Diapause Hormone

A hormone that induces the tendency of insects to enter diapause. In silkworms, the diapause hormone is present in the pupal stage of females, and causes the eggs to diapause after they are deposited.

► Diapause

Diaprepes Root Weevil, *Diaprepes abbreviatus* (L.) (Coleoptera: Curculionidae)

STEPHEN L. LAPOINTE
USDA, ARS, Fort Pierce, FL, USA

The tropical root weevil *Diaprepes abbreviatus* was described by Carl Linnaeus as *Curculio abbreviatus* in the tenth edition of his *Systema Naturae* in 1758 from specimens collected in the West Indies. *Diaprepes abbreviatus* is found on Puerto Rico and Hispaniola and in the Lesser Antilles from Grenada and Barbados in the south to the Virgin Islands in the north, Hispaniola, and possibly Cuba. The species appears to be absent from Trinidad and Tobago, and from Jamaica. *Diaprepes abbreviatus* was discovered in Orange County, Florida, USA, in 1964. Since then, this highly polyphagous weevil has established in 23 Florida counties. In 2000, *D. abbreviatus* was found in a citrus grove in the Rio Grande Valley of Texas. In 2005, it was discovered infesting ornamental palms in an urban area of Orange County, California, USA, and subsequently found in Los

Angeles County and San Diego County. Several putative species of *Diaprepes* that vary in coloration and elytral striation have been synonymized with *D. abbreviatus*. A questionable species, *D. rohrii*, is reported only from St. Croix, U.S. Virgin Islands, while *D. abbreviatus* is apparently absent from that island. *Diaprepes rohrii* may simply be another color morph of *D. abbreviatus*. By 1933, it was recognized that the various forms of *Diaprepes* found throughout Hispaniola, Puerto Rico, and the Lesser Antilles were most likely a single species, fundamentally similar both structurally and behaviorally. Puerto Rico is the most likely center of origin because of the high degree of distinct, stable phenotypes on the island.

Host Plants

Some of the earliest mentions of *D. abbreviatus* refer to it as a common pest of sugarcane as early as the latter half of the nineteenth century on the island of Barbados. The weevil has an extremely wide host range and has been reported to attack over 200 plants including economically important crops from diverse botanical families (e.g., banana, bean, cacao, cassava, citrus, corn, cotton, mango, onion, peanut, pecan, potato, sugarcane, sweet potato, yam), ornamentals (palms and many others), and exotic weeds in the U.S. (e.g., kudzu and Brazilian pepper). In 1900, *D. abbreviatus* was reported in large numbers on Puerto Rico attacking guava and young coffee plants. In 1915, it was reported to be generally distributed over the island of Puerto Rico but causing particular damage to sugarcane. In Florida, *D. abbreviatus* has become a principal pest of orange and grapefruit and only low levels of host plant resistance within sexually compatible citrus germplasm have been reported. Its ability to infest ornamental plants in commercial nurseries, especially species of palm produced in southern Florida for interstate shipment, apparently accounts for its recent appearance in Texas and California.

Natural Enemies

The toad, *Bufo marinus*, was imported to Puerto Rico from Barbados in 1920 and again from Jamaica in 1924 to control white grubs (*Phyllophaga* spp.) and *D. abbreviatus*. It was alleged at the time that the introduction of the mongoose for control of rats resulted in an increase of populations of *D. abbreviatus*. Although the mongoose failed to control its intended victims, apparently it was more effective at destroying species of reptiles and birds that preyed on insects. More recent efforts at classical biological control in Florida introduced five species of egg parasitoids from the Caribbean for control of *D. abbreviatus*. Two eulophid species (*Quadrastichus haitiensis* Gahan, an endoparasitoid from Puerto Rico, and *Aprostocetus vaquitarum* Wolcott, an ectoparasitoid from Dominican Republic) are considered to be established in parts of southern Florida. The trichogrammatid *Ceratogramma etiennei* Delvare from Guadeloupe failed to establish. Two species have been recently introduced: *Fidiobia dominica* Evans (Platygastridae) from Dominica and *Haeckeliania sperata* Pinto (Trichogrammatidae) from St. Lucia. While reports refer to percent parasitism of egg masses, there is little evidence to indicate that egg parasitoids have been effective in reducing economically damaging populations of *D. abbreviatus*. No parasitoid of adults or larvae has been reported.

Species of entomopathogenic nematodes (*Steinernema riobrave* and *Heterohabditis indica*) are commercially available for use in Florida citrus to control *D. abbreviatus*. Efficacy of nematode treatments is associated with soil characteristics, with better control reported on lighter, sandy soils compared with heavier, poorly drained soils. Nematodes are formulated in products for delivery in irrigation water (nemagation).

Life Cycle and Description

The entire life cycle (egg to egg) can occur in approximately 154 days under ideal conditions but may be considerably longer in the field where temperature and moisture conditions vary. Generations overlap, with adults emerging throughout the year in the tropics and southern Florida. In central Florida, adults are absent during the coldest months. No evidence of diapause has been found, although larvae can endure long periods of low soil moisture. Emergence of adults in the Caribbean was observed to occur following onset on spring rains. In Florida, adults are most active during the period of high rainfall and temperature from June through October. Northern expansion of this species appears to be constrained by winter soil temperatures below 12°C for periods >30 days.

Eggs

Eggs are laid in masses of approximately 100 between leaf surfaces apposed and cemented in place by the female. Eggs complete development in approximately 7 days at 26°C with a lower developmental threshold of 12°C and an upper thermal limit between 30 and 32°C. The niche created by the female apparently provides conditions of temperature and humidity required for egg development.

Larva

Neonate larvae fall to the ground where they disperse and burrow into the soil. The lower threshold for development of neonates was estimated to be 15°C. Larval development to pupation occurs in approximately 125 days at 26°C. At the onset of pupation, larvae reared on artificial diet can weigh as much as 600 mg, depending on conditions of temperature and humidity experienced during larval development.

Pupa

The pupa creates a chamber in the soil by means of a writhing motion. Pupation is completed in approximately 3 weeks at 26°C. Initially, the exarate pupa is callow, becoming darker as pupation proceeds.

Adults

Adults vary in size between approximately 1 and 2.5 cm in length. Mean male length and mass are less than mean female size. Adults produced on artificial diet vary in weight from about 250 –350 mg. Males engage in prolonged bouts of guarding behavior and can remain mounted and intromitted for hours. There is anecdotal evidence for adult aggregation, presumably mediated by an as yet undiscovered pheromone. *Diaprepes* adults are largely black but covered with colored scales that range from ashy white to dull orange and bright yellow. Distinct phenotypes occur within defined geographic regions, marked by varying colors and patterns of elytral stripes. The length and number of raised ridges on the elytra devoid of scales varies between populations. On St. Lucia and Puerto Rico, there is subspecific variation in color and elytral ridges linked by intergrades. On Puerto Rico, western lowland populations of *D. abbreviatus* tend to have whitish elytra. They are brownish in southern and eastern lowlands including Culebra and Vieques. In the western central mountains, there is a larger phenotype often with yellow elytra and an additional strip per elytron; in the eastern mountains, a smaller, grayish, sometimes greenish variety prevails. On Barbados, the weevil was described in 1912 as pale-green with dark, bronze stripes. Emergent adults require 24–48h to fully sclerotize within the pupal chamber in the soil. Initially, adults possess a deciduous mandibular spur that likely facilitates adult emergence from the soil and is subsequently lost. Females have been estimated to produce on the order of 5,000 eggs over the adult lifespan that may be as long as 3–4 months in the field. Females cease oviposition at temperatures below 15°C.

Damage

Diaprepes abbreviatus was described in 1987 as the single most serious insect pest of agriculture, horticulture, and silviculture on Puerto Rico. In the 1930s, *D. abbreviatus* rivaled the sugarcane borer, *Diatraea saccharalis*, as the most serious pest of sugarcane in Barbados. The weevil, an apparently indigenous insect, did not infest sugarcane for centuries despite its extensive cultivation on Barbados. Infestations on sugarcane and sweet potatoes were not observed prior to 1901. By 1904 it had become fairly abundant, but not serious until 1909, and since that date it has increased in virulence every year. In 1922, loss was estimated at 3.5 tons and in 1929 at 5–6 tons of cane/acre on Barbados. Adult feeding damage consists of notching of leaf margins. Adult damage to citrus is considered minor. Larval damage to citrus is a function of direct damage to roots and secondary infection of wounds by pathogenic fungi, particularly *Phytophthora* spp. For this reason, damage is more severe in poorly drained soils conducive to fungal pathogens. While larvae remain external to citrus roots, they bore into and inhabit subterranean parts of sugarcane, sweet potato, potato, cassava, and other plants with tuberous roots or tubers.

Management

Sampling

A modified Tedders trap, consisting of a base of two interlocking vanes topped by a mesh receptacle has been used to estimate relative adult density. Since no pheromone or attractant is known for this species, such traps are inefficient and yield only very small numbers of weevils. The trap is based on the tendency for newly emerged adults to walk over the soil surface to dark vertical shapes. A more productive, active sampling method uses a beat sheet to sample individual trees.

Insecticides

Chlorinated hydrocarbon and other highly persistent insecticides were used as barriers to neonate weevils, for control of larvae in the soil, and as adulticides until the removal of such materials from the market. The waning of the era of persistent insecticides coincided with the introduction of *D. abbreviatus* into the United States. Several modern insecticides are effective against adults. However, because of the short residual effectiveness of foliar sprays and the prolonged period of adult emergence, adulticides may only be effective when used frequently over large areas. Porous soils and a vulnerable water table in Florida limit the use of soil insecticides on citrus. At least two species of entomopathogenic nematodes are marketed as bioinsecticides for this species.

Cultural Practices

Publications from the Caribbean in the early 1900s recommended pulling cane stumps after harvest to expose larvae and suggested "a few head of poultry" be kept on hand during the operation. It was suggested that fully developed larvae disperse from the cane stools in search of moist soil to pupate, sometimes moving a considerable distance in the soil. Large numbers of adults emerged after the first heavy rains of May/June. In 1939, a system of cash payments was advocated for collection and destruction of adult weevils. It was noted that continuous cropping of cane increased damage from *Diaprepes*. In 1911, school children on Barbados, St. Kitts and Antigua were enlisted to collect and destroy adults – 30,000 were captured and destroyed on one estate during 1 month. Adult weevils were reported from pigeon pea, corn, bean, and sweet potato (considered an especially good host for the weevil). Cooperative campaigns over a decade to reduce populations on Barbados were deemed successful due to the fact that the island is small, densely populated, and had a minimal amount of uncultivated land.

Manual collection of newly emerged adults, especially from cane fields, was facilitated by planting attractive host plants such as pigeon pea (*Cajanus cajan*) or other fast-growing shrubs or trees on field borders. A "bare-root method" has been suggested wherein soil is removed from the roots at the base of citrus stems thereby limiting access by larvae to the crown and thereby reducing the possibility of girdling. Kaolin-based particle films have shown some promise in reducing oviposition in field trials in Florida.

Host Plant Resistance

Only low levels of plant resistance to *D. abbreviatus* have been reported from sexually compatible citrus genotypes. Higher levels of resistance occur in related citroid fruit trees and some nonhost legumes. Recently, active isolates of *Bacillus thuringiensis* (Bt) have been discovered, raising the possibility of a genetically engineered rootstock transformed to express a *Diaprepes*-active toxin gene.

Biological Control

The toad *Bufo marinus* was imported to Puerto Rico from Barbados in 1920 and again from Jamaica in 1924 to control white grubs (*Phyllophaga* spp.) and *D. abbreviatus*. Two species of egg parasitoids have been established and two other species have recently been released in southern Florida but are constrained by prey availability during the winter months at more northern latitudes. They are not expected to establish in central Florida, Texas, or California unless periodic releases are made. Entomopathogenic nematodes are the only other biological control methods currently used.

Diatomaceous Earth

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

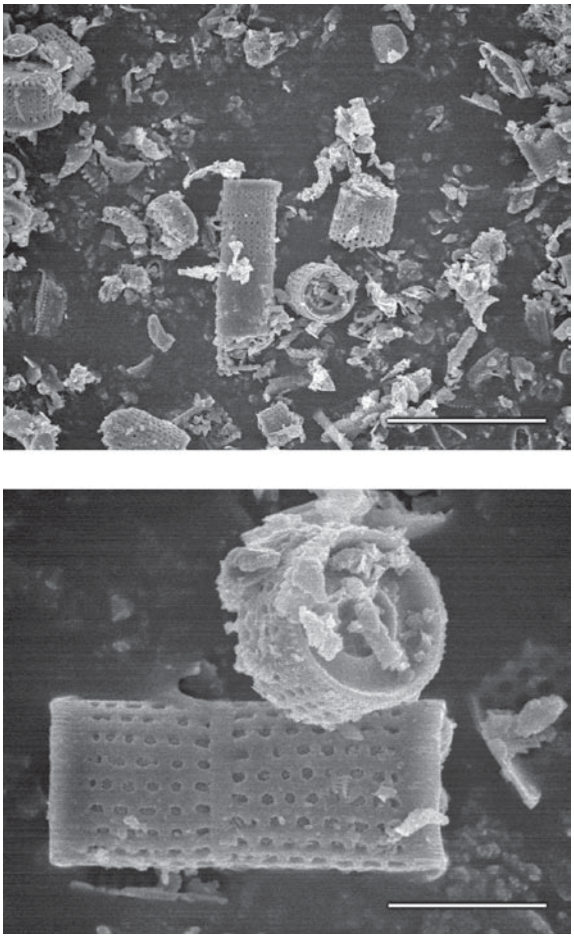
Diatoms are microscopic algae that live in both fresh and saltwater environments. They become impregnated with silicon from their environment as they grow, leaving a "skeleton" consisting of silicon dioxide (SiO_2) when they die. These diatoms are small. Many elongate forms are only 10–15 microns in length and 5 microns in diameter; others are spherical. They usually are free-floating, and a major component of oceanic plankton. They can be extremely numerous, and comprise the most important primary producers for small animal life in oceans. It is estimated that 25% of all organic carbon fixation (conversion of carbon dioxide and water into sugars by photosynthesis) on earth occurs in oceans due to diatoms. They also are a major source of oxygen. Most are not consumed, of course, and when the algae perish, their bodies accumulate, leaving silica deposits of up to 300 m thick in some areas. These compressed silicaceous deposits, consisting of 85–95% silicon dioxide, are mined for various industrial purposes such as abrasives for polishing, brightening agents in paint, and as filtering or insulating agents.

Why is Diatomaceous Earth Insecticidal?

Diatomaceous earth (also called diatomite), dust, and other small particulate matter have been used for thousands of years to protect stored grain from insects. Diatomaceous earth and dust kill insects by absorbing the waxy fats and oils from the epicuticle of insects. If sufficient waxy material has been absorbed, the insect cannot maintain proper water balance, and perishes due to dehydration. To a lesser degree, diatomaceous earth affects insects through abrasion, though this attribute is very compatible with the effects of oil sorption. Lastly, some repellency effects have been documented, though this is the least important attribute.

Environmental Interactions

Diatomaceous earth and dust are more insecticidal in arid environments. Moist grain (greater than about 15%) or humid storage conditions (> about 70%) can negate much of the benefit due to wax loss by insects. High temperatures enhance effectiveness of diatomaceous earth by increasing the rate of water loss. Insects also differ in their innate susceptibility; diatomaceous earth particles (Fig. 47) are more likely to adhere to hairy or rough-bodied species. Insects with these characteristics, and smaller species (with a large surface-to-volume ratio), or species with a thin epicuticle or thin wax coating, are more susceptible to death from diatomaceous earth. Insects that imbibe food in a liquid form (e.g., sucking insects or mites) are less likely to suffer the effects of diatomaceous earth than those that metabolize water from their food. Efficacy of diatomaceous earth interacts with high temperature (e.g., 50–60°C), but some insect species exposed to a combination of diatomaceous earth and high temperatures perish more rapidly than those exposed to diatomaceous earth and lower temperatures, whereas in other species exactly the opposite response is observed.



Diatomaceous Earth, Figure 47 Diatomaceous earth particles viewed with a scanning electron microscope; in the upper image, the bar at the lower right represents 30 microns; in the lower image, the bar represents 7.5 microns.

Variability Among Diatomaceous Earths

The size and shape of diatomaceous earth varies according to the dominant species living in the ocean or lake, and so the wax-absorption properties vary as well. Diatomaceous earth often possesses oil absorption values of about two to three times its own mass. The properties that define oil holding capacities are not well known, but particles of 45 microns or greater seem to be inferior. In addition to silicon dioxide, diatomaceous earth deposits may contain any of several contaminants, including aluminum, magnesium, iron, phosphorus, sulfur, salt, moisture, volcanic ash, clay, chert, and limestone. Diatomaceous earth products usually contain at least 90% silicon dioxide, however. Diatomaceous earth may be heated to high temperatures (called calcined diatomaceous earth) or left unheated (uncalcined); only uncalcined material is used as an insecticide. Aqueous solutions of sodium silicate can be dried and formulated into very light powders that are more effective (require less material); this is called silica aerogel. Silica aerogel, with its low density, is difficult to apply because it tends to float in the air, so is not often used. Diatomaceous earth is not flammable, is odorless, and is insoluble. Its color varies. Most deposits consist principally of amorphous silica, but a small proportion of crystalline silica occurs, and at a higher proportion in marine deposits.

What is Affected by Diatomaceous Earth?

Diatomaceous earth has been shown to kill ants, bedbugs, silverfish, caterpillars, crickets, termites, fleas, earwigs, beetles, ticks, mites and many other arthropods. However, the usual target is stored grain insects. *Cryptolestes* spp. are the most susceptible, followed by *Sitophilus*, and then by *Oryzaephilus*, *Rhyzopertha*, and *Tribolium* spp. Efficacy seems to be related to physical properties of the dust, rather than its chemical composition. As noted previously, high moisture levels reduce its effectiveness. Some diatomaceous earth formulations contain a low percentage of some other insecticide, commonly pyrethrum and piperonyl butoxide. Diatomaceous earth is usually applied as a dust, but sometimes as a water-based slurry. In addition to functioning as a grain protectant, diatomaceous earth is sometimes used to protect fabric and wood structures.

Safety

Diatomaceous earth is considered to lack acute or chronic health effects when consumed by mammals.

Sometimes diatomaceous earth is fed to livestock to control worms and other internal parasites. Thus, residues on food are not considered hazardous to humans. The known deleterious effects of diatomaceous earth derive from chronic inhalation of dust, as might occur among miners and processors. Amorphous silica is classified as not carcinogenic, but crystalline silica can cause lung problems. Applicators should be provided with protection of eyes, lungs, and skin. Slurry formulations also reduce the risk of inhalation.

Dictyopharidae

A family of insects in the superfamily Fulgoroidae (order Hemiptera). They sometimes are called planthoppers.

► Bugs

Dictyoptera

The orthopteroid insects (crickets, katydids, grasshoppers, grylloblatids, stick insects, cockroaches, mantids, termites, and earwigs) have been divided into numerous groups, and one of these is called Dictyoptera. Dictyoptera is usually considered to be an order comprised of the mantids, cockroaches, and sometimes the termites. They seem to share a common origin, and have filiform antennae, are mandibulate, often are winged and have thickened forewings, possess concealed genitalia, and possess pronounced cerci. In one scenario, the Blattodea or Blattaria (cockroaches), Mantodea (mantids), and Isoptera (termites) are considered to be suborders. Some consider mantids and termites to be families of cockroaches, however. In another scenario, Dictyoptera is considered to be a superorder, with these same groups as orders rather than suborders. Though acknowledging the relatedness of these taxa, we treat the roaches, mantids, and termites as orders, and ignore the term Dictyoptera.

Differential Grasshopper, *Melanoplus differentialis* (Thomas) (Orthoptera: Acrididae)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

In North America, this grasshopper occurs widely in the central and western regions of the United States, and in northern Mexico; in Canada it occurs in southern Saskatchewan and British Columbia. Within the United States it is absent from the Atlantic and Gulf Coast region, except that it occurs in Pennsylvania, New Jersey, and Maryland. It is infrequent in the Pacific Northwest area. Also, within the large geographic area generally inhabited by differential grasshopper, it is rare in arid environments.

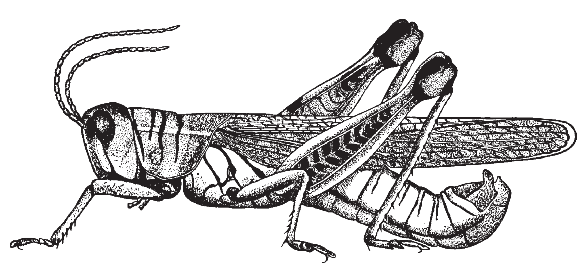
Life History

Melanoplus differentialis has a single generation annually, with the egg stage overwintering. This is a late-season species, with eggs hatching about 3 weeks after those of twostriped grasshopper, *Melanoplus bivittatus* (Say), and 2 weeks after *Melanoplus sanguinipes* (Fabricius). In Colorado, eggs hatch in June, usually within a 2-week period. Nymphs complete their development in July-August; adults are present from August-October.

The eggs are creamy white, yellowish, or light brown in color. They are elongate-cylindrical in shape, tapering to a blunt point at each end. The eggs are about 4–5 mm long and 0.85 mm in diameter. Eggs are clustered within an elongate, cylindrical pod consisting of 40–200 eggs arranged in four columns and held together by frothy material. The eggs are deposited in the soil, and the upper portion of the pod is plugged with additional froth. Eggs are normally deposited among the roots of grasses and weeds, especially along edges of fields, and in moist soil. Embryonic development occurs in the autumn after eggs are deposited, but the embryo enters diapause at about the point of 50% development, and must endure a period of cold before commencing growth.

The nymphs normally develop during the warmest period of the summer, and complete their development in about 30 days, though development times are extended if weather is cool. There are six instars, and the nymphs are not distinctive in appearance. First instars are greenish, yellowish or brownish with an indication of a black stripe on the outer face of the hind femora. Instars two through six are similar but possess a curved dark stripe extending from the back of the eye across the pronotum, and bordered below by a narrower white stripe. The black stripes on the femora are pronounced. The hind tibiae are light green or gray. The nymphs increase in body length from 5.3–6 mm in the first instar, to 5.2–6.8, 9.4–12.6, 12–14, 18–21.5, and 22–32 mm in instars 2–6, respectively. The number of antennal segments is 12, 14–17, 19–20, 21–22, 25–26, and 26 in instars 1–6, respectively.

The adults are fairly large grasshoppers, the males measuring 28–34 mm in length, the females 32–44 mm. They display more color variability than most grasshoppers. They may be principally brownish green, or yellow, or almost entirely black, though the yellow form is most abundant. The most distinctive feature of these grasshoppers is the row of black marks, arranged in herring-bone fashion (Fig. 48) on the outer face of the hind femora. These markings are not so evident in the infrequent black form, which instead bears four white blotches on its otherwise black hind femora.



Differential Grasshopper, *Melanoplus differentialis* (Thomas) (Orthoptera: Acrididae), Figure 48
Adult of differential grasshopper, *Melanoplus differentialis* (Thomas).

The forewings in all except the black form are uniform grayish or brownish; the hind wings in all forms are colorless. The males bear large, boot-shaped cerci.

Like many other grasshoppers, differential grasshopper tends to roost on elevated locations at night. This allows them to bask in the morning sun, and to assume activity early in the day. Bushes and other tall vegetation are favorite perches.

The host plants preferred by differential grasshopper are tall broadleaf plants such as those typically associated with fence rows, irrigation ditches, and fallow fields. It prefers plants in the family Compositae such as ragweed, *Ambrosia* spp.; sowthistle, *Sonchus asper*; sunflower, *Helianthus annuus*; and prickly lettuce, *Lactuca scariola*; though it will feed on other broadleaf plants such as kochia, *Kochia scoparia*; and smartweed, *Polygonum* sp.; and on such grasses as bermudagrass, *Cynodon dactylon*; slender oat, *Avena barbata*; barley, *Hordeum* sp.; and Johnsongrass, *Sorghum halepense*. In North Dakota alfalfa fields, differential grasshopper reportedly ate kochia, *Kochia scoparia*; quackgrass, *Agropyron repens*; squirreltail grass, *Hordeum jubatum*; bristly foxtail, *Setaria* spp.; and field bindweed, *Convolvulus repens*, in addition to alfalfa. On prairie, they ate mostly stickseed, *Lappula echinata*; wavyleaf thistle, *Cirsium undulatum*; quackgrass, *Agropyron repens*; and pepperweed, *Lepidium densiflorum*.

Crops sometimes injured include alfalfa, clover, corn, cotton, soybean, sugarbeet, timothy, and small grains such as barley and wheat. However, during periods of great abundance all crops are at risk because under such conditions virtually all green vegetation may be consumed.

Weather affects the distribution of differential grasshopper, but in a manner somewhat different from some other grasshopper species. Differential grasshopper is associated with dense vegetation, so it follows that it would thrive in areas with adequate moisture to support lush growth of plants. It is a common, and damaging, species on the eastern edge of the Great Plains, where rainfall is plentiful, and relatively infrequent along the drier western edge of this region. Sometimes, during periods of higher than normal precipitation, its abundance expands into areas of the Great Plains normally dominated by species better adapted to dry conditions, such as migratory grasshopper, *Melanoplus sanguinipes* (Fabricius). When weather returns to normal, however, migratory grasshopper resumes its status as the dominant species.

High levels of precipitation are not entirely advantageous for differential grasshopper. Precipitation during the warm months leads to outbreak of disease in differential grasshopper populations. This is a short-term response, and disease outbreaks occur only when grasshoppers are abundant. Differential grasshopper seems to be more susceptible to disease than some other species, including migratory grasshopper. Precipitation accompanied by cool weather during the hatching period is detrimental to differential grasshopper, as is the case for all grasshoppers, largely because it disrupts feeding during the critical early life of the grasshopper. The late onset of winter can favor grasshopper population increase because it allows adults additional time to produce eggs.

Damage

This species seemingly has benefited from agricultural practices more than most grasshoppers, with grasshopper survival increased by the abundance of weeds associated with crops, and the irrigation practices of western farms. It also readily exploits disturbed sites in cities and towns. Unlike some of the arid environment-loving species, its numbers and damage may increase following long-term increases in precipitation. The damage caused by differential grasshopper principally takes the form of leaf removal. Plants may be completely defoliated, or left ragged. Because this grasshopper tends to roost in elevated locations at night, where they may nibble while resting, trees and shrubs outside the normal dietary range are sometimes severely injured.

Management

Liquid formulations of insecticides are commonly applied to foliage to protect against damage. Because grasshoppers rarely develop in crops, but instead invade from weedy areas, it is often the edges of crop fields that are most injured. Therefore, application of insecticide to the borders of crop fields is often adequate to protect an entire field. It is even better to apply insecticides to the developing grasshopper populations in weedy areas before they move to crops. This not only minimizes damage to crop plants, but often results in younger grasshoppers being targeted for elimination. Younger grasshoppers are more susceptible to insecticides, with large nymphs and adults sometimes difficult to kill.

Application of insecticide-treated bait is an effective alternative to foliar treatments for *Melanoplus* spp. because these grasshoppers spend considerable time on the soil where they come into contact with baits. Bait formulations are bulky and more difficult to apply than liquid products, so they are less often used, but have the advantage of limiting exposure of crops to insecticide residue and of minimizing mortality of beneficial insects such as predators and parasitoids due to insecticide exposure. Also, the total amount of insecticide active ingredient necessary to obtain control is usually considerably less when applied by bait because the grasshoppers actively seek out and ingest the toxin. Finally, for relatively expensive products that must be ingested to be effective, such as microbial insecticides, baits are the most effective delivery system.

The attractant used most commonly for grasshopper bait is flaky wheat bran, though other products such as rolled oats are sometimes suggested. No additives, other than insecticide (usually 5% active ingredient), are necessary because the wheat bran alone is quite attractive to *Melanoplus* grasshoppers. Other additives such as sawdust, water, vegetable or mineral oil, molasses, amyl acetate, salt, or sugar have been suggested, but provide little or no additional benefit over dry bran. The bait should be broadcast widely to maximize the likelihood of grasshopper contact, and should be applied while grasshoppers are in the late instars because adults ingest less bait.

Elimination of weeds within, and adjacent to, crops is the most important cultural practice, and can have material benefit in preventing damage to crop borders. However, during periods of weather when grasshoppers become numerous they may move long distances and invade crops.

Tillage is an effective practice for destruction of eggs. Deep tillage and burial are required, shallow tillage having little effect. All the crop-feeding *Melanoplus* species deposit some eggs in crop fields, especially during periods of abundance, but it is fence row, irrigation ditch, field edge, and roadside areas that tend to be the favorite oviposition sites, so tillage is not entirely satisfactory unless other steps are taken to eliminate grasshopper egg pods from these areas that cannot be tilled. Though providing suppressive effects, deep tillage is not consistent with the soil and water management practices in many areas, so may not be a good option.

Row covers, netting, and similar physical barriers can provide protection against grasshoppers. This approach obviously is limited to small plantings, and can interfere with pollination. Also, grasshoppers are capable of chewing through all except metal screening, so this approach does not guarantee complete protection.

The natural enemies of differential grasshopper don't seem to offer much promise for effective suppression. The microsporidian pathogen *Nosema locustae* is well studied as a microbial control agent of *Melanoplus* spp. and is available commercially. It is fairly stable, and easily disseminated to grasshoppers on bait. However, its usefulness is severely limited by the long period of time that is required to induce mortality and reduction in feeding and fecundity. Also, the level of mortality induced by consumption of *Nosema* is quite low, often imperceptible. It is best used over very large areas, not just on individual farms, and should be applied at least 1 year in advance of the development of potentially damaging populations.

Fungi have also been investigated for grasshopper suppression. A grasshopper strain of *Beauveria* *bassiana* has been effective in some trials, and *Metarhizium anisopliae* var. *acridum* has worked well for grasshopper and locust suppression in Africa and Australia, so it may prove useful for *Melanoplus* spp. Behavioral thermoregulation by grasshoppers, wherein they bask in the sun and raise their body temperatures, is potentially a limiting factor for use of fungi. Basking grasshoppers easily attain temperatures in excess of 35°C; such high temperatures decrease or even prevent disease development in infected grasshoppers. Inconsistent quality control in production of fungi also limits use of these organisms for grasshopper control.

Digger Bees

Members of the family Anthrophoridae (order Hymenoptera, superfamily Apoidae).

► Bees
► Wasps, Ants, Bees and Sawflies

Digitate

Pertaining to structures with finger-like processes.

Dilaridae

A family of insects in the order Neuroptera. They commonly are known as pleasing lacewings.

► Lacewings, Antlions and Mantidflies

Dimboa

An acronym for 2,4-dihydroxy-7-methoxy-1,4,-benzoxazin-3-one, a naturally occurring compound in corn (maize) that provides some resistance against caterpillars.

Dimorphic

Having two distinct forms. Among insects, winged and wingless forms are a common example of dimorphism.

Dinidoridae

A family of bugs (order Hemiptera, suborder Pentamorpha).

► Bugs

Diopsidae

A family of flies (order Diptera). They commonly are known as stalk-eyed flies.

► Flies

Dioptidae

A family of moths (order Lepidoptera). They commonly are known as American false tiger moths and oakworms.

► American False Tiger Moths
► Butterflies and Moths

Diphyllostomatid Beetles

Members of the family Diphyllostomatidae (order Coleoptera).

► Beetles

Diphyllostomatidae

A family of beetles (order Coleoptera). They commonly are known as diphyllostomatid beetles.

► Beetles

Diploid

Having two copies of each chromosome.

Diplurans (Diplura)

This is an order of hexapods in the class Entognatha. These hexapods are sometimes considered to be insects (class Insecta). This order is also known as Entotrophi.

Classification

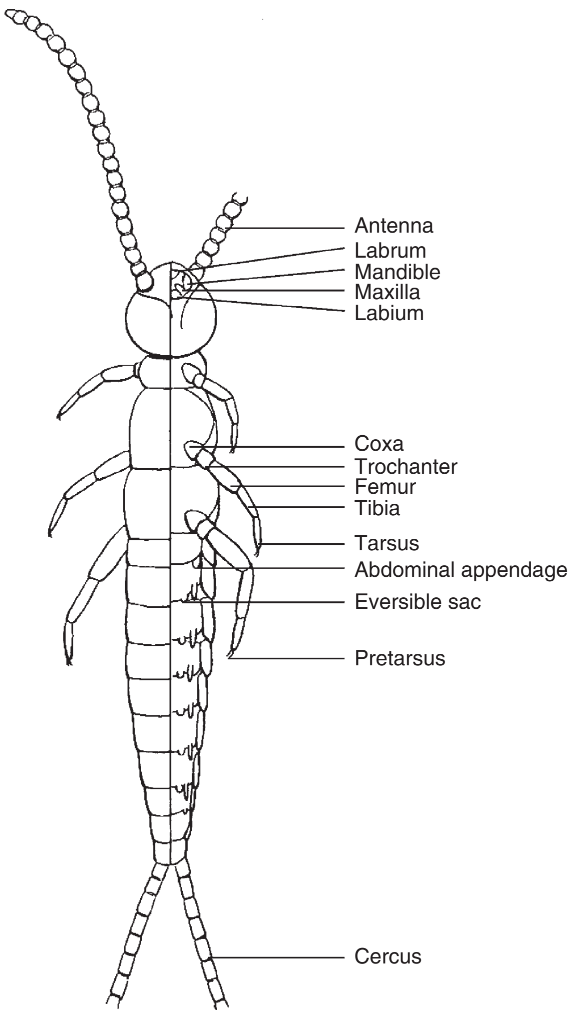
About 660 species are known from throughout the world, though this groups is not well known. The Campodeidae is well represented in the Holarctic region, with the other families more common in the subtropics and tropics. The taxonomy of Diplura is confused, but six families in two suborders are sometimes recognized:

Class: Entognatha
- Order: Diplura
  - Suborder: Rhabdura
    - Superfamily: Projapygoidea
      - Family: Anajapygidae
      - Family: Projapygidae
    - Superfamily: Campodeoidea
      - Family: Procampodeidae
      - Family: Campodeidae
  - Suborder: Dicellurata
    - Superfamily: Japygoidae
      - Family: Japygidae
      - Family: Parajapygidae

Characteristics

Diplurans resemble symphylans (class Symphyla), or perhaps silverfish (order Thysanura), bristletails (order Archeognatha), or proturans (order Protura). However, they have only three pairs of legs, so they are easily distinguished from the (Fig. 49) many-legged Symphyla. Also, the presence of only two cerci rather than three caudal filaments distinguishes diplurans from silverfish and bristletails. They are distinguished from proturans (order Protura) by the presence of antennae.

Diplurans are usually less than 10 mm in length, though their size range is 2–50 mm. They are elongate, soft-bodied, and brownish. The integument is thin, and few scales are found on these animals. The body regions, including the three thoracic segments, are distinct. The head is distinct, and the antennae long, many-segmented, and slender. Compound eyes and ocelli are absent. The biting and chewing mouthparts are entognathous (recessed in the head). The mandibles are elongate. They are wingless, and the three pairs of legs are similar in appearance and moderately short. The tarsi are one-segmented. The abdomen consists of ten well-developed segments and a small 11th segment. The tip of the abdomen bears a pair of cerci. The cerci vary greatly among the taxa, from long, many-segmented antenna-like appendages to stout, strongly sclerotized forceps used for prey capture. Most of the abdominal segments also bear small appendages. Trachea are present, but Malpighian tubules are vestigial or absent. The immatures greatly resemble the adult stage, differing principally in the number of antennal segments. They are considered to have incomplete metamorphosis.



Diplurans (Diplura), Figure 49 **A diagram of a dipluran showing a dorsal view (left) and a ventral view (right). Note that the cerci are abbreviated.**

Biology

These small animals are found among fallen leaves and in decaying vegetation, under logs and stones, and in soil and caves. They vary in dietary habits; some feed on vegetation whereas others eat other small soil-inhabiting arthropods. Sperm transfer is indirect, with males producing stalked spermatophores which the female takes up without courtship. Eggs are deposited in the soil. They can be long-lived, with the life span requiring 2–3 years in some species. The number of molts is considerable; up to 20 molts per year are known.

► Mayflies

Direct Flight Muscles

Muscles that connect directly to the wing bases and power the wings directly.

Directive Coloration

Colors or marks on potential prey organisms that divert the predator from the more vital regions of an organism. Thus, for example, a bird might be induced to grasp a butterfly in the wing region rather than the abdomen.

Direct Pests

Pests that inflict injury directly on the portion of the commodity that is harvested for sale.

