countries. An extended quarantine period usually is imposed, thus restricting the movement of horses for competition. Because it is difficult to differentiate between vaccinated and infected animals, generally there are restrictions on importing vaccinated animals.

Antibodies to African horse sickness viruses have been found in other animals such as elephants, camels, and bovines, but there is no apparent illness and their impact on the transmission cycle is not known. Dogs can become infected and die by eating meat from the carcass of an infected animal. Antibodies to African horse sickness have been found in wild canids and other carnivores, most likely also via feeding on infected carcasses. Humans have been infected only rarely, generally through laboratory accidents with vaccine strains.

African horse sickness has never been found in the New World. However, there are species of *Culicoides*, particularly the *C. variipennis* complex, present throughout the U.S. Some members of this complex are competent vectors of African horse sickness viruses in the laboratory, and will be competent vectors in the field should an African horse sickness virus be introduced. Vector competence for the *C. variipennis* complex varies considerably for the closely related bluetongue viruses, but we lack information on similar variation for African horse sickness viruses. The implications of this for an introduction of any of the African horse sickness viruses is unknown, but requires further study.

African Mahogany-Feeding Caterpillar, Heteronygmia dissimilis aurivillius (Lepidoptera: Lymantriidae)

HANS G. SCHABEL
University of Wisconsin, Stevens Point, WI, USA

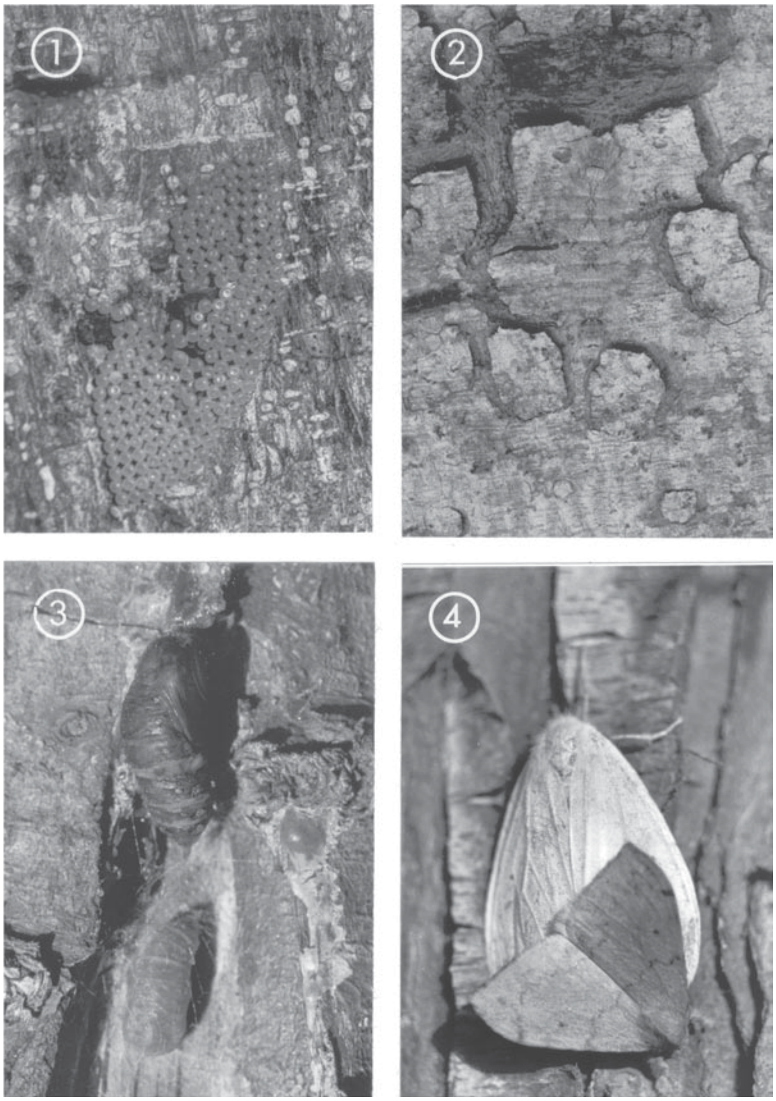
Several genera and species of mahoganies in various parts of the tropics are highly valuable timber species, among them African mahogany (*Khaya* spp.). Relatively few defoliators are known to target this genus, among them caterpillars of several silkmoths, the nymphalid Charaxes and the lymantriid *Heteronygmia*. Only the latter, presumably monophagous on *Khaya*, appears to have pest potential as indicated by small-scale outbreaks observed in Morogoro, Tanzania, in the 1980s.

A succession of four generations per year allow *Heteronygmia dissimilis* to be active most of the year, except for a period of estivation during the hottest season, i.e., from November to February. Eggs are found from early March to late October with peaks from May to August, i.e., during the cool, dry season. Egg clusters are located mostly on the lower trunks of trees and consist of 24–130 glossy, globular or dimpled spheres, each about 1 mm in diameter. They hatch 6–10 days after oviposition, depending on the season (Fig. 24).

Caterpillars of various instars are found anytime between early March to the end of November, with periods of greatest abundance from June to September. All larval instars are hairy and last instars occur in two color phases. One of them is milky-green; the other, more common one, a highly camouflaged, brown to greyish-white mottled bark pattern including up to three, more or less distinct dorsal saddles. Caterpillars feed solitarily, and move with great speed and agility when disturbed, including a hopping and ballooning response during the first four instars. Early instars skeletonize *Khaya* leaflets at night and spend the day motionless on or underneath leaflets. Older instars are free feeders and rest on the lower trunk during the day. All instars shun the foliage of just-expanding shoots. There are five instars in males and six in females, each of them lasting from 5–6 days.

Pupae are found from late February to early December, abundantly so from June to September. They often are cradled in loose leaf shelters tied together by sparse strands of silk or in other hiding places, such as under bark scales.

The moths are present from February to mid-November, most abundantly so from May to September. They rest during the day and are attracted to lights at night. Slender male moths are light to dark or reddish brown with substantial plumose antennae, whereas the white to cream-colored females are bigger and more robust with smaller antennae. Males have wingspans of about 40 mm and are able fliers, while females with wingspans of about 50 mm, are reluctant to take to the air and then only as poor fliers. Both sexes have faint to more pronounced grey line markings and a small black dot on each front wing. Before oviposition, the greatly distended abdomen of the female is greenish. Male moths reach adulthood after an average of 41 days (September/October), females after about 45



African Mahogany-Feeding Caterpillar, Heteronygmia Dissimilis aurivillius (Lepidoptera: Lymantriidae), Figure 24 **Egg (top left) (2x), last instar larva (top right) (1x), pupa (bottom left) (1.7x) and (mating) adult stages (bottom right) (2x) of *Heteronygmia dissimilis*, respectively. Both sexes are represented in the bottom figures, the larger females being above in each picture. (Photo: H. Schabel et al. 1988; reprinted with permission from ICIPE, the International Centre of Insect Physiology and Ecology.)**

days of development. On the average, each female produces about 200 eggs, laid in several batches.

While no field control of *Heteronygmia* has been undertaken to date, a laboratory study documented full protection of *Khaya* leaves from defoliation by *H. dissimilis*, following application of 1% crude, aqueous seed extracts of the neem tree (*Azadirachta indica*).

Numerous arthropod predators of the caterpillars and pupae are believed to be generalists with little impact. On the other hand, four hymenopterous and two dipterous parasites affecting various stages of *H. dissimilis* seem more specific. Seasonally, egg parasites in particular had significant impacts on this insect and in conjunction with the fungus *Paecilomyces farinosus*, which severely decimated pupae during the rainy season, were responsible for serious setbacks in the annual buildup of *H. dissimilis*. As a result, natural controls seem to be quite effective with this insect.

African Maiden Moths (Lepidoptera: Thyretidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

African maiden moths, family Thyretidae, include 212 species, all African. The classification remains controversial and various specialists also place the group within Arctiidae. The family is in the superfamily Noctuoidea, in the section Cossina, subsection Bombycina, of the division Ditrysia. Adults medium-size (23–57 mm wingspan). Haustellum usually reduced or vestigial; antennae pectinate; wings very elongated, with reduced hindwings (some with greatly reduced hindwings). Maculation typically dark with white or hyaline patches, or more colorful. Adults perhaps mostly diurnal; often wasp mimics. Larvae are thought to be leaf feeders, but most species remain unknown biologically. Host plant records include Thymelaeaceae and Ulmaceae, for the few species known biologically.

African Pine-Feeding Grasshoppers, *Plagiotriptus pinivorus* (Descamps) and P. Hippiscus (Gerst.) (Orthoptera: Eumastacidae)

HANS G. SCHABEL
University of Wisconsin, Stevens Point, WI, USA

These grasshoppers are excellent examples of indigenous insects that developed a preference for an exotic plantation-grown crop, in this case pines. *Plagiotriptus pinivorus* attained some prominence after causing persistently severe defoliation of exotic pines, especially *Pinus patula*, in Malawi in the 1960s, resulting in significant tree mortality. A smaller scale defoliation of *P. patula* was observed at Morogoro in Tanzania in the mid-1980s, which was attributable to another, very closely related species, *Plagiotriptus hippiscus*. Both of these grasshoppers are highly polyphagous, including herbaceous hosts, shrubs and both angiosperm and gymnosperm trees. The prime requirement for *P. pinivorus* seems to be access to evergreen or semi-evergreen vegetation in areas of moderate to heavy rainfall, i.e., mostly at altitudes between 1,525–2,135 m, but occasionally as low as 490 m.

Plagiotriptus pinivorus in Malawi exhibits three generations every 2 years, and the complete life cycle takes about 1 year. Nymphs and adults have been observed on pines throughout the year, except from December to late January. Copulation occurs anytime, but peaks from October to January and May to June. During copulation, the small male assumes a characteristic dorso-lateral position by clinging to one of the hind femurs of the female. Both males and females are promiscuous. About 7–20 days after the last mating, females seek bare soil and dig a shallow pit to lay a batch of up to six eggs. They then resume voracious feeding in the trees, before laying other batches of eggs at 17–35 day intervals.

Eggs incubate from 49–248 days, with an average of 115 days. The winter population hatches from April to May, maturing in November, while the summer population hatches from December to January and matures from May to July. Within the same batch, an average of 34 days and a maximum of 88 days may elapse between first and last hatch.

Nymphal peak emergence and rainfall are strongly correlated in February, allowing prediction of emergence two weeks in advance. Another smaller peak in emergence in August, however, cannot be explained by rainfall. The first instar nymph is ephemeral (about 12 h), and will molt immediately when reaching the soil surface, before feeding on ground vegetation for the next 2–3 weeks. Advanced instars complete their life cycle on trees, each instar lasting about one and a half to over two months. Young instars are wasteful feeders. There are generally six instars for males and seven for females. Despite the extra instar, females develop more rapidly and reach adulthood at about the same time as do males.

Adult males (Fig. 25) are about 1.5–2 cm long, moderately robust grasshoppers. Their abdomen, shield-like pronotum and greatly enlarged hind femora are strongly compressed. A minute set of non-functional wings, not found on nymphs, is hidden under the pronotum. The thread-like antennae are about one third the length of the head. The abdomen is strongly reflexed over the back in the male. The insect is largely leaf-green, but sports inconspicuous, small areas of blue, pink, red and white on various parts of the legs, wings, antennae and the pronotal

African Pine-Feeding Grasshoppers, *Plagiotriptus pinivorus* (Descamps) and *P. hippiscus* (Gest.) (Orhthoptera: Eumastacidae), Figure 25 ***Plagiotriptus hippiscus*** **female (above) and male (below) with size comparison (shaded) (drawing, Paul Schroud).**

ridge. Eyes are golden yellow. Females are about twice the size of males, more robust and generally less compressed. They are uniformly leaf-green, except for the golden yellow eyes and valves of the ovipositor. Their wings are also minute and hidden under the pronotal shield.

Numerous invertebrate and vertebrate predators, including skinks, birds and blue monkeys, as well as parasites were documented, but ultimately they were deemed insufficient by themselves to reduce populations of the grasshopper to non-damaging levels. As a result, sticky bands and chemical controls were relied on for monitoring and control purposes, respectively. In the 1960s in Malawi, gamma-BHC at 0.5% proved the most effective insecticide for ground and aerial applications at ultra-low volume formulations. Spraying of road banks was particularly recommended, as insects clustered there for oviposition in the bare ground.

African Primitive Ghost Moths (Lepidoptera: Prototheoridae)

John B. Heppner
Florida State Collection of Arthropods, Gainesville, FL, USA

African primitive ghost moths, family Prototheoridae, comprise 12 species of small moths from South Africa. The family is in the superfamily Hepialoidea, in the infraorder Exoporia. Adults small (18–mm wingspan), with head rough-scaled; haustellum reduced and vestigial mandibles present; labial palpi long and porrect, 3-segmented; maxillary palpi short and 3-segmented; antennae short. Maculation is brown or gray, with various darker spots. Biologies and larvae remain unknown.

African Slug Caterpillar Moths (Lepidoptera: Chrysopolomidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

African slug caterpillar moths, family Chrysopolomidae, are a small African family of about 30 known species. Two subfamilies are known: Ectropinae and Chrysopolominae. The family is in the superfamily Cossoidea (series Limacodiformes) in the section Cossina, subsection Cossina, of the division Ditrysia. Adults medium size (24–52 mm wingspan), with head scaling smooth; haustellum and maxillary palpi absent; antennae short and bipectinate in males. Body robust. Wings rounded and broad (some with irregular distal margins). Maculation mostly pale brown, often with subapical wing line and light discal spot; hindwing with forewing line and coloration continued (Fig. 27). Adults nocturnal as far as is known. Larvae leaf-feeding and slug-like, with small spines; often colorful. Host plants include Celastraceae. No economic species are known.

Agaonidae (Hymenoptera)

HANNAH NADEL
USDA-ARSSan Joaquin Valley Science Center, Parlier, CA, USA

A tropical family of about 750 species of miniscule wasps (order Hymenoptera) that are mutualistically associated with fig plants (*Ficus* spp.). The associations are usually between a unique pair of fig and wasp species and are crucial for the reproduction of both. The winged female wasp enters a young floral receptacle, the flask-like syconium, and lays single eggs in many of the tiny female flowers lining its inner surface. Carrying pollen from her natal fig, she deposits it onto the stigmas during oviposition, ensuring seed production for the fig and food for her own offspring. The syconium will generally not ripen without pollination. The female is trapped inside the syconium and dies there. After the larvae develop and pupate in seed-galls, the wingless adult males emerge first and chew holes into galls to mate with the quiescent females inside, and then cooperatively chew an opening through the syconial wall. The changed atmosphere inside the syconium wakes the females, which chew out of their galls, actively or passively pick up pollen, and leave through the opening. The females of some species actively gather and carry pollen in thoracic pockets or specialized leg structures. The cultivated fig, *Ficus carica*, has many varieties that no longer rely on pollination to produce edible ripe syconia. However, a few varieties still require the pollination service provided by the agaonid partner, *Blastophaga psenes*.

Agathiphagidae

A family of moths (order Lepidoptera). They commonly are known as Kauri moths.

► Kauri Moths
► Butterflies and Moths

Agassiz, Jean Louis Rodolphe

Louis Agassiz was born at Môtier-en-Vuly, Switzerland, on May 28, 1807. He displayed an early interest in natural history. In 1824 he entered Universität Zürich for medical training, then moved to Universität Heidelberg in Germany. In Heidelberg his interest in natural history increased. His next move was to Universität München and, while there in 1829 and still only 21 years old, he published a work on Brazilian fishes, using the collected materials of von Martius and von Spix. His next zoological endeavor was to begin research on fossil fishes. In 1831, he moved to Paris still with the ambition of completing his medical training. However, he spent part of each day studying fossil fishes and he came under the influence of Cuvier and adopted the latter's views of creation. Thus, according to Agassiz, each species was the result of separate creation, not of evolution. In 1832–1846 he was a professor at Université de Neuchâtel, Switzerland. In 1836, Louis began to study glaciers and their effects, on which he published works in 1840, 1846 and 1847. In Switzerland, he also published a large catalog "Nomenclator zoologici" of the names of animals, of which some fascicles were on insects. In 1846 he moved to the USA, was welcomed as a famous scientist, and in 1848 was appointed professor of zoology and geology at Harvard University. At Harvard, he clashed with Asa Gray, professor of botany, about evolution, because Gray supported Darwin's theory. However, it was Louis' efforts and influence that led to the foundation of the Museum of Comparative Zoology at Harvard University, an institution that became very influential in research on insect systematics. He also was a co-founder of the U.S. National Science Foundation. He died in Cambridge, Massachusetts, on December 14, 1873. His son Alexander and two daughters of his first marriage accompanied him to the USA (his first wife having died in Switzerland). Alexander Agassiz (1835–1910) likewise became a zoologist. Louis Agassiz remarried in 1850 in the USA.

Agnathous

This term is used to refer to insects that lack mandibles, which essentially means that they lack mouth structures.

► Mouthparts of Hexapods

Aggressive Mimicry

This is a type of mimicry in which a predator mimics their prey, allowing ready capture and consumption of the victim.

► Mimicry
► Myrmecomorphy
► Myrmecophiles

Agonoxenidae

A family of moths (order Lepidoptera). They commonly are known as palm moths.

► Palm Moths
► Butterflies and Moths

Agricolous

This refers to species that dwell in agricultural habitats.

Agricultural Chemicals

Pesticides, adjuvants, and other chemicals, other than fertilizers, that are used to enhance crop production.

► Insecticides
► Acaricides or Miticides

Agricultural Consultant

Someone trained in the agricultural and management sciences who provides plant and animal production and protection services for a fee. Independent crop consultants sell the advising service only, deriving no income from sale of products, whereas other crop consultants usually derive some income from product sales such as pesticides or fertilizer.

► Careers in Entomology

Agricultural Crop Pests in Southeast Asia Including Southern China

EMMETT R. EASTON
University of Hawaii at Manoa, Honolulu, HI, USA

Southeast Asia is often called the Oriental faunal region and includes the provinces of southern China south of the Yangtse river (Anhui, Fujian, Guangdong, Guangxi, Guizhou, Hainan, Hubei, Hunan, Jiangshu, Jiangxi, Sichuan, Yunnan and Zhejiang) as well as the island of Taiwan, islands and peninsular area of Hong Kong, Macao and those countries to the south including Vietnam, Malaysia, Singapore, Myanmar (Burma), Cambodia and Laos, as well as portions of Pakistan and India. The northern provinces of India share similar faunal elements as southern China as both are at a similar latitude. The insect fauna of northern China is more Palearctic in nature and many of the northern species will differ from those in the southern provinces or elsewhere in Southeast Asia.

Insects of Rice

What are believed to be key pests, or those of major importance as opposed to minor can vary from country to country. In Vietnam and southern China, the rice stemborer complex of lepidopterous insects includes the yellow or small rice borer, *Scirpophaga incertulas* (Wlk), the striped rice-stalk borer, *Chilo suppressalis* (Wlk), the dark-headed rice borer, *C. polychrysus* (Meyr) (all Pyralidae) and the noctuid pink borer, *Sesamia inferens* (Wlk). Although they are considered minor pests in some regions, because the rice plants are able to tolerate some damage and can compensate for light infestations, these insects have been ranked as major pests in the countries of Malaysia and Thailand. The yellow or small rice borer, *Sc. incertulas*, has a wide distribution in Southeast Asia and is found in India, Pakistan, Sri Lanka, Bangladesh, Myanmar (Burma), Vietnam, Singapore, Taiwan and Hong Kong.

The common names of these insects generally refer to the color of the larval stage such as the pink borer, *S. inferens*, with pinkish-colored larvae, or the yellow larvae of the small rice borer. The head capsule in larvae of *C. suppressalis* is brown in color while larvae of *Sc. incertulas* are yellow with brown heads and the pink borer caterpillar, *Sc. inferens*, is pink in color and larger when mature than the other species. The larvae tunnel as caterpillars into the stems of the rice plants. There they feed on the plant tissues and destroy the growing points of the plant causing wilting of new shoots, eventually producing a condition known as "dead heart." In mature plants, empty panicles appear white in color, and the condition is known as "white-head." Masses of eggs are generally laid on the leaves in the case of the female dark-headed borer or striped rice borer. Pupation generally occurs in the stem with these species. The female pyralid moths in the genus *Scirpophaga* have a scale tuft at the tip of their abdomens, while female moths in the genus *Chilo* have no scale tuft at the end of the abdomen. The female *Sc. incertulas* has a yellow forewing, which is whitish in *Sc. nivella*.

The eggs of stemborers are often attacked by the parasitoid wasps *Trichogramma* sp. (Trichogrammatidae) and *Telenomus rowani* (Scelionidae). In Malaysia, granular insecticides have been used to control rice stem borers when the incidence in stems (tillers) exceeds 10%, but this practice is not recommended in southern China or in northern Vietnam where the plants are able to tolerate some damage and compensate for injury.

Rice Leafhopper and Planthopper Complex

The rice leafhopper and planthopper complex includes *Nephotettix virescens* (Dist) and *N. nigropictus* (Stål), the green rice leafhoppers (Hemiptera: Cicadellidae) and *Nilaparvata lugens* (Stål) and the brown plant-hopper (Hemiptera: Delphacidae). These leafhoppers are important in Thailand and Malaysia as well as in India and Pakistan, while the planthopper is more widely distributed and is found in southern China, India, Taiwan, Japan and some of the Pacific Islands. The planthopper is unusual in that it is able to migrate between land masses and migrates from East China to Japan annually. This insect also has migrated to Macao (where rice is no longer grown due to urbanization) from mainland China.

Nephotettix virescens is an important vector of two viral diseases in Malaysia. The first disease is similar to yellow dwarf disease and the second is called Tungro disease. Both cause a stunting of plant growth, the first disease a general yellowing and profusion of tillers, while the second causes a reddening of the leaves. Both diseases decrease crop yield.

The eggs of the rice leafhoppers are laid in rows within leaf-sheaths. The five nymphal stages are completed in 17 days in Malaysia. Leafhoppers generally feed on the upper parts of the plant, while the planthopper, *Nilaparvata*, feeds at the base of the plants near the water line. The brown planthopper is sometimes considered the most serious pest of rice in Asia. They cause a "scorching" of the plants, or a condition known locally as "hopperburn," when the number of nymphs and adults per clump of rice exceeds 900 or more. The eggs are generally laid in plant tissue. The young resemble the parents except for their smaller size and absence of wings. Five nymphal stages generally require two weeks to develop. Predators can include the staphylinid beetle *Paederus fuscipes* and the coccinellid beetle *Harmonia octomaculata*.

In Thailand and Malaysia, another important pest of rice is the rice gall midge, *Orseolia oryzae* (W.-M.) (Diptera: Cecidomyiidae), which is also found in Pakistan, India, Bangladesh, Sri Lanka and parts of Indonesia as well as in southern China, where it is considered of minor importance. The larvae of the fly feed between the leaf sheaths and, when reaching the apical buds, can lacerate tissue and can cause the formation of a gall known locally as a "silver" or onion shoot. The adults are delicate looking midges, long and brown in color with long legs. Upon hatching, the pale, 1 mm long larva grows to 3 mm and becomes reddish in color. The pupa, when formed, is pinkish and turns red with age. Grassy vegetation near the rice fields is often associated with the presence of the midge.

The rice leaf folder, *Cnaphalocrocis medinalis* (Gn), (Lepidoptera: Pyralidae), is considered one of the more important pests of rice in southern China as well as in Malaysia and Thailand. It is also found in India, Pakistan, Sri Lanka and Bangladesh. The larvae fold the leaf while feeding and transparent patches form so that the rice plant appears ragged. The adult moths lay eggs on young, 4 to 6-week-old plants or in nursery stock in Malaysia. Early instar caterpillars feed by scraping the epidermis from rice leaves, while later instar caterpillars fold them. The opposite edges of the leaf, or one edge of the leaf, is attached to the midrib by silken threads produced by the larvae. Pupation occurs inside a silken cocoon within the folded leaf. Parasitoid wasps, such as *Apanteles opacus* (Braconidae) or *Temelucha philippinensis* (Ichneumonidae), often keep populations in check in Malaysia.

The lepidopterous armyworm and cutworm complex, including the rice armyworm, *Mythimna loreyi* (Duponchel), and the rice ear-cutting caterpillar or paddy armyworm, *Mythimna separata* (Wlk), are important pests in Thailand and southern China. The paddy armyworm affects rice in Pakistan, Sri Lanka, India and Bangladesh. The larvae feed on leaves and stems and can defoliate the plants.

The rice skipper, *Parnara guttata* (Bremer & Grey) (Lepidoptera: Hesperiidae), was formerly considered a major pest in southern China, but recent mass production and release of parasitic wasps has probably lowered its status to a minor pest. The larvae roll the apical portion of the leaves, web the sides and cut off the apex, forming long, conspicuous tubes.

Sugar Cane Insects

The lepidopterous sugar cane borer complex in Thailand includes several pyralids including the yellow top or early shoot borer, *Chilo infuscatellus* (Snellen), the sugar cane stem borer, *Chilo sacchariphagus* (Bojer), the white top borer, *Scirpophaga excerptalis* (Walker) and the noctuid sugar cane stalk borer, *Sesamia inferens* (Wlk).

The larvae of these insects bore into the shoots of sugarcane. As the common name suggests, the larvae of the yellow top or early shoot borer tunnel into the growing shoots of the plant, while the larvae of *C. sacchariphagus* bore into the stems. The noctuid moth larvae of purple stalk borer, *Sesamia inferens*, previously discussed as a pest of rice, also affects sugar cane, but sugar cane is not preferred for oviposition as are rice and grasses. The larvae are colored purple to pink dorsally and white ventrally and have a reddish-orange head capsule. The adult moth is fawn-colored with dark brown streaks on its forewings and whitish hindwings.

In Malaysia, the white sugar cane aphid, *Ceratovacuna lanigera* Zehntner, a mealybug-like insect (Hemiptera), causes injury. The non-winged females and nymphs are covered by a waxy layer, while the winged adults are bluish-green in color and are not covered with a layer of wax.

Fruit Tree Insects: Mango-Citrus-Banana-Litchi

One of the most important fruit tree insects is considered to be the Oriental fruit fly, *Batrocera dorsalis* Hendel (Tephritidae). It is found in Hawaii as well as in other Pacific islands and the southeast Asian countries of Thailand and Malaysia where it is a serious mango pest. In southern China, where there are fewer mangoes grown, it is considered a minor pest. In addition to mangoes, the guava and carambola are affected in Malaysia. The larvae or fly maggots feeding inside the skin of the fruit cause it to decay. Female flies puncture the skin of the fruit with their ovipositors, laying several eggs inside. The larvae can hatch in one day and develop through three instars in about a week. When mature, they are able to leave the fruit by "flipping" themselves in the air and dispersing to enter the ground to pupate. Fruits can be protected from these flies by bagging them using paper bags. The use of traps treated with methyl eugenol as an attractant has met with some success, but as only the males are attracted, it is not totally effective as a control.

In Malaysia, a longhorn beetle known as the mango shoot borer, *Rhytidodera stimulans* (White), tunnels into the young growing shoots of the tree. Eventually it kills the outer branches, which often break off during subsequent wind storms. In southern China, the citrus long-horn beetle, *Anoplophora chinensis* (Forst.) (Cerambycidae), is considered one of the most important pests of citrus trees. The larvae of these beetles tunnel under the bark of young trees and sometimes into the heartwood, which can cause the death of the plants. The adult beetles have striking black and white body coloration. Parasitoid wasps have difficulty reaching the larvae that bore into young healthy trees.

Butterflies (Lepidoptera) are not considered to be serious pests of agricultural crops in the northern hemisphere with the exception of the small white, *Pieris rapae*. However, in the semi and tropical regions of the world, cold climatic conditions are not as severe and the insects often do not have to enter diapause (hibernation), so there can be continuous generations in some regions almost throughout the year. Papilionid butterflies, as well as several species of skippers (Hesperiidae), cause injury to plants because they are able to oviposit in both the spring and the fall.

In Southeast Asia, the lemon or lime butterfly, *Papilio demoleus* (L.), and another species known by the common names of the common Mormon swallowtail or the white-banded swallowtail, *Papilio polytes* L., lay their eggs on the undersides of leaves of citrus plants and are considered important in southern China as pests of citrus. Another species, *Papilio xuthus* L., is also becoming increasingly important, particularly in the Pacific island area. The first instar in these Papilionid butterflies are colored differently than older larvae, which may be an adaptation that protects them from predators such as birds or lizards. The early stage larva resembles a bird or lizard dropping as it is dark brown in color with white markings that may appear to be unappetizing to the predator. When the caterpillar is older, its color changes to green with grey and white markings. Hand picking the larvae is probably an adequate control in young plants.

The orange spiny whitefly, *Aleurocanthus spinifera* (Quaintance) (Hemiptera: Aleyrodidae), is an important insect in southern China as well as India, Sri Lanka, Bangladesh, Malaysia and Thailand. The adults are l mm in length and lay eggs on the undersides of leaves. There are three nymphal stages and the third-stage nymph appears blackish in color with waxy secretions on the outer edge of the body so it looks superficially like an insect pupa. Both the nymphs and the adults remove plant nutrients when feeding, and the honeydew produced by the nymphs encourages a sooty mold to grow on the upper surfaces of the leaves and the fruits. Heavy infestations of this insect cause fruit production to fall off. A parasitic wasp, *Eretmocerus serius* (Aphelinidae), has been effective in regulating the orange spiny whitefly in Malaysia.

Aphids, such as the black citrus aphid, *Toxoptera aurantii* (Bayer de Fonscolombe), and the brown citrus aphid, *Toxoptera citricida* (Kirkaldy), are important in southern China and also range into India, Sri Lanka and Bangladesh.

Fruit-piercing moths, such as *Othreis fullonia* (Cl.) (Noctuidae), pierce the ripening fruits of citrus, mango, papaya and guava or banana in order to obtain sap. A short, stout proboscis with a barbed tip enables the moth to puncture the skin of the fruit and can permit the entry of plant pathogens such as viruses or secondary rots that can cause premature fruit drop. Fruit-piercing moths are considered of major importance today in southern China. Management of their populations is difficult as the immature of *O. fullonia* do not feed on citrus trees. Instead, the caterpillars feed on the foliage of the *Erythrina* species of shade trees. On the Pacific island of Guam, the eggs can be laid on the foliage all year round and the insects are considered to be major pests as they feed on ripe banana, mango, papaya, pomegranate and guava as well as tough-skinned citrus fruits.

On banana plants, there are two species of leaf rollers or banana skippers in Southeast Asia, one of which is *Erionota thrax* (Hesperiidae), which rolls the banana leaves in Malaysia, Thailand and in southern China. The caterpillars cut and roll strips of banana leaf, then hide in the roll that is held together by silken threads. They emerge at night to feed and are often covered with a white powdery secretion.

Litchi and Longan Fruit Insects

The litchie stink bug, *Tessaratoma papillosa* (Drury) (Hemiptera: Tessaratomidae), has been considered the most important pest of litchi (*Litchi chinensis*) and longan (*Euphoria longan*) fruit trees in the Guangdong region of southern China, including Hong Kong and Macao as well as Vietnam and Thailand. The adults are mostly brown dorsally and whitish underneath. Immature bugs, more brightly colored than the adults, have red markings dorsally often with a white waxy secretion underneath. Plant sap is taken from the stems of fruit trees. The saliva of the bug can stain the clothing of fruit tree workers. Also, the fluid is extremely irritable if it gets in the eyes. An effective biological control of the litchie stink bug has been developed in southern China by the Guangdong Entomological Institute in which the egg parasitic wasp, *Anastatus japonicus* (Eupelmidae), has been mass-reared and released to achieve control in the Fujian, Guangdong and Guangzi provinces. Biological control of the litchie stink bug has also been reported from the northern highlands of Thailand.

Vegetable Insects

The diamondback moth, *Plutella xylostella* (L.) (Lepidoptera: Plutellidae), is currently considered among the top 25 most important arthropod pests in southern China. It was the first agricultural pest in Malaysia to be reported resistant to pesticides, and it is also an important pest in Thailand as well as in India. Its distribution has been considered cosmopolitan. Cruciferous plants, such as the cabbages, are affected. The caterpillars penetrate the epidermis of leaves, mining the tissue and making windows or holes in it. The adult is recognized by the pale triangular or diamond-shaped marks seen on the midline of the back when the wings are closed.

The caterpillar is pale green in color, and it wriggles violently when disturbed, sometimes falling off the edge of the leaf. A microbial insecticide, *Bacillus thuringiensis*, is effective in the control of the diamondback moth, but farmers in some areas of Malaysia have not accepted it because this method takes longer to kill the caterpillars than other insecticides.

The green stink bug, *Nezara viridula* (L.) (Hemiptera: Pentatomidae), is a cosmopolitan insect in Southeast Asia that damages developing vegetables, such as potato, sweet potato, tomato and cotton, by their feeding punctures. Three color varieties or subspecies of this insect are recognized in southern China. An all-green form, known as *N. viridula smaragdula*, is the most common, accounting for 75–80% of vegetable bugs observed in Macao in l996. A second form with yellow on the head and pronotum, *N. viridula torquata*, makes up about 10% of the stink bug population, while the least common form is mostly all yellow with green spotting on the hemelytra and abdomen, and is called *N. viridula aurantiaca* (1.0%).

The small white butterfly, *Pieris rapae* (L.) (Lepidoptera: Pieridae), along with two other species, is still considered important in southern China and Southeast Asia. The small cabbage butterfly, *Pieris canidia* (Sparrman), also damages nasturtium. In both species, larvae feed singly in the cabbage heart, make holes in the leaves and cause frass accumulation. The insects are also found in India, Taiwan and the

Philippines, and breeding can be continuous with up to eight generations annually, which is not the case in northerly regions, where overwintering occurs in the pupal stage.

The Asian corn borer, *Ostrinia furnacalis* (Guenee) (Lepidoptera: Pyralidae, Pyraustinae), is more important in the northern countries of Southeast Asia including southern China where corn is grown. The Guangdong Entomological Institute rates it as a highly important pest there. The larvae bore into the stalks and the ears of corn, and can also survive on foxtail millet, *Setaria italica*, and on *Panicum* grasses. The eggs are laid in clusters of 10–40 underneath leaves about a week before the plant forms its inflorescence. The young larvae can scarify the leaves and later, bore into the stem. Pupation generally occurs within the stalk, but can occur within the ear. The Asian corn borer's range includes India, Sri Lanka, Korea, China, Hong Kong, Taiwan, Vietnam, Japan, Malaysia, Thailand, Singapore and Indonesia.

Agroecology

ROBERT MCSORLEY
University of Florida, Gainesville, FL, USA

Agroecology is the application of ecological principles to agricultural production systems and the resources needed to sustain them. A convenient unit of study is the agroecosystem, often a single agricultural field. A major difference between an agroecosystem and a natural ecosystem is in the level of human intervention and management involved. Like natural ecosystems, agroecosystems consist of living (biological) and nonliving (chemical, physical) portions. The science of agroecology examines the living organisms (collectively called the community) in the system, their interactions with one another, and the environmental factors that influence them.

Nutrient Cycling

The organisms within an ecological community depend on one another for energy and materials. Green plants are referred to as producers since they are at the base of the food chain in ecosystems. Initially, carbon and energy are stored in plant tissues through the process of photosynthesis. Consumers must obtain their carbon and energy by eating plants or other organisms. Therefore carbon and other materials move from green plants to herbivores to carnivores, including predators and parasites. The different levels of energy production and consumption (producers, herbivores, predators) are called trophic levels, although in reality many organisms do not restrict their feeding to one level. For instance, some Hymenoptera that are parasitoids as larvae may feed on pollen or nectar as adults. As a result, the paths along which materials move through the organisms in the community can be quite complicated, and collectively they make up the food web within the community.

Many nutrients, including nitrogen, phosphorus, potassium, and other elements, are essential components of plant and animal tissues. These nutrients have distinct cycles in ecosystems, and they cycle in food webs along with carbon and other materials. Nutrients are released into the soil during decomposition of organic molecules, where they are converted into forms that can be taken up by plant roots, completing the nutrient cycle. Microarthropods such as mites and springtails are particularly important in the decomposition process.

Cropping Systems

Crop performance depends on a range of key resources including nutrients, water, soils, and other environmental factors, and many agricultural management practices are aimed at optimizing and conserving these resources. Various types of cropping systems may be selected to address specific goals or conservation issues. Conservation tillage and other reduced tillage practices are important for soil conservation and reduction of erosion. The crop residues that remain on the soil surface in uncultivated sites can also aid in conservation of water and organic matter, and may provide some nutrients when they decompose (Fig. 28). Monoculture allows a grower to specialize by growing only one crop, while polyculture permits a grower to diversify by growing multiple crops on the same land. Multiple cropping on the same site may occur at the same time or over time. In the United States, the most common form of multiple cropping is crop rotation, in which different crops are grown on the same site in different seasons or years. Cover crops are crops with limited market value that are grown on the site during seasons that are unfavorable for growing the main economic crops for the region. In the southeastern United States for example, a winter cover crop of rye (*Secale cereale*) or crimson clover (*Trifolium incarnatum*) may be grown in a field reserved for cotton or peanut production during the summer. Cover crops can provide various advantages, including erosion reduction, increased supply of nitrogen, competition with weeds, or hay for animals. Green manures, which are usually legume cover crops, are grown specifically for their nitrogen-rich residues and soil fertility benefits. Intercropping, or mixed cropping (Fig. 29), refers to the growing of two or more crops at the same time on the same land. The practice is quite common in some regions, and many variations exist. Some tropical subsistence intercropping systems are especially diverse and complicated.

Pest Management

The cropping system used has a direct effect on pest management, which is an important aspect of agroecology. For example, monoculture may encourage buildup of some pests, such as corn rootworms (*Diabrotica* spp.) or wireworms (Elateridae), that can be managed by appropriate crop rotation. In many cases, the use of intercropping has resulted in less severe pest outbreaks and increased diversity of natural enemies compared to monocultured systems.

Tritrophic (plant-herbivore-predator) interactions and the structure of the food web may be affected by changes in the cropping system, such as use of an intercrop, or changes in crop variety or fertility level. The development and use of biologically based pest management tactics such as use of natural enemies or resistant varieties require a detailed knowledge of pest biology and ecology, including life cycle, population dynamics, and interactions with the physical and biological environment, including potential competitors, predators, and parasites. Such tactics may be directed toward preventing pest buildup rather than reacting to high pest numbers already present in crisis situations. However, the design of a system in which pest numbers are less likely to reach crisis levels, due to the presence of effective natural enemies for example, requires advanced planning based on sound ecological data.

Landscape Ecology

An individual agroecosystem does not stand alone, since organisms, materials, and energy move freely in and out of the system. Landscape ecology examines the agroecosystem in the context of the surrounding region or landscape, an essential

Agroecology, Figure 28 Residues from a previous rye crop cover the soil surface between plant rows in this conservation tillage system.

approach in dealing with migrating insects or regulated pests. The condition of field borders, hedgerows, and adjacent fields critically affects pest management within a specific field. Movement of pesticides, fertilizers, and other potential pollutants from the agroecosystem to natural ecosystems is a major environmental concern.

Many natural ecosystems are highly dependent on recycling, since cycles of nutrients, water, and other materials tend to be relatively closed. In contrast, an agroecosystem is not a closed system, because its purpose is to produce harvest for export to other ecosystems. This process depletes essential resources from the agroecosystem

Agroecology, Figure 29 One of the simplest forms of intercropping is to use one crop as a windbreak, like the sugarcane planted along with the eggplant crop shown here.

which must be restored if the system is to remain productive. The movement of essential resources into the agroecosystem and the recycling of existing resources are therefore critical concerns, to anticipate and ensure that supplies of critical resources for agricultural production will be conserved over time to sustain future agricultural production.

Defensive behavior that also serves as an alarm signaling mechanism.

Air Sacs

The trachea of insects are sometimes dilated or expanded to form pouch-like structures called air sacs. Their occurrence varies among taxa, but their presence lowers specific gravity and enhances air exchange, thus enhancing flight.

Alarm Pheromones of Insects

EMMA NAPPER, JOHN. A. PICKETT
Rothamsted, Harpenden, Hertfordshire, UK

Alarm pheromones are defined as chemical substances, produced and released by an organism, that warn or alert another of the same species of impending danger. This is exemplified by many species of aphids (Hemiptera: Aphididae) in which the pheromone is caused to be released by attack, for example, by predators, with ensuing dispersal by which individual aphids may avoid a subsequent attack. However, the term alarm pheromone also is employed when the responding individuals are stimulated to show aggression towards the attacking agent. This is common in the social Hymenoptera; for example, the honeybee, *Apis mellifera* (Hymenoptera: Apidae), and many ant species respond aggressively to their alarm pheromones.

As alarm pheromones can benefit the survival of members of the species involved, it is common for insects that employ alarm pheromones to live in congregations for some or all of their life cycle. In the case of social Hymenoptera, the colony is genetically related, and in asexually reproducing aphids, the colony is clonal. Although the survival of siblings or clones by alarm pheromone response at the cost of the attacked individual appears altruistic, in genetically related colonies, genes from the individual will predominate in the survivors and be passed on to their kin.

Hemipteran Alarm Pheromones

Alarm Pheromones of Aphids (Hemiptera: Aphididae)

When disturbed or attacked, many aphid species release alarm pheromone from droplets secreted from tube-like structures called cornicles on their dorsal posterior. This phenomenon has been studied exclusively in the asexual forms and most often in asexually reproducing wingless females. Aphids nearby exhibit a variety of behaviors ranging from stopping feeding and moving away, to running or dropping off the plant and even attacking the predator. However, not all aphids in a group respond. The relative risks of predation and costs of escape, for example, cessation of feeding and risk of desiccation, affect the likelihood of any particular response. In studies of the peach-potato aphid, *Myzus persicae*, the pea aphid, *Acyrthosiphon pisum*, and the rose-grain aphid, *Metopolophium dirhodum*, early stages were found to be less sensitive to alarm pheromone than later ones.

However, older wingless *M. persicae* require the greatest stimulation of alarm pheromone before responding, while winged *M. persicae*, particularly those not feeding, are extremely sensitive to alarm pheromone. The lack of response from the early stages suggests that the risk of predation to these nymphs is lower than the risk involved in ceasing to feed and dropping from the plant. When young *M. dirhodum* respond to alarm pheromone, they do so by moving to another part of the plant rather than by dropping. Winged adults, on the other hand, are more responsive to alarm pheromone, perhaps because they can more readily move off the host. The sugarcane woolly aphid, *Ceratovacuna lanigera*, also shows different reactions to alarm pheromones at different life stages; it shows attack behavior until adult, when the normal aphid dispersal response takes over.

Considerable variation is seen between aphid species in their sensitivity to alarm pheromones and in both the speed and the form of the response. This variation often can be explained by differences in the ecology of the species. Some aphids, particularly those tended by ants, stay on the plant and respond by walking or "waggling" their abdomens rather than falling off the plant. These aphids appear to depend more on the protection afforded by their ant attendants than their own defensive mechanisms. Aphids that walk away from a source of alarm pheromone tend to form new clusters a short distance from the original site, thus ensuring continued ant attendance.

Susceptibility to insecticide also has been found to correlate with responses to alarm pheromone. Susceptible strains produce more pheromone and respond more quickly and in higher numbers than insecticide-resistant strains. In addition, clones collected from around the world showing knockdown resistance to pyrethroid insecticides, and esterase-based insecticide resistance, showed lower levels of disturbance to the synthetic alarm pheromone. These aphids may therefore suffer increased predation or parasitism in the absence of insecticides, affecting the evolutionary fitness of insecticide resistant clones. This may be due to physiological effects associated with resistance, which could affect mobility or sensitivity of the nervous system to stimuli.

Aphids that have dropped from a plant may re-colonize or may move to another host plant further away. The turnip aphid, *Lipaphis erysimi*, and *M. persicae* dislodged by alarm pheromone are less likely to return to the original host plant than when mechanically dislodged. Similar patterns of behavior are found in *A. pisum*. Aphids dislodged by a predator or experimentally with synthetic alarm pheromone spend longer "running" before the "search" for a host plant began, whereas aphids dislodged mechanically are more likely to begin to search for a host plant immediately.

Droplets secreted from the cornicles comprise two types of material: a volatile, rapidly vaporizing fraction which is the alarm pheromone, and a waxy fraction, consisting mainly of triglycerides, that crystallizes on contact with foreign particles outside of the aphid's body. The waxy component appears to function as a sticky or quick-setting irritant to predators and parasitoids and a releasing substrate for the alarm pheromone component.

The main component of the alarm pheromone (Fig. 30) of many aphids is the sesquiterpene hydrocarbon (E)-β -farnesene (**1**). Other components may also be present as found in the alarm pheromone blend of the vetch aphid, *Megoura viciae*, which contains the monoterpenes (-)-α -pinene, (-)-β -pinene, (Z,E)-α -farnesene and (E,E)-α -farnesene, in addition to (E)-β -farnesene. There is a high degree of cross-activity of both natural alarm pheromone and (E)-β -farnesene among species within the aphid subfamilies, Aphidinae and Chaitophorinae. This is typical of insect alarm pheromones in general, since such cross-activity does not reduce their evolutionary value. However, the main component of the alarm pheromone of the spotted alfalfa aphid, *Therioaphis maculata*, and the sweet clover aphid, *T. riehmi*, in the Drepanosiphinae, is the cyclic sesquiterpene (-)-germacrene-A (**2**).

In the turnip aphid, *L. erysimi*, it has been demonstrated that isothiocyanates, acquired from chemicals in the host plants, synergize the effect of the alarm pheromone. These isothiocyanates are likely to be released from aphid honeydew so that, when there is a high number of other aphids in the immediate vicinity, the percentage of aphids responding to alarm pheromone increases.

Alarm Pheromones of True Bugs (Hemiptera, Heteroptera)

The Pentatomidae is the dominant family of stinkbugs, or shield bugs. The family comprises many species that are pests of economic importance, especially in warmer climates. These insects secrete a complex mixture of chemicals when strongly molested. The energetic cost of the defense response, especially production of defense chemicals, is significant and considerable provocation usually is required to cause release. In adults, the source of the defense compounds is the metathoracic gland, while in nymphs it is the dorsal abdominal glands. These are precursors to the metathoracic gland in adults and perform the same defense function. The chemical content of these secretions is similar throughout the order; for example, the components of the secretion of the stinkbug *Cosmopepla bimaculata* are a complex mixture of hydrocarbons, aldehydes and esters. The secretion, which can be ejected from either or both metathoracic glands in controlled amounts or even resorbed, displays a defensive function as a predator repellent. In one case, researchers have shown uncommon dedication in describing the repellency by squeezing adults in their mouths and chewing nymphs. The effects were a burning sensation and numbness of the tongue for up to two hours. In addition to repelling predators, the secretions possess alarm pheromone activity and cause adults to drop off plants. In the field, *C. bimaculata* are found highly clumped and the occurrence of large

numbers living together gives an evolutionary advantage to possessing an alarm pheromone.

Six-carbon-long aldehydes, in particular (E)-2-hexenal, are common components of defensive secretions and are found in many families of heteropterous insects, including the Pentatomidae, Coreidae, Pyrrhocoridae, Cimicidae, Cynidae and Alydidae. it is thought that the general irritant properties of aldehydes provide a repellent effect to predators with hydrocarbons such as n-tridecane, another ubiquitous component, acting to spread the oily secretion so that the aldehydic components can exert full irritant effect. (E)-2-Hexenal has been reported to have the added dual functions of both alarm and aggregation pheromone, depending on the stimulus concentration, as well as use as a defense chemical. In the case of the bed bug, *Cimex lectularius*, and *Eurydema rugosa*, low concentration of (E)-2-hexenal acts as an aggregation pheromone while high concentration produces an alarm response. Alternatively, it has been reported that n-tridecane, the other

ubiquitous component of defense secretions, is a bifunctional pheromone for the southern green stinkbug, *Nezara viridula* (Heteroptera: Pentatomidae), which causes dispersal at high concentration (one individual equivalent) and aggregation at low concentrations. The multifunctional aspect of these compounds has important repercussions for their practical use as dispersal agents for pest species in the field, as the low concentration response of aggregation may dominate once the applied high concentration of compounds has diminished.

The pentatomid bug *Erthesina fullo* is a major pest of pine and hardwood trees. Both sexes produce a secretion from the metathoracic gland causing conspecific adults to drop from plants, fly or move away. The secretion comprises nine identified compounds, esters and aldehydes (about 35%) including (E)-2-hexenal and (E)-4-oxo-2-hexenal (**3**) and long chain alkanes, including 50% n-tridecane. Likewise, adult and nymph secretions from *Dysdercus cingulatus* (Heteroptera: Pyrrhocoridae) revealed 55 identified compounds, although the major components are again aldehydes and n-tridecane, features common with several more species of pentatomids from the genus *Chlorochroa* and *Piezodorus guildinii*.

The leaf-footed bug, *Leptoglossus zonatus* (Heteroptera: Coreidae), is an economically important pest of Brazilian corn. An extract obtained from the metathoracic gland by immersion in hexane showed that the major compounds were all of six-carbon length: hexanal, hexanol, hexyl acetate, hexanoic acid, and (E)-**4**-oxo-2-hexenal (**3**). (E)-2-Hexenal was found in the nymph extracts but not in the adult, an example of the general rule that exocrine chemistry of heteropterous nymphs is distinct from that of the adult. In this case, different life-stages possess different alarm pheromone systems. When tested individually, all components produced varying degrees of alarm response in adults and nymphs and even mating insects would stop and disperse, over-riding the sex pheromone response. These compounds are not species specific and are, for instance, found in *L. oppositus* and *L. clypealis*, a situation that mirrors the cross-activity of (E)-β-farnesene in many aphid species (see above), providing more evidence that this non-specific activity does not reduce alarm pheromone value in evolutionary terms.

Adults of the bean bug, *Riptortus clavatus* (Heteroptera: Alydidae), a pest of Japanese soybean, secrete (*E*)-2-hexenyl acetate in its defensive response. This causes an alarm response in adults and nymphs. Interestingly, adults also produce (E)-2-hexenal, and although some response was found when tested at high concentration, there was no response at physiological concentration, suggesting that this compound is not an alarm pheromone.

The examples shown above demonstrate that alarm pheromones of heteropteran families are based on a chemical selection general to insects of a wide taxonomy and show little species specificity. The alarm behavior caused by high concentrations of n-tridecane or (E)-2-hexenal is rationalized easily but the aggregation due to low concentrations is more difficult to explain. Perhaps these substances are constantly emitted in very small quantities due to their volatility and act so as to direct individuals to a region where conspecifics can be found and therefore where food most probably is located, as well as the defensive advantage in being part of a large group.

Triatomine bugs (Heteroptera: Reduviidae) are blood-sucking insects that live throughout the Americas and cause public health problems by transmitting the protozoa *Trypanosoma cruzi*, the causative agent of Chagas disease, to humans. Secretions from Brindley's gland (a simple sac, metathoracic in origin) of several species all revealed isobutyric acid as the major component. Subsequently, other short-chain and branched-chain fatty acids have been identified, and together with isobutyric acid, they act as a powerful defensive secretion. Pure isobutyric acid vapor, however, also caused an alarm response in *Rhodnius prolixus* while another report revealed that low concentrations of isobutyric acid attracted *R. prolixus* adults. This defense compound therefore shows the same multifunctional alarm and aggregation properties as described for components of the stinkbug secretions (see above). Triatomine bugs are inactive and hide during the day, congregating in protective sites. This aspect of group living can help explain the evolutionary advantage in possessing aggregation and alarm responses.

Alarm Pheromones of Social Insects (Hymenoptera)

The Honeybee (Hymenoptera: Apidae)

When the honeybee (*Apis mellifera*) is attacked, alarm pheromones released serve to muster help and to direct the attack. Specialized guard bees present at the nest entrance carry out attacks. Although these guards are relatively few compared to the colony population, release of alarm pheromone can result in synchronized attacks by more than 100 workers against an intruder. Guard bees initiate attacks by raising their abdomens, protruding their stings and releasing alarm pheromone from the sting chamber. The workers then alert the rest of the hive by wing beating, aiding dispersal of the pheromone, and by running into the hive. After a few seconds, many excited bees may rush out of the hive entrance and search, or stop and assume a characteristic tense and aggressive posture with a slightly raised body, wings extended, mandibles agape and antennae waving. In this highly activated state, they will fly to attack at the slightest further provocation. These two stages of alarm response are called alerting and activation and are characteristic of alarm pheromones.

Alerted workers need to search for and discover the enemy to prevent any further threat. To do this, they rely on other cues to direct the attack such as odor, jerky movement and hairy body covering. Once the threat is located, it is stung, injecting a dose of venom. However, the shaft of a sting is barbed and a bee is unable to withdraw it from the skin of vertebrates, so the sting, together with associated motor apparatus and glands, are severed from the bee as it attempts to fly away and are left attached to the enemy. The severed sting apparatus continues to pump venom into the victim and alarm pheromone is dispersed from the exposed under-surface of the sting shaft membrane to mark an enemy and make it a more obvious target.

The main alarm pheromone component of the sting gland was identified in 1962 as isopentyl acetate (**4**). Although a number of other compounds are known to be present, isopentyl acetate and (Z)-11-eicosen-1-ol (**5**) account fully for the activity of the sting pheromone. The roles of the two compounds in the pheromone appear to differ, with (Z)-11-eicosen-1-ol responsible for prolonging the activity of isopentyl acetate. Other compounds such as 1-hexanol and 1-butanol increase the number of bees responding.

Stinging bees often grip an enemy with their mandibles and deposit an alarm substance. At the hive entrance, more bees examine mandibular gland extracts of worker honeybees applied to filter paper than examined unscented filter paper. 2-Heptanone (**6**) has been identified from the mandibular gland secretion, and when filter papers or small corks carrying 2-heptanone were placed at the hive entrance, the guard bees were alerted and attacked them. As the mandibles are used for grasping an intruder, it seems likely that the main function of 2-heptanone is to label the intruder to be attacked.

Under certain circumstances, honeybee alarm pheromones are repellent. The presence of alarm pheromone deters honeybees from foraging at dishes of sugar syrup and from exposing their Nasonov glands and fanning which normally attracts other bees. Furthermore, a high concentration of alarm pheromone repelled foraging bees from crops including oilseed rape, normally highly attractive to bees, in an area that had many honeybee colonies.

Alarm Pheromones of Ants (Hymenoptera: Formicidae)

The Formicidae is a huge family comprising thousands of ant species, all of which are social insects, living in colonies that vary hugely in size. Members of an ant colony may be differentiated into castes that specialize in carrying out particular tasks and vary in their response to alarm pheromone. Soldiers show a more aggressive response, are more likely to respond when the threat is closer to the nest and may be specialized to deal with vertebrate predators. Also, workers of the Texas leaf-cutting ant, *Atta texana* (Formicidae: Myrmicinae), have a lower threshold for alarm pheromone response than the queen and males. Other factors governing the type and intensity of alarm response are the age and size of ant colony. When alarm pheromone is present in sufficient concentration to excite the workers, other stimuli are needed to direct an attack. Workers often will touch everything they encounter and the full-scale alarm response may rely on additional cues, such as the presence of an alien object. Alarm pheromones also may function with acoustic alarm signals. Ant species in the sub-family Dolichoderinae produce vibration signals using their mandibles to scratch the ground or the abdomen to hit the ground, increasing alarm behavior in other workers. Vibrations are produced also by leaf-cutting ants which act as warning signals. Alarm pheromones also are used by ants to attract attention if they are trapped, and may be released by reproductive ants just before mating flights to ensure that aggressive workers protect them from potential predators.

The context in which a worker encounters an alarm pheromone also influences the response. Workers of the grass-cutting ant *Atta capiguara* (Formicidae: Myrmicinae) are less likely to show alarm behavior if already engaged in a task. Foragers carrying leaves do not respond to alarm pheromone, whereas minor workers and foragers that are not carrying leaves do respond.

Ant alarm pheromones may be produced from one or several sources. The army ants or Eciton ants (Formicidae: Ecitoninae) and the rare *Leptanilla* sp. (Formicidae: Leptanillinae) of Indonesia have large mandibular glands, which are believed to be the sole source of the alarm pheromone. However, other species rely on a combination of secretions from several glands. *Formica* and *Myrmica* species use products from the poison and Dufour's gland (both opening near the base of the sting), as well as the mandibular gland. Ponerine ants (Formicidae: Ponerinae) use secretions from the pygidial gland as alarm components, whereas the poison gland is the most important gland of several other species, including the harvester ant, *Messor barbarus* (Formicidae: Myrmicinae).

Ants are able to detect and respond to specific isomers of their alarm pheromone. *Myrmica rubra* and *M. scabrinodis* use 3-octanol (**7**) as the alarm pheromone produced from mandibular glands. Experiments carried out using the two optical isomers (**8a, b**) of this compound showed that *M. rubra* workers only responded to one of the isomers, (*R*)-3-octanol (**8a**), while *M. scabrinodis* workers reacted more strongly to the natural 9:1 mixture of R and S isomers. This work suggests that there may not only be specific chemicals but also species-specific mixtures of isomers. Many other *Myrmica* species have 3-octanol and 3-octanone as alarm pheromones but may have species-specific ratios of the two, which allow ant species to only show a full alarm reaction to their specific alarm pheromone blend.

Myrmica species of grass-cutting ants share the main component of alarm pheromone, 4-methyl-3-heptanone (**9**), but they have species-specific modifying components. The response to 4-methyl-3- heptanone was compared to that elicited by the bodies of workers that had their heads crushed to release the natural alarm pheromone. 4-Methyl-3-heptanone and bodies caused the same level of attraction but the full range of alarm behavior was seen only with the bodies. In contrast, workers of the giant tropical ant, *Paraponara clavata* (Formicidae: Paraponera), produce two components, 4-methyl-3-heptanone and 4-methyl-3-heptanol.

Atta capiguara is a grass-cutting ant species that lives in colonies with hundreds of thousands of workers. Workers are polymorphic, varying in size from small minors and medias to the larger foragers and soldiers. Minors and medias do most of the nest tasks whereas foragers collect the grass; however, minors often are found on foraging trails despite the fact they do not carry grass. They are believed to be patrollers as they have a stronger response to alarm pheromone than foragers and soldiers. Minors of other *Atta* species are also more efficient at recognizing intruding ants than other castes.

As is the case with honeybees described above, the complete alarm response can be described by a number of behaviors. These behaviors and their elicitors have been dissected in an elegant piece of research on the African weaver ant, *Oecophylla longinoda*. The major workers produce a secretion from the mandibular gland comprising four active components: hexanal, hexanol, (*E*)-2-butyl-2-octenal (**10**), a dimer of hexanal produced chemically by self-condensation, and 3-undecanone (**11**). Hexanal, a highly volatile component with an active space of 5–10 cm (the area around an emission where the concentration is at or above that required for a behavioral response), causes the ants to be alerted, making quick runs in random and changing direction with mandibles open and antennae waving. Hexanol attracts directly to the source at a range of 1–5 cm; it is repellent at very close range and also causes further excitement. As the hexanol disperses, 3-undecanone is attractive over this close range and, along with (*E*)-2-butyl-2-octenal, acts as a marker for attack and biting to hold the source occurs. This process is called a local attack. In addition, *O. longinoda* also has a mass attack alarm response. The poison gland of the major and minor workers contains venom that is ejected by raising the gasters above vertical when an attacked object is held in the jaws. The venom contains a blend of straight chain hydrocarbons and formic acid. Formic acid initiates approach and attack while n-undecane causes mandible opening, gaster raising and also short-range approach to the source. The combination of these behaviors allows location and initial attack of still and moving objects followed by recruitment of workers to continue attack.

The properties that make alarm pheromone cues for conspecifics also enable them to act as cues for parasites and predators of ants to find their prey. *Apocephalus paraponerae* is a parasitic fly that attacks the ant *Paraponera clavata*. Females and males of *A. paraponerae* are attracted to injured, fighting or freshly killed workers. After finding a worker, the female lays a few eggs, which will hatch and then feed on the victim for 3–7 days. Both male and female *A. paraponerae* also feed on the wounds of the injured workers and gather near their victims to mate. The heads of *P. clavata* workers contain two chemicals, 4-methyl-3-heptanone and 4-methyl-3-heptanol, which are particularly attractive to *A. paraponerae*. These compounds are common alarm pheromone components of ants and are released when the workers are stressed. However, it has been suggested that because these parasites use alarm pheromone for finding their host, *P. clavata* may be under pressure to reduce the amount of alarm pheromone released and that this ant may even have lost alarm behavior response as a result of this pressure. Similarly, the zodariid spider, *Habronestes bradleyi* (Zodariidae), a predator of the meat ant, *Iridomyrmex purpureus*, detects the alarm pheromone, in this case 6-methyl-5-hepten-2-one (**12**), given out by fighting workers and uses it to locate its prey.

Alarm Pheromones of Thrips (Thysanoptera: Thripidae)

Thrips are small, economically important pest insects, often known as thunderflies. The defensive behavior of thrips includes raising and lowering the abdomen and secretion of a droplet of anal fluid highly repellent to predatory ants. Western flower thrips, *Frankliniella occidentalis* (Thysanoptera: Thripidae), are not social but tend to be found in clumped distributions. Adults and nymphs of western flower thrips produce an anal droplet containing decyl acetate and dodecyl acetate (**13**) in a molar ratio of 1.5:1. Each component, at levels of 1 ng, produces the alarm response of walking away from the source or dropping from leaves. The response, however, is only over short distances and limits the potential for pheromone use in pest management.

Cockroach Alarm Pheromones (Blattodea: Blattidae)

Defensive secretions are well known in cockroaches. They are produced from ventral inter-segmental glands and comprise an organic and an aqueous phase. In the case of the Florida woods cockroach, *Eurycotis floridana* (Dictyoptera: Blattidae), 90% of the organic phase (which comprises 85% of the total secretion) is (E)-2-hexenal, a compound found in many heteropteran bugs and discussed above. The rest of the organic secretion comprises approximately 40 other components, including mainly aldehydes, alcohols and carboxylic acids, while the aqueous phase contains gluconic acid, glucose and gluconolactone. The secretion acts as a conspecific alarm pheromone in these gregarious insects with nymphs responding at lower concentrations than adults do. Ethanolic extracts of the American cockroach, *Periplaneta americana*, also repel conspecifics from aggregations in daytime shelters. However, there was no evidence that this repellent is released by living insects as an alarm pheromone but is instead endogenously produced from dead insects and is effective against other cockroaches with diverse phylogenetic relationships. The effect, therefore, is not pheromonal, as the authors explain the activity in terms of unsaturated fatty acids (oleic, linoleic and linolenic acids) which emerge as signals of death and injury among organisms from a wide phylogenetic background. Both of the reports described above provide evidence that the use of alarm pheromones to increase dispersal for pest management purposes will be of limited value. Due to the aggregation effect at low concentration, treated areas could become attractive. Also, if low concentrations were used as attractants in a lure and kill approach, dead insects would repel others before they become ensnared.

Alarm Pheromones of Beetles (Coleoptera)

Despite the vast numbers of species in the order Coleoptera, inhabiting a wide range of ecological niches, little is known of the existence of behavioral responses to alarm pheromones they may possess. Species of beetles that are group-living are most likely to demonstrate alarm responses. Gyrinid beetles (Coleoptera: Gyrinidae), known as whirligig beetles, live in open habitats on fresh water surfaces and typically aggregate in groups containing hundreds of individuals, dispersing in the evening to forage. Although easy to detect by fish, they are seldom preyed upon due to a repellent secretion released as a last resort to physical attack. The secretion also acts as an alarm pheromone over short distances, increasing locomotory activity and defensive movement, such as diving and active underwater swimming. Although alarm dispersal after attack can occur, the aggregations of beetles themselves indicate to experienced predators to avoid the group and confer an aposematic effect acting at the group level rather than the individual level.

Lacewing Alarm Pheromones (Neuroptera: Chrysopidae)

The green lacewing, *Chrysoperla carnea* (Neuroptera: Chrysopidae), is an important predator of pest aphids and, as such, is a beneficial insect. It discharges a malodorous secretion from glands at the anterior of the prothorax. The major component of this secretion has been identified by gas chromatography, mass spectroscopy and chemical synthesis as (Z)-4-tridecene (**14**) and gas chromatography coupled electroantennagrams revealed that it is detected by the lacewing antennae. Predatory ants displayed avoidance behavior in response to it, suggesting a defensive function, and in laboratory experiments, adult lacewings avoid entering areas where it is present. In the field, it acts as an antagonist to trap catches using known attractants and, as such, could be described as an alarm pheromone. Another species of lacewing, *Peyerimhoffina gracilis*, also produces the identical compound. As lacewings are not known to be gregarious, the exact ecological purpose of this compound is being investigated.

Conclusions

It can be seen that alarm pheromones are used widely by a broad taxonomic diversity of insects and elicit equally varied behavioral responses, including escape or aggressive behavior. Alarm pheromones are generally low molecular weight, organic compounds and so are volatile, dispersing quickly, and do not persist in the environment. In addition, the chemical nature of the alarm pheromone often is unstable, increasing the lack of persistence. This allows conspecifics to be alerted very quickly over a fairly large area and yet not cause false alarm after the danger has passed. Alarm pheromones are often produced in glands responsible for biosynthesis, storage or release of defense secretions. This association between alarm pheromones and defense glands, including those near the sting or mandibles, has led to the hypothesis that alarm pheromones have evolved from chemicals that originally had a defensive role, or are themselves defense compounds that have taken on an additional alarm pheromonal role. The fact that known defense components have additional multifunctional pheromonal roles of alarm (high concentration) and aggregation (low concentration) also points to the possibility that these pheromonal roles have evolved from compounds originally used for defense. Of particular interest is the common lack of species specificity found in alarm pheromones, which is in contrast to that of other pheromones. Sex pheromones, for example, are so specific that they can be the sole identifiable trait in defining morphologically identical populations, such as within the species complex of the sandfly, *Lutzomyia longipalpis* (Diptera: Psychodidae). However, the alarm pheromone of different aphid species is (E)-β-farnesene and different species of *Atta* grass-cutting ant use 4-methyl-3-heptanone. In addition, production of (E)-2-hexenal and n-tridecane is ubiquitous as multifunctional pheromone components in terrestrial true bugs, and it is possible that (E)-4-tridecene may reveal itself to be common in green lacewings. Discrimination between these behavioral signal compounds, therefore, is not essential to their function as alarm pheromones, and there may even be evolutionary benefits in being able to respond to alarm pheromones of related species of insects.

► Sociality of Insects

Alary Muscles

JAMES L. NATION
University of Florida, Gainesville, FL, USA

The alary muscles, so named because of their general wing or delta shape in many insects, lie immediately on top of the dorsal diaphragm. The muscles probably aid the dorsal diaphragm in providing support for the heart, the part of the dorsal vessel in the abdomen. The muscle fibers fan out from a small point of origin on the lateral wall of the dorsum to a broad insertion on the heart in many insects, presenting the typical delta appearance. In some insects, however, the delta shape is not so evident. Some alary muscle fibers pass beneath the heart and extend laterally from side to side, and thus help to support the heart. In places, the fibers may also run parallel to the long axis of the heart for a short distance. The pairs of alary muscles tend to agree with the number of pairs of ostia, the (usually) lateral openings in the dorsal vessel that allow hemolymph to flow into the heart in the abdomen. Alary muscles generally do not occur in the thorax, but in some insects, a few ostia open outward in the thorax, allowing hemolymph to flow outward.

In addition to support, the alary muscle may assist in the expansion (diastole) of the heart after each contractile wave passes a given point, and thus aid in pulling hemolymph into the incurrent ostia. They are not necessary for diastole, however, as evidenced by severing them with little or no apparent effect on the heart beat.

Alate (pl., Alatae or Alates)

The winged forms of insects, particularly aphids.

Alderflies

Members of the family Sialidae (order Megaloptera).

► Alderflies and Dobsonflies

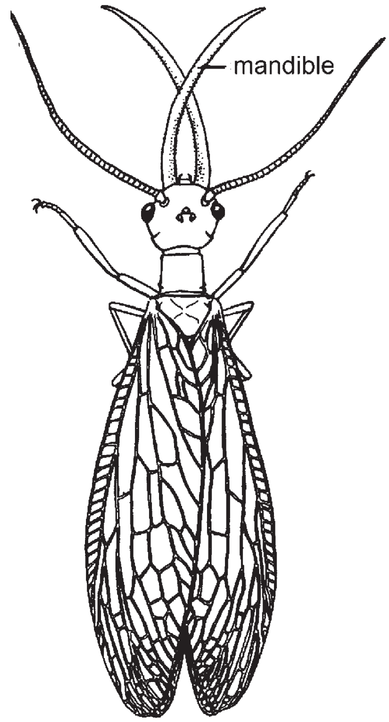
Alderflies and Dobsonflies (Megaloptera)

LIONEL STANGE
Florida Department of Consumer and Agricultural Services, Division of Plant Industry, Gainesville, FL, USA

The order Megaloptera comprises about 190 species in 60 genera in two families. All the larvae are aquatic. The larvae, especially of Corydalinae, are among the most primitive of the Holometabola. The metamorphosis from larva to adult is relatively simple.

The family Sialidae, commonly called alderflies, is a small group of about 70 species in about eight genera. They are worldwide. Most of the adults have a similar appearance and are usually dark brown to black in coloration. They lack ocelli and have the fourth tarsomere bilobed. They are an ancient group known from the Permian, about 200 million years ago, and evidently have not evolved much since then. In fact, the wing venation has many features in common with the Protoperlaria, a fossil order considered by some as ancestral to the Plecoptera. The adult life span is probably short since the reduced mouthparts do not seem adapted for extensive feeding. The eggs are laid in rows, forming large masses situated on branches, bridges, and other objects overhanging the water. The larvae hatch and fall into the water where they are predacious on other aquatic insects, especially caddisflies. There are as many as 10 larval instars which may last up to two or more years until pupation. The larva crawls out of the water and digs into the bank to form an earthen cell several feet from the edge of the water. The genera are restricted geographically. The genus *Sialis* Latreille is Holarctic, *Protosialis* Van der Weele is South American, *Austrosialis* Tillyard and *Stenostialis* are Australian, *Haplosialis* Navas is from Madagascar, *Leptosialis* is African, *Indosialis* Lestage is Oriental and *Nipponsialis* Kuwayama is Japanese. The larva has seven lateral processes and the abdomen terminates in an elongate process. The only world compilation is by Van der Weele (1910) but is greatly out of date.

The family Corydalidae, or dobsonflies, is characterized by having three ocelli and the anal region of the hindwing is very wide, folded fanlike at rest (Fig. 31). The fourth tarsomere is not modified. There are several hundred species in about 20 genera and two subfamilies.



Alderflies and Dobsonflies (Megaloptera), Figure 31 **Adult dobsonfly (Corydalidae).**

The Corydalinae with about 60 species, is distributed in the New World (three genera), South Africa (one genus) and Asia (five genera). This subfamily does not have pectinate antennae and the head is usually quadrate, often with a postocular spine. Often there are more than four crossveins between the radius and radial sector. The male terminalia are distinctive with a well developed ninth gonostylus. Many of the species are very large. *Corydalis* Latreille is the largest genus in the New World with about 30 species. The males of this genus often have the mandibles greatly extended which is similar to *Acanthacorydalis* Van der Weele from Asia. *Platyneuromus christil* (Navás) from Central America, has a tremendously expanded postocular flange. The larva has eight lateral processes and the abdomen ends in a pair of claw-like structures. In America, the larvae are called hellgrammites and are used for fishing. In one case, a larva was found inside a fish stomach many hours after ingestion. Glorioso (1982) has provided a good reference.

The Chauliodini was reviewed by Kimmins (1954) who recognized 12 genera. The genera are restricted in distribution similar to the Corydalinae and are found in the Cape region of South Africa (two genera), North America (four genera), Chile (three genera), Australia (one genus), Madagascar (one genus), and Asia (four genera). Males and rarely females have pectinate antennae in some genera.

Aldrovandi, Ulisse (Ulysse, Ulysses)

Ulisse Aldrovandi was born in Bologna, Italy, in 1522. He studied law in Bologna, and then philosophy and medicine in Padua and Rome, earning a doctorate in medicine in 1552. In 1560, he was appointed professor in Bologna, a position that he held for 40 years. He lectured mainly on pharmacology, but he collected natural history objects and employed artists to draw them. He published four large volumes during his lifetime, but his friends and pupils used his voluminous manuscripts to publish 10 more volumes after his death. His (1602) "De animalibus insectis libri VII" was the first book to be published on insects, although the "insects" included various other kinds of invertebrates. A chapter was devoted to the structure of the insect body. Insect reproduction and metamorphosis were described; respiration and the senses of touch, taste, and smell are discussed, and the life of honey bees is described. He died in 1605.

Alexander, Charles Paul

Charles Alexander was born in New York state on September 25, 1889. He entered Cornell University in 1909, receiving B.Sc. and Ph.D. degrees in 1913 and 1918, respectively. He was employed as systematic entomologist in the Snow Entomological Museum at the University of Kansas in 1917–1919 and then by Illinois Natural History Survey in 1919–1922. Next he moved to Massachusetts Agricultural College and was placed in charge of teaching entomology. He served as chairman of the Department of Entomology and Zoology for 10 years, for the last three of which he was dean of the School of Science (of what had by then become the University of Massachusetts). He was president of the Entomological Society of America in 1941–1943 (two terms). His almost exclusive subject of research was the family Tipulidae (crane flies) about which he published over 1,000 papers and described over 10,000 species, an enormous production. After retirement from teaching, he moved his insect collection to his house and continued working on it until the death of his wife, Mabel, in 1979. Two years later he transferred his collection to the National Museum of Natural History in Washington, DC. He died at home in Massachusetts on December 12, 1981.

Alfalfa Leafcutting Bee, *Megachile rotundata* (Hymenoptera: Megachilidae)

MARK S. GOETTEL
Agriculture and Agri-Food Canada, Lethbridge, AB, Canada

The alfalfa leafcutting bee, *Megachile rotundata* Fabricius (Hymenoptera: Megachilidae), has been successfully semi-domesticated within the last 50 years to pollinate alfalfa for seed production in North America. Honey bees are inefficient pollinators of alfalfa and, although bumbles bees and some other wild bees are efficient pollinators, they have proved difficult to manage. The use of the alfalfa leafcutting bee has succeeded in greatly increasing the seed yield of alfalfa. In western Canada, the average alfalfa seed yield using this bee exceeds 300 kg/ha, whereas without it is usually less than 50 kg/ha. The genus *Megachile* contains many species that nest in tunnels in dead trees or fallen logs. Most are solitary, but *M. rotundata* is gregarious and, although each female constructs and provisions her own tunnel, she will tolerate close neighbors. This behavioral characteristic is one of the main reasons why this species has been amenable to management on a commercial scale. *M. rotundata* is of eastern Mediterranean origin and was first found in North America in the 1940s near seaports. It probably gained entry as diapausing pre-pupae within tunnels in the wood used to make shipping crates or pallets.

Life History

Once a suitable tunnel has been found, the female uses her mandibles to neatly cut oblong pieces of leaves or flower petals which she uses to build cells end to end in the tunnel, starting at the far end and finishing near the entrance (Fig. 32). About 15 leaf pieces are arranged in overlapping layers and cemented together to form a thimble-shaped cell with a concave bottom. The cell is then provisioned with nectar and pollen. During this process, the female enters the tunnel head first, regurgitates the nectar, then turns around to remove the pollen from the scopa (the pollen-collecting hairs on the underside of her abdomen) and tamps the pollen into the nectar with the tip of her abdomen. The provisions for each cell consist of about two-thirds nectar and one-third pollen, requiring 15–25 provisioning trips. It is while collecting the nectar and pollen that the bees pollinate the flowers that they visit. When the cell has been adequately provisioned, the female lays a single egg directly on the surface of the provisions and then caps the cell with several circular leaf pieces. She then proceeds to construct the next cell, repeating this process until the tunnel is filled. She then plugs the end of the tunnel with 10–15 leaf pieces cemented together to form a plug. Females continue filling tunnels with cells until pollen and nectar sources are no longer available. Upon hatching, the larva immediately begins feeding on the provisions within its cell, undergoing four instars before reaching maturity. It then deposits a ring of fecal pellets within the cell and spins a tough silken cocoon within which it overwinters as a diapausing pre-pupa. During the feeding period, the waste

Flowers are pollinated while the bees visit the flowers to collect nectar and pollen for provisioning their cells. (2) A single egg is deposited on the surface of pollen/ nectar provisions within a cell which the female constructs within tunnels using oblong pieces of leaves or flower petals. (3) The egg placed into the cell hatches within 2 to 3 days and the larva immediately begins to consume the provisions. The larva pupates after undergoing 4 instars. (a) single egg, (b) 3rd instar, and (c) 4th instar larvae within the cell. Cell caps have been removed. (4) X-ray of leafcutting bee cells used to determine quality of commercial bees. (a) empty cell, (b) chalkbrood cadavers, (c) *Pteromalus venustus* parasitoid cocoons. (5) Nesting boards separated to show arrangement of bee cells constructed within the tunnels. In the fall, the boards are removed from the field and the cells are stripped from the boards using specialized automated equipment. (6) Chalkbrood cadaver within the cell. Note the ring of frass deposited on the outside edge of the cell. Normally, the larva would spin a tough silken cocoon within which it overwinters as a diapausing pre-pupa. Larvae infected with chalkbrood usually succumb just after defecating and just prior to cocoon spinning.**

products of digestion are accumulated internally until the larva defecates just before forming the cocoon. In the spring, the pre-pupa pupates. After a pupal period of 3–4 weeks, the adult emerges and chews its way out of the cocoon. Mating takes place soon after emergence of the adults. Females store enough sperm from a single mating to fertilize all of their eggs. Soon after mating, the females seek out suitable sites in which to excavate tunnels or select suitable preexisting ones, either natural or man-made.

Domestication

The gregarious nature of *M. rotundata* and its willingness to accept artificial domiciles has permitted the commercial scale management of this species for crop pollination. Initially, observant alfalfa seed producers in the northwestern U.S.A. noticed that this species, which had undergone a population increase following natural establishment, would nest in man-made structures such as shingled roofs and they started to provide artificial tunnels by drilling holes in logs positioned around the edges of the seed fields. The next step was to provide nests consisting of wooden blocks drilled with closely spaced tunnels. Although reasonably successful on a small scale, this method was not suitable for the management of the large numbers of bees (50,000–75,000/ha) required for commercial alfalfa seed production. Consequently a "loose-cell" system was developed. This system uses 10 mm thick boards of wood or polystyrene which are grooved on both sides and stacked together to form hives of closely packed tunnels about 7 mm in diameter and 150 mm in length. At the end of the season, the boards are separated and the cells removed using specialized automated equipment. After being stripped from the boards the cells are tumbled and screened to remove loose leaf pieces, molds and some parasites and predators. The clean cells are then placed in containers for overwintering storage at about 50% R.H. and 5°C. In the spring, the cells are placed in trays for incubation at 70% R.H. and 30°C. A few days before the bees are due to emerge, the trays are moved to especially designed shelters spaced throughout the alfalfa seed fields. By selecting the date when incubation begins, and if necessary manipulating the incubation temperature, the emergence of the bees can be adjusted to coincide with the start of alfalfa bloom.

An advantage of the loose cell system of management is that it facilitates the control of parasitoids, predators and disease, and assessment of the quality of the progeny. Leafcutting beekeepers routinely send samples of cells to specialized leafcutting bee "cocoon" testing centers, where they are x-rayed and incubated to provide estimates of numbers of intact cells, incidence of parasites and pathogens, and sex ratio. These data are used to determine stocking rates and to set a price if bees are to be marketed. The proportion of females, which is usually only about a third, is of particular interest because they are the primary pollinators.

Natural Enemies

About 20 species of insects are known to parasitize or prey on the immature stages of the alfalfa leafcutting bee. The most important of these are several species of chalcid wasps, including *Pteromalus venustus* Walker, *Monodontomerus obscurus* Westwood, *Melittobia chalbii* Ashmead and *Diachys confusus* (Girault). The most widespread and damaging is *P. venustus*, which probably arrived in North America with its host. The female parasitoid pierces the host cocoon with her ovipositor, stings the larva or pupa to paralyze it, and then lays some eggs on its surface. The parasitoid larvae then feed upon the bee larva eventually killing it. Normally 15–20 adult *P. venustus* emerge from each host cocoon.

Two other enemies, which are more of biological interest than economic significance, are several species of cuckoo bees, *Coelioxys* (Megachilidae) and the brown blister beetle, *Nemognatha lutea* LeConte. Cuckoo bees are very similar to leafcutting bees, but lack the structures required for collecting pollen. The female cuckoo bee lays her egg in the partially provisioned cell of the leafcutting bee while the rightful owner is out foraging. When partly grown, the cuckoo bee larva kills the leafcutting bee larva and usurps the provisions. Brown blister beetle females lay their eggs on flowers and the first instar larvae (triungulins) attach themselves to any bee that visits the flower. When the bee returns to its nest, the triungulin detaches and begins feeding on the cell contents, destroying 2 or 3 cells before reaching maturity.

Several stored-product insects including the driedfruit moth, *Vitula edmandsae serratilinnella* Ragonot, and stored-product beetles such as the sawtoothed grain beetle, *Oryzaephilus surinamensis* (Linnaeus), the red flour beetle, *Tribolium castaneum* (Herbst) and the confused flour beetle, *Tribolium confusum* (Jacquelin du Val) can cause serious damage during overwintering storage, especially if sanitation practices are lax.

Most of the parasitoids and predators can be largely controlled by proper construction of hives and nesting materials, physical removal during the loose-cell processing and strict hygiene during storage. However, successful control of the major pest, the chalcid *P. venustus*, often requires carefully controlled fumigation using dichlorvos (2, 2-dichloro-vinyl dimethyl phosphate) resin strips.

The only disease causing significant losses to the leafcutting bee industry is chalkbrood, caused by the fungus *Ascosphaera aggregata* Skou. The disease was first reported in leafcutting bees in 1973, and remains most severe in the western U.S. states, where losses of more than 65% of bees are not uncommon. Bee larvae become infected after consuming pollen provisions contaminated with the fungal spores which germinate within the midgut and penetrate into the hemocoel. Larvae soon die and turn a chalk white color as the mycelium fills the body. Sporogenesis occurs beneath the host cuticle resulting in the formation of ascospores which are bound in "spore balls" within ascomata. At this stage, the cadaver turns black. Spores are spread by adults that must chew their way through infected cadavers in order to exit their nesting tunnels. Chalkbrood can be adequately managed through strict hygiene and decontamination of the bee cells, nest materials and shelters. Initially, decontamination was performed by dipping in household bleach. However, fumigation with paraformaldehyde has become the method of choice, and is highly effective for the control of both *A. aggregata* and foliar molds, which can sometimes pose a health risk to the beekeeper.

Alfalfa (Lucerne) Pests and their Management

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

Alfalfa (lucerne), *Medicago sativae*, is one of the most important legumes used in agriculture. It is the principal roughage for ruminants, as well as being an important source of protein in animal diets. It is surpassed only by grass, corn, and soybean as an animal feed, and is especially important to the dairy industry. The USA is the world's largest producer of alfalfa, but it also is an important crop in Australia, Europe, Argentina, China, South Africa, and the Middle East.

There are other uses for alfalfa, though they are minor. Alfalfa sprouts are a salad ingredient, alfalfa shoots are sometimes consumed as a leafy vegetable, and dehydrated alfalfa is sometimes formulated as a tablet to be consumed as a dietary supplement. Alfalfa is a cross-pollinated species. It relies on insects, often domesticated leafcutting bees, honey bees, alkali bees, and various wild bees, for pollination. Wind pollination does not occur because the blossom is structured in a way that physical "tripping" to expose the stigma to the anthers is required. Bees manipulate the blossom when foraging for nectar and pollen and thereby "trip" the blossom, an action that results in the bee being struck in the head. An interesting aspect of pollination is that some bees learn to avoid the tripping process to avoid being struck, thereby robbing the flower without pollination occurring. Older honey bees are good at avoiding tripping, but naïve young honey bees trip the blossom and provide pollination.

Alfalfa is normally harvested before, or at, the initiation of flowering, which maximizes protein content of the harvested hay. Because pollinators are often present in alfalfa fields during the bloom period, care must be taken when using insecticides for pest suppression to avoid products that are highly toxic to pollinators, at least if seed production is a concern. However, most alfalfa is grown only for forage, and without regard for seed production. Thus, insecticide use may include the bloom period, though if pollinator populations are reduced, other crops that require pollination may be inadvertently affected.

Alfalfa is unusual as a field crop in that it is a short-lived perennial, living 3–12 years. It may be harvested from once to 12 times per year, depending on climate and growing conditions. It has deep roots, and is resistant to drought, though in arid climates it is irrigated. It is tolerant of cold, growing well in cool and cold climates. It does not tolerate hot, humid climates, however.

Alfalfa often is cut and dried before it is baled and stored. To speed up the process of drying, alfalfa is commonly flailed or passed through a set of rollers to break or crush the stems, facilitating the drying process. The crushing process is called crimping and sometimes can cause problems for horses because blister beetles (Coleoptera: Meloidae) are incorporated into the hay (see below, blister beetles). Dried alfalfa is tied into bales of various sizes, including large cylindrical bales, and stored under shelter, or packaged in plastic, to avoid moisture. If the alfalfa is to be fed to cattle, however, it is not dried, and instead it is finely chopped and stored in trenches, silos, or bags where it can ferment and maintain high nutrient levels. Cattle are not very susceptible to poisoning by blister beetles.

Alfalfa has undergone considerable breeding to produce strains that have not only suitable agronomic conditions, but also are disease and pest resistant. Nevertheless, insects can damage alfalfa nearly everywhere it is grown. Some of the important pests are listed in the table, and the most important are discussed below.

Alfalfa Weevil, *Hypera postica* (Gyllenhal) (Coleoptera: Curculionidae)

In many regions, this is the most important pest of alfalfa. It is found in Europe, the Middle East, Central Asia, and North America. Alfalfa weevils overwinter as adults in the soil of weedy, brushy areas near alfalfa fields. They disperse to alfalfa in the spring and oviposit within the stems. The eggs are oval and yellow. Early instars developing from these eggs are slate colored, but develop a bright green color and a white stripe down the middle of the back as they mature. Larvae have a black head capsule. They display four instars and will grow to about 8–10 mm in length. After feeding for 3–4 weeks, larvae spin loosely constructed cocoons on

Alfalfa (Lucerne) Pests and their Management, Table 5 Some pests of alfalfa (lucerne), and locations where they are considered to be damaging (Continued)

Feeding behavior	Primary taxon	Common name	Scientific name	Location
		Alfalfa snout beetle	*Otiorhynchus ligustici*	N. America
		African black beetle	*Heteronychus arator*	Africa, Australia
		Whitefringed beetle	*Naupactus leucoloma*	Australia, S. America
		Small lucerne weevil	*Atrichonotus taeniatulus*	Australia

plants or in litter on the soil, pupate, and emerge as adults in 1–2 weeks. Adults are 5–6 mm long, have a long snout, and have a dark stripe down the back. They are light brown at emergence and darken in several days. The number of generations varies according to climate, but eventually they leave fields for grassy, brushy, weedy areas where they become inactive until the onset of winter.

Damage is caused by the larval stage which feeds on leaves; damage ranges from pinholes to skeletonization of leaves. Adults generally cause minor damage. Peak damage is usually just prior to the first cutting or after the first cutting, as both larvae and adults feed on new growth; this can seriously affect regrowth of the stand. Also, cool, cloudy weather exacerbates damage done by the alfalfa weevil. Cool and cloudy weather conditions slow the regrowth rate of alfalfa, and also increase the daily feeding period of the weevil because both larvae and adults tend to hide under crop residue during bright sunlight and will not actively feed during such periods.

Weevil larvae can be found early in the Spring. It is important to scout for live larvae and injured terminals on the first crop, but also subsequent crops. Sweep net sampling can be used to detect weevil presence. Several species of wasps can be effective in maintaining weevil populations below economic threshold levels. Among the effective parasitoids are *Bathyplectes curculionis* (Thomson), *B. anurus* (Thomson) and *B. stenostigma* (Thomson) (Hymenoptera: Ichneumonidae); *Microctonus aethiopoides* Loan and *M. colesi* Drea (Hymenoptera: Braconidae) *Oomyzus incertus* (Ratzenberg) (Hymenoptera: Eulophidae); *Dibrachoides dynastes* (Forester) and *Peridesmia discus* (Walker) (Hymenoptera: Pteromalidae); and *Anaphes luna* (Girault) (Hymenoptera: Mymaridae). A fungal pathogen, *Zoophthora phytonomi* Arthur (Phycomycetes: Entomophthoraceae), attacks weevil larvae and can control populations in several days, though it is most effective under moist conditions. These biological control agents are extremely effective control measures in all but major outbreak periods. However, when fields show damage on 35–40% of plant tips more than 7–10 days prior to harvest, chemical suppression is often initiated.

Early harvest (first crop) is very effective in killing larvae, and is preferred to chemical control if the planned harvest is less than 7–10 days away. If harvesting is used to control alfalfa weevil, the stubble and debris should be examined closely for adults and larvae, and stems should be examined for feeding signs. It may be necessary to spray stubble, though in many areas producers can avoid insecticide use consistently through timing of harvest.

Root Weevils, *Sitona* spp., *Atrichonotus taeniatulus* (Berg), Others (Coleoptera: Curculionidae)

Root weevils such as clover root curculio, *Sitona hispidula* (Fabricius), in North America; and sitona weevil, *Sitona discoideus* Gyllenhal, small lucerne weevil, *Atrichonotus taeniatulus* (Berg), in Australia, and whitefringed beetle, *Naupactus leucoloma* Boheman in Australia and South America, can be significant pests of alfalfa. Although the adults commonly feed on the foliage, the principal damage is due to larval feeding on the roots of the alfalfa plant.

Eggs are laid in fall or spring, on the soil surface or lower parts of plants. Eggs hatch in the winter or spring. White, legless larvae move into the soil and feed on roots until they pupate. Pupae are found just below the soil surface. Adults emerge in the summer months and live up to a year. The adults are brown or black, blunt-snouted weevils up to about 10 mm long. There is one generation per year. Adults migrate by crawling, and thus infest new areas rather slowly.

The adults feed on alfalfa leaf margins, leaving crescent-shaped notches, and chew on stems and leaf buds of seedlings, but this tends to cause minor loss. Most damage is caused by the larvae. First larval instars feed on root nodules and lateral roots; later instars feed on the taproot. Feeding on the taproot can girdle the plant, resulting in plant death. Such damage also weakens the overall vigor of a stand, perhaps contributing to winter-kill and increased susceptibility to disease.

It is difficult to control larvae because they are in the soil and largely protected from insecticide. Suppression aimed at adults usually requires multiple applications. It is inadvisable to plant alfalfa into a field which has previous ly been infested, to plant into fields previously supporting legume crops, or to seed alfalfa next to established stands.

Blister Beetles (*Epicauta* spp.) (Coleoptera: Meloidae)

There are several species of North American blister beetles that can be of concern in alfalfa. They are a problem not because of their food habits (they tend to feed mostly on blossoms) but because they contain the toxin cantharidin within their bodies. When alfalfa is harvested, if the hay is crimped it may contain crushed blister beetles that may prove toxic to horses that ingest the hay. The most abundant blister beetle in alfalfa fields generally is the black blister beetle, *E. pensylvanica* (De Geer). However, the species that is most toxic is *E. vittata* (Fabricius).

Most blister beetles are recognized by the shape of their body. They are narrow, cylindrical, and soft. The region between the head and wings is distinctly narrower than the wings, and is usually narrower than the head. Most species have one generation per year, although some have two. Blister beetles overwinter as larvae. The adults begin to emerge in the Spring and adults deposit their eggs where grasshopper egg pods may occur, as larvae feed on the grasshopper eggs.

If grasshoppers are not abundant, then blister beetles are unlikely to be abundant. When both are numerous, it is advisable to harvest alfalfa early, before bloom, as this is the only time that beetles are attracted to the crop. There is some yield loss associated with this approach, of course, and an alternative it to treat the crop with insecticides. If insecticide is used, alfalfa should be harvested as soon as possible after the pre-harvest interval expires, to get hay out of the field before it is re-infested. A principal problem with blister beetle management is that the beetles tend to aggregate. Thus, there may be relatively few beetles in field, but a large number in one location, and these may be crushed together and concentrated into one or a few bales of hay. Thus, they are hard to detect by standard sampling methods. When alfalfa hay is purchased for horses, it is advisable to acquire early-crop hay, or hay from areas free of high grasshopper populations. Alternatively, inspection of the hay as it is fed to horses can reveal the presence or absence of beetles.

Potato Leafhopper, *Empoasca fabae* (Harris) (Hemiptera: Cicadellidae)

Potato leafhopper is indigenous to eastern North America. Adults are about 3.5 mm long, wedge-shaped, winged, and green. Nymphs are similar in appearance, but are smaller, yellowish-green to fluorescent green, and wingless. Each Spring, potato leafhoppers migrate north from southern states where they overwinter. Timing of the first and subsequent arrivals in the north is heavily dependent on weather patterns. Adults lay eggs in stems and leaf veins; eggs hatch in 6–9 days in mid-summer. Each generation takes approximately 30–35 days to mature, resulting in several generations.

Adults and nymphs both feed on alfalfa with piercing-sucking mouthparts, sucking plant sap and injecting a toxin into the plant. Damage is called "hopperburn," and is a yellow wedge-shape area beginning at the tips of leaves. The leaves may eventually turn entirely yellow or reddish. Plants may become stunted. Leafhoppers cause yield loss, reduced nutritional quality of alfalfa, and reduced plant vigor that results in increased winter-kill and slower regrowth of the crop the next spring.

In some regions of the USA, the potato leafhopper is the worst insect pest of alfalfa, and can cause losses of 80% or more if not controlled. Leafhoppers are not generally a problem in the first crop in an established stand, but as the population increases, all subsequent crops will need to be monitored for infestation. The characteristic hopperburn will not appear until some yield and quality loss has occurred, so it is important to scout for leafhoppers weekly on the second and subsequent crops. Scouting may be concluded 7–10 days prior to harvest.

Potato leafhopper economic thresholds are based on plant height. Scouting is accomplished by sweep net sampling. As an example, following are treatment thresholds recommended for Minnesota, USA.

Average plant height	# adult leafhoppers/ sweep
< 3 inches	0.3
3–7 inches	0.5
8–12 inches	1.0
> 12 inches	2.0

Although the potato leafhopper has natural enemies, they often get left behind when the adults disperse. Thus, a combination of crop monitoring and insecticide suppression is often the principal management strategy. Chemical control of potato leafhopper is effective, but should not be used if harvest is within seven days of harvest. Cutting will kill a large percentage of nymphs, and will force adults out of the field. Cutting is the control of choice if thresholds are reached within seven days of harvest. Additionally, early harvest may be an alternative to insecticides when thresholds are reached late in the year.

Aphids (Hemiptera: Aphididae)

Several aphids are pests of alfalfa, including pea aphid, *Acyrthosiphon pisum* (Harris); blue alfalfa aphid or bluegreen aphid, *Acyrthosiphon kondoi* Shinji, cowpea aphid, *Aphis craccivora* Koch; green peach aphid, *Myzus persicae* Sulzer; and spotted alfalfa aphid, *Therioaphis maculata* Buckton.

All these aphids are small, measuring 3 mm or less. Their color varies, depending on species. They may or may not be winged. In most climates, in early Spring nymphs hatch from eggs that were laid in the fall; these aphids are all female. Females can reproduce without mating when conditions are favorable, and they do so in Spring and Summer. In the Summer, the entire life cycle takes only a few days. Males appear in late Summer, and mate with females to produce eggs capable of overwintering.

Aphids use piercing-sucking mouthparts to remove plant sap, and prefer to feed on young growth. Aphid feeding can result in stunted or wilted plants. The plants may also turn yellow.

Aphids commonly attain high densities in alfalfa, but in most years natural enemies keep aphid populations at levels that are not economically important. Many natural enemies of pea aphids exist, including green lacewing larvae (Neuroptera: Chrysopidae), damsel bugs (Hemiptera: Nabidae), and parasitic wasps

(Hymenoptera, various families), lady beetles (Coleoptera: Coccinellidae), and disease (fungi).

Plant Bugs (Hemiptera: Miridae)

Several species of plant bugs affect alfalfa, but the most common are tarnished plant bug, *Lygus lineolaris* (Palisot de Beauvois), and alfalfa plant bug, *Adelphocoris lineolatus* (Goeze). Adult tarnished plant bugs are brown, winged, and 4–6 mm long; nymphs are green, wingless, and the third and subsequent instars have black spots. Adult alfalfa plant bugs are light green, winged, and 7.5–10 mm long; nymphs are green, wingless, and have red eyes. Tarnished plant bugs overwinter as adults; alfalfa plant bugs overwinter as eggs in plant tissue. During the growing season, the entire life cycle takes 20–50 days, depending on temperature. There are two to five generations per year.

Plant bugs suck sap from plants and inject toxic saliva into the plant. They cause leaves to crinkle, plants to be stunted, and flower buds to abort. They are abundant in all but the earliest portions of the season. Although traditionally considered mostly a seed pest, plant bugs also contribute to forage yield reductions. If bugs are abundant more than seven days prior harvest, chemical control may be warranted.

Grasshoppers (*Melanoplus* spp. and *Phaulacridium* spp.) (Orthoptera: Acrididae)

Everywhere alfalfa is grown, grasshoppers and locusts will feed on the crop. However, they are only casually associated with alfalfa, attacking the crop only when abundant. None feed preferentially on alfalfa. In North America, the principal pests are *Melanoplus* spp., and in Australia *Phaulacridium* spp. is the major grasshopper pest. These economically important grasshoppers overwinter as eggs. Populations disperse into cultivated fields or pastures as their populations build through the season. Most egg laying occurs in late summer and fall in production areas; most species prefer uncultivated, grassy or weedy areas, and lay eggs 1–3 cm below the soil surface.

Grasshoppers are generally considered a minor pest except during periods of great abundance, and then they can do great damage. An exception is Australia, where wingless grasshopper has become an increasingly severe pest of alfalfa. Damage has increased in Australia due to widespread cultivation of alfalfa, which is more suitable than grasses for nymphal growth and survival. Grasshopper nymphs and adults damage alfalfa by chewing on leaves from the margin inward in an irregular pattern. Attacks are often on new growth, but will occur on any stage. The margins of fields are most likely to be damaged.

In North America, grasshopper infestations are more severe in warm and dry years. Warm, dry weather immediately following egg hatch favors survival of nymphs, because nymphal growth rates and survival are lower in cool, wet weather. Long, warm autumns prolong the egg-laying season, and result in larger populations in the next growing season. It can take 3–5 years for populations to build to economically important levels. In Australia, drought also is implicated, but mermithid nematodes are a critical element in grasshopper biology. Absence of rainfall, and clearing of drier, higher elevation pasture impedes the ability of the nematodes to parasitize the grasshoppers.

Grasshoppers are naturally suppressed by numerous natural enemies, but when weather conditions favor the grasshoppers their populations increase quickly. The natural enemy population increases as their food supply becomes more available, but the lag in natural enemy abundance can result in crop damage by the grasshoppers. Weedy fence rows, irrigation ditches, and fallow fields are important sources of grasshoppers. Weed populations should be managed, which may require tillage or burning to make these habitats less productive for grasshoppers.

Cutworms, Armyworms and Budworms (Lepidoptera: Noctuidae)

The caterpillars of several moths can become abundant enough to cause significant loss to alfalfa. Among these are the armyworms *Mythimna* spp., *Persectania* spp., and *Pseudaletia unipuncta* Haworth; variegated cutworm, *Peridroma saucia* (Hübner); army cutworm, *Euxoa auxiliaris* (Grote); granulate cutworm, *Agrotis subterranea* (Fabricius); beet armyworm, *Spodoptera exigua* (Hübner); budworm, *Helicoverpa punctigera* (Wallengren), and many others. The important species vary among regions, though they are similar ecologically.

The larvae of cutworms, armyworms, and budworms range in color from greenish-yellow to brownish-black. Larvae are 2–5 cm long at maturity. The wings of the adults vary from tan to dark brown with mottling or stripes. Pupae are 1–3 cm long and are reddish-brown to black in color. There are one to six generations per year. Larvae overwinter in the larval or pupal stage, depending on species.

Larvae feed on stems and leaves of plants, and can limit regrowth after harvest. Larvae will also cut the stems of seedlings. Their occurrence as economic pests is sporadic. Although these insects have many natural enemies, when they are abundant insecticides are the preferred approach to population reduction.

Lucerne Flea, *Sminthurus viridis* (Collembola)

Sminthurus viridis, the lucerne flea or clover springtail, is an insect relative (hexapod) belonging to the order Collembola (the springtails). It is bright green with a roughly spherical body and may swarms in large numbers on living plants, including alfalfa or lucerne, thus the first part of the common name. The second part of the common name was given for its jumping ability and its minute size, not because it is a flea or related to fleas. This species has a patchy distribution in Europe and North Africa, and has been accidentally introduced to Australia, where it is most injurious. It also affects lupine flowers, lentils, beans, and field peas. Immature lucerne fleas consume small patches of foliage, whereas adults consume the entire leaf except for the veins. Early season spraying of insecticide is the most common recommendation to curb their damage.

Mites (Acari)

Mites generally are not major pests of alfalfa, but under arid conditions or along the margins of fields they can be quite damaging. The most important are clover mites, *Bryobia* spp. (Acari: Tetranychidae), and redlegged earth mite, *Halotydeus destructor* Tucker (Acari: Penthaleidae), in Australia, and twospotted spider mite, *Tetranychus urticae* Koch (Acari: Tetranychidae) in North America. They rupture the cells of leaf tissue, imparting a silver or yellow appearance, and reducing yield.

Pest Management in Alfalfa

Alfalfa is an excellent crop for the practice of modern pest management tactics because (i) it is quite tolerant of damage; cosmetic injury is not important; (ii) it is a perennial crop, providing harborage throughout the year for an immense assemblage of insects, including predators and parasitoids; (iii) it is an important crop, so extensive research on the pests have been conducted; (iv) it is amenable to various cultural manipulations, and produces multiple crops over a large portion of the year; and (v) it is a favorite crop for rotations, so there is ample opportunity to integrate its culture with the culture of other crops.

The principal tactics used for alfalfa production include scouting and use of an economic threshold for decision making, natural and classical biological control, cultural control, and chemical control. The economic threshold varies among insect species, geographic locations, crop management practices and economic conditions, but most locations have established such benchmarks for initiating chemical control. A large number of insecticides are registered for this crop, so growers have ample opportunity to select products according to their need and budget. A modest level of host plant resistance apparently exists in alfalfa, and although resistance is effective mostly against aphids, there is also some success with alfalfa weevil and leaf hoppers.

A large number of beneficial arthropods have been moved around the world in an effort to attain biological suppression of invading alfalfa-feeding insects. In some cases this has met with success. For example, alfalfa blotch leafminer, *Agromyza frontella* (Diptera: Agromyzidae), was considered a serious pest when it first invaded the eastern USA, but following release of wasp parasitoids it fell to minor pest status. Similarly, the status of spotted alfalfa aphid, pea aphid and blue alfalfa aphid was affected by importation of beneficial insects. A native entomopathogenic fungus, *Zoophthora phytonomi*, has adapted to the invasive alfalfa weevil and sometimes provides good suppression. Pea aphid is affected by the fungus *Erynia neoaphidis* under favorable weather conditions. Generalist predators such as lacewings, lady bird beetles, nabids, soft-winged flower beetles, big-eyed bugs, and minute pirate bugs are often active in alfalfa, and provide good suppression of aphids, thrips, and also consume eggs and young larvae of caterpillars.

Cultural manipulations are the most important tactics for management of alfalfa pests. In particular, early harvesting can provide acceptable or even nearly complete control of alfalfa weevil, alfalfa blotch leafminer, several caterpillars, aphids, and leaf hoppers because when the crop is cut the insects are exposed to lethal levels of heat and dryness, or the environment becomes so unsuitable that the insects move elsewhere. Crop rotation is most important for root feeding pests, many of which take several years to develop damaging populations. Strip cropping is commonly recommended because the uncut areas retain populations of natural enemies, allowing the beneficial insect to move into newly harvested alfalfa as it regrows and becomes infested with pests. Farmers rarely embrace this approach, however, opting for operational efficiency over economic pest control.

Alga (pl., Algae)

An aquatic non vascular plant, often very small in size. Algae can reach pest status when weather and nutrient levels favor its growth, and pesticides may be needed to suppress it.

Alien

An organism that is native elsewhere. These are also referred to as exotic or foreign.

► Invasive Species

Alienicolae

In heteroecious aphids, viviparous parthenogenetic females developing on herbaceous (secondary) host plants.

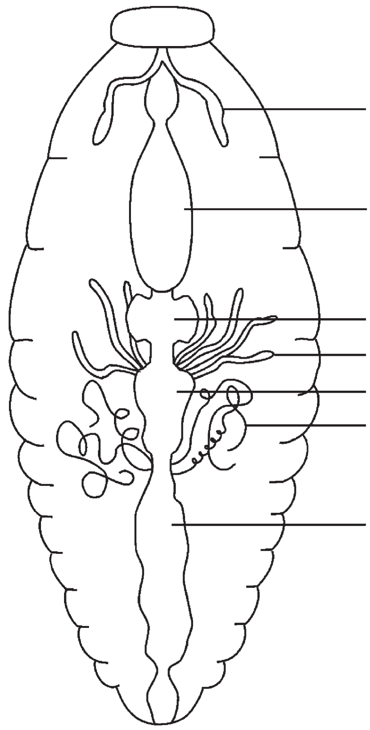
► Aphids

Alimentary Canal and Digestion

JAMES L. NATION
University of Florida, Gainesville, FL, USA

Insects feed upon many different kinds of food, including paper, wood, plant phloem and xylem sap, plant leaves, roots and stems, animal tissues, hair, wool, and vertebrate blood. The alimentary canal (often simply called the gut in much of the literature) evolved to accommodate such diverse foods in a variety of morphological and physiological ways. Thus, there is no "typical" insect alimentary canal just as there is no typical insect. Nevertheless, there are similarities in the structure of the alimentary canal in all insects and nearly all must digest some of the same complex molecules, such as proteins, lipids, and carbohydrates.

In every insect alimentary canal three regions can be identified morphologically and physiologically: the foregut or stomadeum, the midgut or mesenteron, and the hindgut or proctodeum (Fig. 33). One or more of these regions may be greatly reduced in size, or expanded in size, depending upon the feeding behavior of the insect. A cuticular layer, the intima, attached to the epithelial cells, lines the fore- and hindgut regions. The old intima is partially digested and the residue sloughed off into the gut and excreted at each molt, and a new intima is secreted. The midgut does not have an attached cuticular lining, but may have a non-attached peritrophic membrane that separates the food enclosed within from the delicate surface of the midgut cells. If a peritrophic membrane is present, it is often secreted several times each day.



Alimentary Canal and Digestion, Figure 33 A generalized drawing of the alimentary canal in a cockroach to show the major divisions of the canal. Many variations occur in the overall structure of the alimentary canal in insects, and this is not intended to suggest that the cockroach alimentary canal is typical of insects.

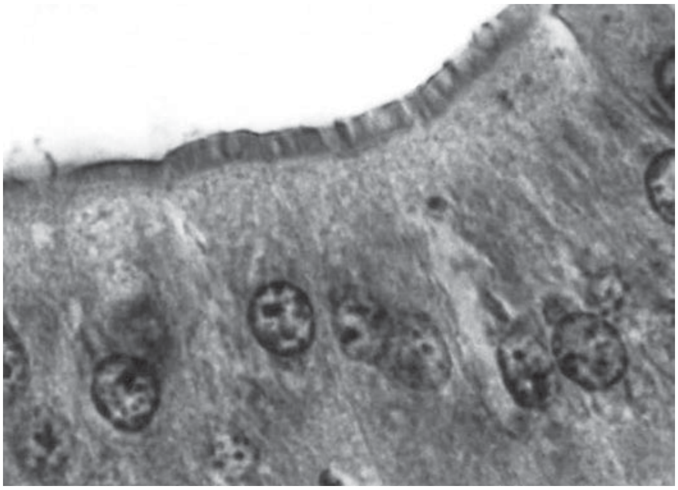
The Foregut

The buccal cavity (mouth), pharynx, esophagus, crop, proventriculus and attached salivary glands comprise the foregut. Secretions from the salivary glands attached near the mouth are swallowed with the food, lubricate the food, and may begin some carbohydrate digestion. In some insects the crop is not a noticeably modified part of the foregut, but often the crop comes off the foregut as a diverticulum. In other insects it is an enlarged portion of the foregut. In opportunistic and possibly irregular feeders such as praying mantids, the crop composes more than half of the alimentary canal, apparently an evolutionary development to store a large amount of food when available and tide the mantid over periods when prey is scarce. Some insects (for example, many orthopterans) regurgitate enzymes from the midgut into the crop, and these enzymes, along with salivary secretions, digest food in the crop. The digested food components still enter the midgut to be absorbed, and there is no evidence that the crop ever secretes enzymes itself. The cuticular intima creates a barrier even against the absorption of water from the crop. The proventriculus controls the entry of food into the midgut in liquid feeders, but in many insects it is modified into a grinding apparatus with hard, sclerotized ridges and spines, and heavy musculature for breaking and tearing the food into smaller particles.

The Midgut

The midgut in most, but not all, insects is the main site for digestion, absorption, and secretion of digestive enzymes. The epithelium is a single layer of cells, but several types of cells occur in some insects. The most common cells are tall, relatively narrow ones called columnar or primary cells by various authors. They have extensive microscopic microvilli on the apical or lumen surface (Fig. 34) and extensive invaginations of the basal cell membrane, features that greatly increase the surface area on both sides of the cell over which secretion and absorption occur. The columnar cells are the primary cells that secrete digestive enzymes and absorb digested products. In all insects that feed as adults and live for days or weeks, there are small regenerative cells distributed at the base of the columnar cells, or sometimes clustered together in nidi (nests). The regenerative cells grow into mature epithelial cells to replace cells worn out or those that disintegrate to release digestive enzymes. Midgut cells may be completely replaced every few days in insects that live longer lives. Gastric caeca, small finger or sac-like diverticula from the midgut, often arise at or near the origin of the midgut, but may be located at various points along the midgut. The caeca appear to secrete digestive enzymes and may be important in absorption of digested products.

The midgut does not have an attached cuticular lining on the surface of the cells, but midgut cells in the majority of insects secrete a thin membrane composed of chitin and protein, the peritrophic membrane, that surrounds the food and shields the delicate microvilli of the midgut cells from contact with potentially rough and abrasive food particles. Although the peritrophic membrane is thin, varying from 0.13 μm to about 0.4 μm thick, it also is thought to make it more difficult for viruses, fungi, bacteria, and protozoans to get to the surface of the midgut cells where they might be able to enter the cells and create an infection. Some insects produce several peritrophic membranes per day, each encasing the one before it, perhaps increasing protection from random breaks or punctures by larger food particles, and thus affording more protection for the midgut



Alimentary Canal and Digestion, Figure 34 **A brush border of microvilli on the lumen surface of midgut cells in a mole cricket.**

cells from possible fungi, parasites, viruses, and bacteria ingested with the food. A peritrophic membrane occurs in living representatives of some of the earliest insects to evolve, and it is believed to have evolved very early in a generalist scavenger feeder in which protection of midgut microvillar surfaces from food particles, sand, or other hard substances coincidentally ingested was likely to be important. A peritrophic membrane is present in many insects that do not feed upon rough or solid food, such as some blood feeders (but not all blood feeders), and in adult lepidopterans that take flower and plant nectars. Although the peritrophic membrane is not present in all groups of insects, like other gut features, it has been conserved over long evolutionary time, lending support to views that it has multiple functions, especially protection from disease invaders and may even have properties that could bind toxicants and limit their access to cells.

Absorption of digested food substances has not been studied in most insects, but one mechanism has been partially elucidated for absorption of amino acids derived from protein digestion in larvae of Lepidoptera. Interspersed among the tall columnar cells lining the midgut in larvae of Lepidoptera (and some other groups of insects as well) are cells shaped much like a goblet and called, appropriately enough, goblet cells. The apical cell membrane of the goblet cavity has metabolic machinery that uses energy derived from splitting ATP to push or pump protons (H^+) into the goblet cavity. A different set of machinery in the goblet cell membrane, an antiporter mechanism, reabsorbs the protons and simultaneously secretes potassium ions into the goblet cavity. The net result of the secretion of potassium ions is that a strongly alkaline midgut (a midgut pH as high as pH 8 to about 11) is produced, and a high voltage (up to 240 mV in some reports) is created between the gut lumen (positive) and the interior of cells lining the gut. The voltage created by the pump enables an absorptive mechanism in membranes of columnar cells to reabsorb K^+ and amino acids from protein digestion. Thus, potassium ions are recycled between the epithelium cells and the gut lumen and seem to play a major role in amino acid absorption. The high midgut pH may provide plant feeding insects some protection against tannins that are common in the food plants of phytophagous insects. Tannins can complex with an insect's own enzymes and proteins in the food, and may result in reduced digestion and absorption. Many details and the precise metabolic components in the cell membrane that support and enable these secretory and absorptive mechanisms remain to be elucidated, but what is already known emphasizes the complexity of insect digestive functions.

The Hindgut

The hindgut is not only a posterior extension of the alimentary canal, but it also plays a major role in excretion through secretion of some substance into the lumen, and reabsorption of useful substances such as ions, water and some nutrients from the Malpighian tubule effluent. The Malpighian tubules typically arise at the origin of the hindgut (but exceptions do occur) and pass relatively large volumes of an ultrafiltrate of hemolymph components minus proteins into the beginning of the hindgut. The cuticular lining on hindgut cells is thinner and has larger pores than the lining in the foregut, permitting reabsorption of water, some ions, and useful metabolites that are returned to the hemolymph. In most terrestrial insects, water conservation is vital to life, and the hindgut must conserve the water that the Malpighian tubules flush into the hindgut. Waste products such as undigested food material (cellulose, for example, which most plant-feeding insects cannot digest and use), uric acid, and other allelochemicals picked up from the food are concentrated in the rectum and eventually excreted. The hindgut secretes some molecules into the lumen for excretion. Experimental evidence indicates that secretion and selective reabsorption helps regulate pH of the hemolymph in some insects. Specialized cells, the rectal papillae and rectal pad cells, in the rectum of many insects have characteristic ultrastructure and physiological mechanisms typical of highly reabsorptive cells. Water conservation by the rectum results in the relatively dry frass or fecal pellets characteristic of many terrestrial insects.

The highest degree of specialization in the hindgut occurs in those insects that digest cellulose, such as termites. In termites, the hindgut is usually divided into several chambers harboring either bacteria or protozoa that secrete all or part of the cocktail of enzymes needed to digest cellulose. Glucose, liberated from cellulose digestion, may be fermented by the resident microorganisms, with the end products being short chain fatty acids (principally acetic acid) that can be absorbed by the termite and used as an energy source. Some termites release methane, a greenhouse gas, from the metabolic activities of their microorganisms, but whether this is a significant natural source of methane is a topic of debate by various scientists.

Digestive Enzyme Secretion

Midgut cells secrete and release digestive enzymes in several ways. They may enclose digestive enzymes in small vesicles surrounded by a membrane and then release the enzymes into the alimentary canal by fusing the vesicle membrane with the cell membrane. In some insects, parts of the cell (some of the microvilli) or the entire midgut cell may disintegrate and release enzymes into the gut lumen. Of course, when the entire cell breaks down, the cell must be repaired or replaced. Replacement occurs through the growth of the regenerative cells.

Extraoral digestion (digestion outside the insect body) occurs in some insects, including seed feeders and some predatory insects. By injecting enzymes from the salivary glands and midgut into the food source (animal or plant material) and then sucking back the liquefied digestion products, insects can utilize very high percentages of the nutrient value of the food source. Some insects reflux enzyme secretions and partially digested products by repeatedly sucking up and reinjecting the liquefied juices into the food. Refluxing mixes the secretions and fluids and extends the effective life of the digestive enzymes, and is particularly effective when the food contains a limiting boundary, such as the shell of a seed or the cuticle of an insect that acts as a container for the liquefying body contents.

Carbohydrate Digestion

Starch and sucrose are the typical carbohydrates that insects digest from plant food, and glycogen and various sugars are present in animal tissue eaten by carnivorous insects. Cellulose, the major complex polysaccharide present in plant tissue, cannot be digested by most insects. Carbohydrate digestion begins with the action of α-amylase, an enzyme present in the salivary gland secretions of many insects. Amylase works best at slightly acid pH, and hydrolyzes interior glucosidic linkages of starch and glycogen, resulting in a mixture of shorter dextrins. In the midgut *α* -glucosidase and oligo-1, 6-glucosidase (isomaltase) digest smaller dextrins, releasing glucose. Many insects also have one or more *α*- or *β*-glycosidases that digest a broad range of small carbohydrates, such as maltose, sucrose, trehalose, melezitose, raffinose, stachyose, melibiose, raffinose, and stachyose. Some insects can secrete trehalase in the gut to digest trehalose, the principal blood sugar typically in high concentration in insects. *β*-glucosidase, *β*-galactosidase, and *β*-fructofuranosidase act upon various substrates to release simple sugars in the gut. An insect usually has only a few of these carbohydrate digesting enzymes, depending upon the food it eats. For example, *Apis mellifera* honeybees have several *α* -glucosidases or sucrases that act rapidly upon sucrose, usually the principal carbohydrate in the nectar taken by honeybees. They utilize the resulting glucose and fructose for an immediate energy source and for making honey. Termites, some beetles, a few cockroaches, and woodwasps in the family Siricidae digest cellulose with aid (usually) from fungi, bacteria, or protozoa, which produce some or all of the complement of three enzymes necessary for cellulose digestion.

Lipid Digestion

The major storage forms of lipids (fats) in both plants and insects are triacylglycerols, esters of fatty acids with glycerol. Midgut cells, and in some cases symbionts, secrete lipases, which are enzymes that hydrolyze triacylglycerols and release fatty acids and glycerol. Amino acids, proteins, and fatty acylamino complexes act as emulsifiers in the midgut of some insects facilitating the digestion of fats. The glycocalyx layer, a viscous protein and carbohydrate complex that often lies on the surface of the microvilli, probably aid in emulsifying fats and in promoting contact between lipases and triacylglycerols. Fatty acids released from triacylglycerols are resynthesized into the insect's own triacylglycerols and stored in fat body cells. Immature insects typically store relatively large amounts of triacylglycerols, and use some of the released fatty acids during pupation and for egg development. Some insects, for example Orthoptera, Lepidoptera, and some aphids, mobilized fatty acids rapidly enough to use fatty acid metabolism to support flight, but other groups such as Diptera and Hymenoptera cannot release fatty acids from the fat body and transport them to the flight muscles rapidly, and so they only use carbohydrates for flight energy. They still can use lipids during pupation, and for other metabolic processes that occur more slowly.

Protein Digestion

All animals must have a pool of amino acids available for synthesis into proteins, and for repair of tissues and organs. Most animals, including insects, get their amino acids from digestion of dietary proteins. Within insects as a group, there are several different types of protein digesting enzymes, some of which act at acid pH, others at slightly alkaline pH, and some at highly alkaline pH. Usually a particular species will have several different proteinases, but no insect is known to have both an acid-effective proteinase and an alkaline-effective proteinase. The pH of the alimentary canal is important to the action of any digestive enzyme, and no insect is known to have an alimentary canal that is strongly acid in one part and strongly alkaline in another part.

Proteinases are classified broadly as serine, cysteine, aspartic acid, and metallo-proteinases depending upon the amino acid or metal at the active site of the enzyme. Trypsin and chymotrypsin are two endoproteinases with alkaline pH optima (about pH 8) that are common in many insects and which attack large proteins internally at the linkage between certain amino acid, thus breaking the protein into smaller polypeptides. Most insects appear to have several types of exopeptidases that remove the terminal amino acid from a protein or peptide chain. Thus, through the concerted action of both types of digestive enzymes, a protein can be completely digested with release of its component amino acids. Cysteine- and aspartic acid-proteinases have mildly acid pH optima, and are called cathepsins by some authors. All members of a taxonomic group may not have the same type of proteinases. Many beetles have cysteine proteinases most active at slightly acid pH, while some scarabeid beetles secrete serine-proteinases that act at the high midgut pH typical of these insects, and they have no detectable cysteine-proteinases. Lepidoptera typically secrete trypsin-like enzymes active at alkaline pH.

One defense mechanism that has evolved against herbivory in many plants is the presence of proteinase inhibitors, some of which inhibit serine proteinases while others act upon cysteine proteinases. Experimentally, it has been shown that some insects secrete multiple trypsin enzymes (isozymes of trypsin) and others just secrete larger amounts of the same few isozymes after consuming a trypsin inhibitor. This counter action by the insect probably allows some protein digestion to escape ingested inhibitors, but transgenic plants designed to have proteinase inhibitors have been tested and proven to have adverse effects upon the growth of some insects.

Absorption of Digested Products

Few details are known about the absorption of digested products by insects. In many vertebrates, glucose absorption from the alimentary canal requires an active mechanism involving ATP to supply the energy. In those insect that have been studied, glucose from digestion of carbohydrates is rapidly absorbed passively by a process known as facilitated diffusion, and involvement of ATP is not necessary. Fat body cells on the hemolymph side of the gut rapidly synthesize absorbed glucose into the disaccharide trehalose, keeping the hemolymph concentration of glucose low in most insects. Consequently, even low concentrations of glucose in the gut have a favorable diffusion pathway to the hemolymph and continue to be absorbed passively. In larvae of a few lepidopterans that have been carefully studied (*Manduca sexta*, *Philosamia cynthia*, *Bombyx mori*), amino acids are actively absorbed by transport proteins in the apical membranes of midgut columnar cells. Energy for absorption comes from the high K^+ concentration in the gut lumen and high transepithelial potential created by the proton-ATPase pump active in midgut goblet cells. The transport proteins in these membranes show strong specificity for particular amino acids, and transport systems for at least six different amino acids are known, and transport systems for other amino acids probably will be discovered. In the Colorado potato beetle, *Leptinotarsa decemlineata*, transport proteins for leucine and tyrosine have been demonstrated in midgut tissue.

Gut pH

The pH of the alimentary canal is highly variable in different species of insects. The pH of a gut segment influences the action of enzymes secreted into or carried with the food into the gut, influences solubility and toxicity of toxins and plant allelochemicals, and may alter the population of gut microorganisms. In most insects, the crop has little or no presence of buffering agents and tends to be slightly acidic, a factor favoring carbohydrate digesting enzymes. Larvae of Lepidoptera and Trichoptera tend to have a very high midgut pH, varying from about 8 to 10, promoted by goblet cells that secrete potassium and bicarbonate into the lumen of the midgut. They have protein digesting enzymes that are favored by the high pH, and the high pH may afford some protection from tannins and other allelochemicals that they ingest with their plant food.

Illustrative Examples of Diversity in Food, Form and Function of the Alimentary Canal

The following examples are not intended to be a comprehensive review of foods, and alimentary canal structure and physiology, but will merely highlight interesting diversity.

Opportunistic feeders may have evolved modifications to capture and store food when available, and thus survive lean periods when food is not available. For example, the foregut of the praying mantis, *Tenodora sinensis*, is long and wide, and occupies nearly the entire length of the body, apparently an adaptation for storage of prey when it can be captured. The midgut, eight gastric caeca, and hindgut are compressed into the last three abdominal segments. Probably much of the digestion occurs in the posterior part of the crop with enzymes passed forward from the small midgut.

Considering the universal presence of cellulose in plant tissues, relatively few insects evolved the ability to use cellulose as a source of nutrients.

Termites, some beetles, a few hymenopterans, and a few cockroaches do use cellulose as a carbohydrate source. The hindgut of termites is highly specialized for housing gut microbiota that provide the cellulase enzymes needed to digest cellulose, although there is some evidence that certain termites may be able to produce some or all of the several enzymes necessary to completely digest cellulose. Gut variation exists among the castes in a colony; for example, soldiers in the family Rhinotermitidae are fed liquid food by the worker caste, and do not have to digest cellulose so they have reduced gut structure. The workers are responsible for colony construction and nutrition, and they have highly evolved hindgut chambers to hold various types of microbiota. Termites hatch without their gut microbiota, and lose most of their gut symbionts at each molt, but they become reinfested by feeding upon fluid and excreta from older nymphs. Termites in the family Termitidae have symbiotic bacteria in the hindgut, while termites in some other families have flagellate protozoans as well as bacteria in a multi-compartmented hindgut, and they get some or all of their cellulase(s) from their symbionts. Some termites, the Macrotermitinae, cultivate fungus gardens in their underground nests and get their cellulases from the conidiophores of the fungus. Symbionts in the hindgut of some termites can capture atmospheric nitrogen in an organic form, which is probably quite important to many termites because their diet of wood is relatively low in proteins. Some fungus-growing termites convert some of the protons (H^+) and carbon dioxide from the initial fermentation of glucose into methane (CH_4), and some investigators have suggested that termites are a significant environmental source of methane, a greenhouse gas.

Larvae of the woodwasp (Hymenoptera, Symphyta, Siricidae, genus *Sirex*) acquire cellulase and xylanase from fungi ingested with the wood on which they feed. Larvae of cerambycid beetles and of some other beetles feed upon wood in down or dying trees; they generally have long life cycles because wood is so nutrient poor, especially protein poor. Fungi growing in the dead wood and ingested by the larvae may provide additional nutrients and/or enzymes for digesting the wood.

Hemiptera take xylem or phloem sap, both of which are poor in amino acids and protein, but usually rich in sucrose (150 to more than 700 mM). They typically excrete a copious, dilute fluid, and in some, such as aphids, the fluid contains so much sugar that it is called honeydew. They have to ingest large volumes of fluid to get the amino acids, and then they have to get rid of the excess water and sucrose. A characteristic evolutionary feature of the gut in Hemiptera is the filter chamber in which a loop of the hindgut is in direct contact with part of the foregut and a great deal of the ingested fluid diffuses directly into the hindgut from the foregut without passing through the midgut. This, of course, causes loss of some amino acids and other components that may be needed, but water and sucrose, both of which are in excess of needs, are the major components lost. The filter chamber is able to concentrate gut fluid up to 10-fold in some xylem feeders (Cicadoidea and Cercopoidea), but only about 2.5-fold in members of the Cicadelloidea, which are phloem feeders. Xylem feeders probably need to concentrate xylem fluids more because of the lower amino acid content (3–10 mM amino acids per liter in xylem fluid) than do phloem feeders (15–65 mM amino acids per liter in phloem fluid).

Pre-oral digestion with enzymes secreted into the prey occurs in many of the predacious beetles. Seed feeders also employ pre-oral digestion by injecting salivary secretions and possibly regurgitated midgut enzymes into the seed, allowing these to liquefy part of the seed, and then sucking the nutrients and enzymes back. Pre-oral digesters often reflux the liquefied contents by repeatedly imbibing and then reinjecting the mixture of enzymes and digested nutrients into the seed. Refluxing likely conserves enzymes longer, gives them more opportunity to function, and allows the insects to use more of their potential food.

In honeybees and some other related hymenopterans, the midgut is closed off from the hindgut by a plug of cellular tissue during larval development, and any food that cannot be digested and absorbed into the body must remain in the midgut. Just before pupation the connection between midgut and hindgut is opened, and accumulated undigested residue, such as the shells of pollen grains, is excreted into the cell. Adult honeybees clean the cell and the larva pupates inside the cell.

Nectar taken by male and female mosquitoes is stored in a large, sac-like crop that is a diverticulum from the foregut, but blood meals taken by the females are passed directly into the midgut for the beginning of digestion. The midgut is differentiated functionally into an anterior and a posterior region. The anterior part secretes carbohydrate digesting enzymes, and nectar components are digested as fluid from the crop and is passed into the anterior midgut. This arrangement keeps possible trypsin inhibitors that may be present in nectar away from the site of protein digestion, which occurs in the posterior midgut. Simple sugars resulting from digestion, or those already in the nectar, are absorbed in the anterior midgut. The posterior midgut cells secrete trypsin-like enzymes and protein (blood) digestion and absorption occur in the posterior midgut. The posterior midgut cells, more so than anterior midgut cells, have extensive microvilli and basal infoldings characteristic of secretion and absorptive processes. The midgut cells in this region get stretched by the large volume of blood that a mosquito takes if it is allowed to feed to repletion. Consequently, the cells have several types of connecting structures (desmosomes) between cells to help hold them together and prevent excessive leaking of materials in or out between cells while they are stretched.

Larvae of Lepidoptera have a very short foregut, a large, long, relatively straight midgut, and a short hindgut. There is no storage or digestion in the short, nearly vestigial foregut. Nearly all lepidopterous larvae are phytophagous feeders, and the gut modifications appear to be an adaptation to pass food quickly into the long midgut so that digestion can begin. Feeding is nearly continuous when plenty of food is available, and larvae may ingest more than their body weight in food daily. Food moves rapidly through the relatively straight gut and frass droppings are frequent in phytophagous caterpillars. Because the larval and adult forms of Lepidoptera have very different life histories and food habits, the adult gut is quite different from that of the larva. Many adult Lepidoptera feed only upon nectar, which is stored in the crop and slowly released into the midgut for digestion to simple sugars. Some adult Lepidoptera have vestigial mouthparts and do not feed at all; they survive and (females) produce eggs at the expense of body substance, and they generally live only a few days. An unusual food utilized by *Tineola bisselliella* larvae (clothes moth) is wool, and larvae have a very strong reducing action in the midgut that breaks disulfide bonds between adjacent loops of the proteins, causing the wool proteins to lose their three-dimensional shape and unfold. This allows more access for protein digesting enzymes.

Alimentary System

The alimentary system (canal) is a system of tubular structures that takes in food at the mouth, stores the food, fosters digestion and absorption of nutrients, and allows excretion of waste materials from the rectum. It is conveniently divided into the foregut, midgut, and hindgut (Fig. 35).

Allegheny Mound Ant, *Formica exsectoides* (Hymenoptera: Formicidae)

GREGORY S. PAULSON
Shippensburg University, Shippensburg, PA, USA

The Allegheny mound ant, *Formica exsectoides* Forel, is a common mound-building ant of the northeastern and central United States. Workers are approximately 3/8 inch long (1 cm) with a reddish-tan head and thorax, and a dark brown abdomen. In suitable habitat, *F. exsectoides* will form dense populations, their presence easily discernible due to conspicuous mound-type nests which can be as large as 15 feet (4.6 m) in diameter and 4 feet (1.2 m) high. At one site near Altoona, Pennsylvania, researchers counted more than 30 large mounds per acre. Despite the conspicuous nature of *F. exsectoides* nests and its wide geographic range, relatively few papers concerning this species have been published since H.C. McCook's first paper in 1877.

Nests tend to be clustered in the habitat (Fig. 36). Nests in each cluster often will share foraging trails and resources. Although there is little aggression between workers from different nests or nest clusters, the workers still show fidelity to a home nest. Nests of *F. exsectoides* have multiple queens (polygynous) although there is tremendous variation in the number of queens per mound. Over 1,400 queens were reported in one mound, but that is probably an anomaly. Most mounds probably contain fewer than 20 queens. Due to the large number of queens, the reproductive output of a nest can be prodigious resulting in large numbers of workers in a colony. More than 250,000 workers have been found in some nests. Reproductive forms (alates) are present in the nests from mid-summer until early fall. Activity of the ants is related to ambient conditions but, in general, workers are active from late March until November. *Formica exsectoides* are generalist predators, scavengers and collect honeydew from symbiotic hemipterans.

Habitat has a significant effect on physical characteristics of *F. exsectoides* nests. Forest nests tend to be significantly larger in height, width, length, nest footprint and volume than nests in meadows. In general, the nests are round, but it is not uncommon to find elongated nests that are orientated to the sun. The shape of a nest and its orientation may help the ants to maintain a relatively constant internal temperature and relative humidity.

Allele

One of two or more alternative forms of a gene at a particular locus. If more than two alleles exist, the locus is said to exhibit multiple allelism.

Allelochemic

A non-nutritional chemical produced by one species (often a plant) that affects the growth, health, or behavior of another species (often an herbivore).

► Allelochemicals

Allelochemicals

MURRAY S. BLUM
University of Georgia, Athens, GA, USA

For thousands of years insects and plants have been locked in a battle for which survival is the ultimate prize. For insects, plants constitute food sources for growth and development, and in some cases, sites for reproduction. On the other hand, plants attempt to counter insects feeding on their tissues (herbivory) so that their own vigorous growth and development will occur and lead to reproductive success. The consequences of this warfare are great and for humankind the outcomes of these battles may be of major economic significance in terms of the production of various foods. The welfare of various human populations can be threatened if hordes of ravenous insects consume specific crops that are the mainstays of these populations. But plants do not take this "lying down." Over thousands of years, plants have done everything possible to make life miserable for insects. On the other hand, insects have returned the favor many times over. In recent geological time, plants and insects have changed their "spots" (plant-feeding strategies), resulting in an incredible point-counterpoint relationship of these organisms that is characterized by some remarkable developments.

As far as nutrients are concerned, different kinds of plants (species) are fairly similar and can provide an insect herbivore with the basic nutrients required for growth and development. These compounds (chemicals) are called primary compounds because they are required for the insect's growth, development, and reproduction. All insects require these compounds and in theory they should be readily available from a wide variety of plant species. But most species of insects, rather than feeding on many different kinds of plants, limit their plant menu to a relatively small number of plant species (monophagy), most of which are related. Significantly, the limited preferences that insects have for their food plant species are due to non-nutritive compounds that usually vary from one plant group to another. These compounds are not related to the primary compounds identified with growth and development, and it is apparent that these plant-derived compounds (allelochemicals) generally have functions related to other species of organisms. These compounds are obviously not primary compounds but rather secondary compounds (non-nutritive) whose manufacture has been described as secondary metabolism. Indeed, these allelochemicals appear to be responsible for both the associations and non-associations that insects have with specific groups of plant species. In essence, it would be no exaggeration to state that the host-plant preferences of insects really reflect the ability of an insect species to either tolerate, or be repelled by, an allelochemical. Allelochemicals are not mysterious compounds but rather are a very important part of the everyday world, especially in terms of human food preferences. In a sense, the strong food preferences exhibited by insects are not so different from those of humans, with one striking exception. Many insect species are "locked in" to specific food plants, and these insects will reject a foreign plant species and die in the absence of their normal food plant. On the other hand, there is little evidence that human beings will subject themselves to starvation if their favorite foods are not readily available.

A World of Allelochemicals

Fruits and vegetables possess characteristic odors and tastes that create desire (preference) for these foods. Significantly, these tastes and smells are not identified with the primary compounds responsible for plant growth and development, such as sugars, fats, and proteins. Therefore, the plant has invested in producing a variety of chemicals that will not help it grow or reproduce. While an onion may possess a distinctive odor and taste for both insects and humans (not necessarily the same odor and taste for both), this fact hardly justifies the onion spending its energy and resources to produce an onion fragrance. On the other hand, if the taste and odor of onions combine to make this vegetable distasteful and repellent to most plant-feeding insects, then these allelochemicals perform a very vital function. In essence, it is generally believed that these secondary compounds are responsible for protecting plants from herbivores and possibly pathogens as well. A brief examination of some well-characterized allelochemicals offers a means of examining these compounds as agents of defense both as toxins and as repellents.

Oleander, which has a very limited number of herbivores, is extremely toxic because of the presence of allelochemicals that are somewhat related to cholesterol. The odor of the plant probably constitutes an early-warning system that makes potential herbivores aware of the danger of feeding on this plant. The same can be said for the tobacco plant which, like oleander, does not have too many insect herbivores. Leaves of the tobacco plant are quite toxic, but in some South American populations young children become addicted to the nicotine in the leaves before they are ten years old. Nitrogen-containing compounds (alkaloids) produced by opium poppies are powerful repellents for a wide range of insect species, and there is no doubt that compounds such as morphine and heroin, which are powerful human narcotics, were evolved to deter herbivores rather than to function as narcotics for humans.

Alkaloids such as nicotine have been adapted to function as insecticides, and a variety of plant products such as derris, rotenone, ryania, and sabadilla are also used as insecticides in different cultures. In some cases, allelochemicals such as prunasin in cherry leaves cause poisoning in livestock. Not to be outdone, humans have frequently utilized the alkaloid strychnine to murder people. However, it would be a mistake to lose track of the fact that, human abuses notwithstanding, these allelochemicals were evolved as plant protectants long before humans appeared. Obviously, allelochemicals do not provide plants with absolute protection against herbivores. Indeed, probably all plants containing allelochemicals are fed upon by insects, and in many cases these herbivores are only found on a limited number of host plant species. For example, monarch butterfly caterpillars are limited to the milkweed species. Bark beetles limit their attacks to pines and related conifers, developing in environments that are rich in toxic turpentines. These insects have breached the chemical defenses of their hosts, and in so doing, they have "captured" specific kinds of food plants that are either repellent or highly toxic to most other species of insects. Guaranteed these "forbidden fruits," these herbivores should have to share their food resources with very limited numbers of competitors. Barring an ecological disaster does not devastate the populations of their host plant species, this specialization should have much to recommend it. On the other hand, many insect species choose a lifestyle which is characterized by feeding on a variety of unrelated plant species.

Insects like the monarch butterfly and bark beetles that are restricted to a limited number of related plant species are referred to as specialists.

These herbivores have become resistant to the toxic effects of their host plant allelochemicals, and in many cases they appear to be completely immune to the plant toxins they ingest. In the case of monarch caterpillars feeding on milkweeds, it has been demonstrated that these larvae actually grow more rapidly on milkweed plants containing the highest concentration of toxins.

Indeed, allelochemical concentrations may be generally quite high, often averaging 5–10% of the dry weight of the plant. By contrast, plant-feeding generalists feed on a wide range of plant species, often unrelated. However, in general, these herbivores select plant species in which the concentrations of allelochemicals are not too high, enabling them to process low levels of a wide variety of plant toxins.

The immunity of specialists to the toxic effects of the allelochemicals in their diets demonstrates that for these insects these compounds can no longer be considered poisons. Surprisingly, the basis for this important allelochemical resistance, which has great economic significance, was only understood about thirty years ago.

Sequestration and its Consequences

Insects such as the monarch butterfly store compounds in their tissues that render them unpalatable to predators. These compounds, the cardenolides, were ingested by the larvae from their milkweed food plants, and retained in their bodies into the adult stage. The storage of these milkweed compounds is called sequestration, and constitutes a widespread phenomenon among specialists feeding on allelochemical-rich plants. In a sense, sequestration represents the insect's success in utilizing the plant's chemical defenses for its own purposes. Indeed, sequestration can be regarded as a form of detoxication since potentially toxic compounds are removed from the circulation and stored in the tissues.

Sequestration has been detected in at least seven orders of insects including species of toxic grasshoppers, aphids, lacewings, beetles, wasps, butterflies and moths. In general, these insects are brightly (= warningly) colored, a characteristic described as aposematic. Armed with the toxins from their food plants, large insects such as brilliantly colored grasshoppers move very slowly, as if to advertise their poisonous qualities to the world. Obviously the term toxic is relative, since these insects routinely sequester these allelochemicals during normal feeding. However, since these specialists are physiologically adapted for ingesting these compounds, their ability to tolerate these allelochemicals is really not surprising. On the other hand, non-adapted species (e.g., predators) would certainly encounter toxic reactions if they ingested these toxic plant products.

The fates of allelochemicals, which are usually present in mixtures, are not at all predictable after ingestion by an adapted herbivore. Although many compounds are sequestered immediately after ingestion, others may be metabolized before being stored, or even eliminated after being metabolized. In other cases selected allelochemicals in a mixture may be absorbed and sequestered whereas other compounds in the mixture may be eliminated immediately. An examination of the options for initially processing ingested allelochemicals emphasizes the versatility of specialists in treating the toxic compounds produced by their food plants.

Sequestration of Insect Toxins by Vertebrates: A Significant "Allelochemical" Phenomenon

It has become evident that the allelochemical relationship of insects and plants is paralleled by a similar relationship of amphibians and insects. It is now recognized that the sequestration of ingested toxic insect compounds by vertebrates differs little from this phenomenon in insect herbivores and plants. In essence, a variety of insect toxins is sequestered by amphibians and these compounds have similar protective functions for frogs and insects (see *Allelochemicals as phagostimulants*). Frogs exploit insect allomones (defensive compounds) as if they were animal "allelochemicals," and it seems worthwhile to emphasize this congruency in examining the scope of allelochemistry.

Frogs in the genus *Dendrobates* contain mono-, di-, and tricyclic alkaloids which are clearly of ant origin. The alkaloids, termed pumiliotoxins, appear to be products of ant species in the genera *Brachymyrmex* and *Paretrechina* and constitute the only known dietary source of alkaloids of these frogs, not unlike the specialist insects feeding on narrow plant diets enriched with allelochemicals. The same phenomenon has been described for the myrmicine ant *Myrmicaria melanogaster* which synthesizes ten alkaloids. Some of these alkaloids have previously been identified in a dendrobatid frog and a toad.

Neurotoxic steroidal alkaloids, the batrachotoxins, have been isolated from New Guinea birds in the genera *Pitohui* and *Ifrita*. These compounds are among the most toxic natural substances known, and they are not produced by captive birds, suggesting a dietary source. Recently, the batrachotoxins were identified in beetles in the genus *Chloresine* (Melyridae) which are normally fed on by the bird species. Since the genus *Chloresine* is cosmopolitan, it is the possible source of some of the avian alkaloids found in birds in different areas.

Vertebrate sequestration of alkaloids from insects has only recently been explored. Clearly this chemical storage has a common denominator with sequestration of alkaloids by insects (see *Allelochemicals as pheromonal precursors*) and should be examined as a paradigm of comparative physiology. Clearly, insects are pivotal to both systems, either as food for vertebrates or food for insects, with sequestration the major common feature.

Initial Processing of Allelochemicals by Specialists

Once an adapted insect has ingested an allelochemical, a menu of options is available for processing it. An insect species may utilize a variety of adaptive strategies for processing a single compound that is characteristic of the host plant defense.

Immediate Allelochemical Excretion

Some insects essentially fail to absorb ingested allelochemicals from the gut. These compounds are excreted directly and are concentrated in the feces. A lymantriid moth larva that is a specialist on the coca plant, which is the source of the alkaloid cocaine, rapidly excretes this compound with only traces being found in the blood. However, cocaine may still have defensive value for the larva as part of an oral regurgitate that is externalized when the larva is disturbed.

Three different species of moth larvae that feed on tobacco plants rapidly excrete nicotine, a very toxic and reactive alkaloid. There is no evidence that nicotine is absorbed from the gut of any tobacco feeder, but as is the case for the moth larva excreting cocaine, nicotine in oral or anal exudates constitutes an excellent defensive compound.

Allelochemical Metabolism

Many insect specialists rapidly metabolize ingested allelochemicals which are then sequestered, or in some cases excreted. Nicotine, which is both highly reactive and very toxic, is converted to a non-toxic metabolite called cotinine by both tobacco-feeding insects and those that are not tobacco feeders. Since cotinine has virtually no toxicity to insects, it is probable that its production from nicotine constitutes true detoxication.

Cabbage-feeding insects feed on plants that are rich in sinigrin, a compound that yields a highly toxic mustard oil when metabolized.

Although sinigrin can be sequestered without generating the reactive mustard oil in a variety of cabbage-feeding species, cabbage butterflies (whites) actually break down sinigrin and sequester the highly reactive mustard oil. For these butterflies, the mustard oil is more suitable for storage than sinigrin.

Larvae of the tiger moth *Seirarctia* have evolved a novel strategy for coping with the toxic effects of MAM, a compound derived from cycasin which is a constituent in the cycad leaves upon which they feed. When larvae encounter MAM, they convert it to cycasin which is absorbed through the gut wall before being sequestered. Since the enzyme that produces cycasin or MAM is only found in the gut, once cycasin crosses the gut wall into the blood prior to sequestration there is no chance of MAM being generated from cycasin.

Many species of moths, butterflies, and grasshoppers feed on plant species that produce extremely toxic compounds known as pyrrolizidine alkaloids. These alkaloids, present as mixtures, are frequently sequestered by these specialist insects and, in some cases, metabolized plant compounds are the preferred storage forms. For example, larvae of the tiger moth (*Tyria* species) feed on ragwort and primarily sequester the alkaloid seneciphylline, although this compound is present in the plant as the N-oxide. Conversely, the grasshoppers of the *Zonocerus* species convert the ingested alkaloid monocrotaline to its N-oxide before sequestering the compound.

Insects feeding on milkweed metabolize the toxic cardenolides (steroids) produced by these plants, converting them into compounds that can be readily sequestered. The milkweed bug (*Oncopeltus* species) oxidizes cardenolides as a mechanism for converting these steroids into compounds that can be efficiently sequestered. Similarly, larvae of the monarch butterfly store metabolized cardenolides in tissues after oxidizing these compounds into suitable chemical forms for sequestration.

Selective Biomagnification of Allelochemicals in Tissues

There is little indication that the profiles of insect-stored allelochemicals in any way mirror those of their host plant. In a sense, each insect species treats ingested allelochemicals distinctively, so that a compound totally excreted by one species may constitute the main sequestration product of another.

The very toxic grasshopper *Poekilocerus bufonius* sequesters only two of the cardenolides that it ingests from its milkweed food plant. Similar selectivity is shown by moth larvae (*Syntomeida* species) which sequester oleandrin, the main steroid found in the leaves of oleander. On the other hand, a variety of other insects feeding on oleander leaves do not sequester oleandrin.

Similar unpredictability characterizes the sequestration of pyrrolizidine alkaloids by moth larvae. Tiger moths (*Amphicallia* species) sequester the alkaloids crispatine and trichodesmine, whereas the main alkaloid present is crosemperine. Another tiger moth (*Tyria* species) concentrates senecionine in its tissues in spite of the fact that this compound is a trace constituent in the leaves. *Tyria* is no less curious as a sequestrator because it stores jacobine, jacozine, and jacoline as minor constituents in adults, yet these three compounds are major alkaloids in the leaves.

The Diverse Functions of “Captured” Allelochemicals

While highly concentrated allelochemicals may constitute a major deterrent to non-adapted insects, these compounds can represent a real treasure trove for species for which these plant products are non-toxic. Indeed, in the course of exploiting for their own protection compounds that are repellent or toxic to most insect species, specialists have gone beyond the point of simply being resistant to allelochemicals. In many cases, a variety of specialist species have utilized the rich allelochemical pool that is available in order to develop a menu of remarkable functions.

Insect Sequestration of Bacterial Compounds and their Glandular Secretion

Prokaryotes (bacterial types) are almost everywhere and their widespread association with insects is certainly well established. But the bases for these diverse bacteria-insect relationships are, for the most part, *terra incognita*. However, very recent research suggests one very surprising function for bacteria in insect glands.

All major types of metabolism evolved in prokaryotes and the success of these organisms was both cause and effect of changing environments on earth. If these bacteria are sequestered in insect secretory glands, their great metabolic abilities could be utilized to biosynthesize bacterial allelochemicals which could be used as potent defensive compounds. This possibility appears to have been realized as a product of the virtual ubiquity of both insects and their biosynthetically versatile prokaryotes.

Predaceous diving beetles (*Dytiscus* species) are distinguished by their ability to produce defensive steroids, some of which are novel animal products that are limited to species of diving beetles. Furthermore, insects do not synthesize cholesterol which in insects must be obtained from exogenous sterols. However, it now appears that the surprising steroidal versatility of dytiscids may reflect the biosynthetic elegance of bacteria rather than insects.

Adult diving beetles may contain concentrations of at least 10 bacterial species, mostly detected in a variety of organs. Culturing individual bacterial species resulted in the identification of diverse steroids that had previously been characterized in the prothoracic defensive glands of the adults. The steroid-rich secretions of these glands function as vertebrate deterrents that can cause emesis of fish that swallow these beetles. If the dytiscid-bacterial association is typical of a variety of insect species and their bacterial symbiotes, then a multitude of insect-bacterial relationships may require re-evaluation of possible examples of insect sequestration of bacterial allelochemists.

Non-pathogenic bacteria are commonly housed in insects and, in a sense, these prokaryotes are sequestered by their insect hosts. Furthermore, if the bacteria synthesize toxic compounds which may be externalized from a defensive gland (prothoracic glands of dytiscids), then the bacterial products may be regarded as bacterial allelochemicals that have been sequestered. Indeed, bacterial compounds of symbiotic bacteria of insects clearly constitute an unrecognized group of allelochemicals.

Additives in Defensive Glands

Milkweed bugs (*Oncopeltus* species) add cardenolides, derived from their milkweed host plants, to their thoracic defensive gland secretion which considerably enhances the deterrency of their secretion. Similarly, a warningly colored generalist, the lubber grasshopper (*Romalea guttata*) incorporates a large number of allelochemicals derived from a variety of plant species into its thoracic gland secretion. This grasshopper generally feeds on plants with low concentrations of allelochemicals, but if it is fed high concentrations of plants with known repellents (e.g., onion), the odorous secretion can be highly deterrent.

Another toxic grasshopper, *Poekilocerus bufonius*, utilizes allelochemicals as the mainstay of its defensive secretion. This aposematic (very warningly colored) insect sequesters two of six cardenolides from its milkweed diet which are the major irritants in the secretion when it is sprayed at adversaries. Utilization of allelochemicals as defensive gland constituents is particularly pronounced in the swallowtail larvae of *Atrophaneura alcinous*, which feed on leaves that are rich in toxic aristolochic acids. Seven aristolochic acids are sequestered by the larvae and all are transferred to the defensive gland in the head. The acids are concentrated in the gland and are the major deterrents for birds.

Regurgitation and Defecation of Allelochemicals

The intestines of stimulated grasshoppers can discharge ingested plant products which may serve as repellents for predators. Regurgitated allelochemicals can effectively repel ants, as is the case for anal discharges from the hind gut. When tactually stimulated, the milkweed bug, *Oncopeltus fasciatus*, also defecates a solution containing repellent allelochemicals. In this case, they are cardenolides ingested from their milkweed food plant.

Allelochemicals as Tissue Colorants

The cuticular (skin) coloration of many insects is diet-dependent and is highly adaptive since it enables the insect to respond in a positive way to its background color. Diet-induced changes may result in the insect being cryptic (background matching), whereas aposematic species can be background contrasting. Background quality, which is of great survival value, appears to be controlled by allelochemicals that are widespread in the diets of moths, butterflies and true bugs. These insects are particularly sensitive to the carotenoids (e.g., tomato red) that fortify their host plants.

If the large white butterfly, *Pieris brassicae*, is reared on its normal diet of cabbage leaves, the pupae are green and contrast with their background. This toxic insect contains high concentrations of carotenoids, and the carotenoid lutein is concentrated in the cuticle. On the other hand, if these insects are reared on an artificial diet lacking carotenoids, they possess a turquoise-blue coloration and exhibit no response to background. In the absence of carotenoids, these insects are quite conspicuous on their background and could be readily detected by predators.

Allelochemicals as Inhibitors of Toxin Production

Some plant toxins are present in plants in an inactive form only to be converted to toxic compounds after ingestion by herbivores. This is particularly true for many cyanogens (cyanide-containing toxins) that generate cyanide when the leaf surface is broken as would occur with a plant feeder. It now appears that cyanogenesis (producing cyanide) in damaged leaves may be inhibited by allelochemicals that are compartmentally isolated from the cyanogens in the intact leaves.

Leaves of papaya, *Carica papaya*, contain two cyanogens that yield hydrogen cyanide after enzymatic attack. However, tannins, which are widely distributed in plants, inhibit the release of cyanide caused by the action of enzymes that attack the cyanogens. Insects attacking plants containing cyanogens may have adapted tannins to prevent cyanide release, a strategy that may be suitable for other plant groups that yield toxic products after leaf damage.

Allelochemicals as Pheromonal Precursors

Bark beetles (Scolytidae) in the genera *Dendroctonus* and *Ips* convert the hydrocarbons produced by their pine hosts into alcohols that are utilized as either aggregation or sex pheromones (communication compounds) by the attacking beetles. Similarly, butterflies in the family Nymphalidae and moths in the family Arctiidae convert pyrrolizidine alkaloids (PAs) into sex pheromones that are especially critical during courtship. The PAs may be collected from damaged plants by males to be transformed into sexual pheromones that constitute the key to reproductive success. For these males, the allelochemicals (PAs) are identified with reproductive fitness.

Allelochemicals as Structural Paint

Some insects actually "paint" structures with ingested compounds possessing considerable biological activity. Larvae of the parsnip webworm, *Depressaria pastinacella*, apply ingested allelochemicals to silk-webbed flowers that serve as housing units. The applied compounds are derived from wild parsnip, a food plant that is rich in highly toxic furanocoumarins. These compounds are sequestered in the silk glands before being applied to the flowers in which the larvae reside. Since the larvae are quite sensitive to ultraviolet light, the presence of UV-absorbing furanocoumarins on their silken housing is highly adaptive. In addition, because these allelochemicals possess pronounced antimicrobial activity against bacteria and fungi, their presence on the silk can act as a major barrier to pathogens.

Allelochemicals as Metabolites in Primary Metabolic Pathways

Some specialist herbivores metabolize the characteristic allelochemicals in their host plants into compounds that are of major significance in growth and development. In essence, these specialists exploit their food plants by utilizing not only their primary nutrients for growth and development, but their allelochemicals as well.

Larvae of the bruchid beetle, *Carydes brasiliensis*, develop exclusively on seeds of a legume (pea family) that contains canavanine, a foreign amino acid related to arginine. Canavanine is highly toxic when incorporated into proteins by non-adapted herbivores. On the other hand, larvae of *C. brasiliensis* metabolize canavanine into products of great metabolic significance. Large amounts of ammonia are generated for fixation into organic compounds, and an amino acid is produced from canavanine for ready metabolism. Thus, the very toxic allelochemical of the legume has been thoroughly exploited by the beetle larvae as a source for key nutrients.

Beetle larvae in the genus *Chrysomela* also convert a toxic allelochemical into a metabolite with considerable importance in growth and development. These larvae feed on leaves of willow (*Salix*), a rich source of salicin, a toxic metabolite. Metabolism of salicin yields a very effective defensive compound that is sequestered by the larvae in defensive glands. In addition, this metabolism generates enough glucose to account for about one-third of the daily caloric requirements of the larvae. Salicin should be regarded as an allelochemical nutrient.

Allelochemicals as Agents of Sexual Development

Tiger moths in the genus *Creatonotus* feed on plant species that produce high concentrations of pyrrolizidine alkaloids (PAs). These compounds are converted to sex pheromones by the males. Additionally, these allelochemicals control the development of important secondary sexual characters called coremata. The coremata are eversible andraconial (male) organs that are the source of the volatile sex pheromones of the males, and their degree of development is controlled by the amount of PAs ingested by the developing larvae. In effect, PAs are functioning as male hormones that regulate both sex pheromone production and development of the coremata.

Allelochemical Discharge from Non-glandular Reservoirs

Some insects sequester ingested allelochemicals in non-glandular reservoirs that can be evacuated upon demand. Gregarious larvae of the European pine sawfly, *Neodiprion sertifer*, sequester toxic turpentine terpenes in foregut pouches. These pine-derived compounds can be discharged upon demand to function as highly effective predator deterrents. Similarly, lygaeids such as the milkweed bug, *Oncopeltus fasciatus*, sequester cardenolides from their milkweed hosts in dorsolateral spaces on the thorax and abdomen. Significantly, high concentrations of cardenolides are stored in these spaces, resulting in a concentrated deterrent discharge which repels potential predators.

Allelochemicals as Defensive Agents of Eggs

Insects ingesting allelochemicals often utilize these compounds as protectants for the next generation of insects. These plant compounds may be sequestered in the eggs in order to provide a formidable defense against predators and pathogens. The insect embryo must be resistant to the toxic effects of the allelochemicals that have been sequestered in the reproductive system. For example, chrysomelid beetle adults feeding on willow and poplar sequester the toxic allelochemical salicin which is used to fortify the eggs. Salicin has different functions in the embryo and the larvae. For the embryo, salicin is a deterrent toxin which can kill ants. For the young larvae, salicin is converted to salicylaldehyde, a powerful repellent that is not frequently encountered in insects. A wide variety of allelochemicals are sequestered in insect eggs which includes pyrrolizidine alkaloids, aristolochic acids, cannabinoids, quinones, cardenolides and mustard oils. It is evident that the females of a large number of species have appropriated their host-plant defenses (allelochemicals) for protection of their eggs.

Allelochemicals as a Copulatory Bonus

Females may obtain allelochemicals suitable for their own protection and that of their eggs from the seminal ejaculate. For example, males of ithomiine butterflies gather pyrrolizidine alkaloids (PAs) from flowers and decomposing foliage and about half of the PAs are channeled to the spermatophore (sperm packet) that is transferred to the female during copulation. Since the females are rarely found feeding on alkaloid sources, the copulatory bonus ensures that these toxic allelochemicals will be available to protect both the female and her eggs. It is also very significant that the resistance of the spermatozoa to the known toxic effects of the pyrrolizine alkaloids enables the copulatory bonus strategy to be highly adaptive.

Allelochemicals as Synergists for Pheromones

The intimate relationship of specialist insects and their food plants is exemplified by the turnip aphid, *Lipaphis erysimi*, and its alarm pheromone. This aphid is typical of many aphid species. Paired glands near the tip of the abdomen secrete an alarm pheromone that causes both adults and larvae to disperse and drop off of the food plant. The alarm pheromones synthesized by the aphids are key communications chemicals that enable these insects to "abandon ship" when threatened by a predator. Surprisingly, (*E*)-*B*-farnesene, the major alarm agent for a large variety of aphid species, is only weakly active when secreted by the turnip aphid. However, the activity of this pheromonal secretion is increased appreciably by allelochemicals that act as powerful synergists for the major alarm pheromone. These synergists are derived from typical food plant compounds that have been modified by the aphids.

Allelochemicals as Phagostimulants

The close relationship of insect specialists and their allelochemicals is further demonstrated by some species of sawflies and chrysomelid beetles which feed on very bitter food plants. Adults of the turnip sawfly, *Athalia rosae*, feed on the surface of a plant that is not a larval food plant. Compounds in the leaf surface that are responsible for their bitter taste are powerful phagostimulants for *A. rosae*. In addition, these bitter compounds are incorporated into the cuticle, thus providing these sawflies with a cuticular set of "armor" to protect against aggressive predators.

Similarly, species in three genera of chrysomelid beetles utilize cucurbitacins, compounds found in their squash and pumpkin hosts, as phagostimulants that are biomagnified in their bodies. The beetles are rendered distasteful and, as is the case for the sawflies, the allelochemicals possess dual roles that both induce ingestion and promote sequestration of highly distasteful compounds.

Allelochemicals as Inducers of Detoxifying Enzymes

Both generalist and specialist insects can encounter a diversity of allelochemicals with varying degrees of toxicity. For generalists this is particularly true since a generalist diet can sample a wide variety of plant species containing a large diversity of allelochemicals. On the other hand, specialists may encounter fewer allelochemicals but it is likely that these compounds will be at high concentrations. In the case of both feeding modes, it is obviously necessary to possess mechanisms for blunting the toxic properties of the ingested allelochemicals. Detoxication would appear to constitute the key process for neutralizing the toxicities of ingested allelochemicals. The enzymes chiefly identified with converting allelochemicals into less toxic compounds are the mixed-function oxidases, particularly cytochrome P-450.

Mixed-function oxidases metabolize fat-soluble toxins into water-soluble ones that can be excreted. The level of these enzymes may determine the tolerance of an insect for a particular allelochemical. For a generalist ingesting a large diversity of allelochemicals derived from many plant species, the induction of a variety of these oxidases would promote the possibility of detoxifying many kinds of plant compounds. For a specialist, fewer oxidases at very high levels would enable the herbivore to detoxify the very high concentrations of allelochemicals in its restricted food plants.

Mixed-function oxidases play a key role in protecting the southern armyworm, *Spodoptera eridania*, from a host of allelochemicals. Unrelated plant compounds rapidly induce enzymatic increases of 2 to 3-fold in larvae. Significantly, the rise in P-450 activity is immediate and proceeds rapidly over much of its course during the first few hours. These results strongly suggest that P-450 induction is critical to allelochemical tolerance.

Allelochemicals as Allomonal Precursors

In some cases, insects have produced powerful repellents from allelochemicals in their food plants and have thus exploited the plant's defensive chemistry in a very efficient way. Such a strategy is particularly adaptive because the insect has benefited both nutritionally and defensively from feeding on its host.

Host plant exploitation is particularly pronounced in some chrysomelid beetle larvae in the genera *Chrysomela* and *Phratora*. The larvae feed on willow and poplar leaves, both of which contain salicin, a well known feeding deterrent for non-adapted species. The beetle larvae convert salicin to salicylaldehyde and glucose, utilizing the former for defense and the latter for growth. For these chrysomelid larvae, the conversion of salicin to salicylaldehyde is doubly beneficial. Very little energy is used to synthesize salicylaldehyde, compared to what is required to produce other defensive compounds that must be totally synthesized. Because salicylaldehyde is a far more effective repellent than salicin, the beetle larvae receive a very important double bonus by converting the allelochemical into a compound that can be readily stored and secreted from the defensive glands.

Allelochemicals as Communicative "Jamming" Agents

In theory, plant species could reduce or eliminate herbivory if the plants generated volatile compounds identical to or similar to the pheromones utilized by herbivores as signals. If these signals were behaviorally disruptive, feeding could be appreciably diminished, to say the least.

The wild potato, *Solanum berthaultii*, has effectively "jammed" the pheromonal alarm signal of its potential aphid herbivore. (*E*)-*B*-farnesene, an alarm pheromone of the aphid *Myzus persicae*, is also produced by wild potatoes, resulting in repellency and dispersion of the aphids. In effect, the potato has exploited the aphid's herbivory by utilizing a highly disruptive compound that has been evolved by aphids as a warning signal.

Quenchers of Phototoxic Allelochemicals

Diverse plant species produce photo-activated compounds that are highly toxic to insects after digestion. In essence, these compounds generate highly toxic species of oxygen that attack key biochemicals such as nucleic acids. On the other hand, if the herbivore simultaneously ingests allelochemicals that are effective quenchers of toxic oxygen species along with the phototoxins, then survival and prosperity are possible. The availability of these allelochemical antioxidants has enabled some insect species to utilize food plants that are "forbidden fruits" for most herbivores.

Larvae of the tobacco hornworm feed on a variety of plant species that contain the phototoxin α-terthienyl, a constituent of many species of asters (Asteraceae). However, the additional ingestion of β-carotene reduces mortality from 55% (controls) to 3% (+carotene) during 48 h. β-carotene, an effective quencher of toxic oxygen species, is concentrated in the tissues of the larvae where it can serve as a potent antioxidant for photoactivated toxins found in its food plant.

Antibiotic Functions of Allelochemicals

The demonstrated range of allelochemicals against insect-associated viruses, fungi and bacteria makes it probable that these arthropods have commonly exploited plant compounds as key elements in their phytochemical defenses.

A compound commonly produced by conifers is *a*-pinene, which inhibits diverse microorganisms including the insect pathogen *Bacillus thuringiensis*. Along with several related compounds, α-pinene reduces the infectivity of *B. thuringiensis* for larvae of the Douglas fir tussock moth, *Orgyia pseudotsugata*. At concentrations approximating those found in fir needles, *a*-pinene increases the 50% lethal dose for *B. thuringiensis* by 700-fold.

A pathogenic fungus, *Nomuraea rileyi*, frequently attacks lepidopterous (moth) larvae such as the corn earworm, *Helicoverpa zea*. However, the pathogenicity to this larva can be reduced if the moth ingests a tomato alkaloid, α-tomatine. If the larvae ingest α-tomatine prior to exposure to fungal conidia, it increases larval survivorship considerably. The alkaloid is a further asset to *H. zea* because it is quite toxic to larval parasites of the corn earworm.

The pathogenicity of viral pathogens of *H. zea* can also be compromised by host plant allelochemicals. Chlorogenic acid, a common plant compound, is oxidized to chlorogenoquinone by plant enzymes, and this oxidation product binds to a nuclear polyhedrosis virus. Binding to this baculovirus results in a reduction in digestibility and a decrease in infectivity. Furthermore, it appears that the liberation of infective virons in the midgut, which is a requirement for successful infection, is impaired by the binding of chlorogenoquinone to the baculovirus.

Specialists and Generalists: Two Selected Case Studies

Although specialists and generalists may be highly efficient sequestrators, the storage characteristics of both groups differ considerably. Some insights into how these insects manipulate the allelochemicals in their diets have been provided by recent studies of the fates of a variety of ingested plant chemicals. An analysis of these studies demonstrates that the particulars of sequestration are, if nothing else, very unpredictable.

The Monarch Butterfly, *Danaus plexippus*

The monarch is a specialist that feeds exclusively on different species of milkweeds. Milkweeds contain steroids called cardenolides, which are somewhat related to vertebrate hormones such as testosterone. These compounds are toxic and highly emetic, vomiting often following their ingestion by non-adapted species.

Polar (water soluble) cardenolides are sequestered in the large volume of gut fluid possessed by the larvae. Sequestration is much more efficient from plants with low level cardenolide concentrations than with high concentrations. Significantly for the monarch, and not necessarily for other milkweed feeders, it is the large volume of gut fluid that makes it possible to feed and develop on these plants.

The cardenolide-rich gut fluid, which may exceed one-third of the larva's total liquid volume, is withdrawn at pupation to become part of the hemolymph (blood) pool, stored primarily under the wings. Subsequently, the wing scales (bird predators beware), along with the hemolymph, become the richest sources of cardenolides in the body after being withdrawn from the gut fluid. The volume of gut fluid decreases before pupation only to increase again before pupal molting. Again, gut fluid diminishes during pupal development only to increase again in the new adult. The cardenolide-rich gut fluid is again converted to hemolymph during adult development so that very little remains to be lost when the newly developed adult evacuates accumulated waste products from its gut.

The polar cardenolides in the gut fluid clearly are the source of the defensive compounds manipulated by the monarch at all stages. The larval and pupal exuviate (cast skins) eliminated after molting are an excretory form for the cardenolides, as is the case for these compounds in the wing scales. Excretion notwithstanding, the ability of all life stages to manipulate the cardenolide pool is quite pronounced. This is evident in 2-day-old pupae that contain low concentrations of cardenolides in the gut fluid but high concentrations in the hemolymph. However, before wing expansion in the newly developed adult, the cardenolide level in the hemolymph is at its lowest, only to increase to the highest level in any life stage.

The presence of high levels of cardenolides in the blood of the adult demonstrates that these compounds are not locked in tissues but rather are circulating freely, possibly to be utilized upon demand. The warningly colored (aposematic) adult monarch utilizes a defensive system based on compounds that it did not ingest as an adult. Although the complexities of cardenolide sequestration in this species are evident, it is highly significant to understand these ingested steroids are an extraordinarily dynamic state.

The Lubber Grasshopper, *Romalea microptera* (also known as *R. guttata*)

This large grasshopper found in the southeastern United States is quite conspicuous because of it red, black and yellow coloration. It is one of the most aposematic (warningly colored) species in its habitat. This brightly colored grasshopper is especially distinctive because it is a generalist that feeds on a very wide range of plants belonging to a variety of species. Lubber grasshopper is known to feed on 104 plant species belonging to 38 families, many of which produce toxic allelochemicals. Both immature and mature grasshoppers are capable of causing emesis in predators such as lizards, demonstrating that all stages of these insects are protected from at least some predatory vertebrates.

Immature individuals of *R. microptera* produce defensive compounds that cause emesis in both lizard and bird predators. Additionally, mature and adult grasshoppers secrete defensive compounds from paired tracheal (respiratory) glands in the metathorax. These glands only become active near the adult period and their secretion can be extremely repellent to small predatory insects such as ants. At least 50 compounds are produced by the defensive glands, the secretions varying intraspecifically, so that components of females of the same age and population sometimes differ by 70-fold, with some compounds being absent in certain individuals. However, in addition to the compounds synthesized in the metathoracic glands, a number of allelochemicals are sequestered in these glands as a reflection of an individual grasshopper's diet. Indeed, the composition of the metathoracic gland secretion of each grasshopper appears to be unlike that of any other grasshopper, since no two of these generalist grasshoppers have identical diets from which to sequester allelochemicals. For a predator, each lubber secretion may be sufficiently distinctive to make it impossible to learn an olfactory pattern that clearly identifies the prey as lubber grasshopper.

Lubber grasshopper is unusual in being a polyphagous (eating many plant species) insect species that sequesters allelochemicals. In general, monophagous (feeding on one group of plant species) and stenophagous (feeding on a limited range of plant species) insect herbivores characteristically sequester plant compounds, but not generalist feeders. Furthermore, if *R. microptera* is presented with a restricted diet (specialist feeding mode), the number of compounds in the secretions and their concentrations are reduced, and the relative composition of the secretion is markedly different from that of field-collected grasshoppers. Significantly, if grasshoppers are presented with only a single-host plant as a food source, they frequently feed readily, sequestering host-plant volatiles, and exhibit no immediate ill effects. Lubbers feeding only on wild onion sequester a large number of onion volatiles which impart a strong onion odor to the secretion. The secretion is a powerful repellent to hungry ants and is considerably more active than the secretions of field-collected grasshoppers. Compounds in other single-plant diets (e.g., catnip) produce secretions that are similarly active.

The secretion of lubber grasshopper clearly has both a dietary and an individual origin that correlates with great variations in secretory components. The possibility that these grasshoppers can temporarily switch to a monophagous feeding mode in the presence of a preferred host plant is not unreasonable, and can result in a secretion with a high a concentration of sequestered allelochemicals as is characteristic of some specialist insects.

Lubber grasshopper is quite unpalatable and emetic to a variety of vertebrates, especially birds. Diverse bird species have been demonstrated to vomit after ingestion of these grasshoppers, presumably as a consequence of *Romalea*-synthesized toxins that fortify their bodies. While *Romalea* would appear to be completely defended against birds, as is often the case, the best defense has been overcome by a better offense. Shrikes, predatory birds that impale their insect prey on spines or even barbed wire, capture lubber grasshoppers and impale them. However, the birds wait for about 48 h before they remove and eat the grasshoppers. Though shrikes "store" all their food in this manner, in all likelihood the emetic toxin(s) produced by *Romalea* decomposes during the time the grasshopper is impaled.

Allelopathy

The ability of a plant species to produce substances that are toxic to certain other plants. Allelopathic chemicals may affect germination, growth or reproduction of plants.

Allen's Rule

Among mammals and birds, individuals of a species occurring in colder climates tend to have shorter appendages, and a correspondingly lower surface to volume ratio, than members of the same species living in warmer climates. This trend results from the need to conserve heat in cold climates but to eliminate excess heat in hot climates. A variant of this is Bergmann's rule. These rules do not apply to ectothermic animals such as insects.

► Bergmann's Rule
► Thermoregulation

Allochronic Speciation

A mechanism of speciation wherein new species develop in the same place but are separated due to their tendency to occur at different times.

► Speciation Processes Among Insects

Allogenic Succession

A temporal succession of species that is driven by processes from outside the community (contrast with autogenic succession).

Allometric Growth

A growth pattern in which different parts of an organism grow at defined rates. In some cases, the body parts remain proportional (isometric growth), in other cases they do not. Departure from isometric growth is used to explain castes of social insects, which may have disproportionately large heads, mandibles, etc.

Allomone

A chemical that is released by one species that influences the behavior or physiology of a different species. The organism releasing the substance usually benefits. Allomones are a type of semiochemical used in warning.

► Chemical Ecology

Allopatric

Having separate and mutually exclusive areas of distribution (contrast with sympatric).

Allopatric Speciation

A mechanism of speciation resulting from geographic separation of populations, particularly physical barriers such as mountains and oceans.

► Speciation Processes Among Insects

Allophagic Speciation

A mechanism of speciation wherein new species develop in the same place, but are separated by their preference for different food.

► Speciation Processes Among Insects

Allozyme

Allozymes are a subset of isozymes. Allozymes are variants of enzymes representing different allelic alternatives of the same locus.

Almond Seed Wasp, *Eurytoma amygdali* Enderlein (Hymenoptera: Eurytomidae)

NIKOS A. KOULOUSSIS
Aristotle University of Thessaloniki, Thessaloniki, Greece

The almond seed wasp is a serious pest of almonds, *Prunus amygdalus* Batch, in several countries of southeastern Europe and the Middle East, and also in Armenia, Azerbaijan, and Georgia. The adult female is 6–8 mm long and has a black head with dark brown eyes. The thorax and the spindle-shaped abdomen are shiny black. The tibiae and tarsi are light brown while the remaining parts of the leg are black. The male is usually smaller than the female (4–6 mm long). The larva is whitish, legless, tapering in both ends, curved and clearly segmented. Its head is light brown and very small. Its length when fully grown is about 6 mm.

Almond seed wasp is a univoltine species, with a small part of the population completing its life cycle in two or more years because of prolonged diapause. The diapause terminates during the winter. Pupation takes place inside the fruit in late winter to early spring. Adults emerge after boring a circular exit hole through the hard pericarp with their mandibles. Shortly after adult emergence, virgin females release a volatile sex pheromone to attract males for mating. Within a few days they mate and the females start ovipositing (Fig. 37) into unripe, green almonds. Using her long ovipositor, the female drills through the pericarp of unripe, green almonds and the integument of the seed, and deposits a stalked egg within the translucent nucellar tissue. After oviposition, the female deposits onto the fruit surface a host-marking pheromone. This pheromone enables females to discriminate between the infested and uninfested fruit, and to select the latter for oviposition. Thus, a uniform distribution of eggs among available fruits is achieved, and an optimal use of the available fruit for larval development. The newly hatched larva bores through the nucellus and the embryo sac to feed on the developing seed embryo. The larva attains full size in midsummer, and enters diapause within the seed integument of the destroyed almond, which usually remains on the tree in a mummified condition.

Owing to oviposition by the wasp certain varieties suffer a heavy premature drop. In most varieties though, the main damage consists in the consumption of the seed by the larvae. This damage varies depending on the variety. Certain soft-shelled varieties may lose up to 90% of their crop. Others are nearly immune because by the time females emerge in spring their pericarp has become too thick and endocarp too hard for the ovipositor to penetrate. Though not a common practice, planting of resistant varieties might be an effective strategy against this pest.

The pest can be controlled by collection and destruction of mummified fruits before adult

Almond Seed Wasp, *Eurytoma Amygdali Enderlein* (Hymenoptera: Eurytomidae), Figure 37 Female *Eurytoma amygdali* ovipositing into an almond.

emergence in spring, which is an effective measure if applied in large areas by multiple growers. However, the method most commonly used is the application of systemic insecticides against the neonate larvae within the oviposited almonds. This strategy is meant for varieties that do not suffer fruit drop because of oviposition. Recent studies have indicated that a single spraying can be effective if applied when 10–50% of the eggs have hatched. This percentage can be determined by dissecting sampled almonds under a binocular microscope. Estimates of egg hatch can be obtained by knowing the time the first adults emerge from infested almonds in spring. This can be determined by following the exit of adult wasps from infested almonds kept in cages in the orchard, or by following the population of males with the use of sex pheromone traps containing live virgin females as lures.

Alpha Taxonomy

The identification of organisms, and particularly the description and naming of organisms (species) new to science.

► Beta Taxonomy
► Gamma Taxonomy

Alternate Host

One of the hosts of a pathogen or insect where a portion of the life cycle occurs. Often this term is used to refer to a weed host of a crop pest or disease.

Alternation of Generations

Some insects undergo reproduction that involves alternation of sexual and asexual generations. Typically, females produce both males and females but at some point females cease producing males and produce only females parthenogenetically. Later generations then commence production of males again, allowing sexual reproduction to occur before the parthenogenetic cycle begins again. This occurs most often in Hymenoptera and Hemiptera.

► Aphids (Hemiptera: Aphididae)

Altruism

Self destructive behavior that is performed for the benefit of others; sacrifice.

Alucitidae

A family of moths (order Lepidoptera). They commonly are known as many-plumed moths.

► Many-Plumed Moths
► Butterflies and Moths

Alula

The expanded membrane at the base of the trailing edge of the front wing.

► Wings Of Insects

Amazonian Primitive Ghost Moths (Lepidoptera: Neotheoridae)

John B. Heppner
Florida State Collection of Arthropods, Gainesville, FL, USA

Amazonian primitive ghost moths, family Neotheoridae, are defined on the basis of a single species from the Amazonian area of southern Brazil, although two additional species have been discovered for the family recently. The family is part of the superfamily Hepialoidea, in the infraorder Exoporia. Adults medium size (38 mm wingspan), with head roughened; haustellum short and vestigial mandibles present; labial palpi long, porrect and 3-segmented; maxillary palpi very small and 2-segmented. Wing maculation is dark and unicolorous. Biologies and larvae remain unknown.

Amber Insects: DNA Preserved?

Marjorie A. Hoy
University of Florida, Gainesville, FL, USA

Amber is a polymerized form of tree resin that was produced by trees as a protection against disease agents and insect pests. The resin hardened and, sometimes, captured insects, seeds, feathers, microorganisms, plants, spiders, and even small vertebrates that got stuck in the sticky exudate. The hardened resin was preserved in the earth for millions of years, especially in regions where it was deposited in dense, wet sediments such as clay or sand that formed in the bottom of an ancient lagoon or river delta. For thousands of years, people have collected amber. Many people use amber as a gem, but scientists find amber a magnificent way to identify ancient organisms.

Amber can be found in a variety of sites around the world. The composition, color, clarity, and other properties of amber vary according to age, conditions of burial and type of tree that produced the resin. The oldest amber is from the Carboniferous (360–285 million years ago, mya) and can be found in the United Kingdom and in Montana in the USA. Permian amber is 185–145 million years old and found most often in Russia. Triassic amber (245–215 mya) can be found in Austria, and Jurassic amber (215–145 mya) is found in Denmark. Cretaceous amber (65–140 mya) is found in many locations around the world and represents the time when dinosaurs reigned and flowering plants evolved along with a variety of insects. For example, the rich amber deposits in central New Jersey in the USA are from the Turonion period of the Upper Cretaceous, about 92 mya. Other Cretaceous-period amber is found in North Russia and Japan. Baltic amber is found in the Baltic sea where amber has been collected and made into decorative objects for at least 13,000 years. In the Dominican Republic, amber deposits 23–30 million years old are found in rock layers. Dominican amber is particularly rich in insect inclusions. This amber was formed from the resin of an extinct tree in the legume family. Tertiary amber deposits are found in several locations around the world and are from 1.6 to 65 million years old. Tertiary deposits in the USA are found in Arkansas. Some websites with photographs showing amber inclusions can be viewed at:

Insect DNA in Amber?

The ability to amplify dinosaur DNA from insects preserved in amber in the film *Jurassic Park* captured the imagination of the public. Subsequently, the PCR was used to amplify DNA fragments from insects preserved in ancient amber, but these results have been controversial, as have been the results from amplifying dinosaur DNA.

Why the controversy? Is amber a special form of preservative that allows DNA to persist for unusually long periods of time (millions of years)? Amber entombs insect specimens completely, after which they completely dehydrate so the tissue is effectively mummified. Terpenoids, which are major constituents of amber, could inhibit microbial decay. Certainly, preservation of amber-embedded insects seems to be exceptional and insect tissues in amber appear comparable in quality to the tissues of the frozen wooly mammoth (which is "only" 50,000 years old). But is the DNA in these tissues preserved?

DNA has been extracted from a variety of insects in amber, including a fossil termite *Mastotermes electrodominicus* estimated to be 25–30 million years old, a 120- to 130-million year old conifer-feeding weevil (Coleoptera: Nemonychidae) and a 25- to 40-million year old bee. These are extraordinary ages for DNA!

The DNA sequences obtained from all amber-preserved insects meet several, but not all, criteria of authenticity; the fossil DNA sequences "make phylogenetic sense" and DNA has been isolated from a number of specimens in several cases (although the weevil example was derived from a single specimen). However, the extraction and amplification of fossil DNA sequences from amber-preserved insects has yet to be reproduced in independent laboratories, despite multiple attempts to do so, which has cast doubt on the authenticity of the reports.

One of the most controversial claims involved the isolation of a "living" bacterium from the abdomen of amber-entombed bee. Bacterial DNA from a 25-million-year-old bee was obtained and sequenced and a bacterial spore was reported to be revived, cultured, and identified. The classification of the bacterium is controversial because the bacterium could have come from a currently undescribed species of the *Bacillus sphaericus* complex. The modern *B. sphaericus* complex is incompletely known, so the "new" sequence obtained could be that of a modern, but previously unidentified, bacterium because this group of bacteria often is isolated from the soil.

Other claims of amplifying ancient DNA have been disproved. For example, the mitochondrial cytochrome b sequence of an 80-million-year-old dinosaur from the Upper Cretaceous in Utah was later discovered to be, most probably, of human origin. Likewise, a 20-million-year-old magnolia leaf produced sequences that were similar to those of modern magnolias. The authenticity of the magnolia sequences were cast into doubt because they were exposed to water and oxygen during preservation and DNA is especially vulnerable to degradation under such conditions.

The most common ancient DNA analyzed is usually mitochondrial DNA because it is so abundant; however, this abundance makes it easy to contaminate the ancient sample with modern mtDNA. The amplification of ancient DNA remains highly controversial because the technical difficulties are great.

DNA is a chemically unstable molecule that decays spontaneously, mainly through hydrolysis and oxidation. Hydrolysis causes deamination of the nucleotide bases and cleavage of base-sugar bonds, creating baseless sites. Deamination of cytosine to uracil and depurination (loss of purines adenine and guanine) are two types of hydrolytic damage. Baseless sites weaken the DNA, causing breaks that fragment the DNA into smaller and smaller pieces. Oxidation leads to chemical modification of bases and destruction of the ring structure of base and sugar residues. As a result, it is almost always impossible to obtain long amplification products from ancient DNA.

PCR products from ancient DNA often are "scrambled." This is due to the phenomenon called "jumping PCR," which occurs when the DNA polymerase reaches a template position which carries either a lesion or a strand break that stops the polymerase. The partially extended primer can anneal to another template fragment in the next cycle and be extended up to another damaged site. Thus, in vitro recombination can take place until the whole stretch encompassed by the two primers is synthesized and the amplification enters the exponential part of the PCR. This phenomenon makes it essential that cloning and sequencing of multiple clones be carried out to eliminate this form of error in interpretation.

Most archeological and paleontological specimens contain DNA from exogenous sources such as bacteria and fungi, as well as contaminating DNA from contemporary humans. Aspects of burial conditions seem to be important in DNA preservation, especially low temperature during burial. The oldest DNA sequences reported, and confirmed in other laboratories, come from the remains of a wooly mammoth found in the Siberian permafrost; these sequences are "only" 50,000 years old rather than millions of years old.

Theoretical calculations and empirical observations suggest DNA should only be able to survive, in a highly fragmented and chemically modified form, for 50,000–100,000 years. Because only tiny amounts of DNA usually can be extracted from an archeological specimen, stringent precautions and multiple controls are required to avoid accidental contamination with modern DNA.

A methodology to deal with ancient specimens has been proposed that includes careful selection of well-preserved specimens, choice of tissue samples that are likely to have best DNA preservation, and surface sterilization to eliminate surface contamination. The operations should be carried out in a laboratory dedicated to work on ancient specimens and work on ancient DNA should be separated from that on modern DNA. Most importantly, multiple negative controls should be performed during DNA extraction and PCR set up, although a lack of positives in the negative controls is not definitive proof of authentic ancient DNA. Another crucial step is the authentication of the results. Putatively ancient DNA sequences should be obtained from different extractions of the same sample and from different tissue samples from different specimens. The ultimate test of authenticity should be independent replication in two separate laboratories. So far, this type of replication has not been achieved for DNA from amber-preserved arthropod specimens.

Amerasinghe, Felix P

Felix Amerasinghe was a noted Sri Lankan medical entomologist. He was known for his work on the taxonomy and ecology of disease-transmitting arthropods. Amerasinghe graduated from the University of Peradeniya, Sri Lanka, and received his Ph.D. from the University of Bristol, United Kingdom, in 1977. He made important long-term studies in the effects of irrigation on mosquito populations and malaria transmission, and became an authority on Japanese encephalitis. The development of keys for the identification of South Asian mosquitoes was one of his important contributions, greatly enhancing disease surveillance programs.

Amerasinghe worked principally at the University of Peradeniya, but also at the University of Sri Lanka, and in later years joined the International Water Management Institute as research leader, initiating studies on the socioeconomic impact of malaria, malaria parasitology, and molecular biology. He died in Colombo, Sri Lanka, on June 7, 2005.

American Butterfly Moths (Lepidoptera: Hedylidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

American butterfly moths, family Hedylidae, total only 40 known species, all Neotropical. The family is in the superfamily Geometroidea, in the section Cossina, subsection Bombycina, of the division Ditrysia. Adults medium size (35–65 mm wingspan), with head scaling normal; haustellum naked; labial palpi upcurved; maxillary palpi 1 to 2-segmented; antennae filiform. Wings triangular, with forewings somewhat elongated and often with apex emarginated (Fig. 38); hindwings usually more rounded. Body usually narrow. Maculation somber hues of brown and gray, often with apical dark patch and some speckling, plus pale or hyaline patches (rarely mostly pale or hyaline). Adults nocturnal. Larvae are leaf feeders. Host plants are recorded in Euphorbiaceae, Malvaceae, Sterculiaceae, and Tiliaceae.

American False Tiger Moths (Lepidoptera: Dioptidae)

JOHN B. HEPPNER

Florida State Collection of Arthropods, Gainesville, FLa, USA

American false tiger moths, family Dioptidae, total 507 species, primarily Neotropical (505 sp.); actual fauna likely exceeds 800 species. Two subfamilies are known: Dioptinae and Doinae. Some specialists place the family within the Notodontidae. The family is in the superfamily Noctuoidea, in the section Cossina, subsection Bombycina, of the division Ditrysia. Adults medium size (22–58 mm wingspan) (Fig. 39). Maculation mostly very colorful, with various patterns of large spotting, and some lustrous. Larvae and pupae often also colorful Adults are mostly nocturnal, but some are diurnal or crepuscular. Larvae are leaf feeders, particularly toxic plants in families like Aristolochiaceae, Euphorbiaceae, Passifloraceae, and Violaceae, but also on various others like Fagaceae. Very few are economic.

American Grasshopper, *Schistocerca americana* (Drury) (Orthoptera: Acrididae)

JOHN L. CAPINERA

University of Florida, Gainesville, FL, USA

This grasshopper is found widely in eastern North America, from southern Canada (where it is an occasional invader) south through Mexico to northern South America. In the midwestern states, where it is common, the resident population receives a regular infusion of dispersants from southern locations. In the southeast it is quite common, and one of the few species to reach epidemic densities. It is native to North America.

Life History

In warm climates, American grasshopper has two generations per year and overwinters in the adult stage. In Florida, eggs produced by overwintered adults begin to hatch in April-May, producing spring generation adults by May-June. This spring generation produces eggs that hatch in August-September. The adults from this autumn generation survive the winter.

The eggs of *S. americana* initially are light orange in color, turning tan with maturity. They are elongate-spherical in shape, widest near the middle, and measure about 7.5 mm in length and 2.0 mm in width. The eggs are clustered together in a whorled arrangement, and number 75–100 eggs per pod, averaging 85 eggs. The eggs are inserted into the soil to a depth of about 4 cm and the upper portion of the oviposition hole is filled by the female with a frothy plug. Duration of the egg stage is about 14 days. The nymphs, upon hatching, dig through the froth to attain the soil surface.

Normally there are six instars in this grasshopper though sometimes only five. The young grasshoppers are light green in color. They are extremely gregarious during the early instars. At low densities the nymphs remain green throughout their development, but normally gain increasing amounts of black, yellow, and orange coloration commencing with the third instar. Instars can be distinguished by their antennal, pronotal, and wing development. The first and second instars display little wing development but have 13 and 17 antennal segments, respectively. In the third instar, the number of antennal segments increases to 20–22, the wings begin to display weak evidence of veins, and the dorsal length of the ventral lobe of the pronotum is about 1.5 times the length of the ventral surface. Instar four is quite similar to instar three, with 22–25 antennal segments, though the ratio of the length of the dorsal to ventral surfaces of the pronotal lateral lobe is 2:1. In instar five there are 24–25 antennal segments, and the wing tips assume a dorsal rather than ventral orientation but the wing tip does not exceed the first abdominal segment. In the sixth instar (Fig. 41) there are 24–26 antennal segments and the wing tips extend beyond the second abdominal segment. The overall body length is about 6–7, 12–13, 16–18, 22–25, 27–30, and 35–45 mm for instars 1–6, respectively. Development time is about 4–6, 4–6, 4–6, 4–8, 6–8, and 9–13 days for the corresponding instars when reared at about 32°C.

The adult (Fig. 40) is rather large, but slender bodied, measuring 39–52 and 48–68 mm in length in the male and female, respectively. A creamy white stripe normally occurs dorsally from the front of the head to the tips of the forewings. The forewings bear dark brown spots, the pronotum

dark stripes. The hind wings are nearly colorless. The hind tibiae normally are reddish. Overall, the body color is yellowish brown or brownish with irregular lighter and darker areas, though for a week or so after assuming the adult stage a pinkish or reddish tint is evident.

Adults are active, flying freely and sometimes in swarms. They normally are found in sunny areas, but during the warmest portions of the day will move to shade. Adults are long lived, persisting for months in the laboratory and apparently in the field as well. This can lead to early-season situations where overwintered adults, all instars of nymphs, and new adults are present simultaneously. Mild winters favor survival of overwintering adults and apparently lead to population increase if summer weather and food supplies also are favorable.

Adults of American grasshopper tend to be arboreal in habit, and a great deal of the feeding by adults occurs on forest, shade, and fruit trees. The nymphs, however, feed on a large number of grasses and broadleaf plants, both wild and cultivated. During periods of abundance, almost no plants are immune to attack, and vegetables, grain crops, and ornamental plants are injured. American grasshopper consumes bean, corn, okra, and yellow squash over some other vegetables when provided with choices, but free-flying adults normally avoid low-growing crops such as vegetables, corn (maize) being a notable exception.

The natural enemies of *S. americana* are not well known. Birds such as mockingbirds, *Mimus polyglottos polyglottos* (Linnaeus), and crows, *Corvus brachyrhynchos brachyrhynchos* Brehm have been observed to feed on these grasshoppers. Fly larvae, *Sarcophaga* sp. (Diptera: Sarcophagidae) are sometimes parasitic on overwintering adults. Fungi have also been investigated for grasshopper suppression and *Metarhizium anisopliae* var. *acridum* kills American grasshopper quickly under laboratory conditions. This fungus is effective under adverse field conditions in Africa, so it may prove to be a useful suppression tool.

Damage

Grasshoppers are defoliators, eating irregular holes in leaf tissue. Under high density conditions they can strip vegetation of leaves, but more commonly leave plants with a ragged appearance. American grasshopper displays a tendency to swarm, and the high densities of grasshoppers can cause severe defoliation.

Because American grasshopper is a strong flier, it also sometimes becomes a contaminant of crops. When the late-season crop of collards in the Southeast is harvested mechanically, for example, American grasshopper may become incorporated into the processed vegetables. Although most grasshoppers can be kept from dispersing into crops near harvest by treating the periphery of the crop field, it is much more difficult to prevent invasion by American grasshopper because it may fly over any such barrier treatments.

Populations normally originate in weedy areas such as fence rows and abandoned fields. Thus, margins of fields are first affected and this is where monitoring should be concentrated. It is highly advisable to survey weedy areas in addition to crop margins if grasshoppers are found, as this gives an estimate of the potential impact if the grasshoppers disperse into the crop. Also, it is important to recognize that this species is highly dispersive in the adult stage, and will fly hundreds of meters or more to feed.

Management

Foliar applications of insecticides will suppress grasshoppers, but they are difficult to kill, particularly as they mature. Bait formulations are not usually recommended because these grasshoppers spend little time on the soil surface, preferring to climb high in vegetation.

Land management is an important element of *S. americana* population regulation. Grasshopper densities tend to increase in large patches of weedy vegetation that follow the cessation of agriculture or the initiation of pine tree plantations. In both cases, the mixture of annual and perennial forbs and grasses growing in fields that are untilled seems to favor grasshopper survival, with the grasshoppers then dispersing to adjacent fields as the most suitable plants are depleted. However, as abandoned fields convert to dense woods or the canopy of pine plantations shades the ground and suppresses weeds, the suitability of the habitat declines for grasshoppers.

Disturbance or maturation of crops may cause American grasshopper to disperse, sometimes over long distances, into crop fields. Therefore, care should be taken not to cut vegetation or till the soil of fields harboring grasshoppers if a susceptible crop is nearby. Planting crops in large blocks reduces the relative amount of crop edge, and the probability that a crop plant within the field will be attacked.

American Foulbrood

Historically, this is the most virulent disease of honey bees throughout the world. The bacterium responsible for the disease, *Paenibacillus* (= *Bacillus*) *larvae*, form heat- and drought-resistant spores that persist for years and germinate under favorable conditions. It is expressed in older larvae and young pupae, though infection occurs earlier, and young larvae are more susceptible than older larvae. Infected individuals turn darker in color, then black, and eventually collapse into a hardened mass in the cell. Signs of infection include a sour odor, perforated or sunken caps on the cells, and the presence of black deposits in the cells. If foulbrood is present, insertion of a twig or probe into a suspect cell will result in a gummy, stretchy substance being drawn out of the cell, often forming a thread or rope and called "ropy." Field diagnosis is possible by experienced inspectors, but is best confirmed microscopically or by molecular techniques. There are several subspecies of *P. larvae*, and *P. larvae* ssp. *larvae* is considered responsible for American foulbrood, with other subspecies also affecting honey bees.

Transmission occurs by feeding infected honey or pollen, by using infected equipment, and sometimes by installing infected package bees or queens. Feeding bees sugar syrup therefore is preferable to feeding them honey, and disinfection of hive tools is always recommended. Natural transmission from hive to hive can occur through robbing behavior. Queens and workers can carry the disease. Bee colonies that are infected normally are eliminated by burning them. Antibiotics can be fed to colonies to prevent infection.

American Serpentine Leafminer, *Liriomyza trifolii* (Burgess) (Diptera: Agromyzidae)

This leafminer has long been found in eastern North America, northern South America, and the Caribbean. However, in recent years it has been introduced into California, Europe, and elsewhere. Expanded traffic in flower crops appears to be the basis for the expanding range of this species. *Liriomyza trifolii* (Burgess), sometimes known as the American serpentine leafminer, readily infests greenhouses. As a vegetable pest, however, its occurrence is limited principally to tropical and subtropical regions.

Life Cycle and Description

Leafminers have a relatively short life cycle. The time required for a complete life cycle in warm environments is often 21–28 days, so numerous generations can occur annually in tropical climates. Growth at a constant 25°C requires about 19 days from egg deposition to emergence of the adult. Development rates increase with temperature up to about 30°C; temperatures above 30°C are usually unfavorable and larvae experience high mortality. At 25°C, the egg stage requires 2.7 days for development; the three active larval instars require an average of 1.4, 1.4, and 1.8 days, respectively; and the time spent in the puparium is 9.3 days. Also, there is an adult preovipostion period that averages 1.3 days. The temperature threshold for development of the various stages is 6–10°C, except that egg laying requires about 12 C.

Egg

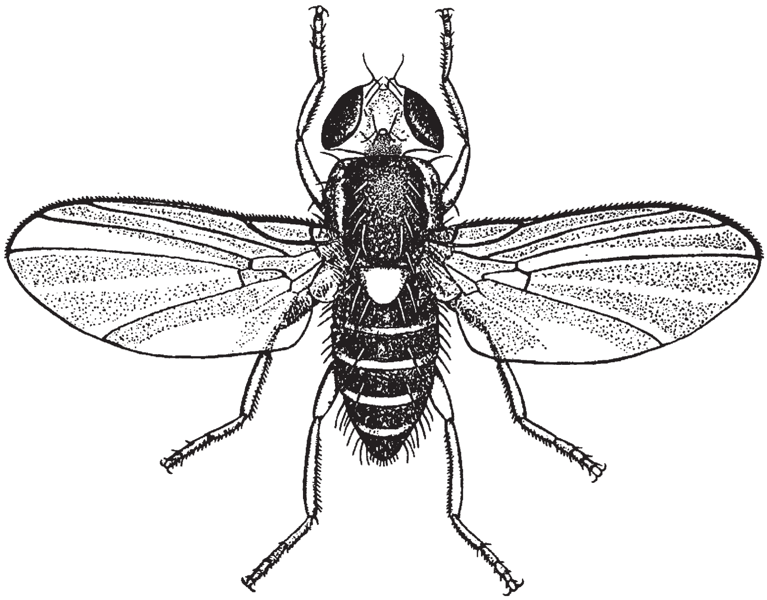
Eggs tend to be deposited in the middle of the plant; the adult seems to avoid immature leaves. The female deposits the eggs on the lower surface of the leaf, but they are inserted just below the epidermis. Eggs are oval in shape and small in size, measuring about 1.0 mm long and 0.2 mm wide. Initially they are clear, but soon become creamy white in color.

Larva

Body and mouth part size can be used to differentiate instars; the latter is particularly useful. For the first instar, the mean and range of body and mouth parts (cephalopharyngeal skeleton) lengths are 0.39 (0.33–0.53) mm and 0.10 (0.08–0.11) mm, respectively. For the second instar, the body and mouth parts measurements are 1.00 (0.55–1.21) mm and 0.17 (0.15–0.18) mm, respectively. For the third instar, the body and mouth parts measurements are 1.99 (1.26–2.62) mm and 0.25 (0.22–0.31) mm, respectively. A fourth instar occurs between puparium formation and pupation, but this is a nonfeeding stage and is usually ignored by authors. The puparium is initially golden brown in color, but turns darker brown with time.

Adult

Adults (Fig. 42) are small, measuring less than 2 mm in length, with a wing length of 1.25–1.9 mm. The head is yellow with red eyes. The thorax and abdomen are mostly gray and black although the ventral surface and legs are yellow. The wings are transparent. Key characters that serve to differentiate this species from the vegetable leafminer, *Liriomyza sativae* Blanchard, are the matte, grayish black mesonotum and the yellow hind margins of the eyes. In vegetable leafminer the mesonotum is shining black and the hind margin of the eyes is black. The small size of this species serves to distinguish it from pea leafminer, *Liriomyza huidobrensis* (Blanchard), which has a wing length of 1.7–2.25 mm. Also, the yellow femora of American serpentine leafminer help to separate it from pea leafminer, which has darker femora. Oviposition occurs at a rate of 35–39 eggs per day, for a total fecundity of 200–400 eggs. The female makes



American Serpentine Leafminer, *Liriomyza Trifolii* (Burgess) (Diptera: Agromyzidae), Figure 42 **Adult of American serpentine leafminer, *Liriomyza trifolii*.**

numerous punctures of the leaf mesophyll with her ovipositor, and uses these punctures for feeding and egg laying. The proportion of punctures receiving an egg is about 25% in chrysanthemum and celery, both favored hosts, but only about 10% in tomato, which is less suitable for larval survival and adult longevity. Although the female apparently feeds on the exuding sap at all wounds, she spends less time feeding on unfavorable hosts. The males live only two to three days, possibly because they cannot puncture foliage and therefore feed less than females, whereas females usually survive for about a week. Typically they feed and oviposit during much of the daylight hours, but especially near mid-day.

Host Plants

Liriomyza trifolii is perhaps best known as a pest of chrysanthemums and celery, but it has a wide host range. For example, at least 55 hosts are known from Florida, including bean, beet, carrot, celery, cucumber, eggplant, lettuce, melon, onion, pea, pepper, potato, squash, and tomato. Flower crops that are readily infested and which are known to facilitate spread of this pest include chrysanthemum, gerbera, gypsophila, and marigold, but there are likely many other hosts, especially among the Compositae. Numerous broad-leaved weed species support larval growth. The nightshade *Solanum americanum*, Spanish needles, *Bidens alba*, and pilewort, *Erechtites hieracifolia*, were suitable weed hosts in Florida.

Damage

Punctures caused by females during the feeding and oviposition processes can result in a stippled appearance on foliage, especially at the leaf tip and along the leaf margins. However, the major form of damage is the mining of leaves by larvae, which results in destruction of leaf mesophyll. The mine becomes noticeable about three to four days after oviposition, and becomes larger in size as the larva matures. The pattern of mining is irregular. Both leaf mining and stippling can greatly depress the level of photosynthesis in the plant. Extensive mining also causes premature leaf drop, which can result in lack of shading and sun scalding of fruit. Wounding of the foliage also allows entry of bacterial and fungal diseases. Although leaf mining can reduce plant growth, crops such as tomato are quite resilient, and capable of withstanding considerable leaf damage. It is often necessary to have an average of one to three mines per tomato leaf before yield reductions occur. Leafminers are most damaging when they affect floricultural crops due to the low tolerance of such crops for any insect damage.

Natural Enemies

Parasitic wasps (parasitoids) of the families Braconidae, Eulophidae, and Pteromalidae are important in natural control, and in the absence of insecticides usually keep this insect at low levels of abundance. At least 14 parasitoid species are known from Florida alone. Species of Eulophidae such as *Diglyphus begina* (Ashmead), *D. intermedius* (Girault), *D. pulchripes*, and *Chrysocharis parksi* Crawford are generally found to be most important in studies conducted in North America, although their relative importance varies geographically and temporally. Predators and diseases are not considered to be important, relative to parasitoids. However, both larvae and adults are susceptible to predation by a wide variety of general predators, particularly ants.

Management

Sampling

There are many methods to assess leafminer abundance. Counting mines in leaves is a good index of past activity, but many mines may be vacant. Counting live larvae in mines is time consuming, but more indicative of future damage. Puparia can be collected by placing trays beneath foliage to capture larvae as they evacuate mines, and the captures are highly correlated with the number of active miners. Adults can be captured by using adhesive applied to yellow cards or stakes.

Insecticides

Chemical insecticides are commonly used to protect foliage from injury, but insecticide resistance is a major problem. Insecticide susceptibility varies widely among populations, and level of susceptibility is directly related to frequency of insecticide application. In Florida, longevity of insecticide effectiveness is often only two to four years, and then is usually followed by severe resistance among the treated populations. Rotation among classes of insecticides is recommended to delay development of resistance. Reduction in dose level and frequency of insecticide application, as well as preservation of susceptible populations through nontreatment of some areas, are suggested as means to preserve insecticide susceptibility among leafminer populations. Insect growth regulators have been more stable, but are not immune from the resistance problem. Insecticides also are highly disruptive to naturally occurring biological control agents, particularly parasitoids. Use of many chemical insecticides exacerbates leafminer problems by killing parasitoids of leafminers. This usually results when insecticides are applied for lepidopterous insects, and use of more selective pest control materials such as *Bacillus thuringiensis* is recommended as it allows survival of the leafminer parasitoids. Because parasitoids often provide effective suppression of leafminers in the field when disruptive insecticides are not used, there has been interest in release of parasitoids into crops. This occurs principally in greenhouse-grown crops, but is also applicable to field conditions. *Steinernema* nematodes have also been evaluated for suppression of leaf mining activity. High levels of relative humidity (at least 92%) are needed to attain even moderately high (greater than 65%) levels of parasitism. Adjuvants that enhance nematode survival increase levels of leafminer mortality, but thus far nematodes are not considered to be a practical solution to leafminer infestations.

Cultural Practices

Because broadleaf weeds and senescent crops may serve as sources of inoculum, destruction of weeds and deep plowing of crop residues are recommended. Adults experience difficulty in emerging if they are buried deeply in soil.

American Silkworm Moths (Lepidoptera: Apatelodidae)

JOHN B HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

American silkworm moths, family Apatelodidae, are exclusively New World, and total 252 species, mostly Neotropical (247 sp.). Three subfamilies are known: Apatelodinae, Epiinae, and Phiditiinae.

American Silkworm Moths (Lepidoptera: Apatelodidae), Figure 43 Example of American silkworm moths (Apatelodidae), *Apatelodes palma* Druce, from Ecuador.

Some researchers consider the family part of Bombycidae. The family is in the superfamily Bombycoidea (series Bombyciformes), in the section Cossina, subsection Bombycina, of the division Ditrysia. Adults (Fig. 43) small to medium size (20–74 mm wingspan), with head scaling roughened; haustellum absent (rarely vestigial); labial palpi small; maxillary palpi absent; antennae bipectinate; body robust. Wings broadly triangular; hindwings rounded. Maculation varied but mostly shades of brown or gray, rarely more colorful, with various markings. Adults are nocturnal. Larvae are leaf feeders. Host plants include various records in Aquifoliaceae, Betulaceae, Bignoniaceae, Lauraceae, Oleaceae, Rosaceae, among others.

American Swallowtail Moths (Lepidoptera: Sematuridae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

American swallowtail moths (Fig. 44), family Sematuridae, total 36 Neotropical species, one of which just reaches into the United States, in southern Arizona. The family is in the superfamily Uranioidea, in the section Cossina, subsection Bombycina, of the division Ditrysia. Adults medium to large (42–100 mm wingspan), with head roughened and eyes large; haustellum naked; labial palpi upcurved, with long second segment and correctly angled short, smooth apical segment; maxillary palpi minute, 1-segmented; antennae thickened, with elongated club (slightly hooked at tip). Wings triangular, with hindwings tailed (usually hindwings with some emarginations); body sometimes robust. Maculation various shades of darker brown, with vertical lines and bands, often brightly colored in the hindwings; often with eyespots on the tails. Adults are nocturnal but some may be crepuscular.

American Swallowtail Moths (Lepidoptera: Sematuridae), Figure 44 Example of American swallowtail moths Sematuridae), *Sematura lunus* (Linnaeus), from Costa Rica.

Larvae are leaf feeders, but few known biologically. Host plants are unrecorded.

American Tropical Silkworm Moths (Lepidoptera: Oxytenidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

American tropical silkworm moths, family Oxytenidae, include 60 species, all Neotropical. Some specialists consider this family a subfamily of Saturniidae. The family is in the superfamily Bombycoidea (series Saturniiformes), in the section Cossina, subsection Bombycina, of the division Ditrysia. Adults medium size to large (45–98 mm wingspan), with head vertex somewhat roughened; haustellum developed; labial palpi very large; maxillary palpi absent; antennae bipectinate; body somewhat slender or robust but with hair-like scales. Wings triangular with with falcate apex but sometimes rounded; hindwings somewhat angled and with short tails or sometimes rounded. Maculation mostly white with paired dark gray vertical striae and hindwings similar, but some species are dark brown with indistinct markings. Adults nocturnal. Larvae are leaf feeders; some mimic snakes. Host plants recorded in Rubiaceae.

Ametabolous

Organisms that do not display the process of metamorphosis. In ametabolous organisms there is little change in body form during growth and molting.

► Metamorphosis

Ametropodidae

A family of mayflies (order Ephemeroptera).

► Mayflies

Amino Acid

Chemical compounds that may occur free, or linked by peptide bonds into proteins.

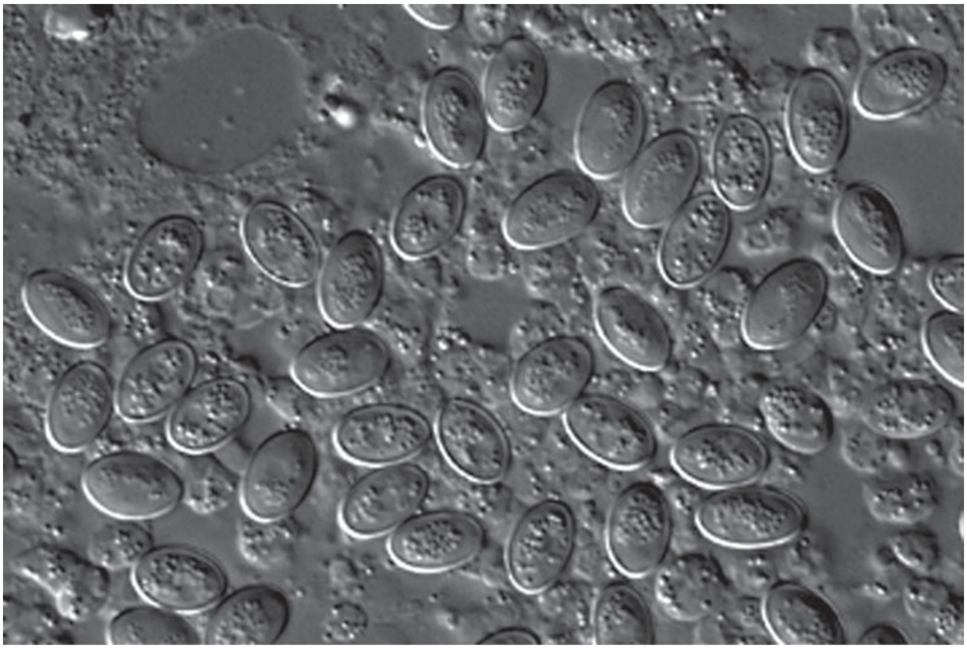
Ammophilous

Sand loving. Organisms inhabiting or preferring sandy habitats are called ammophilous (adjective) or ammophiles (noun).

Amoebae

The two best-studied insect amoebae are *Malpighamoeba mellificae* and *Malamoeba locustae*, which are associated with the honeybee, *Apis mellifera*, and the *Melanoplus* grasshoppers, respectively. The cysts of the honeybee amoeba are ingested and excyst, releasing slender primary trophozoites that penetrate and multiply in the midgut epithelium. Secondary trophozoites emerge from these cells and migrate to the lumen of the Malpighian tubules. These trophozoites, having pseudopodia, feed in the lumen and cause a flattening of the epithelial layer and a distension of the tubules. The brush border in contact with the amoeba swells in size and loses the associated secretory transport vesicles. Infected tubules contain a mix of secondary trophozoites, precysts, and cysts. The primary damage to the host bee is the malfunction of the Malpighian tubules. Both numbers of amoeba and the presence of other disease agents determine the severity of the amoebiasis in the bee. In general, this disease either induces stress or under appropriate conditions in the springtime can be debilitative, resulting in hive dwindling.

Malamoeba locustae, also known as *Malamoeba locusta*, has been detected in a wide range of grasshopper species and in a single *Thysanuran* species. Its life cycle is very similar to that observed with *M. mellificae*. The host grasshoppers ingest the resistant uninucleate cysts, and excysted primary trophozoites invade the midgut and caecal tissues. Within these tissues the trophozoites grow and divide, and within about 10 days release progeny secondary trophozoites into the lumen. These cells migrate to the lumen of the Malpighian tubules and undergo additional cell divisions (Fig. 45). The vegetative development of this amoeba damages the serosal membrane of the tubules, inhibiting their response to insect diuretic hormone. The infected tubules become packed with trophozoites and cysts. At high levels, *M. locustae* may inhibit the excretory function of the tubules and cause the grasshoppers to become lethargic prior to death. The distended, amoeba-infected tubules may rupture, releasing both trophozoites and cysts into the hemocoel. These amoebas are quickly recognized as non-self and are encapsulated by circulating phagocytic



Amoebae, Figure 45 **Light micrograph of the cysts of *Malamoeba locusta* released from infected Malpighian tubules.**

hemocytes. This disease, although a problem in laboratory cultured grasshoppers, is rarely detected in natural populations.

A family of psocids (order Psocoptera).

► Bark-Lice, Book-Lice, or Psocids

Amphipterygidae

A family of damselflies (order Odonata).

► Dragonflies and Damselflies

Amphitheridae

A family of moths (order Lepidoptera) also known as double-eye moths.

► Double-Eye Moths
► Butterflies and Moths

Amphitoky

A type of parthenogenesis in which both females and males are produced.

Amphizoidae

A family of beetles (order Coleoptera). They commonly are known as trout stream beetles.

► Beetles
► Wasps, Ants, Bees and Sawflies

Amplification

In molecular biology, the production of additional copies of a chromosomal sequence, found as either intrachromosomal or extrachromosomal DNA. In medical entomology, the production of increased numbers of virus in a host. This is often a prerequisite to acquisition and transmission of the virus by a blood-feeding insect.

Amplification Hosts

Hosts of viruses that allow amplification of the virus, usually used in the context of arboviruses. Some hosts do not allow amplification, and so serve as an end-point in the virus cycle.

► Dead-end Hosts

Ampulicidae

A family of wasps (order Hymenoptera).

Anagrus Fairyflies (Hymenoptera: Mymaridae)

ELISABETTA CHIAPPINI
Università Cattolica del Sacro Cuore,
Piacenza, Italy

Anagrus species (Mymaridae), among the smallest insects known, are endoparasitoids of eggs of Odonata and Hemiptera. The genus is worldwide and about 60 species is now recognized.

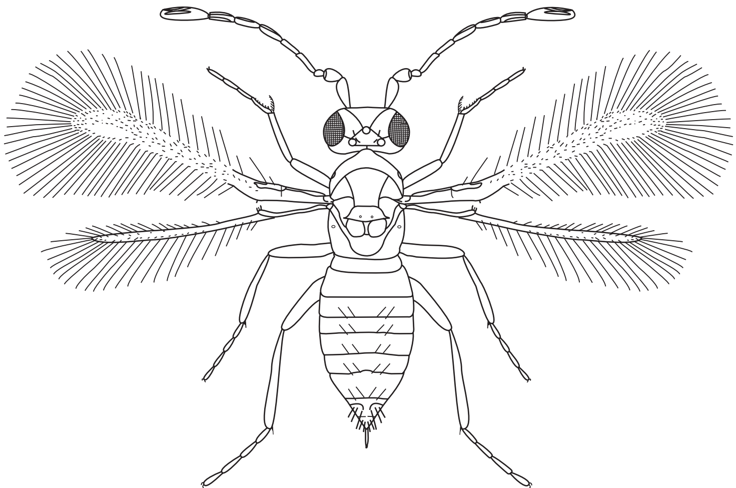
Taxonomy and Adult Morphology

The metasoma of *Anagrus* is not constricted basally, so it appears broadly sessile, the hypochaeta in front of the marginal vein is basal to the first macrochaeta, the tarsi are 4-segmented, the posterior scutellum is longitudinally divided, and the foretibia has a comb-like spur. Adult males and females are similar, differing mainly in their antennae, with nine segments and clubbed in females (Fig. 46) and 13 segments and filiform in males. Body color is often darker in males. The genitalia, both in males (the aedeagus) and in females (the ovipositor), have features of taxonomic importance.

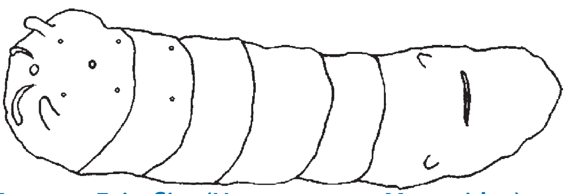
The genus is subdivided into three subgenera – *Anagrella*, *Anagrus*, and *Paranagrus*.

Biology

Like all holometabolous insects, *Anagrus* species have three distinct immature stages, egg, larva and pupa. The egg is stalked, with an ovoid body that swells during embryogenesis. There are two, apodous, larval instars (Fig. 47), which appear completely different from one another. The first instar is sacciform and usually attached to the egg chorion. It does not show any cuticular structure that could serve to feed, breathe or feel. It is completely immobile and probably obtains nourishment and breathes through its cuticle. The second instar is divided weakly into six body segments, has a mouth and a salivary gland opening, two mandibles and an anus, and various other, probably sensory, structures. No spiracle is present. Second instar larvae are very active and fight each other when in the same host egg. The mature larva (prepupa) develops inside the egg into an exarate pupa and does not spin a cocoon. When development is complete, adults are



Anagrus Fairyflies (Hymenoptera: Mymaridae), Figure 46 **Adult female of *Anagrus* sp.**



Anagrus Fairyflies (Hymenoptera: Mymaridae), Figure 47 **Larva of *Anagrus* sp.**

recognizable through the host egg chorion, through which they chew a hole to exit. After emergence the adults shed their waste products (meconium). Males are usually protandrous.

Behavior and Ecology

Reproduction is bisexual or parthenogenetic. The latter reproduction is usually arrhenotokous but, rarely, thelytokous parthenogenesis has been recorded. Females are ready to oviposit as soon as they emerge. Copulation, if it occurs, is usually very quick (some tens of seconds) and inseminated females generally do not copulate again. When fed with sugar water, honey or nectar, adults may live for up to 10 days. It is thought that adult host feeding may occur as in other parasitoids.

Anagrus species mainly parasitize leafhoppers (Cicadellidae), planthoppers, (Delphacidae) and damsel- or dragonfly (Odonata) eggs, all of which are embedded in plant tissue. To reach the eggs, females insert their ovipositor into the slit made by the host or through the plant tissue itself, depending on the species. Adults occur in various habitats, both natural and cultivated, depending on where their hosts occur. This includes dry habitats such as vineyards and beet fields to damp or aquatic ones (ponds) where host eggs are found in plants such as *Cyperus* or *Nuphar*.

Certain *Anagrus* species can develop both as solitary or gregarious parasitoids in eggs of different size, whereas others appear to be much more specialized on eggs of the same size, in which they always develop as solitary parasitoids.

Many *Anagrus* are extremely important because they provide control of potentially serious pests on many agricultural crops. The most important examples are against leafhoppers such as *Empoasca vitis* Goethe and *Zygina rhamni* (Ferrari) in vineyards in Europe and *Erythroneura* spp. in North America, against leaf- and planthoppers such as *Nilaparvata* spp. and *Sogatella* spp. on rice in eastern Asia, and against *Perkinsiella sacharicida* Kirkaldy on sugarcane in Hawaii.

Some biological supply companies mass produce and sell *Anagrus atomus* L. for biological control. Care must be taken to ensure the sanitary conditions of the product as the parasitoid is bred on the natural host eggs inserted into plant tissue, which could be a potential vehicle for other pests or diseases.

Anajapygidae

A family of diplurans (order Diplura).

► Diplurans

Anal Angle

The hind angle of the forewings.

► Wings of Insects

Anal Cell

A cell in the anal area (anal lobe) of a wing.

► Wings of Insects

Anal Comb

This term is applied to a variety of structures that differ depending on the taxon. In flea (Siphonaptera) larvae, it refers to several rows of setae on the tenth abdominal segment; in caterpillars (Lepidoptera) it refers to a ventral projection at the tip of the abdomen that is used to eject frass; in some beetle (Coleoptera) larvae it refers to cerci-like projections near the tip of the abdomen.

Anal Gills

Gills found at the tip of the abdomen and usually consisting of three to five small clusters.

► Abdomen of Hexapods

Anal Hooks

In Lepidoptera, small hook or club-shaped structures at the tip of the abdomen that serve to anchor the pupa to the cocoon or silk pad.

Anal Furrow

The suture-like groove in the membrane of the wing.

► Wings of Insects

Anal Legs (Prolegs)

In holometabolous larvae, especially Lepidoptera larvae, the appendages of the tenth abdominal segment (the terminal prolegs).

Anal Lobe

The posterior region of the wing, occupied by the anal veins.

► Wings of Insects

Anal Loop

A cluster of cells between the anal wing veins, or between the cubitus and anal vein, in Odonata.

► Wings of Insects

Anal Plate

The shield-like plate or dorsal covering on the terminal segment in caterpillars, and some other larvae. It usually is dark in color, and is also called the anal shield.

Anal Tube

Eversible, tubular organs in the anal region of larval Coleoptera. These organs are armed with microspines and assist in attachment to the substrate.

Anal Vein

Longitudinal unbranched vein, or veins, extending from the base of the wing to the outer margin of the wing, below the cubitus vein.
► Wings of Insects

Anamorphosis

Postembryonic development in which additional abdominal body segments are added at the time of molting (the opposite of epimorphosis).

Anaxyelidae

A family of wood wasps (order Hymenoptera, suborder Symphyta). They commonly are known as incense-cedar wood wasps.
► Wasps, Ants, Bees and Sawflies

Ancistrosyllidae

A family of fleas (order Siphonaptera).
► Fleas

Andean Moon Moths (Lepidoptera: Cercophanidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Andean moon moths, family Cercophanidae, include 30 species of mostly austral South American moths. There are two subfamilies: Cercophaninae (four sp.) and Janiodinae (26 sp.). Some specialists consider this family a subfamily of Saturniidae. The family is in the superfamily Bombycoidea (series Saturniiformes), in the section Cossina, subsection Bombycina, of the division Ditrysia. Adults (Fig. 48) medium size to large (24–105 mm wingspan), with head vertex roughened; haustellum absent; labial palpi very large; maxillary palpi absent; antennae bipectinate; body robust, with long hair-like scales. Wings broadly triangular, often with apex falcate, or more rounded; hindwings rounded or emarginated but sometimes with tails. Maculation various, but mostly shades of brown with diagonal line and fainter markings, but some with long tails and lighter tan, and with eyespots. Adults are nocturnal. Larvae are leaf feeders.

Andean Moon Moths (Lepidoptera: Cercophanidae), Figure 48 Example of Andean moon moths (Cercophanidae), *Cercophana venusta* (Walker) from Chile.

Host plants recorded in Celastraceae, Lauraceae, Saxifragaceae, and Tiliaceae.

A family of bees (order Hymenoptera, superfamily Apoidae).

► Bees
► Wasps, Ants, Bees and Sawflies

Andrewartha, Herbert George

Herbert Andrewartha was born in Perth, Australia, on December 21, 1907. In 1924, he entered the University of Western Australia from which he obtained a bachelor's degree in agriculture. He was then appointed as assistant entomologist by the Western Australia Department of Agriculture. He began a study of a weevil pest of fruit trees, *Otiorhynchus cribricollis*, that required detailed autecological studies. In 1933, he moved to Melbourne, appointed by the CSIR as assistant research officer, to work on the autecology of *Thrips imaginis*, a pest of apple trees. He worked in the School of Agriculture and Forestry at the University of Melbourne. While working, he was able to complete a thesis for which he was awarded the degree of Master of Agricultural Sciences. He married, and in 1935 moved to the Waite Agricultural Research Institute in Adelaide. His main duties now turned to a study of *Austroicetes cruciata*, a plague grasshopper, and diapause of its eggs. However, his supervisor, who had been working on *Thrips imaginis*, died suddenly, leaving copious unanalyzed data, whose completion and publication fell to Herbert. The published work was criticized because it concluded that climatic factors were all-important in the population dynamics of the pest, without room for action of biotic factors. But it led to collaboration with L.C. Birch on a book (1954) "The distribution and abundance of animals." Then, after Herbert moved to the Zoology Department of the University of Adelaide, it led to a book designed as a textbook for students: (1961) "Introduction to the study of animal populations." In 1962, Herbert was appointed chairman of the Zoology Department. In the 1960s, with collaborators, he developed a program for control of *Dacus tryoni*, Queensland fruit fly, by release of sterile males. His next book, also co-authored with L.C. Birch was (1984) "The ecological web." He died on January 27, 1992, following his wife by some years, but survived by his son and daughter.

Androconia

In Lepidoptera, glandular wing and body scales. Scent scales.

Androparae

In aphids, viviparous females that are produced on the secondary host in the autumn, and then fly to the primary host to produce males.

► Aphids

Anemometer

An instrument used for measuring wind speed, an important tool when considering use of pesticides because high wind speeds can result in pesticide drift.

Anemotaxis

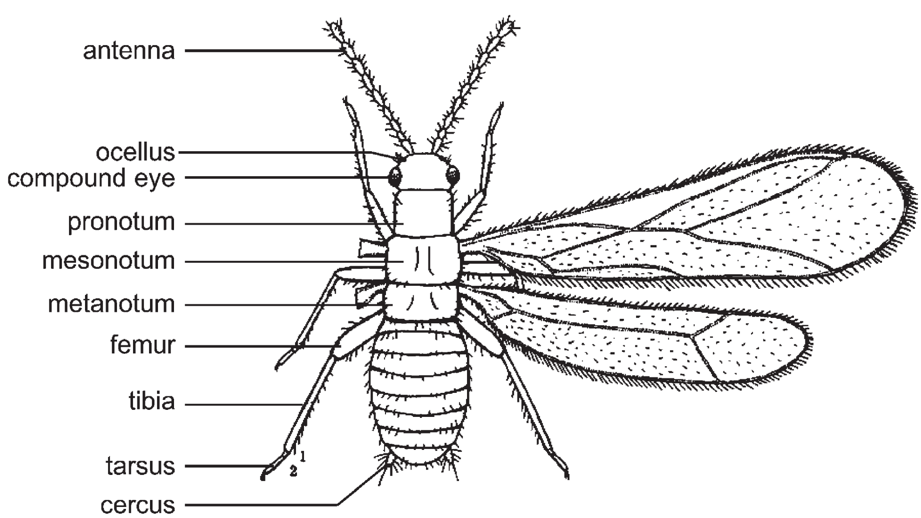
A movement in response to air movement or air currents.

Angel Insects (Zoraptera)

This is a small group of minute insects. They are infrequently encountered, and poorly known. The order name is based on the Greek words *zoros* (pure), *a* (without), and *pteron* (wing). There are only about 30 species described, all in the family Zorotypidae.

Characteristics

Angel insects are only about 3 mm long, with a wing span of 7 mm. They are dimorphic: a wingless form that lacks eyes, ocelli, and is only slightly pigmented, and a winged form (Fig. 49) that bears eyes, ocelli, and is darker in color. They have chewing mouthparts. The antennae are filiform, and consist of nine segments. The legs are unspecialized, the tarsi 2-segmented. The wings have simplified venation, and the wings can be shed, as is the case with termites. The abdomen is cylindrical and consists of 11 segments. Very short, 1-segmented cerci occur near the tip of the abdomen. Metamorphosis is not pronounced.



Angel Insects (Zoraptera), Figure 49 **A diagram of an angel insect showing a dorsal view. The wings are removed from the left side of the body.**

Biology

Angel insects are found beneath bark, in humus, decaying wood, and sometimes in association with termites. They are believed to feed on fungi. Apparently they swarm, and drop wings after swarming. They are gregarious, but there is no evidence of social organization.

Angoumois Grain Moth, *Sitotroga cerealella* (Lepidoptera: Gelechiidae)

This is an important primary pest of stored grain.

► Stored Grain and Flour Insects

Angulate

Forming an angle.

Anholocyclic Life Cycle

A life cycle in which there is a complete lack of male insects (generally aphids). In this type of life cycle only viviparous parthenogenetic females are present throughout the year. (contrast with holocyclic life cycle)

► Aphids

Animal Sleeping Sickness

Also known as nagana, this is a disease of animals caused by protozoans in the genus *Trypanosoma*. In humans the same disease is known as African sleeping sickness or human trypanosomiasis. It is transmitted by tsetse flies in Africa.

► Trypanosomes
► Tsetse Flies
► Sleeping Sickness or African Trypanosomiasis

Anisembiidae

A family of web-spinners (order Embiidina).

► Web-spinners

Anisopodidae

A family of flies (order Diptera). They commonly are known as wood gnats.

► Flies

Anneal

The process by which the complementary base pairs in the strands of DNA combine.

Annual

A plant that normally completes its life cycle of seed germination, vegetative growth, reproduction, and death in a single growing season or year.

Anobiidae

A family of beetles (order Coleoptera). They commonly are known as death-watch beetles.

► Beetles

Anomosetidae

A family of moths (order Lepidoptera). They also are known as Australian primitive ghost moths.

► Australian Primitive Ghost Moths
► Butterflies and Moths

Anoplura

A suborder of wingless ectoparasitic insects commonly known as sucking lice (order Phthiraptera). It is sometimes treated as an order.

► Chewing and Sucking Lice

Anostostomatidae

A family of crickets (order Orthoptera). They commonly are known as wetas and king crickets.

► Grasshoppers, Katydids and Crickets

Anteclypeus

The lower of the two divisions of the clypeus.

► Mouthparts of Hexapods

Antagonist

An antagonist usually is an organism (usually a pathogen) that does no significant damage to the host, but its colonization of the host protects the host from significant subsequent damage by a pest.

Antecosta (pl., antecostae)

An internal ridge on the anterior portion of a tergum or sternum. It serves as a point of attachment for the longitudinal muscles.

Antenna (pl., antennae)

The paired segmented sensory organs, borne one on each side of the head. The antennae commonly protrude forward. Each antenna (Figs. 50 and 51) consists of three segments: the basal scape, a small pedicel, and an elongate flagellum. The flagellum is usually subdivided into many sections.

► Antennae of Hexapods

Antennae of Hexapods

SEVERIANO F. GAYUBO
Universidad de Salamanca, Salamanca, Spain

According to the known data on anatomy and embryology, the antennae are postoral structures of an appendicular nature that have been displaced, and now situated secondarily above the anterolateral regions of the cranium, in front of the mouth.

Taking into account their intrinsic musculature, two fundamental types of antennae can be distinguished:

Segmented Type

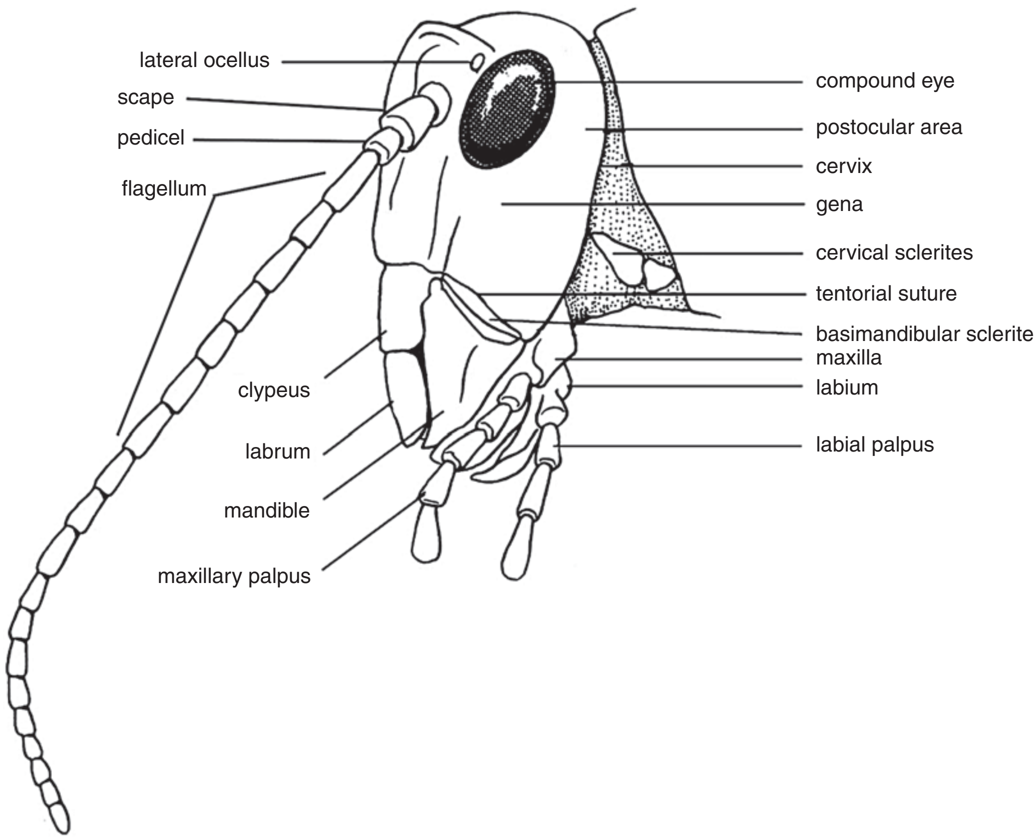
Each antennal division (antennomere) possesses intrinsic musculature (although the last segment generally lacks it). This type is found in Diplura and Collembola.

Annulated Type

Three segments are recognized that, from the basal to the apical zone of the antenna, are called scape, pedicel and antennal flagellum (Fig. 50).

The scape is a robust segment that unites the head capsule with a cuticular reinforcement (Fig. 51), the antennal socket (also called the torulus). In the antennal socket one or two condyles are distinguished, which serve to articulate the scape. The second segment is called the pedicel, and it usually varies in form and development, although it is generally small. Lastly, the flagellum is usually divided into several divisions called flagellomeres.

The movement of the antennae is carried out through extrinsic or motor muscles of the scape, generally forming three or four functional groups. Depending on the insect group, these muscles are inserted in the head capsule or in the tentorium.



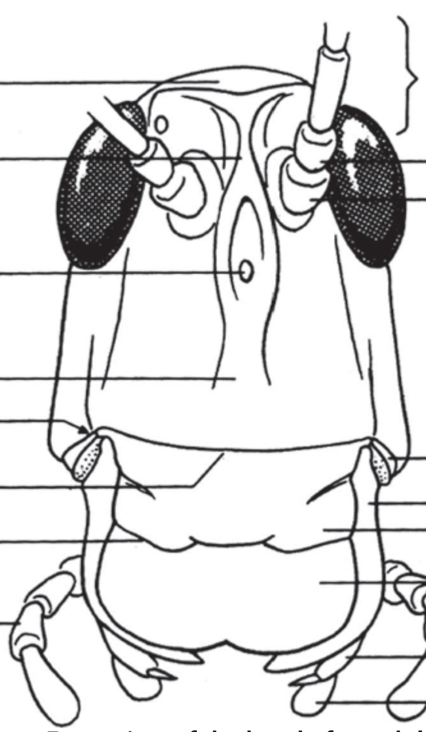
Antennae of Hexapods, Figure 50 **Side view of the head of an adult grasshopper, showing some major elements.**

The antennae usually have bristles and sensilla of different types that act as chemoreceptor-, thermoreceptor- or hygroreceptor-type sensory organs. In addition, the antennae of males display modifications tending to increase their surface area, which permits harboring a great number of sensilla and acting as "detectors" that detect pheromones emitted by the females, and enable (usually) the males to locate the females for reproductive functions. Certain modifications in the antennae of the males can also be related to particular courtship behavior prior to mating.

In relation to the functions carried out by the antennae, it is necessary to highlight the presence, in the pedicel, of Johnston's organ, which is formed by cordotonal sensilla. It is fundamentally a proprioreceptor organ that provides information about the position of the antennae with respect to the head, the direction and force of the wind, or of the water currents in aquatic insects. In addition, it can act as an auditory organ in male mosquitoes and chirinomids, which perceive the sound produced by the females in flight.

The number of flagellomeres is a character that, in certain cases, is related to the sex, as occurs in some Aculeate Hymenoptera in which the males display 11 flagellomeres and the females 10. In others, it represents an important taxonomic character, emphasized in this sense the family Argidae (Hymenoptera: Symphyta) whose individuals display the flagellomere undivided.

Various types of antennae exist (Fig. 52), the appearance of which is owed fundamentally to the variation in form and development of the flagellomeres. The most important are:



Antennae of Hexapods, Figure 51 Front view of the head of an adult grasshopper, showing some major elements.

Filiform

The flagellomeres, normally numerous, are narrow, cylindrical, and of similar size. It is the most common type in the insects.

Moniliform

There exists a narrowing in the union of each flagellomere, which are more or less spherical, with the antenna acquiring a "rosaried" appearance (like the beads of a rosary). There are examples in various families of beetles.

Setaceous

The flagellomeres are extremely fine and diminish in diameter gradually toward the tip; the antenna thus acquires an appearance of seta or hair. The antennae of Odonata constitute a typical example.

Aristate

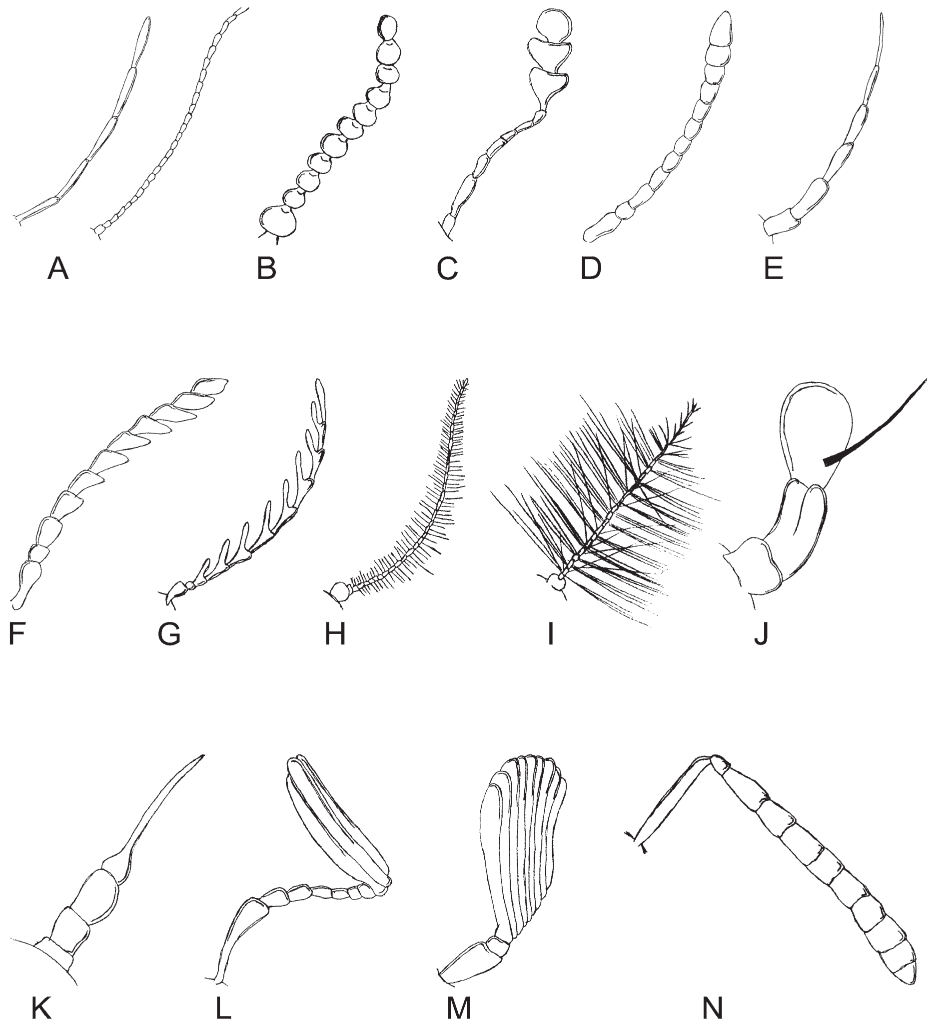
The last flagellomere is normally very wide and bears a conspicuous bristle named the arista. Examples are found in Diptera (Syrphidae and Muscidae).

Stylate

The last flagellomere is prolonged apically in a fine and elongated process named the style. Examples are found in Diptera (Rhagionidae and Asilidae).

Clavate

The flagellomeres increase in diameter gradually toward the apex. Examples are found in Coleoptera (Coccinellidae and Tenebrionidae).



Antennae of Hexapods, Figure 52 **Some common types of antennal forms: A, filiform; B, moniliform; C, capitate; D, clavate; E, setaceous; F, serrate; G, pectinate; H, bipectinate; I, plumose; J, aristate; K, stylate; L, lamellate; M, flabellate; N, geniculate.**

Capitate

In this case the last flagellomeres are of greater diameter, in contrast with the preceding, forming a "club" or "mace." Examples are found in Coleoptera (Nitidulidae and Silphidae).

Serrate

The flagellomeres display pointed, lateral prolongations, on one side or on both. Examples are found in Coleoptera (Elateridae).

Pectinate

The flagellomeres project laterally, forming a fine and more or less elongated projection. When it is produced over two sides of each flagellum, the antennae are called bipectinate. Examples are found in Coleoptera (Pyrochroidae).

Flabellate

The flagellum displays long, flattened or more or less cylindrical expansions. Examples are found in some species of Coleoptera (Scarabeidae).

Lamellate

Only the last flagellomeres display long, lateral expansions. Examples are found in Coleoptera (Scarabeidae, subfamily Melolonthinae).

Plumose

Flagellomeres with numerous long hairs are arranged in a feather-like or whorled form. Examples are found in male mosquitoes (Diptera).

Geniculate

The scape is relatively long, forming a clear angle with the rest of the antenna (pedicel plus flagellum). Examples are found in Hymenoptera (Formicidae and Chalcidoidea), and in Coleoptera (Lucanidae). Within this type of antenna, particular variations can exist, as in the case of the Ormyridae (Hymenoptera: Chalcidoidea), in which the first divisions of the flagellum are of a lenticular type (lens shaped, or double convex).

Antennal Club

On a clubbed antenna, the enlarged distal segments.

► Antennae of Hexapods

Antennal Fossa

A groove or cavity in which the antennae are located or concealed. This is also called the antennal insertion.

► Antennae of Hexapods

Antennal Sclerite

A ring into which the basal joint of each antenna is inserted.

► Antennae of Hexapods

Antennation

Sensory or tactile movements with the antennae that result in contact of the antennae with an object.

Antennule

A small antennal or feeler-like process.

Anterior

This term usually is used to refer to the end of the body containing the head, or the direction of the head, or the front of the insect.

Anthelidae

A family of moths (order Lepidoptera) also known as Australian lappet moths.

► Australian Lappet Moths
► Butterflies and Moths

Anther Smut of Carnations

This is a fungal disease of carnations that is transmitted by insects.

► Transmission of Plant Diseases by Insects

Anthicidae

A family of beetles (order Coleoptera). They commonly are known as antlike flower beetles.

► Beetles

Anthocoridae

A family of bugs (order Hemiptera). They sometimes are called minute pirate bugs.

► Bugs

Anthomyiid Flies

Members of the family Anthomyiidae (order Diptera).

► Flies

Anthomyiidae

A family of flies (order Diptera). They commonly are known as anthomyiid flies or root maggots.

► Flies

Anthomyzid Flies

Members of the family Anthomyzidae (order Diptera).

► Flies

Anthomyzidae

A family of flies (order Diptera). They commonly are known as anthomyzid flies.

► Flies

Anthophilous

Flower loving. Most insects that feed on nectar or pollen are anthophilous, including many butterflies and moths (Lepidoptera), wasps, ants and bees (Hymenoptera), but also numerous flies (Diptera), beetles (Coleoptera) and thrips (Thysanoptera).

► Pollination and Flower Visitation
► Butterfly Gardening
► Night Blooming Plants and their Insect Pollinators
► Pollination by Yucca Moths
► Apiculture
► Plant Extrafloral Nectaries

Anthribidae

A family of beetles (order Coleoptera). They commonly are known as fungus beetles.

► Beetles

Anthrophagy

Feeding on humans by other organisms. The most common anthrophagous organisms are insects, particularly biting flies, followed by lice, fleas, and ticks.

► Mosquitoes
► Lice
► Fleas
► Ticks
► Pathogen Transmission by Arthropods

Anthrophoridae

A family of bees (order Hymenoptera, superfamily Apoidae). They commonly are called cuckoo bees, digger bees, and carpenter bees.

► Bees, Wasps, Ants and Sawflies

Anthropocentric

An interpretation based on the belief that humans are the central fact or element of the universe, and interpreting everything in relation to human values of interests.

Anthropomorphism

The attribution of human qualities or forms to animals or their behaviors.

Anthropophilic

An insect that prefers humans as a source of food. A blood-sucking insect that feeds on humans.

Antibiosis

A characteristic, often a chemical within a plant, that inhibits survival or reproduction when an insect feeds upon it.

► Plant Resistance to Insects

Antibiotic

A chemical produced by a microorganism that affects the ability of another microorganism to survive or grow.

Anticodon

The triplet of nucleotides in a transfer RNA molecule that is complementary to and base pairs with a codon in a messenger RNA.

Antidote

A treatment used to treat the effects of chemical (e.g., insecticidal) poisoning.

Antidiuretic Hormones

Hormones acting on the hindgut to promote water reabsorption and conservation.

Anti-Drift Agent

A compound that is added to pesticides to reduce the number of droplets produced at the spray nozzle, and therefore to reduce the possibility of the product drifting away from the target.

Antixenosis

An effect due to a characteristic, often a physical or chemical attribute of a plant, that deters feeding or oviposition. This is also called nonpreference.

► Plant Resistance to Insects

Antlike Flower Beetles

Members of the family Anthicidae (order Coleoptera).

► Beetles

Antlike Leaf Beetles

Members of the family Aderidae (order Coleoptera).

► Beetles

Antlike Stone Beetles

Members of the family Scydmaenidae (order Coleoptera).

► Beetles

Antlions

Members of the family Myrmeleontidae (order Neuroptera).

► Lacewings, Antlions and Mantidflies

Ant-plant Interactions

Diane W. Davidson
University of Utah, Salt Lake City, UT, USA

Drop a spoon at a picnic and the ubiquity of ants (family Formicidae) is soon apparent. Ants are everywhere, lurking in leaf litter or brazenly scouring terrestrial and arboreal habitats for food in any form. Except in extreme climates that are inhospitable to insects, most terrestrial organisms have necessarily evolved ways to reduce the damage ants can cause, and many have managed even to extract benefits from them. Relationships between ants and humans provide examples: not only have we devised means of protecting our food stores from ants, but we have utilized ants to protect our food. Centuries ago, nests of Old World weaver ants (*Oecophylla smaragdina*) were cultivated in Asian orchards to control plant pests. Workers of this highly predatory species captured and devoured both the juvenile and adult stages of herbivorous (plant-eating) insects.

In some ways, early ants were better suited to serve plants than to injure them. Descended from predatory wasps, they were poorly adapted for herbivory (consumption of plant tissues), and no ant is truly folivorous (leaf-eating). Unable to digest cellulose themselves, ants also differ from termites in lacking gut microbes that can do this for them. Although much of the plant world is therefore not available to ants, plant sap, seeds, and fruit pulp are relatively easy to digest, and many (mostly arboreal) taxa feed on those resources. Such foods tend to be rich in carbohydrate (CHO) but poor in nitrogen (N) (amino acids, peptides and proteins), and dietary excesses of energy-rich CHOs may have subsidized colonization of the arboreal zone, where foragers must commute around a three-dimensional and poorly connected environment. Most ants also scavenge N-rich arthropod carrion, and many are active predators that can potentially benefit plants by attacking their herbivores. In some taxa, associations with intracellular and extracellular gut microbes contribute to the colony's N economy through N-recycling and possibly upgrading (conversion of non-essential to essential amino acids).

When disturbed by ants, many active insects and other animals can simply fly or walk to safety, but for plants and their seeds, as well as for comparatively immobile nesting animals and juvenile insects, there are no ready escape routes. It is in these organisms that we find some of the most unique or unusual adaptations for both defending against ants and exploiting their behaviors to advantage. Here, several categories of interactions between ants and plants are explored, together with some of the myriad ways in which plants have evolved to reduce or promote association with these ubiquitous insects. Included also are the influence of plant resources on ant ecology and evolution, and the effects of ants on the evolution of plant defenses.

Ants as Seed Predators

In warm deserts and other arid regions, ants are often both abundant and diverse, and annual and perennial plants are present more often as seeds than as adults. Here, seed-eating ants abound and may exert strong selection pressures on plant. Selection is mediated mainly by seed consumption, but also by ant effects on soil disturbance and nutrient availability. Seed-eating "harvester ants" typically return seeds individually to a central nest site where they husk and then cache them in underground granaries, often for long time periods. By storing foods that degrade slowly over time, ant colonies can persist in habitats where the production of seeds and other resources is sporadic and unpredictable. During periods of low food availability, many of these ants simply remain underground and forego the risks and poor rewards of external activity.

The small individual sizes and ectothermy of ants are correlated with low foraging costs, enabling these insects to forage economically even for tiny seeds with dispersed distributions. Ants can

Ant-plant Interactions, Figure 53 An extensive nest of leaf-cutter ants in the genus *Atta* (above) and high rates of leaf removal from an unlucky tree (below).

therefore reduce soil seed banks to lower levels than can large, endothermic ("warm-blooded") vertebrate seed-eaters like rodents and birds. Those taxa have higher foraging costs and tend to specialize in feeding on seeds in high density "hotspots," either in soils or on the plants themselves. Though reduced seed densities can potentially affect both plant densities and community composition, ants may commonly have less impact on plant communities than do vertebrate seed predators. This is so because seed predation by ants tends to fall most heavily on offspring of small-seeded plant species, whereas that by vertebrates often targets large seeds. Seedlings germinating from large seeds begin life with more resources than do those from small seeds and are therefore superior competitors within plant communities. Consequently, the removal of small seeds by ants has comparatively little effect on the densities of large-seeded species, while the removal of large seeds by rodents may lead to increases in the densities of small-seeded species.

In at least some localities, differences in seed size specialization by ants and rodents account for disparities in the short-term and long-term effects of these granivores on one another's populations. When seed-eating rodents were removed experimentally in one study, densities of harvester ants first increased and then declined. The short-term increase was likely due to competition between the two types of granivores, as there was some overlap in the sizes and species of seeds used by the two groups. However, rodent removal eventually led to increases in the densities of large-seeded plants, which subsequently out-competed small-seeded species, to the long-term detriment of ants.

Coexisting species of harvester ants often differ in worker body sizes, and small ants cannot carry the largest seeds. To a degree, therefore, worker size differences may remove small and large ants from resource competition with one another, and also determine disparate effects on plant communities. When ant communities are disturbed, either directly or by the introduction of non-native ants, there can be consequences for plant communities. Pathways of interaction can be indirect and complex. For example, if an introduced ant species produces a decline in populations of a native harvester ant, plant species on which the native ants specialize may increase at the expense of other components of the plant community. Such changes in community composition are hard to predict, and often become apparent only over long time periods, especially in arid lands with variable climates.

On an evolutionary time scale, some plants have acquired adaptation that reduce depredation of their progeny by ants. An example of such an adaptation is the use of hygroscopic awns (e.g., that of *Erodium cicutarium*) that alternately extend and coil when wet and dry, respectively, pushing the attached seeds beneath the soil surface. Unlike seed-eating rodents, harvester ants have little access to individually buried seeds, so such awns do appear to proffer a refuge from predation by granivorous ants. Whether mechanical, chemical, or phenological (e.g., timing of seed production), mechanisms of seed escape from granivorous ants remain poorly explored.

Early "Farmers" (Attines)

To the uninitiated, the cutting and transport of leaf, flower and fruit fragments by New World ants in the tribe Attini looks a great deal like herbivory (Fig. 53). However, as was originally proposed by Thomas Belt, a nineteenth century British mining engineer and amateur naturalist, the ants themselves do not digest cut leaves. Rather, they cultivate fungi that degrade cellulose and other plant products otherwise inaccessible to the ants. In more recent members of this group (species of *Atta* and *Acromyrmex*), the workers themselves feed on plant sap released from cut leaves, whereas larvae are fed gonglydia, or swollen tips of fungal hyphae (arms). Together, fungal mycelia and gongylidia supply CHOs (simple sugars, as well as glycogen in *Acromyrmex*), lipids and N (amino acids and protein). On her nuptial flight, the queen carries fragments of fungal gardens in her infrabuccal chamber, adjacent to the anterior digestive tract in the head. After mating, she removes her wings, excavates a terrestrial nest, begins to cultivate her fungal garden, and feeds her first worker brood on trophic eggs composed of resources from her degraded wing muscles.

Workers eventually take over cultivation and maintenance of the fungal gardens. Larger castes cut, drop, and carry the leaf fragments, while their smaller nestmates "hitch-hike" rides on leaf fragments to defend larger workers against parasitic phorid flies, and care for brood inside the nest. There, they lick and shred leaf fragments into finer pieces, and then chew their edges, depositing fecal droppings with digestive enzymes to aid in decomposition. Protein-degrading enzymes are recycled from the fungi themselves through the ant's digestive system, which lacks enzymes to degrade them. New leaf fragments are then inoculated with mycelia of older parts of the garden and fertilized with plant material (recent attines) and/or feces and animal matter (early attines). Through application of growth hormones, enzymes, nutrients, and antibiotics, higher attines maintain their fungi almost in monocultures. Nevertheless, recent studies by M. Poulsen, C.R. Currie, and colleagues have identified a virulent fungal pathogen of the gardens, as well as a bacterium living in fovea (small depressions) in worker exoskeleton. These filamentous bacteria, or actinomycetes, produce antibiotics directed mainly toward the common pathogen.

Although most folivorous insects are limited to eating a narrow spectrum of plant species, use of fungi as agents of digestion may explain leafcutter tolerance of more varied diets. Nevertheless, different taxa of higher attines specialize on grasses or dicots, and specialization exists even within those categories. Like other herbivores, leafcutters are especially likely to harvest tender young leaves, which lack the fiber and lignin to make them tough. For *Atta cephalotes*, J.J. Howard and colleagues showed that, the diet is apparently not chosen in response to energy, nitrogen, or moisture content, but rather to avoid various terpenoids that could poison fungi.

According to U.G. Mueller and colleagues, all attines appear to have descended from a common ancestor that forged relationships with fungi either growing on walls of leaf-litter nests or using ants to disperse their spores. Together, with gene sequence data, the fossil record, and confinement of this group to the New World, suggests that this ant-fungal partnership first formed between 45 and 65 million years ago. Direct transmission of fungi from queens to reproductive daughters provided opportunities for greater specialization and dependency to evolve in both partners. Nevertheless, new fungal species have also been domesticated by older, less specialized ant taxa in recent times.

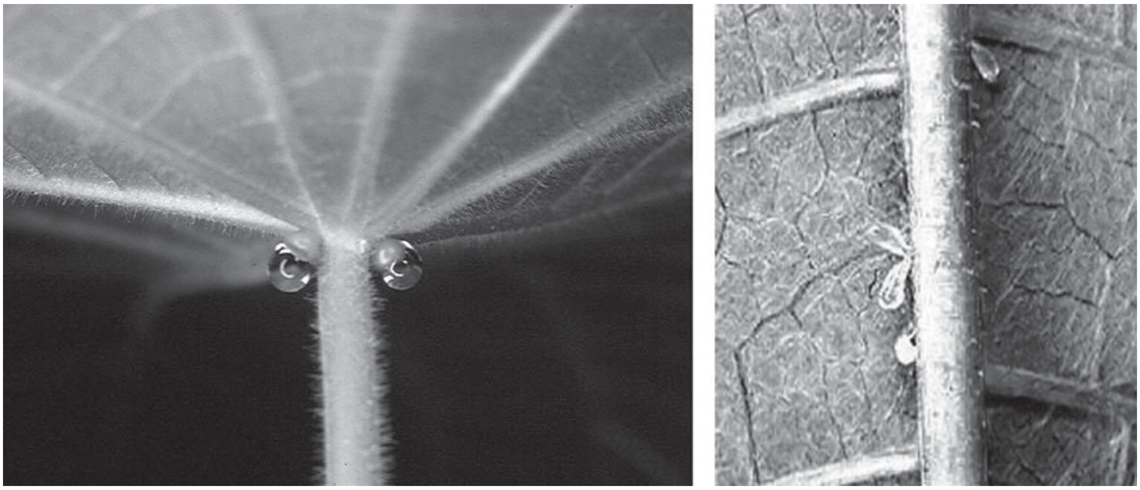
The success of the attine-fungal partnership is measurable in its impact on the forest. Mature *Atta* nests can range over several hundreds of square meters, and worker columns can reach trees more than 100 m from the colony along trails cleared of vegetation. In tropical areas not regularly flooded, attines can be very abundant and exact a considerable toll on plants. Some accounts in the literature judge them to be responsible for 12–17% of all herbivory, but these figures may be too high because they fail to include the mostly invisible losses of plant resources to sap-feeding insects. Throughout much of the Neotropics, higher attines also thrive in disturbed areas dominated by poorly defended pioneer (weedy) plant species. They are similarly destructive to agriculture, and cause millions of dollars in losses annually to crop plants that have been selected by humans for low toxicity.

Ant-plant Interactions, Figure 54 Ants tending Hemiptera outside and inside plant stems: (above) *Azteca* tending mealy bugs (Pseudococcidae) in the New World tropics, and (below) *Podomyrma* sp. tending scale insects (Coccidae, arrows) inside branches of *Chisocheton* (Meliaceae) near Madang, Papua New Guinea.

Pastoralists

Ants may also affect plants indirectly through the farming (or "tending") of insects in the order Hemiptera. With mouthparts highly modified as stylets, or "soda straws," these insects are phloem- or xylem-sucking consumers of plant sap (Fig. 54) and include aphids, leafhoppers, treehoppers, scale insects, and the like. Because plant sap is N-poor, sap-feeding hemipterans must process large quantities of these liquids to concentrate sufficient nitrogen for growth and reproduction. Moreover, while they feed, their relatively immobile immature or nymphal stages are exposed for long time periods to the risks of predation and parasitism. As a by-product of processing large quantities of sap for N, many Hemiptera release excess sugars as "honeydew" from their abdomens. When compensated by this attractive resource, ants forego predation of these insects and even protect them from other natural enemies. Relatively N-rich tissues like young leaves, and the pedicels of flowers and fruits, are particularly good sites for sap-feeders and the ants which herd them there. In Asian rain forests, where plant reproduction is highly sporadic, ants in the genus *Dolichoderus* have evolved as "migratory herdsmen," carrying their sap-feeding mealy bugs over long distances in search of optimal feeding sites.

Hemipteran tending, often compared to human tending of domestic livestock, is a mainstay for many arboreal ants. Still, to balance their diets, ants occasionally harvest some of the tender hemipteran nymphs and consume N-containing hemolymph of these and other arthropods. The relative strengths of positive and negative effects of the ants (herbivore reduction vs. hemipteran tending) determine the net effect of ants on a plant's well-being and reproduction (i.e., its fitness). This net outcome can be positive if herbivores are abundant and tending ants are effective in driving them away. However, as hemipteran populations thrive and grow under ant protection, removal of large quantities of sap can threaten the host plant's health. Living in intimate contact with hosts, Hemiptera also transmit viral and other plant pathogens. Not surprisingly then, plants appear to have fought back over evolutionary time. For example, hairs (trichomes) on leaves or stems prevent hemipteran stylets from reaching the plant surface. Other evolved responses are best understood in the context of the old adage that "the enemy of my enemy is my friend." Thus, many plants may have short-circuited the Hemiptera out of these tripartite interactions by paying the ants directly, i.e., by provisioning them with carbohydrate rewards in the form of sugar-rich extrafloral nectars (EFNs, Fig. 55) or lipid-rich pearl bodies (PBs). J.X. Beccera and D.L. Venable hypothesize that by increasing the CHO:protein ratio in the ants' own diets, plants induce ants to consume more of their Hemiptera. Arguing against this hypothesis for the origin of EFNs are observations of ants tending both sap-feeders and EFNs. Despite such observations, D.W. Davidson and colleagues have proposed that the hypothesis might help to



Ant-plant Interactions, Figure 55 **Myrmecophyte-produced food rewards for ants: (left) Extrafloral nectaries (EFNs) at the junction of leaf blade and petiole of *Endospermum medullosum* (Euphorbiaceae) near Madang, Papua New Guinea; (right) pearl bodies (PBs) on lower leaf surface of *Cecropia engleriana* (Cecropiaceae) at Cocha Cashu, Peru. Both EFNs and PBs also occur in myrmecophilic plants.**

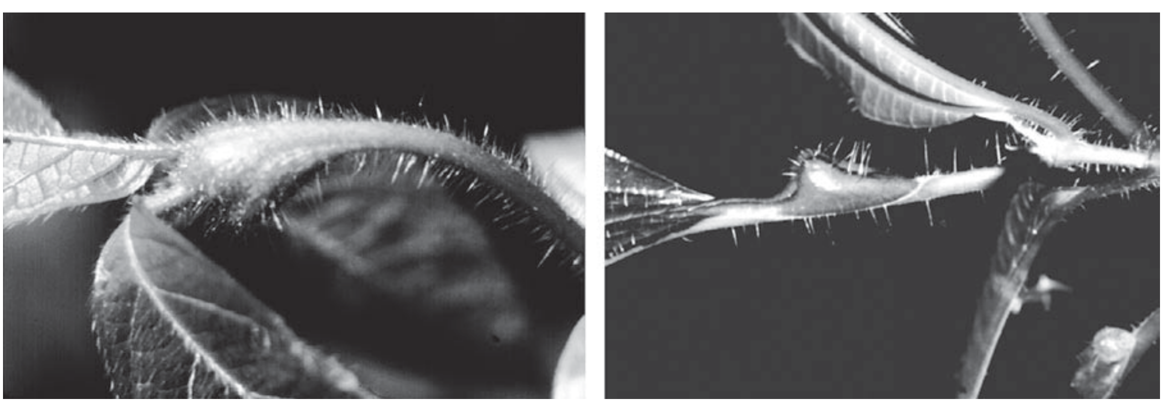
explain early divergence in foraging habits of major ant taxa that differ in their propensity to tend hemiptera versus EFNs.

Biotic Defenses of Plants

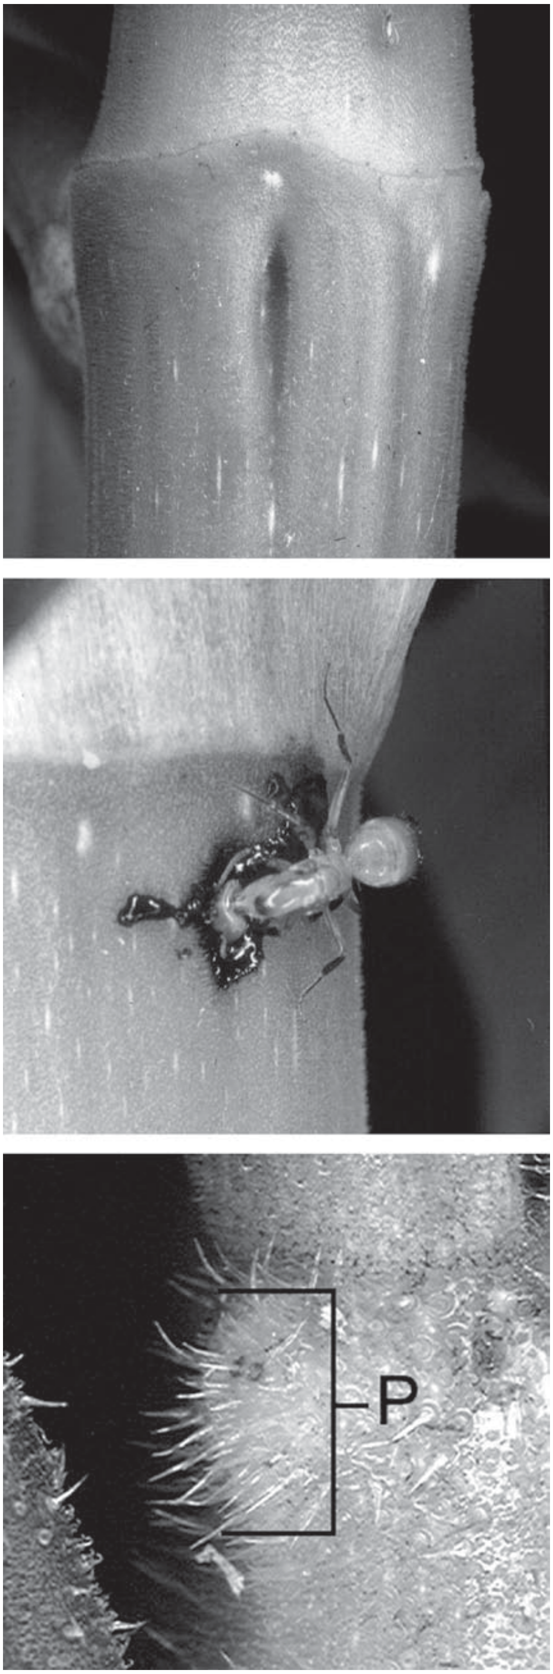
Even in relationships not (or no longer) involving Hemiptera, production of ant attractant foods should increase the presence of ants on vegetative and reproductive plant tissues and help to deter a variety of insect and other herbivores. Plant adaptations for defense by ants, wasps and other potential predators of insect herbivores are referred to as "biotic defenses," since they require the collaboration of other living things.

Some Definitions and Constructs

Whether the anti-herbivore protection of plants by ants is afforded through consumption of Hemiptera or deterrence of other herbivores, such protection completes the requirement for what are termed "mutualistic" interactions. Both parties in these relationships benefit, the ants directly from plant provisioning of resources, and the plants indirectly, usually through deterrence of damaging herbivores. Mostly, these interactions are opportunistic and unspecialized, depending on which ants, herbivores, and plants co-occur within a community. Plants with opportunistic ant associations based on production of food rewards alone are said to be "myrmecophilic" or "ant-loving." In contrast, at tropical latitudes, many ant-plant relationships have become more highly specialized and obligatory. That is, in the context of their natural communities, partners cannot survive and reproduce in the absence of their associates. In this case, resident "phytoecious" ants protect their host plants, (Fig. 56) and "myrmecophytes" (true "ant-plants") provide not only food but housing in stem or leaf structures termed "domatia." Individual ant colonies and myrmecophytes may live together over substantial portions of their life histories in relationships therefore termed "symbiotic mutualisms." (Although often used incorrectly in place of "mutualism," the term "symbiosis" - literally "living together" - is value neutral, including negative interactions like parasitism, as well as mutually beneficial interactions.) "Cheater" ants, which benefit plants less than the evolved partner, or otherwise negatively



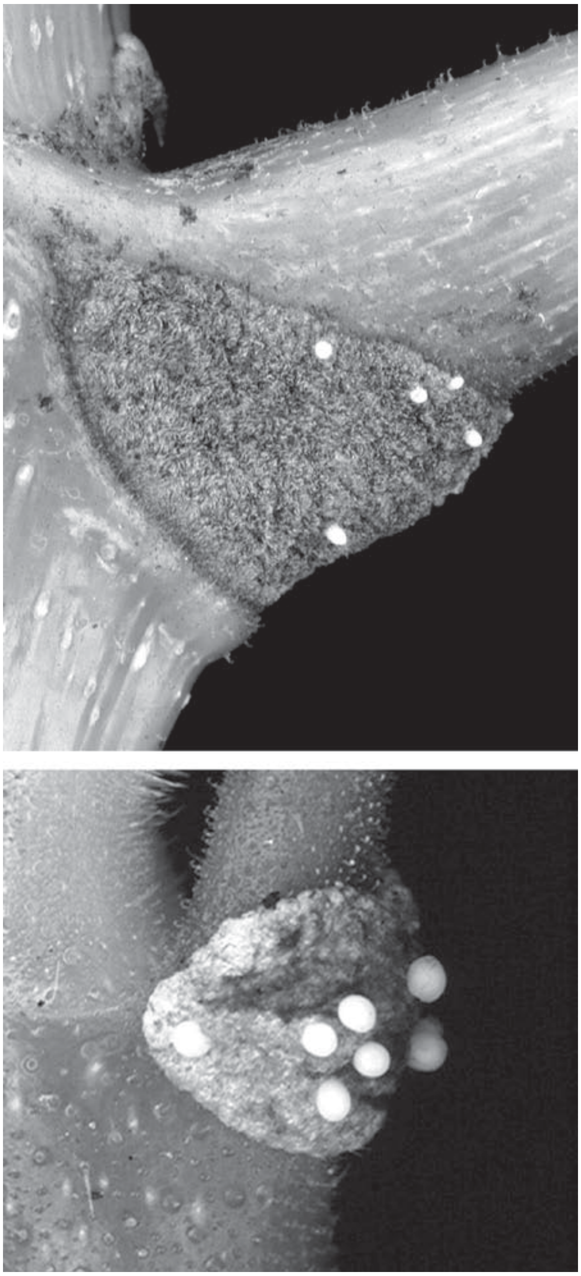
Ant-plant Interactions, Figure 56 **Caulinary (left) and foliar (right) domatia of ant-plants. Forming the domatia of many myrmecophytes are swollen stems or support structures, either naturally hollow or with weak pith, removed by ants. Shown here (left) is a branch of *Duroia hirsuta* (Rubiaceae, vic. Iquitos, Peru), swollen at attachment of large opposite leaves. Tiny ants in genus *Myrmelachista* inhabit these naturally hollow caulinary domatia. Foliar domatia, like that shown here for *Tococa* sp. (Melastomataceae, from Cocha Cashu, Peru) (right) are highly modified and more obviously evolved to accommodate ants.**



impact hosts, may occasionally prevail in symbioses because they are better colonists or competitors.

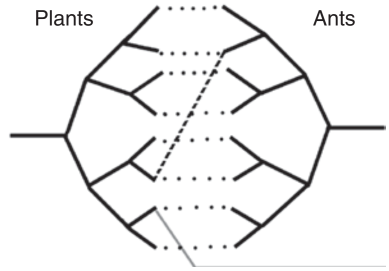
In symbiotic ant-plant relationships, partners are more likely to have undergone coevolution, i.e., reciprocal genetic (evolutionary) responses to selection pressures exerted by each partner on the other. Coevolution has two aspects: coadaptation and cospeciation, and only the former occurs frequently in symbiotic ant-plant partnerships. Illustrating coadaptation (reciprocal adaptation), many plants have evolved restrictive (Fig. 57) entrances to their domatia as a means of favoring colonization by certain ant taxa over others, while queens of phytoecious ants have responded by evolving traits enabling them to recognize and colonize such entrances expeditiously. Similarly, plants and ants may have coadapted with respect to the types or sizes of food rewards offered (Fig. 58) and their utilization or accessibility. In contrast, cospeciation (the co-radiation of ant and plant lineages to give congruent phylogenies) appears to be quite rare even in tropical symbiotic ant-plant relationships. Rarity likely results from the fact that ant and plant propagules (i.e., new queens and seeds) disperse independently, leaving much opportunity for new partnerships to form over evolutionary time. Seeds must germinate and produce seedlings of a threshold size before the next generation of hosts can support ant colonies. Environmental variation or randomness in the abundances of, and proximities

Ant-plant Interactions, Figure 57 The prostomata (stem entrances) of *Cecropia* species come in various sizes and forms correlated with host use by different ant taxa: *Cecropia engleriana* (above) produces a narrow inverted prostoma, recognized and colonized by comparatively small queens of *Azteca australis* (Dolichoderinae) (center); in contrast (below), those of *Cecropia* sp. nov ("pungara") are convex and covered in urticating hairs; this host species attracts much larger queens of a ponerine ant, *Pachycondyla luteola*. Both photos are from Cocha Cashu, Peru.



Ant-plant Interactions, Figure 58 **Food bodies of myrmecophytic *Cecropia* also come in different sizes, as shown here for *Cecropia membranacea* (above), usually associated with tiny *Azteca* ants, and closely related *Cecropia* sp. nov. ("pungara") (below), housing the much larger *Pachycondyla luteola*. Both are from at Cocha Cashu, Peru.**

to, sources of colonizing queens, provide ample opportunity for host-switching or *de novo* colonization by previously uninvolved ant taxa. This



Ant-plant Interactions, Figure 59 **A hypothetical case of cospeciation, illustrated by the congruent or mirror-image phylogenies (= genealogies, solid dark lines) of associated (dotted lines) ant and plant taxa. On each occasion when a plant species splits into two distinct taxa, the associated ant lineage also undergoes a speciation event. For cospeciation to have occurred, splits in plant and ant lineages must have occurred contemporaneously and be attributable to selection imposed by the partner. Otherwise, an ant lineage may have just radiated secondarily over a pre-existing plant lineage. The dotted and grey lines depict two kinds of evolutionary colonization events: respectively, host switching and *de novo* colonization by a previously unassociated ant lineage.**

picture contrasts sharply with that for, e.g., higher attines and their fungi; there, I.H. Chapela and colleagues have shown that queens transmit fungi between generations of colonies, and phylogenies of the two lineages are largely congruent (Fig. 59).

Despite little evidence for cospeciation in symbiotic ant-plant associations, contemporaneous diversification within partner lineages may occur through diffuse coevolution, defined by D.H. Janzen as reciprocal evolutionary responses to a suite of potential partners. Additionally, if host availability were often limiting, phytoecious ants may frequently have colonized non-myrmecophytic relatives of those plants, exerting new selection on these species to evolve ant-attractive traits. Based on multiple independent origins of myrmecophytism in older and more recent Asian *Macaranga*, S.-P. Quek and colleagues have proposed just such a scenario. A parallel argument is that, lacking their typical associates, habitat-switching hosts could have provided evolutionary opportunity for the origin of new phytoecious ant taxa.

These examples are relevant in the context of the different selection pressures driving diversification in myrmecophytes versus phytoecious ants. As noted by D.W. Davidson and D. McKey, proliferation of plant species has been driven principally by colonization of new habitats, accompanied by evolution of new defensive strategies and (correlated) growth rates, etc. In contrast, ants have diversified mainly in response to biogeographic factors and (especially) plant traits favoring certain associates over others (below). Why this asymmetry? Plants grow through seedling stages without their ants, and their success during this most vulnerable period depends on factors such as light and nutrient regimes, i.e., on habitat. Additionally, any of several ant taxa may provide acceptable protection against herbivores. In contrast, phytoecious ants are typically restricted to their hosts throughout the life history, and disparities in host characteristics (e.g., habitat-correlated growth rates and investment in biotic defense) should be highly consequential. This asymmetry in selection pressures is reflected in both the specificity of partnerships and evidence for coadaptation. Individual *Cecropia* species can house ants in different genera or even sub-families, while associated ants do not inhabit plants outside this genus. Similarly, phytoecious ants of bamboos have adapted to these hosts by evolving means of water evacuation from nest culms (active bailing or passive engineering), and they do not live elsewhere. In contrast, no bamboo has been determined to have evolved ant attractants.

Factors Driving Evolutionary Specialization

Factors driving evolutionary specialization in phytoecious ants are apparent from assessing both the taxonomic affiliations of these ants and traits of coadapted partners. Despite the frequent impression that such ants are ferociously aggressive against vertebrates (including many an unfortunate investigator), they appear often to include comparatively weakly competitive ant taxa that persist only in association with myrmecophytes. Several plant traits, separately or in combination, contribute to the capacity of these plants to serve as refugia from natural enemies. First, many myrmecophytes produce nutritionally complete food rewards that eliminate the need for resident ants to forage in more competitive environments off their hosts. *Acacia* and *Macaranga* are examples. Second, derived from taxa in which stem hairs are common, a number of myrmecophytes possess stems and domatia covered with long, dense hairs (trichomes, Fig. 55) that exclude larger-bodied enemy ants, competitors and perhaps predatory army ants, while permitting tiny resident taxa to commute among them. Such hosts include *Cordia nodosa*, *Duroia hirsuta*, and *Hirtella* spp., with tiny *Allomerus* and *Azteca* ants, as well as a variety of myrmecophytic Melastomataceae. Third, many myrmecophytes, e.g., *Macaranga* and *Cecropia*, grow as little-branched, pole-like plants with few points of contact over which enemy ants might invade from neighboring vegetation. Fourth, the mutualism between ants and *Macaranga* has been shown by S.-P. Quek, S.J. Davies, and colleagues to have originated on hosts with irregular “wax blooms” on stems. Many insects, including most ants, have difficulty walking on epicuticular waxes, but as W. Federle and colleagues have demonstrated, “wax-running” ants in at least two genera (*Crematogaster* and *Camponotus*) evolved to utilize the slippery hosts. During the co-radiation of plant and *Crematogaster* lineages, stem types (waxy or smooth) continued to constrain host shifts.

All of the previously described traits are attributes that likely preadapted plants to associate with competitively inferior ants searching for sanctuary. In addition, phytoecious ants themselves have often evolved to reduce interaction with enemies by pruning vines and other vegetation contacting their hosts. (This behavior may coincidentally enhance the host’s light environment.) At least one such ant species (*Pseudomyrmex dendroicus* on

Triplaris americana) even prunes leaves of its own host when they bear invasions of enemy ants. In the Neotropics, a majority of pruning ants defend themselves using proteinaceous stings, which tend to be very effective against vertebrate enemies, but less effective than chemical sprays against social insect enemies, including many other arboreal ant taxa. Also suggesting that pruning evolved to limit invasions of competitors, Federle and colleagues find that ant taxa living on waxy-stemmed *Macaranga* hosts do not prune as intensively as do those inhabiting more recent non-waxy species. The latter ants are also more recent, and the evolution of pruning in ants may have benefited host plants by reducing the cost of epicuticular waxes. The advent of pruning coincides with a switch to more generalized host associations, as ant taxa from waxy stem hosts expanded their host ranges to non-waxy hosts. Finally, M. Frederickson has shown that phytoecious ants best at pruning are not always those that are best at protecting plants from herbivores. Therefore, a myrmecophyte's failure to filter out supposed "cheaters" that didn't prune may be due to alternative benefits provided by the ant species in question.

Conflicts of Interest between Partners

As for partners in virtually all interspecific interactions, the evolutionary interests of paired ants and plants are often in conflict. For example, although selection may favor ant colonies that extract the maximum resource possible from their hosts (e.g., by tending sap-feeders, as well as consuming plant-produced ant rewards), selection on plants should magnify cost-efficiency by producing the greatest protection for the least investment in resources devoted to housing and feeding of ants. The most striking examples of evolutionary conflicts of interest come from cases where ants modify plant architecture in ways that are beneficial to them but harmful to their hosts. Working in African savannahs, M.L. Stanton and colleagues have shown that *Crematogaster nigriceps* attacks the axillary buds of its host (*Acacia drepanolobium*), killing apical meristems (growing tips) and greatly curtailing host reproduction in the process. However, by reducing lateral spread, destruction of meristems may also diminish potential contacts between branches of hosts and those of neighboring acacias, some with competitively superior ants that threaten resident colonies. *Tetraponera penzigi*, a second, competitively subordinate occupant destroys EFNs of its host, perhaps making it less attractive to more dominant ants on neighboring hosts.

Similar conflicts of interest are apparent in neotropical ant-plant relationships. The most common inhabitant of *Cordia nodosa* in southeastern Peru is an *Allomerus* that destroys flowers and fruits of its host. D.W. Yu and N.E. Pierce have shown that ant fecundity is greater on plants with curtailed reproduction, because hosts produce more domatia and associated leaves, sites of food body production. *Cordia* populations might be expected to decline to local extinction under such "cheating" by *Allomerus*, but Yu and colleagues have also demonstrated that alternative and beneficial *Azteca* ants are better long-distance colonists, and that the frequency of association with these ants increases as plant density declines. Finally, T.J. Izzo and H.L. Vasconcelos report that selection on plants to fight back under similar circumstances is apparent in relationships between *Allomerus* and another Amazonian ant plant, *Hirtella myrmecophila*. Reproductive structures of this understory treelet are produced only on older branches from which leaf domatia have been aborted, and where worker ants are therefore few or absent.

Long-Term Evolutionary Histories of Ant-Plant Associations

Over long-term evolutionary history, one can expect "ownership" of host taxa to have changed hands in concert with changes in the fortunes of one-time ant partners and their competitors for the benefits of mutualistic association. Are there regularities in the trajectories that these relationships take over time? One might speculate that competition among ants for plants, together with filtering of ants by plants, could produce even greater specialization by the associated taxa, and that this might be a one-way and largely irreversible process. For ants, possible examples involve several closely related genera of tropical arboreal, stem-nesting ants in the formicine tribe Plagiolepidini. (Together, these genera are set apart from others in the tribe by workers possessing just 9 or 10 antennal segments.) Two Old World tropical genera, *Petalomyrmex* and *Aphomomyrmex*, are each represented by just a single West African species and are specialized to one and two host plant species, respectively. Because the probable closest relatives of these taxa (*Myrmelachista* and *Brachymyrmex*) occur as free-living species in the New World, it seems likely that ancestors of the African species were once free-living and more widely distributed, and that competition could have driven *Petalomyrmex* and *Aphomomyrmex* to extreme specialization. The genus *Myrmelachista* includes both free-living and plant-associated species. On average, the former (mainly with 10-segmented worker antennae) have generalized foraging and stem-nesting habits and reside mainly in high elevation cloud forests along the Andean and Central American mountain chains, normally above the elevational ranges of dominant free-living competitors in ant genera *Crematogaster* and *Azteca*. At intermediate and low elevations, and within the ranges of these dominants, J.T. Longino has found that congeneric species are mostly phytoecious ants, principally inhabiting hosts in plant families Lauraceae and Meliaceae. *Myrmelachista* hosts generally lack domatia and food rewards (i.e., are not true myrmecophytes), and associated ants tend sap-feeders inside stem nests. At least some phytoecious *Myrmelachista* occurring at intermediate elevations apparently do not attack encircling vines, though a congeneric species at lower elevations (likely *M. flavocotea* in a more competitive environment) does prune vegetation contacting its host.

Finally, in Central Amazonia, at least two different *Myrmelachista* species occupy and maintain "supay chacras," or "devil gardens." These are orchard-like stands where all but one or two myrmecophytes (and sometimes small, herbaceous resource plants) are killed by the tiny workers that cut major leaf veins and deposit formic acid in the wounds. Leaves necrose and die, and none but favored host and resource plants are able to recruit new individuals inside these bizarre areas. In summary, it is possible that basal *Myrmelachista* species persist only in the absence of strong competitors, or where competitively dominant ant taxa have driven lowland lineages toward increasing specialization that permits coexistence with strong competitors. However, this hypothesis will remain conjecture until tested rigorously after reconstructing phylogenetic histories of associated lineages.

Natural selection to magnify the colonizing and competitive abilities of particular ant associates, coupled with that to filter cheaters, may eventually reduce partnerships to relationships between single, highly specialized ant and plant species, whose persistence is balanced precariously on the premise that each partner will thrive despite changes in the abiotic (physical) and biotic environment. However, natural selection is short-sighted, capable only of enhancing short-term fitness. Over the long term, it can neither anticipate nor respond to the threat of loss of the sole partner. Therefore, it is reasonable to speculate that fewer than all of the ant-plant associations that have ever existed still exist today. Nevertheless, the most thoroughly studied evolutionary trajectories of phytoecious ants are those described by S.-P. Quek and colleagues for *Crematogaster* of *Macaranga*, and show wax runners breaking away from hosts with waxy stems to occupy plants that should constitute a more competitive environment.

Implications of Exudate-Feeding for the Evolutionary Ecology of Ants

The most conspicuous effects of plants on ant ecology and evolution involve phytoecious ants whose colonies are specialized to live their entire life histories on myrmecophytic plants. However, more generally, plants appear to have markedly influenced the biology of ant taxa feeding substantially as "herbivores," either directly on plant wound secretions and EFN, and/or indirectly, on insect honeydew. Such foods, collectively termed "exudates," consist principally of sugars (EFN) and water and are notoriously poor sources of essential amino acids and proteins. Though a certain amount of carbohydrate might be paired with available nitrogen sources as the "nutritionally complete food" needed to subsidize growth and reproduction, exudate-feeders should be left with an "excess" of CHOs. Natural selection may then favor colonies that are able to deploy excess CHO for acquisition of more limiting nutrient, N.

Across the spectrum of exudate-feeding ants, species appear to accomplish this in one or more of several ways. First, they may use excess CHOs to subsidize rapid locomotion, leading to what have been termed higher "dynamic densities." Faster locomotion enables workers to cover more area per unit time, and potentially, to encounter protein resources at a faster rate. Second, defense of true spatial territories is rare among ants generally, but appears to be commonest in species most apt to have excess CHOs to fund this costly behavior. Third, N-starved ants may also reduce percent body weight N, though there are competing explanations for this pattern. Thus, evolutionary transitions from predation and scavenging to substantial dependence on plant and insect exudates correlate with transitions in chemical weaponry. N-rich proteinaceous compounds, or N-containing alkaloidal compounds (both mediated by stings) are replaced by N-free compounds released as volatile sprays or sticky glues from the same or different glands. Whether such transitions are due to N-limitation, or the ineffective nature of C-based weaponry in killing or paralyzing prey, is currently unsettled.

By "paying" ants mainly in CHO-rich food rewards, myrmecophilic and myrmecophytic plants may encourage predatory behavior by attending ants seeking to balance their diets (above). Recently, D.W. Davidson and S.C. Cook found that rainforest plants supply EFN at sugar concentrations far exceeding those acceptable to most arboreal ants. They therefore suggest that high sugar concentrations may serve to manipulate communities of attending ants by favoring the most protein-limited taxa that would not forage for sugar at lower concentration.

Finally, widespread availability of CHO-rich plant foods in the arboreal zone undoubtedly selected for domination of these foods by placing nests near the food source. For ants already nesting in leaf-litter twigs, this transition may not have been difficult, but appropriate cavity space would not always have been available. Many arboreal ant taxa have therefore evolved the capacity to construct their own nests from carton, silk, or leaves cemented to one another to create cavity space.

Some Parallels Between Ants and Plants

A central theme running through this article has been that the balance of resources accessible to animals (Hemiptera and ants) affects the evolutionary ecology of these organisms by determining the types of resources available for various organismal functions. This argument is no less true for myrmecophytic plants and, in fact, was adopted by ant biologists based on its explanatory power in plants. In rainforest plants, for example, E.W. Schupp and D.H. Feener have shown that N-free but carbon-rich food rewards for ants (EFNs and PBs) are more typical of taxa growing in disturbed habitats under high light, than of groups typical of the dark forest understory. Apparently, high rates of carbon-gain in open habitats enable plants to divert some of that carbon to defense.

A second reason why biotic defenses may occur at high frequency in fast-growing, "pioneer" species of disturbed sites may relate to the shorter average leaf life spans of those species. D. McKey has argued persuasively that shorter leaf life spans should favor foliar defenses that are "reclaimable," i.e., can be diverted from aging leaves to more valuable young leaves as time passes. In contrast, much higher, but one-time, investment in non-reclaimable defenses (e.g., the lignin and fiber contributing to leaf toughness) are warranted only when the life expectancy of leaves is relatively long. One can speculate that the pattern in plants might also be applied to predict aspects of ant biology. For example, a substantial, one-time investment in producing thicker (N-rich) exoskeleton might only be warranted in ant species with long-lived workers. This interesting hypothesis has yet to be tested.

Two final patterns in defensive investment are apparent in at least some myrmecophytic plants, and may extend as well to ants and other social insects. Comparing closely-related pairs of *Cecropia* species from different microhabitats at the same rainforest site, it appears that relatively slow-growing taxa from shaded habitats invest in biotic defenses both earlier and more heavily than do their faster-growing relatives from sunny habitats. The latter pattern is understandable in the context of a cost-benefit analysis of defense. For species growing regularly at low light, leaf replacement is very slow due to resource limitation, so plants ought to defend existing leaves well. Moreover, any opportunity cost of defense (calculated in lost growth, survivorship, and reproduction) would be low in comparison to that for species capable of growing rapidly in high light. The combination of high replacement costs and low opportunity costs is thought to select for high defensive investment. (Applied to ants, this pattern suggests the currently untested hypothesis that mean colony growth rates are inversely related to defensive investment in individual workers.) C. Brouat and D. McKey have argued that, in myrmecophyte lineages with interspecific variation in developmental onset of biotic defense, precocious (early) onset should be the derived state; however, few data are available to test this prediction. Others have suggested that costly chemical defenses produced early in development should be abandoned after onset of biotic defense, but recent tests in genera *Acacia* and *Inga* contradict this theory, and suggest that chemical and biotic defenses may be targeted at different types of herbivores.

With respect to ants and other social insects, parallel reasoning might predict an inverse relationship between colony growth rate and investment in defense of incipient (young) colonies. One form of protection for young colonies is production of "nanitic" workers, scaled-down in size. This strategy enables young colonies to make more workers from a given resource base, and to spread the risks of foraging over more individuals. Are young workers smaller relative to normal workers in otherwise comparable species with intrinsically slow growth rates? Again, relevant data are lacking.

In summary, ant colonies and plants share some intriguing features that make models developed in one taxon potentially useful to investigators of the other taxon. Both types of organisms live anchored to a central place (not perfectly true for ants), grow to indeterminate size set by local resource availability, and add vegetative and reproductive parts in a modular way. These commonalities suggest that we might eventually discover additional models that are useful in explaining life history traits and other characters shared by the two groups.

Nutritional Benefits to Plants (Myrmecotrophy)

Among plants evolving associations with benevolent ants are certain epiphytic higher plants. Depending on trunks and branches of other plant species for structural support, epiphytes grow without directly parasitizing their hosts and obtain water and nutrients from rainfall and aerial deposition. Because high humidity and warm temperatures are conducive to this lifestyle, epiphytic higher plants are exceptionally diverse and abundant in tropical lowland wet forests, and (especially) in misty montane forests. (Tropical Africa is exceptional in this regard, due to frequent and severe droughts during the evolutionary histories of its plant life, and small expanses of montane forests in contemporary times.) By virtue of small size, these unrooted plants stand to benefit significantly from even small quantities of nutrients amassed as workers retrieve prey, discard refuse, and defecate within a confined area. From a mix of vegetable fiber, glandular secretions, refuse, and feces, many ants build "carton" shelters (for themselves and tended Hemiptera), and carton can potentially contribute to plant nutrition.

Two categories of plants, New World "ant-garden" epiphytes and Australasian "ant-house" epiphytes, have evolved a variety of traits that increase frequency and intimacy of relationships with beneficial ants. To encourage seed dispersal to nutrient hotspots in ant nests and carton, both sets of species produce seeds with attractive chemicals and/or food bodies. The common occurrence of methyl-6-methyl-salicylate on seeds of 11 unrelated ant-garden epiphytes, combined with the use of these same compounds as pheromones (within-species communication chemicals), suggests that this chemical could function as an ant attractant. Generations of seed dispersal by ants appears to have allowed ants to "capture" the evolution of their epiphytes, just as humans have captured and diverted the evolutionary histories of their crop species. (Alternatively, in both of these systems, plants may have captured and diverted the evolutionary histories of their gardeners!) The successes of ant-epiphyte partnerships are evident from their often remarkable abundances. Ant gardens can account for the majority of epiphytic higher plants in forests with a distinct dry season, and ant-house plants dominate the epiphytic floras of open kerangas forests in Asia. Whereas other epiphytes cannot survive extended periods of drought, ant-garden taxa benefit from moisture absorbed from the air and stored in the rich, organic ant cartons.

Ant-house epiphytes have evolved even more elaborate adaptations to procure benefits from their ant inhabitants. Those in the sub-family Hydnophytinae (Family, Rubiaceae) are descended from tuberous ancestors whose storage tissues were devoted principally to water storage. Ant-associated species in several different genera have reduced their investments in storage and allocated space within their tubers to two types of cavities used by the ants. Colonies of *Anonychomyrma* and *Philidris* nest in smooth- and dry-walled cavities, while placing feces and refuse in wet-walled cavities with "warts," actually modified roots. The epiphytes satisfy a significant fraction of their nitrogen requirements by tapping into these wastes. Epiphytic *Dischidia* species (Asclepiadaceae) frequently grow adjacent to the Hydnophytinae on the same hosts and are inhabited by the same ant colonies. In addition to their "normal" leaves, which grow appressed to tree trunks, these species produce highly modified leaves, involuted to form the cavities in which ants live. Stomata are concentrated on internal cavity walls formed by abaxial (lower) leaf surfaces. Through their stomata, plants take up the carbon dioxide (CO_2) needed for photosynthesis. When stomata (Fig. 60) open to perform this chore, they lose precious water, an especially limiting commodity for unrooted epiphytes of the hot, dry canopy. However, stomata of ant-house *Dischidia* open into a relatively moist, enclosed space where the partial pressure of CO_2 is enhanced by ant respiration, and this alleviates transpirational water losses. Using stable isotope technologies, K.K. Treseder and colleagues showed that *Dischidia major* from Bako National Park in Sabah, Malaysia, obtains about 39% of its carbon from ant-respired CO_2. Isotopic studies of N revealed that about 29% of the plant's N comes from ant feces, refuse and carton, into which plants insert adventitious roots from the bases of both normal leaves and leaf domatia.

Often growing with the Hydnophytinae and *Dischidia* are ant-occupied ferns in the genus *Lecanopteris*, and any of several ant taxa can occupy each of these epiphytes. Although associations between ants and epiphytes are not obligate for either party, it is rare to find one partner in the absence of the other. This is likely due to the combination of frequent nest site limitation in ants, and water and nutrient limitation in epiphytes.

Ant-plant Interactions, Figure 60 **Myrmecotrophic epiphytes: (upper left) At Cocha Cashu, Peru, 11 different epiphyte species from seven plant families can occur in carton "ant-gardens." This garden contains mainly seedling *Peperomia macrostachya*; (upper right) *Myrmecodia tuberosa* (Rubiaceae, Hydnophytinae) growing on a stunted tree in open "kerangas" forest at Bako National Park, Sarawak; (lower left) cross section of *Anthocephalus* sp., vic. Wau, Papua New Guinea, showing dry-walled cavities inhabited by ants, and wet-walled cavities with warts (modified roots) that extract nutrients deposited as ant refuse and feces; (lower right) Bornean *Dischidia major* (Asclepiadaceae, also from Bako): small, circular, flat leaves are typical of non-myrmecotrophic members of the genus, whereas much larger, involuted leaves have evolved in myrmecotrophic species and house associated ants.**

Myrmecotrophy is commonest in epiphytes, but as P. J. Solano and A. Dejean have shown, it can also occur where ants leave waste in abandoned domatia as colonies move to new growth. Thus, in *Maieta guianensis*, protrubances on domatia walls appear to take up N from waste of *Pheidole minutula*. By an as yet poorly defined mechanism, some rattan palms also benefit nutritionally from ants that build carton nests among spines on external stems. Another monocot (*Guadua* bamboo), apparently cannot take advantage of ant waste inside stems and actually loses N to scale insects tending by resident carpenter ants.

Ants as Seed Dispersers, Pollinators and Partners of Insectivorous Plants

Seed Dispersal

Tropical epiphytes are not the only group of plants to take advantage of the willingness of ants to transport seeds. In general, plants are thought to be selected for both "distance dispersal" and "directional dispersal," and the balance of selection for the two objectives almost certainly varies from species to species. Distance dispersal, or seed dispersal away from the maternal parent, is important for avoiding both asymmetrically strong competition from the mature plant against its seedlings, and transfer of pathogens and seed predators to these offspring. Because ants generally forage over relatively short distances from a central place, they are probably more important in directional dispersal, i.e., directing seeds to "safe sites" or favorable microhabitats. The importance of both forms of dispersal may explain why some "diplochorous" species accomplish both objectives, e.g., by first explosively propelling seeds away from the parent and then using ants to target seeds to a preferred location. The majority of ant-dispersed seeds are taken to or near the nest site, if not into the nest itself, and evolutionary advantages of "myrmecochory" (dispersal by ants) are usually discussed in relation to these sites.

Ant-plant Interactions, Figure 61 **Seeds of *Acacia cana* (northwestern New South Wales, Australia) have white arils contrasting with black seeds and are "displayed" at the soil surface, where ants are most likely to find them.**

Ant-dispersed plants, bearing small food rewards for ants, are common in habitats ranging from rain forests (e.g., herbs in the Marantaceae) to temperate deciduous forests (e.g., violets) and arid lands (North American jimson weed and some Australian acacias and saltbushes, Fig. 61), but the greatest diversity of myrmecochores may occur in areas with infertile soils, Mediterranean climates, and high fire frequency, e.g., especially African fynbos and Australian heath. Depending upon habitat characteristics, hypotheses for the adaptive value of myrmecochory have included giving seeds refuge from fire (chaparral), from competing plants (temperate deciduous forests, where ant nests may be the only vacant sites), or from seed predators (diverse habitats), as well as dispersal to nutrient hotspots on ant mounds (e.g., the nutrient-poor soils of arid Australia). While controversies continue about particular plants and sites, it is likely that each of these hypotheses holds for a subset of plant species.

The rewards that plants offer for seed dispersal fall mainly into the category of "elaiosomes," a kind of aril (= dry fruit) that is rich in oils. Both birds and mammals also feed on arillate fruits. When ant-dispersed species were compared with bird-dispersed (ornithochorous) species in the same sub-genus of Australian *Acacia*, fruits and seeds of the two types of species differed in size, aril composition, color, and presentation. Myrmecochorous seeds were somewhat smaller on average, with arils poorer in lipids (an energy source) and water, but marginally richer in N (amino acids or proteins). In contrast to the colorful arils that ornithochores display prominently on the host, arils targeting ants were white (contrasting readily with black seeds) and presented on the ground after dehiscing. A study by L. Hughes and colleagues compared the elemental composition of myrmecochore arils with that of fleshy fruits from diverse vertebrate-dispersed plant plants. A difference in potassium (K) levels suggested that vertebrate frugivores may require comparatively high levels of K in their fruits. Species growing in poor soils may simply have too little K to produce K-rich fruits, and so may be relegated to myrmecochory. Hughes and colleagues have also identified fatty acids (especially 1,2-diolein) as important components of elaiosomes, which may mimic the composition of insect prey (especially haemolymph) and therefore induce a variety of carnivorous and omnivorous ant species to transport seeds to the nest. Given the ubiquity of ants in most habitats, plants may have evolved to attract ant species that consume only the appendage and not the seed itself. Together, these studies point to syndromes of traits characterizing species with different dispersal agents.

Inconstancy in availability of elaiosomes probably prevents ants from specializing on fruits of a particular plant species. Moreover, aside from making a dispersal unit smaller or larger, it is difficult logistically to direct seeds to particular ant species. Not surprisingly then, relationships between ants and myrmecochorous plants tend to be diffuse rather than species-specific, with a variety of ants carrying seeds of a given plant, and often more than one type of elaiosome in an ant diet. Nevertheless, all ant species are not equal in their effects on plant reproductive success. Interspecific differences among carriers affect transport distances, frequency of dropping without retrieval, and rates of seed burial and escape from seed predators. Despite the opportunistic nature of interactions between myrmecochorous plants and ants, one or more ant species may often have a disproportionate effect on plant reproductive success. For example, at increasing frequency, disruption of ant communities by non-native species (e.g., Argentine ants, *Linepithema humile*) threatens populations of native plants, including rare and endemic (geographically restricted) species.

Ants as Pollinators

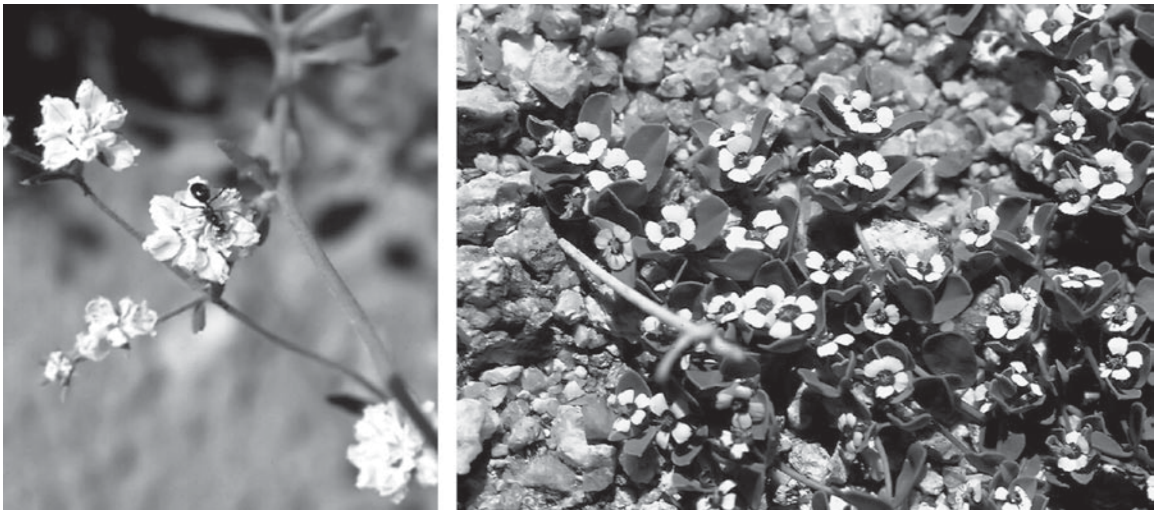
While we think most often of bees, flies and hummingbirds as agents of plant pollination, ants can also be effective pollinators under a restrictive set of circumstances. This is apparent despite observations by A.J. Beattie and colleagues that antibiotic compounds produced by the ants' metapleural and poison glands can suppress pollen germination and pollen-tube growth. (Unlike their wasp ancestors, ants often inhabit nests for multiple generations, and metapleural glands with hygienic function appeared early in ant evolution.) Nevertheless, M. Ramsey suggests that if ubiquitous ants were otherwise effective pollinators, some or even many plant species might be expected to have evolved pollen insensitive to metapleural secretions. The apparent rarity of such immunity suggests that ants may be inadequate as pollinators for some other reason(s). A signal attribute of ants is their tendency to revist food sources such as extrafloral nectaries and Hemiptera. Very likely, conservatism in ant movements detracts from their ability to transmit pollen effectively among individual plants, a requisite for reproduction by self-sterile taxa. Nonetheless, ants may play a role in pollination where smaller plants (e.g., epiphytes or annual herbs) occur at high densities, or by enhancing rates of self pollination when more effective pollinators are scarce.

Among the few plant taxa pollinated by ants, a suite of traits, or an "ant-pollination syndrome" (a term coined by J.C. Hickman) points to the circumstances under which ants can be induced to move among individual plants. Ant-pollinated plants (Fig. 62) tend to be small in stature and mostly prostrate in growth form, so as to preclude the need to compensate ants energetically for walking vertically rather than horizontally. As a consequence of paying little reward, plants encourage workers to keep moving in search of additional nectar or fuel. Other aspects of the ant-pollination syndrome are white color, and open structure, granting ants access to floral nectars, but just small amounts of pollen, and thereby diminishing the need for ants to groom pollen from their bodies. Ant-pollinated flowers also have relatively few ovules, which may all be pollinated even by small pollen deliveries.

Given their general ineffectiveness as pollinators, and their almost universal taste for sweet solutions, ants mostly interact with flowers as parasites of the relationships between plants and their real pollinators. Almost certainly for this reason, numerous plants have evolved barriers to exclude ants from floral rewards, e.g., with dense fields of hairs or sticky bands inside the corolla. It has even been suggested that nectars are made toxic or disagreeable to ants, though the taxonomic and geographic distributions of such nectars remain poorly known. J. Ghazoul presents some of the strongest evidence for floral ant repellents, demonstrating that a diversity of ants are repelled by something in floral tissues themselves. Still unresolved is the extent to which protection of nectar versus pollen has been the principal stimulus for the evolution of ant repellents. At least some pseudomyrmecine and myrmicine (*Cephalotes*) ants feed on pollen, but nectar feeding is more widespread in ants, probably because less specialization of the digestive system was required to use that resource. Nevertheless, early in their evolution, flowering plants must have found ways of protecting nutritious pollen from the ubiquitous and often protein-limited ants.

Relationships Between Ants and Insectivorous Plants

Carnivorous plants of diverse forms occur on infertile soils in various locations throughout the



Ant-plant Interactions, Figure 62 ***Mymecocystus* species pollinate flowers of at least two desert annuals: *Eriogonum abertianum* (Polygonaceae) (left) at Portal, AZ, and *Euphorbia* sp. (Euphorbiaceae) (right) from southern California. The latter is more typical of ant-pollinated plants because of its prostrate growth form. Individual flowers of both species produce minute quantities of nectar, so ants must walk back and forth among individual plants to fill their crops. However, on both species, workers can commute among individuals without energetically costly vertical movement. *E. abertianum* is rare except in years when winter rains continue through the spring; then it grows in almost monospecific stands with branches of adjacent individuals overlapping at the same level.**

world, and are united by their use of trapped insects as N sources. Pitcher plants are a particularly fascinating life form. They lure insects to the slippery edges of steep-walled pitchers into which fluids with digestive enzymes are secreted and protected from dilution by rainfall by a sort of "roof." Ants are among the most abundant prey of pitcher plants, being attracted to the pitcher edges by a form of extrafloral nectar. However, C.M. Clarke and R.L. Kitching show that one *Camponotus* species has evolved a more complicated relationship, perhaps a mutualism, with a carnivorous pitcher plant in Borneo. Thus, the hollow tendrils of *Nepenthes bicalcarata* house ants that feed on both large insects trapped by its pitchers and mosquito larvae therein. Unlike smaller prey, large insects apparently overwhelm the plant's digestive capacity and lead to accumulation of ammonia in the pitcher fluids. Removal of excess prey by *Camponotus* prevents putrefaction of the fluids. Therefore, although the ants do rob some prey from their host plants, the net effect of their presence may be positive.

Effects of Ant-Plant Interactions on the Diversification of Ants

Given the extraordinary diversity and widespread abundance of interactions between plants and ants, the two groups would be expected to have influenced one another's evolutionary histories. This conjecture is supported by recent molecular phylogenetic studies by C. Moreau and colleagues, who show that the diversification of ant "crown groups" (contemporary major taxa) occurred coincidentally with that of flowering plants (angiosperms) in the Late Cretaceous and early Eocene, and involved major taxa of litter ants, as well as the arboreal ants reviewed in the present article.

With respect to plants, relationships with ants likely contributed to recent and rapid diversification of species in the genus *Inga* (Fabaceae), defined in part by EFNs on leaf rhachis, and containing an estimated 300–450 species. Major radiations of ant inhabited plant taxa have also occurred in genera *Cecropia* (Cecropiaceae), *Macaranga* (Euphorbiaceae), Ocotea (Lauraceae), *Tachigali* (Fabaceae), *Triplaris* (Polygonaceae) *Tococa* and *Clidemia* (Melastomataceae), as well as in various genera of ant-house epiphytes in sub-family Hydnophytinae (Rubiaceae).

Ants (Hymenoptera: Formicidae)

DAVID H. OI
U.S. Department of Agriculture, Agricultural Research Service, Gainesville, FL, USA

Ants are one of the most highly evolved and dominant insect groups. They are the largest family of insects in terms of the diversity of species and certainly sheer numbers of individuals. Currently there are well over 12,000 described species of ants, and some suggest that a similar number is yet to be discovered. Individual colonies of some species can contain over 20 million members. Ants belong to the family Formicidae, which consists of 23 subfamilies and 287 genera that are not extinct.

Order Hymeoptera
  Suborder Apocrita
    Superfamily Vespoidea
      Family Formicidae

They are found in all terrestrial regions of the world, including the cold subarctic tundra and dry deserts. About half of the world's precinctive genera are from the Neotropics and a third from the Afrotropical [sub-Saharan Africa] region. The subfamily with the greatest number of species is the Myrmicinae, and is followed by the Formicinae.

Ants are true social (eusocial) insects, which is defined by the following characteristics: (i) cooperative brood care, where immature ants are tended by groups of adults that are not their parents; (ii) overlapping generations, where at least two different generations of adults occur simultaneously in the same colony; and (iii) reproductive and non-reproductive castes, where only the reproductives are capable of producing fertile offspring. The non-reproductives, or workers, perform tasks necessary for colony survival, such as foraging for food, caring for immature ants and reproductives, and nest building. Eusocial insects have a competitive advantage over nonsocial insects because there is a better probability that groups of sterile workers will be able to complete a task necessary for the survival of the reproductive queen, and also complete a series of tasks simultaneously. If a task is not completed by one worker, another worker can finish the job. This is opposed to a solitary insect where the entire burden of completing tasks from start to finish rests with the individual.

Caste determination, or what causes an ant to develop into a reproductive or a worker, is thought to be due to differential genetic expression stimulated by environmental factors. Based on a limited number of species, at least six factors have been identified as being influential in reproductive and worker caste determination: (i) Egg size, where eggs with more yolk and hence larger in size will more likely become queens. (ii) Chilling, eggs and larvae that have been exposed to sufficiently cold winter temperatures tend develop into reproductives in the spring. (iii) Larval nutrition, where food quality and quantity affect larval size. Larvae that reach a threshold size by a critical developmental time become the reproductives. (iv) Temperature, larvae that grow in optimal developmental temperatures tend to become queens. (v) Caste inhibition, production of new queens is inhibited by the presence of a mother queen. (vi) Queen age, where younger queens generally produce more workers. Regulating the occurrence of some of these factors are titers of juvenile hormone. Depending on species and colony conditions, all or just some of these factors may be involved and the degree of the factors' influence also varies. A sequence of criteria may need to be met for an egg to more likely develop into a queen, otherwise it will be a worker. To illustrate, for an egg to develop into a queen the following criteria may need to be met more or less sequentially: (i) is the egg of sufficient size, (ii) did it receive enough winter chilling, (iii) was food sufficient and (iv) temperatures optimal for the larva to reach a critical size by the right time, (v) are mother queens young and preventing new queen development? Meeting criteria will bias or increase the probability of the development of a queen. Determination of major (soldiers) and minor workers in some species is under both environmental and genetic regulation, thus maintaining a characteristic major: minor ratio within a colony. Recently, genetic regulation of workers and queens was found to be absolute in a hybridization zone between two species, where workers were heterozygous and reproductives were homozygous at marker loci for caste determination.

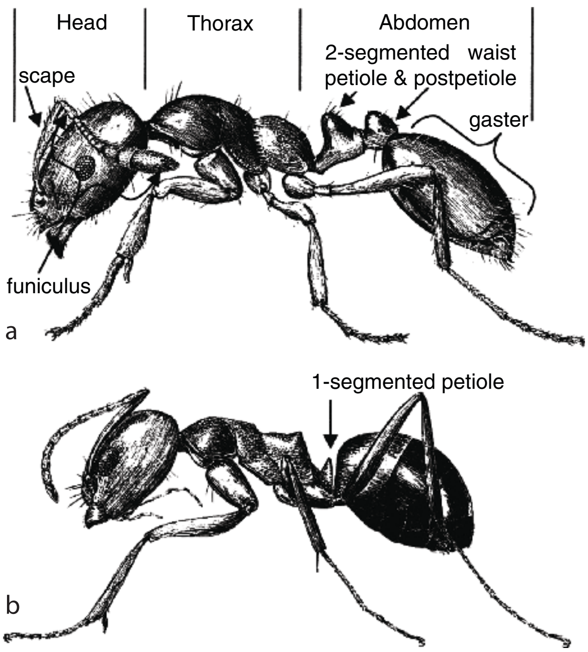
Communication needed to coordinate the activities within a colony is mediated by chemical signals called pheromones. Some of the pheromones that have been isolated include a queen pheromone that allows worker ants to recognize a queen, trail-following pheromone which workers use to mark paths between the nest and food, and alarm pheromones which cause ants to disperse and/or attack. Chemical cues also are used in the recognition of colony nest mates, and play a role in aggression and establishing territorial boundaries between colonies.

Ants are omnivorous and mobile, allowing them to exploit a wide range of habitats. This is in contrast to termites, another abundant eusocial insect, which are restricted to feeding on wood or other vegetation. Moist environments are conducive to microbial contamination. Secretions from the ant's metapleural gland contain antibiotics that disinfect moist environs. Having a portable means of sanitation allows ants to exploit areas that other organisms may not be able to live in. These attributes permitted ants to become a dominant terrestrial organism, especially in the tropics. With their large populations and adaptation to a plethora of ecological niches, ants play an important role in natural ecosystems. They are tremendous earth-movers because of their underground nest building, and thus contribute greatly to the cycling of nutrients. They disperse seeds, scavenge dead organisms, and are a major predator of other arthropods and small invertebrates. In some instances they are directly beneficial to man by being major predators of pests such as crop feeding caterpillars, and ticks of livestock.

Morphology

Ants are easy to distinguish from other insects mainly because of the combination of a thin-waist and the presence of elbowed antennae. The waist refers to a segmented constriction called the petiole, located between the thorax and the gaster. The gaster is composed of the broad 4 or 5 posterior segments of the abdomen. Morphologically ants are distinguishable by having a one or two-segmented waist (Fig. 63); always consisting of a petiole if one-segmented, and both a petiole and a postpetiole if two-segmented. The petiole and postpetiole are actually the second and third segments of the abdomen that are reduced or constricted in size. They often have a distinctive node-like form, however in some species it is scale-like or just a small cylindrical segment. Following (Table 6) is a list of four terms that describe sections of the ant abdomen and the corresponding abdominal segments for ants with one- and two-segmented waists.

The adult workers and queens have antennae that are geniculate, meaning bent or elbowed. The elbowed appearance arises from having a long first, or basal, antennal segment called the scape, followed by 3–11 short segments (collectively called the funiculus). The basal segments in male antennae are usually not long, and thus, the antennae will not appear to be elbowed. Another unique feature of ants is the small opening or orifice of the metapleural gland. This is located just above the basal segment of the third leg, but often requires magnification to be visible.



Ants (Hymenoptera: Formicidae) , Figure 63
Distinguishing morphological structures of ants: (a) two-segmented petiole or (b) one-segmented petiole. Elbowed antenna consisting of a long basal segment (scape) and 3–11 short segments (funiculus); posterior portion of abdomen beyond petiole (gaster) [drawings modified from M.R. Smith 1965, (a) *Monomorium minimum*, (b) *Dorymyrmex pyramicus*].

Ants (Hymenoptera: Formicidae), Table 6
Abdominal segments that compose sections of the abdomen for ants with one- and two-segmented waists

Abdominal Sections	One-segmented waist	Two-segmented waist
Propodeum	abdominal segment 1 fused to posterior of thorax	
Petiole	abdominal segment 2	abdominal segment 2
Postpetiole	None	abdominal segment 3
Gaster	abdominal segments 3–7	abdominal segments 4–7

Life/Colony Cycle

Ants are holometabolous, having a complete life cycle consisting of eggs, larvae, pupae, and adults. Thus, little adult ants do not grow into big adult ants. The eggs, larvae, and pupae are collectively called brood. In general, colony development is as follows: ant colonies originate after a mating flight when winged virgin queens mate with winged males. After mating, the males die, while the newly mated queen sheds her wings and finds a protected location or excavates a chamber in soil. Within this chamber she will lay a batch of eggs and care for the subsequent larvae and pupae until they become adults. These adults are usually sterile females, which are the worker caste, and they will assist the queen by caring for additional brood, foraging for food, and expanding the nest. An important aspect to the survivorship and growth of ant colonies is trophallaxis, or the exchange of regurgitated food among nestmates. Trophallaxis ensures that food is distributed to all members of the colony including the queen and brood. Once the colony is well established, winged virgin females and males (reproductives) will be produced and will proceed to have a mating flight when environmental conditions are suitable. The original colony will continue to be maintained and produce new reproductives as long as the queen is able to produce viable eggs. Depending on the species, queens have been reported to live from less than a year to as long as 29 years. A major variation to this cycle is the absence of a mating flight by the virgin queens in some species. Mating takes place within the nest with either their brothers or males that fly in from other colonies. New colonies are formed by budding, where a portion of the colony, containing adults, brood, and either or both mated or virgin queen(s), separate from the original colony and move to a new location.

In addition to the tremendous number of ant species, there is a broad range of interesting behaviors or life styles among species. Many species have mutualistic relationships with honeydew-producing insects such as aphids and mealybugs

(Hemipteran). Ants will transport and protect these insects in order to harvest the honeydew they produce. In essence, these ants tend and herd the honeydew producers as if they were cows. Some hemipterans carry plant pathogens, and disease spread is facilitated by ants moving the infected hemipterans to other plants.

Another agrarian life-style is that of the leaf-cutting ants that raise their food in fungal gardens within their nest. These ants use leaves and other fresh vegetation to provide a substrate on which to grow the fungus, and these ants can defoliate trees overnight. Leaf-cutting ants cut pieces of leaves or flowers with their jaws and then carry them back to their nest. Once in their nest, they further chew the vegetation and add feces to form a suitable medium for fungal growth. Finally, they plant and maintain a specific fungus species on the substrate. In Central and South America, leaf-cutting species in the genus *Atta* and *Acromyrmex* (subfamily Myrmicinae) can have colonies with an estimated 1–8 million individuals. They build nests consisting of an extensive network of subterranean galleries, and are the most significant pests of agriculture in South America, feeding on citrus, forage grasses, and other crops.

Symbiotic relationships with plants been reported for several ant species. One well-studied mutualistic relationship is that between *Acacia cornigera* trees and the ant *Pseudomyrmex ferruginea* (subfamily Pseudomyrmecinae). The acacia tree produces thorns, which serve as nesting sites for the ants and it produces structures, called Beltian bodies, that are eaten by the ants. The ants protect the plant from herbivorous arthropods and vertebrates, and destroy competing plants that sprout nearby.

Besides their symbiotic interactions with plants and other insects, ant species also have parasitic relationships among each other of which slavery, or dulosis, is one of the more interesting forms. The genus *Polyergus* (subfamily Formicinae) consists entirely of slave-making species. Workers of *Polyergus* colonies dash into the nests of ants in the genus *Formica* (subfamily Formicinae) and steal their larvae and pupae. The stolen immatures are allowed to develop into adult workers and carry out colony maintenance tasks for their abductors. In fact, the *Polyergus* workers are so specialized for raiding and killing other ants that their jaws are like sharp curved sabers, morphologically ill-suited for nest building, tending immatures, and food gathering.

More extreme extensions of this parasitism are species without a worker caste. These species contain only males and queens that are cared for by the workers of a host colony, which they have infiltrated. They are either fed by the workers or steal food from the host queen, which they often mount and hold onto. The eggs of the parasite are reared to adulthood by the host workers. Parasitized host colonies can be smaller in size, presumably because of the partial diversion of resources to the parasites. Examples of these parasitic ants include *Solenopsis daguerrei*, a parasite of imported fire ants (*Solenopsis invicta, S. richteri*), and *Teleutomyrmex schneideri*, a parasite of *Tetramorium caespitum* and *T. impurum* (all in the subfamily Myrmicinae).

In contrast to the symbiotic life-styles, many species of ants are extremely predatory and have gained the reputation of being an unrelenting scourge of the jungle. The subfamily Dorylinae consists of a single genus, *Dorylus*, which contains the African driver ants, also referred to as army ants or legionary ants. Most species are found in the Afrotropical region (sub-Saharan Africa), but a few species are also found in the southern Palearctic, Oriental, and Indo-Australian regions. The various species of African driver ants have colonies with millions of individuals, which regularly move nesting sites and forage for food in large swarming columns or groups. The columns can fan out to produce a large moving front that preys on anything that remains in its path, especially arthropods. At night the colony forms a bivouac, protecting their queens and brood within a mass of worker ants. Thus, there is no permanent nest structure for these nomadic ants. Besides the army ants in the Dorylinae, the subfamily Ecitoninae contain many species of army ants found in the Neotropics, and a few species in the Nearctic. These armies are smaller than the African species, with colonies of hundreds of thousands rather than millions.

The pillaging, nomadic life of the army ants requires a high level of organization and cooperation. Extraordinary cooperative behavior is further exhibited during nest construction by the weaver ants in the genus *Oecophylla* (subfamily Formicinae). These ants are dominant arboreal ants of the Afrotropical region. They link their bodies together to form chains by grasping the petiole of an adjacent worker with their jaws. The living chains are used to pull the edges of leaves together. Once leaves are held in a desired position, other workers bring forth silk-producing larvae and individually press larval heads to one leaf surface then another, resulting in thousands of sticky silk threads being drawn between the leaves to hold them together. Eventually leaves and stems are bound together to form a tent within which a nest of silken galleries is constructed. This communal nest construction is unique in that it involves the use of immature stages that secrete silk on command. It has allowed these ants to build expansive networks of nests across several trees, which can house a colony of over 500,000 individuals.

The adaptability and high reproductive output of many species of ants allow them to thrive in many environments, including that of humans. As such, ants that live in buildings or have high populations in areas used by man are often considered pests. Many pest ants have characteristics that typify the "tramp species". These ants generally (i) spread around the world via human commerce; (ii) can thrive in man-made environments; (iii) have colonies that are not territorial and thus can result in interconnected nest sites; (iv) have many queens per colony; and (v) have limited or no mating flights resulting in colony reproduction by budding. Ants that sting, such as red imported fire ants (*Solenopsis invicta*, subfamily: Myrmicinae), are of veterinary and medical importance. Newborn livestock can be blinded or killed by stings at birth. People who are stung usually develop itching pustules that last for several days, but some can have hypersensitive reactions, resulting in anaphylaxis and even death in rare instances. Non-stinging ants, such as the Pharoah ant (*Monomorium pharaonis*, subfamily: Myrmicinae) may be a nuisance to building occupants and are also known to contaminate sterile surgical units, supplies, and food items in hospitals. Invasive ant species, such as the red imported fire ant and the Argentine ant (*Linepithema humile* subfamily: Dolichoderinae), establish and thrive in non-native locations, invade surrounding areas, and eventually become the dominant faunal species. Invasive ants are a major concern in many areas, ranging from nature preserves to suburbia, because they displace native ants as well as other native organisms.

Control

Controlling pest ants can be a difficult task given their broad habitat range, large populations, and a social organization that protects the queen(s) from external influences such as insecticides. Because traditional control approaches of excluding ants from buildings by sealing cracks and crevices or applying insecticides directly to ants or nests generally do not target the queen, significant population reductions, if any, are temporary. Ant baits, however, were developed to use the foraging and nest mate feeding behaviors of ants to distribute a toxicant throughout a colony, including the queen(s). Ant baits typically contain a toxicant dissolved into a liquid food preferred by the pest ant species. This poisoned food can be mixed with an absorbent carrier such as corn grit or formulated into a gel to facilitate handling and application. Some baits are left in liquid form and must be dispensed in a container that serves as a feeding station.

Key to effective ant bait is a toxicant with the following three characteristics. First, the concentration of toxicant used should not deter feeding on the bait, because ideally enough bait should be readily foraged upon to be shared with adults and immature stages of all castes within a colony. Second, the toxicant should not immediately kill the ants foraging upon the bait. In general, a delay in death or sickness of a minimum of 8 hours from the time of ingestion is required to allow sufficient toxicant to be collected and fed to a significant portion of the colony. If the toxicant causes sickness or death too quickly, distribution of the bait to the rest of the colony stops before enough of the colony is affected, and control will not be obtained. Third, the toxicant should provide a delay in mortality over a wide range of concentrations (typically at least a 10 fold range) because the toxicant is diluted as it is shared among nest mates. Depending on the type of toxicant and colony size, ant baits may take from three days to several months to eliminate a colony. Some bait toxicants do not kill adults but instead disrupt reproduction by the queen, whereby worker caste ants are no longer produced. As the original adult worker population dies naturally, the lack of replacement workers dooms the colony to a slow death as functions that sustain a colony such as food gathering, defense, nest repair, and queen care cannot be carried out.

While ant bait development has been a major focus for ant control, other strategies have been developed for specific species. For example, planting forage grasses that are a non-conducive substrate for the growth of fungus needed by leaf-cutting ants can significantly reduce their populations. Natural enemies of ants are also used to suppress ant populations. In particular, tiny parasitic flies, in the genus *Pseudacteon*, that develop in the heads of ants, and a pathogen, *Thelohania solenopsae*, that debilitates queens are being used to suppress populations of imported fire ants. These natural enemies require development within fire ants and unlike chemical control measures, are self-sustaining and can spread naturally among fire ant populations. Effective control of pest ants, as with most insect pests, generally requires the use of several control tactics adapted for a particular species and circumstance.

Aorta

A tube located dorsally in the insect's body that conducts blood from the heart forward to the head region.

Apatelodidae

A family of moths (order Lepidoptera). They commonly are known as American silkworm moths.

► American Silkworm Moths
► Butterflies and Moths

Aphelinidae

A family of wasps (order Hymenoptera).

► Wasps, Ants, Bees and Sawflies

Aphelocheiridae

A family of bugs (order Hemiptera).

► Bugs

Aphicide

An insecticide that is especially effective against aphids.

Aphididae

A family of insects in the order Hemiptera. They sometimes are called aphids, green flies, and plant lice.

► Aphids
► Bugs

Aphidivorous

Aphid loving. Many insects are associated with aphids because the feed on the honeydew produced by the aphids (e.g., many ants, some flies including mosquitoes) or on the aphids (e.g., many lady beetles and flower flies). Those that feed on the aphids are said to be "aphidophagous."

Aphids (Hemiptera: Aphididae)

DANIEL J. SULLIVAN
Fordham University, Bronx, NY, USA

Aphids are among the most interesting, unusual, and thoroughly studied of all insect groups. They are worldwide in distribution, and are also called plant lice, antcows, green flies, die Blattläuse, les aphides, los áfidos, etc. They have economic importance because many aphid species are pests of agricultural crops, forest and shade trees. Although small in size (1–10 mm) compared to many other insects, professional as well as amateur entomologists have always been intrigued by their specialized life cycles that are influenced by their host plant relationships. This results in both sexual and asexual reproduction, with a highly dependent, almost parasitic mode of sessile existence that can be parthenogenetic during lengthy periods with a telescoping of generations. Yet, when the photoperiod shortens and the temperature cools, offspring are produced that reproduce sexually. In addition, aphids have life cycles with a polymorphism in adults that have wingless (apterous) and winged (alate) forms or morphs, as well as polyphenism or different morphs even within clones. As alates, migration is enhanced, and this can be involved with overwintering behaviors because of host plant alternation. Hence, aphids are excellent animals for the study of multitrophic ecology, behavior, physiology, genetics, evolution, biological control, molecular biology, etc. Besides using field studies of aphids for population sampling and damage assessment, many species can be reared rather easily in the laboratory and greenhouse, thus making them ideal subjects for precise observation and experimentation.

Classification

Aphids are usually classified in the order Hemiptera, series Sternorryncha or sometimes suborder Homoptera along with the psyllids, whiteflies, scale insects, and mealybugs. Another approach is to put aphids in the order Homoptera and suborder Sternorryncha. Some taxonomists have increased the number of aphid families to as many as 20 with a corresponding realignment of the subfamilies. Further phylogenetic studies with molecular techniques are in progress, but in this overview summary the following composite scheme of the major taxa in aphid classification is given below such that there are 8 subfamilies in the family Aphididae:

Order Hemiptera
- Series Stemorrhyncha (= Suborder Homoptera)
  - Superfamily Aphidoidea
    - Family Aphididae (aphids)
      - Subfamily Aphidinae
        - Tribe Aphidini
        - Tribe Macrosiphini
      - Subfamily Calaphidinae (= Drepanosiphinae)
      - Subfamily Lachninae
      - Subfamily Chaitophorinae
      - Subfamily Greenideinae
      - Subfamily Eriosomatinae
      - Subfamily Hormaphidinae
      - Subfamily Anoeciinae
    - Family Adelgidae (adelgids)
    - Family Phylloxeridae (phylloxerans)

Although the number and organization of the subfamilies can vary, there is general agreement that within the family aphididae, the largest subfamily is the aphidinae, followed by the calaphidinae (=Drepanosiphinae), and the Lachninae. There are over 4,000 species of aphids which is a relatively small number compared to many other insect taxa. However, adult polymorphism as winged (alate) and wingless (apterous) morphs, as well as polyphenism within clones increases their overall diversity.

Distribution

Although aphids are found worldwide, their species are most abundant in the temperate latitudes, and less so in the tropics. This preferential distribution may have evolved in response to the selective pressures of the temperate regions having constantly changing, yet rather predictable, environmental conditions. As a result, unlike most other phytophagous (herbivorous) insects, aphids show an inverse relationship between the number of aphid species and the number of plant species in different parts of the world. Hence, there are many more aphid species in the temperate latitudes than in the tropics, although there are more plant species in the tropics than in the temperate regions, but with fewer species of aphids. Most aphids (70%) are in the subfamilies Aphidinae and Calaphidinae (=Drepanosiphinae), and many are pests of crops in these temperate zones. However, when some of these species are introduced (accidentally) into tropical and subtropical regions, they are still able to adapt and become pests in these new environments. In addition, although the tropics and subtropics are fairly constant in temperature and photoperiod, it is surprising that there are some endemic species in these regions that are holocyclic in their life cycles (female cyclical parthenogenesis, alternating with sexual reproduction by males and females) which is more common in the temperate zones. This is in addition to the expected anholocyclic life cycle (absence of males, only parthenogenesis by females) which would be normal in the tropics and subtropics. Aphids find their host plants by random search, and ecologists emphasize the importance of the concept of "plant apparency." Of the more numerous species of aphids in the temperate regions, many are monophagous (feed on one or only a few species of related host plants). However, in the tropics where there are more species of plants and relatively fewer aphid species, these aphids are more polyphagous (feeding on a variety of host plants). Hence, some suggest that aphids originated in the northern hemisphere, and that the tropics presented a barrier to a similar multiplication of species in the southern hemisphere.

Origin and Evolution

Based on the classification given above, in the hemipteran superfamily Aphidoidea are the families Aphididae (aphids), Adelgidae (adelgids), and Phylloxeridae (phylloxerans). Paleontology and phylogeny are two sources of information used by systematists to study the evolutionary history of this group. According to these experts, although paleontology should provide a time scale for their ages, unfortunately the fossil evidence is very limited. Only about 125 fossil species have been described, while the number of extant aphid species is over 4,000. Two kinds of fossils exist: (i) imprints from carbonized remnants in clay, limestone or other sediments, which provide only minimal information because aphids are soft-bodied and are not well preserved; and (ii) amber inclusions which have entire specimens that are often caught in a natural position, and so are much more important as fossils.

Probably aphids, along with the closely related adelgids and phylloxerans, evolved from a common ancestor about 280 million years ago in the late Carboniferous or early Permian Periods when there were seasonal climatic changes associated with the glacial period. They are now classified together in the superfamily Aphidoidea, and their host plants were primitive gymnosperms (Cordaitales, Cycadophyta). By utilizing their specialized piercing – sucking stylets on the phloem and parenchyma tissues of the gymnosperms, polyphagy was most likely the primitive feeding behavior of the superfamily Aphidoidea. As a result of their parasitic mode of life, individual size in these three families (Aphididae, Adelgidae, Phylloxeridae) was similar and rather small. Although their wings were delicate, their light body weight could take advantage of air currents for dispersal. Some consider monophagy as a recent development in aphid evolution, although others speculate that like parthenogenesis, it could have evolved early in the evolutionary history of the Aphidoidea. Another characteristic which aphids share with the adelgids and phylloxerids is the simple nymphal eye of three lenses (triommatidium).

From the Triassic Period (240–205 million years ago), only the front wing of one species of aphid (*Triassoaphis cubitus*) from Australia is known, and it is not easily placed in any superfamily of later periods. Cytogenetic evidence indicates that parthenogenetic reproduction by means of unfertilized eggs may have evolved over 200 million years ago, before these three families (Aphididae, Adelgidae, Phylloxeridae) became independent. This view is supported because a holocyclic life cycle (cyclical parthenogenesis by females, alternating with sexual reproduction by males and females) is now common to all three groups. However, viviparity (live birth) is a special characteristic of aphids, and must have evolved later because the modern adelgids and phylloxerans are only oviparous (lay eggs). By the Jurassic Period (205–138 million years ago), there had developed the recognizable shape of the body, wing venation, proboscis, and legs, while the siphunculi or cornicles and cauda evolved in the Cretaceous Period (138–65 million years ago).

A major botanical event also occurred during the Cretaceous with the evolution of angiosperms (flowering plants), which coincided with the radiation and species diversification of aphids. Within the family Aphididae, the Aphidinae (the largest subfamily of modern aphids) is not represented in the fossil record until the late Tertiary Period (65–1.65 million years ago). Tribes of the second largest subfamily, the Calaphidinae (=Drepanosiphinae), developed much earlier in the Upper Cretaceous and early Tertiary Periods. Concerning the third largest subfamily, the Lachninae, there is limited palaeontological evidence of its evolution. Hence, there is some debate as to the relative age of the lachnids. Because 80% of them live on conifers (which are older than the angiosperms), the lachnids have generally been regarded as ancient, although some genera may have a recent origin.

Metamorphosis

Regardless of whether aphids are born from an egg of oviparous sexual females or live from viviparous parthenogenetic females, their type of metamorphosis is called simple or incomplete: the developmental sequence is egg, to nymph(s), to adult. A nymph resembles the adult, and usually develops in four molts (four nymphal instars or stages) growing larger each time until the adult stage of sexual maturity is reached. This type of metamorphosis is to be distinguished from complex or complete metamorphosis wherein the developmental sequence is from egg, to larva (several molts and instars), to pupa, to adult.

External Morphology

Aphids are mostly soft-bodied insects and relatively small (only 1–10 mm in length), usually being plump and ovoid in shape. Because they are plant-sucking insects, they feed by inserting their slender mouthparts into the plant. These needle-like stylets consist of an outer pair of mandibles and an inner pair of maxillae. The inner faces of the maxillary stylets lock together to form two canals: a large central food-canal for the uptake of plant sap, and a fine duct down which saliva is injected into the plant. The tips of these mouthparts also have a chemosensory function. When the stylets penetrate the plant, they often go between the cells instead of passing through the cells, and in this way they reach the phloem sieve tubes within the veins of the host plant.

Most aphids have well-developed compound eyes (larger in the alates than in the apterous morphs) with a great many individual round lenses called facets or ommatidia. In addition, at the posterior margin of the eye protrudes an ocular tubercle or triommatidium composed of three lenses. Aphids without wings are called apterous, while alate aphids have wings with the hind wings being much smaller than the front wings. Alate aphids (but not apterous) bear three ocelli on the front of the head. The antennae are usually long and thin with five or six segments, and bear placoid sensilla called rhinaria which are the olfactory organs. Legs of aphids do not show much interspecific variation, although more active species tend to have longer legs. Both sets of wings are membranous with the fore wing having two longitudinal veins, one being prominent and the other a weak vein. Both veins run apically into the pterostigma which is a dark, thickened area near the leading edge of the fore wing. When flying, the two pairs of wings work as one, being held together by small hooklets or hamuli on the leading edge of the hind wings that fit into a groove on the trailing edge of the fore wings.

On the dorsal surface of both the thorax and the abdomen, many species have cuticular glands that secrete copious quantities of waxy exudates that are powdery or filamentous or rod-like. As a result, when these species are gregarious, the entire colony appears as a white, powdery or cottony mass. At the end and dorsal surface of the abdomen, there are usually a pair of tubular structures called siphunculi or cornicles. By contraction of a muscle, a droplet of a waxy exudate is discharged through the cornicles which rapidly solidifies in the air. When an aphid is touched or attacked by a predator, one or both cornicles may be raised and the sticky fluid released in a defensive role to gum-up the mouth parts and/or antennae of an attacking predator. This may also function as a pheromone either as an alarm to warn other aphids of a predator or for maintaining distance between aphids on a leaf. Above the anal opening, adult aphids usually have a distinct tail or cauda which varies in shape among species from being short and stubby or long and tapering. In the latter case, aphids can flick off a droplet of honeydew that emerges from the anus. Concerning the external genital organs in the adults, the female genital opening or vulva is only a small slit because there is no ovipositor. On the other hand, the male genitalia have prominent sclerotized claspers and an aedeagus or penis that can be retracted.

Internal Anatomy

Digestive System

Aphids have the usual regions: pharynx, foregut, midgut, hindgut, etc. with subdivisions and associated parts. However, some species have a filter chamber which is a special structure. With some variations, it consists of a concentric filter system in which the tubular anterior region of the midgut is enveloped by the anterior region of the ectodermal hindgut forming a filter chamber. Perhaps this permits selective filtering of the required nitrogen compounds while rejecting the sugars and conveying excessive amounts of water to the hindgut. The precise function is not clear, and since most aphids do not have a filter chamber, it is probably not essential to their method of feeding.

Bacteriocytes

Most aphids have specialized groups of cells called bacteriocytes (or mycetocytes) that usually contain the bacterium *Buchnera aphidicola*. This symbiotic association seems to be mutualistic, and it is not surprising because many insects that live on specialized and often unbalanced diets such as plant sap do indeed possess symbionts. Although their role in aphid biology is still not completely known, they may help the aphid with its nitrogen utilization, synthesis of vitamins, sterols, etc. Although numerous at birth, the bacteriocytes decrease in number during growth. By the end of the aphid's reproductive period, practically none remain, suggesting a contribution to embryonic development. These bacterial symbionts are transmitted transovarially to the embryos so that nymphs are born with them.

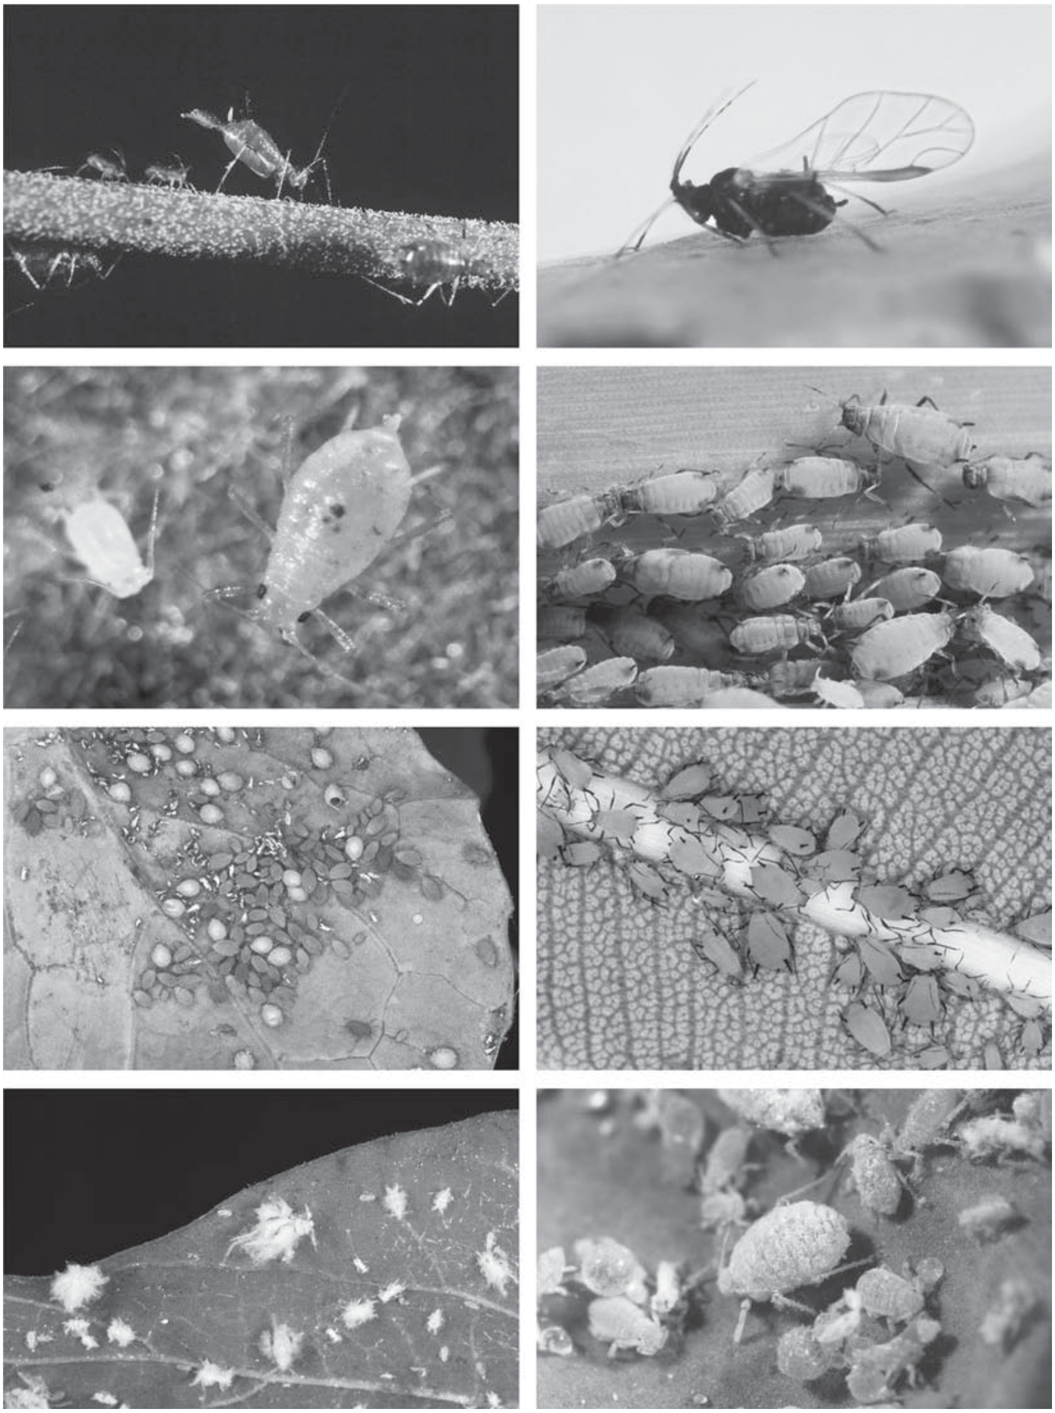
Nervous System

The nervous system comprises four structural parts: brain or supraoesophageal ganglion in the head, suboesophageal ganglion under the brain, thoracic ganglionic mass terminating in the ventral nerve cord, and ganglia plus nerves of the stomatogastric system.

Reproductive System

Female aphids have two ovaries composed of 4–6 ovarioles. They are remarkable because different female morphs can reproduce parthenogenetically (Fig. 64) and be virginopara/vivipara (give birth to live young by larviposition) without mating because males do not exist at this time. At other times, females can reproduce sexually and be ovipara (deposition of eggs that have been fertilized by males). Development of the female embryo depends on whether it is destined to become a vivipara (live birth) or an ovipara (lays eggs). Influences on the adult female can be genetic as well as environmental. Realizing exceptions depending on the aphid species and geographical location, in general when the environment is favorable (long photoperiod, moderate temperature), the viviparous mother will reproduce parthenogenetically. The embryonic female within her will be born alive as a female nymph, and in turn will give live birth to other viviparae also being all females (see below about anholocyclic life cycle). On the other hand, with less favorable conditions (shorter photoperiod, cooler temperature), the oviparous mother will reproduce sexually after mating with a male, and she will lay fertilized eggs (see holocyclic life cycle).

The viviparous parthenogenetic female does not require fertilization, and eggs begin development as soon as they are ovulated from the ovary. Even ovarioles of newly born parthenogenetic females contain developing embryos rather than just eggs. Hence, "telescoping of generations" refers to the fact that a mother can have in her ovarioles developing embryos which in turn also contain embryos or future granddaughters. In the modern family Aphididae, therefore, development may commence even before the mother is born, resulting in a consequent "telescoping of generations." As a result,



Aphids (Hemiptera: Aphididae), Figure 64 **Aphid diversity. Top left, aphid giving birth to a nymph (photo J.L. Capinera); top right, winged brown citrus aphid, *Toxoptera citricida* (photo Paul Choate); second row left, green peach aphid, *Myzus persicae* (photo Jim Castner); second row right, corn leaf aphid, *Rhopalosiphum maidis* (photo Paul Choate); third row left, turnip aphid, *Lipaphis erysimi* (photo Jim Castner); third row right, oleander aphid, *Aphis nereii* (photo Jim Castner); bottom row left, Asian woolly hackberry aphid, *Shivaphis celti* (photo Lyle Buss); bottom row right, cabbage aphid, *Brevicoryne brassicae* (photo Paul Choate). Note copious and moderate amounts of waxy exudate on woolly hackberry and cabbage aphids, respectively.**

postnatal development periods and generation times are short, and reproductive rates are potentially very high. Because aphids are born on the very host plant where they can feed, in many species it requires only 7–14 days for an immature aphid or nymph to metamorphose by several molts into a sexually mature adult when it can begin reproducing. When this is combined with a high fecundity (30 or more nymphs born to each aphid) in a short period of time, the rate of increase is very rapid not only for the individual, but even more so for the entire colony.

The offspring of viviparous parthenogenetic females are born rear first, and are fully active. A nymph is similar in shape to the adult, only much smaller. If destined to be a winged (alate) adult it is either born with wing buds or in some species during the early postnatal period the nymph itself will develop them. This can be triggered by unfavorable conditions due to aphid crowding and/or plant deterioration as well as by seasonal changes such as shorter photoperiod and cooler temperatures. However, colonies founded by alates usually produce only apterous offspring, and only later on might alates develop. Hence, there seems to be a "biological clock" mechanism so that there is a gradual switch to alates that depends on an interval of time.

In the superfamily Aphidoidea, this viviparity (live birth) characterizes the entire family Aphididae. But only females in this family do this, and not females in the families Adelgidae and Phylloxeridae. However, in all three of these families there are sexual females (oviparae) that mate and deposit eggs (see Life Cycles).

Male aphids usually have two to four follicles per testis, although the number, size, and shape varies between species. The vasa deferentia lead to the ejaculatory duct, and in some species there are paired accessory glands.

Excretion

Unlike most insects, aphids have no Malpighian tubules, and excrete nitrogenous waste in the form of ammonia instead of uric acid. The large amounts of water in the diet may dilute the ammonia, and in addition, symbionts in the mycetomes may detoxify it as well.

Ingestion and Digestion

Both as nymphs and as adults, aphids feed by sucking up the sap from the host plant. When the stylets penetrate the plant between the cells, they reach the phloem sieve tubes. In a healthy plant, the sap is under turgor pressure which forces the sap up the food canal between the stylets which reduces the energy needed by the aphid to suck the sap. Nevertheless, there is also a muscular cibarial food pump at the entrance to the pharynx which can be used when the plant wilts and the sap ceases to be under pressure.

Although this plant sap is rich in sugars, it is poor in amino acids that are essential for the growth of the aphid. Hence, aphids ingest large amounts of sap in order to acquire sufficient protein. Although there are less nitrogenous compounds in plant sap compared to leaf tissue (such as would be eaten by other phytophagous insects such as the larvae or caterpillars of lepidopterans), aphids make up for this deficiency by imbibing sap at a very fast rate. The unneeded portion of the sap is mainly sugars which can be stored temporarily in a dilated rectum. This sugary material can be eliminated by ejection from the anus in the form of a sugary droplet called honeydew (see section on Ant-Aphid Mutualism). When aphids are numerous, the leaves of their host plant can become coated with sticky honeydew on which sooty mold fungus can develop causing an economic problem on fruit, vegetables, and even cars parked under a tree.

Sex Determination

As expected, the number of chromosomes varies with aphid species, but all aphids have sex chromosomes for females designated as XX and males as XO. This system of sex determination is called the XX:XO type wherein females have the full diploid complement of autosomes plus one pair of sex chromosomes: XX.

Males also have a diploid set of autosomes, but they have only one sex chromosome (XO) rather than two (not the XY as in some other insects and even humans). As discussed below, in holocyclic life cycles (female cyclical parthenogenesis, alternating with sexual reproduction), sexual females and males are produced in response to cues/stimuli that could be external or internal. On the other hand, anholocyclic life cycles (absence of males, only parthenogenesis by unfertilized females) usually exists when the environment (photoperiod and temperature) is relatively constant.