Dirofilariasis

JAI K. NAYAR
University of Florida, Vero Beach, FL, USA

Dirofilariasis is a complex of veterinary diseases caused by nematodes (round worms) belonging to the phylum Nematoda, order Filarioidea, family Onchocercidae and genus *Dirofilaria*. The genus *Dirofilaria* is divided into two subgenera: *Dirofilaria* and *Nochtiella*. The subgenus *Dirofilaria* contains *Dirofilaria immitis* that causes canine cardiovascular disease (dog or canine heartworm disease) in dogs and dog like carnivores, cats, domestic ferrets, and rarely in humans causing pulmonary dirofilariasis. The subgenus *Nichtiella* contains *Dirofilaria repens* that occurs in dogs and cats, *D. tenuis* in raccoons, *D. ursi* in bears, and *D. striata* in bobcats and panthers. The first three species of *Dirofilaria* in the subgenus *Nochtiella* cause subcutaneous nodules in their vertebrate hosts and in humans. All parasites belonging to this family complete their development in two hosts. The vertebrate is the final host and the mosquito is the intermediate host/vector, except in *D. ursi* where the hosts/vectors are blackflies.

The distribution of *Dirofilaria immitis* is worldwide, thus canine or dog heartworm disease occurs all over the world, especially in tropical and temperate zones. In the United States, it was once limited to the south and southeast regions. However, the disease has spread and is now found in most regions of the United States and Canada, particularly where mosquitoes are prevalent. The distribution is influenced by a reservoir population of animals (usually dogs) that have adult worms in their hearts and microfilariae circulating in the blood, and a mosquito vector in which the early larval stages can develop to the infective larval stage. The distribution of parasites belonging to subgenus *Nochtiella* is more restricted, for example, *D. repens* occurs in Europe, Asia, Africa, and Mediterranean countries, *D. tenus* and *D. striata* occur in southeast U.S.A. and *D. ursi* occurs at the U.S.-Canadian border.

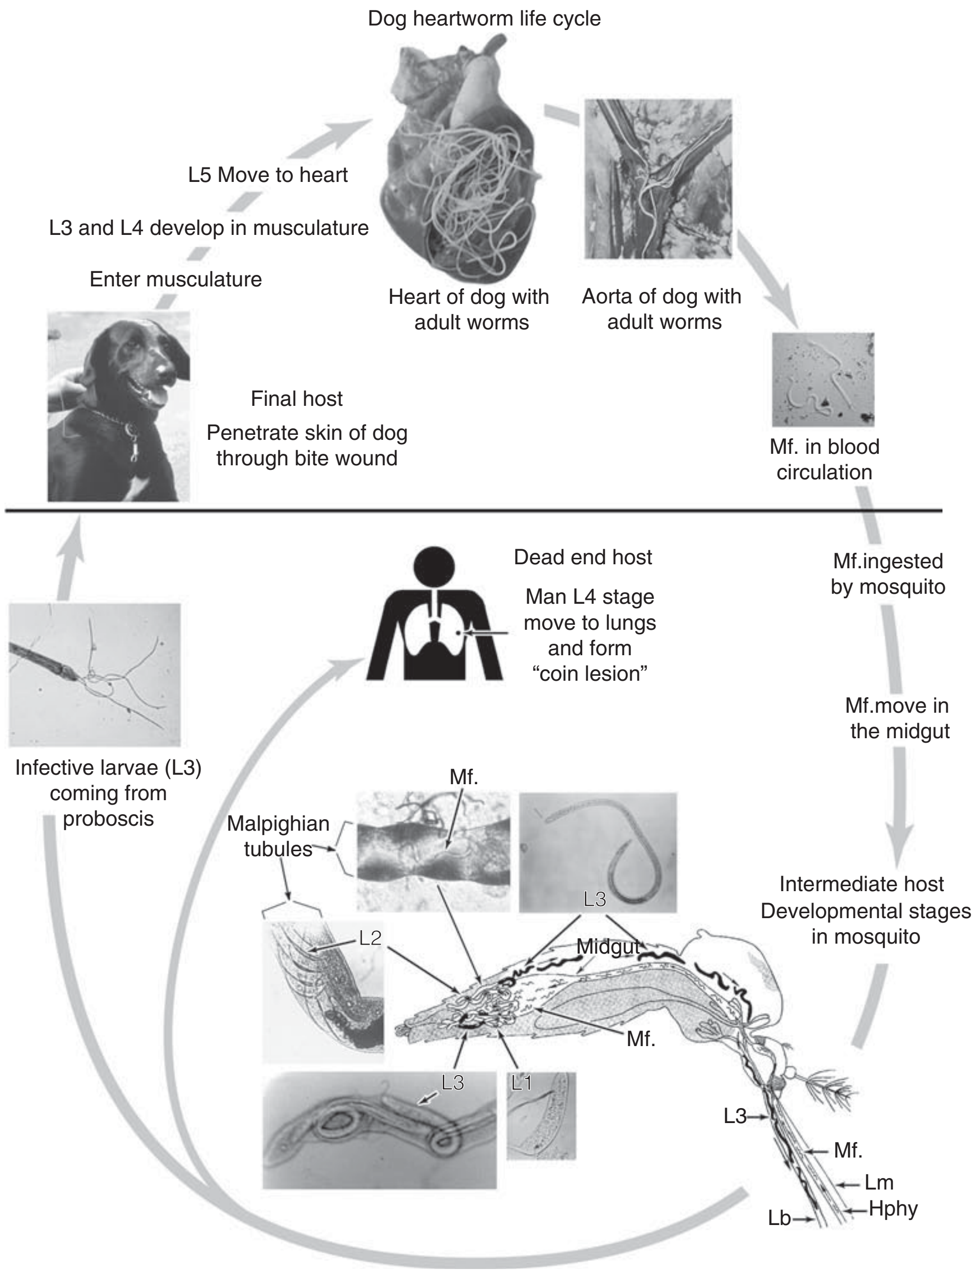
Dog heartworm disease (dirofilariasis) is a serious and potentially fatal disease in dogs and cats. In dogs and other carnivores, the adult worms normally reside in the heart and large adjacent vessels. Adult worms are long, slender and white. Males are 12–16 cm long and have a corkscrew tail, and females are 25–30 cm long. Adult worms cause disease by clogging the heart and major blood vessels leading from the heart. They interfere with the valve action in the heart. By clogging the main blood vessels, the parasite reduces the blood supply to other organs of the body, particularly the lungs, liver, and kidneys, leading to malfunction of these organs. Most dogs infected with heartworms do not show any signs of disease for as long as 2 years. Unfortunately, by the time signs are seen, the disease is well advanced. The signs of heartworm disease depend on the number of adult worms present, the location of the worms, the length of time the worms have been present, and the degree of damage to the heart, lungs, liver, and kidneys from the adult worms and the microfilariae. The most obvious signs are: a soft, dry, chronic cough, shortness of breath, weakness, nervousness, listlessness, and loss of stamina. All of these signs are most noticeable following exercise, when some dogs may even faint and die.

Once infected, a dog is infected for life. The sexually mature nematodes mate in the right ventricle of the heart and discharge unsheathed microfilariae into the bloodstream. Microfilariae are 290–330 μm long and 6–7 μm wide, with tapered anterior end and straight posterior end, without cephalic hooks. They cannot develop further in the dog, but can survive in the blood stream for up to 2–3 years. They circulate throughout the body but remain primarily in the small blood vessels and capillary beds. Because they are as wide as the small capillaries, they may block blood flow. The body tissues and cells being supplied by these capillaries are thus deprived of the nutrients and oxygen normally supplied by the blood. The lungs and liver are primarily affected and destruction of lung tissue that leads to coughing. Cirrhosis of the liver causes jaundice, anemia, and general weakness because this organ is essential in maintaining a healthy animal. The kidneys may also be affected and allow poisons to accumulate in the body.

These circulating microfilariae must be ingested by a mosquito (the vector) during blood-feeding on the infected dog before they can develop further. Soon after the blood meal, the microfilariae move from the mosquito's midgut to the Malpighian tubules where they become intracellular. At a temperature of about 27°C the microfilariae become immobile, shorten and thicken, and develop into the so-called "sausage form" larvae in about 4–5 days, with the first stage larvae continuing until a molt at about 8 days. During the second larval stage, the internal organs of the worm are formed. The second molt occurs at 11–12 days, resulting in the third stage (L3) (Fig. 50) of infective larvae that resemble miniature adults. During the next 2–3 days, they increase in length, break out of the Malpighian tubules, migrate to the hemocoel then move into the head capsule and accumulate in the labium (a mouthpart of the proboscis continuous with the hemocoel). The development in the mosquito can be as short as 10 days at 30°C or as long as 28 days at 18°C. Thus, in 2–3 weeks, microfilariae transform into infective larvae that are about 1300 μm long. As the infected mosquito feeds, the labium is bent back and L3 escape in a pool of hemolymph onto the skin. When the stylets are withdrawn, the L3 enter through the wound. Up to 10 to 12 L3 can be transmitted by a single mosquito. Further development of the infective larvae only takes place in the dog and related species after mosquitoes feed on the vertebrate host. Spread of the disease therefore coincides with the mosquito season. The number of dogs infected and the length of the mosquito season are directly correlated with the incidence of heartworm disease in any given area.

In the dog and other carnivores, infective larvae (L3) after penetrating the skin move in the subcutaneous tissue and molt to L4 in about 10 days post infection. The L4 migrate to muscle bundles (fascial planes, muscle sheaths) and start to grow during the next 60 days and then molt to L5. The L5 migrate through venule walls by 70 days post-infection and are carried through the right ventricle of heart to pulmonary arterioles, most of them arriving there by 3–4 months post-infection. L5 mature to adults after migrating to the right ventricle and pulmonary trunk. If both sexes are present, they mate and the female can produce microfilariae after approximately 6 months post-infection, thereby completing the life cycle. These females can continue producing microfilariae for 5–7 years, which can survive for about 2 years in the blood circulation.

It takes a number of years before dogs show outward signs of infection. Consequently, the disease is diagnosed mostly in 4–8 year old dogs. The disease is seldom diagnosed in a dog under 1 year of age because the larvae take up to 7 months to mature following establishment of infection in a dog. In endemic areas, the average worm burden in the dog is about 15. High worm burdens



Dirofilariasis, Figure 50 Life cycle of dog heartworm (*Dirofilaria immitis*). Stages of filarial worm in dog: L3 = third stage larvae and L4 = fourth stage larvae in musculature and adult worms in heart and aorta of dog. Stages of filarial larvae in the mosquito: Mf = microfilariae, L1 = first stage larvae (sausage stage), L2 = second stage larvae, and L3 = third stage larvae in Malpighian tubules and microphotographs. Lm = labium, Lb = labrum, and Hphy = hypopharynx.

(more than 75) can be demonstrated in acute post-caval syndromes and chronic ascites from tricuspid valve dysfunction. Because of the increased resistance of most animals from repeated exposure to L3 over time, high worm burdens are most likely to occur in dogs which have not been exposed to any mosquitoes with L3 previously and are then bitten by many mosquitoes over a 3 month period. In that case, a dog may have as many as 300 worms.

Feline dirofilariasis is a complex pathological disease, which is principally subclinical. It produces among others, pulmonary vascular disorders with complications caused by clinically significant heart, lung, liver, kidney and thoracic duct diseases as well as CNS signs and symptoms. Generally, the common signs in acute and severe cases include fainting, dyspnea, seizure, intermittent vomiting, diarrhea, blindness, rapid heart beat or syncope. The signs of the chronic stage include stress intolerance, dyspnea, lethargy, loss of appetite, quilothorax, rapid heart beat, abdominal distention (in the case of congestive right heart failure), cyanosis, abnormal liver sounds, systolic murmur (extremely rare), occasional nose bleeding, urinary retention and ascitis. In endemic areas, the average worm burden in the cat is 1–3 worms. In cats, adult worms live for approximately 2 years and sometimes produce very few microfilariae, if at all.

Dirofilaria immitis microfilariae can develop to the infective stage larvae in more than 100 species of mosquitoes, out of more than 3,000 species present worldwide, and these species are considered as potential vectors. In order to be a heartworm vector, besides being resistant to infection but yet susceptible enough to allow larval development, a mosquito species must feed on infected dogs, be well adapted to the region and be abundant and preferably multivoltine. However, about 25 mosquito species mostly belonging to *Aedes* and *Culex* have been collected worldwide with developing larvae in their Malpighian tubules, hemocoel and mouthparts and they have been identified as natural vectors. These are: in North America – *Aedes canadensis*, *Ae. cantators*, *Ae. excrucians*, *Ae. sierrensis*, *Ae. sticticus*, *Ae. stimulans*, *Ae. sollicitans*, *Ae. taeniorhynchus*, *Ae. trivittatus*, *Ae. vexans*, *Culex nigripalpus*, *Cx. quinquefasciatus*, *Cx. salinarius, Anopheles puntipennis,* and *Psorophora ferox*; in Australia – *Ae. annulipes*, *Ae. notoscriptus*, *Ae. vigilax*, *Cx. annulirostris*, and *Cx. quinquefasciatus*; in Japan – *Ae. albopictus*, *Ae. togoi*, and *Cx. quinquefasciatus*; in South Pacific – *Ae. pseudoscutellaris*, *Cx. annulirostris*, and *Cx. quinquefasciatus*.

Dirofilaria immitis is also an occasional parasite of humans, causing pulmonary dirofilariasis. Because infective larvae develop to a limited extent in humans, the latter are referred to as the dead end hosts. The filarial nematodes enter the subcutaneous tissue after a bite from an infected mosquito, develop to the L4 stage, and travel to the right ventricle where they die and embolize the pulmonary vasculature, causing small pulmonary infarctions that subsequently appear as solitary nodules. Although these nodules are usually identified incidentally by chest radiography in asymptomatic patients, the lesions are generally presumed to be neoplastic. The nodules of dirofilariasis are usually round called "coin lesions" in the lungs but sometimes they are dumbbell-shaped. Microscopically, the nodules are granulomas composed of central coagulation necrosis and peripheral fibrosis with round cell infiltration, histiocytes, and multinucleated giant cells. Because these nodules are difficult to be differentiated from primary or metastatic lung carcinomas and the inflammation exists around the nodule, the nodule should be removed surgically. During the last 40 years, approximately 150 cases of human pulmonary dirofilariasis have been reported worldwide.

Three other parasites that cause dirofilariasis, belong to subgenus *Nochtiella,* produce subcutaneous nodules which may be migratory both in their vertebrate hosts and in humans, are *D. repens*, *D. tenuis* and *D. ursi*.

Dirofilaria repens, a parasite of the subcutaneous tissues of dogs and cats, is found in Europe, Asia, and Africa, especially in Mediterranean countries, Russia and Japan. Human infections by *D. repens* are being reported with increasing frequency in all these countries. Both males and females of this parasite are about half the size of *D. immitis*, the females measuring 100–170 mm in length and 0.46–0.65 mm in width and males 50–70 mm in length and 0.37–0.45 mm in width with two to six preanal papillae to the right of the anus and four to five to the left. The microfilariae of *D. repens* occur in the subcutaenous lymph spaces and in the peripheral blood. The microfilariae range in length from 268–360 μm and overlap in size that reported for *D. immitis*. They can be distinguished from *D. immitis* microfilariae by the relative positions of somatic structures such as nerve ring, the excretory cell, the G1 cell, and the anal space along the length of the microfilariae. Development of *D. repens* in mosquitoes follows a similar pattern as that of *D. immitis* in mosquitoes. However, the mosquitoes that support development of the larval stages of these parasites belong to *Aedes* and *Culex* species found in Europe, Asia, and Africa.

Dirofilaria tenuis is a parasite of the subcutaneous tissues of raccoons in the southeastern United States but humans are also infected. More than 20 human cases have been reported from Florida and most of them were from southern Florida. The microfilariae are 370 ± 9 μm long and ca. 7 μm wide and are comparable in size to *D. striata* microfilariae. Development of *D. tenuis* in mosquitoes follows a similar pattern as that of *D. immitis*. The natural vectors of *D. tenuis* in south Florida is *Ae. taeniorhynchus*, however, several other species of mosquitoes, such as *An. quadrimaculatus*, *Ae. triseriatus*, *Psorophora columbiae* and *Ps. Ferox*, are considered potential vectors.

Dirofilaria species causing subcutaneous infections in vertebrates and humans are identified primarily on the basis of structure and arrangement of the ridges. Longitudinal ridges of adult *D. repens* are conspicuous and sharp, separated by a space three to four times the width of the ridge itself. *Dirofilaria tenuis* has a distinctive pattern of low, rounded ridges in a branching network with spaces appearing narrower than the ridges themselves. The cuticle of *D. immitis* is smooth with ridges occurring only on the ventral aspect of the caudal extremity of the male worm.

Dirofilaria ursi is a parasite of the peritracheal and perirenal tissues of bears in North America and Japan and Russia, and rarely of dogs in these areas. Human infections with *D. ursi* causing subcutaneous nodules have been reported in the states and provinces along the U.S.-Canadian border. The intermediate host of *D. ursi* is the blackfly, *Simulium venustum* and perhaps other simuliids in Canada. Development of *D. ursi* microfilariae in simuliids is similar to that observed for other *Dirofilaria* species in mosquitoes, i.e., all species of *Dirofilaria* complete their development in the Malphighian tubules of their vector.

Dirofilaria striata is found in panthers and bobcats in Florida. The adults of this species occur in the intermuscular fascia or free in the peritoneal cavity. The females of *D. striata* are 25–28 cm long and males are 8–9 cm wide. Microfilariae of *D. striata* are significantly longer and more slender than those of *D. immitis* (348 μm × 4–5 μm vs. 299 μm × 5–6.5 μm) and exhibit within the cephalic space two prominent nuclei separated from the main body of the nuclear column. *Dirofilaria striata* has been reported as an accidental parasite of dogs in Florida and adults have been recovered from deep intramuscular fascia of dogs. The potential mosquito vectors of *D. striata* in south Florida are *Ae. taeniorhynchus*, *An. quadrimaculatus*, *Cx. nigripalpus* and *Cx. quinquefasciatus*.

Since canine cardiovascular dirofilariasis is primarily a disease of dogs and cats that are household pets, several diagnostic and preventive measures are used by veterinarians. Canine dirofilariasis can not be controlled unless the mosquito populations are completely controlled. Several diagnostic tests to determine if cats and dogs are infected are as follows: (i) demonstration of the microfilariae of *D. immitis* in a blood sample by concentration techniques, (ii) the detection of circulating microfilarial antigen, (iii) thoracic radiographs can be a screening tool for dogs and cats with suggestive clinical signs of heartworm disease, and (iv) echocardiograms are diagnostic with the typical "double parallel" white lines are noted in the pulmonary arteries or right ventricles of dogs or cats. Routine therapy included: (i) Pre-therapy diagnostic to determine sub-clinical disease, especially of the liver and kidney. (ii) Adulticidal therapy (Immiticide®, Caparsolate®, Filaramide®) to eliminate mature worms. (iii) A rest period of 4–6 weeks to allow the animal to recover from the lung injury associated with worm death. (iv) Microfilaricidal therapy (Heartgard®, Interceptor®) if required. (v) Post-Microfilaricidal check. (vi) Antigen test to determine success of adulticidal therapy. (vii) Preventative medications (Filaribits®, Heartgard®, Interceptor®). Information on all these aspects can be obtained from your practicing local veterinarians.

Discal Cell

A cell, usually enlarged, that is found near the center of the wing.

Discrete Generations

A series of generations in which one generation is completed before the next commences. This is common place for insects with a single generation per year, separated by a period of diapause. With insects having more than one generation per year, however, it is common to have overlapping generations, wherein the early life stages of the succeeding generation overlap the final stages of the preceding generation.

Disease

A process that represents the response of the body to injury or insult. A pathogen is not a disease, but it may cause one.

Diseases of Grasshoppers and Locusts

MARK S. GOETTEL
Agriculture and Agri-Food Canada, Lethbridge, AB, Canada

The importance of grasshoppers and locusts as pests, and the increased concerns over the deleterious environmental and health effects of using chemical insecticides to control their outbreaks, recently has drawn much attention to the possibility of exploiting their pathogens as microbial control agents. Disease often is responsible for suppression of grasshopper and locust outbreaks. Disease causing agents include bacteria, fungi, protozoa and viruses.

Bacteria

Two species of bacteria, *Serratia marcescens* Bizio and *Pseudomonas aeruginosa* (Schroeter) Migula have been implicated in disease epizootics observed in field populations and laboratory-reared locusts and grasshoppers. These bacteria infect their host after being ingested and often spread rapidly in laboratory colonies. However, their role in the natural suppression of grasshopper and locust populations remains unclear.

Bacterial pathogens of locusts and grasshoppers received considerable attention as potential microbial control agents in the early 1900s and in the 1950s. Several attempts were made to use these bacteria to manage grasshoppers and locusts, but these studies never proceeded beyond the stage of surveys and laboratory trials. Concerns over human and environmental safety at the time, as well as product stability, led to the termination of this work.

The commercial success of certain serovars of *Bacillus thuringiensis* as microbial control agents of numerous insect pests has spawned several attempts to isolate related spore-forming bacteria pathogenic to locusts and grasshoppers. Although some toxins, such as the β-exotoxin of *B. thuringiensis*, have a broad activity against a large number of insects, including locusts and grasshoppers, strains producing more species-specific δ-endotoxins highly active against orthopterans have not been discovered to date. However, the continued discovery of new strains of *B. thuringiensis* with specific activity against a broader range of pests and the recent commercial development of a new species of *Serratia* (*Serratia entomophila*) for control of grass grubs provides incentive to continue the search for orthoperan-active bacteria. But at the moment, there is no evidence of naturally occurring bacterial species or strains that would warrant exploitation for locust or grasshopper control.

Fungi

Unlike most other pathogens which must be ingested to cause disease, entomopathogenic fungi generally enter their host via the external cuticle. A handful of species are common in grasshoppers and locusts and these include *Beauveria bassiana* (Balsamo) Vuillemin, *Entomophaga grylli* (Fresenius) Batko species complex, *Metarhizium anisopliae* (Metschnikoff) Sorokin, *Metarhizium anisopliae* var *acridum* (syn = *Metarhizium flavoviride*) and *Sorosporella* spp.

Beauveria bassiana

There are numerous records of *B. bassiana* infecting grasshoppers and locusts and it has been documented causing epizootics amongst locust populations in Africa. The fungus is ubiquitous and infects a wide variety of insects from most orders. Aerial conidia, the infective spore stage of the fungus, adhere to the cuticle of the host, germinate, penetrate through the external cuticle, rapidly proliferate within the host body via hyphal growth and production of yeast-like hyphal bodies or blastospores, killing the host within 4–10 days of infection. Soon after the host dies, and under appropriate moisture conditions, the fungus emerges through the body wall and quickly sporulates, producing numerous conidia on the host surface, often appearing like a white powder completely engulfing the host cadaver.

The fungus has been commercially developed and registered as a microbial control agent against numerous pest insects throughout the world. Field trials with inundative applications of an American isolate against grasshoppers in North America and Africa produced mixed results. Several studies have demonstrated that infected grasshoppers and locusts are able to escape lethal infection by basking in the sun, thereby increasing their body temperature above the thermal threshold for growth of the fungus (see below).

Entomophaga grylli Complex

Fungi in the *Entomophaga grylli* complex are obligate grasshopper pathogens responsible for numerous widespread epizootics worldwide, and are regarded as a key factor in regulating many grasshopper populations. This complex contains several pathotypes that vary in their ability to produce both conidia and resting spores within a single season. The fungus overwinters as resting spores in the soil. A portion of the resting spores germinate each spring, while others remain dormant for two or more seasons. Germinating resting spores produce specialized spores which are forcibly ejected from the soil into the lower canopy where grasshoppers encounter them. Once these spores contact a grasshopper host they germinate, penetrating the body wall, and the fungus then rapidly proliferates within the grasshopper body cavity as protoplastic bodies. Approximately 1 week after initial exposure, infected grasshoppers climb to the top of the plant canopy where they die grasping firmly onto the plant substrate. For this reason, this disease is often referred to as the "summit disease." Depending on the pathotype, at this point, either resting spores are exclusively produced and the insect eventually falls to the ground, the cadaver disintegrates and the resting spores are released into the soil, or alternatively, the cadaver produces either resting spores or aerial conidia, which are responsible for within-season epizootic development.

Natural epizootics of the fungus often produce high levels of mortality, and have been credited for ending grasshopper outbreaks in many North American grasshopper species. There have been several attempts at inundative application of conidia in an effort to induce epizootics (inundative microbial control), however, none were able to achieve satisfactory results. The most important limiting factors were lack of adequate mass production and application techniques and the specific environmental requirements of the fungus for survival and infectivity. Attempts at inoculative introduction (classical biological control) also were not successful. Introductions of North American isolates into Australia and vice versa failed to establish, although the introductions into North America initially were followed by population declines of key pest species. These initial studies suggest that these pathogens have potential for use in biological control, however, further studies are required.

Metarhizium anisopliae var *acridum*

There are records of *M. anisopliae* var *acridum* (formally referred to as *Metarhizium flavoviride*) from grasshoppers in Africa, Australia and Brazil, and natural epizootics have been documented in Africa. The mode of pathogenesis and infection cycle is essentially the same as described above for *B. bassiana*, except that cadavers are covered with a powdery covering that is dark olive green rather than white.

The fungus has been the subject of much research in the last decade and several commercial products for grasshopper and locust control now are available in Africa and Australia. A multinationally funded project, LUBILOSA, spearheaded by CABI and the International Institute of Tropical Agriculture, resulted in the discovery and development of this fungus as a commercial microbial insecticide (Green Muscle™). During this project, many improvements in the formulation, mass production and application of this fungus were made. These developments have resulted in a commercial formulation that can be stored up to 4 years that can be applied through Ultra Low Volume (ULV) application in an oil formulation, and that also offers the conidia some protection from the sun's harmful rays.

Protozoa

Protozoans that infect grasshoppers are mainly microsporidians, but certain Amoebida, Eugregarina, Neogregarina and Ciliophora also are known from grasshoppers. Among the Microsporidia, *Heterovesicula cowani* Lang et al., *Johenrea locustae* Lange et al., *Nosema acridophagus* Henry, *N. cuneatum* Henry, *N. locustae* Canning, *N. montanae* Wang et al., *N. pyrgomorphae* Toguebaye et al., and *Perezia dicroplusae* have been described. No doubt, many more await discovery and description.

The most studied microsporidian of grasshoppers has been *N. locustae*, and it was the basis for the first microbial pesticide (Nolobait™) developed against grasshoppers and locusts. Ingested spores germinate in the gut whereby they release a binucleate sporoplasm into a host cell through quickly extruded polar filaments. Sporoplasms subsequently spread to and replicate in the fat body, eventually depleting the host of its fat reserves.

Spores are mass produced *in vivo* in grasshoppers. Because the spores need to be ingested to initiate disease, commercial formulations are formulated on a wheat bran bait carrier. Extensive field-testing has taken place in North America, Argentina, China and Africa. Although at times application of spores has resulted in considerable decline in grasshopper or locust populations with subsequent carry over in treated areas, in other trials such impacts were not observed. Application of a pathogen such as *N. locustae* can be expected to result in sublethal effects such as delayed development, lower reproduction and reduced feeding. Unfortunately, many assessments measured only short term impact of *N. locustae* rather than long term benefits. Several other microsporidians with greater virulence than *N. locustae*, such as *N. cuneatum*, may better fit the microbial insecticide paradigm. There is also great potential of using microsporidians in the classical sense (inoculative releases) which await exploration.

Viruses

Entomopoxviruses are the only DNA viruses that have been found naturally infecting grasshoppers and locusts. Nearly 15 grasshopper and locust entomopoxviruses have been reported. The most extensively studied among these has been the *Melanoplus sanguinipes* EPV (MsEPV). Although the precise mode of infection of grasshopper viruses has not been studied in detail, pathogenesis probably is similar to that of other entomopoxviruses; ingested viral occlusion bodies break down in the alkaline medium of the gut, releasing the individual virions which then infect midgut cells, presumably replicate, and progeny virus is then released into the hemocoel, eventually infecting the fat body tissues. Virions replicate within the fat body cells and are packaged in proteinaceous crystalline matrices, the occlusion bodies.

Effects of infection vary according to dosage received. In heavily infected grasshopper populations, death can occur in two distinct modes. An initial mortality takes place between 2 and 10 days post exposure, subsides and then mortality increases again during the second mode, 14 days after initial exposure. Occlusion bodies are produced only in grasshoppers dying during the second mode. Infected grasshoppers that escape the early mortality experience a profoundly longer development period, and few develop to the adult stage. During this delayed development period, there is a concomitant reduction of feeding. Prevalence rates of the virus in field populations are extremely low and very little is known about its epizootiology.

Field evaluations on the potential of using grasshopper entomopoxviruses as microbial insecticides were carried out in the United States. The virus was mass produced by injecting grasshoppers and incubating them in an insectary. Infected cadavers were crushed and formulated in a starch granule and then dispersed in the field. Maximum prevalence levels in treated fields reached 23%, however, it is speculated that due to grasshopper dispersal between experimental plots, this may be a rather conservative estimate. At this time, the *in vivo* production is cost prohibitive and feasibility of developing these viruses as grasshopper control products remain questionable.

Grasshopper Thermal Ecology

Locusts and grasshoppers optimize their body temperature through behavioral responses, such as basking in the sun. Recent research has demonstrated that individuals infected with a pathogen will attempt to increase their temperature even further, a phenomenon termed "behavioral fever." Even though behavioral fever has been demonstrated in ectotherms from various taxa in response to infection by a variety of pathogens, to date only *Nosema* and fungi have been found to elicit such behavioral fevers in grasshoppers and locusts. Behavioral fever can result in augmentation in body temperature to the vicinity of 40°C, which usually is well above the upper limits for growth of most pathogens. Furthermore, behavioral fever may enhance the insect immune response by stimulating the production of hemocytes. Consequently, speed of kill and overall mortality can be affected drastically, depending on the environmental conditions prevalent that may or may not allow optimal thermoregulation (e.g., sun, cloud, wind, rain). In microbial control of grasshoppers and locusts, it may be possible to overcome such constraints through application of pathogen cocktails containing pathogens or pathotypes selected for a wide range of thermal possibilities according to the environment that is being treated (e.g., day length and day/night temperatures).

Disjunct Populations

The geographical distribution of a species (or other taxon) consists of widely separated populations.

Disk

A soil cultivator made up of many circular blades that act to break up the soil into smaller aggregates.

Dispersal

Displacement to a new habitat. Dispersal usually is multidirectional and passive, taking advantage of wind currents.

The spatial patterning of individuals in a population in their habitat. This pattern can be broadly described as uniform, random or, most commonly, aggregated.

Dispersion

Dispersion or distribution is a spatial property that can be quantified by explicit spatial indices, or more typically by probability models (e.g., Poisson, Negative-binomial) or empirical models (e.g. Taylor's power law). The measurement of dispersion is dependent on the sample unit size and population density. Dispersion is an important element in the development of a sampling plan.

► Sampling Arthropods

Disruptive Coloration

Color patterns on an animal that confer protection by obscuring the outline of the animal. Typically it consists of strongly contrasting colors. The classic example is the black and white stripes of zebra. In insects, it may be manifested in stripes or bands, especially on larvae, on in spotted or blotchy patterns.

Distal

Pertaining to the part of an appendage furthest from the body.

Distiproboscis

The distal third of the proboscis in muscoid flies; this is the labellum.

Ditomyiidae

A family of flies (order Diptera).

► Flies

Diuretic Hormones

Neuropeptide hormones that promote fluid formation and rapid excretion by Malpighian tubules. In *Rhodnius*, the hormone is released from abdominal nerves associated with the mesothoracic ganglion, but this is not the case with all insects.

Diurnal

Organisms in which the period of activity occurs during daylight hours.

Diverticulum

An invagination or extension of the wall of the alimentary canal with the distal portion closed. Diverticula, when present, typically are associated with the anterior region of the alimentary canal. They are useful for food storage, and especially important when an insect takes infrequent but large meals.

Dixid Midges

Members of the family Dixidae (order Diptera).

► Flies

Dixidae

A family of flies (order Diptera). They commonly are known as dixid midges.

► Flies

DNA

Deoxyribonucleic acid, the genetic molecule.

DNA Probe

Also called a gene probe or genetic probe. Short, specific (complementary to the desired DNA sequence) artificially produced segments of labeled DNA are used to combine with and detect the presence of a specific gene or DNA sequence within the chromosome. The presence of this labeled probe usually is detected visually.

DNAse

Deoxyribonuclease, an enzyme that degrades DNA.

Dobsonflies

Some members of the family Corydalidae (order Megaloptera).

► Alderflies and Dobsonflies

Dobzhansky, Theodosius Grigorievich

Theodosius Dobzhansky was born in Nemirov, Ukraine, on January 25, 1900. While he was still a boy, he collected butterflies and intended to study the systematics of Coccinellidae once he had an education in biology. His university education was in Kiev, where he became an instructor in 1921–1924, and began Mendelian research on *Drosophila* and field research on Coccinellidae. Then he moved to Russia, and taught at the University of Leningrad in 1924–1927 while continuing research on *Drosophila* and Coccinellidae. Then, he moved to the USA. For a year, he worked at Columbia University. He became a researcher

(1928–1940) at the California Institute of Technology where he published his groundbreaking book (1937) "Genetics and the origin of species." He moved (1940–1962) back to Columbia University, then (1962–1971) to Rockefeller University, and finally (1971–1975) to the University of California at Davis. His contribution was to demonstrate that there is much genetic variability in a population, and that this includes many potentially lethal genes. Such genes, however, confer versatility when the population is exposed to environmental change [this theme is reiterated in the work of Edmund Brisco Ford, see below]. His work on population evolution in *Drosophila* fruit flies and humans gave the evidence that linked Darwin's theory with Mendel's law of heredity. He died on December 18, 1975.

Dockage

Reduction in value of a crop or product due to damage, as may occur when infested with insects before or after harvest.

Dog Heartworm

A mosquito-transmitted cardiovascular disease of dogs caused by infection with the nematode *Dirofilaria immitis*.

► Dirofilariasis

Dolabellopsocidae

A family of psocids (order Psocoptera).

► Bark-Lice, Book-Lice or Psocids

Dolichopodidae

A family of flies (order Diptera). They commonly are known as long-legged flies.

► Flies
► Long-legged Flies

Dominance Hierarchy

The physical domination of some individual by others, usually for a long period of time.

Dominant

A gene is dominant when it produces the same phenotype whether it is heterozygous or homozygous. The trait is expressed even if only one copy of the gene is present in the genome.

Dominant Species

A species that makes up a large proportion of the assemblage, or community, biomass or numbers.

Donisthorpe, Horace St. John Kelly

Horace Donisthorpe was born in 1870 and lived in various places in southern England, mainly London suburbs. He was an amateur entomologist, in the sense that amateur means he was not paid for entomological studies. He joined the Entomological Society of London in 1891 (and served in various capacities) and the Zoological Society. His major interests were in beetles, ants, and the fauna living in ant and bird nests. He was an inveterate insect collector with a curious philosophy that the only specimens he would put in his collection were those he had collected himself. His publications range from numerous small notes to books, and the total list amounts to about 800 items. His major works were (1913) a supplementary volume (VI) to Fowler's "Coleoptera of the British Islands," (1915) "British ants," and (1927) "Guests of British ants." The first edition of "British ants" was privately published, and in its endpages has a list of the subscribers who bought copies; perhaps because the initial edition was small, a second edition was published in 1927. "Guests of British ants" is an account of the fauna, including even reptiles, found in ant nests. He died on April 22, 1951, in a hospital in the London area.

Dormant

To become inactive during periods of cold weather.

Dormant Oil

An oil formulation that is applied to plants during the dormant season (usually winter) when the foliage is not present and thus not susceptible to injury (phytotoxicity). It is usually directed to small arthropods or their eggs, and apparently causes suffocation.

► Horticultural Oil

Dorsal

Referring to the upper surface.

Dorsal Diaphragm

A thin cellular layer beneath the heart that aids in blood flow. It is an incomplete wall of muscle and thin cells that separates the region around the dorsal vessel from the rest of the hemocoel.

Dorsal Longitudinal Muscles

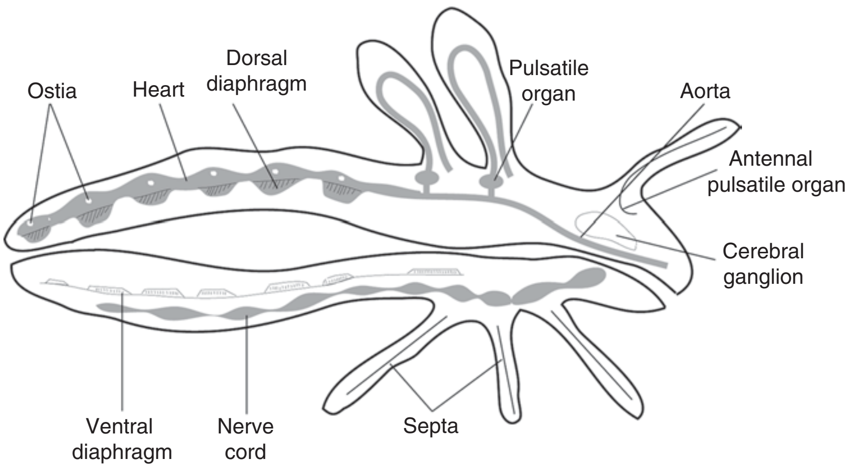
Longitudinal muscles located dorsally in insect thoracic segments that power the downstroke of wings during insect flight. These are indirect flight muscles and are not attached to the wings. They are attached to apodemes at the anterior and posterior of the meso- and metathorax. When contracted, the dorsal longitudinal muscles slightly arch the thorax, causing he wings to move downward.

► Dorsoventral Muscles

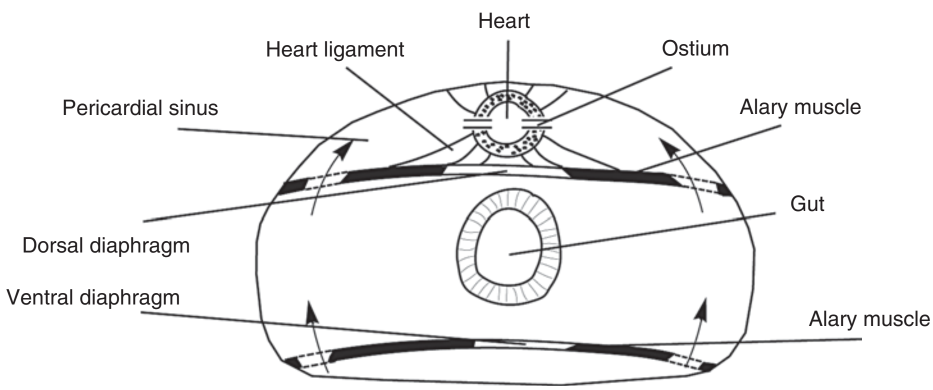
Dorsal Vessel: Heart and Aorta

JAMES L. NATION
University of Florida, Gainesville, FL, USA

The circulatory system of insects is an open system, with the hemolymph pumped by a dorsal vessel that usually (Figs. 51–53) opens into the head. From the head the hemolymph simply percolates backward, bathing all the internal organs, eventually completing the circuit by entering the dorsal vessel through small openings, the ostia. The vessel is often described as consisting of two parts, the "heart" and the "aorta." These terms are borrowed from vertebrate cardiology, but they have little physiological meaning in describing the dorsal vessel of insects. The abdominal portion of the dorsal vessel is often referred to as the heart while the thoracic portion is the aorta. The major criteria for deciding when the heart ends and the aorta begins are the presence of alary muscles and incurrent ostia in the heart portion. The aorta does not have alary muscles and lacks incurrent ostia, but it may have excurrent ostia. Both alary muscles and incurrent ostia occur in the thoracic portion of the vessel in many Orthoptera, and nearly the entire length of the vessel can be called the heart, with a short aorta leading into the head. Typically the dorsal vessel is a simple tube, but in Orthoptera and Dictyoptera the heart has several pairs (four pairs in *Blaberus* sp.) of long diverticula passing



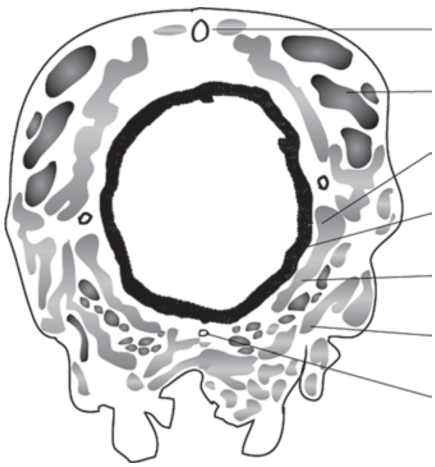
Dorsal Vessel: Heart and Aorta, Figure 51 Diagram of the components of the insect circulatory system; hemolymph moves through the heart and aorta to the head, filtering back through the body cavity and back into the heart via the ostia. Pulsatile organs assist in moving hemolymph through the appendages, especially the wings (adapted from Chapman, The insects: structure and function).



Dorsal Vessel: Heart and Aorta, Figure 52 Cross section of an insect abdomen, showing components of the insect circulatory system and direction of hemolymph flow (adapted from Evans, Insect biology).

out and branching around the laterally located tergo-sternal muscles and ending in fat body tissue. The posterior end of the heart is usually closed, but it is open in immatures of craneflies (Tipulidae), and in Ephemeroptera (mayflies) it divides into three branches, with one passing into each of the three caudal filaments.

In the abdomen, the dorsal vessel (Fig. 53) is located just beneath the tergal cuticle, but in the thorax of some insects portions may be helical (honeybee adults) or meander in long loops through the thoracic musculature in Lepidoptera and Coleoptera adults. The flow of hemolymph in some insects aids in thermoregulation, with thoracic loops acting as a heat exchanger to pick up heat from the thoracic musculature. Some insects can slow down the entry of relatively "cool" hemolymph from the abdomen so that the temperature of the thorax can be kept high for flight on cooler days. Many moths "shiver" by contracting the flight muscles before taking flight on cool days, utilizing the heat generated by muscle action to provide



Dorsal Vessel: Heart and Aorta, Figure 53 Cross section of a caterpillar showing the location of the dorsal vessel (here labeled heart) (adapted from Chapman, The insects: structure and function).

a favorable thoracic temperature for flight. Conversely, the thorax may need cooling on very hot days when muscle action creates too much thoracic heat. At high environmental temperatures large-bodied adult Lepidoptera such as *Manduca sexta* generate too much heat in the thorax, and the abdomen acts as a cooling radiator as hemolymph is allowed to flow rapidly to the abdomen which is less well insulated with scales than is the thorax. Heat is dissipated to the air surrounding the abdomen, and the cooler hemolymph is pumped back to the thorax by the heart.

Dorsoventral Muscles

Muscles running from the dorsal to the ventral components of thoracic segments that power the upstroke of wings during insect flight. These are indirect flight muscles, and they are not attached directly to the wings.

► Dorsal Longitudinal Muscles

Dorsum

The anatomical upper surface of a body; opposite of ventral. The legs are considered to be associated with the lower or ventral surface, and the dorsum is the opposite surface, the top of the head and the "back" of the thorax and abdomen.

Double-Eye Moths (Lepidoptera: Amphitheridae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

Double-eye moths, family Amphitheridae, are an unusual and small family of mostly tropical moths, totaling 57 species, mostly Indo-Australian (one genus occurs in Europe and another in South America). The family is part of the superfamily Tineoidea, in the section Tineina, subsection Tineina, of the division Ditrysia. Adults small (11–22 mm wingspan), with head rough-scaled and eye usually divided; haustellum naked; maxillary palpi 1-segmented. Maculation is colorful and iridescent or duller and pale, and variously marked. Adults active diurnally. Larvae are leafminers, becoming leaf skeletonizers in later instars; host records are mostly in Betulaceae and Aceraceae. The family has been erroneously called Roeslerstammiidae, based on the single European genus, *Roeslerstammia*, named after the Austrian lepidopterist Joseph E. Fischer von Röslerstamm (1787–1866).

Double Sampling

A sampling approach in which an initial sample (usually small) is drawn and used to determined the necessary sample size for a subsequent sample within the same time period.

► Sampling Arthropods

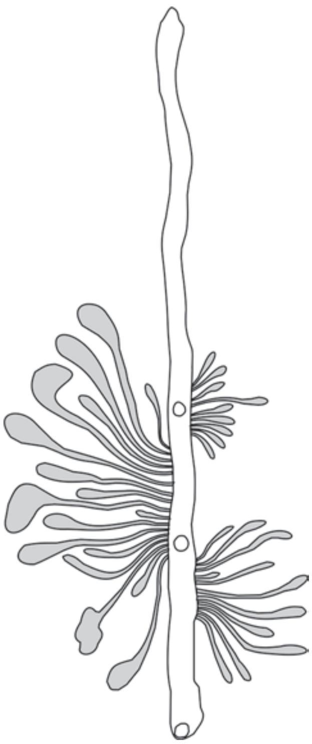
Douglas-Fir Beetle, *Dendroctonus pseudotsugae* Hopkins (Coleoptera: Curculionidae, Scolytinae)

JOSE F. NEGRON
USDA Forest Service, Ft. Collins, CO, USA

The Douglas-fir beetle, *Dendroctonus pseudotsugae*, is a bark beetle that attacks and can cause extensive mortality of its host Douglas-fir, *Pseudotsuga menziesii*, throughout most of its range in British Columbia, the western United States, and south to Mexico. The insect can also attack and reproduce in downed western larch, *Larix occidentalis* and subalpine larch, *L. laricina*, but is not able to complete development on standing larch trees. Western hemlock, *Tsuga heterophylla,* is also reported as a host. Just like with other tree-killing bark beetles, tree mortality results when the insects utilize the phloem of the tree for habitat and nourishment which results in girdling of the tree disrupting the translocation of nutrients. As the tree succumbs to the attack it changes in coloration within a year to a light yellow then to a bright orange before the needles begin to drop. The insect also inoculates attacked trees with blue-stain fungi *Ophiostoma pseudotsugae* and *Leptographium abietinum*, which may assist the insect in overcoming tree defenses.

Under endemic population levels the insect infests scattered trees downed by windstorms or stressed by root disease, defoliation, or fire injury. As populations increase healthy trees can be killed from small groups consisting of a few trees to groups of hundreds of trees. Epidemics can be quite devastating, but they usually only last about 4 years. Initial symptoms of attack include an accumulation of brown-reddish boring dust at the base of the tree and in bark crevices. Resin flow is also often observed, but not always, as it drains from attacks higher in the tree. Attacks are not always successful as the tree is often able to repel the insects from entering the tree by the copious exudation of resin.

The Douglas-fir beetle has one generation per year. There is a variation in flight periodicity from year to year and from one location to another but the primary dispersal flight usually occurs in mid- to late spring. Colonization of new trees is mediated by chemical attractants. Females initiate attacks on new hosts and after mating with a single male, begin constructing an egg gallery (Fig. 54) by tunneling up in the phloem parallel to the grain of the wood. The males assist in gallery construction at first by clearing boring dust and frass at the beginning of the gallery and then helping pack the rest of the gallery with frass. The egg galleries are usually 20–25 cm in length. As the females construct the gallery they lay eggs in niches alternately on both sides of the gallery in clusters of 5–24 eggs. The eggs are white and about 1 mm in length. Eggs hatch in 7–21 days. The larvae are white, c-shaped, and legless with shiny light brown heads. There are four larval instars. Through the summer each larva constructs its own larval gallery leading away from the egg gallery at approximately a



Douglas-Fir Beetle, *Dendroctonus pseudotsugae* Hopkins (Coleoptera: Curculionidae, Scolytinae), Figure 54 **Douglas-fir beetle egg gallery (drawing by Joyce VanDeWater).**

Douglas-Fir Beetle, *Dendroctonus pseudotsugae* Hopkins (Coleoptera: Curculionidae, Scolytinae), Figure 55 **Douglas-fir beetle adult (drawing by Joyce VanDeWater).**

right angle, pupates in a chamber at the end of the gallery, and later transform into the adult. Pupation usually occurs by August with transformation into the adult stage occurring late August-September. As the larvae develop they spread out forming a fan-shaped pattern that is distinctive of this species of bark beetle. The adult is the primary overwintering stage although some larvae may also overwinter. Newly emerged adults (Fig. 55) are light brown but later become dark brown to black with reddish elytra. Older beetles darken with time and become completely black. Adults are stout, cylindrical beetles, 4–6 mm in length.

A number of natural enemies help regulate populations of the Douglas-fir beetle. The most notable include clerid beetle predators *Enoclerus sphegeus* and *Thanasimus undulatus*, the predatory fly *Metedera aldrichii*, parasitoid wasps in the genus *Coeloides* and various woodpeckers.

Infestations of Douglas-fir beetle occur most commonly in overmature stands, with high stocking, and a high proportion of Douglas-fir. The largest trees in the stands are preferred. In downed trees the insect prefers to attack the underside of the tree. Because insect populations may increase rapidly in downed trees, rapid removal of downed trees may help reduce populations. Maintaining vigorously growing stands with adequate stocking levels can help mitigate tree mortality.

Douglasiidae

A family of moths (order Lepidoptera). They commonly are known as douglas moths.

► Douglas Moths

► Butterflies and Moths

Douglas, John William

John Douglas was born in London on November 18, 1814. At the age of 15, he was the victim of a practical "joke" by a schoolfellow, who set alight his pocket full of firecrackers. His extensive burns kept him bedridden for 2 years and required numerous operations throughout his life. While he was bedridden, he turned to the study of botany and drew plant specimens, at which he became proficient. He found employment at Kew Botanical Garden for a few years, but his father obtained for him a better-paying job at the Customs House. He married in 1843. While at Kew, he began collecting insects, and in 1837 published his first entomological paper. Much of his work was directed to Lepidoptera. His major work, coauthored with John Scott, was perhaps "The British Hemiptera, Volume 1, Hemiptera-Heteroptera," published by the Ray Society. Additions and corrections to this work were published from time to time in Entomologist's Monthly Magazine, of which he became editor in 1874. He joined the Entomological Society of London and held several posts, becoming president in 1861. He died on August 28, 1905.

Douglas Moths (Lepidoptera: Douglasiidae)

JOHN B. HEPPNER

Florida State Collection of Arthropods, Gainesville, FL, USA

Douglas moths, family Douglasiidae, comprise only 28 known species, mostly Palearctic (20 sp.). The family is part of the superfamily Tineoidea, in the section Tineina, subsection Tineina, of the division Ditrysia. Adults minute to small (6–15 mm wingspan), with head smooth-scaled; haustellum naked; labial palpi short; maxillary palpi reduced, 1-segmented. Maculation dull with bands of gray or tan, with venation reduced (especially in the hindwings) and with long hindwing fingers. Adults are crepuscular or diurnal. Larvae are leafminers or borers in petioles or stems. Host plants are known in Boraginaceae, Labiatae, and Rosaceae. The family and nominate genus *Douglasia* are named after the British lepidopterist and hemipterist John W. Douglas (1814–1905).

Dragonflies

Certain members (suborder Anisoptera) of an order of insects (order Odonata).

► Dragonflies and Damselflies

Dragonflies and Damselflies (Odonata)

BORIS C. KONDRATIEFF
Colorado State University, Fort Collins, CO, USA

Adult dragonflies and damselflies are two of the most beautiful and better-known insects of world. Their kaleidoscope of colors and aerobatic abilities have fascinated people for many centuries, and much has been written about them. They are conspicuous members of most permanent lakes, ponds, and wetlands. Nymphs of many species are also found in lotic habitats. Nymphs of some species are found in water filled leaf axils of plants, moist leaf litter, and even brackish water. Some species also occur in temporary habitats. Two North American species (family Petaluridae) are found among wet leaves in seepage areas.

Adults are medium to large in size, having wingspans ranging from 20 to 115 mm. Local names that have been applied to this order include, mosquito hawk, devil's darning needle and horse stinger. The order name is Odonata, which means tooth, and refers to the large prominent jaws or mandibles of the adults.

Adult dragonflies (Fig. 56) are easily recognized by two pairs of membranous elongate wings with many veins, long abdomen, bristle-like antennae and large head occupied mostly by the compound eyes. The nymphs are unique as compared to all other insect immatures by having the lower lip (labium) modified into a grasping structure that is elbowed and can be folded. The order includes two distinctive suborders in both the adults and nymphs in North America, the dragonflies or Anisoptera, and the damselflies or Zygoptera. The only other suborder of Odonata, the Anisozygoptera, includes one family, the Epiophlebiidae. This subfamily has two species, one distributed through the islands of Japan and the other in the eastern Himalayas in Nepal. Dragonfly adults are distinguished by hind wings (Fig. 57) that are wider at the base than the front wings, the abdomen long and stout, and when at rest wings are held outstretched. Nymphs are recognized by a long or oval body, and no gill plates at the end of the abdomen (Fig. 57) (instead there are three short pointed structures). Adult damselflies have both the front and hind wing of the same shape and size, a long thin abdomen, and wings held "roof-like" over the body at rest. Damselfly nymphs have elongate and slender bodies and three flat, elongate gill plates at the apex of the abdomen.

All Odonata adults are predators of flying insects, often small flies, but also larger insects such as wasps, butterflies, and even other dragonflies or damselflies. They use the front legs as a "basket" to scoop their prey out of the air. Sometimes adults will pick prey off plants or other substrates. Dragonfly and damselfly nymphs are accomplished visual predators of almost anything they can overpower, including microcrustaceans, other aquatic insects, to tadpoles, and even fish. They use the unique lower lip or labium to grab the prey and bring it to their mouthparts for consumption. Nymphs are either climbers or crawlers stalking their prey or, sprawlers and burrowers ambushing their prey.

Dragonfly nymphs pump water in and out of a gill chamber inside the posterior portion of the abdomen. This type of "jet propulsion" can be easily observed in a pan of water. Damselfly nymphs have three flat gill plates at the apex of the abdomen, providing a larger surface area for oxygen diffusion.

About 5,500 species of Odonata are known from the world grouped in 28 families, of which eleven are recorded from North America. Approximately 440 species have been recorded from North American. A summary of the North American species can be located at the website http://www.afn.org/~iori/nalist.html. Additionally, many useful links to other Odonata websites can be found at http://www.ent.orst.edu/ore_dfly/links.html.

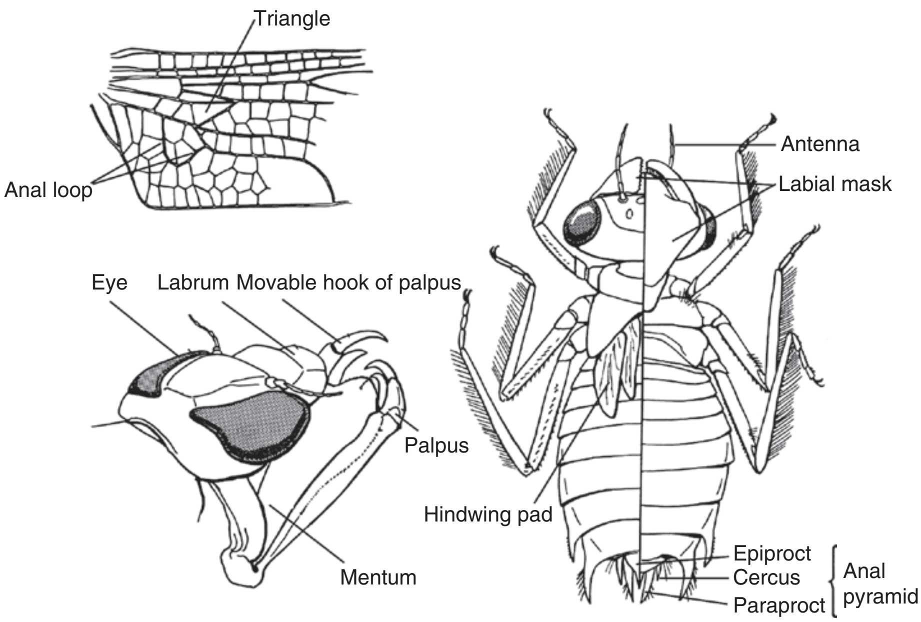
Family: Aeshnidae
Family: Gomphidae
Family: Neopetaliidae
Family: Cordulegastridae
Family: Corduliidae
Family: Libellulidae

A brief synopsis of common North American families is presented below.

Family Calopterygidae (Broad-winged Damselflies)

These well-known groups of familiar stream damselflies are known as the jewelwings (*Calopteryx*)



Dragonflies and Damselflies (Odonata), Figure 57 **Base of dragonfly hind wing (above, left) showing anal loop, a diagnostic character. Diagram of dragonfly nymph (right) showing dorsal (left portion) and ventral (right portion) perspective. Head of immature dragonfly showing the mouthparts (lower left), which are modified for grasping.**

and the rubyspots (*Hetaerina*). The large adults have metallic green bodies, the wings are not abruptly stalked at the base, and they have a skipping type of flight. The long-legged nymphs have a flat, pentagonal head, a very long first antennal segment, and are usually associated with instream aquatic plants, woody debris, and exposed roots of streamside plants. Species are characteristically associated with small to medium sized streams (*Calopteryx*) and larger rivers (*Hetaerina*). Only one generation per year is known for this group. Adults perch horizontally on twigs at the shore. The courtship behaviors of the adults have been extensively studied. The dancing flights are characteristic. Males have distinctive territorial display flights.

Family Lestidae (Spreadwinged Damselflies)

Nymphs of most species inhabit marshes and swamps, temporary standing water, and slow moving streams. The adults of these damselflies are easily recognized by their perching posture, at an oblique angle with partially spread wings. The long abdomen and petiolate part of the lower lip (prementum) easily distinguish the nymphs. One generation per year has been reported for the North American species. The two genera *Archilestes* and *Lestes* are widely distributed. *Archilestes* are usually found in streams of a slow current, even in isolated desert canyons of the Southwest.

Family Coenagrionidae (Narrowwinged or Pond Damselflies)

This family is the most successful of all damselflies in terms of the number of different species and types of aquatic habitats occupied. These are the red, orange, yellow and blue small adult damselflies commonly seen around ponds and various types of wetlands. The adults are known by such common names as sprites (genus *Nehalennia*), forktails (genus *Ischnura*), dancers (genus *Argia*), and bluets (genus *Enallagma*). Nymphs are usually associated with living or dead aquatic vegetation and debris. Nymphs of the genus Argia are often within rocky substrates of riffle reaches of streams. Egg-laying habits of the adult female are often astounding, with some species completely submerging and crawling about. Most species lay eggs just a few centimeters below the surface in plant material, both living and dead.

Family Aeshnidae (Darner Dragonflies)

The adults of these soaring dragonflies include the largest species in North America. Genera such as *Anax* (green darners), *Coryphaeschna* (pilot darners), and *Epiaeschna* (swamp darners) are the giants of this group. Many darners have long slender bodies resembling a darning needle, hence the name. The adults are easily identified by the large eyes meeting on top of the head, with the bodies brown, black and striped or spotted with blue. Nymphs are easily distinguished by the combination of a flat mentum and 6 or 7-segmented antennae. Adults are strong fliers, with some species migrating long distances. Often they feed in swarms. Nymphs are climbers, and are found among living and dead submerged plant material, including woody debris. Some species that occur in streams may be found clinging to submerged logs. Adult females insert eggs into underwater portions of plants. Nymphs may require 2–4 years to complete one generation.

Family Gomphidae (Clubtail Dragonflies)

Adults of clubtails get their name from the enlarged end of the abdomen in males of many species. Adults are beautifully camouflaged with brown or black marked with yellow or green. The eyes are widely spaced on top. Nymphs, like the family Aeshnidae, have a flat mentum, but the antennae are only 4-segmented. Adults usually perch on the ground horizontally and, unlike the darners, they do not soar but skulk around trees or make short distance flights in nearby fields, squatting on stones, sometimes branches of shrubs or on logs. Nymphs are burrowers in soft silt, sand or gravel of streams of all sizes or ponds. Nymphs of the huge dragonhunter, *Hagenius brevistylus*, are found among accumulations of leaves in quiet margins of streams. Most species require 2 years to complete their life cycle.

Family Libellulidae (Skimmer Dragonflies)

The skimmers include some of the most common dragonflies in North America. Almost every pond, lake or wetland has an assemblage of these species. A few species are found in streams. Adults of many species have prominent wing patterns, and many have brightly colored abdomens of red, blue and other colors. Adults can be easily distinguished by the characteristic boot-shaped anal loop of the hind wing. Adults usually perch on tips of stems, and have a gliding type of flight. Nymphs can be usually recognized by the scoop-like labial palps with the distal margins relatively smooth. However, nymphs are often difficult to distinguish from the Corduliidae (in some classifications only recognized as a subfamily, the Corduliinae). Nymphs are sprawlers or climbers, and found in all types of standing water, from hoof prints to the edges large lakes or reservoirs. A few species are even found in brackish water and other estuarine environments. Well-known genera are *Libellula* (king skimmers), *Sympetrum* (meadowhawks), *Erythrodiplax* (dragonlets), *Perithemis* (amberwings), *Erythemis* (pondhawks), *Tramea* (saddlebags gliders), and *Celithemis* (small pennants).

Drake, Carl John

Carl Drake was born on a farm in Ohio on July 28, 1885. He obtained a B.S. degree (and a Bachelor of Pedagogy) from Ohio State University in 1912, then in 1914 an M.S. degree and in 1921 a Ph.D. degree from the same institution. He worked for 4 years as specialist in entomology in the School of Forestry, Syracuse University, then from 1922 to 1946 in the Department of Zoology and Entomology at Iowa State University. In this last position, he was not only departmental head, but also head of the entomology section of the Iowa Agricultural Experiment Station. His taxonomic interests were in lace bugs and semiaquatic Hemiptera, of which he built a large collection. His experiment station obligations as applied entomologist had him working on grasshoppers, chinch bug, Hessian fly, and European corn borer. He was a member of the Central States Plant Board, the National Plant Board, and the American Association of Economic Entomologists. On retirement in 1946, he concentrated on his taxonomic interests, and in 1957 moved to work as an honorary Research Associate of the U.S. National Museum in Washington, DC. By working at the museum 61/2 days per week (he never married), his lifetime publications list grew to exceed 500 papers. He died on October 2, 1965, in Washington, DC.

Drench Treatment

Application of a liquid insecticide to an area, usually soil, until it is completely penetrated.

Drepanidae

A family of moths (order Lepidoptera). They commonly are known as hook-tip moths.

► Hootktip Moths
► Butterflies and Moths

Driver Ants (*Dorylus* subgenus *Anomma*) (Hymenoptera: Formicidae)

CASPAR SCHÖNING
University of Copenhagen, Copenhagen, Denmark

Driver ants are those army ant species in the afrotropical subgenus *Dorylus (Anomma)* that hunt by massive swarm raids on the forest floor and up in the vegetation. Any animal capable of moving fast enough and lacking other effective protective mechanisms flees from such an advancing swarm of hundreds of thousands or even millions of ant workers in search of prey. Hence the raid swarm “drives” many animals before it. Due to their ferocious nature, these ants are recognized by their own name in many tribal languages in sub-Saharan Africa. In Ghana, for example, they are called "Nkran" in the Twi language. In Kenya, people in the Meru tribe use the term "Thuraku" for them. Their common English name was originally coined in 1847 by Dr. Thomas Savage in the description of his observations of *D. (A.) nigricans* colonies in present-day Liberia. Although other authors have subsequently applied the term to all species in the subgenus *Anomma* (as currently recognized) or even to all species in the genus, it is best to stick with its original meaning to avoid confusion.

Taxonomy and Phylogeny

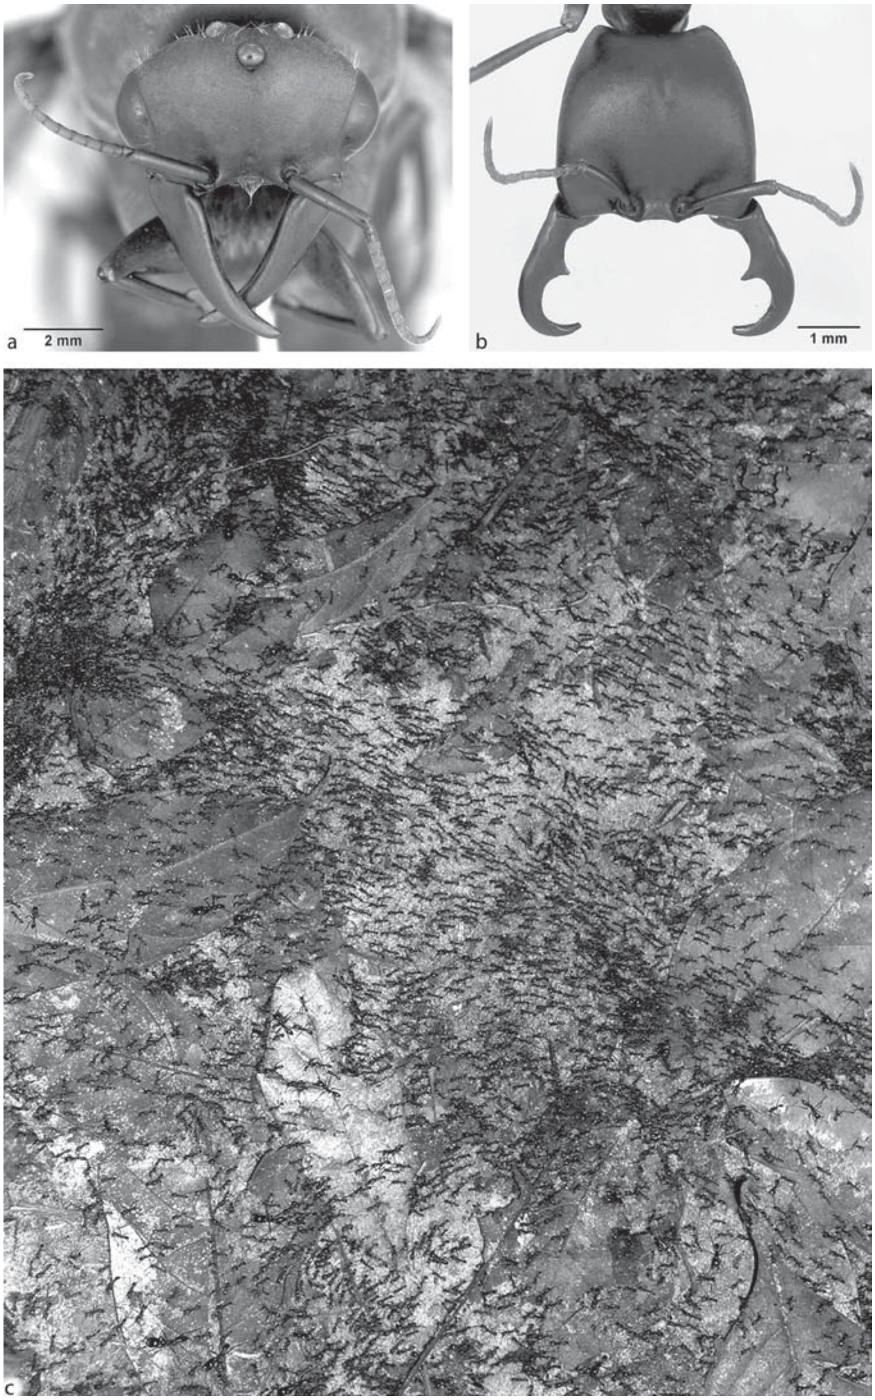
Many species in the genus *Dorylus* (as well as many other army ants) were described based only on a single caste or sex and the associations between these different forms have been hard to establish. Therefore, delimitating the subgenus *Anomma* proved difficult and several other species not showing the typical "driver ant" hunting behavior but foraging less conspicuously in the leaf-litter were also described as species in the subgenus *Anomma* after 1847. But recent evidence from a molecular phylogeny indicates that the subgenus *Anomma* as currently defined is actually paraphyletic. The species that forage in the leaf-litter are more closely related to subterranean species of the subgenus *Dorylus* s.s. than to the driver ants (in the sense of Savage's original functional definition), which form a well-supported clade. This result thus indicates that the foraging in massive surface swarms evolved only once within the genus *Dorylus*. Since the type species for the subgenus *Anomma* is a driver ant, the species hunting in the leaf-litter stratum will have to be removed from *Anomma* in a revised subgenus classification of the genus *Dorylus*. Although more than thirty nominal forms have been described under *Anomma* (including those taxa that turn out to be more closely related to *Dorylus* s.s.), there are probably only about ten species of driver ants.

Morphology

Workers

Driver ant workers can be distinguished from the workers of all other *Dorylus* species by several qualitative and quantitative traits (these apply mostly to the largest individuals). The qualitative traits are the presence of basisternal spines, frontal carinae reduced, mesonotum in lateral view impressed, petiole long and slender, and strongly (Fig. 58) trapezoidal head shape (head width much wider anteriorly than posteriorly). Moreover, driver ant workers have relatively (i.e., for a given worker dry mass) longer mandibles, legs and antennae, and these features are probably adaptations associated with the derived driver ant foraging mode. While their longer mandibles can inflict more painful bites and thus provide better protection against predators, longer legs allow faster and more efficient locomotion, the transport of larger prey items (prey is carried slung underneath the body) and finally perhaps also better climbing of vegetation. Longer antennae, on the other hand, will help workers to follow pheromone trails at higher speed while avoiding collisions in spite of dense traffic. Being more exposed to sunlight during foraging, driver ant workers also tend to be darker than workers of species hunting in leaf-litter and soil. Like workers of all other *Dorylus* species, driver ant workers lack eyes.

The degree of worker polymorphism in driver ants (and other *Dorylus* species) is among the most extreme in ants. In some species the largest workers have a dry mass 200-fold that of the smallest workers. These extreme differences in size are associated with striking differences in the number of antenna segments (varying between eight in the smallest workers and 11 in the largest), hairiness, mandible structure (with many teeth in the smallest workers and only an apical and subapical tooth in the largest), head shape (from rectangular in the smaller individuals to trapezoidal in the largest), coloration (from light brown to very dark or black) and in the relative



Driver Ants (*Dorylus* Subgenus *Anomma*) (Hymenoptera: Formicidae), Figure 58 **Driver ants: (a) Head of a *Dorylus* (*Anomma*) *nigricans* male in frontal view. The mandible is very long and slender and the head is high (photograph by April Nobile, from www.antweb.org); (b) Head of a large *D.* (*A.*) *sjoestedti* worker in frontal view. The head is much wider anteriorly and the mandible has only two teeth (photograph by April Nobile, from www.antweb.org); (c) A raid swarm of *D.* (*A.*) *nigricans* advancing on the forest floor in the Taï forest, Ivory Coast (photograph by Caspar Schöning).**

sizes of several other body parts. In general, it is fair to say that the morphological diversity in a driver ant colony is larger than in some other entire ant genera. This substantial variation has contributed to the confusion in driver ant taxonomy because some species were described more than once based on workers belonging to different size-classes.

Males

In Africa, *Dorylus* males are collectively referred to as sausage flies and the first *Dorylus* males to be found were described as a *Vespa* wasp species by Linné. *Dorylus* males possess a pair of compound eyes and three ocelli. The mandibles of driver ant males are relatively longer and more slender than those of other *Dorylus* species, and their heads are relatively longer than the extremely broad heads of other *Dorylus* males. Moreover, they are much darker.

Queens

Driver ant queens are perhaps the largest ants in the world, those of *D. wilverthi* may be up to 6 cm long and may lay as many as 3–4 million eggs every month. Driver ant queens, like workers, do not possess eyes. It is unclear which characters in the driver ant queen caste are actually apomorphies because the queens of many *Dorylus* species are unknown so that comparative studies are difficult but the shape of the hypopygium of driver ant queens seems to be unique within *Dorylus*.

Behavior

The raiding swarms of driver ants are one of the most fascinating examples of coordinated group activity shown by animals with hundreds of thousands or even a few million ant workers forming a dense carpet acting as a dragnet that sweeps through areas of 1,000 m^2 or more in a single day in search of prey. Workers climb vegetation up to a height of several meters. The swarms can be 30 m or more wide and move forward at a speed between 7 and 25 m per hour depending on the species. The foraging distances of *D. wilverthi* colonies may be up to 220 m. Driver ants are almost exclusively carnivorous but they are also attracted to oily vegetative products such as palm nuts and avocadoes. Their raids appear to be an efficient strategy to harvest abundant and evenly distributed small prey (such as solitary insects) as well as rare and very patchily distributed large prey (such as mammal carcasses). Driver ant prey spectra are therefore extremely diverse. Although quantitative data are lacking, driver ant species are likely to be the most polyphagous predators on earth. Solitary insects (especially their less mobile immature stages) and earthworms make up the majority of the biomass retrieved. Most vertebrates easily escape, but sometimes small amphibians (e.g., frogs), mammals (e.g., mice) and reptiles (e.g., chameleons) fall victim to the raid swarms. Large captive animals such as snakes and monkeys have been reported to be eaten to the bones by driver ants. In the hunting behavior it becomes evident that the extreme worker polymorphism is linked to a pronounced, yet flexible, division of labor. While the proportion of larger workers is very small in the swarm, they are crucially important and disproportionately overly represented in the tasks of pinning down, dismembering and retrieving larger prey. Workers can cooperate in the transport of large prey items with large workers grabbing the item at the front and one or more small workers lifting it off the ground at the back. In the species examined so far, most of the prey biomass is transported by such groups.

At irregular intervals, the entire colony migrates to a new nest site, most probably as a result of resource depletion around the nest. Migrations can last up to 4 days and include the movement of the colony's queen, its workers and its brood carried by the workers. Unlike some army ant species in the subfamily Ecitoninae, the temporal emigration pattern is not linked to a rhythm in the queen's egg-laying activity. Some migrations are triggered by predator attacks on the nests.