Parthenogenesis

This is reproduction without mating, and therefore without a female's egg being fertilized. As mentioned above, all aphids have the normal diploid autosomes, but the sex chromosomes for females are XX and males are XO (lacking an X). Among insects in general (not just aphids), when a female's egg is not fertilized, there can be two types of parthenogenetic reproduction:

Arrhenotokous parthenogenesis by females produces only male offspring that are all haploid (n) from her unfertilized eggs (common in the order Hymenoptera – ants, bees, wasps). In aphids, some authors hold that the male's XO sex chromosome determination is only a "type of arrhenotoky" probably resulting from a mini-meiosis in the unfertilized female by which her two X-chromosomes pair and then separate. Males are then XO with the result that they could produce two types of sperm (X and O). However, during meiosis in the male, those sperm without an X-chromosome (designated O) degenerate. This leaves the X-chromosome as the only viable sperm which can fertilize an adult female's haploid egg (X) resulting in all of her offspring being female (XX). Hence, males are produced by the loss of an X chromosome during a meiotic division resulting in the sex determination of XO. Adult male aphids then produce haploid sperm all of which contain one X chromosome. However, this is not really "arrhenotoky" as traditionally used with other insects because although male aphids have the sex determination of XO, they do have two sets of autosomes, but only one X chromosome.

Thelytokous parthenogenesis by females produces only adult diploid (2n) females from unfertilized eggs, but no males. Female aphids seem to have "diploid parthenogenesis" because there is no reduction division, and development starts from a cell with a complete set of chromosomes including the XX sex chromosomes. Both the adult parthenogenetic females and the sexual females are diploid (2n) with XX sex chromosomes. In anholocyclic life cycles (absence of males, only parthenogenesis by unfertilized females), this reproductive method could continue almost indefinitely, if the environmental conditions permitted. However, in holocyclic life cycles (female cyclical parthenogenesis, alternating with sexual reproduction), sexual females and males are produced. The sexual female produces only haploid eggs (X), and requires mating and fertilization by a male (X) resulting in a diploid zygote with two XX sex chromosomes, such that all aphids hatching from these fertilized eggs are females.

Life Cycles

Life cycles in aphids are varied and complicated, but the essential terms are given below:

Holocyclic life cycle: A viviparous parthenogenetic female produces live nymphs without mating. But, this is cyclical because it is interrupted during the year with the production of males and females that mate, and this oviparous sexual female deposits eggs.

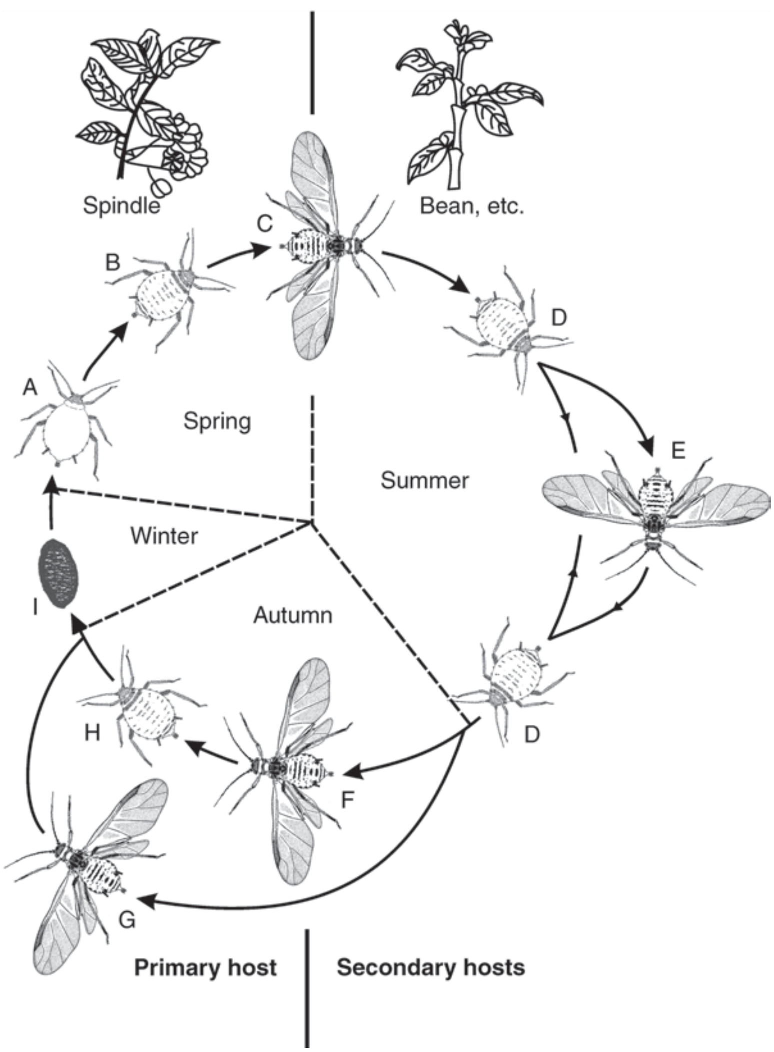
Anholocyclic life cycle: This is the complete absence of males, so that only viviparous parthenogenetic females exist with parthenogenetic reproduction continuing throughout the entire year with all the progeny being female.

Host Plant Alternation

Host plant alternation in aphids involves the two types of life cycles:

Autoecious (monoecious) in which aphids are host plant specific, and live on one or only a few species of closely related plants even within a particular genus during the entire year. Most aphid species (over 90%) are of this type, and as a result, there is usually no need for an annual alternation between primary and secondary hosts, so that the anholocyclic life cycle is common.

Heteroecious or host plant alternation life cycle (Fig. 65) by which about 10% of aphid species spend autumn, winter, and spring on a primary woody host, and the summer usually on secondary herbaceous plants. The primary and secondary host plants usually are unrelated and belong to different families of plants. Although such aphids may be classified as polyphagous, many species are really sequentially monophagous if they live on only one host plant species at a time. This alternation of host plants during the year is accomplished by the holocyclic life cycle described above. These aphids



Aphids (Hemiptera: Aphididae), Figure 65 **Life cycle of the heteroecious holocyclic black bean aphid, *Aphis fabae*. (a) Fundatrix or apterous stem mother, (b) her apterous viviparous parthenogenetic female progeny or fundatri-genia, (c) alate emigrant or spring migrant, (d) apterous virginopara, (e) alate virginopara or summer migrant, (f) alate autumn remigrant or gynopara, (g) alate male, (h) apterous ovipara or mating female, (i) egg (after Dixon 1998; Kluwer Academic Publishers).**

use a specialized reproductive strategy by which the sexual generation produces eggs on the primary (woody) host plant on which they overwinter. This is done because eggs are better able to survive the rigors of a cold winter, snow, etc. The cold period of winter is required before the embryo in the egg can complete its development, and this suspended physiological state is called diapause. The embryo will not hatch until the warmth of spring arrives, and when it does, all of the offspring will be female. This female fundatrix or stem mother on the primary (woody) plant is the first individual to begin the new parthenogenetic line which results in only female offspring all of which are genetic clones of herself. Spring not only provides nutrient availability, but also at this time natural enemies probably have not arrived in dangerous numbers. Again there is a trade-off such that all fundatrices are apterous, thus avoiding unnecessary expenditure of energy on developing wings that are not needed because they do not migrate. Instead, energy can be concentrated on embryological development resulting in very high fecundity of more and more females by viviparous parthenogenesis.

When the colonies of female progeny on the primary (woody) plant become crowded, morphs appear and become alate spring migrants that fly (often with the help of wind currents) to the secondary host plant. The summer secondary host plant is usually herbaceous, and since these alate migrants are all viviparous females, they will produce only females parthenogenetically for as long as this favorable summer weather continues. By dispensing with mating and egg-laying, their numbers can increase at an astonishing rate. These aphids are usually apterous and sessile, remaining on the host plant for long periods in a parasitic "plant lice" mode. But if there is crowding and/or the plant deteriorates, alates will develop in the next generation, thus permitting movement to a new location and even to a new herbaceous host plant. However, such relocation need not be far away if the agroecosystem consists of many acres planted to monoculture. In the autumn, environmental cues (shorter photoperiod and cooler temperature) will trigger the seasonal alternation back to a primary (woody) host plant, and a behavioral change into an alate autumn migrant or gynopara. This parthenogenetic female produces sexual females that will mate with males. Overwintering fertilized eggs are deposited, and the cycle is repeated.

Polymorphism and Polyphenism

Polymorphism means that there are two or more phenotypes or morphs in a population of the same species. Polyphenism means that there are two or more phenotypes or morphs in the same clone. In other words, genetically identical individuals derived from the same mother by parthenogenesis can differ even though they are all clones. This phenomenon is more common in aphids than in any other insect group, especially in aphids that have host plant alternation. In such a parthenogenetic system of genetic clones, females may have as many as eight different phenotypes that differ in such characteristics as morphology, color, physiology, timing of reproduction, developmental time, numbers and sizes of offspring, longevity, host plant preferences, and alternative host plant species. It is probable that some of this variation is not caused only by genetic differences, but also by variations in the host plant and/or the environment.

When environments are regularly cyclical, then seasonal changes and predictable weather patterns can influence the availability and quality of phloem sap that is the basis of aphid feeding. Because of this predictability and reliability, the evolution of aphid species occurred mainly in temperate zone habitats. With this in mind, it is understandable that there has been an environmentally induced morphological and behavioral trade-off so that because alate morphs have energy-costly wings, their developmental time should be slower/longer with a reduced lifetime fecundity compared to the apterous morphs that do not have to expend their energy on wings but rather on offspring production. Hence, there has evolved in aphids both polymorphism and polyphenism that is adapted to changing yet predictable environmental conditions, and resulting in the types of sexual and migrant morphs already mentioned above in earlier sections. No other group of insects can match this diversity.

Soldiers

In addition to the sexual and migrant morphs, there is still another of interest: soldiers. These are female nymphs in only a few (1%) of the more than 4,000 species of aphids, and are found in some but not all gall-forming aphids (see section on Galling). They exhibit a behavior of defending the colony against predators, but they do not molt into reproductive adult females and will never produce offspring. These soldiers aggressively attack invaders, sometimes being suicidal. In some, the fore legs and middle legs are thickened which they use to hold and even crush the intruder. If they have frontal horns, they will use these as well as their stylets as weapons in combat. Both soldiers and normal nymphs can be produced by the same mother aphid. In some species, soldiers (like males) do not have symbionts. Animal behaviorists note the evolutionary convergence of "altruism" in these aphid soldiers with the sterile soldier castes of ants, termites, and thrips.

Color Morphs

Coloration in aphids may be caused by: (i) brown or black pigmentation of the integument (mainly the tergum) or by sclerotization of the cuticle which can give a metallic shine; (ii) body contents show through the cuticle revealing pigments in internal organs, tissues, hemolymph (types of glycosides not found in any other group of animals or plants), bacteriocytes, etc. Colors can vary between and even within species, but the color is usually green, yellow, reddish, creamy, or almost black; (iii) waxy exudates that form a pattern from glands on the body and appear powdery white or grey.

Intraclonal color variation is usually induced by environmental factors, especially temperature, crowding, and poor nutrition. Therefore, it is reversible if these factors revert to the previous state. On the other hand, interclonal color variation is genetically fixed between different color morphs of males and females in some species or between the green and red-pink morphs in the pea aphid (*Acyrthosiphon pisum*), green peach aphid (*Myzus persicae*), and potato aphid (*Macrosiphum euphorbiae*). In the first two aphid species, the red-pink allele is dominant to the green allele, so there may be some biological differences influencing fecundity, reproductive rate, host plant preferences, selection of feeding sites, activity, high or low temperature tolerance, etc. For instance, it seems that thermal conditions may influence the pea aphid when the red-pink morph appears in the summer with the green morph doing better in cooler weather. Also crowding and/or reduced plant nutritional value may cause the red-pink morph of the pea aphid to become green. Any ecological significance such as defensive behavior using camouflage or cryptic coloration has not been demonstrated. However, colonies of some species may use color as aposematic warning behavior against birds or other predators as with the oleander or milkweed aphid, *Aphis nerii*, with its bright yellow color contrasted with black cornicles and cauda, and dark antennae and legs. In other species, some color or pigmented bands may absorb solar radiation that would be advantageous in cool weather.

Aphid Influence on Host Plants

Negative Effect

Aphids like many sucking insects can have a negative effect on the host plant in one or more of the following ways as will be discussed below: nutrient drain, pathogen transmission, salivary toxins, and honeydew excretion.

Nutrient Drain

When aphids are in sufficient numbers, they can drain the plant of its nutrient sap and cause a breakdown in its tissues. Ironically, it could be this less-healthy situation for the plant that satisfies the nutrient needs of this "parasite." As a result, the plant may have its leaf area reduced, growth slowed, early leaf fall, become stunted and/or die before its time.

Pathogen Transmission

The major danger to plants is probably the damage done only indirectly by aphids sucking sap. The greater harm is done when they are inadvertently the vectors of plant pathogens that cause disease. Most important of such plant pathogens are the viruses**.** There is a parallel here between aphids transmitting viruses to plants, and mosquitoes transmitting such pathogens as protozoa and viruses to humans resulting in malaria, yellow fever, etc. Like the mosquito, the aphid's mouthparts are ideally suited for such transmission because the stylets act like a hypodermic needle injecting the virus into the plant as it probes and then sucks the sap. Also, even if the aphid did not have the virus, it would pick it up when it feeds on an already virus-infected plant. A winged aphid (alate) is especially like the mosquito because by flying it can disperse the pathogen to many other host plants.

There are two ways in which an aphid vector can transmit a virus from one plant to another: (i) stylet-borne transmission, where the virus contaminates the mouthparts just by the aphid's probing the host plant. However, this virus is non-persistent on the stylets, lasting only an hour or so, and therefore will eventually disappear on the aphid vector. (ii) circulative transmission, when the aphid actually feeds on an infective plant already having the virus. As a result, the virus invades the body of the aphid. After a latent period, the virus multiplies in the aphid's tissues and enters the salivary glands, from where it can be injected into the next plant when it goes to feed. What is especially dangerous about this mode of transmission is that once infected, the aphid maintains the virus for life, and so continues as a vector being able to infect many other plants in succession.

In either case, more plant viruses are transmitted by aphids than by any other group of animals, and they probably do more damage this way than by merely sucking the sap from plants. Vegetatively propagated plants such as potatoes are especially susceptible because the disease is transferred with the seed tubers to the progeny causing further yield losses. Weeds sometimes act as host reservoirs for such viruses.

Salivary Toxins

Some aphids have toxins in their saliva that cause plant tissues to yellow around the feeding site, and sometimes develop deformities such as leaf-curl, galls, etc. This can negatively influence plant growth and reduce a productive yield of the crop.

Honeydew Excretion

This very natural aspect of aphid biology and behavior is discussed later in the section on "Ant–Aphid Mutualism." In the present context, however, the honeydew that is deposited not only becomes sticky to the touch, but can attract saprophytic sooty-mold fungi to the plant. This may cover the leaf surface and accelerate aging of the plant. It is economically damaging if the fruit or vegetable is blemished and rendered unattractive for sale in a market. Also, car owners are unhappy with this sticky goo on their automobiles if they unknowingly parked under a tree infested with aphids.

Beneficial Effect

Some researchers suggest that aphids may be beneficial to plants in a kind of symbiotic mutualism.

In this unproven scenario, plants benefit by having the aphids remove surplus sugars (especially trisaccharide melezitose) which can be utilized by nitrogen fixing bacteria in the soil. As a result, these bacteria increase in the soil beneath aphid-infested plants and make more nitrogen available for the plant's growth, and hence are beneficial to the plant.

Galling

Some species are called gall aphids because they cause the plant to develop swollen tissues called "galls" that are usually on the leaf or petiole. This involves a combination of both inhibition and stimulation of the plant tissue at the feeding site that results from stylet probing and injection of saliva. Galls are hollow outgrowths on the plant and can appear as abnormalities or deformities. This cecidogenesis or gall-forming behavior is not limited to aphids, but is also produced by hymenopteran gall wasps and dipteran gall flies or midges. Although relatively few species of aphids induce galls, the shape of the galls is often characteristic for each species of aphid, so that the aphid seems to have the major role in forming the shape of the gall. Galls not only give protection to the aphid, but may also provide a better food source in the following way. A gall provides sheltered protection for the aphid from insect predators and parasitoids, and the aphid's feeding may influence the metabolism of the plant and cause physiological changes that could improve the aphid's food supply. Often, there can be intense competition and aggressive behavior among gall aphids for the best feeding sites on a leaf or petiole where a gall can be formed.

The formation of a gall by the plant probably is due to the plant tissue's reaction to aphid feeding when it probes with its stylets and injects large amounts of saliva into the host plant. It is known that a plant growth hormone called indole acetic acid (IAA) is present in aphid saliva, and so it may be that this chemical induces gall formation. However, this growth hormone normally is found in the plant itself which may account for its presence in the sap-feeding aphid. Gall aphids synchronize their development with their host plant, and may even modify the development of the host plant itself. Finally, some galling aphids are unusual in having soldiers (see section above on Soldiers), and these species tend to produce completely closed galls on their primary hosts. However, not all aphid galls are completely closed, but in those that are, a monoclonal colony of aphids can exist within the gall that was started by a fundatrix. Hence, there is probably a long evolutionary history between the plant as host and the aphid as parasite in this galling behavior. As is often true in similar host-parasite relationships among animals, the host plant may not suffer unduly in this parasitic type of symbiosis when both organisms have been in contact with each other over millions of years.

Ant-Aphid Mutualism

There is a symbiotic mutualism between these two major groups of insects by which the ants obtain a sugar-rich food (honeydew) from the aphids, while the ants protect aphids from predators and parasitoids (see section on Natural Enemies). This is the result of a long-term evolutionary history. An ant that imbibes this sugary honeydew can transport it to nestmates in its crop, and then transfer it to another ant by means called trophallaxis. However, not all species of aphids are ant-attended, nor do all species of ants attend aphids, and even myrmecophilous (ant-loving) aphids differ in their dependence on ants. Most myrmecophilous aphids live above-ground and are gregarious, rather large in size, and often conspicuously colored. But as a result of this mutualism with ants, these aphids do not have well-developed defensive structures on their bodies, and do not display escape behavior to avoid an approaching ant nor even a predator or parasitoid, perhaps because they feel "safe" in the company of their ant protectors.

This mutualistic behavior is all the more amazing when it is realized that most ant species are aggressive predators that would normally attack any available prey, especially rather helpless aphids. Yet, the ants that associate with aphids do so in an almost tender way, and "milk" them for their sugary honeydew which comes from the anus. The ant may antennate or stroke the rear of the aphid's abdomen to stimulate this release of honeydew droplets which the aphid does in an accommodating way without any interruption in its normal feeding behavior.

Aphids that are not attended by ants behave differently by raising and contracting the abdomen/rectum, thus ejecting the droplet of honeydew some distance from themselves. Some species even use their hind legs to flick the honeydew away, perhaps to avoid contaminating the colony with this sugary material that might develop sooty-mold fungus. As a general rule, aphids that are not ant attended have a long cauda and long siphunculi or cornicles, perhaps used for defensive purposes against predators and parasitoids, since there are no ants to protect them.

Studies have shown that ants can have a positive effect on the number of aphids, and even on the efficiency of feeding by increasing the ingestion of phloem sap with a resulting increase in the production of honeydew as a reward for the ants. Ant attended aphid colonies are usually larger, feed more heavily, and produce fewer winged (alate) offspring. There can also be a stabilizing effect on aphids, so that the size of the aphid colony may be dependent on the presence of ants. However, when an aphid colony becomes too large, the host plant will deteriorate more quickly and the aphids may move off it leaving the ants behind. To avoid this loss of honeydew source, it may be that ants control the aphid population size and keep it stable so that the host plant will not be excessively harmed. On the other hand, if the aphids become too few to produce an adequate supply of nutritious honeydew, the ants may switch to another and larger myrmecophilous aphid colony or even to a different aphid species that might be nearby.

Ants search plants for aphids, and when they are discovered, the ant returns to the nest laying down a recruitment chemical pheromone trail which worker ants from the nest follow to the aphids. Since many species of ants tend a variety of species of aphids, it has been suggested that at least some elements of the ants'behavior are learned rather than innate. Both ants and aphids make great use of intra-specific and perhaps even inter-specific pheromonal communication. Most ant colonies tend a number of aphid species simultaneously, and it seems likely that there is competition between the aphids for the ants'attention. Seasonal changes in ant availability and their demand for honeydew might be factors in this competition. In temperate regions, host plant availability for aphids and therefore honeydew production vary seasonally, as does the ants'ability to collect these sugars.

It is unclear to what extent there may be predation of aphids by their ant "protectors," but it seems that a significant amount of predation does indeed occur. Perhaps the ants need some protein as well as carbohydrates from honeydew, and in a coevolutionary way the aphids may find limited predation (especially in large colonies) a necessary price to pay for protection from natural enemies, and even for the removal of potentially contaminating sugary honeydew.

Natural Enemies of Aphids

This discussion will be limited to the natural enemies of aphids that are themselves insects, and not other animals such as birds, nor even pathogenic fungi, etc., that also can kill aphids. In entomology, insects that attack, feed on, and kill other insects are called entomophagous insects. However, in the present context, insects that kill aphids are more precisely called aphidophagous insects. As a general introduction, some definitions must be given. Insects that attack, feed on, and kill other insects (not just aphids) are divided into two major categories:

Predators

Predators are insects that attack, feed on, and kill the prey directly. Depending on the species of predator, both males and females as well as the immature stage and/or the adult can do this. Usually, more than one prey is required for the predator to reach adult sexual maturity.

Predators of aphids expend energy and time searching for prey, and so maximum efficiency is achieved when the predator finds an entire colony of aphids and not just an individual. Once in a colony, many predators proceed slowly and stealthily so as not to raise an alarm. An extreme example of such a predator would be the blind, legless larva of a syrphid hoverfly (mentioned below). Examples of major predators of aphids are given next:

Ladybird Beetles (Order Coleoptera, Family Coccinellidae)

These are the best known of aphid predators, and they feed both as immature larvae and also as adults. These are very familiar beneficial insects, but often incorrectly called "ladybugs" because "bug" should be limited to the true bugs in the order Hemiptera that have piercing-sucking mouthparts. They have a convex shape and usually colorful markings. Because they are very common wherever aphids are found around the world, they have been intensely studied for their use in biological control programs. The coccinellids that are brightly colored are demonstrating warning or aposematic behavior, i.e., they are distasteful to their own predators, such as birds. Even their eggs are often orange or yellow. The larvae that hatch from these eggs are notorious for their cannibalism on coccinellid eggs and other smaller sibling larvae because they have to feed almost immediately on some prey or die. As the larva molts and increases in size, it can sometimes consume more than 100 aphids per day. The larva has pointed jaws which it uses to pierce the aphid cuticle. Saliva is then injected into the aphid which digests the body contents into a semi-liquid which can be sucked up. Solid remains of the aphid may be eaten later if the larva is large enough. However, coccinellids have their own natural enemies especially in the orders Diptera and Hymenoptera.

Lacewings (Order Neuroptera, Families Chrysopidae, Hemerobiidae)

These are delicate "nerve-winged" insects with large transparent wings that are often colored light green or brown as is the body. Depending on the species, they feed both as larvae and adults, and are considered important predators of aphids (perhaps second only to coccinellids) and have therefore been used in biological control programs. The larvae have hook-like piercing jaws that are used to suck up the body contents. The aphid prey is held up in the air while it is being eaten. In some species, the adult lacewing lays eggs with each one attached to the end of a vertical stalk which is quite visible when many eggs are laid together on a leaf.

Hoverflies (Order Diptera, Family Syrphidae)

As the name indicates, the adult flies hover in the air over one spot, and then dart to another location. The adults can be seen visiting flowers where they feed on nectar and pollen, and so are also called flower flies. The abdomen is often brightly colored with bands of white or yellow contrasting with a black background, perhaps as mimicry of wasps. It is not the adults that eat aphids, but rather the female lays her eggs close to or within an aphid colony. From each egg hatches a dipteran larva or maggot that is blind and legless, dorso-ventrally flattened and tapered at the anterior end. Like lacewings, the syrphid larva feeds on the aphid by piercing and sucking out the body contents, while holding the prey aloft.

Cecid Flies (Order Diptera, Family Cecidomyiidae)

These tiny flies are often called gall midges although the species that attacks aphids do not form galls on plants. Hence, these cecid flies are also called aphid midges, but the adult does not feed on aphids. Each female can lay about 100 eggs on leaves and stems of plants infested with aphids. It is the maggot-like larva that feeds by piercing the aphid with its long serrated mandibles, sucking out the body contents.

Anthocorid Bugs (Order Hemiptera, Family Anthocoridae)

These are called minute pirate bugs or flower bugs because they are often found on flowers where they may feed on plant juices. Most species are general predators on thrips, mites, and other small arthropods besides aphids. However, the two genera *Anthocoris* and *Orius* are predominantly aphid predators. Being hemipterans, they have simple or incomplete metamorphosis, and the adults as well as the nymphs feed on aphids by sucking out the insides through their styliform mouthparts.

Parasitoids

Parasitoids are insects (orders Hymenoptera and Diptera) in which the adult female attacks what is called the host, but she only indirectly kills the host because the female merely lays her egg in, on or near it. It is the larval offspring from the egg that actually feeds on and kills the host. In older literature, these parasitoids were called parasites, but this terminology was misleading because a true parasite (flea on a dog) usually does not kill the host (dog).

Parasitoids of aphids are micro-wasps (4 to 5 mm in length or smaller) in the order Hymenoptera, and are usually classified both taxonomically and behaviorally in only two families, Aphelinidae (superfamily Chalcidoidea) and Aphidiidae (or Family Braconidae and Subfamily Aphidiinae) (superfamily Ichneumonoidea). These parasitoids are quite host specific in using only aphids as hosts (and no other group of insects). But, even among the thousands of aphid species as possible hosts, different parasitoid species display a feeding behavior that ranges from a continuum of polyphagy to a certain host specificity of oligophagy to monophagy, so that many species of parasitoids limit their attacks to only one or a few species of aphids.

Using as an example a typical species in the genus Aphidius in the family Aphidiidae, the female micro-wasp is quite host-specific, and is called endophagous because she lays an egg inside the live aphid. Her ovipositional behavior is to attack the aphid with a quick thrust of her ovipositor which is usually brought forward between her legs, and is positioned in front of and beneath her head. After the egg has been successfully deposited inside the live aphid, the female departs to attack another aphid, and her involvement with the first aphid is ended. Her offspring, however, is the parasitoid larva that hatches from the egg inside the live aphid that will ultimately kill the aphid. Oddly enough, the aphid host usually continues to feed on the host plant as if nothing had happened and without changing its normal behavior. Over a period of approximately 8–10 days that varies with the species of aphid and parasitoid, the larva molts several times while gradually devouring the aphid internally, finally killing it. Then the fourth and last larval instar spins a cocoon inside the dead aphid, whose exoskeleton becomes hard and changes from its original color to brown (which is now referred to as a "mummy"). The parasitoid larva may fasten the ventral side of the mummy to the leaf. It pupates inside the mummy, and approximately 4–5 days later (or about 12–15 days after the original oviposition) the new adult wasp parasitoid cuts a circular emergence or exit hole in the mummy (usually in the dorsum of the abdomen) and pulls itself out. The adult wasp will find a mate within a short time after emerging from the dead aphid mummy. When fertilized, this new generation of adult female will start the cycle again by attacking and depositing her egg inside another aphid. Note that it is the parasitoid larva that feeds on and kills the host aphid, not the adult female that only oviposits inside the aphid and then departs. Remember that during the moderate summer months, there are long periods in the life cycle of an aphid colony when it is sessile and does not move very far away as long as the host plant provides sufficient nourishment. Perhaps for this reason, micro-wasp parasitoids of aphids have been used quite successfully in biological control programs around the world.

Hyperparasitoids

The micro-wasp parasitoid described above is technically called a primary parasitoid, and it is considered beneficial because it kills the aphid which may be a pest insect. However, there are other species of micro-wasps also in the order Hymenoptera, but not in the same families as the primary parasitoids of aphids just discussed. These micro-wasps have evolved to a higher trophic level so that we have an example of multitrophic ecology and behavior. At the 1st trophic level is the host plant, then at the second trophic level is the herbivorous or phytophagous aphid, and at the third trophic level is the carnivorous or entomophagous primary parasitoid. Finally, at the fourth trophic level is a different species of micro-wasp called a secondary parasitoid or hyperparasitoid that attacks the primary parasitoid while it is still inside the aphid. This food web involving four trophic levels of plant, to aphid, to primary parasitoid, to hyperparasitoid has been used as a model system in community ecology.

Since many aphid species are such worldwide pests, hyperparasitoids of aphids have been especially well-studied, and can be categorized as follows depending on their adult ovipositional and larval feeding behaviors: (i) The female wasp of endophagous hyperparasitoid species deposits her egg inside the primary parasitoid larva while it is still developing inside the live aphid, before the aphid is mummified. But, the egg does not hatch until after the mummy is formed, and then the hyperparasitoid larva feeds internally on the primary larval host still inside the mummy. (ii) The female wasp of ectophagous hyperparasitoid species waits until the primary parasitoid larva has killed the aphid and formed the mummy. Then she drills a hole through the mummy, and deposits her egg externally on the surface of the primary parasitoid larva inside. After hatching, the hyperparasitoid larva feeds externally on the primary larval host while both are still inside the mummy. In both cases, the hyperparasitoid larva then pupates inside the mummy, and as with the primary parasitoid described above, the new adult wasp hyperparasitoid cuts an emergence or exit hole in the mummy (usually in the dorsum of the abdomen) and pulls itself out. The adult wasp hyperparasitoid will find a mate within a short time after emerging from the dead aphid mummy. When fertilized, this new generation of adult female hyperparasitoid will start the cycle again by attacking and depositing her egg in or on a primary parasitoid larva inside another aphid.

There is an economic interest in hyperparasitism because if primary parasitoids are considered beneficial insects (especially when used in biological control programs) then it would seem that hyperparasitoids that attack primary parasitoids might be detrimental. On the other hand, some ecologists suggest that perhaps hyperparasitoids play a positive role in the ecosystem by preventing an excessive increase in the numbers of the primary parasitoids that might so reduce the phytophagous host as to result in the local elimination not only of the insect pest, but also the beneficial primary species as well. If more phytophagous insects of the same species (such as aphids for example) were to move into this local area without sufficient primary parasitoids to attack them, then there might be a resurgence of the insect pest.

Aphid Defenses

As mentioned earlier in the section on polymorphism, there are aphid soldiers in a few species that perform an altruistic role. These are female nymphs that have morphological adaptations to defend a colony against predators. Even if they are not killed in this action, they do not reproduce. Usually, species that have soldiers tend to form closed galls on their primary hosts (see section on Galling). However, the majority of aphid species do not have soldiers, yet many species are still capable of defending themselves by various means such as the following: aggressive kicking, thick defensive cuticles and/or spines, waxing predators and parasitoids, using stylets to attack and kill eggs of predators and even other species of aphids, or suddenly falling off the leaf onto the substrate as a tactic that permits their escape from an impending attack by an aphidophagous natural enemy. Some aphids also emit chemical alarm pheromones that warn other aphids nearby of imminent danger. In this regard, it is interesting that some aphid alarm pheromones may also act as kairomones (communication chemicals between different species) so that predator coccinellid beetles are actually attracted to the aphids.

Control of Aphids

Prevention of damage to plants is especially important when a major agricultural crop could be destroyed by aphids at great financial loss to the farmer. Even forest and shade trees have economic as well as esthetic significance when they are used for logging or as parks. Control involves using methods to protect the crop from aphid attack by various means such as chemicals, natural enemies (biological control), host plant resistance (HPR), modifying aphid behavior, and finally integration of these methods (IPM).

Chemical Control and Resistance

Prior to World War II, chemical control of aphids was limited to nicotine and arsenical products. These aphicides were sprayed on the crop, and at the time seemed to have little negative residual or systemic effects. After the war, however, DDT and other chlorinated hydrocarbons were developed and widely used as broad-spectrum insecticides that were considered to be a panacea not only for control of aphids, but for many other insect pests as well. Although not systemic, they did have residual effects that in the beginning seemed to be a benefit because they were long-lasting. But eventually, evidence from field studies demonstrated that these residues persisted in the ecosystem, and accumulated in the food chain causing unexpected dangers to non-target organisms, especially to fish, birds, and even mammals. In addition, the unintended killing of beneficial insects that were the natural enemies of the insect pest resulted in pest resurgence, traded-pests, etc. The excessive use of these chemicals with these dangerous side-effects was eventually banned in many countries around the world.

New generations of chemical insecticides were developed such as the organophosphates, carbamates, and pyrethroids. To control aphids, special aphicidal properties were emphasized:

1. Selective toxicity: predators and parasitoids not killed, nor any other non-target organisms.
2. Systemic activity: chemical is applied not only to foliage and seeds, but especially to the soil where the roots take it up via the vascular system where aphids feed on the phloem sieve tubes.
3. Residues: Some residual activity may be needed to prevent aphids from reinfesting the crop. In the case of food and fodder crops, however, chemical persistence can be dangerous. Aphicides on such

plants should decompose into harmless compounds before harvest.

4. Rapid action: to prevent transmission of non-persistent viruses, quick mortality of aphids is necessary. Some synthetic pyrethroids show repellent action that deters aphids from settling.
5. Low phytotoxicity: the aphicide should not harm the crop itself because the purpose of the chemical is to protect the plant from aphids without having a toxic effect on the plant.

Application of Aphicides

No general rule can be given because so much depends on local conditions, type of chemical, length of growing season, aphid population size, time of day, weather, etc. Sometimes soil or seed application is sufficient instead of dusting or spraying, and of these two, if the crop is dense, then perhaps dusting is better than spraying. Farm advisors should be contacted because they know the local situation for making recommendations.

Resistance

It is well-documented that chemical insecticides are powerful agents of natural selection so that over time some mutated insects such as aphids develop resistance. This renders the chemical inefficient, resulting in attempts to restore success by repeating applications, then increasing the dosage, etc. In addition, as mentioned above, the beneficial natural enemies are also negatively affected. There are reports of 20 or more aphid species that have developed resistance to various chemical insecticides. The green peach aphid, *Myzus persicae* (Sulzer), is an excellent example. It is a notorious aphid pest that not only has secondary hosts in over 40 different plant families, but it is one of the most important vectors of over 100 plant viruses. Although *M. persicae* is probably of Asian origin, it is now found worldwide.

As a result of many years of subjection to chemical insecticides, natural selection has developed resistance in large populations of many aphid species not only in the field, but especially in greenhouses. The biochemical cause of resistance in aphids is still being studied, and there seems to be a positive correlation between resistance and the activity of enzymes (esterases). It has also been suggested that symbionts are involved in resistance. In any case, although some chemical aphicides may still need to be used, they should be applied judiciously to avoid the typical insecticide treadmill cycle of excessive dependence on chemicals with unintended results such as pest resurgence, traded-pests, etc.

Biological Control

Biological control is the intentional use by humans of an insect pest's natural enemies such as beneficial insect predators and parasitoids as well as pathogens (bacteria, viruses, protozoa, fungi, nematodes, etc.) in order to lower the population level of the insect pest below the economic threshold so that crop loss is reduced and the farmer can have a successful harvest. In the field, the aphids'sessile feeding behavior for long periods of the year makes them especially attractive to natural enemies. In addition, aphids are amenable to studies in the laboratory where many species can be rather easily reared along with their natural enemies for research and experimentation in insect cages, growth chambers, and environmentally controlled walk-in rooms. As a result, and because of their worldwide pest status (especially in the temperate zones), aphids have been the target of many successful biological control programs.

There is an aspect of this method called classical biological control wherein the natural enemy is introduced as an exotic parasitoid or predator from another country or even more frequently from another continent. Also, the insect pest is often an exotic invader into a new habitat or the insect pest could be indigenous. In either case, it seems that the indigenous natural enemies are incapable of keeping the new or old insect under control so that it has now reached pest status. To obtain the exotic natural enemy involves foreign exploration and importation, mass rearing, colonization, establishment, etc. Three examples of this type of classical biological control of aphid pests are given here because they are so well documented, and can be easily referenced in the entomological literature:

1. The first case of successful aphid biological control was against the wooly apple aphid, *Eriosoma lanigerum* (Hausmann), a serious pest of apple in North America and now worldwide in distribution. Beginning in 1920, an aphelinid wasp parasitoid, *Aphelinus mali*, was imported from the United States and became established in 42 countries with generally satisfactory results.
2. Another success was with the spotted alfalfa aphid, *Therioaphis trifolii* (=*maculata*) (Buckton), which invaded the southwestern United States in 1953. Two aphidiid wasp parasitoids, *Trioxys complanatus* and *Praon exsoletum*, as well as the aphelinid *Aphelinus exsoletum* were imported from the Middle East, and resulted in excellent control of this exotic aphid. This case was also important historically because the concept of integrated pest management (IPM) was pioneered during this period by entomologists at the University of California.
3. Finally, although the pea aphid, *Acyrthosiphon pisum* (Harris), was a Palearctic species, it had existed as an exotic invader in North America since the end of the 1800s where it was a pest on alfalfa and peas. Indigenous predators and parasitoids seemed ineffective, so in 1958 the specialized aphidiid parasitoid, *Aphidius smithi*, was imported from India into the western United States. Later in 1963, the polyphagous aphidiid parasitoid, *Aphidius ervi*, was introduced from Europe into the eastern U.S. Both parasitoids have been successfully established resulting in good control. Of ecological interest here is that over time, it seems that *A. smithi* is being replaced in the west by *A. ervi* that was first introduced in the east. However, good control of the pea aphid continues across the continent.

Unlike these three examples of classical biological control involving exotic aphids, it can happen that for various ecological and behavioral reasons the aphid pest is indigenous and the native natural enemies do not control it. In this case, at least the conservation of the existing, indigenous natural enemies is of primary importance. This can even be assisted by augmentation and inundative releases of these indigenous natural enemies from mass-rearing insectaries. Sometimes, exotic but taxonomically closely related species to the indigenous species of natural enemy might be imported from abroad and used to complement the native species, thus improving the possibility of controlling an indigenous pest.

In comparison with chemical control, biological control is non-polluting, non-toxic, and self-perpetuating, and makes no claim about completely eradicating the insect pest. Instead, the population level of the pest is lowered to an economic threshold acceptable to the farmer. Since this involves a living ecosystem, biological control tends to be permanent, and therefore less expensive. Needless to say, whether the pest is an aphid or some other insect, proper scientific procedures demand that extensive research be done on the biological aspects of both the insect pest as well as the natural enemies (indigenous and exotic) in relation to the ecosystem.

Finally, pathogens such as bacteria, viruses, protozoa, fungi, nematodes, etc., can be used as microbial insecticides against insect pests. Aphid diseases have been recognized for over 150 years, but only entomogenic fungi in the order Entomophthorales have been considered as the main pathogen against aphids. Usually warm and humid weather can spread the fungus very quickly into an epizootic, especially when the aphid colony is crowded. The infected aphid becomes brown and inflated with liquid when it dies of mycosis. This can happen in the tropics and greenhouse, but in field conditions in temperate regions humidity is not that predictable. Much can still be done to use the potential of fungi in biological control programs against aphids. The other pathogens such as bacteria and protozoa do not seem to have been demonstrated to cause infections in aphids. Although baculoviruses and picornaviruses can be transmitted transovarially and reduce the longevity of an aphid, no viral epizootics of aphids have been reported.

Host Plant Resistance (HPR)

Many plant species have defenses against herbivores including insects that is genetically heritable, and hence controlled by one or more genes. Resistance of plants to insect attack is related to the heritable qualities of the plant that may reduce the damage. The main task of agronomists is to increase the yield and quality of a crop by standard breeding methods. However, this can also include trying to breed genotypes into crops that make them resistant to insect attack by using one or more of the following mechanisms:

1. Antibiosis: physico-chemical characteristics of the plant that kill the insect;
2. Antixenosis: pest insect is repelled by the plant or at least has no preference for it;
3. Tolerance: the plant can recover even after some feeding damage by the insect.

Plant characteristics vary depending on the species, but host plant resistance can be morphological (leaf size, shape, color, pubescence, thickness, texture), biochemical (lack of nutrients, allomones [feeding repellents, ovipositional and feeding deterrents, toxins], kairomones [attractants for natural enemies]). Entomologists work closely with the agronomists to test or screen the supposedly resistant crops (but still as high-yielding as possible) to see if indeed these genotypes are also resistant to a particular insect pest that is being studied. To do this, hundreds of insect pests are constantly being mass-reared in the insectary. These are used not only for laboratory studies of insect-plant interactions, but especially for the purpose of bringing them into the field for artificial infestation. In the field, these insect pests are placed on the cultivar to be infested and eventually evaluated as to the amount of damage caused to the plant as it grows. It must be stated, however, that HPR to one insect pest does not mean that a cultivar is resistant to other taxa or even to related species. Furthermore, the genotype may not be resistant to other biotypes or races of the same insect pest species that initially showed host plant resistance.

Concerning HPR for aphids, the same general principles and procedures are used as just mentioned above. Hundreds of cultivars have been developed for resistance to aphids for more than fifty important crop plants in the families Leguminosae, Gramineae, Compositae, Cruciferae, Cucurbitaceae, Rosaceae, Solanaceae, etc. The problem of biotypes or races also occurs among aphids because of their parthenogenesis, telescoping of generations, host plant alternation, etc.

Modifying Aphid Behavior

Aphid behavior can be modified by both prevention of landing by aphids in flight, and by repelling aphids that have already landed.

Flying aphids are attracted or repelled from plants by light of a particular wavelength. When winged aphids first fly, they are attracted to the blue-ultraviolet light from the sky. However, after a period of flight this is reversed, and instead of flying upwards, the sky may repel them and they are attracted to the orange-yellow-green light reflected from the leaves below. This behavior might be exploited by using yellow traps to lure them away from crops in a field (though as yet this has not been demonstrated). The yellow trap can be filled with some liquid that kills the aphids that have landed in them. Yellow traps are used extensively to monitor flights of aphids.

Plant odors are volatile substances produced by plants that attract aphids in their host selection. Aphids on agricultural crops tend to be polyphagous, so perhaps specific volatile cues are not too important. However, aphids on perennial crops and wild plants are more oligophagous and even monophagous for which plant odors are needed. Hence, attractant baits have been tried as well as repellent chemicals that may also have a role in aphid control.

Alarm pheromones are released by some species of aphids when they are attacked by natural enemies. It would be advantageous for flying aphids to avoid landing on a plant where aphid colonies are being attacked and have released an alarm pheromone. Synthetic alarm pheromones have been used successfully, but because some are highly volatile, a formulation with a slow release would enhance this control method.

Synthetic chemical repellents would be a non-toxic alternative to insecticides, and are safer to the applicator and to the environment. However, there is a problem with aphids that are vectors of a non-persistently transmitted virus. It would have to have its repellent effect act very quickly before the aphid makes its first probe. Even chemical aphicides have this difficulty in not acting fast enough to prevent that first probe by which an uninfected aphid picks up the virus, or if already infected, then before the aphid probes into a healthy plant. There is a continuing need to study the chemoreception of aphids and their resulting behavioral responses.

Cultural Control

This method involves the use of normal agricultural practices to reduce pest damage not only by aphids but also by other insects. Such cultural techniques can include the following: timing of planting and/or harvesting to disrupt the normal cycle of aphid landing and feeding; crop rotation varies the crop during the season or annually with another plant that would be unattractive to the aphid and/ or less important to the farmer; intercropping uses the same principle but alternates field rows or sections of the crop with another plant; tillage (mechanical manipulation of soil to reduce weeds, improve drainage by plowing, hoeing, etc.); sanitation is the removal of weeds or crop residues that might provide the aphid an alternate host; water management depends on the needs of the host plant and the biology of the aphid species.

Integrated Pest Management (IPM)

In their evolution, aphids have taken advantage of favorable agricultural habitats especially through monoculture, thus making the agroecosystem an attractive food source. Although different species of aphids vary in their host range from polyphagy to monophagy, they are often able to survive on herbs in the vicinity of the crop or simply to fly to another area where a more suitable host plant is more available. Realistically therefore, eradication is all but impossible. Because of various side effects mentioned earlier, reliance only on chemical insecticides should not be the main option. Instead, it is sensible to integrate as many of these control methods just discussed. This concept of integrated pest management (IPM) was first developed at the University of California during the late 1950s. An acceptable definition of integrated pest management (IPM) should include the following entomological and ecological aspects: a pest management system that utilizes all suitable control methods to reduce and maintain the pest population level below that causing economic injury, with special concern for the environment including the insect's natural enemies. This sound ecological philosophy should be applied to aphids and to other insect pests whenever possible.

Important Aphid Species

Although there are over 4,000 aphid species, only a small percentage of these are pests. Nevertheless, it is not surprising that general interest and most of the funded research at universities and institutes should be concentrated on aphid species that indeed are pests of agricultural crops, forest and shade trees because of their commercial and economic importance. With this bias in mind, listed in alphabetical order (English names) is a sampling of some important aphid species: black bean aphid, *Aphis fabae* Scopoli; black citrus aphid, *Toxoptera aurantii* (Fonscolombe); blue alfalfa aphid, *Acyrthosiphon kondoi* Shinji; brown citrus aphid, *Toxoptera citricidus* (Kirkaldy); cabbage aphid, *Brevicoryne brassicae* (Linnaeus); corn leaf aphid, *Rhopalosiphum maidis* (Fitch); corn root aphid, *Aphis* (*Protaphis*) *maidiradicis* Forbes; cotton or melon aphid, *Aphis gossypii* Glover; cowpea or black legume aphid, *Aphis craccivora* Koch; grain aphid, *Sitobion avenae* (Fabricius); green apple aphid, *Aphis pomi* De Geer; green peach aphid, *Myzus persicae* (Sulzer); greenbug, *Schizaphis graminum* (Rondani); oleander or milkweed aphid, *Aphis nerii* Fonscolombe; poplar petiole gall aphid, *Pemphigus populitransversus* Riley; pea aphid, *Acyrthosiphon pisum* (Harris); potato aphid, *Macrosiphum euphorbiae* (Thomas); rose aphid, *Macrosiphum rosae* (Linnaeus); spotted alfalfa aphid, *Therioaphis trifolii* forma *maculata* (Buckton); tulip-tree aphid, *Illinoia liriodendri* (Monell); walnut aphid, *Chromaphis juglandicola* (Kaltenbach); woolly apple aphid, *Eriosoma lanigerum* (Hausmann).

Several of these important aphid species are worth special mention:

Green Peach Aphid

Myzus persicae (Sulzer) is probably the most polyphagous of all aphids. As a result, it is the most important insect vector of plant diseases including transmission of over 100 plant viruses such as curly top of sugar beets, peach yellows, cranberry false blossom, aster yellows, and various potato viruses, etc. It is pr obably of Asian origin on its principal primary host *Prunus persica* (peach), and then followed this host wherever it was planted which is now worldwide in distribution. Its secondary hosts are in over 40 different plant families, including many that are also economically important. In temperate regions it is usually heteroecious holocyclic, but can be anholocyclic where peach is absent and the climate permits winter survival. Because it is relatively easy to rear in laboratories and greenhouses, this aphid's biology, anatomy, physiology, etc., has been intensely researched. In addition, because of its economic importance, the ecology of *M. persicae* has been studied, especially for use with biological control.

Black Bean Aphid

Aphis fabae Scopoli is also heteroecious holocyclic, and in Europe it alternates between *Euronymus* (strawberry bush) and various secondary hosts where it feeds on many agricultural crops including *Vicia faba* (broad bean) and other legumes. Besides this polyphagous behavior, it is a vector of more than 30 plant viruses. It is widespread in temperate regions of the Northern Hemisphere, as well as South America and Africa, except for the hotter parts of the tropics and the Middle East. *A. fabae* may be a complex of species, and outside of Europe where it seems to have originated, its taxonomic status is unclear. However, because of its importance, it too has been intensely studied in both field and laboratory research projects.

Cotton or Melon Aphid

Aphis gossypii Glover is very polyphagous not just on cotton and cucurbits, but also on such diverse crops as citrus, eggplant, okra, peppers, coffee, potato, cocoa, and many ornamentals such as *Hibiscus*. In addition, it can transmit over 50 plant viruses to important crops such as beans, peas, soybeans, crucifers, celery, cowpea, sweet potato, tobacco, tulips, strawberry. Its distribution is now worldwide including the tropics and many Pacific islands. In the temperate latitudes with cold temperatures where crops are raised in greenhouses, *A. gossypii* is a major pest. Perhaps it is of palaearctic origin because it is anholocyclic in Europe. However, it seems to be holocyclic in North America, China, and Japan.

Oleander or Milkweed Aphid

Aphis nerii Fonscolombe is an especially interesting aphid because of its attractive bright yellow color contrasted with black cornicles and cauda, and dark antennae and legs. Such aposematic behavior advertises and warns potential predators that it is unpalatable and even harmful. This is because while feeding, it has sequestered poisonous chemicals (cardiac glycosides) from its host plants mainly in the families Apocynaceae and Asclepiadaceae such as oleander and milkweed. It has thus coevolved by transferring for its own protection the "poisonous" defense of these host plants. Instead of using cryptic or camouflage defense as many other insects do, *A. nerii* demonstrates behavioral convergent evolution with the similarly bright warning coloration (orange and black) of the monarch butterfly that also feeds on milkweed. *A. nerii* then reinforces this aposematic behavior by forming dense colonies that are frequently concentrated on young stems. Also unusual is its life cycle that seems to be only anholocyclic with no sexual morphs. It is widely distributed in the warmer regions of the Old and New World, plus the tropics and subtropics.

Pea Aphid

Acyrthosiphon pisum (Harris) is a large aphid with slender appendages and long cornicles. There are both green and red-pink morphs, similar to the potato aphid, *Macrosiphum euphorbiae* (Thomas), that also has green and red-pink morphs with both aphid species being in the same aphidine tribe Macrosiphini. The pea aphid seems to be a complex of races and subspecies on different host plants, but mostly important legumes such as alfalfa, clover, peas, broad beans, etc. *A. pisum* is a vector of more than 30 virus diseases, and although probably palaearctic in its origin, it is now worldwide in its distribution where it is holocyclic in the temperate regions, and perhaps anholocyclic in warmer climates. Because it can be reared easily in the laboratory with its micro-wasp parasitoids, as mentioned earlier, it was an example of a classical biological control program that was successful.

Summary

Aphids fascinate the non-entomologist as well as amateur and professional entomologists because of their sometimes unique and always unusual biologies. Although small in size, their external morphology and internal anatomy as well as their polymorphism and polyphenism make aphids interesting. One marvels at their reproductive behavior (parthenogenesis, telescoping of generations, sex determination), life cycles (host plant alternation), ant–aphid mutualism, etc. Finally, of course, aphids have had an enormous economic impact as pests on the world's agricultural crops, forest and shade trees, not only by their feeding, but as vectors of plant viruses. This is a great challenge to humankind to control them by using ecologically safe as well as effective methods. Hence, aphids are a rewarding subject for observation and research.

Aphid Flies

Members of the family Chamaemyiidae (order Diptera).

► Flies

Aphodius Grubs (Coleoptera: Scarabaeidae)

At least two species of *Aphodius* are important pests of turfgrass.

► Turfgrass Insects and their Management

Aphrophoridae

A family of bugs (order Hemiptera, suborder Cicadomorpha).

► Bugs

Aphylidae

A family of bugs (order Hemiptera, suborder Pentamorpha).

► Bugs

Apiary

A location where honey bees and bee hives are kept.

► Apiculture (Beekeeping)

Apical

A term pertaining to the apex (tip) or outer end.

Apiculture (Beekeeping)

MALCOLM T. SANFORD[1], JAMES E. TEW[2]

[1]University of Florida, Gainesville, FL, USA
[2]The Ohio State University, Columbus, OH, USA

The science and art of managing honey bees called apiculture or beekeeping is a centuries-old tradition. The first beekeepers were hunters, seeking out wild nests of honey bees, which often were destroyed to obtain the sweet reward, called honey, for which these insects are named. As interest in honey bees grew, so too did the entomological and biological knowledge needed to better manage colonies of *Apis mellifera*. The innovations that allowed modern beekeeping to arise were primarily developed in the 19th century. The most important include the moveable-frame hive, smoker and centrifugal extractor. It is remarkable that these continue to be the hallmark of the beekeeper a century and a half later.

Honey bees are native to the Old World, but were quickly introduced into the Americas and Australia as part of European settlement. This social, perennial insect is now found on all continents and in most environments. Although honey continues to be an important product of honey bees, their most valuable service is pollination. A large commercial pollination effort exists in many countries to ensure maximum quality and quantity of crops pollinated by honey bees. The major crops involved are nuts, berries, fruits and vegetables.

Although the technology employed in beekeeping is traditional, the problems facing present day apiculture are modern and formidable. This is due primarily to worldwide distribution of exotic diseases and pests that have devastated beekeeping industries and honey bees alike. The major problems affecting U.S. beekeeping over the last thirty years come from introduction of the tracheal mite (*Acarapis woodi*), Varroa mite (*Varroa destructor*) and small hive beetle (*Aethina tumida*). These have produced a new kind of beekeeping that is much more aligned with production agriculture because it has become associated with and/or reliant on chemicals. It is an irony that honey bees, heretofore considered wild animals needing minimal human intervention, have become more domesticated, requiring human help to survive human-induced introduction of exotic species.

In spite of the increase in time and effort needed to keep bees in the modern setting, the fascination presented by the honey bee and its products continues. Thus, a small but enthusiastic cadre of novice beekeepers appears each season to take up the challenge of managing one of nature's most complex creatures. This infectious "joy of beekeeping" continues to proliferate across the generations, afflicting both beginners and commercial beekeepers generations removed from the first person in their family to be smitten by the beekeeping bug.

The purpose of this article is to describe aspects of beekeeping that will be important for a basic understanding of the craft by both novice beekeepers and the general public. It includes information on the honey bee colony and its management, as well as that with reference to nectar and floral resources and the use of these important insects in commercial pollination.

Products of the Hive

Many people keep bees because they are fascinated by these social insects. The vast majority, however, are also interested in collecting the useful products of the hive, which include:

Honey: Modified nectar collected by honey bees that is mostly carbohydrate.

Pollen: The male floral part collected by honey bees that is mostly protein.

Propolis: A mixture of resins and oils collected by bees from plants used to "glue" hive parts together and patch holes.

Beeswax: The material that makes up the bee nest.

Royal Jelly: A high-protein food that is used to feed developing queens.

Venom: A mixture of compounds injected by bees for defensive purposes.

The Honey Bee Colony

Honey bee biology is described elsewhere in this document. The colony of *Apis mellifera* is composed of one queen (fertilized female), up to several thousand males (drones) and tens of thousands of workers (unfertilized females). For the purposes of the beekeeper, worker bees are the most important; they are often divided into two classes, young nurse bees (feed the young) and older forager bees (collect pollen and nectar).

Major Developments in Beekeeping

Most new ideas in beekeeping are not novel. A scan of the literature usually will show that they have been developed, sometimes on several separate occasions, by enterprising apiculturists in the past. Three eras have been identified in the development of the craft.

Beekeeping prior to 1500 was primitive (rustic), and consisted of little more than honey hunting, robbing the sweet from established nests. A famous rock painting at Cueva de las Arañas, Spain, depicts this activity as early as 5000 B.C. The Philistines dabbled in beekeeping as did the ancient Egyptians, Greeks, Sumerians, and others. Even before the honey bee was introduced to the Americas, other kinds of bees were kept for honey and wax. The Inca and Maya of the New World cultured the stingless bees (meliponidae). There is a renaissance in this activity in the American tropics, but the term "beekeeping" has always been reserved for those managing the Old World western honey bee (*Apis mellifera*).

From 1500 to 1851 (pre-modern beekeeping), great strides occurred in knowledge about honey bees. The queen was discovered to be female in 1586. Drones were first identified to be males in

1609. Pollen was determined to be the male part of plants in 1750. Drones were shown to mate with the queen in 1792 and recognized as parthenogenic in 1845.

Concurrently with biological knowledge, management technique evolved. For example, the concept of supering (adding boxes on top of colonies for honey storage) was developed in 1665. A wide variety of so-called "patent" hives were marketed in the 1800s, an era known for huge controversy over size and style of box, none of which were really suitable to launch a new kind of beekeeping.

The modern beekeeping era began in 1851 when the Reverend L.L. Langstroth discovered the significance of the "bee space," which led to the invention of the movable-frame hive. Other advances followed: Johannes Mehring developed the first foundation in 1857. Major Hruschka produced an extractor in 1865. Moses Quinby invented the smoker in 1875 and published his first bee book in 1853. Comb honey production began with W.C. Harbison of California in 1857.

The years 1859 to 1890 encompassed the era of comb honey, known as the "golden age of beekeeping." Samuel Wagner published the first issue of *American Bee Journal* in 1861. *Gleanings in Bee Culture* was first published in 1873; it became simply *Bee Culture* in the 1990s. Migratory beekeeping up and down the Mississippi River began in 1878 (it occurred much earlier in ancient Egypt on the Nile). Package bees were first used in 1879. J. George Doolittle developed the concept of commercial queen rearing in 1888, using the grafting (larval transfer) technique.

Lloyd Watson first used instrumental insemination of the queen bee in 1926. This technology spawned studies in controlled genetics, which led to selection of commercial lines such as "Starline" and "Midnite" honey bees. This continues to be of importance and increasingly is responsible for advances in selecting for hygienic behavior (disease resistance) and tolerance to pests.

With recognition that apiculture was a legitimate vocation, the honey bee has been spread worldwide by beekeepers. This continues even today. The Irish and Norwegians may have brought honey bees to the Americas as early as 900 A.D. They came to the colony of Massachusetts in 1665, where the aborigines called them "white man's flies". These insects may have been introduced sooner into the New World by the Spanish conquistadors via Mexico, Florida, or Cuba.

Italian bees (*Apis mellifera ligustica*) were first introduced into the United States in the 1860s, and Frank Benton imported Cyprian and Tunisic stock in the 1870s. Many more introductions succeeded these first attempts. African honey bees (*Apis mellifera scutellata*) were brought to Brazil in 1957. Semen from these so-called "killer bees" was introduced into the United States in the 1960s, but natural migration through Latin America allowed a population to become established in the United States only when it crossed the Texas border in 1990. *Varroa jacobsoni* (now known as *Varroa destructor*) was introduced to *Apis mellifera* in the 1950s via its original Asiatic host *Apis cerana*. This parasitic mite had spread to all continents except Australia by the 1990s. New bee foods, including high fructose corn syrup and the Beltsville Bee Diet® were introduced in the 1970s. Honey became a world commodity in the 1980s. The small hive beetle (*Aethina tumida*) was introduced from South Africa into the United States in 1998.

Sources of Information

Beekeeping information can be found many places. Traditional print resources include:

Bee Culture, A.I. Root Co., P.O. Box 706, Medina, Ohio 44258, phone 1-800-289-7668 extension 3220, fax 330-725-5624

American Bee Journal, 51 South 2nd Street, Hamilton, Illinois 62341, phone 217-847-3324, fax 217-847-3660

The Speedy Bee, P.O. Box 998, Jesup, Georgia 31598-0998, phone 912-427-4018, fax 912-427-8447

The Internet is now a prime source on information. However, it is suggested beginners find the bee inspector and state university extension educator in their state and address questions directly to them. Each year, the magazine Bee Culture publishes a comprehensive list in the April edition.

Equipment

Of all things in beekeeping that are affected by the modern world, perhaps beekeeping equipment is the best candidate to look at within the context of newly evolving technology. Plans for standard, traditional wooden beehives can be found in many publications. Some parts of a beehive are easily made at home, especially brood chambers, supers, tops and bottoms. However, others may not be; frame construction, for example, is best left to commercial manufacturers.

A major equipment consideration is use of beeswax, recycled from the bees themselves. Traditionally bees have been guided to make their nest (comb) through use of embossed beeswax "foundation." This material not only guides the bees in making worker cells, but also saves much time and energy in the bargain. Plastic (wax-coated or not) is being increasingly used for foundation.

Beekeeping equipment is available from many places across the nation. Several concepts are important when considering equipment. These are: (i) standardization, usually based on conserving the bee space; (ii) changes in nominal lumber size, contributing to availability and wastage problems in cutting wooden ware; and (iii) constant development and evaluation of new materials. Although plastics come to mind, there have even been hives made from concrete to withstand tropical conditions. Nevertheless, wood continues to be the material of choice by most beekeepers.

Because individual suppliers or equipment and prices are constantly changing, only an overview of beekeeping implements and paraphernalia is possible here. For up-to-date prices, it's best to consult the bee journals, which actively cater to the trade and bee supply outlets.

Protective equipment for the beekeeper has also followed the same route. New materials such as plastic netting, Velcro® and others have meant that beekeepers can work with more peace of mind during manipulation of colonies.

As already noted, traditional beekeeping equipment is made from wood. However, plastic equipment also is in use for the traditional bee box. Plastic is also widely used as a wax foundation base and in single component plastic frames. Plastic frames resist damage, do not require painting, and do not require assembly. However, it often takes more resources by the bees to "draw out" plastic or beeswax-coated plastic foundation. Some disadvantages of plastic are its tendency to warp and become brittle when exposed to sunlight and difficulty in being sterilized by heat. Various companies use plastic to make containers for bee products. Such containers eliminate the extracting phase of beekeeping and provide a container for honey in its natural comb.

There are all manner of gadgets used in the art and business of keeping bees that do not generally get mentioned in standard references. The following are some of these gems:

1. The slatted (or slotted) rack was used initially to take up the space of a deep bottom board. It assists in ventilation and reduces brace and ladder comb. Some beekeepers swear by it, some at it.
2. A division board feeder is a hollow insert filled with syrup that takes the place of a frame in a super when a population is small. Easily homemade from a board and nails, they quickly feed a small colony.
3. A robber screen can be used to protect small colonies from being foraged by larger colonies, especially during nectar dearth.
4. Top feeders come in various styles. These avert the necessity to open the colony and/or to fill a frame-style division board feeder. Top feeders hold more and are more accessible.
5. A screened ventilated bottom board provides air circulation during both summer and winter. Newer information also suggests these are useful in controlling exotic mite populations.

6. Various painted patterns on the front of colonies can help bees identify their own home, thus reducing drifting (bees losing their way and entering foreign colonies).
7. Drip boards serve several purposes. They collect errant honey leaks from supers stored on them, provide air space between the floor and honey stored in frames, and a space for two-wheeled hand trucks to grip the stack.
8. A screened division board placed between two alien colonies enables them to access each other's odors, while keeping them physically separate. The end result is two queens working together to produce a large population. Eventually they can be joined after this close but separate association, however, one of the queens is eliminated in the bargain.

Building Equipment

Although it can rarely be built more cheaply than it can be purchased, only basic woodworking skills and tools are needed to build wooden beekeeping equipment. Box joints are currently the most common, and according to some, the strongest kind to use in beekeeping applications. Producing them requires a jig, usually home made, to neatly and precisely cut the slots to line up with the fingers. Butt joints are more forgiving; two boards are butted together and simply nailed. The TIM joint is fast but weak. If a colony is not going to be moved, it will probably work okay. The dado joint, used by some manufacturers, is becoming more popular, and is strong enough to withstand the rigors of moving and manipulation. When building equipment, in all instances, respect bee space requirements and be sure to build your equipment to fit standard measurements.

Protecting Wooden Equipment

Some wood may last longer while some may last much less time, depending on the climate, but hives are definitely helped by some type of protective coating. The average life of a bee box is about seven years. Scraped and routinely painted, equipment can go much longer. Since the inside surfaces of bee hives should not be painted, the paint film on the outer surface is often stressed by water migrating to the film from the inside of the hive rather than from the outside. Oil-based paints will readily peel within just a couple of years. Due to ease of application and lower cost, latex paints are better. The rubber-based latex paints will flex and resist chalking and peeling much more than oil paints, but they, too, will finally succumb to mildew and peeling.

Some commercial beekeepers and beekeepers in other countries routinely dip equipment in paraffin or beeswax. This is a good finish that protects the wood from all sides and ends, but requires working around hot, flammable paraffin. Once the equipment has begun to show signs of wear, simply dip it again in hot paraffin to recoat the finish and to remove wax and propolis residue. In recent years, polyurethane exterior stains have become popular and have been consistently improved. As with paraffin impregnation, many of these stains are water repellent, resist mildew and fading, and clean up with water and soap.

A final warning concerns pressure-treated wood. The materials used to preserve the wood are usually toxic to honey bees. Thus, treated wood is not recommended for bee colonies. Even the sawdust is considered a health hazard and dust masks are recommended when working so-called Wolmanized® treated wood.

Wearing Protective Equipment

The most important protective equipment is the veil, which protects the face, the most sought-after target for guard bees. Veils can be used without a helmet, or attached to a pith-type helmet, made of plastic or other material. Almost any hat that keeps the veil material off the face and neck will work. Veils usually have a mesh bottom that is snugged down over the collar onto the shoulders with a variety of ties and/or strings. Veils that attach to the bee suit with a zipper are popular, mostly because they are convenient, easily maintained, and virtually bee proof. They are also more expensive.

Bee suits usually are light in color, but many wear what's available, simply to keep their clothes clean. The white coverall suit is most popular, with a variety of pockets, cuffs and attachments. White is also the most difficult to keep clean. They are made from a variety of materials – cotton, cotton blends and synthetics – each with its own peculiar attributes. Suits should be "roomy," to allow bending and stretching and lifting room, and for other clothes underneath. This also keeps the suit from stretching tautly over the skin underneath, which bees can then easily sting through.

Seasoned beekeepers seldom wear gloves because they feel they lose that "delicate" touch when manipulating colonies. However, many beginners start with them. Most gloves have cloth gauntlets of some type to seal the sleeves of the bee suit. Glove materials range from full leather to plastic to split leather to rubber. Some are ventilated, while others have no fingers. Wearing gloves can help build confidence in manipulating bees. As one gains experience, the finger tips can be cut off, which still protects most of the hand, while ensuring a more sensitive manipulation.

Boots and pants-cuff clasps range from high top rubber boots to baling twine. The goal is to keep bees on the ground from crawling up pants legs – an unnerving experience. Comfort, durability, safety and cost are all important. All equipment should fit the job. A hobbyist with a few colonies will use, and need, different equipment than a commercial pollinator.

Management

The "meat and potatoes" of beekeeping is management. It is often the best manager who makes the most honey from his/her bee colonies. Experience is extremely important if one is to manage bees successfully. There is no better piece of advice for the novice beekeeper than to begin small and only expand as experience is gained. A vital ingredient of this experience is permanent, detailed record keeping and knowing intimately the characteristics of the honey bee ecotype one is working with. One must also master the basics of opening and inspecting a colony with the aid of smoke, yet not destroying its cohesiveness.

Beekeeping knowledge comes about slowly and being able to implement it effectively often takes far longer than expected. In order to appreciate the techniques of beekeeping, one must first gain an understanding of the dynamics of the colony during the year. A recommended exercise for the beginning beekeeper is to construct a beekeeping calendar. Regional characteristics of beekeeping are easily identified through the use of the calendar, which shows average dates of bloom, colony population characteristics and bee manipulations. Such a timetable also can be broken down into a number of beekeeping activities, each requiring certain decisions. These include inspecting a colony in spring, feeding pollen and sugar, monitoring population buildup, controlling swarming, supering, monitoring and removing the honey crop, requeening, preparing for winter and migrating in search of better nectar resources or to move bees into commercial plantings for pollination.

No year is ever the same, so the beekeeper must learn to "think like a bee colony," closely watching environmental changes and anticipating the potential effects on colonies. Major management problems in beekeeping are controlling swarming (the reproductive process of a colony), requeening and managing diseases and pests. Swarming has befuddled even experienced beekeepers. Requeening and queen introduction techniques have been written about for many years, but still confound beekeepers on occasion. Several options often need to be considered for successful introduction of new queens, the life blood of any beekeeping operation. Finally, the challenges of diseases (American and European foulbrood) and exotic pests (mites, beetles) are complex, requiring an understanding of many possible treatment regimes under the rubric of Integrated Pest Management (IPM).

Although controversial, most beginners are advised to begin by managing two colonies. The reasons for this are several. If a hive begins to fail, there are resources in the other the beekeeper can use to help the weaker one along. If one colony is lost entirely, the novice beekeeper may easily lose interest if another colony is not present to take its place.

A Model Bee Yard

Somewhere the perfect bee yard exists, but if so, it is not the general rule. Most are the result of a beekeeper's style that fits both location and management philosophy. Bee yards should be right-up-next-to-the-hives easy to get to all year long. Newly plowed fields, suddenly erected fences, rising creeks, muddy roads, locked gates and the like should be anticipated, and avoided.

The most accessible location is worthless without something for the bees to forage on. There should be enough blooms to produce surplus honey for every colony in the apiary. Field crops, hay crops, tree canopies, weed species, horticultural or oil crops all can work. But there needs to be large areas of blossoms blooming a relatively long time. Water is required all season long, too. A lake, stream or pond is best. Swimming pools, cattle troughs or leaky faucets cause potential neighbor problems and should be avoided as bee watering possibilities.

A wind break, especially during the colder months in temperate latitudes, is recommended. A tree line, fence or hill works best. Air drainage is important. Cold air drains downhill; colonies at the bottom of a hill get "dumped on" in cold weather. Hill tops, too, suffer winds and wind chill problems. Avoid both. Exposure seems important to some. Colonies receiving morning sun start to forage earlier than those in the shade (at least with some races of bees). Southeast is the most common, and probably works best.

Bee colonies must be protected from all manner of pests and predators, including humans. Bear (electric fencing), skunks and possum (fencing), cattle and horses (regular fences, though stout), and neighbor prying eyes (screening, hedges) must all be considered. For large bee yards, an out-building that works as a storage shed, work area, extracting room (sometimes) and lunch room is needed. Most of all, a bee yard should be a pleasant place to visit. Scenic, quiet, distant and, most importantly, not a challenge to use.

Inspecting Honey Bees

The productivity of honey bee colonies should be actively monitored by the beekeeper, whose job it is to recognize certain conditions and help a colony overcome those causing adversity. Generally, inspection will determine the state of the colony in terms of reproductive ability (queen condition; population of worker bees), nutritional resources (honey and pollen stored in the comb) and whether diseases or pests are present.

The latter is increasingly important as exotic organisms continue to proliferate around the globe. Of special significance at the present are two introduced mites, the internal *Acarapis woodi* and external *Varroa destructor*. These mites have caused beekeepers to take a closer look at and often use chemical controls inside the living beehive with the concomitant risks that these substances may harm the colony and/or contaminate its products. As a consequence, honey bees have become much more domesticated, as they are increasingly reliant on beekeepers in many areas of the world to help control exotic bee mites. Other diseases that affect colonies are caused by bacteria, fungi, viruses and protozoans. Of particular significance are two bacterial conditions, American foulbrood (*Paenibacillus larvae* subspecies *larvae*) and European foulbrood (*Melissococcus pluton*).

American foulbrood, in particular, is caused by a spore-forming organism that can resist harsh ecological conditions. Epidemics of this disease are the reason state bee inspection services exist, although many of these have been discontinued recently due to budgetary constraints and lack of support. Discovery of sulfa drugs and later antibiotics has caused a shift in beekeepers' perceptions concerning the disease, which they have actively kept at bay for decades. Unfortunately, the recent appearance of antibiotic-resistant strains of *Paenibacillus larvae* subspecies *larvae* is causing second thoughts by many beekeepers concerning official inspection backed up by apiary legislation.

An important adult disease is known as nosema and is caused by the protozoan *Nosem apis*. This is probably present in every colony of honey bees, but only becomes epidemic when bees are put under stress. It may be far more important in determining bee colony health than is generally given credit.

There continue to be numerous so-called "exotic" organisms that impact colonies of honey bees around the world. Ironically, two of these are ecotypes of honey bees themselves: the Africanized honey bee (*Apis mellifera scutellata*) and the thelytokus Cape of Good Hope bee (*Apis mellifera capensis*). In addition, various mites are found on Asian honey bees (*Apis cerana*, *Apis dorsata*, *Apis laboriosa*) that conceivably could transfer to *Apis mellifera* as *Varroa destructor* did previously. No better example of this constant threat is the surprise introduction of the South African small hive beetle (*Aethina tumida*) into the United States in the late 1990s.

Honey Bee Ecotypes

All honey bees are not the same. This statement, it seems, cannot be said too often around beekeepers and/or the general public. There are those who manage bees exactly the same whether or not their stocks have been selected for overwintering, swarming, rapid brood rearing, pollen collecting and/or stinging. The belief that all honey bees must behave or act similarly no matter the conditions is the root of many beekeeping controversies over the last two centuries, and the reason many lay persons fail to understand the complexities of these stinging insects. Usually, beekeeping "arguments" pertain to whether or not a certain management technique or a special kind of beekeeping apparatus is practical or efficient. The kind of bee a beekeeper has in his apiaries often will determine whether some concept or idea works or doesn't work. All too often, however, the bees' genetics are ignored when contemplating solutions to many of the mysteries of beekeeping.

Unfortunately, most beekeepers really do not know what kind of bee they are using. That's because present bee stock is literally a melting pot of honey bee genes. The predominant races (subspecies or ecotypes) of bees which make up the honey bee genetic mix found in the United States are: Italian (*Apis mellifera ligustica*), Caucasian (*Apis mellifera caucasica*), Carniolan (*Apis mellifera carnica*) and German (*Apis mellifera mellifera*), the dark bee. Each population evolved under certain ecological conditions and natural selection over a long period of time that have provided them with their own particular survival techniques. These ecotypes are thoroughly intermixed and are extremely difficult to separate in novel environments. In addition, other genes of other ecotypes also are present in small quantities.

Because there is such great variability, however, the possibility of quantum leaps in honey bee selection programs is possible. With the coming of the mite *Varroa destructor*, however, the honey bees' genetic base has narrowed in many parts of the world. But fortunately there remain pockets of bees that appear to be resistant (tolerant) and these may provide the foundation for rebuilding a honey bee stock devastated by this parasite.

Africanized Bees

One of the biggest biological stories of the Americas concerns honey bees. Introduction of the African honey bee ecotype (*Apis mellifera scutellata*) has been responsible for raising the public consciousness about these insects. This bee is nothing more than an ecotype adapted to tropical conditions, generally characterized by higher rates of defensive behavior and reproduction. Unfortunately, its fearsome reputation is an outgrowth of sensationalized press coverage of stinging incidents by these so-called "killer bees," which caused deaths of animals and people in Latin America. As a result many people now view honey bees as aggressive rather than defensive, and think them responsible for a good many human fatalities. The reality is that the number of verified deaths by honey bees is much smaller than reported (almost all stinging insects are routinely called bees). This over-sensationalized topic has affected beekeepers in several ways, most notably by loss of access to beekeeping locations. North America is the last frontier for the Africanized (or African) honey bee and its final distribution is still unknown. Nevertheless, the challenge for many beekeepers in the future will be to strike a balance in their communication with the public about the risks/benefits of their bees. Beekeepers also will have to adapt to this ecotype's different behavior, which often can be a radical departure from the European ecotypes previously present.

A special ecotype inhabits Africa known as *Apis mellifera capensis*. This bee is characterized by a high degree of thelytoky, which means workers can become laying queens, producing diploid females, in spite of laying unfertilized eggs. This ecotype has created a crisis of sorts in African beekeeping. It is hoped that this honey bee will not be moved out of its homeland by beekeepers and introduced to the rest of the world. The history of honey bee introductions around the world over the last two centuries, however, is not a good omen in this regard.

Smoking Bees

Within and outside the dark hive, bees communicate extensively by smell. Nectar, pollen, diseases, other insects, brood, the queen, drones – everything in the hive has an odor cue. As complicated as the bees' odor communication system appears to be, the manner that beekeepers have developed to overcome the bees' ability to perceive odors, both inside and outside the hive, is relatively simple, and that is to puff cool, white smoke in and around the hive. For reasons not clearly understood, smoke stimulates bees to move to honey stores and engorge, which reduces their propensity to sting.

Early smokers were little more than a smoldering fire beneath or near a hive. Later, tobacco pipes were modified to direct smoke into hives as were other devices. After evolving through many different designs and styles, beekeepers in North America have a small, but adequate range of smoker designs from which to choose.

Smoker fuels are as numerous as are the beekeepers who use them. Common types include grass clippings, pine straw, sumac pods, cloth rags, rotted wood, wood shavings, and burlap. Essentially, anything can be used that produces cool, white billowing smoke and has not been treated with pesticides, fire retardants or other noxious chemicals. Under normal conditions, smoke is effective for about 2 to 4 minutes before needing to be reapplied.

Moving Bees

Bees can be moved almost any way imaginable. Some, of course, are easier and safer than others. Commercial operations need the economy of size and efficiency. A large, flatbed truck serves that purpose. Some come with a flatbed trailer that attaches to the truck to increase efficiency. These trucks usually have customized tie-downs, tool boxes and equipment storage areas. Getting the bees on and off the truck can be done by hand (muscle) or machine.

Regular two-wheeled carts, sized to hold hives, often are used for moving. Motorized carts are common, as are booms and Tommy-lifts. Fastest are fork-lifts. There are several models available, from the standard, to large, specially designed models for specific bee pallets. Some have cabs, most have protective cages and large tires to navigate easily in muddy conditions. Some can swivel or pivot in the center.

Once loaded on the truck bed (many are built to hold an exact number of pallets), tie-downs can be regular rope, self-tightening straps, or wide canvas belts affixed to wooden frames that are used for extra security. A secure net is required at all times to avoid escaped bees on the road. Anytime bees are moved, the boxes should be fastened, entrances closed, the load netted and tied down to prevent shifting.

An important consideration in moving bees is temperature. Traditionally this has been managed by periodically spraying the load of bees with fresh water when signs of overheating are evident.

Package Bees

The most common way to start a colony, or start beekeeping, is to install a package of bees into an empty home-to-be by removing them from the shipping cage. Packages generally come in three- to five-pound sizes (3,500 bees equal a pound). And there are nearly as many ways to get bees from the shipping cage to the functioning unit as there are people doing the task. But basic biology dictates certain principles be obeyed. A starter box with some or all drawn comb is better than just frames with foundation, as it gives the bees some place to be, and store food immediately, and reduces the amount of gathered food required for wax production, freeing it for brood food.

Bees can be "moved in" by dumping them (they are often sprayed with water first to inhibit flying) inside the box (with three frames removed, then replaced, to accommodate the resultant mass); they also can be dumped directly in front, to march right in; or a combination of the above two techniques, where some are placed inside, the remainder outside. The empty package is removed in a day or so. Once installed, several precautions are recommended. The first rule is: feed, feed, feed. Then feed more, until they don't take any more. Feeding well into the summer may be required if adequate forage is not available.

Checking for queen acceptance, and then queen production is a must, but there is a fine line between too-often and too-seldom observations. It is safer to edge toward the too-often, but just barely. Once established, remove feeders, add supers and prepare for the honey flow and harvest.

Dividing Colonies

Splitting a colony is the easiest and least expensive way to increase the number of hives managed. But there are other reasons to split a colony, and there are nearly as many ways to split one as there are colonies to split.

The overall principle in making a split is to start with a large, healthy, populous colony (or colonies). The goal is to remove some uncapped brood, some honey and pollen resources to a new box, or two, to start a new colony. A new queen may, or may not be, added. Usually the parent colony should not be reduced to less than half its resources so it can continue to keep pace with the season. Bees, brood or food may be taken from more than one parent to successfully build a new split. Splits must have enough nurse bees to care for the brood, some foragers to gather resources, sealed brood for immediate colony expansion, younger brood for continued expansion and some resources for immediate consumption.

Splits are used to "make increase," or for other reasons. Popular swarm control/prevention measures include splitting a large colony to allow room for expansion, and to relieve brood-nest congestion. Often the "new" colony is rejoined to the parent when the swarming urge is over so the actual number of colonies does not increase. One technique used to reduce mite infestation is to divide a colony later in the season, eliminating the older, infested bees, and overwintering the younger, less infested bees.

Feeding Colonies

Providing food to colonies is one of the most time-consuming and tedious tasks facing any beekeeper. Two types of food are required: carbohydrate and protein. Generally, carbohydrates are provided by nectar in nature and the best analogy to this is sugar syrup, made up by dissolving cane sugar in water. This is then provided through various hive modifications or feeders, some of which are mentioned elsewhere in this article.

A relatively new bee food is high fructose corn syrup (HFCS) that is manufactured in huge amounts to service the soft drink and candy trade. Two types exist: 42 and 55. The 55 is generally considered more acceptable to bees because it has more sugar solids. Many beekeepers consider feeding both sugar syrup and HFCS, depending on hive condition. Sugar syrup high in sucrose is considered superior for colony population build up, while HFCS is used strictly to maintain populations.

Most suggested feeding regimens concentrate on providing carbohydrate. However, it must be complemented with protein for a balanced diet. This is provided by pollen to the honey bee in nature. The beekeeper, too, can trap and give back pollen or combine it with soy flour and/or yeast (supplement). Protein supplement often is sold ready-made in patties by beekeeping supply outlets.

Producing the Honey Crop

The beekeeper seeks to have as large a population of worker honey bees as possible coincidentally when the most nectar-producing flowers are blooming. This nectar is stored above a bee colony in the wild. Thus, beekeepers emulate this by adding extra boxes on top of hives (supers) into which bees place the nectar. Nectar is modified by the bees into honey. The insects add enzymes, changing the material chemically, and reducing the moisture content from 80% (nectar) to about 18.6% (honey). The bees determine when the moisture is correct and then cap over the honey with wax. When the supers are filled, they are removed and the honey is extracted from the comb using centrifugal force in special machinery (extractors). Sometimes honey is sold in the comb (known as section or comb and cut-comb).

Extracting the Honey Crop

A large honey crop is clearly a mixed blessing. The more supers that go on, the more honey to be processed. More honey means more work, but it also means more money. For years, clever people have tried to develop equipment to make the uncapping, extracting, pumping, filtering, and bottling procedure more convenient, even easy. Though "easy" extracting has not yet been achieved, the process has become much more streamlined. Old processing equipment was made from galvanized tin with lead solder joints. It was solid equipment that was built to stand years of heavy use. The clutch-drive mechanism was simple, heavy-duty, and a bit dangerous. Belts, drives, shafts, and pulleys were all exposed. In fact, a few early extractors were powered by low compression gasoline engines. Extracting was done outside on occasion, a practice that generally has been abandoned.

Stainless steel with welded joints is now used on extractors. Other metals may impart an objectionable odor. Smaller hobby-type extractors may use plastic barrels. In many instances, variable-speed direct-current (DC) drive motors are used that allow for the gentle extraction of full combs of honey. The equipment is mechanically simpler, but technologically more complicated. It's lighter and more maintenance free. Most commercial honey processing lines would be ordered as follows:

1. uncapper
2. extractor(s)
3. heated sump
4. honey pump
5. filter
6. settling tank
7. bottler

Other equipment in honey processing can include a barrel melter, a flash heater, wax spinner and other equipment-moving devices. A second line would drain honey from wax cappings to the sump. Dried cappings would be melted into beeswax, which could be returned to the bees as foundation.

Managing Swarming

Swarms can be both reproductive and migratory. Little can be done about swarming once the "impulse" is generated in a colony. The best ways to control swarming are providing room in the colony and/or regularly requeening with younger individuals. This is a "preventive" strategy that is much more effective. As stated earlier, once the impulse to swarm gets going, it is almost impossible to stop. Generally swarms are reproductive in nature, especially with European honey bees, and can be both a blessing and a curse. The blessing part is that one can be harvested and put to work in an apiary. A secondary blessing, obviously, is that a swarm happens. That means a colony is healthy enough to swarm, something all too rare in these days of increasing stress on managed honey bees.

The first thing to do with a swarm is collect it. At times this is easy, sometimes impossible. Swarms high in the air can be collected with vacuum devices, long ladders, or heroic gymnastics. Most can be collected into bags, boxes, supers or whatever and transported to permanent housing. The key is to provide ventilation; putting a strong swarm into an air-tight container is a recipe for disaster! Swarms are generally the gentlest of bees, but if left exposed for several days, they can become hungry and much more defensive. Always have a lighted smoker at the ready when working swarms.

The public relations aspect of swarm gathering should not be overlooked. But the macho image many beekeepers display while on the job communicate a mixed message. Once collected and transported, a beekeeper can do many things with this bunch of bees. The deciding factor is often the size of a swarm. Large swarms, about four or five pounds of bees (3,500 bees equal one pound), can easily survive by themselves. Smaller swarms of one to three pounds can be combined with other swarms to start a large colony; or added to another colony to boost its nectar- and pollen-gathering capability during a major flow.

To be safe, all swarms should be considered infested with mites and treated accordingly. As the queen heading the swarm is from essentially unknown heritage, replacing her with a young one of known parentage should be considered.

With the advent of the tropically adapted Africanized (*Apis mellifera scutellata*) honey bee, another kind of swarming is increasingly seen. This is the migratory swarm, thought to be brought on by stress such as lack of forage or water. This kind of swarm often behaves differently than the reproductive one and may be much more defensive, though not always so.

Managing and Rearing Queens

The queen is the key to managing the genetic component of a colony. She contributes one half of all the genes found in a colony, whereas a single drone provides for less than half (queens mate with 17 to 20 drones during a short period in their life just after emerging from the cell). The colony's characteristics, therefore, have a good chance of being perpetuated in the queen and research has shown that queen selection followed by open mating will ensure a good deal of progress in breeding bees with specific traits.

Queen rearing is one of the most demanding beekeeping activities, and more often than not is a true art form. Anybody can produce a queen, but rearing a quality queen with the correct genetic complement for a beekeeping operation is far more difficult. Queen rearing also is directly tied to a timetable, which must be rigidly followed. Often the question is raised whether or not one should produce queens him/herself, let the bees do it, or purchase a queen. There is no easy answer. The only reply may be to ask the question, "Whose quality control is the best under the circumstances, that of nature or of human beings?"

Again, the queen honey bee usually mates with many drones. This ensures large genetic variability, but also means a lack of controlled breeding. It is possible to instrumentally inseminate queen honey bees in an attempt to control genetics in a population. This is not easy, however, and can only be accomplished by trained workers. Most queen rearing facilities produce daughter queens from selected stock that are open mated (uncontrolled) in a natural setting.

Managing Wintering

The honey bee can live in almost any climatic environment, but is most stressed by winter in continental climates. Honey bees can produce a warm brood nest even in the coldest winters if supplied with the proper nutrition and number of workers. This leads to the adage that "honey bees never freeze to death, they starve to death." Beekeepers in cold climates, therefore, have a significant challenge to help their colonies overcome severe conditions of wind and cold. Many pack their hives wintered outdoors in various kinds of materials to conserve warmth. Others move their colonies indoors to protect them. The latter activity was employed by old timers who put their colonies into cellars. This was risky as too much warmth would stimulate a colony to begin to build population, a prescription for disaster. With development of refrigeration, however, it now is routine in some areas to bring smaller-than-normal hives (nuclei) into climate-controlled buildings and keep them in a kind of human-induced diapause, which reduces nutritional requirements to a minimum and conserves worker bee energy and vitality so they can begin to rear brood quickly and efficiently in spring.

An alternative to wintering is to simply collect all the stores and kill colonies off in winter, establishing new hives the following spring with package bees from more tropical areas. This was routinely practiced by Canadian beekeepers who simply purchased bees from the southern US until the border was closed in the early 1980s due to introduction of tracheal and then Varroa mites. To many beekeepers this was a repugnant practice and they were not sorry to see it abandoned. Effective wintering continues to be an important part of bee management as more colonies are lost during this trying time than other seasons of the year.

Nectar and Pollen Sources

Nectar and pollen are the only natural foods of honey bees, strictly vegetarian insects, and each geographic area has different sources of these important foods. Every good beekeeper, therefore, must be somewhat of a botanist in order to make sure the bees are located so they have an adequate food supply. Bee plants may also differ from each other in several ways, such as the kinds of nectaries (nectar glands) each supports and/or the time of day they may secrete nectar and/or produce pollen.

Nectar and pollen production by flowers is dependent on a great variety of environmental conditions such as soil moisture, pH, profile and fertility, as well as rainfall distribution, temperature and humidity. Over the last four decades, there has been an overall decrease in honey bee forage in the United States due to many factors, especially changing agricultural patterns and increasing urban development. Improving nectar production by genetically selecting for varieties of certain crops that produce large amounts of nectar, or purposely planting nectar-producing varieties in so-called "waste" land, along roadways or on lands reclaimed for mining, are some ways suggested to reverse this systematic reduction of bee forage.

Few plants produce the vast quantities of nectar the honey bee needs to make a large honey crop. In the state of Florida, for example, less than ten plants are responsible for sizeable honey crops on a consistent basis. Fortunately, in most areas a number of minor nectar crops usually are found which help support honey bees throughout the year, although they often contribute little to the beekeeper's honey crop. It is of more than passing interest to know that many introduced plants assist honey bees in a number of ways, and the insects may contribute to their proliferation.

Though not as readily available as honey, another type of sweet is collected and processed by honey bees. Aphids and other sucking insects often take more than they need from the plants. The excess is extruded and may be collected by ants or honey bees. The resultant product is honeydew. Some think this might have been the "manna" that descended from heaven as noted in the Bible (Exodus 16:1–36).

Commercial Pollination

Honey bees are cosmopolitan pollinators, transferring pollen both within and between flowers. Although important to many crops (fruits and vegetables), honey bees are not the most effective pollinators in many situations. This has led to some proclaiming that other bees should be used in preference, such as bumblebees (*Bombus* sp.) and/or blue orchard bees (*Osmia* sp.). However, honey bees have significant advantages including very large populations that are easily moved, and a well-known rearing technology.

There is no stable pollination service in the United States of the kind described by S.E. MacGregor in his classic volume on insect pollination. This means that pollination is carried out by a number of independent contractors. More recently, pollination brokers in the western United States have become more common. The vast majority of commercial pollination takes place in California on the almond crop. Literally hundreds of thousands of colonies are needed.

Commercial pollination is a service, a much different business than producing a product like honey or pollen. As such, it is not suited to all beekeepers and each should look carefully at the characteristics of this enterprise before dedicating many resources to it.

Recently, pollination has received more respect from the general public due to a scarcity of feral or wild honey bees caused by devastating effects of exotic bee mites. This represents a teachable moment for beekeepers, who can now describe with pride the value of their insect charges to the public at large.

Honey Contrasted to Pollination

Honey is a world commodity, and is labor intensive to produce. As such, the price of the product can always be expected to be influenced by societies with low labor costs. Indeed, beekeeping is being promoted aggressively as a development tool in many countries because it is relatively environmentally friendly and not capital intensive.

Although honey can be imported cheaply in many instances, a process exacerbated by globalization of world commerce, pollination services cannot. In addition, because no food product is involved, chemical treatment for exotic pests (mites) can be applied in a more forgiving way to colonies used strictly for pollination. This means that in the future there will always be a demand for pollination no matter the price of honey. Because commercial pollination seems more assured in the future, beekeepers should continually carefully consider this activity in their enterprise mix.

Conclusion

The future of beekeeping or apiculture continues to be mixed. On one hand, the honey bee will be more and more important as growers and the general public continue to realize how necessary this insect is for producing a quality food supply through pollination. Because honey is a world commodity, it also is continually under price pressures in developed countries, as it represents a good source of income for countries with a labor-intensive work force. Its reputation is also at risk, however, given the chemicals needed to keep (treated) bee colonies alive and the potential they have to damage the sweet's reputation through contamination. Whether or not honey and/or pollination are primary, there also are other reasons to keep bees, including using their products, both manufactured (royal jelly, honey, beeswax, venom) and collected (pollen, propolis), for the benefit of humanity, as well as for the general joy of communing with nature and one of its fascinating social organisms.

The history of beekeeping activities is long, and it takes time and experience to become a proficient manager of honey bee colonies. This article can provide only some of the basic information on the craft. The authors hope that it will serve as a catalyst for those thinking of taking up the activity, and also a source of basic information for anyone interested in one of humankind's most fascinating activities.

Apidae

A family of bees (order Hymenoptera, superfamily Apoidae). They commonly are called bumble bees, honey bees, and orchid bees.

► Bees
► Honey Bee
► Wasps, Ants, Bees and Sawflies

Apioceridae

A family of flies (order Diptera). They commonly are known as flower-loving flies.

► Flies

Apivorous

Bee eating. Birds, and some predatory insects such as robber flies (Diptera: Asilidae) kill and consume honey bees or, in the case of blister beetles (Coleoptera: Meloidae), ground nesting bees.

Apneumone

A chemical released by a nonliving substance that is beneficial to the receiver. An apneumone is a type of semiochemical.

► Chemical Ecology
► Semiochemicals

Apodal

The condition of lacking "feet" (tarsi). Fly larvae and some beetle larvae, for example, have simple tubercles that aid in movement, but lack legs, including tarsi.

Apodeme

A thickened section of the exoskeleton that serves as a point for muscle attachment. On the external surface, it usually is marked as a suture or fold, but internally there may be a significant invagination.

Apodous Larva

A larval body form that is legless, robust, and C-shaped or spindle-shaped. The head may be well developed, or not. Apodous larval types include curculionoid, muscoid, and apoid.

Apoidae

A superfamily in the order Hymenoptera known as bees. It consists of several families.

► Bees
► Wasps, Ants, Bees and Sawflies

Apoid Larva

A larval body form that is robust, with a well-developed head, and cared for by nestmates or provisioned by the parent. It occurs in ants, bees, and wasps (Hymenoptera).

Apoid Wasps (Hymenoptera: Apoidea: Spheciformes)

KEVIN M. O'NEILL
Montana State University, Bozeman, MT, USA

Apoid wasps are a morphologically, behaviorally, and ecologically diverse group of insects that are common in many habitats. Apoid wasps are most closely related to bees, and are placed with them in the superfamily Apoidea, one of three superfamilies of the so-called "stinging Hymenoptera" or Aculeata; the other two subfamilies are Chrysidoidea and Vespoidea (Table 7).

The subfamily Apoidea is subdivided into the series Apiformes and Spheciformes, the latter of which are the apoid wasps. Thus, the term "apoid wasps" refers to all members of the superfamily Apoidea that are not bees. Of the four families making up the Spheciformes (Heterogynaeidae, Ampulicidae, Sphecidae, Crabronidae), all but the Heterogynaeidae were formerly placed in the single family Sphecidae (*sensu lato*) in the superfamily Sphecoidea. But recent consensus splits the old Sphecidae into the Ampulicidae, Sphecidae (*sensu stricto*), and Crabronidae. The correspondence in taxonomic names between this recent family-level classification and what we might call the "classical" system represented in *Sphecid Wasps of the World* by Richard Bohart and Arnold Menke is given in the following table. The reason for the recent taxonomic reworking is sound. The "old" Sphecidae and Sphecoidea were artificial groupings evolutionarily, because the wasps in what we now call the Crabronidae are actually more closely related to bees than they are to the Ampulicidae or the "new" Sphecidae.

The Apoidea, as a whole, likely has its origins in the early Cretaceous, and it is the wasps that predate the bees. Species of over two dozen extinct apoid wasp genera, including members of the

Apoid Wasps (Hymenoptera: Apoidea: Spheciformes), Table 7 Superfamilies of aculeate wasps (classification of the Apoidea is after *The bees of the world* by Charles Michener)

Superfamily	Series	Families	Included groups
Chrysidoidea		multiple families	cuckoo wasps, bethylid wasps, and others
Vespoidea		multiple families	ants, social wasps, spider wasps, velvet ants, and others
Apoidea	Apiformes	seven families	bees
	Spheciformes	Heterogynaeidae	apoid wasps
		Ampulicidae	
		Sphecidae	
		Crabronidae	

Ampulicidae, Sphecidae, Crabronidae, and the extinct family Angarosphecidae, have been found in Cretaceous deposits. Over 9,500 described extant species of apoid wasps are unequally distributed among the four families and over 250 genera. Bees, in contrast, are divided among seven families, 425 genera, over 16,000 described species, and perhaps 30,000 species overall (Table 8).

As a group, apoid wasps share a number of traits that unite them with bees in a discrete evolutionary lineage: (i) a gap present between tegula (at the base of the wings) and the apex of the posterior edge of the pronotum; (ii) a broadly U-shaped pronotum when viewed dorsally; and (iii) the "propodeal triangle" on the dorsal posterior of the abdomen. A dozen or so shared traits link bees in a single clade within the Apoidea. For example, bees feed pollen and nectar to their young, and continue to eat both pollen and nectar as adults. In contrast, with perhaps one exception, all apoid wasps either feed their young arthropod prey or are brood parasites in the nests of other carnivorous wasps; the single exception is the genus *Krombeinictus* (Crabronidae) from India whose females provision with pollen and nectar. Adult wasps feed on nectar, sap, or honeydew, and some consume body fluids of prey. Another marked difference between apoid wasps and many bees is that body hairs are simple in the former, but often branched or even plumose in the latter, where they function to trap and carry pollen (though this may not have been their original function).

As a group, apoid wasps vary widely in habits and body size, form, and color. Most species are sexually dimorphic to a greater or lesser extent, females having almost universally larger body sizes and stouter mandibles. Also, only females have stings. Females of ground-nesting species also commonly bear two features not found in either males or in females of species that nest in other locations. The first feature is conspicuous rows of "rake spines" on their foretibia that aid in digging in soil. The second feature is flattened pygidial plates that aid in tamping soil in place during nest construction. Males of some species exhibit peculiar anatomical structures used in courtship and mate competition. Examples include the clypeal and abdominal hair brushes that male beewolves (*Philanthus*) use to disseminate sex pheromones, and the expanded translucent foretarsal plates of male *Crabro* that sport species-specific color patterns and which are apparently placed over female's eyes during courtship.

Heterogynaeidae

While the Heterogynaeidae are clearly apoid wasps, their exact relationship to the other three families is somewhat controversial. Heterogynaeids are small wasps, 1.5–5.0 mm in length, that are restricted in

[d]females are scavengers of dead arthropods.
[e]*Nysson* and *Stizoides* are brood parasites whose larvae feed on prey provisioned by other wasp species.

distribution to the eastern Mediterranean region, southern Africa, and Madagascar. Nothing is known about their biology, but there are hints that it may be unique among apoid wasps: females have such short wings as to make them flightless and they have been observed active at night; based on morphological evidence, it has been inferred that heterogynaeids are parasitoids, though they probably do not dig in soil.

Ampulicidae

The Ampulicidae have rather elongate bodies and legs that make them proficient runners; they range up to 3 cm or so in body size, and may be metallic blue or green in color. Though geographically widespread, ampulicids appear to be relatively consistent in their habits. Females of all species prey on cockroaches that are stung into temporary paralysis, placed singly in existing cavities, and quickly covered with debris after a single egg is laid on each prey. Venoms of certain species are known to have specific pharmacological effects on cockroaches, which are somewhat subdued following stinging, but remain active enough that the female wasp can lead them to the nest cavity, as if walking a tethered cow to pasture. Nests of ampulicids may have multiple cells separated by partitions made of plant debris, but are relatively simple compared to nests constructed by many Sphecidae and Crabronidae.

Sphecidae

The wasps in what is now called the Sphecidae are sometimes referred to as "thread-wasted wasps" in reference to their narrow cylindrical petioles. Sphecids often have quite striking body colors, including the metallic blue (*Chlorion aerarium*), black and yellow (*Sceliphron caementarium*), and black and orange with either silver (some *Ammophila*) or golden hairs (*Sphex ichneumoneus*). The family includes some of the largest apoid wasps, including members of the genera *Dynatus*, *Parasammophila*, and *Sphex* that can reach as long as 4–5 cm; sphecids are rarely less than 1 cm long, though this is the case for some *Ammophila* and *Prionyx*. Sphecids are more diverse in their nesting habits than are ampulicids. Some dig nest burrows in soil, others nest in existing cavities in wood or construct mud nests *de novo*. Certain species of *Chlorion*, on the other hand, are parasitoids that construct no nests at all, but simply sting their cricket prey and then place it back in its own burrow. Prey of sphecids include three orders of insects, along with spiders; some take prey that are large relative to their own body size. *Palmodes laeviventris* (which preys upon Mormon crickets, *Anabrus simplex*), *Sphex ichneumoneus* (which takes crickets and katydids), and certain *Ammophila* (that take large caterpillars) may provision with prey that approach or even exceed the adult female in body mass.

Crabronidae

The Crabronidae, the largest and most diverse of apoid wasp families, contains 90% of the apoid wasps. Crabronids range in size from 1.5 mm long *Spilomena* that prey on psyllids and thrips, to 35 mm long *Sphecius speciosus* that prey on cicadas, and 45 mm long *Editha magnifica* that take butterflies. Even individual genera can exhibit wide size variation; *Philanthus* in North America, for example, range from the 5 mm long *Philanthus parkeri*, predators of tiny andrenid bees, to 25 mm long *Philanthus bicinctus*, predators of worker bumble bees. As a group, crabronids prey on insects of at least 17 orders, along with spiders. The reproductive biology of the Ampulicidae, Sphecidae, and Crabronidae are covered in more detail below.

Reproductive Biology of Females

The reproductive strategies of female apoid wasps fall into three broad categories: parasitoidism, brood parasitism, and nest-provisioning. The nest provisioners include solitary, communal, and eusocial species, the latter two of which will be discussed in the following section. Unlike some apoid wasps, no vespid wasps or bees are parasitoids, and only the bees include brood parasites. However, apoid wasps have just barely crossed the threshold into eusociality, whereas bees and vespid wasps contain some of the most highly eusocial Hymenoptera.

Among apoid wasps, parasitoids lay their eggs singly on a host insect that has been stung by the adult female wasp; no nest is constructed by the female parasitoid, though she may return the host to its own burrow and cover it with debris. Parasitoids are found in the Ampulicidae, a few genera of Crabronidae (*Chlorion*, *Larra*), and perhaps the family Heterogynaeidae, though this has yet to be confirmed. Brood parasitic apoid wasps occur in the crabronid tribe Nyssonini (226 species) and genus *Stizoides* of the Gorytini (29 species). Brood parasites enter provisioned nest cells of other apoid wasps and deposit their own eggs (one per nest cell); the brood parasite larva then feeds on the host's stored prey, the host egg having been already killed either by the adult female parasite at the time of oviposition (*Stizoides*) or the parasite larva itself (Nyssonini).

The vast majority of female apoid wasps are solitary nest-provisioners that work without assistance from conspecifics to construct a nest and provision each of its brood cells with one or more paralyzed prey. The prey placed in a cell must provide all of the nourishment required by the maggot-like larva (one per nest cell in almost all species) that remains restricted to its own nest cell throughout development. Apoid wasp nest types can be grouped in five categories: cavity nests; nests excavated in plant material; nests excavated in soil; free-standing mud nests; and free-standing nests made of various materials bound with silk. In some genera, different species may construct nests in different categories.

Cavity nests, those built within existing cavities, are often constructed in old beetle tunnels in wood, but have also been found in such locations as empty snail shells, old plant galls, pitcher plants, rolled leaves, and gaps between stones or between boards on the siding of houses. Such nests usually contain multiple cells separated by a species-specific choice of materials; for example, *Chalybion* uses mud; *Isodontia*, chopped grass fragments and plant fibers; *Passaloecus*, conifer resins; *Nitela*, wood chips; and *Podium*, an eclectic mix of detritus, mud, and resin. Wasps that excavate their own nest tunnels in plant materials may tunnel through the pith of plant stems (e.g., in raspberry or sumac) or rotten wood in logs. Cells may be arranged in a linear sequence, and tunnels in the same nest may diverge into separate branches. Nests excavated in soil are, by far, the most common type of nest among apoid wasps. They may be simple, unbranched shallow tunnels terminating in the single brood cell, as is the case for some or all species of *Ammophila*, *Bembecinus*, *Bembix*, *Podalonia*, and *Prionyx*. Other species dig branched nests with side tunnels leading to as many as 1–2 two dozen brood cells provisioned in succession over a period of several weeks. Single and multi-celled nests can be found not only among different species of the same genus, but among different females in one species. Free-standing nests constructed *de novo* by females may be built of mud sculpted into species-specific shapes, as is the case for species of *Pison*, *Sceliphron*, and *Trypoxylon*. Mud nests may be attached to vines, trees, cliff faces, or nowadays, buildings; they may also have multiple cells.

In most cases, each nest cell is completely provisioned and closed off by the adult before the next cell is begun, but there is some variation in the duration and timing of provisioning relative to the developmental schedule of offspring. Most species are *mass provisioners* that completely provision cells with one or more prey before the egg hatches. More rarely, females are *progressive provisioners* that continue to bring in prey after the egg hatches, sometimes until the larva is ready, or nearly so, to spin its cocoon. Among solitary apoid wasps, only certain *Ammophila* provision two cells simultaneously. During provisioning, females of those species that hunt relatively small prey carry the prey in flight from hunting grounds to the nest. Prey are usually carried in the wasp's legs, sometimes with the aid of the mandibles, but some *Oxybelus* tote prey impaled on their stings, whereas *Clypeadon* females carry their ant prey grasped by the thorax using structures on the terminal abdominal segments aptly referred to as "ant clamps."

When they leave nests to forage, females of nest-provisioning apoid wasps face two problems in particular, other than the obvious need to find, sting, and transport their prey: the necessity to protect the unguarded nest from natural enemies and the need to find their way home again. Before departing to hunt, wasps often plug the entrance temporarily as a means of excluding intruders. And when a nest is completed, the female may construct an even more elaborate closure and take steps to conceal the entrance; in ground nesting species, this involves often elaborate and prolonged leveling of the mound of excavated soil adjacent to the nest entrance. Nevertheless, although these actions are likely successful in many cases, apoid wasp larvae are plagued by a variety of natural enemies that commence their attacks at varying times in the life cycle of the wasp. Brood parasites, which include not only other apoid wasps, but mites, flies (Phoridae, Sarcophagidae), and non-apoid wasps (Chrysididae) that feed on the wasps' own prey, may kill the wasps' young either directly or indirectly (through starvation). Parasitoids that feed directly on wasp larvae or pre-pupae include, among other insects, flies (Bombyliidae), beetles (Rhipiphoridae), and other aculeate wasps (Chrysididae and Mutillidae).

Several detailed studies attest to the fact that female wasps often have excellent homing abilities that lead them back to their nest, even when that nest is one of many hundreds or thousands densely packed into the apparently featureless soil surface of a nesting area. As far back as 1930, Niko Tinbergen's research showed that a *Philanthus triangulum* female can relocate her nest by learning the image of the landscape surrounding the nest and matching the memorized image to the configuration of local landmarks when she later returns with prey. The initial task of learning the image is apparently accomplished during an orientation flight, which in the case of *P. triangulum*, begins when the female circles the nest in flight, then gradually expands the diameter and height of her loops before departing for her hunting grounds. The form of the orientation flights varies among species, but females of all species share an uncanny ability to find their way home, even after being transported several hundred meters away by researchers.

When we examine the ovaries of female apoid wasps, we find several features that vary among species and correlate with overall reproductive strategies. First, although the paired ovaries of nest provisioning species each have three ovarioles (except for *Oxybelus* which have two), each ovary of brood parasitic species is comprised of four ovarioles (and sometimes five in *Stizoides renicinctus*). Second, although it is common for females of nest provisioners (especially progressive provisioners) to carry a maximum just one or two mature oocytes in their ovaries at a any time, brood parasites commonly carry 4–6 mature oocytes; and the parasitoid species *Larra amplipennis* can carry as many as 21. Third, the eggs produced by nest provisioners tend to be larger (relative to overall body size) than those of brood parasites or of *Larra*. All in all, this meshes with the fact that nest provisioning apoid wasps, because they invest so highly in individual offspring, have relatively low lifetime fecundities compared to parasitoids and brood parasites in their same families. Thus, it is likely common that even the most successful females of some nest provisioners can expect to have fewer than ten offspring during their lives. This contrasts markedly with the high potential fecundities of non-aculeate parasitoid Hymenoptera (e.g., Braconidae, Ichneumonidae).

Communal and Social Species

The vast majority of apoid wasps are solitary species, each of whose females occupies a nest alone and provisions it without assistance from conspecifics. Nests of both ground- and mud-nesters do sometimes occur in dense aggregations, but true communal and eusocial behavior is relatively rare among apoid wasps. Communal nests, in which small groups of females share a main nest burrow, but in which each provisions her own brood cells, have been reported in several genera (e.g., *Cerceris*, *Moniaecera*, *Spilomena*). In the Neotropics, *Microstigmus comes* is eusocial, inhabiting nests in which (i) two generations of adult females are present (likely a mother and her daughters), (ii) each nest cell is provisioned cooperatively, and (iii) one female is the primary egg layer. The nests, which are founded by one or more females, have as many as 18 brood cells and 10 adult females (as well as a smaller number of adult males). The nests of *Microstigmus* are unique among apoid wasps, that of *M. comes* consisting of a 1–3 cm deep bag of plant fibers embedded in a matrix of silk and suspended from the underside of a leaf by a short, coiled petiole. Other *Microstigmus* create similar nests, but embedding small pieces of bark, wood, leaf hairs, lichens, sand, or stone in the silk mesh. The use of silk produced by adults in nest construction is limited among apoid wasps to *Microstigmus* and other Pemphredoninae (e.g., *Arpactophilus*, *Psenulus*); however, larval apoid wasps commonly incorporate silk into their cocoons. Finally, whereas other social insects build nests gradually, expanding their size over time, *Microstigmus* construct their silken abodes all at once and so are limited to their confines until all cells in the nest are completed.

Mating Strategies

In 1960, a comprehensive review of the diversity of male apoid wasp behavior would have occupied a brief paragraph, but we now have a much better understanding of male behavior. Perhaps the best-known male behaviors are the so-called “sun dances” of sand wasps (Bembicinae) in which hundreds or thousands of males swarm over the surface of nesting areas seeking newly emerged virgin females (as in many species of *Bembix*). A variation on this theme sees males attempting to rendezvous with females at the point at which they emerge from the ground when they leave their natal nests (e.g., *Bembecinus quinquespinosus*, *Bembix rostrata*, and *Glenostictia satan*).

In other species, males defend discrete territories that are often plots of ground in emergence or nesting areas, as is the case for *Sphecius* (cicada-killers) and many *Philanthus* (beewolves). Or males may defend individual nests that are in the process of being provisioned by females (as in some *Trypoxylon* and *Oxybelus*, for example). Less commonly, males establish territories at hunting sites frequented by females (e.g., *Aphilanthops subfrigidus* which defend territories in mating swarms of prey, and *Mellinus rufinodus* which defend feces that attract flies hunted by females). In yet other species, territories are situated in locations that have no other apparent attractiveness to females other than the presence of the males themselves (e.g., *Eucerceris flavocincta*, *Philanthus basilaris*). While defending their territories, male wasps may engage in rowdy battles that involve, depending on the species, wrestling, biting, head butting, abdomen slapping, or mutual flights in which the contestants swirl about one another at dizzying speeds. One should not be left with the impression, however, that males of any given species have just one way to find a mate, as alternative mating tactics are common. Male *Stictia heros*, for example, may patrol the nesting area in the morning, but shift to defending territories later in the day. And some males of *Philanthus zebratus* patrol the air space above the nesting area, while others simultaneously defend scent-marked territories nearby.

Ultimately, it appears that in most cases it is the females that control which males are successful. Females, after all, are usually the larger sex, so are physically dominant to males (and in the case of *Philanthus basilaris*, may even prey upon them). So mating is sometimes, though not always, preceded by obvious courtship activities during which the male induces the female to copulate. This, however, is one of the least-studied aspects of apoid wasp reproductive biology.

Economic Significance of Apoid Wasps

A least one genus of apoid wasps, *Larra*, whose females prey on mole crickets, includes species that have found some success as biological control agents. Other genera contain species that may provide some natural control of pests such as aphids (*Passaloecus*), biting flies (*Bembix*, *Stictia*), cutworms (*Podalonia*), grasshoppers (*Prionyx*, *Tachysphex*), Mormon crickets (*Palmodes*), and leafhoppers (many genera). On the negative side of the ledger, apoid wasps can be a nuisance to those people that cannot abide the presence of a wasp, no matter what its activities. In North America, large territorial males of the cicada-killer wasp, *Sphecius speciosus*, sometimes bother homeowners and park visitors who mistake male investigatory flights for something more hostile. The large nest mounds of female cicada-killers that appear in otherwise immaculate lawns are considered unsightly by some. In Africa, *Palarus latifrons* and *Philanthus triangulum* can be outright pests when large numbers of females invade apiaries and decimate worker honey bee populations. And we know very little about the potential effect of apoid wasp predators on the biology of other beneficial insects such as native pollinators and biological control agents.

Apolysal Space

During molting, a very small space is created by the separation of the epidermis from the old cuticle. This space, called the apolysal space, contains molting fluid during the process of cuticle digestion.

Apolysis

Separation of the epidermal cells from the inner surface of the endocuticle. This is the first step in the process of molting.

Apomorphic

A character that is derived and not ancestral.

Apomorphy

When considering classification and phylogeny, a derived character state.

Apophysis

An internal or external elongate projection of the body wall.

Apoprogonidae

A family of moths (order Lepidoptera). They also are known as African skipper moths.

Aposematism

HEATHER J. MCAUSLANE
University of Florida, Gainesville, FL, USA

Aposematism is a strategy used by many organisms that increases their conspicuousness, and alerts or warns potential predators of their toxicity, their ability to inflict pain or, more simply, their unpredictability. Insects have evolved this strategy to a high degree, although it is found occasionally in other terrestrial organisms such as snakes, lizards, and frogs, and in aquatic organisms such as nudibranches. Aposematic signals usually are visual in nature and involve bright and contrasting coloration, usually black and red, yellow or orange or black and white. Visual signals may be enhanced by certain odors, sounds or behaviors, presenting a multimodal signal that predators may recognize and learn more easily.

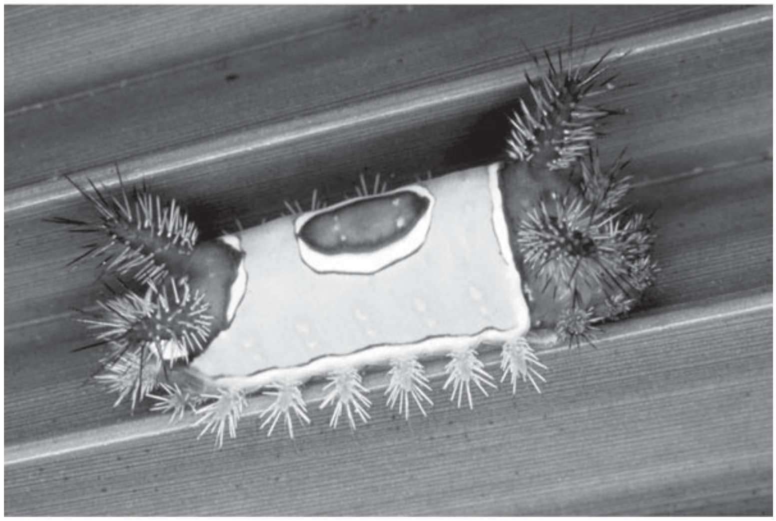
Visual aposematism as an antipredator strategy only works well against predators with color vision and good learning ability. Birds, and to a lesser extent lizards and amphibians, are the most common predators for which aposematic coloration (Figs. 66 and 67) is an effective deterrent. The naïve predator associates the particular color pattern of an aposematic organism with the unpleasant after effects of eating or attempting to eat it. Aposematic insects usually back up their warning signal with chemical defenses (unless they are harmless mimics of another toxic organism). These chemical defenses may be toxins that are stored inside the insect's body that could cause death if ingested and absorbed by the predator. However, the toxins themselves often are emetic (for example, cardiac glycosides in the Monarch butterfly, *Danaus plexippus*, and lucibufagins in *Photinus* fireflies), meaning that they cause the predator to regurgitate the prey item before a lethal dose of the toxin has been absorbed. The toxins also are often bitter so that the predator is less likely to pursue the attack once the bitter compounds have been contacted. In other insects, toxins are not stored within the body but are injected into predators through sharp urticating hairs or spines (for example, larvae of the saddleback moth, (Fig. 68) *Sibine stimulea*). In these insects, the predator is warned of the prey item's distastefulness without having to breach the cuticle of the aposematic organism.

The naïve predator may need only one trial to associate the color pattern of the aposematic insect with emesis or a bitter taste but more often, learning takes several trials. The speed of learning can be enhanced in several ways. If the predator encounters several toxic insects with the same aposematic pattern within a short period of time, it appears to learn the warning

Aposematism, Figure 66 **Aposematic insects are often aggregated, perhaps increasing the rate at which predators associate aposematic coloration with toxicity. The orange and black larvae of the oleander caterpillar, *Syntomeida epilais* (Ctenuchidae), aggregate in the early instars on oleander, *Nerium oleander*, a plant containing heart poisons (cardiac glycosides) (photo by James Castner).**

Aposematism, Figure 67 **The black and white larvae of the Giant African Skipper (Hesperiidae) also aggregate on their host plant (photo by Andrei Sourakov).**

coloration faster. This may explain why aposematic insects are often gregarious, living in small, usually related, groups. For example, oleander caterpillars, *Syntomeida epilais* and oleander aphids, *Aphis nerii* live gregariously on oleander which contains heart poisons. Other factors that can increase the rate of learning are the pairing of the visual pattern with acoustic signals or olfactory signals. Many aposematic insects hiss, stridulate or make some other noise when predators attack them. Arctiic moths and lubber grasshoppers, *Romalea guttata*, commonly do this. The association of sound with the color pattern and bitter chemical toxins in the aposematic



Aposematism, Figure 68 **Larvae of the saddleback moth, *Sibine stimulea* (Limacodidae), advertise their urticating hairs with a pronounced brown and white "saddle" on the lime-green bodies (photo by James Castner).**

insects help the predator better remember the color pattern. We are becoming increasingly aware that many insects release volatile pyrazine compounds when under attack. These nitrogen-containing compounds are extremely odorous at low concentrations and are thought to produce a universal warning odor in plants and animals.

Insects that are aposematic often exhibit what we might call bold behavior, at least for an insect. They are usually active during the day and are not cryptic, rather feeding in an exposed position. Aposematic adults may have an exaggerated slow flight, as do *Heliconius* butterflies and many arctiid moths. Larvae may wave tentacles and other long protuberances from their body to warn predators. Larvae of the Monarch butterfly (Fig. 69) integrate aposematic behaviors into their multimodal signal to warn of their toxicity. In addition to being conspicuously striped white, yellow and black, they release pyrazine from the head collar region when roughly handled and nod their heads up and down every 2 s while simultaneously twitching their anterior filiform tentacles.

Aposymbiotic

Separated from its symbiotes, or symbiote-free; this usually refers to mutualistic symbiotes.

(a)

Aposematism, Figure 69 **Larvae of the Monarch butterfly, *Danaus plexippus* (Danaidae), use a multimodal signal to warn potential predators. Their aposematic coloration of black, white, and yellow stripes is enhanced with the release of pungent pyrazine and the behavioral display involving rhythmic nodding of the head and twitching of the filiform tentacles (photo by Lyle Buss).**

Apotome

A narrow anterior portion of each abdominal sternum, separated by a fold from the rest of the plate. They are present in Apterygota, but indistinct in Pterygota.

► Abdomen of Hexapods

Apparent Resources

Food resources (either insect or plant) that are "easy to locate" or apparent to potential predators or herbivores. Apparent resources often are protected against consumption by generalist and specialist predators, and generalist or specialist herbivores, by possessing broadly effective (though metabolically expensive) chemical defenses such as digestibility reducing substance (contrast with unapparent resources).

Appeasement Substance

A secretion presented by a social parasite that reduces aggression by the host insects, and aids parasites in being accepted as members of the colony.

Apple Maggot

► Apple Pests and their Management

Apple Pests and their Management

ARTHUR M. AGNELLO
New York State Agricultural Experiment Station, Geneva, NY, USA

Insects with chewing mouthparts inflict great damage on foliage, causing leaves to be skeletonized, riddled with holes, eaten around the edges, or entirely consumed (e.g., larvae of moths, sawflies, and beetles). Other insects suck sap from leaves, stems, or other plant parts, producing a characteristic spotting or browning, curling, or wilting. Feeding on stems or twigs results in dwarfing or wilting. Damage is caused both by removal of the sap and by injury to the plant tissue (e.g., scale insects, aphids, and true bugs). Also included in this category (Fig. 70) are mites, such as the European red mite and the two-spotted spider mite, which damage the leaves by piercing the cell walls with bristle-like mouthparts and ingesting their contents, including the chlorophyll. The injury results in off-color foliage that, in severe cases, becomes bronzed.

Scale insects are usually minute, but if they are abundant enough to encrust bark, twigs, or stems they can kill orchard and shade trees. Aphids produce a curling of the leaves and, when feeding on fruit, may cause it to be stunted or misshapen and may change the sugar content, greatly impairing the flavor.

Many insects feed as miners in leaves or as borers in stems, roots, or fruits. Feeding between the upper and lower surfaces of the leaf may cause as much defoliation as external feeding. There are about 500 leafmining species in the United States (e.g., spotted tentiform and apple blotch leafminers).

Tunneling causes serious damage. Insects that tunnel into fruit include codling moth, oriental fruit moth, apple maggot, and plum curculio. Damage with more serious consequences can be done by insects that tunnel into the tree trunk, bark, or foliar shoots, such as apple-boring beetles (roundheaded, flatheaded), dogwood borer, American plum borer, European corn borer, and oriental fruit moth.

Injection of a chemical into plant tissues while the insect feeds causes abnormal growth (e.g., rosy apple aphid) or produces a gall (woolly apple aphid). Each species of gall insect produces a characteristic gall on a certain part of a particular plant.

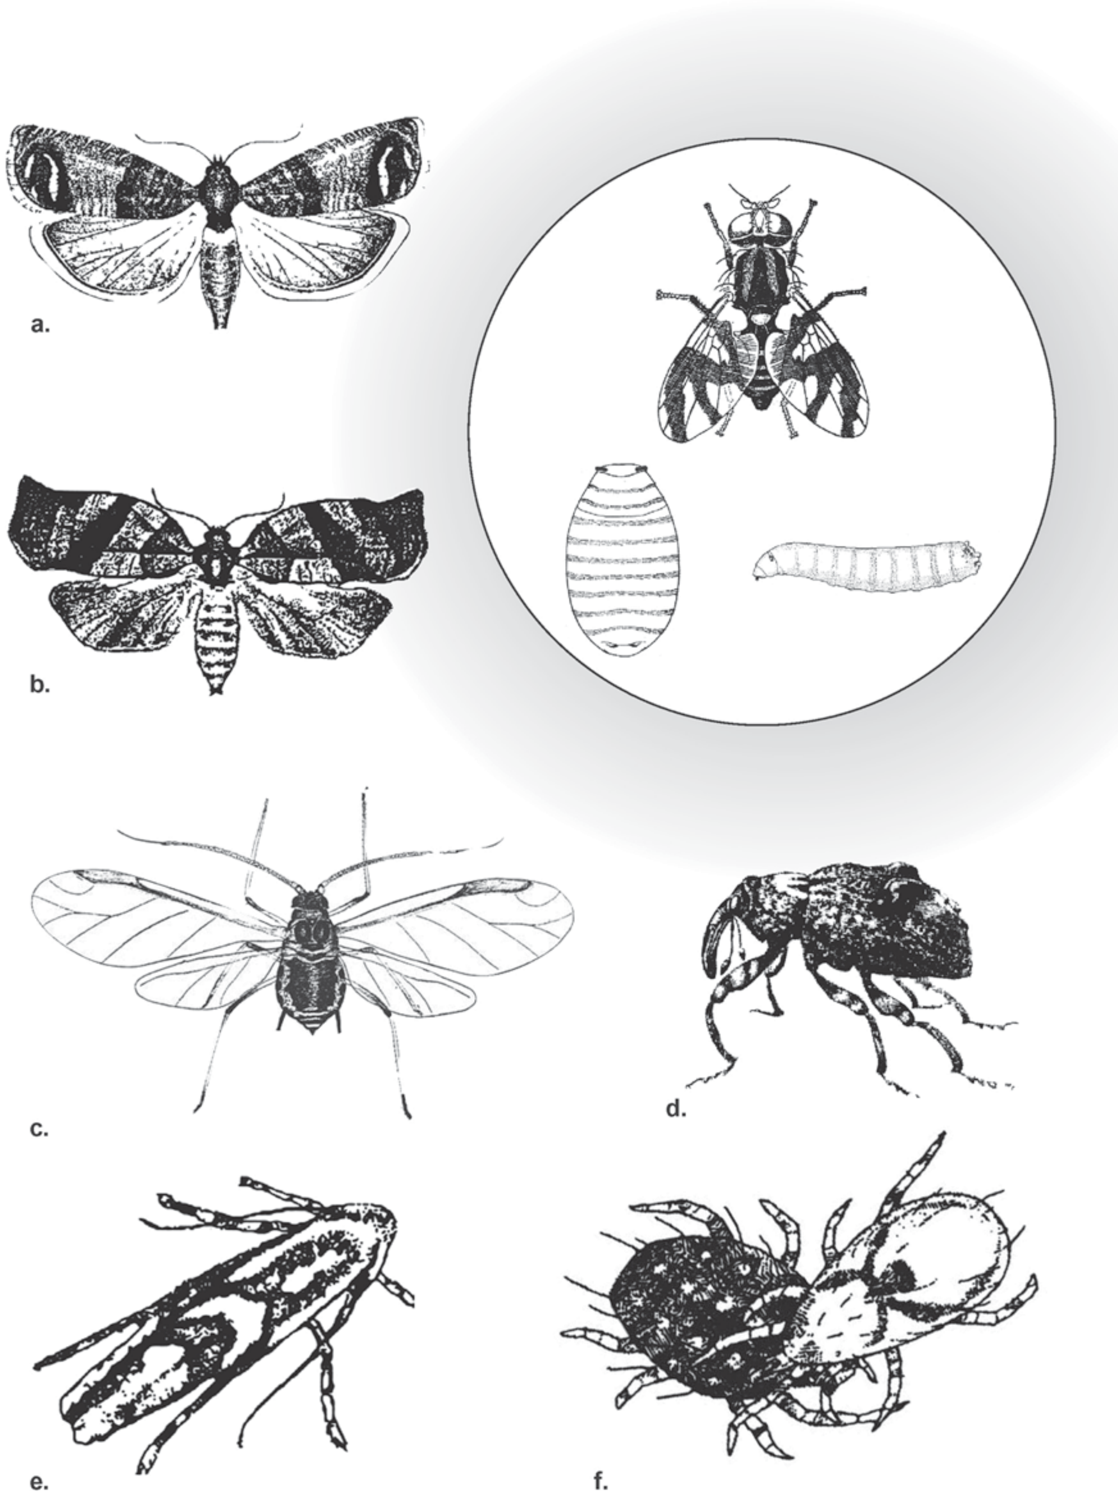
Insects at the larval and nymphal stages (e.g., woolly apple aphid) that live in the soil and attack the underground plant parts cause extensive damage.

Shelters in plants are built by leafrollers and leaf folders, which roll or fold the leaves and tie them with silk, feeding in the shelter so formed. Leaf tiers and webworms tie several leaves or even entire branches together, producing large silken webs or tents.

A few insects injure plants when they lay their eggs, particularly in stems or fruits (e.g., plum curculio, apple maggot, periodical cicadas, tree crickets, leafhoppers).

Major Economic Pests

Early researchers in New York estimated nearly 500 species of insects known to feed on apple. Fortunately, only a relatively small number of these ever reach economic pest status. A survey conducted in the northeastern U.S. identified a



Apple Pests and their Management, Figure 70 **Some North American apple pests: (a) codling moth; (b) obliquebanded leafroller; (c) rosy apple aphid; (d) plum curculio; (e) spotted tentiform leafminer; (f) European red mite attacked by predatory mite; within circle, apple maggot adult, larva and pupa.**

total of 191 phytophagous (plant-feeding) insect species in managed and abandoned apple orchards. Most numerous were species of Lepidoptera (mostly moths and their caterpillars, 43%) and Hemiptera (leafhoppers, plant bugs, aphids and scale insects, 32%). Current tabulations of actual economic pests list just over 60 species in New York, approximately half of which are considered important enough to warrant specific control recommendations. This compares with 17 pest species for pear, 12 for peach, and seven for tart cherry and plum. A similar accounting in other production regions reveals certain species with a worldwide distribution, and others, largely representing the above major orders, that are prevalent only in specific areas (Table 9). The following are some of the key pests in the northeastern U.S. growing regions.

Rosy Apple Aphid, *Dysaphis plantaginea* (Passerini)

Biology and Impact

The rosy apple aphid is the most damaging of the aphids that attack apple. Its saliva, injected while feeding, is translocated to nearby fruit, causing leaf curling and small, deformed apples. The rosy apple aphid can be distinguished from other aphids by its long cornicles and purple-rose color. It overwinters as an egg on twigs, in bud axils, and in bark crevices. The overwintering eggs of the rosy apple aphid are oblong and pale green at first, then turn shiny black. Rosy apple aphid nymphs are visible beginning around the tight cluster bud stage but are most easily observed at the pink bud stage. The first adults appear around bloom. Second-generation adults appear two to three weeks after petal fall. Some of these move to alternate hosts (such as narrowleaf plantain) and the rest remain in the orchard. The third generation develops by mid-July and moves to alternate hosts. In later summer, adult rosy apple aphids return to the trees to lay eggs.

Decision Making

Because rosy apple aphid populations are highly variable, it is important to assess their densities before making a treatment. Sampling can begin at the tight cluster bud stage but is better done at the pink stage when rosy apple aphid nymphs are more easily seen. Rosy apple aphid densities are estimated by sampling 10 fruit clusters from the interior canopy area of 10 trees. Treatment is generally recommended if one infested cluster is found, but for experienced samplers of rosy apple aphids, this is probably too conservative and a threshold of three to five infested clusters would be more appropriate.

Control

It is not known how important natural enemies (such as larvae of the fungus gnats, Cecidomyiidae) are in regulating rosy apple aphid populations. Several pesticides can effectively control this pest when applied at the pink bud stage. A material should be used that will conserve natural enemy populations, such as *Typhlodromus pyri*, an important mite predator.

Spotted Tentiform Leafminer, *Phyllonorycter blancardella* (Fabricius)

Biology and Impact

The spotted tentiform leafminer was introduced from Europe in the 1880s. Its host plants include apple, wild cherry, hawthorn, quince, plum, and crabapple. Spotted tentiform leafminer overwinters as a pupa in leaf litter on the ground. Adults emerge at the green tip apple bud stage and lay small, flattened eggs that are deposited singly on leaf undersides. Egg laying begins when leaves unfold after the half-inch green bud stage, and deposition is nearly complete by the end of the pink bud stage. Its five larval stages are divided

into sap-feeders (instars 1–3) and tissue-feeders (instars 4–5). The second-generation adults begin emerging in early June in the northeastern states (average date is June 13 ± 8 days), and larvae are usually present in early July. Third-generation larvae are usually present in late August.

The spotted tentiform leafminer damages only foliage, which the larvae eat and mine. This causes reduced photosynthesis and possibly sequestered nutrients. Foliar damage can cause smaller fruit size, premature drop, and poor color. Damage caused by the second generation is usually of the greatest concern. Third-generation leafminers usually are not a problem if the second generation was controlled properly.

Decision Making

A sequential sampling plan can be used to classify spotted tentiform leafminer egg density at the pink stage or the density of sap-feeding mines immediately after petal fall. Treatment is recommended if eggs average 2 or more per leaf on leaves 2, 3, and 4 of a fruit cluster at the pink stage, or if sap-feeding mines average 1 or more per leaf on these leaves at petal fall. Sampling can be completed in approximately 10 min.

Proper timing is essential for both the assessment of second-generation leafminer densities and control, if required. If done too early, sampling will underestimate the population. If control is applied too late, it will not be effective. Sampling for "sap-feeding mines" should be done at approximately 690 degree-days (base 43°F) after the start of the flight of the second generation. On average, second-generation spotted tentiform leafminer moths begin flying in early to mid-June. A decision regarding the third generation is generally not required unless the density of the second brood exceeds two mines per leaf.

Control

Many parasitoids effectively limit spotted tentiform leafminer populations in some orchards. Most important are the wasps *Apanteles ornigis*, *Sympiesis marylandensis*, and *Pnigalio maculipes*. Insecticide sprays applied in July and August probably do the most harm to these natural enemies. Some leafminer pesticides are effective without being toxic to natural enemies such as mite predators. Depending on the product chosen, application can be made any time from initial egg deposition until the larvae enter the tissue-feeding stages.

Obliquebanded Leafroller, *Choristoneura Rosaceana* (Harris)

Biology and Impact

The oblique banded leafroller prefers plants in the Rosaceae family but will feed on many unrelated deciduous trees. This leafroller overwinters as a second-or third-instar larva on the tree within closely spun cocoons or hibernacula. Larvae become active in the spring when buds begin to open. As foliage pushes from the buds, larvae often tie leaves together and conceal themselves in the resulting chamber. Spring-generation moths emerge in early June in the northeast, with peak activity in mid-June. First-generation larvae complete their development in late July or early August. Summer-generation moths begin flying in early August. Second-generation larvae feed primarily on foliage, but may cause surface injury to fruit if they are very abundant. After feeding briefly, second-generation larvae enter their winter hibernacula.

Spring-generation larvae may eat away large portions of developing fruit. If the fruit survive, they are misshapen with large, deep cavities of healed-over injuries. Fruit damaged by first-brood larvae generally falls off the tree. If not controlled, this spring generation of obliquebanded leafroller may cause only small fruit losses (2–4%).

The principal impact of summer-generation obliquebanded leafroller is its feeding damage to the fruit. This generally occurs if a leaf is webbed to an apple or clustered apples touch each other. Feeding areas on the fruit are shallow, irregular, and may range from small punctures to large excavations. This injury is more serious than that caused by the overwintering generation because most injured fruits remain on the tree.

Decision Making

During bloom or immediately after petal fall, spring-generation larval densities can be classified as above or below a treatment threshold using a sequential sampling procedure. Treatment is recommended if more than 3% of fruit spurs contain live obliquebanded leafroller larvae. Sampling can usually be completed in approximately 10–15 min.

Sampling for the summer-generation larvae should take place approximately 600 DD (base 43°F) after the start of the first summer flight. On average, summer-generation obliquebanded leafroller moths start flying the first or second week of June. The value of knowing the precise date of this event on a local basis cannot be overemphasized. If information on adult moth flight is not available, July 5 to 10 is a rough approximation of the appropriate sampling period in the northeast. At 600 DD after the start of the adult flight, populations can be classified according to whether the average percentage of terminals infested with live larvae is greater than 3%.

Control

Several parasitoids attack the obliquebanded leafroller, but their effectiveness in regulating leafroller populations in commercial orchards is largely unknown. Most growers favor chemical sprays to reduce damage caused by this insect. A contact insecticide is sometimes applied at bloom to petal fall. Most orchards with a history of leafroller infestation require 1–2 pesticide applications against the second-generation larvae. Selective pesticides, including insect growth regulators and those that are based on the bacterium *Bacillus thuringiensis* are compatible with IPM because they are not toxic to natural enemies (especially mite predators).

European Red Mite, *Panonychus ulmi* (Koch)

Biology and Impact

The European red mite overwinters as an egg on the tree. Egg hatch is usually closely correlated with tree phenology, ordinarily beginning at the early pink bud stage and continuing into bloom. If egg hatch does not coincide with the pink stage, it is usually delayed and starts during early bloom. European red mite adults normally appear by petal fall, but few eggs are laid by the first generation of adults on leaves until the first week after petal fall. Early hatching European red mite nymphs feed on older fruit cluster leaves and may cause bronzing by petal fall if populations are high. Early season damage before petal fall is usually insignificant, but some studies have shown that heavy damage in early to mid-June can reduce yields during the next season.

In the summer months, the European red mite damages apple leaves by inserting its mouthparts to feed on plant juices. This injury reduces the capacity of the leaf to use sunlight as an energy source (photosynthesis), which may lead to reduced yield and fruit quality. Recent studies of European red mite impact have found that the only effect of moderate European red mite injury during the mid- to late season was a reduction in the color of some red varieties of apples. These results have identified the densities of mites that can be tolerated at various times of the growing season.

Decision Making

The natural mortality of overwintering eggs can be substantial but is highly variable (10–to 60%). Therefore, sampling or rating schemes are generally not used for predicting the potential early season severity of the European red mite in commercial orchards by assessing the density of overwintering eggs. During late bloom and petal fall, the European red mite is concentrated on older fruit cluster leaves, and therefore the overall density of the first generation will be overestimated by counting mites on the oldest leaves at that time.

Early control of the European red mite is essential to prevent early season damage during the postbloom period. One method used to quantify mite presence is the "mite-day" concept, which measures the number of mites and the period of time they are present on the leaves. One mite-day is equivalent to an average of one mite feeding on a leaf for one day. Thus 10 mite-days can be accrued by one mite feeding on a leaf for 10 days or 10 mites feeding for one day. The current economic threshold of approximately 550 total mite-days (for the growing season) assumes that no significant accumulations of mite-days occur before mid- to late June. Therefore, a protective prebloom oil treatment is currently recommended for control of early season European red mites.

During the summer, the need for a miticide to control the European red mite can be determined from a sample of the mite population in an orchard. A sampling procedure is available that determines mite presence based on examination of leaves of intermediate age. This procedure divides mite populations into three categories: greater than threshold, below threshold, and much below threshold. The last two categories provide an indication of when the population must be sampled again. If the density is much below threshold, the population should be sampled in 11–16 days. If it is minimally below threshold, it should be sampled again in 6–10 days. If mite predators are present, these intervals can be lengthened by approximately 50%.

Sampling involves recording on a chart the presence or absence of mites in distinct samples of leaves and continues until a decision on whether to treat them can be reached. From petal fall until June 30, a threshold of 2.5 mites per leaf is used. From July 1 to 31, the threshold is 5 mites per leaf. From August 1 to 15, a threshold of 7.5 mites per leaf is used. Treatment for mites is not currently recommended after mid-August. Adherence to these thresholds will prevent serious injury.

Control

The European red mite is an induced pest in commercial apple orchards. This means that pesticides used against other arthropods usually destroy naturally occurring mite predators, allowing European red mite numbers to increase to damaging levels. Several major predators of the

European red mite may be found in commercial orchards, depending on the part of the country where they are located:

Typhlodromus pyri (Scheuten)

Adults of *T. pyri*, a major predacious mite species, are present in the tree at about the time of the European red mite hatch. These predators control low to moderate densities of European red mites but do not regulate high populations. This mite predator is very effective against the European red mite and when present in substantial numbers it will eliminate the need for chemical mite control. *T. pyri* spends its entire life in the tree, overwinters as an adult female, and is active by bloom. It prefers to feed on the European red mite but will sustain itself on other food sources. Once established in an orchard, if it is not disrupted by pesticides, *T. pyri* will keep European red mite populations to densities of less than one mite per leaf year after year. It may take two to three years for *T. pyri* to become abundant in an orchard once a selective pesticide regimen is adopted.

Amblyseius fallacis (Garman)

A. fallacis is also an effective predator of the European red mite, but its continued presence in the tree from year to year is not reliable. It overwinters both in apple trees and in the ground cover beneath them. Ground cover, however, appears to have little influence on number and movement of *A. fallacis* in the tree. *A. fallacis* was previously believed to a poor biological control agent because it did not move into the trees until late in the growing season after the European red mite had reached problem levels. More likely, *A. fallacis* numbers often remain low until late in the season because pesticides toxic to them are used early in the season. If a site has a history of *A. fallacis*, pesticides should be managed to conserve it. Because *A. fallacis* remains in the tree year-round, even early season applications of pyrethroids are damaging to it.

Metaseiulus occidentalis (Nesbitt)

Predominantly found in drier climates such as the northwestern states, this predator can also provide biological control of the European red mite in commercial apple orchards. It has high reproductive and prey consumption rates, and disperses readily into orchards. However, it requires the presence of an alternative prey population in the orchard, such as apple rust mites, to preserve its population numbers when red mites are at low levels.

Zetzellia mali (Ewing)

This minute yellow mite is present in nearly all orchards, overwintering as a gravid female in concealed parts of the tree. Although it prefers older rust mites and the eggs and immature stages of European red mites and two spotted spider mites, it feeds on all stages of these species. It undoubtedly helps to control European red mites but is of little benefit if it is the sole predator species present.

Stethorus punctum (Leconte)

This small, black ladybird beetle feeds on several small arthropods, including European red mites. It is more common in orchards in the middle Atlantic states. Success in controlling European red mites depends on keeping a relatively high population of European red mites in the tree (3–5 mites per leaf).

For chemical control during the early season, petroleum oil is often recommended (a 2% solution at the half-inch green bud stage or 1% at the tight cluster stage) as an early season IPM program. Oil is relatively safe to predators, relatively economical, and European red mite populations have never shown resistance to it. Furthermore, a thorough application of oil applied before foliage is fully developed can kill nearly all the eggs present. Other early season treatment options include contact miticides or ovicides applied at the pink bud stage or at petal fall. Miticides will likely cover less of the foliage present by this time, and most are able to be overcome by the development of resistance in local mite populations, so this is a less desirable alternative.

Relatively few miticides can control European red mite during the summer. The available contact miticides must be chosen by their individual performance traits, including their activity against specific mite stages and beneficial arthropods, rate of action and length of residual effectiveness, optimal application conditions for each, and any possible resistance that may be exhibited by local mite populations. Because of the limitations of all contact miticides, good spray coverage is essential.

Some research has been done on the use of highly refined petroleum oils to control summer mite populations. Acceptable season-long control has been achieved by using a multiple-spray program starting at petal fall, followed by periodic monitoring throughout the summer. Potential difficulties with this approach include leaf damage and incompatibility with some of the fungicides used to control summer diseases.

Plum Curculio, *Conotrachelus nenuphar* (Herbst)

Biology and Impact

Plum curculio adults move into orchards from overwintering sites in hedgerows or the edges of woods and are present in the trees from the late pink stage to early bloom before the fruit is susceptible to damage. Adults are active in the spring when temperatures exceed 60°F. Adult females oviposit in fruit during both day and night but feed mostly at night. Depending on temperature, overwintering adults remain active for two to six weeks after petal fall.

Although adults may feed on blossoms, apples are not susceptible to damage until petal fall, at which time adults damage fruit by both feeding and ovipositing. Unlike fruit injured by other pests, many apples damaged by plum curculio will remain on the tree until harvest. Because adults are not highly mobile, orchards near overwintering sites, woodlands, and hedgerows are most susceptible to attack. Fruit damage is usually most common in border rows next to sites where adults overwinter.

Decision Making

Monitoring for the plum curculio is not often recommended because of the amount of time and labor involved and because it is generally assumed to be present in every orchard where populations are endemic. Nonetheless, various techniques have been used to monitor plum curculio damage and the presence of adults:

- Clubs or shakers can be used to jar adults from limbs into catching frames or cloths for counting.
- Polyethylene funnels hung under branches can be used to capture adult PC.
- Immature "scout apples" hung in trees near the edges of orchards serve to measure oviposition scars before petal fall so potential damage can be estimated before control sprays are applied.
- Oviposition scars on immature fruit can be counted in orchards starting at petal fall to estimate damage. Because substantial oviposition and damage can occur even after a single warm day and night, frequent scouting for damaged fruit is necessary after petal fall.

Control

Several species of wasps parasitize the eggs and larvae of the plum curculio. Ants, lacewings, and ground beetles prey on larvae in the soil, and some fungi kill larvae. These organisms are not usually sufficient to regulate populations of plum curculio in commercial orchards.

The plum curculio is difficult to control completely with insecticides. Relatively high rates and persistent applications are important because adults may be active for two to six weeks after petal fall depending on temperatures. Several commercial products are available to control this insect. In normal orchards that are not near woodlots or hedgerows and have not suffered previous damage, a single application at petal fall will provide seasonal control. In problem orchards, a petal fall application followed by a second spray 10–14 days later will provide adequate control. In orchards with chronic problems, or in seasons when adult activity is prolonged by unusually cool and wet weather, two cover sprays applied 10–14 days apart after petal fall may be necessary to prevent late damage. Research on heat unit accumulation and plum curculio oviposition has proposed that control sprays are no longer necessary whenever the last spray has been applied within 10–14 days after the accumulation of 340 DD (base 50°F) from petal fall.

Codling Moth, *Cydia pomonella* (Linnaeus)

Biology and Impact

The codling moth overwinters as a larva in a cocoon under loose bark on the tree trunk. Adults emerge during bloom, and the first flight continues until about 30 days past petal fall. Eggs, laid singly on the upper surface of leaves or fruit, start to hatch at petal fall and continue for two to three weeks. Larvae feed only on fruit. Surface bites, referred to as stings, cause blemishes, and deeper injuries are caused by feeding inside the fruit. Fruits injured by extensive internal feeding usually drop in the middle of June at which time early season damage becomes noticeable.

Adults from the second or summer generation of codling moth start to fly about mid-July, and the peak flight occurs around the first week in August. Larvae from this generation are active in fruit throughout August. Fruit damage by second generation larvae is generally more serious than that of the first.

Decision Making

Adult males can be captured in pheromone traps, but numbers of males captured in these traps cannot be related to potential fruit damage. Thus, pheromone traps are used only to monitor the seasonal activity patterns of adults within an area. It is not practical to monitor commercial apple orchards for CM eggs or larval fruit entries because of the theoretical zero tolerance for internal fruit damage. Developmental models, based on temperature accumulations after the first catch of males, can be used to predict the first egg hatch of codling moths. This approach is used to time initial control sprays for the codling moth at 250–360 DD (base 50°F) after first adult catch for the first generation, and 1260–1370 DD after this same biofix date for the second generation.

Control

The codling moth is attacked by both parasites and predators, but these natural enemies cannot effectively control this pest in commercial orchards. To kill the larvae before they enter the fruit, chemical sprays for the codling moth must be initiated before the eggs hatch. The codling moth is most effectively controlled by the same conventional insecticides used against the plum curculio, but it can also be controlled by more selective pesticides such as bacteria (*Bacillus thuringiensis*), insect growth regulators, viruses, and botanicals, although many of these products are less effective than standard insecticides.

Apple Maggot, *Rhagoletis pomonella* (Walsh)

Biology and Impact

The apple maggot overwinters as a pupa in the soil. Adults from the single annual generation of flies emerge in late June to early July. Females cannot lay eggs until they become reproductively mature, 7–10 days after emergence. Females lay eggs in fruit and the larvae develop there, emerging in the autumn after the fruit has fallen and entering the soil to pupate. Flies are active from July to mid-September, but commercial orchards require protection only from about mid-July through August. Flies do not reach orchards in large numbers until mid-July, and before this date, fruit remaining on the tree is unfavorable for larval development so early infestations do not cause sustainable populations in the orchard. In addition, for unknown reasons, fly activity between late August and mid-September generally does not result in serious damage in most commercial orchards.

Larval tunneling inside fruit causes it to become rotten and unmarketable. Early stings caused by punctures from female ovipositors may severely deform the fruit of some varieties, even though no larvae survive.

Decision Making

Monitoring to determine whether control sprays are necessary is recommended only in orchards that are not near large sources of outside infestation, such as abandoned orchards or those with no indigenous infestations of flies. In early to mid-July, red sphere traps baited with apple volatile lures are hung in trees along the edge of the block closest to an abandoned orchard or a stand of woods. These traps are checked one to two times per week. A spray of a suitable insecticide is applied if a cumulative average of 3–5 apple maggot flies per trap is captured. After spraying, trap catches are not checked again until after a 10 to 14-day period, during which spray residues would kill any immigrating flies.

Theoretically, there is absolutely no tolerance for apple maggot damage in fruit. In practice, apple maggot damage is not usually detected in normal fruit inspections unless there is approximately 3% fruit damage.

Control

Small wasps parasitize apple maggot larvae in fruit, and predators such as birds and crickets may eat larvae or pupae in or near the soil. In natural, unsprayed apple and hawthorn trees, apple maggot populations are not regulated by natural enemies. Parasites and predators are also ineffective at controlling apple maggot in commercial orchards.

Apple maggot flies have a limited migratory capability, so all apple and hawthorn trees within 1/4 to 1/2 mile of commercial orchards should be removed if possible. Dropped fruit should not be allowed to remain beneath the tree for more than one or two days. Eliminating fruit drops will break the life cycle of flies in an orchard by preventing larvae from exiting the fruit and entering the soil.

Apple maggot flies can be trapped in small, well-pruned trees that are not near large sources of outside infestations. A relatively high density of sticky red spheres (plain or volatile-baited) is required, approximately 1 trap per 100 apples. Mass trapping is usually less effective than chemical control, and apple maggot may still damage 1–5% of fruit from mass-trapped orchards.

Most commercial orchards have no indigenous populations of flies. Therefore, chemical control sprays are usually directed against flies immigrating into orchards from outside, unsprayed hosts, including both apples and hawthorns. Most broad-spectrum insecticides are remarkably effective in controlling adults. Insecticides must kill females before they oviposit in the fruit. Residual effectiveness of insecticides is particularly important in controlling apple maggot in commercial orchards when flies are continuously immigrating.

Aquatic Entomology and Flyfishing

JOHN R. WALLACE, FRANK D. L. RINKEVICH
Millersville University, Millersville, PA, USA

The use of aquatic insects as lures for fish dates back to the second century A.D. In the seventeen volume treatise, *De Animalum Natura*, the Roman Aelianus discussed his observations of fish consuming insects at the water surface and how Macedonian fishermen used dry flies or spinners to catch what were thought to be trout from the Astraeus River. Not until fifteen centuries later did Charles Cotton propose the utility of aquatic insects in fishing. In 1836, Alfred Ronald's *Fly Fisher's Entomology* was published. This publication elaborated on fly tying methods and fishing techniques from an entomological perspective. Most recently, fly anglers are attempting to increase their knowledge about insects, specifically aquatic insects, in terms of imitating fish food items or "matching the hatch." This quest for entomological knowledge by anglers, in addition to aquatic scientists and fish managers, has prompted the need for better taxonomic and ecological treatments friendly to both the scientist and the angler. In order to create a functional artificial imitation of an insect to improve one's chances of catching a trophy fish, the angler requires basic identification, ecological and behavioral information of both insects (prey) and fish (quarry).

Terminology: Entomology Versus Flyfishing

As with many fields of scientific study, understanding the complexities of both entomology and fly fishing requires an understanding of both languages. While the term "fly fishing" technically refers to only one insect order, Diptera, in reality it encompasses all insect and non-insect invertebrates used as food by fish. Representatives from several orders of terrestrial insects (e.g., Hymenoptera, Orthoptera, Diptera, and Lepidoptera) are common food items of fish and are mimicked with artificial flies. However, aquatic insects are the primary interest of anglers and are the majority of fly patterns mimicked. For example, there are thirteen orders of insects that are classified as aquatic. Only 3% of all insects have a life stage in an aqueous environment. Some of these orders are entirely aquatic whereas others have a few semi-aquatic representatives. Truly aquatic orders are those in which all of their members exhibit some portion of their life cycle in an aquatic habitat. The orders, Ephemeroptera (mayflies), Plecoptera (stoneflies), and Trichoptera (caddisflies) are examples of truly aquatic orders. Semi-aquatic orders are largely terrestrial with a number of families exhibiting life stages in or near water. Coleoptera (beetles), Diptera (flies), and Lepidoptera (butterflies) represent semi-aquatic orders.

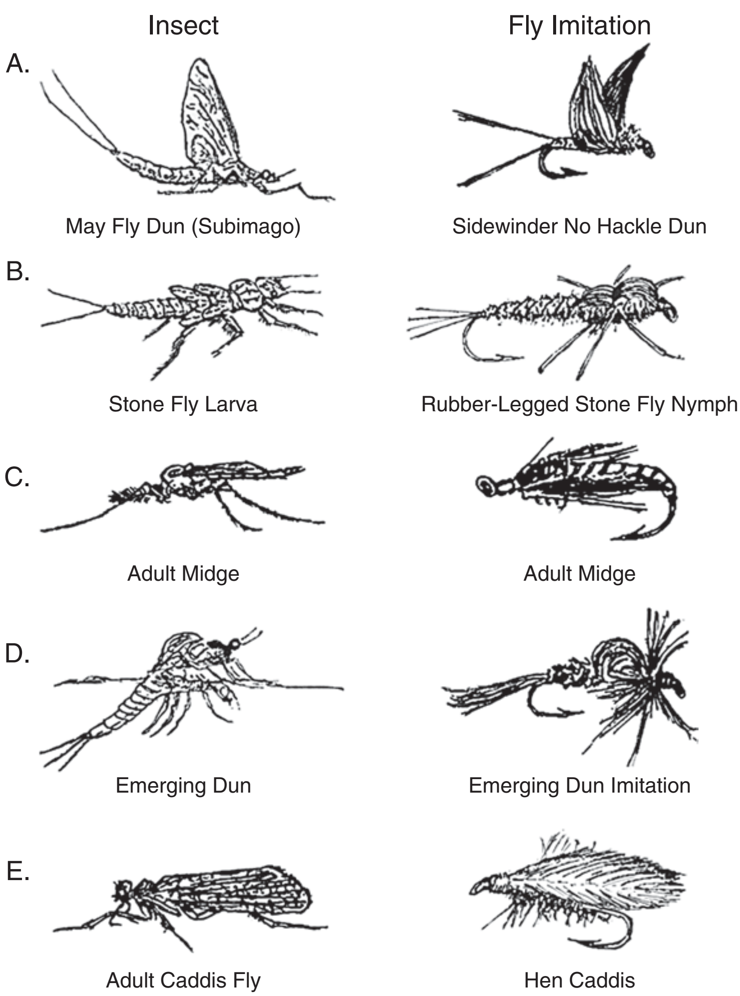
Typically, anglers refer to an emergence of insects (but more specifically to those with aquatic larval stages) as a "hatch." What the angler will call a nymph, the entomologist would refer to as the larval stage of an insect. Mayflies are the only group of insects that have a non-reproductive adult stage (the subimago); anglers refer to this stage as "duns." Post-ovipositing mayflies typically die with their wings spread on the water surface, and anglers term these "spinners," referring to the spinning action they exhibit while floating on the water surface. In addition, anglers refer to reproductively mature insects that end their life cycle on the water surface either by nature or that accidentally hop, fly or are blown onto the water surface as "dry flies." Fly patterns will mimic the larval and adult stages of both terrestrial and aquatic insects.

The sports angler often refers to insects by a number of colloquialisms. Educated fishermen often use the term caddis or caddisfly in reference to the order Trichoptera, fishflies for Megaloptera, and sandflies for some Diptera. Mayflies are known by a variety of names such as drakes or upwings.

Morphological Importance

Although the standard "mantra" of the dedicated fly angler is that the three most important aspects to catch fish are presentation, size and pattern, anglers must be familiar with many aspects of insect morphology. Most often, hand-tied flies incorporate the obvious features of the insect they are imitating. For many mayfly presentations, large characteristics such as wing size, caudal filaments, and body color are considered when tying flies. Small traits such as specific setation, paraglossae, and tarsal segments are often ignored largely due to their size relative to the insect and the investment of time that would be spent including these features in a fly. A fish will not recognize these small features because, at times, they may see the lure for only a few seconds.

Flies fit into two general classes based on their presentation. Dry flies are presented on the surface and signify the adult stage. Wet flies are fished below the surface and represent larvae. Success of the presentation is largely dependent on the time of the year. Presentation should mimic the natural life cycle of the native insects. A sample taken with a kick seine or observation of emergences will indicate what type of fly to use. An emergence of mayflies in the summer is the reason why an adult mayfly mimic presented on the surface may outfish a wetfly of a caddisfly. Several aquatic insect orders are often used as models for fly tying and as live bait. There are many fly imitations of caddisflies, mayflies and stonefly larvae (Fig. 71), as well as aquatic Diptera larvae and adults, due to their ecological importance of providing food for fish.



Aquatic Entomology and Flyfishing, Figure 71 A collection of common aquatic insects used as mimics for wet and dry artificial fly patterns. (A, C, D, and E = represent dry flies; B represents a wet fly or nymph). Illustrations by Mike Gouse (published in Swisher D, Richards C (1991) Emergers. Lyons & Burford Publishers, New York, NY).

Ecological and Behavioral Importance

Though fly fishing strategists argue over imitation vs. presentation, fly fishing tactics that employ ecological and behavioral aspects are as important as using a fly pattern based on the appearance of natural insects. Although insect abundance is important, fish will not eat the most abundant insect if it is not available to them. Three ecological aspects important in the availability of a particular insect include: stage of development, habitat use and activity (either associated with drift or foraging for food).

Although aquatic insect larvae are most abundant after hatching, they are not as available as fish food due to their small size and ability to avoid predators. In terms of energetics, a small insect is equivalent to small energetic payoffs. However, as aquatic insects grow and develop from one stage to the next they become more obvious to fish predators through their feeding activities. Thus, availability increases as insects grow and develop. Emergence for aquatic insects is a risky task. It is these emergers that are most available as they struggle to reach the water surface, plant stem or emergent rock from which they attempt to emerge as adults. Fish will concentrate feeding efforts on emerging insects if the adult stage escapes quickly. Those adult insects, both terrestrial and aquatic, that expire on the water surface are readily fed upon by fish.

Aquatic insects inhabit a wide variety of microhabitats within a given stream or pond, including rock or log surfaces, on plant stems or other submerged vegetation, as well as swimming openly in the water column. Habitat use by aquatic insects is relative to their needs. For example, foraging for food may put an insect in a different microhabitat other than used during non-feeding periods. Some mayflies may exhibit this behavior switch. Diel feeding activities among Phantom midges (Chaoboridae) also is an example of this type of behavior. Finally, phenological aspects of aquatic insect activity related to emergence, drift and oviposition increase insect availability. Some of these ecological/behavioral phenomena are tied to weather changes, lunar activity, water temperature and current regime.

Viruses transmitted by arthropods. This is an acronym for ARthropod-BOrne VIRUSes.

Archaic Bell Moths (Lepidoptera: Neopseustidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

Archaic bell moths, family Neopseustidae, include nine known species (six from Southeast Asia and three from Chile). The family forms a monobasic superfamily, Neopseustoidea, and the only member of the infraorder Neopseustina, of the suborder Glossata and subcohort Myoglossata. Adults small (14–27 mm wingspan), with head roughened; haustellum short, with vestigial mandibles; labial palpi 3-segmented and somewhat upcurved; maxillary palpi 5-segmented; antennae are mostly rather long and somewhat thickened. Maculation is pale, usually translucent with gray spots, and wing shapes rather broad and quadrate. When resting the wings are held in a rounded shape that resembles a bell. Adults are crepuscular or diurnal. Biologies and larvae remain unknown, but species in Chile are thought to possibly feed on native bamboos.

Archaic Sun Moths (Lepidoptera: Acanthopteroctetidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Archaic sun moths, family Acanthopteroctetidae, are very similar to Eriocraniidae, and include only four species, all North American except for one in the Palearctic (originally described in a separate family Catapterigidae). The family, plus the related Eriocraniiidae, are the only members of the superfamily Eriocranioidea, which form the infraorder Dacnonypha of the suborder Glossata. There are two subfamilies: Acanthopteroctetinae and Catapteriginae. Adults small (11–16 mm wingspan, with roughened head scaling and only short 2-segmented labial palpi; maxillary palpi are 5-segmented and folded; haustellum is reduced and vestigial mandibles are present. Maculation is more somber than in Eriocraniidae and adults are thought to all be diurnal. Larvae are blotch leafminers on *Ceanothus* (Rhamnaceae) in the single known biology.

Area-Wide Insect Pest Management

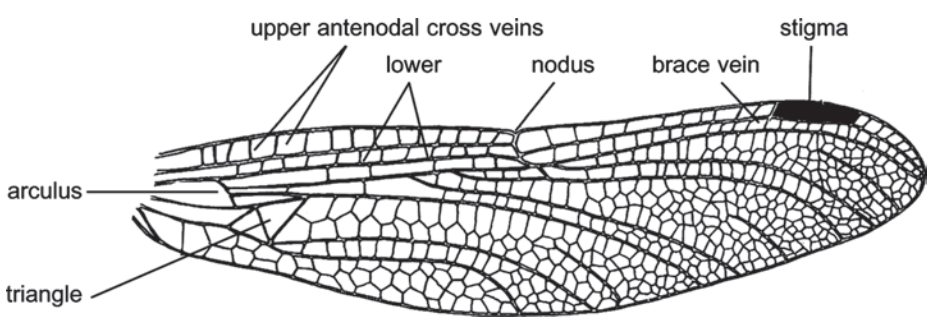
WALDEMAR KLASSEN
University of Florida, Homestead, FL, USA

Area-wide pest management is one of several major plans or strategies for coping with pest problems. Management of localized populations is the conventional or most widely used strategy, wherein individual producers, other operators and households practice independent pest control. However, since individual producers or households are not capable of adequately meeting the challenge of certain very mobile and dangerous pests, the area-wide pest management strategy was developed.

The area-wide pest management strategy includes several substrategies including (i) management of the total pest population in all of an ecosystem, (ii) management of the total pest population in a significant part of an ecosystem, (iii) prevention, which includes containment of an invading population and quarantine, and (iv) eradication of an entire pest population from an area surrounded by naturally occurring or man-made barriers sufficiently effective to prevent reinvasion of the area except through the intervention of man.

Characteristics of Area-Wide Pest Management

Immigration of pests into a managed ecosystem prevents their eradication. However, it is easy to underestimate the tremendous impact of the immigration of pests from small untreated foci into a managed area. For example, very few codling moths, *Cydia pomonella* (L.) develop in the well managed commercial apple orchards, but researchers found that the number of codling moths that overwintered in the in Wenas Valley of Washington State dropped by 96% when a few abandoned orchards and neglected noncommercial apple trees were either removed or sprayed with insecticide. This study indicated that most of the codling moths in commercial orchards originated on untreated host trees that in aggregate were <5% of the host resources of the codling moth. Similarly, experience in coping with the pink bollworm, *Pectinophora gossypiella* Saunders,

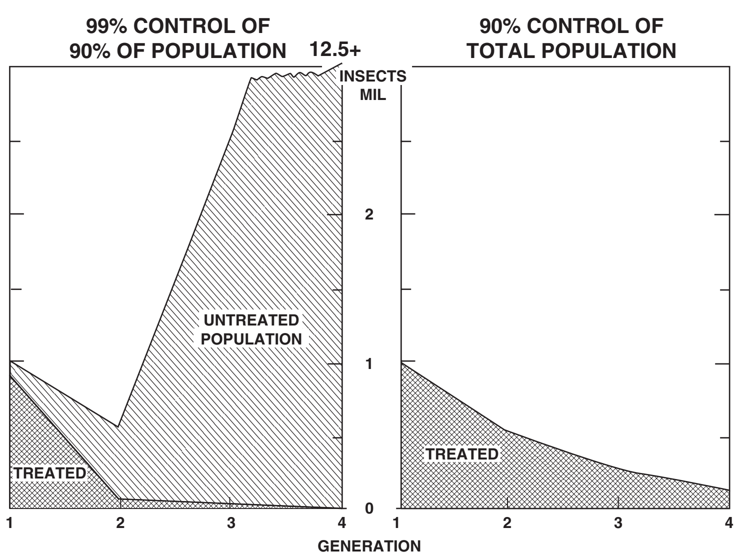


Arculus, Figure 72 **Front wing of a dragonfly (Odonata).**

and cotton boll weevil, *Anthonomus grandis* Boheman, have shown that a few growers who do not destroy crop residues immediately after harvest provide the food required by these pests to reproduce and to enter diapause. This lapse in field sanitation can directly cause the occurrence of devastating levels of these pests in the following season on neighboring farms.

The implications of allowing a small fraction of a population of a major pest species to reproduce without control can be seen graphically (Fig. 73). E. F. Knipling calculated that over a period of a few generations more pest individuals would be produced if 1% of the total population were allowed to reproduce without control, while 100% control was applied to 99% of the population, than if only 90% control was imposed uniformly on the total population. Thus, Knipling elaborated the basic principle of total population suppression: "Uniform suppressive pressure applied against the total population of the pest over a period of generations will achieve greater suppression than a higher level of control on most, but not all, of the population, each generation." Therefore, it is very important to eliminate any places of refuge or foci of infestation from which recruits could come to re-establish damaging densities of the pest population in areas of concern.

For the most part, the control of many highly mobile and very destructive pests is carried out by individual producers who rely heavily on the use of insecticides. Although other control technologies are often incorporated into the producer's integrated pest management (IPM) system, these technologies, too, are usually applied by producers independently of other producers. Such an uncoordinated farm-by-farm IPM strategy provides opportunities for the pest population to build up and to establish damaging infestations in well-managed fields. Consequently, on most farms insect pest populations increase to damaging levels each year, and the farmer is forced to apply



Area-Wide Insect Pest Management, Figure 73 **Results of a model that show that outcome of neglecting to suppress a small fraction of a pest population in an agroecosystem versus the effects of uniformly suppressing the entire pest population. On the left, 10% of the population is untreated and it produces a large number of individuals in four generations, while the 90% of the population that is treated declines. On the right, the entire pest population in the agroecosystem is suppressed uniformly and its numbers decline from generation to generation. (After Knipling, 1972. Reproduced with permission of the Australian Journal of Entomology.)**

broad-spectrum fast-acting insecticides as a rescue treatment (Table 10). This defeats the primary goal of the IPM system, which is to take maximum advantage of naturally occurring biological control agents.

Moreover, application of insecticides when an insect pest population reaches the economic threshold does not prevent the losses that occur before the threshold has been reached. For commodities that are planted on vast areas, such losses in aggregate are immense. For example, the world production of corn (maize) is roughly 600 million metric tons. Avoidance of a loss of 3% would make available 18 million metric tons, which could be a major factor in alleviating hunger. Some examples of crop losses caused by insects.

Area-wide pest management differs from the conventional pest management of local pest populations in several important ways. The area-wide strategy focuses on managing the insect populations in all of the niches in which they occur, while the conventional strategy focuses narrowly on protecting the crop, livestock, people, buildings, etc., from direct attack by pests. The area-wide strategy requires detailed multiyear planning and an organization dedicated exclusively to implementing the strategy. The conventional strategy involves less planning, tends to be reactive, and is implemented independently by individual operators or households. The area-wide strategy tends to utilize advanced technologies, whereas the conventional strategy tends to rely on traditional tactics and tools that can be reliably implemented by non-specialists.

The use of separate organizations to conduct area-wide programs provides opportunities to utilize sophisticated technologies and professional management. Computer-based models are utilized in planning and management. Satellite imagery is used in area-wide programs to identify localities of alternate hosts that can be treated to reduce pest populations that produce migrants that cause the damage in commercial production areas. Area-wide programs acquire or develop highly sensitive detection systems, and employ geographic information systems software to help manage data. They may implement approaches to prevent or retard the development of insecticide resistance or loss of host plant resistance. Computer programs and real-time environmental data to predict insect populations can be effectively used in an area-wide program but usually not on an individual farm basis. Thus, pest immigration patterns, analysis

Area-Wide Insect Pest Management, Table 10 Percent crop losses in the USA caused by various insect pests without and with control measures

		Percent loss

Sugar cane	*Diatraea saccharalis*	28.6	8.0

of weather to predict increase or decreases of populations, genetic analysis to determine resistance levels, etc., are utilized in area-wide programs.

Finally, area-wide programs are able to take advantage of the power and selectivity of specialized methods of insect control that for the most part are not effective when used on a farm-by-farm basis. These include the sterile insect technique (SIT), certain programs of inundative releases of parasites, semiochemicals, mating inhibitors, large scale trap cropping, treatment of hosts on public lands and in private gardens, etc.

Benefits of Area-Wide Pest Management

Experience has shown that pest suppression on an area-wide basis can be more effective than on a farm-by-farm basis for reducing losses caused by highly mobile pests and for capturing the benefits of highly mobile natural enemies. Area-wide programs enable many producers to pool resources in order to utilize technologies and expertise that are too expensive for individual producers. These may include mass rearing facilities, aircraft, information technologies and highly trained specialists. In addition, a coordinated area-wide program can achieve the avoidance or internalization of external costs. External costs (externalities) are the harmful effects arising from pest control operations that affect parties other than the pest control ker, but for which no compensation is paid to the persons harmed. For example, spray drift onto neighboring properties frequently provokes disputes. Also, pesticide use to protect agricultural crops has caused insecticide resistance to develop in insect vectors of disease.

Finally, economies of scale can be captured in area-wide programs, although complex trade-offs may be involved. The more mobile the pest and the more uniform the damage caused by the pest, the larger can be the area under coordinated management. The total costs of pest detection and monitoring and suppression per hectare of crop usually decline as the size of the managed area increases. However, the per hectare organizational costs usually increase as the project size increases because of the increased need for meetings and other communication costs. For these reasons, in very large programs such as the effort to eradicate the cotton boll weevil from the USA, the vast area was subdivided into a number of zones. Also, considerable organizational cost savings may be realized in instances where towns, municipalities or cooperatives already have structures in place for communication, decision-making, collection of fees, etc.

Contingencies Often Dictate Changes in Strategy

Contingencies often arise that require replacement of one strategy with another. For example, at various times during the 43-year campaign to remove the screwworm from the United States, Mexico and Central America, different pest management strategies had to be selected. This program began when an unusual series of frosts beginning early in December 1957 killed all screwworms in the southeastern USA north of a line in southern Florida from Tampa to Vero Beach. Sexually sterile flies from a culture in a research laboratory were released in a broad band north of this line to contain the pest population while a high capacity rearing facility was being readied. This containment strategy was replaced by the strategy of eradication in the summer of 1958 when the mass rearing facility was able to produce 50 million sterile flies per week, and eradication was accomplished in 1959.

A similar change of strategies was employed in eradicating the screwworm from west of the Mississippi River. Beginning in 1962, the parasite population was strongly suppressed north of the U.S. border with Mexico, and the influx of flies from Mexico was retarded by the release of sexually sterile flies in a 130 km-wide zone along the entire USA-Mexico border. (For political reasons in 1966, the U.S. Secretary of Agriculture declared the screwworm to be eradicated from the United States, even though it was obvious to entomologists that unless the parasite was removed from northern Mexico, it would continuously reinvade the United States.) However, the eradication strategy could be implemented soon after the governments of the USA and Mexico reached an agreement in 1972 to eradicate the parasite as far south as the Isthmus of Tehuantepec. Operations against the screwworm in Mexico began in 1974, and the last screwworm case occurred in the United States in 1982.

In the next phase, these containment and eradication strategies were employed to eradicate the parasite from all of Central America to Panama, where a sterile fly barrier was established in 2001.

Legal Authority for Area-Wide Pest Management

The legal authority needed for area-wide and other regulatory programs is still evolving. In about 1860, the grape phylloxera, *Phylloxera vitifoliae* (Fitch), was transported from the United States to France. Within 25 years of its arrival, this insect had destroyed 1 million hectares of vineyards or fully one-third of the capacity of France to produce grapes. In order to protect the German wine industry, the government of Germany in 1873 passed the first law that provided for quarantines and regulatory control of agricultural pests. Other governments quickly followed the example set by Germany. In 1881 representatives of many European countries met and developed a set of regulations governing the movement of grape propagating material.

In about 1880 the San Jose scale, *Aspidiotus perniciosus* Comstock, was established in California. Its rapid spread throughout the country on nursery stock, and the failure of a program to eradicate it, caused Canada, Germany and Austria-Hungary to prohibit the admission of American fruit and living plants beginning in 1898. This crisis led to the passage, by the U.S. Congress, of a series of eleven federal acts beginning in 1905 on quarantine and the regulation of interstate shipments in the USA. In 1999, most of these acts were consolidated into the Agriculture Risk Protection Act of 2000. Indeed, most countries adopted legislation on: (i) prevention of the introduction of new pests from foreign countries, (ii) prevention of spread of established pests within the country or state, (iii) enforcement of the application of control measures to prevent damage by exotic pests, to retard their spread or to eradicate them. In many countries, the law allows people who wish to organize a program against a pest to hold a referendum. If the referendum passes by a certain margin (usually 67%) then all parties at interest must cooperate in the venture.

Currently, in Florida, the program to eradicate citrus canker has been delayed for several years. This pathogen is carried considerable distances on driving rains, and to achieve eradication, the Division of Plant Industry has found it necessary to destroy all citrus trees within a radius of 578 m from an infected tree. Homeowners in urban areas, who do not understand the need for such drastic action, feel that workers who enter residential yards and destroy citrus trees as part of the eradication program violate their rights. Thus, the Broward County Circuit Court has ruled that program employees must have a separate court-issued warrant to enter each privately owned property. The need to apply for tens of thousands of warrants has prompted the Florida Department of Agriculture and Consumer Services to appeal this ruling. The outcomes of this and other judicial proceedings are likely to more clearly define procedures that must be followed in conducting eradication programs, and the levels of reimbursement owed to affected homeowners. Unfortunately, the tensions between urban and rural populations caused by the adversarial nature of this process are likely to persist for many years.

Apathy, Outrage and Area-Wide Pest Management

Some of the programs conducted on an area-wide basis, especially those aimed at eradication, have aroused opposition. The strategy of eradication emerged just over one century ago as the brainchild of Charles Henry Fernald of the University of Massachusetts. Under Fernald's leadership, Massachusetts attempted to eradicate an introduced pest, the gypsy moth, *Lymantria dispar* L., in an 11-year campaign from 1890 to 1901. Initially, the primary eradicant was Paris green spray. The use of Paris green, which suffered from modest efficacy and phytotoxicity, had to be abandoned because of adverse public reaction including threats of violence and mass protests.

Those stakeholders who are not primarily concerned with the economic dimension of the pest problem tend to be highly concerned with ecological, environmental, social and human health implications of area-wide programs. Therefore, leaders of area-wide pest management programs need to be highly sensitive to the perceptions and attitudes of the public toward certain program operations. Often, eradication efforts must be conducted by the ground rules of the urban rather than the rural setting. In programs to eradicate the Mediterranean fruit fly in California and Florida, members of the public strongly protested the aerial pesticide applications even if the same insecticide was used without dissent for mosquito abatement. On the other hand, the same public generally has applauded the release of Mediterranean fruit fly sterile males.