Colonies nest in the soil, usually at the base of trees. Over the period of a nest stay, workers may bring up large amounts of soil (40 kg or more) to the surface. In the nest, the workers form a big cluster that hangs suspended from roots and contains the brood and queen. Quite often, colonies reoccupy old nests that they or other colonies had used before.

Driver ants reproduce by colony fission like honeybees. Colony fission directly creates colonies with worker populations large enough for conducting swarm raids. When a colony has grown to a large enough size, the queen lays eggs that develop into queens and males. The sex ratio is highly male-biased. Only a few (two to fifty) queens, but several hundreds or up to a few thousand males, are reared. After about 4 weeks, the queen pupae hatch and all but one of the virgin queens are killed in ways not yet understood. At this point the old queen leaves the nest with about half the worker population. The remaining queen will subsequently mate with several males that fly in from foreign colonies. The males in this nest hatch after about 8 weeks and then in turn fly off at night in search of foreign nests with virgin queens ready to mate. When the males have flown off, the new queen and the remaining workers form a new functional colony and are free to migrate to new foraging grounds. Although there is a tendency for colonies to reproduce towards the end of the dry season, colony fissions take place throughout the year. In two species, colonies have been observed to produce males without a subsequent colony fission.

Ecology

With a worker population of up to nine million individuals, driver ant colonies form the largest single-family insect societies on earth, and thus have a voracious appetite. The immediate effect of their raids is a reduction of the biomass and perhaps the diversity of invertebrates in the foraging areas. Driver ants therefore create a mosaic of patches in different stages of recovery from prey extraction. By this mechanism, they may promote diversity in the invertebrate communities, but to date studies examining the effect of driver ant raids on the prey population dynamics are lacking. This issue becomes both more complex and interesting when one considers that up to three driver ant species can coexist at a site. Depending on the degree of resource partitioning between them, the combined impact on the invertebrate communities in the vegetation and on the forest floor may be very strong.

Driver ant colonies are hosts to diverse assemblages of so-called myrmecophiles. These are animals (such as certain staphylinid beetles and isopods) that have evolved mechanisms to integrate into the colonies without the ants identifying them as non-nestmates. These mechanisms represent either chemical or tactile camouflage (or both). It is difficult to examine what exactly all these species are doing in the colony but it seems likely that the majority are parasitic, while others are commensals. Blind snakes of the genus *Typhlops* parasitize driver ant colonies by feeding on the brood or on the prey brought in by the foraging workers.

The number of bird species specializing in attending the raid swarms to catch animals flushed by the advancing ants (and sometimes stealing prey from them) is much smaller than in South America where many dozens of "ant-birds" are closely associated with two swarm-raiding ant species in the subfamily Ecitoninae. The paucity of specialized ant-following birds in Africa is puzzling in view of the higher colony density and diversity of driver ants.

In spite of their painful bites, driver ants are preyed on by several mammals, including pangolin, honey badger, aardvark, gorilla, Jackson's mongoose and the common chimpanzee. The last species is the only one known to employ tools when taking driver ant prey. After opening the nest with the hands, so-called ant-dipping wands are inserted into the mass of ants in the central nest cavity. When enough ants have climbed the wand, it is removed and the ants are swiped off the tool with the hand or mouth and then hastily eaten. The effect of mammal predation on the growth and fitness of driver ant colonies has not yet been studied. *Dorylus* species in the subgenus *Typhlopone* are the most important invertebrate predators of driver ants. They attack driver ant colonies in their nests through tunnels in the soil and sometimes destroy them.

Finally, driver ants are also ecologically important because they move large amounts of soil, not only in nest construction but also when preparing their foraging and migration trails as "roads" with an even surface or as trenches and tunnels. The soil carried to the surface during nest construction is enriched with the indigestible prey remains and thus presumably rich in nitrogen and other plant nutrients.

Habitat and Distribution

Driver ants are restricted to sub-Saharan Africa. Within this vast region, they occur primarily in forests and other humid habitats. Some species appear to depend strictly on forest, while others such as the East-African *D. (A.) molestus* live in a wide range of habitats such as scrubland in proximity to rivers, woodland, agroforestry systems (e.g., banana, cocoa and coffee) and forests from sea level up to 3,000 m altitude.

Economic Importance

Driver ants provide a valuable pest-control service when invading houses and hunting in cultivated land. However, these benefits are probably outweighed by the damage they cause when attacking humans and livestock. Unlike termite alates, driver ant males are not eaten by people, although they would appear to be nutritiously rewarding. The reason is probably that their availability is far less predictable and that termite alates are much softer and easier to roast and chew.

Droplet Spermatophore

A spermatophore (capsule containing sperm) that is attached to a thread-like stalk, which in turn has an adhesive base for placement on a substrate. Male Collembola often distribute their sperm in this manner.

Drosophilidae

A family of flies (order Diptera). They commonly are known as small fruit flies, vinegar flies, or pomace flies.

► Flies

Drumming Communication and Intersexual Searching Behavior of Stoneflies (Plecoptera)

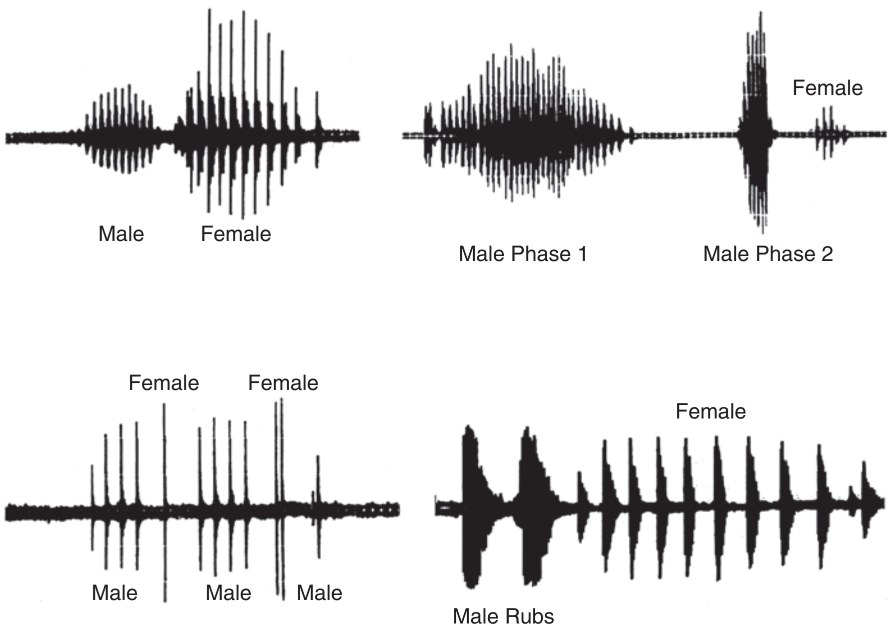
KENNETH W. STEWART
University of North Texas, Denton, TX, USA

Stoneflies of the Northern Hemisphere suborder Arctoperlaria have evolved the most diverse and complex system of vibrational communication known in insects. Only leafhoppers and delphacid planthoppers possibly have evolved signals as complex as those of stoneflies, but relatively few species of those two groups have been studied. The first studies in the 1960s and 1970s that were designed to quantify the drumming communication of stoneflies established that: (i) vibrational signals were produced by percussion, with either the unmodified or specialized distal, ventral portion of the abdomen, (ii) duets were either "2-way" (male call-female answer sequences) or "3-way" (male call-female answer-male reply sequences), (iii) male calls were more complex than female answers or male replies, (iv) the signals of both sexes and their duet pattern were species-specific and therefore probably fixed action behaviors, and (v) during duetting, males searched for stationary females, establishing that the behavior was part of the mate-finding system. Intensive research in the past three decades has revealed that signals are produced in some groups by methods other than percussion, that the rhythms and exchange characteristics of both males and females vary in complex ways and that the search behaviors in relation to drumming are more than simple "bee-line homing" of the male on females.

The entire mating system of stoneflies involves both their intersexual communication with vibrational signals and the associated aggregation and movement (searching-related) behaviors of both sexes. The typical system in Arctoperlaria involves the sequence of: (i) encounter site aggregation of sexes, (ii) species-specific calling by males with vibrational signals during a ranging, non-oriented search, (iii) duet establishment when females within communicable range answer with vibrational signals, then (iv) a localized, oriented search by the moving male toward the now stationary female until location and mating are accomplished. Males are polygamous and continue calling and searching during their short reproductive lives. Typically, only virgin females answer males and, once mated, reject subsequent male advances by raising and curving their abdomens.

There is obviously no fossil record for vibrational communication in stoneflies, so formulation of a paradigm on how the behavior originated and has been further developed has of necessity depended on patterns revealed from modern species. Out-group comparisons with the Grylloblattodea, other orthopteroid groups and the Southern Hemisphere stonefly suborder Antarctoperlaria, indicate that ancestral stoneflies were non-drummers. The first trace of the behavior probably resulted from males accidentally bumping their unmodified abdomen while searching for females, followed by the possible defensive response of females to the vibrations by becoming motionless and stationary. Selection progressively reinforced the male bumping and female response into behavioral actions until a relatively simple, sequenced duetting (male calls-female answers) developed, that represents an ancestral pattern. The signals of both sexes were produced by percussion and were monophasic volleys of even spacing and little amplitude modulations (Fig. 59).

Out-group comparisons have indicated further that species-specificity and behavioral isolation were then derived from this ancestral pattern (and are represented in modern species) by either: (i) retention of the ancestral pattern with slight modifications of signal characteristics (number of beats, overlap of the male-female duet, changing the beat interval rhythm or amplitude modulation) in both male and female signals; (ii) major rhythm changes, particularly in male calls, by phasing or grouping of signal beats; (iii) changes in the method of signal vibration



Drumming Communication and Intersexual Searching Behavior of Stoneflies (Plecoptera), Figure 59
Patterns of signaling among stoneflies: upper left, ancestral-type signaling duet of *Pictetiella expansa;* upper right, duet with a diphasic male call of *Acroneuria abnormis;* lower left, symphonic exchange with grouped male call and grouped-interspersed female answers of *Isogenoides zionensis;* lower right, signal exchange with a 2-rub male call and female percussion answer of *Doroneuria baumanni.*

production from ancestral percussion to abdominal substrate stridulation (rubbing), or in rare cases, body jerking or pushups without touching the substrate (tremulation); or (iv) combinations of these changes. The result in modern arctoperlarian stonefly species is an exciting and highly derived and complex array of signal and duet patterns, each unique to particular species, and in some cases fairly uniform in pattern among particular genera or families.

The most specialized male calls involve his rubbing the substrate with a specialized, and probably co-evolved, abdominal knob or hammer. Each rub probably represents a modified and prolonged ancestral percussion stroke, using the knob or hammer that may be uniquely ridged or dimpled. This produces a squeaking sound on resonant substrates. Males of various species produce one to seven rubs, always answered by their females with percussion-produced signals.

Little is known about the searching behaviors of species once duet communication between males and females has been established. Recent studies have established that the vibrational communication definitely functions to reduce the time required for males to find females, and that females can be sexually selective by not answering males that call with abortive calls, or by remaining stationary only for some specified time that allows a more fit drumming-searching male to find her. Males generally search by triangulation during duetting with females on flat surfaces. On naturally branched surfaces, such as live or dead plant stems, a male progressively calls on the main stem and on each branch just beyond each bifurcation toward an answering female, effectively determining whether her answering vibrational signal comes from in front or behind him, and therefore whether she is out on that branch or on a branch further away on the main stem. In species that use tremulation, males fly and land on riparian shrubs and call on leaves; if a female sitting on another leaf responds, he moves toward her, testing leaf by leaf just beyond each petiole junction. Females in this case move to the petiole-leaf junction and become stationary, effectively insuring that once the male finds her correct leaf location, he does not have to search the entire leaf surface to finally make contact with her. This can be described as a "fly-tremulate-search" pattern. All stonefly species that have been studied appear to utilize an initial and specific type of sexual encounter site for initial aggregation of the sexes. This is followed by a ranging search with males intermittently calling for females, then beginning a more localized and oriented search once females answer with signals that reveal her location. Mating of stoneflies ensues almost immediately after males find females; no elaborate courtship behaviors have been discovered.

Dubas Bug (Old World Date Bug), *Ommatissus lybicus* Bergerin (Tropiduchidae: Hemiptera)

YOUSIF ALDRYHIM
King Saud University, Riyadh, Saudi Arabia

The Dubas bug or Old World date bug feeds on the leaves of the date palm trees, *Phoenix dactyifera*, in Iraq, Iran, Saudi Arabia, Bahrain, Oman, Egypt, Lybia, Algeria and Trinidad. It is closely related to *Ommatissus binotatus* DeBerg, which attacks the wild palm, *Chamaerops humilis*, in

North Africa, Spain, and in the southeastern region of the former Soviet Union.

Description

The adult female is about 5–6 mm in length, yellowish green and has up to ten dark spots on the head and 7th and 8th abdominal segments. The adult male is about 3–3.5 mm in length. It differs from the female by the absence of the dark spots on the 7th and 8th abdominal segments, the more tapered abdomen and the greater length of the wings relative to the abdomen. The eggs are elongated, cucumber like and about 0.5–0.8 mm in length. They are bright green in color at deposition, then change to yellowish white and later to bright yellow. The nymphs are bright brown and have dark stripes on the dorsal surface of the thorax and abdomen. The tip of the abdomen terminates in an extension or cauda-like structure and has 16 white waxy filaments, each about 3 mm long. The eyes are red and the nymphs can walk and jump up to 60 cm.

Symptoms and Economical Importance

The adults and nymphs feed on the sap of the leaflets and midribs of the date palm frond. At high levels of infestation, Dubas bugs attack the fruit stalks and the fruit. Dubas excrete heavy honeydew and dust sticks to it. The infested leaflets become light green and yellow green in color. Necrotic areas (damage) are noticeable on the infested fronds and are caused by egg-laying. Dubas bug is an occasional pest, meaning that it becomes an important pest for a season or two, followed by less damage in the coming seasons. At high levels of infestation, 50% of the date yield may be lost. Dubas bugs may cause indirect damage to crops that are grown under the infested date palm trees due to the dripping of honeydew.

Biology

Dubas bugs have two generations per year, a spring and autumn generation. Dubas bugs hibernate in the winter and aestivates in the summer as eggs in the axial veins and midrib of the date palm fronds. A female deposits an average of 100 eggs during its life-span. Eggs hatch in April and in September in the spring and autumn generations, respectively. Newly hatched nymphs disperse into the frond folds or onto young fruits, and commence feeding. The nymphs pass through five instars. Nymphal duration is about 6 weeks. The adults can fly, and their habitat is the same as the nymphs.

Control

A small chalcidiod wasp parasitizes the eggs of the Dubas bug. The larvae of lacewings also prey on the Dubas nymphs and adults. The adult beetles of three species of the coccinellids attack the nymphs and adults of the Dubas bugs.

Certain cultural practices help to keep the trees healthy. Good drainage and windbreaks help to reduce injury by this pest. Systemic insecticides can be used at high levels of infestation. Aerial application of insecticides is most useful for wide-ranging infestations, or when the height of the date palm trees makes it difficult to apply chemical pesticides from the ground. However, aerial application increases scale insect infestations because the pesticide kills their natural enemies.

Dudgeon Carpenterworm Moths (Lepidoptera: Dudgeoneidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

Dudgeon carpenterworm moths, family Dudgeoneidae, includes only six species in the single genus *Dudgeonea*, with two species from Africa, one from India, and three from Australia. The family is in the superfamily Cossoidea (series Cossiformes) in the section Cossina, subsection Cossina, of the division Ditrysia. Adults medium size (28–72 mm wingspan), with head somewhat rough-scaled; haustellum absent; labial palpi upcurved; maxillary palpi 3-segmented; antennae pectinate (rarely bipectinate). Body robust; abdomen with small tympanal organs. Wings elongated; forewings rounded at termen (Fig. 60). Maculation dark with golden or light spots; hindwing pale. Adults nocturnal as far as is known. Larvae mostly unknown, but one Australian species is a stem borer on Rubiaceae. The family and genus *Dudgeonea* are named after the British lepidopterist Gerald C. Dudgeon (18??-1930), who published mostly on Indian Lepidoptera.

Dudich, Endre

GEORGE HANGAY
Narrabeen, NSW, Australia

Endre Dudich was born on the March 20, 1895 at Nagysallü, in Bars Shire, Hungary. At an early age his interest was influenced by his father, who was a medical practitioner and liked zoology. He attended college in Esztergom (Northern Hungary) continuing his studies at the Pázmány Péter University of Science. During World War I, his university studies were interrupted with three and a half years of military service, during which he served on the front. He received his diploma in 1920 and in 1922 the doctorate. Due to the friendship and encouragement of Elemér Bokor, he focused his research on the Coleoptera and the invertebrate fauna of caves. However, one of his main achievements was a major work on zoological taxonomy (Rendszeres állattan. Pécs, 1927), which has established him as a leading scientist of that field. In 1934 he was commissioned to establish the Institute of Zoological Taxonomy. He worked in this institute until his death. Endre Dudich pioneered modern taxonomical and zoogeographical research in Hungary and created the country's first underground research station in the Baradla Cave (northeastern Hungary). He became a leading expert in the biological research of caves and from 1958 until 1970 he directed scientific work at the Danube Research Station at Alsü Göd, north of Budapest. He kept working until his death on the February 5, 1971.

Dufour, Léon Jean Marie

Léon Dufour was born at Saint-Sever, France, on April 11, 1780. He was a veteran of the French army, with service in Spain during the Napoleonic wars. He married and had children. His publications spanned the years 1811–1864, reported work on the anatomy, behavior, development, physiology, and taxonomy of filarial nematodes, earthworms, crustaceans, arachnids, and insects (Orthoptera, Coleoptera, Diptera, and Hymenoptera), and numbered over 230. He was awarded France's highest medal, as an officer of the Legion d' Honneur. He died on April 18, 1865.

Duponchel, Philogène August-Joseph

Philogène Duponchel was born in France toward the end of 1774. At the age of 16 he was in the French army during the Revolutionary War, after his parents fled from France. He became a bureau chief in the war administration. He was not discharged from the army until 1816, but he used his free time for entomological studies. He married and had two children. His interest was especially in Lepidoptera. He was a friend of Latreille, Dejean, and Duméril, and was guided in his studies by them. He was a co-founder of the Société Entomologique Française, at one time a president of it, and held other roles in it at various times. With Chevrolat as co-author, he contributed to d' Orbigny's (1842) "Dictionnaire universel d' histoire naturelle…" He died in Paris on January 10, 1846.

Dyar, Harrison Grey

Harrison Dyar was born in New York on February 14, 1866. He obtained a B.S. in chemistry from Massachusetts Institute of Technology in 1889, and an A.M. and Ph.D. From Columbia University in 1894 and 1895, respectively. His Ph.D. research was "On certain bacteria from the area of New York City," but before that he had published (in 1894) "A classification of lepidopterous larvae," and for that evidence of training and interest, he was offered in 1897 an unpaid position as Custodian of Lepidoptera at the U.S. National Museum. He occupied the position for the next 31 years, publishing constantly on Lepidoptera, and receiving no financial compensation for his work: he was independently wealthy. However, his other interest was in nematocerous Diptera, and he studied Culicidae, Simuliidae, Psychodidae, and Chaoboridae. With Frederick Knab, he published a four-volume work "The mosquitoes of North and central America" which was initiated as the result of a grant from the Carnegie Institution to L.O. Howard who was another of the authors. "Dyar's rule" was the result of his studies on the growth of caterpillars, in which he stated that the "width of the head capsule of the larva follows a regular geometric progression in the successive instars." He has been remembered by some as a cantankerous man who was quick to criticize others. He owned and edited the entomological journal Insecutor Inscitiae Menstruus, which was published from 1913 to 1927. He died on January 21, 1929.

Earwigflies (Mecoptera: Meropeidae)

JAMES C. DUNFORD, LOUIS A. SOMMA, DAVID SERRANO
University of Florida, Gainesville, FL, USA

There are two known extant members of the family Meropeidae worldwide. The North American earwigfly, *Merope tuber* Newman, is found in eastern North America, and the Australian earwigfly, *Austromerope poultoni* Killington, is found in Western Australia. One additional species, *Boreomerope antiqua* Novokschonov, is an extinct, fossil meropeid known from the Middle Jurassic of Siberia. The vernacular name for earwigflies is derived from the male genital claspers that superficially resemble the forficulate cerci of earwigs (Dermaptera).

Meropeid genera are hypothetically closely related to Eomeropidae, probably basal to more derived mecopterans (e.g., scorpionflies, *Panorpa* spp.), and could provide a clue to the phylogenetic link between Mecoptera and Siphonaptera. Meropeid larval and pupal stages remain undescribed and may be an important link in better understanding the evolution of advanced holometabolous insects.

The specific epithet for the North American earwigfly, *tuber*, Latin for swelling, knob, hump or protuberance, is a reference to the jugum, a distinct lobe on the basal posterior margin of the forewings. The jugum of *M. tuber* was originally described as a "*tubere*" and "knob" by Newman in 1838, and is used to produce audible stridulations by rubbing against a ridged portion of the thorax, or could function as part of a wing interlocking mechanism.

The Australian earwigfly was named in honor of E.B. Poulton, who first collected it in southwest Western Australia in 1914. There are several morphological features that separate the two extant meropeid genera, namely wing venation and the presence of an apical spine on the basal segment of the male genital claspers of *A. poultoni*. *Austromerope* adults also bear a lobe or jugum on the base of each forewing but they are much smaller than the juga on *Merope*.

At present, meropeid immature stages have not been described, and much of their general biology remains unknown. *Merope tuber* (Fig. 1a, b) adults are apparently nocturnally active and have been recorded primarily from deciduous, mesic woodlands, usually near streams. Seasonal records reported for *M. tuber* include dates encompassing early May through late November. For more than 150 years *M. tuber* were considered rare, but recent collection methods (i.e., pitfall, light, and various flight traps) reveal that this secretive mecopteran is more abundant than what was once thought. Published records of *Merope* previous to 1954 were for localities in or east of the Appalachian Mountains. Since that time, specimens have been collected increasingly farther west. Through 1993, the recorded range of *M. tuber* was from southeastern Canada to northern Georgia, west to Kansas, Minnesota and eastern Iowa, largely restricted to environmental conditions similar to those known along the Appalachian range and eastern mesic forests. However, more recent collection records indicate that *M. tuber* is also found further south (e.g., Alabama and Florida) suggesting that it may have found refuge in some of these disjunct areas during glacial advances.

Austromerope poultoni have been (Fig. 1c) collected in light and pitfall traps containing alcohol preservatives and taken in a wide variety of somewhat xeric habitat types, including Jarrah and Karri forests, Wandoo woodland and heath. Seasonality records for adult *A. poultoni* include a range of dates between July (midwinter) and December (early summer). Adults likely live within or below the litter layers in these habitats and they are not commonly encountered, but like *M. tuber* have recently been collected in greater numbers due to more thorough sampling efforts.

Earwigs (Dermaptera)

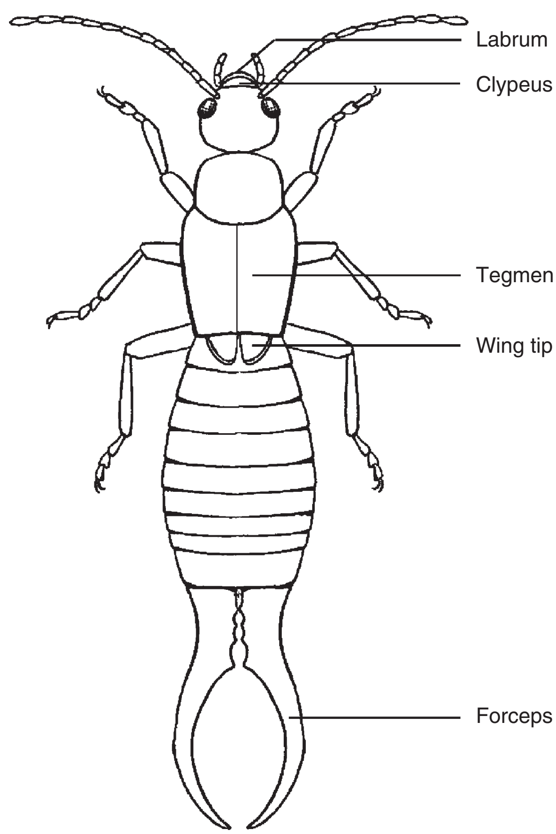
Earwigs are, in some respects, one of the most readily recognized orders of insects. However, this applies only to the "typical" earwigs bearing forceps-like cerci. There are some animal-parasitic groups that lack the forceps-like cerci. The order name is based on the Greek words *derma* (skin) and *pteron* (wing).

Classification

There are three suborders of earwigs, but two are very small. Nearly all the 1,500 known species occur in a single suborder, Forficulina. Suborder Hemimerina consists of ten blind, wingless species that live on giant rats in tropical Africa. They have small filiform cerci. Suborder Arixenina consists of five species that live on bats in Southeast Asia. Similarly, they are nearly blind, wingless, and have straight cerci.

Characteristics

Earwigs are elongate insects with biting/chewing mouthparts. They range in size from 4 to 80 mm. Earwigs usually are uniform black or brown, but some are striped. The antennae are moderately long, consisting of 6–15 segments. They may bear two pairs of wings, or be wingless. The forewings (when wings are present) are modified into short, thickened covers (called tegmina) for the functional hind wings. The hind wings fold beneath the tegmina and are unusually oval, with veins radiating from the central region of the wing. The legs are moderately short and unspecialized. The tarsi consist of three segments. Both males and females bear cerci. The cerci are undivided, and in most species are modified into heavily sclerotized forceps-like structures called, appropriately enough, forceps (Fig. 3). The shape of the cerci can be used to distinguish species, sex, and sometimes age. Metamorphosis is incomplete. Earwigs are predominantly tropical insects.



Earwigs (Dermaptera), Figure 3 Diagram of an earwig, shown dorsally.

Biology

Earwigs tend to be nocturnal, hiding during daylight in soil, leaf litter, under bark, and other cryptic, humid locations. Most are omnivorous, but a few are predatory or live on vertebrates as ectoparasites. The common name "earwig" likely is derived from the tendency of earwigs to crawl into dark crevices including, perhaps, a human ear. This rarely, if ever, occurs. Females earwigs display some elements of sociality, specifically maternal care for eggs and young earwigs. The female protects and cleans the eggs and young from her mate as well as other potential predators, but the nymphs disperse when about half grown. There are 4–5 nymphal instars. They nymphs are hard to distinguish from the wingless adults except by size. The cerci also are not completely developed, tending to be less curved than as adults. However, females display a similar tendency of having less curved cerci, relative to males, so the age of earwigs can be difficult to ascertain.

► Piroplasmosis

Eastern Equine Encephalitis

C. Roxanne Rutledge
University of Florida, Florida Medical Entomology Lab, Vero Beach, FL, USA

Eastern equine encephalitis (also known as EEE, eastern encephalitis, and eastern equine encephalomyelitis) was first recognized in North America in horses from Virginia, Delaware, New Jersey, and Maryland in 1933. The virus that causes EEE was first isolated from brains of animals in 1933 and recovered from human central nervous system (CNS) tissue in 1938. The virus is transmitted through the bite of an infected mosquito. Infection in mosquitoes, wild birds, horses, and humans is uncommon, but causes a high mortality in susceptible hosts. Infection with the EEE virus can cause a range of CNS complications from mild or none at all, to severe encephalitis (swelling of the brain). EEE is sometimes referred to as eastern equine encephalomyelitis, meaning swelling of the brain and spinal cord. Vertebrate hosts that are most susceptible to severe complications include humans, horses, and some exotic birds. EEE virus has been isolated in eastern North America, eastern Canada, Central and South America, Jamaica, Trinidad and Tobago, Cuba, Haiti, and Dominican Republic.

Virus

Eastern equine encephalitis virus is an RNA Alphavirus in the family Togoviridae. The virus is transmitted to mammalian hosts by mosquitoes. Avian hosts may acquire the virus from mosquitoes and in some instances, without the mosquito vector. In pheasants, the virus can spread from one bird to another through cannibalism and pecking.

Mosquito Vectors

In the enzootic cycle (mosquito-bird-mosquito, present in the animal community at all times), the mosquito vector of EEE virus in the eastern United States is *Culiseta melanura*, a mosquito that prefers to feed on birds. *Ochlerotatus* (formerly *Aedes*) *sollicitans*, a salt-marsh mosquito, may be the main vector during outbreaks in humans and horses, as it will feed on birds, humans, and horses.

Studies suggest that *Coquilletidia perturbans*, *Ochlerotatus* (formerly *Aedes*) *canadensis*, and *Aedes vexans* may be important vectors in southeastern Massachusetts. In tropical countries, the primary mosquito vectors are *Culex nigripalpus*, *Culex taeniopus*, and *Ochlerotatus* (formerly *Aedes*) *taeniorhynchus*.

Bird Hosts

Birds naturally infected with EEE virus include ring necked pheasants, pigeons, chukar partridge, Pekin ducks, turkeys, a number of passerines, owls, whooping cranes and shore birds. Antibodies to EEE virus have been found in some of these bird hosts, and EEE virus has been isolated from others.

Transmission Cycle

Eastern equine encephalitis virus is an arbovirus (arthropod-borne virus) that is passed from one host to another through the bite of an infected mosquito. In the eastern United States, the EEE virus circulates between birds and mosquitoes in freshwater swamps. The mosquito acquires the virus from an infected bird. Wild birds may have a viremia (the occurrence of viruses within the peripheral bloodstream of the host) without the signs of infection seen in other animals. After an incubation period in the mosquito, other hosts may then be infected when the female mosquito takes a blood meal. Mosquitoes that feed strictly on birds will maintain a local enzootic cycle of EEE. Mosquitoes that feed on a wider range of hosts may infect humans and horses, which serve as a dead-end for the virus. Neither infected humans nor horses have enough circulating virus to infect mosquitoes. The virus has an incubation period of 4–10 days once it has entered a previously uninfected vertebrate host. During the incubation period, the virus may invade the spinal cord and brain. Infection can potentially lead to death of the vertebrate host.

Disease in Humans

Symptoms in humans can be mild, flu-like symptoms to severe encephalitis manifested by fever, headache, and nausea followed by drowsiness, convulsions, and coma. The case fatality rate is 35–65% of clinical cases. Some humans who are infected with the virus develop neutralizing antibodies but do not develop clinical illness. In children under 5 who survive the disease, mental retardation, convulsions, and paralysis often are observed. Estimated total costs associated with each human case is from $21,000–$3 million for severe infections. There is no human vaccine for EEE virus. There is no specific treatment for eastern equine encephalitis. This combined with the lack of a human vaccine emphasizes the importance of personal protection from mosquito bites. Personal protection using mosquito repellent is the best method for preventing infection.

Disease in Horses

The disease in horses is often biphasic with fever starting 18–24 h after infection that lasts about 1 day. Four to six days post-infection, fever starts again and lasts from 1 to 4 days and nervous system signs appear: depression, head close to the ground, flaccid lips, weight loss, and a legs-apart stance. Death occurs within 5–10 days post-infection and the mortality rate is 75–90% with brain damage occurring in animals that survive. There is no specific treatment for EEE in horses. The method of prevention in horses is in the form of an effective horse vaccine that is available to all horse owners.

Disease in Birds

Pheasants exhibit signs including fever, depression, diarrhea, ataxia, tremors, and paralysis of one or both extremities. Initially, infections in pheasants occur from mosquito bites. Later on, the disease can be spread from bird to bird through pecking and cannibalism.

Emus are susceptible to EEE virus and exhibit acute onset of depression, profuse hemorrhagic diarrhea, anorexia and ataxia. Terminally, these birds show extreme exhaustion, hemorrhagic diarrhea and vomiting. Infection in emus causes moderate morbidity and high mortality. Treatment is supportive only, and there is some degree of immunity provided with the equine bi- or tri-valent vaccines.

Detection/Diagnosis

In humans, diagnosis of EEE is based on signs of encephalitis and virus isolation from CNS tissues or blood. A confirmed case of EEE includes the following: a clinically compatible disease (febrile illness, encephalitis) and onset of illness during a period when arbovirus transmission is likely to occur and either a stable elevated antibody titer to an arbovirus or specific IgM (antibody formed early in an immune response; it is a less persistent antibody that indicates recent or chronic infections) antibody in serum, and either a fourfold or greater change in serum antibody titer, viral isolation from tissue, blood or spinal fluid, or specific IgM antibody in the cerebrospinal fluid.

Diagnosis of EEE in horses includes a history of the animal, physical exam, and lab tests to analyze blood or cerebrospinal fluid for antibodies or virus. Since the disease progresses rapidly in horses, EEE confirmation is usually made after the horse' s death. At this point, examination of brain tissue is required to confirm brain lesions or attempt virus isolation.

Epidemics and Epizootics

Massachusetts experienced an epidemic of EEE in 1938 with 38 human cases (74% mortality) and 248 horse cases (90% were fatal). In 1947, an epidemic occurred in Louisiana that killed 90% of the approximately 14,000 infected horses and 9 of 15 humans with the virus died. The Dominican Republic reported 9 deaths among 13 infected humans and 516 horse cases in 1948–1949. An accurate mortality rate in horses during that epidemic is not obtainable as all sick animals were ordered killed when the cause of the epizootic was determined. From 1939 to 1954, there were 27 reported epizootics in pheasants in New Jersey. An epizootic occurred in Panama in 1973 causing 40 deaths in 100 infected horses. The Centers for Disease Control reports 153 confirmed human cases spread throughout 20 states from 1964 to 1997. Fifty of the human cases occurred in Florida (33%). Small outbreaks and sporadic cases in humans continue to occur in various locations throughout the known transmission zone.

The numbers of EEE horse cases are probably severely under-reported. The United States Department of Agriculture reported 26,468 cases of encephalitis in horses from 1956 to 1970. Of the mere 2,620 that could be specifically diagnosed, 605 cases were due to the EEE virus. Many horses are euthanized before a confirmation can be made. Because brain tissue is required for confirmation of EEE in horses, some horse owners are reluctant to provide the necessary tissues or to incur the expense of the laboratory confirmation.

Future Outlook

EEE virus transmission likely will continue in the known transmission zones. There will be some years with many horse and human cases. As humans and animals move into EEE endemic areas near marshes and swamps, and natural wetlands are preserved, contact with infected mosquitoes is likely to continue and perhaps expand the areas of transmission. The susceptibility to EEE virus for many exotic animals is unknown; importation of such animals into EEE virus transmission zones may also subject them to the levels of mortality seen in emus, pheasants, and horses. Prevention of EEE through the use of vaccines in animals and personal protection in humans is increasingly more important as source reduction of mosquito larval habitats is discouraged or illegal in natural wetlands and mosquito control professionals have fewer methods for controlling the vectors of EEE virus.

Eastern Lubber Grasshopper, *Romalea microptera* (Beauvois) (Orthoptera: Acrididae)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

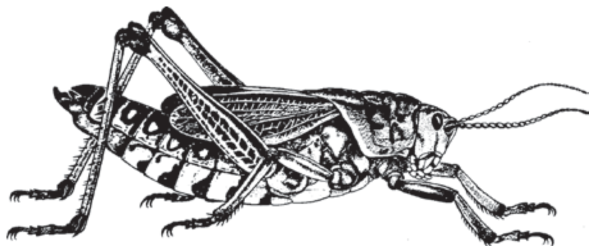
This grasshopper is common in the southeastern United States from North Carolina to eastern Texas, including the entire peninsula of Florida. It is common in many areas of the southeastern USA, and well known to the populace due to its large size and use in biology classrooms for dissection exercises. Unfortunately, the scientific community uses two different scientific names for the same species, and *R. microptera* is also called *R. guttata* (Houttuyn). The latter is probably the correct name, but because the former designation was used for many years, this proposed "correction" is introducing unnecessary confusion.

Life History

There is one generation per year, with the egg stage overwintering. These grasshoppers are long-lived, and either nymphs or adults are present throughout most of the year in the southern portions of Florida. In northern Florida and along the Gulf Coast they may be found from March–April to about October–November.