Normally the public is apathetic towards technological programs. However, certain factors inherent in programs and in the manner in which they are managed can precipitate an almost irreversible shift of the public's attitude from apathy to outrage. A sense of outrage can be evoked by involuntary exposure to pesticide residues, imposed levies or fees, quarantines, right of trespass, unfair and inequitable sharing of risks, costs and benefits, temporary loss of control of one's property or field operations, the perception that endangered species may be harmed, etc.

Acceptance of risk by the public is more dependent on the public's confidence in the risk manager than on the quantitative estimates of risk consequences, probabilities and magnitudes. The public' confidence in the managers of an area-wide program is of paramount importance.

In each area-wide program, a special effort must be made to anticipate and identify those factors that may be emotionally upsetting to various people and to take preemptive actions to avoid or mitigate adverse reactions. Public officials must be kept apprised, effective two way communication with the public must occur, surrogates of the public must be included in oversight and decision-making processes, and referenda may have to be conducted to secure support and funding for the program.

Invasive Pests, Global Trade and Area-Wide Pest Management

The rapid globalization of trade in agricultural products, and increasing tourism, have dramatically increased the spread of invasive harmful organisms. We have entered an era of an unprecedented level of travel by exotic invasive organisms. The greatest harm being done by non-indigenous invasive organisms is occurring on islands, and major pests are becoming established with increasing frequencies on all continents except, perhaps, Antarctica. For about one century many countries have relied on inspection of arriving cargo and passengers at the port of entry as a primary exclusionary strategy. However, volumes of arriving cargo are doubling every 5–6 years, and it is not possible to increase similarly the human and other resources devoted to inspection at ports of entry. Clearly exclusion at the port of entry is no longer sufficient to protect against exotic pests, even though a number of emerging technologies are likely to facilitate safeguarding activities. Thus, in order to stem the influx of exotic pests, it is important to shift primary reliance from exclusion at the port of entry to off-shore actions, namely on pest risk mitigation in the areas of production and elsewhere, certification at the point of origin, and preclearance at the port of export.

An important approach to offshore mitigation is the creation of pest-free areas. Indeed, countries that export raw agricultural commodities can effectively remove the threat of exotic pests to the importing country by creating and maintaining pest-free areas. A pest-free area is one that lacks a quarantine-significant pest species, and is separated from infested areas by natural or artificial barriers. There are two types of pest-free areas: (i) pest-free zones are large geographic areas, such as the entire country of Chile, that is certified free of tropical fruit flies of economic importance, and (ii) pest-free production fields, that require the demonstrated suppression of quarantine pests to non-detectable levels. Area-wide pest management is an important tool for promoting safe trade and contributing as much as possible to the complementary goals of food security and economic security for all countries.

Requirements to establish pest-free fields of crop production include a sensitive detection program, suppression of the quarantine-significant pest to non-detectable levels, strict control of the fields, and safeguards to prevent infestation during packing and transit to the port of export. For example, Florida is able to export grapefruit to Japan by creating pest-free grapefruit groves in about 22 counties. Regulatory experts from Japan inspect the entire process of production, packing and transit. Similarly fruit groves free of the South American cucurbit fruit fly, *Anastrepha grandis* (Macquart), have been created in Mossoro, Brazil and Guayaquil, Ecuador.

The concept of pest-free fields based on bait sprays and the sterile insect technique was pioneered during the early 1960s against the Mexican fruit fly along the Mexico-USA border Mexico. Also in the early 1960s, the Citrus Marketing Board in Israel developed a concerted area-wide program against the Mediterranean fruit fly that has been able to meet the certified quarantine security requirements of fruit importing countries. Chile used the sterile insect technique to rid the entire country of the Mediterranean fruit fly, *Ceratitis capitata* (Wiedemann). By 1980 the entire country of Chile had become a medfly-free zone, and since then Chilean fruits in huge volumes have entered the U.S. market without the need for any quarantine treatments. This has dramatically strengthened the economy of Chile. Now Argentina, Peru and other countries have sterile insect technique programs that they hope will enable them to become fly-free zones with free access to markets in southern Europe, Japan and the United States. Also Mexico has used the sterile insect technique to get rid of the Mediterranean fruit fly. Indeed Mexico is ridding large sections of its territory of all fruit fly species of economic importance. The Mexican states of Baja California, Chihuahua and Sonora have been freed of all economically important species of fruit flies, so that citrus, stone fruits, apples and vegetables are being exported from these states without any postharvest treatment.

A more recent, highly significant development has been the continuous area-wide release of sexually sterile male medflies over the Los Angeles Basin and around high-risk ports in southern Florida. This further reduces the risk of pest establishment in these port areas.

Selected Episodes in the History of Area-Wide Pest Management

Migratory Locusts

Migratory locusts probably were one of the plagues that caused prehistoric man to attempt forms of group or area-wide control. Because migratory locust swarms can be seen approaching from a distance and descending onto crops, it seems likely that people banded together and used whatever means at hand to stamp out as many as possible. No doubt invasions of armyworms, leafcutter ants and other insects caused people to cooperate in combating them. In China, since 707 B.C., more than 800 outbreaks of *Locusta migratoria manilensis* L. have been recorded along the floodplains of the Hwang, Huai and Chang Jiang rivers. In 1929, an outbreak devastated 4.5 million hectares of cropland. Consequently, about 120 million people were mobilized to modify the floodplains by damming, terracing and reforestation. Over almost 30 centuries, the Chinese slowly developed an area-wide pest management program that now folds together knowledge of biology, ecology, forecasting cultural practices, and water management.

During the late 1920s, catastrophic locust plagues were widespread in Africa and southwest Asia. Boris Uvarov and Zena Waloff of the British Ministry of Overseas Development responded by establishing the International Unit of Locust Research. This Unit became the Antilocust Research Centre and it provided the focal point for international cooperation in coping with plagues of the desert locust, the red locust and the African migratory locust. The Centre created databases and provided a sustained regular flow of information on the status of locust populations throughout their ranges. The Centre developed a system of monthly forecasting. Uvarov was able to interest the FAO in creating the International Desert Locust Information Service to coordinate forecasting and the planning of campaigns. Leadership in these vitally important functions has been assigned to the FAO's Locust Group.

In recent decades locust experts have attempted to shift the prevailing strategy from reactive to proactive, and eventually to outbreak prevention. The reactive strategy initiates interventions after plague status has been reached in order to contain the magnitude of the damage. The proactive strategy seeks to prevent the occurrence of plague status by intervening against localized outbreaks. Proaction requires early detection of bands and swarms, preferably still in breeding areas, and prepositioning of locust campaign supplies. The outbreak prevention strategy seeks to intervene before the phase shift from solitary to gregarious. Possibly the outbreak prevention strategy would rely substantially on inducing epizootics by inoculating breeding populations with selective pathogens. A difficulty in implementing the proactive strategy and moving toward the outbreak prevention strategy is that donor support tends to wane in the absence of full-blown plagues.

Insect Vectors of Human Diseases

Doubtless the scientific pioneers of area-wide approaches were influenced strongly by concepts from the field of public health and hygiene. About 2,500 years ago the Greek spirit and the Roman capacity for organization had produced a highly developed system of hygiene in what is now southern Europe. The Romans procured safe supplies of water by means of aqueducts, practiced daily bathing and removed garbage from cities. The rationale for these measures was explained by Varro (116–27 B.C.), who served Pompey and Julius Caesar. Varro asserted that minute living creatures cause malaria. He wrote: "In damp places there grow tiny creatures, too small for us to see, which make their way into our bodies…and give rise to grave illness." However, with the collapse of the Roman Empire and the storms of folk-migrations, classical hygiene eroded. Nevertheless, raging outbreaks of malaria, typhoid, typhus and bubonic plague during the latter Middle Ages reawakened concepts of hygiene and public health. Doctors and public authorities joined forces to erect walls against these plagues. Dr. Johann Peter Frank (1745–1821) had considerable success in persuading the rulers of Europe during the late 1700s and early 1800s to establish public hygiene policies and to enforce them vigorously. While only a 21-year old student at the University of Strasbourg, Frank called for "systematic action by the authorities" to intervene in the lives of all citizens in order to forestall or halt epidemics. The discoveries of Pasteur, Koch and others on the nature of diseases were foundation stones for rational policies of public health.

Mosquito-Borne Diseases

Through collective action within communities, even without an overall national plan and central coordination, malaria in southern Europe and North America largely disappeared in consequence of education, the universal adoption of window screens, destruction of habitats of *Anopheles* larvae and the treatment of all cases with quinine.

Investigations conducted in the late 1800s and in early years of the 1900s on the transmission by mosquitoes of deadly diseases led to widespread use of area-wide programs. Yellow fever, dengue, filariasis and malaria were shown to be transmitted by various species of mosquito. In 1892 Howard, and in 1900 Ross, began to recommend that the habitat of mosquito larvae over extensive areas be either treated with kerosene or drained. These practices were first implemented in west Africa to combat malaria, and soon adopted by communities in many countries. Mosquito abatement districts were pioneered by John B. Smith in New Jersey. The New Jersey Mosquito Extermination Association, founded in 1912, provided the model for the organization and operation of area-wide mosquito abatement districts of which there are about 260 in the United States and a thousand or more worldwide.

Yellow fever was wiped out in Havana, Cuba, under the leadership of Dr. W. C. Gorgas, who in 1898 implemented a strict sanitation program to prevent breeding of the disease vector, *Aedes aegypti* L. Subsequently, Gorgas implemented a program in the Panama Canal Zone against *Aedes aegypti* and *Anopheles* spp. vectors of yellow fever and malaria, respectively. This highly effective program was key to the successful construction of the Panama Canal.

Because the *Plasmodium* pathogen requires 12 days to develop in the mosquito vector before it can be transmitted to man, residual sprays can sufficiently reduce the proportion of mosquitoes that survive 12 days, and so interrupt malaria transmission. Therefore, in 1955 the World Health Assembly urged WHO to lead and organize worldwide eradication of malaria. By 1959, almost 65% of the people at risk were protected and this percentage rose to 74 by 1970. Malaria eradication was claimed in 37 countries, and the incidence of malaria had dropped dramatically in many countries. In Sri Lanka, the number of cases dropped from more than 2.8 million per year to just 17 in 1963, but then the effort floundered as WHO was unable to deal with the widespread hue and cry for local control. In 1969, the Global Program disintegrated. Soon DDT was banned in the United States and WHO's resources for malaria were reallocated. Malaria resurged to more than half a million cases per year in Sri Lanka and to more than 100 million cases worldwide.

In 1969 and 1970, the Indian Council for Medical Research and the WHO initiated several projects relevant to area-wide control. Unfortunately, in 1974 these projects became the target of a press campaign by writers who feared that these projects were actually a USA-funded effort to develop methods of biological warfare. Because the government of India was unable to restore confidence, the projects were terminated.

Many authorities maintain that the area-wide use of insecticide impregnated bednets is superior to house spraying for suppressing malaria, that a considerable pool of effective technology relevant to the application of the SIT against mosquito vectors was developed three decades ago, and that area-wide programs against malaria vectors can move ahead as soon as the international community develops the political will to do so.

Onchocerciasis Control Program in West Africa

River blindness is caused by the microflilariae of the *Nematode Onchocerca volvulus*, and is transmitted by the *Simulium damnosum* species complex of black flies. People and blackflies are alternate hosts of this parasite, and it has no other hosts. The female parasite lives in the human skin and gives birth to the microfilariae for most of her lifespan of 12 years. Microfilariae may invade the human eye, and blindness typically sets in between the ages of 30 and 39 years. A number of small-scale larviciding operations against the vectors were mounted beginning in 1950, and beginning in 1960 the European Development Fund financed a major campaign in a 60,000-km^2 zone at the intersection of Mali, Burkina Faso and Cote d'Ivoire (Fig. 74).

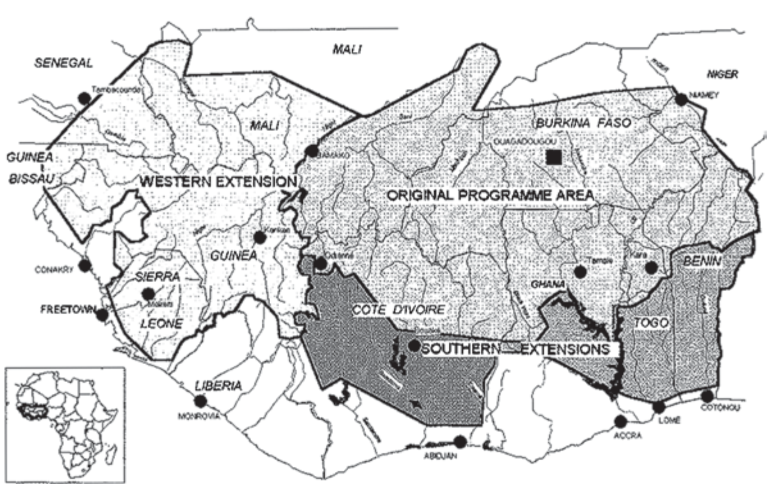
In 1974 the international community approved the Onchocerciasis Control Program and the World Health Organization was designated as Executing Agency. In order to manage the Program, National Onchocerciasis Committees were established in the seven participating countries (Benin, Burkina Faso, Cote d'Ivoire, Mali, Niger and Togo). A Joint Programme Committee has served as the supreme governing body and receives guidance from an Expert Advisory Committee. A Committee of Sponsoring Agencies coordinates the activities of the World Bank, FAO, WHO and UNDP. The Onchocerciasis Fund was created to accept donations, and the World Bank oversees it.

The Programme Director is assisted by seven units: Office of Director, Administrative Management, Epidemiological Evaluation, Vector Control, Applied Research, Biostatistics and Information Systems and Devolution. The latter conducts training and coordinates devolution activities with participating countries.

The limits of the program area were extended several times because of invasions of infective black flies over greater distances than initially foreseen. Thus the program area expanded from 654,000 km^2 in 1974 to 1,066,000 km^2 by 1990.

Two intervention tactics have been employed area-wide: larviciding largely by helicopter but also manually where streams are overgrown with vegetation, and treatment of humans with the microfilaricide, ivermectin. Because the period of development from egg to pupa rarely exceeds 1 week, larviciding must be carried out on a weekly basis. Seven insecticides are employed on a rotational basis to prevent the development of resistance. In order to achieve the proper concentration of insecticide in the flowing water, an automated hydrological surveillance network was created and real-time data are fed to an on-board computer to enable the pilot to properly manage spray operations.

The results of the program have been dramatic (Fig. 75). As a result of this program, 25 million hectares of land suitable for cultivation have become available, and rapid resettlement is underway. Because vector control operations were phased out in 2002, ivermectin remains as the only means of control.



Area-Wide Insect Pest Management, Figure 74 **The original area of the Onchocerciasis Programme established in 1974 and the subsequent western and southern extensions required to exclude migration of the black fly vectors. (After World Health Organization, 1994.)**

Reproduced from World Health Organization, 1994. CMFL is the community microfilarial load (geometric mean of microfilarial levels in all people in a given community).

Chagas Disease Vectors

Chagas disease, first recognized in 1909, has been ranked as the most important parasitic disease in the Americas. Although the infection is still largely incurable, transmission can be halted by (i) eliminating the domestic vectors, blood-sucking reduviids of the subfamily Triatominae, and (ii) screening blood donors to avoid risk of transmission through transfusions. Small-scale vector control programs began during the 1940s based on spraying the interior of homes with benzene hexachloride or dieldrin to control the primary vectors, *Triatoma infestans* (King) and *Rhodnius prolixus* (Stahl), as well as several other species of Triatoma. However, these programs suffered from under-funding and interruptions of funding, so that reinfestation occurred.

In 1983 a national program was launched in Brazil to eliminate the primary vector, *Triatoma infestans*, based initially on use of benzene hexachloride and later on pyrethroids. Although not without difficulties, this Brazilian program proved to be highly successful, and it inspired an area-wide program encompassing the Southern Cone countries (Argentina, Bolivia, Brazil, Chile, Paraguay, and Uruguay) plus Peru. This 10-year program was launched in 1991 under the leadership of the Pan American Health Organization with funding, in part, from the European Union. Total program costs were estimated at US $190 million to $350 million. The program's tremendous technical and economic success (internal rate of return of 30–60% largely based on savings in health costs) spurred a similar Central America Initiative (El Salvador, Guatemala, Honduras and Nicaragua) and an Andean Pact Initiative (Colombia and Venezuela).

Each program began with a centrally managed attack phase of about 3 years in which all homes are sprayed by trained professionals, followed by a more community-based phase, which relies substantially on the efforts of homeowners and local authorities. Adventitious transmission may be accomplished by sylvatic vector species, which can enter houses to form domestic colonies. In addition, migrant workers and other travelers can carry vectors. Currently, vector populations in Mexico and the Amazon Basin remain as major challenges. Elsewhere, the focus is shifting to epidemiological surveillance and care of people already infected.

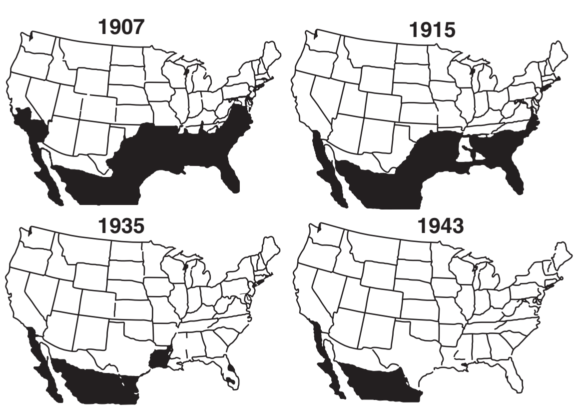
Cattle Ticks

The discovery in 1889 by Theobald Smith and colleagues that cattle fever is caused by a tick-transmitted parasite of red blood cells led to the initiation in 1906 of a county-by-county effort to eliminate the two *Boophilus* tick vectors (Fig. 76) from the United States. Many pastures were rendered tick-free by excluding all host animals until all ticks had starved to death. Livestock were dipped in an arsenical solution at 2-week intervals. Quarantines were used to prevent the movement of infested cattle into areas that had been cleared. By 1943, after 37 years of grueling effort, the ticks had been eliminated entirely from the United States for a total cost of about $40 million dollars, or the equivalent of the annual losses suffered before the program was initiated. Quarantines have been effective in preventing these ticks from becoming re-established from their populations in Mexico. A broadly shared vision sustained this program in spite of war and the great economic depression.

Contributions of Natural Enemies

Area-wide pest management began to be practiced widely during the nineteenth century using natural enemies. During the eighteenth and nineteenth centuries, people began to understand the roles of natural enemies in preventing insect outbreaks. Further, the powerful synthetic insecticides were not available to allow small holders independently to protect their crops and livestock. The beneficial work of coccinellids and other predators had been common knowledge for centuries, and they were collected and distributed for insect control. Insect parasitism was discovered only around 1700 by Leuwenhoeck in the Netherlands and in 1706 by Valisnieri in Italy. Emperor Francis 1 of Austria ordered Vincent Kollar to publish his work on the role of natural enemies in suppressing pests. Kollar's great work appeared in 1837 and the English translation appeared in London's Gardner's Magazine in 1840.

E. F. Knipling has analyzed the potential contributions of parasitoids to area-wide pest suppression. Parasite augmentation could be an especially desirable preventive measure because the release of host specific parasites poses no danger to humans, beneficial organisms, or the environment. Highly misleading conclusions have been drawn from past augmentation experiments, because the experiments were done in small non-isolated areas. Most pest arthropods and parasites or predators are highly mobile. Therefore, meaningful results can be obtained only if augmentation experiments are conducted over large areas. Even though many species of natural enemies have developed efficient host finding by following odor plumes of



Area-Wide Insect Pest Management, Figure 76 Progress in eradicating *Boophilus* ticks in the United States, 1906–1943.

kairomones emanating from the host, under natural conditions the level of parasitization does not threaten the host with extinction. Augmentation utilizes the host resources in nature to produce large numbers of parasite progeny. If done properly, parasite augmentation for several generations can become a self-perpetuating suppression measure. Augmentation causes progressive increases in the rate of parasitism with each succeeding parasite generation, provided that the initial rate of parasitism is above 50%. In addition, a host-dependent species will tend to distribute itself proportionally to the distribution of its host. No other method of insect control has the characteristic of concentrating its suppressive action where it is most needed.

Lasting Suppression of Cottony Cushion Scale by Vedalia Beetle

That classical biological control can provide area-wide solutions was dramatically illustrated against an exotic pest in California in 1888 and 1889. At that time an introduced pest, the cottony cushion scale, *Icerya purchasi*, was killing hundreds of thousands of citrus trees. However Albert Koebele was able to introduce a scale predator, the vedalia beetle, *Rodolia cardinalis* (Mulsant), from Australia and New Zealand. Less than 11,000 vedalias were distributed, but they spread throughout the entire citrus growing area of southern California and saved the industry. The vedalia beetle continues to effectively protect citrus in California, and nothing needs to be done other than to avoid the use of certain insecticides, which would decimate this invaluable natural enemy.

Lasting Suppression of Cassava Mealybug by *Epidinocarsis lopezi*

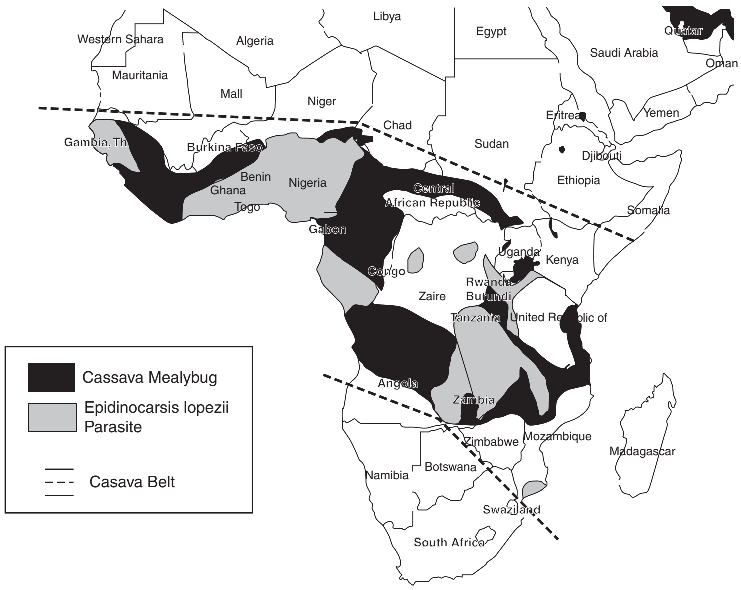
Almost exactly 100 years after the great vedalia success, a team led by Dr. Hans Herren of the International Institute for Tropical Agriculture (IITA) successfully implemented the largest classical biological control program in history. In 1973, cassava near Brazzaville and Kinshasa was found to be attacked by the cassava mealybug, *Phenacoccus manihoti* (Matile-Ferrero). In a few short years immature crawlers were dispersed by wind throughout sub-Saharan Africa.

The cassava mealybug created starvation and hardship for many of the 200 million people for whom cassava had become a staple crop. In 1981, an excellent parasitoid, *Epidinocarsis lopezi* (DeSantis), found in Paraguay by A.C. Bellotti, proved capable of bringing the cassava mealybug under control. The parasite was mass-reared and released by aircraft over 38 countries (Fig. 77) of sub-Saharan Africa (an area much larger than the combined area of the United States, Mexico and India) with excellent results. This singular accomplishment required strong and imaginative leadership and action by IITA, generous funding by donors, and brilliant scientific and technical work by Herren's team and their cooperators in Africa, Europe, and the Americas.

Area-Wide Conservation of Predators of the Brown Planthopper

In many cases, natural enemies are effective only if most smallholders in an area work to conserve them. Because both pests and natural enemies are mobile, their populations distribute themselves throughout the region in which their food sources are available. Even smallholders who do not participate in the conservation program receive some of its benefits. They get a free ride, and for them this is a positive externality of the program. On the other hand, the movement of natural enemies off the property of the participating farmer to that of the free rider is a negative externality.

The brown planthopper, *Nilaparvata lugens* (Stål), has been the scourge of rice production in southeast Asia for many years. However, during the 1980s, Indonesia (with technical assistance from FAO and Germany's GTZ) simultaneously



Area-Wide Insect Pest Management, Figure 77 **Biological control of the cassava mealybug in sub-Saharan Africa by mass rearing a parasite from Paraguay and distributing it by air over 38 countries.**

achieved substantial increases in rice production and major reductions in insecticide use. Generally, brown planthoppers are effectively controlled by indigenous spiders and other predators. Moreover, since insecticides have a greater impact on the predators than on the pest, the brown planthopper populations are able to resurge after being sprayed. In the past, farmers induced resurgence by beginning to spray at 40 days after transplanting the rice. However, cage studies showed that the smallholder who delays spraying until 65 days after transplanting saves two insecticide applications, and realizes a yield increase of about two tonnes, for a total benefit of US $588 per hectare.

It is possible to model what happens when some smallholders delay spraying to conserve natural enemies but others do not. If about 10% of smallholders conserve natural enemies, they gain only one-fifth of the potential benefit. If 30% of smallholders conserve natural enemies, they gain only one-quarter of the potential benefit, and the free riders gain about 7%. When 50% of small holders conserve natural enemies they gain one-third of the potential benefit, and the free riders gain about 18%.

When 70% of smallholders participate, they gain almost 60% and the free riders gain about 40%, and when 90% participate, they gain about 83% of the potential benefit, while the free riders gain 66%. Clearly, a conservation program is almost futile until about one-half of the smallholders participate, and the program becomes progressively more beneficial as the percent participation increases toward 100.

Bark Beetles

Dendroctonus pine bark beetles are dangerous pests in forestry because of their mass attacks on healthy trees. During the first decades in the twentieth century, foresters focused on destroying the developing broods of potentially destructive beetles before they could emerge and attack valuable trees. This was implemented by felling dead trees, peeling and burning the bark or by storing the infested logs in millponds until they could be sawed into lumber. The futility of such attempts by focusing directly on killing beetles became apparent when, in 1932, an extremely cold winter occurred and destroyed at least 80% of the beetles in western North America. The destruction of the beetle broods by frost was more complete, extensive and uniform than could be accomplished by forest managers. Yet, within 2 years the beetle populations had resurged and were again killing ponderosa pine on a vast scale.

However, forest entomologists recognized that the most vulnerable trees were those that lacked vigor or were in decline. Thus, in 1937 control of bark beetles based on susceptibility of trees to attack was pilot tested in California by a program called sanitation-salvage logging. In this approach, up to 20% of trees at highest risk of beetle attack were removed and sawed into lumber. During the first year following the removal of the most vulnerable trees, losses to bark beetles were reduced by 90%, and losses remained low for at least 10 years after the selective logging.

Boll Weevil Eradication in the USA

E. F. Knipling, with the support of the National Cotton Council, was determined to eradicate the boll weevil from the United States because the weevil necessitated the use on cotton of one-third of the insecticides used in U.S. agriculture. Also, highly insecticide-resistant boll weevil populations had emerged. Newsom and Brazzel, at Louisiana State University, had discovered that in the fall of the year the boll weevil enters a reproductive diapause and hibernates in trash along the edges of cotton fields. Brazzel showed that the number of weevils surviving the winter is reduced 90% if insecticides are applied just before diapausing weevils leave the fields. Moreover, Knipling's analysis showed that if insecticide sprays were targeted also to kill the generation producing individuals going into diapause, then the number overwintering would be reduced by more than 99%. Knipling's model was verified, and this ignited great interest in actually eradicating the boll weevil. An effective pheromone-baited trap was developed for detection. Weevils were sexually sterilized with the anti-leukemia drug, busulfan.

In 1971–1973, a large pilot field experiment to assess the feasibility of eradication was centered in southern Mississippi. The eradication zone was surrounded by three buffer zones. Very intensive suppression was implemented in the two inner zones, and farmers were expected to practice diligent control in the outer zones, although some grew cotton simply to qualify for government payments and with no intention to harvest a crop. Only one application of the suppressive system was made, because of a shortfall in appropriations. Nevertheless, the boll weevil was suppressed below detectable levels in 203 of 236 fields in the eradication zone. All of the 33 lightly infested fields were located in the northern one-third of the eradication zone and less than 40 km from substantial populations farther north. In the southern two-thirds of the eradication zone, no reproduction could be detected in any of the 170 fields. Knipling and some others concluded that the available technology was sufficiently effective to achieve eradication. Their experience with the screwworm indicated that eradication could be accomplished iteratively, following an application of the suppressive system that clears the pest from most of the target zone. Next, surviving populations are delimited and similar suppressive measures are applied to them. In this iterative fashion, the aggregate range occupied by the pest is progressively reduced toward zero. However, some felt that the technology was not adequate to mount an eradication campaign, unless a single application of the system of suppression eliminated all weevils in the target zone.

A Cotton Study Team appointed by the National Academy of Sciences drafted a very negative interpretation of the results. Because Knipling was a member of the Academy, he had access to this draft, and he wrote a strong rebuttal. Therefore, the Cotton Study Team wrote a "toned down statement" that continued to express strong reservations about the feasibility of eradicating the boll weevil, but concurred to conduct a new trial eradication program in North Carolina.

Grudgingly the Academy team legitimized the concept of continuing large-scale eradication experiments, but with the caveat that they would probably fail.

The new trial program, started in 1978 in Virginia and North Carolina, was highly successful. Subsequently, piece-meal programs, each run by a separate foundation, have removed the boll weevil from about 5 million acres in Virginia and the Carolinas, Georgia, Florida, south Alabama, California, and Arizona. These programs have caused significant reductions in pesticide usage, and the eradication efforts are continuing. Thus, the job is about half done. However, the corrosive effect of the Academy's report persists. The US Congress reduced the share of federal funds from the traditional 50 to <30% of the cost. However, such cost sharing is no longer guaranteed, and in 1997 the US Department of Agriculture initiated a program of making loans to officially recognized boll weevil eradication foundations. Moreover, the process of eradication is being conducted piece-meal with a minimum of technology. Pheromone traps are used to delimit infestations, and the attack begins with insecticides applied late in the growing season against weevil still reproducing and those entering diapause. As many as 15 insecticide applications per year are made against dense persistent populations. Planting by all growers is synchronized and delayed, short season varieties are grown, harvested as soon as possible, and stalks are destroyed immediately after harvest. Eradication is usually accomplished by the end of the third growing season.

Attempts to Sharply Define the Area-Wide Pest Management Strategy

A few scientists have attempted to sharply define the area-wide pest management strategy. Knipling stated: "Area-wide pest management is the systematic reduction of a target key pest(s) to predetermined population levels through the use of uniformly applied control measures over large geographical areas clearly defined by biologically based criteria." D. A. Lindquist wrote: "An area-wide insect control program is a long-term planned campaign against a pest insect population in a relatively large predefined area with the objective of reducing the insect population to a non-economic status".

Both of these definitions have considerable merit and they fit the majority of area-wide programs. However, slightly different definitions may be needed to describe programs on the conservation of natural enemies (which can tolerate some free-riders) and on classical biological control where the adaptation of the introduced biological agent to all new environments cannot be known in advance of making releases. Also, in programs to contain an invasive pest population, it may not be possible to clearly define the boundary of the pest population. In the similar vein, A. T. Showler stated: "Locust swarms can be highly variable, influenced by many factors, including geography, vegetative conditions, land-use patterns, environmental sensitivity, availability of resources and tactics, prevailing winds, insecure areas, and rainfall patterns. Reliance on a single control strategy is therefore unrealistic. A more appropriate approach would be to develop specific strategies that will fit with projected scenarios, mostly by harmonizing them with national contingency plans." The common thread that runs through all area-wide pest management programs is the strong emphasis on preventing the existence of any places of refuge or foci of infestation from which recruits can come to re-establish damaging densities of the pest population in areas of concern.

Benefit-Cost Assessment and Discounting Net Returns

Usually, investments in area-wide programs are made with the expectation that program benefits will accrue over a multi-year time horizon. Therefore, we must discount future benefits to balance them against present or near term expenditures. The stream of discounted annual benefits and costs for many years of an undertaking can be summed up and expressed as a single value, known as the present value net benefits (PVNB). The formula for calculating the PVNB for a 15-year project is as follows:

$$PNVB = NB_1 + w_2NB_2 + w_3NB_3 + w_4NB_4 + w_5NB_5 + w_6NB_6 + wtNB_t + w_{15}NB_{15}$$

where NB_t represents the net benefits in year t, and w_t represents the weighting factor for year t. The weighting factors are a function of a discount rate (r):

$$w_t = \frac{1}{(1+r)^t}$$

The discount rate is the opportunity cost of the money, or the interest value that money could earn if allocated to the best alternative use. This rate may be established by subtracting the national inflation rate from the bank interest rate for savings. In normal times, this procedure will generally produce a figure around 4 or 5% in developed countries. This represents the reasonable person's discount on the future, because people put their money in the bank to gain this premium, and otherwise they would spend it now. So, the benefit of eradication next year is worth 5% less if it is brought back to the present. Benefits in 20 years are only worth 37% of their face value when brought back to the present. In riskier economic environments, discount rates will be much greater, so the calculated net present value of future benefits may be insignificant. However, for programs involving vectors of human diseases, the futures of groups of people are at stake, and it does not seem appropriate to discount benefits in the manner appropriate for private investments. The health of the human population 30 years in the future seems just as important as the health of the population at present. Nevertheless, investments in vector control programs must be subjected to critical analysis in the interest of efficient and sound management. However, if high discount rates (e.g., 25%) are selected commensurate with economic risk in many developing countries, then it seem unlikely that vector control programs in these countries would ever be launched.

Knipling's Imperative

When the World Food prize was awarded to Knipling and Bushland, Knipling stated: "If major advances are to be made in coping with most of the major arthropod pest problems, then the tactics and strategies for managing such insects, ticks and mites must change. They must change from the current, limited scale, reactive, broad-spectrum measures to preventive measures that are target-pest specific and rigidly applied on an area-wide basis." Great and enduring strides can be made by adopting the strategy of area-wide pest management to help meet world food, health and environmental challenges.

Argasid (Soft) Ticks (Acari: Ixodida: Argasidae)

IGOR USPENSKY
The Hebrew University of Jerusalem, Jerusalem, Israel

The family Argasidae is second to the family Ixodidae with regard to its medical and veterinary significance and the number of species. According to the novel classification based on a phylogenetic analysis of relationships at the generic to subgeneric level, the argasid ticks comprise four genera and about 185 species, among which three genera are represented by a large number of species: *Carios* (87 species), *Argas* (57 species) and *Ornithodoros* (36 species, one of which consists of three subspecies). The fourth genus (*Otobius*) is represented by three species. Not all researchers fully agree with the currently proposed systematic groupings of the family. This classification has its weaknesses but is considered superior to traditional classifications. In any case, further molecular taxonomic study is necessary.

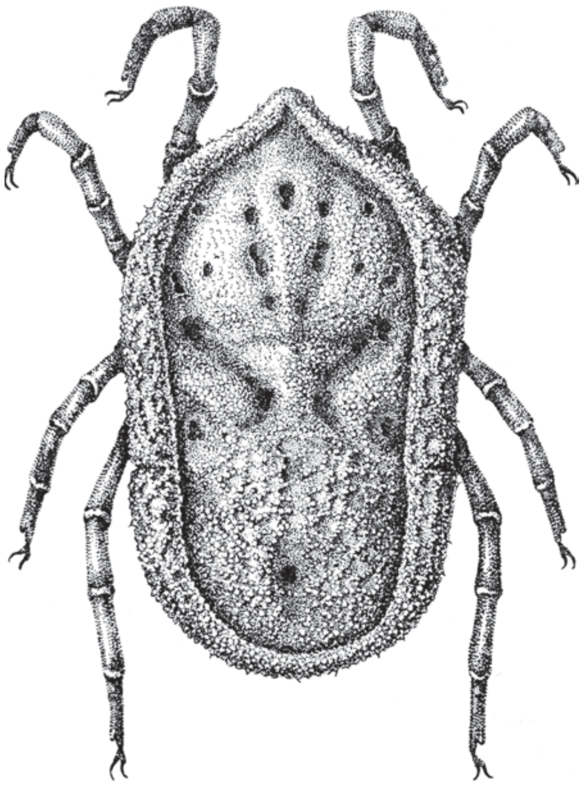
The main morphological difference between argasid and ixodid ticks is the lack of the scutum in argasids; thus, they are called "soft ticks." The lack of the scutum leads to the absence of such a clear sexual dimorphism in the adult stage of this family compared with ixodid ("hard") ticks. The integument of the Argasidae looks wrinkled and leathery. The mouthparts are located on the ventral side of the body, covered by the frontal margin of the body, and are invisible from above.

There are a number of significant biological differences between soft and hard ticks. Firstly, argasid ticks have several nymphal stages (instars), varying from 2 to 8, usually from 3 to 6. The number of instars is not constant, and is controlled by exogenous factors such as the size of the blood meal and the ambient temperature during development. Secondly, nymphs and adults of argasid ticks cannot engorge as much blood as ixodid ticks. The integument of adult argasids is strongly folded and capable of stretching during feeding, but does not grow at that time. Females of most argasid ticks increase their body mass after feeding by only 3–6-fold. The blood feeding time of argasid ticks is much shorter than that of ixodids, taking from several minutes to 1–2 h, and male gorging taking 1.5–2 times less than that of females. In contrast, nymphal argasids feed in much the same manner as ixodids; this is explained by their capacity to create new cuticle during feeding. Thirdly, adult ticks can gorge blood several times during their life, and can oviposit after each feeding. The maximal number of possible feedings is unclear, though as many as nine feedings have been documented.

Ecology

Argasid ticks are spread over all continents (with the exception of Antarctica) but have been studied very unevenly; in particular, there is insufficient information on this group in South America and Australia. Both in the Palaearctic and the Nearctic, soft ticks inhabit regions with a hot climate, mainly deserts, semi-deserts and southern savannas (steppes, veldts, prairies), but some species penetrate as far north as 50–55°N. The maximum number of species and their greatest abundance are known in foothill areas (300–900 m above sea level), but some ticks can be found at higher elevations (a maximum of 2,900 m above sea level for the cave tick *Ornithodoros tholozani* (Fig. 78) in the Pamirs).

Almost all species of argasid ticks are nidicolous, i.e., they live in or near shelters of various kinds. *Ornithodoros transversus* is an exceptional species that spends its entire life on the giant tortoises of the Galapagos Islands. Endophilous nidicoles inhabit bird and rodent nests, mammal burrows, and caves as well as stalls, poultry houses and farms. Harborage-infesting parasites live near nests or burrows, very often in rock or stone ledges as well as in human dwellings and temporary human-made cabins in places of resting, hunting or fishing. In such shelters, ticks inhabit all kinds of cover: cracks and crevices on walls, sandy or



Argasid (Soft) Ticks (Acari: Ixodida: Argasidae), Figure 78 **The cave tick, *Ornithodoros tholozani*.**

dusty soil surface of burrows and caves, spaces between nest fibers, etc. Ambient conditions, such as air temperature, relative humidity and light intensity, are more uniform and suitable for ticks in shelters than in the surroundings; this enables tick survival in extremely unfavorable areas. Being dependent on the hosts living in the shelters, the ticks have developed different patterns of adaptation, the main one being their unusual ability to persist without feeding. This is especially characteristic of nest and burrow inhabitants because death of the host or migration to another habitation are common phenomena, whereas active migration between shelters is not typical for most argasid ticks except in several species parasitizing ungulates and hares. Under laboratory conditions, unfed adult *O. tholozani* survived without feeding for more than 10 years and unfed adult *Argas lahorensis* for as long as 18 years.

As a rule, females of argasid ticks are characterized by gonotrophic harmony, though the number of eggs in each batch may fluctuate widely. After each complete blood feeding, they lay off-host from 50 to 200 eggs. If blood feeding is not complete, the number of eggs laid diminishes proportionally. During its entire life, a female can lay up to 1,200 eggs. Female oviposition depends on their insemination, which occurs off-host, and can take place either before or after feeding. Some cases of female insemination several months after feeding, followed by oviposition, have been described. One mating is sufficient for several ovipositions. Multiple gonotrophic cycles have been recorded among the Argasidae. There are some exceptions from gonotrophic harmony when a female lays eggs without feeding, using nutritional reserves remaining after nymphal feeding.

Feeding Behavior

Several feeding nymphal instars and repeated feedings in adult females allow us to describe the Argasidae (with a few exceptions) as multi-host ticks, though consecutive feedings may take place on the same host. Most argasid species feed on specific groups of hosts and, in a broad sense, can be considered specialists. Ticks of some subgenera of *Argas* parasitize birds available to them during nesting or resting. The genus *Carios* contains nearly all bat-associated argasids. When the ticks are offered unusual hosts, they either do not feed at all or have some abnormalities in their metamorphosis after such feeding. An extreme specialization was observed in Cuban *Carios natalinus* and *C. tadaridae*, which parasitize only bats of the genera *Natalus* and *Tadarida*, respectively. In contrast, such ticks as *Ornithodoros erraticus*, *O. tartakovskyi*, or *O. tholozani* must be considered generalists. They can feed on any mammals, birds and reptiles available to them. Among exceptions are the one-host *Ornithodoros transversus* and the two-host *Otobius megnini* and *A. lahorensis*. The latter species demonstrates some characteristics of exophilic ticks which are followed by adaptations to hot xeric environments. This tick has an extremely high critical temperature of the epicuticle (61°C in contrast to 42 to 54°C in other species studied) and minimal water loss under low RH. Among other adaptations are the development on the host from larval attachment until engorgement of nymphs of the last instar with a constant number of nymphal instars (3) and nymphal feeding at each instar for several days which increases the blood meal size and, hence, the number of eggs laid (300–500).

A capacity of unfed argasid ticks to parasitize and feed on engorged specimens of the same species presents an interesting phenomenon called homoparasitism (homovampirism, in Russian literature). Usually, unfed nymphs and males parasitize engorged nymphs of late instars and females. Unfed ticks prick the integument and gut walls of engorged specimens, and suck the gut contents. As a rule, such an operation is not followed by the death of the victim, so that this phenomenon cannot be called cannibalism. This phenomenon has been documented many times for a number of species of both *Argas* and *Ornithodoros* under laboratory conditions, but there are also a few observations from the field. Apart from this, feeding of unfed ticks on engorged specimens of other species has also been recorded.

Depending on the conditions of tick habitats, ticks have different forms of seasonal activity. The seasonality is absent or weakly pronounced in ticks inhabiting shelters with a relatively stable microclimate. In the tropical zone, ticks attack hosts, feed and oviposit all year round according to observations on the African tampan *Ornithodoros moubata*. A similar pattern of activity was recorded on *O. erraticus* inhabiting the Nile grass rat burrows in Egypt. In the subtropical and especially temperate zones, the seasonality in tick activity is much better defined. Ticks feed and oviposit during the summer and have one or two gonotrophic cycles during this period. In the winter months, a morphogenetic diapause in the form of ovipositional delay takes place in argasid species that parasitize migratory birds. Such diapause also occurs in ticks parasitizing bats, which hibernate in cool caves. Photoperiod seems to be the main but not the only factor regulating the induction and termination of diapause. A prolonged hunger is not considered diapause even when it continues for several years.

The abundance of argasid ticks in their shelters can be extremely high. A single cave inhabited by bats may contain hundreds of thousands of bat-parasitizing argasids. Cases have been documented when seabirds abandoned their nests in the middle of the breeding season because of enormous tick density. Especially high tick density has been noted in abandoned habitations of Central Asia. Such constructions are even more dangerous than dwellings; the longer ticks are without hosts and the hungrier they become, the more aggressively they attack occasional visitors. In past centuries special "bug traps" full of hungry argasids were used by Central Asian rulers for the torture of prisoners who died from exsanguination by thousands of ticks. The capability of argasid ticks to migrate varies depending on the habitation of a particular species. Endophilous nidicoles inhabiting nests, burrows and caves are usually considered non-migratory species because the distance to the host is very short. Harborage-infesting species can migrate over larger distances measured in many meters. As in the hard ticks, the migration toward a host is influenced by a spectrum of factors, such as CO_2, host body heat, various odors, etc. However, the effect of a single stimulus is weaker than for hard ticks, and the maximal effect has been observed when all stimuli worked together.

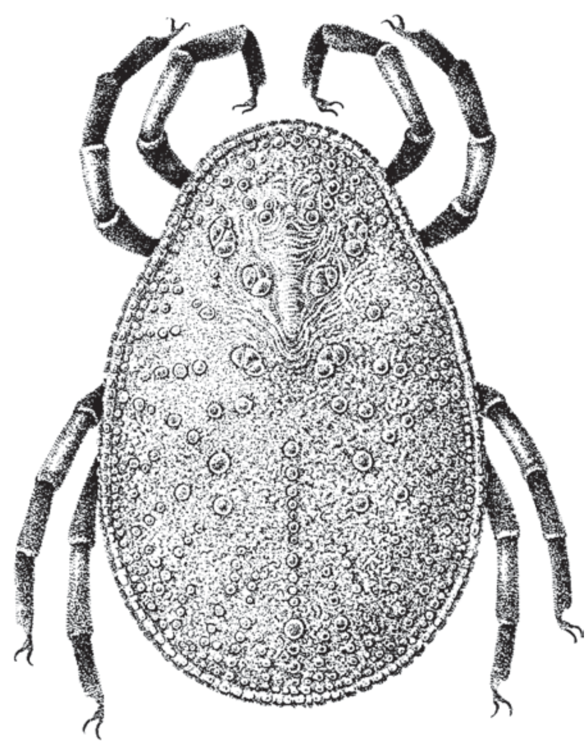
Evolutionarily, the Argasidae are more primitive than the Ixodidae. This primitivism is exemplified by a number of characteristics, such as rather narrow ecological patterns, low capacity for active migrations, existence of many nymphal instars, and slight morphological difference between the last nymphal instar and the adult stage. These characteristics are considered typical for more primitive forms among different groups of the Arachnida.

Medical Importance

The medical significance of argasid ticks is mainly determined by their participation in transmission of many species of *Borrelia* pathogenic to humans. These closely related bacteria are causative agents of tick-borne relapsing fevers. Each species of *Borrelia* is transmitted by its specific tick vector. *Borrelia duttoni* and its vector *Ornithodoros moubata* were the first combination of such kind recognized in Africa in the very beginning of the twentieth century. The disease occurs in the central, eastern and southern parts of the continent and humans are the primary reservoir host, which is unusual because in other combinations, mammals, especially rodents, are the main reservoir hosts. More than 15 combinations of *Borrelia* with particular species of argasid ticks are recently known worldwide. They occur in North, Central and South America, Africa, and the Mediterranean area, including some European countries, the Caucasus, Asia from the Near East to western China. In the western and southwestern United States the following combinations have been identified: *B. hermsi*-*Ornithodoros hermsi*, *B. parkeri* -*O. parkeri*, *B. turicatae*-*O. turicata*, *B. mazzottii*-*Carios talaje*. The ticks are capable of transovarial and transstadial passage of *Borrelia* for many generations, as well as of prolonged preservation of pathogens, even during prolonged hunger. The passage of pathogens from hungry to engorged specimens as a result of homoparasitism has been proved experimentally. Because tick vectors are nidicolous, the human infection depends on human closeness to tick habitation. Tick species inhabiting human dwellings, such as *Ornithodoros moubata* and *O. tholozani*, are especially dangerous vectors. In other cases the infection takes place only when humans intrude into tick shelters or settle themselves nearby.

Veterinary Importance

Some argasid ticks are also of veterinary importance. *Ornithodoros porcinus porcinus* and *O. erraticus* are the main vectors of the African swine fever virus, an acute contagious disease affecting domestic pigs and several wild representatives of the family Suidae. Epidemics of this disease have occurred in many African countries, as well as in some southern European-Mediterranean countries, but also in Brazil and Central America (Cuba, Dominican Republic, Haiti). *Ornithodoros coriaceus* transmits *Borrelia coriaceae*, the causative agent of epizootic bovine abortion in the western United States. Cattle, and especially sheep, densely parasitized by *Argas lahorensis*, may suffer from large losses of blood and often die. Some representatives of the genus *Argas* that are closely connected with poultry transmit destructive diseases of domestic birds. Fowl (or avian) spirochetosis caused by *Borrelia anserina* affects chickens, geese, ducks, turkeys, pheasants and some other fowl and decorative birds. The fowl tick, *A. persicus* (Fig. 79), the most important cosmopolitan poultry parasite, is the main vector of the pathogen. The pigeon tick *A. reflexus* (and,



Argasid (Soft) Ticks (Acari: Ixodida: Argasidae), Figure 79 **The fowl tick, *Argas persicus*.**

perhaps, other species from the *A. reflexus* group) also participates in transmission of the disease. The mode of transmission is unique for tick-borne borrelioses, by contamination from infectious tick feces. Transovarial passage of the pathogen has been proved. Fowl spirochetosis is spread worldwide: in North, Central and South America, Europe, Australia and many regions of Asia and Africa. *Argas persicus* is also responsible for transmission of a rickettsia, *Aegyptianella pullorum*, infecting some fowl. The disease is especially destructive for young chickens. *Argas walkerae*, whose adults transmit this disease in South Africa, also causes paralysis in chickens when its larvae feed on them.

A number of other human and animal pathogens have been isolated in nature from some species of argasid ticks, but there is not enough data to consider such ticks as competent vectors. On the other hand, some argasid ticks have been successfully infected by different pathogens in the laboratory, and maintained the pathogens for some time, but this also does not constitute proof of the tick importance in transmission of the disease. Nevertheless, the involvement of argasid ticks in the transmission of other diseases is very possible.

Human Response to Tick Feeding

Human skin reacts to argasid bites, sometimes rather severely. People are often insensitive at the time of the tick bite but later a strong itch appears followed by scratching and the appearance of ulcers. The strength of the human reaction depends on the tick species. Evidence of *Ornithodoros tholozani* bites may be in evidence for many months. *Argas* ticks living in towns and parasitizing pigeons often inhabit human dwellings, even some apartments in many-story buildings, and may cause allergic responses and toxicoses in humans. Many cases of anaphylactic reactions (sometimes even with fatal results) caused by bites of *A. reflexus* have been reported in European towns where pigeon populations increased dramatically during past decades. Such reactions are typical for other members of *Argas reflexus* group (e.g., for *A. latus* in Israel).

The most severe form of tick toxicosis is tick paralysis, which only occurs after prolonged feeding. In argasid ticks, the known cases of tick paralysis were described only for larvae characterized by prolonged feeding. Larvae of several *Argas* species cause paralysis of fowl with total recovery after all larvae drop off the host. Paralysis and death of sheep and cattle caused by *Argas lahorensis* has been reported from some European countries, Caucasus and Central Asia after attachment of 100–200 nymphal ticks of the slow-feeding third instar.

Management of Tick Populations

Personal prophylaxis is the basis of human protection from argasid ticks. It is necessary to avoid resting and overnighting in sites where tick attacks are possible. The most efficient method of tick eradication in human dwellings is the improvement of dwellings so that ticks are deprived of possible shelter. The maintenance of good sanitary conditions in poultry houses and farms with limited use of acaricides should maintain the abundance of fowl ticks at a low level. The acaricidal treatment of domestic animals infested by argasids is an effective mode of tick control. Some animal diseases, such as African swine fever, can be eradicated either by very severe quarantining of the infected herds or by destroying the infected herds together with the ticks infesting the animals. Only a small number of pathogens, parasites and predators of argasid ticks are known, thus it is impossible to estimate the prospects of their use for argasid tick control.

Argentine Ant, *Linepithema humile* (Mayr) (Hymenoptera: Formicidae: Dolichoderinae)

ALEX WILD
University of Arizona, Tucson, Arizona, USA

Identification and Taxonomy

Argentine ants belong to the subfamily Dolichoderinae, or odorous ants, characterized in the worker caste by the presence of a single constricted petiolar segment, the lack of a sting, and a transverse slit-like anal orifice. Worker ants (Fig. 80) of the genus *Linepithema* can be further recognized by the combination of the anterior clypeal margin bearing a medial concavity and a distinct mandibular dentition bearing a series of larger teeth interspersed with two to three small denticles.

The Argentine ant is distinguished from all other *Linepithema* species in the worker caste by a lack of erect setae on the mesosomal dorsum, the presence of dense pubescence on the mesopleuron, large compound eyes comprised of 80–110 ommatidia, and the long antennal scapes that are as long or slightly longer than head length. Worker ants are uniformly reddish brown to dark brown and are between two and three millimeters in length. *Linepithema humile* males are unmistakable as they have an unusually robust mesosoma, longer than the gaster, that bears a distinctly concave posterior propodeal face.

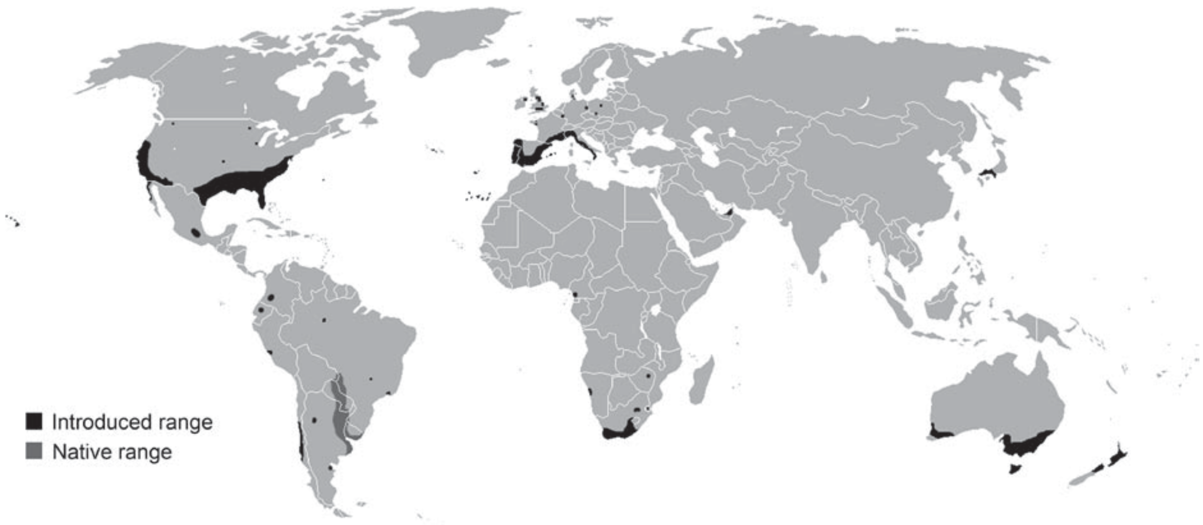
Argentine Ant, *Linepithema humile* (Mayr), (Hymenoptera: Formicidae: Dolichoderinae), Figure 80 A foraging Argentine ant, ***Linepithema humile*.**

Much of the early literature about this species is found under the name *Iridomyrmex humilis*. The change to current nomenclature occurred when recent phylogenetic research revealed a number of new world dolichoderine species, including the Argentine ant, to be unrelated to true *Iridomyrmex*, a strictly Indo-Australian group.

Distribution

The natural distribution of *Linepithema humile* (Fig. 81) extends in the south from the Buenos Aires province across Paraguay to the Pantanal in the north, and is closely associated with major waterways in subtropical South America's Paraná River drainage. This species typically inhabits lowland forests and grasslands in the Paraná and Paraguay floodplains.

In the eighteenth century, *L. humile* began to appear elsewhere in the world, arriving on the Atlantic island of Madeira in the 1850s and in the southern United States and in Portugal in the 1890s. In spite of its humid subtropical provenance, this insect has been most successful invading Mediterranean climates. Thriving introduced populations are now found in California, Mexico, Hawaii,



Argentine Ant, *Linepithema humile* (Mayr), (Hymenoptera: Formicidae: Dolichoderinae), Figure 81 **Current distribution of Argentine ant, *Linepithema humile*.**

Ecuador, Colombia, Chile, Peru, South Africa, Japan, temperate Australia, New Zealand, numerous Pacific islands, and throughout the Mediterranean region. Occasional populations persist indoors in northern Europe and North America. Microsatellite evidence suggests that at least some of these introduced populations originated in Argentina near the port city of Rosario.

Biology

Like most ant species, Argentine ants are haplodiploid and eusocial. They live in colonies composed largely of sterile female workers and a smaller number of fertile queens and males. Unlike most ants, queens of *L. humile* do not fly, mating instead in the nest. Genetic evidence suggests that queens are singly mated. For reasons that remain obscure, up to 90% of queens in a colony are periodically executed by the workers. Males are present in early summer and disperse by wing at dusk. As for all Holometabola, metamorphosis is complete. Development time is dependent on temperature and has been estimated at 445 degree-days above a 16°C threshold for workers. Under field conditions, the process from egg to adult can take several weeks to several months.

Argentine ants possess a number of life history traits that facilitate colonization and possibly pre-adapt this species as a globally successful invader. First, Argentine ant colonies have a large number of fertile queens, in some colonies running into the thousands. This polygyny increases the chance that an isolated nest fragment will contain a queen and be able to grow into a successful colony. Second, colony reproduction occurs by budding. Argentine ants do not have to pass through the high mortality bottleneck at colony founding endured by haplometrotic species that found new colonies with single queens drawing on body reserves. Indeed, *L. humile* queens without workers are incapable of founding new colonies, but propagules as small as 10 workers with a queen or even female brood can mature into populous colonies. Finally, Argentine ants cope with frequent disturbance of nesting sites. Nests tend to be superficial and transitory, occupying the top level of soil or litter. The ants move among existing nests and establish new nests frequently in response to changes in moisture and temperature. In their native range colonies will climb trees to escape rising flood waters.

Argentine ant colonies can reach extraordinary sizes, inhabiting a diffuse system of interconnected nests spanning a few meters to several hundred kilometers or more. While colony networks in the native range are restricted to at most a few thousand square meters, introduced populations normally comprise unicolonial "supercolonies" on the scale of landscapes or even continents. Supercolonies are thought to arise following population bottlenecks at introduction that produce genetic homogeneity among descendents. Such colonies are normally diagnosed using aggression assays and have been documented to cover coastal Chile, California, most of Southern Europe, and parts of Australia.

Argentine ants, like all *Linepithema* species, are trophic generalists. They predate and scavenge a wide variety of protein sources, often arthropods, and display a high affinity for honeydew. Argentine ants recruit quickly to food sources using chemical communication and are often seen running in active foraging trails. The trail pheromone is (Z)-9-Hexadecenal, produced by the Pavan's gland at the tip of the abdomen.

Effects

Introduced populations of *L. humile* penetrate both human-disturbed and natural habitats. They disrupt ecosystem processes both through active predation and exploitative competition. Community diversity is often reduced following invasion, and Argentine ants have been documented displacing native arthropods in California, Hawaii, Japan, South Africa, and Spain. Long term effects of Argentine ant invasions have included changes in South African fynbos plant community structure via displacement of native seed-dispersing ants, and local extinction of *Phrynosoma* lizards in California following the decline of their native ant prey.

Damage to agriculture stems largely from the ants' association with honeydew-producing pests. The ants protect their insect symbionts from attack by predators and transport them to uninfested plants, leading to outbreaks in populations of aphids, scale insects and mealybugs. Argentine ants are especially problematic in orchards and greenhouses where they confound biological control efforts.

The extent of Argentine ant invasion is likely limited by a combination of abiotic conditions and interactions with other ant species. Invasions are facilitated in arid regions by development-related increases in moisture from irrigation and run-off. Highly competitive local ant communities may limit the spread of the Argentine ant. In the southeastern United States, for example, Argentine ant numbers declined following the introduction of the fire ant *Solenopsis invicta*.

Management

The diffuse network structure of Argentine ant colonies renders control more difficult than for many other ant pests, as extirpated nests are readily replenished from neighboring areas. Effective control is unlikely to be gained with any single strategy, and pest managers may have to experiment with different approaches to treat an infestation. Treatment of Argentine ants around homes should include cleaning indoor ant trails when they appear, removal of potential water and food sources, and sealing the ants' entry points into the house. Control using toxic baits is often effective, and boric acid-based liquid baits are generally more palatable to the ants than most commercially available ant baits. As a last resort, appropriate perimeter insecticides or repellents may be applied. For agricultural infestations, chemical or physical barriers applied to individual plants have reduced ant damage.

No specialized natural enemies are known for the Argentine ant, but this insect has received relatively little research in its native range and some may yet be discovered. Recent work suggests that native populations may be held in check by intraspecific competition among colonies and interspecific competition with species such as *Solenopsis invicta*, also native in the Paraná drainage. If this is the case, long-term strategies for limiting the effects of Argentine ants may include the maintenance of robust native ant communities.

Argidae

A family of sawflies (order Hymenoptera, suborder Symphyta).

► Wasps, Ants, Bees and Sawflies

Argyresthiidae

A family of moths (order Lepidoptera). They commonly are known as shiny head-standing moths.

► Shiny Head-Standing Moths
► Butterflies and Moths

Arista

A large hair or bristle on the antennae of flies.

► Antennae of Hexapods

Armored Scales

Members of the family Diaspididae, superfamily Coccoidae (order Hemiptera).

► Bugs
► Scale Insects and Mealybugs

Army Ants

Ants that display group predatory and nomadic behaviors. The nest site is changed at regular intervals, and workers forage in groups.

► Ants

Army Cutworm, *Euxoa auxiliaris* (Grote) (Lepidoptera: Noctuidae)

This insect is found in the Great Plains and Rocky Mountain regions of the United States and Canada. It has been recorded from all states west of the Mississippi River, and as far east in Canada as Ontario, but attains high densities only in semiarid areas, especially along the western edge of the Great Plains.

Host Plants

Army cutworm has been reported to feed on a large number of plants. It is known principally as a pest of small grains, perhaps because these crops dominate the landscape where army cutworm occurs. It damages such field crops as alfalfa, barley, clover, flax, rye, sanfoin, sunflower, sweet clover, timothy, vetch, and wheat. Among vegetable crops, it has been reported to damage beet, cabbage, celery, corn, onion, pea, potato, radish, rhubarb, tomato, and turnip. Other crops injured include such fruit crops as apple, apricot, blackberry, cherry, currant, gooseberry, peach, plum, prune, raspberry, and strawberry. Army cutworm also feeds on noncultivated plants such as bluegrass, *Poa* spp.; bromegrass, *Bromus* spp.; buffalograss, *Buchloe dactyloides*; grama grasses, *Bouteloua* spp.; field pennycress, *Thlaspi arvense*; dandelion, *Taraxacum officinale*; lambsquarters, *Chenopodium album;* and lupine, *Lupinus* spp.

Natural Enemies

Many natural enemies have been found associated with army cutworm, and both hymenopterous parasitoids and disease have been documented to cause considerable mortality. In the central Great Plains, mortality studies over a 20-year period demonstrated parasitism levels of up to 33% and disease incidence of up to 57%. Not surprisingly, incidence of disease was greatest at high armyworm population densities. In a 3-year study in Oklahoma, researchers found that <12% of larvae were parasitized, with most parasitism due to two species, *Meteorus leviventris* (Wesmael) and *Apanteles griffini* Viereck (both Hymenoptera: Braconidae). A polyembryonic wasp, *Copidosoma bakeri* (Howard) (Hymenoptera: Encyrtidae), causes larvae to consume more food, to become larger, and live longer; this can result in the appearance of artificially high rates of parasitism, which sometimes exceeds 50%.

Among the other parasitoids known from army cutworm are such wasps as *Apanteles marginiventris* (Cresson), *A. militaris* Walsh, *Chelonus insularis* Cresson, *Macrocentrus incompletus* Muesebeck, *Microplitis feltiae* Muesebeck, *M. melianae* Viereck, *Rogas* sp., *Zele melea* (Cresson) (all Hymenoptera: Braconidae); *Campoletis flavicincta* (Ashmead), *C. sonorensis* (Cameron), *Diphyus nuncius* (Cresson), *Exetastes lasius* Cushman, and *Spilichneumon superbus* (Provancher) (all Hymenoptera: Ichneummonidae). Flies known to parasitize this species include *Bonnetia comta* (Fallen), *Euphorocera claripennis* (Macquart), *Mericia* spp., *Peleteria* sp., *Periscepsia cinerosa* (Coquillett), *P. helymus* (Walker), and *P. laevigata* (Wulp) (all Diptera: Tachinidae).

Several viruses are known to infect army cutworm, including entomopox, granulosis, and nonoccluded viruses. The relative importance of each is uncertain, but the granulosis virus is unusually pathogenic.

Life Cycle and Description

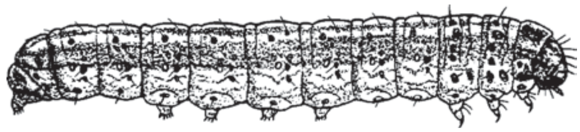
There is a single generation per year throughout the range of this insect. Eggs are deposited on soil in August-October. Eggs hatch in autumn or early winter, and larvae overwinter, feeding actively in the spring. Pupation occurs about a month before adults appear. Adults first become active in April-May in southern locations such as Kansas and Texas, whereas in more northern locations such as Alberta and Montana they may not appear until June-July. The moths migrate from the plains, where the larvae develop, to higher elevations in the Rocky Mountains, where the adults feed on nectar from flowers. The adults return to the plains in August-September.

Egg

Eggs are deposited singly or in small clusters just beneath the soil surface on a solid substrate. The eggs are a slightly flattened sphere, measuring about 0.6 mm in diameter and 0.5 mm in height. The egg is white to yellow initially, becoming gray to brown as the embryo matures. The egg is marked with about 18 very narrow ridges that radiate from the apex. Survival of eggs is reported to be affected by moisture, and above-average rainfall in late summer and autumn tends to assure good insect survival and damaging populations the subsequent year. Field-collected females were reported to produce 200–300 eggs, with the potential to produce about 500 eggs.

Larva

The eggs hatch in the autumn or early winter but the larvae are usually not noticed until spring when they increase in size and begin to consume considerable foliage. There are 6–7 instars, with head capsule widths of 0.26–0.30, 0.40–0.45, 0.65–0.72, 1.04–1.21, 1.70–2.10, and 2.90–3.40 mm, respectively, for instars 1–6 among larvae with only 6 instars. Additional instars apparently occur when larvae feed on less suitable host plants. The body color of the larvae is (Fig. 82) grayish brown, but bears numerous white and dark brown spots. There usually is evidence of 3 weak light-colored dorsal stripes. Laterally there tends to be a broad dark band, and the area beneath the spiracles is whitish. The head is light brown with



Army Cutworm, *Euxoa auxiliaris* (Grote) (Lepidoptera: Noctuidae), Figure 82 Larva of army cutworm *Euxoa auxiliaris*.

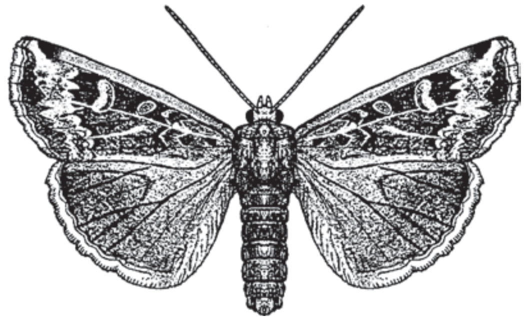
dark spots. Larvae attain a length of about 40 mm. They usually are found beneath the surface of the soil, emerging in late afternoon or early evening to feed. On cloudy days, however, they may be active during the daylight hours. Larvae will assume a migratory habit when faced with food shortage, and large numbers will proceed in the same direction, consuming virtually all vegetation in their path. It is this dispersive behavior that is the basis for their common name, and larvae have been observed to disperse over 4 km.

Pupa

Pupation occurs in the soil, in a cell prepared by the larva. The walls of the cell are formed with salivary secretion, which hardens and provide a degree of rigidity. The depth of pupation varies according to soil and moisture conditions, but may be any depth up to 7.5 cm. The larva spends about 10 days in the cell prior to pupation. Duration of pupation is 25–60 days. The pupa is dark brown in color, and measures about 17–22 mm in length and 6 mm in width.

Adult

The adults measure 35–50 mm in wingspan. They are quite variable in appearance, with five named subspecies, but moths generally assume two basic forms. One common form has the leading edge of the forewing marked with a broad (Fig. 83) yellowish stripe, and the remainder of the wing blackish but marked with white-rimmed bean-shaped and round spots, and a light transverse line. In another common color form the forewing is mottled brown,



Army Cutworm, *Euxoa auxiliaris* (Grote) (Lepidoptera: Noetuidae), Figure 83 Army cutworm adult, light form.

bearing bean-shaped and round spots but lacking bands and stripes. In all cases, the hind wings are brownish with dark veins, and darker distally. The brown body of the moth is quite hairy.

As previously noted, the adults are migratory, dispersing from the plains to the mountains annually. In transit and in the mountains they feed on nectar from flowering plants. They are nocturnal, and seek shelter during the daylight hours. They have the habit of aggregating in houses, automobiles, and other sheltered locations where they become a nuisance, soil walls, and induce allergic reactions among some individuals. They also may aggregate in natural shelters in mountainous regions, where they become prey for bears. In the Rocky Mountain region they are commonly called "miller moths".

Damage

These insects principally are pests of small grain crops grown in arid regions, although a number of irrigated crops also are at risk. Larvae readily climb plants to consume foliage, eating holes in vegetation initially, and eventually destroying the entire plant. Although they burrow into the soil during the daylight hours they do not normally feed below-ground. However, when succulent food is in short supply they will follow the plant stem down into the soil. When food supplies are exhausted large numbers of larvae may disperse in search of additional food.

Management

Adults can be captured in light traps and pheromone traps. However, males are attracted to the sex pheromone only during the autumn flight. Pheromone traps positioned at a height of 1 m or lower are more effective than those place higher. Larvae can be recovered from soil by raking through the top 5–7 cm.

Persistent insecticides can be applied to vegetation to kill army cutworm larvae when they emerge from the soil to feed; *Bacillus thuringiensis* is not effective. Larvae also will accept bran bait containing insecticide.

Cultural manipulations are not generally effective to prevent oviposition because moths will deposit eggs on barren soil. Delayed planting of crops can be effective, however, as larvae complete their development on weeds or starve before crops are planted. If larvae are dispersing, creation of deep ditches with steep sides, or filled with running irrigation water, may prevent invasion of fields.

To protect plants grown in the home garden, barriers are sometimes used to reduce access by cutworms to seedlings. Metal or waxed paper containers with both the top and bottom removed can be placed around the plant stem to deter consumption. Aluminum foil can be wrapped around the stem to achieve a similar effect. Because larvae will burrow and feed below the soil line, the barrier should be extended below the soil surface.

Armyworm, *Pseudaletia unipuncta* (Haworth) (Lepidoptera: Noctuidae)

John L. Capinera
University of Florida, Gainesville, FL, USA

Armyworm also occurs in many areas of the world, including North, Central and South America, southern Europe, central Africa, and western Asia. It is known principally as a grain pest. It does not overwinter in northern latitudes, but disperses northward each spring, and then southward during the autumn. Because it is found widely, it has acquired several common names, including true armyworm, rice armyworm, and American armyworm.

Life History

Although not surviving year-round in cold winter areas, larvae apparently overwinter at intermediate levels, and in warm weather areas all stages may be found during the winter. The number of generations varies among locations, but in North America two generations occur annually in Ontario, Canada, whereas in the USA there are 2–3 generations in Minnesota and New York, 4–5 are reported in Tennessee, and 5–6 in southern states. A complete generation requires 30–50 days.

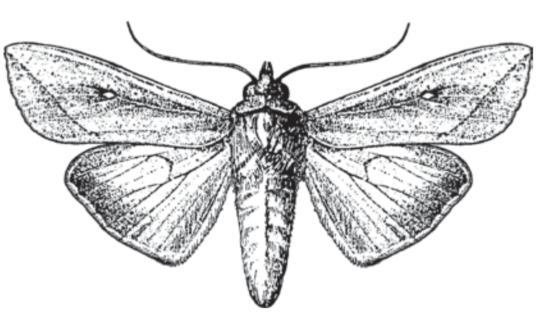
Females deposit eggs in clusters consisting of two to five rows, in sheltered places on foliage, often between the leaf sheath and blade, especially on dry grass. Often females seem to deposit large numbers in the same vicinity, resulting in very high densities of larvae in relatively small areas of a field. Nevertheless, the eggs are very difficult to locate in the field. The eggs are white or yellowish, but turn gray immediately before hatching. Eggs are spherical, and measure about 0.54 mm (range 0.4–0.7 mm) in diameter. The egg surface appears to be shiny and smooth, but under high magnification fine ridges can be observed. The egg clutches are covered with an adhesive secretion that is opaque when wet but transparent when dry. As the adhesive material dries it tends to draw together the foliage, almost completely hiding the eggs. Mean duration of the egg stage is about 3.5 days at 23°C, and 6.5 days at 18°C, but the range is 3–24 days over the course of a season. Hatching rates are affected by temperature, with cool weather more favorable for embryonic survival. In Tennessee, about 98% egg hatch occurs in early spring and autumn, with hatching rates dropping to less than 30% during the summer; this probably accounts for the evolution of the dispersal behavior in this species.

Larvae normally display 6 instars, though up to 9 instars have been observed. Mean head capsule widths (range) are 0.34 (0.30–0.37), 0.55 (0.49–0.63), 0.94 (0.83–1.12), 1.5 (1.29–1.70), 2.3 (2.08–2.56), and 3.3 (3.04–3.68) mm, respectively, for instars 1–6. Head capsule widths increase slightly with increased temperature up to about 30°C. Larvae attain a body length of 4, 6, 10, 15, 20, and 35 mm, respectively, during instars 1–6. Except for the first instar, which is pale with a dark head, the larvae of armyworm are marked with longitudinal stripes throughout their development. The head capsule is yellowish or yellow-brown with dark net-like markings. The body color is normally grayish green, but a broad dark stripe occurs dorsally and along each side (Fig. 85). A light subspiracular stripe often is found laterally beneath the dark stripe. Development time varies with temperature. During summer larvae complete their development in about 20 days, but this is extended to about 30 days during the spring and autumn, and greatly prolonged during winter. Instar-specific development times recorded during early summer in Tennessee are 2–3, 2–3, 2–4, 2–3, 4–5, and 7–10 days for instars 1–6, respectively. The larvae tend to disperse upward following hatching, where they feed on tender leaf tissue. If disturbed, they readily extrude silk and spin down to the soil. Larvae in instars 3–6 are active at night, seeking shelter during the day on the soil beneath debris or clods of soil.

Larvae pupate in the soil, often under debris, at depths of 2–5 cm. Pupation occurs in an oval cell that contains a thin silken case. The pupa is moderate in size and robust, measuring 13–17 mm long and 5–6 mm wide. The pupa is yellowish brown initially, but soon assumes a mahogany brown color. The tip of the abdomen bears a pair of hooks. Duration of the pupal stage is 7–14 days during summer but longer early and late in the season, sometimes lasting 40 days.

The adult is a light reddish brown moth with a wing span measuring about 4 cm. The forewing is fairly pointed (Fig. 84), appearing more so because a transverse line of small black spots terminates in a black line at the anterior wing tip. The forewing is also marked with a diffuse dark area centrally containing one or two small white spots. The hind wings are grayish, and lighter basally. Adults are nocturnal. Mating commences 1–3 days after moths emerge from the soil, and usually 4–7 h after sunset. Eggs are normally deposited within a 4–5 day period (range 1–10). Females produce an average of 4.9 egg masses (range 1–16). Reproductive capacity varies, with authors reporting mean egg production anywhere from 500 to 1500 per female. Feeding is necessary for normal oviposition. Mean longevity at warm temperatures is about 9 days in males and 10 days in females (range 3–25) whereas at cool temperatures mean longevity of males is 19 days and females 17 days.

Armyworm generally prefers to oviposit and feed upon plants in the family Gramineae, including weedy grasses. Thus, such grain and grass crops as barley, corn, millet, oats, rice, rye, sorghum, sugarcane, timothy, and wheat may be consumed, as well as wild or weed grasses. During periods of abundance larvae feed more generally, damaging such crops as alfalfa, artichoke, bean, cabbage, carrot, corn, celery, cucumber, lettuce, onion, parsley,



Armyworm, *Pseudaletia unipuncta* (Haworth) (Lepidoptera: Noctuidae) Figure 84 Adult of armyworm, *Pseudaletia unipuncta* (Haworth).

parsnip, pea, pepper, radish, sugarbeet, sweet potato, watermelon, and others. Adults feed on nectar of various flowers and sometimes feed on other sweet foods such as ripe and decaying fruit.

The importance of natural enemies, especially parasitoids, has been studied, though nearly all data are derived from periods of high armyworm density, which is not typical for this insect. Over 60 species of wasp and fly parasitoids are known, and vary considerably from time to time and place to place in importance.

Predators readily consume armyworm larvae. Ground beetles (Coleoptera: Carabidae) are especially effective because larvae spend a great deal of time in association with soil, but various predatory bugs (Hemiptera: various families), ants (Hymenoptera: Formicidae), and spiders (Araneae: Lycosidae and Phalangiidae) also feed on armyworm. Avian predators are often credited with destruction of armyworms. The bobolink, *Dolichonyx oryzivorus* (Linnaeus), prospers during outbreak years and has sometimes been called the "armyworm bird" in North America. Other birds of note include the crow, *Corvus brachyrhynchos* Brehm, and starling, *Sturnus vulgaris* Linnaeus.

Diseases commonly infect armyworms, especially during periods of high density. Bacteria and fungi, particularly the fungus *Metarhizium anisopliae*, are reported in the literature. Nematodes are sometimes considered to be important mortality factors. However, undoubtedly the most important diseases are viruses; several granulosis, cytoplasmic polyhedrosis, and nuclear polyhedrosis viruses often kill virtually all armyworms during periods of outbreak, especially when larvae are also stressed by lack of food or inclement weather.

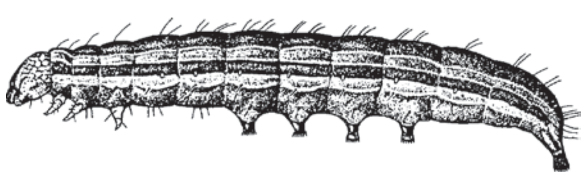
Armyworm attains high densities irregularly, often at 5–20 year intervals. The exact cause is unknown, but outbreaks often occur during unusually wet years and are preceded by unusually dry years. Armyworm is not well adapted for hot temperature; survival decreases markedly when temperatures exceed about 30°C. Consequently, at southern latitudes populations are higher early and late in the year, but at northern latitudes it is a mid season pest.

Damage

Larvae initially skeletonize foliage, but by the third instar they eat holes in leaves, and soon afterwards consume entire leaves. Larvae of armyworm (Fig. 85) are notorious for appearing out of nowhere to inflict a high level of defoliation. This occurs for several reasons: a highly clumped distribution of young larvae, with most of the crop uninfested until larvae are nearly mature and highly mobile; a tendency by larvae to feed on grass weeds preferentially, only moving to crops after the grass is exhausted; occurrence of a preponderance of feeding, about 80%, in the last instar; the nocturnal behavior of larvae, which makes them difficult to observe during the day; and the gregarious and mobile behavior of mature larvae, which form large aggregations or bands (hence the common name "army" worm). As previously noted, grasses and grains are preferred, but as these plants are consumed larvae disperse, often in large groups, to other plants. During outbreaks, few plants escape damage.

Management

Adults can be captured with blacklight traps, and a sex pheromone has been identified and can be used for population monitoring. It is advisable to examine crop fields for larvae, especially if moths have been captured in light or pheromone traps. Fields should be examined at dawn or dusk, because larvae are active at this time. If it is necessary to check fields during the day, it is important to sift through the upper surface of the soil and under debris for resting larvae.



Armyworm, *Pseudaletia unipuncta* (Haworth) (Lepidoptera: Noctuidae), Figure 85 Larva of armyworm, *Pseudaletia unipuncta* (Haworth).

Larvae will consume wheat bran or apple pomace baits treated with insecticide, but foliar and soil-applied insecticides are also effective, and used frequently.

Cultural practices have limited effect on armyworm abundance due to their highly dispersive behavior. However, grass weeds are a focal point of infestation, and should be eliminated, if possible. Not surprisingly, no-till and minimum tillage fields experience greater problems with armyworm, relative to conventional tillage fields. Proximity to small grain crops is considered to be a hazard due to the preference of moths for such crops, and the suitability of grains for larval development. In Virginia, destruction of winter cover crops by herbicide application is more favorable to armyworm survival than is mowing of cover crops, apparently because predators are more disrupted by herbicide treatment. Prior to the availability of effective insecticides, deep furrows with steep sides were sometimes plowed around fields to prevent invasion by dispersing armyworm larvae. Although this approach remains somewhat useful, it is rarely practiced.

Arnett, Jr., Ross Harold

Ross Arnett was born on April 13, 1919, in the state of New York. He attended Cornell University and earned a B.S. degree in 1942. That same year, he married Mary Ennis, spent a short time working for the New York Conservation Department, then joined the U.S. army. His army duties had him controlling mosquitoes in Florida, and then teaching mosquito taxonomy in Panama. In October 1945, he was discharged by the army, and returned to Cornell University as a graduate student. He received his master's degree in 1946, having studied medical and aquatic entomology. For his doctoral research, he returned to his early interest in beetles, beginning a taxonomic revision of the North American Oedemeridae, and he received his Ph.D. in 1948. He was employed (1948–1954) by the U.S. Department of Agriculture as a taxonomist at the U.S. National Museum, 1954–1958 as professor of biology at Saint John Fisher College in New York state, 1958–1963 as professor of biology at the Catholic University of America (in Washington, DC), 1966–1973 at Purdue University (Indiana), and 1973–1979 at Siena College (New York state). Thereafter, he left academic life and derived his income from publishing. His research interests were in the family Oedemeridae. ("false blister beetles"), on which he published several scientific papers. However, it is as a teacher (he guided several graduate students in taxonomy of Coleoptera) and author of books and journals and publishing projects that entomologists knew him best. His "Beetles of the United States. A manual for identification" was the standard identification reference from its publication in 1962 until its replacement by the two-volume "American Beetles" (volume 1: 2000, volume 2: 2002) that he began. In 1947 he founded The Coleopterists' Bulletin and was for years its editor (it was later and ungrammatically renamed by others The Coleopterists Bulletin). In 1985 he founded the journal Insecta Mundi, which is now published by the Center for Systematic Entomology, of Gainesville, Florida, as a low-cost outlet for taxonomic publications on insects. He published a book on Coleoptera collections of North America, which later was greatly expanded to become "The insect and spider collections of the world" (1986) and still later (1993) was revised, and another (Entomological Information

Storage and Retrieval, 1970) on documentation, both of which were ahead of their time. He was author or coauthor of books on botany, on "How to know the beetles," of "Simon and Schuster's Guide to Insects," and of two volumes on "The Beetles of northeastern North America." His "American Insects" (1985) won the R.R. Hawkins award from the American Association of Publishers, but coleopterists would argue that his works on Coleoptera were far greater. He was the founder of a short-lived journal featuring colored photographs (hitherto rarely seen in entomology because of cost, yet common in everyday advertisements for commercial products) called Insect World Digest, and of two publishing companies (Flora and Fauna publications, and Sandhill Crane Press), which helped entomologists and other biologists to publish their works. He was the instigator in the 1970s of the "North American Beetle Fauna Project," whose ambition was to catalog and document all of the North American Coleoptera. He was the greatest proponent of North American coleopterology for over 50 years. He died on July 16, 1999, in Gainesville, Florida, survived by his devoted wife, Mary Ennis Arnett, who died on January 3, 2002, and eight children.

Arthropod-Associated Plant Effectors (AAPEs): Elicitors and Suppressors of Crop Defense

HANS T. ALBORN, ERIC A. SCHMELZ
USDA ARS CMAVE, Gainesville, FL, USA

Interactions between plants and insects have played a significant role in the evolution of both groups of organisms. In response to herbivory, plants have evolved the ability to perceive and defensively respond to insect herbivores (or potential herbivores), either directly, by inducing biochemical changes that impede pest growth or indirectly, by promoting advantageous interactions with beneficial organisms, often through the release of volatile signals. These volatile signals indicate to parasitic and predaceous insects the location of potential prey. Insects may also partly inhibit these induced plant responses by limiting the accumulation of defense-related biochemicals at the feeding site. We collectively refer to substances that either negatively or positively alter plant responses to attack as arthropod-associated plant effectors (AAPEs). Those effectors that increase a plant's defense against an arthropod pest are termed elicitors while those that reduce a plant's defense are suppressors.

Research on arthropod-associated elicitors and suppressors of plant responses traces its roots to the 1972 discovery by Clarence Ryan and colleagues that feeding by Colorado potato beetle (*Leptinotarsa decemlineata*), as well as mechanical damage to tomato plants, rapidly increases the concentration of leaf protease inhibitors. This ultimately led to the discovery of systemin, an 18 amino acid peptide, and established the existence of peptide signals in plants. In 1988, Marcel Dicke and colleagues demonstrated that herbivory by spider mites (*Tetranychus urticae*) induced plant volatiles in lima bean (*Phaseolus lunatus*) leaves, which in turn served as attractants for predatory mites (*Phytoseiulus persimilis*). Shortly thereafter, Jim Tumlinson and colleagues demonstrated similar volatile-mediated tritrophic interactions among the beet armyworm (*Spodoptera exigua*) herbivore, corn (*Zea mays*), and host-seeking parasitic wasps (*Cotesia marginiventris*). In corn, this rapidly induced increase in volatile emission could not be stimulated by mechanical damage alone yet was readily mimicked by the application of beet armyworm oral secretions to wounded leaves. In 1997 the fatty acid-amino acid conjugate *N*-17-hydroxylinolenoyl-L-glutamine, termed volicitin, was discovered in the oral secretions of beet armyworm. This elicitor of corn leaf volatiles marked the first AAPE isolated and identified from insects.

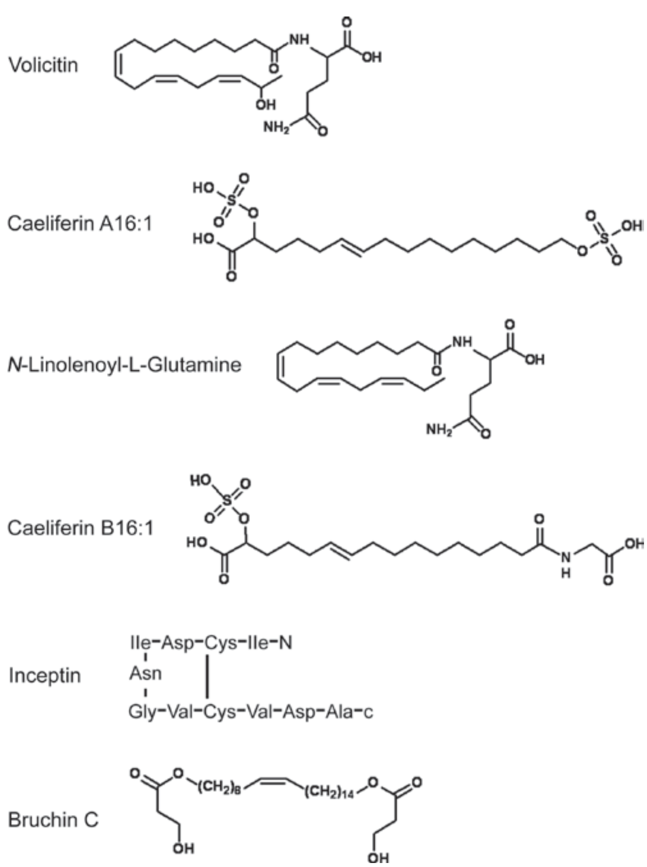
During arthropod feeding or oviposition, mechanical wound responses in the plant can be greatly amplified by the presence of elicitors. Elicitors are specific bioactive chemicals present at the plant wound-site that may be derived from the insect, the plant, or from the interactions between organisms. The mode of action of elicitors may vary, but increasingly some classes are predicted to act as ligands that bind plant receptors (likely membrane-bound extracellular leucine-rich repeat receptor kinases) initiating a complex cascade of signal transduction leading to induced plant responses. Typically, over the course of a few hours, elicitors will cause a rapid induction of defense-related phytohormones, including jasmonic acid, ethylene, and salicylic acid which serve as both markers and signals for subsequent plant defense responses. In contrast to elicitors, suppressors of plant defense may act through direct insect-derived protein/enzyme interactions within the plant. The majority of recently identified AAPEs described below act as elicitors of plant defense; however, glucose oxidase acts as a suppressor of plant defense.

Volicitin

In 1997, Hans Alborn and colleagues isolated and identified volicitin from the larval oral secretions of the beet armyworm (BAW), *Spodoptera* *exigua*. Subsequently, other analogous fatty acid amide elicitors have been identified in the oral secretions of several other species of Lepidoptera. This class of elicitors consists of plant fatty acids, typically linolenic, linoleic, and oleic acid, or their 17-hydroxy analogs, conjugated with glutamine or glutamic acid. They were initially thought to be specific for Lepidoptera but recently they have also been found in katydids, crickets and fruit flies. Thus far, three herbivore-produced fatty acid-amino acid elicitors, volicitin, *N*-linolenoyl-L-glutamine and *N*-linolenoyl-L-glutamate (Fig. 86), have been demonstrated to have significant activity in inducing plants to produce and release volatile organic compounds that are synthesized by several different biosynthetic pathways, including the lipoxygenase, shikimate and isoprenoid pathways. Fatty acid amides seem to have activity on a broad range of plants, although some clear exceptions exist (see inceptin below). A significant release of volatiles can typically be detected a few hours after an application of about 10 pmol volicitin/corn seedling.

Caeliferins

In the early 1990s, when working on the isolation of volicitin, the Tumlinson group observed that not only feeding by lepidopteran larvae but also feeding by the American grasshopper (*Schistocerca americana)* induced corn seedlings to release volatile organic compounds. This led to the recent discovery of a new type of elicitor named caeliferins. These



Arthropod-Associated Plant Effectors (AAPEs): Elicitors and Suppressors of Crop Defense, Figure 86 Structures of some elicitors.

compounds are comprised of saturated and monounsaturated, sulfated alpha-hydroxy fatty acids (with fatty acid chains of 15–20 carbons) in which the omega carbon is functionalized with either a sulfated hydroxyl or a carboxyl conjugated to glycine via an amide bond. In the oral secretions of the American grasshopper, the 16-carbon analogs are predominant and also most active in inducing release of volatile organic compounds when applied to damaged leaves of corn seedlings. It appears that caeliferins, which are the first non-lepidopteran elicitors of volatiles identified in insect herbivores, might be present in most, if not all, grasshoppers (members of the suborder Caelifera), but not in crickets or katydids (suborder Ensifera). Interestingly, oral secretions of at least some crickets and katydids contain some of the same glutamine and glutamic acid-based fatty acid amides that are found in Lepidoptera larvae. Preliminary results indicate that the activity of caeliferins might be restricted to monocotyledons where the response mimics that of volicitin. The typical lowest active dose is about 100 pmol/corn seedling.

Inceptin and Related Peptides

In cowpea (*Vigna unguiculata*) and beans (*Phaseolus vulgaris*), herbivory by fall armyworm (*Spodoptera frugiperda*) larvae and applications of oral secretions elicit phytohormone changes and induce volatile emission due to the presence of a disulfide-bridged peptide termed inceptin. Inceptin and related fragments are derived from the γ-subunit of chloroplastic ATP synthase (cATPC) present in leaf tissue. As a result of insect gut proteolysis, the oral secretion of larval fall armyworm contains a mixture of related peptides derived from cATPC, including additional amino acids at the N terminus and also C-terminal truncations. Inceptin is the one of the most potent AAPEs known to date, and has measurable elicitor activity starting at 1 fmol/leaf. Inceptin elicits a rapid and sequential induction of defense-related phytohormones, such as jasmonic acid, ethylene and salicylic acid, and also stimulates the emission of large amounts of volatile organic compounds. However, inceptin has additional roles in direct plant defense including upregulation of protease inhibitor transcripts and reduced growth of larvae on induced tissues. Similar to established peptide signals with known plant receptors, such as systemin and flg22 (derived from bacterial flagellin), inceptin is also believed to act as a ligand that specifically binds a plant receptor initiating these responses. In cowpea and beans, insect gut proteolysis following herbivory generates inappropriate fragments of an essential metabolic enzyme that enables plant non-self recognition.

Bruchins

The first beetle-derived elicitor of physical plant defense was described from the cowpea weevil (*Callosobruchus maculatus* F.). Oviposition of pea weevil (*Bruchus pisorum* L.) on pods of specific varieties of pea (*Pisum sativum* L.) promotes neoplastic cellular growths that impede entry of neonate weevil larvae into the pod and increase the probability of predation, parasitism and dehydration. This class of elicitors, collectively named bruchins, represents long-chain α,ϖ-diols, partly or entirely esterified with 3-hydroxypropanoic acid. Like the inceptin peptide, bruchins exhibit potent biological activity with as little as 1 fmol (0.5 pg) inducing neoplastic growth on pea pods. Supportive of a role for specific plant receptors, only pea plants harboring the yet uncloned Np allele exhibit these responses.

Glucose Oxidase

The first demonstration of a suppressive effect of AAPEs came from studies of the corn earworm (*Helicoverpa zea*) feeding on leaves of tobacco (*Nicotiana tabacum*). During herbivory larvae secrete the salivary enzyme glucose oxidase (GOX) from the spinneret which reacts with glucose to form hydrogen peroxide and gluconic acid. GOX levels in labial glands vary considerably dependent upon larval diet and host plants. Insect secretion of glucose oxidase limits the wound-induced accumulation of the toxic alkaloid nicotine following herbivory. As a product of GOX, hydrogen peroxide may either directly or indirectly inhibit wound-induced nicotine accumulation but this hypothesis awaits confirmation.

Other Systems for Consideration

Enzymatic activity consistent with β-glucosidase has been found in larvae of the cabbage white butterfly (*Pieris brassicae*). Applications of β-glucosidase preparations from almonds have been reported to promote volatile emission in excised leaves of Brussels sprouts (*Brassica oleracea* L. var *gemmifera*) that have been additionally wounded. Curiously, the role of β-glucosidase as an elicitor of plant volatile emission has not been followed up on in over a decade nor demonstrated outside of the aforementioned experimental system. Many lytic enzymes have the potential to influence plant physiological responses; however, clear and careful experimentation is required prior to demonstrating a substance to be a relevant effector.

Alkaline phosphatase activity has been demonstrated to exist in the salivary glands of adult whiteflies (*Bemisia tabaci* B biotype, syn. *B. argentifolii*) and is also secreted into artificial diets. This enzyme exists as a candidate AAPE but at this time no specific action on plant physiology has been shown. Alternatively, the pore-forming peptide alamethicin and larger polypeptides from preparations of cellulysin, originating from the fungus *Trichoderma viride*, are potent inducers of plant defense responses. These bioactive substances have been demonstrated to have activities similar to known AAPEs yet they are not known to exist in the secretions of arthropods at meaningful levels. Many additional plant-insect systems, such as the plant response to oviposition of insect eggs, have been clearly demonstrated to involve putative AAPEs, yet the majority of these await detailed characterization.

Significance of AAPEs

Many insect herbivores are vulnerable to predators and other natural enemies only during narrow developmental windows. For example, the parasitoid wasp *Cotesia marginiventris* must locate hosts before the end of the caterpillar's second instar. Long range attraction to the hosts is mediated by herbivore-induced plant volatiles, yet the amount of mechanical damage caused by first instar larvae is low. Elicitors, whether plant-or arthropod-produced, serve an important ecological function in amplifying plant signal transduction cascades such that a significant response (i.e., release of volatile organic compounds) is generated from a very modest initial injury.

Photosynthetic organisms have had to cope with biotic stress in the form of microbes long before the existence of insects. A significant component of plant pathology research focuses on the molecular aspects of how plants recognize pathogens and the mechanisms by which pathogens avoid recognition. Emphasis on this area of inquiry arose from necessity and the microscopic nature of the interactions. Entomologists have additional levels of complexity to confront including insect behavior, multiple instars of development and complex multitrophic interactions. Studies involving these visible markers have historically been more numerous than molecular level investigations. Plant breeders strive to maintain insect resistance in new crop cultivars, ideally one step ahead of emerging insect biotypes that overcome these defenses. Currently, numerous examples of genes responsible for plant resistance to insects are being identified as receptor kinases. These receptors are not directly toxic and by themselves do not result in plant resistance. Instead, ligand (i.e., elicitor) binding to receptors triggers induced plant responses that result in resistance. In plant pathology research, some virulent pathogens lack key biochemicals or possess slightly modified protein sequences enabling evasion of receptor-mediated plant recognition. We can fully expect the same interactions to be occurring in insect pests that are specialized on specific crops.

Once basic insect recognition systems are understood in plants at molecular and mechanistic level, strategies will be tractable to transgenically modify and promote a plant's ability to induce rapid defense responses. Some examples of future research on insect biotypes that overcome plant resistance will likely demonstrate mechanisms involving the alterations of receptor-ligand binding interactions. Currently not a single plant-insect interaction involving AAPEs is understood at this level. This research direction is essential for further progress. Understanding the chemistry of the AAPEs that mediate these interactions is more than just a research curiosity. AAPEs represent literal and figurative keys to induced plant defense and resistance to insect pests.

Arthropods

Those members of the phylum Arthropoda. Animals with jointed legs. The principal arthropod taxa of interest to entomologists are:

Phylum Arthropoda
- Subphylum Trilobita – Trilobites (these are extinct)
- Subphylum Chelicerata
  - Class Merostomata – Horseshoe crabs
  - Class Arachnida – Arachnids (scorpions, spiders, ticks, mites, etc.)
  - Class Pycnogonida – Sea spiders
- Subphylum Crustacea – Crustaceans (amphipods, isopods, shrimp, etc.)
- Subphylum Atelocerata
  - Class Diplopoda – Millipedes
  - Class Chilopoda – Centipedes
  - Class Pauropoda – Pauropods
  - Class Symphyla – Symphylans
  - Class Entognatha – Collembolans, proturans, diplurans
  - Class Insecta – Insects

In addition, the Phylum Onychophora is sometimes considered to be arthropods, but it is best considered to be a separate phylum, evolutionarily intermediate between arthropods and annelids.

► Centipedes
► Diplurans
► Entognatha

- ► Millipedes
- ► Mites
- ► Pillbugs and Sowbugs
- ► Proturans
- ► Scorpions
- ► Spiders
- ► Springtails
- ► Ticks

Articulation

A connection or joint between two sections of the cuticle, or structures. Articulations take many forms, ranging from membranous or lightly sclerotized area between two plates, to a ball and socket joint.

Ascalaphidae

A family of insects in the order Neuroptera. They commonly are known as green owlflies.

► Lacewings, Antlions and Mantidflies

Ascosphaera apis

One of the best-known ascomycetous insect pathogens is *Ascosphaera* (Plectomycetes). *Ascosphaera apis* causes chalk-brood disease mainly in honey bees, a condition that may not necessarily be serious depending upon the hygienic behavior of the insects; colonies from which diseased brood is removed by worker bees appear to be resistant to the disease. The fungus is usually heterothallic, and during sexual reproduction the trichogyne (receptive female hypha) fuses with a nutriocyte, an inflated part of the ascogonium. The nutriocytes develop asci and ascospores that form into tightly packed spheres called spore balls. The chambers that encase the spore balls are termed the sporocysts, and these appear as dark specks on mummified larvae. Enzyme analysis has been used to identify strains of *Ascosphaera*, whereas certain morphological characteristics can facilitate separation of species. These characteristics include ascospore shape, size, color and arrangement, as well as the size, color, etc., of sporocysts. The location (i.e., subcuticular, external) of the cysts also can be relevant in identification, although it has been reported that cysts of *A. apis* can occur beneath the integument in carpenter bee larvae.

Ascosphaera spores can initiate infection in healthy bee larvae either by breaching the external cuticle or through the digestive tract. Chilling appears to facilitate the infection process, and the peripheral brood, where the temperature may be lower, is therefore more easily infected. Some species of the fungus can infect solitary insects; for example, *A. aggregata* commonly occurs in alfalfa leafcutting bees. The infection is initiated only by ingestion of the spores. The hyphae invade the midgut wall and hemocoel, and eventually replace most of the larval tissues. This species of Ascosphaera does not readily digest chitin, so that sporulation is subcuticular, in contrast to *A. apis* in which the mummified surfaces usually are covered with white mycelia and darkened cysts. When sexual reproduction in *A. aggregata* is complete, and the mature ascospores are formed, the fungal mat becomes dark brown and is hard and dry. This species requires a complex medium for *in vitro* growth and thus appears to be a true obligate parasite. Other species are considered to be opportunistic since they can grow saprophytically, or only infect stressed insects.

Ascoviruses

The members within the proposed Ascoviridae family are characterized by the accumulation of virion-containing vesicles (asco = sac, or bladder) in the hemolymph of host noctuid larvae. The membrane-bound vesicles (1–10 μm) contain hundreds of enveloped allantoid shaped virus particles that are 300–400 nm in length and 130 nm in diameter. The outer surface of the bilayer viral envelope possesses a characteristic reticulate pattern. Purified ascoviruses contain a complex of 12 structural proteins ranging from 11 to 200 kDa. Ascoviruses encapsidate a circular dsDNA (140–180 kbp) having a G + C ratio of 60%. Comparative sequence analysis of the DNA polymerase genes suggests that ascoviruses and iridoviruses shared a common ancestor. Presently, ascoviruses have been detected in several noctuids including *Autographa californica*, *Trichoplusia ni* (TAV), *Spodoptera frugiperda* (SAV), *Heliothis virescens* (HAV), *Heliocoverpa zea* (HZV), and *Scotogramma trifolii* (STV). Southern blot hybridization studies have demonstrated that the SAV genome (140 kbp) differed from the closely related TAV and HAV genomes (180 kbp). Histological examinations revealed that TAV and HAV both replicated in the nuclei of epidermal and mesodermal insect tissues, whereas SAV replication was restricted to fat body tissue.

Ascovirus infections normally retard growth and development of diseased larvae. This virus, originally identified as a Rickettsial-like organism, is slow acting, causing larval death after a prolonged period (20–30 days) of arrested larval growth. These viruses infect a limited number of cells within a particular tissue. Examination of the milky infected hemolymph under light microscopy revealed the presence of numerous virion-containing vesicles. These vesicles are produced by infected cells that undergo an apoptotic-like cleavage. *In vivo*, infected larvae have been observed to discharge infectious virus from the eversible gland. The vesicles, when fed to neonate larvae, resulted in erratic infection patterns (2–85%). However, challenge with a minutin pin dipped in virus suspensions resulted in 100% infection rates. As few as ten vesicles are infectious when delivered into the insect hemocoel. Research has demonstrated that ascoviruses can be mechanically transmitted from infected larvae to healthy larvae during oviposition by parasitoids. The ascoviruses are able to outcompete the developing parasitoid and successfully infect host larvae. It has been suggested that the incidence of ascovirus in noctuid populations, ranging from 1 to 25%, may be associated with the presence of larval parasitoids.

Asian Citrus Psyllid, *Diaphorina citri* Kuwayama (Hemiptera: Psyllidae)

JAMES H. TSAI
University of Florida, Ft. Lauderdale, FL, USA

The Asian citrus psyllid *Diaphorina citri*, is of Far Eastern origin and is also called the oriental citrus psyllid. Its known range of distribution covers tropical and subtropical Asia including India, Burma, Thailand, Nepal, Sikkim, Hong Kong, Ryukyn Islands, the Philippines, Malaysia, Indonesia, Ceylon, Pakistan, Afghanistan, Reunion, and Mauritius. It is also found in Saudi Arabia in the Near East, and Brazil in South America. This insect was first discovered in the United States in 1998, and is now widespread in southern Florida.

Diaphorina citri causes severe damage to citrus by: (i) withdrawal of a large quantity of sap from the foliage, affecting the overall growth of citrus, and promotion of sooty mold on honeydew secreted onto leaves, which results in reduction of photosynthesis; and (ii) efficient transmission of greening bacterium (*Liberobacter asiaticum*) by *D. citri*. The greening disease (Huanglungbin) is a limiting factor in citrus production in the Far East, though it does not occur in Florida. Citrus infected by the greening agent initially shows leaf mottling and chlorosis symptoms, followed by stunted growth, unseasonable bloom and leaf and fruit drops. Eventually, branch dieback and a general decline will result. Fruits from infected trees are small, uneven in size, off color, and having objectionable flavor. In Southeast Asia, mandarins and oranges are the main citrus trees planted in commercial groves, and they are the most susceptible cultivars. *Liberobactor asiaticum* is a phloem-limited, gram-negative bacterium which also can be readily transmitted by grafting and propagating with infected plant material. Both the nymph and adult can transmit the greening agent in 15 min acquisition feeding time. The incubation period in the vector is about 3 weeks. The infectious vector can retain the pathogen for life.

The length of the life cycle of Asian citrus psyllid varies from 27 to 117 days, depending on rearing temperature and host plants. The average developmental time for the immature stages is from 14 to 49 days within 15–28°C. *D. citri* nymphs undergo five instars. The adult longevity averages from 34 to 88 days within the temperature range of 15–30°C. The maximal longevity of individual females is 117 and 51 days at 15 and 30°C, respectively. The individual female may lay more than 748 eggs at 28°C. A total of 1,378 eggs have been reported to be deposited by a single female on grapefruit. Asian citrus psyllid can feed and breed on most citrus spp., two species of *Murraya* and three genera of Rutaceae. The developmental time of immature stages on various host plants varies significantly, ranging from 69 days on sour orange to 85 days on grapefruit. The average adult longevity on rough lemon is significantly longer than those on orange jassamine, grapefruit and sour orange. However, the females preferentially lay more eggs (averaging 858 eggs/female) on grapefruit than the other hosts mentioned above. The egg incubation period is about 4 days regardless of host plants. Eggs are deposited within 2 cm lengths of terminal tissue, including leaf folds, petioles, axillary buds, upper and lower surfaces of young leaves and tender stem. The egg is anchored on a slender stock-like process arising from the plant tissue. The egg is elongate, with a broad basal end and tapering towards its distal and curved end. The average size of egg measures 0.31 mm long and 0.14 mm wide. Freshly deposited eggs are light yellow, turning bright orange with 2 distinct red eye spots at maturity.

First and 2nd instar nymphs mostly aggregate and feed on the inside of folded leaves, the terminal stem and between the axillary bud and the stem of tender shoots. Young nymphs are quite docile and they only move when disturbed or overcrowded. The nymphs continuously secrete a copious amount of honeydew from the anus, and thread-like waxy substance from the circumanal glands, resulting in the growth of black sooty mold on the lower leaves. The average size of 1st instars measures 0.30 mm in length and 0.17 mm in width with light pink body and a pair of red compound eyes. The measurement of 2nd instars averages 0.45 mm long and 0.25 mm wide. The rudimentary wing pads are visible on thoracic dorsum. The average size of 3rd instars is 0.74 mm long and 0.43 mm wide. The wing pads are well developed and the segmentation of antenna is evident. The 4th instar averages 1.01 mm long and 0.70 mm wide. The wing pads are well developed; the mesothoracic wing pads extend towards 1/3 of compound eyes and the metathoracic wing pads extend to 3rd abdominal segment. The 5th instar averages 1.60 mm long and 1.02 mm wide. The mesothoracic wing pads extend towards the front of compound eyes; the metathoracic wing pads extend to 4th abdominal segment. In some mature nymphs, the abdominal color turned bluish green instead of pale orange.

Adults of *D. citri* (Fig. 87) are often found to rest on the terminal portion of plants, especially on the lower side of the leaves, with their heads pointing to the leaf surface at a 30° angle. When disturbed, they readily take flight to a short distance. The females only oviposit on the tender shoots. In the absence of suitable tissue, oviposition ceases temporarily. The average size of the adult female is 3.3 mm in length and 1.0 mm in width; the mean size of the adult male is 2.7 mm long and 0.8 mm wide.

Control of Asian citrus psyllid can be achieved by insecticide application. It is advisable to target the nymphs, (Fig. 88) as they are less mobile and concentrated on terminal tissue. However, other non-chemical control methods have been widely accepted; they include the use of such natural enemies as syrphids, chrysopids, coccinellids and parasitic wasps. The success in Reunion of using the eulophid (*Tamarixia radiata* Waterston) to control Asian citrus psyllid is a good example of biological

control. Other control measures, such as injecting infected trees with tetracyline antibiotics, establishing disease free nursery and monitoring and removing diseased trees from the grove are also known to be effective.

Asparagus Aphid, *Brachycorynella asparagi* (Mordvilko) (Hemiptera: Aphididae)

John L. Capinera
University of Florida, Gainesville, FL, USA

Asparagus aphid is found widely in eastern Europe and along the Mediterranean Sea. It invaded North America about 1969, where it was first detected in New York. It dispersed (or was dispersed) quickly, attaining North Carolina in 1973, British Columbia in 1975, Missouri and Washington in 1979, Alabama, Georgia, Oklahoma and Idaho in 1981, and California in 1984. Although it is abundant across the northern portions of North America, and very abundant along the west coast including southern California, it is uncommon in the humid southeastern states.

Life History

Oviparous aphids deposit overwintering eggs on asparagus ferns in September or later. Beginning in about March, eggs hatch into aphids that develop into stem mothers (fundatrices). Fundatrices move to asparagus spears and give birth to about 18 nymphs. Subsequent generations may be apterous (wingless) or alate (winged). Sexual forms are produced in the autumn, mate, and the females deposit eggs on the asparagus plant. Duration of a complete generation is about 15–19 days at 25°C.

The eggs initially are green in color, but turn shiny black within 1–2 days. Females produce, on average, 10.5 overwintering eggs during their life span. The elliptical eggs are deposited in the lower one-third of the asparagus canopy.

The grayish green nymphs exhibit four instars, the durations of which are about 2 days each, regardless of the morph or sex. Thus, nymphal development time averages about 8–9.5 days. Each female produces about 55 nymphs at 23°C, but only 27 and 9 at 14 and 32.5°C, respectively.

Both the alate and apterous adult viviparous aphids are present throughout the summer months, and reproduce parthenogenetically. The adults are relatively small, measuring 1.2–1.7 mm in length, and with short antennae. They are elongate oval in shape, and green or gray-green in color, often covered with a whitish waxy secretion. They blend in well with asparagus foliage, but impart a slightly bluish gray tint when the infestation is heavy. The most important character for distinguishing viviparous asparagus aphid from other asparagus-infesting species is the inconspicuous cornicles and long cauda of *B. asparagi*. Egg-producing females survive up to about 20 days.

This aphid feeds only on species of *Asparagus*. In addition to garden asparagus, *Asparagus officinalis*, it is known to feed on ornamental *Asparagus* spp.

A large number of native predators, parasitoids, and insect diseases affect asparagus aphid. Among the most important are ladybirds (Coleoptera: Coccinellidae), green lacewings (Neuroptera: Chrysopidae), and a parasitoid of many aphid species, *Diaeretiella rapae* (M'Intosh) (Hymenoptera: Braconidae). Other species of some importance are brown lacewings (Neuroptera: Hemerobiidae), the predatory midge *Aphidoletes aphidimyza* Rondani (Diptera:

Cecidomyiidae), flower flies (Diptera: Syrphidae), and other wasps (Hymenoptera: Braconidae and Aphelinidae). Natural enemies are reported to keep the population in check in eastern North America, but once attaining the arid western regions of North America asparagus aphid developed into a severe pest, and was seemingly little influenced by natural enemies. This suggests that climate plays a significant role, perhaps in conjunction with weather-sensitive natural enemies such as fungi.

Damage

Aphids feed on the new growth, causing shortening of the internodes, rosetting, dwarfing, and reduced root growth. Asparagus aphids deplete the sugars, particularly in the roots, and to a greater degree than some other aphids. Heavily infested plants have a bushy or bonsai-like appearance. Aphid infestation can kill seedlings or small plants in a relatively short time. Older, well established plantings may show damage and even death in the year following infestation by aphids, especially following a particularly cold winter. Freezing and aphid infestation are synergistic; together they reduce survival and vigor of dormant asparagus crowns greater than either aphid feeding or freezing alone. The threat of damage is much greater in western areas than in eastern North America, and it remains an infrequent pest in Europe.

Management

Egg hatch can be predicted from temperature models. Eggs can be separated from foliage by washing with petroleum cleaning solvent. Nymphs can be extracted from plants by heat or methyl isobutyl ketone. Aphid distribution tends to be clumped, with most aphids in basal regions of the plants. A sample of about 140 branches per field is optimal for making management decisions.

Foliar insecticides can suppress aphids, but multiple applications may be necessary, especially under high density conditions. Granular systemic insecticides may provide long term control. Some research has also been done to demonstrate the possibility of delivering insecticides to asparagus through the irrigation system.

Several cultural practices for suppression of asparagus aphid were investigated. Autumn and spring tillage reduce aphid overwintering but also reduce subsequent spear production. Mowing and herbiciding within asparagus fields can destroy early season aphids and delay the buildup of damaging populations. However, destruction of wild (volunteer) asparagus is the most important cultural practice available because it eliminates overwintering sites and limits invasion of aphids into commercial, aphid-free fields. Herbiciding, burning and removal of asparagus crowns by digging are all viable options to eliminate volunteer asparagus.

Aspergillus spp. Fungi

Aspergillus spp. fungi cause a disease in honeybees called stonebrood. Several species may be involved, although *A. flavus* and *A. fumigatus* are most commonly implicated.

► Stonebrood

Aspirator

A device used to collect small terrestrial arthropods. Although there are many variations in design, the principle behind the designs is the same – air current causes the insect to be sucked (aspirated) into a tube or tubing that leads to a container/receptacle area. The key feature of the aspirator is that although the arthropod can be sucking into the container, it cannot be sucked further (inhaled in the case of mouth aspiration) because a fine screen blocks its egress, so it is retained/captured. The principal variables associated with aspirators are the form of suction (mouth or mechanical), length and shape of the tube/intake, and the size of the container/receptacle. This apparatus works well for small and/or weakly flying insects.

Assassin Bugs, Kissing Bugs and Others (Hemiptera: Reduviidae)

EVA RIBES[1], MARTA GOULA[1], XAVIER JEREMÍAS[2]
[1]University of Barcelona, Barcelona, Spain
[2]Museum of Natural Science (Zoology), Barcelona, Spain

The Reduviidae are a large, cosmopolitan, and morphologically diverse family of predatory true bugs. They include assassin bugs (genera include *Melanolestes*, *Psellipus*, *Rasahus*, *Reduvius*, *Rhiginia*, *Sinea*, and *Zelus*), wheel bugs (*Arilus cristatus*), kissing bugs (species of *Triatoma*, *Rhodnius* and *Panstrongylus*), ambush bugs (genera *Apiomerus* and *Phymata*), and thread-legged bugs (the subfamily Emesinae, including the genus *Emesaya*).

Taxonomy

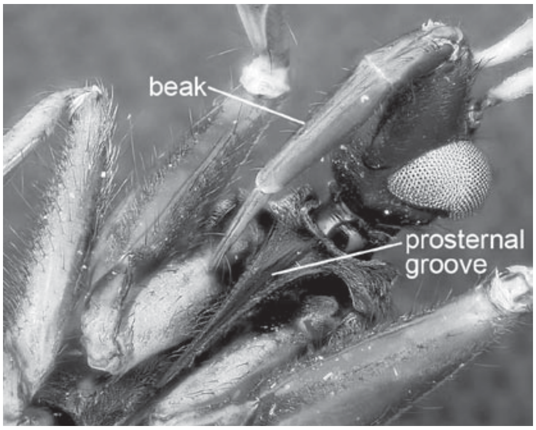
In 1843, Amyot and Serville recognized the reduvids as a discrete group. In its present systematic organization, the large family Reduviidae contains around 25 subfamilies, about 930 genera and 6800 species. Composition of subfamilies and relationships between them remain unsettled. Subfamilies Harpactocorinae (about 2,000 species), Reduviinae (about 1,000 species), Emesinae (about 900 species), Stenopodinae (more than 700 species) and Ectenodeminae (more than 600 species) together total more than 80% of known reduviid species. An additional five minor subfamilies contain only 3 or 4 species. Ten genera contain between a hundred and two hundred species each.

Morphology

Adult bugs vary greatly in body size, ranging from 3.5 mm in such reduviids as the genus *Empicoris* (Emesinae) to 40 mm in the genus *Arilus* (Harpactorinae). The body shape is also extremely variable. Reduviidae may be robust and oval, as occurs in the genus *Reduvius,* to elongate and thread-like, as in the genus *Empicoris*. Body coloration may be cryptic or aposematic. Most species are dark in color, with hues of brown, black, red, or orange. Others are masters of disguise and camouflage, colored to blend with their substrate or to resemble their prey. Many species are very hairy or spiny, with varied body expansions.

Reduviidae can be distinguished from other bug families by their elongated head, with a transverse groove behind the compound eyes, and the short, prominent, apparently three-segmented rostrum curved (Figs. 89 and 90) outwards from the head. A characteristic of the family is that the tip of the rostrum, in repose, fits into that groove.

The head has a pair of large compound eyes, usually two ocelli, and a pair of four-segmented antennae about the same length as the body. However, subdivision of antenna segments gives an appearance of antennae with a larger number of segments. The forewings (hemelytra) lack the costal feature, and the membrane usually has two elongated cells and a few veins emanating posteriorly. Legs are usually long, normally with 3-segmented tarsi, although the tarsal formula is variable.



Assassin Bugs, Kissing Bugs and Others (Hemiptera: Reduviidae), Figure 89 **A ventral view of the reduviid head, showing the curved rostrum and a groove located ventrally. A characteristic of the family is that the tip of the rostrum, in repose, fits into that groove.**

The male genitalia are usually symmetric and the ovipositor of females is usually plate-like. Eggs have three or more micropyles.

Biology

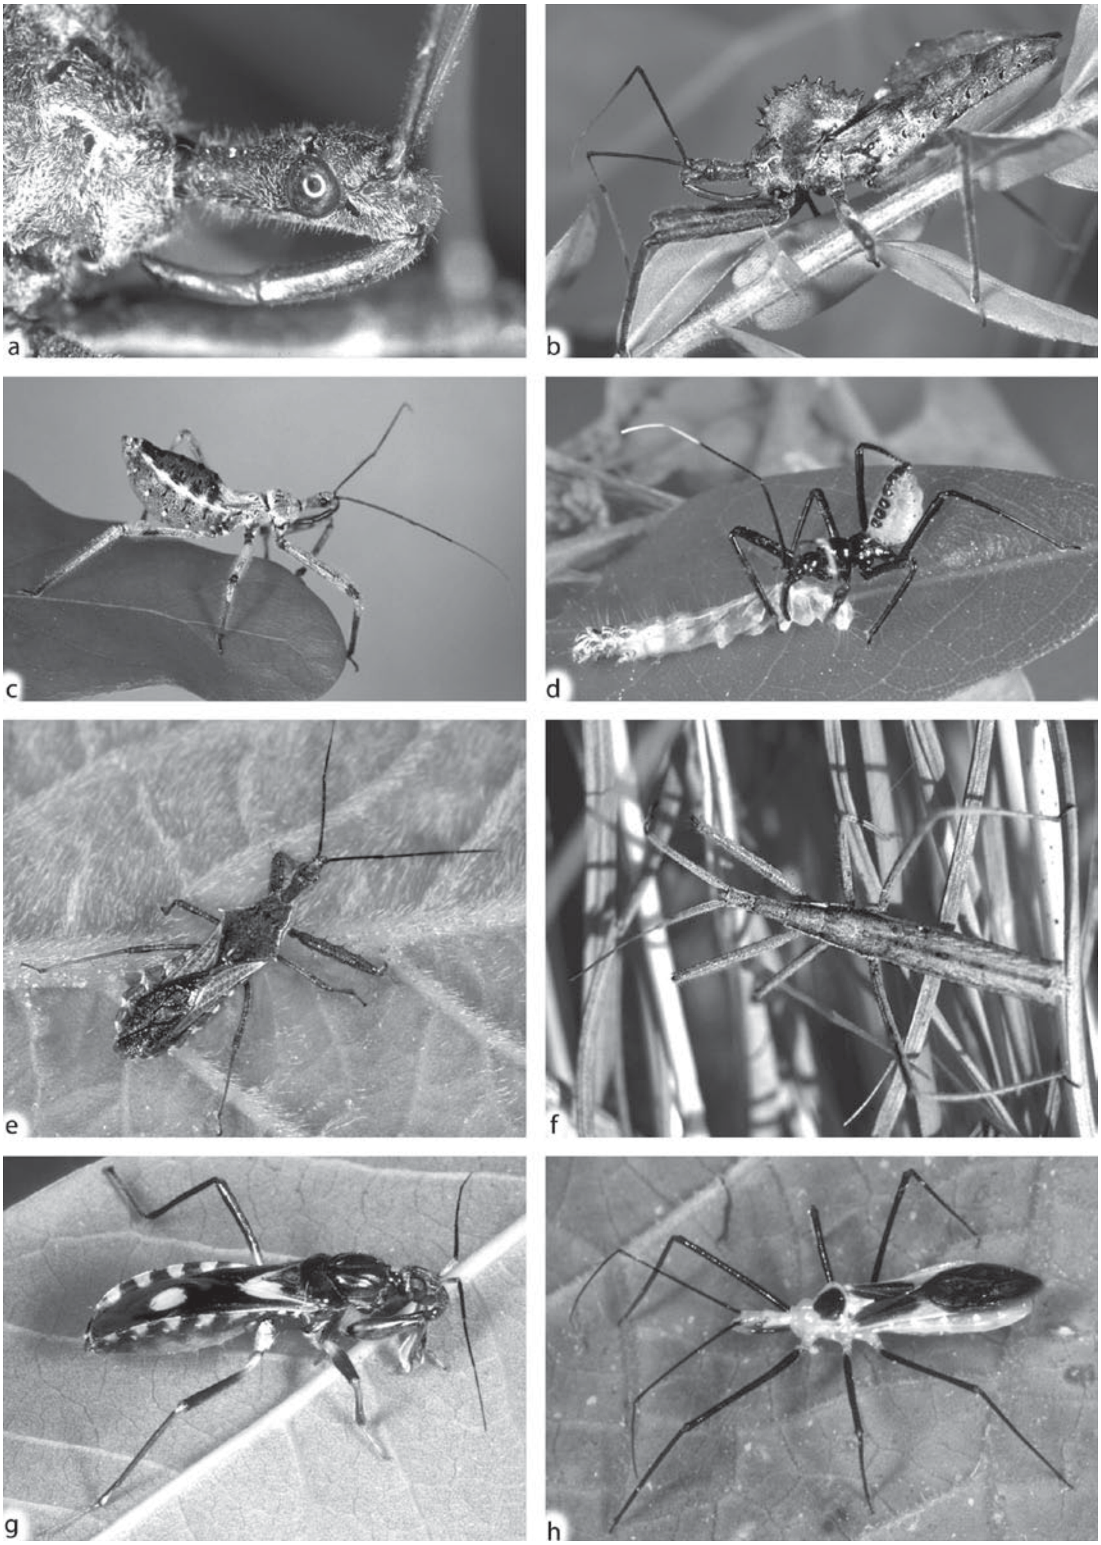
Despite their abundance and interest, reduviids have been largely ignored, and we do not know much on their biology. Triatominae are the exception, as their relationship with human diseases has stimulated their study under laboratory conditions.

Reduviidae may live in a variety of habitats in the wild, and tend to occupy warm environments. Sylvatic triatominae are found in burrows and nests of wild vertebrates, among rocks, fallen timber, hollow trees, roots, palms and bromeliads. In the subfamily Emesinae, some species are cavernicolous, but lack the characteristics common to many cave dwellers such as eyelessness or depigmentation. Among Emesinae and Triatominae, some species are domestic or peridomestic, which increase the medical importance of Triatominae as vectors of the protozoan *Trypanosoma cruzi*. The attraction of Triatominae to light also enhances the likelihood that they will enter inhabited structures and contact humans.

Reduviidae are well adapted for their physical environment. They may pass through inclement periods in the egg, nymphal or adult stage. Number of generations per year ranges from one to several, but in other cases the completion of life cycle may take more than 1 year. Longevity is also very variable among species. Some Salyavatinae live <2 weeks, whilst some Reduviinae live for about 7 months.

Except for Triatominae, which are hematophagous and feed on vertebrate blood, all reduviids prey on other insects. First step of attack is with the legs, whose length allow a longer attack distance. Also, the legs of some of these bugs are covered in tiny hairs that serve to make them sticky to grip prey while they feed in the manner of flypaper. Other assassin bugs (subfamily Apiomerinae) go one step further and collect certain plant resins which they spread over their front legs; these resins are very attractive to insects, and to bees in particular. Once the prey is grasped, the reduviid feeds by puncturing it with sharp stylets in their rostrum, injecting saliva which will paralyze the prey and liquify its tissues, to then finally sucking up the body fluids. The saliva is commonly effective at killing prey substantially larger than the predatory bug itself. In contrast, the genus of the small reduviid *Ptilocerus* uses chemical lures located in a special ventral abdominal gland to trap and prey on ants. The ants are very attracted by this secretion, which paralyses them. Also, reduviids that tackle large and dangerous prey like wasps or bees tend to make the first stab near the victim's head or neck, thus ensuring that their toxic saliva has maximum effect in the shortest possible time.

In Triatominae, ingestion of blood is possible thanks to different enzymes present in the bug saliva that counterbalances the hemostatic response on the part of the vertebrate host. Bug saliva is provided with anticoagulants (preventing the coagulation of host blood in the insect's suction apparatus), apyrases, platelet antiaggregation factors, antiserotonin, antihistamine, tryalisine (lytic protein which



Assassin Bugs, Kissing Bugs and Others (Hemiptera: Reduviidae), Figure 90 Some reduviids: (a) Anterior view of a reduviid, showing their elongated head and the short, prominent, apparently 3-segmented rostrum curved outwards from the head; (b) adult wheel bug, *Arilus cristatus.* This is one

permeabilizes mammalian cells), emollient factors, antithromboxane and a vasodilator. Blood is stored in the crop and stomach of triatomine. Several days later, erythrocytes are lysed, and the accessible hemoglobin is then digested. Blood ingestion is needed by nymphs to complete development, and by adults to perform reproduction, as cyclical egg laying is related to blood meals.

Reduviids are generally polyphagous, but there are also cases of prey specialization. For example, the subfamily Emesinae contains a number of genera (*Eugubinus*, *Ploiaria*, *Emesa*, *Stenolemus* and *Empicoris*) in which elongate, thread-legged member species feed on insects caught in spiders' webs, or on the spiders themselves. These slender, slow-moving bugs never get trapped in the spider silk, as they avoid the sticky spirals and walk very carefully so that they are not trapped in the spider silk. An extraordinary case of coprophagy is found in the Indian harpactorine *Lophocephala guerini*, which feeds on fermenting cow dung. Its microhabitat is underneath stones, in association with the formicine ant *Anoplolepis longipes,* and it is always attended and guided by these ants. However, the trophic habits of most reduviid species are still unknown.

Courtship behavior is much like in other insects, although it has some characteristic features. The sequential acts of mating behavior can be categorized into arousal, approach, riding over (precopulatory riding of Harpactorinae), nuptial clasp, extension of genitalia and connection, copulation, and postcopulatory acts. The fecundity varies between 50 eggs of the Stenopodainae to the 670 eggs of Harpactorinae. Eclosion and ecdysis occur usually in daytime.

Many species glue their eggs to the plants, often in a group, sometimes covering the eggs with a gelatinous material. Ground-dwelling species may bury their eggs in the soil, and some species of the subfamily Reduviinae have more well-developed ovipositors, suitable for the insertion of eggs into cracks.

A few species are known to guard their eggs, and in this case, the males perform the guarding. In the genus *Rhinocoris*, the female lays a batch of eggs on the plant leaf immediately after copulating. The male stands by and, when the female finishes laying, takes up his position aside the egg mass. Over the course of the next days the female lays additional egg batches. While the male is guarding he generally does not feed, unless an easily catchable prey comes his way. However, when the eggs have all hatched, he loses interest and moves away. Exceptionally, the guarding male may be relieved by a female that had copulated with him.

In the majority of nymphs and adults, the rostrum can be used to produce sounds (stridulation) by being scraped along a medially located, ridged groove on the underside of the thoracic segments. The aim of this acoustical communication may be mate attraction, courtship and copulation. In other cases, the aim is intimidation, and thus, some reduviids stridulate defensively. Non-receptive females may emit male-deterring vibrations.

Reduviids have an array of defensive and offensive behaviors, accompanied by morphological adaptations. These behaviors threaten other

of the largest and most easily recognized reduviids. It is found in North America and Central America, where it feeds on numerous insects, but also inflicts a nasty bite when handled by humans; (c) nymphal wheel bug, *Arilus cristatus*; (d) nymphal wheel bug, *Arilus cristatus*, feeding on a leaftier larva; (e) adult *Sinea diadema*. This species is found through most of North America including Mexico, where it inhabits meadows and crop fields. It often is reported to be an important predator of crop pests; (f) nymphal *Vibertiola cinerea*, an African savanna-inhabiting species that is now found in the Iberian Peninsula. Its host plant is the grass *Hyparrhenia hirta*, where it blends in well due to its elongated body; (g) *Rasahus* sp. bugs are found predominantly in the neotropics; (h) *Zelus longipes* is found throughout the western hemisphere where its often found feeding on caterpillars (photo credits: f, Eva Ribes, University of Barcelona; others Lyle Buss, University of Florida).

insects, aid escape from enemies and larger prey, and give protection from cannibalism. Some nymphs and adults of different subfamilies (Reduviinae, Cetherinae, Salyavatinae, Triatominae) will cover and camouflage themselves with debris, including soil particles or the remains of dead preyed insects, which are affixed by sticking objects to the viscid secretions of specialized setae located on the dorsum. The elongated slender bodies of *Rhaphiodosoma* and *Vibertiola* species (Harpactorinae) and stenopodaeines provide camouflage among the elongated grasses where they live, imparting protection from vertebrate predators. In other cases defense is active, as in harpactorine nymphs, which often fight to the death.

Some Aspects of Distribution

The distribution of Reduviidae is nearly cosmopolitan, though most taxa inhabit the tropical and subtropical regions, where they are particularly varied and abundant. Of the 6,800 species, 16% occur in Oceania, 37% in sub-Saharan Africa and 21% in the neotropics. Certain taxa with a wide distribution suggest transport by humans and their goods, or by migratory animals.

Ecological and Economic Significance

As predators, Reduviidae play a role in biological control. Their worldwide distribution, abundance, diversity, large pest prey record, amenability for mass culturing, ready synchronization and freedom from hyperparasites and predators are the merits of reduviids as potential biological control agents.

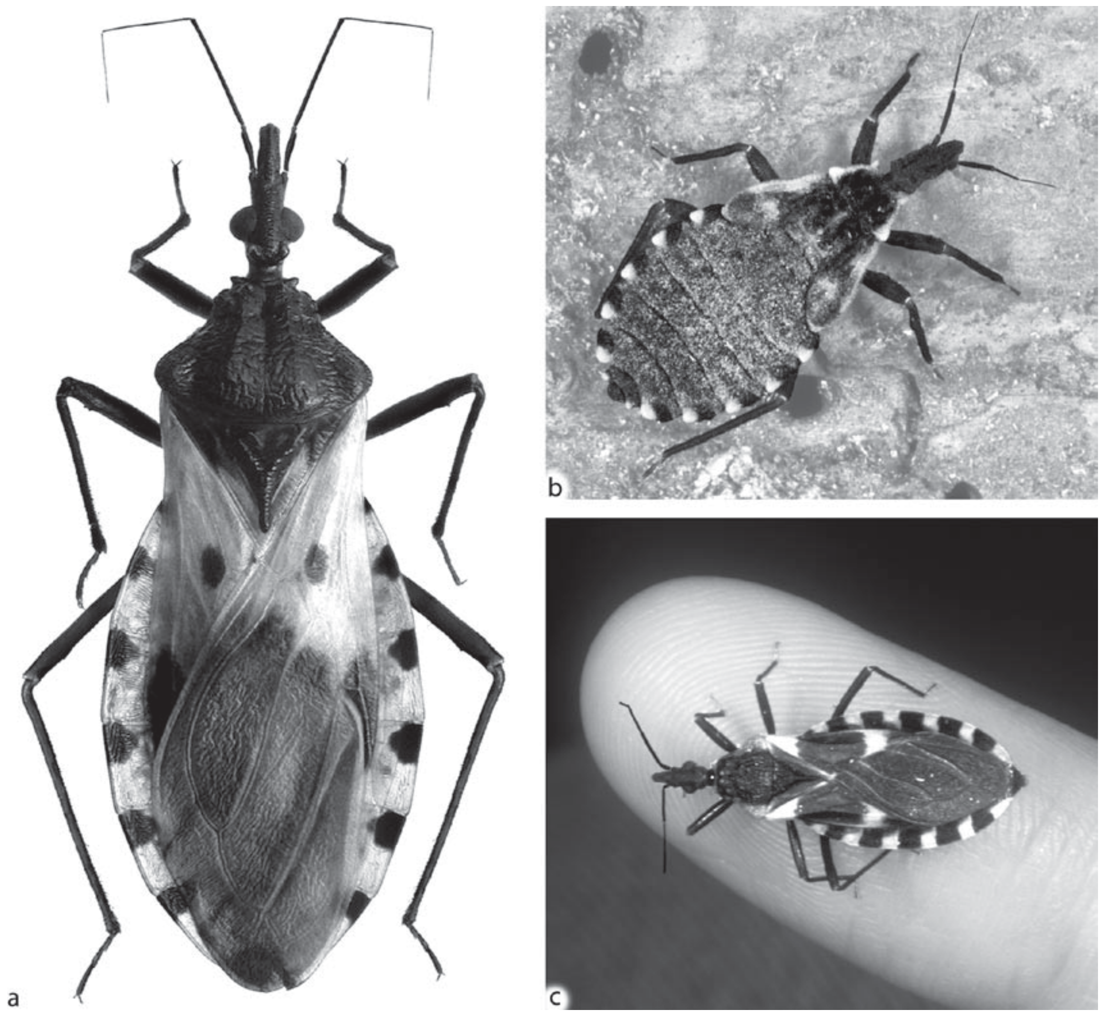
More than 150 reduviids predators belonging to 53 genera and seven subfamilies have been found preying upon a wide array of insect pests. Some species have been known to feed on cockroaches or bedbugs (in the case of the masked hunter *Reduvius personatus*) and are regarded in many locations as beneficial. They kill more prey than they need to satiate themselves. Reduviids exhibit a positive numerical response by killing more prey in terms of available prey population per predator at a given time, and by increasing their population through higher fecundity and survival.

In spite of their merits as beneficials, their potential as biocontrol agents of pests has been little studied. The better studied species in this area focus on *Rhinocoris fuscipes*, *R. kumarii*, *R. marginatus*, *Ectomocoris tibialis* and *Acanthapsis pedestris*. Other promising groups of predatory reduviids are species of *Sinea* and *Zelus*, which may help regulate insect pests on cotton. Recently, *Amphibolus venator* has been reported as a useful predator on last-instar larvae, pupae and adults of the stored-product insect pest *Trobolium confusum* (red flour beetle [Coleoptera: Tenebrionidae]). *Amphibolus venator* is commonly found in stored product facilities, shipments of groundnuts, warehouses or in rice milling facilities, and preys on other stored-product insect pests.

Because of their polyphagy, reduviids may not be useful as predators on specific pests, but they are a valuable help when a variety of insect pests occur. The counterpart of that polyphagy is that from time to time they may attack beneficial arthropods. A few of them appear to specialize on insects of some value; for example, several apiomerine reduviids feed on bees of the genus *Trigona*, that are useful pollinators.

Unfortunately, assassin bugs interact with human health negatively. They may become a nuisance, as many assassin bugs have been known to bite humans when not handled carefully. For some species the bite is known to be very painful, sometimes causing allergic reactions, and bites can become infected, as with any wound. Some of them are known to produce toxic saliva containing powerful enzymes similar to those in snake venom. As with any severe allergic reaction in humans, side effects of repeated bites may include shock and possible death. The fecal material of some reduviids can cause irritation of the eyes and nose and temporary blindness in humans.

Most important to human health are some blood-feeding triatominae species, also known as kissing bugs due to their habit of biting humans in their sleep on the soft tissue of the lips and eyes. A number of these hematophagous species are able to transmit a potentially fatal trypanosome disease known as human Chagas disease (HCD), also named American trypanosomiasis, caused by the protozoan *Trypanosoma cruzi*. These reduviids belong to genera *Triatoma*, *Rhodnius* and *Panstrongylus*, and the three most important species in this regard are *Triatoma infestans*, *T. dimidiata* and *Rhodnius prolixus* (Fig. 91). About 50 additional species belonging to the three genera mentioned above can also act as disease vectors, but they are more local in distribution so they are not as important, or as well known. Other genera involved locally in transmission of HCD are *Meccus* (Mexico), and *Microtiatomba* and *Parabelminus* (Brazil). Infestation rates of triatominae by *Trypanosoma cruzi* vary greatly from one area to another. As examples, in Brazil, 41% of 2412 triatominae bugs were infested whereas in Panama, 68.8% of 740 *Rhodnius pallescens* were infested, but only 17.7% of 94 *Triatoma dimidiata* were. In Yucatan (Mexico), infection rates of



Assassin Bugs, Kissing Bugs and Others (Hemiptera: Reduviidae), Figure 91 Kissing bugs or bloodsucking conenoses, *Triatoma* spp.: (a) adult *T. dimidiata*; (b) immature of *T. sanguisuga*; (c) adult of *T. sanguisuga* (photo credits: a, Ron Cave; others Lyle Buss, both University of Florida).

Triatoma dimidiata by *T. cruzi* ranged from 0% (in Tipoco) to 25% (in Tella). In Santander (Colombia), 48% of *T. dimidiata* contained the protozoan, while in Guayaquil (Ecuador), 50% were infested. Once infested, a bug may be infective for about 2 years. In contrast with other arthropod vectors (i.e., ticks), the protozoan cannot be transmitted to the offspring transovarially.

In 1909, the Brazilian doctor Carlos Chagas discovered the disease, and reported both the vector and the causative flagellate protozoan *Trypanosoma cruzi*. He recognized and described the disease in humans but also investigated the life cycle and other aspects of the protozoan and its insect vector. This disease is mostly found in rural areas, where the Triatominae can breed and feed on the natural reservoirs, such as opossums, raccoons, and armadillos. In fact, wild animals reported as infected with *T. cruzi* belong to the Orders Marsupialia (opposums), Edenteta (armadillos, etc.), Chiroptera (bats), Carnivora (cats, foxes, etc.), Lagomorpha (rabbits), Rodentia (mice and rats, squirrels) and Primates (monkeys). But, depending on the special local interactions of the vectors and their hosts, other infected humans and domestic animals may act as reservoirs too. Among domiciliary and peridomiciliary reservoirs are *Canis familiaris* (dog), *Capra hyrcus* (goat), *Cavia porcellus* (Guinea pig), *Felis domesticus* (cat), *Mus musculus* (mice), *Oryctolagus cuniculus* (rabbit), *Rattus novervegicus* and *Rattus rattus* (rats) and *Sus scrofa* (pig).

Trypanosoma cruzi may have both sylvatic and domestic cycles. The sylvatic cycle involves its circulation among wild small mammals and the Triatominae. The sylvatic cycle usually does not affect humans unless they enter in the wild and disturb the natural balance of wild fauna and flora. The domestic cycle, which has evolved more recently, involves humans, domestic mammals and a small number of Triatominae species that are able to live in domestic or peridomestic habitats. Although some reports on Chagas disease date back to precolumbian times, the real dispersion of the American trypanosomiases occured as a result of European conquest and the resulting disturbance of the natural balance and habitats of *T. cruzi*, its triatomine vectors, and its mammalian reservoirs.

Kissing bugs are strictly nocturnal, taking blood meal for 20–30 min and inflicting no pain to the host. When they feed, the bugs leave (infected) excrement behind on the skin. Transmission of the protozoan occurs when people scratch their bites and allow protozoa in bug defecations to infect their blood. Other forms of transmission are possible, though, such as ingestion of raw food contaminated with parasites, blood transfusion, organ transplantation and placental transmission (from infected mother to fetus).

The human disease occurs in three stages or phases: (i) the primary or acute phase, shortly after the infection, with an incubation of 15 (direct bite)-40 days (blood transfusion infection); symptoms are an inflammatory reaction, with necrosis around the bug bite site; meningoencephalitis and myocarditis are very severe consequences of this stage in children under 10 years old; (ii) indeterminate phase, 8–10 weeks after the acute stage and which may last for years without any symptom; the main danger is that the individual is unaware of being infested, acting as reservoir of *T. cruzi*; (iii) chronic stage that may develop up to 10 years after infection; the main signs are liver and heart dysfunctions, as well as, hypertrophy of the heart and certain parts of the digestive and/or excretory systems. The parasite circulates in the bloodstream, and infects, multiplies and ultimately destroys muscle and nerve cells all around the body, particularly in the heart and digestive system. The negative effects of the disease are reflected in a progressive deterioration of health, associated to increasing apathy, a decreasing capacity to perform work and a general reduction in the quality of life. If no action is taken, disease is lethal.

The disease is distributed in the Americas, ranging from the southern United States to southern Argentina, mostly in poor, rural areas of Central and South America. Domestic infestation in very poor rural zones may be of 1,000 insects per house. Human Chagas disease (HCD) has been spread into nonendemic urban areas by people migrating to cities from rural areas. In most countries where Chagas disease is endemic, testing of blood donors is already mandatory, since this can be an important route of transmission. Up to 18 million humans were affected by this disease in 1990, but recently data suggests nine million people affected, after coordinated initiatives throughout the endemic HCD area. Of some 100 million at risk of acquiring the disease in 1990, now about 60 million people are out of risk. About 200,000 new cases, and about 70,000 deaths are reported annually. Rates of human infection in endemic areas are very different, relating to different vector species or populations. In Zacapa (Guatemala), where *R. prolixus* is the principal vector, 38.8% of 373 people were infected. In contrast, in Santa Rosa (Guatemala), where *T. dimidiata* is the only vector found, only 8.9% of the 428 people studied had the protozoan. The same trends were reported in Honduras, in relationship to HCD vectors. Outside of the Americas, one genus and several bug species occur in India, where theoretically they may transmit Chagas disease.

Once infected, there are some pharmaceuticals useful to fight infections, but they are very toxic and have a lot of undesirable secondary effects. The best way to reduce HCD incidence is prevention, either by fighting the vector (*Triatoma*) or improving housing and sanitary conditions in the rural area. Vector insects may be eliminated by using sprays and paints containing insecticides (synthetic pyrethroids). Although resistance development is much lower than in mosquitos (due to long life-cycle and use of different insecticides), significant levels of resistance to deltamethrin and other pyrethroids have been reported in *Rhodnius proxilus* (Venezuela) and *Triatoma infestans* (Brazil and Argentina). Recently, oil-formulated *Beauveria bassiana* has been used against *T. sordida* and has proven to be useful in peridomestic areas of central Brazil. This could lead to implementation of integrated control by alternating application of fungi in the rainy season with synthetic insecticides in the dry season, or a combined application of fungi and insecticides in the rainy season. Those strategies could promote an efficient and permanent reduction of triatomine vectors in peridomestic areas. Also, several plant extracts showed insecticidal activity against triatomines. As examples, plants belonging to genera *Salvia*, *Annona*, *Neurolaena*, *Tagetes*, *Erythroxylon*, *Cassia*, *Senna* and *Cabralea* elicited an increase in the mortality rate (16–52%) of *Rhodnius neglectus*. Topical treatment of *T. infestans* with *Achryrocline* extracts resulted in a 45% mortality of triatomine bug. Five plant species (*Aspidosperma macrocarpon*, *Talauma ovata*, *Guarea guidonia*, *Guarea kunthiana* and *Simarouba versicolor*) from the Brazilian biome Cerrado, selected according to ethnobotanical information, have been tested in the form of 24 plant crude extracts on *Rhodnius milesi*. Most promising results were obtained from ethanolic extract of the root bark of *S. versicolor* (probably due to its antifeedant growth regulating activity) and the hexane extract of the root of *G. guidonia* (by a not yet clear activity). In addition to investigating new methods to kill triatomine bugs, considerable success has been made preventing bugs taking up residence in human domiciles.

However, the peridomicilium (considered to be the area within 100 m proximity of human dwellings) has been shown to be crucial in management of HCD. Henhouses, pigpens, corrals, perches, piles of tiles, bricks, wood and straw have to be taken into account. In research conducted in 121 peridomiciliary environments in rural areas of the state of Ceará (Brazil), triatominae (2670 specimens collected) were present in 30% of the environments, with 68.7% being shelters for domestic animals (mainly goat/sheep corrals, perches, henhouses and pigpens), and 32.3% were piles of bricks, roofing tiles or wood. Also, palm trees growing near human habitations are of great importance in HCD, as *Rhodnius* species breed in the crowns of many genera of palm trees. Specificity among insect and palm tree species may be very strict, as is the case of *R. brethesi* on *Leopoldinia piassaba*, or *R. colombiensis* on *Attalea butyracea*, but this is not always the case, as in *R. pallescens* or *R. pictipes*, which dwell in association with five host palm species each, or *R. prolixus*, with 13 host palm species. Peridomestic palm trees, especially in the presence of bird nests, may be regarded as high-risk habitats. In Ecuador, the palm seed endosperm (vegetable ivory or "tagua") and leaves of *Phytelephas aequatorialis* are used for handicraft manufacturing and roof thatching; as a result, those palms, which are the primary habitat of *Rhodnius ecuadoriensis* (a major vector of Chagas disease in Ecuador and Peru), are often found around dwellings.

For urban dwellers who spend vacations outdoors or camp in the wilderness, or who sleep at hostels or primitive houses in HCD-endemic areas, a mosquito net is recommended to reduce the risk of infection. If the traveler intends to travel to an area of HCD prevalence, he/she should get information on the incidence of Chagas disease from traveler advisories, such as the USA's Communicable Disease Center (CDC).

The Southern Cone Initiative against HCD was launched in 1991, following a resolution of the Ministers of Health of Argentina, Bolivia, Brazil, Chile, Paraguay and Uruguay. It focused on interruption of *T. cruzi* transmission by eliminating domestic vectors (particularly *T. infestans*), extending screening of blood donors, and promoting maternal screening and specific treatment of infected newborns. Similar initiatives were launched in 1997 for Central America and the Andean Pact countries. Those multinational initiatives, coordinated by the Pan American Health Organization (PAHO) allowed that on June 9, 2006, at the 15th annual meeting, the Intergovernment Commission of the Southern Cone Initiative against Chagas disease declared Brazil to be free of Chagas disease transmission due to *Triatoma infestans*. Also in Uruguay, Chile, most of Argentina, Bolivia, Paraguay and parts of Central America, transmission has been effectively eliminated. In 2004, a surveillance initiative was announced for the nine countries of the Amazon basin. To assure and increase the success obtained in this 15-year initiative, surveillance and control of the disease and its vector are currently on the agenda of all endemic countries. It is essential to keep in mind the perennial need of surveillance, data assimilation and selective interventions, as triatomines will always be present in the wild, as well as *T. cruzi* and its wild reservoirs. Schools and hospitals (obstetrics, blood donors, organ transplantation) are essential surveillance hot-spots where infestations may be detected and controlled.

Aster Leafhopper, *Macrosteles quadrilineatus* Forbes (Hemiptera: Cicadellidae)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

Aster leafhopper is native to North America, where it is nearly everywhere. It is most common, however, in the central region of the continent. Also, it overwinters poorly in cold areas. Most areas with aster leafhopper problems are invaded annually by leafhoppers originating in the southern Great Plains. In the mild-climate northwest, however, leafhoppers are able to overwinter successfully, and long-distance dispersal is not an important factor.

Life History

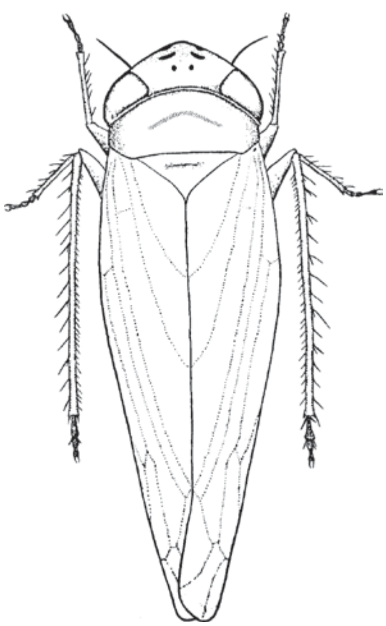
This insect overwinters in the egg stage in northern locations, and in the adult stage in warmer climates. In northern areas, there are three generations per year, whereas up to five generations may occur in more favorable midwestern locations. Because the generations overlap, and are initiated by both overwintering eggs and migrating leafhoppers, it is difficult to discern the generations. Total generation time requires about 27–34 days.

Eggs are deposited in leaf, petiole, or stem tissue, often near the juncture of the leaf blade and stem. They are deposited singly, but often in short rows of up to five eggs. They require a moist environment, and perish if the foliar tissue desiccates. The eggs are translucent when first produced, soon turning white. They average 0.80 mm in length (range 0.73–0.87 mm) and 0.23 mm in width. They are slightly curved, with one side concave and the opposite side convex, and taper to a blunt point at each end. The incubation period of the egg is about 7–8 days.

Newly hatched nymphs are nearly white, but soon become yellow and gain brownish markings, including dark markings on the head. There are five instars, the duration of which are about 3–4, 4–5, 3–4, 4–6, and 5–7 days, respectively, when reared at 21–25°C. The body length measures about 0.6–1.0, 1.2, 2.0, 2.5, and 3.0 mm in instars 1–5, respectively. As the nymphs mature, they gain spines on the hind tibiae, the number increasing from about 6–7 to 8–9. The tip of the abdomen also bears spines. The wing pads are indistinct through the third instar, but are apparent in the fourth instar, and overlap the abdominal segments in the fifth instar.

The adults (Fig. 92) are small, the males about 3.2–3.4 mm long, and the female 3.5–3.8 mm. These insects are light green in color, with the forewings tending toward grayish green and the abdomen yellowish green. There are six pairs of black spots, some of which are elongated almost into horizontal bands, starting at the top of the head and extending along the front of the head almost to the base of the mouthparts. The six pairs of spots are the basis for the other common name of this insect, "six-spotted leafhopper." Strong winds moving north in the spring transport adults into midwestern and northern crop production areas annually. Adults usually arrive in advance of egg hatch by overwintering populations, and populations of long-distance dispersants greatly exceed resident leafhoppers. Arrival time in the north varies, but May arrival dates are common.

When dispersal was studied in the western Great Plains of North America, the western edge of the principal migration path, overwintering of the adult leafhoppers was found only in Texas, USA, although north of Texas eggs may overwinter. By May, northward movement was evident, with adults present in Kansas, Nebraska, and South Dakota, where no nymphs had been found previously. By June the leafhoppers had progressed northward into Montana and North Dakota, and westward into Colorado and Wyoming. Thus, northward migration occurs rather rapidly, and the leafhoppers are present during most of the growing season in these areas.



Aster Leafhopper, *Macrosteles quadrilineatus* Forbes (Hemiptera: Cicadellidae), Figure 92 **Adult of aster leafhopper, *Macrosteles quadrilineatus* Forbes.**

Aster leafhopper has a wide host range. It tends to overwinter on grains such as wheat and barley, and on grasses, clover, and weeds, then dispersing to other crops in the summer months. Several vegetable crops are damaged by aster leafhopper, including carrot, celeriac, celery, corn, lettuce, parsley, potato, and radish, but among vegetables only lettuce is consistently suitable for leafhopper reproduction. Other crops fed upon are barley, clover, dill, field corn, flax, oat, rice, rye, sugarbeet, and wheat.

In Washington, USA, studies indicated that the most important breeding areas were mixtures of clover and pasture grasses, followed by clover, sweet corn, oats, carrots, lawn grasses, rye, field corn, and various weeds. Among the weeds favored were fleabane, *Erigeron* spp.; ragweed, *Ambrosia* spp.; dandelion, *Taraxacum officinale*; wild lettuce, *Lactuca canadensis*; tumble mustard, *Sisymbrium altissimum*; and lambsquarters, *Chenopodium album*. Low, sparse, and young vegetation provided the best habitat. In Minnesota, large crabgrass, *Digitaria sanguinalis*; horseweed, *Conyza canadensis*; barnyardgrass, *Echinochloa crusgalli*; fowl-meadow grass, *Poa palustris*; and barley, wheat, and oats were especially suitable for reproduction. Carrot, dill, potato, and radish were important adult food plants, but not good breeding hosts.

Natural enemies are not well known, or very important in the population ecology of aster leafhopper. The most important enemies are the parasitoids *Pachygonatopus minimus* Fenton, *Neogonatopus ombrodes* Perkins, and *Epigonatopus plesius* Fenton (all Hymenoptera: Dryinidae). The best known among these is *P. minimus*, which has caused up to 37% parasitism.

Damage

Leafhoppers pierce leaf tissue of plants and remove the sap. The feeding punctures cause death and discoloration of individual plant cells, resulting in a yellow, speckled appearance in affected plants. This feeding damage, while unsightly, is minor in comparison to the damage caused to a great number of vegetable crops by transmission of aster yellows by leafhoppers.

Aster yellows is a plant disease caused by a mycoplasma-like organism (MLO), and is transmitted almost exclusively by aster leafhopper. Such crops as carrot, celery, cucumber, lettuce, potato, pumpkin, and squash are affected. Losses of 50–100% are reported due to this disease. MLO-infected plants are discolored, stunted, and deformed. On carrots, for example, the symptoms are red or yellow foliage and excessively hairy, bitter-tasting roots. On lettuce, symptoms are chlorosis, stunting, and lack of head formation.

Management

Leafhoppers are sampled with sweep nets, especially from grasses and grain fields. Yellow sticky traps are also useful and easy to use, and light traps equipped with fans for suction also have been used effectively to capture leafhoppers.

In addition to sampling for leafhopper abundance, it is also desirable to determine the proportion of leafhoppers that harbor the MLO. Formulas based on both insect number and disease incidence, called the "aster yellows index," have been developed to trigger control measures before the pathogen is widely transmitted to susceptible crops. Leafhoppers are collected before they enter an area, fed on aster plants, and the plants read for disease. This works effectively to alert large areas, such as entire states, but is not useful for local prediction.

Insecticides commonly are used to kill leafhoppers, and thereby minimize disease transmission. Because there are protracted acquisition and incubation times associated with this disease, chemical-based disease suppression is feasible. Insecticides are especially effective in the absence of long-distance dispersal by leafhoppers. Systemic insecticides are often favored due to their persistence, but contact insecticides can also be effective. Insecticides are often applied at 5–7 day intervals. Because it takes 10–15 days for infected plants to show signs of infection, it is not necessary to treat plants just prior to harvest.

Crop varieties differ in their susceptibility to infection with aster yellows; this is well studied both for carrots and lettuce, two of the more susceptible crops. Cultural manipulations can also enhance resistance. In studies conducted in Minnesota, very significant reductions in disease incidence were shown where aluminum foil mulch was used. Straw mulch was equally effective. Row covers, where economically feasible, should provide good protection against leafhoppers and disease transmission. Destruction of weed species known to harbor aster yellows is desirable.

Aster leafhopper acquires the MLO by feeding on infected perennial or biennial weeds or crop plants. Acquisition requires a prolonged period of feeding, usually at least 2 h, before the leafhopper is infected. Usually <2% of dispersant leafhoppers become infected. There is evidence that the MLO multiplies in the body of the leafhopper, and there is an incubation period of about 2 weeks in nymphs, and 6–10 days in adults, before the insects are capable of transmitting aster yellows. Leafhoppers remain infective for the duration of their life, but the MLO is not transmitted between generations through the egg stage. Thus, there is ample time for insecticides to interrupt disease transmission.

Asterolecaniidae

A family of insects in the superfamily Coccoidae (order Hemiptera). They sometimes are called pit scales.

► Bugs

Aster Yellows

This is an important insect-vectored disease that affects many plants. See also, Transmission of Plant Disease by Insects.

► Transmission of Plant Diseases by Insects

Ateluridae

A family of silverfish (order Zygentoma).

► Silverfish

Athericid Flies

Members of the family Athericidae (order Diptera).

► Flies

Athericidae

A family of flies (order Diptera). They commonly are known as anthericid flies.

► Flies

Astrotaxis

Taxis response with respect to the sun, moon, stars or polarization of light.

Asymmetric Competition

Competition between two individuals or species in which one is more severely affected than the other.

Asymmetric PCR

Single-stranded DNA produced by providing an excess of primer for one of the two DNA strands. Asymmetric primer ratios are typically 50:1–100:1. Single-stranded DNA produced can be sequenced directly without cloning.

Asynchronous Muscle

Muscle in which the frequency of contraction is not controlled directly by nervous impulses, with the contraction frequency a property of the muscle. Asynchronous muscle produces several to many contractions in response to a single nervous stimulation. (contrast with synchronous muscle)

ATP

Adenosine triphosphate is the primary molecule for storing chemical energy in a cell.

Atrophy

Decrease in size of a tissue, organ, or part after full development has been obtained. In pathology, a condition in which the affected cells undergo degenerative and autolytic changes, become smaller, and have a lessened functional capacity.

Attelabidae

A family of beetles (order Coleoptera). They commonly are known as leaf-rolling weevils.

► Beetles

Attenuation

The process of decreasing the virulence of a microorganism.

Attractant

An odor, or the material producing an odor, that attracts insects.

Attraction of Insects to Organic Sulfur Compounds in Plants

YOSHIHARU MATSUMOTO
University of Tokyo, Tokyo, Japan

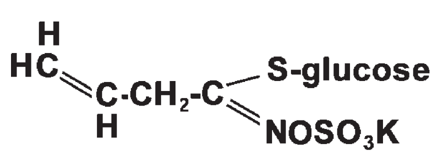
Among the secondary plant metabolites, two types of organic sulfur compounds are of considerable importance: glucosinolates and cystein derivative amino-acids, and their respective breakdown products. These compounds, in various ways, influence the diversity of organisms associated with plants bearing these compounds.

Glucosinolates

Glucosinolates (=mustard oil glycosides) occur predominantly throughout the order Capparales, consisting of Brassicaceae (=Cruciferae), Capparaceae, Moringaceae, Resedaceae, Tovariaceae, and sporadically in some other families (e.g., Caricaceae, Limnanthaceae, and Tropaeolaceae). About 50 different glucosinolates are found in Brassicaceae, and over 100 glucosinolates throughout the plant kingdom. Several to about twenty glucosinolates occur in each cruciferous species. For example, in leaves there are 14 glucosinolates in cabbage, 12 in cauliflower, 11 in Brussels sprouts, 7 in broccoli and Chinese cabbage. In roots, there are 18 glucosinolates in turnip and 8 in kohlrabi. In oilseeds, there are 9 glucosinolates in rapeseed and turnip rape, and 5 in mustard. Glucosinolates having a bitter taste are broken down to mustard oils (isothiocyanates) and other substances by enzymes which are known as myrosinases.

Isothiocynates, in general, have hot and pungent odors. However, those which have a bigger molecule lose pungent odor and have more sweet and mild odors. For example, 2-propenyl isothiocyanate (allyl isothiocyanate, C_3H_5NCS), which is (Fig. 93) split from sinigrin, has a very pungent odor; however, 2-phenylethyl isothiocynate ($C_6H_5CH_2CH_2NCS$), which is derived from gluconastrutiin, has a sweet odor.

E. Verschaffelt, a botanist from the Netherlands, first noticed the relationships between insects and glucosinolates early in the twentieth century. He found that the host plants of the large and small white butterfly larvae, *Pieris brassicae* and *P. rapae*, were limited to the plants containing glucosinolates. By smearing sinigrin on leaves which had been rejected before, the larvae came to readily attack and feed on some of these. Half a century later, this result was verified and developed by Thorsteinson and his group in Canada with the diamondback moth, *Plutella xylostella*, using artificial agar diet containing a known quantity of glucosinolate. Sinigrin, sinalbin, glucocheirolin, and progoitrin stimulated larval feeding in the presence of glucose. After these important works, the stimulation of feeding by glucosinolates, mainly sinigrin, was shown in a variety of specialist herbivores feeding on cruciferous plants: the cabbage aphid, *Brevicoryne brassicae*, the cabbage fly, *Delia brassicae*, the cabbage beetle, *Phaedon cochlearia*, and *P. brassicae*. The gravid female white butterflies tap the leaf surface with their forelegs (called "drumming") when they attempt to oviposit on leaves. They receive chemical



Attraction of Insects to Organic Sulfur Compounds in Plants, Figure 93 Chemical structure of sinigrin.

stimulation from glucosinolates in leaves via the sensilla on their tarsal undersurface. Glucobrassicin (3-indolylmethyl glucosinolate) is effective at 10^{-6} M, 1,000-fold more effective than sinigrin (2-propenyl glucosinolate), in initiating oviposition by *P. brassicae*. Each crucifer plant has a few or many glucosinolates so that they seem to work together.

In Japan during the 1950s, the olfactory stimulation of insect by isothiocynates was first proven by Sugiyama and Matsumoto with both of adults and larvae of the vegetable weevil, *Listroderes costirostris*. This species is a typical generalist, feeding on over 120 species in 28 plant families, in which Brassicaceae are among the important host plants. Each allyl-, 1-butyl-, 2-butyl-, phenyl-, benzyl-, 2-phenylethyl isothiocynate evoked every step of the chain reaction of host selection behavior in adults, consisting of the orientation (=attraction), antennae tapping and final continuous biting (=feeding) against the odor-material in the absence of any taste substances or nutrients. For newly hatched larvae, nine isothiocynates, methyl-, ethyl- to 2-phenylethyl, 1-naphtyl isothiocynates indicated a significant attractiveness, increasing with an increasing number of CH_2 groups. These results clearly show that not only the specialist herbivores, but also the generalist herbivores, use plant odors as the token stimuli for their host selection behavior. In Germany, the attraction of the flea beetles, *Phyllotreta crucifera* and *P. striolata*, by allyl isothiocynate was first shown in field trapping. Thereafter, allyl-isothiocynate was proven to be effective in attraction to the cabbage root fly, *Delia radicum*, the turnip root fly, *D. floralis*, *D. brassicae* adults, and also in stimulation of oviposition by *P. rapae* and *P. xylostella* females. The cabbage seed weevil, *Ceutorhynchus assimilis*, is attracted by isothiocynate mixtures similar to the composition of odor chemicals in oilseed rape plants. However, omission of two isothiocynate, 3-butenyl isothiocynate and 4-pentenyl isothiocynate from the mixture significantly reduces the attractiveness.

In general, favorable effects such as feeding and oviposition stimulation by glucosinolates and attraction by isothiocynates are observed in specialist herbivores on Brassicaceae. Contrarily, unfavorable effects such as feeding and oviposition inhibition and repulsion are observed in non-adapted herbivores, such as the bertha armyworm, *Mamestra configurata*, Colorado potato beetle, *Leptinotarsa decemlineata* and the desert locust, *Schistocerca gregaria*.

Plant breeding strategies have concentrated on reducing the glucosinolate content of rape seeds because of reducing the risk of causing goiter and organ abnormalities in livestock animals. However, the response of insects to the glucosinolate and/or isothiocynate content is not so simple. A worker reported that *Phyllotreta cruciferae* and *P. xylostella* larvae fed at equal rates on *Brassica juncea* and its low-glucosinolate lines, indicating that these species are insensitive to sinigrin. Another group of workers reported that the feeding activity, such as the proportion of time feeding and area damaged, by *P. xylostella* larvae is higher on the lines with low myrosinase activity than on the lines with high mirosinase activity. In contrast, the feeding activity of the southern armyworm, *Spodoptera eridania*, a generalist, is not related to myrosinase activity. Relative growth rates of both insect species are lower on cotyledons of lines with high glucosinolate content, but are not related to myrosinase activity in the lines. Thus, glucosinolate reduction is not always promising for protecting crops against the insects.

Organic Sulfur Compounds in *Allium* Plants

V. G. Dethier first proposed investigation of behavioral reactions of typical allium-feeders to organic sulfur compounds, which seemed to be characteristic of odor in allium plants. During the late 1950s to early 1960s, the fast progress of instrumental analysis brought forth the component data of onion volatiles. Allium plants produce very specific sulfur compounds. Cysteine derivative amino acids are converted by enzymatic splitting into sulfenic acids and thiosulfinates, which evolve into numerous substances. This results in production of odorous substances consisting mostly of mono-, di-, tri-sulfides, and n-dipropyldisulfide (n-DPDS, n-$C_3H_7SSC_3H_7$) and 1-propanethiol (1PTH, n-C_3H_7SH), which are reported to be the main components of onion odor. The attraction and oviposition stimulation of female onion fly, *Delia antiqua*, by these two compounds was first demonstrated by Matsumoto and Thorsteinson in laboratory experiments and field trapping in Manitoba, Canada in 1963–1964. However, no attraction nor oviposition stimulation was observed to di-methyldisulfide (DMDS). Newly hatched larvae also were shown to be attracted to over 20 compounds of various mono-, di-sulfides and alkyl-thiols, including DMDS. The larvae are likely to be less strict in the selection of odor chemicals.

Over 10 years later, the analysis of green onion-seedling odor was conducted in Canada and Japan independently, so that nine alkyl di- and trisulfides including n-DPDS and 1PTH were found. A propylthio (n-C_3H_7S) moiety was shown to be essential for a compound to induce attraction and oviposition stimulation activities. The compounds having butylthio (n-C_4H_9S) or amylthio (n-$C_5H_{11}S$) moiety also were reported to be attractive, although these compounds were not found in volatiles from onion. The green onion seedlings of susceptible cultivars give a larger quantity of propylthio compounds than those of resistant cultivars, because the allinase activity is higher than in the resistant cultivars.

Host finding by the leek moth, *Acrolepiopsis assectella*, an allium specialist, is also controlled by sulfur compounds, with propylpropanethiosulfinate (n-$C_3H_7SOSC_3H_7$) the most attractive. The adults of Diadromus pulchellus, an endoparasitoid of the young larvae of *A. assectella* and *P. xyllostera*, use the volatiles from the frass excreted by their hosts, and from the plant leaves fed by their hosts. In the volatiles from the frass of both moths, the same three disulfides (dimethyl, dipropyl, and methyl propyl) are the most abundant substances. Thus, volatile sulfur compounds in allium plants have been found to favor the host finding by an allium specialist, but to deter the approach and attack to the plant by generalists. This is similar as in glucosinolates.

Audinet-Serville, Jean-Guillaume

Jean-Guillaume Audinet-Serville was born in Paris on November 11, 1775. The family wealth was lost during the French revolution, and Jean-Guillaume was sent to work in a coal store. The wife of the director of the store, Mme. de Tigny, author and correspondent of several notable entomologists, influenced him to collect and study insects. He married, and had three children before losing his wife. Latreille asked him to continue a work that Palisot de Beauvois had left incomplete due to the death of that entomologist. Thus, the 15th (last) part of "Insectes recueillis en Afrique et en Amérique…" was written by Audinet-Serville and published in 1819. Another famous work, Olivier's "Encyclopédie méthodique," was likewise incomplete, and here again Latreille persuaded Audinet-Serville, with help from Lepelletier de St. Fargeau and Latreille, to write volume 8, published in 1825. A third work, "Faune française" was also completed by Audinet-Serville in 1830, when he wrote the natural history of Coleoptera. Then, in 1831, he began publishing his own studies, first on the genus *Pirates*, and then "Revue méthodique de l' ordre des orthoptères," both in the pages of Annales des Sciences Naturelles. Other works followed, of which a notable one in 1839 was on "Orthoptères" and formed a supplement to Buffon's series of volumes "Histoire naturelle…." He died on March 27, 1858. His collections were broken up and sold to various collectors.

Audouin, Jean-Victor

Jean-Victor Audouin was born in Paris on April 2, 1797. He began to study law, but turned instead to medicine. His (1826) thesis was on the chemistry, pharmaceutical uses, and medical effects of "cantharides" (cantharidin), and on the beetles that produce it. He was made assistant to Latreille, and then succeeded Latreille as chairman of entomology at the Muséum National d' Histoire Naturelle, and reorganized and enriched the collections. In 1829, he coauthored a book with Milne Edwards on natural history of Crustacea. His (1834) book "Histoire naturelle des insectes" was of several volumes. He contributed some of his work to Cuvier's "Règne animal…" In 1838, he was elected a member of the Academie des Sciences. He did not build a personal collection of insects. He also published on applied entomology with a book (1842) "Insectes nuisibles à la vigne." With Brongniart and Dumas he founded the journal Annales des Sciences Naturelles. He died in Paris on November 9, 1841.

Augmentation

The practice of rearing and releasing biological control agents to effect pest suppression. This is also called augmentative biological control.

► Augmentative Biological Control

Augmentative Biological Control

MARJORIE A. HOY
University of Florida, Gainesville, FL, USA

Augmentation involves efforts to increase populations or beneficial effects of natural enemies (parasitoids, predators, pathogens, entomopathogenic nematodes) of pest insects, mites and weeds. Various techniques can be employed in augmentation, but augmentation typically involves releases of natural enemies or environmental manipulation to enhance effectiveness of naturally occurring natural enemies. Environmental manipulation may involve providing alternative hosts or prey, food or nesting sites or modifying cropping practices to favor natural enemies.

Periodic releases may be labeled inundative or inoculative, depending upon the numbers of natural enemies released and the time interval during which they are expected to provide control. The distinction between inundative and inoculative augmentative releases may become blurred. Inundative releases involve releasing large numbers of natural enemies with the goal of achieving an immediate effect on pest populations. In essence, the natural enemies are "living pesticides." Pathogens and nematodes are commonly released inundatively. Parasitoids or predators are less often released in this manner because it is more difficult to mass produce high quality natural enemies inexpensively. For inoculative releases, relatively small numbers of natural enemies are released early in the cropping season and it is assumed that they will multiply and provide control of the target pest later in the season.

Examples of Augmentative Releases

Augmentation is an appropriate tactic to consider if indigenous natural enemies cannot suppress pest populations to an adequate level because the natural enemy population lags behind that of the pest, or if the natural enemies cannot persist over winter. Releasing natural enemies into crops that are sprayed with pesticides that are toxic to the natural enemies is unlikely to be effective unless the sprays are applied in a selective manner.

Examples of augmentative releases include releases of *Cryptolaemus montrouzieri*, a coccinellid predator of mealybugs into California citrus groves. This ladybird beetle has established permanently only in a narrow coastal area of California and does not overwinter elsewhere, so releases of 10–20 *Cryptolaemus* beetles per tree at the beginning of the summer can result in control of the mealybugs during the growing season. Periodic releases of the parasitoid *Aphytis melinus* are made to control California red scale on citrus grown in the coastal citrus region of California; approximately 200,000–400,000 wasps per acre are released. Several species of phytoseiid predatory mites have been released to control the two-spotted spider mite, *Tetranychus urticae*, in strawberries in California. Releases became essential and cost effective after this spider mite developed resistance to the pesticides used previously to control it. Releases of the parasitoid *Muscidifurax raptor* to control house flies, *Musca domestica*, on dairy farms can be effective if conducted as part of an integrated pest management program.

Augmentative releases are extensively employed in European glasshouses (or greenhouses). Releases of parasitoids or predators are made to control spider mites, whiteflies, leafminers, aphids and other pests on cucumbers, tomatoes and sweet peppers. For example, greenhouse whiteflies, *Trialeurodes vaporariorum*, are controlled by releases of a pathogenic fungus, *Aschersonia* sp. or a parasitoid wasp, *Encarsia formosa*. Several aphids can be controlled with releases of the cecidomyiid predator *Aphidoletes aphidimyza*, and the aphid *Myzus persicae* can be controlled by releases of the parasitoid *Diaeretiella rapae*. Leafminers, *Liromyza* sp., can be controlled by releases of several commercially available parasitoids. The two-spotted spider mite, *Tetranychus urticae*, a major pest of both ornamental and vegetable plants, is controlled by releases of the phytoseiid mite *Phytoseiulus persimilis*. Much of the information developed for releasing natural enemies in European glasshouses can be adapted to control glasshouse pests elsewhere because these pests are widely distributed.

Controversies about Augmentative Releases

Some augmentative release programs are controversial. For example, egg parasitoids of the genus *Trichogramma* attack eggs of many Lepidoptera. These tiny wasps have been mass reared and released against moth pests on millions of hectares of crops around the world. However, their efficacy rarely has been documented. It is suspected that efficacy may be less than expected because the wasps usually are reared, for economic reasons, on host eggs other than those of the target pest. Parasitoids produced on alternative host eggs may be of lower quality (small in size or with crumpled wings). Effective *Trichogramma* releases may require releasing as many as 150,000–500,000 wasps per hectare every 2 weeks during the growing season. Other elements of effective *Trichogramma* releases include collecting the species or biotype (specific strain) that attacks the target pest in the target crop for mass rearing. Reestablishing colonies on an annual basis using field-collected material has been recommended in order to maintain high quality.

Some augmentative releases of natural enemies have appeared to be effective because they induced the farmer to stop pesticide applications. However, the released natural enemy may not have provided control, which was actually provided by naturally occurring parasitoids, predators and pathogens. Knowingly using augmentative releases as a "placebo effect," in which the pest control is achieved by native natural enemies which are no longer disrupted by pesticide applications, is considered unethical because the consumer pays for unnecessary natural enemies.

Other releases of natural enemies may be of little direct benefit to the consumer purchasing them. For example, releases of some predators (such as some species of lady beetles or lacewing adults) may provide limited benefit at the release site because these predator species may be genetically programmed to fly long distances prior to settling down to feed and reproduce.

Another, more recent, issue that has been raised is whether some natural enemy species released in augmentative biological control programs could become permanently established in the environment. If the natural enemy is not native, some have questioned whether the natural enemies could have unintended effects on nontarget species in natural environments, perhaps reducing biodiversity. In the USA, importation of nonnative natural enemies, whether for classical biological control or for augmentative releases, must be approved by the U.S. Department of Agriculture after undergoing risk analysis.

When and Where are Releases Made?

Augmentative releases are most likely to offer practical alternatives to pesticides in situations where the crops are of high value, the natural enemies are reliably available at competitive prices, and guidelines on release methods, rates and timing are available. However, relatively few predators and parasitoids (probably <50) have been evaluated for efficacy, reliability and economic feasibility.

Augmentative releases can be hampered if high quality parasitoids and predators are not be available at the right time. Mass rearing of parasitoids and predators is restrained by high costs, lack of effective artificial diets, ineffective or limited quality controls and an inability to stockpile or store natural enemies during periods when they are not needed. Typically, parasitoids or predators are reared on insect hosts or prey, which are themselves reared on plants, making the rearing system complex and expensive. Maintaining pure and vigorous colonies of both hosts and natural enemies, as well as disease-free plants, requires skill and resources. If effective artificial diets could be developed for additional natural enemies, costs could decline and availability could increase. Although artificial diets for some arthropods are available, many diets are less effective than natural foods in producing high quality natural enemies. Concerns have been raised as to whether parasitoids or predators reared in insectaries are less fit than desired. For example, sex ratios in parasitoid populations reared in the laboratory often change due to inbreeding. Optimal methods for maintaining quality and genetic variability need to be developed to increase the effectiveness of natural enemies reared for augmentative releases in biological control programs.

Relatively few microbial products are available for pest management programs despite the fact that it may be easier and less expensive to produce viruses, bacteria or fungi than to rear parasitoids or predators. The commercial production of microbial pesticides involve a series of steps, including: isolating a suitable pathogen by screening a large number of isolates to identify those which show activity against the target pests; conducting laboratory and greenhouse tests to evaluate the efficacy of potential agents and to determine what environmental issues could affect their effectiveness;

producing commercial scale quantities of the product, which usually involves fermentation; developing the correct formulation of the microbe so the product can be stored, handled and applied effectively in the field; conducting efficacy trials of the agent under field conditions using commercial types of formulations. Microbial pest control products are expected to increase in popularity, but are not expected to replace synthetic organic pesticides. These microorganisms often are not pathogenic to predators and parasitoids, which can allow these agents to be compatible.

Several problems limit the use of microbial pesticides. Microbial products are not always reliable under field conditions due to limitations in both formulation and the microorganism itself. The activity of the microorganism may be too specific, which can be a disadvantage when there are multiple pests in the cropping system. Most microbial products have a short residual activity in the field (especially in comparison to synthetic organic pesticides), which makes it necessary to make multiple applications which increases labor and product costs. Microbial products may act slowly, making them appear ineffective or allowing excessive damage to occur in the crop.

Some Logistical and Ethical Issues

Augmentative biological control with releases of natural enemies requires that the user (grower, farmer, home owner) have considerable information. Consumers need to be informed before using augmentative biological control or consult with a knowledgeable pest control advisor. Some augmentative releases should be considered experiments because necessary information is lacking. It is possible that the release rates and timing may not have been evaluated under the specific climatic conditions and crop production conditions at the release site.

Detailed information about the pest species you wish to control is usually required for effective augmentative releases of natural enemies. Some natural enemies, such as some lady beetles, are generalists and will eat many species of aphids. However, even generalist lady beetles may not eat all species of aphids because the aphids are repellent or contain toxic chemicals. Many pests require specific natural enemies to achieve control. For example, a predatory mite that is known to feed on spider mites may not consume other plant-feeding mite species such as rust mites or tarsonemid mites. Many parasitoids have a very limited host range, sometimes limited to one or a few species. Thus, a taxonomic identification of the pest to species or strain may be required.

Next, the best natural enemy(ies) for that target pest need to be identified. Companies provide lists of pests against which their products may be applied, but these may be less than reliable. Consult your land grant university extension service, the U.S. Department of Agriculture or licensed pest control advisors for additional information as to which natural enemies are appropriate for your target pest.

One of the most difficult questions to answer is "how many do I have to purchase for release"? This question should be answered after careful consideration; if too few natural enemies are released, the releases will be ineffective and the funds used to purchase the natural enemies will be wasted. Furthermore, the additional damage to the crop caused by the pest could reduce yield or quality.

There are some common "rules of thumb" in release rates: for example, releasing 1 predatory mite for each 10 or 20 spider mites will provide relatively rapid pest population suppression. However, even this release rate is inadequate if the 10 or 20 spider mites have caused economic damage to the plant prior to the release; an average of ten mites per leaf results in different levels of damage than an average of ten mites per plant. Thus, information about the damage the plant can tolerate is needed. Different cultivars of a crop may vary in sensitivity to feeding by pests, so release rates and timing may have to be tailored to the specific crop cultivar.

To calculate the number of natural enemies required in an augmentative release program, the number of pests should be estimated by an effective sampling scheme. For example, it may be useful to estimate the mean number of spider mites per leaf, the mean number of leaves per plant and the mean number of plants per acre or hectare to calculate the total number of mites present and, thus, the number of predators to order. Do not forget to allow for a continued population increase between the time you calculate the pest population density and the time you receive the natural enemies (typically several days to a week later). The sooner the releases occur the less damage will accrue to the crop plant.

Once the natural enemies arrive, follow the directions on how to store them before releasing them, monitor the containers to be sure the natural enemies are healthy, and follow the directions on how to release them. Once the releases have occurred, know how to monitor the release site to be sure the natural enemies are performing as expected.

Time is of the Essence

Because natural enemies are relatively expensive, it is desirable to release them as early as possible in a pest population outbreak so that fewer natural enemies are required to perform the job. Waiting until the pest population is abundant increases costs and reduces the likelihood that the natural enemies will perform effectively.

Many natural enemies arrive from commercial producers as adults, and they may have been stressed during shipment. As a result, they may require a "lag time" before they feed or reproduce on the target pest. Furthermore, many natural enemies, such as predatory mites, typically live as adults less than a week; if we assume that the adults were collected immediately after emerging for shipping and the shipping process takes 1 day, such individuals will still have "lost" approximately 2 days in their potential effectiveness.

Ideally, augmentative releases will be planned prior to the start of the growing season and a monitoring program will be implemented so that releases can be scheduled as soon as the target pest population appears.

Costs of Releasing Natural Enemies

Costs of releasing natural enemies depend on the number that must be released. It is often the case that too few natural enemies are released and, as a result, in inadequate control occurs. In California strawberries, it was estimated to cost approximately US $600 per acre to release predatory mites to control two-spotted spider mites in strawberries. This cost was accepted because the spider mites were resistant to the currently registered pesticides and no other effective control method was available. Furthermore, the high value of strawberries (approximately $30,000 per acre) made this control cost feasible. In lower value crops, augmentative releases might not be economically justifiable.

- What is the specific pest you need to control?
- Which natural enemies are known to perform well on that specific pest species under similar climatic and geographic conditions?
- How many pests do you have? Per leaf? Per plant? How many plants per row or acre? How many acres?
- What is the effective release rate for that natural enemy? For example, should the natural enemy be released in a ratio of one natural enemy to each 10 pest individuals? If so, the earlier the releases can be conducted, the less expensive such releases will be. For example, If hundreds of spider mites are present on each plant, then it is expensive and difficult to release sufficient predators to suppress them; it would be better to make releases when less than one spider mite per leaf is present.
- Calculate the number of natural enemies needed based on release rate, area to be covered and abundance of the pest per plant, row, acre.

- Are multiple releases needed over days or weeks to achieve the necessary level of pest suppression?
- How should the natural enemies be stored and handled after your receive them from the commercial producer to reduce mortality and enhance effectiveness after release?
- When should releases be conducted (time of day, temperature conditions) and in what manner? For example, do natural enemies disperse readily or should they be released on each plant or each leaf.
- How can you monitor the results of the releases to know if the natural enemies are performing as expected?
- Does the commercial producer provide information on release rates, timing, methods, and guarantee quality of the natural enemies during shipping?

Key Research Needs

Additional resources committed to improving augmentative releases of natural enemies could increase the use of this pest management tactic. These include research to develop adequate quality control tests so that only high quality natural enemies are shipped from the commercial producers. Appropriate tests should be conducted to confirm that the correct natural enemy species is shipped, that it is disease free, vigorous and viable. Research should also be devoted to developing improved methods for producing natural enemies at peak demand times, or for storing natural enemies without a loss in quality, so that adequate numbers are available when needed. High quality, but inexpensive, artificial diets could reduce production costs. Shipping and storage methods could be improved; many natural enemies arrive stressed or, even, dead. Finally, accurate information on release rates and timing could be improved and developed for additional geographic regions and climates.

Because data are not available for all situations, many augmentative releases of natural enemies should be considered experiments and conducted on a relatively small scale initially until it is clear that the necessary information is available and appropriate for the new situation.

Future of Augmentation

Pests in greenhouses in Europe, in which eggplants, cucumbers and tomatoes are grown, are often under complete biological control due to augmentative releases of natural enemies. There are several moderately large companies that produce natural enemies for this market, provide information on release rates and timing, and provide other information. Control of pests of ornamental plants in Europe is less often achieved by augmentative biological control because damage to foliage or flowers reduces quality. Greenhouse-grown crops in other geographic areas may be limited due to difficulties in obtaining natural enemies in a timely fashion, differences in pest and disease complexes, and differences in climatic conditions.

Citrus growers in California have developed grower-owned cooperatives to produce natural enemies. This approach has proven successful for over 50 years, suggesting that grower-owned cooperatives might be a useful model for increasing the use of augmentative releases in other crops in other geographic areas.

Augmentative releases can be an effective pest management tool for many pests in a diverse array of crops. However, augmentative biological control requires that the pest manager have considerable information on pest and natural enemy biology, an understanding of pest-natural enemy dynamics, and the availability of adequate numbers of high quality natural enemies for release at the right time. Thus, it is an information-intensive and logistically critical management approach.

Augmentation has the potential to become a more dominant component of pest management programs if sufficient resources are devoted to

Some natural enemies considered suitable for augmentative biological control

Natural enemy	Pest
Predators	
Amblyseius barkeri	*Thrips tabaci, Frankliniella occidentalis*
Amblyseius cucumeris and A. degenerans	*Thrips tabaci, Frankliniella occidentalis*
Anthocorus nemorum	Thrips
Aphidoletes aphidimyza	Aphids
Cryptolaemus montrouzieri	Mealybugs and some scalaes
Chrysoperla carnea	Aphids
Hippodamia convergens	Aphids
Metaseiulus occidentalis	*Tetranychus urticae, T. pacificus*
Orius sp.	*Frankliniella occidentalis*
Phytoseiulus persimilis	*Tetranychus urticae*
Parasitoids	
Aphelinus abdominalis	*Macrosiphum euphorbiae*
Aphidius colemani	*Aphis gossypii*
Dacnusa sibirica	*Liriomyza bryoniae, L. trifolii, L. huidobrensis*
Diglyphus isaea	*L. bryoniae, L. trifolii, L. huidobrensis*
Encarsia formosa	*Trialeurodes vaporariorum, Bemisia tabaci*
Eretmocerus californicus	*Bemisia tabaci*
Leptomastix dactylopii	*Planococcus citri*
Metaphycus helvolus	Scales
Opius pallipes	*Liriomyza bryoniae*
Trichogramma spp.	Lepidopteran eggs
Pathogens	
Bacillus thuringiensis	Lepidopteran larvae
NPV-virus	*Spodoptera exigua*
Trichoderma harzianum	*Fusarium* spp.
Verticillium lecanii	Aphids
Entomopathogenic nematodes	
Heterorhabditis spp.	*Otiorrhynchus sulcatus*
Steinernema spp.	Sciaridae

obtaining the necessary information and improvements in rearing and deployment.

Auricular Openings

Lateral, slit-like openings to the insect heart by which blood is admitted into the dorsal vessel. These are also known as ostia or incurrent ostia.

Australian Archaic Sun Moths (Lepidoptera: Lophocoronidae)

John B. Heppner
Florida State Collection of Arthropods, Gainesville, FL, USA

Australian archaic sun moths, family Lophocoronidae, have six known species in Australia. The family comprises its own superfamily, Lophocoronoidea, and is the only member of the infraorder Lophocoronina, of the suborder Glossata. Adults small (10–15 mm wingspan), with head roughened; labial palpi 3-segmented; haustellum short and vestigial mandibles are present; maxillary palpi are long and 4-segmented. Maculation is pale monotone with some darker spotting. Biologies and larvae remain unknown, but adults are crepuscular in eucalyptus sclerophyll woodlands.

Australian Lappet Moths (Lepidoptera: Anthelidae)

John B. Heppner
Florida State Collection of Arthropods, Gainesville, FL, USA

Australian lappet moths, family Anthelidae, total 100 species, all from Australia. There are two subfamilies: Munychryiinae and Anthelinae. The family is in the superfamily Bombycoidea (series Bombyciformes), in the section Cossina, subsection Bombycina, of the division Ditrysia. Adults medium size to very large (22–166 mm wingspan), with head vertex scaling (Fig. 94) rough; haustellum absent (sometimes short or more rarely long); labial short and mostly upcurved but some more porrect; maxillary palpi vestigial; antennae bipectinate (serrate to filiform in some females); body robust. Wings broadly triangular

Australian Lappet Moths (Lepidoptera: Anthelidae), Figure 94 **Example of Australian lappet moths (Anthelidae), *Munychryia senicula* Walker from Australia.**

and rounded (rarely somewhat acute or even falcate); hindwings rounded (rarely somewhat acute); rarely with micropterous females. Maculation mostly shades of brown with few markings, but some more marked or lighter. Adults nocturnal, but at least one species with diurnal males. Larvae are leaf feeders and generally colorful. Host plants recorded in several plant families, including Casuarinaceae, Gramineae, Leguminosae, and Myrtaceae, among others. Some species have urticating larval setae.

Australian Primitive Ghost Moths (Lepidoptera: Anomosetidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

Australian primitive ghost moths, family Anomosetidae, comprise a single genus with 1 known species from Australia. The family is in the superfamily Hepialoidea, of the infraorder Exoporia. Adults small (18 mm wingspan), with head rough-scaled; haustellum short and vestigial mandibles present; labial palpi short, 3-segmented; maxillary palpi minute, 2-segmented; antennae short. Maculation is darkened with some darker forewing spots. Biologies and larvae remain unknown.

Australian Sheep Blowfly, *Lucilia cuprina* Wiedemann (Diptera: Calliphoridae)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

Sheep in many areas of the world are plagued by fly problems, but Australia, with 103,000,000 sheep, has the most severe fly problems. The problem starts when wool becomes excessively wet. Continually wet wool is irritating to the sheep's skin, and a condition called "fleece rot" develops. Fleece rot results in skin inflammation and the secretion of serum from the irritated skin. Such a site is soon teeming with bacteria. The wet, serum-containing wool is attractive to ovipositing flies, and soon the maggots hatching from those eggs feed not only on the fleece, serum, and bacteria, but the underlying skin. The problem is exacerbated by the presence of urine, feces, sweat or other animal secretions, all of which are attractive to flies. The attack of flies on sheep in this manner is called "flystrike," and this condition can result in the death of animals or the expense of treatments to prevent or cure this fly-based problem. The problem is greatest in environments where warmth and moisture occur frequently, and the cost for fly treatments and loss of sheep due to flies is estimated at $100–150 million annually in Australia. The principal problem fly is *Lucilia cuprina*, known in Australia as Australian sheep blowfly or primary green blowfly. It is responsible for over 90% of the flystrike in Australia, but other flies can be involved.

Beginning in about 1988, *L. cuprina* first appeared in New Zealand, greatly exacerbating the flystrike problem with sheep there, and extending flystrike attacks into a nearly season-long problem. In recent years, about half of the flystrike incidents in New Zealand were caused by *L. cuprina*, but the proportion attributable to this fly seems likely to grow as it continues to spread.

Sheep producers can take several actions to reduce or prevent flystrike. The mechanical removal of the wool around the tail, anus and vulva (in ewes) is called "crutching," and helps prevent flystrike because these sites are most likely to stay wet and soiled, and thus attractive to ovipositing females. However, the wool grows continuously, so repeated removal of wool is necessary for this process to be effective, and is not cost-effective for large producers of sheep. A more permanent treatment is the surgical removal of skin around the anus and vulva, resulting in wrinkle-free and wool-free tissue in these areas, which tend to remain clean and free of flies. This surgery is called "mulesing," and is normally conducted on lambs a few weeks after birth. It takes about 4 weeks for the wounds to heal, and should be conducted before flies are active, or they will be attracted to the wounds, making the problem worse. Mulesing is quite controversial because it is painful for the sheep, and is being phased out in Australia. The tails of lambs also can be docked to reduce the tendency of the anal region to remain soiled and wet, and this practice evokes less opposition. A common alternative to crutching and mulesing is chemical protection, though this also requires repeated treatment. Other alternatives include limiting sheep raising to regions that are too dry or cool for optimal fly population growth. Some breeds of sheep, such as Merino sheep, are particularly prone to problems because the are very wrinkled and have a very dense wool. Historically, Merino is the preferred sheep in Australia.

Over 90% of the flystrikes in Australia are initiated by *Lucilia cuprina*, an introduced species. As is generally the case with blowflies, the primary hosts are carrion, but when sheep are afflicted with fleece rot or have thick mats of wet wool, female flies will deposit eggs on live sheep. The presence of even a few flies (7–10 per hectare) is enough to cause severe problems if susceptible sheep are present. The adults are metallic blue or green in color, and about 9 mm long. Flies initiate oviposition only after completing a protein meal, which enables egg production, and then up to 250 eggs can be deposited in a single batch on soiled wool. Each female typically produces two to three egg clusters during her life span of 2–3 weeks. The eggs hatch within 8–24 h, and the maggots feed and grow to a length of 10–15 mm in about 3 days. They then drop to the soil, usually during the night or early morning, and pupate. About a week after pupation, the adults emerge and start the cycle again. Thus an entire life cycle is completed in about 2 weeks. They reproduce best under warm (at least 18°C), wet conditions, but cannot tolerate high (over 38°C) temperatures, so fly populations may decrease during the middle of the summer in hot areas. Thus, peak blowfly populations tend to occur in spring, and late summer or autumn, in Australia.

Sheep producers have several options when it comes to control of sheep blowfly. Producers can apply organophosphate insecticides for rapid fly control, but these products tend not to be very persistent (2–4 weeks), and resistance to some organophosphates is known. Insect growth regulators take longer to take effect, but persist longer (up to 14 weeks). Other products are available, of course, and confer different advantages. Resistance to pyrethroid insecticides is widespread in Australia. The insecticides are sometimes applied by hand, which is advantageous because they can be directed to the areas of the animal most susceptible to flystrike. To reduce labor costs, automated (walk-through) sprayers are sometimes used, but such applications are less directed and commonly less effective in their coverage of sheep. Applications are most common soon after shearing, and if applications are delayed, unacceptable insecticide residues on the sheep may result.

In addition to chemical treatment, growers have recently adopted the practice of trapping flies. Traps consist of buckets with special lids containing entrance cones that allow the blowfly to enter but not leave the trap. Each bucket contains a number of chemical lures that mimic the odors of fleece rot, urine, feces, and animal carcasses. Once trapped inside the bucket, the flies die from dehydration. Traps are distributed at a rate of one trap per 100 sheep, and they are recommended to be used early in the season when the fly population in naturally at its lowest. In addition to removing flies from the population, and thereby reducing the rate of flystrike, the traps are useful for monitoring population densities.

Optimal management of sheep blowfly is accomplished with implementation of an integrated or multi-faceted approach. This involves reducing the attractiveness of sheep to flies by docking lamb's tails, and by shearing, crutching or mulesing all sheep. Keeping the flocks separated helps reduce the movement of flies from flock to flock. Regular inspection of the flock is desirable, and catching and shearing of sheep, and spot treatment of sheep with fly infestations is desirable. Trapping and monitoring of adult fly populations with fly traps are helpful. Treatment of the entire flock may be necessary if the fly population becomes high, but timing needs to be optimized to avoid contamination with pesticide residues. Avoidance of pesticides with a history of fly resistance is important.

Some of the other calliphorid species associated with sheep in Australia, and their local common names, include:

- *Lucilia sericata* Meigen, the European green blowfly. This invader is the principal sheep blowfly in the United Kingdom, but only a minor pest in Australia. It is virtually identical to *Lucilia cuprina* in appearance.
- *Calliphora stygia* (Fabricius), the eastern goldenhaired blowfly. This fly is native to Australia. It is brown and about 13 mm long. It prefers cooler weather, disappearing in the summer months.
- *Calliphora augur* (Fabricius), the lesser brown or bluebodied blowfly. This native fly is a secondary species, not usually attacking sheep until other species have attacked. It is mostly brown, but has a metallic blue patch on its abdomen. It is about 11 mm long. It is found commonly in the summer. It differs from most other blowflies in depositing larvae rather than eggs.
- *Chrysomya rufifacies* (Macquart), the green hairy maggot blowfly. This is another native, secondary species. It is metallic green, and can be distinguished from *Lucilia* by the broad bands on its abdomen and its black forelegs. The adult is about 9 mm long. The larvae are distinctive, bearing sharp spines (the "hairs") over its dark body. It also is known to feed on other maggots.

Australian Silkworm Moths (Lepidoptera: Carthaeidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Australian silkworm moths, family Carthaeidae, are a monobasic relict family in Bombycoidea with a single species from western Australia. The family is in the superfamily Bombycoidea (series Bombyciformes), in the section Cossina, subsection Bombycina, of the division Ditrysia. Adults large (75–100 mm wingspan), with head scaling roughened; haustellum developed; maxillary palpi small, 3-segmented; antennae bipectinate, or apparently tripectinate (serrate in females); body robust. Wings broad and triangular but termen rounded; forewing with somewhat acute apex (Fig. 95). Maculation gray with large dark eyespot medially on all wings and band of gray-brown at base and along termen; hindwing reddish at apex with blue in eyespot. Adults are nocturnal (usually after midnight).

Australian Silkworm Moths (Lepidoptera: Carthaeidae), Figure 95 **Example of Australian silkworm moths (Carthaeidae), *Carthaea saturnioides* Walker from Australia.**

Larvae are leaf feeders, with numerous clubbed setae. Host plants are only in Proteaceae.

► Web-Spinners

Australian Parasite Moths (Lepidoptera: Cyclotornidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

Australian parasite moths, family Cyclotornidae, include only five known species from Australia. The family is in the superfamily Cossoidea (series Limacodiformes) in the section Cossina, subsection Cossina, of the division Ditrysia. Adults small (10–30 mm wingspan), with head scaling average; haustellum absent; labial palpi short; maxillary palpi absent; antennae filiform (thicker in males). Body robust. Wings elongated and rounded. Maculation somber hues of gray, with mainly a single forewing marking (one species is yellow and black). Adult activity uncertain but may be crepuscular. Larvae flattened, with lateral protrusions; highly evolved as parasites of leafhoppers, scale insects, or psyllids (Hemiptera) in early instars, and then as predators of ant larvae. The ants tolerate the predatory larvae, keep them in their nests and care for them, since they give the ants desirable exudates. Eggs are laid on plants frequented by likely hemipteran hosts and young larvae then search for a suitable host to parasitize upon hatching; eggs are tended by protective ants.

Autogenic Succession

A temporal succession of species that is driven by processes within the community (contrast with allogenic succession).

Autogenous

Among blood-feeding insects, the ability to produce eggs without a prior blood meal.

Autoradiography

A method for detecting radioactively labeled molecules through exposure of an x-ray sensitive photographic film.

Autoregulatory Control

Regulation of the synthesis of a gene product by the product itself. In some systems, excess gene product behaves as a repressor and binds to the operator of its own structural gene.

Autosomes

All chromosomes except the sex chromosomes. Each diploid cell has two copies of each autosome.

Autotomy

Self-amputation which functions as an escape mechanism. Under some circumstances, body parts are deliberately shed to avoid capture by predators. Arthropod legs are shed readily, and when this occurs early in life they can be regenerated, in whole or in part.

Autotroph

Organisms that obtain energy from the sun and other materials from inorganic sources (contrast with heterotroph).

Auxiliary Vein

A supplementary vein. The subcosta is often considered to be auxiliary.
► Wings of Insects

Auxiliae

Small plates beneath the base of the pretarsal claws, bearing the pulvilli (if present). These are sometimes known as auxilliary sclerites.
► Legs of Hexapods

Avermectins

Macrocyclic lactones derived from a soil-dwelling microbe, the actinomycete *Streptomyces avermitilis*. They are chloride channel agonists. These materials are considered to be broad spectrum, slow acting, natural pesticides, and display activity against helminths, insects, mites, and nematodes. They are used widely to treat animals for parasitic organisms, but also for insect and mite pests in agriculture. They degrade readily and lack persistence and mobility, so are valued in integrated pest management programs and even in some organic agriculture situations. Common commercial products include Abamectin, Agrimek, Avert, Avid, and Vertimec.

► Insecticides

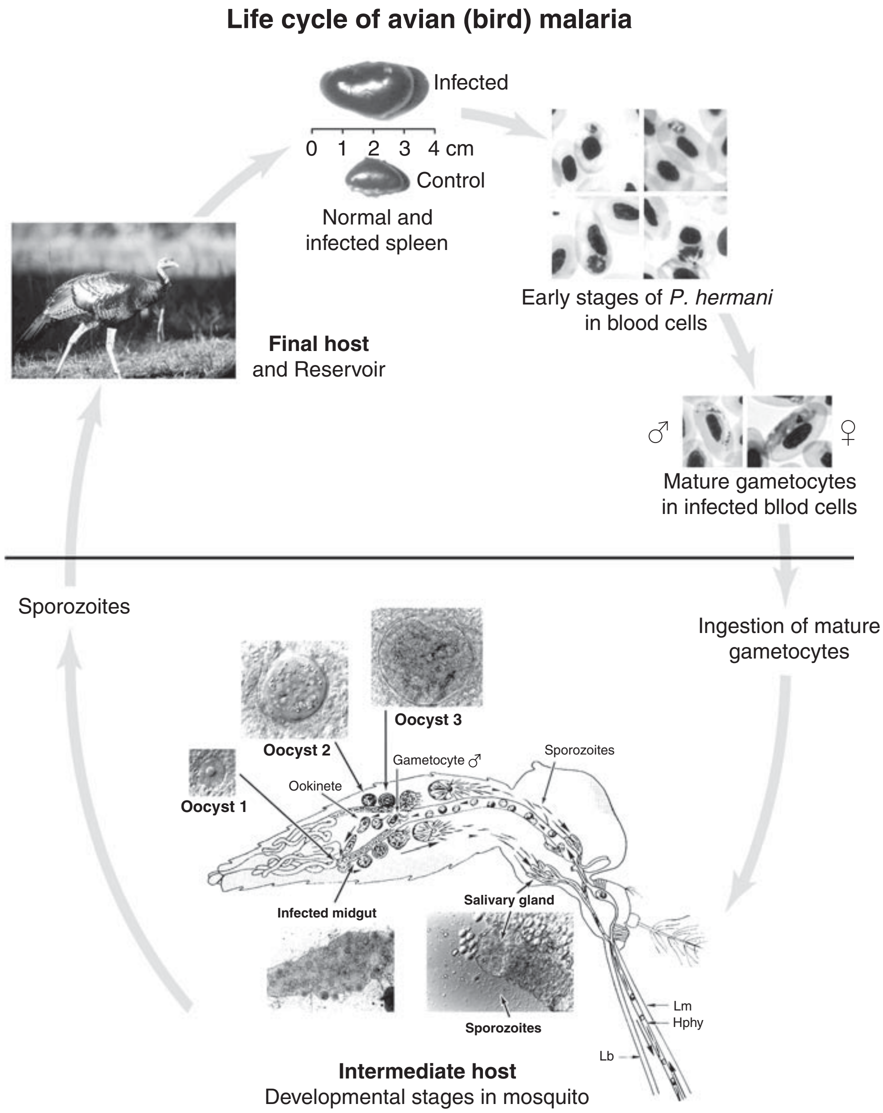
Avian Malaria, Bird Malaria

Jai K. Nayar
University of Florida, Vero Beach, FL, USA

Avian malaria is an infectious disease and it is found all over the world, especially in tropical and temperate areas. It produces a wide range of effects in avian hosts, from no apparent clinical signs to severe anemia and death. It has served as an experimental model for human malaria during the early history of malaria research. Avian malaria is not one disease, but many and is caused by distinct species of a protozoan blood parasite, *Plasmodium*, that is transmitted by mosquitoes. It belongs to Class Sporozoa, Subclass Telosporidia, Order Coccidiomorphida and Suborder Haemosporidina, and Genus *Plasmodium*. There are about 30 species of *Plasmodium* parasites recognized that infect birds world-wide and they are grouped into four subgenera depending on the shape and size of the parasite in erythrocytes and presence or absence of schizogony: *Haemamoeba* species have round gametocytes; *Huffia* species have elongate gametocytes and schizogony in primitive red cells; *Giovannolaia* species have relatively large asexual stages and no schizogony; and *Novyella* species have small asexual stages and no schizogony.

Plasmodium parasites in birds are primarily blood parasites, but in the acute phase they do infect a variety of other tissues, the lungs, endothelial cells of capillaries in the brain, and the reticular cells of the splenic Malpighian body. The parasites multiply in all of these tissues. Later generations of the parasites are less selective in host cell preference and the parasites may be found in various other tissues. In the chronic phase the parasite causes little harm. Several species of mosquitoes belonging to genera *Anopheles*, *Culiseta*, *Mansonia*, *Aedes*, *Armigeres* and *Culex* are found to be experimentally susceptible to different *Plasmodium* species that infect birds, but the natural vectors are mostly *Culex* and rarely *Aedes* species.

The life cycle of *Plasmodium* (*Huffia*) *hermani*, a parasite of wild turkeys (*Meleagris gallopavo* L.) that was described (Fig. 96) from Florida in 1975, will serve as an example. This parasite was discovered after specialized subinoculation technique of blood (heparinized or citrated) from chronically infected wild older turkeys into young poults of broad-breasted-white domestic turkeys. In turkeys (both wild and domestic) the malaria parasite infection causes anemia, splenomegaly, and reduced weight gains in poults. Natural infection of the young turkey poults begins with the bite of an infected culicine mosquito. Sporozoites introduced with the salivary gland secretions are carried to the reticular cells of the splenic Malpighian body. After a minimum of three generations of exoerythrocytic development in these cells that takes about 10–14 days, the stage of parasite called merozoites may spill over in the blood circulation and invade basophilic cells of the erythrocyte series, or may continue asexual reproduction. These merozoites after invasion of basophilic cells of the erythrocyte series transform into trophozoites (uninucleated, either elongate or round), schizonts (rounded with 6–14 nuclei arranged peripherally as a rosette) and finally elongate slender gametocytes (male and female) with irregular margins in mature erythrocytes. Time required may vary from 2 to 4 days. In general erythrocytic avian merozoites appear to be able to choose among four possible fates. Most may continue schiozgony in erythrocytes, but some may become micro- and macro-gametocytes (male or female gametocytes, respectively) or they may re-initiate asexual reproduction in the tissues as phanerozoites. Northern bobwhites



Avian (Bird) Malaria, Figure 96 **Life cycle of *Plasmodium hermani*. Stages of avian malarial parasite in mosquitoes: oocyst 1 = young oocyst about 4 days old, oocyst 2 = about 7 days old, oocyst 3 = about 10 days old. Lm = labium, Lb = labrum, and Hphy = hypopharynx.**

(*Colinus virginianus*) in Florida is also a natural and experimental host of *P. hermani*.

Natural and experimental vector for *P. hermani* in wild turkeys and northern bobwhites in Florida is *Culex nigripalpus*, but experimental studies indicate that other culicines (*Cx. salinarius* and *Cx. restuans*) may be involved to a lesser degree. *Plasmodium hermani* is not transmitted by *Cx. quinquefasciatus* in Florida and it does not infect young chicks (*Gallus domesticus*). Three additional species of turkey malaria have been reported from other parts of the U.S.A. These are *P. hexamerium-like* from Texas, *P. lophurae* from Wisconsin, and *P. kempi* from Missouri, Wisconsin, Minnesota and North Dakota. Natural vectors of these species of avian malaria are presumably also culicines although they have not been determined. Experimental studies have shown that *Cx. tarsalis* and *Cx. pipiens pipiens* can be infected with *P. kempi*. Other species of *Aedes*, *Culiseta* and *Wyeomyia* can be experimentally infected with avian malarias, but their contribu tion in natural transmission of the parasite is unknown. In some of the experimental mosquitoes that are not natural vectors, a defense reaction occurs and development of oocysts in the mosquitoes is compromised by intracellular melanization of the developing oocysts.

The developmental cycle of the avian malarial parasite within the susceptible mosquito is similar in all vector species and begins with the ingestion of erythrocytes (blood cells) containing male and female gametocytes from the infected bird. As the blood meal passes into the gut, the change in the environmental factors induces gametocytes to emerge from the erythrocytes (within 4–6 h). The microgametes (male gametocytes) begin the prefertilization process by undergoing exflagellation. Soon thereafter individual microgametes are released, which swim actively to the macrogametes (female gametes) and penetrate them culminating in fertilization. This results in the formation of a zygote, which elongates and undergoes cytoplasmic changes and forms motile ookinetes (within 24 h). The mature ookinetes migrate intracellularly through the midgut cells and move into the outer wall of the midgut facing the hemocoel, where the ookinetes form a tumor like body, or oocyst. Within 8–12 days, the timing depending on temperature and species of the parasite, schizogony within the oocyst produces hundreds, or even thousands of sporozoites. Sporozites are spindle-shaped organisms measuring about 8–9 μm in length and about 1 μm wide. These are liberated into the body cavity by rupture of the oocyst wall, and some find their way into the salivary glands, where they mature in 1–2 days. A bite of an infected mosquito causes infection in young turkey poults and starts the life cycle all over again.

Recently, *Cx. nigripalpus*, *Cx. restuans* and *Cx. salinarius* were shown be experimental vectors of *P. elongatum* from 3 raptors species (red-tailed hawk, bald eagle and eastern screech owl) in Florida and *Cx. restuans* was shown to be the experimental vector of *P. forresteri* n. sp., from several species of raptors from Florida and Georgia.

Normally epizootics of avian malaria are rare. Several species of avian malaria, e.g., *P. gallinaceum*, *P. juxtanucleare* and *P. durae* are the most dangerous for poultry, producing up to 90% mortality. In addition, there are a few documented cases where avian malaria has been shown to either eliminate or reduce bird populations. Until 1826, birds were plentiful in Hawaii and mosquitoes were absent from the region. Introduction of *Culex pipiens* from ships traveling to Hawaiian Islands introduced a lethal form of avian malaria, which eliminated indigenous bird populations. In another case, it is suggested that an abnormally early rainy season over a 2-year period in southern Florida in the 1960s resulted in a widespread malaria epizootic in wild turkey populations, which caused a significant decline in the wild turkey population. In recent years, avian malaria has caused severe mortality in exotic bird populations, especially penguins, in zoos across the U.S.A.

Axenic

Free from associated organisms. Including internal symbionts.

Axenic Culture

Culture of insects in the complete absence of other species (usually of microorganisms), including internal symbionts.

Axiidae

A family of moths (order Lepidoptera) also known as gold moths.

► Gold Moths
► Butterflies and Moths

Axillary

This refers to the point of origin of a structure, often a junction or angle. Thus, the axillary region of the wing is the wing base, and the axillary lobe in Diptera is the sclerite covering the base of the wing.

Axon

A portion of the nerve cell that transmits nerve impulses away from the cell body to a synapse. This also is called nerve fiber.

► Nervous System

Azadirachtin

This is a triterpenoid derived from the neem tree, *Azadirachta indica*. It is found in many parts of the tree, but is particularly concentrated in the seeds, from which it is extracted as used as an insecticide. It also has other properties, including medicinal. Although azadirachtin is a principal factor in insecticidal products, it is not the only active property, and is not especially useful as a feeding deterrent, though crude extractions of the tree contain feeding deterrents.

► Neem

B

Babesia

A genus of Protozoa that is transmitted to animals by ticks.

► Babesiosis
► Piroplasmosis

Babesiosis

Several related diseases caused by infection with *Babesia* protozoans, and transmitted by ticks.

► Piroplasmosis

Bacillary Paralysis

A disease of silkworm larvae caused by ingestion of spores and parasporal crystals of *Bacillus thuringiensis*.

Bacillus larvae (=Paenibacillus larvae; Bacteria)

The bacterium responsible for causing American foulbrood in honey bees; it is now known as *Paenibacillus larvae*.

► American Foulbrood
► Paenibacillus

Bacillus sphaericus

COLIN BERRY
Cardiff University, Cardiff, Wales, United Kingdom

The bacterium *Bacillus sphaericus* is best-known to entomologists because of the toxicity of some strains to the larval stages of mosquitoes. This toxicity will be examined below but first, some consideration of the taxonomic group that is known as "*Bacillus sphaericus*" is necessary.

Taxonomy

Identification of a bacterium as a *B. sphaericus* isolate is based on relatively few morphological features (e.g., the possession of a spherical terminal spore) and a limited number of biochemical tests (e.g., inability to ferment sugars). As a result, the classification contains a heterogeneous collection of strains and it has been shown that, at the DNA level, these can be divided into five major homology groups (groups I-V), each of which could be considered as a separate species. All of the insecticidal strains of *B. sphaericus* are found within a subdivision of one of these groups – Group IIA; however, not all strains that fall within this group are insecticidal. It is the insecticidal strains of *B. sphaericus* and their properties that will be considered further below.

Target Range

Bacillus sphaericus is toxic to a small range of dipteran target insects, principally mosquitoes (with some possible activity against *Chironomus* species). Within the mosquitoes, *B. sphaericus* is often seen as most active against *Culex* species with lower activity against *Anopheles*, *Mansonia* and *Psorophora* and lowest activity against *Aedes* species. However, these generalizations should be treated with caution as some *Aedes* species are as sensitive as *Culex* species so that susceptibility must be judged at the species level and not by genus. In addition, activity of a *B. sphaericus* toxin has been reported against the German cockroach, *Blattela germanica*.

Field Use

Bacillus sphaericus strains have been used in control programs worldwide to suppress mosquito populations that are of nuisance or public health importance. For this purpose, only strains showing high-level, spore-associated toxicity are used (e.g., VectoLex® and Spherimos® from Valent BioSciences, or Sphaerus® from Bthek Ltda). For production of maximum toxicity, as well as for ease of production and storage, such formulations are produced from fully sporulated *B. sphaericus* cultures that can be sprayed or applied as blocks or granules that disperse in the aqueous habitats.

The Insecticidal Toxins

Insecticidal strains of *B. sphaericus* owe this property to the fact that they produce protein toxins. To date, several different types of toxins have been identified. The names of these toxins, along with notes on their mechanisms of action, are given in the table below.

All the toxins except sphaericolysin exert their effects on the gut of the aquatic larval form of the mosquito after ingestion of the bacterium. The binary toxin (Bin) is produced on sporulation whereupon it is deposited in spore-associated crystal As shown in the figure of *B. sphaericus*, (Fig. 1) the spore is the round body at the top, the crystal is the grey, rhomboid body in the center, and both are contained within the elongated exosporium. Once eaten by a mosquito larva, the crystal dissolves and its two component proteins (BinA -42 kDa and BinB -51 kDa) are able to bind to specific receptors in the gut before lysing the cell by pore formation. Note: although the Bin proteins form a spore associated toxin crystal, they are not related to the majority of the crystal-associated Cry and Cyt toxins of *Bacillus thuringiensis*. Most highly toxic *B. sphaericus* strains produce only the Bin toxin in association with spores (Mtx toxins are produced only in vegetative cells and in very low quantities). The existence of only one toxin in spores applied in mosquito control programs in the field can lead to resistance in target populations. A few strains of *B. sphaericus* can overcome this resistance in *Culex* mosquitoes. These

Bacillus sphaericus*, Table 1** **Toxins of *Bacillus sphaericus

Toxin (molecular wt.)	Mechanism of action	Reference
Bin (51 and 42 kDa)	Pore formation	Oei et al. (1992), Schwartz et al. (2001)
Mtx1 (100 kDa)	ADP-ribosylation	Thanabalu et al. (1993)
Mtx2 (31.8 kDa)	Pore formation	Thanabalu and Porter (1996)
Mtx3 (35.8 kDa)	Pore formation	Liu et al. (1996)
Cry48/Cry49 (136 and 53 kDa)	Pore formation	Jones et al. (2007)
Sphaericolysin (53 kDa)	Pore formation	Nishwaki et al. (2007)

strains produce a novel toxin pair, Cry48/Cry49, which are deposited as crystals outside the exosporium. The Cry48 protein is related to 3-domain Cry toxins of *B. thuringiensis* while Cry49 is related to the Bin proteins. Both components are required for toxicity to *Culex* larvae and do not appear to kill other insects (including *Anopheles* and *Aedes* mosquitoes).

Despite reports of resistance developing in mosquito populations, careful use of this bacterium is likely to enable the continued favorable use of this product for integrated control programs in the field.

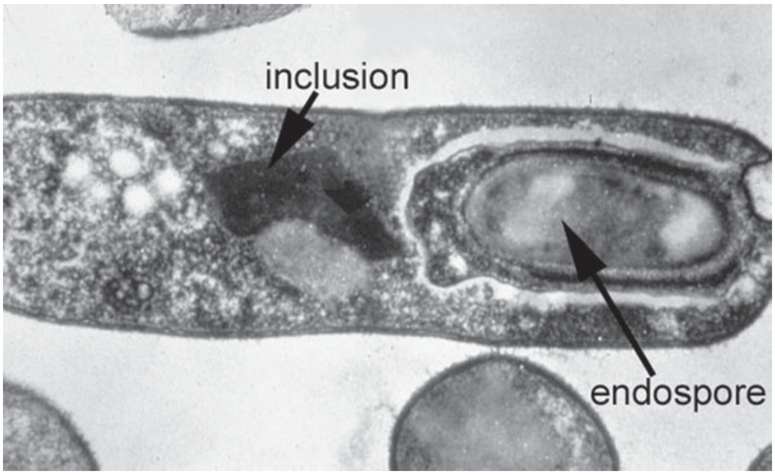
Bacillus thuringiensis

Bacillus thuringiensis was initially described early in the 1800s as the causal agent of the "sotto bacillus disease" of the silkworm *Bombyx mori*. Later studies by Aoki in 1915 demonstrated that this bacterial agent produced a crystalline toxic material at sporulation. In 1911, Berliner isolated the type species *Bacillus thuringiensis var. thuringiensis* from the flour moth in the province of Thuringia, Germany. Following this report, a series of papers demonstrated that *B. thuringiensis* could infect and kill a variety of lepidopteran host insects. Until the 1970s, all *B. thuringiensis* isolates were characterized as being toxic to immature insects within the order Lepidoptera. However, today various *B. thuringiensis* subspecies have been identified which are lethal to lepidopterans, dipterans, coleopterans, and/or nematodes.

Historically, *Bacillus thuringiensis* has been isolated from environments associated with insect populations and/or plant material. For example, *B. thuringiensis* was discovered initially in silkworm farms. Additional *B. thuringiensis* isolates have been detected in various insectaries, stored product environments, and grain processing facilities. Studies have suggested that *B. thuringiensis* is a normal inhabitant of the foliage of plants. However, the soil habitat has been the primary source for isolating novel *B. thuringiensis* isolates. Whether or not *B. thuringiensis* undergoes saprophytic development in soil is unclear. Many bacilli considered to be close relatives of *B. thuringiensis* are known to inhabit hypogean environments. Presently, it has been estimated that over 60,000 isolates of *B. thuringiensis* are being maintained in culture collections worldwide.

Members of *B. thuringiensis* are rod-shaped (1.0–1.2 by 3–5 microns), gram positive, facultative anaerobes which utilize carbohydrates as preferred energy sources. Classification based on 16S rRNA sequence data clusters *B. thuringiensis* with *B. cereus*, *B. mycoides*, and *B. anthraxis* within the *B. subtilus* group. Bacteriological tests define *B. thuringiensis* isolates as being closely related to *B. cereus*. In fact, the ability of *B. thuringiensis* to produce the crystalline inclusion is the major feature that separates it from *B. cereus*. Acrystalliferous strains of *B. thuringiensis* generated by plasmid curing are nearly identical to *B. cereus*. The growth of *B. thuringiensis* on relatively simple media (0.1% glucose, 0.2% NH_2SO_4, 0.2% yeast extract) is biphasic and involves both a



***Bacillus thuringiensis*, Figure 2** **Electron micrograph of thin section of sporulating cell of *Bacillus thuringiensis*. Note the thick-walled endospore and endotoxin-containing crystalline inclusion.**

vegetative cell division phase and a sporulation phase. During sporulation, *B. thuringiensis* produces both the (Fig. 2) endospore and crystalline inclusions. The endospore, highly resistant to environmental stress, provides a mechanism for long-term survival of *B. thuringiensis*. This mesophilic bacterium can be produced easily on solid media or under submerged fermentation conditions. The rapid growth and sporulation of *B. thuringiensis* in relatively inexpensive media under submerged fermentation conditions have been key factors in its successful development as a biopesticide. Many of the advances made in the fermentation industry over the past three decades have improved the quality of *B. thuringiensis* products.

Initially, it was presumed that the *B. thuringiensis* was an infectious agent and much effort was spent on maximizing the delivery of bacterial spores to host insects. Early field experiments in the 1960s involving applications of spore-based formulations against pest insect populations produced erratic results. By the 1970s, it was demonstrated that the primary insecticidal activity of *B. thuringiensis* against lepidopteran hosts was due to the δ-endotoxins comprising the crystalline inclusions. These endotoxins are extremely potent and are toxic to target insects at picomole concentrations. However, with certain insects such as the larvae of the Indian meal moth *Plodia interpunctella*, the addition of spores synergizes the activity of the δ-endotoxins. Potentially, this synergism is due either to additional toxins in the spore coat or to the outgrowth of vegetative cells from ingested spores. Many commercial formulations containing high levels of δ-endotoxin have proven to be as effective as chemical insecticides yet exhibit high specificity to target pests without detrimental effects on beneficial insects and animals. By the 1990s, *B. thuringiensis*-based products represented more than 90% of the biopesticides used worldwide. Until the 1980s, it was proposed that microbial-based products such as *B. thuringiensis*, unlike their chemical pesticide counterparts, did not select for resistance in treated insect populations. The critical element required for the selection of *B. thuringiensis* resistance is the same as that required for resistance to the neurotoxic insectides: a multigenerational (continuous) exposure of the host to the mortality agent. With *B. thuringiensis*, this may be achieved either by a conventional spray program or by a contiguous planting of B.t.-transgenic plants.

Early work on the mode of action of the δ-endotoxin addressed the effect of extracted inclusions on lepidopteran larvae. Initial symptoms, occurring within one hour of ingestion of inclusions, include a cessation of larval feeding and gut paralysis. The endotoxin-induced gut paralysis retards passage of ingested plant material and spores, allowing spores to germinate and undergo vegetative development. At later stages, intoxicated larvae display a general paralysis followed by death within one to two days post-challenge. Histological studies demonstrated that the toxins released from inclusions and proteolytically activated in the gut lumen specifically target the midgut columnar cells. Examination of midgut tissue dissected from treated larvae initially revealed that columnar cells are slightly swollen but over time goblet and columnar cells become heavily vacuolated. At the late stages, midgut cells dislodge from the basement membrane and are sloughed off. At subcellular levels, the δ-endotoxins produce pores in the membrane. The activated toxin recognizes specific cell membrane receptors and then generates small pores in the cell membrane. The subsequent depolarization of the columnar cell stimulates the closure of the gap junctions, causing an increase in intracellular pH and cell hypertrophy. Without a functional columnar cell, the K^+ pump in goblet cells ceases to function. Intoxicated cells, due to increases in internal pH and loss of ion transport, become osmotically sensitive and lyse.

Importantly, the δ-endotoxins are primary translation products of bacterial genes and are amenable to genetic engineering techniques. By the early 1980s, U.S. and European laboratories had successfully isolated, cloned, and characterized genes coding for δ-endotoxins. During the past two decades over 90 different protoxin genes containing representatives of both Cry and *cyt* classes have been cloned and sequenced. The technology developed to study the structure and function of the δ-endotoxin has provided the foundation for the genetic engineering of this class of biopesticides. In several respects, the δ-endotoxin gene has played a pivotal role in agricultural biotechnology. The δ-endotoxins derived from recombinant bacteria represent the first group of genetically engineered products released into agricultural systems. To date, recombinant microbes expressing δ-endotoxin genes have been field tested worldwide in numerous agricultural systems. Secondly, the δ-endotoxin genes have been used as models for optimizing the gene expression in transgenic plants. Over the past decade, researchers have manipulated the δ-endotoxin gene and have altered the protoxin profile as well as the toxicity and specificity of individual Cry toxins. Significantly, Cry gene expression in transgenic plants has provided protection against insect herbivory

Bacteremia

The presence of bacteria in the hemolymph or blood of invertebrates and other animals without production of harmful toxins or other deleterious effects

Bacteriophage

A virus whose host is a bacterium

Bacteriophage Wo

JASON M. MEYER, MARJORIE A. HOY
University of Florida, Gainesville, FL, USA

Bacteriophages are obligate intracellular viruses that infect and kill bacteria. These viruses are ubiquitous and shape aspects of bacterial population ecology in almost every environment on earth. Bacteriophage WO infects the alpha-proteobacterium

Wolbachia, which is commonly associated with insects, mites, nematodes, and terrestrial isopods. *Wolbachia* is notorious for causing reproductive alterations in its hosts such as feminization, male killing, cytoplasmic incompatibility, and parthenogenesis. The diversity of *Wolbachia* strains and their influence on host biology has stimulated research encompassing broad topics including genetics, ecology and evolution. In addition, removing obligate *Wolbachia* infections from filarial nematodes has provided a novel treatment for human disease. The significance of both basic and applied research involving *Wolbachia* has made it one of the most well understood endosymbiont-host associations.

Virus-like particles (bacteriophage WO) were discovered inside *Wolbachia* cells in the reproductive tract of the mosquito *Culex pipiens* using electron microscopy in 1978. Bacteriophage WO particles are approximately 40 nm in diameter with short tails, contain linear double-stranded DNA, and are found near the *Wolbachia* cell membrane. Since its discovery, researchers have focused on characterizing the basic biology, distribution, and evolution of bacteriophage WO.

Bacteriophage WO has both a lysogenic phase, where its genetic information is integrated into the *Wolbachia* chromosome as a prophage, and a lytic phase, where the virion resides in the cytoplasm and can lyse *Wolbachia* cells. Little is currently known about what triggers the virus to kill *Wolbachia*. Bacteriophage WO may prevent excessive proliferation of *Wolbachia*, and this may have evolutionary implications for long-term maintenance of the association with the host.

Bacteriophage WO is transmitted transovarially inside arthropod eggs along with its host *Wolbachia* cells. This transmission mechanism provides an efficient and stable means for *Wolbachia* and its associated bacteriophage WO to infect arthropod populations at a high frequency. This notion is substantiated by the similarity of the G + C content and codon usage of phage and *Wolbachia* genes, indicating a long-term evolutionary tie between bacteriophage WO and *Wolbachia*. However, it also appears that both *Wolbachia* and bacteriophage WO are horizontally transmitted between different arthropod species by unknown mechanisms. This is supported by evolutionary studies showing incongruence between phylogenetic trees constructed using DNA sequences from *Wolbachia* and bacteriophage WO. Interestingly, some insects host multiple strains of *Wolbachia* that are infected with different types of bacteriophage WO, and even individual strains of *Wolbachia* can harbor multiple phage types. *Wolbachia* has a broad and dynamic host range that may be facilitated by the horizontal transfer of virulence factors it acquires from bacteriophage WO.

In 2000, the first bacteriophage WO was completely sequenced using DNA isolated from the Mediterranean flour moth *Ephestia kuehniella* Zeller (Lepidoptera: Pyralidae) infected with *Wolbachia*. A total of 33 open reading frames were detected among a genome of approximately 25,000 base pairs of DNA. The open reading frames represent the DNA coding information that dictates the construction and assembly of proteins. Some of the putative proteins identified were related to proteins known from a diverse group of other bacteriophages, while others showed no significant similarities to known phage proteins. Additional bacteriophage WO types have since been sequenced using DNA isolated from *Wolbachia* infecting the almond moth, *Cadra cautella* Walker (Lepidoptera: Pyralidae), and from *Wolbachia* infecting *Drosophila melanogaster* Meigen (Diptera: Drosophilidae).

Using the polymerase chain reaction (PCR), the putative minor capsid protein gene, *orf7*, is commonly used to detect bacteriophage WO in *Wolbachia* strains infecting arthropods. More than 100 *orf 7* sequences of bacteriophage WO have been deposited in GenBank as of May 2007. The *orf 7* gene has been detected in many, but not all, *Wolbachia*-infected arthropods. Using species representing multiple orders of arthropod hosts, between 70 and 100% of the *Wolbachia* strains tested are PCR-positive for bacteriophage WO. However, multiple *Wolbachia*-infected species of parasitoids in the genus *Trichogramma*

(Hymenoptera: Trichogrammatidae) and the parasitoid *Diaphorencyrtus aligarhensis* Shafee, Alam and Agarwal (Hymenoptera: Encyrtidae) lack bacteriophage WO. In addition, the nematodes *Dirofilaria immitis*, *Litosomoides sigmodontis*, *Setaria equine* and *Brugia malayi*, and a population of the predatory mite *Metaseiulus occidentalis* (Nesbitt) all had *Wolbachia* infections but lacked bacteriophage WO, based on PCR analysis of the *orf7* gene.

In vitro cultures of *Wolbachia* must be maintained using insect cell cultures because the endosymbiont is intracellular. Currently, no methods have been developed to transform (genetically modify) *Wolbachia* that would provide a tool to study its interactions with arthropods in detail. Bacteriophage WO has the potential to be developed as a vector to genetically modify *Wolbachia* because it integrates into the *Wolbachia* genome and its genes are actively expressed.

Baculoviridae

A family of insect pathogenic viruses known as baculoviruses.

► Baculoviruses

Baculoviruses

The insect baculoviruses, the nucleopolyhedroviruses (NPVs) and the granuloviruses (GVs), are the most intensely studied insect viruses. Historically, the first reports of a baculovirus-induced viremia were associated with the silkworm *Bombyx mori*. The spread of sericulture from Asia to Europe led to the introduction of the affiliated diseases grasserie or jaundice disease (NPV), as well as flacherie (non-occluded virus, bacteria), into the silk-producing regions. In the sixteenth century poem titled "De bombyce," Marco Vida describes the rupture of tissues and the release of fluid from diseased silkworm larvae. It is presumed he is describing the last stages of *B. mori* NPV-induced jaundice. In 1856, the Italian scientist Maestri made the first scientific observation of the causal agent of jaundice. With the aid of the compound microscope, he described the presence of polyhedral bodies (Fig. 3) or occlusions in the fluid and tissues of diseased silkworm larvae

By the late 1890s, J. Bolle reported that the polyhedral bodies were proteinaceous crystals resistant to various solvents but sensitive to alkaline solutions. Bolle reported that healthy silkworms that fed on the polyhedral bodies contracted jaundice. The intracellular inclusions described initially by Bolle as *Microsporidium polydricum* were named later by Prell as *Crystalloplasma polyhedricum*. Glaser and Chapman, who in 1916 reported that the infectious agent was a filterable agent of dimensions much smaller than the micron-sized polyhedral bodies, questioned the infectious nature of the polyhedral bodies. They and others proposed that the polyhedral bodies were metabolic by-products and not causal agents of the disease. The nature of the polyhedral

bodies and capsules finally was resolved in the 1940s by the German scientist G. Bergold. He and co-workers examined alkali-treated baculovirus inclusions under the newly developed electron microscope and described the occluded, rod-shaped virus particles.

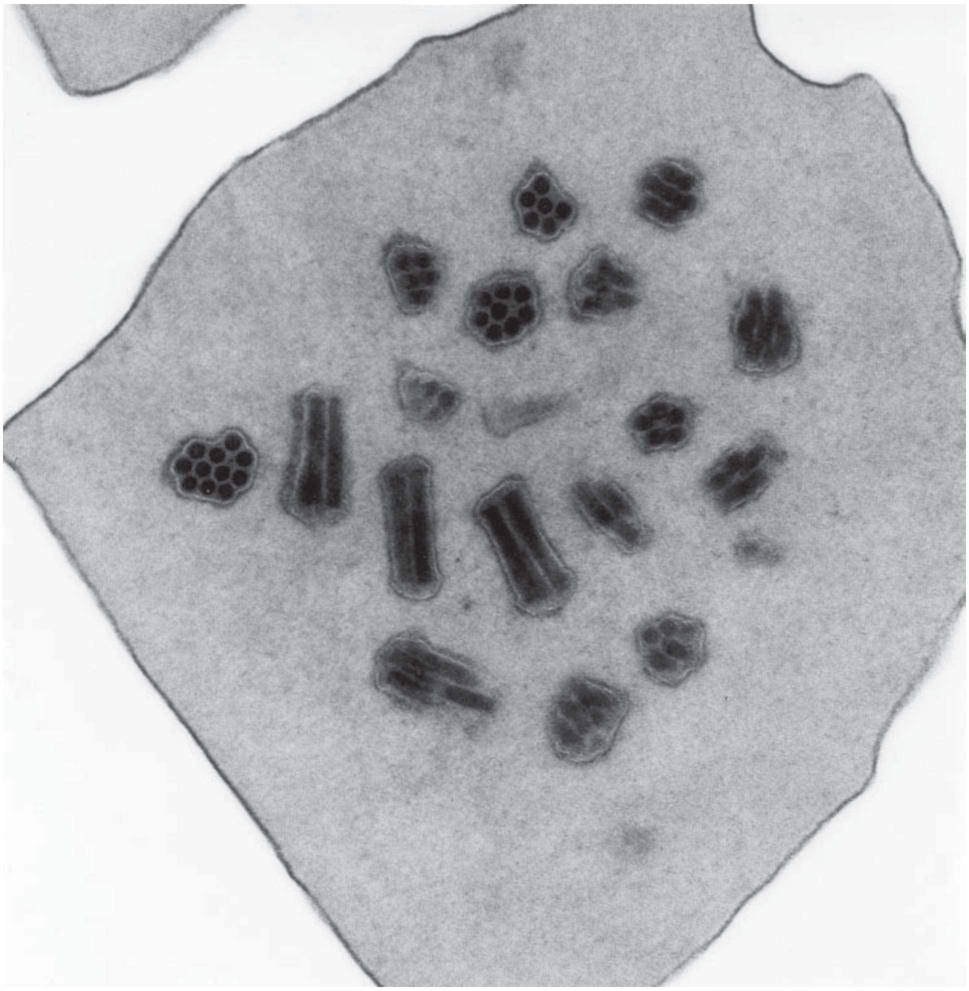
In the late 1930s, the French scientist A. Paillot described a new type of viral disease in the cabbage butterfly, *Pieris brassicae*, that, unlike the NPVs, produced numerous minute capsules (granules). Using high-speed centrifugation, Paillot and co-workers determined that the infectious entities were associated with the granules in the high-speed pellets. Paillot observed that this viral disease, termed pseudo-grasserie, multiplied in the fat body and caused infected larvae to exhibit a whitish coloration. In the early 1930s, he described a similar disease in the cutworm *Euxoa segetum* that caused nuclear hypertrophy of infected fat body cells followed by the formation of the granules. In 1947, Steinhaus discovered a similar disease in the larvae of the variegated cutworm, *Peridroma margaritosa*, the first report of this disease outside of France. To date, granulosis viruses have been found to infect only lepidopteran hosts. These viruses are considered to be among the most specific insect viruses, capable of infecting a single species or species within the same genus

Prior to their identification, baculoviruses were recognized as important natural regulators of various lepidopteran defoliators. At the end of the nineteenth century in central Europe, nun moth (*Lymantria monacha*) populations were decimated periodically by a wilt disease. Prior to death, infected insects migrated to the tops (Wipfeln) of the trees, attached by their prolegs, and died. Upon death, the body disintegrated and released infectious fluid. Initially, the causal agent of the disease, known as Wipfelkrankheit, was described as a bacterium, then later as a protozoan within the genus *Crystalloplasma*. Although it was not properly named, a great deal was learned from these early studies of this disease agent. Experiments showed that the infectious material resisted putrification and was stable for 3 years when stored in a dry state. Furthermore, the disease agent persisted in the soil and could be extracted from washings using differential centrifugation. This agent was transmitted per os; the fluid released from the cadavers was highly infectious to healthy larvae. Finally, it was reported that the infectious agent displayed specificity to certain insect species. For example, the fluid released from diseased nun moth larvae was infectious to the related gypsy moth, *Lymantria dispar*, but was harmless to silkworm larvae. Throughout the 1920s, a program in Europe promoted the spread and distribution of the causal agent into disease-free areas. This involved a variety of tactics, including the use of mortars to deliver infectious material into the tree canopy. The field studies on the nun moth NPV suggested that this disease operated as a density-dependent disease agent

In the United States, a similar scenario was observed in populations of the gypsy moth, an imported defoliator of deciduous hardwoods. This insect, originally imported as an alternative silk producer, escaped into the oak forests and spread throughout southern New England. In the early 1900s, collapses of gypsy moth populations were attributed to the natural occurrence of wilt or flacherie disease. At this time, Glaser and Chapman initiated a series of key studies on this disease. Microscopic examination revealed that this virus replicated initially in the tracheae then spread to virtually all the insect tissues. Infected cells were recognized by the large number (Fig. 4) of intranuclear occlusion bodies. In 1913, Glaser and Chapman reported that the filterable agent, the causal agent of gypsy moth wilt disease, was sensitive to sunlight and to heat treatment. In 1916, it was determined that the occlusions could be disrupted readily when placed in alkaline solutions and could be re-formed by neutralization of the alkaline solution.

One of the classic examples of biological control of insects has involved the introduction of a baculovirus. In Canada, the European pine sawfly, *Neodiprion sertifer*, was introduced and became established as a major forest defoliator. In the early 1950s, T. Bird (Canadian Forest Service) reported that a sawfly virus imported from Sweden was highly virulent to *N. sertifer* larvae. The introduction of this virus resulted in widespread epizootics that spread through the sawfly population and provided a natural control of this defoliator. This virus, unlike the lepidopteran baculoviruses, was transmitted easily from infected adults to the egg stage. The combination of its high virulence and ability to be vertically transmitted were responsible for its ability to provide effective long-term control of this pest insect. The natural occurrence of baculovirus epizootics and their potential to be manipulated as biological control agents against key pest insect defoliators served as the catalysts for baculovirus research during the past 30 years. During this period more than 4,000 research papers have been published on baculoviruses, of which more than 3,000 have focused on the nucleopolyhedrovirus group. In the 1970s and early 1980s, the major focus was studying the effects of wild-type baculovirus strains on insect population. From the mid-1980s to the present, the emphasis has been directed at the biochemistry and molecular biology of these viruses. This work, in addition to providing detailed insight into the workings of this complex virus, has provided the scientific community with a highly efficient eukaryotic expression vector system that is being used commercially to produce various protein products. Lastly, the basic research has provided a means to engineer the baculovirus, which in future years may provide highly efficacious recombinant strains for managing insect pest populations (Table 2).

Nucleopolyhedroviruses are horizontally transmitted to susceptible insects per os; larvae become infected by ingesting foliage contaminated with occlusions. In limited cases, chronically infected adults may disseminate baculovirus onto the chorion surface during oviposition,



Baculoviruses, Figure 4 **Transmission electron micrograph of a thin section of the multiply embedded nucleopolyhedrovirus, not the crystalline protein matrix within which are embedded membrane bound rod shaped virus particles. Ingestion of these occlusions by host insects results in the digestion of the matrix protein and release of occluded virus.**

resulting in a vertical transfer of the pathogen to progeny caterpillars. Not all baculoviruses cause lethal infections; latent infections can persistently infect insect colonies in which the virus is transmitted within the egg stage. At present, very little is known about the frequency and impact of such persistent baculovirus infections on natural insect populations. The initiation of baculovirus epizootics has been attributed mainly to insects contacting and ingesting overwintering virus inocula that are associated with plant and/or soil substrates. It is likely that latent infections play a role in both the initiation and maintenance of natural virus epizootics. During the epizootic phase the primary route of baculovirus transmission is per os. Ingested viral occlusions are disrupted by the action of alkaline proteases in the midgut lumen. The types and amounts of gut proteases produced by an insect influence the processing of ingested occlusions. Increased feeding rates, as displayed by mature larvae, may result in the rapid passage of ingested food containing intact or only partially digested occlusions, thereby preventing contact with the midgut

tissue. Alternatively, the ingestion of plant material that either buffers gut alkaline conditions or contains endogenous protease inhibitors or antiviral allelochemicals may reduce the susceptibility of an insect to baculovirus infection.

The released occlusion derived virus (ODVs) must bypass the peritrophic membrane in order to access the initial target midgut cells. The peritrophic membrane is a dynamic structure that varies among different species and between the different developmental stages. As insects mature they often display a developmental resistance to infection that is related in part to the production of a well-defined peritrophic membrane. The ODVs do not orientate to the microvilli in any particular fashion, suggesting that the anti- receptors, if present, are distributed throughout the ODV envelope. The viral membrane fuses to the microvillar membrane and the nucleocapsids are released into the cytoplasm. Nucleocapsids are transported to the nucleus and attach to the nuclear pores of the columnar epithelial cells. In addition to directly infecting the columnar cells, investigators have reported that parental nucleocapsids can traverse the columnar cells and infect underlying regenerative cells. Viral development in the columnar epithelial cells may be aborted by the preferential sloughing off of infected cells and by the removal of the midgut layer at larval molt. Therefore, the ability of a baculovirus to infect the regenerative cells may play a key role in maintaining a systemic infection.

The naming of the different viruses includes the initial letter of the host species followed by mnv (multiply embedded nucleopolyhedrovirus), Snpv (singly embedded nucleopolyhedrovirus) or Gv (granulovirus).

In the midgut cells, viral particles either attach to the nuclear pore and uncoat, or enter the nucleus and uncoat. The release of the viral genome into the nuclear region marks the initiation of the primary replication phase. In various lepidopteran hosts the majority of baculoviruses produce only the non-occluded virus; occlusions are not normally synthesized in either virus-infected columnar or regenerative cells. Unlike other enteric viruses (e.g., Cypoviruses), the virus released from the infected columnar cells do not horizontally spread to adjacent midgut cells but can infect adjacent tracheal cells or migrate to the basal face of the midgut. However, the basement membrane, comprised of exocellular matrix proteins, surrounds the basal face of the midgut and is believed to act as a barrier to prevent the large-scale release of baculoviruses into the hemocoel. The virus that has penetrated the tracheal cells can undergo a complete replication cycle and may then infect neighboring tracheal cells. Utilizing the host tracheal system as a conduit, the virus can access and infect other susceptible insect tissues. In addition to being disseminated via the tracheal conduit, NPV-infected hemocytes also can spread the virus to healthy tissues

During baculovirus replication, various viral proteins are produced which modulate the host at the cellular as well as organism level. Baculoviruses may contain genes that code for proteins with anti-apoptotic activities that block the internal cell suicide program. Premature cell death would abort the production of viral progeny particles. Baculovirus replication also has been observed to disrupt the developmental program of host insects. For many years it has been known that baculovirus infection retards larval development and prevents the larval-to-pupal molt. In the late 1980s baculoviruses were found to contain a gene (egt) which codes for a ecdysteroid UDP-glucosyl transferase (egt). The egt gene encodes for a 57 kDa polypeptide with 506 aa. The egt holoenzyme, an oligomer of 3–5 subunits, catalyzes the transfer of glucose or galactose from UDP-glucose or UDP-galactose, respectively, to ecdysteroids producing inactive sugar conjugates of this steroidal hormone. Expression of the egt gene inhibits the molting process and maintains the host in the larval stage. This gene is non-essential, deletion mutants retain their ability to infect and to replicate both in cell culture and in host insects. However, egt expression alters host ecdysone titers, results in a massive reprogramming of host tissues, and disrupts larval molting and pupation. The prolongation of the larval stage results in increased viral yields. Alternatively, the disruption of pupation due to viral infection reduces the likelihood of viral-infected adult insects. Since the initial report in AcMNPV, homologous genes have been detected in various NPVs.

In non-midgut tissues, NPVs, in addition to producing the baculovirus phenotype, produce massive numbers of the ODV phenotype and associated occlusion bodies. The very late stage of NPV development is characterized by the presence of hypertrophied, infected nuclei becoming filled with highly refractile occlusions. Virtually all host tissues become infected and larvae are extremely fragile. Frequently, NPV infected larvae will disintegrate into a puddle of occlusion bodies. This “wilting” symptom is believed to result in part from the production of virally encoded hydrolases having either proteolytic or chitinolytic activities. The production of this enzyme, detected in culture supernates at 12 h post-infection, is under the regulation of a late gene promoter. This enzyme, stable between pH 3 and 10, is believed to be partially responsible for the liquefication of baculovirus-infected insects. The disintegration of infected insects also is aided by the production of various viral proteases. A variety of viral, host, and environmental factors determine the rate and level of occlusion formation in a baculovirus-infected insect. Regardless, the biomagnification of baculoviruses in their respective lepidopteran hosts is phenomenal. Neonate larvae may be infected by ingesting as few as 1–10 occlusions, succumb to viremia within 4–12 days, and then release 10^7 occlusions into the environment.

Bagworm Moths (Lepidoptera: Psychidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Bagworm moths, family Psychidae, total 1,001 known species, mostly Palearctic and African, with only 88 known for the New World; actual fauna likely (Fig. 5) exceeds 1,200 species. The family is now divided into six subfamilies, although various tribes are sometimes elevated as additional subfamilies: Lypusinae, Naryciinae, Taleporiinae, Penestoglossinae, Psychinae, and Oiketicinae (most of the subfamilies have also been treated as separate families in the past). The family is part of the superfamily Tineoidea, in the section Tineina, subsection Tineina, of the division Ditrysia. Adults minute to medium size (4–60 mm wingspan), with very rough head scaling; haustellum vestigial and naked; labial palpi reduced, 1 to 2-segmented but fused together (rarely 3-segmented); maxillary palpi; antennae usually bipectinate. Maculation mostly dull colored, but sometimes with clear wings or translucent wing spots; some are spotted; rarely colorful. Adults are mostly diurnal or crepuscular. Larvae are mostly leaf feeders or feed on lichens, all making distinctive types of larval cases, or bags. Pupation is within the larval case and females often remain there in a wingless or larviform shape, using pheromones to attract the winged males. A number of species are economic and many are general plant feeders.

Bait

A food or food-like substance that is used to attract pests. It often is combined with an insecticide to poison insects, slugs, snails and rodents.

► Food-Based Baits

Balanced Mortality Hypothesis

The belief that the level of reproduction is scaled to the probability of survival, with insects living in hostile environments having higher levels of reproduction than those occurring in more benign environments

Balance of Nature

This is the idea that in nature there exists an inherent equilibrium founded on the interactions of plants and animals, resulting in a stable, continuing system of life on Earth. This belief is fundamental to many cultures, though Carl Linnaeus is often credited with popularizing it ("oeconomia naturae") in his writings of 1749. Sometimes this natural order was attributed to divine providence, but at other times maintained by nature. Once a popular notion, it no longer is popular with ecologists.

Some elements of "balance" exist, such as the adaptations of different elements in a natural ecosystem such that resource production and use are commonly balanced and optimized. However, the so-called "balance" is continually upset by natural events and by the activities of humans. Outbreaks of insects are an example of the disequilibrium that calls into question the notion of "balance." However, the resistance of systems to perturbation, the resiliency (rapidity of return to equilibrium after perturbation) of both producer and consumer organisms, and the persistence (tendency of organisms to persist even when faced with catastrophic changes in abundance), can be construed as supportive of the balance hypothesis, or at least supportive of the idea of continuance or constancy.

Much of the disagreement about the "balance of nature" is due to differences in scale. Ecosystems are mosaics of patches, and environmental stochasticities or biological feedbacks that appear to be destabilizing or catastrophic on a local scale may be much less so when viewed on a larger scale. Clearly, ecological stability is scale-dependent, and broad-scale stability (metastability) usually exists only at the meta-scale.

Banana Pests and Their Management

WILLIAM TINZAARA,[1] CLIFFORD S. GOLD[2]
[1]Bioversity International-Uganda, Kampala Uganda
[2]CIAT-Uganda, Kampala Uganda

Bananas are among the most important food crops in the world. Despite their importance, banana yields are continuously declining due to attack by insect pests. Insects attack the banana rhizome, pseudostem, leaf and fruit. The most serious insect pest on a global basis is the banana weevil. Other pests include the sugarcane weevil, pseudostem weevil, banana scab moths, banana skipper, banana thrips and banana aphids. Pests of minor or localized importance include the spiraling whitefly, mealybugs, big-headed ant, chinese rose beetle and coconut scale. Thrips cause cosmetic damage directly to the fruit, reducing marketability. Most pests do not attack the bunch and cause indirect damage. For example, banana weevils attack the rhizome and pseudostem causing yield reductions through plant loss, delayed maturation and bunch weight reduction. Some pests, such as *Pentalonia nigronervosa*, are vectors of serious diseases. In this article, the pest status, distribution, biology and control options of major pests of banana are discussed.

Banana Weevil, *Cosmopolites sordidus* (Germar) (Coleoptera: Curculionidae)

The banana weevil is the most important insect pest of banana and plantain. Its host range is restricted to wild and cultivated clones of *Musa* (banana, plantain, abaca) and *Ensete*. The insect originated in southeast Asia and has spread to all important banana and plantain growing areas. It is not normally a pest in its area of origin.

Because of its importance, detailed treatment of this insect is provided elsewhere in the *Encyclopedia*.

► Banana Weevil, *Cosmopolites sordidus*

Sugarcane Weevil, *Metamasius hemipterus sericeus* (Coleoptera: Curculionidae)

The sugarcane weevil *Metamasius hemipterus sericeus* (Olivier) (Coleoptera: Curculionidae: Dryophthorinae) primarily infests banana, plantain, sugarcane and, less commonly, ornamental palms. The insect is endemic to the America tropics. It has been found on plantain in West Africa but has not been reported from East Africa.

The importance of *M. hemipterus* as a pest of banana is disputed but it is considered more serious than the banana weevil, *Cosmopolites sordidus*, in the banana growing areas of western Colombia. In this region, *M. hemipterus* is known to transmit *Erwinia chrysanthemi* pv *paradisiaca* causing rotting of the banana pseudostem. Some authors argue that *M. hemipterus* is unimportant or only a secondary pest of banana.

There are three recognized subspecies, all of which attack banana: *M. h. hemipterus* (L.) is distributed from Puerto Rico through the Lesser Antilles and into most of South America; *M. h. sericeus* (Olivier) is found in the Greater Antilles, southern Florida (USA) and from Nicaragua to Ecuador; while *M. h. carbonarius* (Chevrolat) occurs from Mexico to El Salvador and Honduras. The three subspecies have similar external morphological features and all show extreme variation in color. The adults are 9–14 mm long black adults with red or yellow markings. The base of the elytra is one-half to one-third red or yellow on a black background. The pronotum and venter are black to red and black. This species can be confused with *Metamasius calligsona* which infests bromeliads. *M. hemipterus* adults are active fliers (unlike *C. sordidus*).

Biology

The three subspecies of *M. hemipterus* have similar biology. The adults are most often found in moist, dark places. They are attracted to, and oviposit in, healthy banana pseudostems, rotting banana plants, banana residues, damaged or stressed sugarcane stalks, ripe fruit (i.e., pineapple, mango, papaya), or palm sheaths or stems. More is known about the oviposition habits of *M. hemipterus* on sugarcane than on banana. The weevil is attracted to stalks damaged by either mechanical cultivation, harvesting equipment, rats, borers, disease or natural growth cracks. In some cases, *Metamasius* females prefer to deposit eggs on sugarcane that has been damaged by *Diatraea* (Lepidoptera: Pyralidae). In Colombia, this type of damage is known as the *Diatraea-Metamasius* complex. *Metamasius hemipterus* has also been observed infesting canes used as seed pieces.

The females lay their eggs in cracks and damaged areas of bananas and sugarcane, or in petioles and crown shafts of certain species of healthy palms. The adult can live up to 60 days during which time the female can deposit 400–500 eggs. This contrasts with the biology of *C. sordidus*, which is longer lived but produces far fewer eggs. As with *C. sordidus*, *M. hemipterus* places single eggs in holes made in the host by the insect's rostrum.

The oval egg is 1.2–1.5 mm in length and creamy-white. The egg stage is 3–7 days. The cream-color, yellowish larvae are typical legless weevil grubs and similar in most aspects to other members of the Rhynchophorinae. Fully developed larvae are 1.3–2.0 cm. The larval stage lasts 50–60 days.

Metamasius hemipterus larvae can be differentiated from those of *Cosmopolites* by color (creamier coloration), behavior (more active), and morphological features (stigmata, cranial sutures, and structures on the labium and clypeum). Mature *M. hemipterus* larvae construct a fibrous pupal case (similar to that of the giant palm weevil, *Rhynchophorus palmarum*) and pupation takes place mostly within the banana pseudostem. The pupal stage is 10–20 days. Thus, depending on temperature, the life cycle is completed in 63–86 days.

Pest Status

Damage in banana is caused by the larvae, which feed in the upper part of the pseudostem. The larvae bore into the stem causing extensive physical damage and, in heavy infestations, can kill the plant. The first symptoms of *M. hemipterus* attack are yellowing of the lower leaves and consequent rotting of the pseudostem. In cases of extensive damage to the pseudostem, the plants cannot resist the weight of fruit, increasing the likelihood that the plants may double and eventually die. The pest has also been reported to attack the banana rhizome and cause damage similar to that of *C. sordidus*. Moreover, there are reports that *M. hemipterus* did not show any preferences between rhizome and pseudostem tissue of the cultivars Gross Michel (AAA) and Bout Rond. Unfortunately, there are no yield loss data for *M. hemipterus* in banana.

Larvae of *M. hemipterus* can seriously affect the ornamental palms *Phoenix canariensis*, *Ptychosperma macarthurii*, *Ravenia rivularis*, and *Roystonia*. Larval tunneling in palms starts in the petioles, wounds in petioles, crown, stem and then extends into healthy leaf or stem tissue. Affected palms are often characterized by the production of an amber-colored, gummy exudate in the stem, crown shaft or petioles, and galleries in the leaves, petioles and stems.

Trapping and Monitoring

Trapping of adults is often used to monitor weevil numbers, although interpretation of trap captures is difficult. The use of a “sandwich trap” using banana pseudostem as an attractant has been suggested. A maximum of ten weevils per trap per week have been captured using banana pseudostem disc traps, although the number of weevils collected at these traps was consistently too low to accurately assess weevil density. Fermenting sugarcane has also been used to attract *M. hemipterus*. An average of 30 weevils per trap using pieces of bamboo filled with pieces of fermenting cane have been captured. Tests conducted on different trap designs and the response of adults to semiochemicals demonstrated that weevil counts increased with combinations of ethyl acetate, sugarcane and/or the aggregation pheromone metalure, compared with the use of any compound alone. The major male-produced aggregation pheromones and host kairomone compounds have identified the trap designs and protocols that can be used for enhanced monitoring of weevil populations in the field. In addition, it has been demonstrated that pheromone and host-baited traps can be used to mass trap *M. hemipterus* infesting banana and sugarcane in Costa Rica.

► Control Measures

Chemical Control

Labeled rates of acephate, carbofuran, chlorpyrifos, cyfluthrin, disulfoton, imidachloprid, isofenphos, lindane and vydate have been demonstrated to kill adults of *M. hemiperus*. The data suggest that poisoned sugarcane traps may be adequate for control of *M. hemipterus*, although inadequate control with chemical insecticides has also been reported. Moreover, chemically based pest controls represent short term and questionable strategies for resource-poor farmers in developing countries, along with accompanying health and environmental concerns.

Cultural Control

Sanitation of residues harboring the weevil has been recommended. This procedure is done by cutting up pseudostems and allowing them to dry up. No data are available on efficacy.

Biological Control

Both entomopathogens and naturally occurring biological control agents affect sugarcane weevil.

Entomopathogens

The use of entomopathogens provides a promising, yet still expensive means of control of *M. h. sericeus*. The entomogenous fungi *Beauveria bassiana* (Balsamo) Vuillemin and *Metarhizium anisopliae* (Metchnikoff) Sorokin have gained considerable attention as potential control for weevils. For example, studies have demonstrated that naturally occurring *B. bassiana* was an important mortality factor to adults of *M. hemipterus* in Florida. *Beauveria bassiana* infection increased up to 70% between March and April 1991 when more than ten weevils were captured per trap. In Brazil, *B. bassiana* and *M. anisopliae* caused high death rates of adults applied under laboratory conditions.

Applying fungal formulations to traps made from banana pseudostems was considered the most effective delivery system, while applications outside traps were deemed impractical. It was observed that *M. hemipterus* adults were more susceptible to infection by both fungi than *C. sordidus* adults. In Cuba, a strain of *B. bassiana* from the sweet potato weevil, *Cylas formicarius elegantulus*, which is reported to be highly pathogenic to *M. hemipterus* and *C. sordidus* was isolated. More information is needed on the effect of these fungi before pest management decisions can be made.

The nematode *Steinernema carpocapsae* has been demonstrated to be effective against *M. hemipterus* larvae, but not adults. However, the authors concluded that chemical insecticides and entomopathogenic nematodes would need to be applied frequently and over a long period of time for effective management because of the weevil's high reproductive potential and the cryptic habitat of the immature stages.

Natural Enemies

Reported predators of *M. hemipterus* include labidurids, histerids, staphylinids, carabids, cicindelids, formicids and reduviids. Little is known on the control potential of predators. In Florida, Colombia and Ecuador, surveys for predators and parasitoids of *M. hemipterus sericeus* have been unsuccessful. There are reports that trials with the tachinid *Microseromasia sphenophori* failed. However, the tachinid *Admontia* spp, observed parasitizing *Metamasius quadrilineatus* in Honduras, could be tested as a possible parasitoid of *M. hemipterus*. Thus, to date, very little research has been done on parasitoids of *M. hemipterus* in the neotropics, so it is unclear whether or not effective biological control will be possible.

Banana Pseudostem Weevil, *Odoiporous longicollis* (Coleoptera: Curculionidae)

The banana pseudostem weevil, *Odoiporous longicollis* (Olivier) (Coleoptera: Curculionidae) is considered a minor to important pest of banana and Manila hemp in parts of India, Nepal, Burma, Sri Lanka, Thailand, Indonesia, China and elsewhere in Asia. The weevil bears a superficial resemblance to the banana weevil, *Cosmopolites sordidus* (Germar), but is slightly larger and its elytra do not completely cover the abdomen. The color of the adult weevil varies with age from reddish-brown to black. Sexing of adults is based on punctuation of the rostrum. Males also tend to be smaller than females. The sex ratio ranges from as 1:1.2 (male:female) to 1:1.5.

Biology

The weevil is characterized by long life span, negative phototropism, thigmotropism, gregariousness, hydrotropism and death mimicry. Most adults live 6–10 months, although some can survive for more than 2 years. In contrast to the banana weevil, the adult readily flies, although it has been described as a poor flyer. Still, it has sufficient capability to move between proximal banana stands. In spite of being negatively phototrophic, diurnal flight occurs.

Oviposition is in the leaf sheaths of living plants or residues. The weevils are especially attracted to, and readily oviposit in, cuts in banana material. Some authors have suggested that ovipositing females prefer stressed plants, while others observed greater oviposition in residues than in living plants. The greatest oviposition has been found in pseudostems with a girth of 25–50 cm, with little oviposition in plants less than 25 cm or more than 75 cm in girth. The eggs are placed singly in chambers made with the female's rostrum. The egg stage has been reported as 3–4 days and 5–12 days.

The larvae pass through four instars. The first instar remains near eclosion sites in the same leaf sheath. Subsequent instars bore into the inner leaf sheaths or pseudostem. The mature larvae may be twice the size of those of banana weevil. The larval stage has been reported by several authors to be 14 days, 3–6 weeks and 26–68 days.

The prepupa forms a pupal chamber within the host plant. Pupation is within a cocoon formed out of plant fibers. The prepupal stage lasts 3–9 days, while the pupal period has been reported as 3–20 days. Following emergence, the adults may pass extended periods and even mate within the host plant. The pre-oviposition period lasts 1 month.

Pest Status

The adult weevils feed on living and decomposing banana leaf tissues, but eat little and are not considered pests. Damage is done by the larval stage. The larvae attack the pseudostem and stem of banana plants, although they will occasionally feed within the rhizome. This contrasts with the banana weevil, which attacks the rhizome and uncommonly enters the pseudostem. As such, pseudostem borer damage may be clearly visible, while banana weevil damage can only be observed by dissection of the rhizome. The pseudostem borer will attack both living plants and harvested stumps.

Larval damage can lead to the rotting of pseudostem tissues and breakage in the wind. Breakage of damaged plants is potentially a serious problem, although such losses are rarely quantified. Thus although the weevil has been described as an important pest, there are no available data on plant loss and/or yield reductions. Further work in this area is required for the development of any integrated pest management program.

Control Measures

Cultural Control

There is limited information available on control of banana pseudostem weevil. Selecting new and clean sites, use of clean planting material, crop sanitation (e.g., burying infested residues), rogueing of infested plants, crop rotation (to rid fields of weevils), and trapping by placement of residue slices on the ground has been recommended. Because the weevil flies and its dispersal capacity has not been determined, it is unclear how effective the use of these cultural methods might be. One scientist reportedly collected more than 2 million weevils in traps over a 4-month period, but did not provide information on the effect of this trapping program on weevil populations.

Chemical Control

Swabbing of the pseudostem and weevil holes with insecticides has also been recommended. No data are available on efficacy.

Host Plant Resistance

Host plant resistance has been suggested to be effective in reducing weevil infestations. In India, one variety was found to be completely free of the weevil, while two others appeared resistant. In screened banana germplasm studies, six varieties were found to be severely infested, three heavily infested, four moderately infested, and 27 lightly infested.

Banana Scab Moth, *Nacoleia octasema* (Lepidoptera: Pyralidae)

Banana scab moth, *Nacoleia octasema* (Meyrick) (Lepidoptera: Pyralidae), is a serious pest of bananas in the Samoan Islands and elsewhere in the southwestern Pacific. The pest also attacks *Heliconia* spp. and *Pandanu*s spp. Other moths that attack banana but are considered of minor importance include *Opogona sacchari* and *Othreis fullonia*.

Biology

Banana scab moth females lay eggs on banana flower bracts or leaves as the inflorescence emerges. Larvae hatch, enter the flower, and feed on the developing fruits within. The feeding results in rough and irregular scars (brownish-black) on fruit skin. Large infestations can scar the entire fruit and cause deformed fingers.

Eggs are laid singly or in small, flattened, almost transparent clusters of a few to over 20 eggs. The eggs hatch in 3–4 days and the larvae enter the banana lower, where they feed. The larval period is 11–19 days. Pupation is inside a loose silken cocoon, often placed between banana fingers, in folds of the dead leaves still attached to the pseudostem, or in litter near the base of the plant. Adult moths emerge in 8–10 days and are short-lived, dying after about 3–10 days. Females lay approximately 80–120 eggs during their lifetime. The moths are rarely seen, because they hide among dead leaves and vegetation during the day and are active only during the early night.

Pest Status

Banana scab moth females lay eggs on the outside of the banana flower bracts or on nearby leaves as the flower first emerges. Upon hatching, the larvae enter the flower and feed on the developing fruits within. Feeding results in irregular dark brown to black corky blotches on the fruit skin. Light damage may be superficial and confined to the upper end and outer side of the curved fingers. Heavier infestations can scar the entire fruit, cause deformed fingers, or penetrate into the flesh of the fruit.

Control Measures

Uses of biological control, resistant varieties, or cultural controls have not proven effective for managing banana scab moth.

Chemical Control

Chemical control works well when used properly. Because the larvae begin damaging the developing fruits when they are still enclosed inside the flower, the best control can be achieved by injecting an insecticide into the flower after it first becomes visible, but before it starts bending over from the vertical position. A single injection at this stage, applied about 1/3 of the way down from the flower tip, will percolate down to protect all the hands inside. This protection will last until the bracts begin to fall away and no more egg laying occurs.

Some growers prefer to lift or remove the flower bracts and dust or spray insecticide onto the fruits after the flower has bent over. This method can stop some of the damage, but not all of it, because by this stage feeding has already begun.

Flowering is more or less continuous in banana plantations in American Samoa, and the stage at which insecticide must be applied lasts only a few days for each plant. Therefore, it is important to check the plantation frequently to ensure that all emerging inflorescences are treated.

Biological Control

Several kinds of natural enemies attack the banana scab moth, but in general they do not provide sufficient control to reduce damage to acceptable levels. Spiders and ants may prey on the immature stages of banana scab moth. Parasitic wasps may also help reduce banana scab moth numbers. In the Samoan Islands, the most common parasitoid is *Chelonus* sp. (Hymenoptera: Braconidae), which lays its egg inside the egg of the scab moth. The *Chelonus* larva then develops inside the scab moth egg and larva. It finally emerges from the nearly full grown scab moth larva to spin a cocoon nearby in which it pupates.

Host Plant Resistance

Some banana varieties appear to be less susceptible to scab moth damage. Left untreated, these varieties may produce a satisfactory product for markets that can tolerate some damage.

The Banana Skipper, *Erionota thrax* (Lepidoptera: Hesperiidae)

The banana skipper, *Erionota thrax* (Linnaeus) (Lepidoptera: Hesperiidae) is a minor to severe pest of bananas and *Musa textilis* in Southeast Asia and Papua New Guinea. Damage has also been reported from bamboo, coconut and other plants although it has been suggested that other species may be responsible for the records on palms and bamboo. Banana clumps in isolated villages in Java had a very patchy damage distribution, ranging from severe defoliation to nil on clumps growing within close proximity. Heavy rainfall and strong winds are unsuitable for banana skipper. Entry of water into the leaf rolls drowns the larva (particularly the first instar) and wind-torn leaf laminae are unsuitable for the production of leaf roll shelters. For these reasons, outbreaks in Malaysia and Indonesia are more common after a drought and in wind protected areas.

The banana skipper is a large brown *Hesperiid* with large yellow spots on the forewings above. Adults are less often seen although the caterpillars can be quite common on the host plants. This may be due to the fact that the butterfly is only active during the early morning hours and just before dusk. It is sometimes attracted to the lights of dwellings and flies towards the lights in the evenings.

The caterpillars can be found where the banana plants (*Musa* spp.) are cultivated. Occasionally, an infestation is severe enough for the species to be considered one of the banana farmer's pests. The characteristic rolled up portions of the banana leaves are a dead giveaway to the presence of the caterpillars. Pupation takes place in a rolled up leaf as well, and the adult butterfly emerges after about 7 days. The caterpillar swings from side to side when disturbed, and exudes a greenish fluid. The pupa also wriggles violently when disturbed.

Biology

The adult butterfly lays bright yellow eggs singly or in groups of up to 25. Oviposition is mostly on the lower leaf lamina midway between the midrib and the outer edge. Eggs turn bright red and the pale green larvae hatch after about 5–8 days. The larvae move to the outer leaf lamina where they commence feeding and then produce loose rolls by cutting the leaf and rolling the lamina towards the midrib. Larvae feed and grow within the rolls, commencing a new roll once the midrib is reached. The second and subsequent three instars are covered in a white waxy powder that provides protection from drowning during high rainfall. The larval stage lasts 20–30 days, depending on temperature. Pupation occurs within the leaf roll and lasts 8–12 days. Adults emerge in the afternoon and are most active in the evening and early morning when they actively fly around banana plants to mate and oviposit.

Pest Status

Direct fruit production losses is only significant following heavy defoliation since banana plants can withstand at least 20% leaf lamina loss before production is affected. Nonetheless, bananas in Southeast Asia are grown for aesthetic value and for culinary purposes where even minor infestations would be detrimental.

Control Measures

The banana skipper is adequately controlled by a range of beneficial insects such that other control measures are seldom required. In Indonesia, egg parasitoids, including *Ooencyrtus erionotae*, *Agiommatus* sp. and *Anastatus* sp., can parasitize 50–70% of the eggs. Young larvae are attacked by *Apanteles erionotae* while older third instar larvae are preferred by *Scenocharops* sp. The pupal parasitoids *Brachymeria* sp., *Xanthopimpla* sp. and *Pediobius* sp. also contribute to biological suppression of *E. thrax*. If unusually heavy outbreaks occur, the collection and destruction of leaf rolls may reduce subsequent damage.

Banana Thrips (Thysanoptera: Thripidae)

Species of thrips that attack and damage banana include Chaetanaphothrips orchidii (Moulton), C. signipennis, Caliothrips bicinctus, Frankliniella parvula, Heliothrips haemorrhoidalis (Bouché), Hercinothrips bicinctus (Bagnall), Thrips hawaiiensis (Morgan), and Tryphactothrips lineatus. The banana thrips H. bicinctus (Bagnall), C. bicinctus, C. orchidii, C. signipennis, T. hawaiiensis and T. lineatuss are the most important peel-blemishing insects, producing a range of damage symptoms on immature fruit.

Thrips cause superficial skin blemishes on immature and developing banana fruit. Damage is primarily cosmetic although severe attacks may result in splitting of the peel with subsequent development of secondary rots. Usually only fruit grown commercially requires treatment with prophylactic pesticides. In Australia, chemical treatments are routinely applied to prevent the rusty brown discoloration caused by the pantropical banana rust thrips *C. signipennis*. The closely related *C. orchidii* (Moulton) causes similar damage in Central and South America. The banana flower thrips *T. hawaiiensis*, a widespread and polyphagous flower feeder in Oriental and Pacific regions, damages fruit at flowering as it oviposits and feeds on fruit during and immediately after emergence of the inflorescence. The slightly raised, silvery grey lesions caused by these thrips are locally referred to as "corky scab."

In Mexico, *Frankliniella parvula* prefers to oviposit in the epidermis of young banawna fruits and less frequently in the flower parts. In Yemen, *Scirtothrips aurantii* and *Thrips pusillus* cause fruit spotting on bananas. Small circular spots first appear on the surface of the fruit, gradually enlarge, blacken, and develop into oily, water soaked lesions.

In Australia, *T. hawaiiensis* causes a superficial skin injury locally referred to as corky scab. Adults are attracted to the emerging inflorescence. Female oviposition and subsequent nymphal and adult feeding cause damage on the developing fruit while the bunch is wrapped closely in the bracts. Oviposition punctures result in localized raised "pimples" which disappear as the fruit develops, while the superficial grazing by the thrips develops into the slightly raised silvery-grey areas of corky scab. This damage is more prevalent during dry periods and is more commonly associated with fruit fingers on the lower bunch hands, the rachis and attacked cushion.

Biology

Eggs are inserted into the plant tissues including fruit, pseudostem and leaf petioles, depending on species. Surfaces that are in close contact are preferred for oviposition and development. The eggs hatch in 1–2 weeks. Nymphs are clear to straw-colored and, like the adults, shun sunlight, quickly dispersing when disturbed from their cryptic hiding places between adjacent fruit or from under leaf bracts on the pseudostem. Pupation takes place on the plant or in the soil near the base of the plants, depending on species. Banana rust thrips (*C. signipennis*) may spend part of their life cycle in the soil, while banana flower thrips stages all occur on the host plant. For example, in Australia, the entire life cycle of *T. hawaiiensis* is spent on the fruit or other parts of the plant. During summer months, the period from egg to adult for this species is 3 weeks.

Pest Status

Thrips can scar, stain, or deform banana fruits by feeding on the fruit skin. Thrips are small, winged insects that feed on banana flowers and/or the tender green skin of developing fruits. The two factors of feeding site and species determine the type and extent of fruit damage. Thrips outbreak can occur during periods of dry weather. Thrips cause superficial skin blemishes on immature and developing banana fruit. Damage is primarily cosmetic although severe attacks may result in splitting of the peel with subsequent development of secondary rots. Usually only fruit grown commercially requires treatment with prophylactic pesticides.

Most of the species are found in the inflorescences or between fruits. The skin of severely infested fruit may crack, allowing secondary invasion of pathogens. In Brazil, injury by *T. lineatus* is regularly observed on 30-day old fruits, or fruits larger than 32 mm in diameter.

Control Measures

Cultural control methods, such as clean cultivation and removal of trash, promote the exposure of pupae to desiccation, but do not provide effective control. In Brazil, use of chemical control as soon as the flowers are formed, elimination of flowers after the fruits are formed, removal of alternate host plants, and covering banana bunches with a bag impregnated with insecticides have been recommended. There are no known useful natural enemies of banana thrips. Reportedly there is a lack of effective predators for *C. signipennis* in north Queensland, Australia, although a number of generalist predatory bugs, coccinellids and chrysopids feed on flower thrips and can reduce their numbers.

Chemical control methods consist of enclosing the bunch inside an insecticide-treated bag. This practice, once widespread, is still recommended in South America. A single pesticide injection into the emerging inflorescence, a treatment specifically aimed at the banana scab moth, is also efficacious against *T. hawaiiensis* and helps protect from early *C. signipennis* infestation. Attaching a piece of chlorpyrifos impregnated ribbon to the upper bunch stalk also provides extended protection against *C. signipennis*. Untreated polythene bunch covers significantly reduced damage compared to uncovered fruit, while bunch covers impregnated with 1% chlorpyrifos provided almost total protection.

The Banana Aphid, *Pentalonia nigronervosa* (Hemiptera: Aphididae)

The banana aphid, *Pentalonia nigronervosa* Coquerel, (Hemiptera: Aphididae) is present worldwide where banana (*Musa* spp.) is grown. The aphid is a serious problem on banana because it is a vector of Banana Bunchy Top Virus (BBTV), the most damaging virus disease of bananas. The preferred host of this aphid is banana but also may infest many tropical and subtropical food and ornamental plants, including *Alpinia purpurata* (floral red and pink ginger), *Xanthosoma* ("ape or elephant ear), cardamom, *Heliconia*, tomatoes, taro, *Calla*, *Costus*, kahili ginger, torch ginger, and *Zingiber*.

The banana aphid is present just about everywhere banana is grown. It has been reported throughout tropical Africa, Atlantic Islands, Australia, California, Florida and Hawaii (USA), Central America, Cook Islands, Egypt, Fiji, Kiribati, India, Indonesia, Malaysia, Madagascar, Marshall Islands, Mauritius, Mexico, Micronesia, the Middle East, Mozambique, New South Wales, Papua New Guinea, the Philippines, Réunion, Samoa, northern South America, Taiwan, Tokelau, Tonga, Tuvalu, Vanuatu, Wallis Island, and much of the West Indies.

Biology

Reproduction in the banana aphid is entirely parthenogenetic (without mating). Females give birth to live female young. Males are not known for this species. The life cycle (nymph to adult) is completed in 9–16 days. The adult life span ranges from 8 to 26 days; there could be as many as 30 generations produced per year in Hawaii.

There is no egg stage. Young are born live. Like most other aphid species, the banana aphid has four nymphal stages. Newborn nymphs are oval at first and become slightly elongated. They are reddish brown, with four segmented antennae, and measure 0.1 mm in length. The second stage nymphs are similar in appearance and measure approximately 0.7 mm long. The third nymphal stage individuals are light brown, measuring about 0.9 mm in length; the compound eyes are more noticeable beginning with this stage, and the nymphs have five-segmented antennae. The fourth stage nymphs have six-segmented antennae, are light brown in color, and are 1 mm long. The first, second, third, and fourth nymphal stages last 2–4, 3–4, 2–4, and 2–4 days, respectively.

Adult banana aphids are small to medium sized aphids (1–2 mm), shiny, reddish to dark brown or almost black. They have six-segmented antennae that are as long as the body. Alates have prominent, dark (brown or black) wing veins. Adults start producing young one day after reaching maturity. They can give birth to four aphids per day with an average production of 14 offspring per female.

Colonies of the banana aphid are commonly found in the upper leaf sheaths and lower flower bracts of the ginger stem. The entire inflorescence may be infested. Small colonies occasionally occur on the leaf blade. Ants are associated with the banana aphid. The ants feed on the honeydew secreted by the aphid and, in turn, establish new aphid colonies and ward off natural enemies. Winged adults often develop after 7–10 generations of wingless individuals. Dispersing winged adults establish new colonies on other new host plants. Although they are not strong fliers, they may be carried considerable distances by light winds. Flight activity peaks between 9:00–11:00 A.M. and 5:00 P.M. to dusk.

Pest Status

The banana aphid is a phloem feeder that uses its long stylets to pierce plant tissues to suck the sap directly from the vessels. This can cause plants to become deformed; the leaves become curled and shriveled, and in some cases galls are formed on the leaves. Young plants may be killed or their growth checked if there is sufficient feeding by the banana aphid. However, direct damage by this aphid is generally negligible.

The insects do far more harm as vectors of numerous viruses, including bunchy top. The aphid picks up the virus while feeding on a sick plant, then spreads it to healthy banana plants in subsequent feedings. Both wingless (apterous) and winged (alate) aphids are able to transmit viruses. Transmission is usually in a non-persistent manner where the virus is taken up into the aphids' mouthparts while feeding on an infected plant and transferred to a healthy plant during subsequent feedings. In non-persistent transmission, the virus reproduces in the plant, and aphids simply aid in transporting the virus. With these types of virus-vector associations, the aphid acquires the virus and is only able to transmit the virus temporarily. Once all the infective charge is reduced by feeding or the passing of time, the aphid is unable to transmit the virus until it feeds on infected tissue again.

Symptoms of banana bunchy top disease include bunched, yellow leaves at the top of the plant, dark green streaks on the leaves and midribs, progressively smaller leaves, leaf curling, and small, distorted fruits. Since the aphid harbors the virus only temporarily, it needs a regular diet of infected plant tissue to remain infective.

Control Measures

Farmers typically manage banana bunchy top disease by destroying infected plants, which serve as a reservoir for the virus, and controlling aphids with insecticides. A wasp that is a known parasitoid of the aphids and ladybird beetles that prey on them was introduced in Hawaii as biological control agents. However, none will control banana aphid adequately enough to prevent the transmission of BBTV.

Chemical Control

Chlorpyrifos and acephate foliar sprays have been effective in reducing aphid populations and the attending ants. Immersing flowers and foliage in hot water at 49°C for 10 min kills banana aphids. This treatment is safe for many commodities, but preconditioning may be required.

Biological Control

Introductions of the braconid *Lysiphlebius testaceipes* were made in 1923, 1953, and 1965 by the Hawaii Department of Agriculture to combat aphids. The sources of the introduced wasps include Japan, Cuba, California, and Mexico. This parasitoid is established on all populated Hawaiian Islands and is a known parasitoid of the banana aphid.

Biological control experts from the Hawaii Department of Agriculture have introduced ladybird beetles to the islands to control insects. *Coccinella 7-punctata* var. *brucki* was brought in from Okinawa in 1958 and is established on the major islands, and is listed as a banana aphid predator. Other predators that have been successfully introduced to combat aphids are *Coelophora inaequalis*, *C. pupillata*, *Hippodamia convergens*, *Scymnodes lividigaster*, *Diomus notescens* (Coleoptera: Coccinelidae), and *Nesomicromus navigatorum* (Neuroptera: Hemerobiidae). The larvae, as well as the adults, of ladybird beetles and lacewings are very active aphid feeders, and have been found, along with syrphid fly larvae, in floral red ginger in Hawaii.

An entomopathogenic fungus, *Acremonium* sp., was also observed on banana aphids. The fungus observed to reduce reproduction, development and population of banana aphid, *Pentalonia nigronervosa*, a vector of bunchy top virus diseases of banana.

The banana weevil is the most important insect pest of banana and plantain. Its host range is restricted to wild and cultivated clones of *Musa* (banana, plantain, abaca) and *Ensete*. The insect originated in Southeast Asia and has spread to all important banana and plantain growing areas. It is not normally a pest in its area of origin.

Banana weevil larvae bore in the corm, damaging the root and vascular system, reducing nutrient and water uptake, and weakening the stability of the plant. Attack in newly planted banana stands can lead to crop failure. In established fields, weevil damage can result in plant loss (death of suckers, toppling, snapping), reduced bunch weights, mat disappearance (following failure to produce suckers), and shortened stand life. Damage and yield losses increase over time. Yield losses may exceed 50% in ratoon crops. Stand life can be reduced from more than 30 years to less than five.

Banana weevil pest status is affected by clone selection, ecological conditions, and management system. Highland bananas (AAA-East Africa) and plantains (AAB) are most susceptible. Other clonal groups, including export dessert bananas (e.g., Cavendish, AAA), tend to be moderately to highly resistant. *Ensete* is susceptible, but usually grown above the pest's upper elevation threshold and therefore escapes attack.

The Host Crop

Banana is an herbaceous perennial that is propagated through lateral buds giving rise to new plants (suckers). The plant consists of an underground corm and a pseudostem composed of overlapping leaf sheaths. The true stem emerges from the corm, grows through the pseudostem, and bears the inflorescence. The plant dies after the bunch matures. A group of plants sharing a common corm comprise a mat. Suckers may be detached from the mat and planted elsewhere.

Edible bananas are ultimately derived from two wild progenitors, *Musa acuminata* and *M. balbisiana*. Banana clones (or cultivars) are assigned to genome groups (e.g., AB, AAA, AAB, ABB, AAAA) based on ploidy and the relative genetic contribution of *M. acuminata* and *M. balbisiana*. Cooking, roasting, dessert and brewing types are grown. Production systems range from kitchen gardens and small, low input stands to large-scale export plantations.

Biology and Life Cycle

Adult Stage

Adults are uniform black or dark brown and average 12.5–13 mm in length. The sex ratio is 1:1. Males can be distinguished from females on the basis of small pits on the rostrum extending beyond the point of insertion of the antennae and by greater curvature of the last abdominal sternite. Males are on average 20% smaller than females in size and weight.

The banana weevil displays a classical "K" selected life cycle with long life span and low fecundity. Adults may live 4 years though most live less than 1 year. They are free living but closely associated with banana mats and cut residues. They are usually hidden during daylight hours and most often observed at traps. The adults feed on rotting banana tissues and can survive months without food. They require moist environments and die within days if maintained on dry substrates. Banana weevils are attracted to their hosts by volatiles, especially those released from damaged corms. Males produce an aggregation pheromone attractive to both sexes.

Banana weevils are negatively phototrophic and most active between 2100 and 0400 h Temperature thresholds for activity are 15–18°C. Flight is uncommon. Dispersal by crawling is limited; fewer than half move 50 m in a year. The banana weevil's narrow host range and limited dispersal capability preclude immigration of adults into isolated stands. Dissemination is primarily through movement of infested planting material (suckers).

Ovipositing weevils prefer flowered plants and crop residues but accept all plant stages. Females are attracted to freshly cut corms, making suckers detached from banana mats especially vulnerable; a single larva can kill a young plant if it damages the growing point. Oviposition rates are usually 0.5–4 eggs per week, although averages of 14 eggs per week have been observed. Low fecundity contributes to the slow build-up of weevil populations over time.

Immature Stages

Eggs (0.5 × 2 mm) are cylindrical and laid in the corm and base of the leaf sheaths. Eggs are deposited singly in holes (1–2 mm deep) excavated by the female with her rostrum. Eclosion rates are 80–100%. Larvae emerging in leaf sheaths usually move to the corm, although feeding in the true stem and, rarely, the pseudostem also occurs. In the corm, the larvae prefer cortical tissue to the central cylinder. The larvae pass through 5–8 instars. Pupation is in a bare chamber near the plant surface.

In West Africa, developmental thresholds and thermal requirements were 12°C and 89 degree-days for eggs, 8.8°C and 538 degree-days for larvae, and 10.1°C and 121 degree-days for pupae. Under ambient tropical conditions, stage duration is 6–8 days for eggs, 21–55 days for larvae, and 6–8 days for pupae. In addition to temperature, larval stage duration is affected by clone, plant stage, size of corm, and weevil density. The data suggest extended periods of low night-time temperatures (e.g., at higher elevations) are bottlenecks for immature development and/or adult survival. The banana weevil is rarely important at elevations above 1,600 m.

Semiochemicals

Both males and females are attracted to hosts by kairomones containing mono- and sesquiterpenes. Attraction to corm material is greater than to pseudostems. Field observations suggest that banana weevils are attracted to both susceptible and resistant clones and will accept any clone for oviposition. A male aggregation pheromone (sordidin) is attractive to both sexes. This has been synthesized and is commercially available as lures. The attraction range of semiochemicals is unlikely to exceed 10 m and may be much less.

Monitoring

Accurate assessment of banana weevil population levels and damage are necessary for understanding pest status, screening germplasm and evaluating the impact of intervention strategies. The insect's biology makes assessment and control difficult.

Damage Assessment

The reclusive behavior of the adults and the difficulties in measuring larval damage in the interior of the corm has resulted in a multitude of scoring and evaluation systems. These include monitoring adult numbers through trapping; measuring damage to the corm periphery; and measuring internal corm damage through cross and longitudinal sections. Some of these methods are subjective, making results hard to interpret or compare. Moreover, sites of banana weevil attack may differ among clones. In Uganda, for example, the dessert banana Ndiizi (AAB) had similar levels of damage to the corm surface as that of highland cooking banana (AAA-EA), but only 16% as much internal damage within the corm.

Damage to the corm interior is better related to yield loss than damage to the corm periphery, while damage to the central cylinder is more important than damage to the corm cortex. Measuring larval damage in cross sections at the collar (corm-pseudostem junction) and 10 cm below the collar in recently harvested plants is recommended. A common method is to visually estimate percentage cross section surface area consumed by weevil larvae in the central cylinder and cortex, respectively.

Yield losses tend to increase over time. In one trial, yield losses increased from 9% in the plant crop to 48% in the third ratoon. In Ghana, weevil damage in plantain stands was often low in spite of susceptible germplasm, favorable temperatures and low management levels. Shifting agricultural systems predominated with most plantain abandoned after two crop cycles. As such, short plantation life precluded adequate time for weevil populations to build up to damaging levels. Weevil problems became evident in the few plantations maintained beyond two cycles.

Population Densities

Adult populations may be monitored using traps made from corm or pseudostem residues. However, interpretation of trap data is difficult as a multitude of factors (e.g., materials, size, number, location, weather) influence trap catches. Therefore mark and recapture studies (using pseudostem traps) are recommended for estimating population densities. Weevils are marked by scratching the elytra. In Uganda, densities among proximal farms ranged from 850 adults/ha (1.5 per mat) to 149,000 adults/ha (240/mat), while in Cameroon density estimates for subplots ranged from 10 to 337 adults/mat.

This within-site variability suggests that management plays an important role in regulating weevil populations. Weevil pressure is widely believed to be associated with clonal susceptibility, management levels, bad drainage, acid or low fertility soils, weedy fields, inadequate sanitation, extended droughts and nematode infestations. However, on-farm and on-station studies have failed to find strong relationships between weevil damage and management factors or plant stress. Moreover, only a modest relationship ($r = 0.22$) existed between weevil adult density and damage across 50 farms within one watershed. Population estimates may be a poor indicator of economic status if a high population reflects build-up on residues rather than maturing plants. Also, adult populations may be as much as 2.5 times higher in mulched than in unmulched plots because of more favorable soil moisture conditions.

Pest Status

The pest status of banana weevil was once controversial as many clones are resistant and attack in some (e.g., Cavendish, AAA) is often realized on crop residues where damage has no effect on yield. Meaningful yield losses have now been demonstrated in highland banana (AAA-EA) and plantain (AAB) systems. The banana weevil has also been shown to be an important component of yield decline leading to the disappearance of highland bananas in its traditional growing areas in East Africa.

Crop establishment may be impeded if planting is in an already infested field or if planting material carries eggs and larvae. Plant loss of up to 40% has been recorded in newly planted highland banana and plantain stands. In fields with minor initial infestations of banana weevils, population build-up is slow and problems may not appear for several years. In a highland banana trial in Uganda, damage to the central cylinder increased from 4% in the plant crop to 17% in the third ratoon. Similarly, in surveys of plantain systems in Ghana, damage increased from 2% in the plant crop to 7% in the second ratoon. Damage will have a greater effect on yield if the same mat has sustained heavy attack in preceding crop cycles. Thus, single cycle yield loss trials may underestimate weevil importance. For example, yield losses in several highland banana trials went from negligible in the plant crop to 48–60% within a few years.

Yield loss is reflected in plant loss, reduced bunch weights and dying out of mats. Plant loss attributable to banana weevil attack in two highland banana trials increased from 4% in the plant crop to 29% in the third ratoon, while heavily damaged plants suffered reductions in bunch weights of 20–45%. In another trial, 35% of banana mats died out in 5 years in plots infested with weevils, compared to 2% mat loss in controls. This suggests that the weevil can severely reduce stand life. Farmers in central Uganda reported that banana weevil had contributed to reductions in highland banana stand life from >30 years to 4 years, while in Colombia the weevil reportedly reduced plantain stand life to two to three crop cycles.

Integrated Pest Management

Current research results suggest that no single control strategy will provide complete control for banana weevil. Therefore, a broad integrated pest management (IPM) approach, combining a range of methods, might offer the best chance for success in controlling this pest. The components of such a program include cultural control (habitat management), biological control, host plant resistance, botanicals and (in some cases) chemical control.

Cultural Control (Habitat Management)

Cultural controls for banana weevil include clean planting material, selected cropping systems, improved agronomic practices to promote plant vigor, crop sanitation (destruction of crop residues) and trapping with crop residues.

Clean planting material: Infested suckers provide the principal entry point of banana weevils into newly planted fields. Thus, clean planting material eliminates the most important source of infestation in new plantations. The insect's low fecundity and slow population growth suggest that a reduction in initial infestation level can retard pest build-up and damage for at least several cycles. The use of clean planting has been widely recognized and promoted.

Recommended methods include the use of tissue culture plantlets, paring and selection of weevil-free suckers, pesticides, and entomopathogens. Tissue culture plants are insect-free at the time of planting. Once established in the field, it is unclear whether tissue culture plants are more or less susceptible to banana weevils than plants grown from suckers. Paring (removal of the outer corm surface) eliminates most eggs and first instar larvae, and exposes weevil galleries, allowing farmers to reject heavily damaged suckers. Paring cannot remove larvae that have penetrated below the corm surface. Suckers may be dipped in pesticide solutions or pesticides may be applied to the planting hole. Alternatively, *Beavueria bassiana* formulations can be applied to planting holes to reduce weevil attack of suckers. None of these methods assure elimination of weevils. Adults may already be in the field from a previous planting or may invade from nearby plantations. As a result, the benefits of clean planting material may be limited to a few crop cycles.

Selected cropping systems: Mixed cropping systems often result in lower insect pressure by reducing immigration rates, interfering with host plant location and increasing emigration rates. However, banana weevils are sedentary insects that live in perennial systems with an abundant supply of hosts. Coffee intercrops and residues (e.g., husks) may repel banana weevils but this requires further study. Otherwise there is little evidence that intercrops or insect-repellent green manures (*Canavalia*, *Mucuna*, *Tephrosia*) have meaningful effects on banana weevil populations.

Crop Sanitation

Banana residues serve as adult refuges and oviposition sites and contribute to population growth. In Uganda, 25–32% of adult weevils were associated with prostrate (cut or fallen) residues, while another 10–12% was found in standing stumps. In Australia, 60% of adults emerged from residues. For some clones, banana weevil damage is much higher on residues than on growing banana plants. It is widely believed that destruction of crop residues (splitting of harvested pseudostems and/or removal of corms) lowers overall weevil populations and reduces damage on standing plants in susceptible clones. In Ugandan field surveys, sanitation level had more impact on weevil pest status than any other management practice. In on-farm trials, increasing sanitation level from low to high for 3 years reduced adult population density from 52,000 to 13,000 ha^{-1}, lowered corm damage by 41% and increased yield by 70%.

Trapping

Traps exploit banana weevil attraction to crop residues. The most common are split pseudostem traps (30–60 cm lengths split longitudinally and placed flush on the soil surface at the base of banana mats) and disk-on-stump traps (a piece of cut corm placed on top of a banana stump). Inclusion of corm material in a trap increases its attractivity to weevils. Thus disk-on-stump traps tend to have higher weevil catches than pseudostem traps. However, pseudostem trapping is more often recommended for systematic trapping studies because a single harvested plant can only support one disk-on-stump trap (fixed in space), while the same plant can provide material for many pseudostem traps (placed where the farmer deems most useful). The effect of trapping on weevil populations will, in part, reflect trap density and trapping frequency. Intensive trapping in established fields results in a gradual decline in weevil numbers with a lag time required before effects are manifested in reduced damage. In a 1-year study in farmer's fields in Uganda, weevil numbers declined by 61% in farms with intensive trapping (1 trap/mat/month), 53% with moderate trapping (0.3–0.6 traps/mat/month) and 38% in farms without trapping. Trapping success was affected by management level and weevil immigration from neighboring farms. Although farmers were convinced that trapping was beneficial, adoption was low due to resource and labor requirements.

Biological Control

Biological control efforts against banana weevil have included the use of exotic natural enemies (classical biological control), endemic natural enemies and microbial control (e.g., entomopathogens, entomophagous nematodes). Microbial control agents may require repeated applications as biopesticides and entail application costs on the part of the farmer.

Classical Biological Control

Introduced pests, unimportant in their areas of origin, often reach damaging levels when released from the control of co-evolved natural enemies. The banana weevil appears to fit this pattern. Searches in southeast Asia identified histerids (*Plaesius javanus* Erichson and *Hololepta* spp.), staphylinids (*Belonuchius ferrugatus* Erichson and *Leptochirus unicolor* Lepeletier), a hydrophilid (*Dactylosternum hydrophiloides* MacLeay), a cucujid (*Canthartus* sp.), and a leptid (rhagionid) fly (*Chrysophila ferruginosa* (Wied.)) as predators of banana weevil. Of these, *P. javanus* appeared most important. Between 1913 and 1959, 45 attempts were made to introduce eight natural enemies from Asia to other banana growing regions in the world. *P. javanus*, for example, was released in Australia, Oceania, Latin America and Africa. In most cases, the predators did not establish and in no case did they provide control. Recent searches for egg and larval parasitoids in Indonesia came up empty handed. Classical biological control of banana weevil, therefore, remains an elusive objective.

Indigenous Natural Enemies

Reported arthropod predators of banana weevil immatures include nabids, cydnids, capsids, reduviids, mirids, thrips, rhagionids, sarcophagids, histerids, carabids, hydrophilids, staphylinids, tenebrionids, labiids, carcinophorids, and formicids. Ants appear to be the most promising while other predators seem of little importance. In Cuba, the myrmecine ants *Pheidole megacephala* and *Tetramorium guineense* (Mayr) reduced banana weevil populations and damage by 54–69% following artificial establishment of ant colonies in plantain stands. In Uganda, *Pheidole* sp. and *Odontomachus troglodytes* were most effective in reducing weevil egg and larval populations in pot experiments. Both species readily entered and removed larvae from galleries in crop residues.

Microbial Control

Microbial agents tested against the banana weevil include entomopathogenic fungi (e.g., *Beauveria bassiana* and *Metarhizium anisopliae*) and entomopathogenic nematodes (e.g., *Steinernema* spp. and *Heterorhabditis* spp.). Entomopathogenic fungi and nematodes are most often used to kill adult weevils. *Beauveria bassiana* has been established as an endophyte, although its potential against banana weevil immatures is not yet clear.

Although a number of strains of entomopathogenic fungi and entomopathogenic nematodes have shown promise in the laboratory and in preliminary field studies, efficient and economically viable mass production and delivery systems still need to be developed, while the performance of microbial control agents against banana weevil under different agro-ecological conditions is not well understood. Only in a few sites have entomopathogens been reported to establish following applications in banana fields. Without adequate establishment, entomopathogens will require repeated applications as a biopesticide. This will entail continued production, distribution and storage costs that will be passed on to the farmer.

The conidia of *Beauveria* and *Metarhizium* enter the insect through its spiracles or digestive system or by producing extracellular proteolytic, chitinolytic and lipolytic enzymes which facilitate penetration through the insect's cuticle. The fungi can kill the insect through direct attack on the insect's nutrients or through toxic metabolites. Dead insects kept in moist environment quickly developed surface growth of mycelia. *Beauveria bassiana* can invade the haemocoel where it produces a toxin, beauvericin, that reduces competition with bacteria and weakens the immune system. Strain virulence is often related to toxin production.

Natural rates of infestation are normally low (i.e., <5%). Nevertheless, numerous strains of *B. bassiana* and *M. anisopliae* have been demonstrated to kill >90% of banana weevils when applied topically in the laboratory or in pot trials. In Ghana, *B. bassiana* applications to planting holes reduced damage to suckers, while in Brazil, Colombia, Costa Rica, Cuba and Uganda, applications *B. bassiana* at the base of established mats in banana or plantain stands reduced weevil populations and/or increased yields. In Uganda, transmission from infected to uninfected weevils under field conditions was 13%. While these studies demonstrate field potential, cost-effective production and delivery systems still need to be developed. However, field establishment of *B. bassiana* tends to be low, so repeated applications are usually necessary.

Entomopathogenic nematodes in the genera *Steinernema* and *Heterorhabditis* have been tested against banana weevil, most notably in Australia. Infective juvenile nematodes enter through natural orifices (*Steinernema*) or interskeletal membrane (*Heterorhabditis*). After entering the host, the nematodes penetrate mechanically into the haemocoel and release *Xenorhabdus* bacteria which cause septicemia and death within 1–2 days. In Brazil, entomopathogenic nematodes were widespread in plantain stands, but naturally occurring mortality of banana weevils was low and, as with entomopathogenic fungi, viable delivery systems are an important consideration. The cryptic habitat of weevil larvae within living plants makes delivery against these stages difficult; therefore, applications of entomopathogenic nematodes should target adult weevils.

The most effective entomopathogenic nematode delivery system, developed in Australia, capitalizes on the weevil's attraction to cut corms and damaged plants. This system employs conical shaped cuts in residual corms, i.e., a cone is cut and removed, and then loosely replaced into the corm. These cuts attracted adult weevils and provided thigmotactic stimuli that encouraged them to remain at the infection sites. The holes also buffered the delivery site against temperature extremes and provided excellent conditions (high humidity, moderate temperatures, protection against ultraviolet light) for nematode persistence. The nematodes were released at a density of 250,000 per hole in a formulation including a polyacrylic gel (to reduce water build-up and incidence of nematode drowning) with an adjuvant of 1% paraffin oil (to encourage the weevils to raise their elytra, exposing the first spiracle for nematode entry). However, controls based on entomopathogenic nematodes are more costly than pesticides in Australian commercial banana systems.

Host Plant Resistance

Highland bananas (AAA-EA) and plantains (AAB) are most susceptible to banana weevil attack. Some variability exists among clones within these genome groups. Among highland bananas, for example, Atwalira and Kisansa displayed weevil damage scores two to three times higher than those for Mbwazirume and Nakyetengu, while the degree of penetration into the central cylinder was greatest for Nakitembe, Namwezi and Musakala.

In screening trials, *Ensete* appeared to be highly susceptible. However, in Ethiopia where the crop is most widely grown, *Ensete* escapes attack because most production is above the weevil's upper elevational threshold. Export Cavendish dessert bananas (AAA) are generally considered resistant, although serious banana weevil problems may occur in some areas (e.g., southeastern coast of South Africa). A wide range of other banana dessert and brewing types (AB, AAA, AAB, ABB) are moderately to highly resistant to banana weevil.

Antixenosis (nonpreference) is of little importance. Laboratory and field studies suggest that banana weevils (i) appear to be attracted equally to susceptible and resistant clones, and (ii) will accept all clones for oviposition. Clonal attraction and acceptance (i.e., number of eggs) were not related to damage. In one field trial, oviposition was similar on resistant Pisang awak (ABB) and susceptible five highland bananas (AAA-EA), while subsequent damage was 5–25 times higher on the highland clones. Thus, antibiosis appears to be the most important in conferring host plant resistance to banana weevil.

Antibiotic factors are those which negatively influence larval performance (i.e., poorer survivorship, slower development rates, reduced fitness). These factors may be physical (e.g., sticky sap and latex, corm hardness), antifeedants, toxic secondary plant substances and nutritional deficiencies. To test these factors, banana weevil larvae are commonly reared on potted plants or excised corm material. One difficulty in this system is that resistant factors may quickly break down after harvest or *ex situ*. For example, Pisang awak (ABB) is highly resistant to banana weevil in Indonesia; larvae freely feed without problems in its residues. Similarly, Yangambi- Km5 is highly resistant to banana weevil, often showing no damage in screening trials, yet larvae may be successfully reared on excised corm material taken from this clone.

Nevertheless, screenhouse and laboratory studies have shown that immature banana weevils may have higher mortality, extended developmental periods and lower pupal weights on resistant clones. Corm extracts from resistant Pisang awak placed on corm material of susceptible highland banana clones severely inhibited larval feeding while extracts from other clones did not. A bioassay-guided separation process of the Pisang awak extract was then undertaken using chromatographic techniques. Two of the 16 fractions obtained were found to be very active against weevil larvae. However, the compounds responsible for activity against banana weevil have not been identified.

To date, there have been no attempts to breed bananas or plantains for resistance to banana weevil. Conventional breeding of banana is a difficult and complicated procedure as the most widely used clones are triploids and sterile. This entails crossing wild diploid and highly fertile males to female triploid clones followed by extensive hybrid selection. Nevertheless, there does appear to be useful sources of resistance within the available germplasm. The wild diploid Calcutta-4 (AA), Yangambi-Km5 (AAA) and the hybrid FHIA-03, for example, show high levels of resistance and might be exploited in breeding programs. Corm hardness has been shown to be a key resistance mechanism and screening for this trait may assist in weevil improvement. Secondary metabolites found in resistant clones also appear to be important.

Transgenic approaches (i.e., biotechnology) are also being used to develop resistant clones by transforming banana through insertion of foreign genes, in particular cysteine proteinase inhibitors (cystatins) from rice and papaya and toxins derived from the bacterium *Bacillus thuringensis* (Bt). Cysteine proteinases are mid-gut enzymes that many beetles, including banana weevil larvae, use in the digestion of dietary proteins. Cysteine proteinase inhibitors are defensive compounds produced by some plants in response to insect attack or wounding. These inhibitors impede digestion resulting in protein deficiency and stunted development. Bt has been used as a biopesticide in the control of several insect pests. More recently, Bt toxin genes have been inserted into crop plants to improve resistance.

Successful incorporation of cysteine proteinase inhibitors from rice and papaya into banana tissue reduced banana weevil larval body weights by 60% in 10 d. Current efforts are to insert the genes into banana plants. In preliminary bioassays, incorporation of the Cry3A Bt toxin into artificial diets resulted in 30% mortality of banana weevil larvae. It is believed that high rates of mortality can ultimately be achieved by pyramiding cysteine proteinase inhibitors and Bt toxins. Research in this area is on-going.

Botanical Control

In Kenya, varying formulations of neem (*Azadirachta indica*) seed derivatives (neem seed powder, neem kernel powder, neem cake and neem oil) applied to banana material greatly (i) reduced adult settling on corm pieces, (ii) reduced oviposition rates, (iii) reduced eclosion success, (iv) increased larval penetration time, (v) extended larval development, (vi) increased larval mortality, (vii) reduced larval weights, (viii) impeded population build-up in field trials, and (ix) reduced damage in pot and field experiments. Neem kernel powder and neem oil appeared toxic to the banana plants and may have interfered with nutrient and water uptake, whereas neem seed powder and neem cake displayed phytotoxic effects only at very high application rates. Neem applications in farmers' fields in Tanzania also resulted in reduced damage. In spite of these encouraging results, neem has not been widely adapted by farmers due to availability and costs.

Chemical Control

Chemical pesticides for control of banana weevil may be applied to protect planting material (through dipping of suckers or applications in planting holes), periodically applied at the base of the mat after crop establishment, and/or applied to pseudostem traps to increase trap catches. There have been numerous studies on the relative efficacy of different insecticides under different formulations and application rates, persistence and the appearance of insecticide resistance in banana weevils. At least 45 pesticides have been used at one time or another against banana weevil. Insecticide resistance in banana weevil has been documented in Australia, Latin America and Africa for a range of chemicals including cyclodienes, organophosphates, and carbamates. Cross-resistance has also been demonstrated. Nevertheless, chemicals remain an important part of banana weevil control although costs often make them prohibitive for subsistence farmers. Pesticides remain the fastest action method that can be used to bring a weevil outbreak under control.

Band

A transverse line, usually wide, crossing the body. This term often is confused with "stripe," a term used to designate a longitudinal line running the length of the body. The term band is also used to describe an aggregation of insects, usually immature grasshoppers or caterpillars, dispersing in the same direction.

Band Application

An application in which an insecticide (or other chemical) is applied in strips, usually to the planting bed or seed row.

Barb

Any of a number of sharp projections armed with teeth or hooks. Insects sometimes have spines or setae equipped with projections pointed backward (to the base, or away from the point) that cause them to remain imbedded once contact with them is made. Presumably they function in defense, especially against vertebrate predators. Structures bearing such projections are said to be barbed, and the occurrence of numerous setae is sometimes described as barbate. A small barb is called a barbule.

Barber, Herbert Spencer

Herbert Barber was born in South Dakota on April 12, 1882. His father, an engineer, encouraged his son's interest in natural history. At the age of 16 he was given employment as an insect preparator at the U.S. National Museum. He worked at such tasks as arranging the Hubbard and Schwarz collection of Coleoptera, but including a collecting trip with Schwarz to Arizona and New Mexico. Although he was employed continuously at the museum until retirement, his pay was, after some years, and until his retirement, provided by the U.S. Department of Agriculture. In time, by association with entomologists and through experience, he began to publish results of his own studies. His publications eventually amounted to some 90 papers. One of the most intriguing was on his discovery of the strange life history of *Micromalthus* (Coleoptera: Micromalthidae) in which there are several forms of larvae, and that some larvae may produce eggs and larvae. He died in Washington, DC, on June 1, 1950.

Bark Beetles in the Genus *Dendroctonus*

BARBARA J. BENTZ
U.S. Department of Agriculture Forest Service, Logan, UT, USA

The genus *Dendroctonus* (Coleoptera: Curculionidae, Scolytinae), originally described by Erichson in 1836, currently includes 19 species that are widely distributed. Seventeen species occur between Arctic North America and northwestern Nicaragua, and an additional two species are in northern Europe and Asia. *Dendroctonus* species attack and infest conifer hosts (Pinaceae) in the genera *Larix*, *Picea*, *Pinus*, and *Pseudotsuga*. Species within the genus can be identified by the host species they attack, egg gallery patterns, population behavior, and morphological distinctions. The smallest species is *D. frontalis* (male length 2.0–3.2 mm) and the largest is *D. valens* (male length 5.3–8.3 mm). Members of the *Dendroctonus genus*, which means "tree killers," are noted as the most economically and ecologically significant species affecting forest ecosystems in western North America. Tree mortality resulting from *Dendroctonus* outbreaks can adversely affect timber management, forest planning, and recreational opportunities. In contrast, disturbance events caused by native bark beetle species are important drivers of forest succession, foster heterogeneity and biodiversity, promote biomass recycling, and play a critical role in the fire ecology and overall health of many ecosystems.

Dendroctonus beetles are monogamous, and spend the majority of their lifecycle in a cryptic habitat beneath the bark of host trees where larvae feed within the inner bark or phloem. Relative to the length of their life cycle, only a short time is spent as an adult moving from tree to tree. The majority of the species in this genus is capable of killing the host tree in one generation. In fact, death of the host is often a requirement for successful brood production. Although most of the species are capable of attacking and killing standing, vigorous trees, recently fallen trees are favored by some species. The female is the colonizing sex in the majority of *Dendroctonus* species. After attack of a new host, mating typically occurs in a nuptial chamber beneath the bark and an egg gallery is initiated. Adults of a few species, however, mate before emerging from the brood host. Eggs are laid either singly along the sides of the gallery, or in clumps. Egg galleries may be either vertical or sinuous, and larvae mine and feed horizontally in the phloem, either singly or en mass, depending on the species. Pupation takes place in individual niches within the phloem or in the outer bark of the host tree. Upon adult emergence, which is usually temperature dependent, beetle dispersal to a new host occurs and the process begins again.

Aggregation, which facilitates host selection and mating, is an important life history strategy of most, although not all, *Dendroctonus* species. Aggregation is often a response to chemicals produced by the host tree, adults from the same or a different species attacking the host tree, microbes, or a combination of these factors. Aggregation on a single host tree allows for a mass attack by conspecific beetles, thereby overcoming the resin defensives of the conifer hosts. To overcome the defenses of healthy, vigorous hosts, many beetles must attack within a short time (1–3 days). Conversely, trees of poor health may be overcome by fewer beetles (e.g., endemic population levels). Because a single tree is a limited resource, some *Dendroctonus* species have evolved a response to a series of chemicals that interrupt aggregation. These chemicals act to space beetle attacks along a single tree and signal incoming beetles to begin attack on another, nearby tree. Synthetic forms of both attractive and interruptive aggregation chemicals have been developed for many *Dendroctonus* species. The attractive aggregant chemical(s) are commonly used, often with traps, for monitoring and control of many economically important species in the genus. The complexity of the signal for interruption of aggregation has made it difficult to identify the chemical makeup of compounds, as well as, the specific biological action of the compounds within the population ecology of many *Dendroctonus* species. Consequently, the current use of synthetic interruptive aggregation chemicals is limited.

As with most poikilothermic organisms, temperature is a strong driving force of *Dendroctonus* population dynamics and an important controller of seasonality. Diapause, which is often temperature related, is typically considered the universal adaptation of insects for maintaining seasonality. However, with the exception of an adult reproductive diapause in *D. rufipennis* and *D. pseudotsugae*, and a prepupal diapause in *D. rufipennis*, this physiological timing mechanism appears to be absent in the *Dendroctonus* genus. Instead, *Dendroctonus* seasonality appears to be under direct temperature control. Life cycle duration in the genus is variable depending on the species, latitude, elevation, and microclimate of the population. Species in the south can have as many as seven generations per year, whereas in the north, or at high elevation some species require up to 3 years to complete a single generation. Intraspecific latitudinal differences in many temperature-associated life history traits exist as well. Global climate warming will undoubtedly have significant impacts on the distribution and seasonality of the *Dendroctonus* species.

Many *Dendroctonus* species carry spores of symbiotic fungi either passively on the exoskeleton or in specialized structures of the integument called mycangia. The fungi are disseminated among host trees via adult *Dendroctonus* beetles. Although little research has been conducted on fungal associations of the majority of *Dendroctonus* species, the work that has been done shows both a benefit and a detriment to the beetle, depending on the particular fungal associate. Benefits gained include protecting the beetle brood from other antagonistic associates, aiding beetles in overcoming host tree defenses through pathogenic action of the fungi, altering the moisture composition of the phloem, and providing or concentrating nutrients essential for reproduction or development.

Native *Dendroctonus* bark beetles play significant roles in long term forest ecosystem function and structure. However, forest conditions in many parts of the *Dendroctunus* range in North America have changed from conditions that existed prior to pre-European colonization. The result is large landscapes vulnerable to *Dendroctonus* outbreaks which are often in conflict with current land use objectives. The formulation of effective management strategies for *Dendroctonus* populations requires careful consideration of all aspects of land use including timber production, the urban/wildland interface, wilderness, watershed, recreation and wildlife. Synthetic attractive and interruptive aggregation chemicals and silvicultural options are available for some species to aid in the prevention and suppression of large scale outbreaks. Any action, including no action, should be tightly tied to the management objectives for the landscape under consideration. Restoration of the landscape to reestablish ecological integrity after an outbreak is also important for maintaining long-term ecosystem health.

Bark-Lice, Book-Lice or Psocids (Psocoptera)

ARTURO BAZ
Universidad de Alcalá, MadridSpain

The insects of the order Psocoptera (=Copeognatha, Corrodentia) are commonly called psocids, although outdoor species living on tree trunks and branches have been called bark-lice, whereas indoor species, sometimes found in old books, have been called book-lice. The Psocoptera are a small order of paraneopteran insects (near 4,000 species have been described around the world) which are found in a wide range of terrestrial ecosystems throughout the world. Most psocids inhabit trees and shrubs, some others occur in ground litter, others are found on rocks and in the nests of birds and mammals. Some live on herbs and grasses, and a few in moss, whereas others are found in caves. Lastly, several species are found in domestic habitats. The Psocoptera share certain morphological features with the lice (orders Mallophaga and Siphunculata; Phthiraptera of some authors), and these taxa are grouped together in the superorder Psocodea by some authors. Fossil insects identified as psocids have been reported from as far back as the Permian period in Kansas, Russia and Australia. These, together with Jurassic material from Germany and Russia, differ in many ways from more recent forms. So, although these fossils are quite psocid-like, some doubts exist about their ordinal placement. The earliest unquestionable fossil psocids are those from Cretaceous amber. These Cretaceous forms are essentially modern and do not show any clear connections with the older fossils of doubtful assignment.

Morphology

Psocoptera are free-living exopterygote insects ranging in body length from 0.6 to 25 mm, although rarely exceeding 10 mm.

Head

The head capsule is large compared to the rest of the body, with a large bulbous postclypeus. The antennae are long and filiform with 11–50 flagellomeres. The eyes commonly are large and globose, varying from multi-faceted structures down to the complete reduction in a cavernicolous species. Three ocelli are usually present in winged forms, but absent in apterous species. The Y-shaped epicraneal suture is prominent. The mouthparts (Figs. 6–10), although retaining a chewing function, are specialized. The mandibles are asymmetrical, and each has both grinding and cutting edges. In the maxillae the cardo is not differentiated; the galea is a large, fleshy lobe, whereas the lacinia is a narrow, sclerotized rod (the pick). The lacinia is perhaps the most specialized and characteristic psocid structure. The lacinia may be used to scrape food from the substrate, but such has not been directly observed. Some authors inferred that the lacinae may be used as "picks," because psocids move laciniae vertically in a manner which suggests this may be so. Also, they appear to be used to support the head whilst feeding and may act to regulate the depth of feeding on the substrate. The maxillary palpi are 4-segmented.

Bark-Lice, Book-Lice or Psocids (Psocoptera), Figure 7 Mandibles of ***Cerobasis guestfalica.***

The labium has reduced one- or 2-segmented palpi, and the chitinous mentum is divided apically into lateral halves (paraglossae) by a small protuberance (glossa) representing the opening of the salivary glands to the exterior. The labrum is simple, with the distal margin bearing two groups of setae: an anterior group of 4–10 sensilla, and a posterior group which has some taxonomic value. The palatal lining of the labrum and the anteclypeus is the hypopharynx, which has a characteristic structure. The lingua bears a pair of ventral sclerites (lingual sclerites) which are connected to the median sitophore sclerite by ligaments; these lingual sclerites when protruding are capable of taking up water from the atmosphere (Fig. 11). The sitophore sclerite is situated on the ventral surface of the base of the cibarium. On

the dorsal surface of the cibarium wall (opposite the sitophore) is a knoblike process that is believed to move against the sclerite in the manner of a mortar and pestle and facilitate the grinding up food.

Thorax

The thorax unites to the head with a membranous and flexible neck. In a general way, the prothorax of both winged and apterous psocids is clearly separated from the other thoracic segments. Legs are slender, and hind legs are longer, which allows them to carry out small jumps. The coxae of hind legs are modified in many species by having cuticular projections of various kinds. The most usual are a small blister-like projection on the inner surface, an ovoid "rasp" bearing rows of small denticles; in some cases near the "rasp," a rounded area of similar size can be found. These structures are called "coxal organs" or "Pearman's organs" (Fig. 12) and the function is unknown, although it has been suggested that they are stridulatory. The small trochanters are articulated with the coxae but their junction with the femora is usually immovable. The femora are simple, but sometimes markedly convex on their outer surface. Tibiae may have a row of characteristic ctenidiobothria (setal sockets, having four to ten conspicuous teeth, with each bearing a simple spine) along the ventral surface. The tarsi are of either two or three segments (all the immatures possess two segments and this character remains in some adults); all except the apical segment have apical spines, and ctenidiobothria may be present on the basal or all segments. The tarsus terminates in a pair of claws; the base of each claw usually has two ventral projections: the proximal one is setiform and the distal (the pulvillus) is of various forms. Some pulvilli are greatly expanded, whereas others are slender or narrow. Expanded pulvilli can act as a

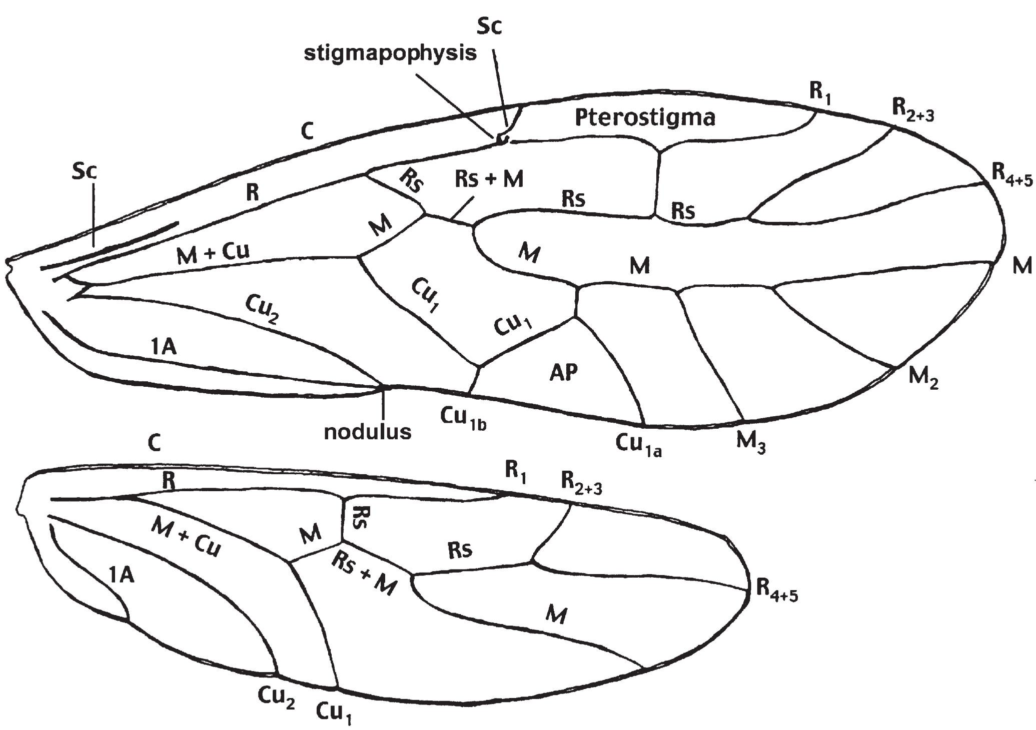
Bark-Lice, Book-Lice or Psocids (Psocoptera), Figure 12 Metathoracic leg (**a**); Pearman's organ of ***Psococerastis gibbosa*** (**b**); ctenidiobothria from a metathoracic tibia (**c**); detail of a metathoracic tarsus (**d**).

sucker, enabling the insect to walk on smooth surfaces. Most foliage-frequenting psocids have a pulvillus of this type, whereas most bark-frequenters have a narrow pulvillus. Two pairs of wings (Fig. 13) are found in many psocids, although one or both pairs may be reduced in size, showing various states of reduction (brachyptery, micropterty) and sometimes absent (aptery). Some species are dimorphic, with macropterous individuals of one sex (usually males) and apterous or micropterous individuals of opposite sex (usually females). The anterior wings are larger than the hind pair. At rest they are held rooflike over the body. The fore and hind wings are coupled during flight and at rest. Most psocids have simple venation, with few crossveins.

In the forewing, the costa (*C*) forms the wing margin. The subcosta (*Sc*) is often greatly reduced to a small vein at the base of the wing (the basal sector) and a short vein closing basally the pterostigma (the distal sector). The radius (*R*) runs more or less parallel to the costa and forms the posterior border of pterostigma. The radial sector (*Rs*) terminates in an apical fork, named the radial fork, which is composed of R_{2+3} and R_{4+5}, and contacts the median (*M*) in the middle of the wing. At this junction, the two veins (*Rs* and *M*) may meet in a point, be linked by a short crossvein or be fused for a short length. M usually has three branches (M_1, M_2, M_3). The first cubital vein (CU_1) reaches the posterior border of the wing, sometimes simply, but in many psocids it is two-branched, forming a cell known as "areola postica" (*AP*), which is bordered by CU_{1a} and CU_{1b}. The presence and shape of the "areola postica" vary considerably in different groups of psocids, and it may be joined to the median, or fused with it or completely free. The second cubital vein (CU_2) is morphologically distinct from the more anterior veins. It is simple and unbranched. Behind this is one anal vein (*1A*), which reaches the wing margin near the same point as CU_2. When the vein *1A* reaches the margin at the same point as CU_2 it forms the "nodulus." In a few groups a small second anal vein (*2A*) is



Bark-Lice, Book-Lice or Psocids (Psocoptera), Figure 13 Wings of ***Stenopsocus stigmaticus.***

present. The cells take the name of the vein immediately anterior to them. The one exception is the large "discoidal cell" bordered by *M* and *Cu1*, and present in the forewing of the family Psocidae and others forms in which *AP* is joined to *M*. In the hind wing the venation is more reduced. *Sc* is often vestigial, R_1 reduced and simple, *Rs* forked in two branches as in the forewing, *M* usually simple but sometimes having two branches, both cubital veins are simple, and one small anal vein is usually present. As in the forewing, the form of the *R-M* junction can be variable. Of particular interest is the fact that in the families Lepidopsocidae and Amphientomidae the forewings are typically covered by scales, and give the insect the appearance of a small moth. In this case, the shapes of scales are sometimes of specific value. Psocids possess two independent methods of wing coupling. At rest, some species have a protrusion at the base of the pterostigma on the underside of the forewing, formed from modified trichia and tracheolar rings of R_1; this projection (known as "stigmapophysis") engages the costal vein of the hind wing in repose (Fig. 14). Similar structures for coupling wings in repose can be found in the family Lepidopsocidae, where it is composed of a row of comb-like teeth on *Sc* or R_1. When they fly, many psocids have another mechanism for coupling wings. Underside the forewing the distal end of Cu_2 possess a hook which engages the hind costa in flight.

Abdomen

The abdomen consists of ten segments and the terminal region (telson) formed by three lobes: the epiproct which is dorsal and the paraprocts which are lateral. In many psocids the last tergite (tg 9 + 10) and the distal half of tergite eight are strongly sclerotized, forming a structure called the clunium. The epiproct is, normally, a very simple structure, of rounded, trapezoidal or triangular shape in both sexes. In some species, the male epiproct bears rows or fields of hooks or denticles. The paraprocts are variable in shape. On the dorsal basal region there is often a well-defined area (sensorial field) containing long setae each rising from a sunken rosette-like socket. These setae are called "trichobothria" and are, presumably, involved in the orientation in flight or air currents. Near the apex of the paraprocts of the Trogiomorpha is a long, thickened spine (anal spur).

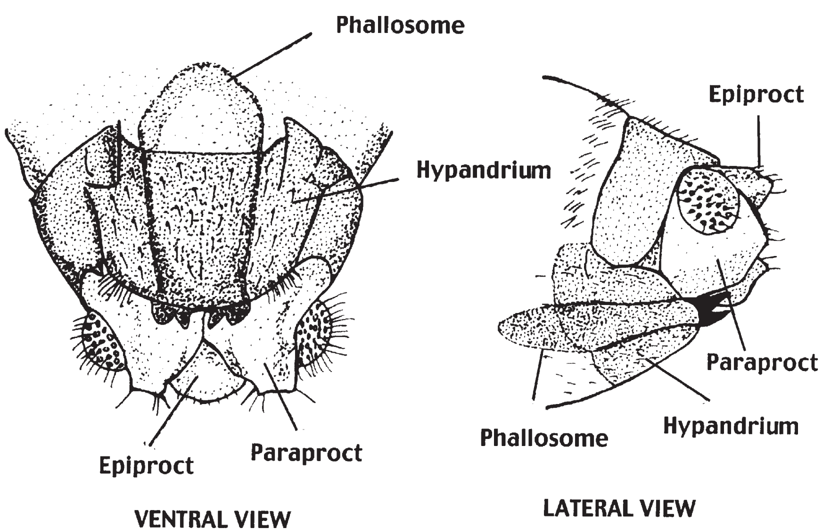
Male genitalia comprise a hypandrium (male subgenital plate) and a phallosome (copulatory apparatus). The hypandrium is an expansion of the 9th sternite, defining a cavity in which lodges the phallosome. The hypandrium varies from a broad shield, varying from slightly convex and weakly sclerotized to a strongly convex and heavily sclerotized, and bearing apophyses of different kinds. The phallosome (Figs. 15 and 16) comprises the endophallus, the parameres and the aedeagus. The endophallus is a membranous structure which is everted during copula. Its surface is adorned with small sclerites (radulae). The parameres are symmetrical, sclerotized structures with small pores sensilla on the distal end. From each paramere an inner branch often protrudes; these branches are fused apically, forming a sclerotized arch (the aedeagus).

Female genitalia comprise, in the majority of species, a subgenital plate, one pair of gonapophyses from the 8th segment (ventral valvulae), two pairs of gonapophyses from the 9th segment (dorsal valvulae and external valvulae), the modifications of the 9th sternite around the spermapore, and the spermatheca or "receptaculum seminis" (Fig. 17). The subgenital plate is a extension of the 8th sternite; commonly it is a large broad plate having the apical margin rounded. However, in many groups a pronounced median posterior lobe is present which has (Fig. 17) been termed the "egg guide." The ventral valvulae are shorter than the others, glabrous, and apically pointed. The dorsal valvulae run parallel to the ventral valvulae, and sometimes resembles it in appearance. The external valvulae are attached to the surface of the base of the dorsal valvulae, and commonly are broad and setose. The spermapore (female gonopore) opens between the gonapophyses in the 9th sternite. Sometimes the cuticle around the spermapore is heavily sclerotized to form a distinct plate (spermapore plate).

The internal structure of psocids resembles that of other insects. The tracheal system usually opens to the exterior by means of two pairs of thoracic and eight pairs of abdominal spiracles. Four Malpighian tubules are attached at the posterior end of the midgut. The nervous system is very simple and comprises the following ganglionar centers: brain, subesophageal ganglion, prothoracic ganglion, pterothoracic ganglion and the abdominal ganglion. The reproductive system in females comprises two ovaries, each with three to five polytrophic ovarioles, lateral oviducts which open into a larger median duct, and a spermatheca. In the males the testes are round or three-lobed.

Systematics

Living Psocoptera are divisible into three well-defined suborders: Trogiomorpha, Troctomorpha and Psocomorpha. The earliest fossils from the



Bark-Lice, Book-Lice or Psocids (Psocoptera), Figure 15 **Male terminalia of *Mesopsocus unipunctatus.***

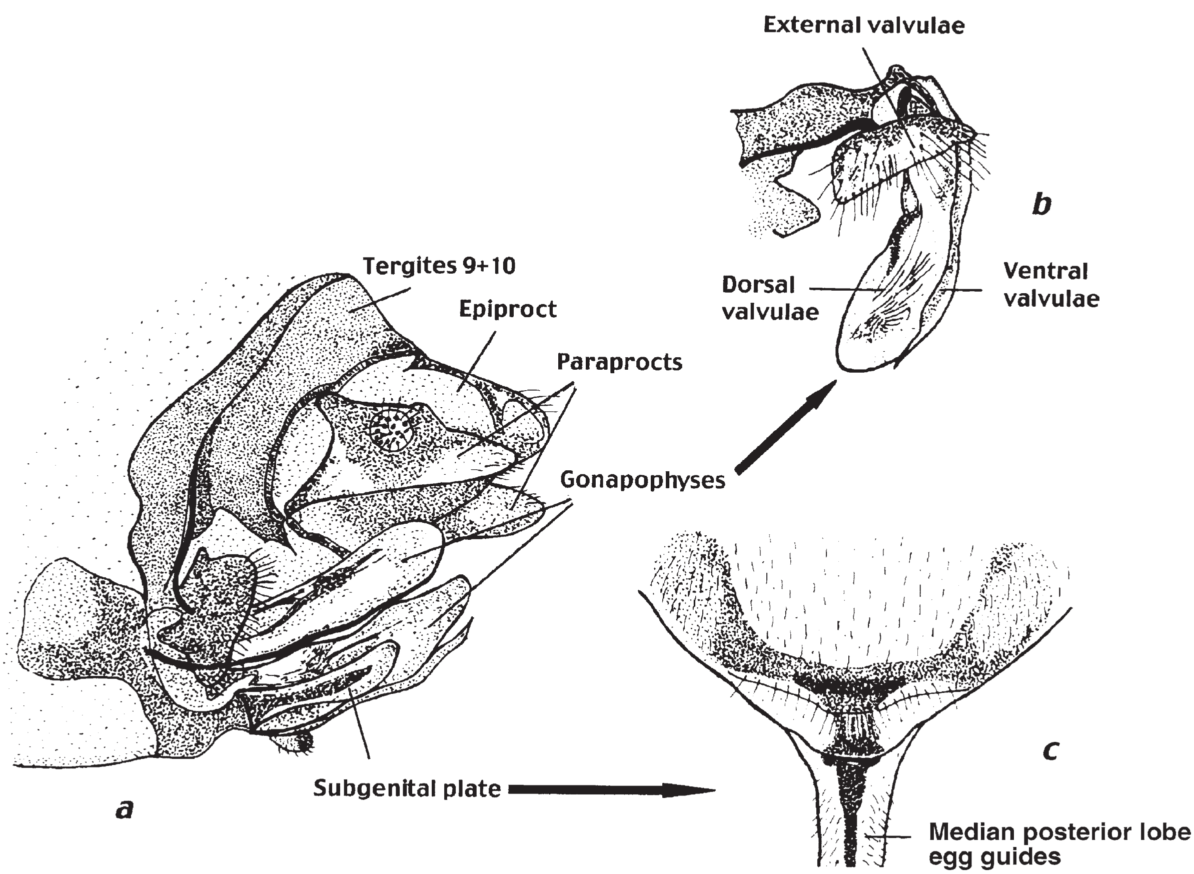
Lower Permian of Kansas, regarded as Psocoptera by some authors, differ from modern species in wing venation and mouthpart characters. Thus, they have been placed in a distinct suborder, Permopsocina. The Trogiomorpha contain the most primitive forms, and the Psocomorpha the most advanced.

Suborder: Trogiomorpha

Diagnostic characters of Trogiomorpha are as follows: antennae with more than 20 segments; hypopharyngeal filaments separate, never fused on midline; tarsi of the adults 3-segmented; labial palps 2-segmented; pterostigma not thickened



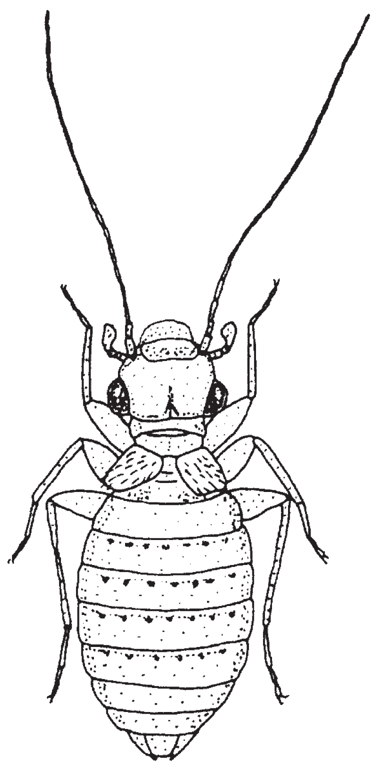
Bark-Lice, Book-Lice or Psocids (Psocoptera), Figure 17 **Female terminalia of *Metylophorus nebulosus* in lateral view (a); detail of the gonaphyses of *Metylophorus nebulosus* (b); detail of the subgenital plate of *Metylophorus nebulosus* (c).**

or absent; and paraprocts with strong posterior spine.

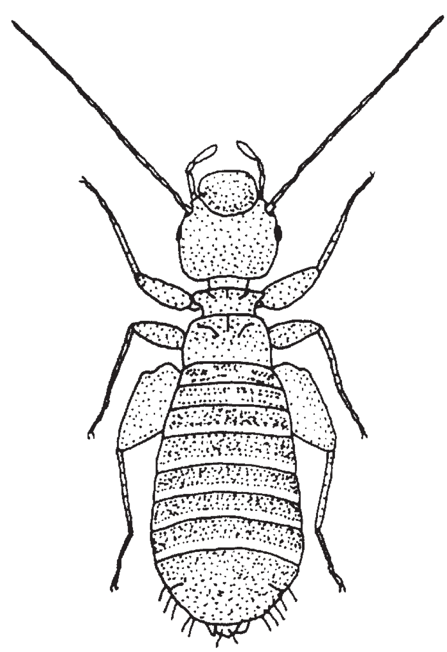
This suborder (Fig. 18) contains five families into two family groups: Atropetae (Lepidopsocidae, Trogiidae and Psoquillidae) and Psocatropetae (Psyllipsocidae and Prionoglarididae). Lepidopsocidae (the major family of the suborder) form a primarily tropical group of bark- and leaf-litter inhabiting forms recognized by their moth-like appearance caused by the scales that cover their body and wings. Trogiidae comprise species with reduced wings (apterous or brachypterous); this cosmopolitan family includes several domestic species, in particular *Lepinotus* sp., which causes great infestations in granaries and warehouses. Psoquillidae and Psyllipsocidae are both small and widely distributed families. Psoquillids are commonly found on bark whereas Psyllipsocids occur in caves or leaf-litter. Both families include some domestic species; for instance, some species of the genus *Dorypteryx* (Psyllipsocidae) are exclusively found in domestic situations. Lastly, the Prionoglarididae are a small family containing three genera (*Prionoglaris* from the Palaearctic, *Speleketor* from the United States and *Sensitibilla* from Namibia) and seven species. The members of these families live almost exclusively in caves or under stones.

Suborder: Troctomorpha

Characters of Troctomorpha (Fig. 19) are: antennae with 14–15 segments, rarely with fewer segments (the only exception is the Palaearctic genus *Nephax* which possess antennae of 13 segments), the flagellar segments beyond the fifth usually with secondary annulations; hypopharynx with filaments separated only in distal region; tarsi 3-segmented; labial palps 2-segmented; forewing, when present, lacking sclerotized pterostigma.

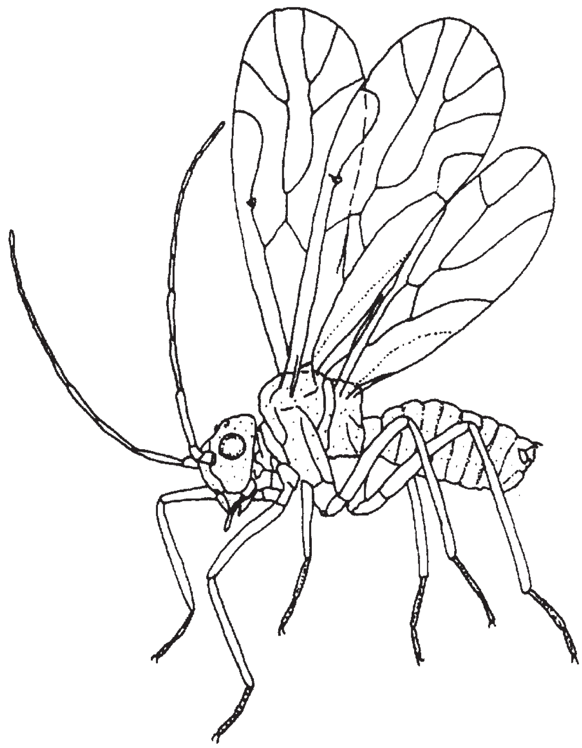


Bark-Lice, Book-Lice or Psocids (Psocoptera), Figure 18 ***Trogium pulsatorium*** **(Trogiomorpha).**



Bark-Lice, Book-Lice or Psocids (Psocoptera), Figure 19 ***Liposcelis bostrychophila*** **(Troctomorpha).**

This suborder contains eight families in two family groups: Amphientometae (Musapsocidae, Troctopsocidae, Manicapsocidae, Compsocidae and Amphientomidae) and Nanopsocetae (Liposcelididae, Pachytroctidae and Sphaeropsocidae). The largest families in this suborder are the Liposcelididae (near 150 species), Amphientomidae and Pachytroctidae. The Liposcelididae are a cosmo-politan group of apterous psocids (although a few species possess reduced wings) whose members are recognized by their small size (1–2 mm) and their greatly enlarged hind femora. The family includes a number of common booklice (*Liposcelis* spp.) found in houses, warehouses and ships holds where they may cause measurable weight loss and quality deterioration in stored grain. Some authors concluded that *Liposcelis* spp are secondary pests of grain whose diet is supplemented by mold. Outdoor species occur in leaf-litter and under bark. The other families are mainly tropical, occurring in both the Old and the New World.



Bark-Lice, Book-Lice or Psocids (Psocoptera), Figure 20 ***Lachesilla pedicularia*** **(Psocomorpha).**

Suborder: Psocomorpha

This suborder is characterized by possessing antennae with 13 or fewer segments, never with secondary annulations. The labial palpus is 1-segmented, lacking-basal segment. The hypopharynx has chitinous filaments separated in posterior region. The forewings usually are present, with sclerotized pterostigma. Adults have 2- or 3-segmented tarsi.

This very large suborder contains nearly 80% of all known species of Psocoptera. It consists of 23 families, in four family groups: Epipsocetae (Epipsocidae, Dolabellopsocidae, Ptiloneuridae and Cladiopsocidae). Epipsocidae are the largest family of this group with 133 described species, mostly tropical and subtropical in distribution. In some species, females are apterous or brachypterous. Most species live in particularly damp situations: under stones, in caves, on dead branches in humid forests, or in damp leaf litter. The family group Caeciliusetae comprises the following families: Asiopsocidae, Caeciliusidae, Stenopsocidae and Amphipsocidae. The Caeciliusidae are one of the largest families of Psocoptera, with nearly 400 known species. It is a family of worldwide distribution, in which most species are foliage dwellers. Amphipsocidae (150 species) are a large family widely distributed in the Old World (a few species can be found in the Americas); these psocids are generally found on broad-leaved foliage. The group Homilopsocidea was erected to hold those families which could not easily be associated with families in the other family groups. The result is a heterogeneous assemblage of 11 families (Lachesillidae, Ectopsocidae, Peripsocidae, Calopsocidae, Pseu-docaeciliidae, Bryopsocidae, Trichopsocidae, Elipsocidae, Philotarsidae, Mesopsocidae and Archipsocidae). Most of these families are of cosmopolitan distribution and can be found forming part of the psocid faunas around the world. Lachesillidae consist of more than 250 species (most of them living in the Americas), primarily found in dry foliage. Some species (e.g., *Lachesilla pedicularia*) are widely distributed, occurring in granaries, warehouses and human habitations, occasionally in great numbers. Ectopsocidae and Peripsocidae are two closely related families, and are cosmopolitan in distribution (although Peripsocidae are more diverse in the Oriental region). Some species of Ectopsocidae (*Ectopsocus briggsi*) and Trichopsocidae (*Trichopsocus clarus*) are commonly found on fruit-bearing trees, and possibly are involved in the transmission of pathogenic fungi. Pseudocaeciliidae and Archipsocidae are mainly tropical groups. Some species of Archipsocidae live in massive aggregations under sheets of webbing that may cover an entire tree. Philotarsidae live on bark or low vegetation. Members of this family can be found around the world but are especially common in the Oriental region. Elipsocidae and Mesopsocidae are bark inhabitants, and also may be found in many types of bushes. Both families are abundant in temperate regions.

Lastly, the family group Psocetae consists of four families (Psocidae, Psilopsocidae, Myopsocidae and Hemipsocidae). Psocidae are the largest family in the order with near 600 known species. It is a cosmopolitan group of psocids which are, in a general way, darkly colored and live on bark or, occasionally, on the ground or under stones. Myopsocidae (near 150 species) are large, tropical Psocoptera living on bark. The members of this family usually have densely spotted brown wings.

Reproductive Biology

Courtship and Mating

Many observations of courtship in various species of psocids show that elaborate behavior patterns may be involved, and that behavioral differences may constitute effective isolating mechanisms for closely related species. In a general way, mating it is preceded by the male nuptial dance, in which the male describes circles around the females. Simultaneously, males vibrate the wings or, in apterous species, vibrate the antennae. Courtship requires a variable time (2–20 min) and is followed by mating. The male approaches the female from the side or from behind, passes over her in a forward direction, then backs underneath, and copulation ensues. The copulation has a variable duration, ranging from the 5–10 s (as observed in *Stenopsocus stigmaticus*) to 2–4 h in the Trogiidae. Copulation length depends on the degree of complexity of the genitalia, and the sperm transmission mode. In the species with extremely short copulation, the terminalia are very simple and little sclerotized in both sexes. Also, the spermatophore is directly deposited on the atrium from which the sperm is transferred to the spermatheca. In other species the coadaptation of the genital apparatus is more intense, which explains the long duration of copulation. In the Atropetae and the Amphientometae, sperm are transferred in a liquid medium into the spermatheca within a structure called a "sperm packet." This structure apparently is formed by glandular secretions of males and females, a process that lengthens the duration of the copulation.

Eggs, Oviposition, Hatching, Viviparity, Parthenogenesis

Eggs of Psocoptera are often simple, elongate ovoids or cylinders without a micropyle, and usually are smooth, lacking any conspicuous sculpture. In the more primitive psocids, however, eggs have pronounced areolate folds or a crest on the upper surface. Observations on psocid eggs allow us to recognize four categories of egg deposition:

1. Eggs laid bare: (a) webbed, (b) not webbed.
2. Eggs encrusted with material from the digestive tract: (a) webbed, (b) not webbed.

There is a systematic and an ecological basis for the pattern of egg deposition. Thus, species which are open bark inhabitants (as Psocidae) lay unwebbed encrusted eggs, whereas leaf inhabiting species (Caeciliusidae, Pseudocaeciliidae) usually lay bare, webbed eggs.

Batch size varies considerably, but egg number is constrained by the fact that two follicles mature in each ovariole at once, thus imposing a maximum batch size (for example, 12 eggs in *Graphopsocus*; 16 in *Caecilius* and *Stenopsocus*, and 20 in *Ectopsocus briggsi*). However, larger batches are occasionally laid by such species (32 eggs in the first batch of an individual of *Graphopsocus cruciatus*). This is a rare phenomenon, but occurs because the presence of two eggs in an ovariole does not inhibit maturation of further follicles.

Hatching is accomplished with the aid of a specialized egg burster on the frontal region of the pronymph. This egg burster has the form of a blade or tooth, or a row of several spines. By pushing this structure against the egg cuticle, the pronymph creates a hatching orifice, and the nymph is partially extruded through this orifice. The first instar then emerges from the pronymphal cuticle attached to the hatching orifice.

Viviparity is an unusual habit in the psocids. Only a few species are known as viviparous. In the best-known viviparous genus of psocids (*Archipsocopsis*), females lack gonapophyses and the abdomen may contain more than a dozen embryos in different stages of development. Eggs remain in the ovarian tubules and pass down the common oviduct to the exterior.

Parthenogenesis in psocids is widespread. The usual form of parthenogenesis is obligatory thelytoky, although a few examples of facultative thelytoky are known. This mode of reproduction is known in at least 12 families, representing all three suborders. However, the situation actually is more complex, as demonstrated by *Caecilius flavidus* and *Psocus bipunctatus* (two European species). These species consist of two races, one bisexual and other parthenogenetic. Females of the parthenogenetic race in the presence of males of the bisexual race provoke no reaction from the males, whereas the introduction of a female of the bisexual race is immediately followed by a nuptial dance by the males, which eventually results in copulation. Meanwhile, the parthenogenetic females remain indifferent. This incompatibility of the races within the same species could be the rule in all Psocoptera possessing such biologic races, driving reproductive isolation of the races. This ultimately can be responsible for speciation. More recently, in the common domestic psocid pest *Liposcelis bostrychophila* dense concentrations of small bacterial inclusions have been found. These bacteria are tentatively identified as *Wolbachia*, a genus implicated in changes in reproductive function (in which parthenogenetic reproduction is included) in many other insect groups.

Postembryonic Development

The juvenile instars of psocids (nymphs) generally resemble adults in body form and markings. They lack functional ocelli, never have more than two tarsomeres, and early instars have fewer flagellomeres than adults of their species. Nymphs of some genera of the families Troctopsocidae, Psocidae and Myopsocidae have gland hairs, which in some cases retain bits of debris, thus forming a camouflaging coat over the body surface. The usual number of nymphal instars in psocids is six for the two sexes, but this can be reduced to five (micropterous form of *Psyllipsocus ramburii*), four (apterous females of *Embidopsocus enderleini*) or, more rarely, three (apterous males of *Embidopsocus enderleini*). The reduction of instars number is frequently associated with alary polymorphism, in which some species with sexual alary dimorphism differ in instar number between sexes: the apterous sex having one less instar than the macropterous one. Also, the reduction of the number of larval stages is generally regarded as a case of neoteny, and associated with the reduction of other characters (lack of ocelli, only two tarsomeres and reduction in numbers of ctenidiobothria and paraproct trichobothria).

Feeding

Psocids are herbivores or detritivores, feeding on microflora and organic debris on the surface of vegetation and other substrates. They are among a relatively small number of insects that actively exploit these food resources (according to some authors, the psocids together with the Collembolans constitute the guild of epiphyte grazers). The primary components of their diet are green algae of the genus *Pleurococcus*, lichens (especially corticicoles and lapidicoles) and fungal spores and hyphae. Although it is common to find pollen grains in their alimentary tract (mainly of coniferous trees), detritus of all types and even remains of dead arthropods (probably already in decomposition) are consumed. A few psocids are partial predators, taking insect eggs and possibly scale insects. The differences in the diet depend on the habitat occupied by the species. For example, the bark-inhabiting psocids feed on pleurococcine algae and lichens. Leaf-inhabiting psocids feed primarily on small leaf fungi, and often ingest small amounts of leaf tissue with the fungal hyphae. Domestic psocids feed on mold that develops on the organic matter found on furniture in dwellings, and on the rotted wood and the old papers found in basements. Psocids that live in the kitchens of houses become consumers of stored food (flour, cereals, rice, bags of tea, etc.).

Natural Enemies

Parasites

The intestine of most species contains gregarines (Protozoa) fixed to the intestinal wall. These gregarines are also found in the feces, and can infect other individuals.

Psocids have been mentioned occasionally as intermediary hosts of tapeworms (Cestoda). Cestode larvae of the genera *Thysanosoma*, *Thysaniezia* and *Avitellina*, have been found in various psocid species of the genera *Lachesilla*, *Lepinotus*, *Liposcelis*, *Ectopsocus* or *Rhyopsocus*.

Other organisms parasitizing psocids are nematodes that live in the abdominal cavity, and fungi of the order Entomophtorales (species of the genus *Erynia*).

Parasitoids

The parasitoids of psocids are Hymenoptera attacking both eggs and nymphs.

Parasitic Hymenoptera that attack the eggs belong to the genus *Alaptus* (Mymaridae), and include several species. In general, only a few eggs of each batch are parasitized, and each egg contains only a single individual of *Alaptus*. Some studies reveal that the proportion of parasitized eggs varies between 6–10% although in some species of *Mesopsocus*, proportions of 20–70% have been observed. Parasitic Hymenoptera attacking the nymphs belong to the genus *Leiophron* (Braconidae: Euphorinae). The proportion of parasitized nymphs is sometimes 50–60%, as has been reported in some populations of *Caecilius flavidus* studied in England.

Ectoparasites

The presence of larvae of Acari (genus *Hauptmannia*) living as ectoparasites on psocids has been mentioned. Some phoretic Acari (Phytoseiidae) attached to larvae of psocids have also been described.

Predators

The main predators of psocids are arthropods and vertebrates. Among the arthropods, numerous species that feed on eggs, nymphs or adult psocids have been reported. For example, several arachnids (Acari, spiders, Opiliones, pseudoscorpions) and numerous representatives of various orders of insects (Dermaptera, Heteroptera, Neuroptera, Hymenoptera [ants], Diptera and Coleoptera) are known. The main vertebrate predators on psocids are birds. Many bird species include psocids in their diet, although they represent only a small fraction of the total insect captures: 1.5% in the diet of swifts (*Apus pallidus*) that hunt flying insects, or 3.6% in the diet of treecreepers (*Certhia*) and nuthatches (*Sitta*) that hunt on the trunks of trees.

Occasionally, predation by reptiles has been mentioned, as in the case of an arboricolous lizard in Chile.

Defense Mechanisms

Most psocids possesses features or develop behaviors to avoid parasites and predators. These defense mechanisms can be included in several categories:

First, defense by hiding is called crypsis. Among psocids, many examples can be recognized: eggs covered with silk and detritus helps reduce detection, nymphs with glandular hairs covering the body surface to which detritus adheres, and both adults and nymphs with color patterns matching the substrate where they live. Protective coloration has been well studied in British populations of the species *Mesopsocus unipunctatus*, providing a case of industrial melanism for this species (the darker individuals are more frequent on trees near industrial areas as a consequence of differential predation by birds).