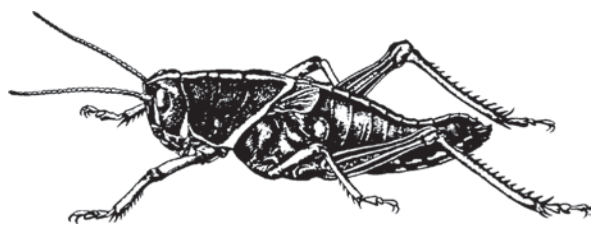
The eggs of lubber grasshoppers are yellowish or brown in color. They are elongate elliptical in shape and measure about 9.5 mm in length and 2.5 mm in width. The are laid in neatly arranged clusters, or pods, which consist of rows of eggs positioned parallel to one another, and held together by a secretion. Normally there are 30–50 eggs in each pod. Ovipositing females are reported to prefer mixed broadleaf tree-pine habitats with intermediate soil moisture levels, avoiding both lowland, moist, compact soil and upland, dry, sandy soil. The female deposits the pod in the soil at a depth of 3–5 cm and closes the oviposition hole with a frothy secretion or plug. The plug allows the young grasshoppers easy access to the soil surface when they hatch. Duration of the egg stage is 6–8 months.

Young nymphs (Fig. 4) are highly gregarious, and remain gregarious through most of the nymphal period, though the intensity dissipates with time. Normally there are five instars, though occasionally six instars occur. The nymphs are mostly black with a narrow median yellow stripe along the pronotum and abdomen, along the edges of the pronotum, and on the lower side of the abdomen. The legs are well marked with red. Their color pattern is distinctly different from the adult stage, and so the nymphs commonly are mistaken for a different species than the adult form. The early instars can be distinguished by a combination of body size, the number of antennal segments, and the form of the developing wings. The nymphs measure about 10–12, 16–20, 22–25, 30–40, and 35–45 mm in length during instars 1–5, respectively. Antennal segments,



Eastern Lubber Grasshopper, *Romalea microptera* (Beauvois) (Orthoptera: Acrididae), Figure 4 Adult of eastern lubber grasshopper, *Romalea microptera* (Beauvois).

which can be difficult to distinguish even with magnification, number 12, 14–16, 16–18, 20, and 20 per antenna during instars 1–5, respectively. The shape of the plates immediately behind the pronotum changes slightly with each molt. During the first instar the ventral surface is broadly rounded; during the second instar the ventral edges begin to narrow slightly and point slightly posteriorly, and also acquire slight indication of venation; during the third instar the ventral edges of the plates are markedly elongate, point strongly posteriorly, and the veins are pronounced. At the molt to the fourth instar the orientation of the small, developing wings shifts from pointing downward to pointing upward and posteriorly. In instar four the small forewings and hind wings are discrete and do not overlap, though the forewings may be completely or partly hidden beneath the pronotum. In instar five, the slightly larger wings overlap, appearing to be but a single pair of wings. Nymphs can complete instars 1–4 in about 7 days each, with the terminal instar requiring 10 days. However, under cool conditions 60 days are required for nymphal development.



Eastern Lubber Grasshopper, *Romalea microptera* (Beauvois) (Orthoptera: Acrididae), Figure 5 Nymph of eastern lubber grasshopper, *Romalea microptera* (Beauvois).

Adults often are colorful, but the color pattern varies. Often the adult eastern lubber normally is mostly yellow or tawny (Fig. 5), with black on the distal portion of the antennae, on the pronotum, and on the abdominal segments. The forewings extend two-thirds to three-fourths the length of the abdomen. The hind wings are short and incapable of providing lift for flight. The forewings tend to be pink or rose in color centrally whereas the hind wings are entirely rose in color. Darker forms of this species also exist, wherein the yellow color becomes the minor rather than the major color component, and in northern Florida a predominantly black form is sometimes found. Adults attain a large size, males measuring 43–55 mm in length and females often measuring 50–70 mm, sometimes 90 mm. Both sexes stridulate by rubbing the forewing against the hind wing. When alarmed, lubbers will spread their wings, hiss, and secrete foul-smelling froth from their spiracles. They can expel a fine spray of toxic chemicals for a distance of 15 cm. The chemical discharge from the tracheal system is believed to be an anti-predator defense, and to consist of chemicals both synthesized and sequestered from the diet. Vertebrate, but not invertebrate, predators are affected.

Eastern lubber grasshopper has a broad host range. At least 26 species from 15 plant families containing shrubs, herbs, broadleaf weeds, and grasses are eaten. A preference has been observed for pokeweed, *Phytolaca americana*; tread-softly, *Cnidoscolus stimmulosus*; pickerel weed, *Pontederia cordata*; lizard's tail, *Saururus* sp.; sedge, *Cyperus*; and arrowhead, *Sagittaria* spp. Though its preferred habitat seems to be low, wet areas in pastures and woods and along ditches, lubbers disperse long distances during the nymphal period. They are gregarious and flightless, their migrations sometimes bringing large numbers into contact with crops where they damage vegetables, fruit trees, and ornamental plants. Lubbers seemingly display little preference among vegetable crops, feeding widely on whatever is available. In choice tests they favor broccoli, Brussels sprout, carrot, pea, and squash relative to other common vegetables. Under field conditions, they seem to display preference for corn, cowpea, and peanut. Also, they seek out and defoliate amaryllis, Amazon lily, crinum, narcissus, and related plants in flower gardens. In Florida, they sometimes damage young citrus trees.

The natural enemies of lubber grasshoppers are poorly documented. Vertebrate predators such as birds and lizards learn to avoid these insects due to the production of toxic secretions. Naïve vertebrates gag, regurgitate, and sometimes die following consumption of lubbers. However, loggerhead shrikes, *Lanius ludovicianus* Linnaeus, capture and cache lubbers by impaling them on thorns and the barbs of barbed wire fence. After 1–2 days the toxins degrade and the dead lubbers become edible to the shrikes. Undetermined flies and nematodes have been reported from lubbers, and it is possible to infect lubbers experimentally with the grasshopper-infecting nematode *Mermis nigrescens*.

Damage

Lubber grasshoppers are defoliators, consuming the leaf tissue of numerous plants. They climb readily, and because they are gregarious they can completely strip foliage from plants. More commonly, however, they will eat irregular holes in vegetation and then move on to another leaf or plant.

Management

Management practices are not well developed. Insecticides applied to the foliage or directly to the grasshopper will prove lethal. However, due to their large size they often prove difficult to kill. Insecticide treatment is more effective for young grasshoppers. Because they are dispersive, and may continue to invade an area even after it is treated with insecticide, it is difficult to afford protection to plants.

Ecdysone Agonists, A Novel Group of Insect Growth Regulators

GUY SMAGGHE
Ghent University, Ghent, Belgium

The diacylhydrazines are a novel class of chemically and mechanistically new insect control agents that were discovered and characterized by researchers of the Rohm and Haas Co. (Pennsylvania, USA) in the mid-1980s. The first member of this group was RH-5849 (N-tert-butyl-N'-benzohydrazide) that had interesting foliar and root-systematic insecticide activities against a range of lepidopteran, coleopteran and dipteran pests. More recently, another more commercial analog was introduced, tebufenozide (N-tert-butyl-N'-(4-ethylbenzoyl)-3,5-dimethylbenzo-hydrazide; RH-5992; Mimic™, Confirm™, Rondam™) that is a more potent and selective foliar caterpillar control agent. In addition, halofenozide (N-tert-butyl-N'-(4-chlorobenzoyl)benzohydrazide; RH-0345; Mach 2™) that is a more effective soil insecticide for white grub and caterpillar control in turf, and methoxyfenozide (N-tert-butyl-N'-(3-methoxy-o-toluoyl)-3,5-xylohydrazide; RH-2485; Runner™, Intrepid™, Prodigy™) exhibits high insecticide efficacy and selectivity against Lepidoptera including Pyralidae, Pieridae, Tortricidae and Noctuidae. In this respect, Rohm and Haas was granted a "Presidential Green Chemistry Award" from the U.S. Government for the discovery of these non-steroidal ecdysone agonists. Due to the commercial success, screening bioassays were initiated to discover new 20E acting compounds, e.g., chromafenozide (Nippon Kayaku Co., Japan) and benzamide (3,5-di-*tert*-butyl-4-hydroxy-N-isobutyl-benzamide, DTBHIB, Sumitomo Co., Japan).

Chemistry and Physical Properties

The dibenzoylhydrazines can be readily synthesized from tert-butylhydrazine hydrochloride and the corresponding substituent benzoyl chloride using Schotten-Bauman conditions. The presence of the bulky tert-butyl group on the hydrazine allows the acid chlorides to be reacted in a sequential and highly regio-specific manner.

The dibenzoylhydrazines (Fig. 6), although not steroids, mimic actions of the insect molting hormone, 20-hydroxyecdysone, binding directly to the binding sites of 20-hydroxyecdysone and acting as full agonist at that site. As a consequence, treated larvae express all the classic symptoms of an untimely and severe overdose with 20-hydroxyecdysone, called hyperecdysonism. Treatment induces premature apolysis, which is the primary mode of action, and larvae stop feeding. Within 3–12 h after uptake, molting was initiated, and by 24 h, intoxicated larvae prematurely slip their old head capsules in an attempt to ecdyse. However, normal successful ecdysis was inhibited. In addition, abnormal cuticle deposition and other molting irregularities were seen, such as a lack of sclerotization and tanning of the new cuticle, absence or conspicuous low number of endocuticular lamellae, hindgut extrusion and loss

of hemolymph and molting fluid, that results in desiccation and ultimate death.

Insecticidal Mode of Action

The dibenzoylhydrazines manifest these typical effects via interaction with the molting hormone receptor complex that consists of a heterodimer of two steroid receptor superfamily members, i.e., the ecdysteroid receptor (EcR) and the Ultraspiracle (USP) protein. This hormone-protein complex binds then to the ecdysone responsive elements on the DNA. These chemicals permit the expression of genes and behavioral events that are dependent upon the presence of 20-hydroxyecdysone. However, those processes that are dependent upon the absence of 20-hydroxyecdysone, such as the expression of dopa-decarboxylase enzyme for tanning and the ecdysis behavior (production/release of the neuropeptide eclosion hormone), are prevented due to the persistence in the insect tissues (Fig. 7).

In adults, the dibenzoylhydrazines caused a reduction of egg production and fertility in various target Lepidoptera, Coleoptera and Diptera. However, the exact mechanism of action is not clear.

Insecticidal Properties and Efficacy Against Target Pests

The dibenzoylhydrazines were tested in larvae and adults from at least 16 different insect orders, and toxicity is most pronounced when exposure and uptake occur via ingestion. Tebufenozide and methoxyfenozide perform a high selective toxicity against Lepidoptera. These compounds are marketed around the world for control of important agricultural caterpillar pests in cotton, vegetables, top fruit, grapes, ornamentals, forestry and rice. Targets are, for instance, beet armyworm, *Spodoptera exigua*, cabbage looper, *Trichoplusia ni*, codling moth, *Cydia pomonella*, grape berry moth, *Lobesia botrana*, spruce budworm, *Choristoneura fumiferana*, rice leafroller, *Cnaphalocricis medinalis*, and others. Use rates typically range between 30 and 300 g of active ingredient/ha depending on the target crop and pest.

Safety to Non-target Organisms

Tebufenozide and methoxyfenozide had little or no effect on a panel of non-lepidopteran pests (Coleoptera, Hemiptera, mites and nematodes) when tested at high rates (from 18 to 1500-fold greater than that producing 90% mortality in Lepidoptera). Likewise, laboratory and field experiments showed that there are little or no adverse effects at normal rates on a wide range of non-lepidopteran beneficial insects such as honeybees and bumblebees (Hymenoptera), many predatory insects (Hemiptera, Coleoptera, Neuroptera, Odonata, Plecoptera, Trichoptera, Ephemeroptera) and mites (Acarina), several caterpillar endoparasitoids (Hymenoptera) and certain insect predators such as spiders (Arachnida). These compounds appear to be highly caterpillar selective and highly compatible for integrated pest management (IPM). Treatment also was found to be safe towards several non-arthropod invertebrates such as earthworms and nematodes, and has a low acute toxicity for a representative crustacean (*Daphnia magna*).

For vertebrates, several representative mammals, bird and fish species (rat, quail and trout) were, at a minimum, four orders of magnitude less susceptible to methoxyfenozide and tebufenozide than is a representative lepidopteran species. These compounds are non-irritating (rabbit), non-sensitizing (guinea pig), non-mutagenic and non-oncogenic (mouse, rat and dog). Methoxyfenozide has a dietary no effect level (NOEL) of 1950 mg/kg in a two-generation rat development bioassay. In retrospect, this relative lack of vertebrate toxicity might have been anticipated since such organisms do not synthesize or utilize 20E, the ecdysone receptor complex (EcR and USP) or any other closely homologous substances.

Ecdysozoa

The concept of a superphylum called Ecdysozoa was proposed only in 1997, following molecular analyses that suggested close relatedness among some invertebrates that shed their three-layered cuticle periodically. However, a similar concept had been proposed 100 years earlier based on morphology. The characteristics that link the ecdysozoans, in addition to the three-layered sheddable cuticle composed of organic material, include the absence of locomotory cilia, production of amoeboid sperm, and the absence of spiral cleavage in the embryonic stage. There are two major groups within this scheme of classification, encompassing several phyla. Only the Arthropoda (over 6 million species) and Nematoda (over 20,000 species) are speciose, the other phyla being fairly minor in importance. The phyla involved are:

- Ecdysozoa
  - Panarthropoda
    - Arthropoda
    - Onychophora
    - Tardigrada
  - Cycloneuralia
    - Kinophora
    - Priapulida
    - Loricifera
    - Nematoda
    - Nematomorpha

This grouping has yet to win wide acceptance, as these taxa seem to be polyphyletic.

Ecdysteroids

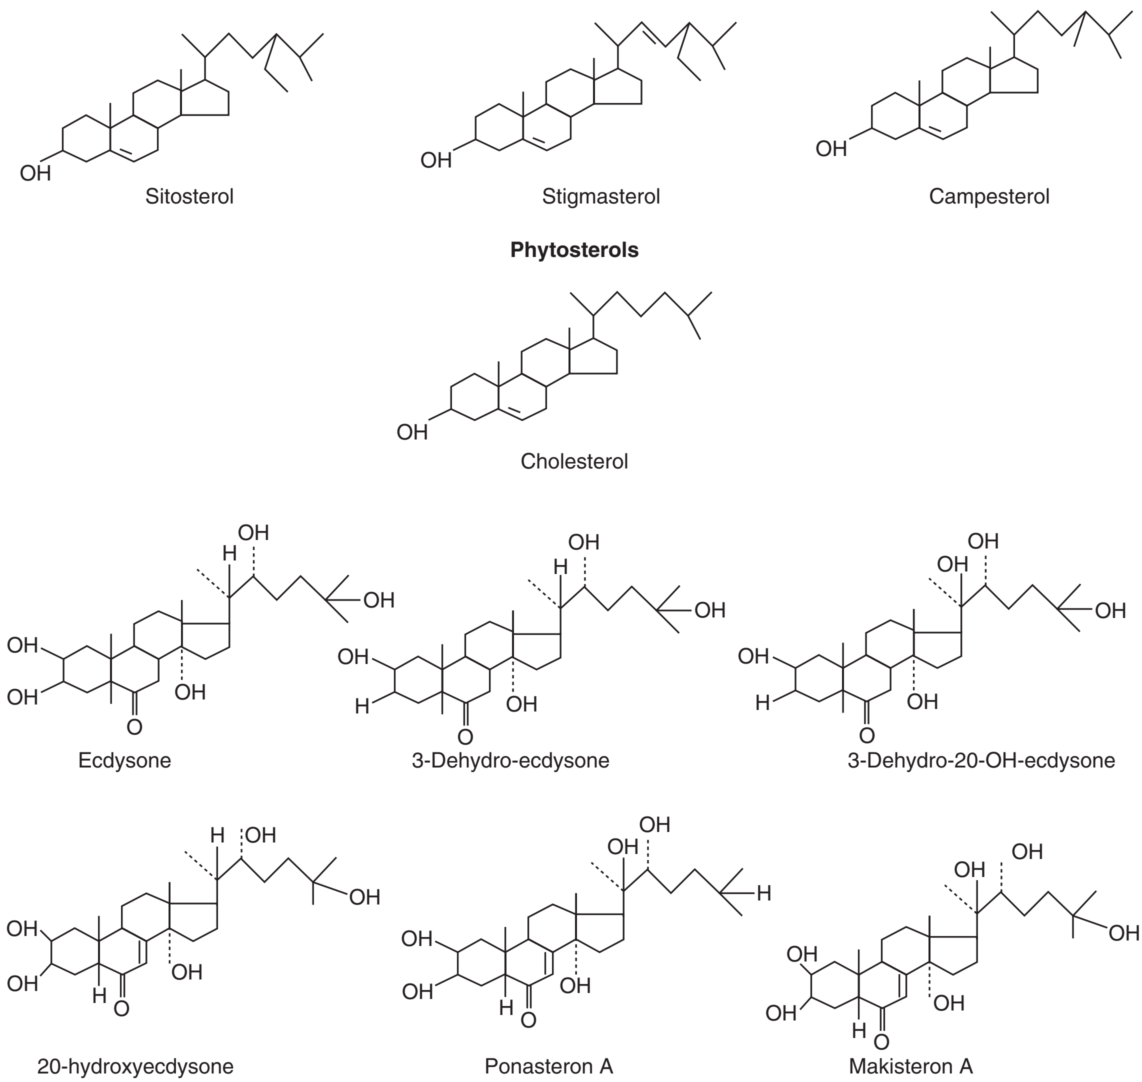
ELI SHAAYA
The Volcani Center, Bet Dagan, Israel

Ecdysteroids are hormones that regulate a wide variety of cellular processes in the life cycle of arthropods. Pulses of ecdysteroids coordinate the complex events during molting and metamorphosis in postembryonic development which are essential in the life of the insects. Two of the most common and studied ecdysteroids hormones in insects are ecdysone = (α -ecdysone) and 20-OH-ecdysone = (ecdysterone, crustecdysone).

Research on insect hormones began in 1934, when V.B. Wigglesworth, in his study on the physiology of ecdysis in the Hemipteran *Rhodnius prolixus* described the metamorphosis in this blood sucking bug. One year later, G. Fraenkel published a study of the hormone causing pupation in the blowfly *Calliphora erythrocephala*. From P. Karlson's autobiography we learn that, in 1943 he started the work on the isolation of the molting hormone of insects, and only in 1954, Bütenandt and Karlson had succeeded in isolating a crystalline form of ecdysone. In order to obtain reasonable amounts of the hormone, they had to use 500 kg of male silk worm pupae, (*Bombyx mori*). The exact structure of ecdysone was fully elucidated in 1965, independently by the Karlson group, and the crystallographers Hüber and Hoppe. Later, in the year 1966, the structure of 20-OH-ecdysone(20E), which is regarded in most arthropods as the predominant active hormone, was sequentially established by Dennis Horn' s group as crustecdysone and Hoffmeister group as ecdysterone. The concept of steroid hormone action on gene expression was first developed by studies on the mode of action of ecdysteroids in Dipteran flies. This was due to the findings in 1960 of Clever and Karlson, that ecdysteroids can activate transcription in polytene chromosomes of the midge, *Chironomus tentans*. Evidence to support this concept was the visible enlargement of specific regions of polytene chromosome puffs of the target cells.

Origin and Site of Synthesis

Cholesterol, originating either from the insect diet or from the conversion of dietary C28 and C29 phytosterol, is the common precursor of ecdysteroids (Fig. 8). All insects and other arthropods are unable to synthesize de novo the steroid nucleus, therefore require exogenous or dietary source of sterol for normal growth. The prothoracic glands, comprising a single steroidogenic cell type in most insects, are the predominant site of ecdysteroids biosynthesis during postembryonic development. In flies, higher insects, the prothoracic glands is a part of an organ, the ring gland, which also includes the corpus cardiacum and corpus allatum. The latter is the site of ecdysteroids release to the hemolymph. In some insects, epidermal, oenocytes and gonadal cells are alternative sites for ecdysteroids production, especially during adult life, at a time the prothoracic glands are no longer present. In female ovaries, the epithelium of the follicle cells produces ecdysteroids, which play a crucial role in the induction of vitellogenesis. During embryogenesis, in the absence



Ecdysteroids, Figure 8 **Structural formulae of some important phytosterols, ecdysteroids and cholesterol.**

of any differentiated site of ecdysteroids biosynthesis, many insects are able to elevate their ecdysone titer by metabolizing maternal ecdysteroid conjugates to active hormones.

In crustaceans, ecdysteroids are produced by the Y-organ glands, and control a number of processes in the life cycle of the animals, similar to insects.

The Regulation of Ecdysteroid Synthesis

The regulation of ecdysteroids synthesis is very complex, and under the control of peptide hormones as well as the sesquiterpenoid juvenile hormone (JH). Ecdysteroids are mainly synthesized by the prothoracic glands and released into the hemolymph upon stimulation by the prothoracicotropic hormone (PTTH), a neuropeptide produced by the insect brain. The periodic increase in ecdysteroids titer critical to insect development reflect to a large degree the activation of the prothoracic gland by PTTH. The structure and mode of action of PTTH has been investigated in a number of insects. PTTH is synthesized as a preprohormone and it is expressed in a number of neurosecretory cells of the brain. It occurs in multiple forms large and small, some are active others not, depending on the insect species. Binding of PTTH to the membrane receptor elevates intracellular Ca^{2+} influx, and the action in turn enhances cAMP formation. As a consequence cAMP-dependent protein kinase is stimulated. The activated kinase stimulates ecdysteroid production. PTTH acts at critical steps in the regulation of ecdysteroids levels in developing insects. The concentration of active ecdysteroids is modified by target cell specific hormone metabolism. The prohormones ecdysone, 3-dehydroecdysone and 3-dehydro-20 hydroxyecdysone, which are secreted into the hemolymph, are metabolized to the more active compound 20E, which is in most arthopods the predominant active hormone. In various species of Hemiptera, Makisterone A is regarded as the major molting hormone. Like vertebrates, a series of cytochrome P450 is involved in the various steps of 20E synthesis from cholesterol. There are indications that at least two cephalic factors are able to stimulate ovarian ecdysteroidogenesis in the blow fly: one acting via cAMP independent mechanism, and the other using cAMP as a second messenger. Although the ecdysteroids have been characterized, ecdysteroids biosynthetic pathways and enzymes involved in the hormones biosynthesis are not yet fully elucidated. Also, little is known about the genes involved in the biosynthesis of the hormones.

PTTH is not the sole regulator of ecdysone biosynthesis. JH exerts an indirect tropic effect on the prothoracic glands, probably mediated by a stimulatory protein in the hemolymph, possibly a precursor steroid carrier. Also, the developmental state of the prothoracic glands to respond to the regulatory effectors appears to be a key factor in the regulation of ecdysone synthesis. During larval-pupal development, regulatory effectors, hormone interactions, and competence of the prothoracic glands may all be integrated to regulate the ecdysteroid titers. There is experimental evidence for the existence of a neuroendocrine regulation of ecdysteroid synthesis in ovaries of *Aedes ageptii* and *Locusta migratoria*. It may be significant to mention that in *Locusta* there are structural similarities between the larval (PTTH) and adult ecdysiotropins.

In crustaceans, ecdysteroid synthesis is regulated by molt-inhibiting hormone (MIH). This neurohormone exerts opposite effects compared to PTTH in insects by inhibiting ecdysteroid synthesis in the Y-organs. MIH also increases cAMP second messenger which activates protein kinases, following alteration of cellular Ca^{2+} levels. The contrasting steroidogenic effects of PTTH and MIH probably arises from differences in the cellular kinase substrates. In insects such substrates enhance ecdysteroid secretion by increasing the translation of granular protein. In crustacea, MIH stimulates changes leading to the inhibition of both protein synthesis and steroidogenesis.

Ecdysteroids Metabolism

Activation

The metabolism of the prohormones ecdysone, 3-dehydroecdysone and 3-dehydro20-hydroxyecdysone to 20-hydroxyecdysone, is regarded as an activation mechanism, converting the poorly active precursors, to the highly active 20-hydroxyecdysone, the principle molting hormone. This refers mainly to higher insect species like Dipterans. Other insect species use both ecdysone and 20-hydroxyecdysone as hormonal messengers. There are speculations that during evolution in higher insects ecdysone lost its hormonal role and is merely a prohormone.

Inactivation Mechanism

Inactivation mechanisms of ecdysteroids are common in the various insects tested. Ecdysone and/or 20-hydroxyecdysone are inactivated primarily by:

1. Esterification, acetylation, posphorylation.
2. Epimerization, oxidation followed by isomeric reduction of the C-3 hydroxyl group.
3. Hydroxylation of the C-26 methyl group followed by oxidation to ecdysonoic acid.
4. To a lesser extent by esterification of the C-2 hydroxyl group on the A nucleus of the molecule.

Inactivation of ecdysteroids varies according to the tissue and developmental stage. In other arthropods, the inactivation mechanism of the active ecdysteroids is similar to insects.

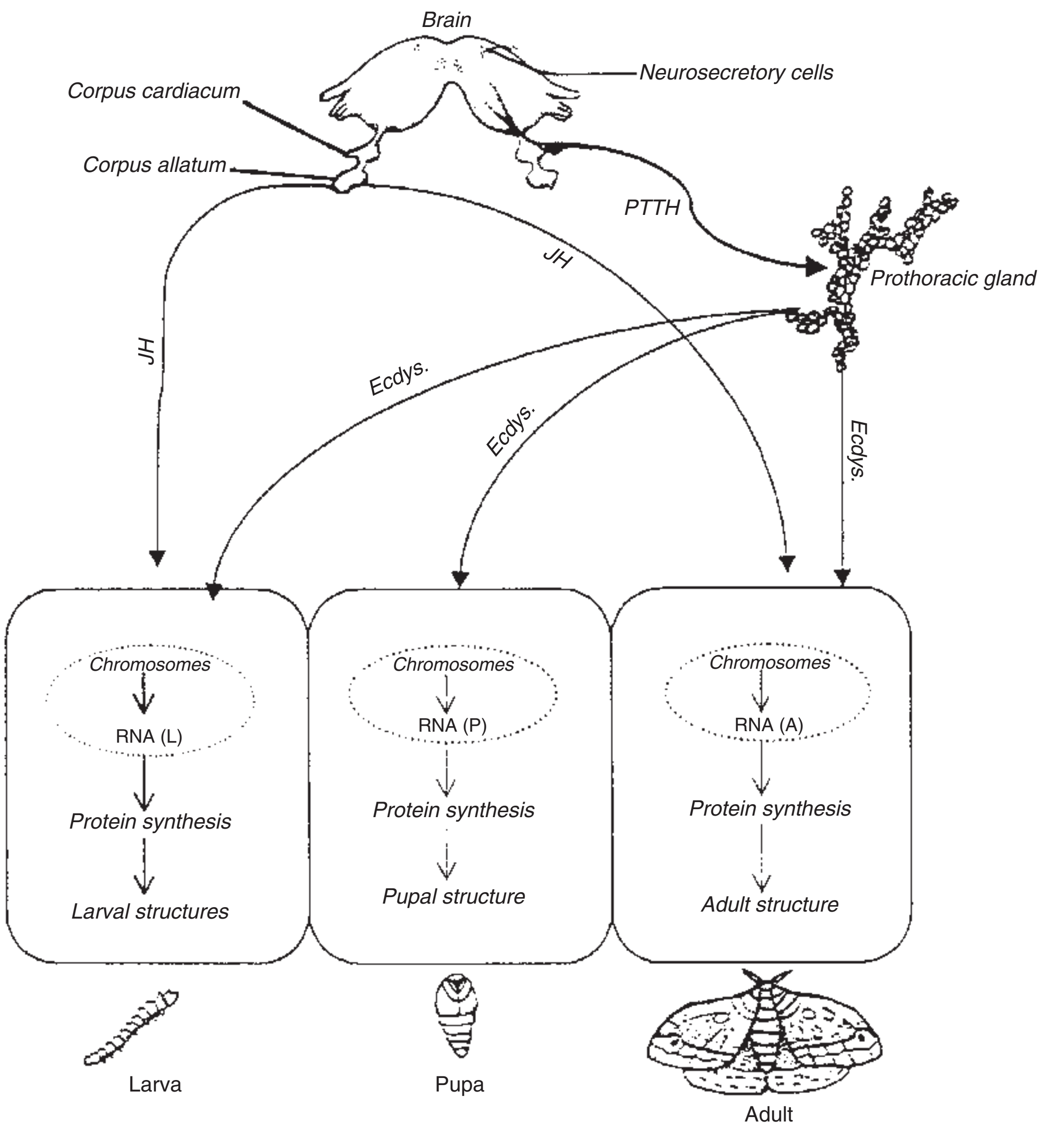
Storage Mechanisms

A large portion, up to 98% in some insect spp., of the ovarian ecdysteroids are esterified to phosphate conjugates at the C-22 hydroxyl group. Occasionally, more complex conjugates bearing nucleotides on the phosphates are found together with the 22-phosphates. These ovarian conjugates are present in newly laid eggs, and gradually metabolized during embryogenesis to the active hormone. It may be relevant that the eggs contains enzymes involved in ecdysteroid metabolism.

Mode of Action of Ecdysteroids: Molecular Aspects

Metamorphosis transforms the insect larva into a reproductive adult through a complex series of developmental events involving cell proliferation, differentiation, remodeling of structures for new functions, and finally programmed cell death. In insects, these developmental processes are coordinated by pulses of ecdysteroids that include the principle hormone 20E and in some insects ecdysone, which have morphogenetic functions of its own, and also JH. The ecdysteroids cause molting (Fig. 9) and also are responsible for the changes in the genetic programs that are necessary for metamorphosis, whereas the presence of JH in the larva prevents these changes from taking place, but does not prevent the molting response. Thus, metamorphosis ensues when ecdysteroids rise in the absence of JH in the final larval instar. In most insects, exogenous JH at this time causes the formation of a supernumerary larva, but in the higher Diptera JH does not prevent pupariation nor pupation, but disrupts the development of the adult organs, thereby causing the death of the insect. The target tissues of ecdysteroids contain proteins which bind to the hormone. The binding has a high affinity for the hormone, and a limited number of binding sites per target cell, which is characteristic of steroid hormone receptors. In addition, the binding proteins exhibit a differential affinity for the various ecdysteroids, depending on their biological activity.

Determination of the mode of action of ecdysteroids at the genomic level was based on a series of pioneering studies using *Chironomus* and *Drosophila* which showed that in polytene



Ecdysteroids, Figure 9 Schematic diagram of the principal endocrine organs of Lepidopteran insects and the regulation of metamorphosis by their hormones. Ecdys. = ecdysteroids; JH = juvenile hormone.

chromosomes certain stage-dependent puffs could be induced by exogenous ecdysone. This model interaction of the hormone with the hormone-receptor complex recognizes specific DNA response elements, and triggers a cascade of gene activity that directs the molting process. Over one hundred different genes are known to be regulated by ecdysteroids. Hormonal regulation is gene and tissue specific, and is modified according to the developmental stage of the insect. The general molecular mechanism of steroid hormone action must be diversified to adapt hormone action according to the physiological needs. Target cell specific hormone metabolism is one way to adapt molting hormone action in a tissue specific manner. Beside molting, ecdysteroids regulate a large number of processes including spermatogenesis, oogenesis, reproduction, embryogenesis, diapause, change in insect color, behavior, metabolism and cell death. Ecdysteroids also regulate the concentration of enzymes responsible for the synthesis and degradation of 20E, and thus modulate ecdysteroid titer; regulate the central nervous system sensitivity to eclosion hormone and ecdysis triggering hormone; and the regulation of melanization by the induction of the enzyme dopa decarboxylase. The relatively simple ecdysone-inducible genes of salivary gland glue proteins or larval serum proteins-1 of fat body, for example, have a single transcript. However, other ecdysone-inducible genes show a complex pattern of transcription and stretch over regions of 50 kb or more.

Involvement of Ecdysteroids in the Control of Reproduction and Embryogenesis

Vitellogenic ovaries synthesize ecdysteroids at a given stage of their development. In some dipteran species, ecdysteroids synthesis starts at almost the same time as the onset of vitellogenin synthesis, whereas in other species like orthopterans the synthesis starts only towards the end of vitellogenin uptake. These ecdysteroids are either released into the blood of the female or accumulate inside the oocytes and are transferred in the newly laid eggs. This situation is common in most insect species. However, the ratio of the amounts released into the blood, to those retained in the oocytes seem to vary between insect orders. In locusts, for example, only 2% of the ecdysteroids produced by the ovary is released into the blood of the female, the other 98% accumulates in the newly laid eggs. In *Galleria* (Lepidoptera), this ratio is 1:1. It should be mentioned, however, that in most insect species most ovarian ecdysteroids are conjugates, and may escape detection.

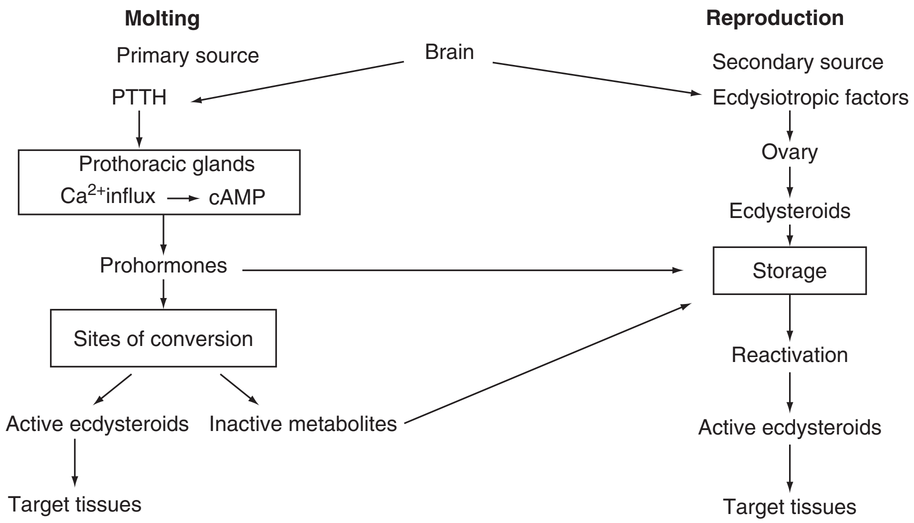
In higher insect orders, like the Diptera, ovarian ecdysteroids play a role in the control of vitellogenin synthesis, whereas in other orders they play a role in the early events of embryogenesis. Ecdysteroids also control additional events in a variety of insect species. For example, in mosquitoes, separation of incipient follicles from the germarium, and control of release of ovulation hormone, is controlled by ecdysteroids.

As regards the possible involvement of ecdysteroids in the control of vitellogenesis in dipterans, ecdysteroids can stimulate the synthesis of vitellogenin mRNA, both in females and males. In female Diptera, ecdysteroids stimulate the fat body to synthesize increased amounts of vitellogenin; it is possible that the fat body has to be primed by JH to become responsive to ecdysteroids.

The involvement of ovarian ecdysteroids (Fig. 10) in the early events of embryogenesis is based on the remarkably high concentrations, about 10^{-4} M of ecdysteroid conjugates of ovarian origin, present in newly laid eggs. As embryogenesis proceeds, the conjugates are then hydrolyzed by enzymatic activity, resulting in the surge of free ecdysteroids. The presence of enzymes responsible for these transformations has been monitored in a number of insects. In the newly laid eggs, the maternal conjugate first is hydrolyzed to the active ecdysteroid needed to trigger some specific processes, then it metabolized to an inactive molecule. Indeed, during embryogenesis there are a certain number of peaks of ecdysone and/or 20-hydroxyecdysone which coincide with cuticle deposition, either by the serosa or by the embryonic epidermis. Thus, via a large supply of ecdysteroid conjugates, the mother controls ecdysone-triggered events of embryogenesis which occur prior to the stage when the embryo has acquired its own capacity to biosynthesize ecdysone *de novo*.

Ecdysteroids in Non-arthropods Metazoans

Many protostomians contain ecdysteroids; the main ecdysteroids which were identified in non-arthropods are similar to those found in the different insects such as ecdysone, 2-deoxy-ecdysone, Ponasterone A, 20-hydroxyecdysone and 20, 26-dihydroxyecdysone. As in arthropods, these ecdysteroids are found both in free or esterified (polar or non-polar) forms. The concentration of



Ecdysteroids, Figure 10 Simplified scheme of ecdysteroid production in insect molting and reproduction.

ecdysteroids recorded in non-arthropods are generally lower than those found in arthropods. Titre fluctuations have been recorded in relation to reproductive cycles, embryonic metamorphosis and integumental events. This indicates that in non-arthropods ecdysteroids might play roles similar to those that they exert in arthropods.

It is of interest to mention that human patients infested by trematodes, cestodes and nematodes contained ecdysteroids in their blood and urine. The potential of this finding for diagnosis, and possibly even for interfering with the parasite' s development or reproduction, is of interest. The detection of ecdysteroids in sera or urine of humans may contribute to diagnosis of helminth infection. It is premature to speculate that these finding open a novel way of fighting parasitic infection. It is questionable whether or not these parasites use ecdysteroids for the control of their reproduction and development.