On the other hand, some cases of mechanical defenses are known: the ability of the Liposcelidiidae to run backward swiftly, the surprising jumping abilities of some species (*Dorypteryx*, *Psocathropos*, and the females of *Cyrtopsochus*), or the partial autotomy of the antennal flagellum as have been observed among some species, such as *Prionoglaris stygia*. Some species combine two defense methods. For example, *Hemineura bigoti* blend in well with dried Genista bushes, but *H. bigoti* also shows a hiding behavior that consists of revolving around the *Genista* shoots, thereby keeping out of sight of possible predators.

Some authors suggest the existence of mimicry in some species. The best example is the case of *Chelyopsocus garganicus*, which resembles a beetle, a less consumable species.

Dispersal

Interchange of psocids between different habitats, and extension of habitat or geographical range, occurs frequently and may result from one or more of three interrelated forms of dispersal. These are:

1. Aerial dispersal by flight, as revealed by the abundance and frequency of catches in aerial traps (suction traps or Malaise traps).
2. Passive dispersal. Psocids, like many other small insects, frequently become incorporated in the aerial plankton after active take-off, and may be transported over considerable distances. On the other hand, phoresy of psocids on vertebrates has been observed. Psocids have been recovered from the plumage of several species of birds, and from rats, chinchillas, puppies and humans.
3. Hitchhiking in vehicles or cargoes. This method is probably responsible for the broad occurrence of many domestic species. In fact, most of them are cosmopolitan despite being flightless.

Ecology

Habitats

Psocids occupy a wide range of habitats, although the various habitat categories of psocids intergrade substantially. The following ecological categories hold for a great majority of psocids:

Trees and Shrubs (*Foliage-Frequenting and Bark-Frequenting Psocids*)

Most psocids live on trees and bushes, but not all occupy the same parts of the plant. So, in a general way, we can consider two categories of psocids: foliage-frequenting and bark frequenting.

The foliage-frequenting habitat has been adopted by relatively few species, but some groups use this habitat. Some of them contains species that live on live leaves. The claws of most of these species lack a preapical tooth, and the pulvillus is broad. With the aid of this pulvillus, psocids moves without problems onto flat leaf surfaces. Also, the presence of abdominal vesicles in some species guarantees adherence that is particularly effective against the action of the wind. Other psocids that can also be considered foliage inhabitants are those that live on dead leaves, including those that remain attached to the trees, as well as those that fall to the ground. This habitat (the dead leaves) harbors an epiphytic microflora that is attractive to some psocids (members of the families Lachesillidae and Ectopsocidae). For example, several Brazilian *Lachesilla* species appear to be closely associated with palm foliage, and their numbers are considerably greater on dead foliage than on living fronds. In general, psocid abundance tends to be greater on dead foliage than on living foliage if the two types are available together.

Most of the psocids living on trees are bark-frequenters. In fact, in some areas, psocids are the most abundant animals found feeding on bark surface microfloral communities. Some families are almost exclusively found on this habitat (Psocidae, Myopsocidae, Mesopsocidae, Peripsocidae and Philotarsidae). In these species, the shape of the claws is different: the claws possess a preapical tooth and the pulvillus is, in general, setiform and with the apex pointed, which favors the attachment to a surface more or less rough. Among the psocids living in barks and trunks, an important group is the subcortical psocids, which live under the bark, where they find food and protection. They show morphological adaptations for subcortical existence: extreme dorsoventral flattening with legs inserted laterally, apterism or somewhat thickened forewing held flat on the abdomen (rather than in a more vertical position of other arboreal psocid) and a strong tendency towards alary polymorphism. The principal psocid group of this category is the family Liposcelididae.

Low Vegetation

Some species have a clear preference for low vegetation (herbaceous or woody). This fauna is typically found in those ecosystems where low vegetation predominates (heathers, brooms, gorses, thyme, grasses and herbs). Some examples of true grass-frequenting psocids are *Asiopsocus meridionalis* in semi-arid regions of Spain, *Peripsocus alboguttatus* on heaths in southern Britain, or *Caecilius antillanus* in Brazil.

Litter

Psocoptera are a small portion of the active mesofauna of litter and are encountered in litter habitats in many parts of the world. However, distribution of litter Psocoptera is extremely variable. For example, in northern temperate regions only a small part of the total psocid fauna is found in this habitat, whereas in the southern temperate zone of South America (Chile), edaphic Psocoptera may be more diverse than arboreal species. Traditionally, the litter psocid fauna has been included in three ecological categories:

1. Primary litter dwellers. These species spend their entire life in the litter, and do not frequent other habitats. Species typical of this category are Lepinotus reticulatus and many species of Liposcelis.
2. Secondary litter dwellers. These species have generations in two distinct habitats each year, with at least one being in the litter. Some species that could be included in this category carry out seasonal local migrations from the litter onto trees and vice versa. For example, in a Mediterranean species (*Hemineura sclerophallina*) the edaphic populations are composed only of nymphs, with a peak during July, while the nymphal populations on trees have a

peak during October (adults are found exclusively on plants). The edaphic populations are restricted to the dry season when the humidity conditions are, presumably, more suitable for psocids in leaf litter than in trees.

3. Casual litter dwellers. These species do not normally breed in litter, but are present intermittently as a result of falling from trees.

Generally, the bulk of primary litter dwellers belong to the more primitive suborders, while Psocomorpha are relatively rare in this role.

Rock Surfaces

A few psocids appear to have become specialized for dwelling on the surface of rocks. This category includes species that are located under the stones on soil, as well as species living on the stones of walls (for example, on the walls of old houses). In Europe, members of the families Psocidae, Myopsocidae, and Peripsocidae such as *Psocus bipunctatus*, *Neopsocus rhenanus*, *Myopsocus eatoni* and *Peripsocus subfasciatus* are habitually found in this habitat type, although most of such species have broader habitats, either in the litter or on bark with similar lichen or algal associations.

Caves

Nymphs and adults of psocids are regularly found in caves. Psyllipsocidae (in Europe the most common psocid in caves is *Psyllipsocus ramburii*) and Prionoglarididae are perhaps particularly characteristic of caves. Some authors hypothesize that the hypogean fauna (from caves and similar habitats) had a remote origin in Cretaceous tropical forests. These forests disappeared during the early Tertiary, as a consequence of climatic change, and the fauna moved to colonizing some subterranean habitats. In the case of psocids, it has been suggested that the Psyllipsocidae (an ancient group) may have survived by avoiding competition with more recent forms by inhabiting caves or similar habitats.

Bird and Mammal Nests

Psocids frequently have been reported from mammal and bird nests. For ground-nesting mammals, the psocids are primarily leaf-litter species, while for tree-nesting species the psocids usually are those occurring on bark. Psocids are common inhabitants of bird nests, because psocids find favorable conditions in the bird nests. The association between psocids and the birds in the nest is not parasitic because the psocids feed on the microflorae that grow on the nest material. Most species of psocids living in bird nests are apterous or micropterous and are members of the families Trogiidae, Liposcelididae and Ectopsocidae. Less frequently, some psocids species live inside the nests of other insects. For example, *Liposcelis formicaria* and *Liposcelis myrmecophila* occur in ant nests, *Lachesilla pedicularia* is found in nests of wasps of the genus *Polistes*, and numerous species of psocids have been reported in the hives of honey bees.

Domestic Habitats

Among the Psocoptera, a considerable number of species (predominantly Trogiomorpha and Troctomorpha) occur in houses and other buildings, feeding mainly on fungal hyphae, spores of molds, and on green algae. Psocids are common inhabitants of domestic environments such as humid rooms, basements, damp walls and room partitions. Psocids are commonly associated with products in food stores, granaries, warehouses, railway boxcars and ships' holds. Many species seem to be exclusively domestic, including some species of the genus *Dorypteryx*, *Ectopsocus* and *Liposcelis* (*Liposcelis mendax* is frequently encountered in rice). Psocids are usually not seriously unhygienic, causing only minor problems of contamination and allergies. Their principal damage to buildings is their effect on property values: lawsuits resulting from the presence of psocids often prove costly. For example, in a Spanish coastal town, three species of psocids were involved in spreading infestation of the alga *Pleurococcus* on recently constructed buildings, and were the basis of a legal conflict.

Ecological Distribution

Altitudinal Distribution

Although some psocid habitats are distributed over a wide altitudinal range, many of the psocids present are usually limited to a part of this range. In the most comprehensive work concerning altitudinal distribution of psocids, only two of 53 species of psocids found on mango (*Mangifera indica*) in Jamaica were found throughout the plant's altitudinal range of 150–1,200 m. An altitudinal zonation of psocids has also been observed in central Spain between a range of 900–1,700 m. In this case, of the 15 species studied, three showed preferences for the low altitude, four were distributed mostly at high altitudinal levels, while the remainder were distributed throughout the altitudinal range. The same has been observed in Swiss National Park; only 14 of 55 species were taken in the upper alpine zone (above 1,900 m) and 24 were not found above the montane level (to 1,500 m). So, from the available data, psocids can be classified into three altitudinal groups:

1. eurytopic species, found over most of the range.
2. low altitude stenotopes, restricted to lower elevations.
3. high altitude stenotopes, found at higher elevations only.

Although data are not available from most parts of the world, it seems that individuals at the upper end of an altitudinal gradient may be larger than those lower down. In Jamaica, there was a linear increase in the size of females of *Pseudocaecilius citricola* and *Hemipsocus roseus* with increasing altitude. This tendency is probably due to temperature gradients.

Substrates and Plant "Preferences"

Psocids are not strictly phytophagous because they feed on the microflora that grows on the plants. However, occasionally they show a certain specificity toward their substrate plant. In a general way, this specificity refers to groups of plants. For example, among the foliage-frequenting psocids, a marked division exists among those that live on conifers and those that live on broad-leaved trees. Also, they are more frequent on plants with rough leaves (*Ulmus* spp.), or with small leaves that are easily moved by the wind (*Betula* spp.). However, among the bark-frequenting species this specificity is less marked. The ecological conditions of a site that favors a type of vegetation can be more important for psocids than the presence or absence of certain substrate plants. In central Spain, some well defined psocid communities have been found, in particular those that live in the Spanish juniper forests (*Juniperus thurifera*) and in the Scots pine forests (*Pinus sylvestris*), suggesting that changes in structure and composition of psocid communities can be determined by both climate and vegetation types. Psocid faunas inhabiting different plant species are affected by taxonomic relatedness and by architectural similarities among the substrate plant species. For example, there are discrete faunal communities on shrublands (*Cistus* sp., *Rosmarinus* sp., and *Genista* sp.), junipers (*Juniperus thurifera*, *J. sabina*, *J. comunis* is *J. oxycedrus*), pines (*Pinus pinaster*, *P. nigra*, *P. halepensis*, *P. sylvestris*) and oaks (*Quercus faginea*, *Q. pyrenaica*, *Q. rotundifolia*).

Humidity

The thinness of the integument of psocids (particularly in the nymphs) is responsible for the fact that most psocids are very susceptible to desiccation. This means that relative humidity is a limiting factor to psocids and that, therefore, high humidity is desirable. Psocids can ingest water with the food or, exceptionally, as liquid, but it is generally insufficient to prevent desiccation. However, psocids are able to actively take up water from the atmosphere. This process (this is not exclusive of psocids because it is also found in some Mallophaga) is carried out with the mouthparts. The lingua bears a pair of ventral sclerites) which are connected to the median sitophore sclerite by ligaments; these lingual sclerites are capable of taking up water from the atmosphere and driving it by means of the tubular filaments into the alimentary tract.

Psocids and Humans

In general, psocids are of little economic and health importance to man. Occasionally they may cause human health problems such as skin diseases or scalp infestations. The dead bodies of some domestic psocids in household dust are responsible for allergies and asthmatic attacks. Also, several species of psocids serve as intermediate hosts of some cestodes, particularly of the fringed tapeworm of sheep. Psocids also have been revealed to be disease vectors on plants. For example, *Ectopsocus briggsi* may occasionally disseminate fungal pathogens on fruit-bearing trees by leaving viable spores in feces deposited on uninfected sites. As mentioned previously, three species of psocids were involved in spreading infestation of the alga *Pleurococcus* on recently constructed buildings.

Some species of psocids can be considered to be pests. Among the psocids occurring out-of-doors, the large webs of Archipsocidae have occasionally required removal due to their unsightliness. Those of *Archipsocus nomas* in Florida, for example, are sometimes removed by scrubbing larger branches and trunks of trees with oil emulsions. In Europe, the species *Lachesilla pedicularia* can form dense clouds that are a temporary nuisance. However, most of the psocid species that become pests are domestic species. Most of the domestic psocids occur in large numbers in houses or stored products when the environmental conditions are particularly favorable (namely *Lepinotus* and *Liposcelis*). In general, they have been assumed to cause little damage, but the observations on some species of *Liposcelis* that cause primary damage to stored grain indicate that some species may cause direct economic loss. On the other hand, although domestic psocids are generally only contaminants, the appearance of some species in large numbers can cause a direct damage to insect collections, herbaria, older books and animal products. Most of these species (genus *Liposcelis*) are difficult to eliminate because they can survive without food and tolerate unfavorable conditions of temperature and relative humidity, recovering their normal activity once the environmental conditions become favorable. Also, as a consequence of the parthenogenetic mode of reproduction in many of these species, they are able to multiply in an explosive way and to expand their population very quickly. Some authors suggest maintenance of relative humidity of less than 50% with temperatures of 15°C or less, in order to retard development and slow the increase in populations. However, though such measures may be feasible in temperate regions, they are likely to prove extremely difficult in many tropical areas. Other control measures include the use of insecticides in varied forms; one of the most widely used is pyrethrin dust.

Barley Thrips, *Limothrips cerealium* (Haliday)

A thrips (Thysanoptera) pest of some grasses, including wheat.

► Wheat Pests and Their Management
► Thrips

Basal

A term used to refer to the base or point of attachment, or the portion of the appendage nearest the main body.

Basalare

A small section above the principal pleuron, anterior to the wing, to which flight muscles are inserted.

Base Pair (bp)

Two nucleotides that are in different strands of nucleic acid and whose bases pair by hydrogen bonding. In DNA, adenine pairs with thymine and guanine pairs with cytosine.

Basement Membrane

A noncellular layer that separates the epidermal cells from the hemolymph. This membrane is the innermost layer of the integument.

► Epidermis
► Cuticle

Basic Reproductive Rate

(R_0) The average number of offspring produced by a population of individuals over the entire course of their life.

Bat Bugs

Members of the family Polyctenidae (order Hemiptera).

► Bugs

Bates, Henry Walter

Henry Bates was born in Leicester, England, on February 8, 1825, and developed an early interest in entomology. At the age of only 17 or 18 he published notes on Coleoptera in the Zoologist. At about the age of 20, he met Alfred Russel Wallace, who was then teaching English in a school in Leicester and had an interest in botany. Through the influence of Bates, Wallace began to collect beetles. In 1847, Wallace proposed a trip to Pará, Brazil, to collect insects and other natural history objects, having read W.H. Edwards' "Voyage up the Amazon". These two explorers, together with Bates' brother, sailed from Liverpool for Pará in April 1848. They intended to support themselves by the sale in Europe of natural history objects that they expected to collect in Brazil. Many hardships followed. These included his affliction with yellow fever, the death of Bates' brother, and the loss at sea of Wallace's first collection of natural history objects. Nevertheless, he persevered (Wallace traveled separately after the first 2 years, and departed from Brazil years sooner than Bates), and assembled large collections, including over 14,500 species of insects, of which 8,000 were new to science during the 11 years that he spent in Brazil. He returned to England, worked on the specimens he had collected, and published. In 1861 his paper "Contributions to an insect fauna of the Amazon Valley"; was read before the Linnean Society. It explained mimicry (see Batesian mimicry). In 1863, his two-volume book "A naturalist on the river Amazons"; was published by John Murray with an introduction by Charles Darwin, to great acclaim. These works resulted in his being offered the job of assistant secretary to the Royal Geographical Society in 1864. This at last freed him from financial worry, but reduced the time available for him to work on his Amazonian insects. He later contributed (1881–1889) volumes to the series "Biologia Centrali-Americana";, published numerous other works, and was twice president of the Entomological Society of London. He died on February 16, 1892.

Bates, Marston

Marston Bates was born in the state of Michigan, USA, on July 23, 1906. He graduated from the University of Florida with a B.S. degree in 1927. He worked for the United Fruit Company in 1928–1931. He entered Harvard University and was awarded an A.M. degree in 1933 and Ph.D. in 1934. In 1935–1937 he worked as a research assistant at Harvard. In 1937–1952, he worked at various laboratories of the Rockefeller Foundation, and his studies of mosquitoes in northern South America contributed to an understanding of epidemics of yellow fever. In 1952–1971 he was a faculty member of the University of Michigan. He contributed much to ecology of mosquitoes and to environmentalism. His books include (1949) "The natural history of mosquitoes", (1950) "The nature of natural history", and (1955) "The prevalence of people". He died on April 3, 1974.

Bat Fleas

Members of the family Ischnopsyllidae (order Siphonaptera).

► Fleas

Bat Flies

Members of the families Streblidae and Nycteribiidae (order Diptera).

► Flies

B Chromosomes

B chromosomes are non-vital supernumerary chromosomes found in many organisms. They are thought to be derived from normal chromosomes, and often transmitted at higher rates than expected, thus exhibiting "drive."

Beach Flies

Members of the family Canacidae (order Diptera).

► Flies

Beaded Lacewings

Members of the family Berothidae (order Neuroptera).

► Lacewings, Antlions and Mantidflies

Beak

A prolongation of the head, usually referring to the snout of weevils. This term also is used to describe the jointed piercing-sucking, or sucking, mouthparts of Hemiptera.

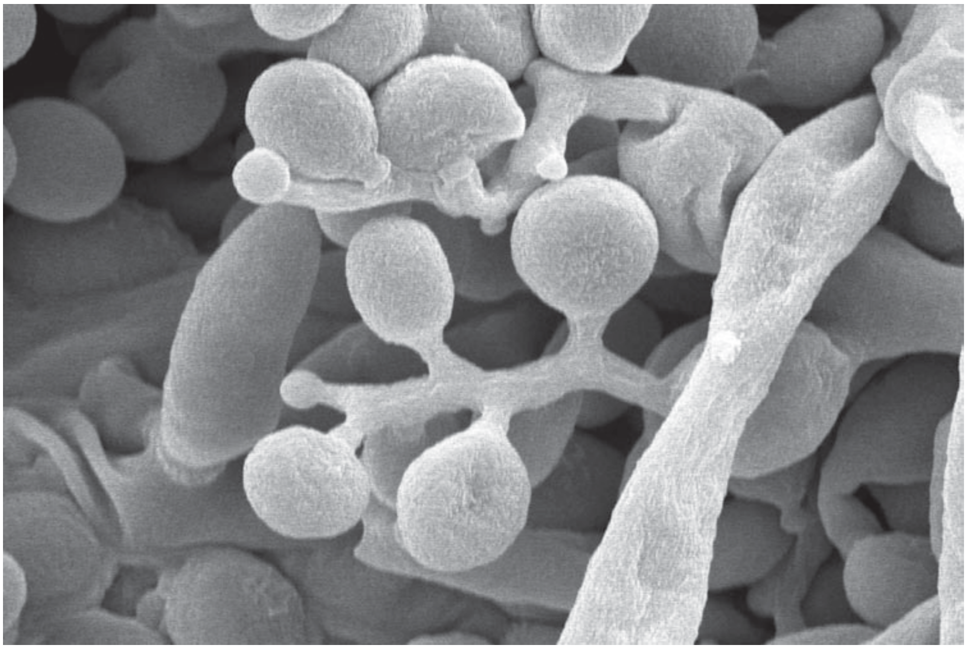
Beauveria

Jacqulyn C. Pendland, Drion G. Boucias
University of Florida, Gainesville, FL, USA

The genus *Beauveria* (Deuteromycota) includes several entomopathogenic species, the most notable being *B. bassiana*. *Beauveria* has a worldwide distribution and has a wider host range than the other Deuteromycetes infecting insects from most orders. In addition to *B. bassiana*, three other species, including *B. brongniartii* (=*tenella*), *B. relata*, and *B. amorpha* have been identified. The latter two species are South American isolates from Lepidopteran larvae and Coleoptera, respectively. *Beauveria brongniartii* (*B. tenella*), found predominantly in soil-inhabiting insects, has been described as a naturally occurring pathogen of mosquito larvae. *Beauveria bassiana*, the white muscardine fungus, was observed around 900 A.D. in silkworms in Japan. Insects mummified by *B. bassiana* also were used for medicinal purposes, e.g., as an antiseptic for wounds and sore throats. Importantly, it was through a study of this fungus that the germ theory of disease (i.e., the idea that microorganisms could cause infectious disease in animals) was postulated by A. Bassi in 1834. Also of historical significance is the discovery that a 25 million-year-old worker ant embedded in amber was covered with a fungus similar to present day *B. bassiana* isolates.

The infective propagules, the conidia of *Beauveria*, are dry, hyaline (colorless), and globose to oval in shape (Figs. 21 and 22). The conidiophores can occur singly or can be grouped in irregular clusters or in whorls; the base of the conidiophore is inflated or flask-shaped, with conidia borne on a distinctive apical zigzag extension (rachis). Like other entomopathogenic hyphomycetes, *B. bassiana* conidia initiates infection of host insects at the outer integument, although invasion through the alimentary tract has been reported in certain ants and termite hosts. Successful infection by *B. bassiana* by cuticular penetration depends upon a number of factors. For example, younger insects are usually more easily infected than older larvae. Specific *Beauveria* strains are infectious to adult insects such as grasshoppers, as well as to insects undergoing a molt. The type of plants that the target insects consume is also important since some plants produce compounds inhibitory to fungal growth. Conidial germination on a susceptible host requires optimal temperature and humidity (>75%). Conidia, for example, will not infect overwintering adult Colorado potato beetles because the soil is too dry and cool; however, post-emergent beetles can become infected later in the spring when conditions are more favorable. Even if conditions are optimal for the germination and penetration processes, *B. bassiana* conidia must first bind to the host cuticle after contact has been made. Attachment, as in the case of other fungi that produce dry conidia, is likely due to the hydrophobicity of both the conidial and cuticular surfaces. In *B. bassiana*, conidial hydrophobicity can be attributed, at least in part, to the presence of a hydrophobin-type protein in the outermost rodlet layer. In addition to attachment, conidial surface hydrophobicity may prevent desiccation of the propagules and aid in their dispersal. Fungal enzymes may help to consolidate attachment of *B. bassiana* conidia to host cuticle.

Beauveria, **Figure 21 Adult mole cricket, *Scapteriscus vicinus*, infected with *Beauveria bassiana*. Note the external conidiospores emerging from the head, thorax, and leg regions.**



Beauveria, **Figure 22 Scanning electron micrograph of the conidiophore of *Beauveria bassiana*.**

Under the proper conditions, germination of *B. bassiana* conidia occurs within hours. Studies have shown that different strains of *B. bassiana* produce different amounts of cuticle-degrading enzymes. There are several classes of enzymes produced by *B. bassiana* during germination, including proteases, chitinases, and lipases that function in the breakdown of host cuticle.

Penetration of insect cuticle (e.g., *Helicoverpa zea*) by *B. bassiana* germ tubes usually does not involve the formation of appressoria. Once the germ tubes penetrate the cuticular and epidermal regions, the fungus grows towards the hemocoel, where blastospores become evident at about 48 h post-infection. *In vivo* produced blastospores, unlike *in vitro* cells, lack a formal cell wall and contain a thin fibrillar layer on the plasma membrane. In *Heliocoverpa zea*, there is very little tissue damage until 60–70 h post-infection, when the fat body may show some signs of deterioration. The gut and Malphigian tubules can become affected at 6–7 days, when death and mummification also occur. However, the gut, muscle, silk glands, and tracheae can remain intact during the entire infection process. Death is likely due to nutrient depletion, dehydration, and/or toxin production by the fungus.

Host response to *Beauveria* invasion varies, of course, depending upon the insect and its susceptibility to the particular isolate used. Melanized patches (dark spots) can occur on the cuticle at the penetration site, thus indicating the induction of phenoloxidase activity in the insect. In grasshoppers injected with *B. bassiana* conidia, levels of phenoloxidase in the hemolymph were found to increase by 24 h post-treatment. After topical application with conidia and penetration of the cuticle, as the fungus reaches the hemocoel, host immunoreactive hemocytes may surround the hyphal tip and further melanization reactions can occur. If *B. bassiana* cells become surrounded by hemocytes either via phagocytic and/or nodulation or granuloma-type mechanisms, the fungus can still remain viable as an intracellular parasite, and later emerge from the insect blood cells to continue growth and replication in the hemocoel and tissues. Thus, *B. bassiana* can overcome host cellular defense response even if it has already been initiated, and as mentioned earlier, some toxins produced by the fungus appear able to suppress such responses (phagocytosis, nodulation) entirely. *Spodoptera exigua* larvae injected with *B. bassiana* blastospores show both a reduction in the overall number of immunocompetent granular hemocytes and a suppression in their abilities to spread and form filopodia.

In addition to being a ubiquitous soil entomopathogen, certain strains of *B. bassiana* have been reported to be endophytic and colonize plant tissue. Unlike most insect mycopathogens, *B. bassiana* has been associated with fatal respiratory infections in some cold-blooded animals, including tortoises, crocodiles and American alligators. One strain causes the rupture and/or death of fish embryos due to attachment of the conidia to the chorion with subsequent germination and penetration of the fungus. A second strain tested also caused teratogenic responses, including abnormalities in embryos. As a result of these tests, there is some concern that large-scale applications of *B. bassiana* conidia could be harmful to aquatic ecosystems. Infections in the lungs and nasal passages of mammals have been reported but are rare since the fungus probably does not grow well at 37°C; however, *B. bassiana* can cause allergic reactions in some people.

Beauveria conidia from field-collected cadavers can be inoculated onto mycological media such as SMY agar or broth and maintained in culture by transfer at regular intervals to fresh media. *Beauveria*, less fastidious than *Nomurea rileyi*, can be grown on oatmeal agar or potato dextrose media, and stored at ultra-low temperatures (-70°C). Isolation of *Beauveria* from a soil environment may require the selective media containing antibiotics such as streptomycin, tetracycline, gentamycin and cycloheximide to eliminate bacterial growth and N-dodecylguanidine acetate (dodine) to inhibit growth of other soil fungi.

Due to its broad host range, including members within the orders Lepidoptera, Coleoptera and Hemiptera, and to the fact it is cultured easily on inexpensive media, *B. bassiana* has long been targeted as a potential biocontrol agent. Insect pests such as the Colorado potato beetle, *Leptinotarsa decemlineata*; European corn borer, *Ostrinia nubilalis*; codling moth, *Laspeyresia pomonella*; Japanese beetle, *Popillia japonica*; European cockchafer, *Polyphylla fullo*; chinch bug, *Blissus leucopterus*; and the European cabbageworm, *Pieris brassicae*, are susceptible to *B. bassiana*. However, the inability to produce and formulate fungal propagules that are stable and provide consistent mortality rates in constantly changing biotic and abiotic conditions has restrained large-scale development of this mycopathogen. For example, over the years both *B. bassiana* and *B. brongniartii* have been targeted to control some soil-inhabiting insects, but due to this hypogean environment, *Beauveria* is placed in direct contact with the antagonistic soil microfauna that can be lethal or can inhibit its growth.

Beck, Stanley Dwight

Stanley Beck was born in the state of Oregon on October 17, 1919, but grew up in the adjoining state of Washington. As a young man he worked in a lumber mill for a year to save money to pay for a university education. With those funds, he entered Washington State University to study biology, and earned a B.S. degree in 1942. He then served 3 years in the U.S. navy. From 1945 to 1950 he was a graduate student at the University of Wisconsin at Madison, earning an M.S. degree in 1947 and a Ph.D. in zoology in 1950. At the same university, he was appointed assistant professor in 1950, a full professor in 1964, and a distinguished professor in 1969. He taught a course on insect physiology. His research interests were in host-plant resistance to pests, and insect nutrition and metabolism. His publications were 138 scientific papers and several books including (1963) "Animal photoperiodism" and (1968) "Insect photoperiodism". He received several awards, was elected to the U.S. National Academy of Sciences in 1988, and served as president of the Entomological Society of America. His accomplishments were the more remarkable because by 1952 he was essentially paralyzed by poliomyelitis and was confined to a wheelchair for the rest of his life. He died on July 8, 1997, in Madison, Wisconsin, survived by his wife, Isabel, and three of his four daughters.

Bed

In modern agriculture, a raised area of soil into which crops are planted (planting bed). Beds are bounded by furrows which sometimes are used to deliver irrigation water to the beds. In traditional agriculture, a bed (seed bed) is also an area used to grow seedlings for later transplant into fields.

Bed Bugs (Hemiptera: Cimicidae: *Cimex* spp.)

DINI MILLER
Virginia Tech University, Blacksburg, VA, USA

The Cimicidae are obligate blood feeding ecto-parasites of humans and other animals. There are 74 species of cimicids, including the human bed bugs, bat bugs, chicken bugs, swallow bugs, and pigeon bugs. Cimicids are organized into 22 genera and 6 subfamilies. Of the 22 genera, 12 have evolved to feed exclusively on bats while another 9 genera feed exclusively on birds. There is only one genus, *Cimex*, which contains species that feed on multiple hosts, typically specializing on birds, bats, or humans. Of all the cimicid species only three feed on humans. These include *Leptocimex boueti* Brumpt, a West African species that feeds on humans and bats; *Cimex hemipterus* F. (tropical bed bug), found in both the new and old world tropics feeding on humans and chickens; and *Cimex lectularius* L. (common bed bug), which is found all over the world and feeds on humans, chickens and bats.

Cimicids that feed on humans get their common name "bed bugs" from their long history of harboring in human dwellings, particularly in those locations where the host would come to rest at night (bed or bedding). By harboring in the "bed," the bugs could feed undisturbed while the host was asleep.

While the origin of the bed bug is unknown, it is thought that human bed bugs were originally ecto-parasites of bats. When humans moved into caves and either lived with the bats or removed them, the bat parasites adapted to the presence of the new host. Those bat bugs that survived and proliferated on human blood continued to inhabit human environments.

The exact geographic origin of human bed bugs is also unknown, but both Neanderthal man (100,000 years ago) and, later, Cro-Magnon man (12,000 B.C.) populated caves in the Middle East. It is most likely in these Middle Eastern caves where humans began their cohabitation with the ancestral bed bug. As humans began to practice agriculture (8000–5000 B.C.) within the "fertile crescent" (present day Iraq), people moved from their cave dwellings into villages near their agricultural fields. It has been speculated that bed bugs were transported into these newly civilized environments, thus becoming permanently associated with humans and human dwellings.

Morphology

Adult bed bugs are easily identified by their brownish red color and their lack of wings. The body is broadly flattened and ovoid, typically 5–8 mm in length and about 4 mm wide. Because the adults only have wing pads, the first 11 dorsal abdominal segments are usually easy to see when the body is not engorged.

The morphology of the bed bug head is very similar to that of other cimicids. The multifaceted eyes of the bed bug look like small knobs protruding from the sides of the head. The antennae of the bed bug are 4-segmented and project forward from a small protuberance between the eye and clypeus. The third and forth segments of the antennae are thinner than either the basal or second segment.

The most prominent feature on the head is the labrum. The labrum extends out from the clypeus at the extreme anterior of the head and is marked with a labral suture. The labium arises just below the labrum, at the anterior margin of the head, and has three segments. When the labium is held at rest (under the bed bug head), the ventral side of the labium contains a longitudinal groove which holds a fascicle of mandibular and maxillary stylets. Between the maxillary stylets are a large food canal and a smaller salivary canal. The food canal and the stylet fascicle are connected with the cibarial pump inside the head of the bed bug. The 3-segmented labium, including the maxillary and mandibular stylets and the food and salivary canals, are collectively referred to as the rostrum (Fig. 23). The rostrum pierces the host's skin and the cibarial pump is used to pump the blood from the host into the head of the bed bug.

The pronotum of the bed bug is very distinct and the shape or hairiness of the dorsal side is often used for species identification. In general the pronotum is broad, surrounding the base of the head within the concave anterior margin. The sides of the pronotum extend up around the base of the head in a wing-like fashion.

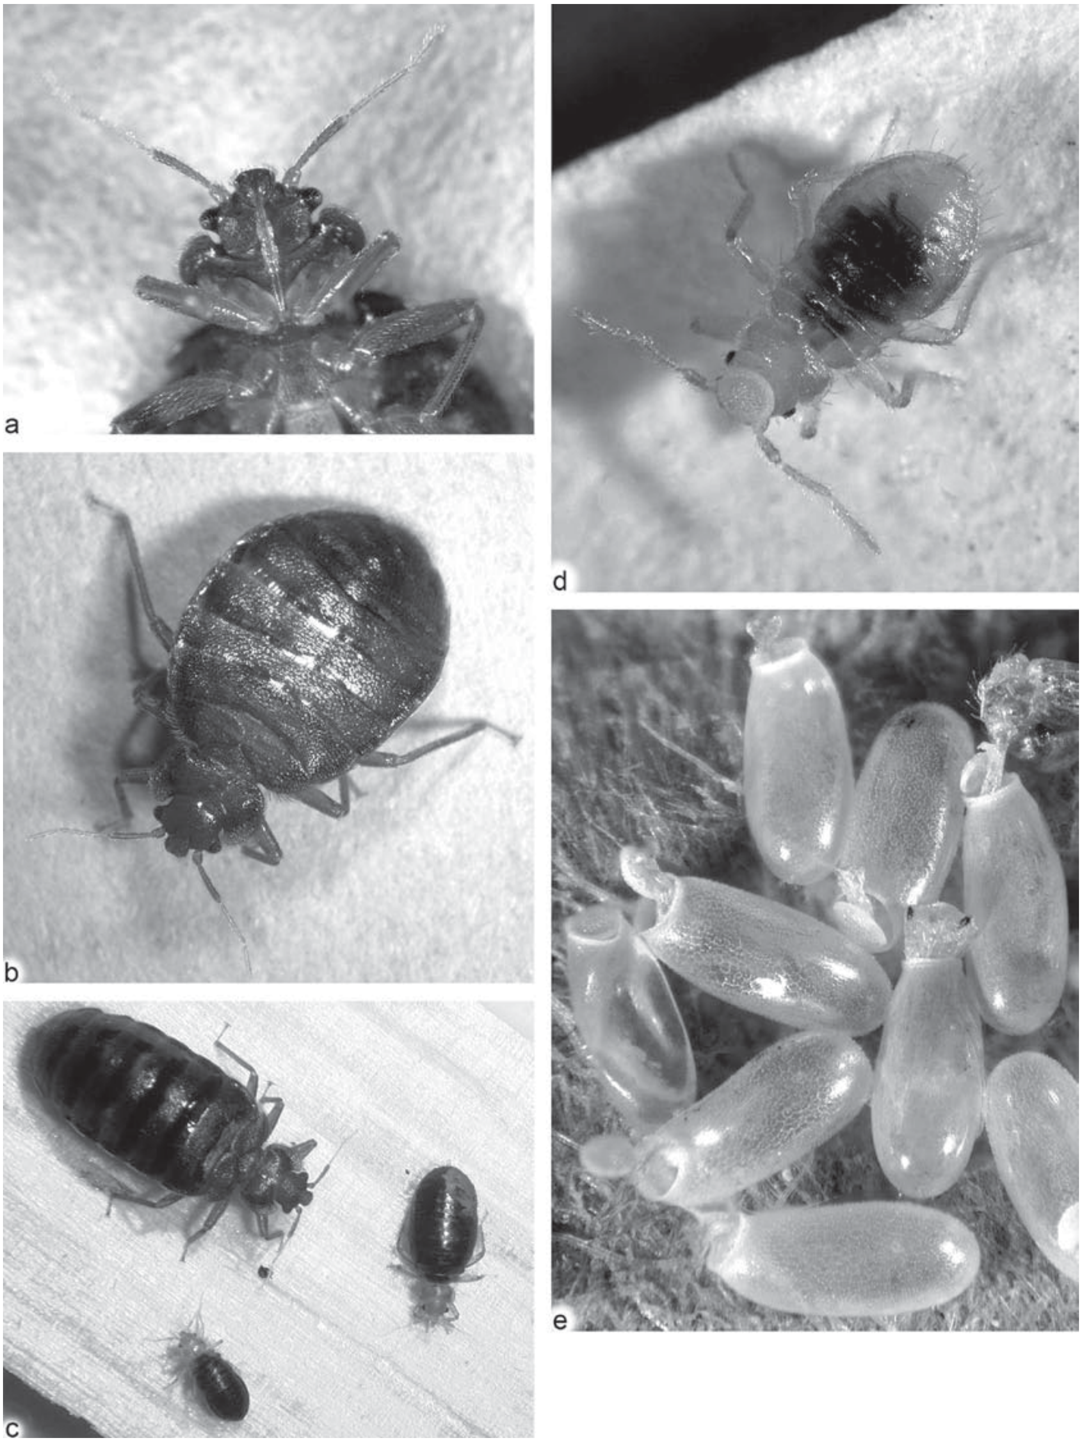
The abdomen of the adult bed bug consists of 11 segments and is completely sclerotized. However, the sclerotized abdomen is capable of enormous expansion due to the wide intersegmental membranes and the "hunger folds" (ventral membranous sections) located within the second and fifth abdominal segments. The female reproductive organs (gonapophyses) are homologous to the ovipositor found in other species and are located on the ventral side of the 8th and 9th abdominal segments. The female spermalege or paragenital sinus appears as a notch located on the ventral side of the abdomen between the 5th and 6th segments. The genitalia of the male bed bug also originate on the ventral side of the abdomen near the apex. The male abdomen is narrower at the apex than that of the female and the 9th segment is longer and asymmetrical. The male paramere is strongly curved to the left and lies in a groove within the 9th segment.

Immature bed bugs differ from adults in their morphology in several ways. First, they lack the characteristic reddish color of the adults. Nymphs are typically translucent white, making their internal structures visible after a blood meal. Nymphs also differ from adults in that not all of their abdominal segments are sclerotized, particularly on the ventral surface of the abdomen. Nymphs also have a 2-segmented tarsus while the adult tarsus is 3-segmented. Finally, immature bed bugs lack any structures associated with reproduction.

Life Cycle

The bed bug life cycle is unique in that it begins with an unusual form of copulation known as traumatic insemination. Unlike other hemipterans, *Cimex* males never insert their copulatory organs into those of the female. Instead the male awkwardly mounts the female's back and wraps his abdomen around the right side of her body. He then punctures her body wall, wounding the female as he inserts his copulatory organ into her paragenital sinus or "Organ of Berlese" to inject his sperm. Mating usually lasts for several minutes but can last up to half an hour in some cases. Within 2 h of mating the male spermatozoa pass from the female Organ of Berlese into her abdominal cavity. Once in the hemocoel, the spermatozoa accumulate at the base of the oviducts, moving into the seminal conceptacles within 12 h.

After mating, a female held at 23°C will begin to produce eggs within 3 days. Several sources have indicated that female bed bugs, when fed regularly, are able to produce viable eggs for 5–7 weeks after a single mating. However, mated females will usually cease oviposition after about 11 days without an additional blood meal. Under laboratory conditions (23°C and 75% RH) a typical female that has been fed and mated regularly can produce 3–4 eggs every day averaging more than 200 eggs total over her entire lifespan. Under natural conditions fecundity can be quite variable, depending not only on the availability of mates but also temperature and nutrition. Egg production is closely correlated to ambient temperature, the weight of the unfed female, and size of the female blood meal. An increase in temperature from 17 to 23°C has been shown to produce as much as a ten-fold increase in weekly egg production among well fed, mated females. The mean weight of unfed females also influences egg production. As expected, larger females produce more eggs. Also, because larger females tend to take larger blood meals, the size of the blood meal has also been shown to result in increased egg production.



Bed Bugs (Hemiptera: Cimicidae: *Cimex* spp.), Figure 23 **The common bed bug, *Cimex lectularius*: (a) ventral morphology of adult bed bug head showing the rostrum, pronotum, and antennae; (b) adult female bed bug; (c) engorged adult and early instar bed bugs; (d) partially fed first instar bed bug with egg cap on head; (e) first instar bed bug emerging from egg.**

Oviposition occurs 3–6 days after mating. The bed bug eggs are about 1 mm in length, white, elongate, and slightly bow shaped. Upon oviposition, eggs are coated with sticky cement that dries quickly causing them to adhere to the substrate on which they were deposited. The eggs are typically laid in cracks and crevices near a harborage site and take 6–10 days to hatch, although temperature variation may alter hatch time. As a first instar bed bug emerges from the egg, anti-peristaltic movements of the gut drive fluid into the head, deploying hatching spines to dislodge the egg cap. After hatching, most first instars will stay near the egg capsule until they leave in search of their first blood meal. Several studies have indicated that bed bug survivorship is closely linked to the amount of energy they have to expend searching for a host. This is particularly true for first instars. While quite ambulatory for their size, first instars are at great risk of dehydration compared to the older life stages. Therefore, we can assume that many first instars are lost before they ever consume their first blood meal simply because they hatched too far from a host.

Bed bugs have five nymphal instars, each requiring a blood meal to complete development. Each nymphal stage can feed within 24 h after molting and all bed bugs are typically stimulated to feed at slightly less than weekly intervals. At higher temperatures (27°C), the feeding interval can be reduced to every 3 days, and all nymphal instars molt more quickly when exposed to warmer temperatures. In studies conducted on nymphal stages 1–5, it was found that the mean number of days between the blood meal and molting ranged between 2.1 days at 35°C and 26 days at 15°C. Ordinarily, nymphal bed bugs will feed once per instar, with each instar lasting 3–5 days at optimal temperatures (23°C). If insufficient blood meals are taken, secondary blood meals will be necessary before molting can occur. So although the average time from egg to adult is often reported as about 1 month, that time period can be extended to 4 months or more depending on the ambient temperature and the availability of regular blood meals.

Behavior

Bed bugs are thigmotrophic and seek out harborages where their bodies can be in direct contact with surrounding surfaces. They are often found aggregating in cracks and crevices of homes and other structures, or wedged into mattress tufts or staple holes where they can remain undisturbed. In hotel rooms they are often found behind removable headboards or picture frames hanging on the wall. They can also be found hiding in the wood frames of the box springs or the stuffing. In some heavy infestations, the best harborages are already filled so many bed bugs will take up residence along baseboards, behind posters on the wall, or under the carpet tacking. Bed bugs will typically avoid locations exposed to air movement but may be seen aggregating in the open on the ceiling or at the ceiling/wall junction if no other space is available. The stimulus that prompts bed bugs to leave their harborages is not well understood but obviously they have to leave in order to feed. After feeding, bed bugs will return to these same harborages after their meal and remain there while digesting. The digestion period after feeding results in the accumulation of fecal material (black spots of dried blood) in preferred harborage locations.

Bed bugs are nocturnal, usually avoiding the light. Studies have indicated that bed bugs are most active after 3:00 A.M., a time when the host would most likely be in a deep sleep. However, bed bugs will feed during the daylight hours if they are hungry and a host is available. The question regarding how these nocturnal insects are able to navigate between the host and their harborage is quite controversial. Little is known about bed bug vision, but it is suspected that they do not see well because of their nocturnal and parasitic lifestyle. Bed bugs are thought to use pheromone and odor cues for navigation. However, bed bugs have been tested repeatedly and have never been observed to detect heat sources or host odors over distances >12 cm. Several researchers have suggested that bed bug searching behavior in the natural environment must be completely random. However, others claim that random searching would be too costly for bed bugs to have achieved their obvious reproductive success. Regardless of how bed bugs detect their food source, there is no question that they have evolved to take advantage of the diurnal nature of the human host. They feed at night when the host is unconscious, thereby increasing their chances of feeding to repletion. After feeding they quickly abandon the host and return to their harborage where they remain during the daylight hours, thus decreasing their chances of being detected.

Bed Bug History

References to the bed bug as the bane of human existence appear in some of the earliest recorded history. Aristotle made reference to bed bugs in his *Historia Animalia* (384–322 B.C.), and many other historical texts document the presence of bed bugs in Greece in 499 B.C., Italy in 77 A.D., and in China by 600 A.D. Because bed bugs have co-existed with humans for centuries, many common names and folk remedies have been created regarding them. Bed bugs are known by over fifty common names in a number of different languages. The English language names include wall-louse, red coat, pursuer, crimson rambler, wall flounder, and the mahogany-flat. In addition to the various common names, there are several folk sayings that are related to bed bugs, including "crazy as a bed bug" or "snug as a bug in a rug."

Bed bugs have long been a target of folk remedies. Some remedies may have been somewhat effective while others, though creative, were probably useless. The plant *Actaea cimicifuga* or bugbane has long been regarded as viable bed bug treatment, and may have had some potential for repelling bed bugs away from the sleeping host. However, the snap bean (*Phaseolus vulgarius*) has demonstrated true potential for bed bug control. In the Balkans, the leaves of this bean plant were placed under the beds in infested rooms. Foraging bed bugs would become entangled in the hairs on the bean leaves during the night. In the morning, the leaves were simply swept up and burned to destroy the bed bugs. While the practice of sleeping over bean leaves most likely provided at least some bed bug relief, the ancient remedy of hanging the feet of a dead stag or rabbit at the foot of the bed (as host decoy), probably had little effect. Another folk method of bed bug prevention that is still used today is to place the legs of the bed frame in pans of water or kerosene. Although this method is thought to work, there have been many anecdotal references to bed bugs circumnavigating these barriers by crawling up the wall and dropping onto the sleeping host from the ceiling.

In spite of all of the recorded history of cohabitation with humans, bed bugs are still "the bug that nobody knows." The reason for this "bed bug denial" is that there is a social stigma associated with bed bug infestations. Many people believe that bed bugs only infest overcrowded or unsanitary housing. Therefore, you can only get bed bugs if you visit or live in these poor conditions. This has never been true. Bed bugs do not discriminate between human hosts and infest every social class and nation across the globe. The bed bug's ability to infest any human environment has been confirmed by the resurgence of bed bug infestations in industrialized nations over the past decade. During the 1990s, new bug infestations appeared first in five star hotels and other expensive tourist locations within the United States, Australia, Singapore, and Europe.

Geography of the Bed Bug

Today, *Cimex hemipterus* F. (tropical bed bug) and *Cimex lectularius* L. (common bed bug) are by far the two most important and widespread cimicid parasites of humans. Both are thought to have originated from the Old World but are now found all over the globe. Colonies of *C. hemipterus* have been cultured from such diverse locations as Vietnam, Taiwan, Panama, Uganda, Venezuela, Cuba, India, and Florida in the United States. Although *C. hemipterus* has a worldwide distribution, its range rarely extends beyond the tropics, therefore it has been described as strictly a tropico-politan species.

C. lectularius is a truly cosmopolitan bed bug and has expanded its range with humans throughout Europe and into the Americas. Records of *C. lectularius* have been collected from all over the world with the exception of Antarctica. However, Antarctica will no doubt have *C. lectularius* by the end of the decade due to the eco-tourist industry that has recently developed on that continent. In many tropical locations, the distribution of *C. hemipterus* and *C. lectularius* overlap. Yet, unlike *C. hemipterus*, *C. lectularius* is able to survive in both tropical and temperate climates. Interestingly, *C. lectularius* does not typically occur where populations of *C. hemipterus* are well established. Some authors have speculated that the reason for this absence is that *C. lectularius* is susceptible to fungal infection in tropical locations of high humidity while *C. hemipterus* is not. A more interesting suggestion is that the distribution of *C. lectularius* is limited by the fact that interspecific copulation is common between the two species and yet has a deleterious effect on *C. lectularius*. For example, one older study suggested that sperm fluid of *C. hemipterus* males was toxic to *C. lectularius* females. Later research indicated that the deleterious effects of interspecific copulation were due to the fact that attempts of *C. hemipterus* males to mate with *C. lectularius* females resulted in female mortality. The reason suggested for this mortality was that the paragenital sinus of the *C. lectularius* female was not suited to accommodate the *C. hemipterus* paramere. The most recent study regarding the viability of mixed bed bug populations determined that the fecundity of *C. lectularius* was compromised in the presence of *C. hemipterus*. Specifically, it was found that in mixed populations, *C. lectularius* females laid only sterile eggs when *C. hemipterus* accounted for >75% of the individuals. However, the potential negative impacts (if any) of *C. hemipterus* males on *C. lectularius* females living in mixed populations have yet to be fully determined.

Public Health Importance

Because bed bugs are blood feeders and have typically been associated with poor living conditions, they have long been suspected of being potential vectors of human disease. In fact, studies prior to the 1960s identified many diverse disease organisms that were collected from the bed bug gut, body and feces. These pathogens included those responsible for plague, murine typhus, smallpox, poliomyelitis, yellow fever and at least 20 other diseases. However, there has been no conclusive evidence that bed bugs transmit any of these diseases to humans. More recently, bed bugs have been evaluated for their ability to become infected with and transmit Human Immunodeficiency Virus (HIV) and Hepatitis B. HIV has been found to survive in bed bugs for several days after ingestion, but there has been no epidemiological evidence indicating that HIV could be transmitted from an infected bed bug to a host during the feeding process. While Hepatitis B cannot be transmitted from bed bugs to humans via the taking of a blood meal, there is evidence to suggest that the Hepatitis B virus may be mechanically transmitted to humans in bed bug feces or when bed bugs are crushed during the feeding process. However, as of this writing there is no medical record of such a transmission ever taking place.

Disease transmission is not the only health issue associated with bed bugs. In many cases, the number of bed bug bites or reactions to the bites has been cause for concern. When a bed bug bites, the mandibles and maxillae form a compact bundle (fascicle) that is rapidly injected into the host's skin. During the act of piercing, the toothed mandibles move in a rapid alternating motion slicing their way through the skin tissues slightly ahead of the maxillae. After the tissues are breached, the fascicle probes in all directions, backwards and forwards, often cutting across or entering small capillaries and larger vessels. The probing can result in numerous small hemorrhages throughout the tissues. The bed bug fascicle probes for a vessel of suitable size from which to begin feeding. Blood vessels that are too large or too small are ignored. Once the fascicle finds a suitable vessel, the maxillae enter the blood vessel and inject the saliva (anticoagulant). The pressure in the vessel causes the host's blood to rush up the food canal into the bed bug head, allowing for feeding to be completed in a matter of minutes. However, the destructive nature of the probing coupled with the injection of the bed bug saliva can produce a wide variety of reactions within the host.

It has been well documented that many people do not react to bed bug bites; however, some people can suffer severe skin reactions that last for several days. There have been many reports of married couples staying in infested hotel rooms where the wife or husband was made miserable by hundreds of itching bed bug bites while their spouse experienced nothing at all. It has also been suspected that hypersensitive individuals living with large populations of bed bugs may actually suffer asthma attacks after being bitten repeatedly by bed bugs. The reactions of people who are sensitive to bed bug bites vary widely in severity and may be immediate, delayed or both.

Bed bug saliva contains many proteins that trigger the body's immune response. The immediate immune response usually involves the development of an inflamed reddish weal that will start to itch within a couple of hours and may continue to itch for 1–2 days. People who experience the delayed response are typically unaware that they have been bitten for several days. They then begin to experience localized itching and swelling (sometimes very severe) around the bite site and the delayed response may last for longer than a week. Perhaps the worst scenario for sensitive people who experience the delayed reaction is to inadvertently spend several nights sleeping in an infested location. Only with the onset of the delayed immune response, do they realize that they have been subjected to hundreds of bed bug bites.

Fortunately, the suffering caused by receiving hundreds of bed bug bites typically has no long term physiological effects, provided the person is able to leave the infested area or have the bed bugs eliminated. Today, the most common medical consequences of bed bug bites are secondary bacterial infections that can occur from vigorous scratching and excoriation. Yet historical records indicate that excessive bed bug feeding has been known to cause iron deficiencies among infants in India.

Although bed bug bites do not produce any long-term physiological problems, the psychological aftermath of dealing with a bed bug infestation may be significant. Many people suffer from stress and anxiety after an encounter with bed bugs and are fearful that bed bugs may be infesting their homes or living on their bodies. Most people who suffer from bed bug anxiety have had an infestation in their home or have been bitten severely while traveling. Still other sufferers have never had an encounter with bed bugs, but have been told about bed bugs or have had it suggested that their itching skin may be the result of bed bug bites. Regardless of whether they have encountered real bed bugs or not, people who suffer from bed bug anxiety have great difficulty sleeping for fear that bed bugs are crawling on them. They often get up several times a night to check themselves or their children for bed bugs. Some people have moved several times and discarded most of their furniture and other belongings. Many have also paid thousands of dollars for repeated bed bug exterminations that have not worked to their satisfaction. Another characteristic of these sufferers is that they often withdraw from family and friends and spend hundreds of hours on the computer researching bed bug cures and participating in internet-based bed bug support groups.

Although not everyone who suffers from bed bug anxiety has experienced a real infestation, the potential for bed bug infestation is very real. Bed bugs have enjoyed a long history of infesting human environments and it was only within the last century that certain developed nations have enjoyed a brief respite from these noxious pests.

Control History

At the turn of the twentieth century the bed bug was a common household pest in the United States and the world. Bed bugs were frequently encountered in quality hotels and motels, laundromats, movie theaters, city buses, and taxis. Bed bugs were easily transported home via a traveler's clothing, vehicle, or luggage. Once inside the home, bed bugs could find harborage in furniture, cracks and crevices in the floor or walls, behind wallpaper, or under carpeting. The easy transportability of the bed bug coupled with the war-time movement of people in the United States and Europe (1914–1945) led to millions of homes and other structures becoming infested. However, the importance of the bed bug as a household pest began to diminish in the 1940s and 1950s with the use of pyrethrum insecticides and DDT. These insecticides were applied liberally to all walls, floors, mattresses, bed frames, curtains, cupboards, and any other surface that could be occupied by bed bugs. Complete control was usually obtained within a matter of days, and with the use of DDT, the residual activity was so long that the sprayed areas remained toxic and bed bug free for months. Therefore, in the latter half of the twentieth century the bed bug was almost eradicated in the United States and Europe, with only a few persistent populations surviving in locations where living conditions were exceptionally poor.

Current Pest Status

In the early 1990s pest management professionals began to receive complaints about new bed bug infestations within the United States. By 2001, many pest control firms were reporting tenfold increases in bed bug calls every year. While new infestations were found to be particularly common in hotels, bed bugs were increasingly being reported in homes, apartments, retirement communities, health care facilities, college dormitories, youth camps and used furniture outlets. The resurgence of the bed bug after its supposed eradication has presented a number of unique challenges to a variety of commercial industries which in their own way have contributed to the bed bug problem.

First, within the pest management industry, most pest management professionals are too young to have had any personal experience with bed bug control. This lack of experience has resulted in many incomplete and ineffective bed bug treatments since the bed bug resurgence began. Second, the medical profession has had very little experience with bed bugs, so many bite complaints were misdiagnosed, allowing bed bug infestations to continue in homes where they might have been treated had they been correctly identified. Leaders in the hospitality industry were also slow to admit that bed bugs were a problem in hotels. Therefore, the hoteliers did not readily develop bed bug prevention or treatment plans because they failed to recognize the potential damage that bed bugs could cause their industry. For example, when bed bugs were first (re)discovered in the United States, it was in five-star hotels in cosmopolitan locations like Los Angeles and New York City. The hotel industry was immediately faced with million dollar lawsuits initiated by clients who had been bitten while staying in their facilities. These lawsuits received extensive press coverage and immediately associated the hotel brand name with bed bug infestations. It was only after a number of these bed bug cases were reported that the hospitality industry began to address the expanding bed bug problem. Finally, an unanticipated source of bed bug proliferation has been the rapidly growing organic foods industry in the United States. Organic poultry farms house thousand of chickens that are being raised for either meat or eggs. There have been several documented infestations within these organic facilities where bed bugs have been found cohabitating with and feeding on the chickens. Because these facilities are pesticide-free, the bed bugs in these facilities number in the millions, causing stress to both the chickens and migrant workers. While the transport of these bed bugs to other locations has not been documented, there is the potential for these bed bugs to be shipped all across the nation via the thousands of delivery trucks that bring eggs and other poultry products to food distribution centers every day.

While the exact cause of this recent, worldwide increase in bed bug activity is not known, there are several factors that may have contributed to the resurgence of bed bugs in the USA. It has been suggested that international travel from developing nations has increased the distribution of bed bugs throughout the world. However, international travel has been common for many decades and bed bugs have only recently (1990s) become recognized as a widespread problem. Another possibility for the bed bug increase has been the reduction in residual insecticide use indoors. Because of concerns about human exposure risk, routine interior applications of spray insecticide have been greatly reduced in favor of integrated pest management (IPM), where pesticides are applied only on an "as needed" basis. IPM also uses insecticide baits as the primary method for controlling crawling insects. However, pesticide baits have no effect on blood sucking parasites. Thus, it is thought that in the absence of the residual sprays, bed bug populations have been able to establish unchecked. One final possibility that deserves consideration is that bed bug populations across the world have become resistant to insecticide products used in developing nations and the USA. If this is the case, it is reasonable to suggest that the increasing population pressure has led to the widespread dissemination of bed bugs throughout the world.

Historical records indicate that bed bugs developed resistance to a number of the insecticides used for their control. These chemicals included DDT, methoxychlor, dieldrin, aldrin, carbaryl, Malathion and other organophosphates. Many of these older chemistries have been banned by the US Environmental Protection Agency and are no longer available for bed bug treatment. However, because bed bugs have not been a problem in the USA for over 40 years, few of the existing pesticide products are labeled for bed bug control and many of these products have the same type of active ingredients. The majority of insecticide products that are labeled for the treatment of bed bugs are either natural pyrethrins, or pyrethroids. Because these active ingredients have been used for decades all over the world, and because they are from the same chemical class, it has been suspected that the newly emerging bed bug populations might already be resistant to pyrethroids.

As of 2007, bed bug resistance to a number of pyrethroids has been documented. Field populations of bed bugs have been found to have variable levels of resistance to permethrin, deltamethrin, beta-cyfluthrin, and lambda-cyhalothrin. In some cases, the resistance of field collected bed bugs exposed to specific active ingredients was found to be 1,000 times that of susceptible laboratory strain bed bugs. Likewise, the time to mortality for bed bugs confined on dried pyrethroid product residues was found to be significantly greater than that of the laboratory strain bed bugs. For example, the time it took to kill 50% of the laboratory strain bed bugs (LT_{50}) confined on panels treated with a formulation of deltamethrin (0.06%) was 61 min. However, when testing bed bugs collected from an infested apartment in Arlington, Virginia, the LT_{50} for deltamethrin was 19 days and 2 h.

Interestingly, in tests evaluating the potential repellency of pyrethroids to bed bugs, it was documented that neither the field nor the laboratory strain bed bugs found pyrethroids repellent. In choice tests where bed bugs could aggregate on either a panel treated with a pyrethroid product or a panel treated with water, there was no significant difference as to where the bed bugs chose to aggregate. In fact, many bed bugs remained in contact with the pyrethroid treated panels until they died, even though they could leave the panel to aggregate somewhere else at any time during the test.

In addition to pyrethroid resistance, these resurgent bed bug populations are not readily susceptible to the non-pyrethroid products labeled for their control. For example, pyrethroid dusts usually take several days to kill resistant bed bugs. Desiccant dusts like silica aerogel, diatomaceous earth or limestone and corn bran dusts can also take days or even weeks to kill bed bugs confined on the material. Because bed bugs do not groom, stomach toxicants like boric acid have no effect on bed bugs. Even crack and crevice sprays containing pro-insecticides like chlorfenapyr may take longer than a week to kill bed bugs, thus allowing them to reproduce prior to suffering any toxic effects. The insect growth regulator hydroprene, which has been a widely used juvenile hormone analogue for cockroach control, has been found to function as a chitin synthesis inhibitor in bed bugs, disrupting the final molt. Yet, although hydroprene kills close to 50% of exposed bed bugs during the final molt, the surviving adults are not sterilized and produce a greater number of viable offspring than unexposed bed bugs after taking their first adult blood meal. Finally, "non-toxic" mattress treatments containing isopropyl alcohol, sodium laurel sulfate or protein degrading enzymes typically kill over 80% of bed bugs that are directly sprayed with these products. However, these treatments have no residual activity once the product is dry, and like most insecticides, these non-toxic mattress treatments have no effect on bed bug eggs.

Current Management Practices

Because of their cryptic lifestyle, bed bug management begins with a thorough inspection of the infested site by a qualified professional. In many cases, infested rooms will be taken completely apart and all personal belongings inspected for live bed bugs, bed bug eggs and fecal spots. Personal belongings are then bagged for treatment, laundering, or disposal. Because clutter provides numerous harborages for bed bugs and makes insecticide applications very difficult, a "bare walls" approach is generally required to provide adequate control. After all clutter and personal belongings have been removed, the infested room and furniture can then be treated.

A back-pack vacuum cleaner with HEPA filter is recommended for the removal of live bed bugs and their cast skins. The removal of live bed bugs and their debris will not only reduce the bed bug numbers but will aid the pest management professional in identifying incipient infestations in future inspections. Once vacuuming is completed, the vacuum cleaner bag must be sealed in a plastic bag and removed from the structure immediately. It should be noted that although the vacuum cleaner will be able to remove the majority of live bed bugs it will not be able to remove the bed bugs eggs which are typically cemented to the surfaces on which they are laid. Therefore, additional treatment(s) will be necessary.

A frequently used method of reducing bed bug harborage sites is the use of sealants and caulk. Because early instar bed bugs are capable of occupying extremely small cracks it is important to inspect the walls and ceilings very carefully for bed bug harborages around switch plates, wallpaper seams, electrical outlets, inside nail holes and screw heads, around window frames, and in staples holes. Caulking and sealing these harborages will force bed bugs to wander in search of new harborage space, causing them physical stress and increasing their chances of exposure to insecticide residues.

Steam cleaning is rapidly becoming a widely used method of bed bug control. Professional steam cleaners can be used to kill bed bugs hiding in baseboards, under carpeting, in mattress seams and in the wooden components of box springs. Professional cleaners that produce dry steam at temperatures >60°C (140°F) are preferred because they produce enough heat to compensate for the insulating properties of mattresses and other upholstered furniture which might otherwise prevent bed bugs from reaching their thermal death point. When purchasing a steamer for bed bug control, it is important to select a machine with a steam head large enough to disperse the steam at a low velocity. The small steam head of some machines will disperse the steam with such force that the bed bugs and eggs are blown off the treatment areas into other parts of the room. Although steaming bed bugs is a slow and laborious task, steam cleaning is one of the most effective methods for killing both bed bugs and their eggs.

After steaming, the treated mattress and box springs should both be placed inside a bite proof, escape proof mattress cover. A variety of products are available for covering mattresses, however, most were not designed to function as a bed bug prevention tool. Many tear easily or have zipper casings that are large enough for bed bugs to crawl through. However, there are mattress covers that have been tested to ensure that bed bugs cannot get inside the cover and any bed bugs already trapped inside the cover cannot escape or bite through the fabric. Although mattress covers cannot prevent a future bed bug infestation, they do keep the client from having to throw the mattress away.

All bedding and any clothing articles that are suspected of being infested with bed bugs must be laundered. Both clothing and bedding should be bagged and marked so that they are not mixed with uninfested articles during the cleaning process. All items should be laundered at a temperature >49°C (120°F) for more than 10 min with laundry detergent. Bed bugs, like all insects, are very susceptible to drowning when exposed to soap, so the addition of laundry detergent will ensure a quick kill. Placing bed clothes in a dryer at 60°C (140°F) for 20 min or longer is also recommended to make sure that no bed bug eggs survive.

Because bed bugs are susceptible to high temperatures, heat fumigation is being used to eradicate bed bugs from large commercial facilities. Using the heat fumigation technology developed for the treatment of grain silos, fans are used to blow air in from the outside to raise the atmospheric pressure inside the facility. The air is then heated and monitored to make sure that all locations inside the building reach the appropriate temperature (bed bug thermal death point) and pressure. The heat treatment is then maintained for a period of hours to ensure that all bed bugs and bed bug eggs are killed. Although heat fumigation is an effective bed bug treatment, the cost, like that of chemical fumigation, is often prohibitively expensive for the average consumer.

Exposing bed bugs to cold temperatures will kill bed bugs but the duration of exposure is often too long to be practical. For example, the thermal death point for adult bed bugs exposed to cold temperatures for 1 h is −18°C (−1°F). Yet, most conventional freezers have a minimum temperature of 0°C (32°F), thus requiring that the bed bugs be frozen long enough to achieve 100% kill. Attempting to kill bed bugs at 0°C will take several days at least, and if the bed bugs are insulated in clothes or bedding it may take several weeks of exposure to ensure that all bed bugs are killed and bed bug eggs are no longer viable.

Although increased sanitation and exclusion techniques are necessary to remove bed bug harborages, these techniques alone will not control an established infestation. Therefore, chemical methods must also be employed as part of a comprehensive bed bug management program. As stated earlier, most modern pesticides will not control bed bug infestations when used individually. However, combinations of products with different formulations and modes of action have been evaluated in the field and have been found to produce satisfactory control. These products must be applied according to the product label and the treatment area must be regularly monitored to make sure that the products are working. Field evaluations have determined that microencapsulated products containing pyrethroids are an effective residual spray because the micro capsules stick to the bed bug body allowing for enough exposure time to kill resistant bed bugs. These products can be used for application into cracks and crevices where bed bugs hide and also along baseboards or ceiling/wall junctions where bed bugs will often harbor when the infestation levels are high. In addition to the crack and crevice applications, products labeled for upholstery treatment can be applied to infested furniture as well as to the mattress and box springs. Some mattress products have residual activity (pyrethroids) while other "non-toxic" products do not. The non-toxic products that contain isopropyl alcohol or sodium laurel sulfate as the primary killing agent will kill bed bugs on contact. Yet, these products evaporate almost immediately after application and bed bugs that survive the treatment will continue to bite and reproduce. Residual dusts are particularly useful in the frame of the box springs and wood components of the other furniture because they stay within the application site and have a very long residual. Residual dusts containing pyrethroids also adhere to the bed bug's body allowing for the long exposure period (possibly days) necessary to kill resistant bed bugs. "Non-toxic" desiccant dusts will also kill bed bugs but they too may take several days to work. Baseboard, and crack and crevice treatments with insect growth regulators are useful in that they will kill many immature bed bugs during the final molt. However, there is no evidence that insect growth regulators will kill or sterilize adult bed bugs. Although aerosols and foggers are frequently used for bed bug elimination, they are not effective control products because they do not penetrate into bed bug harborages.

Overall, a complete bed bug treatment should include the removal of infested items for either treatment or disposal, the laundering of infested clothes and bedding, the elimination of clutter, the sealing of all small cracks and holes that might provide bed bug harborage, a complete vacuuming of all carpeting and furniture, steam cleaning of upholstered furniture and mattresses to kill bed bugs and their eggs, and treatment of the mattresses and box springs with a non-toxic mattress treatment (preferred) or a labeled residual insecticide. After treating the mattress, both the mattress and box springs should be encased in bite proof, escape proof mattress covers. The infested room should be treated with a combination of residual insecticide spray and an insect growth regulator. These products should be applied according to the label to cracks and crevices, baseboards, and any other bed bug harborage locations. The infested room and all adjoining rooms should then be inspected (and/or treated) weekly to determine the efficacy of the treatment products and to make sure that the bed bug population is being eliminated.

Summary

Most entomologists and pest management professionals believe that the resurgence of human bed bugs (both *Cimex lectularius* and *Cimex hemipterus*) presents the single greatest indoor pest management challenge in decades. Since the bed bugs' widespread reappearance in the 1990s, the common bed bug has become a full blown epidemic with new infestations reported in most European countries and in all 50 states in the United States. Likewise, the tropical bed bug has spread throughout the tropics in the last 10 years increasing its range to infest Australia and reestablishing populations in Singapore and other tropical nations where they had been previously eradicated. Because these insects have never completely disappeared from developing nations they have been continuously treated with many insecticide products over the last 50 years. This continuous pesticide pressure has selected for bed bug resistance, particularly to pyrethroids. These pyrethroid resistant populations present a unique problem in developed nations where public opinion and federal legislation has eliminated entire classes of insecticides from indoor use due to their perceived toxicity. Pyrethroids have been one of the few chemical classes that remain available for indoor use due to their low mammalian toxicity. As a result, pyrethroids are the most frequently used class of chemistry for bed bug control in the United States today. However, with increasing bed bug resistance these products will gradually become less effective at controlling new infestations. Because of the prevalence of bed bug resistance many researchers believe that the bed bug epidemic will become much more severe in the future.

The key to bed bug control in developed nations will ultimately be education. People will have to accept that bed bugs exist and learn how to avoid transporting bed bugs to their homes (from hotels, taxis, air planes, camp cabins, movie theaters, laundromats, day care centers, multiple unit housing, etc.) during the course of their daily activities. The ability of the average citizen to identify bed bugs and bed bug evidence will be critical for them to successfully protect themselves and their home from bed bug infestations.

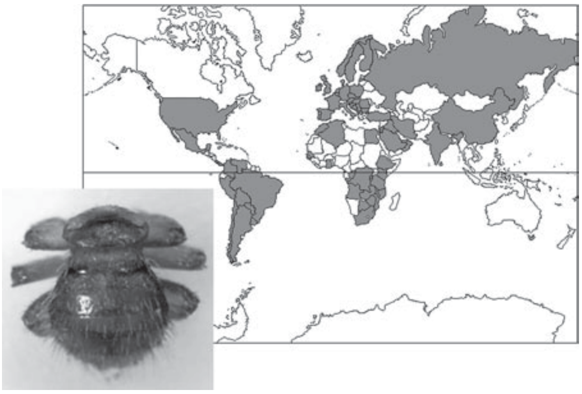
Bee Louse, Bee Fly, or Braulid, *Braula coeca* Nitzsch (Diptera: Braulidae)

JAMIE ELLIS
University of Florida, Gainesville, FL, USA

The bee louse, *Braula coeca* Nitzsch (Diptera: Braulidae), is a wingless fly that lives as a commensalist in western honey bee (*Apis mellifera* L.) colonies. Not much is known about the bee louse as its biology has been studied only irregularly since the 1920s. The fly is presumed to be harmless to its host, although this point is debatable. It is found in many countries, and because no true economic damage can be attributed to the fly, it probably poses a minimal threat to bees.



Bee Louse, Bee Fly, or Braulid, *Braula coeca* Nitzsch (Diptera: Braulidae), Figure 24 An adult *Braula coeca* (photo by James Ellis, University of Florida), and its worldwide distribution (from Ellis, Munn (2005) The worldwide health status of honey bees. *Bee World* 86(4):88–101).

Bee Louse Life Cycle and Behavior

Adult bee lice (Fig. 24) are small (<1.5 mm long) and are covered in spine-like hairs. They are round in shape and unlike most flies, have neither wings nor halteres. They are reddish-brown in color, which often leads to their misdiagnosis as varroa mites, *Varroa destructor*. Structurally, physically, and their location on the adult bee all are similar or the same for varroa. One noticeable difference between the bee louse and varroa is the presence of six legs on the bee louse while varroa has eight. Further, the adult bee louse has a raised appearance while varroa are flatter and more oval than the bee louse. Despite this, both are very small and difficult for most people to distinguish with the naked eye.

The eyes of adult bee lice are located just above the antennae. They occur as pale spots on the surface of the cuticle and are surrounded by pigmented chitinous rings. The terminal joint of a bee louse's 5-segmented tarsi is divided and modified with comb-like teeth, an adaptation that allows the fly to cling to bees. The thorax is very short. When viewed dorsally, it is less than half as long as the head, resembling an abdominal segment. The scutellum is absent.

Presumably, bee louse adults feed on nectar and pollen, as well as food and other excretions passed between adult bees trophallactically. Regarding the latter, bee louse adults often are found on the heads of workers, drones, and especially queens. More than 180 bee louse adults have been found on a single queen.

While on the head of its host, the fly will steal food from the mouth of its host as the host is fed, or is feeding another bee. There is some evidence that bee louse adults can induce regurgitation from the bees. They accomplish this by scratching the upper edge of the bee's labrum until the bee extends its tongue, at which time they will feed on food or other secretions that the bee offers.

Bee louse eggs are white, oval shaped, and have two lateral flanges. The flanges are flat and extend parallel to each other toward the long axis of the egg. The eggs range from 0.78–0.81 mm long and 0.28–0.33 mm wide without the flanges. Including flanges, the eggs average 0.84 × 0.42 mm (l x w). Female bee lice can oviposit a number of places in the bee nest (empty cells, brood cappings, debris on the floor) but only eggs oviposited on honey cappings hatch. The incubation period of the egg can range from 2–7.4 days, depending on the season.

After the incubation period, larvae emerge from the eggs oviposited on the waxy cappings of honey comb. Upon emergence, the larvae construct a tunnel under the cell cappings. This is the most noticeable damage attributed to the bee louse. Larvae tunneling under the cell cappings can visually taint the waxy cappings. Although some consider this damage, it is of minor economic importance. Regardless, the intersecting tunnels are a common sign of bee louse presence. Many beekeepers have seen this damage but few recognize it for what it is. It is believed that bee lice larvae feed on honey and pollen residues encountered while tunneling under the cell cappings. There is a modicum of control suggestions for the bee louse, largely because it is not considered a major pest. However, many of the synthetic pesticides used against varroa also demonstrate activity against the bee louse.

Larvae of the bee louse have three larval instars, ranging from 7.1–10.8 days. Following this time, the larvae become prepupae, a stage that can last from 1–2.7 days. During this time, the prepupa has a creamy-white appearance. The developing pupa is enclosed in the larval skin. The white/yellowish pupae are 1.4–1.7 mm long × 0.5–0.75 mm wide. The life cycle begins again as the adult fly emerges.

Bee Milk

Also called royal jelly, this is a substance that is secreted by *Apis* nurse bees from a gland on their head (the hypopharangeal gland), mixed with crop contents, and fed to bee larvae. All bees are fed bee milk for the first 3 days, but larvae destined to become queens are fed this material throughout their larval development whereas future workers are switched to nectar and pollen.

Bee Mites

Some species of mites (Acarina) can be serious pests of honey bees.

Bees (Hymenoptera: Apoidea: Apiformes)

JAMES H. CANE
USDA-ARS Bee Biology and Systematics Laboratory, Utah State University, Logan, UT, USA

Bees essentially are wasps that turned to pollen for dietary protein. A combination of distinctive features, taken together, make bees unique among insects. (i) Sociality, characterized by overlapping generations, cooperative brood care and a reproductive division of labor between fertile queens and sterile female workers, has evolved multiple times within the bee lineage. Presumptive intermediate stages of sociality are represented by at least several living species, and thus are available for observation, evolutionary study, and experimental manipulation. (ii) Bees, unlike most other herbivorous insects, dine solely on pollen and nectar or floral oils. This dietary transition from their carnivorous ancestors was accompanied by the evolution of branched body hairs which aid bees in picking up pollen, plus modification of the hind legs or ventral abdominal surface for carrying large loads of pollen. These features typically distinguish bees from wasps. (iii) Unlike most insects, each adult female of every non-parasitic bee species, whether social or not, rears her young in a nest. Thus, all food and shelter needs of bee larvae are provided by their mother, or one or more sisters if the species is social, or the host female if the species is parasitic. (iv) From the central nest, females daily venture forth repeatedly on spatially extensive foraging trips to acquire floral resources for their brood. These trips require remarkable navigational skills equaled by few other insect taxa. (v) As a consequence of their extensive foraging at flowers, bees have become the primary biotic agents of pollination for continental floras worldwide. No other animal group so dominates this, or the other great plant-animal mutualism, seed dispersal.

Evolutionary History

Bees (Hymenoptera: Apoidea: Apiformes) likely arose in the Cretaceous, perhaps 120 million years ago, when they diverged from the carnivorous habits of their closest relatives, the sand wasps (Hymenoptera: Apoidea: Spheciformes). Flowering plants (angiosperms) had made their debut by this time. Most paleontological material consists of bees entombed in amber (polymerized tree resins) millennia later. Specimens from the Eocene (40 million years ago) are common. They are typically workers of the stingless bees (Meliponini) that probably became mired while gathering resin to seal their nest cavities. These represent highly evolved social genera that remain extant today, suggesting a much earlier origin for bees. Tantalizing casts of much earlier fossil nest cells are also reported, but their identity remains controversial.

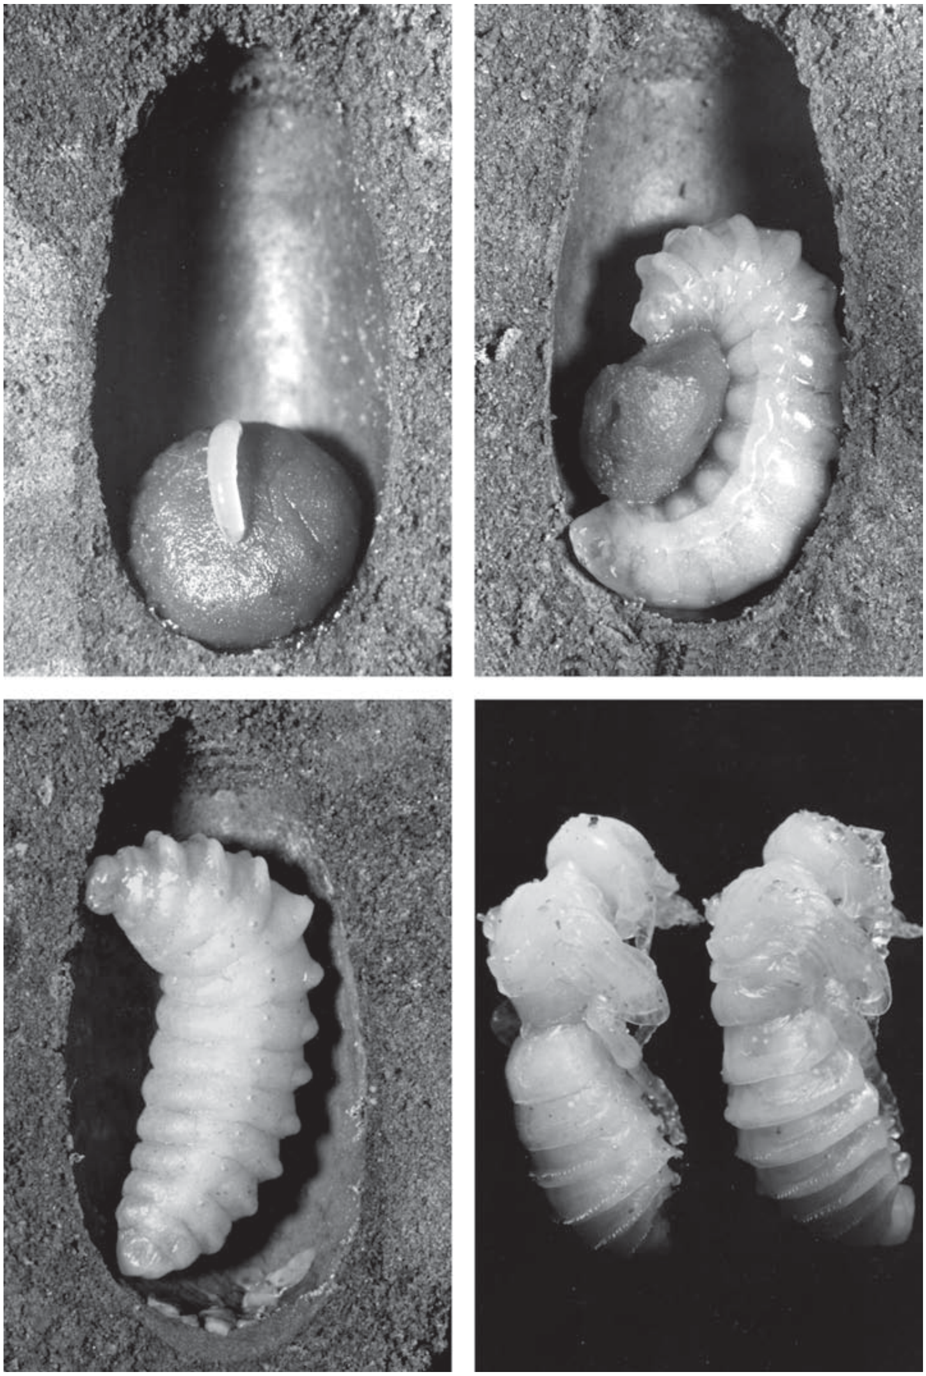
Diversity and Distribution

There are more species of bees today than the sum total of mammals, reptiles, amphibians and birds; 17,000 species of bees have been described, perhaps another 10,000 await discovery. They are distributed among only seven families. The largest genus (*Andrena*) has 1,400 described species; many have more than 100. Bees are native to all continents but Antarctica. Few species are found on isolated oceanic islands, but ranges of some hardy species extend well north of the Arctic Circle. Only social bees achieve maximum diversity in lowland tropical rainforests. Non-social (or solitary) species are most diverse in drier, more seasonal biomes of the world' s temperate zones. These include the Mediterranean Basin and areas of similar climate around the world (e.g., western South Africa, southern California, central Chile and Argentina, much of Australia) and the more vegetated, warm deserts (e.g., Sonoran, Chihuahuan and Colorado deserts of the southwestern U.S. and adjacent Mexico). Warmer grasslands also can be productive, such as the Great Plains of the U.S. In these regions, several hundred bee species can be easily expected in any given locality.

Development and Life Cycle

Like other insects with complete metamorphosis, bees pass through four discrete life stages (Fig. 25). Bee eggs are sausage-shaped. Those of the solitary, non-parasitic species can be proportionally huge for an insect; eggs of some large carpenter bees (*Xylocopa*) are 16 mm long. Non-social bee species are much less fecund than most insects, laying only 10–25 eggs in their lifetimes, averaging one to two per day. As with other Hymenoptera, progeny sex is determined by egg fertilization: male eggs remain unfertilized and are thus, haploid. Bee larvae are gently curved, soft, white, blind, largely immobile and defenseless grubs. Only specialized instars of some cleptoparasitic species are mobile and armed with powerful mandibles, adaptations that they use to assassinate host larvae before consuming the host' s provision masses.

Larvae of nearly all solitary species and most eusocial species receive an individual cache, or mass provision, of pollen moistened with nectar, or occasionally, floral oils. Provision shape and consistency varies from firm, spherical pellets to a soupy gruel on which the larva actually floats. Larvae pass through four molts (so five instars) to



Bees (Hymenoptera: Apoidea: Apiformes), Figure 25 **Bee life cycle, illustrated using the alkali bee, *Nomia melanderi* (Halictidae): (top left) egg atop a completed provision mass. Note the polished waterproof cell lining applied to the soil matrix; (top right) third instar larva feeding on remaining provision; (lower left) prepupa, the post-feeding larval resting stage; (lower right) two pupae (removed from their nest cells) (photos by William Nye).**

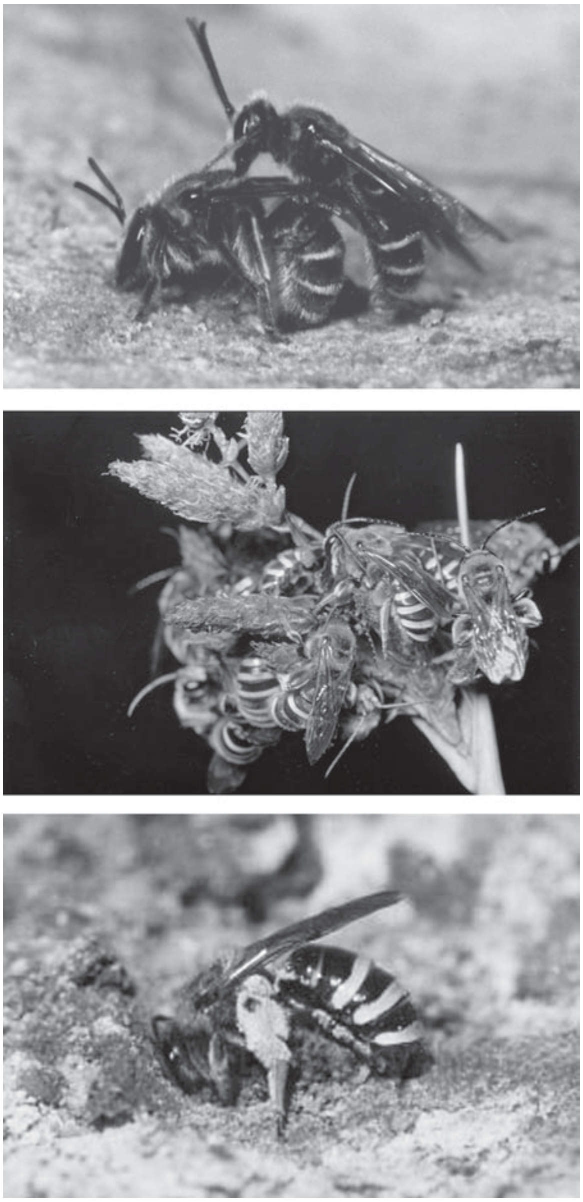
accommodate their rapid growth, consuming their provision mass in a few weeks. Larvae do not defecate until they are mature. Once the provision mass is consumed, larvae of many (but not all) species then spin a cocoon. The final larval stage is the prepupa, which is more robust and resistant to desiccation than the earlier instars, but still grub-like. This is the typical resting, or diapause, stage for those temperate-zone species whose single adult generation flies later in spring or summer. Unlike most other insects, bees do not weather inhospitable seasons as pupae. Rather, bee pupae are quite delicate, resembling waxen versions of the adult. If a bee species is one that flies in the early spring (allowing little warmth for further development), then the pupal stage lasts only a few weeks, yielding an adult that will remain in the cocoon (or nest cell) to overwinter. Some halictids (sweat bees), as well as bumble bees, emerge as adults, mate, and then disperse before overwintering.

Nesting

All larval bees live in a nest selected, constructed, maintained, defended and provisioned by their mother, sisters (social species) or host (parasitic bee). A genus of bee often can be recognized by its nesting substrate and nest architecture. Most bee species nest underground, typically excavating a central, cylindrical tunnel that is either partitioned into nest cells, or from which lateral tunnels branch that terminate in nest cells. Soil cliffs as well as more horizontal surfaces are used. Excavated soil on horizontal surfaces is often heaped in a small cone or delta of irregularly sized pellets, the "tumulus." Nest depths differ among species, ranging from a few centimeters to several meters if in sandier soils. Cells are often egg- or barrel-shaped, just large enough for a mother bee to fit with her assembled provision mass. Cell walls are commonly smoothed, even polished, usually with the addition of a secreted waxy or membranous waterproof lining, or alternatively, plant resin. Other bee species nest above ground, excavating pithy stems of plants or adopting abandoned tunnels chewed by wood-boring larvae of beetles and some other insects. Some carpenter bees (*Xylocopa*) can chew tunnels directly into sound wood. The highly social honey bees and stingless bees often build their nests in hollow tree cavities. Free-standing nests are made by a few paleotropical honey bees (pendant wax combs) and a few other bees (mostly orchid bees and some megachilids that use clay or resin).

Mating Biology

Male bees do not contribute to nesting (excavation, foraging, defense) (Fig. 26). With few exceptions, males are not welcome in the nest. They spend their days patrolling for receptive conspecific females, and their nights sleeping on flowers or vegetation, or in shallow burrows underground. Males of various species enhance their encounter rates with females using one or more search and/or advertisement strategies employing scent and vision. Among non-social species, males are often protandrous, emerging some days before females of the year. Males of floral specialists may patrol preferred floral hosts, especially if females of their species mate repeatedly during their lifetimes. Males also may patrol nesting sites; among species whose females mate but once and whose nests are aggregated, males may compete intensively to find freshly emerged virgin females, guided by the virgin female's scent. Conversely, males may apply scent-marks to attract females to a sort of trapline that males patrol. These can sometimes extend for hundreds of meters. Honey bees, some bumble bees and large carpenter bees maintain aerial territories. Some orchid bees reportedly form "leks" perfumed with scents synthesized from floral oils of orchids. A few recent cases report flightless males that linger in their natal nests to mate with their sisters. In general, courting and mating are brief affairs for bees. Most species are monandrous, each female mating but once in her lifetime. All



Bees (Hymenoptera: Apoidea: Apiformes), Figure 26

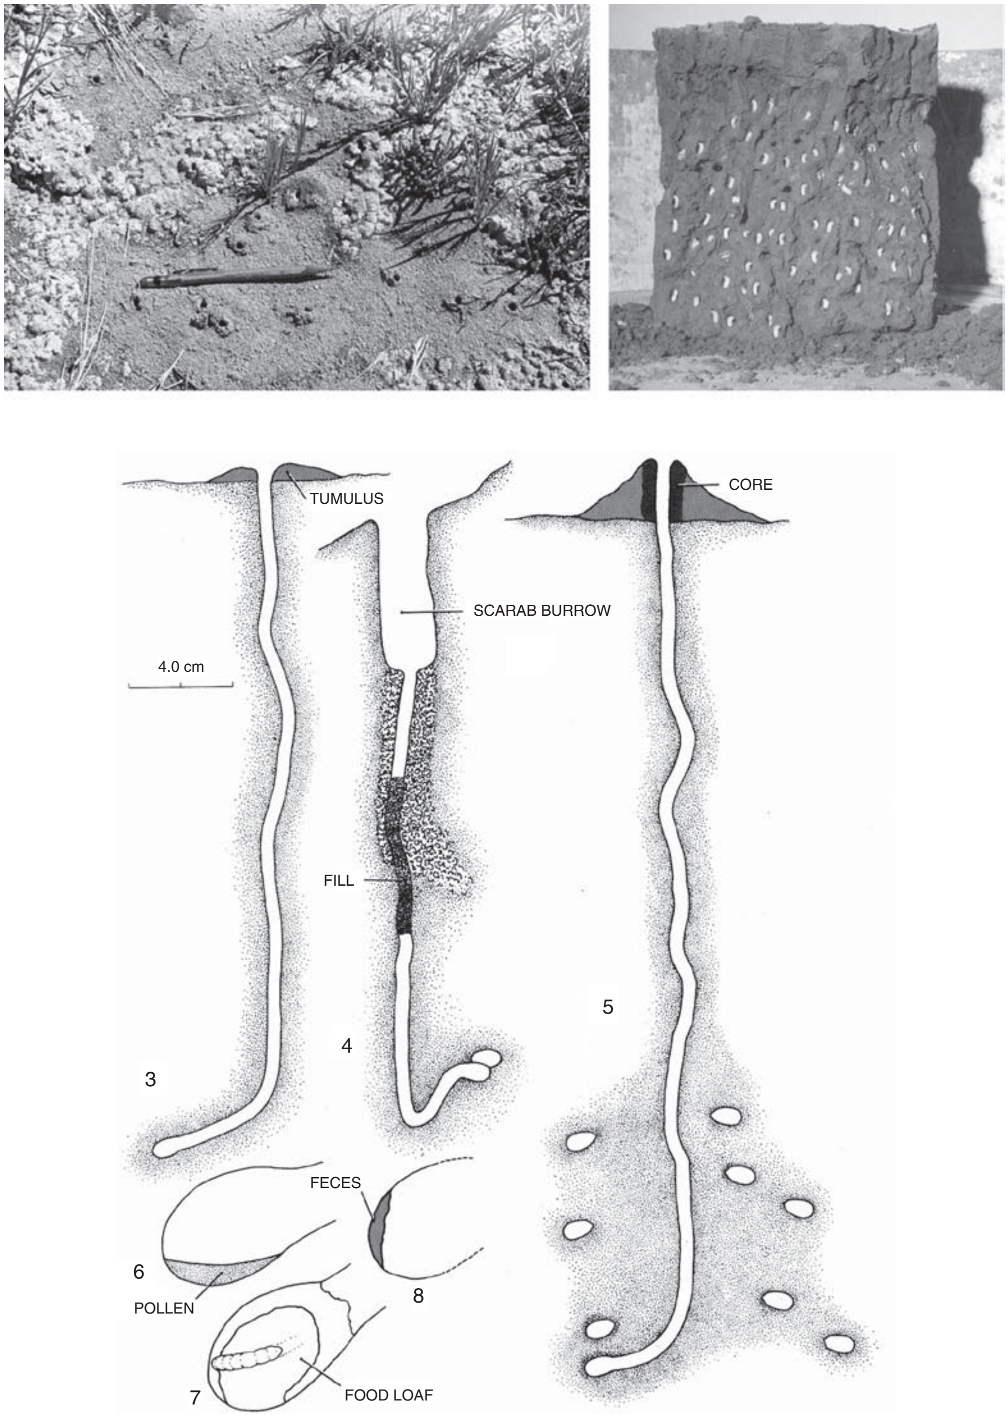
female bees are able to store live sperm to varying degrees; at the extreme, queens of social species store live male sperm for months or even years. Hence, sperm often outlive the male bees that produce them.

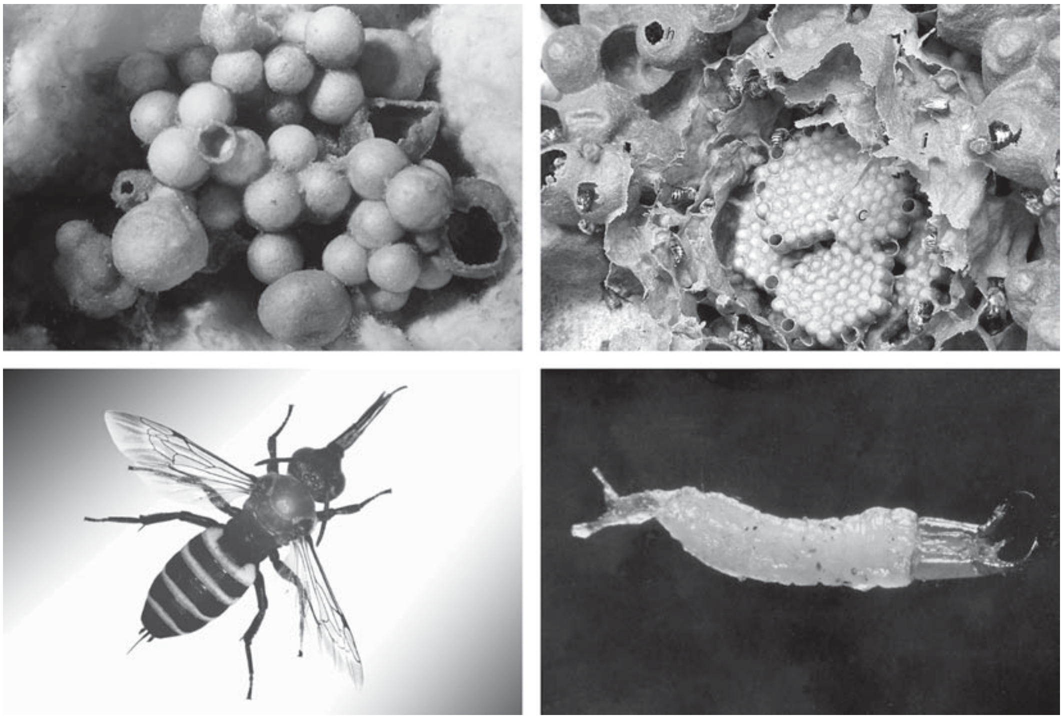
Sociality

Bees have lineages representing all degrees and hypothesized evolutionary steps of sociality, including reversion to solitary habits. Populations of a few species range from solitary to social depending on ecological circumstance. Less social arrangements include: communal species, wherein reproductive females sometimes share in a single nest's construction and defense but otherwise act solitarily; semisocial colonies founded by a group of (likely) sisters; subsocial species in which mothers actively care for growing daughters, that in turn may linger as adults to aid their mother; and several other much rarer arrangements. Many non-social species, especially ground-nesters, will nest gregariously (Fig. 27) in populous aggregations of hundreds to many thousands of individuals. During adult activity, these bee "cities" can be dramatic, with a dense traffic of foragers and patrolling males producing a loud, daylong hum.

The hallmarks of higher sociality ("eusociality") are an overlap of generations (mothers and daughters), cooperative brood care by workers, and reproductive division of labor (queens and workers). Workers are rarely, if ever, mated, and so, if they lay eggs, these are male. For primitively eusocial species (some sweat bees and carpenter bees, nearly all bumble bees), nests are founded in the spring by a single, mated female (gyne), as with solitary species. In rare cases, there are several foundresses. This mother bee builds a nest and prepares cells. Each cell receives a ball (Figs. 28 and 29) of pollen moistened with nectar and a single egg. The cell is then sealed. Emerging daughters remain with the nest rather than dispersing, helping their mother construct, provision and defend her nest. The original foundress, mother to the nest, then becomes the colony's primary egg-layer (queen). The more eusocial species have morphologically distinct queens and workers. Primitively eusocial colonies grow to, at most, a few hundred workers. Late in the summer or early autumn, reproductives are produced, and mate; only the future queens pass the winter in diapause.



Bees (Hymenoptera: Apoidea: Apiformes), Figure 27 **Gregarious nesting (above left) showing dark soil tumuli atop a square meter of soil surface (photo by James Cane); core (1 cu. ft.) of nesting soil (above right) from alkali bee nesting aggregation, showing numerous white prepupae in their individual nest cells (photo by William Nye); schematic (below) of an excavated subterranean nest of the neotropical bee *Tapinotaspis tucumana* (Apidae). Nests and enlarged views of three nest cells (Reproduced with permission from the American Museum of Natural History. Artwork by Jerome Rozen, Jr.).**

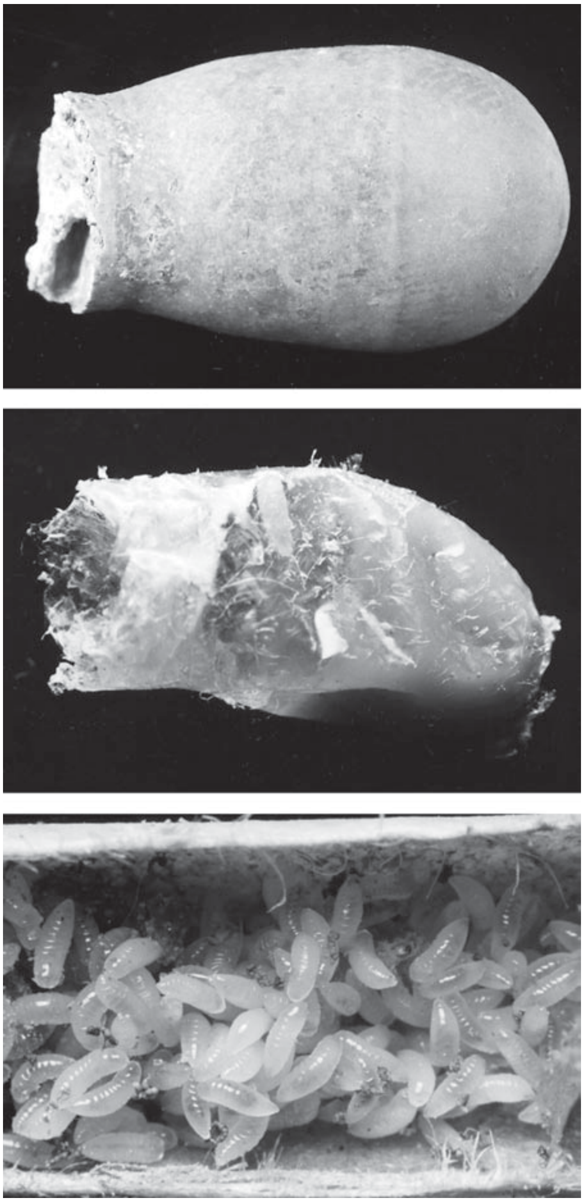


Bees (Hymenoptera: Apoidea: Apiformes), Figure 28 **Laboratory nest of the bumble bee *Bombus morrisoni* (Apidae) (above left) showing nest cells and honey pots clustered amid insulative cotton batting; Nest of a Brazilian *Melipona* sp. (Apidae)(above right). The thin pliable sheets of the involucrum (i) have been peeled back to reveal the topmost tier of horizontal combs (c). Between the involucrum and the wall of the cavity are the large pollen pots and honey pots (h). Honey is visible in those pots that remain open (Photo by James Cane); adult female of the cleptoparasitic bee, *Triepeolus dacotensis* (Nomadinae) (lower left). Note paucity of hairs, lack of pollen-transporting structures, and the exserted sting; first instar "assassin" larva of *Triepeolus dacotensis* (Nomadinae) (lower right). Note its long recurved mandibles, which are used to grip and kill the host egg or young larva. Subsequent instars resemble normal bee larvae (photos by William Nye).**

Only the stingless bees (Meliponini) and honey bees (*Apis*) are highly eusocial. Most reside in the humid tropics. Their colonies are tightly integrated and perennial, populated by thousands of workers headed by long-lived queens that are dependent on worker care. Their colonies reproduce by "fissioning," when swarms of workers accompany a queen to found a new colony.

Foraging

Except for queens and drones of highly eusocial species, all bees visit flowers. For males and individuals of cleptoparasitic species, it is only for self-maintenance and sometimes mates. All other females seek, gather and transport nutritious substances (typically pollen and nectar) and sometimes, nesting materials for their progeny. Species of honey bee size will regularly fly a kilometer or more to desirable bloom. Using the sun and local landmarks for navigation, they can then fly directly home at 15–25 kilometers per hour to find a nest entrance that is often no bigger than the bee, and, in the case of gregarious species, that is imbedded in an aggregation of hundreds or thousands of like-looking entrances of their conspecifics.



Bees (Hymenoptera: Apoidea: Apiformes), Figure 29 **Cast of nest cell of *Anthophora* (Apidae) (above); provisioned nest cell of ground-nesting *Colletes* (Colletidae), showing the thin, translucent membrane made of secreted polyesters (center); larvae of parasitic *Melittobia* wasps (Hymenoptera: Eulophidae) in nest cell of an *Osmia* bee (below) (photos by William Nye).**

Bees always take nectar at flowers. Nectar powers bees' flight and contributes carbohydrates and water to larval diets. Typical nectar sugars are glucose, fructose and sucrose. Few nectars are toxic. A retractable, complex proboscis allows bees to sip or lap nectar. A bee's access to nectar is constrained by body size, tongue length, and the flower's dimensions. Some carpenter bees, stingless bees and bumble bees regularly rob deep, tubular flowers of their nectar by perforating the corolla near its basal nectaries. Perhaps because bees can readily assess nectar volume, sugar constitution and its concentration, individuals and species can and will compare nectar yields of various flowering species, optimally choosing the most rewarding species at any given time. Some flowers, mostly tropical, secrete calorically rich oils rather than nectar. These are mopped or wiped up by bee species that have pads and "squeegees" of hairs specialized for the task, to be incorporated into larval provisions and sometimes, nest cell linings. Some ground-nesting species and many eusocial species synthesize and secrete their own calorically rich substances that they blend into progeny provisions.

Bees also seek pollen at flowers, which is their key dietary source of proteins, fats, minerals and sometimes starches, for themselves and their offspring. Pollen, of course, also contains the male gametes of flowering plants, so it really serves two reproductive purposes, plant ovule fertilization and bee reproduction. No effective dietary substitute for pollen has yet been devised for bees. Few animals match the nitrogen assimilation efficiency of bees, despite the indigestibility of the external shell, "exine," of pollen grains.

Pollen, in most cases, dusts the foraging bee as a powder that lodges in the vesture of branched hairs that envelop its body. Harvest may be enhanced by buzzing, biting, scraping and scrabbling. Many specialized structures, hairs and behaviors of foraging females then work in concert to efficiently groom and accumulate pollen from the body for transport. Pollen is transported in a brush of hairs called a "scopa," often on the hind legs (or under the abdomen of megachilids). A few taxa carry pollen internally in their crop (e.g., Hylaeus). Bumble bees, honey bees, orchid bees and stingless bees carry pollen in a pollen basket, or "corbicula," on the hind leg, a smooth, slightly concave surface surrounded by guard hairs that holds a damp pollen pellet.

Anthers of some flowers (e.g., tomato and blueberry) shed their pollen through apical pores or slits like a salt shaker. These require vibration to dispense their content of pollen. Some bees shake this pollen free by battering or stroking the anthers with their legs, while others bite the anthers to squeeze out pollen. Species of many genera can shiver their flight muscles while on the flower, sonicating these anthers to eject their content of pollen. This buzzing is audible. The effect can be duplicated with a vibrating tuning fork. Bumble bees frequently use this method of pollen extraction, even for flowers with anthers of normal morphology.

Many bee species are floral generalists ("polylectic"), taking pollen from many taxa of flowers, a necessity for the long-lived colonies of social bees. Foraging individuals often will display floral constancy, selectively visiting sequences of conspecific flowers on a given foraging trip, despite the availability of alternatives. Such preferences are labile, perhaps reflecting learning or memory constraints. In contrast, a third or more of the non-social species in a community may be "oligolectic." This is a fixed species-specific predilection to collect pollen from the same small subset of available flowering species, commonly one or several related genera within a plant family. Such unwavering fidelity is particularly common among desert bee faunas and vernal bees of the temperate zone. The reason(s) for oligolecty are not fully understood. In some cases, oligoleges seem to accumulate at reliable pollen hosts that produce generous quantities of pollen (e.g., willow, sunflowers, creosote bush, and blueberries). For other species, the association seems to reflect phenological specializations (e.g., crepuscular flowers, early spring blooms) or more or less private floral resources eschewed by other species (e.g., oil flowers of *Lysimachia* and their associated *Macropis* bees). Unlike insect herbivory, host chemical defenses rarely, if ever, dictate floral specialization by bees.

Pollination

Bees are the most important and cosmopolitan biotic pollination agents in most continental habitats, and for most prevalent plant families, such as the Asteraceae, Fabaceae, Lamiaceae, Orchidaceae, Rosaceae and Solanaceae. Few nocturnal flowers are pollinated by bees. Reciprocal co-evolution between bees and their flowers seems, at best, diffuse in nearly all cases, although adaptations that enhance attraction, resource extraction and pollination are evident everywhere. Most collected pollen ends up in a larval provision, not on a flower's stigma, but bees are still vastly more efficient than wind in moving pollen to receptive flowers. Bees are essential pollinators of some vegetable crops (or their seeds), many prominent fruit and seed-oil crops, forage legumes and a few nut or fiber crops. Crops that contribute the starches and refined sugars to the human diet are typically wind-pollinated or vegetatively propagated. Home and market gardeners benefit from pollination services of wild bees. In large mechanized agriculture, however, only hived honey bees can generally supply the millions of inexpensive foragers needed for pollination. In the past half-century, though, a growing minority of tree fruit, forage seed and greenhouse crops are benefiting from pollination services of managed solitary bees and bumble bees (rather than honey bees), a trend that seems likely to continue, given their often superior pollination efficiencies and the devastating effects of new pest problems suffered by honey bees.

Diseases, Parasites and Predators

Among insects, the superior life expectancies of bees result largely from superior maternal care of offspring. Females actively deter predators and parasites by biting, stinging and by use of chemical repellents. Nest cells are waterproofed and possibly fumigated with applied glandular secretions or plant resins. Despite such extensive maternal care and defenses, bees are nonetheless plagued by diseases, parasites and predators. Feeding larvae, in particular, succumb to various viral, bacterial and fungal diseases. Microorganisms commonly spoil provision masses, too. Nematodes and mites (mostly external) are ubiquitous bee parasites. Many larval insects devour the contents of bee nests, including clerid and meloid beetles. Others are internal or external parasitoids, including chalcidoid wasps, bombyliid flies and strepsipterans. The elaborate structural defenses of stingless bee nests attest to the intense predation pressures of ants and social parasites of the tropics. Adult bees are subject to the myriad predators of other mobile insects.

Cleptoparasitic, or cuckoo bees, are analogous to cowbirds and European cuckoos, surreptitiously inserting their eggs into the provisioned nest cells of their bee hosts. There are thousands of cleptoparasitic species, most associated with specific genera of host bees. They directly or indirectly exterminate the host larva, ultimately consuming its provision. Adult females spend much of the day searching for and evaluating host nests. They display numerous subtle adaptations to conceal their eggs from the host female and repair damage incurred to nest cells during oviposition. Odor concealment and mimicry may be practiced as well. Social bee species (other than *Apis*) host their own parasitic bees, often evolving from within their host's genus. Psithyrus queens usurp bumble bee nests, enslaving unwitting host workers to produce parasite progeny. Robber genera among the stingless bees (e.g., *Lestrimelitta*) raid host nests for honey and pollen.

Conservation

Human activities also can harm bees. Bees tend to be sensitive to broad-spectrum insecticides, which if used indiscriminately or carelessly by farmers or homeowners during bloom, can poison adults, or later, their progeny. No genetic resistance has been shown. Herbicides, when used to kill wildflowers, remove available forage for bees. Habitats and constructs that are extensive, monotonous and inhospitable (e.g., lawns, parking lots, wheat fields) fail to fulfill bees nesting and/or foraging needs, although bees can readily fly through a finer patchwork mosaic of these features if interspersed with favorable nesting and foraging habitats. Unlike accidental or misguided introductions of plants, vertebrates and shellfish, exotic bees have generally been of little ecological consequence, although ill-guided international trade (or smuggling) of honey bees and bumble bees has been disastrous in some recent cases. The greatest risk attending intercontinental transport of live bees is likely to be the inadvertent transport of diseases and pests, such as those that are currently devastating apiculture, especially *Varroa* and tracheal mites.

The Families of Bees

Seven families of bees are currently recognized. The Colletidae, Halictidae, Andrenidae, Melittidae and Stenotritidae are grouped as short-tongued bees, while the Megachilidae and Apidae are long-tongued bees. The five more common families are considered here.

Family Colletidae: Yellow-Faced, Masked and Plasterer Bees

Distribution: Worldwide, but Greatest Diversity is in the Southern Hemisphere, Including Australia. This is probably the oldest extant bee family. No studied species nests socially. Pollen is transported dry in hair brushes of the hind leg (e.g., *Colletes*) or mixed with nectar and carried internally in the crop (e.g., *Hylaeus*). Their tongue tips are distinctively bilobed. They nest underground, or rarely, in mortar and even sandstone (e.g., *Colletes*), in pithy stems (e.g., *Hylaeus*), or adopt holes in wood. The plasterer bees are so named for the peculiar, secreted, transparent, polyester membranes used to waterproof their nest cells; those of *Hylaeus* contain silk strands. *Hylaeus* (=*Prosopis*) (570 species) and *Colletes* (330 species) are the commonly encountered genera in the U.S. and Europe; *Leioproctus* has 300+ species in Australia and temperate South America; *Nesoprosopis* has radiated in the Hawaiian Islands, where many of its species appear to be endangered. This subgenus contains the only cleptoparasites in the family. *Hylaeus* may be the most cosmopolitan of all bee genera, found on all continents but Antarctica as well as many oceanic islands, their dispersal facilitated by their stem-nesting habits.

Family: Andrenidae

Distribution: Worldwide, Except Australia, Rare in the Moist Tropics. Species of this family nest underground. The family includes two enormous genera: *Andrena* (1,400 species, ubiquitous in north temperate regions) and *Perdita* (600 or more species, mostly of the American Southwest and northern Mexico). *Perdita* are small-bodied, including the tiniest bee, *Perdita minima* (slender, 2 mm long, 1/3 mg). A few species of *Perdita*, *Andrena* and *Panurgus* nest communally; no studied andrenid is social. There are no cleptoparasitic species in this family. Pollen is carried on the hind legs, and in some species, is moistened with nectar. Probably all *Perdita* are oligolectic, as are the majority of *Andrena* and species of other genera.

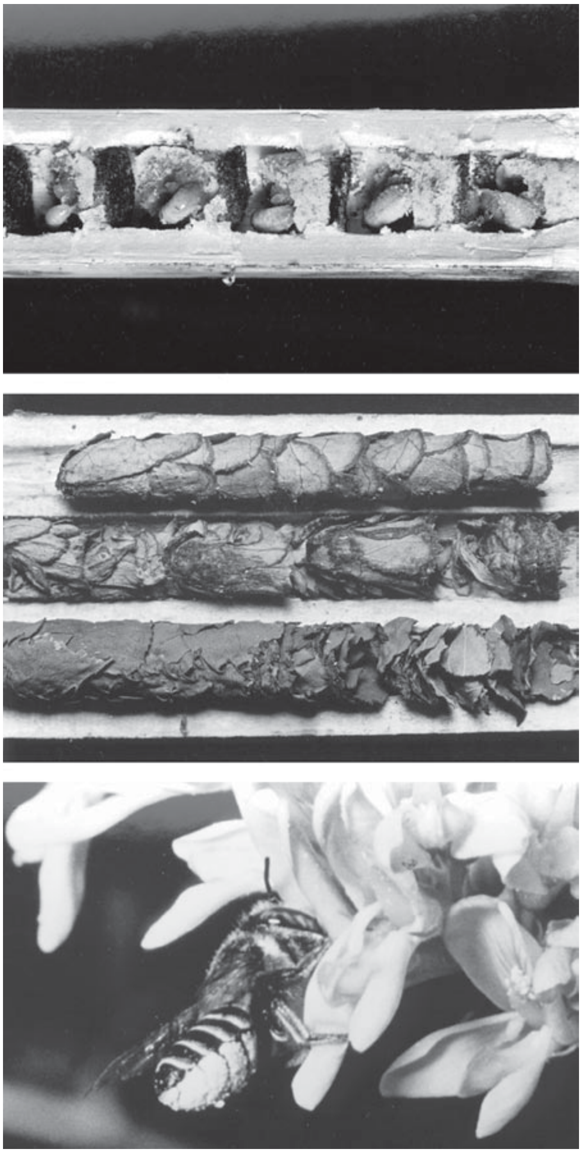
Family Halictidae: Sweat Bees, Alkali Bee, etc

Distribution: Worldwide. Most halictids are small or medium sized. Some taxa are commonly known as sweat bees because they alight on people's skin to lap up sweat for the salts that it contains. Many halictids are darkly colored, others are a brassy or brilliant emerald green. Some *Nomia* have striking pearly green or orange abdominal bands. Pollen is carried on the hind legs, typically dry. Their nests are burrows in soil, or occasionally, rotting wood, sometimes in dense aggregations. The common, cosmopolitan cleptoparasite genus in the family is *Sphecodes* (250 species). Halictids illustrate an unprecedented diversity of social organization, particularly among the 1,000+ species of *Lasioglossum*.

The alkali bee, *Nomia melanderi*, is the world's only intensively managed ground-nesting bee. In regions of the western U.S., alfalfa (=lucerne) seed growers construct large subirrigated nest sites with salt-crusted surfaces. Densities of 400 nests/m^2 over a hectare or more can be obtained with this gregarious bee. Nest sites can remain populous for more than 50 years. Another effective alfalfa pollinator, *Rhophitoides canus*, is less intensively managed in regions of eastern Europe for alfalfa seed production.

Family Megachilidae: Leaf-Cutting Bees, Mason Bees, Carder Bees and Others

Distribution: Worldwide. The common names for groups in this large family refer to the remarkable diversity of exogenous materials that they typically use to line or construct their nest cells. Many nest above ground in twigs, stems and wood, and will readily adopt drilled holes in these substrates (termed "trap nests"). A few even nest in abandoned snail shells. *Megachile* and others line their nest cells, and partition and cap their nest tunnels, with strips and disks neatly cut from leaves or petals; other species build with leaf pulp, resin, nectar, mud, plant hairs, or pebbles. Foraging females of non-parasitic species can be easily recognized, as they are unique in (Fig. 30) carrying pollen in a scopa solely beneath the abdomen. Nearly all species are solitary. There are several cleptoparasitic genera (notably *Coelioxys*, 300 species). *Megachile* is a cosmopolitan genus (900+ species); *Osmia* (300 species) are common in the Northern Hemisphere. The world's longest bee is *Megachile pluto* at 39 mm. Many megachilids are important pollinators, especially for plants in the



Bees (Hymenoptera: Apoidea: Apiformes), Figure 30 **Nest of *Osmia* (Megachilidae) in reed, split open to reveal partitioned nest cells each occupied by a single larva with its mass provision of pollen moistened with nectar (above); three nests of a leaf-cutting bee (*Megachile*: Megachilidae), consisting of a linear series of cells each wrapped with cut leaf pieces (center); female of the alfalfa leaf cutting bee, *Megachile rotundata*, visiting alfalfa flowers (below). Note the pollen load carried dry in a scopa of hairs beneath her abdomen. To the right is a "tripped" flower, the staminal column pressed against the banner petal. Good alfalfa pollinators trip the flowers frequently (photos by William Nye).**

pea and clover family (Fabaceae). The cavity-nesting species are the most successful stowaways in transoceanic travel.

The alfalfa leaf-cutting bee, *Megachile rotundata*, came to the U.S. from the Near East as a stowaway before 1937. Burgeoning feral populations of this bee prospered in the semi-arid western U.S. The species' value as an alfalfa pollinator soon became apparent. A multimillion-dollar industry developed in North America for cheaply mass rearing of this species for sale to alfalfa seed growers. Wooden or foam boards, each with several thousand nesting holes, are placed in shelters in alfalfa fields. Each shelter receives 50,000 or more females. This bee is versatile, pollinating other crops too, such as hybrid canola and various vegetable seeds.

Several species of mason bees in the genus *Osmia* are more recently being managed in Japan, the U.S. and Europe to pollinate tree crops in the rose family, such as apples, plums, sweet cherries and almonds. One of these species has been dubbed "the blue orchard mason bee." Only 250–300 blue orchard bees are needed to pollinate as many apple or cherry flowers as two to three hives of honey bees.

Family Apidae: Carpenter Bees, Orchid Bees, Bumble Bees, Stingless Bees, Honey Bees

Distribution: Worldwide. This family is large, ecologically diverse and continues to be taxonomically perplexing. One or more tribes of this family is most closely related to the lineage that evolved into today's highly eusocial Apinae. Many cleptoparasitic species are included (1,600 species). This unwieldy group is best recognized by its constituent tribes, of which there are many. Select ones are treated here.

Subfamily Nomadinae: Cuckoo Bees

Distribution: Worldwide. This is the largest group of cleptoparasitic bees (Nomada alone has 800 species). Most species are glossy, quite hairless and wasp-like with a rugged exoskeleton. They can commonly be seen patrolling low over the ground for host nests.

Subfamily Xylocopinae: Carpenter Bees

Distribution: Worldwide. Carpenter bees typically excavate nests above ground in pithy stems or even bore into sound wood. Cells are unlined. Most species are solitary, but some are subsocial or even primitively eusocial. Females overwinter as mated adults; they can be very long-lived. The large carpenter bees (*Xylocopa*) are primarily tropical. They can resemble bumble bees, but have a smooth, glossy dorsal abdomen and transport their pollen dry. *Xylocopa* pollinate commercial passion fruit; they are also adept nectar robbers. Males of some *Xylocopa* hover for hours in aerial territories, pursuing any and all small airborne objects. The small carpenter bees (*Ceratina*) nest in dead stems of roses, sumac, elderberry and some grasses.

The Corbiculate Apinae: Orchid Bees, Bumble Bees, Stingless Bees, Honey Bees

Distribution: Worldwide. This quartet of tribes contains all of the highly eusocial bees, as well as the primitively eusocial bumble bees and the mostly solitary orchid bees. All secrete wax, which they incorporate into their nest structures. They carry pollen on a specially adapted, smooth region of the hind leg referred to as the pollen basket or "corbicula." Taxonomists formerly grouped these four tribes as a separate family.

Tribe Euglossini: Orchid Bees

Distribution: New World Tropics, from Central Mexico into Argentina. The orchid bees are so named because the males collect scents from orchid flowers and, in the process, pollinate the orchids. The orchids provide no food, but rather produce scents which male euglossines collect and place in a glandular pocket of their enlarged hind legs. These perfumes attract mates. Several species have intricate male displays. These large bees are flying jewels, sporting metallic emerald, cobalt, violet and bronze colors as well as red, orange and yellow. They are important pollinators of many endangered tropical orchids and probably the Brazil nut, too.

Tribe Bombini: Bumble Bees

Distribution: The Americas, Europe, Asia, North Africa. Bumble bees (*Bombus*) are large, furry, often black and yellow, orange or red bees. They are common in the world's cooler climates, following mountain ranges into the tropics. Few species live in deserts or rainforests. They nest shallowly underground, often in abandoned rodent nests, or sometimes above ground, either in tree cavities or, less commonly, beneath a leaf heap on the forest floor. They actively brood larvae to warm them, and fan their wings at the colony entrance to cool its contents. Few other bees can fly in cooler weather. *Bombus* consists of primitively eusocial species and a lesser number of social parasites. They are important pollinators in alpine, boreal and subarctic habitats. Queens of species such as *B. nevadensis* and *B. dahlbomi* are the world's most massive bees, weighing a gram or more (the weight of a raw almond).

Bumble bees are important pollinators of several crops, especially red and crimson clover. The honey bee proboscis is too short to probe such deeply tubular flowers. Bumble bees, having longer tongues, work these flowers efficiently. Bumble bees have been imported into New Zealand and Chile for clover pollination. They aid in the pollination of several other crops like alfalfa, and several fruits, especially blueberries, cranberries and kiwi. A multimillion-dollar global business has emerged from Europe for year-round propagation of disposable bumble bee colonies to pollinate greenhouse vegetables like tomatoes, peppers, eggplants and squashes. Introduction of these few managed species outside of their native ranges can lead to feral populations that pose problems for native *Bombus* and perhaps other bees.

Tribe Meliponini: Stingless Bees

Distribution: Old and New World Tropics. The stingless bees are highly eusocial, and as a group, exhibit a sweeping diversity of adaptations and natural history traits. Their permanent colonies can be populous, containing between 300 and 80,000 workers. Although stingless, many can defend their nests with irritating bites sometimes accompanied by caustic secretions. Queens are morphologically distinct from workers, their status sometimes determined genetically, in other cases as an individual larva's reproductive gamble. Of the 260 known species, 70% are found in Central and South America. They are the most common insects in Dominican and Baltic amber.

Stingless bees usually build nests in tree hollows, although some species nest on exposed surfaces, in underground cavities, or in termite or ant nests. Workers fashion a hard shell of "batumen" for the nest, consisting of wax blended with resin, mud or vegetation. Intricate nest entrance platforms and tubes are fashioned from wax, resin, or even plant latex. Within this shell, honey and pollen are stored in large irregular waxen pots. These rim the brood chamber, whose exterior is delineated by layers of pliable, delicate sheets of the "involucrum," made of insulative wax imbued with resin. Within this chamber are the waxen combs dedicated to brood rearing, grouped in horizontal tiers supported by thin pillars, reminiscent of nests of hornets or yellow-jacket wasps. Cells are typically mass provisioned with pollen, honey, and in some genera, glandular secretions (in a few cases, consisting of digested carrion). Some genera (e.g., *Lestrimellita*) rob nests of other stingless bees for their honey and pollen stores.

Colony fission is unlike *Apis*, because for meliponines, the new home is selected and furnished before the swarm issues from the parent colony. Workers assemble a complete new nest using materials transported from the parent colony. Only then does a group of workers and new queen fly to the new nest. The old queen is too large to fly and remains with the parent colony and its workers.

Workers of some stingless bees recruit nestmates to food sources, but in ways different from *Apis*. Scouts of some species scentmark trails from productive flowers to the nest, depositing mandibular gland secretions on surfaces every few meters. Returning to the nest, this scout buzzes loudly; the longer the buzz, the greater the distance of the food from the colony. The scout's behavior excites others which follow the odor trail to the resource. This method of recruitment communicates not only the direction and distance of food from the nest, but can lead other foragers directly to the food at any height by means of the odor trail. This three-dimensional road map is especially adaptive in towering tropical forests where flowers are frequently found high in the leafy canopy.

Stingless bees benefit people in several ways. In the Neotropics, *Melipona* colonies are cultured for honey in special wooden hives, although yields are meager (2–5 pounds per year). Stingless bees pollinate numerous tropical crops, but their economic impact has not been widely estimated. Stingless bees are promising pollinators for greenhouse crops.

Tribe Apini: True Honey Bees

Distribution: Europe, Asia, Africa, Now Introduced to all Continents Except Antarctica. There are 11 currently accepted species of true honey bees, all of the genus *Apis*. These are very different from all other bees, such that their evolutionary origins and ancestry remain unresolved. The genus is largely restricted to tropical Asia. Taxonomic diversity is centered in Indonesia, Malaysia and the Philippines, where new species continue to be discovered. Only the familiar western honey bee or "hive" bee, *A. mellifera*, is also native to Europe, northern Asia, and most of Africa. Its colonization of cooler regions was facilitated by its honey storage habits that fuels the workers' warming of their brood. Because we value this species for honey, wax and pollination, and can manage it in transportable hives, it has been further introduced throughout most of the world.

The western honey bee is among the most studied animals on the planet. Certainly their hallmark behavior is the remarkable abstract dance language performed by foragers and scouts for precisely communicating distance, direction and quality for resources, translating the direction of gravity into celestial bearings. Once thought unique to *Apis mellifera*, this and other behaviors now have been observed and studied for some of the lesser-known species of *Apis*, too.

Colony activities of *Apis* require sophisticated coordination. Much of the information is communicated olfactorily using pheromones. Like the Meliponini, all *Apis* are highly eusocial, maintaining populous perennial colonies. Queens, drones and workers are morphologically distinct. Among bees, only worker *Apis* have a barbed sting that lodges in the skin and continues to pump venom even after the worker bee has been killed and swept away. Colonies reproduce by fissioning, again like stingless bees, but in *Apis*, it is the old queen that departs with the swarm, whose workers then scout out a suitable nesting site at which they must construct their combs unassisted by the parent colony. This seems a riskier strategy, but it does allow swarms to disperse more widely. Honey bees thermoregulate their colonies using evaporative as well as convective cooling. Some tropical species undertake mass defecation flights to further nest cooling. Only *Apis* produce the familiar waxen vertical combs of uniform hexagonal cells that are reused over and over to house pollen, nectar (as honey) or progeny, although the wax itself cannot be recycled. Very unusual for bees, larval honey bees are fed progressively rather than with a cache of food, which together with the uniform comb dimensions, yields adults of very consistent size.

Species of *Apis* can be assigned to one of three groups, based on body size and nesting habits. Two dwarf honey bees, exemplified by *A. florea*, have small colonies of a few thousand small workers that construct beneath a branch a single exposed comb the size of a waffle. The top of this comb is broadened horizontally; recruitment dances performed on this surface are oriented simply in the direction of the food source. Several giant honey bees (e.g., *A. dorsata*) also build a single exposed vertical comb, often in conspicuous groups, but beneath a stout branch or cliff. Living curtains of the huge workers envelop the massive comb; when disturbed, they pour off *en masse* to assail any intruder. They are nonetheless robbed for honey. The remaining species of *Apis* build nests that consist of multiple wax combs housed in a hollow tree or rock cavity. Cavities enhance defense and insulation, but present problems with ventilation for temperature, humidity and atmospheric control. The most familiar representatives of this group are *A. cerana* and *A. mellifera*, which share many similarities, including their management in hives.

Beesoniidae

A family of insects in the superfamily Coccoidae (order Hemiptera).

► Bugs

Beeswax

Beeswax is produced by *Apis* bees. It is produced only by young worker bees. Beeswax consists of fatty acids, esters, and hydrocarbons, and is secreted from glands on the ventral surface of the abdomen. The beeswax is used by the bees to construct honeycomb cells, in which their young are raised. After removal of honey from the honeycomb, the wax is purified and used for many products, particularly candles, wood furniture polish, shoe polish, lubricants, and skin treatments.

Beet Armyworm, *Spodoptera exigua* (Hübner) (Lepidoptera: Noctuidae)

JOHN L. CAPINERA
University of Florida Gainesville, FL, USA

Beet armyworm is a tropical insect, native to Southeast Asia. It is now found around the world, except for South America. Because it is a tropical insect, and lacks a diapause mechanism, it can overwinter successfully only in warm areas or in greenhouses. Daytime temperatures below 10°C are deleterious, and it rarely overwinters in areas where frost kills its host plants. Despite its inability to overwinter in cold areas, beet armyworm nevertheless invades temperate areas annually. Despite this invasive potential, however, it is not normally considered a threat in temperate areas, except sometimes in greenhouses.

Life History

Seasonal activity varies considerably according to climate. In warm locations, all stages can be found throughout the year, although development rate and overall abundance are reduced during the winter months. The life cycle can be completed in as few as 24 days, and six generations have been reared during 5 months of summer weather in Florida. However, generation times of 50–126 days have been observed, with a total of five generations annually, in southern California.

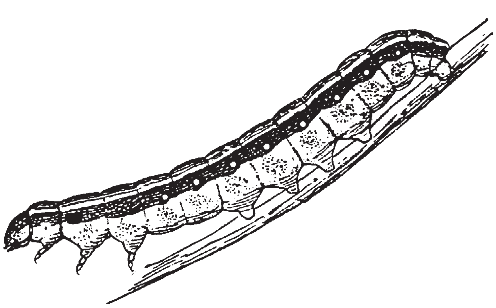
Eggs are laid in clusters of 50–150 eggs per mass. Females may deposit over 1,200 eggs during their lifetime, but normal egg production is about 300–600. Eggs are usually deposited on the lower surface of the leaf, and often near blossoms and the tip of the branch. The individual eggs are circular when viewed from above, but when examined from the side the egg is slightly peaked, tapering to a point. The eggs are greenish to white in color, and covered with a layer of whitish scales that gives the egg mass a fuzzy or cottony appearance. Eggs hatch in 2–3 days during warm weather, but the incubation period is extended to about 4 days when it is cool. The developmental threshold for eggs is estimated at 12.4°C.

Normally there are five instars, although additional instars are sometimes reported. Duration of the instars under warm (summer) conditions is reported to be 2.3, 2.2, 1.8, 1.0, and 3.1 days, respectively, and at constant 30°C, instar development time was reported to be 2.5, 1.5, 1.2, 1.5, and 3.0 days, respectively. Total larval development time is also influenced by diet quality. The developmental threshold for larvae is estimated at 13.6°C. Only 1 mm long at hatching, the larvae attain a mean length of 2.5, 5.8, 8.9, 13.8, and 22.3 mm during instars 1–5, respectively. Head capsule widths average 0.25, 0.45, 0.70, 1.12, and 1.80 mm, respectively.

The larvae are pale green or yellow in color during the first two instars, but acquire pale stripes during instar 3. During instar 4, larvae are darker dorsally, and possess a dark lateral stripe. Larvae during instar 5 are quite variable in appearance, tending to be green dorsally with pink or yellow color ventrally and a white stripe laterally. A series of dark spots, dashes or triangles (Fig. 31) is often present dorsally and dorsolaterally. Sometimes larvae are very dark in color. The spiracles are white with a narrow black border. The body is practically devoid of hairs and spines. It is easily confused with other caterpillar pests.

Initially the larvae of beet armyworm are gregarious, feeding as a group and skeletonizing plant foliage. As they mature they become solitary and quite mobile, often traveling from plant to plant. Cannibalism may occur when larvae are at high densities or feeding on food low in nitrogen.

Pupation occurs in the soil. The larva generally constructs a pupal chamber near the soil surface, digging only about one cm beneath the surface. The chamber is constructed from sand



Beet Armyworm, *Spodoptera exigua* (Hübner) (Lepidoptera: Noctuidae), Figure 31 Mature larva of beet armyworm, *Spodoptera exigua* (Hübner).

and soil particles held together with an oral secretion that hardens when it dries. The pupa is light brown in color and measures about 15–20 mm in length. Duration of the pupal stage is 5–7 days during warm weather.

The moths are moderately sized, the wing span measuring 25–30 mm. The forewings are mottled gray and brown, and normally with an irregular banding pattern and a light colored bean-shaped spot. The hind wings are a more uniform gray or white color, and trimmed with a dark line at the margin. Mating occurs soon after emergence of the moths, and oviposition begins within 2–3 days. Oviposition extends over a 3–7 day period, and the moths usually perish within 9–10 days of emergence.

This insect has a wide host range, occurring as a serious pest of vegetable, field, and flower crops; even trees are sometimes attacked. Among susceptible vegetable crops are asparagus, bean, beet, broccoli, cabbage, cauliflower, celery, chickpea, corn, cowpea, eggplant, lettuce, onion, pea, pepper, potato, radish, spinach, sweet potato, tomato, and turnip. Field crops damaged include alfalfa, corn, cotton, peanut, safflower, sorghum, soybean, sugarbeet, and tobacco. Weeds also are suitable for larval development, including such common plants as lamb's-quarters, *Chenopodium album*.; mullein, *Verbascum* sp.; pigweed, *Amaranthus* spp.; purslane, *Portulaca* spp.; Russian thistle, *Salsola kali*; parthenium, *Parthenium* sp.; and tidestromia, *Tidestromia* sp. Although the host range is wide, there are significant differences in suitability even among hosts considered to be suitable.

Numerous natural enemies have adapted to this pest. Among the most common parasitoids are braconid wasps, and the tachinid *Lespsia archippivora* (Riley) (Diptera: Tachinidae). Predators frequently attack the eggs and small larvae; among the most important are minute pirate bugs, *Orius* spp. (Hemiptera: Anthocoridae); bigeye bugs, *Geocoris* spp. (Hemiptera: Lygaeidae); damsel bugs, *Nabis* spp. (Hemiptera: Nabidae); and a predatory shield bug, *Podisus maculiventris* (Say).

Pupae are subject to attack, especially by ants. Fungal diseases, *Erynia* sp. and *Nomurea rileyi*, and a nuclear polyhedrosis virus also inflict some mortality. The important mortality factors vary among crops, and among geographic regions. None except the nuclear polyhedrosis virus are highly specific to beet armyworm, which may explain why they are not especially effective. Virus is considered to be the most important mortality factor in Mexico.

Damage

Larvae feed on both foliage and fruit. Young larvae feed gregariously and skeletonize foliage. As they mature, larvae become solitary and eat large irregular holes in foliage. They also burrow into the crown or center of the head on lettuce, or on the buds of cole crops. As a leaf feeder, beet armyworm consumes much more cabbage tissue than diamondback moth, *Plutella xylostella* (Linnaeus), but is less damaging than cabbage looper, *Trichoplusia ni* (Hübner). This insect is also regarded as a serious pest of celery in California, and damage is directly correlated with abundance of late instar larvae late in the season. However, damage to foliage and petioles (stalks) during the first half of the growing season is of little consequence because these plant parts are removed at harvest. Tomato fruit is most susceptible to injury, especially near fruit maturity, but beet armyworm is not considered to be as threatening to tomato as is corn earworm, *Helicoverpa zea* (Boddie). Larvae not only damage tomato fruit, but may appear as contaminants in processed tomato.

Management

Pheromone traps can be used to detect the presence of adult beet armyworm. Visual sampling for damage and larvae, combined with an action threshold of 0.3 larvae per plant, was used successfully on cabbage in south Texas to determine the need for crop treatment with insecticides. Regular monitoring of crops, probably about twice per week, is recommended because adults frequently invade from surrounding crops or weeds.

The relatively high abundance of beet armyworm has stimulated frequent application of insecticides. Chemical insecticides and *Bacillus thuringiensis* are commonly applied to foliage to protect against defoliation. Insecticide resistance is a major problem in management of this insect, possibly because it attacks crops such as flowers, cotton, and vegetables – crops that are treated frequently with insecticides. Beet armyworm abundance is favored by frequent insecticide use, and it is considered to be a secondary or induced pest in some crops. Also, intensive use of insecticides for beet armyworm control in vegetables such as celery has stimulated outbreaks of other pests, principally American serpentine leafminer, *Liriomyza trifolii* (Burgess).

Host plant resistance in several crops has been studied for its contribution to beet armyworm pest management. In tomato, for example, resistance is correlated with total glycoalkaloid concentration in the fruit tissue. However, leaf tissue does not have any effective antibiotic chemistry, so larvae are able to develop on plants even if they have unsuitable tomato fruit.

Several insect pathogens may prove to be useful for suppression of beet armyworm. A nuclear polyhedrosis virus isolated from beet armyworm is fairly effective as a bioinsecticide under greenhouse conditions, where inactivation by ultraviolet light in sunlight is not a severe problem. It is as effective as commonly used insecticides, but presently is not commercially available. Entomopathogenic nematodes (Rhabditida: Steinernematidae and Heterorhabditidae) successfully infect both larvae and adults of beet armyworm, and infected adults can fly short distances, helping to spread the pathogens. Use of nematodes is similarly constrained by environmental conditions, but these biological control agents are available commercially.

Beetles (Coleoptera)

MICHAEL C. THOMAS
Division of Plant Industry, Florida Department of Agriculture and Consumer Services Gainesville, FL, USA

The present era could with some justification be called the "Age of the Beetles." Members of the order Coleoptera comprise the largest order of life. One out of every five species of living things on Earth is a beetle. No one knows precisely how many beetle species have been described, but estimates start at 250,000. Beetles live in almost every habitat where insects are found but do not come to the attention of the layperson as often as members of some other orders which are more conspicuous by virtue of their size or habits. The majority of beetles are capable of flight and some fly quite well, but none has adopted the truly aerial lifestyle of butterflies and dragonflies. Most spend the greater part of their lives in cryptic habitats – under bark and in dead wood, in soil and leaf litter, in the water of ponds, lakes, and streams. Although some beetles are among the largest insects, most are quite small; indeed, some are among the smallest of insects.

Nevertheless, beetles are unrivaled in their diversity of form and color and in the nearly endless ways they have found to live, feed, and reproduce.

Beetles are holometabolous insects which have the front wings hardened and serving as protection for the hind wings which are used exclusively for flying. The front wings, or elytra, are usually raised during flight; at rest, they meet in a straight line along the back. When not in use, the hind wings are folded longitudinally and transversely and hidden under the elytra. Beetles also possess chewing mouthparts, usually 11-segmented antennae, and the abdominal sternites are usually more heavily sclerotized than the tergites.

Anatomy

The body of an adult beetle is composed, like all insects, of three regions: head, thorax, and abdomen. What is visible in dorsal view in beetles, though, is the head, prothorax, and elytra (singular, elytron), which cover the meso- and metathorax, and usually all of the abdomen.

The head bears the eyes, chewing mouthparts, and usually 11-segmented antennae. The size and placement of the compound eyes varies widely within the order, and eyelessness is fairly frequent, especially in soil and litter inhabiting beetles, and those which dwell in caves. The presence of ocelli occurs in only a very few small groups. Mouthparts may be borne on the end of a rostrum (most notably in weevils, Curculionidae). Beetles exhibit almost endless modifications of the mouthparts, especially of the mandibles, which may be the most striking feature of the individual, as in Lucanidae and some Cerambycidae. The antennae in beetles range from simply threadlike (filiform) or beadlike (moniliform), to gradually (clavate) or abruptly (capitate) clubbed, or saw-like (serrate), or with the club segments asymmetrically developed and capable of opening and closing like a fan (lamellate), or elbowed like an ant's antennae (geniculate), or feathery (pectinate or flabellate). Although most beetles have 11-segmented antennae, reduction in the number of segments (to only one or two segments in extreme examples) is common, while an increase in the number of segments is quite uncommon.

The thorax is composed of three parts: the prothorax bears the forelegs; the mesothorax gives rise to the forewings, or elytra, and the middle legs; the metathorax bears the hind wings and hindlegs. The legs are 5-segmented, composed of (from closest to the body) the coxa, trochanter, femur, tibia, and tarsus. The tarsus is composed primitively of five tarsomeres, but this is often reduced and the tarsal formula (the number of tarsomeres on the front, middle, and hind legs) is important in beetle identification. The elytra generally completely cover the dorsal part of the metathoraz and abdomen, but are secondarily short in many groups (Staphylinidae, Silphidae, Cerambycidae, etc.). They almost always meet in a straight line, one of the very few exceptions being the genus *Meloe* in the Meloidae.

The dorsal part of the abdomen is usually soft, except in those groups with abbreviated elytra; the ventral surface of the abdomen is almost always heavily sclerotized.

Life Cycle

Beetles undergo complete metamorphosis. The life cycle of the typical beetle includes egg, three to five larval instars, pupa, and adult. A few beetle families have more complicated life histories: Micromalthidae have multiple larval forms and paedogenesis (reproduction by larvae); several families, e.g., Meloidae, Ripiphoridae, Passandridae, undergo hypermetamorphosis, with the first instar larva being considerably different from succeeding instars. The length of the life cycle varies widely within the order, but generation length of most beetles falls within a few weeks to 1 or 2 years. A few beetles, notably some Cerambycidae, under extraordinary conditions can spend decades as larvae.

Evolution

It is generally agreed the beetles are most closely related to the neuropteroid orders. The first fossils of true Coleoptera date back to the Triassic. They were preceded by a group of beetle-like insects called the Protocoleoptera that arose in the Lower Permian. By the Jurassic, many modern families had arisen, and most of the rest appeared during the Cretaceous, coincident with the rise of the flowering plants. Interestingly, many of the Cenozoic amber fossils can be attributed to modern genera.

Classification

Beetles were recognized as a distinct group of insects as far back as the ancient Greeks, but the classification within the group has been in a state of flux up to the present day. The limits of the order are well understood, with the only issue being whether to include or exclude the twisted-wing parasites (Strepsiptera). Most now treat them as a separate order near Coleoptera, but some have argued that their true affinities lie with the Diptera. Within the Coleoptera, the general classification is fairly well accepted but disagreement persists on the ranking or placement of some family-level groups. The classification presented here is that used in the two-volume American Beetles (Arnett and Thomas 2000, Arnett et al. 2002), the most recently published, major general work on beetles.

There are 166 families of beetles in the world; 131 of those occur in America north of Mexico. The order is divided very unequally into four suborders: Archostemata, Myxophaga, Adephaga, and Polyphaga.

Archostemata

Only four families comprise this primitive suborder. Beetles very similar to present-day Cupedidae are known from the Lower Triassic. Two families, Cupedidae and Micromalthidae, are known from the Nearctic. Most are found in decaying wood. The sole member of Micromalthidae, *Micromalthus debilis* LeConte, has an unusual and complex life history, including paedogenesis.

Myxophaga

Another four families have been assigned to this, the most recently recognized suborder. Two families, Microsporidae and Hydroscaphidae, occur in the Nearctic. The few minute species are associated with algae.

Adephaga

Nine families comprise this suborder, the only one that is composed exclusively (except for one small family of wood-inhabiting beetles, the Rhysodidae) of predacious beetles. Eight families occur in the Nearctic, the Carabidae or ground beetles, being by far the largest family in the suborder, with 2,635 species and subspecies being recorded from the Nearctic and about 40,000 for the world. Carabids often are found on the ground under stones or logs, or in leaf litter, but many, especially in the tropics, are arboreal. They are usually small to moderate in size. Most are darkly colored, but many exhibit brilliant metallic colors. Most ground beetles are predacious, feeding on soft-bodied insects, but some are specialized predators of snails and millipeds. A few are seed feeders. Beetles in most of the other families spend most of their lives in fresh water.

Polyphaga

All the rest of the beetle families are assigned to this suborder. It has been subdivided into several series and numerous superfamilies.

Series: Staphyliniformia

This series is composed of two superfamilies.

Superfamily: Hydrophiloidea
Three families, two moderately sized and one small, comprise this superfamily. The Hydrophilidae are predominantly predacious and aquatic. The Histeridae and Sphaeritidae are terrestrial and predacious. Superfamily: StaphylinoideaThis family contains six small or moderate-sized families and one huge one, the Staphylinidae, which has more than 4,100 species in the Nearctic and more than 46,000 worldwide. All the families occur in the Nearctic. Staphylinids, or rove beetles, often are found around decaying vegetable material and dead animals, where they feed on fly larvae and other insects. Many staphylinids live in the nests of social insects, ants and termites primarily, and show many physical and behavioral adaptations to that way of life. Most staphylinids have very short elytra and flexible abdomens.

Series: Scarabaeiformia

This series contains only the single superfamily

Superfamily: Scarabaeoidea
This superfamily contains 11 small or moderate-sized families and one very large one, the Scarabaeidae. There are more than 27,800 species of scarab beetles in the world; about 1,700 occur in the Nearctic. This superfamily includes the relatively small but well-known Lucanidae (stag beetles) and Passalidae (bess beetles). The Scarabaeidae include some of the largest known beetles, such as the members of the genera *Dynastes* and *Megasoma* in the New World, and *Goliathus* in tropical Africa. Males of many scarabs bear spectacular horns on the head and/or pronotum with which they battle each other for females. Scarab beetles have extremely diverse feeding habits. Many feed on dung of mammals, some being extremely specific on the kind of dung they will accept. Dung beetles provision burrows with dung for their larvae, some rolling balls of dung away for burying and sculpting the dung ball into special shapes. Some even tend the dung to prevent the growth of mold on it. Many others feed in soil, humus, and decaying wood. Some, like the Japanese beetle *Popilia japonica* Newman, feed on living plants and are economic pests of extreme

importance. Many others are found in nests of social insects, primarily ants and termites.

Series: Elateriformia

This series contains five mostly small superfamilies.

Superfamily: Scirtoidea

Four families, three of which are found in the Nearctic, comprise this superfamily. Two families, Eucinetidae and Clambidae, contain small to minute beetles that are found in leaf litter and apparently feed on fungus. Scirtidae are aquatic as larvae and adults generally are found in wet habitats.

Superfamily: Dascilloidea

Only two small families, Dascillidae and Rhipiceridae (Figs. 32 and 33) comprise this superfamily. Larvae of Rhipiceridae are hypermetamorphic and parasitic on immature annual cicadas (Heteroptera).

Superfamily: Buprestoidea

Two families, Schizopodidae and Buprestidae, are included in this superfamily. The Schizopodidae are a small family, confined to the western Nearctic. The Buprestidae are one of the larger families of Coleoptera, with 788 species and subspecies recorded from the Nearctic and more than 14,000 in the world. These often brilliantly colored beetles are mostly wood borers as larvae, although some are leaf miners. A few are of economic importance.

Superfamily: Byrrhoidea

There are 12 mainly small families assigned here; most of the species are aquatic or subaquatic. All but one of the families are found in the Nearctic. The water penny beetles, Psephenidae, with their remarkably flattened larvae, are found on rocks in streams.

Superfamily: Elateroidea

Fifteen rather diverse families comprise this superfamily, all but three of which are found in the Nearctic. The largest family is the Elateridae, or click beetles. There are about 10,000 species of click beetles in the world, with 965 recorded from the Nearctic. Click beetles (and a few of the other families) bear a “click” mechanism on the pro- and mesosternum that allows them to fling themselves into the air with some force if they are placed on their backs. Members of one mostly tropical group of click beetles are luminescent. Other large or widely distributed families include the Lampyridae, Lycidae, Cantharidae, and Eucnemidae.

Series: Bostrichiformia

The series includes two small superfamilies, plus the Jacobsoniidae, which have not been placed in a superfamily.

Superfamily: Derodontoidea

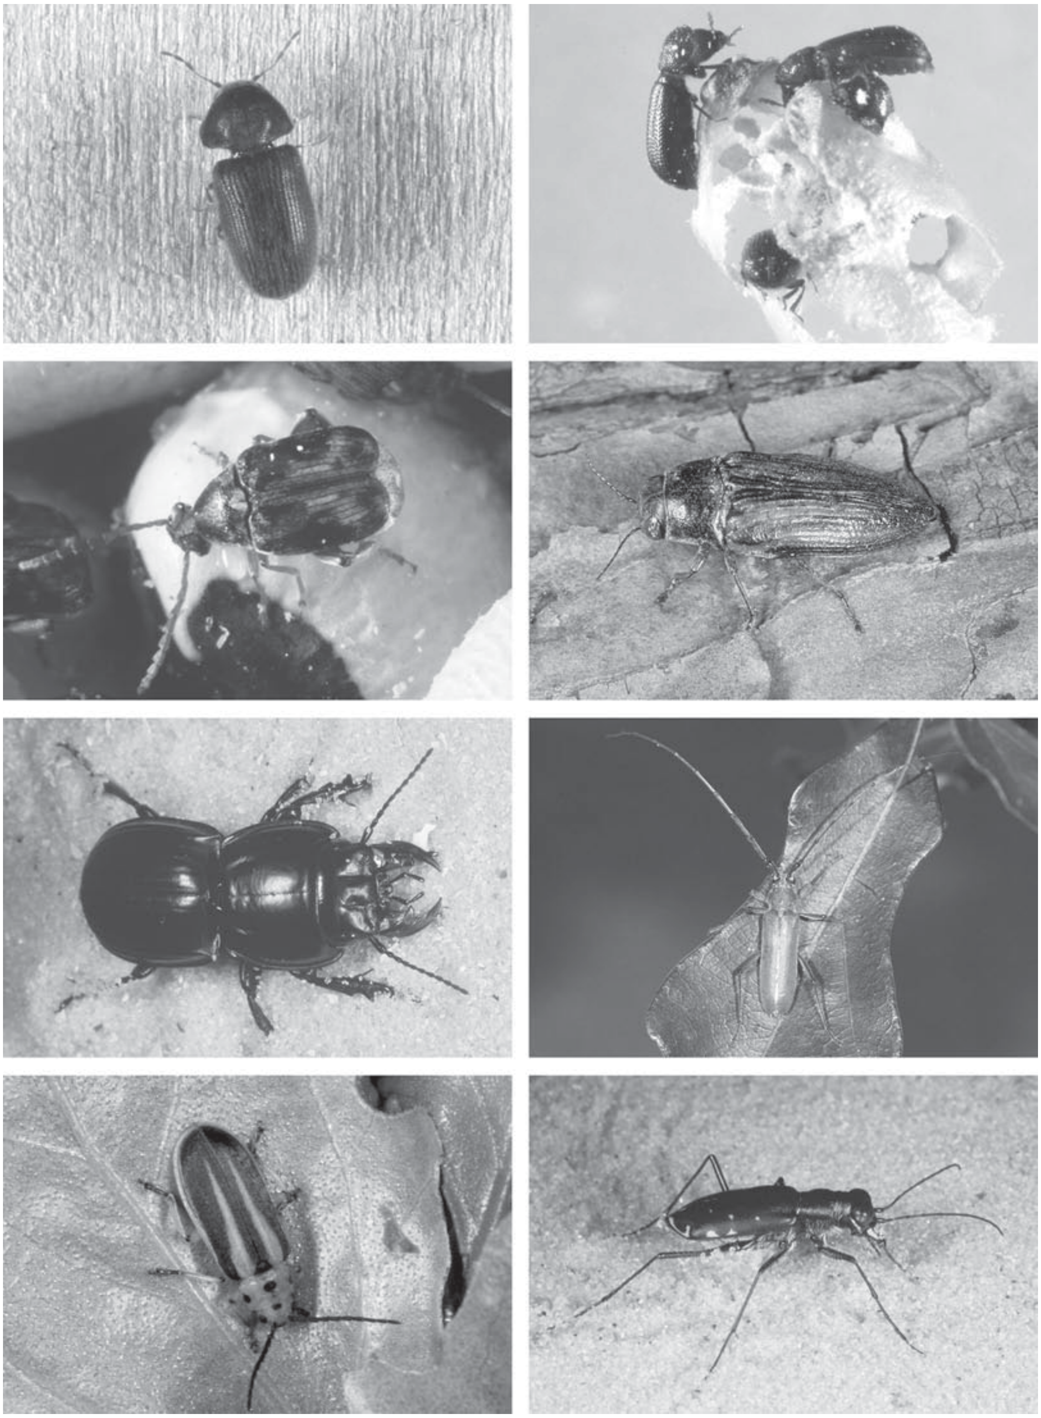
Only the Derodontidae are included in this superfamily. They are found on slime molds.

Superfamily: Bostrichoidea

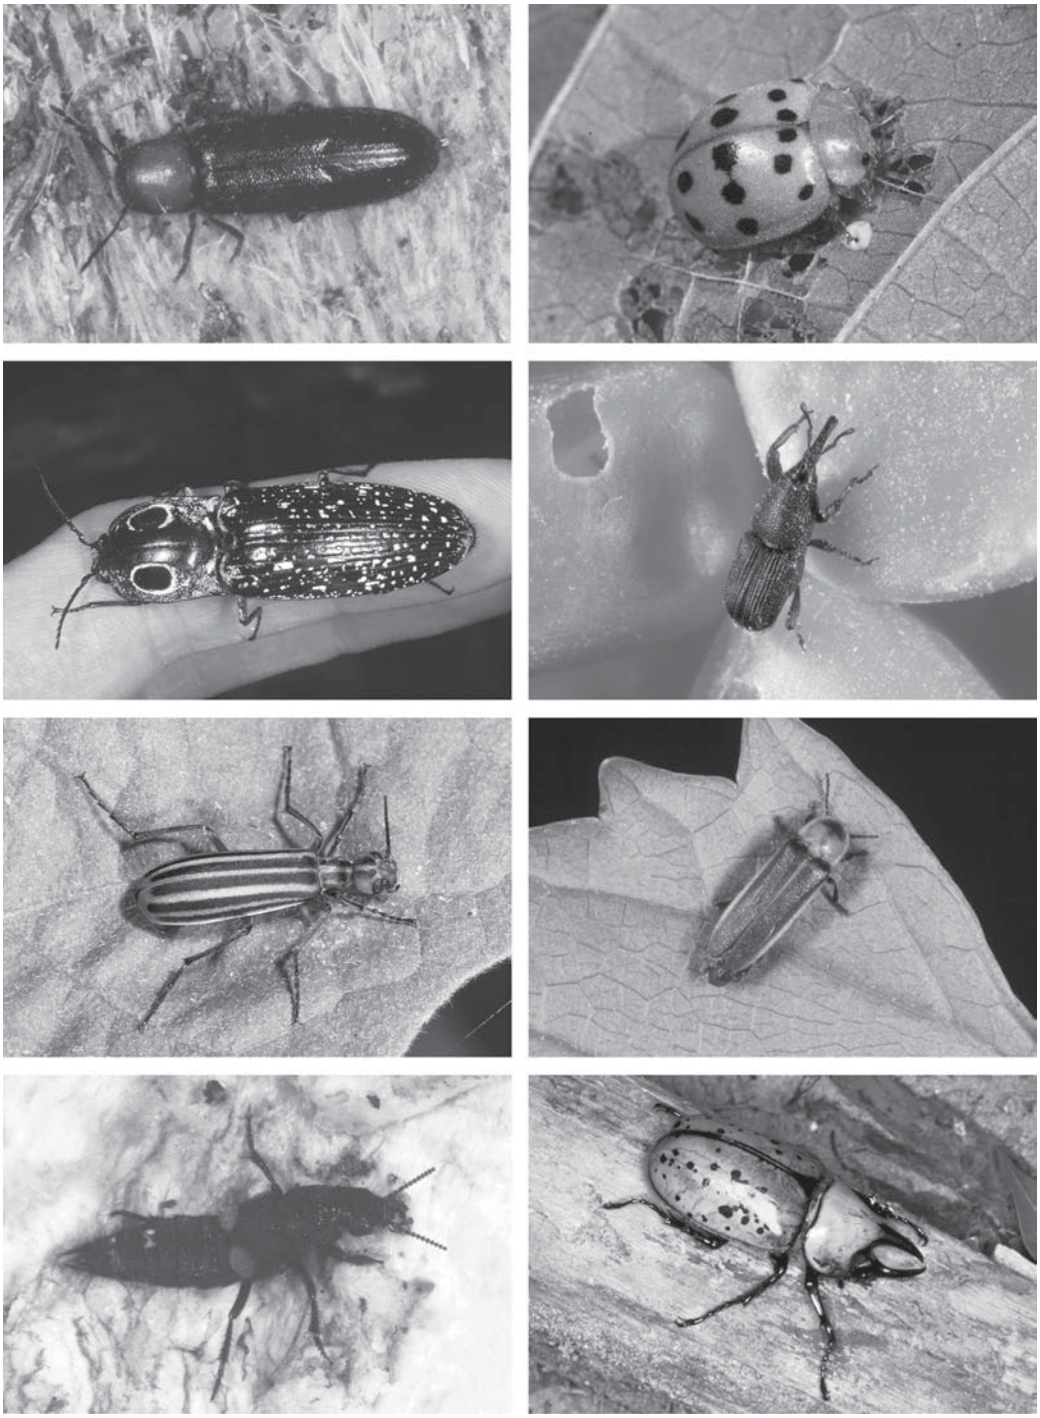
Four families are included here, Nosodendridae, Dermestidae, Bostrichidae, and Anobiidae. The last three including many economically important pests of animal products such as wool, leather, feathers, and silk (Dermestidae) and stored products and wood or wood products (Bostrichidae and Anobiidae).

Series: Cucujiformia

This huge series contains the rest of the Coleoptera, arranged in six superfamilies.



Beetles (Coleoptera), Figure 32 **Some representative beetles: top left, drugstore beetle, *Stegobium paniceum* (Anobiidae); top right, lesser grain borer, *Rhyzopertha dominica* (Bostrichidae); second row left, cowpea weevil, *Callosobruchus maculatus* (Bruchidae); second row right, *Buprestis lineatus* (Buprestidae); third row left, *Pasimachus sublaevis* (Carabidae); third row right, banded hickory borer, *Knulliana cincta* (Cerambycidae); bottom left, *Trirhabda bacharidis* (Chrysomelidae); bottom right, *Cicindela punctulata* (Carabidae) (photos by Lyle Buss).**



Beetles (Coleoptera), Figure 33 **Some additional representative beetles: top left, *Neorthopleura thoracica* (Cleridae); top right, Mexican bean beetle, *Epilachna varivestis* (Coccinellidae); second row left, eyed click beetle, *Alaus oculatus* (Elateridae); second row right, maize weevil, *Sitophilus zeamais* (Curculionidae); third row left, striped blister beetle, *Epicauta vittata* (Meloidae); third row right, a firefly, *Photinus tanytoxus* (Lampyridae); bottom left, a rove beetle, *Platydracus fossator* (Staphylinidae); bottom right, Hercules beetle, *Dynastes titus* (Scarabaeidae) (*Dynastes* and *Epilachna* by Jim Castner; other photos by Lyle Buss).**

Superfamily: Lymexyloidea

This superfamily contains only the ship-timber beetles, Lymexylidae, a small group of soft-bodied, wood-boring beetles.

Superfamily: Cleroidea

Three moderate-sized families of predominantly predacious beetles comprise this superfamily.

Superfamily: Cucujoidea

This is a large superfamily composed of 31 mostly small to moderate-sized families, ten of which do not occur in the Nearctic. Members of most of the families are associated with fungus, but some are predominantly predacious, such as the largest and best-known family, Coccinellidae, and a few (Bothrideridae and Passandridae) even contain species which have parasitic larvae.

Superfamily: Tenebrionoidea

This is the second largest superfamily with 30 families, six of which do not occur in the Nearctic. Most of the families are small to moderate in size, but the Tenebrionidae are one of the largest families of Coleoptera, with about 19,000 species worldwide and about 1,100 in the Nearctic. Although the Tenebrionidae are found in all kinds of habitats, the family is especially well represented in deserts. They are usually sombre in coloration, hence their common name of darkling beetles, and often are found on the ground under rocks and logs.

Superfamily: Chrysomeloidea

The superfamily contains five families, two of which are very large. The longhorn beetles, Cerambycidae, contains more than 20,000 species worldwide and more than 900 in the Nearctic. They are generally elongate, handsome beetles with long to very long antennae. Most are associated with dead or dying woody plants, although some attack living trees. Many are of economic importance. Some very large forms occur in the tropics and are among the largest beetles. The leaf beetles, Chrysomelidae, include about 35,000 species worldwide and about 1,720 in the Nearctic. Chrysomelids differ from cerambycids in usually being smaller, less elongate, and with shorter antennae. Often they are brightly colored. Leaf beetles are associated predominantly with living plants, feeding on the foliage and roots. Many are economically important pests of agriculturally important crops. The seed beetles, Bruchidae, often are combined with the leaf beetles. Several are important pests of stored legume seeds.

Superfamily: Curculionoidea

The largest family of living organisms is included among the eight families in this superfamily. The weevils, Curculionidae, contain more than 60,000 species worldwide and about 2,400 in the Nearctic. As presently defined, the Curculionidae are restr-icted to curculionoids with geniculate antennae. They are almost entirely herbivorous, attacking all parts of all kinds of plants. Many of the worst agricultural pests are weevils. The Brentidae, or primitive weevils, are mostly tropical but one oak pest occurs in the eastern Nearctic. The Anthribidae, or fungus weevils, are associated with fungi of various kinds.

Classification of the Order Coleoptera Linnaeus 1758.

Suborder: ARCHOSTEMATA Kolbe 1908
- Cupedidae Laporte 1836, The reticulated beetles
- Ommatidae Sharp and Muir 1912
- Crowsonellidae Iablokoff-Khnzorian 1983
- Micromalthidae Barber 1913, The telephone-pole beetles

Suborder: MYXOPHAGA Crowson 1955

Lepiceridae Hinton 1936

Microsporidae Crotch 1873, The minute bog beetles

Hydroscaphidae LeConte 1874, The skiff beetles

Torridincolidae Steffan 1964

Suborder: ADEPHAGA Schellenberg 1806

Rhysodidae Laporte 1840, The wrinkled bark beetles

Carabidae Latreille 1802, The ground beetles

Gyrinidae Latreille 1810, The whirligig beetles

Haliplidae Aubé 1836, The crawling water beetles

Trachypachidae C. G. Thomson 1857, The false ground beetles

Noteridae C. G. Thomson 1860, The burrowing water beetles

Amphizoidae LeConte 1853, The trout-stream beetles

Hygrobiidae Régimbart 1878

Dytiscidae Leach 1815, The predacious diving beetles

Suborder: POLYPHAGA Emery 1886

Behavior of Insects: Genetic Analysis by Crossing and Selection

MARJORIE A. HOY
University of Florida, Gainesville, FL, USA

Sometimes, as will be demonstrated in examples below, mutations in a single gene or a few major genes will alter the behavior of insects. The genetic basis of this behavior can be assessed by traditional techniques. Traditional behavior-genetic analysis primarily employs one of two experimental appro-aches: crossing and selection. A third traditional approach, which is limited to *D. melanogaster*, involves analysis of fate maps in genetic mosaics. This method allows the researcher to locate the anatomical site of abnormalities that affect behavior in *D. melanogaster*. In addition, molecular genetic methods are becoming important in the analysis of insect behavior, but are discussed in a separate entry.

Although a specific behavior sometimes can be altered by the mutation of a single gene in a pathway leading to the behavior, an insect's behavior often is influenced by many genes. In such situations, analyses of behavior have traditionally required the use of a statistically based approach called quantitative genetics.

Crossing Experiments

Crossing experiments are used to assess the mode of inheritance of a particular behavior. The behavior (phenotype) of the F_1 and backcross progeny indicates whether the behavior under study is determined by a single gene or more than one gene. The phenotype indicates whether there is dominance (a single copy of the gene is sufficient to determine the behavior under study), sex linkage (the gene is located on a sex-determining chromosome) or maternal influences (the behavior is determined by the behavior of the mother, which suggests that the trait may be determined by factors in the cytoplasm rather than in the chromosomes located in the nucleus). If the trait is determined by many genes, it is difficult to determine the number of genes, their relationship to each other, or their location on specific chromosomes because most insect species lack sufficient genetic markers.

A crossing experiment involves mating individual insects that differ in a particular kind of behavior. The behavior of their progeny (the F_1 generation) and the progeny produced by crosses between the F_1 progeny and one of the original parental types (backcross progeny) is also evaluated. Ideally, the environment experienced by the parental, F_1 and backcross generations is controlled so that all individuals experience the same conditions. It is easiest to interpret the results of crossing experiments if the individual insects that are crossed differ only with regard to a single behavioral attribute.

Selection Experiments

Selection experiments provide a second traditional method to determine the degree to which a given behavior is determined genetically. Selection experiments do not usually allow the researcher to resolve the mode of inheritance. In a selection experiment, individuals with a specific behavioral attribute are allowed to reproduce and this process is repeated over succeeding generations until a plateau in the selection response is obtained. The behavior of the selected population is altered *if* genetic variation for the attribute is present in the initial colony *and* the selection procedures have been appropriate. The response of the population to selection can be analyzed to estimate whether the trait is heritable. An example of a selection experiment is provided by the analysis of migratory behavior in the milkweed bug *Oncopeltus fasciatus*.

Migratory and nonmigratory behaviors of *Oncopeltus fasciatus* were shown to be under genetic control. Strains of *O. fasciatus* were selected for two attributes: wing length and propensity to fly. Bidirectional selection (selection for increased or decreased wing length) on wing length was performed for 13 generations and the flight behavior of the selected individuals was monitored. Individuals also were selected for flight duration; those whose flight times totaled 30 min were considered "fliers," while those with the shortest flight times were labeled "nonfliers."

Response to selection on wing length was rapid, and flight tests of the long- and short-winged insects indicated there was a positive correlation between wing length and flight duration. Selection after two generations for flight or noflight likewise resulted in divergent responses, indicating a large genetic component to flight behavior.

Behavior Determined by One or a Few Genes

How often are insect behaviors determined by one or a few genes? How often are behaviors determined by many genes? The following examples provide some examples of behaviors determined by one or a very few genes.

Susceptibility to American Foulbrood in the Honeybee

The genetic basis of susceptibility to foulbrood disease caused by the bacterium *Bacillus larvae* in honeybees (*Apis mellifera*) originally was analyzed by Walter Rothenbuhler. Differences in resistance in different bee strains were attributed to differences in "hygienic behavior" in worker (sterile female) bees. To understand the genetic basis of the hygienic behavior, two inbred honeybee strains with differing levels of resistance were crossed and the behavior of the F_1 and backcross progeny was characterized. This research was one of the first to show that a specific behavior was determined by a few genes.

"Hygienic" workers consistently remove dead larvae and pupae from the brood nest at a high rate, thus slowing the spread of the bacteria through the colony by reducing contamination. The hygienic behavior has two components: (i) the uncapping of infected cells, and (ii) removal of the dead bee larvae. Crosses between "hygienic" and "nonhygienic" bees yield F_1 worker bees that are nonhygienic, indicating that the gene, or genes, conferring the hygienic behavior are recessive.

Progeny produced by backcrosses to the pure hygienic strain yielded approximately 25% hygienic worker progeny, which is consistent with the hypothesis that hygienic behavior is determined by two recessive genes. Under this two-gene model, hygienic worker bees have two copies of each of two genes, called *u* and *r*. Hygienic bees (*uurr*) both uncap the cells (*uu*) containing dead brood and remove them (*rr*).

As expected, worker bees that contain two copies of u but only one copy of the gene for removal (*r*) will uncap the cells, but not remove dead brood. The workers that contain only one copy of the uncapping gene (*u*) but two copies of the removal gene (*rr*) do not uncap brood, but will remove them if the cells are uncapped for them. Workers that contain only one copy each of *u* and *r* (u^+u, r^+r) are unhygienic, and will neither uncap nor remove brood. Rothenbuhler' s research on hygienic behavior became a classic in textbooks of behavior genetics because it was one of the first examples to demonstrate that behavior was inherited. The model has been confirmed, although one analysis of the data suggest that three genes might be involved in this behavior.

Research on hygienic behavior indicates it may be a general response to remove pathogens and parasites from the nest. It is clear that the expression of hygienic behavior also depends on colony strength and composition of worker types within the colony. Analyses of the olfactory responses of hygienic and non-hygienic bees to diseased brood indicates that hygienic bees have a higher sensitivity to low concentrations of the odor of diseased bee pupae. Such differences are due to a lower stimulus threshold and not a direct result of age or experience of the bee, suggesting that non-hygienic bees may be unable to detect diseased brood readily.

Understanding hygienic behavior in *A. mellifera* has great practical importance in maintaining effective colonies of pollinators and honey producers. Studies on hygienic behavior has resulted in practical recommendations to bee keepers for selecting colonies resistant to chalk brood (a fungal disease) and the pest bee mite *Varroa*. So far, no negative effects have been associated with hygienic behavior and such colonies produce as much honey as nonhygienic ones.

House-Entering Behavior in *Aedes aegypti*

The mosquito *Aedes aegypti* is an important vector of human disease and understanding its behavior could result in better management of this pest. House-entering behavior by *A. aegypti* from East Africa has been analyzed by crossing different populations that exhibited different behaviors, which were controlled by genes with additive effects. One population of *A. aegypti* commonly enters houses (domesticated or D), while others rarely do so (one is called peridomestic [P]; and the other is a wild or feral [F]; population).

Three populations of *A. aegypti* were collected either inside houses (D), near a village (P), or from tree holes in a forest (F). The populations then were bred in insectaries and crossed to produce hybrid (DP, PD, DF, FD, PF, FP) populations. The original and hybrid populations were then marked with different colored fluorescent powders and released near houses. Marked mosquitoes were captured inside houses and in the village area. Of the mosquitoes entering houses, 45% were from the domestic (D) population, 14% from hybrids between the domestic and peridomestic population (DP and PD), 10% from the peridomestic population (P), and 6% were hybrids between the domestic and feral populations (DF and FD). Only 1.5 and 0.6% of the PF and FP hybrids were collected in the house, and the feral population (F) entered the house with a frequency of only 0.6%. The recapture rates in the village area were in the reverse order. These results clearly indicate that the behavior is genetically determined.

Domesticity in *A. aegypti* is a complex phenomenon that includes a variety of behaviors, including a preference for ovipositing in man-made containers, ability of larvae to develop in drinking water stored in clay pots with a low nutritional content, and preferences for feeding on man (rather than birds) inside houses, as well as resting and mating indoors. No doubt *A. aegypti* speciated long before man began to build houses, but *A. aegypti* has adapted rapidly to human habitats, and the domestic form of *A. aegypti* is the only one known that is entirely dependent on man.

Foraging in *Drosophila*

Drosophila melanogaster larvae feed on yeast growing on fruit. Naturally occurring populations contain individuals that vary in the distance the larvae travel while foraging for food, a difference attributed to a single gene called *foraging*. Natural populations comprise approximately 70% "rovers" (who forage long distances) and 30% "sitters" (short distance foragers). The rover behavior is dominant to sitter, indicating a single-gene mode of inheritance. Sitter larvae grow at a normal rate and are of normal size. Both sitters and rovers are maintained in the field by natural selection. It appears that density-dependent selection can shift gene frequencies so that rovers are selected for in crowded larval environments and sitters in less crowded ones.

The *foraging* gene codes for a cyclic guanosine monophosphate (cGMP)-dependent protein kinase, and rovers have higher kinase activity than sitters. Thus, subtle differences in this kinase can lead to naturally occurring variation in behavior. Another gene, *Chaser*, also may affect larval foraging by increasing foraging path length.

Other Behaviors Influenced by One or a Few Genes

Crossing experiments have shown that a specific behavior is influenced by one or a few genes in the flour moth *Ephestia kuhniella* (silk mat spinning by larvae prior to pupation), the mosquito *Aedes atropalpus* (egg maturation without an exogenous source of protein such as blood), and the parasitoid wasp *Habrobracon juglandis* (flightlessness). In the silkworm *Bombyx mori*, females with the *piled egg* gene deposit eggs in a peculiar manner. *B. mori* larvae with the *Non-preference* gene are unable to discriminate mulberry leaves from others. When two tephritid fly species (*Procecidochares*) were crossed that differ in their host preference (each having only one host plant), the behavior of their progeny segregated in a manner consistent with hypothesis that the control of host preference is determined by a single gene.

A variety of mutants determined by major genes have been identified in *D. melanogaster* that affect behavior, including *Shaker*, *Hyperkinetic* and *eag*, which are expressed when the flies are anesthetized with ether. *Hyperkinetic* (Hk) causes a vigorous steady leg shaking, and mutations of *Shaker* cause vigorous and erratic shaking and a strong scissoring of wings and twitching of the abdomen. The *eag* mutant flies (*ether a-go-go*) are less vigorous in their shaking. The *easily shocked gene* of *D. melanogaster* is one of the class of "bang-sensitive" paralytic genes. Flies with this mutated gene exhibit a transient paralysis following a brief mechanical shock. A temperature-sensitive recessive mutant gene (*parats*) causes *D. melanogaster* to become immobile above 29°C. The *couch potato* locus causes flies to be less active and exhibit abnormal responses to gravity and light, resulting in altered flight behavior. The *couch potato* gene is unusually complex, spanning more than 100 kb and encoding three different messenger RNAs.

Many "single gene" mutants that affect the morphology of *D. melanogaster* also affect behavior. Some mutant flies exhibit abnormal behavior because they are unable to perform the reaction to a stimulus due to altered morphology. Other mutants exhibit altered behavior because perception of cues is impaired. For example, flies with *white* eyes may exhibit abnormal courtship behaviors.

Alterations in the brain affect behavior and genes involved in the behavior can be analyzed by mutagenesis and mosaic analysis. For example, eight different genes affecting walking behavior in *Drosophila melanogaster* strains were analyzed by chemical mutagenesis, histological analysis, and analysis of genetically mosaic flies. These eight genes caused structural defects in the central complex of the brain and affected walking motivation, fast response to light, and response to gravity. Because the aberrant behaviors were associated with changes in a portion of the insect brain called the central complex, the mutant flies confirmed that the central complex controls behavior. The central complex also regulates other behaviors (flight, singing, preening, escape).

Pheromone communication in the European corn borer *Ostrinia nubilalis* is genetically determined. Females of the E- and Z-strains of *O. nubilalis* produce different ratios of enantiomeric (molecules that are chemically the same but mirror images of each other) molecules of their sex pheromone (a substance released by an organism that causes a reaction by another individual of the same species, in this case it serves as a sexual attractant). Hybrids between these two strains produce an intermediate pheromone blend. Analysis of the F_2 and backcross progeny indicated the types of pheromones produced are controlled by a single gene, although one or more modifier genes controls the precise ratio of the isomers in hybrid females.

Males of the two *O. nubilalis* strains are attracted to the appropriate pheromone blends in the field, but hybrid males respond preferentially to the pheromone produced by hybrid females rather than to the pheromones produced by the two parental female types. The response of males to the pheromone is determined by a single sex-linked gene. The olfactory sensillae of the two types of males are different, which is controlled by an autosomal gene. Hybrid males give intermediate results when their antennae tested for their electrophysiological responses, with E- and Z- olfactory cells yielding approximately equal responses, suggesting that multiple genes are involved. The genes determining variation in pheromone production and organization of male olfactory sensillae are not closely linked and are probably on different chromosome.

Behaviors Determined by Multiple Genes

Behavior is often controlled by multiple genes with small additive effects. With such behaviors, the task of teasing apart the respective roles of genes and environment requires statistical methods of analysis. *Drosophila* behaviors determined by multiple genes include locomotor activity, chemotaxis (response to chemicals), duration of copulation, geotaxis (orientation to gravity), host plant preference, mating speed, phototaxis (response to light), preening, and the level of sexual isolation within and between species. Multiple genes may influence host plant adaptation and host preference in insects. Learning may affect host preference. Host plant choice usually is a hierarchy of several components.

A particularly interesting example of genetic analysis of host preference in insects is that of *Drosophila sechellia*, which is endemic to the Seychelles archipelago in the Indian Ocean and is morphologically almost identical to its cosmopolitan sister species *D. simulans* and to the endemic island species *D. mauritiana*. When crossed to either of these species, *D. sechellia* produces fertile hybrid females and sterile hybrid males. *D. sechellia* uses the fruit of *Morinda citrifolia* as its host, which may have allowed it to escape competition with other species of *Drosophila* there.

Host Plant Specialization in *Drosophila sechellia*

Drosophila sechellia breeds only in *Morinda citrifolia*, which is toxic to other *Drosophila* species. *D. simulans* breeds on a variety of plants in the same geographic area but cannot survive on *Morinda*. The two species can be crossed and F1 hybrids are produced. The number of genes involved in resistance was estimated to be three to five based on a biometric approach. An analysis using marker genes suggests that all chromosomes, except the Y and the small fourth, carry genes affecting resistance. Thus, resistance appears to be neither very simple nor highly polygenic.

D. sechellia is stimulated by *Morinda* to produce eggs, but oviposition in *D. simulans* is inhibited by this plant. In hybrid progeny, the inhibition observed in *D. simulans* is dominant. F_1 hybrids and backcross progeny exhibit intermediate, approximately additive, behavior. These differences result in isolation of the two species in nature, although they overlap geographically. Thus, their ecological niches are determined by tolerance to toxic products (including octanoic and hexanoic acids) in the ripe *Morinda* fruit, with *D. sechellia* exhibiting a strong preference for *Morinda* fruits, an ability to detect fragrant volatiles from *Morinda* over a long distance, and a stimulation of egg production by *Morinda*. By contrast, egg production in *D. simulans* is inhibited by *Morinda* and octanoic acid in the fruit is toxic to *D. simulans.*

Other Behaviors Determined by Multiple Genes

Other insects in which specific behavioral attributes have been shown to be complex include: *Musca domestica* (number of attempts to mate by males); *Phormia regina* (high and low ability to learn to extend the proboscis to a stimulus applied to the forelegs); hybrid crickets (call rhythm of males; female response to calling songs); *Anopheles albimanus* (ability to avoid pesticides); *Apis mellifera* (high and low collection of alfalfa pollen, and stinging behavior). The propensity for cannibalism by larvae of *Heliothis virescens* is determined by multiple genes. Most of these behaviors were analyzed by selection experiments.

Behavior: Molecular Genetic Analyses

MARJORIE A. HOY
University of Florida, Gainesville, FL, USA

Molecular genetic techniques are beginning to provide powerful new methods to analyze insect behaviors such as olfaction (response to odors), learning, circadian rhythms (daily periodicity), and mating behavior. Prior to the use of molecular methods, genetic analyses of behavior primarily involved crossing and selection experiments to resolve whether the behavior was genetically determined and the mode of inheritance of the gene(s) involved (e.g., the genes were dominant or recessive, sex-linked or autosomal, determined by single genes or more than one).

Now that the complete sequence of the genome of the fruitfly *Drosophila melanogaster* is available, it is easier to isolate specific genes that could be involved in behavior. In addition, the genetic modification of *D. melanogaster* by *P*-element mediated transformation makes it possible to insert genes from one species of *Drosophila* into the genome of another, and their effect(s) on behavior can be determined. Transgenic *D. melanogaster* carrying markers such as green fluorescent protein (GFP) also allow scientists to determine when and where specific genes are active.

Molecular genetic analyses of learning and memory in *Drosophila* may provide a means to study one of the most challenging frontiers in neurobiology. Molecular genetic methods may identify some of the individual genes among the "many" involved in determining the interesting and complex behaviors exhibited by insects.

Analyses of insect behavior employ techniques from several disciplines, including anatomy, biochemistry, ecology, ethology (study of animal behavior in the natural environment), genetics, psychology, physiology and statistics. These disciplines are required because an insect perceives the environment through its sensory systems. The external sensory stimuli are transduced into electrical information, which is then processed and decoded, leading to a behavioral response. Behavior can be divided into several sequential steps: stimulus recognition, signal transduction, integration, and response or motor outputs.

The Insect Nervous System

Behavior is based on the structure and function of the insect central and peripheral nervous systems. The insect brain contains around 10^5–10^6 neurons. It consists of three main divisions, the protocerebrum, deutocerebrum and tritocerebrum. In each of these divisions, different neuropil regions are located; a neuropil is a dense network of interwoven axons and dendrites of neurons and neuroglial cells in the central nervous system and parts of the peripheral nervous system.

In the protocerebrum, higher sensory centers are present that are associated with vision and other sensory receptors (the mushroom bodies and central complex). The superior protocerebrum, with the pars intercerebralis, contains different sets of neurosecretory cells that supply neurohemal organs in the corpora cardiaca and corpora allata, which are located in the head or prothorax in insects. The optic lobes flanking the protocerebrum consist of the most well-organized neuropils in the brain.

Mushroom bodies in the brain are associated with olfactory pathways, including olfactory learning. Among the insects, mushroom bodies differ greatly in size and shape, with the number of cells ranging from 2,500 in *Drosophila* to 50,000 in the cricket *Acheta*, 170,000 in the honey bee and 200,000 in the cockroach *Periplaneta*

The antennal centers are found in the deutocerebrum; in the tritocerebrum, neurosecretory neurons and neurons associated with the control of feeding and foregut activity are found. The brain is connected to the subesophageal ganglion via connectives and to the thoracic and abdominal ganglia, or ventral nerve cord.

Information is transmitted in the insect via nerves and by neuropeptides that coordinate the development and behavior of insects. Both neurosecretory cells and neurons use neuropeptides as messengers. Many different types of neuropeptides have been identified, including proctolin and adipokinetic hormone, that serve as both hormones and neurotransmitters or neuromodulators. Neuropeptides range in size from three amino acid residues (thyrotropin-releasing hormone) to more than 50 (insulin). They are generated from larger precursor proteins, ranging from 90 to 250 amino acids in length. A number of genes have been identified that code for neuropeptides, including bombyxin or prothoracicotropic hormone (PTTH), eclosion hormone (EH), FMRFamide- related peptides, diapause hormone and pheromone iosynthesis-activating neuropeptide (PBAN). The genes for many of these neuropeptides have been identified, cloned and sequenced.

Neuropeptides are released as cotransmitters and modulate fast transmission at neuromuscular junctions. A given neuropeptide may occur at several different sites, including central nervous system circuits and peripheral synapses, and at peripheral targets (muscles and glands). Neuropeptides regulate behavior by coordinating temporal and spatial activity of many neuronal circuits. Each of the circuits controlling behavior employs sets of sensory neurons, interneurons and motor neurons. Thus, multiple neural networks share neural elements. Molecular genetic analysis is providing rapid progress in understanding neuropeptide receptors and second messenger pathways. Research on neuropeptides and their receptors indicates that they have roles during embryonic development and as cytokines in the immune systems of insects.

Molecular genetic analyses are providing significant advances in our knowledge of behavior. "Behavior" is a complex phenotype to study because it involves the functioning of the whole organism, is dynamic, and changes in response to the environment. Molecular genetic methods are unlikely to replace traditional methods of behavior analysis, but the ability to identify, clone, and sequence specific genes in *D. melanogaster* makes it possible to understand several behaviors (including the periodicity of biological rhythms, mating behavior, locomotion, and learning) that are influenced by single genes.

It is now possible to clone a gene from one *Drosophila* species, insert it into a P-element vector, and introduce the exogenous gene into mutant strains of *D. melanogaster* to confirm that the putative gene does, in fact, code for the behavior of interest. Cloned genes from *Drosophila* can, in some cases, be used as probes to identify genes from other arthropods, which then can be sequenced and compared. The availability of the complete genome of *D. melanogaster* allows analyses of behavior that could not be conducted previously, as will be described in the discussion of olfaction in *D. melanogaster* (see below).

The Photoperiodic Clock

The potential that molecular genetics offers is exemplified by the analyses conducted using the period, and other clock genes, of *D. melanogaster*. Most insects exhibit particular behaviors at a specific time of the day, which due to the action of a circadian (approximately 24 h) clock that allows the insect to measure time. Circadian rhythms have a number of characteristics: (i) The clocks that regulate such behavior usually are free running in constant environments and are not simple responses to changes in light or temperature. (ii) Although the rhythms are free running, an initial environmental signal is required to start the clock. Among the cues that set the clock are alternating light and dark cycles, high and low temperature cycles, or short pulses of light. (iii) The circadian rhythm is relatively insensitive to changes in temperature (temperature compensated). (iv) The clock can be reset by altering the cues that entrain the clock.

Drosophila melanogaster reared in constant darkness exhibit circadian locomotor activity rhythms as adults. However, the rhythms of the individual flies composing these populations are not synchronized with one another. Rhythms can by synchronized if dark-reared flies are exposed to light treatments as first-instar larvae (or as later instars). Light treatments occurring prior to hatching of the first-instar larvae fail to synchronize adult locomotor activity rhythms, indicating the clock functions continuously from the time larvae hatch until adulthood. The rhythm can be advanced, delayed, or unchanged, depending on the phase of the cycle at which the cue is given.

Molecular genetic analyses of *Drosophila* clock mutants is providing a fundamental understanding of the mechanisms of the circadian clock. Rapid advances have been made in the past few years in understanding the molecular aspects of circadian clocks in a variety of organisms. Circadian rhythms are found in all organisms, probably evolved early, and common genetic elements are present in *Drosophila*, the fungus *Neurospora*, mammals, and cyanobacteria. In *Drosophila*, the genes called *period, timeless, Clock, cycle, doubletime* and *cryptochrome* are now known to be involved in the circadian clock.

The Period (Per) Gene of Drosophila

The *period* gene of *Drosophila* is located on the X chromosome. When the wild type gene (called per^+) is mutated, eclosion (emergence of adults from the pupa), locomotor activity and the length of the interpulse interval of the courtship song are affected. Eclosion of wild type flies typically occurs around dawn, when the presence of dew and high relative humidity increase their survival rate. Locomotor activity then decreases during midday and is followed by increased activity in the evening.

Three classes of *per* mutants exist; they either shorten (*per* mutants have 19-h eclosion rhythms instead of 24-h patterns), lengthen (per^L mutants have 29-h eclosion rhythms), or completely abolish circadian eclosion and locomotor activity rhythms (per^0 mutants). Flies with the per^0 mutation eclose arrhythmically, but periodicity in eclosion can be restored by *P* element-mediated transformation of arrhythmic flies using the wild type per^+ allele.

The *per* gene is approximately 7 kb long and the protein produced has a series of threonine-glycine (Thr-Gly) repeats in the middle of the gene. The region encoding the Thr-Gly repeat is polymorphic in length within and between *Drosophila* species and plays a role in the thermal stability of the circadian phenotype. For example, either 17, 20 or 23 repeats are found in *D. melanogaster* populations. A clinal pattern occurs along a north-south axis in Europe and North Africa, with the shorter sequences in southern Europe, suggesting that the length polymorphism cline is maintained by natural selection under different temperature conditions.

A large number of tissues express the normal (per^+) product, including embryonic, pupal and adult nervous systems, as well as the esophagus, gut and ovaries. The per^+ gene product (the PER protein) is predominantly found in cell nuclei in adult *Drosophila*, and per^+ messenger RNA levels undergo daily fluctuations, producing a feedback loop in which PER affects the oscillations of its own messenger RNA. The fluctuations in per^+ messenger RNA are due to fluctuations in gene transcription because the per^+ messenger RNA has a relatively short half-life, which is consistent with the hypothesis that PER acts to regulate its own gene activity.

The per^+ genes from *Drosophila simulans, D. virilis, D. pseudoobscura* and *D. yakuba* have been cloned and sequenced. Parts of the gene are conserved among them and parts are highly diverged, which suggests that conserved regions may encode basic functions common to all (clock-type functions), while the variable regions may affect species-specific differences influencing love songs, locomotor activity and eclosion.

Two X-linked loci, *Clock* and *Andante,* are components of the circadian clock, causing slightly shortened and lengthened cycles, respectively. In addition, other mutations on the autosomal chromosomes induce flies to emerge as adults from the pupal stage early in a light-dark cycle; *phase-angle* flies emerge in the pre-dawn part of the cycle instead of just after dawn while *gate* flies to fail to eclose during this narrow time window. The *cryptochrome* (*cry*) gene is an important clock component because it encodes a circadian photoreceptor in *Drosophila*. The gene product, CRY, belongs to a family of blue light-sensitive proteins, which includes photolyases and plant blue light photoreceptors. Flies over expressing CRY are hypersensitive to light. The CRY protein is probably the only dedicated circadian photoreceptor in *Drosophila.*

Song Cycle Behavior in *Drosophila*

The courtship song is produced when males vibrate their wings and consists of two components: (i) courtship hums, and (ii) a series of pulses with interpulse intervals, which can fluctuate between 15 and 85 ms. The variation in interpulse intervals ranges from a period of 56 ms in *D. melanogaster* and 35–40 ms in *D. simulans*. *D. melanogaster* males with the per^S mutation sing with 40-ms periods, per^L males sing with 76-ms periods, and per^0 males are arrhythmic.

The genetic basis of species-specific song instructions was confirmed by the transfer of the per^+ gene from *D. simulans* into *D. melanogaster* via P element-mediated transformation. The *D. simulans* per^+ gene restored a rhythm in these transgenic *D. melanogaster* and the transgenic *D. melanogaster* males had mean period lengths in their song cycles of approximately 35 ms, which is characteristic of *D. simulans* males. Thus, substitutions in four or fewer amino acids in the per^+ locus was shown to be responsible for this species-specific courtship behavior.

Other Effects of *Per*

The *per* alleles affect locomotion, cellular rhythms and development time. Flies with per^S develop faster than wild type flies and per^L flies develop more slowly than the wild type.

It has long been thought that circadian oscillations provided the clock for photoperiodically induced diapause in insects. Diapause is a genetically determined state of arrested development that is induced prior to the onset of detrimental conditions. Hibernal diapause, which allows insects to survive over winter, is often induced in insects when insects develop during a period of cool temperatures under a short daylength, which means they must be able to measure light and dark cycles. However, per^+ appears to have no influence on the photoperiodic clock in *D. melanogaster.*

Females of a wild-type strain of *D. melanogaster* (Canton-S) and strains with *per* mutations were able to discriminate between diapause-inducing short days and non-inductive daylengths. *D. melanogaster* adult females exhibit an ovarian diapause when reared and held under short days and low temperature (12°C). Females exposed to long days at the same temperature reproduce.

The critical daylength (the photoperiod at which 50% of the individuals enter diapause) for Canton-S females at 12°C is approximately 14 h of light per 24 h. Photoperiodic response curves for the *per*^{S}, *per*^{L} and Canton-S strains were almost identical, although *per*^{0} flies showed shortened critical daylengths. However, *per*^{0} females are able to discriminate between a long day and a short day.

Many behaviors, including learning, involve temporally patterned events. The interval between presentation of the conditioned stimulus and reinforcement is important in associative learning. The conditioned stimulus must be presented before the unconditioned stimulus and the unconditioned stimulus must follow the conditioned within a relatively brief interval. It was thought that the *per*$^{+}$ gene could be involved in learning, based on the observation that *per*^{L} males in one experiment did not exhibit normal experience-dependent courtship behavior. However, males with the wild type or *per*^{S} and *per*^{0} alleles could be conditioned normally.

Learning in *Drosophila*

It is difficult to produce a single definition of learning. Learning can be defined as a change in behavior with experience, but this definition would not exclude responses such as growth and maturation, or other processes that are triggered by events such as mating or feeding. Another definition is a reversible change in behavior with experience, but this excludes phenomena in which the modification caused by some experience is fixed and resistant to further change. Another definition is that learning is a more or less permanent change in behavior that occurs as a result of practice, but this definition is ambiguous.

The following properties are characteristic of learning in insects: (i) The individual's behavior changes in a repeatable way as a consequence of experience. (ii) Behavior changes gradually with continued experience, often following a "learning curve" to an asymptote. (iii) The change in behavior accompanying experience declines in the absence of continued experience of the same type or as a consequence of a novel experience or trauma.

Insect populations vary in their ability to learn. Genetic variability within strains has been used to analyze learning in *Drosophila*, *Phormia* flies and the honeybee *Apis mellifera*. *Drosophila melanogaster* can be sensitized and habituated, learn associations with positive or negative reinforcement, and be classically conditioned. *Drosophila melanogaster* can learn to run away from specific odors that they previously experienced with electric shock and hungry flies can learn to run toward odors previously associated with a sugar reward. Flies can learn visual, tactile, spatial and proprioceptive cues. Analyses of memory mutants in *Drosophila*, including the genes *dunce*, *rutabaga*, *amnesiac*, *radish*, *zucchini*, *cabbage*, *tetanic*, *turnip*, *linotte* and *latheo*, indicate that memory consists of distinct phases: short-term, intermediate, long-term and anesthesia-resistant memory.

Genetic analyses of learning in *Drosophila melanogaster* began in the mid-1970s in Seymour Benzer's laboratory when *D. melanogaster* was trained to avoid an odor associated with an electric shock. The learned avoidance lasted only a few hours, but the odor avoidance test was used to screen mutagenized flies for strains that had normal olfaction and aversion to shock, but an abnormally-low ability to associate odors with shocks. The mutants obtained were poor learners but each had different phenotypes. One mutant strain, *amnesiac*, had a nearly normal learning ability but forgot rapidly. The *dunce* flies had a shortened memory for several different conditioned behaviors due to a defective gene for cAMP-specific phosphodiesterase, an enzyme that regulates levels of cyclic AMP (cAMP). The *dunce* flies have elevated cAMP levels; cAMP is part of a second messenger signaling pathway in nerve cells that help form associative memories. *dunce* flies have impaired synaptic transmission because the excess of cAMP leads to hyper polarization of the synaptic terminals, resulting in a chronically lowered availability of neurotransmitter.

The *dunce* gene is one of the largest and most complex identified in *Drosophila*, extending over 140 kb. It produces, by the use of multiple transcription start sites and alternative splicing of exons and differential processing of 3′ sequences, at least eight to ten messenger RNAs ranging in size from 4.2 to 9.5 kb. One unusually large intron (noncoding sequence inside the coding region) is 79 kb in length and contains at least two other genes (*Sgs-4* and *Pig-1*) within it. This genes within an intron arrangement is uncommon. One of the contained genes, *Sgs-4*, is expressed in larval salivary glands and provides the glue used by larvae to attach themselves to the surface for pupation. *Sgs-4* is transcribed in the same direction as *dunce*. The second gene, *pre-intermolt gene*, also is expressed in larval salivary glands but is transcribed in the opposite direction. Genes homologous to *dunce* have been identified in mice, rats and humans. The mammalian counterparts of *dunce* function in regulating mood. The *dunce* gene is expressed in the mushroom bodies in the brain of *D. melanogaster.*

Mushroom bodies are important for olfactory learning and memory. In *D. melanogaster* these structures are paired and consist of about 2,500 neurons that send dendrites into a neuropil just ventral to the perikarya where inputs arrive from the antennal lobes and other centers of the brain. Mushroom bodies receive olfactory information from the antennal lobes through their dendrites located in the calyx, a region of the brain just ventral to the mushroom body. Mushroom bodies house part of the short-term memory for odors, are required for courtship conditioning memory and are necessary for context generalization in visual learning, as well as regulating the transition from walking to rest. By analyzing a *Drosophila* strain with *alpha-lobes-absent*, a mutation which causes flies to lack either the two vertical lobes of the mushroom body or two of the three median lobes which contain branches of the vertical lobe neurons, it was found that long-term memory requires the vertical lobes. Short-term memory was normal in flies lacking either vertical lobes or the two median lobes.

Learning probably requires other brain centers, including the antennal lobes, the central complex and the lateral protocerebrum in insects. During metamorphosis, the nervous system of holometabolous insects such as *Drosophila* changes significantly. A controversy has existed as to whether flies retain learned behavior after metamorphosis from larvae to adults, but there is no evidence that larval conditioning induces a change in adult olfactory responses. This is not surprising because larval sense organs undergo histolysis during the pupal stage and adult sense organs are formed *de novo* from imaginal discs. The mushroom bodies of the fly brain are extensively rewired during metamorphosis.

Drosophila carrying the mutant *turnip* have difficulty in olfactory discrimination, conditioning of leg position, larval, visual and reward learning. The *turnip* gene is located on the X chromosome and is associated with reduced protein kinase C activity. Specifically, the *turnip* mutant is defective in phosphorylation of pp76, a membrane protein in head tissues. Protein phosphorylations have been implicated repeatedly in changes underlying learning and short term memory.

Additional genes, including *radish*, *amnesiac*, *cabbage*, *latheo* and *linotte*, are involved in abnormal learning or memory of *D. melanogaster*. For example, flies with the X-linked *radish* mutation initially learn in olfactory tests, but their subsequent memory decays rapidly at both early and late times after learning. The *radish* flies show normal locomotor activity and sensitivity to odor cues and electric-shock reinforcements used in the learning tests. Anesthesia-resistant memory, or consolidated memory, is strongly reduced in *D. melanogaster* with the *radish* phenotype.

The *rutabaga* gene codes for an adenylyl cyclase, is expressed in *Drosophila* mushroom bodies, and is involved in olfactory short-term memory. *Volado*, which codes for an α -integrin that mediates cell adhesion and signal transduction, is expressed in mushroom body cells of *Drosophila* and mediates short-term memory in olfactory learning. Integrins have diverse biological roles, including cell-cycle regulation, cell migration and cell death (apoptosis), functioning as mediators of interactions between cells with the extra cellular matrix or with counter receptors displayed by their cells. They can also transduce information across cell membranes bi-directionally

The enlightenment obtained from the study of these *Drosophila* learning mutants is providing an understanding of learning in higher organisms.

Functional Genomics of Odor Behavior in *Drosophila*

The ability to respond to odors is essential for survival and reproduction, allowing insects to select mates, find and choose food, and locate appropriate oviposition sites. A beginning has been made in understanding the complex genetic basis of odor behavior in insects using *D. melanogaster* as a model system.

Odors are received by olfactory receptors located on the third antennal segments and the maxillary palps, which send their axons to the antennal lobes in insect brains. Each third antennal segment in *D. melanogaster* contains about 1,300 olfactory receptor cells and each maxillary palp carries 120 chemosensory neurons. These neurons project to 43 glomeruli in the antennal lobe of the brain. From there, processed olfactory information is relayed to higher-order brain centers (the mushroom body and the lateral horn of the protocerebrum).

D. melanogaster has approximately 1,300 olfactory receptor neurons and *D. melanogaster* is able to recognize and discriminate between a large number of odorants. Each olfactory sensory neuron responds to several odorants, but respond maximally to only one. While the average olfactory receptor gene is expressed in 20 olfactory neurons, some receptor genes are expressed in only two to three neurons. Seven olfactory receptor genes are expressed solely in the maxillary palp.

It is thought that there are fewer than 100 types of odor receptors in insects, and perhaps as few as 50 or 60. By contrast, mammals have more than 10,000 different receptor types. The approximately 50–60 odorant receptor genes in insects encode a novel family of proteins with seven predicted membrane-spanning domains; these genes are unrelated to vertebrate or nematode chemosensory receptors, suggesting the genes evolved in an independent manner throughout evolution. Furthermore, the *Drosophila* genes are poorly grouped into subfamilies of similar sequences because they are only 17–30% similar to each other.

Learning in *Apis mellifera*

Mushroom bodies in the Hymenoptera are much larger than those in *Drosophila*, which may reflect the importance of the mushroom bodies for functions underlying social behavior, learning and memory in the honey bee. Many Hymenoptera (ants, bees, wasps) have complex behaviors that include caring for their brood either as individual females or as a social group of females. Bee species such as *Apis mellifera* feed, protect and nurse larvae, store food and respond to adverse environmental factors. They search for nectar and pollen at unpredictable sites, learn the celestial and terrestrial cues that guide their foraging trips over long distances and allow them to find their nest sites once again. They learn how to respond to the changing position of the sun, to a pattern of polarized light during the day, and to landmarks. Associative learning is an essential component to foraging behavior and dance communication. Hive mates attending a dance performance learn the odor the dancing bee carries and seek out that same odor when they forage for food.

The complexity of bee behavior makes it an ideal organism to analyze to better understand learning, especially in response to odors. Associative olfactory learning in honey bees has several features similar to higher forms of learning in vertebrates.

Pheromones in Insects

Insects use chemical cues as signals to find mates, food, oviposition and hibernation sites. Molecular genetic methods are now being used to study various aspects of pheromone response behavior. For example, genes that code for proteins involved in the synthesis of pheromones, the perception of semiochemicals, and the processing of the signals are being cloned and characterized.

Pheromone biosynthesis appears to use one or a few enzymes that convert the products of normal primary metabolism into compounds that act as pheromones. For example, pheromones arise from isoprenoid biosynthesis, or by the transformation of amino acids or fatty acids. A number of the genes encoding the enzymes involved in transforming metabolites into pheromones have been cloned and sequenced. The production of pheromones by insects is regulated by three hormonal messengers: juvenile hormone III, ecdysteroids, and a neuropeptide called PBAN (pheromone biosynthesis activating neuropeptide).

Perception of the volatile pheromone is mediated by olfactory organs (sensillae) located primarily on the antennae. Receptor neurons on the antennae appear to respond to one particular chemical (specialist neurons) while others appear to respond to a number of compounds (generalist neurons). Pheromones are often perceived in combination with other chemicals, including plant volatiles.

The detection of pheromones and other chemicals by insects involves proteins (odorant binding proteins, OBPs) that carry the compounds from the surface of the antennal sensilla through the sensillum lymph to the G-protein-coupled receptors and the olfactory neurons. The odorant binding proteins (which includes pheromone binding proteins) are small, soluble proteins that are concentrated in the sensillum lymph.

Genes and complementary DNAs encoding odorant binding proteins of many insects have been cloned. Analysis indicates that the binding proteins of unrelated species have low levels of amino acid sequence similarity, although they do have a conserved region with cysteines that may be important for function. It appears that there has been gene duplication and divergence of odorant binding protein genes, with moth proteins belonging to one branch and the proteins of other insects not closely related.

The molecular receptors in an olfactory system involve G-protein-coupled seven transmembrane proteins. Such proteins also are found in the mouse and rat, where the number of such genes number approximately 1,000 or nearly 1% of the genome, indicating that odor reception is an important component of the mammalian genome. Sequencing the *Drosophila* genome has allowed receptor similar proteins to be identified in an insect. The receptors are in large multigene families and expressed at different times during antennal development. The receptor genes were found by searching the *Drosophila* genome to identify sequences that might encode transmembrane domains.

Once an odor or pheromone has activated the olfactory receptors, it needs to be deactivated. Several enzymes have been found that appear to degrade odor stimulants, including esterases, oxidases, and glutathion transferases. Multielectrode recording of the *Manduca sexta* antennal lobe indicates that the relative timing of action potentials may convey information about odor concentration and mixture. A large and diverse family of genes coding for taste receptors have been identified in *Drosophila* that are expressed in the proboscis.

Rapid advances in understanding olfaction and gustation in insects, especially based on molecular genetic analyses of *D. melanogaster*, promise to advance our understanding of how insects perceive chemical cues in their environment.

Unfortunately, early evidence suggests an extreme divergence of receptors within *D. melanogaster* that make it difficult to use homology to isolate odor receptor genes from other insects.

Divergent Functions of *Est-6* and *Est-5* in *Drosophila* Species

Evolutionary changes in gene regulation can be a prerequisite for macro evolutionary change and species divergence. One case study involves an analysis of the esterase 6 enzyme in *Drosophila melanogaster* and its homologue (esterase 5) in *D. pseudoobscura.* This gene influences behavior in *D. melanogaster* but has a very different function in *D. pseudoobscura.*

Esterase-6 (*Est-6*) in *D. melanogaster* influences male mating speed and rate of remating by females. Fast and slow variants of esterase 6 protein, as detected by electrophoresis, are produced in natural populations of *D. melanogaster*. More esterase 6 protein is produced in adult males than in females. The enzyme is highly concentrated in the anterior ejaculatory duct of males and is transferred to females during the first 2–3 min of the 20min copulation. Enzyme activity in females can be detected up to 2 h after mating and influences the timing of remating by females. Males transfer a substance in the seminal fluid which is converted in the females' reproductive tract by esterase 6 into a pheromone that serves as an antiaphrodiasiac. The antiaphrodiasiac reduces the sexual attractiveness and receptivity of females, reducing the likelihood she will remate. Because the sperm from the most recent male takes precedence in fertilizing a female's eggs, this behavior appears to encourage monogamy in *D. melanogaster* females. *Est-6* also influences the rate of mating of males in *D. melanogaster*. Males with the slow variant of the protein require 10.2 min to achieve copulation with females, while males with the faster-moving protein require only 5.7 min.

Once the *Est-6* gene was cloned, it was used as a probe to identify homologous genes in related species, which can provide clues to the evolution of behavior. *Est-6* was used to isolate a homologous gene (*Est-5*) from *D. pseudoobscura*. Surprisingly, *Est-5* has a different function in *D. pseudoobscura*. Approximately 40% of *Est-5* is expressed in the eyes of *D. pseudoobscura*, with the remainder expressed in the hemolymph of both sexes. Despite these different patterns of expression, *Est-6* and *Est-5* have similar protein products, messenger RNA transcripts, and DNA sequences.

When *Est-5* from *D. pseudoobscura* was cloned into a P element and introduced into *D. melanogaster*, its activity and pattern of expression in *D. melanogaster* matched those of *D. pseudoobscura*. These results imply that regulatory sequences in *Est-5* have been conserved since the divergence of the two species 20–46 million years ago, suggesting that the enzyme in the common ancestor of these two species had a more extensive expression pattern. After the species diverged, regulatory mutations may have occurred that enhanced *Est-5* expression in the eyes of *D. pseudoobscura*, while mutations in *Est-6* led to increased expression in the male ejaculatory duct of *D. melanogaster*. Thus, the use of homology to identify behavioral (and other) genes can lead to surprises.

Courtship Behavior in *Drosophila*

Mating behavior of *D. melanogaster* is stereotypical, with a fixed sequence of actions that are under genetic control. Courtship involves visual stimuli, acoustic signals, and pheromones. Male courtship behavior involves six elements in the following fixed order: orienting → following → wing vibration → licking → attempting to copulate → copulation.

Sexual differentiation in *Drosophila* is controlled by a short cascade of regulatory genes, the expression of which determines all aspects of maleness and femaleness in the body and the central nervous system, including complex behaviors. Such sexual behavior is irreversibly programmed during a critical period as a result of the activity or inactivity of the major control gene *tra*$^{+}$. Male behavior is replaced by female behavior when *tra*$^{+}$ is expressed around the time of puparium formation.

Other genes indirectly affect courtship behavior in *Drosophila*, including genes that involve: general behavior (*yellow*, *inactive*, *couch potato*, *cuckold*, *minibrain*, *nerd*); visual behavior (*white, optomotor-blind, no-receptor-potential-A*); olfaction (smellblind); learning/memory genes (*dunce*, *rutabaga*, *amnesiac*, *Shaker*, *ether-a-go-go*); regulating periodicity of behavior (*period*), courtship song mutants (*cacophony, dissonance, croaker, fruitless*); female receptivity (*spinster*).

The *fruitless* mutation is involved in both sex determination and courtship behavior and is active in the central nervous system. Males with the *fruitless* mutation may court both females and males without copulating. Male flies expressing this gene are unable to bend their abdomens in the presence of females they are courting because they lack a male-specific Muscle of Lawrence. Some *fruitless* mutations cause males to be homosexual (they do not court females), while others cause males to be bisexual (they court both males and females). The *fruitless*$^{+}$ gene is the first gene in a branch of the sex-determination hierarchy functioning specifically in the central nervous system, with mutants of this gene affecting nearly all aspects of male sexual behavior. It is at least 140 kb long and produces a complex array of transcripts by using four promoters and alternative splicing; the male-specific transcripts are only expressed in a small fraction of the central nervous system.

Another mutation, *dissatisfaction*, is necessary for some aspects of sex-specific courtship behavior and neural differentiation in flies of both sexes. Mutant males are bisexual but, unlike *fruitless* males, attempt to copulate. Males with the *dissatisfaction* phenotype take longer to copulate with females while females are unreceptive to male advances during courtship and do not lay mature eggs.

Mating behavior of females involves the following sequence: stopping moving → offering the courting male a chance to lick the female's genitalia → allowing males to attempt copulation. Nonreceptive females leave the courting male, and if the male pursues her, she may kick him. Nonreceptive virgin females persistently repel male approaches by lifting their abdomens up to block physically any contacts with males. Nonreceptive fertilized females lower their abdomen, extrude their ovipositors and eggs to repel males. Thus, female receptivity varies with age, diet, hormonal condition and mating experience. The *spinster* mutation affects female sexual receptivity throughout their lives, and *spinster* females continuously leave, kick, or fend off courting males.

Both *D. melanogaster* and *D. simulans* females produce contact pheromones, which consist of cuticular hydrocarbons that elicit wing displays by males. These chemical signals have a low volatility, and thus act at a very short distance (a few mm) and thus are perceived by contact rather than smell. Flies from a given strain, sex, and age produce a reproducible pattern of cuticular hydrocarbons, the biochemical pathway of which is under genetic control. The most important hydrocarbons involved in mate recognition or stimulation are 7-tricosene and 7-pentacosene. One mutation, *Ngbo*, influences the ratios of 7-tricosene and 7-pentacosene in *D. simulans*. Another, *kete*, reduces the amount of 7-tricosene and all other linear hydrocarbons but does not affect the ratio. Flies homozygous for both *kete* and *Ngbo* have reduced viability and fertility, perhaps because they have very little 7-tricosene.

Experiments were conducted to eliminate all known cuticular hydrocarbons in *D. melanogaster* in order to determine how mating behavior would be modified. The results were surprising; contrary to expectation that *D. melanogaster* females lacking cuticular pheromones would induce no courtship by males, such females remained attractive. Additional analysis indicated that undetermined pheromone(s), probably also cuticular hydrocarbons, were present on both control and transgenic flies. These newly discovered pheromones could represent ancestral attractive substances in *D. melanogaster* and its sibling species. An absence of inhibitory pheromones leads to high levels of interspecific mating among *Drosophila* species, suggesting that cuticular hydrocarbons are important in maintaining reproductive isolation.

Studies of Human Neurodegenerative Diseases and Addictions in *Drosophila*

Drosophila is perhaps unique among eukaryotes in the variety and level of sophistication that can be applied to understand its neurobiology. *Drosophila* is being studied, as well, to gain knowledge about various neurodegenerative diseases in humans.

Modeling diseases in simple invertebrate systems is attractive because genetic interactions can be used to define cellular cascades mediating, for example, death of neurons in Parkinson disease, the second most common neurodegenerative disorder in humans. Transgenic *Drosophila* containing a mutant form of the human α -synuclein gene exhibit the essential features of the Parkinson's disease in humans, making it possible to study the function of α -synuclein and determine the underlying pathogenic mechanisms in a genetically tractable animal.

The *spongecake* mutant of *Drosophila* shows degenerative changes similar to that seen in humans with Creutzfeld-Jakob disease, while the *eggroll* mutant produces changes similar to those seen in humans with Tay-Sachs disease. The *beta-amyloid protein precursor-like (Appl)* gene of *Drosophila* encodes a homolog of the human α -amyloid precursor protein which gives rise to α -amyloid, a major component of the plaques in the patients suffering from Alzheimer's disease. Another protein associated with human Alzheimer's disease, presenilin, has been found in *Drosophila* and studies suggest it may also be involved in the development of the pathology. *A Drosophila* homolog was identified for the human gene for copper/zinc superoxide dismutase; mutants of this gene are implicated in Lou Gehrig's disease.

A recessive mutant (*bubblegum*) in *D. melanogaster* exhibits adult neurodegeneration similar to that seen in the human disease adrenoleukodystrophy (ALD), otherwise known as the disease cured in the movie "Lorenzo's Oil";. In ALD, high levels of very long chain fatty acids are produced that can be lowered by dietary treatment with a mixture of unsaturated fatty acids; feeding the ALD flies one of the components, glyceryl trioleate oil, blocked the accumulation of excess very long chain fatty acids and eliminated the development of pathology. Thus, *bubblegum* flies provide a model system for studying mechanisms of disease and screening drugs for treatment.

Drosophila also has been proposed as a model organism for studying the genetics of alcohol abuse and drug addiction in humans. Alcohol addiction and many types of drug addictions appear to share common mechanisms. For example, the "dopamine hypothesis" suggests that addictive drugs may activate certain areas of the human brain leading to an increase in dopamine neurotransmitter release. Elevation of dopamine probably provides a sense of well being, pleasure, or elation (positive reinforcement). Dopamine is not the only neurotransmitter acting in alcohol abuse; glutamate, serotonin, and GABA also are may be involved. Furthermore, four of the five circadian genes (*period, clock, cycle, doubletime*) identified in *D. melanogaster* influence the fly's responsiveness to cocaine and suggest a biochemical regulator of cocaine sensitization.

Selection of *D. melanogaster* for resistance to ethanol was shown to be determined by multiple genetic components. Mutant strains with different responses to ethanol and different responses to the effects of acute ethanol exposure on locomotor behaviors are remarkably similar to those described for mammals. Thus, study of *Drosophila* could pave the way for an in-depth study of the genes involved in acute and chronic effects of ethanol. In *Drosophila*, as in mammals, dopaminergic pathways play a role in modulating specific behavioral responses to cocaine, nicotine or ethanol.

Sleep even occurs in *Drosophila* and may be a model for understanding sleep in other animals. Flies that are "resting" are sleeping, which involves the flies choosing a preferred location, becoming immobile for periods of up to 157 min at a particular time in the circadian day, and becoming relatively unresponsive to sensory stimuli. When rest is prevented, the flies tend to rest despite stimulation and then exhibit a rest "rebound." Drugs that affect sleep in mammals alter "rest" in flies, suggesting conserved neural mechanisms. During sleep, an animal cannot forage for food, take care of its young, procreate or avoid the dangers of predation, indicating that sleep must serve an important function. Sleep disorders in humans are common, but the genes underlying these disorders are unknown.

Molecular Analyses of Complex Behaviors

The genetic basis of many behavioral attributes in insects is probably determined by many genes. Furthermore, behavior is determined, not only by genetic composition, but also by the environment and can be influenced by learning. The effects of the environment may mask those of the genotype, making genetic analysis imprecise. While elaborate statistical techniques have been developed for quantitative genetic analyses, a thorough understanding of behaviors that are quantitatively determined has been slow to develop.

Understanding the mechanisms of behavior determined by single genes is hard work, but relatively straight forward. Understanding the mechanisms of behavior determined by many genes requires ingenuity and extensive effort. However, such research offers many rewards. For example, advances in understanding the molecular genetic basis of social behavior in bees and ants could allow us to understand the evolution of female choice, kin recognition, reciprocal altruism, and the organization of insect societies.

Analysis of insect behavior using insect molecular genetic approaches is still in its infancy, but the disciplines of ethology, genetics, physiology, and molecular biology promise to revolutionize the field.

Beklemishev, Vladimir Nikolayevich

Inna Ioffe-Uspensky, Igor Uspensky
The Hebrew University of Jerusalem, Jerusalem, Israel

V.N. Beklemishev was born on October 5, 1890, in Hrodna, then a portion of Poland incorporated into the Russian Empire. He grew up in a large harmonious family with a high level of culture and education. From the family he received a good intellectual and moral education that strongly influenced him. He studied in the local grammar school which he left as the top pupil. He was interested in natural history and he collected insects and read books by Braem, Fabre and other naturalists. In 1908, he entered the University of St.-Petersburg specializing in zoology. After graduating from the University (1913) he was kept there "to prepare for the title of Professor." In 1918 he received his Master's degree in zoology and comparative anatomy with the right to lecture. However, because of terrible famine and collapse after the October Revolution of 1917 he left St.-Petersburg (Petrograd) for Perm' (in the Ural Mountains) where he received the position of an associate professor in the University of Perm'. By 1920 he was approved as a full professor in the faculty of medicine. He lectured in many general and special courses and carried out intensive research on the morphology of invertebrates, biocenology and hydrobiology. The wide range of his interests and his excellent erudition in various fields of biology were of great importance when in 1924 he headed an entomological study at the Malarial Station of the Medical and Biological Institute of Perm'. Working on the ecology of *Anopheles* larvae, he studied hydrobiological characteristics of larval biotopes and the habitat distribution of mosquito larvae. He evaluated the significance of water bodies in different landscapes not only from an entomological but also from an epidemiological point of view. As a result, he formulated the doctrine of landscape malariology which allowed the planning of control measures based on the characteristics of a particular landscape. In 1932 he was invited to Moscow to head the Department of Medical Entomology in the Tropical Institute (later the Martsinovsky Institute of Medical Parasitology and Tropical Medicine). The biology of adult mosquitoes was the main aspect of his interest at that time. Together with his followers he studied the population biology of different species of *Anopheles*. These fundamental works included the detailed study of mosquito morphology, mosquito behavior, gonotrophic cycles, physiological age, etc. He wrote that any finding illuminating unknown features in *Anopheles* biology would be important for the success of malaria control. From mosquitoes he moved to the study of other groups of arthropods which allowed him to develop a concept of the "life scheme" of species, which is considered as the total amount of species adaptations to the environment. His concept is rather close to Hutchinson's concept of a fundamental ecological niche, developed later. He liked and estimated the comparative analysis as the mostly fruitful approach in biological study. He was the founder of the comparative parasitology of bloodsucking arthropods. Comparing the life schemes of bloodsucking arthropods, he distinguished main types of their parasitism. He considered the origins and development of arthropod parasitism on terrestrial vertebrates. He developed well-balanced systems of relationships between parasitic arthropods and their hosts and showed the role of such systems in biocenoses. During the 1950s he worked intensively on the problem of tick-borne encephalitis in the USSR and significantly contributed to the understanding of the structure of natural foci and epidemiology and epizootiology of this infection. All his ideas were not only theoretical constructions but the result of laboratory studies and field expeditions to different areas of the USSR in which he participated together with his younger fellows. His main publications include: "Ecology of the malarial mosquito (*Anopheles maculipennis* Mgn)" (1944); "The planning of settlements and the problem of malaria" (1949); "Manual of medical entomology" in two volumes (editor and the author of many chapters) (1949); "Key to arthropods injuring human health" (editor and the author of some chapters) (1958). He was also the editor of many proceedings and books. Unfortunately, most of his papers were published only in Russian. He was well known among world zoologists as the author of his greatest work "Principles of comparative anatomy of invertebrates" which had three editions in the USSR (1944, 1952, 1964) and was also published in Romania, Poland and the German Democratic Republic. In 1969 this monograph was published in English (Edinburgh). In recognition of his works he was elected to the Academy of Medical Sciences of the USSR, and twice he was awarded the USSR State Prize. He was elected to the Polish Academy of Sciences. He was also much revered by his numerous pupils many of whom became well-known specialists. His interests were not limited by biology only. He knew history, liked and knew Chinese art and philosophy, and he liked poetry, fine art and architecture. He wrote verses himself. He died on September 4, 1962. In 1970 his pupils published a collection of his most important papers under the title "Biocenological principles of comparative parasitology."

Bell, William J

Bill Bell was born in Boston, Massachusetts, on January 10, 1943. His B.S. degree in biology and education was earned in 1964 from Bridgewater State College, M.A. in zoology in 1966 from the University of Massachusetts, and Ph.D. in 1969 from the University of Pennsylvania. The subject of his Ph.D. research was the role of juvenile hormone in vitellogenesis. Then followed a 1-year postdoctoral fellowship at the University of Texas before he was appointed assistant professor of entomology at the University of Kansas. His career was spent in Kansas, and he was promoted to full professor at the age of 33. He taught undergraduate and graduate classes and, between 1970 and 1996 had trained 18 Ph.D. and eight M.A. students in his laboratory. His research interests, begun with developmental biology, expanded to reproductive physiology, chemoperception, and related behaviors, and began to include field work. He served as editor of Journal of the Kansas Entomological Society (1982–1984), co-editor of Environmental Entomology (1984–1987), and as editorial board member of Journal of Insect Physiology. He served as editor of Journal of Insect Behavior, which he and Tom Payne founded, from 1988 until his death. He published over 100 research papers and reviews, edited three books, and wrote two: (1981) "The laboratory cockroach," and (1991) "Searching behavior: the behavioral ecology of finding resources." He died on October 17, 1998, after a long illness, survived by his one son and former wife.

Belostomatidae

A family of bugs (order Hemiptera). They sometimes are called giant water bugs and toe biters.

► Bugs

Beneficials

Organisms that provide a benefit to crop production, especially natural enemies of pests and plant pollinators such as bees.

Benthic Community

The community of organisms inhabiting the bottom of a body of water.

Bertha Armyworm, *Mamestra configurata* Walker (Lepidoptera: Noctuidae)

PETER G. MASON
Agriculture and Agri-Food Canada, Eastern Cereal and Oilseed Research Centre, Ottawa, ON, Canada

The bertha armyworm, *Mamestra configurata*, atta- cks canola (*Brassica napus L.* and *Brassica rapa* L.) in the northern great plains of North America. Other crops subject to damage by bertha armyworm include flax, *Linum usitatissimum* L., sweet clover, *Meliotus officinalis* L., and alfalfa, *Medigaco sativa* L., although development is not completed or progeny are undersized. Bertha armyworm is a Nearctic species, apparently restricted to dry grassland-type habitats in western North America. It prefers the native weed *Chenopodium album* (lamb's-quarters) but successfully develops on B. napus and B. rapa varieties with low isothiocyanate and glucosinolate levels (canola). *Mamestra configurata* has one North American relative, *Mamestra curialis* (Smith). The larvae of the two species are difficult to separate but adults are distinguished by the wing markings and by characters of the male genitalia. The two species also occupy different habitats, *M. curialis* occurs primarily in forested areas while *M. configurata* is found in grassland areas.

Importance

The economic impact of bertha armyworm is attributed to its importance as a major pest of canola crops. Young larvae consume the leaf foliage of canola and the plant generally compensates for this damage. The fifth and sixth instars cause the greatest damage because they feed on the developing nutrient rich seedpods, adversely affecting seed quality and lowering seed grade. Since 1922, bertha armyworm outbreaks have occurred at intervals of varying length and persist from one to three years. Since 1970, the increase in the incidence of bertha armyworm outbreaks has been associated with the extraordinary increase in the number of hectares planted to canola. Most outbreaks are local and not synchronized with those of other areas. Widespread outbreaks cost producers $10s of millions in yield losses and control costs.

Biology

Bertha armyworm has a univoltine life cycle requiring 6–8 weeks from egg to pupa, which overwinters. Adults emerge from the soil from early June to early August and are attracted to canola fields that are in bloom. The moths are nocturnal, and females copulate during the 2nd or 3rd night after emergence, remaining in copula for about 17 h. Females lay single-layered masses of 20–200 eggs on the underside of leaves of host plants, depositing 75% of their egg complement during the first week after emergence and up to 3,500 eggs during their lifetime.

Eggs are spherical, slightly flattened on the ventral surface, about 0.45 mm in diameter and with a series of longitudinal ridges and depressions (sculpting) radiating from the upper mitotic pole. The white eggs develop for approximately one week. As development takes place the eggs become almost black. Just before they hatch, the black headed first instar larvae are visible through the chorion.

First-instar larvae hatch and immediately disperse from the egg mass to feed on foliage. The larvae feed at night and when disturbed they may drop off the leaves using a fine silk thread which they use to climb back onto the plant. Large larvae may drop off the plants and curl up when disturbed, behavior typical of cutworms and armyworms. The first four instars feed on foliage and, although they prefer foliage, the final two instars feed on the developing pods, the most nutrient-rich plant part during this time of the growing season. The final instar larva consumes 70–80% of the total food consumed by the six larval stages. The dark color of the last two larval instars makes them noticeable in the crop. At summer's end the mature larvae drop to the ground and seek shelter in cracks 5–16 cm below the soil surface where they pupate. Larvae vary greatly in color, particularly the older individuals.

Newly hatched first instar larvae have a distinct black head and are about 0.3 cm long and are covered with sparse but distinct setae. The next five instars have light brown head capsules and the body setae are less evident. The first four instars are green, usually with distinct, narrow, whitish, stripes on their back, and a wider but indistinct band on the side of the body. Most fifth instar larvae are green, others brownish green, or brown with darker markings. The sixth instar, about 4 cm long, is commonly velvety black or brown with conspicuous yellowish-orange stripes along each side and a green underside which contrasts with the dark dorsum. Individuals of the velvety black form have three narrow, interrupted white stripes along their backs. In nature, many variants are found, singly or in homogenous groups, and appear to represent different species, increasing the difficulty of accurate identification. Larvae may exhibit limited local migration, typical of armyworms, when their preferred food source is consumed.

Pupae are reddish, slender, 5.5 mm wide and 18.5 mm long, gradually tapering caudally with flexible abdominal segments. The terminal spines are stout, about 0.7 mm long, close set but slightly divergent, and slightly out-curved at the tip. Males and females are distinguished by the structure of the terminal abdominal segments. Bertha armyworm pupae are not easily distinguished from other cutworm pupae. The pupae undergo a facultative diapause, induced by temperature and photoperiod cues experienced by 4–6 instar larvae. If fall conditions are unusually warm some pupae continue development and will emerge. Over-wintering mortality of pupae is important and is influenced by duration of exposure to temperatures near or below freezing.

The adult is large with a wingspan of about 4 cm. The forewing is mostly grey with patches of black, brown, olive and white scales. The distinguishing feature of the bertha armyworm moth is the broad olive band adjacent to the subterminal line, defined by white markings on the inner side of the forewing.

Outbreaks of bertha armyworm are sporadic, yet consist of huge numbers of larvae infesting canola crops. Population monitoring is important for determining the potential for damage. Adult bertha armyworm can be detected by close inspection of lamb's-quarters and canola plants where they roost during the day on the underside of leaves. Egg masses and early instar larvae are found by inspecting the underside of leaves. The dark late instar larvae are readily visible when feeding on developing seedpods on the tops of canola plants, even at a distance. Area-wide pest management programs use traps baited with a species-specific sex pheromone to monitor bertha armyworm adult numbers. The data are refined and mapped using geographical information systems (GIS) to provide an early warning of outbreak potential. Producers in areas of high risk are advised to regularly inspect their crops to assess larval densities.

Management

Chemical insecticides are registered for use against bertha armyworm. The decision to apply insecticides is based on the larval densities associated with the value of the crop and the cost of spraying.

However, insecticides harm natural enemies, particularly parasitoids of the bertha armyworm.

Cultural control methods for reducing the impact of bertha armyworm include crop rotation and tillage. Crop rotation has limited effectiveness because adult bertha armyworm are strong fliers and readily invade neighboring crops. Fall tillage may increase the overwintering mortality of pupae and spring cultivation may injure the pupae but these methods are not used where minimum tillage is practiced.

Naturally occurring diseases, such as the fungus *Entomophthorales* sp., a "nuclear polyhedrosis virus" (NPV), and the microsporidian *Nosema* sp., are important larval mortality factors at high population densities and NPV infections in up to 95% of local populations have been recorded. Of the native parasitoids, only *Banchus flavescens* Cresson (Ichneumonidae) and *Athrycia cinerea* (Coquillett) (Tachinidae) cause significant mortality in bertha armyworm populations. During outbreaks, *B. flavescens*, which attacks early instar larvae, is usually the most abundant parasitoid, although *A. cinerea* occasionally is more abundant. Parasitism significantly reduces food consumption by bertha armyworm larvae. The effect of arthropod predators on bertha armyworm populations is unknown. Vertebrates, particularly birds, may be important when population densities are high. How natural enemies regulate bertha armyworm populations between outbreaks is not known.

Berytidae

A family of bugs (order Hemiptera). They sometimes are called stilt bugs.

► Bugs

Bequaert, Joseph Charles

Joseph Bequaert was born in Thourout, Belgium, on May 24, 1886. He earned a Ph.D. from Universiteit Gent in natural sciences in 1908. In 1910–1912, he worked for the Belgian sleeping sickness commission, and in 1913–1915 in what was then the Belgian Congo. He emigrated to the USA and became (1917–1922) an associate of the American Museum of Natural History as entomologist, malacologist, and botanist. He became a U.S. citizen in 1921. In 1923–1925 he worked as an instructor in entomology at Harvard Medical School (Massachusetts, USA), in 1925–1945 as assistant professor, and in 1929–1956 as curator of insects in the Museum of Comparative Zoology at Harvard University and in 1951–1956 as Agassiz Professor of Zoology at the same institution. Then he moved to the University of Houston (Texas, USA) as professor of biology, moving to the University of Arizona in 1960. His final move was to the University of Massachusetts. He married Frances A. Brown in 1927 and they had two children. His interests were in entomology (especially medical entomology) and malacology (especially medical malacology); he published major works in both areas and was president of the American Malacologists' Union in 1954. He died in Amherst, Massachusetts, USA, on May 24, 1982.

Beraeidae

A family of caddisflies (order Trichoptera).

► Caddisflies

Bergmann's Rule

Among mammals and birds, individuals of a species occurring in colder climates tend to have a larger body mass, and a correspondingly lower surface to volume ratio, than members of the same species living in warmer climates. This trend results from the need to conserve heat in cold climates but to eliminate excess heat in hot climates. A variant of this is Allen's rule. These rules do not apply to ectothermic animals such as insects.

► Allen's Rule

► Thermoregulation

Berlese, Antonio

Antonio Berlese (Fig. 34) was born in Padua on June 26, 1863. As a boy, he was interested in natural history and collected insects and mites. His studies at Università di Padova (the University of Padua) resulted in a degree in 1884 in natural sciences. He worked for a few months in a school of human anatomy, but then accepted a post at Stazione di Entomologia Agraria in Florence, which Adolfo Targione Tozzetti had founded and then directed. Finishing a professional course in 1887, he worked as Targioni's assistant until 1890 when he was nominated for a position as professor of general and agrarian zoology at R. Scuola Superiore di Agricoltura di Portici, where he worked until 1903. Then, he was nominated director of the R. Stazione di Entomologia Agraria in Florence, succeeding Targioni. He built up this station little by little until it became one of the best-equipped in Italy. From his first publication in 1880, he worked 47 years without interruption, producing a total of 275 publications. A large part of his work was devoted to the study of mites, in which he built a collection of 12,750 slide-mounted specimens. Another major endeavor was his work on olive fruit fly, and yet another on the scale *Diaspis pentagona*. His two-volume book "Gl'insetti, loro organizzazione, sviluppo, abitudini e rapporti coll'uomo" with 2,187 figures, was published in parts, from 1904 to 1923. His awards included a prize of 10,000 lire from the R. Accademia di Agricoltura di Torino, a gold medal from the province of Venezia in 1913, an award of 75,000 lire from the

Berlese, Antonio, Figure 34 **Antonio Berlese.**

council of the province of Udine in 1924, and honorary membership in the Société Entomologique de France. He died in Florence on October 24, 1927.

Berlese Funnel

An extraction devise used to separate and extract small arthropods from leaf litter or similar material. A Berlese funnel normally consists of a funnel with a wire mesh insert that support the plant material above a reservoir containing alcohol or another preservative. As the arthropods move about, particularly as they move deeper into the funnel to escape drying of the plant material, they slip down the funnel into the reservoir containing liquid where they are retained for identification. This technique is useful for many arthropods, but not for those that may fly to escape, or those that are very fragile and perish from desiccation before they can escape the plant material. A modern variant of the Berlese funnel is the Tullgren Funnel, which is simply a Berlese funnel with an incandescent light suspended above the funnel to provide a source of heat and to extract the arthropods faster. Another variant uses a cover to eliminate escape by insects capable of flight, and to more efficiently direct the heat generated by the light bulb. Most "Berlese" funnels now used are actually Tullgren funnels, but the distinction is not generally appreciated.

Bernhauer, Max

Max Bernhauer was born in Müglitz, Austria (otherwise known as Mohelnice, and now in the Czech Republic) on September 24, 1866. His education was in Olomonic (now in the Czech Republic) and then at Universität Wien ("the University of Vienna," Austria), but the final degree he obtained in 1899 was as *doctor juris* ("doctor of law"), not as a biologist. He worked as a notary in Austria. It was Ludwig Ganglbauer, in particular, who instructed Max on Coleoptera. His first two papers were published in 1898. Because of the dearth of people willing to study and identify Staphylinidae, Max was soon presented with an endless flow of specimens collected from around the world, and asked to identify them (cost free, of course). For Max, this was a seemingly endless opportunity to classify and describe the species of the huge family Staphylinidae, and to build his collection. He collaborated with Karl Schubert and Otto Scheerpeltz in producing a world catalog (published by Junk-Schenkling as part of "Coleopterorum Catalogus";), completed in 1926 and listing 12,740 species, but expanded to 19,900 species by 1932 by Otto Scheepeltz and continuing to grow. The world total of Staphylinidae as of the year 2000 exceeded 45,000 species, and Max Bernhauer had described 5,251 of them, including 342 new genera, in his 285 publications, a spectacular achievement for an "amateur" coleopterist. Names of the vast majority of the species that he described are still considered valid, even though he was not in the habit of providing illustrations or keys for identification, so that confirmation of identity of the species he described is often very difficult. He died on March 13, 1946, in Horn, Austria. His collection was sold, soon after his death, a negotiation achieved by Rupert Wenzel, to the Field Museum of Natural History, Chicago, USA. There seems to have been a teacher-student train Erichson-Ganglbauer- Bernhauer-Scheerpeltz among the German-speaking students of Staphylinidae, which, unfortunately, ended with Otto Scheerpeltz.

Berothidae

A family of insects in the order Neuroptera. They commonly are known as beaded lacewings.

► Lacewings, antlions, and mantidflies

Bertram, Douglas Somerville

Douglas Bertram was born in Glasgow in 1913. His Bachelor's degree was from Glasgow University, after which he did graduate research and was employed as a demonstrator in the Zoology Department of that university. In 1938 he moved as Lecturer in Entomology to Liverpool School of Tropical Medicine, began insect cultures, and performed research on fowl malaria. In 1940, he enlisted in the British army and served in Egypt and Greece, but was captured in Crete and remained a prisoner in Germany for the duration of the war. In 1946, he returned to Liverpool for two years and worked on cotton rat filariasis and on control of warble fly. In 1948, he was appointed as Reader in the Department of Medical Entomology in the London School of Hygiene and Tropical Medicine, later becoming head of the department. His research was directed to mosquitoes, especially their age-grading, and their transmission of viruses and fowl malaria, but extended to other biting families of biting flies, and to biological control of triatomine bugs. He traveled extensively to tropical countries to further his research. He was consultant in entomology to the British army, fellow of the Royal Entomological Society, of the Institute of Biology, and of the Royal Society of Tropical Medicine and Hygiene. He died in 1988.

Bess Beetles (Coleoptera: Passalidae)

JACK SCHUSTER
Universidad del Valle de Guatemala, Guatemala City, Guatemala

Bess, patent-leather, or passalid beetles are common, primarily tropical insects. A few of the approximately 600 species occur in temperate regions (China, Japan, Korea, Canada, U.S., and Tasmania, but not Europe, though the largest collection in the world may be that of the Paris Museum of Natural History). Five species have been collected in the U.S. (Compare to Guatemala, the size of North Carolina, with 84 species!) The most common, *Odontotaenius disjunctus* (Illiger), is known from the East Coast to the riparian forests of the eastern Great Plains north to Manitoba and Ontario, and south to Texas and Florida. Another species, *O. floridanus* Schuster is known only from sand hills of Florida scrub habitat which used to be islands during previous interglacial times. Two other species, *Passalus punctiger* Lepeletier & Serville and *P. punctatostriatus* Percheron, were collected at the beginning of the twentieth century in eastern Arizona; they may have been brought from Mexico in wood shipped by train. They haven't been collected in the U.S. since that time. A fifth species, *Ptichopus angulatus* (Percheron), was recently collected in Arizona. This has been expected; it occurs in leaf-cutter ant nests just south of the Rio Grande in Texas.

Flightless beetles tend to originate on islands or (in passalids especially) on isolated mountains, resulting in high levels of endemism (an endemic organism is one found only in a given area, e.g., endemic to Guatemala, or endemic to Pike's Peak). The distribution of endemic passalids correlates with the distribution of other endemic organisms. Because passalids are relatively easy to find, they can be used as indicator organisms for areas of endemism, especially for cloud forests on tropical mountains. For example, eight areas of endemism have been identified for Guatemala and adjacent Chiapas, Mexico, on the basis of passalid distributions. This is important for prioritizing areas for conservation.

Only one fossil passalid is known, similar, if not identical, to a species known from the lowland neotropical forests, today reaching only to northern Mexico. This fossil, from Oregon, implies the presence of such forests there in the Oligocene, more than 25 million years ago.

The classification of the Passalidae is:

Order: Coleoptera
 Superfamily: Scarabaeioidea
  Family: Passalidae
   Subfamily: Passalinae
   Subfamily: Aulacocyclinae

The Aulacocyclinae are restricted to the area from India to Oceania and Australia. The Passalinae are mostly pan-tropical. This subfamily is divided into two tribes: Proculini, restricted to the Americas, and Passalini, which is mostly pan-tropical.

Most passalids live in rotting wood; a few live in other habitats, such as leaf-cutter ant detritus chambers, termite nests or under the roots of epiphytic bromeliads – all sites of decaying organic matter. Those in wood prefer broadleaf trees; oak is a favorite. Some occur in palms and a few in pines, but few in other conifers. They are most common and diverse in tropical lowland and montane wet forests; up to ten species may be found in a single log (in Brazil). Some, flatter species, are specialized for living under the bark; others bore deep into the logs. They appear to be quite important as wood decomposers in forest ecosystems.

An unusual number of species of other organisms are associated with passalids, especially mites and certain fungi, perhaps due to their boring in wood (other groups with high mite diversity include scolytid beetles, also wood borers). At least ten species of mites are associated with *O. disjunctus* in the eastern U.S. Various animals attack passalids, including vertebrates (birds and mammals, and probably some reptiles and amphibians), nematode worms, tachinid flies, and reduviid assassin bugs.

Passalids are in the superfamily Scarabaeioidea together with the more famous scarab beetles. They are large beetles (length 11 to more than 80 mm) and are orange or reddish when they hatch from the pupal case; most change to a shiny black color as they mature. Most have grooves (striae) in the elytra (wing covers). Many have a horn of some sort in the center of the head. In the Americas, most have three lamellae in the antenna, some four or five; some Old World species have more lamellae. Certain Old World passalids have an asymmetrical "face"; such asymmetry is rare among animals.

Beetles of some other families look remarkably like passalids; indeed, one tenebrionid from Africa has the epithet *passalioides*. Tenebrionids and lucanids which resemble passalids also live in rotting wood; however, certain carabids (e.g., *Scarites*) are superficially similar to passalids, but live underground. Some scarabs resemble passalids, but live in dung or underground as well.

Eggs are placed in a specially constructed nest of masticated wood pieces and feces (frass) and are red. As they mature they change to brown, then green when ready to hatch. The larvae are easy to recognize; they look like white grubs though not as curved and they have only four easily visible legs. Actually, they do have 6; the hind pair is reduced to a scraping organ that is rasped against the base of the second pair of legs. This produces a sound, the function of which is unknown.

The larvae (and adults) require frass for feeding; even adults will die if no feces are included in their diet. They apparently have an "external rumen," as do rabbits; they feed on the fungi and bacteria and the products of microorganism digestion that are in the feces.

The larvae pupate in a specially constructed cocoon of frass that the adults and larvae build together. The fact that young adult siblings of a larva will repair a damaged pupal case implies a high level of subsocial behavior for these beetles. Adults live at least two years in nature and to at least 5 years in the laboratory. Some species have large "colonies" with many individuals; others seem restricted to a pair and perhaps their offspring. Generally, only mature individuals migrate. Though adults may be found flying or walking at many times of the year, they appear to be most commonly migrating at the beginning of the rainy season in the tropics.

Adults stridulate as well, producing sounds by rubbing the dorsal surface of the abdomen against the hind wings. In species that don't fly, the wings are reduced to thin straps, but with the stridulatory area preserved. Passalids are known to produce up to 14 different acoustical signals in one species, more than many vertebrates. Pheromones, chemical communication, is also apparently used. Sounds are used when fighting other individuals, usually of the same species. Also, sounds are important in courtship, which involves a "dance" that can last as long as 12 h in the laboratory. At least in some species, copulation occurs in the tunnels of a log; however, *O. disjunctus* has been observed copulating during flight! At least in the laboratory, copulation begins venter to venter, a rare position for insects.

Beta Taxonomy

The arrangement of species into higher categories of classification.

► Alpha Taxonomy
► Gamma Taxonomy

Bet-Hedging

Variable life history strategies within an insect population resulting from genetic or phenetic polymorphism. Bet-hedging is manifested by variation in diapause, wing development, rate of development, rate of reproduction and other critical life history traits. Bet-hedging equips a population to survive variable and unpredictable environments that may favor certain traits in one season and certain traits in others.

Bethylidae

A family of wasps (order Hymenoptera).

► Wasps, ants, bees, and sawflies

Bias

In sampling, an unidirectional deviation of an estimate from the true mean or variance of a population.

► Sampling Arthropods

Bibionidae

A family of flies (order Diptera). They commonly are known as March flies.

► Flies

Bicaudate

Having two cauda, or filamentous tail-like processes, at the posterior end of the body.

Biddies

A family of dragonflies in the order Odonata: Cordulegastridae.

► Dragonflies and Damselflies

Biennial

A plant that completes its life cycle in two years and usually does not flower until the second growing season.

Bifid

This refers to a structure that is forked, or divided into two parts or lobes. More commonly it is described as bifurcate.

Bifurcate

This refers to the division of a structure into two parts, as when it is forked; it is also called bifid. The point where the division occurs is called the bifurcation.

Big-Headed Flies

Members of the family Pipunculidae (order Diptera).

► Flies

Bilateral Symmetry

This refers to symmetry of the body in which one side is a mirror image of the other side. When divided along the main axis, insects are almost always bilaterally symmetrical, with the left and right halves being mirror images.

Binomial Nomenclature

A system of naming organisms with two names, the genus and species. This binomial is also known as the scientific name, and is in Latin. The first of the two names is the genus, and is capitalized. The second is the species, and is not capitalized. Both words are italicized. The author's name (the person who first provided a technical description of the species) often follows the scientific name. If the genus name has been changed since the organism was named by the author, then the author's name is placed in parentheses to indicate that a change has been made. When several species in the same species are discussed together, then "species" may be abbreviated spp. For example, in discussing the genus *Spodoptera*, we might refer the members as *Spodoptera* spp. On the other hand, a single species is indicated as "sp."

Binomial Sampling

A sampling method that involves recording only the presence or absence of members of the population being sampled (such as an insect pest) in a sample unit (such as a leaf), rather than counting the numbers of individuals. This is a type of presence-absence sampling. (contrast with enumeration sampling).

► Sampling Arthropods

Biphyllidae

A family of beetles (order Coleoptera). They commonly are known as false skin beetles.

► Beetles

Bioassay

The use of a living organism to determine the effect of any chemical (or biological agent), such as a semiochemical, upon the organism.

Biocenology (Biocoenology)

Study of the organization and functioning of communities, particularly a descriptive analysis of assemblages of interacting populations within a particular area. This term is most popular in Europe; elsewhere it is referred to as synecology or community ecology. In some respects, it is the "opposite" of autecology.

► Biocenosis

Biocenosis (Biocoenosis)

An association of interacting, living creatures in an area. The environment or habitat is usually uniform, and the community self-sufficient. This term is most popular in Europe; elsewhere it is referred to as an "ecological community."

► Biocenology

Biocides

Chemicals that kill a wide range of living organisms.

► Insecticides
► Acaricides

Bioclimatic Models in Entomology

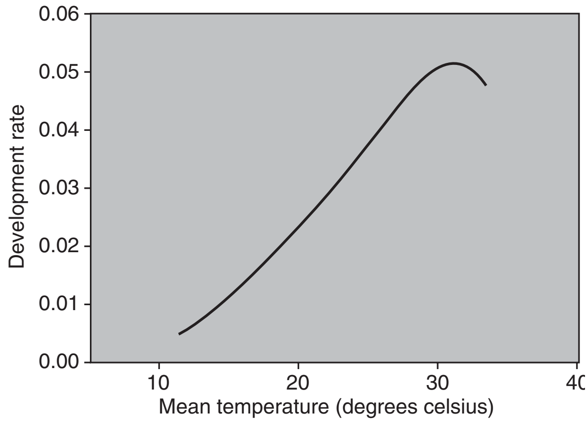
SUSAN P. WORNER
National Centre for Advanced Bio-Protection Technologies, Lincoln University, Canterbury, New Zealand

Because climate has such a profound effect on the distribution and abundance of invertebrates, quantification of climatic influences on insects has been of considerable interest to entomologists for well over a century. While simple predictive models were developed early on, easier access to computers in the 1970s resulted in the development of computer based models to predict the biotic potential of insects in relation to climate. Simple bioclimatic models are often used to predict population events so that control methods can be more precisely applied, reducing costs to the grower as well as insecticide use. Decreased insecticide use helps preserve natural enemies, reduces insecticide residues in crops, and delays the development of insecticide resistance. Other benefits are the conservation of petroleum products, increased safety to farm workers, local residents and the environment. Additionally, models of insect biotic potential and life cycle timing can increase the precision of sampling and monitoring programs, and application of biological control procedures. More complex bioclimatic assessment models have been designed to predict the potential establishment and distribution of insect species, often to assess the risk of invasion into areas where they are not normally found.

Temperature Models

Of all the climate variables that directly affect insects, temperature has the greatest influence. The influence of temperature on insect development rate, growth and fecundity has been quantified for many species. The relationship often observed in laboratory conditions between insect development rate and temperature (see development rate figure, Fig. 35) is well used by applied entomologists to predict timing and phenology of insect life cycle events. The relationship is usually nonlinear throughout the range of temperatures in which a species can survive; however, a number of mathematical functions, both linear and non-linear, have been used to describe it. Such functions comprise simple models for prediction of timing or phenology of life cycles, or can form the basis of more complex bioclimatic models.

There are three basic approaches to modeling insect development in relation to temperature. The oldest and most widely used model is a simple linear description of insect development in relation to temperature (see development rate figure). The linear model forms the basis to the well known thermal summation or degree day (DD) approach to timing prediction. Degree days



Bioclimatic Models in Entomology, Figure 35
Generalized nonlinear (solid line) and linear development rate curves.

are also called thermal units, heat units, or growing degree days. Degree days are simply the number of degrees above a threshold temperature required for growth. If temperatures are held constant in the laboratory, for example at 20°C, and if the lower threshold, T_0, for growth or development of the insect life stage of interest, is 5°C, then degree days per day or the amount of influential heat to which the insect is exposed is 20–5°C = 15 DD. Degree days per day are accumulated over the time it takes the particular life stage to complete development. For example, if that life stage takes 10 days to complete development, that time is converted to physiological time by 15 DD ×10 days = 150 DD required for development. To predict events in the field, some meaningful point or biofix from which to start degree day accumulation and some method to calculate degree days from the daily diurnal temperature curve are required. There is a large amount of literature on application of this method in applied entomology and plant growth studies.

Of special interest is how the relationship between insect development and temperature is used in forensic entomology. As gruesome as it might be, species of blowflies are often the first to find a dead body, on, or near which, they lay their eggs. By judging the age of the life stages of the fly larvae or pupae, and by applying the particular relationship between temperature and development for the fly species, the forensic entomologist can often determine the time of death of the unfortunate person. Of course, when investigating a suspicious death, things are not usually that easy and many factors that influence the temperature experienced by the flies need to be taken into account. For example, whether the body is found inside a building, a vehicle, shallow grave or other enclosed space, or whether it is found outdoors exposed to the elements is of importance. Even the heat generated by the maggots could influence the rate of development of the flies.

Notice that the linear model is confined to the more linear portion of the development rate curve (see development rate figure). Intrinsic to the use of the linear model is the assumption that development is proportional to temperature. This means that the reciprocal of the slope (1/slope) of a regression line fitted to the developmental data obtained at constant temperatures gives the DD required for development. The linear regression equation can also be used to calculate the lower threshold (T_0) for development which is defined as – a/b, where a, is the intercept and b is the slope of the regression line. The thermal optimum (if required) is often estimated by visual inspection of the development rate curve.

The linear or degree day model is easy to develop and use. While the linear model is clearly wrong in the sense that the lower and upper curvilinear portions of the development rate curve are ignored, this may not matter when field temperatures lie within the developmental extremes, but inaccurate predictions will result when temperatures stray too often beyond these points.

The second approach to predicting insect phenology in relation to temperature encompasses the many non-linear mathematical descriptions or functions used to describe nonlinear development of insects. These functions can range from a simple sine-curve fitted to the nonlinear data to more complex biophysical models or equations. Non-linear models require rate summation for timing prediction. Rate summation can be described as:

$$D = \Sigma r(T(t))dt$$

where development D is a function of temperature T which in turn is a function of time t, r is the development rate and dt is the time increment. For good precision the time increment should be hourly. While these models provide a more accurate description of the developmental relationship they are more difficult to develop and complicated to apply in practice.

Distributional Models

The third approach to life stage development in relation to temperature is represented by distribution models of insect phenology that include temperature dependant development as well as variation in development rates within the population at any particular temperature. Such models require considerable research investment but can give important information about the uncertainty of prediction and good estimates of limits to development in regions where the species is not normally found. In general, however, complexity does not ensure more accuracy, and a comparative approach is often required. Additionally, there are also differences in the performance of phenological models under variable temperature conditions that need to be taken into account.

The biological realism or practicality of each approach to phenological prediction has been widely debated. Unfortunately, that debate is not helped by the fact that the appropriateness of a model is often judged on how well it fits the observed data rather than on rigorous validation using independent data. Rigorous validation requires that a model is validated against an adequate sample of the real world. One or two sites or seasons are clearly not enough.

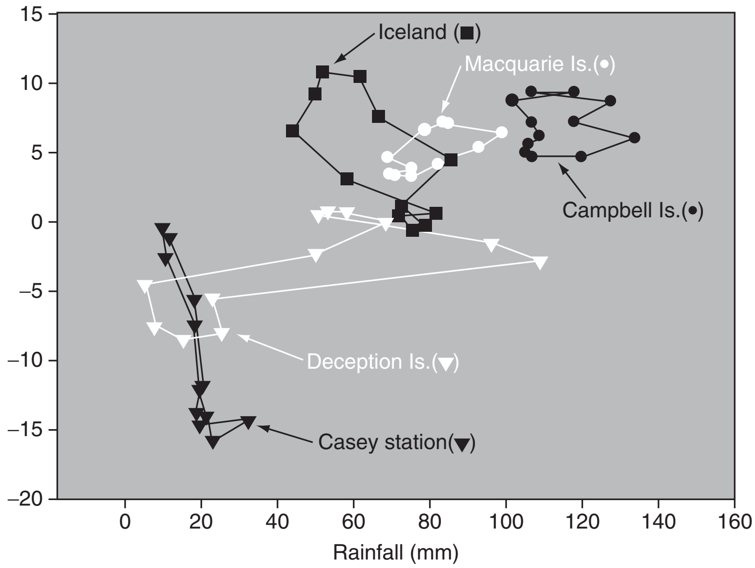
Currently, no model provides an accurate description of development in all circumstances, especially under fluctuating conditions. Clearly, we are limited by the accuracy of the temperature data that is available and that may dictate the level of accuracy that is achievable. In many cases when great accuracy is not necessary (or achievable) the simple degree day approach may be all that is required.

Obviously, other climate variables have potential to influence insect population processes, and therefore the distribution and abundance of insect species in any locality. Models that incorporate other climate variables to predict insect distribution and abundance range from simple graphical approaches called climatographs or climographs to more complex models that are process orientated. The graphs use a combination of climatic factors to predict areas that are suitable for establishment of a particular species and allow quick comparisons between sites. The simplest climatograph is a plot of the profiles of mean monthly temperatures and rainfall totals for a locality. A much more useful climate diagram or climatograph, however, can be a plot of mean monthly temperatures against mean monthly rainfall totals or humidity such that the points for the 12 months of the year are joined to create a polygon. At a glance one can see different shaped climate diagrams may or may not overlap indicating times of the year where different regions may or may not have similar climatic conditions (see climatograph figure, Fig. 36).

Multivariate Models

Other bioclimatic approaches include the use of multivariate statistical models to predict insect distribution and abundance in relation to climatic variables. Multivariate approaches such as principal components analysis (PCA) and discriminant analysis can overcome the limited dimensions that constrain graphical models. Alternatively, multivariate methods can help reduce large amounts of environmental data to a few important variables, and are often used to pre-process data to reduce the number of input variables to improve subsequent analysis by other statistical methods or models.

Because the relationship between insects and their environment can be complex there have



Bioclimatic Models in Entomology, Figure 36 Climatographs for sites in the Antarctic region compared with Iceland. Graphs were compiled to determine how likely insect species that have invaded and established in some areas of the Arctic could survive the climatic conditions in representative sites of the Antarctic and sub-Antarctic regions.

been many other attempts to characterize their response to a range of abiotic and biotic factors. Such models are called bioclimatic "envelope" models and are a type of species distribution model wherein the current geographical distribution of the species is related to local climatic variables to enable prediction of survival or establishment in new areas or climates. The most well known and well used model that combines insect species' response to a number of climate variables into meaningful, manageable indices, is called CLIMEX. CLIMEX is a computer based system that provides two levels of analysis. First is a simple match function that can be used to find climates elsewhere in the world that are analogous to, or match, within a specified level of similarity, the area of interest. Given further information on insect biological parameters, CLIMEX can give estimates in the form of simple indices of the favorability of particular geographic region for insect population growth and development. CLIMEX includes detailed long term weather data, comprising maximum and minimum temperatures, evaporation or relative humidity and rainfall for several thousand sites throughout the world.

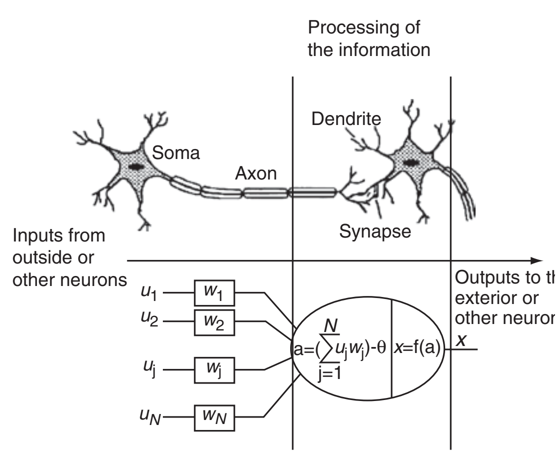
At the second level of complexity the CLIMEX program is designed to predict the potential distribution of the species by calibrating its biological responses to the climate of its current distribution. The species responses are modeled by a series of stress indices that include cold, hot, dry and wet parameters that define particular environmental limits to the sustained growth and development of the population. These indices are then combined in an "Ecoclimatic index" that describes the overall favorability of geographic locations for that particular organism. There are many examples of bioclimatic assessments of insect species using CLIMEX particularly for quarantine or risk assessment purposes. Despite being relatively easy to use, CLIMEX, like many models, should not be used as a black box, it requires a level of expertise or training to optimize its use and to ensure correct interpretation of results.

There are now many examples of bioclimatic models that have been applied to a range of taxa. Some of the most well known are STASH, BIOCLIM, CLIMATE, HABITAT, GARP and DOMAIN. In fact, the number of computer-based models, statistical approaches and machine learning techniques applied to bioclimatic prediction continue to increase, apparently driven by research interest in the distributional changes of species in response to climate change.

Computational Intelligence

More recently, applied computational intelligence models such as artificial neural networks (ANN) and other machine learning techniques have been successful for bioclimatic assessment of insects as well as other species. Such models have the advantage that they can model complex nonlinear data and they are not constrained by the distributional characteristics of data as more conventional parametric statistical models may be. In some comparative studies, ANN have been shown to be better than other methods for modeling species distribution in response to climate. The most common ANN used for prediction is the multi-layer perceptron or MLP.

ANN were first designed to mimic the vertebrate brain and consist of a network of processing elements called neurons in usually three layers; the input layer, the hidden layer and the output layer. All neurons of each layer are connected to all the neurons of the adjacent layer. As in the animal nervous system, each processing element in the network receives input from many others in the network. Each of the inputs or independent variables (U) is multiplied by its associated weight or coefficient and this dictates the strength or size of each input. The modified inputs are summed and the result is further modified by what is called a transfer function, which is usually a sigmoid function, but can be Gaussian or even a simple linear function. The result is either fed forward to other neurons in the network or becomes the network's output. The complex network algorithm adjusts the weights of the network connections over many hundreds or thousands of iterations to minimize, by least squares, the difference between the observed values and its own output values. The unique algorithm and structure means an ANN can learn to fit extremely complex functions and therefore is very useful for predicting species presence or absence based on a number of climate variables. Another advantage of machine learning approaches is that correct procedure involves training (fitting) but also testing and validation of the models. This procedure assesses how well the model can generalize to new data and as a result, over-fitting, the scourge of more conventional approaches, is avoided.Of all the modeling and statistical methods described above, none can answer all the questions concerning insect species biotic processes in relation to climate. The seemingly broad range of approaches can complicate the choice of model. Interestingly, when different models are compared over many re-organizations of the data used to create them (Fig. 37), some models can perform better than others on a particular data set, but can perform worse than the others when using a different data set. That means it is important to compare the efficacy of new methods with more standard approaches. While the bioclimatic models described here cannot replace more detailed modeling of individual species



Bioclimatic Models in Entomology, Figure 37
Comparison of a biological and artificial neuron.

responses to climate, they can provide important information to guide and inform decisions when more detailed data are lacking. Additionally, many approaches, if correctly applied, have potential for knowledge discovery that will increase our scientific understanding of how a range of abiotic variables can influence the distribution and abundance of insects.

Biocontrol

An abbreviation for "biological control."

Biogeographic Realms

Dissimilar distributions of animals (and therefore best called zoogeographic realms). The animals are usually isolated geographically and defined by continents, but sometimes separated by mountain ranges or other physiographic features.

► Zoogeographic Realms

Biogeography

KENNETH W. MCCRAVY
Western Illinois University, Macomb, IL, USA

Biogeography is the study of spatial patterns of biological diversity. Biogeography is often organized into two sub-disciplines, historical biogeography and ecological biogeography, although there is overlap between the two. Historical biogeography is "big picture" biogeography. It is concerned with explaining patterns in the distributions of organisms (usually at higher taxonomic levels) using the geological history of the Earth. Historical biogeography often involves large, even global, areas, and frequently deals with extinct taxa. Ecological biogeography, on the other hand, examines interactions among organisms and their environment to explain spatial distribution patterns, usually at species and sub-specific levels. The spatial and temporal scales are generally smaller in scope than is the case with historical biogeography. As the above definitions suggest, biogeography is a highly interdisciplinary science, drawing on evolutionary biology and systematics, ecology, and the earth sciences. Biogeography is a young discipline, first beginning to coalesce into a distinct science in the mid-1900s. The first scientific periodical devoted to the discipline, the Journal of Biogeography, first appeared in 1973. The number of books and journal articles devoted to some aspect of biogeography has increased dramatically in the last few decades. But while it only recently emerged as a distinct science, biogeography as a field of endeavor has been practiced for centuries, and many of the greatest scientists of their time were biogeographers, though they may not have referred to themselves as such.

Questions about the diversity of life and its distribution across the world have been asked since the time of the ancient Greek philosophers, and probably before. But the flowering of eighteenth century exploration greatly expanded knowledge of biological diversity and led to a corresponding increase in attempts to explain the patterns seen in this diversity. At that time, explanations were hindered by the prevailing literal acceptance of the Bible, and Carolus Linnaeus (1707–1778) himself wrestled with the contradictions between present-day patterns of global biodiversity and biblical literalism.

For instance, Linnaeus hypothesized a "paradisiacal mountain" to explain the spread of species from Noah's point of landing. This mountain would have all the different environments of the Earth at different latitudes, which were colonized by the different animals as they left the Ark. These animals would then be well-suited to colonize their respective habitats as they migrated throughout the world. While these ideas may seem naive in hindsight, Linnaeus' logic was astute, and his efforts in recording the type of environment in which each species was found can be considered a precursor of the subdiscipline of ecological biogeography.

The French naturalist Georges Buffon (1707–1788) was among the earliest to seriously consider that the earth's climate, species, and even the position of the continents were not fixed, but mutable. He observed that environmentally similar but separated regions have distinct faunas, an insight that became known as Buffon's Law. Attempts to explain Buffon's Law would occupy the attention of naturalists for decades, and would require an acceptance of the dynamic nature of the Earth and its species. The German botanists Johann Reinhold Forster (1729–1798), Karl Willdenow (1765–1812), and Alexander von Humboldt (1769–1859) collected innumerable plant specimens from around the globe, and found that Buffon's Law applied to plants as well as animals. Von Humboldt is generally recognized as the "father of phytogeography." The Swiss botanist Augustin de Candolle (1778–1841) recognized distinct phytogeographic regions, and was the first to coin the word "endemic."

New discoveries in geology and paleontology would provide a framework for further advances in biogeography. The eminent geologist Charles Lyell (1797–1875) and others used the fossil record as evidence of the mutability of the Earth's climate and sea levels, and asserted the antiquity of the Earth. The biblically based time frame of a few-thousand-years-old Earth was difficult to reconcile with observed biogeographic patterns. The revolutionary theory of evolution by natural selection developed by Charles Darwin (1809–1882) and Alfred Russel Wallace (1823–1913) was critical in providing an explanation for the adaptation and diversification of organisms across time and space. Wallace would devote his life to the study of biogeography, and would become known as the "father of zoogeography." He wrote three seminal books, and developed detailed maps of the Earth's biogeographic regions. He was also the first to note the sharp division between Southeast Asian and Australasian faunas in the East Indies, a division that is now known as Wallace's line. Many of the principles proposed by Wallace are still active areas of current research among today's biogeographers. It is difficult to overestimate the contributions of Alfred Russel Wallace to the science of biogeography. British zoologist Philip Lutley Sclater (1829–1913) was also an important figure in early efforts to define the Earth's biogeographic realms. Earlier attempts to define biogeographic regions were based to a great extent on artificial boundaries, and Sclater felt that these maps were too arbitrary. His goal was to develop a system reflecting "the most natural primary ontological divisions of the Earth's surface," based on biotic similarity and dissimilarity. Being an ornithologist, he based his system on passerine birds. His system of biogeographic regions, with some revisions, is still in use today (Fig. 38).

Despite the efforts of these and other early biogeographers, explanations of the disjunct distributions of many plant and animal groups, particularly in the southern hemisphere, remained elusive. This was due in large part to the fact that biogeographers were preoccupied with mechanisms by which the organisms themselves might have dispersed across the continents. But the idea that continents might move, or drift, relative to one another over geological time was even more difficult for the scientific community to accept. This was despite the fact that much geological, paleontological, and biogeographical evidence supported a dynamic Earth with moving continents. For instance, the disjunct southern distributions of groups such as the temperate ground beetle tribe Migadopini were difficult to explain using dispersal models or short-lived land bridges, but fit well with a Gondwanaland scenario. Based on evidence from a variety of fields, the German meteorologist Alfred Wegener (1880–1930) developed the theory of continental drift in the early 1900s. However, his ideas were largely rejected by scientists initially. There were a variety of reasons for this, the most important being the lack of a known mechanism by which continents could move. But the overwhelming evidence for seafloor spreading and plate tectonics amassed by the 1960s vindicated Wegener by providing just such a mechanism.

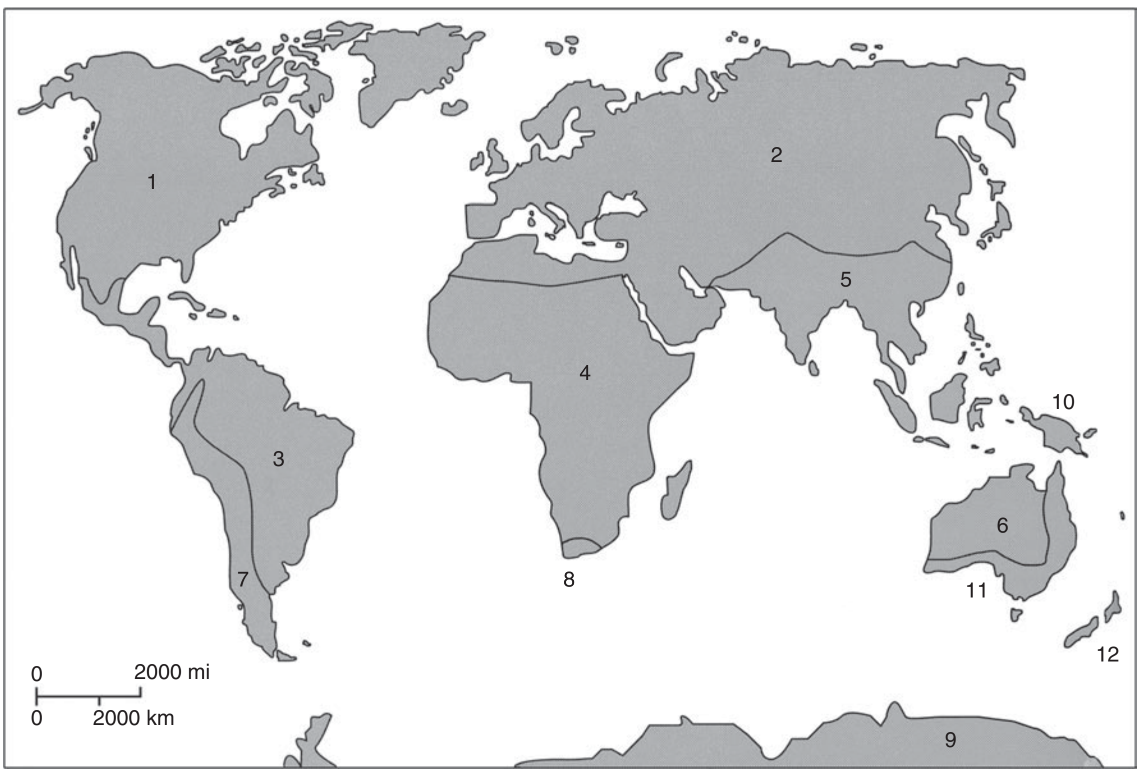
During the last half-century, the study of historical biogeography has been bolstered by increased methodological rigor in biogeographical analysis. Botanist Leon Croizat (1894–1982) developed the method of "panbiogeography" largely in response to what he believed was an over-reliance on difficult-to-test dispersal models of geographic distributions. Croizat connected the known distributions of taxa with lines, or "tracks" and then combined corresponding tracks into "generalized tracks." Croizat asserted that it would be unlikely that several taxa, with different dispersal capabilities and ecological requirements, would exhibit the same dispersal patterns. He reasoned that these distributions were established before being interrupted by geographic barriers such as oceans. These explanations required hypothetical land bridges and drifting of islands, which most biogeographers considered unrealistic. Furthermore, Croizat never really accepted Wegener's theory of plate tectonics, even though it would have provided reasonable explanations for many of the patterns Croizat observed. Although Croizat's panbiogeography never gained a wide following among biogeographers, he was a pioneer in emphasizing the importance of geographic isolation, or "vicariance," in speciation. General acceptance of the theory of plate tectonics by the biogeographical community gave a further boost to the importance of vicariant events in explaining geographic distributions, at the expense of dispersalist models, which were considered less testable than the vicariance models.

Famed evolutionary biologist Ernst Mayr's (1904–2005) studies of geographic distributions and speciation were instrumental in fostering a synthesis between evolutionary biology and biogeography, as was the work of German entomologist Willi Hennig (1913–1976). Hennig developed the methods of phylogenetic systematics, or cladistics, which provided a rigorous framework for testing hypotheses of evolutionary relatedness. Cladistics adheres strictly to classifications reflecting natural phylogeny, based on the sequence of branching as reflected by shared derived character states. This approach fits well with vicariance-based biogeographical methods. Development of molecular-based approaches and their application to biogeographical problems has also led to significant advances. The 1980s saw the development of the field of phylogeography, which has revolutionized biogeographical analysis. This approach seeks to explain recently occurring evolutionary relationships and geographical patterns at the level of species and species complexes, using molecular approaches to produce "gene trees" that reflect the spread of lineages.

Probably the most influential work in ecological biogeography in the last half-century was Robert H. MacArthur (1930–1972) and Edward O. Wilson's theory of island biogeography, unveiled in the 1960s. Interestingly (and sadly), an earlier form of this seminal theory was independently developed by lepidopterist Eugene G. Munroe in the 1940s but, for a variety of reasons, Munroe's work in this area has remained virtually unnoticed. The theory of island biogeography questioned the long-held view that species diversity and distributions on islands necessarily changed slowly, over evolutionary time. MacArthur and Wilson asserted that the number of species found on islands was a result of more proximal factors – rates of immigration and extinction, which in turn are affected by island size and distance from the mainland. These ideas provided a much needed theoretical framework for the study of biota not only on oceanic islands, but on isolated terrestrial habitat islands as well. The theory of island biogeography has also had a profound effect on the field of conservation biology. David Quammen's excellent book, Song of the Dodo: Island Biogeography in an Age of Extinctions, provides insight into the development of the theory and its implications for conservation biology, as well as criticisms of the theory. For some fascinating ideas in the area of human biogeography and the geographical patterns of wealth and power, see Jared Diamond's Guns, Germs, and Steel: The Fates of Human Societies and Collapse: How Societies Choose to Fail or Succeed.

Insect Biogeography

Many important contributions to our biogeographical knowledge base have been made by entomologists. Many of these contributions revolve around applications in pest insect control, such as studies of the migration patterns of the African migratory locust and range expansions of the gypsy moth, Africanized "killer" bees, and fire ants in the United States. In addition, many dramatic range contractions and extinctions, involving a variety of plant and animal groups, have been caused by introduced insect vectors of plant and animal diseases, or introductions of the causative agents themselves. The introduction of

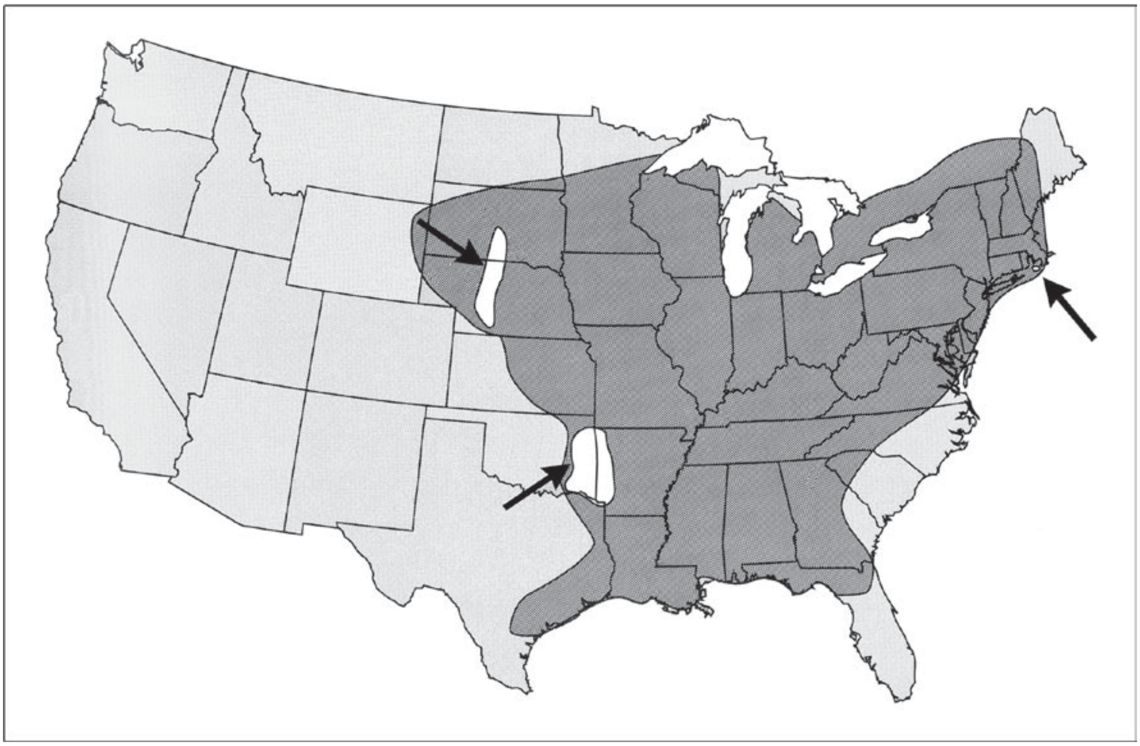


Biogeography, Figure 38 **Global biogeographic kingdoms and regions based on modern biogeographic analyses. This is more detailed than the original Sclater-Wallace portrayals and is not yet widely used. Numerical designations: 1–2, Holarctic kingdom (= Laurasia); 1, Nearctic region; 2, Palearctic region; 3–6, Holotropical kingdom (= eastern Gondwana); 3, Neotropical region; 4, Afrotropical region; 5, Oriental region; 6, Australotropical region; 7–12, Austral kingdom (= western Gondwana); 7, Andean region; 8, Cape or Afrotemperate region; 9, Antarctic region; 10, Neoguinean region; 11, Australotemperate region; 12, Neozelandic region (after Morrone 2002, J Biogegr 29:149–152).**

mosquito-borne avian malaria in Hawaii has devastated many species of lower-elevation birds there. The American elm, once a prominent part of North American landscapes, has been virtually extirpated by Dutch elm disease. The introduced smaller European elm bark beetle is a primary vector of the Dutch elm fungus.

Other studies have a strong insect conservation slant, such as analyses of the range collapse of the American burying beetle. This insect was distributed over most of the eastern United States until the mid-1900s, but is now restricted to a few widely separated locations in Nebraska and South Dakota, Oklahoma and Arkansas, and the northeast (Fig. 39). Evidence for impacts of global climate change on biotic distributions has been provided through analyses of insect distributions, such as that of Edith's checkerspot butterfly, a species that ranges along the coast of western North America from Canada to Mexico. Declines of this species do not appear to correlate with obvious human impacts such as habitat alteration. However, surveys of this species have shown that local extinctions have taken place primarily at low-altitude and low-latitude locations, as would be expected if increased temperatures were an important cause.

As mentioned earlier, some of the most important theoretical advances in biogeography have involved entomologists and the study of insects. Willi Hennig, the founder of phylogenetic systematics or cladistics, was a dipterist who produced many important works in the area of fly systematics. Hennig was drafted into the German army during World War II, and did some of his systematics work while held as a prisoner of war. Another entomologist, Lars Brundin (1907–1993), studied southern hemisphere chironomid midges. He was a pioneer in the use of cladistics in biogeographical analysis. Brundin produced a cladogram reflecting the evolutionary relationships of his chironomid



Biogeography, Figure 39 **Range decline of the American burying beetle, *Nicrophorus americanus* (Coleoptera: Silphidae). The original range is indicated by dark shading, the existing range by the small unshaded areas designated by arrows.**

species. He then inserted the name of the continent on which each species is found. This resulted in a "taxon-area cladogram." The sequence of divergence of the chironomid species corresponded well with the sequence of the separation of Gondwana into the southern continents (Africa was the first continent to break away, and the African species were the first to diverge, etc.). Thus, systematic and biogeographical evidence reinforced each other. Among other things, this work showed that geological information could be used to suggest which of several plausible cladograms is likely correct.

Ecological biogeography has also benefited greatly from entomological research. Ecologist Robert MacArthur and entomologist Edward O. Wilson developed the groundbreaking theory of island biogeography. The major tenets of the theory, in highly simplified form, are: (i) an island will contain an equilibrium number of species, (ii) this equilibrium number is a function of the balance of two processes, immigration and extinction, and (iii) immigration and extinction rates are in turn a function of the size of the island, and the distance of the island from the mainland. MacArthur and Wilson reasoned that small islands will have higher extinction rates than large islands, because populations of species on smaller islands will be smaller and thus more likely to become extinct. Likewise, islands far from the mainland will have lower immigration rates than islands near the mainland. Therefore, small, far islands will have low equilibrium numbers of species, and large, near islands will have larger equilibrium numbers of species.

Wilson, with his student Daniel Simberloff, also provided an early rigorous test of the theory through experimental defaunation studies on small mangrove islands in the Florida Keys. In this study, methyl bromide was used to kill all insects and other terrestrial arthropods on the islands. Follow-up surveys were then done to monitor recolonization of the islands. Several aspects of the theory were supported. After defaunation, the islands did eventually return to roughly their original numbers of arthropod species. In addition, the most isolated island had the fewest species, and the lowest recolonization rate. However, other studies have not supported the theory, and the theory has been criticized for a variety of reasons, such as lack of consideration for the biology of the organisms and their ecological and evolutionary interactions. For instance, it has been suggested that very small organisms, such as many insects, would be unlikely to reach saturation population levels on any but the smallest of islands. So, for most islands within the size range that humans consider important, the theory may only apply to organisms of larger size, such as vertebrates.

As is the case in other sciences, biogeographers are constantly searching for patterns in nature. Many have been discovered, and, often, insects play important roles in providing data in support of, or as exceptions to, these patterns. It has been observed in many groups of plants and animals that species diversity increases as one progresses from the higher latitudes to the tropical regions. Several theoretical explanations for this pattern have been proposed. Many insect groups fit this pattern. However, some do not. These exceptions include two huge families of parasitic wasps, the Ichneumonidae and Braconidae, as well as the sawflies and aphids. There are many possible reasons for these exceptions. It has been suggested that aphids are more diverse in temperate regions because many aphid species are specialist feeders that have difficulty locating suitable host plants from long distances. Therefore, they should fare better in regions where plant species are clumped, such as the agricultural lands of temperate regions, than in tropical regions where plant assemblages consist of many species that are each present at low densities. As is often the case, it is the exceptions to the rule that provide the most interesting research questions.

Another interesting biogeographical pattern has been termed "geographic parthenogenesis." Parthenogenesis is the production of offspring from unfertilized eggs, usually with the asexually produced offspring being female. "Geographic parthenogenesis" refers to a pattern in which parthenogenetic organisms occupy different geographic ranges than their closely related, sexually reproducing relatives. The parthenogens are often associated with what could be considered "marginal" habitats. These include more northerly latitudes, higher altitudes, disturbed habitats, islands or island-like patches of habitat, or dry environments. Such patterns have been observed in many insect groups. One interesting example is *Pelecinus polyturator*, a parasitic wasp with a huge latitudinal geographic range that extends from eastern and central North America, through the southwestern U.S. and Central America, down through South America to Argentina. *Pelecinus polyturator* exhibits patterns consistent with geographic parthenogenesis. In the northern part of its range males are extremely rare, but in tropical regions males are abundant and sexual reproduction is apparently common. Insect species in other groups, including mayflies, aphids, and stick insects, have also been found to exhibit geographic parthenogenesis.

For centuries now, biogeographers have provided fascinating insights into the patterns and processes of the natural world. As human-caused changes continue to affect global biodiversity, it will be critical that we increase our knowledge of the factors determining the geographic distributions of organisms. The science of biogeography will continue to be at the forefront of these efforts.

Biological Clock

The biological/physiological timing device inside an organism that allows it to establish regular biological rhythms. It is self-sustained, but synchronized by natural biological patterns such as light and dark cycles.

► Biological Clock of the German Cockroach

Biological Clock of the German Cockroach, *Blattella Germanica (L.)*

HOW-JING LEE
National Taiwan University, Taipei, Taiwan

Have you had a terrifying experience of seeing an oily flat creature running for cover when you open a cupboard to look for a midnight snack? Even worse, while you are watching TV a cockroach runs swiftly under your feet to reach the other end of sofa! This tiny crawler is no stranger to us. It is our unwanted and unavoidable housemate, the German cockroach.

The German cockroach, *Blattella germanica* (L.) is a cosmopolitan species and well-adapted to human shelters such as houses, buildings, and factories, and sometimes it is even found on public transportation. They feed on almost any organic matter. Although no life threatening disease is transmitted by them, the existence of the German cockroach poses a health threat to humans (allergy, diarrhea) and represents deteriorating hygiene.

Since we live with the German cockroach under the same roof, our daily life coincides with its activities. We rarely see them during daytime, but we encounter them frequently at night. Do they avoid their only natural enemy, humans, during the day, or is their activity schedule controlled by a biological clock? The scientific evidence shows that timing of its activity is scheduled according to its endogenous biological clock.

What Is a Biological Clock?

A biological clock is a timing device inside an organism to give time signals so that an organism can perform proper behaviors at the right time. This self-sustained, endogenous clock is easily entrained (synchronized) by environmental signals such as light-dark cycles, temperature cycles, and other environmental changes, and allows an organism to adapt to its environment properly in time. Such an environmental time signal has been called a "Zeitgeber" (from the German for "time-giver").

There are several lengths of rhythmic period on earth, such as half-day tidal cycles, day-night cycles, semilunar and lunar cycles, annual cycles, and seasonal cycles that are caused by the movements of sun, earth and moon. Since these predictable environmental changes are consistent events, organisms depend on their endogenous clocks to synchronize with the rhythmic changes of environment. Among various lengthened environmental cycles, the daily cycle is the most prominent and universal environmental condition to influence the survival of organisms. From primitive prokaryotic single-cell cyanobateria to highly evolved eukaryotic mammals, virtually all organisms possess an endogenous circadian clock (the term "circadian" is derived from the Latin for "about a day"). Therefore, many scientists focus their research interests on circadian clocks.

Characters of Circadian Clocks

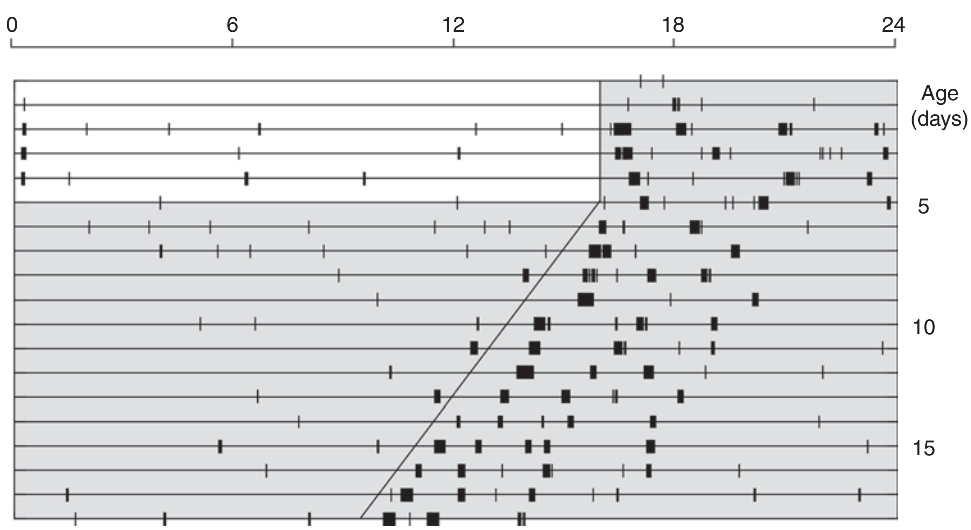
The most important characteristics of a circadian clock are: (i) a self-sustained oscillator with a period close to 24 h, (ii) a free-running rhythm under constant environmental conditions (such as constant temperature and continuous light or dark condition), and (iii) temperature-compensation. The first two characters are the essential ones that should be used as the definition of the circadian clock. When we remove all the environmental time signals from an organism, it should follow its own endogenous circadian clock and express an approximate, but not exact 24 h rhythm. Only when this free-running rhythm is expressed under an artificial, constant condition, can we definitely infer a circadian clock in this organism. The third character is the key feature to allow the clock to run as accurately as possible in different seasons or temperature conditions. Since the speed of all biochemical processes within an organism depends on the temperature, the property of temperature compensation can keep the molecular biological clock running in a constant pace regardless of environmental temperature fluctuation. This character is especially essential in ectothermal animals, those which depend on external conditions to maintain their body temperature (Fig. 40).

Molecular Clock Mechanisms

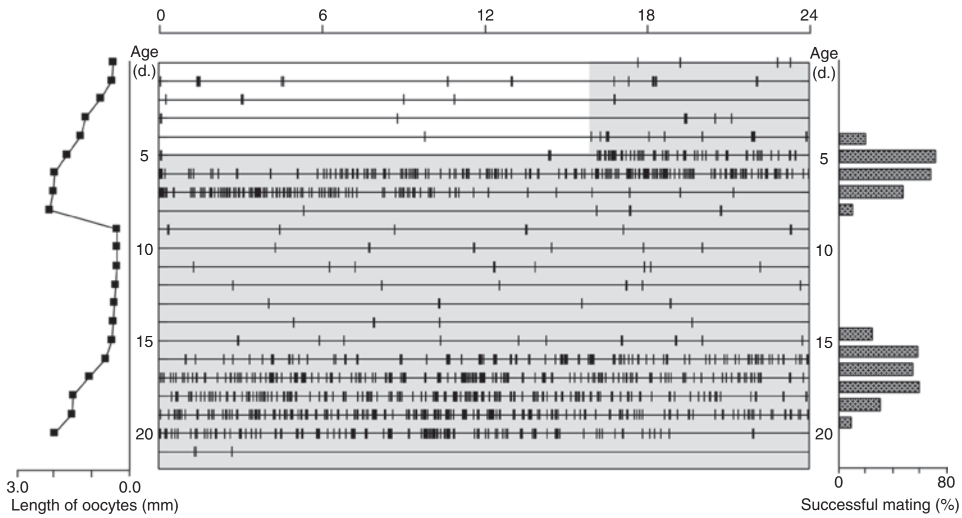
The biological clock operates in a negative feed back loop composed of various molecules. Although no universal scheme of molecular clock exists in all organisms, the molecular clock mechanisms in the fruitfly *Drosophila melanogaster* underlie the clockwork of the German cockroach. The simplified molecular clock scheme includes two clock genes, *period* and *timeless*, which are activated and transcribed-translated to PERIOD and TIMELESS proteins in the cytoplasm of cells. The phosphorylation of PERIOD enables it to bind with TIMELESS to form a heterodimer, which in turn translocates into the nucleus to inhibit further transcription of *period* and *timeless* genes. When the diminishing concentration of PER-TIM heterodimer reaches a certain low level, the *period* and *timeless* genes will be reactivated and cause another cycle. This process takes about 24 h lag time. Light can degrade the TIMELESS protein. If there is reduced TIMELESS available to bind PERIOD, then there is more delay of inhibition on the two clock genes, which prolongs the cycle and changes the clock phase. This molecular mechanism explains the synchronization of circadian clock phases with the light-dark cycles of the environment(Fig. 41).

Ecological Significance

The ecological function of biological clocks is the main reason these clocks occur in various



Biological Clock of the German Cockroach, *Blattella Germanica (L.)*, Figure 40 The locomotor activities of a male adult German cockroach at 28°C, 12L:12D cycles for 5 days then switched to constant darkness conditions. Each horizontal line shows 24 h, with each day attached below the previous day. A vertical line indicates the onset of locomotion. The shaded areas of the actogram represent darkness. The superimposed line across the actogram represents the predicted onset time of the locomotion according to its circadian period (τDD = 23.5 h) (modified from Lin and Lee, 1996).



Biological Clock of the German Cockroach, *Blattella Germanica (L.),* Figure 41 The locomotor activities of a virgin female adult German cockroach at 28°C, 12L:12D cycles for 5 days then switched to constant darkness conditions. Daily development of ovaries represented by the length of oocytes is shown on the left side of the actogram. The mating window for a virgin female is displayed on the right side of the actogram. Other symbols as above (modified from Lee and Wu, 1994; Lin and Lee, 1996).

organisms across five kingdoms. We can identify the three most important ecological functions of a circadian clock: (i) the timing of each behavior is so important that every organism within a species should time each movement very accurately. This is the key function an endogenous circadian clock can provide. (ii) Although most environmental changes are fairly rhythmic and predictable, some conditions (such as continual raining, sudden cold or heat) might cause long lasting interruption on environmental rhythmicity. These unpredictable environmental changes may last a few days and cause organisms to perform behaviors solely depending on their circadian clock for good timing. (iii) Every day is a new challenge for an organism. The active tasks ahead require good preparation in physiological conditions to overcome challenges. In order to be well-prepared for the challenge, organisms depend on their circadian clock to trigger the whole cascade of reactions. The physiological preparation in organisms occurs in the rest phase of the daily cycles. A circadian clock can provide good timing to start preparation and achieve survival in danger-ridden environments.

Natural selection has shaped the proper behaviors of organisms to act in the right place at the right time. Good timing is certainly involved in life and death decision-making processes. An endogenous circadian clock is definitely a key asset to survive and prosper for the species.

Biological Clock of the German Cockroach

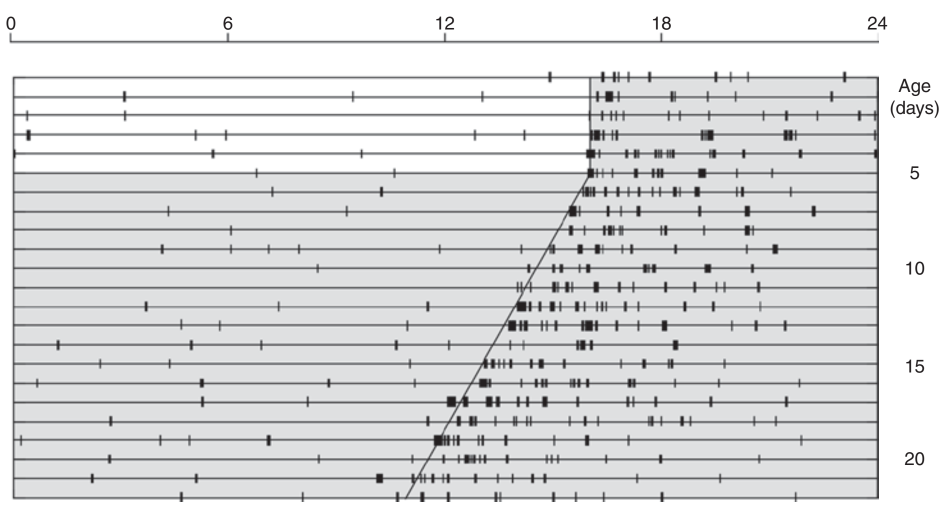
With some background information about biological clocks, we can turn our attention to the circadian clock of the German cockroach. Since it would be difficult to actually see the working clock in a multi-cellular animal, a circadian rhythmic behavior or physiological parameter can be selected and monitored as the overt expression of the endogenous clock. The locomotor circadian rhythm is chosen as the focal point of this article.

The German cockroach is a nocturnal insect, and its locomotor activities mainly occur during the scotophase (dark phase) of the daily photoperiod condition. Once the light-dark cycles are artificially changed to constant darkness condition, a male adult's free-running rhythm continues to regulate locomotion for greater activity during the time that would represent scotophase in light-dark cycles. The circadian period of the male adult is approximately 23.5 h. From this activity pattern, we know there is an endogenous clock driving its locomotion in circadian rhythmicity.

When female adults are put into the same condition, their locomotion does not show a circadian rhythm. Their locomotion is concentrated to the few days before the formation of ootheca (egg case), and activity is distributed relatively evenly across the 24 h period. This locomotor pattern coincides with the developmental cycles of ovaries. When the ovaries reach at certain developmental stage, female adults become active. Their locomotion even occurs during the day, clearly counter to the nocturnal nature of the species. In addition, this locomotor pattern coincides with the narrow mating-window of the females. When the females become sexually receptive, their daily locomotion increases significantly. Once the females mate, their locomotion decreases immediately. We conclude that locomotion represents mate-finding activities and that the locomotor pattern of female adults does not display a circadian rhythmicity.

Since possessing a circadian clock is a genetic trait for the species, female adults should also have a circadian clock underlying their arrhythmic locomotion. When the ovaries are surgically removed during the last instar, they express a locomotor circadian rhythm of 23.6 h, the same as found in male adults (Fig. 42). This circadian rhythmicity also can be seen in starving female adults whose ovaries do not develop. The locomotor circadian rhythm of females is masked by the endogenous development of ovaries. This masking effect is a unique characteristic of the biological clock in the German cockroach.

A critical function of the circadian clock in reproductive behavior is to provide good timing for bringing potential mates together. However, why does the timing of mate-finding behavior not synchronize between the sexes of the German cockroach? This question certainly implies that the masked circadian rhythm of female adults does not impair the chances of meeting males. It requires a detailed analysis of the reproductive strategies of the German cockroach to unveil the



Biological Clock of the German Cockroach, *Blattella Germanica (L.),* Figure 42 The locomotor activities of an ovariectomized female adult German cockroach at 28°C, 12L:12D cycles for 5 days then switched to constant darkness conditions. The circadian period is calculated as 23.6 h. Other symbols as above (modified from Lin and Lee, 1996).

mystery of endogenous masking effects on the locomotor circadian rhythm.

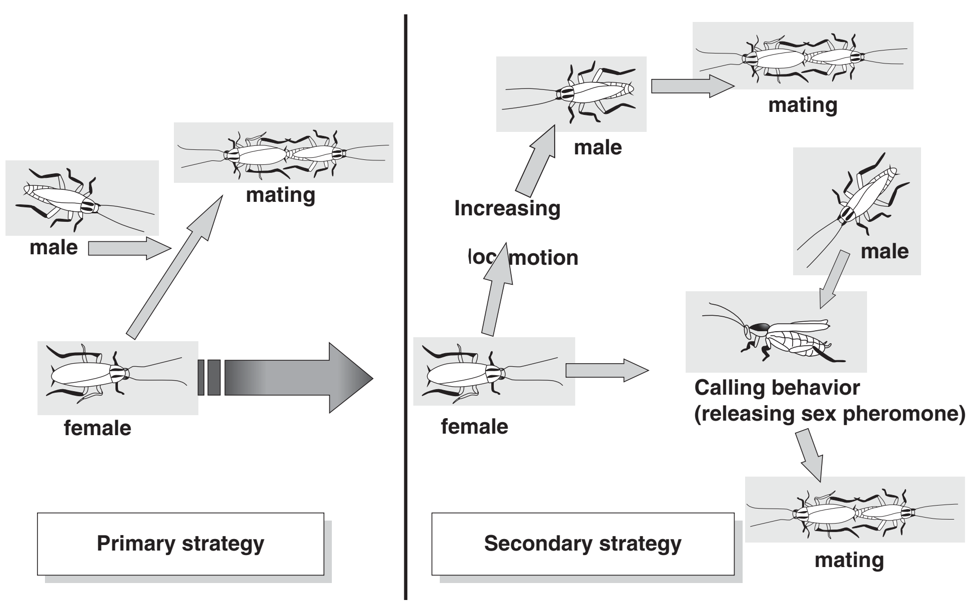
Although German cockroaches are not social insects, they do live in groups. The groups are composed of immature and adult cockroaches of both sexes, and are maintained by an aggregation pheromone secreted by every individual. This style of living provides easy opportunity for both sexes to meet when they are sexually mature. Thus, the timing of mate-finding locomotion becomes less critical in comparison with solitary cockroach species. The masked locomotor circadian rhythm does not handicap the chances of mating pair-formation. Random (Fig. 43) mate-finding is largely dependant upon group living and is the primary strategy of the species.

Since female adults produce an ootheca regardless of their mating status, the nutrient-rich oothecae is wasted when the females do not mate during the narrow mating-window. The penalty for losing the mating opportunity is severe enough to drive female adults into locomotion to find mates regardless the time of the day. The masked locomotor circadian rhythm, therefore, reflects the high importance of mate-finding. In addition, sexually mature females release sex pheromone to attract males. Combining these two mechanisms, the female adults try to mate in time.

These complicated reproductive strategies guarantee the survival and propagation of the species. In fact, the high priority of reproduction causes a unique masking effect on the mate-finding locomotion of the female. This arrhythmic locomotion is the result of high demand on mate-finding locomotion during the sexually receptive period of female adults. Underneath this arrhythmic locomotion, however, an endogenous circadian clock paces daily locomotion.

Conclusion

The biological clock of the German cockroach runs continuously in both sexes. It drives locomotion to express circadian rhythm in male adults, but adult females fail to show circadian rhythmicity. An endogenous masking factor caused by the developing ovaries obscures the overt rhythm of locomotion in females. Although this desynchronizing locomotion does not fit into the mode of



Biological Clock of the German Cockroach, *Blattella Germanica (L.)*, Figure 43 Mating scheme for the German cockroach (modified from Tsai and Lee, 1997).

function for a circadian clock, the masked arrhythmic locomotion becomes part of reproductive strategy that ensures a mating opportunity for sexually mature females.

Biological Control by *Neoseiulus californicus* (McGregor) (Acari: Phytoseiidae)

NORMA E. SÁNCHEZ, NANCY, M. GRECO, CLAUDIA V. CÉDOLA
Universidad Nacional de La Plata, La Plata
Argentina

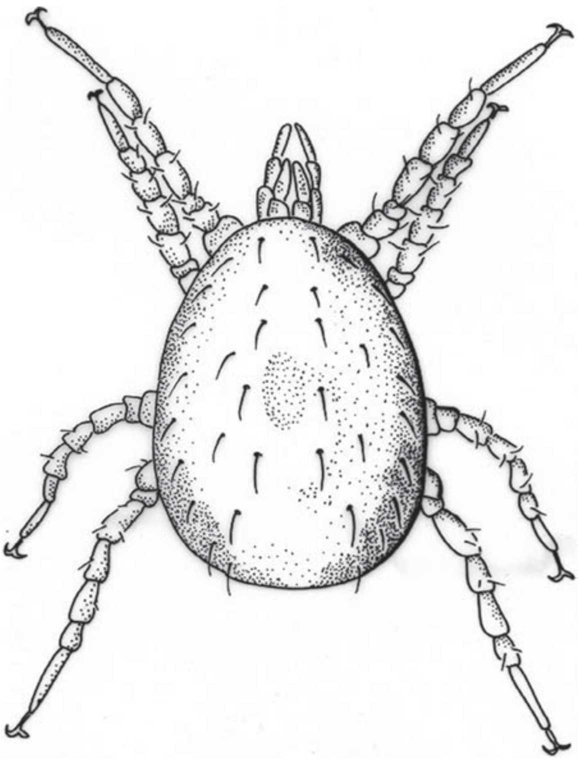
Neoseiulus californicus is a predator mite that provides an effective biological control of *Tetranychus* spp. spider mites in strawberries, corn, grapes, roses, fruit trees and ornamentals. It has a worldwide distribution in arid and humid areas, including semi-tropical and temperate South America, and arid areas of southern California and southern Europe.

This predator is very small in size. The adult measures 0.25–0.5 mm in length and is pear shaped and slightly orange in color. It passes through four developmental stages (egg, larvae, nymph and adult). Eggs are oval and translucent. At 25°C, the eggs hatch after two days. Larval and nymphal (proto- and deutonymph) stages require about three days to complete development. Then, it takes approximately five days to reach the adult stage. Adult longevity is approximately 20 days, and the oviposition period is 13.5 days. A female can lay three eggs a day (Fig. 44).

Neoseiulus californicus, as well as other predatory mites (e.g., *N. fallacis* (Garman), *Phytoseiulus persimilis* Athias-Henriot and *Mesoseiulus longipes* (Evans)) is commercially produced and used to control the two-spotted spider mite, *T. urticae* Koch, in North American and European greenhouse horticulture.

A related species in the same genus, *N. fallacis*, coexists with *N. californicus* in the Northern Hemisphere. Both species are morphologically similar and have been rated as specialized predators of spider mites, but *N. californicus* seems to be more generalist than *N. fallacis*. Pollen of different plants such as maize, almond, castor bean, avocado, and some grasses, as well as thrips are alternative food.

In South America, releases of predatory mites are not commonly used, and regular applications



Biological Control by *Neoseiulus Californicus* (McGregor) (Acari: Phytoseiidae), Figure 44
***Neoseiulus californicus* (McGregor).**

of acaricides are made to control pest mites. However, in commercial strawberry greenhouses in Argentina, *N. californicus* is the main established enemy of the two-spotted spider mite. Although this predator consumes fewer prey than other phytoseiid species, it has longer survival under starvation conditions. Moreover, the ability to feed on other food sources may contribute to its persistence in the absence of spider mites. This trait may be of critical importance for the success of conservation biological control.

Conservation biological control means the environmental manipulation to protect and enhance natural enemies. This is an ecologically, environmentally, and economically sound solution to pest problems for growers of developing countries.

Recent studies in La Plata (Buenos Aires, Argentina) showed that *T. urticae* and *N. californicus* populations exhibit a high spatial coincidence and the predator is very efficient in locating the prey. This predator seems to be a promising natural enemy for controlling *T. urticae* through the implementation of conservation techniques. Taking into account that the ability to tolerate acaricides is a serious constraint on successful conservation of phytoseiid predators, the reduction of unnecessary acaricide treatments may enhance persistence of predator mite populations.

At present, efforts are being made to reduce the number of chemical applications through monitoring of the prey/predator ratio and pest population trend to avoid both unnecessary pesticide applications and economic damage. However, more field studies are needed to help elucidate other factors that contribute to increase, and to effectively preserve the natural populations of this predator in annual as well as perennial systems. Among these factors, plant diversity may be a critical feature to increase natural enemy persistence through: (i) provision of alternative prey/host at times when the pest is scarce, (ii) provision of supplementary food, and (iii) provision of refuge (for mating or overwintering).

It is also known that physical and chemical characteristics of the food plants of prey can affect natural enemy potential effectiveness. A good example of this is the negative way in which persistence of *N. californicus,* plant colonization, and consumption of *T. urticae* are affected by tomato leaf glandular hairs. This finding reveals the risk of generalizing the effectiveness of *N. californicus* from one crop to another.

The implementation of conservation biological control is still receiving inadequate consideration in developing countries. The potential and utility of *N. californicus* as a biological control agent is worth further investigation.

Biological Control of Invasive Plants in Latin America

JULIO MEDAL[1], MARICELA MARTÍNEZ [2]
[1]University of Florida, Gainesville, FL, USA
[2]Instituto Mexicano de Tecnología del Agua (IMTA), Jiutepec, Morelos, Mexico

An invasive plant is an exotic that has been introduced, intentionally or by accident, into a new region where it successfully establishes, reproduces, and spreads, eventually replacing the native vegetation. Invasive plants or weeds, also called "biological pollutants," threaten natural ecosystems and human-modified habitats by reducing biological diversity and by causing significant reductions in crop yields and other harmful effects on property, humans, and domesticated animals. The success of the exotic plant to become invasive in a new geographical region can be partially attributed to the fact that the exotic has been introduced without the arthropod natural enemies and disease-producing pathogens that limit its reproduction in the area of origin.

Manual removal and herbicides are the major invasive plant management practices currently used in cultivated crops in Latin America. Biological control, or the use of natural enemies such as arthropods, pathogens, and fish to reduce the population and reproduction of the exotic invasive, has been traditionally practiced in developed countries such as the United States, Australia, Canada, South Africa, and New Zealand, primarily in rangeland situations, conservations areas, and aquatic systems.

A frequently cited example of a successful biological control project is the control of prickly pear cactus, *Opuntia stricta* Haworth (Cactaceae) in Australia by the pyralid moth *Cactoblastis cactorum* Bergroth (Lepidoptera: Pyralidae) introduced from Argentina in the 1920s. However, this is also a good example of conflicting interests, as the invasive plant (cactus) is harmful in Australia and biological control was needed. On the other hand, it is useful as human and animal food, and as an ornamental plant for people in other regions (Mexico, Caribbean, southern regions of the USA). Here, the successful biological control agent in Australia, *C. cactorum*, threatens the native endemic cactus, so it is not regarded as a "hero" but as a "pest," and control measures including the use of natural enemies and the sterile insect technique are being undertaken.

Other well-known examples of classical biological weed control include the effective control of Klamath weed and alligator weed. Klamath weed or St. Johnswort, *Hypericum perforatum* L. (Clusiaceae) was controlled in the western USA by two European leaf-feeding beetles, *Chrysolina quadrigemina* (Suffrian) and *Chrysolina hyperaci* (Forster) (Coleoptera: Chrysomelidae), imported from Australia in the mid 1940s. In Florida, USA, complete biological control of alligator weed, *Alternanthera philoxeroides* (Martius) Grisebach (Amaranthaceae) in aquatic environments was achieved by the introduction of the flea beetle *Agasicles hygrophila* Selman and Vogt (Coleoptera: Chrysomelidae) from Argentina.

Interest in biological control of invasive plants using host-specific insects and pathogens has increased in the last decade due to the public's concern about the negative effects of pesticides in the environment, a greater demand for pesticide-free agricultural products, the reduction in the number of pesticide registrations, the development of plant resistance to commonly used herbicides, and the intensified oil crisis which increases the cost of using herbicides. A recent catalogue of biological control agents and their weeds listed 949 releases involving at least 350 organisms against

133 target weeds as of 1996. Forty-one (31%) of these weeds are considered under complete or substantial biological control.

Biological control is not a panacea and is not without an element of risk. The advantages of classical biological control over other invasive plant control methods are that it is highly specific to the target plant, it has little or no impact on non-target organisms, it does not pollute the environment, it is relatively inexpensive, and it provides self-sustaining and permanent control of the invasive plant when it works. Among the disadvantages of biological control of invasive plants with introduced insects are that it is unpredictable, and even if the insects establish, biological control may not suppress the invasive plant population enough to achieve the desired level of control.

Several factors make biological control with insects especially difficult in field crops. First, disturbance from planting, cultivation, and pesticide applications is not conducive to the establishment of the biological control agent. Second, because several species of invasive plants usually require control simultaneously, multiple biological control agents are needed. Finally, rapid control (usually within one month of planting) is necessary in order to prevent crop damage. Once invasive plant-feeding insects establish, they are unlikely to build up damaging populations in a single field season. Highly specific plant pathogens may be better suited to control invasive plants in field crop situations. Native plant pathogens can be formulated and applied as bioherbicides, or exotic pathogens can provide effective control of the invasive plants following inoculative releases. Lastly is the conflicting interest issue mentioned previously. A plant that is perceived as a nuisance by one group of people can be considered a beneficial plant by another group. Beekeepers are a good example of a special interest group that may object strongly to biological control because they may value the invasive plant as a source of nectar and pollen.

Biological Control Activities Against Invasive Plants in Latin America

The use of insects and pathogens as biological control agents of invasive plants in South America has been quite limited. Compared with the advances achieved in biological control of arthropod pests for the same region, the use of insects for control of invasive plants is in its infancy or initial stages of development. Chile can be considered a pioneer in this field, with biological control activities of invasive plants initiated in 1952 against the non-native invasive *Hypericum perforatum* L. (Clusiaceae). This project has been a great success, providing highly effective control of this weed. Other biological control projects initiated in Chile in the 1970s that had only moderate successes or have been ineffective include *Galega oficinalis* L., *Ulex europaeus* L. (Rosaceae), *Rubus constictus* Lepeure & Mueller, and *Rubus uifolius* (Rosaceae). Research efforts using insects or pathogens for biological control of invasive plants in Chile continue, with more intensity in the last decade due to enhanced funding provided by national institutions. In Argentina, there is only one case known of biological control, that of the invasive aquatic plant waterhyacinth, *Eichhornia crassipes* (Mart.) Solms (Pontederiaceae) in the province of La Rioja located in the west-central part of the country. The waterhyacinth-feeding weevil *Neochetina bruchi* Hustache (Coleoptera: Curculionidae) was introduced from the province of Buenos Aires and it was able to reduce the aquatic plant infestation from 50% to 8%.

Biological control of aquatic invasive plants in Mexico has been implemented with more intensity during the last decade using a combination of insects and pathogens against waterhyacinth. Most of the current aquatic plants have been introduced by humans from their native habitats, and are free from their natural enemies and diseases. Invasiveness is a response to the high level of nutrients in the urban, industrial and municipal wastewater. Aquatic invasive plants causes water loss through plant evapotranspiration, displacement of native species, public health risks, obstruction of channels and drains in irrigation systems, intakes to hydroelectric plants, restriction to tourist, recreational and fishing activities, and increasing sedimentation with subsequent shortening of the useful life of the body of water. In Mexico, more than 62,000 ha have been infested by aquatic invasive plants. The most important species are waterhyacinth, followed by water fern (*Salvinia* spp.), pondweed (*Potamogeton* sp.), cattail (*Typha* sp.), hydrilla (*Hydrilla verticillata* L. Royle), waterlettuce (*Pistia stratiotes* L.), and duckweed (*Lemma* spp.).

In 1993, the Aquatic Weed Control Program was initiated in Mexico by presidential mandate in response to the increasing need to control the overwhelming presence of invasive plants in the water sources. As part of this program, a biological control project was included. In Mexico, waterhyacinth is the most prolific invasive aquatic plant, infesting an estimated 40,000 ha of water. This plant was probably introduced in Mexico in the early 1900s. Chemical and mechanical control methods have been used to manage waterhyacinth, but these methods are expensive and several annual applications are needed. The difficulties in controlling this aquatic invasive are related to the plant's rapid growth rate and its ability to reinfest via the seed bank or by flood-borne plants. For these reasons, the only long-term and sustainable solution is the application of an integrated approach to waterhyacinth management in which biological agents play a key role.

The host-specific Brazilian weevils *Neochetina eichhorniae* Warner and *Neochetina bruchi* Hustache have been used in many countries worldwide to control waterhyacinth with relative success. *Neochetina eichhorniae* was introduced to Mexico from the US in the late 1970s. However, other reports indicated its presence in some Mexican water bodies as early as 1967. Another three waterhyacinth insects that have been observed occurring naturally in Mexican water bodies are *Sameodes albigutalis* (Warren) (Lepidopera: Pyralidae), *Cornops aquaticum* (Bruner) (Orthoptera: Acrididae), and *Orthogalumna terebrantis* (Wallwork) (Acari: Galumnidae). There is no evidence of them being native to Mexico, and they could have arrived with waterhyacinth plants introduced in the past. The Brazilian weevil *N. bruchi* was introduced into Mexican quarantine from the USDA Aquatic Plant Management Laboratory in Fort Lauderdale, Florida, USA. Although the *Neochetina* species are well established in Mexico, the effectiveness of biological control requires the use of additional agents to complement existing ones.

Several highly virulent waterhyacinth pathogens have been collected, identified, screened for plant host range, mass-produced, and field evaluated in Mexico. After selecting two specific and highly virulent fungal pathogens, *Cercospora piaropi* Tharp., and *Acremonium zonatum* (Saw) W. Games, the combined effects of the plant pathogens and the *Neochetina* weevils were evaluated in a seven ha water reservoir in the central part of Mexico in the state of Morelos. A total of 9,800 weevils were released and two applications of a mixture of the fungal pathogens were carried out. After three months of the combined application of the fungi and weevils, the reservoir was free of waterhyacinth. The dramatic reduction in waterhyacinth coverage was due to the increasing amount of a natural pathogen (*C. piaropi*) already present in the water reservoir, the introduction at the same time of another highly virulent pathogen (*A. zonatum*) combined with the leaf feeding scars made by the *Neochetina* adult weevils and stem damage by the *Neochetina* larvae. Weevil feeding allows the transmission of the pathogens, which results in increased disease incidence. This approach of combining insects and pathogens to get a better control of an invasive aquatic plant is currently implemented by the Instituto Mexicano de Tecnología del Agua in different regions of Mexico.

In Honduras, a limited number of biological control activities against waterhyacinth were initiated in the 1990s. The *Neochetina* weevils were introduced and released in a body of water at the Pan-American Agricultural University

"El Zamorano" located 20 miles east of Tegucigalpa. Control of waterhyacinth has been a complete success in this body of water through the combined effect of the *Neochetina* and manual removal of the fewer and smaller plants damaged by the feeding of the adult/larvae stages of the weevil.

In 2005, some biological control activities against aquatic invasive plants were initiated in Nicaragua. Aquatic systems have been sampled to determine the arthropods fauna associated with waterhyacinth and waterlettuce, which invades several lakes and rivers in Nicaragua, preventing fishing, navigation, and running of the hydroelectric plants that provide electricity to a large part of the country. A new species of *Cornops sp*. (Orthoptera: Acrididae) was found feeding heavily on waterhyacinth, and host-specificity range studies are being undertaken.

The first biological control activity in Brazil against a non-native invasive plant, *Tecoma stans* (Bignoniaceae) was initiated in 2000. This medium-size tree is originally from the southern USA, Mexico and Central America, and it is invasive in uplands and pasture areas in southern Brazil (the states of Paraná and Rio Grande do Sul) where it replaces native vegetation. The rust fungus *Prospodium appendiculatum* (G. Winter) Arthur was found attacking this plant in southern Brazil, and no other potential specific agents has been found in field explorations conducted in recent years. Initial foreign exploration in the area of origin (Nicaragua, Costa Rica) of *T. stans* was conducted for several days in June 2006 and several potential natural enemies were collected on the plant. Additional field explorations are planned once funds become available.

Exportation of Latin American Biological Control Agents

Contrary to the limited importation of biological control agents into Central and South American countries, as of the late 1900s, 127 insect species had been exported and used in other regions of the world, mainly Australia, Canada, the continental United States and Hawaii, New Zealand, India, and several African counties, principally South Africa. The three countries from which most of the biological control agents have been exported are Mexico (42 species or 33.1% of the total exported), Brazil (30 species or 23.6% of the total), and Argentina (20 species or 15.8% of the total). This trend has continued into this century and is supported by local personnel and institutions (e.g., USDA-ARS Biological Control Laboratory in Hurlingham, Argentina) established by foreign countries that have invasive plants native to South America.

Limitations on the Implementation of Biological Control of Invasive Plants in Latin America

Among the main limitations to carrying out biological control projects against invasive plants in South America is the limited number of technical personnel with training in this discipline. Some efforts of training in this field were initiated by the University of Florida in cooperation with the Universidad Nacional Agraria of Nicaragua, the Instituto de Investigaciones Agropecuarias of Temuco, Chile, and the USDA-ARS South American Biological Control Laboratory of Hurlingham, Argentina. Three intensive weed biological control courses were given in Nicaragua during June 2002, 2004, and 2006 with 78, 51, and 46 participants, respectively. This kind of training is necessary to prepare the personnel required for the implementation of biological control programs in the region.

Another important factor that limits the implementation of invasive plant biological control projects is the limited availability quarantine facilities that exist in the region. However, most of the South American countries already have quarantine facilities for the introduction of parasites/predators for biological control of arthropod pests. These installations could be modified and adapted for the introduction of biological control agents of invasive plants. Countries that have quarantines to handle natural enemies of invasive plants include Brazil, Argentina, and Chile.

A third and very important limiting factor is the lack of funds. Economic resources for any type of agricultural research are scarce and competition for grants is highly competitive. The funding required to initiate a new project for biological control of invasive plants is relatively high. Nevertheless, the ecological and/or economic benefits that will be obtained if agents become established and successful are quite substantial.

Potential for Biological Control of Invasive Plants in Latin America

The successes with biological control of invasive plants in conservation areas, agricultural situations, and aquatic systems obtained in other countries could be duplicated in Central and South America. The diversity and complexity of the agricultural practices by South American farmers suggest that management of invasive plants should be biologically based (biological control using native or introduced insects and/or pathogens) and integrated with conventional control methods. For example, cultural practices (plant density, non-tillage, intercropping, crop rotation, organic agriculture) that contribute to preservation of natural enemies of the invasive plants should be encouraged. Invasive plant pathogens can be integrated with the more disruptive chemical and mechanical methods most commonly used for high-cash crops, or in situations where the availability of manual labor is limited.

The twenty most important invasive plants in Central and South America are shown in the accompanying table: *Amaranthus spinosus* L. (Amaranthaceae; common name "spiny amaranth" in the USA, "bledo" in Central America); *Ambrosia artemisiifolia* L. (Asteraceae; common name "Amargosa," distribution North and South America); *Bidens pilosa* L. (Compositae; common name "mozote"); *Coniza bonariensis* (L.) Cronq., (Asteraceae; common name "varilla," distribution tropical America); *Cyperus rotundus* L. (Cyperaceae; known as "coyolillo" in Central America, "coquito" in Colombia); *Desmodium tortosum* (Swarts) Dc., (Fabaceae; known in Central America as "pega-pega"); *Echinocloa colona* (L.) Link (Poaceae; known as "arroz de monte" or "arrocillo," plant originally from Eurasia and very common in South American rice fields); *Eichhornia crassipes* (Pontederiaceae; common name "jacinto de agua," "lirio de agua," or "lirio acuático"); *Eragrostis plana* Nees (Poaceae; common name in Brazil "capim annoni"); *Pistia stratiotes* (Araceae; known as "lechuga de agua" in Central America and "alfaça de agua" in Brazil); *Portulaca oleraceae* L. (Portulacaceae; known as "verdolaga" in Central America), *Richardia scabra* L. (Rubiaceae; common name "botoncillo"); *Ricinus communis* L. (Euphorbiaceae; highly toxic plant known in South America as "castor" or "higuerilla"); *Rottboellia cochinchinensis* (Lour) Chyton (Poaceae; known in Central America and in the Caribbean as "la caminadora"); *Sida acuta* Burn. f. (Malvaceae; known as "escobilla negra"); *Solanum torvum* Swarts (Solanaceae, a spiny bush common in South America known as "lava platos" or "huevo de gato," a name also applied to various species of *Solanum*); *Sorghum halepense* (L.) Pers. (Poaceae; known as "grama Johnson"); *Taraxacum officinale* Weber (Asteraceae; originally from Europe and known in South America as "lechuguilla"); *Tecoma stans* (L.) Kunth ex HBK. (Bignoniaceae, known as "guabillo" in Central America, it is invasive in southern Brazil); and *Ulex europaeus* L. (Fabaceae; known in South America by the common name "tojo"). These invasive plants cause significant economic or ecological damage in Central and South America and justify the research and implementation costs of biological control. In some cases, the costs for implementing biological control programs in Central and South America can be reduced by making use of the existing technology that has been successful in other regions of the world, thus, biological control with insects and/or pathogens could provide

Biological Control of Invasive Plants in Latin America, Table 3 The twenty most important invasive plants in Central and South America

Scientific name	Common name	Family	Origin
Amaranthus spinosus	Bledo	Amaranthaceae	Tropical America
Ambrosia artemisiifolia	Amargosa	Asteraceae	America
Bidens pilosa	Mozote	Compositae	America
Conyza bonariensis	Varilla	Asteraceae	Tropical America
Cyperus rotundus	Coyolillo	Cyperaceae	India
Desmodium tortuosum	Pega-pega	Fabaceae	Tropical America
Echinocloa colona	Arroz de monte	Poaceae	Eurasia
Eichhornia crassipes	Lirio acuático	Pontederiaceae	South America
Eragrostis plana	Capim annoni	Poaceae	South Africa
Pistia stratiotes	Lechuga de agua	Araceae	South America
Portulaca oleraceae	Verdolaga	Portulacaceae	India
Richardia scabra	Botoncillo	Rubiaceae	South America
Ricinus communis	Higuerilla	Euphorbiaceae	Tropical Africa
Rottboellia cochinchinensis	La caminadora	Poaceae	India
Sida acuta	Escobilla negra	Malvaceae	Tropical America
Solanum torvum	Lava platos	Solanaceae	Africa
Sorghum halepense	Grama Johnson	Poaceae	Mediterranian
Taraxacum officinale	Lechuguilla	Asteraceae	Europe
Tecoma stans	Guabillo	Bignoniaceae	Mexico
Ulex europaeus	Tojo	Fabaceae	Europe

Biological Control of Weeds

JAMES P. CUDA
University of Florida, Gainesville, FL, USA

Weeds are universally recognized as significant pests worldwide because they interfere with food and fiber production, and are considered the most important threat to biodiversity after habitat destruction. Weeds cause 90% of agricultural losses, and herbicides account for approximately half (47%) of the world's agrochemical sales. The economic effect of weeds on the U.S. economy is staggering. Weed-associated losses and costs in the mid 1990s were estimated to be in excess of $20 billion annually, with non-native or invasive weed species accounting for $13 billion, or 65%.

An invasive weed is a non-native plant that exhibits rapid population growth following its arrival in a new environment where it did not evolve. The success of the weed in its new habitat is due in part to the absence of the natural enemies that normally limit its reproduction and spread in its native range. Classical biological control seeks to reunite an invasive weed with one or more of its coevolved natural enemies to provide permanent control of the weed. Thus, classical biological control can be defined as the planned introduction and release of undomesticated target-specific organisms (usually arthropods, nematodes or plant pathogens) from the weed's native range to reduce the vigor, reproductive capacity, or density of the target weed in its adventive range. The term "adventive" in this definition acknowledges the fact that the arrival of a weed in a new geographical area can occur by any means (e.g., immigration), and is preferable to the term "introduced," which is restricted to actions taken by people. Biological weed control as it is defined here specifically excludes natural regulation (the action of organisms without human intervention), cultural control practices (grazing management, crop rotation, etc.), and plant competition (the deliberate use of one plant species to competitively exclude another). Although plant competition is not included in the definition of biological weed control, it is an essential component of the overall process that can affect the outcome of a biological control project.

Plant predation (or herbivory in the case of weed biological control) and plant competition are entirely different ecological processes. An introduced natural enemy (arthropod, nematode, or pathogen) damages or consumes portions of the weed, which rarely leads to plant death but results in a loss of biomass or nutrients that weaken and stress the plant. In plant competition, the weed and its competitors are interfering with each other for use of a common resource (e.g., light, water, nutrients or germination sites). It is the subtle interaction between these two distinct ecological processes that can lead to the permanent decline of a weed population. An invasive weed is less likely to recover from the effects of selective herbivory from biological control agents if competition from desirable native plant species is strong.

Classical biological control offers several advantages over other weed control methods: (i) it provides selective, permanent control of the target weed; (ii) it is relatively inexpensive to develop and implement compared to other methods of weed control; (iii) introduced biological control agents are self-replicating and will spread on their own throughout the infested area; and (iv) because they are living organisms, biological control agents are biodegradable.

Some of the strengths of classical biological control also contribute to its shortcomings: (i) once biological control agents are established, they cannot be recalled if desirable species are attacked; (ii) control is not immediate and may require 5–10 years for agents to attain damaging levels; (iii) natural enemies for controlling every weed may not exist; and (iv) agent establishment and suppression of the target weed are not guaranteed.

Recent examples of successful biological control of adventive weeds with introduced invertebrate organisms in the last 20 years are shown above.

Procedures in a Classical Weed Biological Control Project

From the beginning, weed biological control scientists have continued to develop and refine procedures for locating, screening, releasing and evaluating biological control agents (Summary of steps, Table 5). All countries currently

Biological Control of Weeds, Table 4 Recent successes in classical biological control of weeds with invertebrate organisms worldwide since 1980

Weed species	Country
Aquatic and Wetland Weeds	
Alligatorweed, *Alternanthera philoxeroides* (Martius) Grisebach	China, New Zealand, Thailand
Azolla, *Azolla filiculoides* (Lamarck)	South Africa
Purple Loosestrife, *Lythrum salicaria* L	Canada, USA
Water Fern, *Salvinia molesta* (D. S. Mitchell)	Australia, Fiji, Ghana, India, Kenya, Malaysia, Namibia, Papua New Guinea (PNG), South Africa, Sri Lanka, Zambia
Water Hyacinth, *Eichhornia crassipes* (Martius) Solms-Laubach	Australia, Benin, India, Indonesia, Nigeria, PNG, South Africa, Thailand, Uganda, Zimbabwe
Water Lettuce, *Pistia stratiotes* L	Australia, Botswana, Ghana, PNG, South Africa, Sri Lanka, Zambia, Zimbabwe
Terrestrial Weeds	
Annual Ragweed, *Ambrosia artemisiifolia* L	Russia
Giant Sensitive Plant, *Mimosa invisa* (Martius)	Australia, PNG
Leafy Spurge, *Euphorbia esula* L	USA
Nodding Thistle, *Carduus nutans* L	Canada, USA
Purple Sesban, *Sesbania punicea* (Cavanille) Bentham	South Africa
Spinyhead Sida, *Sida acuta* (Burman) f	Australia
Tansy Ragwort, *Senecio jacobaea* L	USA, Australia

CAB International, Queensland, Australia, 223 pp; McFadyen REC (1998) Biological control of weeds. Annu Rev Entomol 43:369–393; Spencer NR (ed) (2000) Proc X Int Symp Biol Cont Weed, Bozeman, Montana, USA, 4–14 July 1999. United States Department of Agriculture, Agricultural Research Service, Sidney, Montana, and Montana State University, Bozeman, MT conducting weed biological control projects follow this protocol in one form or another to ensure that candidate organisms are safe to introduce.

Importance of Host Specificity

Host specificity is fundamental to biological weed control because it ensures that an introduced agent will not become a plant pest. Host specific, coevolved natural enemies are considered good candidates as they are incapable of reproducing on plants other than their weedy hosts, and have proven to be the safest to introduce because they are least likely to damage nontarget species. Because these host-specific natural enemies reproduce only in the presence of their host plants, they are able to regulate weed abundance by operating in a self-sustaining, density dependent manner.

Selecting organisms as candidates for classical weed biological control can be a complicated and lengthy process because scientists must identify those natural enemies that have developed a high degree of specificity with their host plants. Scientists conduct various types of host range tests in the field and laboratory (oviposition, adult feeding, and larval development) depending on the biology of the agent. Several screening tests usually are required to demonstrate with confidence the estimated host range of the agent. Candidate

Biological Control of Weeds, Table 5 Summary of steps involved in a classical weed biological control project

Step	Description
Target selection	Review literature about target weed, related plants and known natural enemies; identify and resolve conflicts of interest; conduct cost-benefit analyses; seek approval and funding
Overseas and domestic surveys	Locate native range of target weed and survey for natural enemies; assess biocontrol potential of each organism in country of origin; conduct faunal surveys in adventive range
Host specificity studies	Examine host range of organisms in native range; compile list of test plants and import promising candidates into quarantine of country of introduction for further testing
Approval of agents	Submit screening report to appropriate regulatory agencies to obtain approval for release; respond to requests for additional host testing or other concerns
Rearing and release	Obtain release permit; mass rear biocontrol agent; identify and implement most effective release strategy; release biocontrol agent at various sites to increase likelihood of establishment
Evaluation	Conduct field studies to confirm establishment and spread of biocontrol agent on target and nontarget species; use replicated manipulative experiments to determine effect of biocontrol agent on target weed populations
Technology transfer	Provide training to land managers and extension agents about using biocontrol agents; collaborate with user groups to determine best strategies for integrating biocontrol with other control methods

Sources: Julien M, White G (eds) (1997) Biological control of weeds: theory and practical application, ACIAR Monograph No. 49. ACIAR, Camberra, Australia; Luken JO, Thieret JW (eds) (1997) Assessment and management of plant invasions organisms that fail the host specificity requirement are dropped from further consideration. According to established guidelines, no organism can be introduced into a new environment before its host range is determined.

Taxa Used in Classical Biological Control of Weeds

Through 1996, there have been at least 1,150 deliberate releases of invertebrate organisms against invasive weed species in 75 countries. Five of the countries shown here – the United States, Australia, South Africa, Canada and New Zealand – account for most of the activity, based on the number of weed species targeted and agents released.

A large number of families and species are represented in these releases, and they are listed by the taxonomic groupings shown on p. 307. The taxa used in biological control projects worldwide are predominantly insects, but mites, nematodes, and fungi also have played an important role in controlling adventive weeds in some cases. Overall, 25% of all releases made before 1985 contributed to the control of the target weed.

Classical Biological Control of Weeds in Aquatic Habitats

Compared to terrestrial weeds, biological control of aquatic weeds with insects has been remarkably successful since it was first attempted in the United States against alligatorweed (*Alternanthera philoxeroides* (Martius) Grisebach) in 1964. Complete or substantial biological control of several other aquatic weed species has been achieved in most countries where it has been attempted. Although a higher proportion of failures than successes has occurred in the field of weed biological control, the overall success rate for the aquatic weeds is extraordinary. A close examination of the various projects suggests this high success rate may be correlated with the growth form of the weeds, the taxa used as biological control agents, susceptibility to disease-causing pathogens, fluid nature of the aquatic environment, or some combination of these factors.

Biological Control of Weeds, Table 6 Number of weed species targeted and agent species released in the five most active countries through 1990

Country	Weed species	Agent species
United States	54	130
Australia	45	123
South Africa	28	61
Canada	18	53
New Zealand	15	15

Sources: Bellows TS, Fisher TW (eds) 1999 Handbook of biological control. Academic Press, San Diego, CA ;Julien MH, Griffiths (eds) (1998) Biological control of weeds: a world catalogue of agents and their target weeds (4th ed) CABI Publishing, New York, NY

The aquatic form of alligatorweed, water hyacinth (*Eichhornia crassipes* (Maritius) Solms-Laubach), water lettuce (*Pistia stratiotes* L.), salvinia (*Salvinia molesta* D. S. Mitchell), and water fern (*Azolla filiculoides* Lamarck) have been predictably controlled using classical biological control. An interesting pattern emerges when the weed and insect attributes associated with these successes are considered. (i) All of the aforementioned aquatic weeds are either free-floating, or produce floating mats in the case of alligatorweed. This plant growth form is susceptible to wave action and currents that are unique to aquatic environments. (ii) Reproduction in these weeds is primarily by rapid vegetative growth. High genetic uniformity usually associated with vegetative reproduction was thought to be a necessary prerequisite for successful biological control. (iii) These floating weeds are highly susceptible to secondary infection. Aquatic plants that have sustained damage by insects or disease will rot and disintegrate very rapidly. (iv) Beetles (Insecta: Coleoptera) have been responsible for most of the control, especially weevils. Coincidentally, most invertebrate organisms released for classical biological control of weeds worldwide have been beetles.

Classical Biological Control of Weeds in Stable and Ephemeral Habitats

Historically, only perennial weeds of relatively stable environments (e.g., pastures, rangelands, and aquatic systems) were regarded as appropriate targets for classical biological control with host specific introduced natural enemies. Habitat stability coupled with minimal disturbance were thought to be necessary prerequisites for successful biological control. Conversely, crop weeds were deemed inappropriate targets for classical biological control with most of these organisms because of their vulnerability to conventional cultivation practices (e.g., soil tillage, mowing) and the same pesticides used against crop pests. Also, there was the belief that invertebrate biological control agents cannot develop damaging populations quickly enough to be effective against crop weeds because rapid control is needed to prevent the weed from overwhelming the crop. Finally, most crop weeds are multi-species assemblages of short-lived annuals that traditionally were not considered amenable to biological control by introduced host-specific organisms with the exception of fungi.

Several recent examples, however, have shown that classical biological control is feasible in some intensively managed agricultural environments where most of the problems are caused by one or two species of adventive crop weeds. Field bindweed (*Convolvulus arvensis* L.), which is native to Eastern Europe, is a serious pest of corn, cotton, sorghum, turf and wheat in much of the United States and Canada. An eriophyid mite (*Aceria malherbae* Nuzzaci), imported from Greece in 1989, has proven to be effective in controlling field bindweed infestations in some parts of Texas and Oklahoma, and can survive repeated mowing. The mite attacks the plants by producing galls on the leaves, petioles, and stems that stunt new growth, deform the leaves, and limit seed production.

Puncturevines (*Tribulus terrestris* L. and *T. cistoides* L.) are annual and perennial herbaceous plants, respectively, native to the Mediterranean region and Africa. In the 1960s, these two adventive weeds were serious pests of croplands and pastures primarily in arid regions of the southwestern United States and Hawaii. Puncturevines were not only invasive but produced spiny burs, capable of penetrating tires, that were injurious to livestock. Two weevils imported from Italy, a stem borer [*Microlarinus lypriformis* (Wollaston)]; and a seed feeder [*M. lareynii* (Jacquelin du Val)]; gave complete control of both puncturevines in Hawaii, and provided substantial control of the annual species in many areas of the Southwest.

Three ragweeds that are native to North America are adventive species in the former Soviet Union where they have become invasive. One of these ragweeds (*Ambrosia artemisiifolia* L.) caused serious problems because it was infesting croplands and was difficult to control using conventional herbicides and cultural methods. A defoliating leaf beetle [*Zygogramma suturalis* (Fab.)]; obtained from Canada and the United States, was released in the former Soviet Union in 1978. This leaf beetle built up enormous populations and provided complete control of this ragweed under certain conditions. On one farm, yields of alfalfa, sainfoin and corn increased dramatically as the beetles completely destroyed all the ragweeds in the infested fields.

More recently, the invasion of natural and conservation areas by immigrant plant species or introduced ornamental plants that have escaped cultivation has generated considerable interest in classical biological control as a weed management tool. Invasive weeds of natural areas have been called "biological pollutants." Unlike other forms of environmental pollution whose effects are reversible once the source of the pollution is removed, invasive weeds pollute the environment after they become established by continuing to proliferate and spread causing potentially irreversible ecosystem damage. Incipient populations of adventive weeds often are indistinguishable from the native flora, and they usually avoid detection until severe ecological harm already has occurred. Eventually, these invasive natural area weeds change the landscape by displacing more desirable native plant species, altering fire regimes, increasing soil erosion, contributing to the loss of wildlife habitat, causing some plants and animals to become rare or endangered, and diminishing the aesthetic value of recreational areas. In some cases, invasive natural area weeds even cause human health problems.

Biological control offers an attractive alternative to conventional chemical and mechanical control methods that are too costly and damaging to the environment, especially on large tracts of public lands set aside for nature preserves as well as state and national parks. Some recent examples of successful biological control programs against invasive weeds of agricultural as well as natural areas are listed on p. 305. Although it has not been confirmed, there is every indication that insects introduced into Florida from Australia for biological control of melaleuca (*Melaleuca quinquenervia* (Cav.) S. T. Blake) are contributing to the successful integrated management of this invasive wetland tree weed that is threatening the ecology of the Florida Everglades

Biological Insecticides

Insecticides made with insect pathogens that are formulated to be applied like conventional chemical insecticides.

► Insecticides
► Microbial Control of Insects

Biology

The study of life. This is an "umbrella" term that includes all aspects of the study of life, including biochemistry, genetics, and taxonomy. Some taxonomic texts include a section with heading "Biology" under which the authors assemble information about behavior and natural history, as if taxonomy were somehow not part of biology.

Bioluminescence

Light produced by living organisms from a chemical reaction, usually involving the protein luciferin and the enzyme luciferase.

► Fireflies
► Fireflies: Control of Flashing
► Glowworms

Biomagnification

Increase in the concentration of a persistent chemical along a food chain, with the top-level predators accruing the highest concentration. Biomagnification is of special concern with long-lived pesticides, which can be retained in fat tissues rather than being excreted. Biomagnification is also known as biological concentration and food chain concentration.

► Biological Amplification

Biomass

The mass of a living organism of a defined type and from a defined area. Biomass, often expressed as dry weight, is used to estimate abundance and to ameliorate the differences between a few large individuals and many small ones.

Biome

A large ecological unit or ecosystem defined by vegetation, climate, and geography, though a biome can be found in more than one place. Examples of biomes are salt marshes and steppe regions.

Biopesticide

A product that consists of biological organisms, usually microbial agents or their products, for pest suppression. Biopesticides usually are applied as inundative or augmentative biological control agents.

►Microbial Control of Insects

Biorational Pesticides

Pesticides that are considered to be safe to humans or the environment, and based on microbial agents or naturally occurring chemicals (e.g., pheromones, hormones). Because these are based on chemical products rather than on living organisms, they are classified as chemical control rather than biological control.

►Pheromones
►Microbial Control of Insects
►Botanical Insecticides

Biosphere

The ecosystem that includes the entire earth.

Biosystematics

The branch of systematics (classification) in which the genetic and evolutionary relationships between taxa are investigated.

Biota

The species of plants and animals occurring within a defined area.

Biotechnology

The manipulation of organisms to provide desirable products. It has broader meanings, as well, including all parts of an industry that creates, develops and markets a variety of products through the molecular manipulation of organisms or using knowledge pertaining to the molecular biology of organisms. In pest management, it is the use of genetically modified organisms in the production of crops or animals, including in the production of insect-suppressive agents.

Biotic Disease

Disease caused by a pathogen, such as a bacterium, fungus, or virus.

Biotic Potential

The rate at which a species will increase in the absence of limits.

Biotic Release

The escape of a population from the regulatory effects of its natural enemies, resulting in a population increase or outbreak.

Biotope

An area of uniform environmental conditions occupied by a similar community. This term is most popular in Europe. It is essentially equivalent to "habitat," but although habitat is often used in conjunction with populations, biotope is used to describe a community.

Biotype

A race or strain of an organism that differs in some way from the principal population, often in susceptibility to a pesticide or in association with a food plant. In the case of host plant associations, such biotypes are sometimes called "host races."

Bipectinate

The presence of comb-like structures on opposing sides, usually used to refer to a form of antennae.

► Antennae of Hexapods

Bird and Rodent Fleas

Members of the family Ceratopsyllidae (order Siphonaptera).

► Fleas

Bird Cherry-Oat Aphid

► Wheat Pests and Their Management

Bird Lice

Members of the family Philopteridae (order Phthiraptera).

► Chewing and Sucking Lice

Bird Malaria

► Avian (Bird) Malaria

Birnaviruses

The family Birnaviridae contains three genera, the *Avibirnavirus* (infectious bursal disease of chickens), the *Aquabirnavirus* (infectious pancreatic necrosis virus of fish), and the *Entomobirnavirus* (*Drosophila X* virus). Birnaviruses are icosahedral viruses and lack a viral membrane. Characterized as medium-sized viruses (60 nm diameter), they encapsidate two segments (A, B) of linear dsRNA (total size 6–7 kbp). Unlike other dsRNA viruses (reoviruses), Birnavirus dsRNAs extracted from the viral capsid can serve as m-RNA; under in vitro conditions, the dsRNA molecules can bind to ribosomes and undergo translation. Segment A is polycistronic and codes for three gene products, whereas segment B is monocistronic and codes for one gene product.

The *Drosophila X* virus (DXV), the type species of the *Entomobirnavirus*, was discovered initially as a contaminant in insect cell lines. Sequence analysis of DXV has revealed that segment A contains two open reading frames (ORFs) consisting of a 3096 bp and 711 bp sequence. The 3096 bp ORF codes for the 114 kDa polyprotein which is processed post-translationally by virus-encoded protease to generate VP-2, VP-3, and VP-4. In most birnaviruses, the second ORF codes for a small, arginine-rich peptide. Segment B encodes for VP-1 putative viron associate RNA polymerase. DXV is polytropic and can replicate in the cytoplasm of both the mesodermal and epidermal cells of *D. melanogaster*. DXV replication results in extensive lysis of *Drosophila* cells within 26 h. Surviving cells maintain DXV in a repressed form (they are persistently infected) and are immune to a second challenge with DXV. Laboratory colonies of *D. melanogaster* infected with DXV exhibit anoxia sensitivity and do not recover after being anesthetized with CO_2 or N_2.

Bíró, Lajos

George Hangay
Narrabeen, NSW, Australia

Lajos Bíró was born on the 29th of August 1856 in Tasnád, Szilágy Shire, in Transylvania, (which was then part of Hungary). He was the sixth child of a poor cabinetmaker. His father wanted him to become a woodworker also, but young Lajos had a keen interest in natural history. Thanks to his teacher, Ferenc Török, he became quite an expert in insect collecting and various other zoological preparation techniques. From an early age he longed for the tropics but coming from a poor family and living in land-locked Hungary, he could only dream about exotic countries and the exploration of their zoological wonders. To satisfy his ambitions in discovery and research, he built an extensive insect collection of Hungary and adjacent lands. To become a university student was out of the question because of the family's financial circumstances. The only way for him to obtain some sort of a tertiary education was to become a priest. He attended Protestant Theology – but only for two years, as he couldn't develop a deep religious belief and became a teacher. From his meager earnings he tried to save up for a tropical journey. At the same time his reputation as an entomologist grew and eventually he gained government employment as grape phylloxera inspector/consultant at the Entomological Institute in Budapest. The tragic death of Samuel Fenichel prompted Bíró to take important steps towards the realization of his childhood dreams: to grasp the emerging opportunity and embark on a journey to New Guinea. To obtain the necessary financial support, he sold his collection of over 20,000 specimens to the Hungarian National Museum and secured an agreement with its management for the purchase of the material he was to collect during the expedition. He left Hungary on the 7th of November 1895 and arrived to Friedrich-Wilhelmshafen (today Madang) in Kaiser Wilhelm Land or German New Guinea (today Papua New Guinea) on the 1st of January 1896. During the following 6 years, Bíró relentlessly worked towards his goal to explore as much as possible of New Guinea's insect fauna. He was a very ambitious and prolific collector. His activities were not restricted to insects alone as he also collected other zoological and ethnographical specimens as well. The total number of his New Guinean zoological collections exceeded 200,000 specimens, while the ethnographical objects numbered over 6,000. These collections are still not fully processed yet, although its study by many researchers, including Bíró himself, generated over 100 papers, describing 2,000 species new to science. After his New Guinean years, Bíró continued his work as an entomologist, mainly focusing on Hymenoptera and Coleoptera. His greatest strength was evident in the field, where his acute sense of observation and excellent collecting methods yielded valuable information and great numbers of specimens. He has conducted fieldwork in many European locations, including Turkey, Bulgaria, Crete, etc., and he was commissioned by the British Royal Geographical Society to train young zoologists in India and Burma. In recognition of his achievements, in 1926 he was awarded an honorary doctorate by the Ferenc József University of Science in Szeged (Hungary). Fellow workers named about 150 newly described species after him. He passed away in 1931 at the age of 75. Bíró is considered today as one of the most outstanding Hungarian field entomologists, who unselfishly served his nation and his science.

Biting Midges, *Culicoides* spp. (Diptera: Ceratopogonidae)

ALISON BLACKWELL
University of Edinburgh, Midlothian, Scotland, United Kingdom

Culicoides is the most important of four genera of the family Ceratopogonidae which feed on the blood of vertebrate animals. *Culicoides* includes more than 1,400 named species, and at least 50 are thought to be vectors of disease, spreading pathogens to man and animals.

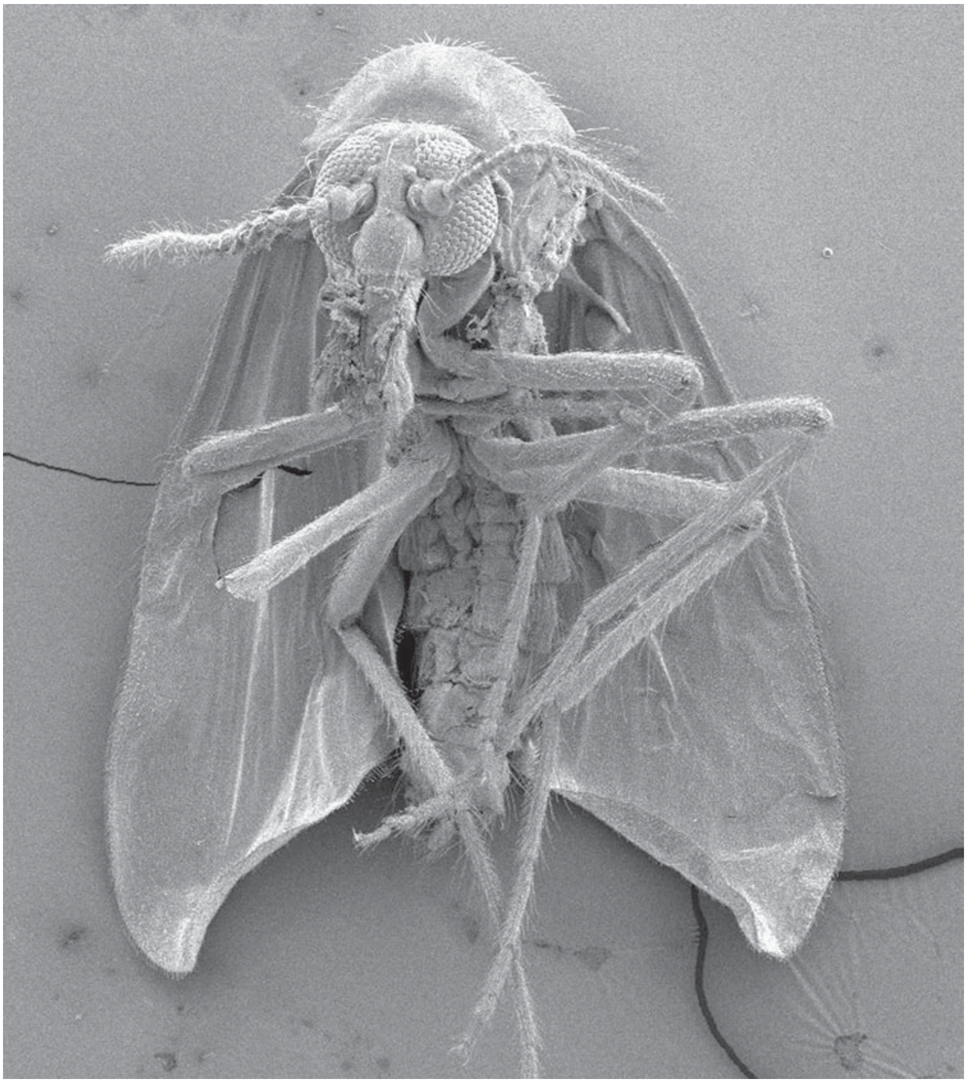
Classification and Recognition

Order: Diptera
Suborder: Nematocera
Infraorder: Culicomorpha
Superfamily: Chironomoidea
Family: Ceratopogonidae
Subfamily: Ceratopogoninae
Tribe: Culicoidini
Genus: Culicoides

The Ceratopogonidae as a whole is a family of small nematocerous flies, 2–4 mm in length with a wingspan of usually less than 2 mm. Although closely related to the non-biting midges, or Chironomidae, they are easily distinguished by the female's biting mouthparts, their short fore legs and characteristic venation on their membranous wings. They are most commonly known as "biting midges" but there are numerous geographical variations, including "sandflies," "punkies," "no-see-ums," "no-nos," "moose-flies" and "biting gnats." Some names are particularly expressive, for example, the Gaelic name for the Scottish Highland midge is *Meanbh-chuileag* (tiny fly) emphasizing its diminutive, 1.4 mm wingspan.

Culicoides are some of the smallest ceratopogonids, 1–2 mm in length, partly distinguishing them from the other blood-feeding genera (*Leptoconops*, *Austroconops* and the subgenus *Lasiohelea* within the genus *Forcipomyia*). The small head has a large pair of compound eyes in addition to five-segmented maxillary palps, which are outside of the short set of sucking and piercing mouthparts (in the female), held perpendicular to the body axis. There is also a prominent pair of segmented antennae, with long mechanoreceptors on the male antenna, giving it a feathery appearance. The dorsal thorax (mesonotum) is frequently covered in a distinctive pattern of dark spots or other markings, accompanied at the proximal end by a pair of small, elongate "humeral pits," distinguishing *Culicoides* from other genera. The body is generally a variation of brown or black, but some species are yellowish-brown/orange (Fig. 45).

The wings of *Culicoides* are often an immediate identification feature for the amateur, with the majority (but not all) having a series of dark and pale spots covering the wings, which are folded, scissor-like at rest or when feeding. Other genera, such as *Austroconops*, lack any pattern on their wings. The wings have been a major taxonomic feature of the Ceratopogonidae, with a number of admirable works detailing the degree and pattern of venation, wing color and markings, and the degree of coverage by macrotrichia, which are fine, short hairs that often cover the wing surface (Fig. 46).