Phytoecdysteroids

Analogues of ecdysteroids occur in a variety of plants: pteridophyta, gymnosperms, and angiosperms. The ecdysteroids isolated from plants are ecdysone, 20E, 3-epi-20-hydroxyecdysone, 20-hydroxyecdysone 22 acetate, ponasteron A and many others of less importance. The physiological relevance of these phytoecdysteroids in the plants, which are identical to the zooecdysteroids, is not thoroughly studied. A high concentration of ecdysteroids may contribute to the protection of the plant against invertebrate predators by mimicking the natural hormones and disturbing the hormonal balance within the insect. They can act as antifeedants or antagonize the action of the ecdysteroid hormones.

Echinophthiriidae

A family of sucking lice (order Phthiraptera). They sometimes are called seal lice.

► Chewing and Sucking Lice

Eclosion

Egg hatching. Escape of the immature insect from the egg chorion. This term also is sometimes used to describe emergence of the adult from the pupal stage.

Eclosion Hormone

A neurosecretory polypeptide produced by the brain and released into the hemolyph, stimulating molting.

► Metamorphosis

Ecnomidae

A family of caddisflies (order Trichoptera).

► Caddisflies

Ecological Community

A group of populations that interact within a certain geographic area. The biotic portion of an ecosystem. It is also called a community.

Ecological Homologues

Species that have niche parameters that are almost identical. Such species typically do not coexist, and evolve in different geographic regions.

Ecological Management

This term is equivalent to cultural management or cultural control. This is the manipulation of the environment or practices to prevent invasion, minimize damage, or eliminate pests. It depends on the use of normal planting, production, harvesting practices rather than specialized equipment or techniques. A good example of ecological management would be manipulation of planting dates, making them either earlier or later depending on circumstances, to avoid infestation.

► Cultural Control of Insect Pests

Ecological Niche

The role of an organism including the resources used and habitat occupied.

Ecological Succession

Replacement of members of a community over time in response to community change. This process is normally thought of as a botanical phenomenon, wherein grasses are replaced by small shrubs, then large shrubs, then small trees, and finally large trees. However, insects display corresponding changes as other members of the community change. It is also called succession.

Ecology

The study of organisms in relation to their environment. News writers often substitute the term ecology when they mean environment.

Economic Injury Level (EIL)

A level of pest abundance or damage at which the cost of control equals the crop value gained from instituting the control procedure.

► Economic Injury Level (EIL) and Economic Threshold (ET) Concepts in Pest Management

Economic Damage

Damage that exceeds a visual or aesthetic effect, causing a monetary loss.

► Economic Injury Level (EIL) and Economic Threshold (ET) Concepts in Pest Management

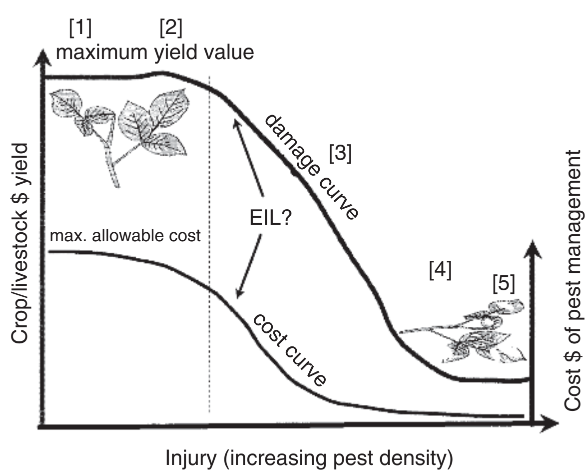
Economic Injury Level (EIL) and Economic Threshold (ET) Concepts in Pest Management

DAVID G. RILEY
University of Georgia, Tifton, GA, USA

One of the fundamental concepts of integrated pest management is that each pest species has a definable relationship in terms of damage to the plant or animal host that it attacks. This relationship is often referred to as the damage curve (Fig. 11), which is often determined relative to yield loss. This damage curve can take several forms, but was summarized by Higley and Peterson as having a tolerance or overcompensation phase ([1] no yield response, or [2] positive yield response to injury), a linearity phase ([3] e.g., yield loss = – a (unit injury) + b), and a desensitization and an inherent impunity phase ([4] decreasing and finally [5] no additional yield loss per unit injury). The curve can be used with various methods to determine whether or not any action or pest management tactic (e.g., pesticide, biological control, cultural control, etc.) is needed to reduce the damage associated with this pest. Also, this relationship is uniquely characterized by a critical point, the economic injury level (EIL), or the point in the agricultural production system where the costs associated with pest management equal the benefits from the pest management actions. In other words, below the pest population represented by the EIL there is no need to take pest control actions because they are not economically justified, but economic damage can occur when the pest population densities are above the EIL.

A simple, robust model of the EIL relationship between pest control costs and benefits from control actions was developed by Pedigo et al. as:

where C = management cost per production unit, V = market value per production unit, D = damage per unit injury, I = injury per pest equivalent, and K = proportional reduction in injury with management. They later combined D + I into a single variable, D′ = percent yield loss per pest. A variation on this formula that is often used that assumes 100% control is: EIL = (C × N)/(V × I), where N = the number of pests causing injury, and I = percent yield loss (similar to the D′ value above). In an example using the EIL = C/VD′ K formula, if a seasonal average of one insect/plant causes a



Economic Injury Level (EIL) and Economic Threshold (ET) Concepts in Pest Management, Figure 11 **Example of a pest damage curve (thick line) and associated cost of pest control (thin line) used to estimate at economic injury level (EIL).**

10% reduction in yield, the market value of the crop is \$0.4/lb fruit and you expect 5 lb fruit/plant yield, the cost of control is \$0.04/plant, and you can count on a 75% reduction in damage with the control tactic used, then:

EIL = \$0.04 cost per plant/(\$0.4/lb×0.5lb/insect × 0.75)
= 0.27 insects/plant

Notice that if you halve the number of insects required to inflict 10% yield loss, you halve the EIL value. In contrast, if you double the cost of control you double the EIL value, again balancing the tradeoff between control costs and benefits. In reality, the EIL value can be difficult to calculate exactly because of the temporal and dynamic nature of pest damage and crop value. In the example above, an early season average of one insect might result in 15% yield while late season results in only 5% yield, so the estimate based on a seasonal mean would not be very precise for a given period during the season. One way to avoid large seasonal differences is to calculate an early-season and a late-season EIL, for example:

$EIL_1 = C/VD_1'K$ and $EIL_2 = C/VD_2'K$
or
EIL_1 = \$0.04 cost per plant/(\$0.4/lb×0.75 lb/insect × 0.75)
= 0.18 insects/plant
EIL_2 = \$0.04 cost per plant/(\$0.4/lb×0.25lb/insect × 0.75)
= 0.5 insects/plant

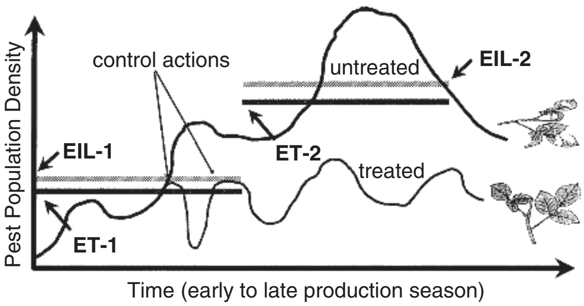
The EIL can be based on a single, seasonal mean, based on periods during the season with similar responses (e.g., seedling, vegetative, fruit formation, or simply early versus late season), or be accurately calculated over time for the life span of the affected host. This latter determination of a dynamic EIL requires a great deal of data and is seldom accomplished for most crop or livestock systems. In addition, the EIL formulas often assume a linear response to injury at any given time during the season, which may not be entirely accurate. Even so, an assumption of linearity can be generally sufficient for the range of pest injury critical for an EIL determination.

Estimates based on the aforementioned EIL formulas are in use for many agricultural pests and have successfully provided pest management decision criteria for many production systems, mainly because of both their effectiveness and ease of use. It should be noted that in commercial production systems, economic injury levels are likely to be close to a maximum allowable pest management cost because these systems have traditionally focused on maximizing returns and reducing risks to production. What is often lacking in these estimates of EILs is an environmental cost factor. The environmental cost would adjust the pest management cost by taking into consideration not just what the farm spends on management tactics, but also an estimated average cost to the environment or agro-ecosystem where the farm exists. Using the environmental economic injury level:

$$EIL = (C+EC)/VDIK$$

proposed by Higley and Wintersteen and adding an environmental cost of \$0.04/plant would increase the EIL to 0.53 or double its previous level in the aforementioned example. There will likely be a high degree subjectivity in this kind of environmental cost estimate. Even with its complications, the EIL is fundamental for understanding the interaction of pests with their host, but the calculation of economic thresholds from these data is quite a different problem, which will be discussed in the next section.

An economic threshold (ET) is typically the pest population density at which a pest control action (e.g., pesticide, biological control, cultural control, etc.) should be taken in order to prevent an increasing pest population from reaching economically damaging levels, which is the economic injury level (EIL). As shown in the diagram of the two-level fixed economic threshold (Fig. 12), two different fixed economic thresholds are esti-



Economic Injury Level (EIL) and Economic Threshold (ET) Concepts in Pest Management, Figure 12 **A two-level, fixed economic threshold with treated (narrow line), i.e., effectively controlled to stay below the EIL, and untreated (thick line) pest populations.**

mated for a single pest in a given cropping season depending on if the time frame is early season (ET-1) or late season (ET-2) as:

$$ET_1 = 90\% \times EIL_1 = 0.16 \text{ insects/plant}$$
$$ET_2 = 90\% \times EIL_2 = 0.48 \text{ insects/plant}$$

Also as an example, the pest population levels of a treated field (control actions taken) versus an untreated field (no control action) are indicated by the narrow and solid lines, respectively (Fig. 12). What can be seen from this example is that, on several levels, time is as critical a component in the estimation of economic thresholds as pest numbers. Also, it is clear that frequent pest monitoring or scouting will be required to track pest population density through time with some accuracy. In this example, it is assumed that approximately twice as many insects are required to cause an equal amount of yield loss in late season (EIL-2) as early season (EIL-1). Another aspect of time is that there may be an increase in the pest population or damage over time, and will tend to increase at a determined rate, excluding massive emigration events, as the season progresses. Finally, there is a time component in the duration of delay from when a pest population reaches an economic threshold, when control actions are actually implemented, and when the reduction of the pest population begins to occur. This can directly affect the threshold value, because the purpose of the threshold is to prevent the pest population density from reaching the EIL. As Pedigo stated, "the ET actually represents the time for taking action against a pest; population density serves as a convenient index of that time."

Economic thresholds for agricultural pests vary greatly in their accuracy (how close the estimate is to a true ET) and their precision (degree of variation around an estimated value) depending on the method used for its development. In the broadest sense, thresholds in the literature are either more subjective (based on an educated guess or "guesstimate") or more objective (based on research data used to estimate an EIL and an effective method for relating the EIL to a threshold level for initiating pest management actions). In either case, the objective is to prevent the pest population from reaching an economically damaging level. However, a low level of accuracy, often associated with subjective estimates called "nominal thresholds," can lead to either underestimating or overestimating the pest population level where action should be taken. An underestimate will result in more control costs than is economically justified, whereas an overestimate will result in crop or livestock damage that could have been avoided economically with the appropriate timing of an effective control tactic. Even though an objective ET can be more accurate than a subjective ET, the objective ET' s precision can be greatly influenced by the method in which an EIL is calculated. An EIL based on seasonal population means relative to final yield loss can be very accurate, but not very precise for individual dates during the season. Using the previous example of 15% yield loss during early season and 5% yield loss during late season for an equal number of pests, the calculated EIL values for early and late season are 0.18 and 0.53, respectively. If a single EIL = 0.27 is used for the entire season, then there will be an overestimated ET early in the season and an underestimated ET late in the season, causing the same problem as a lack of accuracy, even if it is likely to a lesser degree.

A subjective ET can be based on effective observational data as, for example, by adjusting the threshold higher or lower after each production season based on yield response, so that a reasonably accurate ET is developed through a long term process of iteration. Generally, a subjective ET is fixed at a value or named by consensus for a given use period and is thus referred to as a nominal threshold. In fact, a significant number of thresholds in use today are based on this method. The problem with this method is that it does not define the mechanism behind the EIL and ET, and can thus be affected by changes in production factors, e.g., crop variety, climate, market-driven planting dates, etc., to some unknown degree from year to year. At the very least, a subjective ET can be a starting point for threshold development, and potentially provide significant pest management benefits.

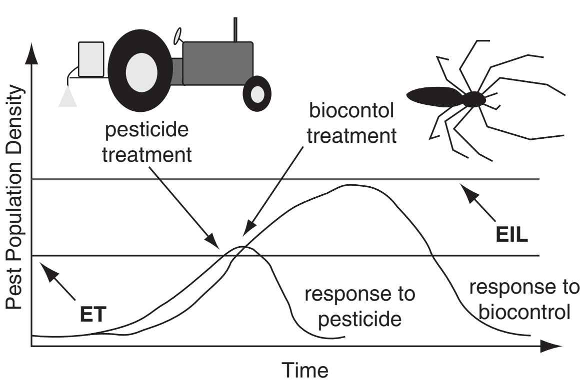
Although objective determinations of ET are research-based, they also can have a range of sophistication and complexity beginning with a simple fixed ET. The fixed ET is set at a specific percentage of the determined EIL, usually based on conservative estimates for preventing significant crop loss. In the example for a single seasonal EIL determination described in the previous section, the estimated EIL = 0.27 insects per plant would result in 2.7% yield loss that cannot be economically prevented within the conditions of the example. If there was a relatively high risk of loss, for example above 10%, a conservative threshold might be set at half, regardless of whether or not the additional control actions are economically justified. High levels of threats of injury can even lead to abandoning the ET altogether. In the other direction, if a new, highly effective (100% control) and inexpensive ($0.01/plant) control product is introduced into the system, not only does the EIL drop to 0.05, the expected yield loss at this level is so low at 0.5% that the tendency will be to leave the ET at or even above the EIL = 0.05. In this case, increasing the EIL could be justified by using other decision criteria, like environmental costs that have not been included in the initial EIL determination. Subjective judgments on the overall percentage crop loss that can be tolerated tend to vary more at the low injury levels than the high injury levels since high injury levels are not commercially tolerated. What is not considered in detail with the fixed ET is the actual time between control actions and the time it takes for the pest population to increase to the predicted EIL. In most cropping systems, weekly scouting reports are followed by weekly curative actions in the form of pesticide applications. If a cultural or biological control tactic is used that needs time to affect the overall pest population, the estimation of this time becomes critical. In this case, more descriptive thresholds based on the mechanisms of pest population dynamics are needed to accurately predict when the population level will reach the EIL.

Descriptive thresholds are of two general types, stochastic and deterministic. The deterministic model assumes a fixed and unique outcome, whereas a stochastic model incorporates probabilities based on demographics. Thus, the stochastic ET is based on an estimated pest population growth based on average population dynamics, with an associated probability of error. An economic threshold based on sequential sampling of a pest population is a good, fairly complex example of a stochastic ET. A simple example, based on highly predictable pest population dynamics, would be if a pest population prior to reaching an EIL is known to increase at a given exponential rate that doubles the population ($y = 2^x$ where y = pest numbers and x = generation time) after each generation time and the scouting interval (e.g., 7 days), is equal to one generation time. Then using the EIL = 0.27, the threshold would simply be:

$$\text{ET} = \text{EIL} - (\text{EIL}/2) = 0.27 - (0.135)$$

This simplistic example only works if the control action and response can occur between scouting intervals, that you can accurately predict that the EIL will be reached by the next scouting event, and that there is no great need to modify the value to include an additional margin of error based on a probability analysis.

The deterministic ET relies on knowledge of age-specific parameters and life processes of the pest population. It can still require probability estimates for specific processes, such as the average mortality of a beneficial insect that would affect the estimate of "K" in the calculation of an EIL, but the key mechanisms that determine pest population growth are defined. Biological control or long term cultural control tactics could benefit from the use of this type of threshold. A typical difference in the response time for a biological control tactic versus a chemical control tactic is illustrated in Fig. 13. In this example, both tactics provide equally high levels of control, but the response to the pesticide is fast, so the ET could be set closer to the EIL value than it can with the biological control. To estimate the biological control response it might be necessary to calculate life table data for both the predator and prey species (crop pest) and relate this to temperature, time and spatial dynamics; a fairly complex proposition. As the time increases between the initiation date of an effective control action and the



Economic Injury Level (EIL) and Economic Threshold (ET) Concepts in Pest Management, Figure 13 Delayed response to a biological control tactic.

control response of the pest, these descriptive thresholds can become more crucial.

Economic Threshold (ET)

The point at which corrective measures must be taken to prevent damage from attaining or exceeding the economic injury level; a level of damage or insect abundance that warns the agriculturist of impending problems.

► Economic Injury Level (EIL) and Economic Threshold (ET) Concepts in Pest Management

Ecosystem

A complex of organisms and their physical environment that interact as a defined ecological unit. Ecosystems may be natural, or modified by human activity. Ecosystems generally are not defined by political boundaries. The biotic and abiotic components and their interactions within a certain geographic area. Ecological communities pluts their physical environment.

Ecotone

The transition zone between two different communities. An example of an ecotone is fresh water marshes that serve as a transition between grassland and lakes.

Ectadene (pl. ectadenia)

Accessory glands of ectodermal origin found in the male reproductive system of some insects.

► Accessory Gland
► Reproduction

Ectophagous

Feeding on the outside of a host.

Ectopsocidae

A family of psocids (order Psocoptera).

► Bark-Lice, Book-Lice or Psocids

Ecotype

A subspecies or race that is adapted to a particular set of environmental conditions.

Ectognathous

A hexapod with mouthparts that are not recessed into the head; rather, they are exposed. This is also known as ectotrophus. Such mouthparts are typically found in insects. This type of mouthparts distinguishes them from some related hexapods, the Entognatha (collembolans, diplurans, proturans), which have recessed mouths.

Ectotherm

An organism that uses energy from the environment rather than metabolic heat to regulate its body temperature. Insects are generally considered to be ectotherms, but some display endothermic behavior and physiology.

► Thermoregulation in Insects

Ectoparasite

A parasite that develops externally on the host. Typical ectoparasites include fleas, lice and ticks of vertebrates. However, some ectoparasites affect insects, particularly some mites. Insects that develop externally on their insect hosts (usually wasps) are more correctly called ectoparasitoids, but usually are called ectoparasites, too.

Edaphic

Pertaining to the soil.

Edwards, Henry

Henry Edwards was born in the country of Herefordshire, England, on August 27, 1830. He studied law, but he worked as an actor and his hobby was the collection of butterflies, in both of which occupations he became nationally rated in the US. In 1853, he travelled with a theatrical company to Australia, Peru, Panama, California, and Mexico, and managed to collect butterflies (and various other invertebrates) in all these places. From 1865, he lived in California, and was associated with the "Old California Theatre." His butterfly collection, eventually consisting of 250,000 specinmens, became one of the finest in the US. In 1867 he was elected member of the California Academy of Sciences, and he published a series of papers entitled "Descriptions of Pacific coast Lepidoptera." In 1877, he moved to the U.S. east coast, joined the New York Entomological Society, and edited the journal "Papilio" (1881–1883). In 1881–1882 he published an important paper on Aegeriidae, and in 1889 (after a sojourn in Australia), he published a "Bibliographical catalogue of the described transformations of North American Lepidoptera." He died in New York city on June 9, 1891. His butterfly collection was bought by his friends (for benefit of his wife) and presented to the American Museum of Natural History in New York.

Edwards, William Henry

William Edwards was born in the state of New York on March 15, 1822, and took an early interest in natural history. He attended Williams College in Massachusetts, graduating in 1842. Then in the city of New York he studied law and was admitted to the bar in 1847. In 1846, after leaving college, he journeyed to Brazil to collect birds, butterflies, and other specimens. This resulted in his first book, "Voyage up the Amazon" in 1847, which influenced soon-to-be travellers Bates and Wallace. As a practicing lawyer, he had time to indulge his passion for butterfly collecting, and later for rearing butterflies from their eggs, and during his lifetime published some 200 papers. His major work was a three-volume book "The butterflies of North America" which appeared between 1872 and 1897, and received accolades. He died on April 2, 1909.

Eelworm

A nematode.

Efficiency

A measure of the level of precision or accuracy per unit of cost (time or currency).

► Sampling Arthropods

Egg

The first free-living stage of most insects, contained within a chorion (shell).

Egg Burster

A raised area such as a ridge or bump on the head of an embryo that is used to mechanically rupture an egg shell during hatching.

Egg Case

The case or covering secreted by an insect that contains or protects the egg cluster. It is most commonly found in orthopteroid insects. The egg case is also known as an oötheca.

Egg Pod

A clutch of eggs surrounded by a capsule. Also called egg case or ootheca. This term is generally reserved for orthopteroid insects.

► Eggs of Insects

Eggs of Insects

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

Nearly all insects produce eggs (oviparity) during the adult stage, though some seemingly can produce living offspring (viviparity) indefinitely, and a few retain their eggs internally until after they hatch (ovoviviparity), depositing partly grown progeny (e.g., sheep keds and tsetse flies). Eggs are a common means of passing through unfavorable (dry season or winter) periods when food is unavailable, though because other stages of insects can enter diapause, egg-overwintering is by no means universal. Most eggs are spherical, oval, or elongate. The degree of sculpturing and ornamentation varies, as does their color. They may have ancillary structures such as anchors (e.g., wasp parasitoids) or floats (e.g., mosquitoes). They may be deposited singly or in batches, but typically a species is consistent in its pattern of oviposition.

The Egg Shell

The egg shell, or chorion, of insects is proteinaceous. It apparently lacks chitin, the polysaccharide responsible for the hardness of the exoskeleton. The insect egg shell suffers from the same problem faced by other terrestrial egg-layers: because the water molecule is smaller than the oxygen molecule, the gas exchange needed for respiration also results in dehydration (water loss). There is no ready means to allow gas exchange without some moisture loss. Thus, insects have evolved various means to facilitate gas exchange while minimizing water loss. Their challenge is appreciably more difficult than for birds and reptiles because their eggs are much smaller and therefore have a much larger surface to volume ratio, leading to greater potential for water loss. Insects tend to have mores complex egg shells than birds and reptiles to accommodate this challenge.

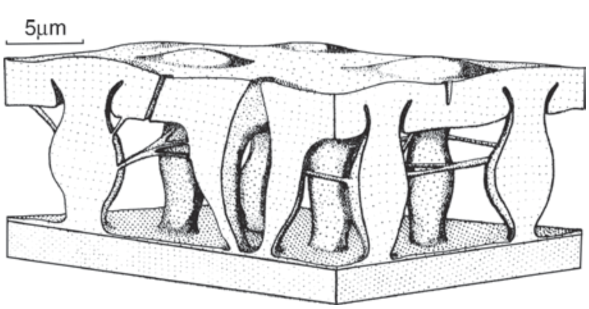
In general, insects have solved the surface area to volume ratio problem with respect to their larval and adult forms by evolving a waxy covering over their entire body. To solve the gas exchange problem, they have closable spiracular openings that allow bursts of gas exchange with minimal water loss. However, insects generally have opportunity to feed and ingest additional moisture, so the spiracle-based system does not have to be absolutely efficient. It does require that the insects be well enough developed that the closure mechanisms function reliably. With embryos and their chorion, this solution does not work, necessitating a modification. This is not to say that the eggs do not have a waxy covering, because they do, but there are no functional spiracles associated with the chorion.

Most terrestrial eggs, but not most eggs laid in water, have air-containing meshworks within the chorion. The chorionic meshwork contains a layer of gas, and has holes (aeropyles) that connect it to the outside. The holes, which measure less than a micron to several microns in size, provide continuity with the ambient atmosphere, allowing gas exchange. Their small size and small number help in water conservation. Often there are vertical columns within the chorion; they connect the external, relatively impervious layer of the chorion with the internal serosa (membrane covering of the embryo), and between the columns the gas is free to move. Not surprisingly, the chorionic meshwork system has undergone considerable modification in the different taxa, ranging from complex multi-layered systems to stalked aeropyles and the absence of meshwork.

Eggs that are found in water or likely to be submerged often are adapted to function with the aid of a plastron. A plastron is a film (bubble) of gas that has an extensive water-air interface that aids in the extraction of oxygen from water. The plastron is usually held in place by hairs or meshworks, and largely maintains its volume during use. It functions as a physical gill; as the insect withdraws oxygen from the plastron the relative concentration of nitrogen increases, stimulating more oxygen to flow into the plastron from the surrounding water, and nitrogen to flow out of the plastron into the water. Aquatic insects with plastron respiration in their eggs are normally found in fast-flowing, oxygen-rich water or along the edges of ponds and lakes where the water level changes. It may seem surprising that terrestrial eggs also often have adaptations that allow plastron function, but it is not unusual for rain to wet eggs and the eggs to remain wet for hours or even days, so it is a useful adaptation even in the terrestrial environment.

In addition to facilitating gas exchange and water conservation, the chorion must, in some cases, allow uptake of water or liquid nutrients from the environment. Hydropyles, structures that allow the uptake of water, are found on some eggs. Water is absorbed when the embryo is rapidly growing, and the egg enlarges in size. The eggs of most aquatic insects absorb water, but terrestrial insects that deposit their eggs where moisture may occur (e.g., grasshopper eggs in soil) also may have eggs that enlarge. The hydropyle is formed interiorly from the serosal (Fig. 14) layer, but may be visible externally by an extension of the chorion. Uptake of water sometimes causes the chorion to crack, leaving the embryo protected principally by the membranes. Some moisture can be absorbed from the air; partly desiccated eggs may reabsorb moisture from the air if the humidity is adequately high.

On the outside of the chorion the female may also secrete glue that attaches the egg to a substrate. Also secreted in some cases are jelly-like materials, oothecae, pods, or egg cases containing the individual eggs. The glands that secrete these are known by various names including accessory, mucous, cement, and collateral glands.



Eggs of Insects, Figure 14 **Cross section of an egg shell of showing air-containing meshwork. Note that the chorionic columns support the outer layer of the eggshell (above) above the internal serosa (below). The air in the meshwork is connected to the outside by small holes (aeropyles) as shown (left center of diagram) (adapted from Hinton 1981).**

Defenses of Eggs

Various protective devices are evident in eggs, mostly to avoid predation. The defenses against predation can be grouped into three general types: deceptive devices, chemical protection, and mechanical protection.

Most species seek to conceal their eggs. They may be deposited in soil, plant tissue, or beneath stones, for example. They may be cryptically colored to avoid being seen. Some are essentially transparent, so they resemble the substrate. Several Lepidoptera have eggs with a black spot apically, purportedly resembling eggs from which a parasite has emerged. Eggs strung together resemble plant organs such as tendrils. Egg deposited apically on a plant may appear to be seeds. Some eggs resemble plant galls (Fig. 15).

Insects are sometimes poisonous or distasteful, so it is not surprising that chemicals are sometimes found on or in the eggs. For example, adult blister beetles (Coleoptera: Meloidae) are well known to contain cantharidin, and this occurs in the egg stage as well. Similarly, cardiac glycosides from milkweed plants deter birds from eating caterpillars, and their eggs are not only invested with these chemicals but they advertise their presence by being bright yellow colored. A few moths use the poisonous setae from the molted exoskeleton of the larval stage to protect their eggs by spreading the setae over the eggs.

Mechanical protection of eggs can be gained by layering eggs with non-poisonous setae or scales. The moth *Aesicopa patulana* (Lepidoptera: Tortricidae) rings its eggs with a palisade of erect scales. The ootheca of cockroaches (Blattodea) and mantids (Mantodea) deter predation by all but the most determined predators. Plant structures are useful mechanical barriers against predation. Bark beetles (Coleoptera: Curculionidae: Scolytinae) oviposit

beneath bark, making access by predators difficult. Adults of the sugarcane rootstalk borer weevil, *Diaprepes abbreviatus* (Coleoptera: Curculionidae) oviposit between two leaves that are glued together; for access to the eggs, predators and parasitoids must penetrate the leaf tissue first. The chorion of a few eggs, such as those of range caterpillar, *Hemileuca oliviae* (Lepidoptera: Saturniidae) are so hard that many predators avoid feeding on them.

Size of Eggs

Formerly, it was postulated that hemimetabolous (exopterygote) insects had proportionally more yolk available to the developing embryo and the neonates were well advanced in development, producing a young insect that closely resembled the adult form. In concert with this logic, holometabolous (endopterygote) insects were considered to be yolk-deficient, and the young were forced to hatch earlier in development, and therefore forced to produce young that were not miniature adults, but more embryonic in form. This line of reasoning is no longer accepted, and indeed there is no evidence that hemimetabolous insects produce larger eggs than holometabolous insects.

Insect egg size is best correlated with the size of the female parent; large insect species typically produce larger eggs (Table 1). This is only a correlation, however, and there is considerable variation, as can be seen in the accompanying table, in which egg length is presented as a function of adult body length. Thus, micro type tachinid eggs are only about 1% of the length of the adult body, whereas at the other extreme, aphid eggs average 44% of the length of the adult.

To give insect egg size some perspective, consider that the length of a newborn human is about 50 cm, or 30% the size of the average human mother. If a human were to give birth to offspring in proportion to the size of aphids, it would measure 73 cm, nearly 50% larger. On the other hand, if humans gave birth to babies on the scale of some tachinid flies, they would measure only 2.2 cm, less than 5% of the length of the average newborn. Surely the range in insect egg size is considerable.

It is difficult to determine which insects produce the smallest and largest eggs, due in part to

Eggs of Insects, Table 1 Mean insect egg length as a proportion (%) of adult body length

the paucity of data but also because it can be calculated based on actual dimensions or on a proportional basis. Likely the smallest eggs are the microtype tachinid eggs, both in absolute terms and proportionally. For example, the eggs of *Zenilla pullata* (Tachinidae) are only 0.027 by 0.020 mm. However, more data on (Fig. 15) the eggs of some of the smallest insects such as trichogrammatids and mymarids (Hymenoptera) should be obtained, as these are especially minute insects. On the other extreme, the eggs of carpenter bees (Hymenoptera: Apidae: Xylocopinae) are reputed to be the largest, at least in terms of absolute size. For example, *Xylocopa auripennis* and *X. latipes* produce eggs that measure about 3.0 mm in width and 16.5 mm in length. These are large bees, but by no means are they particularly large insects. As noted previously, aphids likely produce the largest eggs if the size of the female is considered.

Egg size is affected by latitude, particularly by mean temperatures. Insects occurring in cooler climates (closer to the north or south pole) tend to produce larger eggs than those inhabiting warm climates (closer to the equator), at least if comparisons are made within a species or closely related forms. At the coldest part of the range inhabited by insects, however, which is perhaps less hospitable, egg size begins to diminish. Thus, for most species, optimal (largest) egg size is at the cooler end of the range, but not the very coldest.

Intraspecific variation in egg size at a single location or within a single egg cluster also occurs, though it is less well documented. Environmental quality affects mean egg size, as does maternal age. With poor food quality, inadequate food availability, or old age, insects tend to produce smaller eggs. There is also a heritability component to egg size; individuals developing from smaller eggs have longer development times, develop into smaller individuals, have a higher mortality rate, and produce smaller eggs. One might expect, then, that resource-limited female insects would produce only a smaller number of large eggs rather than produce any small eggs. However, optimal egg size (i.e., that which confers increased fitness), varies with environmental conditions. Thus, the traditional view that progeny from large eggs are qualitatively superior or more vigorous, though largely true, is subject to qualification. Phenetic variation results in production of progeny that are able to cope effectively with unpredictable but recurrent instabilities in their environment. In short, there are some circumstances when smaller eggs produce individuals that are more, not less, fit under those particular circumstances. Under cool weather conditions the larvae from some insects have been shown to be more fit. Also, the slower growing larvae from small eggs sometimes live longer, grow larger, and produce more eggs. Thus, there is selective pressure for variation in egg size.

Number of Eggs

The number of eggs produced by a female insect (fecundity) varies considerably (Table 2). Undoubtedly, social insects are the most fecund. Although data on fecundity of social insects is often lacking, data on honey bees are reliable, so the estimate of up to 2,000 eggs per day, or 220,000 per year, or about 600,000 eggs in a lifetime seems reasonable. Termites, on the other hand, can produce 30,000 eggs per day and live 15–20 years, so their reproductive output is likely unsurpassed. Ants have a more modest reproductive output, perhaps several hundred eggs per year and 5,000–6,000 over the course of a lifetime.

To maintain a stable population, a female need produce only two eggs that will result in reproductively successful adults. However, some species encounter extraordinary mortality, so they produce large numbers, as mentioned above. On average, most insects produce 50 to several hundred eggs, and their reproductive output is correlated with their life style (niche). The effects of life style and mortality rate are clearly demonstrated by beetles in the family Meloidae. Those that feed on grasshopper eggs (principally *Epicauta* spp.) are deposited by females after she

has located a grasshopper egg pod in the soil. Thus, the likelihood of survival is relatively good because the meloid offspring do not have to search to find a host, and the female may deposit less than 100 eggs per batch. In contrast, those species that feed on bees must climb up on flowers and attach to a visiting bee to obtain a ride back to the bee's cell where it can attack larval bees. This obviously is a more precarious existence, and such meloids produce 2,000–3,000 eggs per batch. Similarly, those tachinids that oviposit directly on hosts lay a few hundred eggs over the course of their life span, whereas those that scatter them about on food plants in hope that they will be consumed and infect a host insect produce many more eggs, perhaps 5,000–6,000. Some examples of fecundity are shown in the following table.

When considering intraspecific variation in fecundity, reproductive output is positively correlated with the size of the insect pupa or adult. High fecundity can lead to crowding and intraspecific competition for food resources, however, causing a reduction in pupal or adult mass and reduction in fecundity. Thus, in the absence of regulatory mechanisms such as specific parasitoids and disease, populations tend to cycle markedly, with periods of high fecundity preceding crowding and reduction of fecundity following crowding. The resulting low population, then, is freed from the competition and fecundity again cycles upward. Some insects seem to be competition limited, and demonstrate violent swings in abundance. More commonly, however, the swings in abundance are ameliorated by natural enemies.

Mating normally stimulates oviposition, and females that are not mated usually delay oviposition, scatter their eggs in an abnormal manner, and lay fewer eggs. Not all species display this pattern of oviposition, however. Not surprisingly, those that display facultative parthenogenesis may not be influenced by mating status. But, surprisingly, some insects oviposit normally even when not mated and producing nonviable eggs.

Oviposition

The site of egg deposition is incredibly varied, reflecting the vast diversity of life styles displayed by insects. Deposition ranges from apparently random, as when stick insects (Phasmida) drop eggs to the ground while feeding in tree tops, to highly selective, as when wasp (Hymenoptera) hyperparasites select specific locations on specific ages of parasitoids within specific hosts in specific habitats, and also check to determine that the prospective host is not already parasitized before ovipositing. Some of the interesting locations for egg deposition include:

- Under water, glued to a substrate such as plant tissue. This is common among insects where both the adult and immature stages dwell in the water such as predaceous diving beetles (Coleoptera: Dytiscidae) and backswimmers (Hemiptera: Notonectidae).
- Dropped into water, or near the water and in a location likely to be flooded. This occurs in mosquitoes (Diptera: Culicidae), horse flies and deer flies (Diptera: Tabanidae), and caddisflies (Trichoptera).
- Deposited on or in a host insect. This is common among parasitic Hymenoptera and Diptera, and they may deposit their egg free within the host insect's hemocoel, within a specific organ, attached to the body wall internally or externally, or only within a certain stage (e.g., the host egg).
- The parasitic insect oviposits on the host while the latter is flying. This requires that the female be equipped with claspers to hold the host while egg deposition occurs, as in thick-headed flies (Diptera: Conopidae).
- The insect is phoretic rather than parasitic, and oviposits on an insect to take advantage of the phoretic insect's behavior. This occurs with human bot flies (*Dermatobia hominis* [Diptera: Oestridae]) in South America, which oviposit on mosquitoes that then seek out humans and other mammals, the eventual host of the bot fly. The truly clever aspect of this is that the bot fly egg hatches when the mosquito is blood-feeding, and falls onto the host where it burrows in and feeds.
- The female deposits her eggs on the back of the male, as in some giant water bugs (Hemiptera: Belostomatidae), which then provide aeration and protection for the eggs.

Distribution of Eggs

Eggs can be deposited individually, in small clusters, or in large clusters. Often, ovipositional cues stimulate egg laying, and the cues may be physical, chemical or biological. Aggregation pheromones are among the best-known stimuli affecting oviposition. For example, bark beetles (Coleoptera: Curculionide: Scolytinae) release pheromones that, in conjunction with host plant volatiles, stimulate mass attack and oviposition, allowing the beetles to overcome the innate resistance of trees to attack, and facilitating survival of their brood. Indeed, many insects benefit from the mutual stimulation of feeding siblings, and are better able to overcome structural defenses of plants when they feed as part of a group. There may also be some benefits to gregariousness of young larvae because they are able to present a collective defense against predation. Plant allelochemicals deter feeding by generalist herbivores, but herbivore species that adapt to such chemical defenses often come to use the defensive chemicals as attractants, feeding stimulants and oviposition stimulants. Other factors affecting egg laying include host sex pheromones, host-produced sounds, surface texture, surface color, and light intensity.

Eickwort, George C

George Eickwort was born in New York City on June 8, 1940. An early interest in entomology persuaded him to study at the University of Michigan, where he obtained a B.S. in 1962 and M.S. in 1963. He then went to the University of Kansas and obtained a Ph.D. in 1967. He was hired as assistant professor in the Department of Entomology of Cornell University. He was heavily involved in teaching at undergraduate and graduate levels, and in 1986 received a Distinguished Achievement Award in teaching from the Entomological Society of America. He guided 24 Ph.D. and six M.S. students. His research centered on Halictidae (sweat bees). In summers, he taught at the Rocky Mountain Biological Laboratory. He died in a car accident in Jamaica on July 11, 1994.

Elm Leaf Beetle, *Xanthogaleruca (=Pyrrhalta) luteola* (Müller) (Coleoptera: Chrysomelidae).

STEVE H. DREISTADT
University of California, Davis, CA, USA

The elm leaf beetle is the primary defoliator of elm trees. Its range includes Canada, Central Asia, Europe, the Middle East, North Africa, Siberia and the United States. More recently, this insect has become established in Australia and South America.

The elm leaf beetle feeds only on elms (*Ulmus* spp.) and occasionally, on *Zelkova serrata*, also an Ulmaceae. Other key pests that attack only elms include the European elm scale, *Gossyparia spuria*

(Modeer); the European elm bark beetle, *Scolytus multistriatus* (Marsham); and Dutch elm disease, *Ophiostoma* (=*Ceratocystis*) *ulmi* (Buisman), a pathogen vectored by the elm bark beetle. However, there is great variability in pest susceptibility among and within elm species. Elms of Asian origin generally are more resistant (in some instances virtually immune) to both the elm leaf beetle and Dutch elm disease, while many Eurasian and North American elms are highly susceptible. Many pest-resistant elm cultivars have been developed and elms continue to be selectively bred to replace the hundreds of thousands of American elms, *Ulmus americana*, killed by Dutch elm disease.

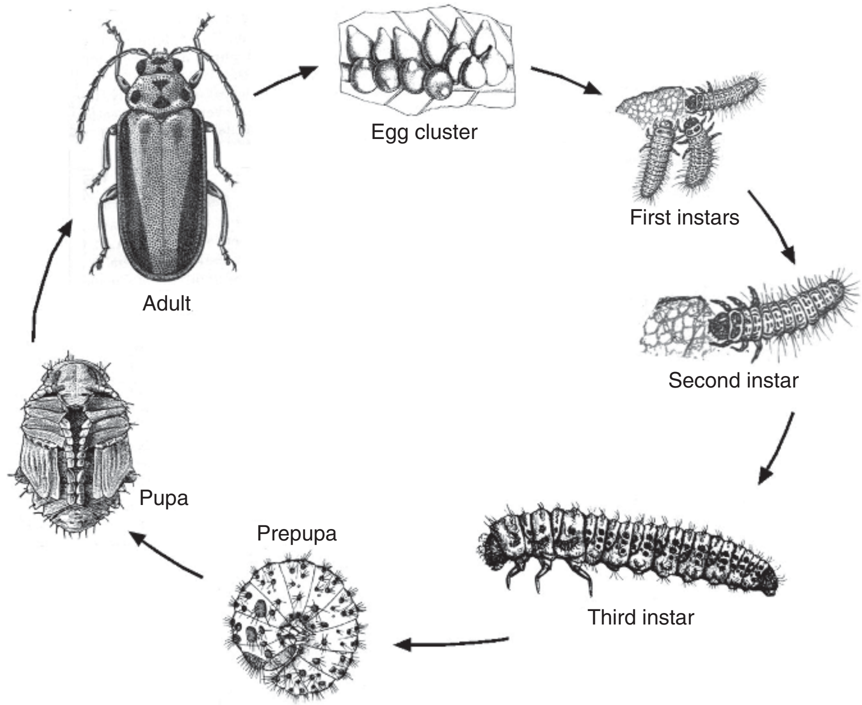
Elm leaf beetle larvae skeletonize the lower leaf surface, while the adults chew entirely through the leaf, often in a shot hole pattern. Defoliation eliminates summer shade, reduces the aesthetic value of trees and causes annoying leaf drop. Repeated, extensive defoliation weakens elms, causing the trees to decline. Severe defoliation possibly increases tree susceptibility to elm bark beetles and Dutch elm disease.

The adult beetles are about 8 mm long and are olive-green with black margins on each wing cover. The females lay yellowish eggs in double rows of about 5–25 on the underside of leaves. Each egg is about 1 mm wide and 1.5 mm tall and becomes grayish before hatch. The larvae appear black initially, but after feeding, become a dull yellow or green with rows of tiny, dark tubercles (projections). The larvae develop through three instars (Fig. 17). Third instars are up to about 1 cm long and have dense rows of dark tubercles that resemble a black stripe down each side, making them easy to distinguish from first- and second-instar larvae. The pupae are about 6 mm long and are bright yellow to dull orange in color.

Adult elm leaf beetles commonly overwinter in bark crevices, litter, woodpiles, or in buildings. The adults fly to foliage in the spring to feed and lay eggs. After feeding in the canopy for several weeks, mature larvae crawl down the tree trunk, become curled inactive prepupae, and then develop into yellowish pupae. After about 10 days, the adult beetles emerge from the pupae around the tree base and fly to the canopy to feed and (during spring and summer) lay eggs. The elm leaf beetle has about two annual generations in much of its range, but this varies with weather and location. For example, typically there is only one complete generation a year in northeastern California, while up to three generations can occur in central and southern California. Temperature monitoring can predict the seasonal emergence of adults and when each life stage occurs in the field, but are location-specific.

Good cultural care of trees is an essential component of integrated pest management. Many European and American elm species are adapted to summer rainfall and require proper irrigation to grow well in Mediterranean climates such as California and parts of Australia. Avoid pruning elms during the spring and summer as the European elm bark beetle is attracted at this time to fresh pruning wounds, and can introduce Dutch elm disease. If planting or replacing elms, consider using cultivars resistant to both Dutch elm disease and the elm leaf beetle (e.g., "Frontier," "Prospector"). Avoid elms that are highly susceptible to both the elm leaf beetle and Dutch elm disease (e.g., English elm, *Ulmus procera*, and Scotch elm, *U. glabra*).

Several natural enemies kill elm leaf beetles, but generally do not provide adequate control by themselves. A small, black tachinid fly, *Erynniopsis antennata*, oviposits on larvae, feeds inside, and emerges from mature beetle larvae or prepupae. *Erynniopsis antennata* is native to Eurasia and has been introduced in parts of the United States. Its black to reddish, cylinder- or teardrop-shaped pupae occur during spring and summer at the base of trees. *Erynniopsis antennata* overwinters in adult beetles, emerging as adults in spring, although this is not readily observed. *Erynniopsis antennata* is the most important elm leaf beetle parasitoid in California, but its effectiveness is limited by a secondary parasitoid, *Baryscapus* (=*Tetrastichus*) *erynniae*, and some apparent asynchrony between the host and the parasite life cycles.



Elm Leaf Beetle, *Xanthogaleruca (=Pyrrhalta) Luteola* (Müller) (Coleoptera: Chrysomelidae), Figure 17 **Elm leaf beetle stages and life cycle. adult, larvae: L.O. Howard. 1895. Control of two elm-tree pests. Cornell University Agricultural Experiment Station Bulletin 333.**

Oomyzus (=*Tetrastichus*) *brevistigma* parasitizes mature elm leaf beetle larvae and pupae. One or more small, round holes in the beetle pupae can indicate where this parasitoid has emerged. This species is of uncertain origin, but is the most important elm leaf beetle parasitoid in the eastern United States. *Oomyzus brevistigma* can be laboratory-reared in large numbers and cold-stored for several weeks, suggesting it is a good candidate for inundative biological control of its host.

An egg parasitoid, *Oomyzus* (=*Tetrastichus*) *gallerucae*, occurs in Eurasia and scattered locations where it has been introduced in the United States. It leaves round holes when it emerges from the beetle eggs, which remain golden. When the beetle larvae have emerged, the egg shell is whitish with more ragged holes. *Erynniopsis antennata* and *Oomyzus brevistigma* have been introduced to Australia and Argentina in an effort to provide classical biological control of the elm leaf beetle.

Historically, this pest was managed by foliar application of broad-spectrum insecticides, including lead arsenate beginning in the late 1800s, DDT starting in the 1940s, and more recently, various organophosphates (e.g., acephate and malathion), carbamates (carbaryl) and pyrethroids (e.g., bifenthrin, fluvalinate). Current recommendations are to use an integrated program that incorporates resistant elms, good cultural practices, conservation of natural enemies and regular monitoring. For example, presence-absence egg sampling can be used in California to predict the extent of defoliation and treatment need based on the percentage of one-foot branch terminals infested with beetle eggs. If needed, controls include foliar spraying with *Bacillus thuringiensis* subspecies *tenebrionis*, or spot application to bark (bark banding) with a broad-spectrum insecticide to kill larvae migrating down the trunk. Systemic insecticides (e.g., abamectin, imidacloprid) that are applied without spraying minimize environmental contamination, and if applied to soil, avoid the tree injury that occurs during injecting or implanting insecticide into roots or trunks. Where beetles entering buildings to overwinter is a problem, they can be excluded by screening openings and sealing exterior cracks and crevices. University Cooperative Extension services can provide more specific pest management recommendations.

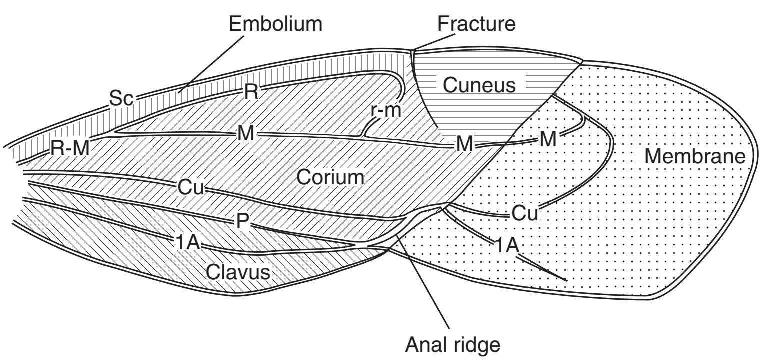
Embryogenesis

SUSANNE D. DYBY
Beaulieu-sur-mer, France

Embryogenesis in insects starts with an intricate, ordered building of the egg by the female. The female fills an egg with cytoplasm and yolk, beginning with the future posterior end of the embryo. The egg also is supplied with cytoplasmic determinants by the mother, and specific types of determinants are more concentrated in one end of the egg than the other. Cytoplasmic determinants are ribonucleic acid particles (RNPs) that code for transcription or translation factors, gene regulators, growth factors, kinases and other enzymes. These cytoplasmic determinants specify the anterior-posterior and the dorsal-ventral body axes: they initiate a developmental sequence that activate specific zygotic regulatory genes in a region-specific pattern. This pattern narrows and becomes refined with time, because each new set of activated genes allows the establishment of more developmental fates, and for an increasingly precise allocation of fates within each region.

In many holometabolous insects, the basic body plan of the larva is specified very early in development, before and during the cellular blastoderm stage. Some of the genes that regulate early development are known as "gap genes," "pair rule genes" and "homeobox genes." Along the ventral-dorsal axis in hemimetabolous and



Embolium, Figure 19 **Front wing of a bug (Hemiptera: suborder Heteroptera), thickened basally and membranous distally.**

holometabolous insects, the future mesoderm lies ventral-most. Ventrolaterally lies a band of nuclei/cells committed to neural development, and located more dorsally is the ectoderm and extraembryonic ectoderm. Endoderm is derived from a small region anterior and posterior to the mesoderm as well as from the inner yolky region of the egg.

The initial allocation of fates along the anterior-posterior axis is set by gap genes, which code for regulatory proteins. Gap genes divide the embryo into several large regions (loss of a functional gap gene leads to a loss of a large portion of the body). Gap genes induce, but also restrict the expression domains of primary pair rule genes, narrowing these domains to a bisegmental pattern. The primary pair rule genes induce other pair rule genes. Each pair rule gene has a bisegmental pattern of activity that overlaps some, but not all, of the other domains. Their combined expression patterns create a series of stripes and establish the segmental nature of the insect body. Pair rule genes activate segment polarity genes that maintain anterior to posterior patterning within each segment. Segment polarity genes must remain active until the adult stage. Gap genes and pair rule genes also activate homeobox genes (e.g., selector genes) that regulate the anatomical characteristics of segments. Within each insect segment, one finds that each nucleus has received an almost unique developmental address. Such positional information collectively builds an organized body plan.

A number of genes that set up the body axes and segments in *Drosophila* have conserved functions in a diversity of animals from centipedes and horseshoe crabs to other hemimetabolous and holometabolous insects, and likewise vertebrates and humans. Although developmentally crucial genes in hemimetabolous orders are similar to those in holometabolous embryos, their temporal expressions are different. Hemimetabolous embryos may take more than two months to complete embryogenesis at room temperature. In hemimetabolous insects, the onset of pattern formation is not simultaneous across the entire body, but proceeds in an anterior to posterior direction. In orders such as Blattodea, Dermaptera, Isoptera, and Embiidina, segments are added by means of posteriorly directed growth and must include *de novo* DNA synthesis. In others orders such as Phasmida, Orthoptera and Hemiptera, the basic body regions are unrefined but present. Segments develop larger size and anatomical complexity one by one. In contrast, a *Drosophila* larva breaks out of its egg shell approximately 22 h after fertilization. In such quickly developing insects, segmentation proceeds almost simultaneously across the body.

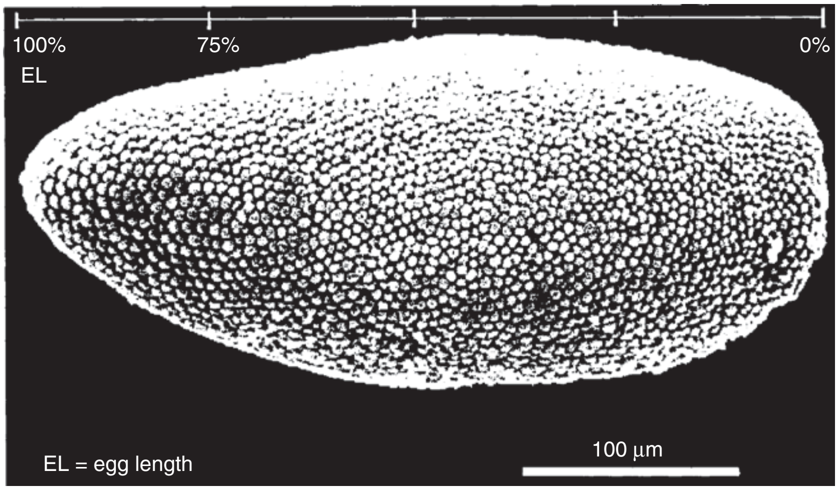
Insect cells have been thought of as having a mosaic form of development, that is, exhibiting a fixed and invariant commitment to a particular fate that is not altered by, for example, transplantation to other regions of the embryo, even during early embryogenesis. In holometabolous orders, this specificity is due to the flurry of genetic activity that occurs during early development (described briefly above). However, some embryonic tissues from holometabolous insects are able to regulate, i.e., develop variably in response to the surrounding cells. For instance, cell-cell communication between different cell types is essential for normal development of the midgut and mesoderm. In hemimetabolous insects, there is a far greater ability within the egg to regulate the cells' final fate. Krause's experiments with stone crickets (Gryllacrididae, Orthoptera) induced embryonic twinning, partial duplications, and triplications, thereby demonstrating that embryonic cells produced flexible responses to new developmental circumstances.

Early development in animals is characterized by cleavage divisions, whereby the single large egg is subdivided into a host of small cells, which is followed by morphogenetic movements that reshape the embryo. Insects are special in that they undergo 10–13 rounds of nuclear divisions before forming cells. Most nuclei migrate to the periphery of the egg, and cells are formed when the egg's plasma membrane folds inward to separate and enclose individual nuclei. The cellularization process takes approximately one hour in *Drosophila* (Fig. 22), but in other insects there can be region-specific differences in the onset of cell formation. The cellularization process produces the cellular blastoderm, consisting of an embryonic and extra-embryonic component. In termites (Isoptera) and walking sticks (Phasmida), an uneven distribution of nuclei precedes the separation into the embryo and extraembryonic tissue after the cellular blastoderm stage. In other hemimetabolous orders (for example, Odonata, Plecoptera, Orthoptera) and in most holometabolous insects, the distribution of nuclei is practically uniform. However, in parasitic Hymenoptera, cleaving nuclei associate into clusters and form cells. Each cluster gives rise to one embryo, and two (as in Platygastridae) to 1,500 (as in Encyrtidae) young can emerge from a single egg. This phenomenon of polyembryony is another example of regulative, as opposed to mosaic development, within holometabolous orders.

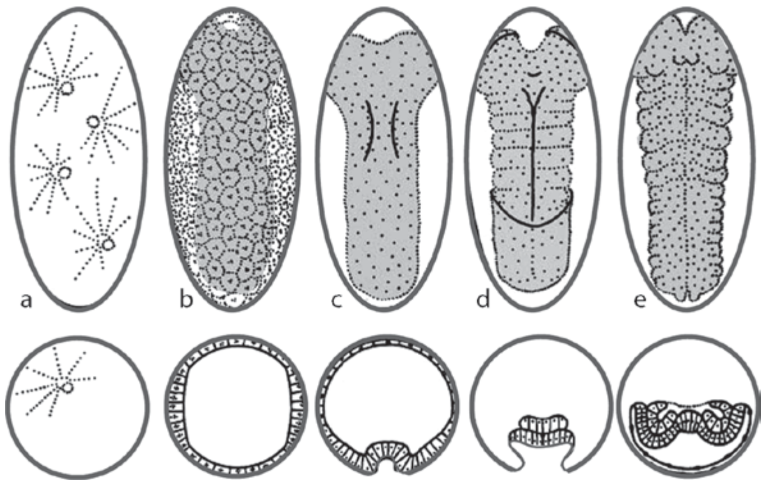
Most insect eggs have a substantial amount of yolk that lies to the interior of the cellular blastoderm (Fig. 20). Eggs of hemimetabolous insects tend to contain more yolk than eggs of holometabolous insects. Insects are defined as engaged in meroblastic cleavage – incomplete cleavage of the yolky region, and in superficial cleavage – the yolk lies interior to the cellular blastoderm, filling the central region of the egg.

Extraembryonic cells develop into the serosa that line the inner surface of the egg, the amnion that encloses the embryo, and vitellophages and yolk cells. Vitellophages will form a provisional inner lining of the future midgut and aid in the digestion of yolk. They are usually digested before hatching, but may become incorporated into the epithelial lining of the gut in Odonata. In *Drosophila*, signals from yolk nuclei (vitellophages or yolk cells) are essential for the proper cell migration by prospective gut tissue so that a digestive tube is formed.

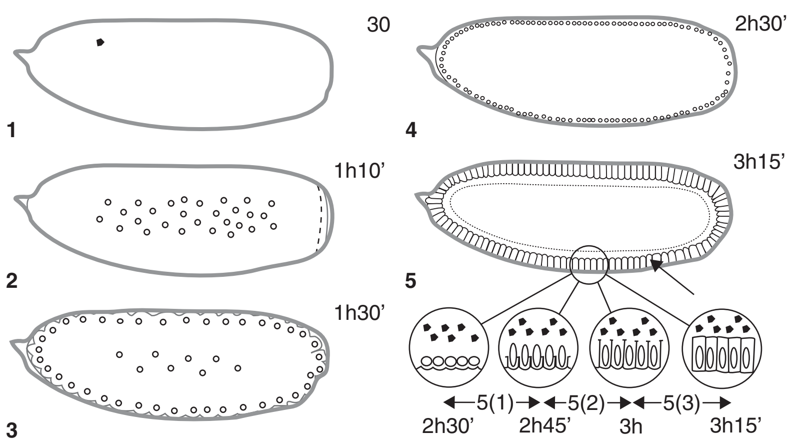
Morphogenesis, the creation of form, describes the cell movements that must take place to create an ordered body plan. At the blastoderm stage (Fig. 21), the embryo consists of a single layer of cells. In hemimetabolous insects, the separation between the extraembryonic component and the embryo involves a convergence of the embryonic cells toward the ventral and posterior side of the egg. In holometabolous insects like coleopterans, lepidopterans and dipterans, embryonic cells also converge toward the ventral side, but this



Embryogenesis, Figure 20 **Cellular blastoderm stage in the fruit fly *Drosophila melanogaster*. Anterior region is to the left and the dorsal side is up (Scanning electron micrograph by S. Dyby).**



Embryogenesis, Figure 21 **Steps in the early embryogenesis of insects. Top row: ventral view of egg, anterior end up. Bottom row: diagrammatic cross sections at the levels indicated by bars in top row. (a) Multiplication and migration of nuclei within the ooplasm. (b) Cellularization of the superficial part of the ooplasm. The resulting blastoderm initially consists of uniform cells but soon regional differences in cell density and shape indicate segregation into germ anlage and prospective embryonic covers. (c) The prospective mesoderm starts to invaginate along the midline of the germ anlage (gastrulation). (d) Germ band after gastrulation, with segment borders and amniotic folds forming. The folds shown over head lobes (top) and abdomen approach each other and finally fuse, thereby closing the amniotic cavity. (e) Advanced germ band stage, with appendage buds, transient coelom anlagen, and amniotic cavity (Modified from Sander, 1976).**



Embryogenesis, Figure 22 **Early development of a fly embryo, showing stages from 1 to 5 (Modified from Lawrence, 1992).**

migration movement occurs in concert with an extension movement along the anterior-posterior axis that dramatically lengthens the embryo, now described as the germ band. Germ band elongation allows for body segmentation to take place without a process of segment-by-segment addition. This is defined as a long-germ band development. In contrast, when the majority of body segments forms one after the other, this is described as the short-germ band type.

The germ band develops an inner mesodermal and outer ectodermal cell layer during gastrulation. The entire mesodermal cell sheet invaginates, that is, the cell sheet buckles inward in some species; in others, mesodermal cells ingress individually once a midventral groove has formed by means of cell shape changes. The mesodermal cells rearrange to line the inner surface of the ectoderm, then engage in cell divisions. They form segmentally reiterated clusters of cells called somites. The ventral-most component of the somites – the visceral or splanchnic mesoderm – will differentiate into the musculature of the midgut, fat body, gonads, and blood, whereas the rest – the somitic mesoderm – form segmental muscles, the dorsal vessel (heart muscle), and musculature of the foregut, hindgut and genitalia. Limb musculature is derived from the ventrolateral region of the somites. Cephalic mesoderm contributes to the musculature of the head, pharynx, mouthparts and the anterior portions of the foregut.

A ventrolateral region of the ectoderm is neurogenic and gives rise to the nervous system. In hemimetabolous embryos, neuroblasts generally ingress while the mesodermal somites are forming and each region of the germ band matures. In holometabolous embryos, neuroblasts ingress just after the mesoderm cells line the inner surface of the ectoderm, that is, after gastrulation and an accompanying rapid elongation of the germ band. In the procephalic region where the brain develops, the neuroblasts stay on the surface longer. Ingressed neuroblasts divide several times and give rise to ganglion mother cells. The latter divide symmetrically or asymmetrically, with the asymmetrical division producing a ganglion cell or neuron. Neuroblasts and ganglion cells associate into neuromeres, which are segmentally reiterated cell clusters separated by intersegmental ridges. The neuromeres become connected by axonal bundles that build longitudinal connectives and transverse commissures. This early arrangement of the central nervous system is altered by fusion of specific neuromeres to bring about the final arrangement of ganglia. The optic lobes of the brain connect to two thickened ectodermal cell plates that develop into lateral ocelli. An extensive peripheral nervous system is established, beginning with the appearance of somatic muscle cells and the progenitors of sensory cells.

The rest of the ectoderm turns into epidermis, apodemes, glands, sensory organs, tracheal system, Malpighian tubules, and epithelia of the foregut and hindgut. The non-neurogenic ectoderm cells tend to stay connected as a cell sheet (epithelium) so that the primary morphogenetic changes occur by epithelial invaginations or evaginations. Limb formation and gnathal appendages begin as an evagination or a budding outward by the ectoderm. The Malpighian tubules begin as flat outpocketings of the hindgut epithelium and elongate into long convoluted tubes during late embryogenesis. The salivary glands derive and invaginate from the labium. They elongate into two long tubes that join into a common duct by the labium. The first invaginations of the tracheal system appear as tracheal pits, one for each thoracic and abdominal segment. Further internal tracheal branching continues by invagination, cell migration, and rearrangements. Cell fusions produce the final tracheal network, followed by deposition of cuticle and tanning.

The insect gut consists of the foregut, midgut and hindgut. Aspects of gut development are similar across most insect orders, although the final anatomy and physiology of the gut vary with the type of food that the juvenile insect ingests, digests, absorbs, and excretes. The gut primordia are found at the anterioventral side of the embryo and at its posterior extremity. The primordia invaginate and involute during or just after gastrulation, forming hollow sacs. The innermost part of these sacs is endoderm, which dissociates from the prospective foregut and hindgut and migrates along the inner body wall and comes in contact with the visceral mesoderm that becomes the musculature of the midgut. Together with the visceral mesoderm, the midgut endoderm forms a tube around the yolk that lies inside the embryo. The encircling of the yolk proceeds in a ventral to dorsal direction. The foregut and hindgut epithelium are ectoderm derivatives, whereas most of the midgut epithelium is endodermal in origin. The anterior portion of the midgut epithelium has both endoderm and ectoderm contributing to gastric caeca, outpocketings of the gut that often harbor a bacterial community. The foregut and hindgut musculature differentiates before the midgut is entirely formed. In lepidopterans, the contractions of foregut and hindgut help turn and reposition the embryo within the extraembryonic membranes during mid-embryogenesis. The stomodael nervous system derives from the dorsal roof of the foregut, and develops into the endocrine glands, corpora cardiaca and corpora allata, a frontal ganglion, connectives, and a recurrent nerve that loops back to the brain.

The germ band is open dorsally in both hemi- and holometabolous orders. The amnion covers this dorsal opening, and is replaced by embryonic cells during a process called dorsal closure. The ectodermal cells rearrange and migrate dorsally, as do the cardioblasts and the midgut mesoderm and endoderm. In insects with long-germ band development, dorsal closure is preceded by germ band shortening. The germ band not only shortens, but also expands, and the embryo takes up room previously occupied by yolk. Once dorsal closure is completed, it is tissue organization and differentiation, rather than morphogenetic reshaping of the germ band, that occupies most the time left before the juvenile insect hatches from its egg. In lepidopterans and other orders, an embryonic molt of newly formed cuticle occurs during late embryogenesis. Tanning and pigmentation occur in the tracheal tree, mouthparts, head capsule, setae, integument, and other cuticular elements.

Diapause is common during the egg stage. A complex mix of environmental and genetic factors influence the female's laying of eggs that are capable of diapause. The stage of developmental arrest is usually determined genetically and may occur during early, mid-, or late embryogenesis. Some insects can withstand drying-out. The eggs of some African locusts, for example, remain viable after three years of desiccation.

Emergence

Escape of the adult from the body covering of the terminal immature stage or pupa; sometimes used to describe eclosion.

Emerson, Alfred Edwards

Alfred Emerson was born in the state of New York, USA, on December 31, 1896. He moved with his parents to Chicago in 1905. In a family of artists, he was the first scientist. In 1914 he went to Cornell University with the objective of studying poultry science, but chose entomology instead. While he was at Cornell, he visited the New York Zoological Station in Guyana, met zoologist William Beebe, and at the latter's suggestion began to study termites. In 1920, he completed his M.A. degree, married, and took his new wife on his second trip to Guyana. A third trip followed, in 1924, but meanwhile he had in 1921 accepted a position as instructor at the University of Pittsburgh. He completed requirements for a Ph.D. degree from Cornell in 1925, then moved to the University of Chicago, where he stayed for the rest of his career. His major contribution to entomology was the over 100 papers he published on the systematics, phylogeny, distribution and natural history of termites, including fossil species. He co-authored (1949) "Principles of animal ecology" which was the major North American text on the subject of its time. But, his first wife died of a heart condition that year. He received numerous awards and was elected to the National Academy of Sciences in 1962. He died in New York state on October 3, 1976, survived by two children from his first marriage and by his second wife, Eleanor, whom he married in 1950. His termite collection of about a million specimens, representing 1,745 species, was given to the American Museum of Natural History.

Emery's Rule

This postulates that in colonies of social insects, their social parasites are similar in appearance to the hosts and closely related phylogenetically.

Emigration

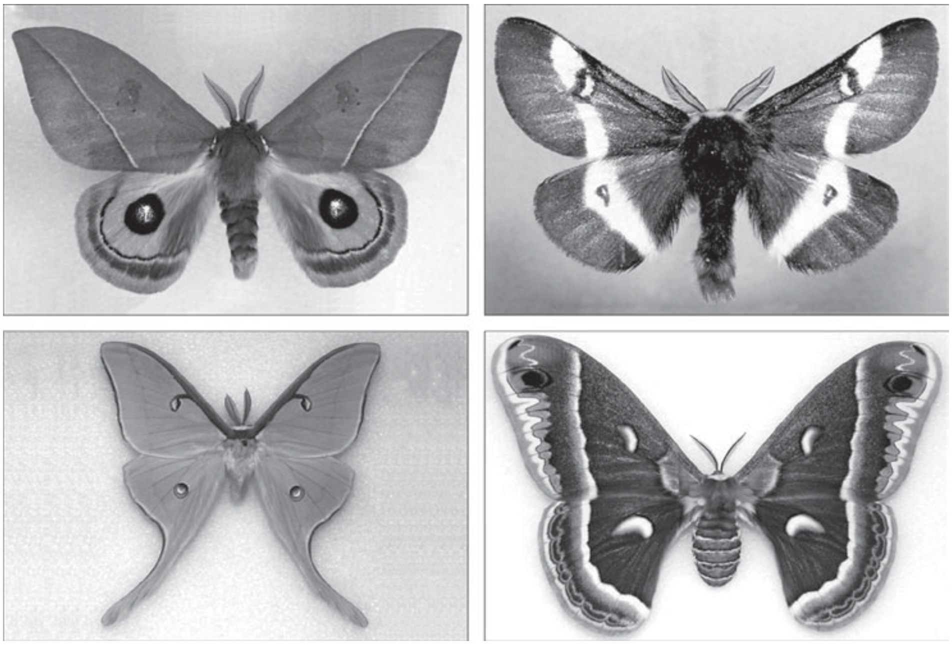
Movement of individuals out of an area to another location (contrast with immigration).

Emperor Moths (Lepidoptera: Saturniidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Emperor moths, family Saturniidae (also called giant silk moths, and including Buck moths, io moths, and royal moths), include 1,435 species worldwide, but are predominately Neotropical (860 sp.). The family is in the superfamily Bombycoidea (series Saturniiformes), in the section Cossina, subsection Bombycina, of the division Ditrysia. There are seven subfamilies: Arsenurinae, Ceratocampinae, and Hemileucinae are all New World, plus Agliinae (Palearctic), Ludiinae (Afrotopical), Salassinae (Oriental), and Saturniinae.

The larger species, in the subfamily Saturniinae, are more diverse in Africa (225 sp.) and tropical Asia (125 sp.), yet are the only subfamily found in all regions of the world. Hemileucinae forms the largest subfamily, with 630 species, mostly Neotropical. Adults medium size to very large (30–300 mm wingspan), with head vertex roughened; haustellum absent or short; labial palpi short; maxillary palpi vestigial; antennae bipectinate (some actually quadripectinate), smaller in females; body robust, with long hair-like scales. Wings broadly triangular, often with apex falcate (especially in males of some genera), or more rounded; hindwings rounded but sometimes with tails (sometimes extremely long) (Fig. 23). The longest hindwing tail lengths are about 130 mm (not counting the basal area of the hindwing), equally long and thin in the Neotropical genus *Copiopteryx* and in the African genus *Eudaemonia*, and long but wider tails in the giant Madagascan *Argema*. Maculation various, but mostly shades of brown with eyepots (sometimes hyaline) and terminal border bands, or white with spots, or other coloration; hindwings often with large eyespots (especially in Hemileucinae). Adults mostly nocturnal or crepuscular, but some are diurnal. Larvae are leaf feeders and many are polyphagous, some being communal or gregarious; many are extremely large. Many larvae have bizarre spines and scoli; many are urticating (especially in Hemileucinae). Host plants are extremely varied, particularly in broadleaf forest tree families, but at least 48 plant families are involved. Some species are economic for agriculture, but major urticating larvae are involved in dermatitis and more severe allergic reactions (the most toxic seem to be the genus *Lonomia* in Brazil), and in a few cases even from adult scales.



Emperor Moths (Lepidoptera: Saturniidae), Figure 23 Examples of Emperor moths (Saturniidae): top left, (subfamily Hemileucinae), *Automeris cecrops* (Boisduval) from Arizona, USA; top right, *Hemileuca* maia (Drury) from Florida, USA; lower left, (subfamily Saturniinae), *Actias luna* (Linnaeus) from Florida, USA; lower right, *Hyalophora cecropia* (Linnaeus) from Florida, USA.

Empididae

A family of flies (order Diptera). They commonly are known as dance flies.

► Flies

Empusidae

A family of praying mantids (Mantodea).

► Praying Mantids

Empodium

A single spine or pad-like structure found between the tarsi of Diptera.

► Legs of Hexapods

Emulsifier

A surfactant used to stabilize the distribution of one liquid in another (i.e., create an emulsion).

Emulsion

A pesticide formulation in which droplets of one liquid are dispersed within another liquid (e.g., oil in water).

Emulsifiable Concentrate

An insecticide formulation in which an emulsifying agent has been added to allow an active ingredient and solvent that normally would not mix with water to be effectively dispersed in water.

Encapsulated Pesticide

Enclosure of a small amount of pesticide within a covering such as polyvinyl to provide controlled (prolonged) release of the toxicant. Such formulations are also referred to as micro-encapsulated.

Encapsulation

The enclosure of an invader, usually a parasitoid larva, within the blood of the host insect by a layer of hemocytes.

Encephalitis

A group of arthropod-borne viruses (arboviruses) affecting the nervous system of vertebrate animals, including humans. Often these viruses are spread by mosquitoes. Signs and symptoms of infection include stiff neck, headache, confusion, rash, fever, arthritis, inflammation of the brain, coma, paralysis, and death. Some of the viruses and diseases include:

Alphaviruses

Eastern equine encephalitis

Western equine encephalitis
Venezuelan equine encephalitis
Flaviviruses
St. Louis encephalitis
Japanese encephalitis
West Nile fever
Yellow fever
Dengue
Bunyaviruses
LaCrosse encephalitis
Reoviruses
Colorado tick fever
African horse sickness viruses

Although vaccines are available for some arboviruses, prevention hinges mostly on limiting or eliminating exposure to blood-feeding arthropods.

Endangered Area

An area where ecological factors favor the establishment of a pest that, if established, will cause an economically important loss in the area.

► Invasive Species
► Regulatory Entomology
► Risk Analysis (Assessment)

Endangered Species

Endangered species are those considered to be at risk of extinction in a relatively short period of time. Other species experiencing population decline are considered to be at less risk, and are classified as threatened, or are placed in another category to designate that they or their habitat is at risk. Following (Table 3) is a list of insects "of concern" established by the United States Fish and Wildlife Service. [STATUS: E is endangered; T is threatened; C is candidate taxon, ready for proposal; DA is delisted taxon; PE is proposed endangered; EmE is emergency listing, endangered; PE is proposed endangered.

Endemic

Populations occurring at low levels of abundance in an area, though on occasion they may move to a more abundant state (an outbreak or epidemic). This term is sometimes, but incorrectly, used to describe indigenous or precinctive populations.

Endemism

The condition of being indigenous to, and restricted to, a specific area.

► Precinction

Enderleinellidae

A family of sucking lice (order Phthiraptera). They sometimes are called squirrel lice.

► Chewing and Sucking Lice

Endocrine Gland

A gland that discharges its products, generally hormones, into the inside of an insect (Fig. 24) (contrast with exocrine gland).

► Endocrine Regulation of Insect Reproduction

Endocrine Gland, Figure 24 Cross section showing the relationships of the principal endocrine glands with the brain (adapted from Chapman, The insects: structure and function).