Biting Midges, *Culicoides* Spp. (Diptera: Ceratopogonidae), Figure 45 **Female *Culicoides nubeculosus*.**

In addition to the wing characteristics, further identification to species is best carried out from slide-mounted specimens. For example, the third segment of the maxillary palp contains a large pit containing palpal sensilla. Some species have small pits, each bearing individual sensilla. These sensilla are generally considered to be concerned with carbon dioxide (and hence host) detection in the female midge, with smaller numbers found in the non-blood-feeding male. The shape and size of the palpal pit, and the numbers of sensilla are often used as taxonomic tools. Likewise, the antennal sensilla are pivotal to species identification. The antenna consists of a small, flattened ring with a triangular apex (the "scape"), a globular, cup-shaped pedicel, which is enlarged in the male antenna to accommodate a well-developed Johnston's organ and the antennal flagellum, having 13 sub-segments. *Culicoides* antennae bear approximately 300–350 (male) and 200–250 (female) sensilla. Of greatest importance to the taxonomist is the number and positions of the sensilla coeloconica and sensilla trichodea. Further taxonomic detail can also be gained from both the male and female genitalia. More recently, species differentiation has been carried out by molecular techniques, particularly species complexes, such as the *C. imicola* complex, where subspecies differentiation can be difficult using morphological features alone (Figs. 46 and 47).

Culicoides larvae are aquatic/semi-aquatic and swim with a distinctive eel-like motion. They are found in a variety of environments, such as mud, salt-marsh, compost and leaf litter. Some of the most important veterinary species breed in damp ground contaminated to a degree with animal excreta and other organic matter. The slender larvae are primarily pale, sometimes with thoracic markings. The pharyngeal skeleton of the sclerotized head capsule is a key taxonomic feature.

Distribution

Culicoides are the most widespread of the Ceratopogonidae, occurring throughout the world, with the exception of the polar regions. The only large inhabited land masses from which they are known to be absent are New Zealand and the southern most areas of South America.

Ecology and Behavior

Life Cycle and Population Dynamics

The cylindrical or cigar-shaped *Culicoides* eggs (30–200 per batch) are laid on the chosen substrate surface, where they hatch (2–10 days depending on temperature) and the larvae move down into the substrate, where they live as omnivores/detritivores. The larvae commonly remain close to the substrate surface. In Scotland, more than 50% *Culicoides impunctatus* larvae have been recovered from the top two cm of the soil surface. *C. impunctatus* appears to show a weak photonegative response, with a greater proportion in deeper samples during the day than at night. This daily migration is far more marked in *Culicoides furens* larvae, which live in the muddy banks of mangrove channels. With vegetation often sparse, predation by birds is a serious threat during the daylight hours, perhaps explaining the fact that larvae feed on algae at the mud surface during the night and on nematodes deeper down in the mud during the day. In addition to a vertical component, the spatial distribution of *Culicoides* larvae also appears to have a horizontal component. Even in apparently homogeneous environments such as the Scottish Highlands, *Culicoides* larval distribution can be directly correlated with soil conditions (water and organic content) and key indicator plant species. A similar situation is seen with the salt-marsh species *Culicoides melleus*, with larval distribution related to soil pH and areas of *Distichlis spicata* (Gramineae).

There are four larval instars, and the time required for larval development varies with temperature. Development may be completed in 14 days in warmer areas, with up to seven generations produced each year. In more temperate regions, this is reduced to one or two generations with the final larval instar often acting as the over-wintering stage, although some species will aestivate as eggs. In Scotland, the over-wintering period for *Culicoides* lasts for up to 9 months, followed by two adult generations during the summer. The pupal period lasts between 2 and 10 days.

Nightly trapping program can reveal significant information on the structure of *Culicoides* populations, including autogeny (e.g., females laying their first egg batch without taking a bloodmeal), protandry (e.g., males emerging before females), in addition to reproductive and survival rates, themselves allowing the calculation of a species' vector competency (e.g., the likelihood of it being able to transmit a disease pathogen). In association with climate data, it is possible to construct models of the influence of a range of climatic conditions on midge flight and biting activity.

Records of midge dispersal rates vary enormously. Whereas male midges appear to remain close to emergence sites, host-seeking females may move several kilometers from a breeding site. One report suggests that *Culicoides mississippiensis* travels more than 3 km in 24 h, without wind assistance. When wind carriage does become important, midges can travel considerable distances and increasing evidence suggests that disease outbreaks in areas where particular *Culicoides*-transmitted diseases are not endemic may start in this way. For example, the outbreaks of bluetongue virus in Sardinia in 2000 and 2001 may have been caused by infected midges carried on the wind from Northern Africa.

Mating Behavior

Mating in *Culicoides* spp. has been studied for only a small number of species, and despite the general hypothesis that mating is initiated in male swarms (as in many other nematocerans), there are only a few records of *Culicoides* spp. swarms (including *Culicoides nubeculosus* and *C. impunctatus*). Since the conditions required for male swarming (still, warm and humid) can be rare in some temperate regions, it has been suggested that for species living in these areas (e.g., *C. impunctatus* in Scotland), at peak emergence periods it may be energetically more profitable for males to wait in the vegetation for emerging females, i.e., some species may be facultative swarming species. Male swarming can be stenogamic (swarming adjacent to hosts on which females are feeding) or eurygamic (no host involved), depending on the species. Distance and contact sex pheromones have been implicated in the mating of *C. nubeculosus* and *C. melleus*, respectively. Both of these species have been the subject of detailed studies of the mating process, including mate "selection" by the female, spermatophore formation and sperm transfer.

Host Finding and Feeding Behavior

In addition to a bloodmeal, which is necessary for female *Culicoides* to develop their eggs (including all egg batches laid after the first batch by autogenous species), a carbohydrate source is also important for most species. Direct evidence of sugar feeding in the field, however, is rare. The small number of published records include *C. mississippiensis* feeding from flowers of yaupon holly plants (*Ilex vomitoria*) in Florida.

The majority of *Culicoides* show some degree of host preference and this has been investigated by a number of different techniques, including precipitin tests, fluorescent antibody tests, latex agglutination tests, ELISA tests and most recently, DNA analysis by PCR. These tests help to refine the definition of a particular species such as, for example, ornithophilic (bird-feeding) or mammalophilic (mammal-feeding). Many species show further specialization within these broad classes. For example, using an ELISA assay, single, blood-fed *C. impunctatus* were screened against nine different potential bloodmeal hosts. The results showed that cattle, deer and sheep were the primary hosts for this species.

Culicoides spp. biting midges have a highly sensitive olfactory system, which is used in combination with other senses to locate their bloodmeal hosts accurately. The olfactory system is based around the antennae and maxillary palps, the morphology and ultrastructure of which has been fully documented for a number of species. Recent studies have used antennal responses as a screening tool to identify behaviorally active compounds. This has involved the development of electrophysiological techniques, in particular the recording of electroantennograms (EAGs) which, combined with behavioral studies and field trapping programs with active compounds, has led to the identification of several semiochemicals involved in the host location behavior of *Culicoides* spp. For mammalophilic species, one ubiquitous host-derived attractant is 1-octen-3-ol, with others including acetone, butanone and L(+) lactic acid. Responses to each of these can be either enhanced or synergized by the addition of carbon dioxide. For one species, *C. impunctatus*, there is evidence of pheromone involvement in host-seeking, with the production of a volatile "recruitment" pheromone by parous, host-seeking females, possibly analogous to the invitation pheromone of some mosquito species. Variations in these chemical cues between individuals may account for some degree of intra-species selection by *Culicoides*.

Visual cues are also important in bloodmeal host location by a range of blood-feeding insects including both diurnal and crepuscular species. *Culicoides* spp. appear to be no exception. Field populations of *C. impunctatus* in Scotland were attracted to solid-outlined, black, rectangular targets and this response was enhanced in the presence of CO_2.

Culicoides are "pool-feeders," using their finely toothed mandibles and maxillae to pierce the skin, working in a scissor-like fashion to create a pool of blood from which the insect feeds. Prior to this behavior, however, some midges display a degree of choice concerning the area to feed from. This appears to be particularly the case with large hosts, including cattle and horses. The size of the *Culicoides* bloodmeal has been estimated at 4×10^{-2} ml, with a process of rapid diuresis acting to concentrate the blood.

Biting Behavior: Implications for Man and Animals

Disease Transmission

Culicoides spp. biting midges are most important as vectors of a number of serious livestock pathogens, including African horse sickness virus and bluetongue virus (which cause OIE list "A" diseases in their equine or ruminant hosts), bovine ephemeral fever virus (which significantly reduces milk yields in cows and causes sterility in bulls), Akabane virus (which causes abortions and congenital deformities in ruminants), Palyam viruses (which cause abortion storms in cattle) and epizootic hemorrhagic disease of deer virus (which kills many species of deer and also causes disease in cattle). Each of these diseases has an established distribution, intricately linked with that of its vector. There are, however, increasing examples of disease incursions into areas previously unaffected, perhaps as a result of relaxations in international trade barriers, and a trend toward more favorable climatic conditions in these areas. For example, bluetongue virus (BTV) occurs as a clinical disease in Africa, the Middle East, the Indian subcontinent, China, the USA, and Mexico where *Culicoides* are active throughout the year. In December 1999, and January 2000, a BTV serotype 2 epidemic occurred in Tunisia, close to the Algerian border. This was the first time the disease had been reported from North Africa. Further outbreaks followed in June 2000, matched by outbreaks in contiguous coastal areas of neighboring Algeria. From there it appears that infected vectors carried bluetongue to Europe, with outbreaks reported by Italy (August: Sardinia, November: Calabria and Sicily), France (October: Corsica, for the first time) and Spain (October and November: Balearic Islands, last infected in 1960). Although there are only a small number of confirmed vectors for BTV (*Culicoides variipennis* and possibly *Culicoides insignis* in the New World, *Culicoides imicola* and possibly *Culicoides obsoletus* in the Mediterranean and Middle East and *C. imicola* and members of the *Culicoides milnei* and *Culicoides schultzei* groups in Africa), laboratory infections have demonstrated that a number of endemic species in officially unaffected countries will support virus multiplication following infection.

Culicoides spp. also transmit a number of protozoans, most of which are avian parasites (*Haemoproteus*, *Hepatocystis* and trypanosomes). In addition, they transmit a variety of filarial worms (including *Onchocerca* spp.), infecting a range of animals, including birds, cattle and horses.

Overall, pathogen transmission to man by biting midges appears to be minimal, although they do transmit several species of filarial worms in tropical and sub-tropical regions (e.g., *Mansonella ozzardie*, transmitted by *Culicoides phlebotomus* in coastal North Trinidad) and a small number of viruses, including Oropouche, which is strongly pathogenic to man in parts of South America and the West Indies.

Animal Welfare

The general irritation caused by midge bites can occasionally also lead to serious health and welfare conditions in both animals and man. Deer herds are often forced off low-lying pastures onto higher, poorer slopes by midge attacks, which has been suggested as the reason why Scottish red deer are weaker than their European counterparts. The distress caused by midges to cattle is also held to be responsible for reductions in milk yields. Horses can also suffer from a number of allergic reactions to midge bites, including "sweet itch" (also known as "Queensland itch" in Australia and "kasen" in Japan), which is an acutely irritating dermatitis, primarily confined to the mane and tail, although it may spread to the rest of the body. The horse's skin becomes thickened, weals and pustules form, and much of the hair of the mane and tail breaks off or is rubbed off, resulting in extensive damage and large sores in addition to financial loss. Causal agents have been identified as *Culicoides pulicaris* (UK), *C. obsoletus* (Canada), *Culicoides robertsi* (Australia), *C. imicola* (Israel) and *Culicoides insignis*, *Culicoides stellifer* and *Culicoides venustus* (USA). Present methods of prevention include judicious stabling during the summer months and a range of antihistamine, cortisone injections and soothing ointments.

Human Annoyance

It is the biting attacks on humans, however, for which midges are most noted in a number of areas, including the Caribbean, California, Florida and Scotland. The annoyance and discomfort they cause can influence outdoor activities significantly and directly affect the local economies, particularly when they rely heavily on tourism. When bitten, the skin reaction of humans is usually mild, including temporary burning and slight swelling. More sensitive individuals, however, can develop weals, blisters and extreme inflammation of the skin. In a very few cases, extreme allergies can lead to hospitalization. Scarring and secondary infection may occur if bites are scratched.

Control

Culicoides control programs have often been met with difficulties, due to a number of factors. These include the fact that their breeding grounds are often widely scattered, difficult to recognize and often within environmentally sensitive areas, thereby limiting the application of control products. The vast populations of adult midges and their extreme mobility and potential for wind-carriage also places limits on the use of chemical control of adults.

Chemical Control

Culicoides spp. are susceptible to the majority of the major insecticide classes and most have been used at some stage against both adults and larvae, with varying degrees of success. Due to the difficulty of targeting adult midges, chemical control programs have concentrated primarily on the larval stages. Early studies (from the 1950s to the 1970s) involved the broadcast application of a number of persistent and broad-spectrum insecticides, including members of the organochlorines (e.g., DDT) and organophosphates (e.g., chlorpyrifos). Although partly successful, today's knowledge of the significant environmental and health risks associated with these products, as well as the potential for the development of resistant strains from such wide applications of broad-spectrum insecticides, precludes their use. Similar concerns are also associated with the use of pyrethroids, investigated for *Culicoides* larval control in the 1980s with populations of *C. varipennis* and *C. mississippiensis* in the USA. For these reasons, alternative larvicides based on naturally occurring products, for example, neem-based products, are being investigated following the growing trend toward integrating botanical products into insect pest-control programs.

Insecticide treatments of adult *Culicoides* have met with less success than larvicidal programs. A number of programs in the 1950s and 60s were based on thermal insecticide fogging, but the results were disappointing, most probably because the insects avoided contact with the insecticide by hiding beneath vegetation. In addition, there is the likelihood that a sprayed area would be reinvaded as soon as the insecticidal mist had cleared, requiring regular (and expensive) re-treatment.

Where *Culicoides* are responsible for outbreaks of livestock disease, direct treatments of the animals with insecticides (e.g., pyrethroids and ivermectin) have been partially successful. Under serious virus challenge conditions, however, permethrin failed to protect cattle from bluetongue virus infection in a Californian dairy.

Habitat Manipulation

Biting midge problems world-wide have been partly alleviated through a variety of measures aimed at altering the suitability of areas for both adult and larval midges. An example is the impounding or flooding of areas in Florida and the Caribbean to eliminate breeding sites of midge larvae which cannot survive in free-water. Alternative strategies have included draining or land-filling breeding sites in salt marshes in Florida to make them too dry for midges to breed. There are various other environmental manipulations, such as stream flushing and shade removal, which are in widespread use in the tropics to control mosquitoes. Such measures have never been used in more temperate regions. In fact, it has been suggested that it is doubtful that any attempt to alter the landscape of localized areas would, in the long term, be successful against biting midges in Scotland. Considering the relatively high mobility of these insects and the vast areas of potential breeding grounds, this is probably true. Additionally, these methods are often extremely expensive, laborious and although they may make the environment less suitable for *Culicoides*, they frequently destroy the habitats of other, non-target organisms.

Repellents

The use of personal repellents can give a degree of protection against biting midges and indeed, this is generally assumed to be the best line of defense. In addition, repellents can be used to treat windows and door screens and even clothing. A range of chemical repellents, in various formulations sold under a number of different trade names, are currently available. The most widely used chemical in insect repellents is DEET (N,N-diethyl-m-toluamide), forming the main active constituent in the majority of over-the-counter preparations, with concentrations varying from 10% to 90%. Since it was first marketed in 1956, DEET has remained the most effective repellent against midges, mosquitoes and other biting pests, although there have been a number of concerns voiced regarding its safety, including a suggested contribution of DEET usage to the psychological effects associated with a number of combat situations. Although DEET toxicity from casual use is thought to be low and there are no definite reports that these products are not safe if used correctly and sensibly, for those people preferring "natural" products, there is no limit to the number of herbal concoctions marketed as insect repellents. These include oils distilled from a range of plants, including lemon-grass, eucalyptus, cypress, lavender, pennyroyal and thyme. A common factor for most of these is that they contain a number of terpenoid compounds, such as citronellal and limonene. There are a number of regional "favorites." For example, in Scotland, the oil derived from the leaves of *Myrica gale* (bog myrtle, sweet gale – Myricaceae), a deciduous shrub that grows widely in the Highlands of Scotland, has repellent properties equivalent to DEET against *Culicoides* spp. In North America, even the US military consider the use of 'Avon Skin-So-Soft'®, as an alternative to DEET to protect them from biting insects.

Traps

Traps are used mainly as population monitoring devices for *Culicoides* spp., although over limited areas, they can offer a degree of control. Traps vary from basic light-suction traps (with blacklights attracting more than whitelights), to more specialized, odor-baited traps. The latter resulted in increased and more specific *Culicoides* spp. catches. Carbon dioxide (often released from a dry ice source) provides the most impressive increase in catch size, although its attractiveness can be enhanced in combination with some of the host-related kairomones that are gradually being identified for *Culicoides* spp. For example, some commercial traps use a combination of carbon dioxide and 1-octen-3-ol.

Biological Control

The possibility of employing biological control techniques for the control of *Culicoides* spp. has been little studied. Predators, parasites and pathogenic microbes suspected of being natural control agents of *Culicoides* spp. were recorded by Bacon in 1970, including viruses, rickettsiae, bacteria, fungi, protozoa and nematodes. Few, however, have been identified and studied in relation to potentially reducing biting midge populations. Nematodes of the family Mermithidae are known to be fatal parasites of Ceratopogonidae larvae, but have been found in only a few species, including *C. variipennis* in dairy wastewater ponds in California. The only report of a fungal pathogen of *Culicoides* spp. is for *Culicoides molestus* larvae in New South Wales, Australia, in which infection rates with the Oomycete Lagenidium giganteum of 1–62% were recorded. Concerning microbial insecticides, *Culicoides* spp. are virtually unaffected by commercial applications used frequently against mosquito larvae, including *Bacillus thuringiensis var israelensis* and *Bacillus sphearicus*.

Ceratopogonid midge species are regularly infested with a variety of ectoparasitic mite species. In particular, adult *Culicoides* have been found carrying phoretic instars of several families of mesostigmatid mites and ectoparasitic larvae of the prostigmatid superfamily Trombidioidea. The trombidioids are of additional interest because, in their free-living adult stage, some species have been seen feeding on larval ceratopogonids. The precise impacts of these mites on their hosts, however, is unknown. Information is lacking on the basic biology of these mites, their precise trophic relationships and perhaps their potential as vehicles and vectors of candidate insect pathogens.

Biting Rate

This is a measure of abundance of biting insects, and is expressed as number of bites per person per period of time. It is usually used in the assessment of mosquito abundance, and rather than have the insects actually bite before they are tabulated, the insects are typically captured pre-feeding, thereby alleviating stress to the census taker, and alleviating the risk of disease transmission. Under these conditions, then, it is actually the insect landing rate that is being measured, and used as an index of the potential biting rate. Biting rate is also used as a component of insect repellent assessment.

Blackburn, Thomas

Thomas Blackburn was born at Islington near Liverpool, England, on March 16, 1844. Ordained a deacon of the Anglican church in 1869, he was transferred to Hawaii in 1870. There, he collected insects of all orders. Next, he was transferred to Australia and became rector of a church at Port Lincoln in 1882, then one at Woodville near Adelaide, in 1886, which position he held for the rest of his life. In England, he and his brother J. B. Blackburn founded "The Weekly Entomologist" which, after two years, was renamed "Entomologist's Monthly Magazine" and is published to this day. In Australia, he collected beetles intensively, but specialized in Scarabaeidae. He became the foremost Australian coleopterist, and published descriptions of 3,069 Australian species. He died on May 28, 1912, at Woodville.

Black Cutworm, *Agrotis ipsilon* (Hufnagel) (Lepidoptera: Noctuidae)

John L. Capinera
University of Florida, Gainesville, FL, USA

The origin of black cutworm is uncertain, though it is now found in many regions of the world, being absent principally from some tropical regions and cold areas. It is more widespread, and damaging, in the northern hemisphere than the southern hemisphere. It annually reinvades temperate areas, overwintering in warmer or subtropical regions. It has acquired several other common names, including greasy cutworm and dark sword grass cutworm.

Long distance dispersal of adults has long been suspected in Europe, China, and North America. The basic pattern is to move north in the spring, and south in the autumn. Studies in the United States demonstrated northward displacement of moths during the spring in the range of 1,000 km in 2–4 days when assisted by northward flowing wind. Similar displacement to the south and southwest has been documented in the autumn.

Life History

The number of generations occurring annually varies with weather conditions. In North America, there are 1–2 generations in Canada but 2–4 in the United States. In Tennessee, USA, moths are present in March-May, June-July, July-August, and September-December. Based on light trap collections, moths are reported to be abundant in Arkansas, USA (a warm climate) during May-June and September-October, and in New York, USA (a cool climate), they occur mostly in June-July. However, light traps are not very effective during the spring flight, and underestimate early season. Thus, the phenology of black cutworm remains uncertain, or perhaps is inherently variable due to the vagaries associated with long range dispersal.

Overwintering has been reported to occur in the pupal stage in most areas where overwintering occurs, but larvae persist throughout the winter in Florida, USA, a subtropical environment. Pupae have been known to overwinter as far north as Tennessee, but apparently are incapable of surviving farther north. Thus, moths collected in the central region of USA in March and April are principally dispersing individuals that are past their peak egg production period. Nonetheless, they inoculate the area and allow production of additional generations, including moths that disperse north into Canada. Duration of the life cycle is normally 35–60 days.

The egg is white in color initially, but turns brown with age. It measures 0.43–0.50 mm high and 0.51–0.58 mm wide and is nearly spherical in shape, with a slightly flattened base. The egg bears 35–40 ribs that radiate from the apex; the ribs are alternately long and short. The eggs normally are deposited in clusters on foliage. Females may deposit 1200–1900 eggs. Duration of the egg stage is 3–6 days.

There are 5–9 instars, with a total of 6–7 instars most common. Head capsule widths are about 0.26–0.35, 0.45–0.53, 0.61–0.72, 0.90–1.60, 2.1–2.8, 3.2–3.5, 3.6–4.3, and 3.7–4.1 mm for instars 1–8, respectively. Head capsule widths are very similar for instars 1–4, but thereafter those individuals that display 8–9 instars show only small increments in width at each molt and eventually attain head capsule sizes no larger than those displaying only 6–7 instars. Larval body length is reported to be 3.5, 5.3–6.2, 7, 10, 20–30, 30–45, 50, and 50 mm for instars 1–8, respectively. Duration of the larval stage is normally 20–40 days. Mean duration of instars 1–6 was reported to be 6.0, 5.0, 4.6, 4.3, 5.6, 4.0 days, respectively, at 22°C. Larval development is strongly influenced by temperature, with the optimal temperature about 27°C. Humidity is less important, but instars 1–5 thrive best at higher humidities.

In appearance, the larva is rather uniformly colored on the dorsal and lateral surfaces, ranging from light gray or gray-brown to nearly black (Fig. 49). On some individuals, the dorsal region is slightly lighter or brownish in color, but the larva lacks a distinct dorsal band. Ventrally, the larva tends to be lighter in color. Close examination of the larval epidermis reveals that this species bears numerous dark, coarse granules over most of its body. The head is brownish with numerous dark spots. Larvae usually remain on the plant until the fourth instar, when they become photonegative and hide in the soil during the daylight hours. In these latter instars they also tend to sever plants at the soil surface, pulling the plant tissue belowground. Larvae tend to be cannibalistic.

Pupation occurs belowground at a depth of 3–12 cm. The pupa is 17–22 mm long and 5–6 mm wide, and dark brown. Duration of the pupal stage is normally 12–20 days.

The adult is fairly large in size, with a wingspan of 40–55 mm. The forewing, especially the proximal two-thirds, is uniformly dark brown (Fig. 48). The distal area is marked with a lighter irregular band, and a small but distinct black dash extends distally from the bean-shaped wing spot. The hind wings are whitish to gray, and the veins marked with

darker scales. The adult preoviposition period is about 7–10 days. Moths select low-growing broadleaf plants preferentially for oviposition, but lacking these will deposit eggs on dead plant material. Soil is an unsuitable oviposition site.

Black cutworm has a wide host range. Nearly all vegetables can be consumed, and this species also feeds on alfalfa, clover, cotton, rice, sorghum, strawberry, sugarbeet, tobacco, and sometimes grains and grasses. In the midwestern USA it is considered to be a serious corn pest. Among the weeds suitable for larval development are bluegrass, *Poa pratensis*; curled dock, *Rumex crispus*; lamb's-quarters, *Chenopodium album*; yellow rocket, *Barbarea vulgaris*; and redroot pigweed, *Amaranthus retroflexus*. The preference by black cutworm for weeds is sometimes quite pronounced, and crops will be attacked only after the weeds are consumed. Adults feed on nectar from flowers. Deciduous trees and shrub such as linden, wild plum, crabapple, and lilac are especially attractive to moths.

Numerous species of natural enemies have been associated with black cutworm, but data on their relative importance are scarce. However, in Missouri, USA, there are reports of 69% parasitism, so natural enemies probably exact a significant toll on cutworm populations. Among the wasps known to attack this cutworm are *Apanteles marginiventris* (Cresson), *Microplitis feltiae* Muesebeck, *Microplitis kewleyi* Muesebeck, *Meteorus autographae* Muesebeck, *Meterorus leviventris* (Wesmael) (all Hymenoptera: Braconidae); *Campoletis argentifrons* (Cresson), *Campoletis flavicincta* (Ashmead), *Hyposoter annulipes* (Cresson), and *Ophion flavidus* Brulle (all Hymenoptera: Ichneumonidae). Larvae parasitized by *Meteorus leviventris* (Wesmael) consume about 24% less foliage and cut about 36% fewer seedlings, so considerable benefit is derived from parasitism in addition to the eventual death of the host larva. Other parasitoids known from black cutworm include flies often associated with other ground-dwelling noctuids, including *Archytas cirphis* Curran, *Bonnetia comta* (Fallen), *Carcelia formosa* (Aldrich and Webber), *Chaetogaedia monticola* (Bigot), *Eucelatoria armigera* (Coquillett), *Euphorocera claripennis* (Macquart), *Gonia longipulvilli* Tothill, *G. sequax* Williston, *Lespesia archippivora* (Riley), *Madremyia saundersii* (Williston), *Sisyropa eudryae* (Townsend), and *Tachinomyia panaetius* (Walker) (all Diptera: Tachinidae). Predatory ground-dwelling insects such as ground beetles (Coleoptera: Carabidae) apparently consume numerous larvae. Although studies in Florida, USA, indicated that 75–80% of cutworms could be killed by a granulosis virus, there is surprisingly little information on epidemiology and of natural pathogens. Rather, such pathogens as viruses, fungi, bacteria, and protozoa from other insects have been evaluated for black cutworm susceptibility; in most cases only relatively weak pathogens have been identified. An entomopathogenic nematode, *Hexamermis arvalis* (Nematoda: Mermithidae), is known to parasitize up to 60% of larvae in the central USA.

Damage

This species occurs frequently in many crops, and is one of the best-known cutworms. Despite the frequency of occurrence, however, it tends not to appear in great abundance, as is known in some other cutworms and armyworms. Black cutworm is not considered to be a climbing cutworm, most of the feeding occurring at soil level. However, larvae will feed aboveground until about the fourth instar. Larvae can consume over 400 sq cm of foliage during their development, but over 80% occurs during the terminal instar, and about 10% in the instar immediately preceding the last. Thus, little foliage loss occurs during the early stages of development. Once the fourth instar is attained, larvae can do considerable damage by severing young plants, and a larva may cut several plants in a single night. Plants tend to outgrow their susceptibility to injury. Corn at the one-leaf stage is very susceptible to damage, but by the 4- or 5-leaf stage plant yield was not reduced by larval feeding. Leaf feeding and cutting above the soil line are less damaging to corn than cutting at the soil surface. Subterranean damage is very injurious.

Management

Adult populations can be monitored with both blacklight and sex pheromone traps. However, light traps are not consistently efficient. Light traps are most effective in the summer and autumn, but the late season generations generally pose little threat to crops. Pheromone traps are more effective during the spring flight, when larvae present the greatest threat to young plants. Trap color affects moth capture rate, with white and yellow traps capturing more than green traps.

Large larvae burrow in the soil, and are difficult to observe. However, larvae can be sampled with bait traps, and this is most effective prior to emergence or planting of seedlings. Various trap designs have been studied, but many employ a container sunk into the soil with the upper lip at the soil surface. The container is baited with fresh plant material and/or bran, and with vermiculite so the larvae can attain shelter. Larvae are effectively captured in baited containers if the vermiculite is not too near the surface, and catches are enhanced if a screen cylinder, which provides a visual stimulus to the cutworms, is suspended above the baited container. If plants are present in the field they compete with the bait in the traps, and trap efficiency declines markedly. The distribution of larvae in the spring is random.

Persistent insecticides are commonly applied to plants and soil for black cutworm suppression, but surface rather than subsurface soil applications are desirable. Larvae readily accept insecticide-treated bran and other baits. Application of systemic insecticides to seeds also provides some protection against larval injury. *Bacillus thuringiensis* is not usually recommended for cutworm control.

Black cutworm larvae feed readily on weeds, and destruction of weeds can force larvae to feed exclusively on crop plants, exacerbating damage. Thus, it is often recommended that weeds not be tilled or treated with herbicide until larvae have matured. Timing is important, however, because prolonged competition between crop and weed plants can reduce crop yield. Presence of flowering weeds also can be beneficial by supporting prolonged survival of parasitoids. In contrast, reduced tillage cropping practices, which often produce higher weed populations, seem to result in increased abundance of black cutworm and higher levels of cutting in corn. This may be due, in part, to the tendency of moths to oviposit on weeds; weedy fields tend to have higher cutworm populations.

Black cutworm populations also tend to be higher in wet areas of fields, and in fields that have been flooded. Black cutworm has been known, at times, as “overflow worm,” due to its tendency to be abundant and damaging in fields that have been flooded by overflowing rivers.

In the home garden, barriers are sometimes useful to prevent damage to seedlings by cutworms. Metal or waxed paper containers with both the top and bottom removed can be placed around the plant stem to deter consumption. Aluminum foil can be wrapped around the stem to achieve a similar effect. Because larvae will burrow and feed below the soil line it is necessary to extend to barrier below the soil surface. Because black cutworm moths, which easily circumvent such barriers, are active during the growing season, this procedure alone may have little value. Use of netting or row covers, in addition to larval barriers, should prove more effective.

Entomopathogenic nematodes (Nematoda: Steinernematidae and Heterorhabditidae) will infect and kill black cutworm larvae, but their populations normally need to be supplemented to realize high levels of parasitism. Their effectiveness is related to soil moisture conditions.

Black Fig Fly (Diptera: Lonchaeidae)

BYRON KATSOYANNOS
Aristotle University of Thessaloniki,
Thessaloniki, Greece

The black fig fly, *Silba adipata* McAlpine, is a pest of wild and cultivated figs, *Ficus carica* L. (Moraceae), occurring in the Mediterranean countries and Iraq. This insect was studied extensively by Silvestri in Italy at the beginning of the twentieth century, although he misidentified it as *Lonchaea aristella* Becker. The adult is glossy black, 3.5–4.5 mm in length, with reddish eyes and brown legs (Fig. 50). The female possesses a long ovipositor with which it deposits its eggs in small groups, beneath the scales protecting the ostiole (eye) of the syconium (fig "fruit"). Oviposition takes place preferably in unripe figs, but ripening ones are also attacked. The larvae feed on the tissues of the syconium, destroying the fruit. Infestation of unripe figs usually results in premature fruit drop, which is frequently mistaken by the growers as due to physiological problems of the trees. The fly completes 4–5 generations per year and overwinters in the pupal stage in the soil.

Observations conducted in Chios island, Greece showed that the flies are attracted and feed mostly on sweet exudates of ripe figs, and on fresh or dry milky fig-tree sap exuded from injured plant parts. As many as 63 pupae were obtained from a single infested, unripe fig, indicating multiple oviposition. The parasitoid *Pachycrepoideus vindemmiae* Rondani (Hymenoptera: Pteromalidae) emerged from *S. adipata* pupae. Males were observed swarming in the afternoon hours, an indication that the mating behavior is related to swarm formations. Hexanol, a generally-occurring plant volatile chemical, is very attractive for the fly and selective, especially for females. Use of McPhail traps baited with hexanol is very effective for monitoring and possibly for control of this fly. Addition of 2% ammonium sulphate in the trap water enhances trap effectiveness. Proteinaceous bait sprays are recommended when better control is needed.

Black Flies (Diptera: Simuliidae)

PETER H. ADLER
Clemson University, Clemson, SC, USA

Black flies are small, morphologically homogeneous insects in the order Diptera, suborder Nematocera, best known for their economic impact as biting and nuisance pests of humans and domestic animals. Adults are readily recognized by their arched thorax, cigar-shaped antennae and strong venation at the anterior margin of each wing. Black flies breed abundantly in flowing freshwater – rivers and streams – throughout the world, from 965 km north of the Arctic Circle to the southernmost tip of South America. Within this vast realm, they are absent only from deserts and islands without flowing water. The immature stages often attain large populations and play an important role in the food web of streams and rivers.

Worldwide, more than 1,700 species have been formally named and described, with the expectation that this number will increase significantly as study of the family continues. The world's species are arranged in two subfamilies and about 24 genera. The largest genus by far is *Simulium*, which occurs worldwide. The greatest number of species, more than one third of the known fauna, inhabits the Palearctic Region, especially Russia. Approximately 260 species are known from North America north of Mexico.

The taxonomy of the family is based primarily on features of the genitalia, legs, and wings of the adults; the cocoons and gills of the pupae; and the head capsule and pigmentation patterns of the larvae. Many species, however, are structurally similar, if not identical, and are known as sibling species. They are typically revealed by studies of the banding patterns in the giant polytene chromosomes of their larval salivary glands. Nearly a quarter of the North American species, for example, were first discovered chromosomally.

The first three stages (egg, larva, pupa) of the life cycle are completed in running water. All types of flowing freshwater are exploited by black flies, from the smallest trickles to the largest rivers. Only a few species can tolerate polluted waters. The female black fly typically deposits its eggs either by dipping to the water's surface during flight to release a few eggs at a time, or by crawling about on wetted vegetation and stones while releasing masses or strings of eggs. The eggs are bluntly triangular, and a female can carry from about 20–800, depending on the species. Larvae hatch from the eggs within a few days to more than half a year. They hold onto objects in the stream, such as rocks and leaves, by means of tiny hooks at the end of the abdomen, which enmesh with a silken pad spun from the salivary glands and applied to the substrate. The larval stage, including six or seven instars, lasts from about a week to six months, depending on the species and water temperature. Mature larvae are 3–15 mm in length. Pupation occurs in flowing water, with a silken cocoon anchoring the pupa to the substrate. Some species burrow slightly into the sand and silt of the streambed to pupate. The pupal stage generally lasts no more than a few weeks. Some species are univoltine, completing only one generation per year. Other species are multivoltine, producing from two to about 15 generations in a year, depending on the latitude and species.

The majority of larval life is spent feeding. Most species feed primarily by filtering particulate matter from the water column, using a pair of head fans, with one fan projecting from each anterior corner of the head. Food particles of an appropriate size, those less than 350 µm in diameter, often include diatoms, bacteria, protozoa, pollen, and organic debris. Most species also can obtain food by scraping it from the surface of stones and other objects in the stream. About 1.5% of the world's species do not have head fans and must obtain all of their food by scraping. These species live in habitats, such as springs and glacial melt waters, where little organic matter is present in the water column. Some species, in addition to filter feeding and scraping, also prey on small arthropods in the stream.

Larvae often space themselves in characteristic patterns depending on the species and water currents. The larvae of some species space themselves closely in moss-like clumps, others space themselves rather widely, and still others pack so densely that they can exceed one million per square meter. For most of their lives, larvae remain attached to objects in the stream. When disturbed or relocating they loop short distances, inchworm fashion, or release their hold of the silk pad and drift downstream either freely or moored to a silk strand, eventually reattaching to a suitable substrate. Drift is particularly frequent at sunset and during the night, and is an important means of avoiding predation by fish and predacious arthropods.

Larvae are susceptible to parasites and pathogens, including mermithid nematodes, protozoa, microsporidia, fungi, and viruses. Only a small percentage, perhaps about 1%, of a population is usually infected, although parasitized larvae often live longer than uninfected individuals and become more apparent as the population ages and the healthy larvae pupate. Most parasites kill the larvae, but some pass through the pupae and into the adults, typically sterilizing the adult.

Larvae of most species pupate singly, but those of some species form large clusters of pupae. The adult that has developed within the pupa forcibly splits the pupal cuticle and emerges in a bubble of air, buoyed to the surface with enough force to break free of the water. The freshly emerged adult then flies to a resting spot where it tans and hardens its exoskeleton.

Adults (Fig. 51) are active during the day. They typically live less than a month, during which time they must mate and acquire food; females also must return to a stream or river to oviposit. The adults of most species probably do not disperse more than 10 km, although some species regularly travel more than 50 km in search of hosts. At least one species in Africa has been reported to disperse more than 500 km from the natal watercourses.

Mating usually takes place shortly after emergence. In many species, the males form aerial swarms over or beside landmarks such as trees, rocks, and waterfalls. Females fly into these swarms and are intercepted by males. The coupled pair quickly leaves the swarm. A small percentage of species, about 2% in North America, mate on the ground at their emergence sites. A similarly small percentage of females do not mate. These non-mating species consist of all-female, parthenogenetic populations, and they occur at northern latitudes.

Both male and female black flies feed on water and a source of carbohydrate, such as floral nectar and honeydew, that fuel their flight activities. Only females feed on blood. The mouthparts of males are

Black Flies (Diptera: Simuliidae), Figure 51
Female black fly (from Cameron 1922; Canadian Department of Agriculture Bulletin).

incapable of cutting skin. Females use their mandibles to snip the skin of warm-blooded animals, while injecting various anesthetics and anti-clotting factors. As the capillaries are severed, a pool of blood forms, which is then imbibed. Not all species have females that feed on blood. In less than 10% of the world's species, the females have mouthparts much like those of the males, too feeble to cut vertebrate flesh. These non-biting females typically occur in northern environments such as the arctic and are facultatively autogenous, meaning that by necessity, they mature their eggs without the benefit of blood. The nutrient reserves for egg production are carried over from the larval stage.

Black flies use a wide range of hosts to acquire a blood meal although many species are quite host- specific. For example, one species of black fly feeds only on loons. Other species feed only on raptors, or only on small or large mammals. Still other species appear to be true generalists. To locate their hosts, females use a series of cues such as color, shape, size, and odor. Carbon dioxide is especially attractive. Species tend either to feed on birds (ornithophily) or mammals (mammalophily). The bird feeders have a thumb-like lobe on their claws, whereas most mammal feeders have simple or slightly toothed talons.

By virtue of their requirement for blood, black flies frequently become pests of humans and domestic animals. Only a fraction of the species, about 15% in North America, actually causes economic problems. The majority of species are not attracted to humans and domestic animals but, instead, feed only on wildlife. Some of the pest species are primarily a nuisance, swarming about the head and entering the facial orifices. Those that take blood represent a more serious threat, either through exsanguination, injection of toxic saliva (simuliotoxicosis), or the transmission of disease agents. Some of the major cattle and poultry pests can cause weight loss, reduced egg and milk production, malnutrition, stampedes, stress-related afflictions, and even death. Humans may develop fever, swollen eyes and glands, headaches, nausea, or even more severe allergic reactions. More typical reactions include itching welts at the site where the person was bitten. Outdoor industries and recreational activities often are severely curtailed by both nuisance and biting species.

Black flies transmit numerous blood protozoans, filarial worms, and perhaps a few viruses to mammals and birds. Human-borne pathogens are transmitted by black flies only in Africa and parts of Central and South America. The most common and serious human disease is onchocerciasis, or river blindness, caused by a filarial worm. Filarial worms also are transmitted to cattle, deer, moose, black bears, and ducks, but apparently cause little economic impact. The major avian pathogens transmitted by black flies are malaria-like blood protozoans that cause a disease called leucocytozoonosis. In North America, turkeys, ducks, and wild birds are affected. The consequences among domestic birds can be grievous and include depressed immune systems, weight loss, decreased reproduction, and even death.

Since the 1980s, the primary means of controlling pest populations of black flies has been with the bacterium *Bacillus thuringiensis* variety *israelensis* (*Bti*), which produces a toxin highly specific to black flies and mosquitoes. When applied to streams and rivers, Bti is an environmentally safe means of management, killing only larval black flies. Management programs are operating in many parts of the world, including Pennsylvania, Quebec, sub-Saharan Africa, and Brazil. Some of these programs cost millions of dollars to conduct every year.

Black Flies Attacking Livestock: *Simulium arcticum* Malloch and *Simulium luggeri* Nicholson & Mickel (Diptera: Simuliidae)

PETER G. MASON
Agriculture and Agri-Food Canada Eastern Cereal and Oilseed Research Centre, Ottawa, ON, Canada

The livestock-attacking black flies, *Simulium arcticum* Malloch and *Simulium luggeri* Nicholson & Mickel, are important pests of cattle and wild ungulates in the northern great plains of Canada. Other black fly species are pests of vertebrates including humans in other parts of the world. Females of *S. arcticum* and *S. luggeri* are greyish or brownish with the dorsum of the thorax uniformly colored. They differ in appearance (the coloration of the tibia of the hind leg is entirely dark in *S. luggeri*, but the basal half is white in *S. arcticum*), and features of the genitalia.

Damage

Economic losses occur due to the massive attacks by female black flies seeking a bloodmeal needed for production of eggs. Dispersal in search of hosts may be 150 km from the rivers where emergence and oviposition take place. In parts of Saskatchewan and Alberta, black flies are limiting to cattle production. Cattle harassed by attacking black flies become frightened and bunch together to escape the blood-seeking swarms. The cattle do not feed normally, resulting in reduced weight gain and milk production. The saliva of *S. arcticum* is toxic to cattle and allergic reaction can cause death. While *S. luggeri* do not have toxic saliva, they swarm in huge numbers around the head, causing livestock to panic, often running into fences and being injured. Bacteria that cause "pinkeye" may be transmitted as black flies land to feed near the eyes of several hosts.

Biology

Simulium arcticum has one or two generations per year, and attacks only cattle and related animals. This species prefers clean rocky locations in large, fast-flowing, silt-laden rivers such as the Athabasca River in northern Alberta. *Simulium arcticum* formerly was the dominant species in the Saskatchewan River but because of hydrological changes caused by hydroelectric developments it ceased to be abundant

Simulium luggeri has up to five generations per year and will attack humans as well as cattle. This species prefers somewhat clear, flowing water near the mouth of middle-sized rivers. The human-induced hydrological changes to the Saskatchewan River drastically reduced summertime river volumes, effectively modifying it from a fast-flowing, silt-laden system to a slower-flowing, clear system. The once deep and turbid river became shallow, clear and slow flowing. This encouraged the growth of massive vegetation beds on previously barren sand bars. This plant substrate served as suitable attachment sites allowing *S. luggeri* to replace *S. arcticum* as the dominant species. Both black fly species have four developmental stage, egg, larva, pupa, and adult. The eggs, larvae, and pupae are restricted to rivers and streams.

Eggs are tiny and trapezoid-shaped. They are "bombed" on the water surface by gravid females flying over the river. The eggs sink to the substrate where they become buried and pass the winter. In spring hatching commences about two weeks after ice breakup.

Newly hatched larvae drift downriver and attach to substrates such as clean rocks or vegetation in the swiftest flowing water. Larvae go through seven instars or growth stages during about three weeks. Larvae of *S. arcticum* are larger (0.9–mm) than those of *S. luggeri* (0.7–4.3 mm). The brown or greenish-grey larvae feed by filtering nutrients from the water using head (cephalic) fans or by scraping algae from the surface of rocks using their mouthparts. When mature, the larva spins a cocoon and pupates within it.

Pupae of *S. arcticum* have paired respiratory filaments and pupation occurs within a boot-shaped cocoon. Respiratory filaments of *S. luggeri* pupae are grouped in threes and pupation occurs within a slipper-shaped cocoon. After a few days the adult escapes from the pupa and floats to the surface in an air bubble.

Adult male and female black flies feed on nectar and other plant juices to sustain their energy requirements. Mating occurs soon after emergence, and females of biting species then seek blood, which is required to produce eggs. After locating a host, settling on its skin, and inserting their blade-like piercing mouthparts, the females suck blood until they become fully engorged. After taking the blood meal they have expanded to twice their normal size. Engorged females seek suitable flowing water habitats in which they lay eggs on particular substrates. Black flies are active during daylight hours but their rate of attack is highest during morning and afternoon. On cloudy days or when storms are imminent black flies may attack viciously at any time of day. Winds can disperse large numbers of adults from breeding areas to surrounding regions, especially open farmland, and shifting winds may disperse black flies to other districts. Cold or rainy weather temporarily ends an outbreak.

Management

Control of black flies attacking livestock is achieved most effectively through use of insecticides. Larvicides are more effective than adulticides because larvae are concentrated in a relatively definable location in rivers or streams and less insecticide is required to kill a substantial number of pest individuals. Larvicide is only applied when and where pest populations are detected. Exclusive use of adulticide is ineffective because of the extreme difficulty in implementing it; it requires repeated (about every 10 days) applications of insecticide spray or fog over large areas of ground in affected communities. In addition, applying insecticide directly to cattle via backrubbers, sprays, etc. has to be safe to the animals and consumers of animal products. Control of adults, however, can be useful as an additional emergency measure, especially on cattle during severe outbreaks. *Bacillus thuringiensis israelensis* is an effective biological insecticide, with little environmental effect.

Disease agents are commonly associated with black flies but the life cycles are almost completely unknown, so knowledge of agent transmission between hosts is lacking. Mermithid nematodes are one of the most promising biological control agents for black flies but their commercial development is hindered by a lack of basic ecological information.

Blackwelder, Richard Elliot

Richard Blackwelder was born on January 29, 1909. His doctoral research was performed at Stanford University, California. That research produced a (1936) monograph "Morphology of the coleopterous family Staphylinidae" in which he acknowledges the help of his advisor, G.F. Ferris, and of R.E. Snodgrass. This work still is the foremost on its subject. Then he published short works on the systematics of North American Tachyporinae (1936, 1938) and Paederini (1939). After graduation he became a Bacon Traveling Scholar for the Smithsonian Institution (1935–1938) during which time he completed a 21-month collecting trip to many West Indian islands (June 1935 through March 1937), returning with 50,000 specimens mostly collected by hand or with a net. This culminated in his (1943) publication of a "Monograph on the West Indian species of the family Staphylinidae," this work, which dealt with the 91 genera and 468 species known to him, has not been bettered. In 1938–1940 he was Assistant Curator of the American Museum of Natural History, and in 1940–1954 Assistant and Associate Curator of the Smithsonian Institution. During these years he published short works on Lispinini and Osoriinae (1942) and the staphylinid beetles of the Cayman Islands (1947), and sundry other papers including, with the help of his wife three supplements to the Leng catalog of North American Coleoptera. His monumental works were (1944–1947, 1957) "A checklist of the coleopterous insects of Mexico, Central America, the West Indies, and South America" and (1952) "The generic names of the beetle family Staphylinidae." The first of these has been cited in just about every subsequent biogeographic study including neotropical Coleoptera and was of enormous importance. In the mid-1960s he explained to this writer the reason for the much-delayed final part (1957), the bibliography, of the first work: that his card index of bibliographic materials had disappeared during one of his absences from the Smithsonian Institution, and he had to rebuild it from his notes and reconsultation of the literature. The second undertaking, generic names, attempted to apply the rules of the International Code of Zoological Nomenclature systematically across the mishmash of usage; although it shook up the established usage, it was largely correct and inevitable. Then he retired from life as a coleopterist and researcher and became a teacher, employed first at St. John Fisher College in New York state (1956–1958) and then at Southern Illinois University (1958–1977). His tremendous energy as a researcher on Staphylinidae in his early years was directed elsewhere by the late 1950s, although he remained an active member of the Society of Systematic Zoologists, published works on systematics in Systematic Zoology and a book "Classification of the animal kingdom" in 1963 and another "Taxonomy" in 1967. He died on January 20, 2001.

Blaisdell, Frank Ellsworth

Frank Blaisdell was born in New Hampshire on March 13, 1862, and moved with his parents and siblings to California in 1870. Despite lack of a high school education, in 1887 he entered Cooper Medical College in San Francisco, and graduated two years later with the degree of Doctor of Medicine. He worked in California at first as a medical practitioner, and from 1900 as an academic at Cooper College and then at Stanford University (into which Cooper College was absorbed). Ultimately he became Professor of Surgery, from which post he retired in 1927. His hobby for decades had been the collection and study of Coleoptera, especially the families Tenebrionidae and Melyridae. After retirement from medicine he worked from the Department of Entomology at the California Academy of Sciences, to which he deeded his collection of almost 200,000 specimens. He published 95 papers in entomology. He died on July 6, 1946.

Blastoderm

The layer of cells in an insect embryo that surrounds an internal yolk mass. The cellular blastoderm develops from a syncytium by surrounding the cleavage nuclei with membranes derived from the enfolding of the surrounding membrane.

Blatchley, Willis Stanley

Willis Blatchley was born on October 6, 1859, in Connecticut, but he grew up on a farm in Indiana that his parents bought in 1860. In 1879, after taking a six-week training course, he became a country school teacher, and it was not until 1883 that he entered Indiana University, majoring in natural science and graduating four years later. From 1887 to 1894 he worked as head of a high school science department. In the first four years of that period he conducted thesis research (a thesis entitled "The Butterflies of Indiana") toward an M.A. degree, awarded in 1891, again from Indiana University. His third degree was an honorary LL.D., awarded in 1921 by the same institution. Schools have long summer vacations, and Willis Blatchley found summer employment with the Indiana State Geological Survey or with the U.S. Fish Commission. The first employment experience may have helped when in 1894 he won the elected position of Indiana State Geologist, and held it for 16 years. His duties were not just as geologist, but also to work on natural resources and natural history. The years 1906–1910 found him working on "Coleoptera of Indiana" as Bulletin 1 of the Indiana Department of Geology and Natural Resources. When another candidate was elected in 1910 as State Geologist, Blatchley retired, and spent the rest of his life working on subjects that appealed to him. He traveled abroad, within the USA, and frequently to Florida where in 1913 he bought a "winter residence" that later he occupied for months each year. With Charles Leng, he published in 1916 "Rhynchophora or weevils of northeastern America"; as sole author he published in 1920 "The Orthoptera of northeastern America," and in 1926 "Heteroptera or true bugs of eastern North America." His books included several of a less technical nature but including observations on insects: (1899) "Gleanings from nature," (1902) "A nature wooing at Ormond by the sea," (1906) "Gleanings from nature," (1912) "Woodland idylls," (1931) "My nature nook," (1932) "In days agone," and (1934) "South America as I saw it." He died in Indianapolis on May 28, 1940, surviving his wife, Clara, by 12 years. His collection of insects, including 470 holotypes, was given to Purdue University.

Blister Beetles (Coleoptera: Meloidae)

Blister beetles are an interesting group of insects, both because of their unusual larval development and because of their toxic effects on humans and livestock. They are widely distributed, but are absent from New Zealand and Antarctica. They are most abundant in warm, dry climates. They number about 3,000 species. Their classification is as follows:

Order: Coleoptera
  Suborder: Polyphaga
    Superfamily: Tenebrionoidae
      Family: Meloidae
        Subfamily: Eleticinae
        Subfamily: Meloinae
        Subfamily: Nemognathinae
        Subfamily: Tetraonycinae

Characteristics

These are medium-sized beetles (usually 3–30 mm, but some up to 70 mm) with 7–11 antennal segments. There are five, five and four segments on the pro-, meso-, and metathoracic tarsi, respectively. The color is variable; though often somber, some are metallic. Body hairs often are absent but sometimes dense. The pronotum of blister beetles is narrower than the head and thorax. The legs are long, and the body is unusually soft for a beetle. The body is often elongate, with the elytra flared at the tips. However, body form varies considerably and though wings usually are normal, some species have short wings and elytra, and are flightless. The immature display hypermetamorphosis. Oviposition takes place on the soil, and young larvae (triungulins) disperse to feed on grasshoppers eggs, or the eggs, larvae and provisions (usually pollen) of ground-nesting Hymenoptera. Once attaining a food supply, the larvae lose their mobility. When disturbed, the adults display reflex bleeding, wherein cantharidin-containing blood is released, principally from the femoral-tibial joints. Cantharidin is a toxic terpenoid that likely imparts some protection from predation, though it also seems to have a role in communication. The beetles also may display death feigning. Cantharidin is produced by larvae, but in the adult stage only by the males. It is transferred to females at mating, and occurs in the eggs.

Life Cycle

Following is an account of black blister beetle development, which is typical of many species. In black blister beetle is a single generation per year, with overwintering occurring in one of the larval instars. The eggs are deposited within a cavity in the soil, in clusters of 100–200 eggs. Because the likelihood of surviving is so small, blister beetles produce very large numbers of eggs, sometimes up to 10,000.

The larval instars of black blister beetle are quite varied in appearance, reflecting the unusual biology of the insect, called hypermetamorphosis. Unlike most insects, the ovipositing female does not locate a food source for her offspring, apparently depositing her eggs randomly. Thus, when young larvae hatch they must dig to the surface and disperse to find a host insect on which to feed. The first instar is thus quite mobile, and equipped with long legs with which to disperse. First instars explore cracks, crevices, and depressions in the soil as they search to find a host. Usually a single egg is adequate for complete development of the first instar. The number of instars is normally 6–7. The larvae are creamy white or yellowish white in color, with brown head capsules. After the first instar the larva moves little, and the legs become relatively shorter and shorter. The sixth instar does not feed, instead digging 2–3 cm into the soil and preparing a cell. The sixth instar may be followed by another nonfeeding instar, or by the pupal stage. The sixth and seventh instars bear only minute legs, and the head capsule is reduced in size and retracted into the body. Black blister beetle larvae consume 21–27 eggs of *Melanoplus differentialis* Thomas during its larval development. This grasshopper, and some other *Melanoplus* spp., produces 100 or more eggs, allowing more than one blister beetle to develop. If blister beetle larvae encounter one another, however, they fight and only one survives. Many grasshoppers produce small egg pods, with less than 25 eggs, thereby limiting the ability of blister beetles to develop. The pupa resembles the adult beetle in form, though the legs and wings are folded against the underside of the body, and there appears to be no tendency for diapause in this stage. The adult digs to the soil surface after pupation.

Other blister beetles sometimes require more than one year to complete a generation, or are multivoltine, depending on the favorability of the environment. The species feeding on bees differ in that the eggs may also be deposited on foliage, where the young larvae are phoretic, attaching to adult bees and are transported back to the nest of the bee.

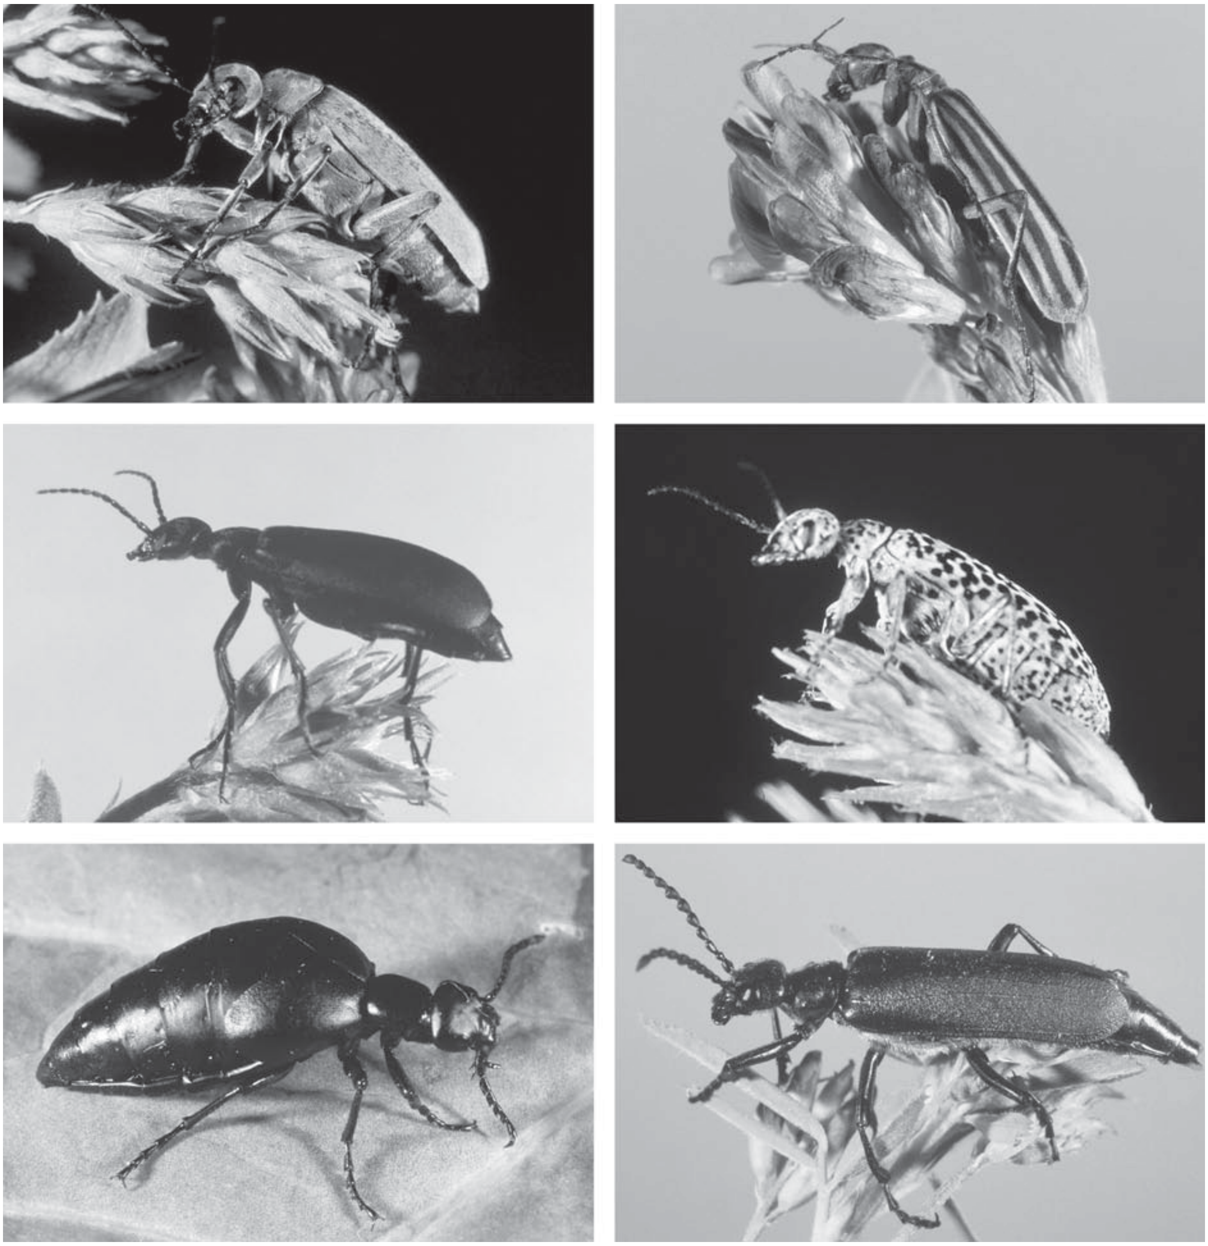
Natural Enemies

Surprisingly little is known concerning the natural enemies of blister beetles, reflecting their minor status as crop pests and the subterranean habits of larvae. Undoubtedly starvation of first instars is a very important factor during most seasons, and cannibalism is prevalent among larvae. Antlike flower beetles (Coleoptera: Anthicidae), false antlike flower beetles (Coleoptera: Pedilidae), and some plant bugs (Hemiptera: Miridae) have been implicated as mortality agents of blister beetles. The larva of the blister beetle *Epicauta atrata* (Fabricius) has also been shown to be predatory on eggs of *E. pensylvanica*, and it is possible that other species within the genus are predatory (Fig. 52).

Damage Caused by Blister Beetles

Epicauta spp. and other blister beetles sometimes feed on crops, though few are commonly destructive. In North America, black blister beetle, *Epicauta pensylvanica* DeGeer, is usually the most common species, and occurs everywhere in the eastern United States and southern Canada west to the Rocky Mountains. Immaculate blister beetle, *Epicauta immaculata* (Say); spotted blister beetle, *Epicauta maculata* (Say); and striped blister beetle, *Epicauta vittata* (Fabricius), are examples of other common crop-feeding blister beetles Other genera of Meloidae occasionally affect crops, but incidents of damage are isolated. Among such occasional pests are *Linsleya sphaericollis* (Say) in the Rocky Mountain region and west to the Pacific Ocean; Nuttall blister beetle, *Lytta nuttalli* Say, throughout the west and east to Nebraska; and *Meloe niger* Kirby, which occurs throughout the United States and southern Canada except for the southeastern states.

Blister beetle adults are found on alfalfa, clover, soybean, and sugarbeet, as well as numerous vegetable and flower crops, fruit trees, and broadleaf weeds. Adults often collect on goldenrod flowers, *Solidago* spp., in the autumn. Indeed, flowers are often a preferred food of many species. Beetles tend to aggregate, apparently in mating swarms, so damage can be severe in relatively small areas of a crop and absent or trivial elsewhere. consumption of foliage, in some instances they prefer blossoms.



Blister Beetles (Coleoptera: Meloidae), Figure 52 **Representative blister beetles: upper left, *Epicauta immaculata*; upper right, *Epicauta lemniscata*; center left, *Epicauta pensylvanica*; center right, *Epicauta andersoni*; lower left, *Meloe laevis*; lower right, *Lytta* sp.**

Preference of blister beetles for blossoms is most noticeable and potentially damaging in alfalfa, where beetles congregate mostly during periods of bloom. Aggregations of beetles can be incorporated into alfalfa hay when it is baled, particularly if the stems are crushed as part of the harvesting process. Crushing, or crimping, aids in the drying and preservation of hay, but also can result in death of aggregations of blister beetles, and incorporation of their bodies into the hay. Blister beetles, even dead individuals, contain a vesicating substance called cantharidin which, when ingested, damages the digestive tract of animals. Cantharidin also causes blisters to form on the skin of sensitive humans who come into contact with crushed beetles, and in formation of blisters in the mouths of livestock, particularly horses. This blistering action is the basis for the common name of the beetles. Cantharidin content varies among species, ranging from 5% cantharadin in *Epicauta immaculata* to about 1% cantharidin in *E. pensylvanica*. Despite the relatively low toxin content in each beetle, large numbers can be incorporated into hay, and horses can ingest enough beetles to cause death. Cantharidin likely serves as a feeding deterrent to most predators, thereby protecting blister beetles and their eggs from consumption. However, some insects are attracted to cantharidin, and this compound is involved in the chemical communication among blister beetles.

In times past in Europe the so-called "Spanish fly," *Lytta vesicatoria*, acquired the undeserved reputation as an aphrodisiac for horses. Likely ingestion of this insect irritated the animals, making them seem more restless and "spirited." Thus, the beetle was sometimes administered to horses, and even sometimes to humans, but the effects can be quite deleterious.

Beneficial Effects of Blister Beetles

The damage caused by *Epicauta* spp. blister beetles is offset, at least during periods of relatively low beetle density, by the predatory behavior of blister beetle larvae. *Epicauta* spp. larvae feed on the eggs of grasshoppers, including many crop-damaging *Melanoplus* spp. During periods of grasshopper abundance the number of blister beetles tends to increase substantially. Studies of egg pod destruction in western areas of the United States during a period of grasshopper abundance, for example, documented that 8.8% of pods were damaged by blister beetles. Although the blister beetles eventually contribute materially to the suppression of grasshopper population outbreaks, the higher numbers of blister beetles often cause greater crop injury during, and immediately after, periods of grasshopper abundance. The larvae of many blister beetles, however, seem to feed principally on ground nesting bees and the bee's nest provisions. Their abundance fluctuates less, and they provide no known agricultural benefits. There is even one instance in Canada where bee-feeding blister beetles interfered with alkali bees being managed for alfalfa pollination.

Management

Blister beetles are not usually pests, though they may become quite abundant during and following long-term grasshopper population increases. Suppression of grasshoppers indirectly suppresses blister beetles by eliminating the food supply of the blister beetle larvae. Direct suppression of blister beetles usually may not occur in conjunction with chemical treatment of grasshopper populations because the grasshoppers can occur earlier in the season, when blister beetles are still in the soil. Blister beetles are easily controlled by application of common insecticides to crop foliage, and small plantings can be protected with row covers or screening. Because some blister beetle is highly attracted to alfalfa, especially during periods of bloom, large numbers of blister beetles may disperse to nearby crops following alfalfa harvest.

Blister Beetle Antennal Twisting Behavior

YIEN-SHING CHOW
National Museum of Natural Science, Taiwan, Republic of China

The blister beetle, *Epicauta hirticornis*, has an interesting pre-copulating behavior. When a male dorsally mounts a female, the male continuously waves its antennae toward the female's antennae. Eventually, the male's right or left antenna, or sometimes both, grasps the corresponding female antennae and wraps around the female antennae (Fig. 53).

In northern Taiwan, blister beetles usually are found aggregating on the leaves of blooming glorybower tree, *Clerodendrum cyrtophyllum* Turcz, and a novel sexual behavior was observed. During their courtship, a male beetle mounts a female from behind and the male's antenna winds around the female's antennae. The sexual behavior of Meloidae has been studied in detail. However, entwining of male and female antennae has not been reported before. The observed frequencies of right-handed and left-handed antennal pairs were 46.7 ± 13.9% and 44.8 ± 12.5%, respectively.

Bluetongue Disease

WALTER J. TABACHNICK
University of Florida, Vero Beach, FL, USA

Bluetongue disease is an insect transmitted disease that occurs primarily in sheep and wild ruminants. The bluetongue viruses that cause the disease are members of a family of viruses called orbiviruses. Although cattle in many regions of the world are often infected with bluetongue virus, cattle rarely show clinical signs of this disease.

Insect Vectors

Bluetongue viruses can be found in the tropics and subtropics throughout the world. The viruses are transmitted by insect species within the genus *Culicoides*, Family Ceratopogonidae. Various species of *Culicoides* transmit bluetongue virus. Different regions of the world contain different species of *Culicoides* involved in bluetongue virus transmission. In South America, *Culicoides* insignis is the primary vector of bluetongue virus. In Africa, the primary bluetongue vector is *Culicoides imicola*, while in Australia the primary vectors are *Culicoides brevitarsis* and *Culicoides wadai*. The *Culicoides* vectors of the bluetongue viruses in parts of Asia include *Culicoides imicola*. However, the *Culicoides* vectors in large parts of Asia have yet to be identified. Bluetongue virus transmission does not occur anywhere in the world in the absence of bluetongue-competent *Culicoides* vector species. The primary North American vector of the bluetongue viruses is a member of the *Culicoides variipennis* complex, *Culicoides sonorensis*.

The Disease

The most severe clinical signs of bluetongue disease occur in sheep. Sheep with bluetongue disease show a rise in temperature lasting 5–days. There can be swelling of the buccal and nasal mucosa, swollen tongue, profuse salivation, hemorrhages in the membranes of the mouth, and hemorrhages in the bands of the hoof, which often leads to lameness. Sheep may vomit because of lesions in the esophagus and pharynx. This sign can lead to their aspirating the contents of their rumen, in pneumonia and frequently in death. Sheep mortality to bluetongue infection may range from 5 to 50% of animals infected with virus.

Although clinical signs in cattle are rare, early prenatal infection with bluetongue in cattle may lead to embryonic death. Cattle develop a very prolonged viremia lasting several weeks where bluetongue virus can be detected in blood and is available to infected susceptible *Culicoides*. As a result cattle are considered important reservoirs for the virus and play an important role in infecting susceptible *Culicoides* vectors and therefore in the disease transmission cycle in more susceptible ruminants. In the western and southern regions of the United States where *Culicoides sonorensis* is present, there are regions where it is not uncommon to find 50% or more of the cattle to have once been infected with bluetongue virus. These animals are known to have once been infected because they contain antibody to one of the United States bluetongue viruses in their blood. The presence of antibody to a virus is evidence of a previous infection.

The Viruses

There are 24 different serotypes of bluetongue virus distributed throughout the world. The viral serotypes are numbered 1–24 and, as with the different species of *Culicoides* vectors, the serotypes also are found in specific regions of the world. There appears to be an association with the particular *Culicoides* vector species in a region and the specific bluetongue virus serotypes found in the geographic region. North America has five bluetongue serotypes (2, 10, 11, 13, 17), Australia has eight serotypes (1, 3, 9, 15, 16, 20, 21, 23), Africa has 21 (1–19, 22, 24) Central America and the Caribbean region has eight (1, 3, 4, 6, 8, 12, 14, 17). Europe has been essentially free of bluetongue virus although there have been a few periodic outbreaks in Spain and Portugal due to *Culicoides imicola*. Bluetongue outbreaks in sheep in Europe occurred for the first time in 2001–2002 in Bulgaria, France (Corsica), Italy (Sardinia) and Greece. The vectors of these outbreaks were not identified, although some appear to have involved *Culicoides imicola*.

Impact and Problems

The presence of severe bluetongue disease can have disastrous consequences on sheep populations. Consequently, in an effort to reduce the potential importation of a bluetongue-infected animal and the possibility of a bluetongue outbreak, many countries impose restrictions on the movement of livestock to their country from any country where bluetongue is prevalent. The Office of International Epizootics is the international agency responsible for developing regulations to protect animals around the world. This agency develops regulations for animal trade between countries. In the case of bluetongue, the regulations in place provide for the safe movement of livestock from bluetongue areas to bluetongue free areas. For example, the United States, where one of five bluetongue serotypes may be found in cattle, has restrictions imposed on its animal export to countries in the European Union that do not have bluetongue virus. United States animal exports must be tested and certified as being free of bluetongue before they can be approved for shipment. This results in lost trade opportunities for United States animal exports. The worldwide result is that bluetongue is the cause of non-tariff trade barriers costing millions of dollars in testing and lost trade opportunities on the international livestock market.

The northeastern region of the United States does not contain the bluetongue vector species, *Culicoides sonorensis*. There is no evidence of bluetongue virus transmission to livestock in this region. Such information is essential to declare a bluetongue free region within a country that could result in improving the livestock trade opportunities for the specific region despite restrictions on bluetongue transmission regions within the same country. The economic costs due to bluetongue are considerable due to its impact on the international livestock market and may approach billions of dollars.

Several different types of bluetongue virus vaccines are available for use in domestic livestock. Unfortunately, each bluetongue serotype requires a specific vaccine for protection. These vaccines have met with varying degrees of success. Some bluetongue vaccines are attenuated forms of the virus that were manufactured using techniques to reduce their virulence in animals. Their advantage is that they can provide protection after a single or booster injection, but unfortunately some have become virulent in the animals or after they have been picked up by blood feeding *Culicoides*. Killed virus as vaccines has been used and these do not become virulent, but often require more boosters to be effective. Bluetongue vaccines have been perfected using molecular biology technology. Unfortunately, the commercial prospects for many bluetongue vaccines have not been realized so that there has been little commercial interest in their development and use. In the United States, lack of interest in the commercial use of bluetongue vaccines is due to several factors. Use of bluetongue virus vaccines must face the challenge that naturally infected animals must be readily distinguishable from vaccinated animals. Undistinguished vaccinates would not be acceptable for international movement, and vaccinated animals should not inhibit or mask naturally occurring infection that would prevent the early detection of an outbreak. Since only cattle used for export are impacted by bluetongue, there is little economic incentive for using the vaccine on the large numbers of United States cattle used for domestic purposes. This reduces the need and commercial value for any vaccine.

Although *Culicoides* control is an option to prevent or interrupt a bluetongue virus outbreak in domestic animals, the biology of these small and very numerous insects is a daunting control challenge. Outbreaks and problems with bluetongue subside due to weather and climatic conditions that naturally reduce *Culicoides* populations. *Culicoides* control has not been shown to interrupt bluetongue transmission.

Bodenheimer, Friedrich (Frederick) Simon

Friedrich Bodenheimer was born in Cologne on June 6, 1897. He was accepted into medical school in 1914 in Munich, but soon volunteered for service in World War I in the German army. He served on the eastern front, realized the level of anti-semitism that existed, resolved eventually to emigrate to Palestine (now Israel), and decided to study entomology as a profession that would be useful in Palestine. He completed his studies at Universität Bonn by 1922, and with a doctorate in philosophy (and specialty in entomology). Before he left for Palestine, he visited the natural history museum in Hamburg, and chose to spend time studying Coccoidea. His viewpoint was that every entomologist should have a thorough taxonomic understanding of one group of insects. His choice of Coccoidea proved appropriate for his future work in Israel. Next, and still before leaving Europe, he spent six months at the R. Scuola Superiore di Agricoltura di Portici in Italy. There, he was able to study with Grandi and Silvestri, in an environment similar to that of Palestine. He moved to Palestine in 1922 and took up his appointment as head of the Division of Entomology (in fact the only entomologist) of an Agricultural Experiment station (in fact the yard of a high school) in Tel Aviv. His first task in Palestine was to inventory the pest species. He did this as a book (1931) "Die Schädlingsfauna Palästinas." In 1923 he married Rachel Ussishkin, and enlisted her help in reviewing pre-Linnean entomological works to produce his (1928–1029) "Materialen zur Geschichte der Entomologie bis Linné," a history of entomology. In 1928, he moved to the Hebrew University in Jerusalem as professor of zoology and was required to lecture to students. A difficulty was that he was required to lecture in Hebrew, that he did not speak Hebrew, and there were no Hebrew texts for the subjects in which he was required to lecture; eventually, he compiled the necessary textbooks, publishing nine of them (and later four in Turkish and one in French). He continued his interests in agricultural pests and published (1951) "Citrus entomology in the middle east," and (1957, with E. Swirski) "The Aphidoidea of the middle east." His professorship in zoology and acquired knowledge over 25 years in entomology and broader aspects of zoology induced him to write (1958) "Animal ecology to-day," in which he emphasized the importance of climate. He published more than 420 works. In 1948, although deemed too old for military service, he nevertheless served in the Israeli army, and was twice wounded. He died on October 4, 1959. He was a legendary figure, the founder of entomology in Palestine (Israel).

Bogong Moth, *Agrotis diffusa* (Boisduval) (Lepidoptera: Noctuidae)

In most respects, Bogong moth is a typical cutworm, and is one of the more important and widespread cutworms in Australia. However, it is distinguished by its migratory tendencies: dispersal into the Australian mountains for a period of aestivation during the summer, followed by dispersal back to the plains in the cooler months. In this respect (as well as morphology) it is quite similar to an American species, *Euxoa auxiliaris* (Grote), also known as army cutworm. However, bogong moth is an interesting and well-known element in the culture of the aboriginal people of Australia, where historically the moths were collected for human consumption, so there is an unusual element of cultural anthropology associated with this moth.

Bogong moth inhabits principally the pasture-land west of the Great Dividing Range of eastern Australia (Victoria, New South Wales, Queensland), but during the summer months the moths migrate to higher country. In particular, they aggregate near Mount Bogong in the Alpine National Park, which serves as the basis of their common name. During the summer, they congregate in caves and rock crevices until autumn, when they return to the plains to deposit their eggs. They can accumulate in tremendous numbers on the floors and sides of the caves. The moths are highly nutritious, and the Aborigines traditionally have taken advantage of this resource and collected them by knocking them into bark, kangaroo skin containers or nets, and then roasting them in the hot ashes of a fire to remove the wings and legs. The moth carcasses were mashed together into "moth meat," which is said to have a nutty flavor resembling almonds or walnuts. They were formed into cakes, and if smoked, preserved well for a week or longer. The fat content is 50–60%, and harvest of moths by aborigines early in the twentieth century is estimated at several tons annually. Some tribes harvested the moths for 2–3 months annually, so the moths were a staple of the aboriginal diet, not just a minor component.

Life Cycle and Description

Eggs are deposited at the base of plants near the soil in the autumn after moths have descended from the mountains. The eggs soon hatch and the winter months are passed in the larval stage. Larvae initially are cream-colored, but later become green with pale and dark stripes, and dark spots. Overall, they are dark dorsally and pale ventrally, with a dark head and prothoracic plate. They attain a length of about 5 cm. They hide in the soil during the day, emerging at night to ascend plants and to feed. The larvae mature in spring, pupate in the soil, and after about a month the adults emerge to feed on nectar at flowers. The adults are variable in color, ranging from brown to almost black. However, they typically bear a dark streak on each forewing that is interrupted by a light circular spot and a light bean-shaped light-colored spot. The hind wing is light brown with a darker border. The wingspan is about 5 cm. The adults migrate to the mountains for the summer months, returning to the lower pasturelands in the autumn. In the mountains, the moths are reported to fly but not to feed. Interestingly, the American equivalent of bogong moth, army cutworm moth, was until recently thought to aestivate during the summer months in the Rocky Mountains, where aggregations are fed upon by grizzly bears, but not by the indigenous people of the region. Army cutworm has since been shown to feed at night on flowers at high altitudes of the Rocky Mountains. Perhaps the bogong moth also sustains itself during the summer by nocturnal feeding.

Economic Importance

Although bogong moth is an important food source for wild vertebrate animals and of the indigenous people of Australia, it is also considered to be damaging to some crops. Larvae feed on a variety of wild broad-leaf herbaceous plants such as cape weed, *Cryptostemma calendula* (Asteraceae), but do not thrive on grasses. Among cultivated plants damaged are alfalfa, linseed, cereal grains, cabbage, cauliflower, and English peas.

These moths also can be a nuisance. Sometimes strong wings carry the moths over the mountains to the cities of the eastern seaboard of Australia, and great numbers invade cities such as Canberra, Melbourne and Sydney.

Bohart, Richard M

Born on 28 September 1913 in Palo Alto, California, USA, Bohart became interested in insects as a young child, and went on to earn three degrees in entomology at the University of California at Berkeley. He taught at the University of California at Los Angeles (UCLA) from 1938 to 1941 before enlisting in the

U.S. Navy. He joined the faculty of the University of California at Davis in 1946 and retired in 1980.

Bohart is known for his contributions on the systematics of wasps and mosquitoes. He authored over 200 publications, including six books. Foremost are "Sphecid Wasps of the World" (with A.S. Menke) and "The Chrysidid Wasps of the World" (with L.S. Kimsey). Over the years, he acquired an outstanding collection of Nearctic Hymentoptera. He also acquired a number of successful graduate students who went on the populate museums, state departments of agriculture, and universities. Indeed, his love of students was said to be surpassed only by his affection for wasps. He died on 1 February 2007, but will long be remembered as one of the world's most important hymenopterists.

Bohartillidae

A family of insects in the order Strepsiptera.

► Stylopids

Boheman, Carl Heinrich

Carl Boheman was born in Jönköping, Sweden, on July 10, 1796. From the age of eight, he showed an interest in entomology. He asked permission of his father to study Latin, because Latin was necessary to read publications on natural history, although his father expected him to become a businessman. In 1812, he became a student at the university of Lund, and began to study law, but abandoned this in 1813 to enter the Swedish army. His army career gave him spare time for his favorite occupation, entomology, but he retired from the army in 1844 with the rank of captain. His army career allowed him to travel and collect insects. In 1841, he was appointed head of the entomological section of the natural history museum of Stockholm. He gave his collection to the museum, and during the following 26 years he built the museum's collections considerably. His greatest published works were his descriptions of new species in eight volumes of Schönherr's "Genera et species curculionidum" (1833–1845), his "Insecta Cafrariae" (1838–1857) and "Monographia cassididarum" (1854–1862). He published about 50 important papers, and was the describer of the boll weevil, *Anthomonus grandis*. In 1867 he resigned from his position, but continued to work at the museum until just a few days before his death in Stockholm on November 2, 1868.

Boisduval, Jean-Baptiste Alphonse Dechauffour De

Jean-Baptiste Boisduval (Fig. 54) was born in Normandy, France, on June 17, 1799. He was employed by Dejean as curator of the latter's insect collection. With Lacordaire as co-author, he published (1835) "Faune entomologique des environs de Paris…" which follows the same theme as Fourcroy's (1785) work. He became one of the most famous lepidopterists of France, was one of the original members of the Société Entomologique de France, and an honorary member in 1866. In 1860 he was awarded honorary membership in the Société Entomologique de Belgique. He collected not only Lepidoptera (acquired not only from Europe but from North America too) but also Coleoptera and Hemiptera, and published about 50 works. He died in Normandy on December 30, 1879.

Boisduval, Jean-Baptiste Alphonse Dechauffour De, Figure 54 **Jean-Baptiste Boisduval.**

His collection of Lepidoptera was sold in France, his Elateridae are in the Natural History Museum (London), and the type specimens of his Curculionidae in Brussels.

Bokor, Elemér

GEORGE HANGAY
Narrabeen, NSW, Australia

Elemér Bokor was born on the 19th of January 1887, at Sátoraljaújhely, in the North- Eastern corner of Hungary. As a young man he was already interested in entomology and in the beetles which lived in caves. Although he received a military education, he carried on with his nature studies, and in 1913 he published some important works on the blind cave-dwelling beetles (új vakbogarak Magyarország faunájából. *Annales Musei Nat*. Hung. XI., 1913, and Három új vakbogár Magyarország faunájából. *Annales Musei Nat. Hung*. XI., 1913). He fought on the Russian Front in World War I as a professional officer of the Austro-Hungarian army. He suffered the life of a prisoner of war in Russia for some years. On his return to Hungary in 1921 he researched the arthropod fauna of 102 caves. In 1923 he surveyed the Abaligeti Cave and the result of this work formed the basis for his doctoral dissertation. He received his doctorate in 1924. Elemér Bokor devoted his life to the research of the Hungarian caves. He has described several new species of cave dwelling coleoptera. He was the president of the Hungarian Speleological Society as well as the Entomological Society, providing great impetus to the work of his colleagues.

Boll Rot of Cotton

This is an insect-transmitted disease of cotton.

► Transmission of Plant Diseases by Insects

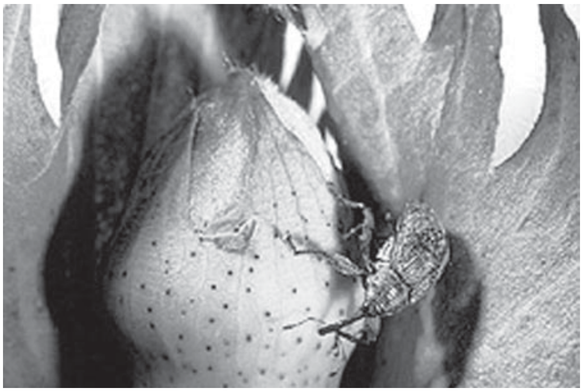
Boll Weevil, *Anthonomous grandis* Boheman (Coleoptera: Curculionidae)

This insect, known also as the cotton boll weevil, is a very serious pest of cotton in the western hemisphere, and has had a significant effect on the history of the United States. Little was known about it until about 1892 when it appeared in Texas, having moved northward from Central America or Mexico. Once it reached the United States, it spread rapidly to the north and east, and slowly to the west, eventually reaching California in 1982. In the early part of the twentieth century, little could be done to prevent damage by this insect, and the agricultural economy of the southeastern United States was seriously disrupted by this insect. Numerous farms, cotton gins and related interests such as stores and banks ceased business because the cotton crop was destroyed. On the other hand, the appearance of boll weevil in the southeast stimulated the diversification of the economy because the residents could no longer depend exclusively on cotton for their livelihood. Thus, the community of Enterprise, Alabama erected a statue in recognition of the beneficial side effects of this devastating pest (Fig. 55). Much later in the century boll weevil gained entry to South America. It now infests cotton growing regions of Argentina, Brazil, and Paraguay.

Boll Weevil, *Anthonomous Grandis* Boheman (Coleoptera: Curculionidae), Figure 55 **Boll weevil statue in Enterprise, Alabama (photo USDA, Agricultural Research Service).**

Description and Life History

Boll weevil is capable of completing its life cycle in 25 days, so 8–10 generations are possible annually. The adult stage overwinters, emerging from beneath leaf debris, bark, trash and other protected places from March to June. It begins to feed immediately and as squares become available they begin production of eggs. Females can produce from 100 to 300 eggs. The white eggs are about 0.5 mm long. The eggs hatch in 3–4 days, and the larva feeds within the square or boll. The larva is white and legless, with a brown head. It matures in about 9 days and measures about 13 mm in length. There are three larval instars, which can be distinguished by head capsule width measurements (0.4, 0.6, and 09 mm, respectively for instars one to three). At maturity, it forms a pupa within the feeding cavity, and then the adult emerges in about 5 days. The adult is gray or brown to black in color, measures about 4 mm in length, and bears a long snout. In the autumn the weevils leave the crop for sheltered (Fig. 56) areas and enter diapause. Diapause is a critical period for boll weevils, and survival is enhanced when weather is moister and above average in temperature.).



Boll Weevil, *Anthonomous Grandis* Boheman (Coleoptera: Curculionidae), Figure 56 **Adult boll weevil feeding on a cotton boll (photo USDA, Agricultural Research Service).**

Host Plants

Boll weevil feeds exclusively on malvaceous host plants, principally cotton but also okra, hollyhock, and hibiscus.

Damage

Boll weevils cause injury when the adults chew into the square (blossom) and boll (fruit) where they feed and deposit eggs. The larvae also feed within these structures, and little or no fiber is formed.

Management

Boll weevils are most effectively managed by a combination of approaches. Some of the approaches include:

1. Early destruction of plants in the field. Early harvest and destruction of crop residue kills many weevils and deprives them of shelter.
2. Use of an early maturing cultivar. Early maturing varieties produce blossoms before many weevils are present, whereas late maturing varieties are attacked by higher numbers of insects, thereby experiencing more damage. Proper agronomic practices also encourage rapid growth and maturity of the crop, hastening development before the end of the season when weevils are most abundant.
3. Insecticide. Application of insecticide can alleviate weevil injury. Applications are made early to control weevils during blossom set and maturity. Applications may also be made late in the year to reduce the number of weevils entering diapause, and thereby reducing the number emerging in the spring of the following year.
4. Eradication. An eradication program is currently under way in the United States. A combination of host destruction, insecticide application, trapping with pheromone-based traps, and release of sterile insects has eliminated boll weevil over much of its former range. Though initially costly, elimination of this key pest brings substantial savings to growers in the long run.

Bonnet, Charles

Charles Bonnet was born in Geneva in 1720 and remained in Switzerland all his life. He received training in law, and practiced it while deeply committed to biological studies. His sight was said to have been so damaged by the age of 25 by his constant use of microscopes that he could barely read or write thereafter. He was an observer and experimenter rather than a taxonomist. In 1745 he published "Traité d' insectologie," in which his "insectes" were all the invertebrate animals except molluscs, and the work contains results of his observations on subjects such as parthenogenesis in aphids, and respiration in caterpillars. His later books included "Contemplation de la nature" (two volumes, 1764–1765) and "Oeuvres d' histoire naturelle et de philosophie" (8 volumes, 1779–1783). He died in 1793.

Borgmeier, Thomas

Thomas Borgmeier was born in Bielefeld, Germany, on October 31, 1892. After graduation from the Gymnasium ["high school"] of Bielefeld, he emigrated to Brazil and became a Franciscan monk. From 1912–1914 he studied philosophy in Curitiba, and from 1915–1918 theology in Petropolis. While he was a student, he became interested in entomology, in 1917 befriending Hermann von Ihering. A wealthy industrialist in Rio de Janeiro donated money that allowed Thomas to buy von Ihering's reprint library and a microscope. He was permitted by the Franciscans to pursue an entomological career. In 1924 he moved to the Museu Nacional in Rio de Janeiro, and then transferred to the new Instituto Biologico in São Paulo in 1928 as assistant in entomology. In 1933 he retuned to Rio de Janeiro as head of the entomological section of the Instituto de Biologia Vegetal in the botanical garden. He founded the journal Revista de Entomologia, and edited and published it until 1951 when financial difficulties ended it. Later he founded the journal Studia Entomologica. About 1973 he retired from entomological activities to a monastery in Rio de Janeiro. During his life, Thomas published 243 papers on ants and on insects associated with ant nests, especially the dipterous family Phoridae. He died on May 11, 1975.

Boric Acid

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

This inorganic compound contains boron and many other non-volatile elements, and has many useful properties. The chemical formula is $H_3 BO_3$ and its sodium salt, or borax, is $Na_2 B_4 O_2 \cdot 10 H_2O$. A more water soluble formulation is $Na_2 B_8 O_{13} 4 H_2O$, known as disodium octaborate tetrahydrate. Formulations of borax and disodium octoborate tetrahydrate usually are known simply as "borates." Boric acid is used as a fungicide, bactericide, antiseptic, and as an insecticide, but has several other useful properties such as a flame retardant. Normally it is produced from borate minerals by reaction with sulfuric acid.

From a toxicological perspective, boric acid is a relatively nontoxic (to people and pets) insecticide. Its oral toxicity is reported to be 2,660 mg/kg in rats. Borax is even less toxic, with oral toxicity to rats estimated at 5,600 mg/kg. These chemicals are not readily absorbed by skin. However, there is some risk associated with chronic exposure to aerosols, so respiratory protection is advised when working around high concentrations. Also, accidental ingestion of large quantities can be lethal. Use of goggles and gloves are recommended for those applying these chemicals.

Normally, boric acid products are active only when insects ingest the material (as a stomach poison), though this can occur during grooming (cleaning the antennae and legs) as well as feeding. It is used in structures to control such urban pests as cockroaches, ants, fleas, termites and silverfish. It may be mixed into bait, particularly for cockroach and ant control, and is quite effective. It also is sprayed onto, or impregnated into, wood for control of termites and wood boring beetles. Application as a dust into wall voids, attics, and cracks and crevices harboring insects also is popular. Because cockroaches spend most of their time in cracks and crevices, application of boric acid into such harborages is advisable. The product is normally blown in with a bulb duster, but must be finely divided to achieve deep penetration. Research has shown that crack and crevice treatment is superior to broadcast treatment for cockroaches. Boric acid is superior to borax for cockroach control. Although it commonly takes several days for cockroaches to die from boric acid poisoning, boric acid is especially useful for sensitive areas like schools, pet shops and zoos. The slow action can be an advantage for cockroach suppression because nymphs will feed on the feces of adults, so boric acid can be transported back to harborages. Similarly, cannibalism of boric acid-killed roaches can kill the scavengers.

Boric acid is often formulated with diatomaceous earth or silica gel (as desiccants) or tricalcium phosphate (to reduce caking). Sometimes other toxicants are included, including pyrethrins or sodium fluoride. Dusts can be repellents, and although boric acid dusts tend to have low repellency, inclusion of additives in boric acid formulations increases the likelihood of the product being repellent. Thus, additives should be kept at low levels. Similarly, when incorporated into bait, boric acid concentrations should be kept low (usually 1%) so insects will not avoid ingestion. Boric acid is sometimes mixed into cleaning solutions when floor mopping in cafeterias.

Though very persistent and water soluble, boric acid is not readily impregnated deep into wood, so although the outside of structural timbers may be protected, termites may burrow through incompletely impregnated lumber. Formulations of borates and penetrating agents such as ethylene glycol are used to improve wood penetration. The formulation can be sprayed or painted onto untreated wood surfaces, or applied as a foam. Penetration is affected by a number of factors, including moisture content, and wood protection is best achieved when the wood is freshly harvested, or re-wetted to take advantage of the solubility of the damp wood to borates. Other factors affecting protection include thickness of the wood and thoroughness of application. For deep penetration, injection may be necessary. Existing fence posts, mailbox supports, and other wood in contact with soil can be protected by drilling a hole and inserting borate gel or rods, then sealing the hole. Boric acid products have herbicidal activity, however, so vegetation adjacent to treated wood can be affected. Overall, boric acid products are very useful for urban pest control, but should be used as a component of a broader management plan, not as the sole component.

Botanical

A product derived from plants or plant parts. This term often is used to describe insecticides derived from plants.

► Botanical Insecticides

Botanical Insecticides

MURRAY B. ISMAN
University of British Columbia, Vancouver, BC, Canada

Botanical insecticides are those products used to kill or repel insects that consist of dried, ground plant material, crude plant extracts, or chemicals isolated from plants. The recorded use of plant material or plant extracts for insect control dates back at least 200 years. Botanical insecticides were important tools for crop protection prior to the discovery of the insecticidal action of DDT; the subsequent development of inexpensive and highly effective synthetic insecticides rendered botanicals all but obsolete. However, botanicals are enjoying renewed interest as the popularity of organically-grown food increases because botanicals are among only a handful of “natural” insect control products that can be used in organic agriculture.

Although botanicals are products of nature, they should not be considered absolutely safe or non-toxic unless so demonstrated. The active ingredients in certain botanical preparations used as insecticides are relatively toxic to animals and humans and several are toxic to fish. However, most are used at very low concentrations of active ingredients, minimizing the risk to humans and wildlife from exposure. On the other hand, the active principles in virtually all botanicals are rapidly degraded in the environment, often by exposure to sunlight, and thus are considered non-persistent. Apart from this generalization, the few botanical insecticides in commercial use vary greatly in their sources, chemistry, toxicity and other properties.

Pyrethrum

Pyrethrum is the most widely used botanical insecticide. It is the oleoresin obtained by solvent extraction of the fresh-picked flowers of the daisy *Tanacetum cinerariaefolium* (Asteraceae), native to the Balkan region of eastern Europe. Most of the world supply of pyrethrum in recent times has come from Kenya, but large scale production is under way in Tasmania (Australia). The oleoresin contains six esters with insecticidal properties. The most potent, pyrethrins I and II, typically make up 20% of the resin by weight. The pyrethrins are axonic poisons in insects and are characterized by a fast knockdown time in flying insects. They degrade rapidly in the presence of sunlight. In purity, the pyrethins have appreciable toxicity to mammals, but given their concentration in the resin and the dosages normally used, pyrethrum has minimal toxicity to mammals. Pyrethrum is a broad spectrum insecticide and has more registered uses (in the U.S.A.) than any other insecticide. Most products containing pyrethrum or pyrethrins as active ingredients are formulated with a synergist, piperonyl butoxide, that prevents the metabolic degradation of the insecticide within the insect's body, thus increasing potency. The rapid environmental breakdown of pyrethrum created the impetus for the industrial development of the synthetic pyrethroids, now the dominant class of agricultural insecticides.

Rotenone

Rotenone is the ground roots or rhizomes of the tropical legumes *Derris* (southeast Asia) and *Lonchocarpus* (South America, also known as cube root), or resins extracted from them. The name is also applied to the major insecticidal constituent, although each plant contains a number of related isoflavonoids, most of which are insecticidal. Rotenone is a mitochondrial poison in insects and vertebrates. In purity it is quite toxic to mammals, but most home and garden preparations contain 1% rotenone at most. Owing to its moderate persistence on foliage (3–5 days) and chronic effects on laboratory animals, there are some concerns about it potential health impacts on humans. It is especially toxic to fish, and in fact, more rotenone is used as a commercial fish poison (piscicide) than for insect control. As a fish poison, rotenone has been used for at least 300 years, and at least 150 years as an insecticide. In insects, rotenone is a slow-acting stomach poison particularly effective against plant-feeding beetles (e.g., the Colorado potato beetle), but much less effective against caterpillars.

Neem

Neem is an extract of the seeds of the Indian neem tree, *Azadirachta indica* (Meliaceae). Native to the Indian subcontinent, it has been widely planted throughout tropical and subtropical regions of the world. Dried neem leaves have traditionally been used in protection against stored product pests. Neem has a diverse array of behavioral and physiological actions against insects, most of which are attributable to the complex triterpenoid azadirachtin. This chemical is reputed to be the most potent antifeedant to insects (it deters insect feeding in nanogram quantities), but is also a potent disruptor of the insect neuroendocrine system. The most obvious manifestation of this latter action is that azadirachtin inhibits the molting process in insects. As such, azadirachtin is a slow-acting insecticide and requires ingestion to be effective. Another interesting property of azadirachtin is its systemic action in some plants. Of primary importance, neem and azadirachtin are non-toxic to most non-target organisms, including humans. Like pyrethrum, neem is rapidly degraded in the environment by sunlight. Neem became commercially available in the U.S.A. in 1990, and is beginning to gain acceptance for insect control in some agricultural commodities and especially in organic food production.

Tobacco

Water extracts of tobacco have been used to kill insects for over 300 years. Nicotine (from *Nicotiana tabacum*, Solanaceae), nornicotine (from *N. sylvestris*) and anabasine (from *Anabasis aphylla*, Chenopodiaceae) are alkaloids that are highly insecticidal. They poison both insects and mammals through a common mode-of-action, by mimicking the neurotransmitter acetylcholine and causing over stimulation of nerve synapses. Unlike some other botanical insecticides, nicotine is very toxic to humans, and poisoning can result not only from ingestion but from dermal exposure as well. As a consequence, nicotine is rarely used for insect control at present, although it is still used as a fogging insecticide in some greenhouses.

Other Botanicals

Other botanicals have seen some commercial use in North America. These include ryania, the ground stem wood of the Caribbean tree *Ryania speciosa* (Flacourtiaceae), containing alkaloids that poison neuromuscular junctions, and sabadilla, the ground seeds of the South American lily *Schoenocaulon officinale*, containing alkaloids that are axonic poisons. Both are examples of plants whose active principles, in purity, are relatively toxic to mammals, but for which the actual plant preparations used have a wide margin of safety to humans.

Essential oils from certain plants have been used traditionally in some regions as insect repellents. The best known among these is oil of citronella, obtained from lemongrass (*Cymbopogon nardus*, Poaceae), used as an alternative to DEET for repelling mosquitoes and biting flies. In addition, monoterpenes and phenols in clove oil, thyme oil, and various mint species have been recently shown to be insecticidal in a wide range of insects. As a result, several home and garden insect control products based on plant essential oils have been developed and these materials may have uses in agriculture (e.g., organic farming) as well.

Numerous other plant extracts have seen regional traditional use, especially in developing countries. Insecticides can be made from the seeds of chinaberry (*Melia azedarach*, Meliaceae), a relative of the neem tree, although in some countries the seeds contain substances that are toxic to animals. In the Peoples Republic of China, an insecticide is made from the bark of *M. toosendan*, considered by

some authorities to be taxonomically synonymous with *M. azedarach*. The product, Toosendanin, is reported to be effective against fruit and vegetable pests. The tropical trees *Quassia amara* and *Ailanthus altissima* (Simarubaceae) contain insecticidal terpenoids that can be extracted from the wood and used for insect control. Dried leaves of *Haplophyton cimicidum* (Apocynaceae) have been used for centuries in Mexico and Guatemala to prepare "cockroach powder" owing to a series of alkaloids in the foliage of the plant. Seeds of the custard apple (*Annona reticulata*, Annonaceae), sweetsop (*A. squamosa*) and soursop (*A. muricata*) contain potent insecticidal acetogenins and have been used for insect control in many tropical countries in the Old and New World. The dried, powdered flowers of *Rhododendron molle* (Ericaceae) have a long history of use as an insecticide in China.

Botanical insecticides are unlikely to displace conventional synthetic insecticides in many pest management contexts, but they should gain increasing favor in situations where human exposure is unavoidable and safety is of primary concern. Botanicals will also see continued use in developing countries where many of the plants from which they are obtained can be readily grown and the insecticidal preparations are a safer and less expensive alternative to imported synthetic pesticides.

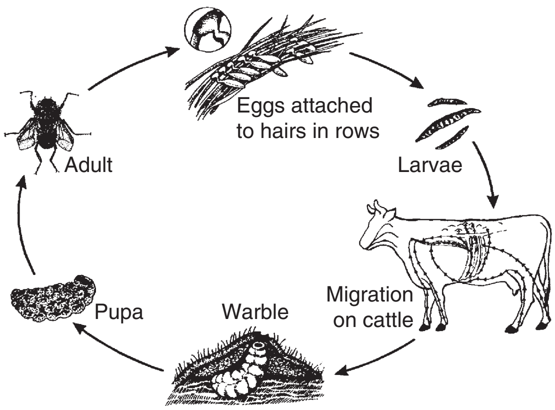
Bovine Hypodermosis: Phenology in Europe

DAVID REINA, JAVIER MARTÍNEZ, EANTIAGO HERNÁNDEZ, IGNACIO NAVARRETE
Universities of Extemadura and Córdoba, Madrid, Spain

The life cycle and biology of the warble fly, *Hypoderma bovis*, and of *Hypoderma lineatum*, exhibit regional and local variation attributable to climatic and weather conditions (Fig. 57).

In Andalusia (southern Spain), it is possible to find *H. lineatum* adults from the middle of February to the beginning of May, first instar larvae (L1) in the esophagus from April to November, third instar larvae (L3) in the back from the middle of



Bovine Hypodermosis: Phenology in Europe, Figure 57 **Life cycle of *Hypoderma* spp. on cattle: eggs (a) are deposited on the legs of the host; larvae (b) burrow into the animal and migrate through the animal, eventually reaching the back where a swelling (warble) is formed (d); the mature larva drops to the soil to pupate (e) and an adult emerges from the pupa.**

November to the end of March, and the mature larva ready to commence pupation from the middle of January to the end of March. Adults of *H. bovis* occur between May and June, L1 from November to January, the period of warbles from mid-December to May, and the dropping of L3 from mid-March to May. It is possible to find third instar larvae of *H. lineatum* in the back of bovines from October to early May. Adults are found during April or May, although in some years some of them can be seen in March. First instar *H. lineatum* appear in the gullet of bovines between September and December. *Hypoderma bovis* is scarcer in western and southwestern Spain, but display the same phenology. In some areas of Portugal, such as the "Alentejo" and "Centro" areas, phenology clearly is similar to that of western Spain, which is logical due to the geographic proximity of these regions.

The phenology (Table 9) is very similar in northern Africa. In Morocco, it is possible to find adults from February to the middle of May, and L3 in the back of the hosts from December to April. In Algeria, adults are found between the end of March and July. The L1 stage can be found in the host's esophagus between August and December, while it is found in the rachis from the beginning of October until the middle of February. Warbles are found during much of the year, from October to March. In other studies, adults occur between March and August (the latter ones probably are *H. bovis*), L1 is observed in the rachis and gullet between July and December, and warbles occur between September and February.

On the other hand, there are significant differences in phenology between northern and southern Spain. In northwestern Spain (Galicia), it is not possible to observe the first flies until the middle of May, but after that they can be seen until the middle of September. First instar larvae are found from the middle of September to the end of January, or from August to December. Warbles are found from February until May. The phenology of *Hypoderma* in the north of Spain is more similar to the countries of central Europe than to the southern areas of the same country.

In the central and eastern regions of France, *Hypoderma* adults and eggs are found between the end of May and the middle of August. First instars (the period of greatest risk due to local and systemic adverse reactions) occur from the middle of August to the end of February. Warbles are found in the backs of hosts during March to May, or possibly from March to July. It is likely that the phenology is intermediate between the countries of central Europe and the southern Iberian peninsula. In Switzerland, the phenology is similar to that in France.

In Ireland, there is a delay in the presence of warbles. Warbles appear in July and August rather than in February and March. Ireland, together with the rest of United Kingdom, and also Holland, are examples of locations where *Hypoderma* are practically eradicated, at least from cattle.

In eastern Europe, specifically Czechoslovakia, extensive investigations have been conducted on *H. bovis* (throughout the country) and *H. lineatum* (in Slovakia). Warbles of *H. bovis* appear in heifers from the end of March to June, and in cows in May to June. Dropping of larvae and pupation were observed from early April to early July, while flies

Bovine Hypodermosis: Phenology in Europe, Figure 58 Warble being removed from beneath the skin of host.

are present from early June to the beginning of September. For *H. lineatum*, the period of warbles was earlier and shorter, from the second half of February to the end of April. Pupation was observed from the end of March to the end of April, and flies from May until the first days of July.

In countries such as Poland, warbles (Fig. 58) have been detected in February, though normally the warbles do not occur until April. When occurring early, warbles are found in April, but when found normally, the warbles do not occur until May and June. It is possible to observe warbles until the end of July. In Romania, the period of activity of adults is May to September for *H. lineatum*, and between August and September for *H. bovis*. The first warbles produced by the second instar larvae appear in the southern part of the country at the end of January or early February. In the north, they occur from March to April. The third stage larvae leave the host's body from late April until the end of July (until August in the northern part of Romania). Thus, the phenology in Romania is similar to central Europe. Sometimes warbles are found in the back and lumbar regions of the host in September and as late as December; in these cases the larvae are dead.

As a general rule, *H. lineatum* occurs earlier than *H. bovis*. The occurrence varies from year to year, however, due to variation in environmental conditions. They occur earlier when it is warmer in the spring, summer or winter. In southwestern Spain, the mean annual maximum temperatures are 20–21°C, with maximum summer temperatures averaging 29–30°C, and mean annual minimum temperatures of 8–9°C. The cooler temperatures of eastern and central Europe slow the biology of these pests.

To avoid damage caused by larvae, knowledge of phenology is important. Before beginning a management or eradication effort, climatic variation in *Hypodermas* must be considered.

Bøving, Adam Giede

Born at Saby, Denmark, on July 31, 1869, Adam Bøving graduated from the University of Copenhagen in 1888. His interests included insect larvae, and those of *Donacia* (Coleoptera: Chrysomelidae) were the subject of his Ph.D. research. Then he was appointed Assistant Curator of Entomology at the Royal Zoological Museum in Copenhagen, and he continued to study beetle larvae. Two years after the death of his first wife, he moved to the United States in 1913 and found employment with the U.S. Department of Agriculture. His work still revolved around beetle larvae, but concentrated on those of economic importance. He took an American wife and citizenship. With F. C. Craighead as coauthor, he published in 1930–1931 in Entomologica Americana, the work "An illustrated synopsis of the principal larval forms of the order Coleoptera." This major work has been much-cited by later authors for the wealth of its informational content; no such comprehensive study appeared in print until the second volume of F. C. Stehr's (1991) Immature Insects. Bøving died in Washington on March 16, 1957.

Brachelytry

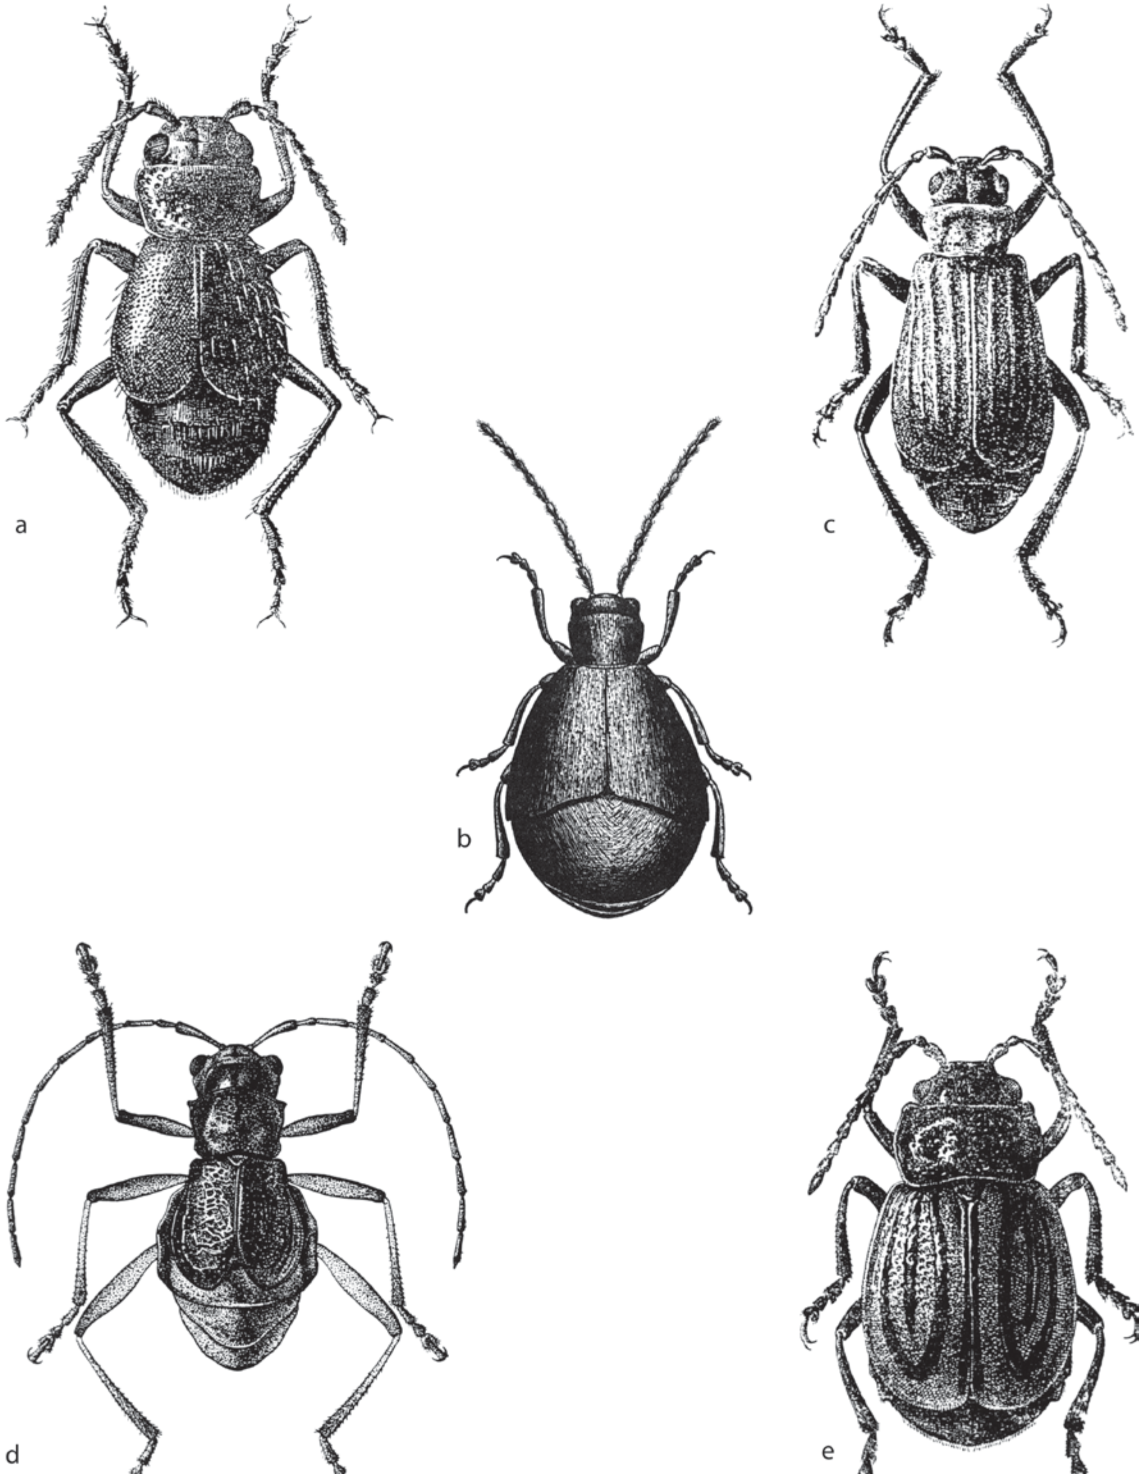
PIERRE JOLIVET
Paris, France

Elytra are characteristic of Coleoptera, and substantial thickening of the first pair of wings (elytra) is uncommon among other orders of insects. The elytra are modified mesothoracic wings, normally rigid and fitting over the abdomen. Brachelytry is the possession of abbreviated wing covers or elytra. Brachelytrous insects are commonly found among the Coleoptera, including the Carabidae, Staphylinidae, Cerambycidae, Histeridae, Meloidae and Chrysomelidae. It seems most common among Galerucinae and is unusual among Alticinae. Both subfamilies are closely related, as part of the Trichostomata. Alticinae, Galerucinae (both Chrysomelidae) and Bruchidae sometimes show only an exposed pygidium, with only a small shortening of the elytra. Some beetle families are exclusively brachelytral, as is the Lymexylidae, but they fly very well, as do most of the myrmecomorphic Cerambycidae. Brachelytry should not be confused with physogastry (the swelling of the abdomen to an unusual degree due to the hypertrophy of fat bodies, ovaries or both), which can result in a similar appearance. In that case, the abdomen is so big that it is protruding over the end of the elytra. Physogastry is common among certain Chrysomelinae (*Gastrophysa*) and Galerucinae (*Agelastica*) (both Chrysomelidae). Brachelytry occurs also in Dermaptera and Gryllidae.

Pseudophysogastry (artificial swelling of the abdomen) is also common among cavernicolous or termitophilous beetles. In many Meloidae (*Meloe*), the elytra appear to fit badly, as among physogastric beetles. The elytra overlap but the beetle is apterous already as a pupa, as in *Timarcha*. This means a long history of apterism. In certain cases, brachelytry can be seen as a consequence of apterism, but many macroelytrous (normal) beetles are alternatively brachypterous or apterous (*Chrysolina banksi*), or totally and permanently apterous (*Timarcha*). Often, in that case, the elytra are fused. They are never fused among brachelytrous beetles.

A set of mutations is surely at the origin of brachelytry, but macroelytrous and brachelytrous individuals do not occur in the same species. Brachyeletry is found mostly among mountainous or desert frequenting species or genera, but also among parasitic species. It seems absent from *arctic* species, which would seem to benefit from protection on the abdomen, though apterism or brachypterism there remains frequent. Brachelytry is also frequently linked with brachy-or apterism, though some brachelytrous beetles maintain complete wings and fly very well. Brachelytry is a very old, derived character (Fig. 59). There are a number of beetle families where the elytra become truncated, with the apical part of the abdomen uncovered, including Hydroscaphidae, Histeroidea, Staphylinidae, Nitidulidae, Inopeplidae, etc. In all these groups, the elytra completely cover the folded wings. In some others, such as the myrmecomorph Cerambycidae and the Lymexylidae, the wings are left free without any protection. The adaptive significance of this feature is not well understood. Among the Staphylinidae, the main adaptive advantage of abbreviated elytra seems to be a greater flexibility in the abdominal region, but that does not explain the truncated elytra of Histeridae. Many beetles with truncate elytra and with wings completely covered live on the ground, and are saprophagous. But there are always exceptions; among the Histeridae, for instance, some genera have the elytra entirely covering the abdomen. In the Staphylinidae, usually there are at least four abdominal segments exposed, sometimes six. There are, however, some Staphylinidae with the elytra not truncate.

There are also cases where the elytra are abbreviated and do not completely cover the folded wings. In *Atractocerus* (Lymexylonidae), the elytra are very reduced and don't cover the wings. There are also some myrmecomorphic Cerambycidae, some Cantharidae (*Malthinus* and *Malthodes*), the male of Stylopidae, and several Rhipiphoridae, which are more-or-less brachelytrous, with exposed wings. In male Stylopidae, the elytra are peculiarly modified to form balancing organs, like the halters of Diptera. Often those beetles are free-living and floricolous. This elytral reduction is increased among some endogeous Staphylinidae (Leptotyphlinae and Osoriinae), where the elytra are reduced to two contiguous scales, covering only the posterior thoracic segments and the first abdominal segment. A similar situation is found among a Moroccan *Staphylotroglops* (Cantharidae). The reduction of the elytra can also be done laterally, revealing the sides of the abdomen (some Cetonidae) or be disjunct on the back (Oedemeridae). There are also cases where only the females are



Brachelytry, Figure 59 Somes cases of brachelytry (**a**) ***Nyctiphantus nocturnus*** (Semenov). Russia. Transcaspia; (**b**) ***Marseulia dilativentris*** (Reiche). apterous and brachelytrous, as with *Metacycla* in Central America (Chrysomelidae: Galerucinae). Also, the elytra are completely absent in the females of glow-worms (Lampyridae), Drilidae and some Scarabeidae (*Pachypus candidae*) (Fig. 60).

Among the parasites, apterism can be linked with shortening of the elytra among the females (*Silphopsyllus*), or even among both sexes (*Platypsyllus*) (both Leiodidae). We find also a total disappearance of elytra among females of *Pachypus* (Dynastidae), *Thylodrias*, and *Rhipidius* (Rhipiphoridae).

Some Examples Among Chrysomelidae

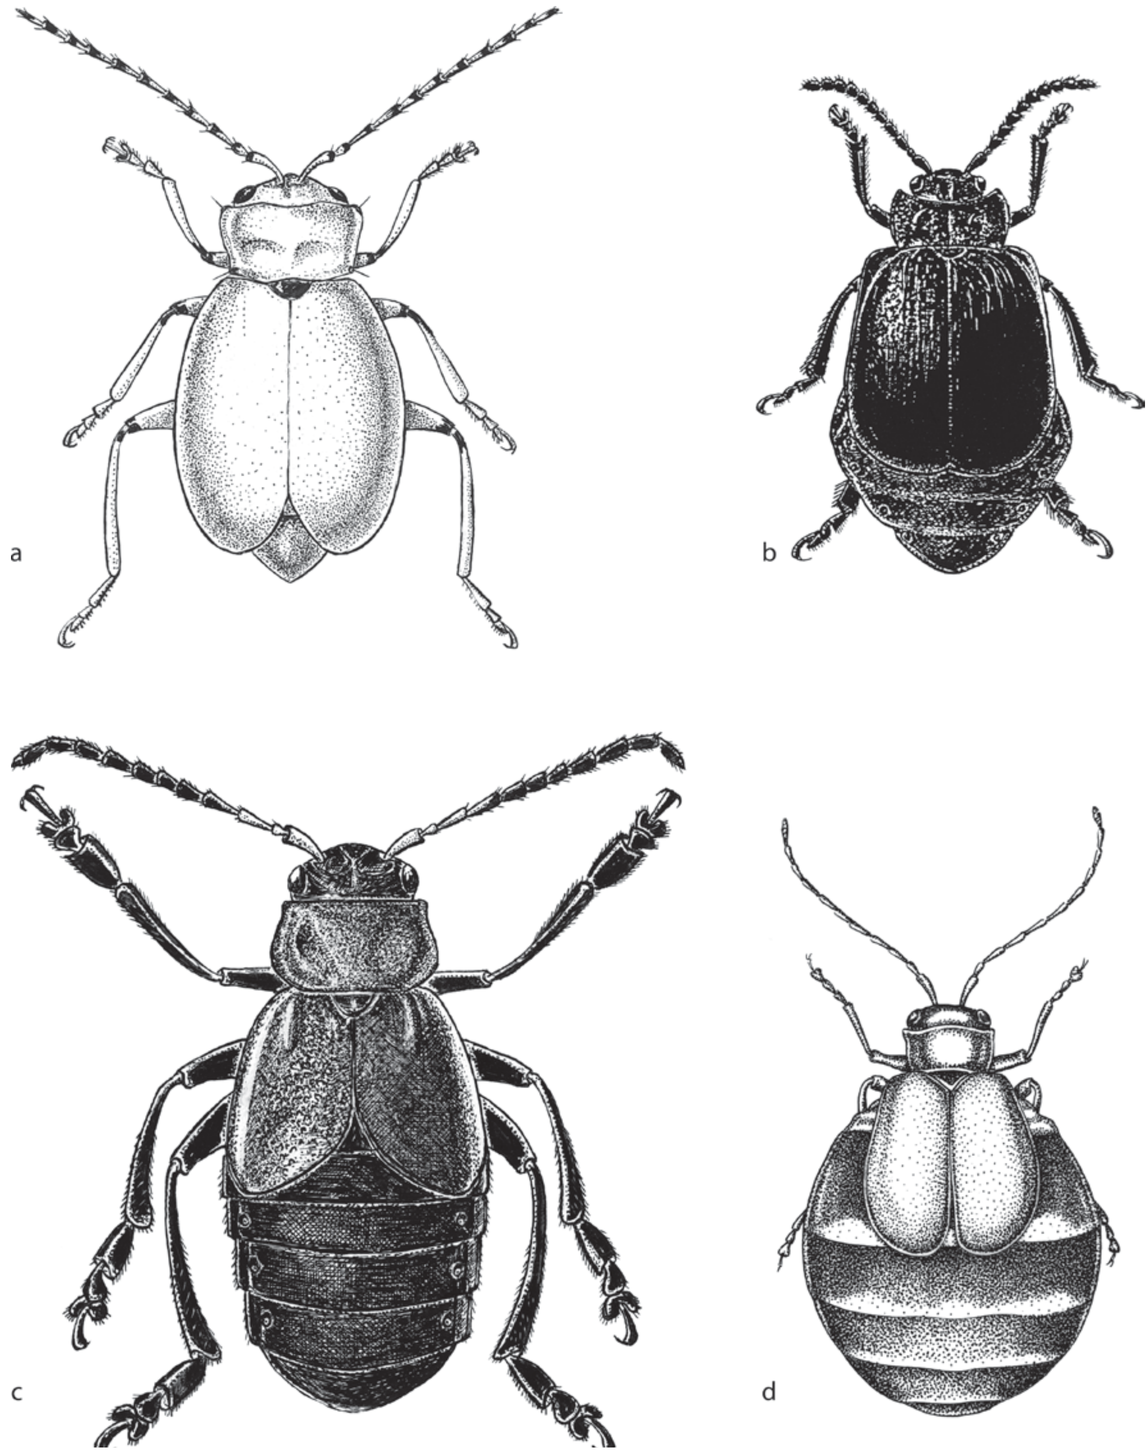
Brachypterism or apterism is common among Chrysomelidae, whereas brachelytry seems limited to Galerucinae and a very few Alticinae. As far as we know, macro-brachypterism seems to be transmitted in Mendelian fashion, when both morphologies are present. Brachelytrism is a derived character, but mixed forms do not exist.

Brachelytrous leaf beetles, which are generally apterous, are evidently devoid of a subelytral cavity, which exists among many apterous Chrysomelinae and Tenebrionidae. Probably, this lack of isolation against cold in mountains or heat and UV in deserts is compensated by other means, such as stronger sclerotizaton of the upper abdomen (tergites).

Brachelytry among Galerucinae is distributed in the Mediterranean region (*Arima marginata*, *Galeruca monticola*, *Marseulia dilativentris*); in mountains or steppe areas of Siberian, Indian and Chinese mountains (*Theone octocostata*, *Galeruca barovskyi*, *Paregeina andrewesi*, *Geinula antennata*); in Australian desert areas, where apterous beetles are common (*Rupilia ruficollis*); in the Ethiopian and East African mountainous areas (*Mahutia alluaudi*); in the Mexican and Central America dry tropics (*Metacycla caeruleipennis*); and in the highlands of South America (*Metalepta tuberculata*). Between 60 and 100 galerucine species in the whole world display brachelytry. Strangely, brachelytrous forms are extremely rare in South Africa and probably absent from Madagascar. Some live in India and Malaysia, but generally are linked with mountains. The genus *Galeruca*, which is essentially palaearctic, has numerous species (nearly 70 taxa) from Western Europe to Siberia, China, and Japan, and normally is macroelytrous and macropterous. However, it displays brachelytrism, joined with brachypterism or apterism, at higher altitudes. It can occur, as *Chrysolina*, above 5300 m in China, Himalayas and Tibet and many of those highland frequenting species are brachelytrous and all apterous. Very few real brachelytrous Alticinae can be quoted: *Hespera brachelytra* from the Yunnan mountains, *Sjoestedtina fordi*, *S. montivaga* from mountains in eastern African, though there may be more.

Flightlessness and brachelytry generally occur in both sexes. *Metacycla* is an exception, with only the female brachelytrous and apterous. Flightlessness is favored in females because it allows greater allocation of resources to egg production (physogastry); however, flight seems retained in males because it increases the probability of finding a mate. Many brachelytrous species walk on the ground and are relatively polyphagous, like *Arima* in Europe, *Galeruca* in China, *Marseulia* in Middle East, *Metalepta* on the Peruvian plateau, or *Rupilia* in Australia. *Metacycla* occurs in Mexico on *Ambrosia ambrosioides*, a small plant (Asteraceae). In this species, the beetle does not walk on the ground, but the male is flying and active, searching for females. The female, black in the collections, is red and pink in some species when alive and probably it is an aposematic color.

A review of the brachelytrous Chrysomelidae (Galerucinae and Alticinae) has been made by Pierre Jolivet, but due to the numerous galerucine genera affected, the list is not complete. The phenomenon is more frequent among mountain, steppe or desert-inhabiting genera and species,



Brachelytry, Figure 60 **Some additional cases of brachelytry (a) *Galeruca littoralis* (Fabricius). South of France. Pygidium prominent. Winged; (b) *Galeruca monticola* Kiesenwetter. France: Pyrenean mountains. Apterous; (c) *Arima marginata* (Fabricius). South of France. Apterous; (d) *Metacycla marginata* Chapuis. Female. Mexico. Apterous; (after Jolivet P (2005) Brachelytry among Chrysomelidae. Lambilionea 105(3):371–384).**

mostly in the tropics, but it also exists in temperate areas. Life on the edge has its constraints, but such mutants not only survived, but have persisted for a very long time. Other families like Staphylinidae seem more consistent; only in the Arctic, where many apterous or brachypterous species occur, brachelytry is absent. Apparently it can be maintained only under hot or relatively temperate climates. Brachelytry seems ancient and linked to harsh environmental conditions. It is known that wing atrophy helps the female in producing more eggs. That must also be the same for brachelytry. There are many cases where only the female is brachelytrous. We must distinguish between elytra fully developed or truncate (brachelytry), but there are degrees between relictual scales (some Staphylinidae) and relative shortening of the elytra. However, very rarely the elytra disappeared completely. Often scales persist. Among Bruchidae, Alticinae, many Galerucinae, very often the end of the abdomen is apparent, but it is not a case of brachelytry.

Certainly the shortening of elytra helps the mobility of the abdomen among the Staphylinidae. Among the Histeridae, the function for truncated elytra is less clear, but among saprophagous beetles the wings are always covered. This may be a necessity in a dirty and humid environment. In the case of Cerambycidae, mimetism with ants could be responsible, but among floricolous groups the wings can remain free. In many cases, the reason for brachypterism is not clearly understood. The case of the *Metacycla* species (Galerucinae) is unique, having physogastric, brachelytrous, apterous females and, macroelytrous, probably flying males. In some species of this genus, the drawings (yellow bands) of the elytra are printed over the upper side of the abdomen. In most cases of brachyletry, the upper abdomen is strongly sclerotized to replace the absence of protection by the lost elytra.

Brachelytry does not seem to be analogous between the various families of beetles. It has appeared independently, for instance, among Staphylinidae and Histeridae. Wing folding also is different in both families. When the beetles are on their back, the staphylinids use their abdomen to recover and attain their footing, whereas histerids use their elytral stump. For Degallier (pers. comm.), histerid elytra are shortened organs, whereas for staphylinids the elytra could be vestigial in relation to an elongated abdomen. There seems not to be any synapomorphy between the two groups.

Often, brachelytry or apterism are connected with a reduced metasternum and various morphological and anatomical correlations (timarchisation of Rüschkamp, 1927). Among ground Chrysomelidae and others, reflex bleeding, hoemocoelous toxicity, thanatosis, aposematism, extra-sclerotization of the abdominal tergites help in protection against predators for those wingless and relatively unprotected beetles. Most of those beetles are black, as in *Timarcha*, but some are brilliantly colored. Black for a ground insect can be aposematic on grasses. A set of mutations should have produced these conditions, and apterism and brachelytry are generally associated with the many usual morphological conditions.

Brahmin Moths (Lepidoptera: Brahmaeidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

Brahmin moths, family Brahmaeidae, are a small family of 28 species, mostly Palearctic and African. There are two subfamilies: Dactyloceratinae and Brahmaeinae. The family is in the superfamily Bombycoidea (series Saturniiformes), in the section Cossina, subsection Bombycina, of the division Ditrysia. Adults medium size to very large (50–180 mm wingspan), with head vertex roughened; haustellum average (rarely vestigial); labial

Brahmin Moths (Lepidoptera: Brahmaeidae), Figure 61 **Example of brahmin moths (Brahmaeidae), *Brahmaea wallichii* (Gray) from Taiwan.**

palpi upcurved or porrect; maxillary palpi vestigial or very small (2-segmented); antennae bipectinate; body robust. Wings broadly triangular but mostly rounded (rarely with apex somewhat falcate); hindwings rounded (Fig. 61). Maculation mostly dark browns with numerous scalloped and concentric light lines, plus other markings; rarely more colorful. Adults nocturnal. Larvae are leaf feeders. Host plants recorded in Asclepiadaceae and Oleaceae.

Bristle-Legged Moths (Lepidoptera: Schreckensteiniidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Bristle-legged moths. family Schreckensteiniidae, are a small family of only five known species (three in North America, one in Central America, and one in Europe). Some place the family in its own monobasic superfamily, Schreckensteinoidea. The family is part of the superfamily Tineoidea, in the section Tineina, subsection Tineina, of the division Ditrysia. Adults are small (10–12 mm wingspan), with head smooth-scaled and hind tibiae with long bristles; haustellum naked; maxillary palpi minute, 1-segmented. Maculation is lustrous in shades of gray or brown, with reduced venation and long hindwing fringes. Adults are diurnal. Larvae are leaf skeletonizers on Anacardiaceae or Rosaceae. The family and nominate genus *Schreckensteinia* are named after the German lepidopterist and coleopterist, Baron Friedrich Roth von Schreckenstein (1753–1808).

Bristletails (Archeognatha)

This is a primitive order of insects known as Archeognatha or Microcoryphia. The order name is derived from the Greek words *archaios* (primitive) and *gnathos* (jaw). Because these insects are wingless, and none of their ancestors appear to be winged, the order is placed (with the order Zygentoma) in the subclass Apterygota; in this regard they (apterygotes) differ from all other insects.

Classification

There are about 250 species found throughout the world

Class: Insecta
  Apterygota
    Order: Archeognatha
      Family: Machilidae
      Family: Meinertellidae

Characteristics

Like other insects (but unlike some similar-appearing wingless animals such as diplurans, order Entotrophi, and proturans, order Protura), the mouthparts are external (ectognathous). They also lack metamorphosis; they do not change in form as they molt, only increase in size. The number of molts is considerable; 20–70 have been reported. They can live from 1 to 4 years.

Bristletails are small, measuring 10–12 mm in length. The body is cylindrical, but somewhat flattened. The thorax is strongly arched, resulting in a "hump-backed" appearance. Bristletails have large compound eyes that are almost touching, and also ocelli. They are covered with scales, and their color is gray, whitish, or brownish. The mandibles are long. The body segments are well-defined, including the three thoracic segments. The tarsi have three segments, the abdomen 11. The abdomen bears a long median apical filament (a tail-like structure) and two shorter lateral cerci. The antennae are fairly long, and least half the length of the body, and filiform.

Biology

Bristletails are nocturnal, and hide during the day is such cryptic habitats as leaf litter and decaying logs. Some frequent the shorelines water bodies, particularly among rocks near the shore. They are known for their ability to leap. Bristletails feed on algae, lichens, and plant debris. Bristletails do not copulate. They transfer their sperm indirectly by suspending droplets of sperm on strands or threads, which are taken up by the female.

Broadcast Application

The application of a material such as an insecticide to the entire surface of a field.

Broad-Headed Bugs

Members of the family Aldyidae (order Hemiptera).

► Bugs

Broadleaf Plant

One of the major plant groups, with net-veined, broad leaves. Synonymous with dicotyledonous plants. (contrast with grass).

Broad Mite, *Polyphagotarsonemus latus* (Banks) (Acari: Tarsonemidae)

This mite affects several important crops.

► Citrus Pests and Their Management
► Vegetable Pests and Their Management

Broad-Shouldered Water Treaders

Members of the family Veliidae (order Hemiptera).

Bugs

Broad-Winged Damselflies

A family of damselflies in the order Odonata: Calopterygidae.

► Dragonflies and Damselflies

Broad-Winged Thrips

Members of the family Aeolothripidae (order Thysanoptera).

► Thrips

Bromeliad Fauna

J. HOWARD FRANK
University of Florida, Gainesville, FL, USA

Bromeliads are a family (Bromeliaceae) of monocotyledonous plants with about 2,500 described species assigned to about 60 genera. Almost all of them are native to the neotropics, but the range of a few extends farther north. Sixteen species are native to southern Florida, three of which attain northern Florida, and one of these reaches southeastern Virginia (USA). Many bromeliad species are epiphytic whereas others are terrestrial. Roots of those that are epiphytic do not penetrate their tree hosts, and serve as holdfasts rather than nutrient-absorbing structures. Thus, minerals are absorbed through the leaves, not the roots, and the plants are not parasitic. In contrast, roots of ground-dwelling bromeliads may absorb minerals. Some bromeliads that grow on the ground dwell on rock surfaces (are saxicolous), some in arid habitats and others in marshy soils. Some major genera are *Aechmea*, *Billbergia*, *Brocchinia*, *Bromelia*, *Catopsis*, *Cryptanthus*, *Dyckia*, *Guzmania*, *Hechtia*, *Hohenbergia*, *Neoregelia*, *Nidularium*, *Pitcairnia*, *Tillandsia*, and *Vriesia*.

A remarkable feature of many bromeliad species in many genera is the ability to impound water in the leaf axils. Water thus impounded is rainwater, or rainwater enriched with nutrients leached from tree canopies (throughfall). Large specimens of many species may impound substantial volumes of water, up to many liters. Depending upon architecture of individual species, each of many axils may hold a separate small pool of water, or the axils may combine to form a central tank. These pools of plant-impounded water are called phytotelmata. They serve to provide a reservoir of water for absorption by the plant. Bromeliads under tree canopies contain fallen, decomposing leaves and seeds and twigs of trees. These decomposing materials provide nutrients that can be absorbed by the bromeliad (dendrophilous nutrition). Decomposition is caused by fungal and bacterial action, and by aquatic invertebrate animals. Bromeliads not under tree canopies depend on inputs of wind-blown nutrients (anemophilous nutrition). Typically, algae use these wind-blown nutrients and a food chain depends upon consumption of algae. Epiphytic bromeliads that lack tanks are said to be "aerobic," and have in the USA been labeled as "air plants."

Some authors define tank bromeliads as those that have a central water-impounding tank, perhaps surrounded by additional water-impounding axils. Others include any bromeliads that impound water in their axils, even if the water is distributed among many axils. The latter position is adopted here for convenience, not because the concept has greater merit.

One bromeliad species, *Ananas comosus* L. (pineapple), is a very important agricultural crop in tropical countries worldwide. A few other species are grown locally in the neotropics to provide food or drink (e.g., *Bromelia pinguin* L. and *Puya raimondii* Harms) or fiber (e.g., *Aechmea magdalenae* (André) and *Neoglaziovia variegata* (Arruda da Camara)). Bromelain, extracted from pineapple fruits, has pharmaceutical use as an anti-inflammatory, and is also used as a meat-tenderizer. There is widespread harvesting of bromeliad inflorescences from the wild as decoration for churches on religious holidays in neotropical countries. Very many species and cultivars and hybrids are grown as ornamental plants especially in Europe and North America.

Bromeliads are used in four ways by animals. First, the habitat formed by bromeliad phytotelmata is exploited by some aquatic animals as aquaria. Second, some small animals live permanently or almost so in the non-water-holding axils of bromeliads, the terraria. Third, bromeliads are used as an occasional place of concealment or hunting grounds, or the impounded water is used as a source of moisture, by some terrestrial animals, so these animals are visitors. Fourth, the bromeliads are eaten by some terrestrial animals. Insects exploit the plants in all four ways, and among the insects using each way are specialist species which have no other means of existence or habitat. Bromeliads are therefore essential to the existence of many insect species. Many other invertebrate animals and a few vertebrates also play a role. Additionally, there are three ways in which bromeliads exploit animals: first, as dispersers of seed; second, as pollinators; and third, as food (carnivory).

Aquatic Animals Using Bromeliad Phytotelmata as Habitat for their Immature Stages

The account below is not intended as a catalog, and it omits some groups and mentions few of the individual species.

Rotifera

Rotifers (wheel animalcules) dwell in many freshwater habitats, and some of these habitats are bromeliad phytotelmata. The earliest mention of a rotifer in bromeliads was in Costa Rica in 1913. The most thorough study to date was made in Jamaica in the early 1990s, when 41 of the 211 species reported from Jamaica were documented from bromeliads. They belong to 12 genera including *Lecane*, *Lepadella*, and *Cephalodella*.

Annelida

An aquatic oligochaete worm, *Dero superterrenus* Michaelsen, was first detected and described from Costa Rican bromeliads and found to be an obligate bromeliad inhabitant. Later, it was found to be quite widespread in neotropical countries. The mystery of how it manages to distribute itself among epiphytic bromeliads – when it seems limited to the aquatic environment of bromeliad axils – was solved when worms were seen to be attracted to bromeliad-dwelling frogs. Quite simply, the worm is phoretic on the moist skin of frogs. This method – phoresy, or "hitching rides" – has been detected in other aquatic invertebrates having limited mobility. In contrast, the aquatic insects present in bromeliad phytotelmata have winged adults, so their ability to disperse is assured.

Crustacea

Ostracods (seed shrimps) found in the water in bromeliad phytotelmata include species of the genera *Metacypris*, *Candonopsis*, and *Elpidium*. The first to be described was *Metacypris bromeliarum* Müller, from Brazil. Others have been found in Colombia, Costa Rica, Jamaica, Mexico, Puerto Rica, and Florida. Some are known from no habitat other than bromeliad phytotelmata.

Cyclopoid and harpacticoid copepods have been found in bromeliad phytotelmata in several neotropical countries and at least some of them are specialists to that habitat. The finding of one of the harpacticoid species (*Phyllognathopus viguieri* Maupas) in cultured bromeliads in Indonesia and the United Kingdom, and another (*Attheyella aliena* (Noodt)) in Germany suggested that these organisms had been transported in horticultural specimens. A cyclopoid species, *Bryocyclops anninae* Menzel, also was found in a botanical garden in Indonesia, although its occurrence in Puerto Rico suggests the latter locality or a wider area of the West Indies is its origin.

Cladocera are rare inhabitants of bromeliad phytotelmata; they are represented only by *Daphnia ambigua* Scourfield in Jamaica and *Alona bromelicola* Smirnov in Nicaragua. *Sesarma* and *Metopaulias* are genera of crabs. *Sesarma angustipes* Dana was described from Brazil (later detected in Trinidad), and *Metopaulias depressus* Rathbun from Jamaica, both in the nineteenth century. They reproduce only in the habitat provided by bromeliad axils, and *M. depressus* provides maternal care to its brood. The crabs are able to climb trees to distribute themselves from bromeliad to bromeliad.

Acari

Arrenurus andrewfieldi Orghidan & Gruia is an aquatic mite known from axils of *Aechmea aquilega* in Venezuela. Other aquatic mites of the same family (Arrenuridae), and some attributed to the family Anoetidae, have been reported from bromeliad phytotelmata in other countries.

Odonata

Larvae of dragonflies and damselflies are aquatic and predatory. They have well-developed legs and thereby are able to climb out of the water from one leaf axil and into the water in another. At least 12 species are now reported to have been detected in bromeliad phytotelmata in neotropical countries, and some of them appear to be specialists to this habitat, having been found nowhere else. These specialists are all species of damselflies, especially of the genus *Leptagrion*.

Hemiptera

Aquatic Hemiptera are represented by eight species of seemingly obligate bromeliad-dwellers in the family Veliidae (sometimes called broad shouldered water striders). Four belong to the genus *Paravelia* and four to *Microvelia*. That these genera belong to separate subfamilies suggests that adaptation to the bromeliad habitat occurred independently at least twice. Veliids are predators.

Coleoptera

Larvae of three families of water beetles have been found in bromeliad phytotelmata in neotropical countries. The families are Dytiscidae and Hydrophilidae (both with predatory larvae), and Scirtidae (once known as Helodidae or Cyphonidae) with larvae believed to be filter-feeding detritivores.

Trichoptera

Larvae of most caddis flies live in freshwater streams. One species, *Phylloicus bromeliarum* Müller, has adapted in Brazil to the habitat provided by bromeliad phytotelmata. From Costa Rica there is a record of a stonefly (Plecoptera) in bromeliad phytotelmata. So all three insect orders with strictly aquatic larvae (Odonata, Plecoptera, and Trichoptera) are represented in bromeliads in neotropical countries.

Diptera

It is the order Diptera (flies) which has the record for the largest number of families (at least 15) and species (hundreds) with aquatic larvae reported from bromeliad phytotelmata. They include larvae of Tipulidae, Anisopodidae, Sciaridae, Cecidodomyiidae, and Psychodidae. They include Ceratopogonidae whose adults are important in pollination of cacao, case-making and non-case-making larvae of Chironomidae. They include Tabanidae, Stratiomyiidae, Phoridae, Syrphidae, Borboridae, Aulacigastridae, and Muscidae.

The family Culicidae (mosquitoes) is especially well represented, with well over 200 species reported in the literature. Furthermore, a few of these mosquitoes are among the best studied denizens of bromeliad phytotelmata. This began with the realization that the subgenus *Kerteszia* of the genus *Anopheles* contains several species which develop only in bromeliad phytotelmata, and *Kerteszia* adults are important vectors of malaria. Studies in Trinidad in the late 1940s were followed by studies in the Brazilian state of Santa Catarina, and were aimed at preventing transmission of malaria to workers on cacao plantations and in urban areas surrounded by forest. Unfortunately, the simplest solution appeared to be destruction of bromeliads, and in southern Brazil this took the form of deforestation of a "cordon sanitaire" around urban areas. Public health workers seem to have adopted a concept that bromeliads are a major source of mosquitoes transmitting diseases. Thus, when Old World forms of dengue fever were detected in the Neotropics, beginning in the late 1970s and with continuing problems, public health workers targeted bromeliads as a source of the vector mosquitoes (*Aedes aegypti* (L.) and, beginning in the late 1980s, *Aedes albopictus* (Skuse)). That concept is almost wholly erroneous, because these species of *Aedes* mosquitoes rarely develop in bromeliad phytotelmata. Likewise, public health workers in Florida have erroneously targeted bromeliads as a source of the *Culex* mosquitoes that transmit West Nile virus in the USA, although such larvae of such mosquitoes rarely develop in bromeliad phytotelmata.

In Florida, larvae of two mosquito species, *Wyeomyia mitchellii* (Theobald) and *W. vanduzeei* Dyar & Knab, are highly adapted to existence in the water in bromeliad leaf axils. Typically, few of them survive to adulthood because of food shortage. Thus, they compete with each other in scramble competition, and they are adept at sequestering the small amounts of food available. They are able to survive weeks of starvation which non-specialist mosquito larvae are unable to do. This also allows them to out compete larvae of other mosquitoes that from time to time occur in bromeliad axils. Females of these mosquitoes have color vision and select light-colored (light green) oviposition sites, in contrast to the dark-colored sites (preferably black) typically selected by tree hole-inhabiting mosquitoes. Females hover over bromeliad axils while ovipositing. When they are not ovipositing or blood-feeding, they may be found perched on the trunks of trees harboring bromeliads. Males perform up-and-down flights over small areas of tree trunks when searching for females. Eggs of *W. vanduzeei* are made exceptionally buoyant by having a wax-like coating of minute mushroom-shaped structures that trap a plastron of air; they float vertically at the water surface and may even be washed out of bromeliad axils during heavy rain. In contrast, the eggs of *W. mitchellii* are coated only with a thin layer of a greasy substance, are less buoyant, and they float horizontally. Larvae depend upon input of dead leaves, twigs, and seeds that fall into bromeliad axils from tree canopies above and are decomposed by fungal and bacterial action. Further breakdown of the organic particles and probably digestion of bacteria and fungi in the guts of mosquito larvae make the nitrogenous content more rapidly available for uptake by the bromeliads. Thus, the presence of the mosquito larvae is helpful to the bromeliads, and the bromeliads provide a habitat for the mosquito larvae, so this is a symbiosis. These mosquitoes are not known to transmit any diseases to humans, although they take human blood as well as the blood of other vertebrates such as rabbits. They are viewed by humans as pests. The most appropriate long-term solution to their population control is biological control by competition. Such biological control would introduce organisms that would compete for nutrients with the mosquito larvae. Such competitors would probably be neotropical species of non-biting midges such as Chironomidae. Use of predators against the mosquito larvae would likely provide no solution at all, because survivors of predation would inherit the food resources and thus develop faster and produce larger and thus more fecund adults (Fig. 64).

Anura (frogs)

Tadpoles belonging to at least five frog genera: *Dendrobates* (Dendrobatidae), *Anotheca*, *Hyla*, and *Sphaenorhynchus* (Hylidae), *Syncope* (Microhylidae), and *Eleutherodactylus* (Leptodactylidae) have been reported from bromeliad phytotelmata. Adults of *Physalaemus spiniger* (Miranda-Ribeiro) (Leptodactylidae) may deposit their eggs in foam nests in bromeliad axils in Brazil, but the tadpoles develop elsewhere. In contrast, tadpoles of *Dendrobates pumilio* Schmidt in Central America are carried up trees to bromeliads on the backs of parents, and the tadpoles develop in bromeliad axils feeding on nutritional eggs provided by the female. Regrettably, the bright colors of many dendrobatid frogs ("poison-arrow" or "poison-dart" frogs) has made them popular in the pet trade, no matter that they are poisonous. To supply the popular demand to keep such frogs in aquaria with bromeliads, hunters have plundered them from their natural environment. Consequently, and because of habitat loss, *D. pumilio* is listed in the IUCN Red Book as a threatened species. Other

Bromeliad Fauna, Figure 64 **Schematic representation of a mosquito and a bromeliad: (a) Female *Wyeomyia* mosquito hovering over a *Tillandsia* sp. leaf axil while ovipositing. (b) Male *Wyeomyia* mosquito performing up-and-down flight over a small area of a tree trunk while searching for females. (c) Schematic showing how *Wyeomyia vanduzeei* eggs may be washed out of *Tillandsia* bromeliads during heavy rain. (d) Schematic showing how leaves and seeds from tree canopies fall and are trapped in bromeliad leaf axils, forming the basis of a food chain. Drawings by John Stark.**

strange development is exhibited by tadpoles of *Syncope antenori* Walker, which develop in the leaf axils of a *Guzmania* bromeliad in Ecuador. Here, the tadpoles are born with yolk-filled gastrointestinal tracts, and are able to complete their development without feeding.

Terrestrial Animals Using Bromeliad Terraria as Habitat for their Immature Stages

Bromeliad terraria are the leaf axils that cannot impound water because they leak. Instead, they accumulate moist organic materials. Typically, inner axils form phytotelmata whereas outer axils form terraria. We may also consider the upper parts of those water-impounding axils that are choked with fallen plant debris as terraria. Bromeliad terraria provide habitat for some specialist organisms and many generalists.

Beetles of the genus *Platynus* (Coleoptera: Carabidae) typify this group. Among the several hundred species of this genus, some have specialized to existence in leaf axils of epiphytic bromeliads, and their adults and immature stages occur nowhere else. Although their food has not been investigated, they are most likely predatory in concordance with their closest relatives. So bromeliads serve as hunting grounds for their adults and larvae. These bromeliad specialists occur in Mexico, Central America, and the West Indies.

In eastern Brazil, a scorpion *Tityus neglectus* Mello-Leitão (Buthidae) and a tarantula spider *Pachistopelma rufonigrum* Pocock (Therophosidae) have been found so often in terrestrial water-impounding bromeliads that their association seems to be obligate. Both are predatory. In Brazil, the spider *Psecas chapoda* (Peckham and Peckham) (Salticidae) reproduces only on the non-water-impounding *Bromelia balansae* Mez. In the southern USA, one spider *Pelegrina tillandsia* Kaston (Salticidae) is constantly associated with the atmospheric epiphytic bromeliad *Tillandsia usneoides* (L.) although the growth form of the plant does not provide terraria.

Ants may nest in bromeliad terraria. Some belong to species that also nest on the ground. Some belong to species that typically are arboreal, nesting in hollow twigs and branches. Some bromeliad species in the genus *Tillandsia* (e.g., *T. paucifolia* Baker) have inflated leaf bases providing cavities protected from rain, and the cavities thus formed are often occupied by ants. The ants may cut a small hole in a leaf base for ease of access to the cavity. Investigation may reveal whether such bromeliads and their ant tenants participate in a mutualism in which the plants also benefit.

Terrestrial Animals Using Bromeliads as Occasional Habitat, the Visitors

These visitors are here defined as animals that neither eat nor reproduce in bromeliads. They may be hunting for prey, they may be seeking moisture or concealment from enemies, or they may be present just because their wanderings have taken them there. In Brazil and elsewhere, adult frogs seek refuge during the daytime in bromeliads. Such vertebrates differ from bromeliad specialist frogs found in some parts of the tropics in that their tadpoles develop in other kinds of habitats. But perhaps because of the presence of frogs (potential prey), bromeliads are visited by snakes and other frog-eating vertebrates. Birds may find drinking water there. In tropical areas with pronounced wet and dry seasons, more individuals and species of insects may be present in bromeliad leaf axils in the dry season, when bromeliads provide oases of moisture as well as prey for the predators among these insects.

Terrestrial Animals Eating Bromeliads

Bromeliads in greenhouse cultivation seem more often to be attacked by scale insects than by insects of any other group, and this may be an artifact due to crowding of plants under unnatural conditions that exclude organisms which could control these pests. In Florida, these scale insects belong to the following six families (numbers of species in parentheses): Asterolecaniidae (2), Coccidae (1), Ortheziidae (1), Pseudococcidae (6), and Diaspididae (8). They can be controlled by chemical pesticides or, perhaps, they may be controlled by opening greenhouse walls to allow ingress of tiny parasitoid wasps (if the greenhouse is in a tropical or subtropical area), or by deliberate release of such wasps purchased from biocontrol supply companies (none of the necessary wasp species seems now to be available commercially, but this could change if there were demand).

Among pests of fruits of cultivated pineapple, the most widespread miner is the larva of a butterfly, *Strymon* (=*Thecla*) *basilides* (Geyer) (Lepidoptera: Lycaenidae). Perhaps it also attacks fruits of wild pineapples and perhaps other members of the genus *Ananas*.

Insect larvae that mine stems of bromeliads include Castniidae and Acrolophidae (Lepidoptera) and Curculionidae and Dryophthoridae (Coleoptera). The castniid species concerned seem not to have been identified to species level, but have been detected by this writer in bromeliads in natural areas in Mexico, Honduras, and Panama and doubtless are yet more widely distributed in the tropics. Fully grown larvae are large (~ 5cm), and their mining activities surely result in plant death. They have not been seen to be abundant and their population sizes may be limited by parasitoids, although such parasitoids have not been detected. Larvae of the one acrolophid species implicated, *Acrolophus vigia* Beutelspacher, are parasitized by larvae of at least one unidentified wasp (Hymenoptera: Braconidae). The subject is of academic interest but currently of no economic interest because *A. vigia* has not been detected in the USA Larvae of at least 24 weevil species specialize in mining stems of bromeliads. They belong to three genera, *Cholus*, *Cactophagus*, and *Metamasius*. The life cycle of the weevil *Diastethus bromeliarum* Champion seems unrecorded. All were classified within the family Curculionidae, but recently the part of that family containing *Cactophagus* and *Metamasius* has been considered a separate family (Dryophthoridae). It is unclear whether any of them is a substantial pest in its native ecosystem. However, some of them cause substantial damage to cultivated pineapples in agro-ecosystems. One of them, *Metamasius callizona* Chevrolat, which is native to southern Mexico and Guatemala, also causes enormous damage to Florida's native bromeliad populations after having arrived as a contaminant in one or more shipments of ornamental bromeliads. A biological control project against *M. callizona* is in progress in Florida with intent to reduce its populations (not eradicate them as is sometimes misstated by the news media); the objective of biological control is not to eradicate.

Insects that have specialized to eat the leaves of bromeliads by chewing the surfaces or by mining are surprisingly few. They include a few leaf beetles (Coleoptera: Chrysomelidae) such as *Acentroptera basilica* Thomson and *A. pulchella* Guérin Méneville in southern South America, the abovementioned adult weevils (Coleoptera: Dryophthoridae and Curculionidae), a few caterpillars such as *Napaea eucharilla* Bates (Lepidoptera: Riodinidae), and larvae of a leaf-mining fly, *Melanagromyza rosales* Woodley (Diptera: Agromyzidae), in Costa Rica. Generalist insects that chew bromeliad leaves include cockroaches (Blattaria), whose actions are scarcely noticeable outside a greenhouse environment, and grasshoppers (Orthoptera: Acrididae). In spring in southern Florida (USA), population explosions of "lubber grasshoppers" (*Romalea guttata* Houttyn (Acrididae)) attack many monocotyledonous plants, including bromeliads; although the damage they cause initially appears severe, the plants seem to recover by new growth. In Andean countries, the spectacled bear, *Tremarctos ornatus* (Cuvier), is reported to include a substantial proportion of bromeliads in its diet.

Larvae of *Epimorius testaceellus* Ragonot (Lepidoptera: Pyralidae) develop within the flower pods of the bromeliad *Tillandsia fasciculata* Swartz, causing considerable local damage. A tiny wasp parasitoid attacks these larvae and may limit populations of this moth.

Animals as Dispersers of Bromeliad Seed

Dispersal of seed in the bromeliad subfamily Tillandsioidea is by wind. The fleshy seeds of many Bromelioidea, however, seem designed to attract feeding by vertebrate animals, and indeed birds have been reported to consume the seeds, pass them through alimentary tracts, and disperse them together with feces in new habitats. The subject of seed-dispersal by animals is not well documented.

Animals as Pollinators of Bromeliads

Feeding by animals at bromeliad nectar may be considered as a special case of phytophagy because this does no harm to the plants, unless perhaps the animals should consume nectar without effecting pollination. There are remarkably few observations of nectar feeding. Those that are mentioned most are by hummingbirds at large flowers of some large bromeliads, and these may well be over-emphasized because hummingbirds are diurnal and easy to see, and by butterflies and a few beetles. Bats are documented as pollinators of the genus *Werauhia*. Feeding by moths is nocturnal, hard to observe, and may be vastly underrated. There is much scope for collaboration between entomologists who can identify the insects effecting pollination and botanists who can identify the bromeliads specifically and demonstrate pollination, especially at night.

Animals as Food for Bromeliads (Carnivory)

In just three bromeliad species (one *Catopsis* and two *Brocchinia*) carnivory has developed, because the plants trap insects which are decomposed by bacterial action in their tanks. Although some writers have deemed this to be "proto-carnivory" because the three bromeliads in question do not produce digestive enzymes, the effect is the same. The first detected instance was in the bromeliad *Catopsis berteroniana* (Schultes) in southern Florida, although the plant has a wider distribution in the neotropics. Although it grows epiphytically, it grows typically above tree canopies, so it accumulates little or no organic debris from trees. It seems to have evolved a method of confusing winged terrestrial insects so that they stumble into it, have difficulty escaping, and drown and are decomposed in the water-filled leaf axils. The two *Brocchinia* species are terrestrial and grow in nutrient-poor habitats in inland Venezuela. We may only hope that the gluttonous commercial trade in carnivorous plants will not plunder these plants from the wild. Hobbyists should at least be warned that the two *Brocchinia* species require cool, humid, breezy climatic conditions that are hard to match in cultivation, that populations of *C. berteroniana* in southern Florida are all in protected lands, that the plants are specifically protected by law, and that none of the plants can withstand freezing temperatures.

Conclusion

In pre-Columbian times, bromeliads and their denizens were a huge ecosystem extending in the Americas from southeastern Virginia (USA) to Argentina. Bromeliads and their animal denizens are being destroyed overwhelmingly by encroachment by human populations. This has been called "development." One of the most species-rich areas was Brazil's Atlantic forest, which has been reduced to less than 7% of its former extent, but a similar story prevails everywhere. Some, especially in Trinidad and Brazil, were destroyed in the twentieth century because of an oversimplified concept that bromeliads are a source of malaria-carrying *Anopheles* mosquitoes, and so the simplest method of controlling malaria is to destroy the forest and the bromeliads. This concept has spilled over, irrationally, to other countries, other bromeliads, other mosquitoes, and other diseases (or no diseases), to which it does not apply.

Lesser constraints on bromeliad populations and their denizens have made their mark because so much has been destroyed by "development." Widespread and vast harvesting of bromeliad blooms for church activities is having an affect. The harvesting of bromeliads from nature has unequivocally contributed to the spread of pest insects internationally. Selective harvesting of the rarest bromeliads for the horticulture trade may be having a negative affect, although a counter-argument has been made that they are being propagated and thus will survive in culture. Destruction of native bromeliad populations in Florida by a pest weevil (which arrived as a contaminant of "ornamental" bromeliads from Mexico) is having an overwhelming negative affect on the bromeliad populations – its affect on the bromeliad fauna in Florida has not yet been addressed although it surely must likewise be negative. We have some idea of the reduction of bromeliad populations throughout their former range, but we have no idea of the reduction of populations of the animals that depend upon bromeliads; we can only guess that it is at very least as bad, most likely worse. Harvesting of selected bromeliad-inhabiting animals from nature, such as *Dendrobates* frogs, threatens their very existence but fortunately most bromeliad-dwelling organisms lack appeal to hobbyists, and so are threatened "merely" by development destroying bromeliads.

Involved biologists have four major options. The first is to study the heck out of native bromeliad faunas in numerous neotropical countries while there still is a fauna. The second is political lobbying for the preservation of tracts of land that may preserve part of the fauna (some of it will inevitably be lost with "development"). The third is to persuade churchgoers of Latin American churches not to harvest bromeliads from nature – to use other sorts of decorations instead of destroying the environment. The fourth is to provide public educational support to laws of many countries that already prohibit "harvesting" of bromeliads from nature for commercial purposes.

Brood

In asocial insects, this generally refers to a cohort of individuals resulting from deposition of a cluster of eggs and developing concurrently. However, sometimes it is used to refer to all the offspring of a parent, which may include several clusters of eggs produced over the lifespan of the female. In social insects, this refers to all the immature offspring of a colony, and may consist of eggs, larvae, nymphs and pupae.

Brood Cell

Among social insects, a cell, chamber or pocket constructed to house the immature stages.

Brooding

A form of parental care wherein the young insects remain near the parent insect (though in some insects surrogate parents are employed). Sometimes the parents actively engage in defense of the young, but often they do not.

Brood Sac

In cockroaches, an internal pouch, usually under the wing covers, where eggs are incubated in females.

Broun, Thomas

Thomas Broun was born in Edinburgh on July 15, 1838. His father and an uncle were naturalists and probably influenced him. At the age of 16, he joined the British army, took part in the Crimean war, and then served in Burma and India during the Indian Mutiny. In 1862 he married and emigrated to New Zealand. At outbreak of the Maori war, he was commissioned as captain, served throughout the war, and attained his majority. After that war, he began to work on New Zealand insects. In 1880 was published his "Manual of New Zealand Coleoptera" which listed 1,140 species. Supplements increased this total to 3,979 species. In 1890 he was appointed Government Entomologist. His type specimens are mainly in the Natural History Museum, London. He died on August 24, 1919 (Fig. 65).

Brown Citrus Aphid, *Toxoptera citricida* (Kirkaldy) (Hemiptera: Aphididae)

JAMES H. TSAI
University of Florida, Ft. Lauderdale, FL, USA

The brown citrus aphid, *Toxoptera citricida*, is believed to originate from China. Until 1900, this insect was confined to southeast Asia, Australia, New Zealand, the Pacific Islands including Hawaii, South Africa, and South America. Since then it has become established in several countries of Central America and many islands in the Caribbean Basin. Brown citrus aphid was first discovered in 1995 in south Florida; in the following two years, this insect had expanded into all citrus production areas in Florida. Because of its ability to transmit citrus tristeza virus (CTV) in an efficient manner, the combina tion of brown citrus aphid and CTV has become an important problem of citrus worldwide. Disastrous epidemics of citrus tristeza virus have occurred in association with brown citrus aphid in Argentina, Brazil, Colombia, and Peru. CTV is known to cause decline and death of citrus trees grafted on sour orange (*Citrus aurantium* L.) rootstock, but some CTV isolates can cause stem pitting regardless of rootstock, and can result in long-term debilitation that reduces yields of sweet orange and grapefruit from 5 to 45%. Currently, there are about 185 million citrus trees in Florida grafted on the susceptible sour orange rootstock. Citrus tristeza poses a real threat not only to Florida's citrus industry, but also to other citrus producing states in the U.S. Brown citrus aphid feeding causes leaf distortion and shortening of terminal growth. Its honeydew provides a good medium for growth of sooty mold. More importantly, brown citrus aphid is the most efficient vector of CTV as compared with other citrus aphids such as *Aphis gossypii*, *A. spiraecola* and *Toxoptera aurantii*. The overall transmission efficiency of CTV by *T. citricida* ranges from 1 to 13% dependent upon CTV isolates and biotypes of vector. Brown citrus aphid reproduces parthenogenetically. Most females start to produce nymphs within 24 h after emergence. Nymphs undergo four instars. The developmental times for nymphal stages vary with temperatures and host plants. Within a temperature range of 8–30°C, the length of nymphal development decreases as temperature increases. The average developmental times for first, second, third and fourth instars are 1–12, 1–13, 2–16 and 2–22 days, respectively. At 5°C, nymphs fail to develop beyond the second instar. At 32°C, the developmental times for all nymphal stages increase compared to those at 28–30°C. The adults can survive and reproduce within the temperature range of 10–32°C (Fig. 66).

The mean longevity of females decline exponentially from 60 days to 7 days as temperatures increase from 10 to 32°C. The maximal longevities of individual females are 90, 62, 47, 30, 19, 15 and

Brown Citrus Aphid, Toxoptera citricida (Kirkaldy) (Hemiptera: Aphididae), Figure 66 Winged and wingless adults of brown citrus aphid, *Toxoptera citricida* (photo P. Choate, University of Florida).

9 days at 10, 15, 20, 25, 28, 30 and 32°C. Fecundity is more affected by temperatures; at 10 and 32°C, the fecundity is adversely affected. The average nymph production by adults within 15–30°C increases to a maximum of 53 nymphs per female at 20°C, then decreases sharply as temperature increases. The daily rate of nymph production varies with adult age. The peaks of reproduction appear at 4 through 10 days after adult emergence, with an average of 2–5 nymphs per day. The duration of reproduction lasts as long as adult longevity within the temperature range of 15–30°C.

The biology of brown citrus aphid is also affected by host plants on which the populations are reared. The average nymphal development periods on rough lemon, sour orange, grapefruit, and key lime are from 5.9 to 6.2 days. However, longer developmental periods (6.5–7.2 days) are required on box orange, calamondin, lime berry and orange jassamine. The average number of nymphs produced per female reared on sour orange, grapefruit, key lime, rough lemon, calamondin, box orange, lime berry and orange jassamine are 59, 43, 34, 43, 33, 18, 21 and 23 nymphs. Female adults live an average of 23 days on these hosts. Because young citrus flush occurs only intermittently in commercial groves, it is believed that plants other than commercial citrus play an important role in sustaining brown citrus aphid populations when young citrus shoots are not available.

Brown citrus aphid can be controlled by a number of pesticides. Hymenopteran insects play a critical role in pollination and fruit set. Pesticide application can greatly affect the pollination process in the blooming season; thus the material and time of application are of great significance in reducing mortality of pollinators. Other biocontrol agents such as parasitoids (*Lysiphlebia* spp., *Aphelinus* sp. and *Lipolexis* sp.), syrphid fly (*Pseudorus clavatus*), ladybeetles (*Cycloneda sanguinea*, *Harmonia axyridis* and *Coelophora inaequalis*), lacewing (*Chrysopa* spp.), and entomopathogenic fungi (*Beauveria bassiana* isolates) show various degrees of effectiveness in control of brown citrus aphid.

Brown Dog Tick or Kennel Tick, *Rhipicephalus sanguineus* (Latreille) (Acari: Ixodida: Ixodidae)

IGOR USPENSKY
The Hebrew University of Jerusalem, Jerusalem, Israel

Rhipicephalus sanguineus is the main vector and reservoir of a group of bacteria now called the *Rickettsia conorii* complex. They are causative agents of a number of similar human diseases known earlier as Mediterranean spotted fever, and distributed all around the Mediterranean and Black Seas as well as in India and some countries of southeastern Asia. According to the current data, new varieties of this disease connected with *R. sanguineus* have been distinguished that are caused by different subspecies of *R. conorii*, namely Mediterranean spotted fever (subsp. *conorii*) in the Mediterranean area, including northern Africa and southern Europe; Israeli tick typhus (subsp. *israelensis*) in Israel; Astrakhan fever (subsp. *caspia*) in the lower reaches of the Volga River in Russia; and Indian tick typhus (subsp. *indica*) in Asia. In addition, the brown dog tick was known as the vector of *Rickettsia rickettsii*, the causative agent of Rocky Mountain spotted fever in Central America, mainly in Mexico. Recently, a focus of this disease with *R. sanguineus* as the only vector was described and investigated in Arizona, USA. The broad distribution of this tick raises concern about such foci in adjacent states. Several new species of *Rickettsia* were also isolated from *R. sanguineus*, and *Rickettsia massiliae* was documented as a human pathogen. The brown dog tick was shown to harbor *Coxiella burnetii* (the causative agent of Q-fever) for many years after the death of the tick. *Rhipicephalus sanguineus* transmits several agents pathogenic for dogs. The causative agent of canine ehrlichiosis, *Ehrlichia canis*, originally described in the Mediterranean area, was later found in numerous areas of the world, and today its distribution completely coincides with the tick's range. *Rhipicephalus sanguineus* also transmits protozoan dog pathogens, such as *Babesia canis* endemic in the USA and Africa, and *B. gibsoni* in the Far East and North Africa. Several other pathogens were isolated from this tick, but their epidemiological or epizootiological significance is either small or unclear. Transstadial and transovarial passage of *R. conorii*, *R. massiliae* and *B. canis* has been proven.

The difficulties of species identification in the genus *Rhipicephalus* resulted in subdividing the genus into groups of closely related species. In particular, the *R. sanguineus* group includes about ten species, with *R. turanicus* being the most difficult to distinguish from *R. sanguineus*. At the same time, genetic analysis of ticks from different areas of the world showed that there are distinct patterns for *R. sanguineus* and that the intraspecific variability of sequences within the species is very low. This means that *R. sanguineus* is a valid species.

The brown dog tick is the only cosmopolitan species of ticks. This species originated from Africa where its hosts were local carnivores and ungulates. Later, dogs became its main and often only hosts. Spread of the tick worldwide has been connected with human transport of dogs over the globe. At present, this tick can be found in all continents between the latitudes of 50°N and 35°S, but sometimes even further in association with dogs living indoors (in houses or kennels). It was recorded from all 50 states of the USA, many sites in Canada, as well as from such European countries as Belgium, Denmark, England, Germany, Norway, Poland and some others. Some cases of human infection with *R. conorii* by ticks inside human dwellings were documented.

Being ecologically flexible and tolerant of a large range of climatic conditions, *R. sanguineus* populates various areas, mainly inhabited localities including human dwellings, but also uninhabited environments which may be humid tropical, subtropical or continental (semi-desert). Unfed ticks are active for the whole year in the tropics, indoors as well as in the field. Under tropical conditions, ticks may have three generations during the year. Year round activity has also been observed in ticks living together with dogs in human dwellings in all regions. Unfed ticks living in the field to the north or south of the tropical zone are active from spring until autumn. Here they have two or sometimes only one generation annually. The more temperate the climatic conditions, the shorter is the period of activity of unfed *R. sanguineus* specimens. In Mediterranean countries, the season of adult activity lasts for 6–8 months, from March-April until October-November, depending on the environmental conditions of a particular area.

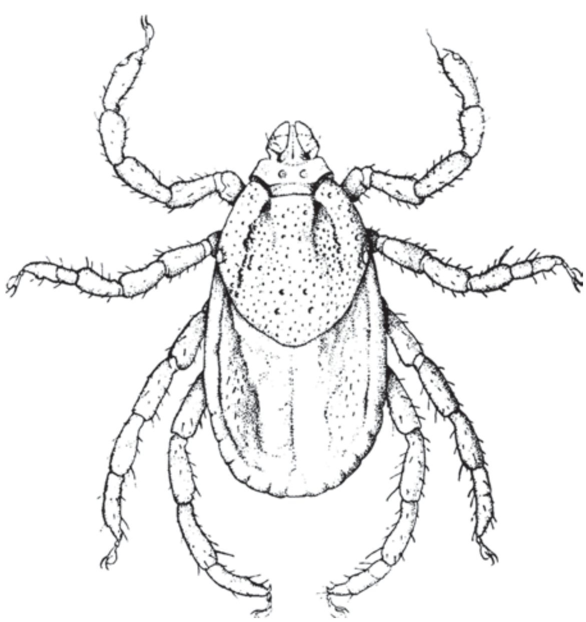
Host seeking behavior of unfed ticks depends on the conditions of their habitation. When the dog ticks live in human localities, they are constantly rather close to their main hosts, often just around the dog's bedding area. When ticks are ready to feed, they migrate a very short distance to their hosts, catch onto them and move over the dog's body looking for an attachment site. In the field, the ticks use an ambush strategy positioning on the vegetation, preferably on the tips of low grass, often in clusters. In the adult ticks, the anterior end of the body usually points towards the ground. Questing ticks can catch onto a passing host or, sensing it from a distance, they move in its direction, rather quickly over the sandy ground. *Rhipicephalus sanguineus* in the open field lives under much more inhospitable conditions than ticks living in dense forests due to low humidity and great fluctuations of ambient temperature. Under such conditions, the ticks are incapable of prolonged questing activity. To replenish their water reserves, ticks must regularly migrate down to the litter and soil where temperature is lower and humidity higher. Dog ticks have eyes and apparently use them effectively both for choice of optimal illumination and for searching for hosts.

The capacity of *R. sanguineus* for active migrations is rather limited. There are no data about tick migrations in tropical areas, but in semi-desert areas the unfed specimens can move upwards up to 20–40 cm, with the difference between ticks of different stages being undetectable. An interesting phenomenon concerning engorged nymphs and females in or near human dwellings has been documented many times: after repletion and detachment, they migrate vertically over the walls looking for suitable sites (cracks, crevices) for molting or egg-laying. The height of such migrations may be up to 2.5 m.

The season of activity for unfed subadults (larvae and nymphs) depends on the seasonality of adult ticks. In the tropical zone, subadults can be active during the entire year, with periodic and sometimes rather small fluctuations in their abundance. Under more temperate climatic conditions, the abundance of unfed subadults increases soon after the decrease in adult abundance, larval activity preceding that of nymphs. The life span of individual adults after molting continues from 3–4 months during summer months, to about 8–9 months if the hibernation followed with behavioral diapause takes place. In continental climates, only engorged nymphs and unfed adults can successfully survive during the winter. Unfed ticks that do not find a host and cannot feed during the activity season die due to complete expenditure of their nutritional reserves.

The brown dog tick (Fig. 67) is a typical exophilic three-host tick. The larva feeds for 3–6 days, the nymph for 4–10 days and an adult female for 6–13 days. Insemination of the adult female takes place on the host after 3–4 days of feeding. Without insemination, the female stops its engorgement and lives in an attached position until insemination, or death from drying. The larvae increase their weight during feeding 10 to 20-fold, while nymphs increase their weight 60 to 75-fold and adult females 70 to 120-fold. The adult males feed for 3–5 days, increasing their weight 1.5 to 2-fold. Henceforth, males migrate over the host body, attaching in different sites. The mass of an unfed larva is 0.02–0.025 mg, whereas the mass of a fully engorged female reaches 200–350 mg and it can lay up to 5,000 eggs. Two main components provide the increase of tick reproductive capacity: minimizing egg size (and, hence, unfed larval mass) and increased capability for interstage growth during nymphal feeding.

The minimal weight of engorgement after which females are capable of laying eggs is about 20 mg. After the female reaches the weight of 170–200 mg,



Brown Dog Tick or Kennel Tick, *Rhipicephalus Sanguineus* (Latreille)Acari: Ixodida: Ixodidae), Figure 67 The brown dog tick, *Rhipicephalus sanguineus.*

the dependence of egg number/mg of engorged female becomes linear and equals approximately 15–17 eggs/mg of the female weight. Weight characteristics and fecundity of the cosmopolitan *R. sanguineus* are different in populations from different regions. The populations from tropical conditions have smaller engorged female weights and, hence, lower fecundity.

The brown dog tick is a host-specific species, having the dog as its main host, though it can also feed on different vertebrates, such as livestock, some carnivores, lagomorphs, rodents, insectivores. All three parasitic stages can use dogs (sometimes the same individual) as hosts. Under conditions of extreme proximity with the host, there are cases where the tick changed from a three-host type of development to a two-host type. Sometimes larvae did not leave the dog after engorgement, and molted to nymphs on the host. In other observations, these were engorged nymphs that molted on the host to adults. Adults actively attack people in the Palaearctic and are the main source of human infection by different pathogens. Until recently, *R. sanguineus* rarely attacked people in the Nearctic, particularly in the USA. However, during the last several decades this tendency seems to have changed and a number of cases of human bites by the brown dog tick have been recorded. The recent outbreak of Rocky Mountain spotted fever in Arizona was connected to heavy infestation of dogs by *R. sanguineus* and numerous ticks of this species in the yards of patients' homesites.

Because the dog is a principal factor in human tick-borne infections, the suppression of ticks on dogs by using systemic acaricides or plastic collars impregnated with acaricides is an effective protection of humans from tick attacks and bites. Dogs heavily infested by ticks are dipped into water mixtures prepared with acaricidal emulsifiable concentrates and wettable or soluble powders. Regular cleaning of kennels, changing beddings, and acaricidal treatment of sites which dogs frequent are necessary measures for tick suppression. Educational programs for dog owners might be useful for increasing their knowledge about tick medical importance. Experiments on the treatment of tick hosts or tick location sites by preparations based on fungi and nematodes have shown that some pathogens have an obvious acaricidal effect. However, it is too early to estimate their real possibility for practical purposes of human protection.