Endocrine Regulation of Insect Reproduction

MARC J. KLOWDEN
University of Idaho, Moscow, ID, USA

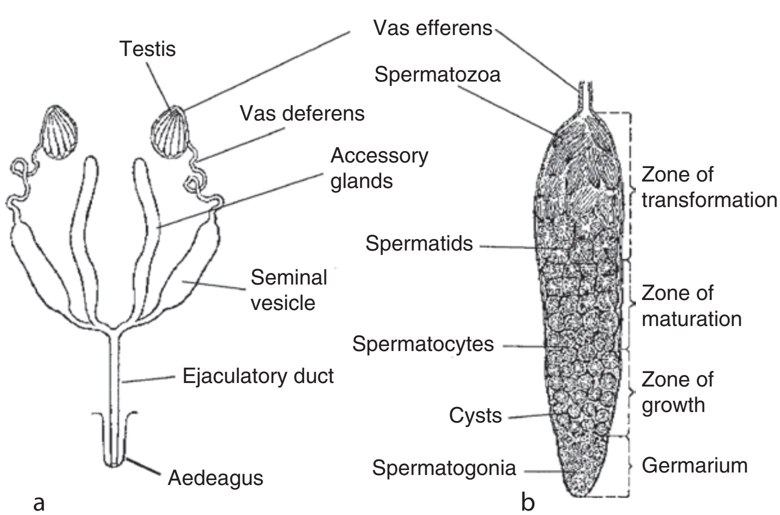
Insects dominate our planet largely because of their enormous reproductive capacity, which is made possible by a most efficient reproductive system. This reproductive efficiency results from the synchronization of the endocrine system that controls reproduction with both environmental signals and the internal physiological state of the insect, so that reproduction is triggered only when it is environmentally and biologically appropriate.

Sites Where Hormones are Released in insects

Insects release hormones from conventional endocrine glands, which are tissues that specialize in the secretion of hormones that are transported by the blood and that act on receptor-bearing target tissues elsewhere in the body. Examples of endocrine glands in insects are the prothoracic glands, which produce ecdysteroids, and the corpus allatum, which produces juvenile hormones (JH). Insects also have hybrids of endocrine glands and nerve cells that are called neurosecretory cells. These cells synthesize neurohormones and release them from specialized neurohemal organs into the bloodstream, affecting distant target tissues. Examples of neurosecretory cells are the medial neurosecretory cells of the brain that release the neurohormone prothoraciotropic hormone from the corpus cardiacum, its neurohemal organ. Receptors present on target cells specifically bind the hormones and produce a biological effect, but non-target cells that lack these receptors are unable to receive the message.

Endocrine Regulation of Male Reproduction

The production of spermatozoa occurs within the follicles of the male testes (see diagram of male reproductive system). Apical stem cells in the anterior stem cell niche of the follicle divide mitotically to form spermatogonia. As these spermatogonia move down through the testes (Fig. 25), they become enclosed by somatic cells that produce cysts around them. The remainder of the



Endocrine Regulation of Insect Reproduction, Figure 25 **(a). The generalized male reproductive system. (b). A single testicular follicle showing the zones of sperm maturation (From Snodgrass, 1935).**

testicular follicle can be divided into zones containing these cysts in successive regions of sperm development. In zone I, the zone of growth, the spermatogonia divide mitotically six to eight times within each cyst to form spermatocytes, each of which remains connected by cytoplasmic bridges, or ring canals. The number of divisions within a cyst is species specific; in *Rhodnius* the spermatocyte stage is reached at eight divisions, or 128 cells per cyst. In zone II, the zone of maturation, the spermatocytes divide meiotically to form haploid spermatids. The cysts continue to move toward the vas deferens within zone III, the zone of transformation, and the haploid spermatids within them differentiate into flagellated spermatozoa. As this differentiation proceeds, the cysts elongate and eventually rupture, releasing the spermatozoa into the vas efferens. These spermatozoa then migrate to the seminal vesicles where they remain until mating takes place. Spermatogenesis is thus a multi-step process of meiotic and mitotic divisions and cell differentiation.

In some short-lived insect species that do not feed as adults, spermatogenesis may occur early during the larval and pupal stages. Sperm are produced throughout the adult lives of longer-lived males. Because the hormonal conditions that exist during these immature and adult periods are vastly different, it has been difficult to generalize a scheme for the hormonal control of insect spermatogenesis. Indeed, it has been suggested that insect spermatogenesis may be a sequential process of differentiation that is completely independent of hormones. There have been some reports of the effects of hormones in a few species of insects, but relatively little is known compared to our knowledge of how hormones control the reproductive system in females.

The few studies that have examined the endocrine control of spermatogenesis suggest that the rate of mitotic divisions of spermatogonia to form spermatocytes is increased by high levels of 20-hydroxyecdysone, but when JH titers are also high, this increase is abolished. In some larval insects, the meiotic divisions of spermatocytes are arrested at prophase until they reach the end of their larval period. A release of 20-hydroxyecdysone unblocks meiosis and allows the cells to proceed to metaphase. An ecdysiotropin produced by the brain induces the synthesis of ecdysteroids by the testis sheaths of several lepidopteran species. While most effects of JH on spermatogenesis are inhibitory, JH has been reported to accelerate spermatogenesis in some insects. The release of mature spermatozoa from the cysts in the testes may display a circadian rhythmicity that is initially inhibited by 20-hydroxyecdysone. The decline of 20-hydroxyecdysone is thus necessary in order for sperm to be released.

The male accessory glands are involved in the synthesis of seminal fluid, the spermatophore, and vaginal mating plugs. They also produce various peptides that have physiological effects on the female when they are transferred during mating. The development and secretions of the male accessory glands are often controlled by JH. The accumulation of some secretory peptides in the glands is enhanced by JH and inhibited by 20-hydroxyecdysone.

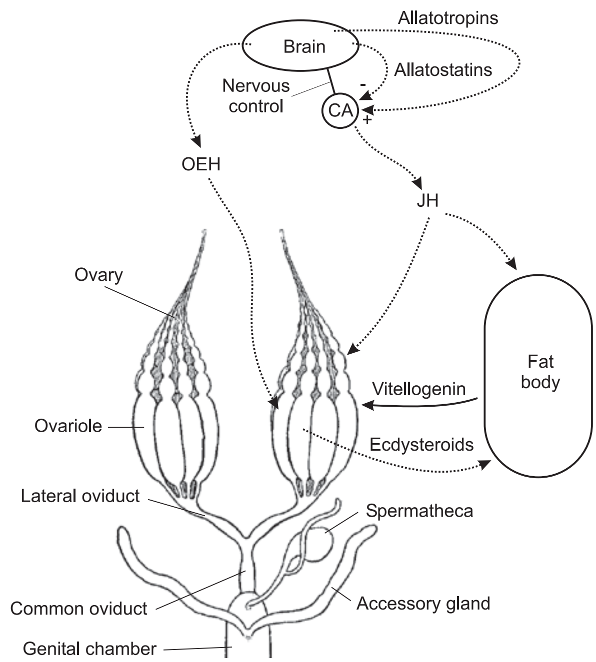
Many insect species undergo a diapause, which is a physiologically programmed developmental arrest that occurs prior to the onset of unfavorable environmental conditions. Spermatogenesis is interrupted in those lepidopterans that undergo a larval or pupal diapause but it resumes once diapause has been completed. It is the lysis of developing gametes before they become mature, rather than any developmental activity, that causes this interruption. The renewal of spermatogenesis occurs as a result of the increasing titers of 20-hydroxyecdysone that occur when diapause is terminated.

There are two different kinds of sperm produced by the single fused testes of lepidopterans. The conventional eupyrene sperm fertilize the egg, but the apyrene sperm have no nuclei and thus no genetic function in fertilization. It has been speculated that by traveling with the eupyrene sperm, they may increase their motility within the female reproductive tract, or provide the eupyrene sperm with nutrients. The differentiation of apyrene sperm from eupyrene sperm in the testis occurs as a result of their exposure to a hemolymph-borne apyrene-spermatogenesis-inducing factor. In some other species, individual males produce sperm of varying lengths, a factor that may contribute to speciation.

Endocrine Regulation of Female Reproduction

The production of oocytes in the female begins within the germarium of the ovariole, where the haploid oocytes are produced from stem cells (see Fig. 26). As they descend through the vitellarium, they take up the vitellogenin that is deposited in the cytoplasm as yolk. The yolk is used by the developing embryo as precursors and energy for growth. Vitellogenin is usually produced by the fat body and released into the hemolymph, from where it is specifically taken up by the oocyte by receptor-mediated exocytosis. The process of vitellogenesis is closely regulated by hormones to insure that reproduction only occurs when all systems are ready.

There is a tremendous amount of ecological variability among insect species and it is not surprising that there is a comparable variability and complexity in the systems that regulate their reproduction. There are but a few generalizations that can be made regarding the endocrine control of female insect reproduction. In short-lived insects that do not feed as adults, the yolk must be derived from reserves that are acquired during the larval stage. In these insects, vitellogenesis occurs while the pharate adult is still within the pupal skin and the adult emerges with a full complement of eggs. In the lepidopteran *Hyalophora cecropia*, this pre-emergence egg development appears to occur in the absence of any identifiable hormonal controls and may simply be a developmental program that is followed by the fat body. In longer-lived insects that undergo multiple cycles of reproduction, vitellogenesis occurs when the fat body is activated by hormones that allow the vitellogenins to be produced cyclically.



Endocrine Regulation of Insect Reproduction, Figure 26 The generalized female reproductive system. The brain regulates the production of JH by nervous control as well as with the various peptides that activate JH synthesis (allatotropins) and inhibit JH synthesis (allatostatins). The JH acts on both the fatty body and the ovaries. An ovarian ecdysteroidogenic hormone (OEH) released by the brain activates the synthesis of ovarian ecdysteroids that act on the fat body to cause the transcription of vitellogenin genes (Modified from Snodgrass, 1935).

The specific hormones that are involved in cyclical vitellogenesis vary considerably among insects, and again there is no single mechanism of hormonal control that can be described. However, there are two general approaches to cyclical egg production. In some insects, the production of vitellogenins is dependent on JH alone, such as in grasshoppers, cockroaches, some lepidopterans, and *Rhodnius*. JH acts directly on the fat body cells, causing them to initiate the translation and secretion of vitellogenin. In contrast, there are a few other insects, including the gypsy moth, *Lymantria dispar*, where low or declining titers of

JH in the last larval instar have been shown to be necessary for vitellogenin production by the fat body. The release of JH from the corpora allata is controlled by the brain, either neurally or hormonally by its production of allatotropins that turn the corpora allata on and allatostatins that turn the corpora allata off.

In many other insects, including most dipterans, both JH and 20-hydroxyecdysone are involved in reproduction. JH regulates the formation of new endoplasmic reticulum in the fat body and the sequestration of the vitellogenin produced, while 20-hydroxyecdysone regulates the rate of its production. Variations in the control of vitellogenesis by 20-hydroxyecdysone are common. Vitellogenin production in the Indian meal moth, *P. interpunctella*, coincides with a decline in the ecdysteroid titer of the pharate adult. Vitellogenin synthesis in the silkworm, *Bombyx mori*, coincides with a rise of 20-hydroxyecdysone.

The control of vitellogenesis in the female mosquito is a good example of the complexity of the mechanisms that have evolved to coordinate reproduction with nutritional state. Vitellogenesis only occurs in female mosquitoes after a blood meal has been periodically acquired, so blood ingestion consequently serves as an experimental method of synchronizing the reproduction of many individuals so that the coordinated events can be better observed in the laboratory. The blood meal provides the precursors for yolk synthesis that are lacking after larval development is completed.

After the adult female emerges, the JH that is released by the paired corpora allata during the first few days of life prepare both the fat body and the ovary for vitellogenesis. In response to an early peak of JH, the fat body cells become polyploid to provide more templates for DNA synthesis during vitellogenesis. JH also stimulates the induction of mRNA in fat body cells, the proliferation of ribosomes, and a development of its responsiveness to 20-hydroxyecdysone. The follicle cells that surround the oocyte-nurse cell syncytium are relatively undifferentiated at emergence, but in response to JH, they begin to differentiate and increase in size.

There are endocrine cells dispersed throughout the midgut epithelium, and in response to the ingestion of a blood meal these cells may trigger the release of the neurohormone ovarian ecdysteroidogenic hormone from the brain, which acts on the ovaries to increase their synthesis of protein and stimulate their production of ecdysone. Although the prothoracic glands, the site of ecdysteroid synthesis in larvae, degenerate and are absent in adult insects, the follicular epithelium of the ovary produces these ecdysteroids in adults. The 20-hydroxyecdysone then activates the transcription of vitellogenin genes in the fat body. The most abundant fat body transcript is a 6.5 kb vitellogenin mRNA that is translated into a 224 kDA pro-vitellogenin and subsequently cleaved and then repackaged into a 380 kDa vitellogenin. The 20-hydroxyecdysone peak also stimulates the follicle cells of the ovary to synthesize the vitelline envelope, the inner layer of the chorion, and acts again on the germarium to cause the creation of a new, secondary follicle. During the later stages of egg development, an oostatic hormone is produced that prevents the maturation of any secondary follicles until the maturing eggs have been laid, and avoids the burden of developing so many eggs that the female could no longer fly.

Endogenous

A property inherent in an organism (contrast with exogenous).

Endogenous Rhythm

Biological rhythms that arise independently of external stimulation.

Endomychidae

A family of beetles (order Coleoptera). They commonly are known as handsome fungus beetles.

► Beetles

Endoparasite

A parasite that lives inside the host.

Endophagous

Feeding within the body of a host, often on the internal organs.

Endophallus

The eversible inner lining of the aedeagus.

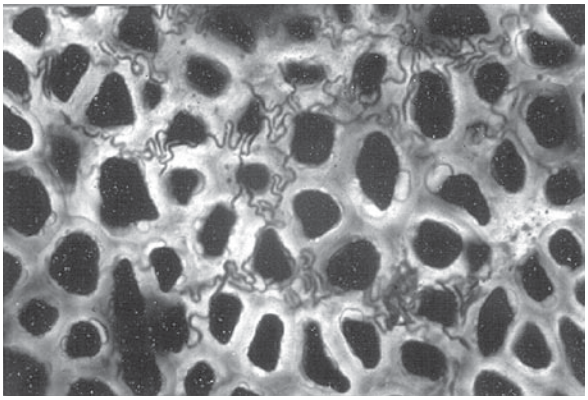
Endophytic Fungi and Grass-Feeding Insects

STEPHEN L. CLEMENT
U.S. Department of Agriculture, Agricultural Research Service Pullman, Washington, DC, USA

Nature had shaped plant defense mechanisms for warding off attack by plant-feeding insects long before humans started domesticating wild plants for food production about 10,000 years ago. As early farmers began developing agrarian societies, they probably observed that cultivated plants differed in their abilities to resist insect attacks. It remained, however, for twentieth century science to determine that variation in plant susceptibility to insect herbivores is often genetically based and results from natural plant chemistry and plant morphological traits (thorns, trichomes). Today, a rich body of literature exists on these plant defense mechanisms and abiotic (light, temperature, moisture, plant nutrient status, air pollutants) factors that influence plant susceptibility to insect attack.

The role of plant microorganisms in determining the outcome of some plant/insect encounters was not widely recognized by entomologists and other scientists until the 1980s. By the beginning of the twenty-first century, however, microorganisms were included in major scientific discussions of plant defensive mechanisms against insect attack. Fungal endophytes (*Epichloë* species and their asexual *Neotyphodium* forms) of grasses are one of the best known microbial groups that adversely affect insect survival. These endophytes (endo [within] and phyte [plant]) live for some or all of their life cycle within grasses and are mostly self-perpetuated through maternal transmission in seed. They are invisible because their host plants show no outward signs of infection.

It was not until microbiologists and animal scientists associated *Neotyphodium* infection (Fig. 27) in pasture grasses with toxic disorders of grazing cattle and sheep in the late 1970s and early 1980s that entomologists and grass breeders linked these fungal endophytes with enhanced grass resistance to insect pests. The first reports appeared in 1982 (New Zealand) and 1983 (United States) and documented enhanced field resistance to the Argentine stem weevil, *Listronotus bonariensis*, and

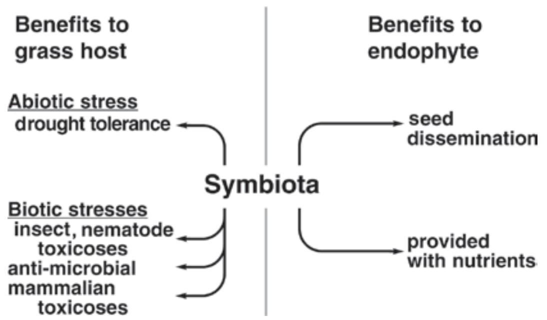


Endophytic Fungi and Grass-Feeding Insects, Figure 27 Section through a tall fescue seed showing mycelium of *Neotyphodium coenophaialum* between the aleurone cells (X100).

sod webworm, *Crambus* sp., in *Neotyphodium*-infected forage and turf perennial ryegrasses, *Lolium perenne*, compared to endophyte-free plants. Interestingly, before endophytes were implicated in ryegrass resistance to the Argentine stem weevil, some investigators attributed variability among ryegrass lines for susceptibility to weevil attack to traits based on plant genes.

After the first reports of *Neotyphodium* based resistance to insects, entomologists and other scientists accelerated the pace of research to generate more information on the extent and nature of specific grass/endophyte/insect associations. These efforts greatly expanded the list of insects negatively affected by endophyte-infected grasses, so, by the year 2000, it contained more than 40 species in five orders (Coleoptera, Lepidoptera, Diptera, Hemiptera, and Orthoptera) of the class Insecta. Concurrent research isolated and identified the chemical constituents (i.e., indole diterpenes, peramine, and pyrrolizidine and ergot alkaloids) of endophyte/host grass associations and characterized the responses of endophyte-infected grasses to a range of abiotic and biotic stresses. An outgrowth of research on the anti-mammalian and anti-insect properties of endophyte-infected grasses was the "defensive mutualism hypothesis," which viewed alkaloids produced by endophytes as defense chemicals that provide adaptive advantage to the infected host grass. Under this hypothesis, the fitness enhancing and anti-herbivore properties of endophyte infection would lead to higher frequencies of infected plants in grass populations. The accompanying figure (Fig. 28) illustrates the known benefits of grass/endophyte associations, which are viewed as symbiota to reflect the intimate association of the two partners. Most of the existing information about grass/*Neotyphodium* symbiota comes from work on forage and turf grasses in the genera *Lolium* (especially perennial ryegrass) and *Festuca* (especially tall fescue, *F. arundinaceae*, and fine fescue species).

Although researchers are far from fully understanding the range of insect responses to endophyte-infected grasses, they have developed a



Endophytic Fungi and Grass-Feeding Insects, Figure 28 **Known benefits to each symbiotic partner. Not every *Neotyphodium*-infected grass host has all of the benefits shown.**

good information base on the outcome of many interactions between grasses, endophytes, and insects. For example, research has shown that both insect deterrence and toxicity result from the production of alkaloids, and that the host grass genotype or species, and the endophyte strain involved in the interaction affect the expression and the type of insect resistance. Three examples illustrate the diversity of responses by plant-feeding insects. As previously mentioned, the first linkage between endophyte infection and insect resistance involved the Argentine stem weevil. This weevil maintains a close association with perennial ryegrass throughout its life cycle in New Zealand, where it is a significant pest of this important pasture grass. Adult weevils prefer to feed and oviposit on ryegrass plants that are free of endophytes, compared to endophyte-infected plants. A chemical, peramine, in endophyte-infected plants appears to be a powerful feeding deterrent to adult weevils. In another example, young larvae of the fall armyworm, *Spodoptera frugiperda*, a caterpillar that feeds on many grass species, prefer feeding on endophyte-free tall fescue, whereas older larvae do not display preference with respect to endophyte infection. This example shows that different life stages of some insects are affected differently by exposure to endophyte-infected grasses. Finally, *Neotyphodium* infection in wild barley, *Hordeum* spp., does not always kill the Russian wheat aphid, *Diuraphis noxia*, a primary pest of wheat and barley, as experiments showed that the aphid was sensitive to some, but not all, *Neotyphodium*/wild barley associations.

Although most of the early insect work emphasized the protective role of endophytes, a few studies documented insect insensitivity to endophyte infection in the late 1980s. Researchers continue to add to the list of insects unaffected by *Neotyphodium* infection in host grasses, thus revealing the variable nature of grass/endophyte/insect interactions, and the fact that endophyte-produced alkaloids do not always function as plant defensive chemicals. The absolute function of most chemicals produced by endophytes is still very much open for discussion and more scientific investigation.

Grass breeders and seed companies quickly developed and marketed *Neotyphodium*-infected *Lolium* and *Festuca* turf grasses after they recognized the benefits associated with endophyte infection. Today, turf grass professionals and homeowners in the United States routinely establish endophyte-infected grasses on golf courses, lawns, and playfields for better stand persistence and insect resistance. Additionally, scientists and commercial seed companies are beginning to take advantage of a vast diversity of *Neotyphodium* species and strains that differ in their ability to produce particular alkaloids. They are doing this by developing and marketing new forage grasses that are *Neotyphodium* combinations with "non-toxic endophytes" that do not produce toxins (e.g., ergot alkaloids) harmful to mammals, but do produce the necessary metabolites for better stand persistence and insect resistance. An expanding area of investigation involves biotechnological manipulations of endophytes for the commercial production of large pools of new grass-endophyte associations for specific purposes, including insect resistance.

examples of endotherms, and although insects generally are considered to be ectotherms rather than endotherms, some display endothermic behavior and physiology.

► Thermoregulation in Insects

Endotoxins

Substances produced by microorganisms which are not secreted into the surrounding medium but are confined within the microbial cell; they are released after autolysis.

Endrő di, Sebő (Sebastian Endrő di)

GEORGE HANGAY, OTTÓ MERKL[1]
[1]Hungarian Natural History Museum, Budapest, Hungary

Sebő Endrő di was born on the October 18, 1903 in Kassa, Hungary, now Kosice, Slovac Republic. He graduated in law from the Pázmány Péter University of Science, Budapest in 1931. He was a keen amateur coleopterist, working as a lawyer for the Danube Steamship Company from 1931 until 1948, then as a lecturer at the College of Horticulture, Budapest (1949–1956) and at the University of Agricultural Science at Göd, North of Budapest (1956–1961). From 1961 until his retirement in 1966 he was employed by the Ministry of Agriculture's Plant Protection Service in Budapest. After his retirement he had a room in the Hungarian Natural History Museum's Zoological Collections, where he conducted research until his death. His first entomological research focused on the beetle fauna of the Börzsöny Mountains, North of Budapest, where his family had a summer house. He set out to explore the beetles of this area together with his son, Sebastian Endrő dy-Younga. Through his long and productive life as a coleopterist, he has studied various sections of the beetle fauna of the Carpathian Basin and of the lands of historical Hungary as well as the scarabaeoid fauna of the World, publishing 222 scientific works. His achievements were highly respected by his colleagues and he was awarded with the Frivaldszky Memorial Plaque (Silver) by the Hungarian Entomological Society in 1967 and with the "In Scientia Entomofaunistica Excellenti" medal by the VIII. Central-European Entomofaunistic Symposium in 1979. Sebő Endrő di is known mainly by his work on the Scarabaeoidea, especially the Dynastinae. His greatest work was the revision of this subfamily of beetles, which was published in the German language in 20 sections, and consisted of 1,600 pages in eight journals. A shorter version of 800 pages in English was published in 1985 (The Dynastinae of the World, Budapest-Hagen, 1985). Dr. Endrő di passed away on the of December 12, 1984 in Budapest. He was a kind and helpful man with an immense knowledge of beetles.

Endrő dy-Younga, Sebastian (Sebestyén Endrő dy-Younga, Sebestyén Endrő dy)

GEORGE HANGAY, OTTÓ MERKL[1]
[1]Hungarian Natural History Museum, Budapest, Hungary

Sebestyén Endrő dy was born on the 26th of June, 26 1934 in Budapest. He became interested in beetles early in his life, following the footsteps of his father, Sebő Endrő di with whom he studied the coleoptera fauna of the Börzsöny Mountains, a wilderness region North of Budapest. He completed his formal studies by receiving his doctoral degree at the Eötvös Lóránt University of Science in Budapest, in 1958. From 1957 until 1965 he was employed by the Hungarian Natural History museum and worked closely with Dr. Zoltán Kaszab. He also published some papers regarding the beetles of the Börzsöny Mountains. In order to distinguish father and son, his father changed the spelling of their family name by replacing the last letter of *Endrődy* with an *i*, consequently he became *Endrődi* and Sebastian added his mother's maiden name by a hyphen to the original family name, thus forming the name *Endrő dy-Younga*, by which name he was known for the rest of his life. His Christian name *Sebestyén* is the Hungarian equal to *Sebastian*. He used the former in his Hungarian publications and the latter in his many works in English and German as well as in everyday life after he left Hungary. For his family and friends he was known as *Sebő*. In 1965, he accepted the position of senior research officer at the Ghana Academy of Science's Crops Research Institute in Ghana, and in 1973 together with his family he moved to the Republic of South Africa. He joined the Transvaal Museum in Pretoria in the same year, and became the Chief Curator of its Coleoptera Department in 1974. He held this position until 1998 when he resigned from it due to ill health. Endrő dy-Younga was a gifted coleopterist, blessed with a sharp mind and extraordinary memory. He was athletic and therefore a very effective, never-tiring field worker, well and truly belonging to the "Kaszab School" of extremely hard-working field entomologists. While in Ghana, he collected hundreds of thousands of specimens, which were sent back to the museum in Budapest. His beetle studies were chiefly focused on the Clambidae, Cybocephalidae and Tenebrionidae but he also researched the coleoptera fauna of the Carpathian Basin, publishing on various families. His 93 publications include major monographs and revisions. From the material that he collected through his life, 1,318 new species were described either by him or by colleagues, and 153 species and six genera were named after him. He received the Frivaldszky Memorial Plaque from the Hungarian Entomological Society. This seemingly frugal formal recognition does not reflect on his popularity as a colleague and friend, and the respect given to him as a coleopterist of immense knowledge. The international community of coleopterists suffered a great loss when he passed away on the February 26 1999.

Enhanced Biodegradation of Soil-Applied Pesticides

JOHN N. MATTHIESSEN
Commonwealth Scientific and Industrial Reasearch Organization, Floreat, WA, Australia

Pesticides are broken down in the environment by physical action such as heat and light, but biological degradation is often a primary means of dissipating such compounds. This is particularly the case for pesticides applied into soil. Microbes usually cause such biological breakdown.

In the past, many pesticides were not readily degraded by either physical or biological action because of their molecular structure. The most notable examples of such persistent compounds were the chlorinated hydrocarbon and cyclodiene insecticides. Since the 1970s these compounds have gradually been phased out by regulation and replaced by toxic, yet biodegradable, pesticides.

While agricultural producers and environmentalists could feel relieved that the major problem of persistent residues in soil, waterways and produce, and accumulation in animal tissue, was now a thing of the past, a strange new twist occurred in some situations. Some pesticides, particularly those applied to soil to control soil-borne pests and diseases, were no longer controlling pests as effectively as they once had. The problem was first noticed in agricultural systems that required preventative application and longevity of pesticide to protect plant roots from insect damage, such as where soil-dwelling pest insects colonized the crop during the course of its growth.

The phenomenon was puzzling – the pests could be shown to still be susceptible to the pesticide (i.e., they had not developed resistance because of prolonged or repeated exposure) and it seemed related only to particular fields, leading to them being labeled "problem" soils. It was some time, and some disastrous pest damage to many crops, before an explanation for these pesticide failures was revealed. It was all to do with repeated applications of a pesticide to the same area of soil.

Enhanced Biodegradation

Soil is a diverse ecosystem intimately involved in the cycling of organic matter, nutrients and moisture. Since it is known that pesticides are mainly dissipated from soil by microbiological metabolism, it is clear that some microbes can utilize apparently toxic compounds as a nutrient or carbon source. Microbes form a highly diverse component of the soil biota, intricately linked to soil processes and complex food webs. By the very nature of their rapid reproduction by cell division, populations of microbial organisms such as bacteria can respond and adapt very quickly to changes in their environment.

This is the basis of enhanced (also known as accelerated) biodegradation. Repeated applications of a pesticide to soil can stimulate the microbes that are able to metabolize the compound. This enrichment of the microbial population can reach a point where degradation of the pesticide occurs too fast to allow it to exert its desired pest control effect. The paradox is that the apparently positive general effect of biodegradation can be transformed into the negative local problem of enhanced biodegradation. Unfortunately, once enhanced biodegradation is induced, there is very little that can be done to cure the problem short of sterilizing the soil – hardly a desirable thing to do.

Enhanced biodegradation differs fundamentally from resistance to pesticides. In situations where resistance develops as a result of repeated exposure to a pesticide, individuals within the pest population carrying the genetic capacity to detoxify the compound have a selective advantage and gradually come to dominate the population. Enhanced biodegradation does not involve the pest directly. The causative organisms are otherwise innocuous members of the soil microbial community that "feed" on the pesticide and take it out before it can exert its toxic action sufficiently on pests to prevent crop damage.

Pesticide resistance comes at a metabolic cost to an organism – energy must be expended to detoxify a compound that has no intrinsic nutritional worth to the organism. Consequently, pesticide resistant genotypes are less fit and will diminish in the population once the selection pressure is removed. Enhanced biodegradation, on the other hand, is a consequence of a nutritional benefit causing proliferation of the adapted organisms. Although they too will diminish in response to reduction in the favored source of nutrition, it is simply a response to resource shortage and not because they are less fit.

A characteristic of enhanced biodegradation is that the effect gradually diminishes if the affected soil is given no further treatments of the pesticide. However, bacteria are mainly responsible and they can form resting stages. Consequently, the phenomenon can rapidly reactivate at an immediately high level if the pesticide is once again applied to the soil. Prevention of the phenomenon is the only sure way of avoiding it.

Unfortunately, enhanced biodegradation approaches by stealth and it is difficult to know what rate of removal of a pesticide from the environment will constitute a problem for control of a pest. The issue will most likely be crop and pest-specific. Acutely toxic pesticides applied when the pest is present are unlikely to suffer the problem, whereas pesticides that need to be applied prophylactically pre-planting to act later in the life of the crop will be at much greater risk.

Soil characteristics affect the risk of onset of enhanced biodegradation. A major factor increasing the risk is high soil pH, which favors proliferation of bacteria over fungi. However, it is known that calcium is an important element in the nutrition of bacteria and calcium content of soil is normally positively correlated with elevated pH. Recent studies confirm that the combined effect of calcium and high pH is required to enhance the risk of enhanced biodegradation. Generally, it seems that sandy soils are more at risk of the phenomenon but this is a broad characteristic that is not easily quantified.

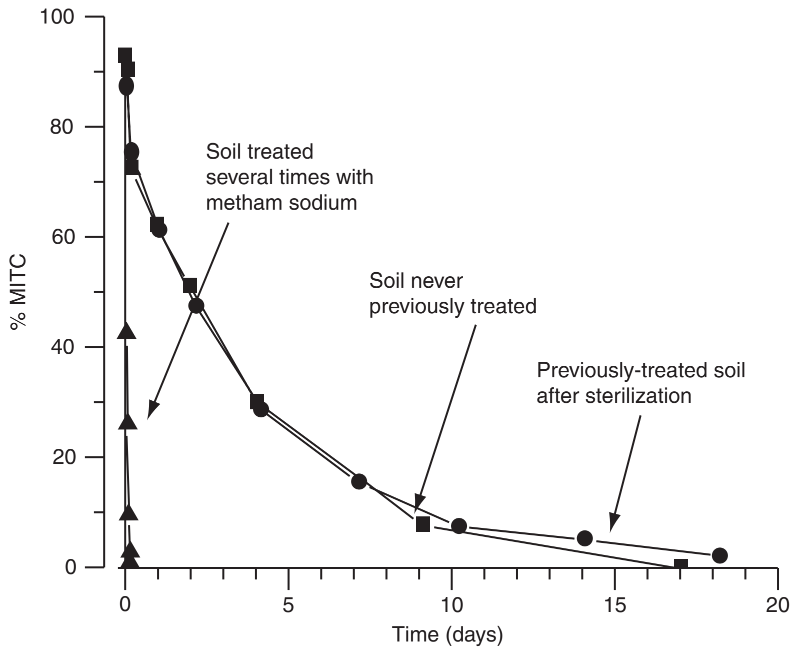
A significant related issue is the phenomenon of cross-degradation, where other pesticides are degraded at an accelerated rate in soil in which they have never been used, but which has enhanced biodegradation to another pesticide. Usually this occurs to structurally related compounds, meaning that new variations of a family of pesticides may be rendered ineffective before being used. This is what occurred to many of the carbamate insecticides used for control of corn rootworm in the American Corn Belt.

An Example

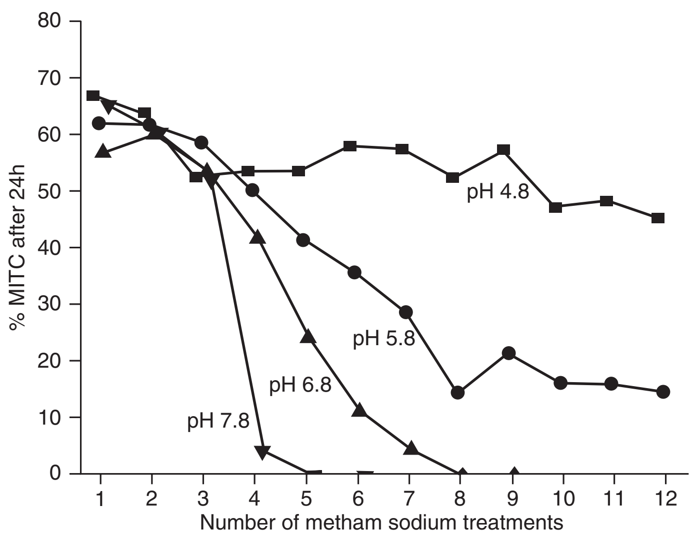
Metham (metam) sodium is a fumigant-like broad-spectrum pesticide widely used for the control of soil-borne pests and diseases. The principal use is in horticulture, which is often characterized by intense production systems with little or no crop rotation. Metham sodium is a somewhat unusual pesticide in that it is not the active pesticidal compound. Rather, it reacts in moist soil to form the toxin methyl isothiocyanate (MITC). Metham sodium, or more accurately the MITC, has been shown to suffer severely from enhanced biodegradation in an intensive horticultural production system where the soil is sandy and its pH is relatively high. It offers a good example of the principles of the phenomenon of enhanced biodegradation.

The accompanying figure shows the percentage of MITC produced and its fate when metham sodium is applied to soil that has either not been previously treated (Fig. 30) and the same type of soil from an adjacent field (Fig. 31) that had been treated approximately annually for about ten years. In the previously untreated soil the MITC was formed at almost 100% of theoretical within about one hour, and it degraded slowly over about 17 days. In contrast, in the previously treated soil only around 45% of the potential MITC was formed and it was completely dissipated within a mere seven hours.

The biological origin of the phenomenon was confirmed by sterilizing a sample of the degrading soil by autoclaving. When subsequently treated with



Enhanced Biodegradation of Soil-Applied Pesticides, Figure 30 **Production and fate of MITC toxin after application of metham sodium to soil never previously treated, soil treated numerous times in the previous ten years, and the previously treated soil after being sterilized.**



Enhanced Biodegradation of Soil-Applied Pesticides, Figure 31 **Amount of MITC remaining in soil 24 h after treatment with metham sodium for a single soil type amended to four pH levels.**

metham sodium, the production and fate of MITC in the soil was identical to the pattern in the soil that had never previously been exposed to the pesticide. Several species of bacteria that could be readily maintained in culture with MITC as the sole nutrient source were isolated from the degrading soil.

The clear influence of high pH (including non-limiting calcium) in exacerbating the risk of enhanced biodegradation is shown in the other figure. Sub-samples of a naturally acidic (pH 4.8) soil were modified to a range of higher pH values and then treated with metham sodium at monthly intervals, with the MITC being measured after 24 h. The highest pH soil developed enhanced biodegradation after only four applications, and the effect was proportional to pH in the other soils.

Implications

The most important aspect of enhanced biodegradation is for those involved in pesticides applied to soil to recognize the reality of the issue, be alert to the warning signs and to understand key risk factors (e.g., high soil pH). Too often in the past the control failures were put down to such things as unfavorable weather, poor application techniques, insufficient chemical or pesticide resistance. This can lead to repeated applications or increased doses – both of which simply exacerbate the problem.

The only option for management of enhanced biodegradation is prevention. One way that this can be achieved is by rotation of pesticides, so long as different types are alternated. However, this often requires a cooperative approach by competing pesticide manufacturers. Other methods that farmers can adopt is lengthening the time between applications of the same pesticide to an area of land through the use of longer crop rotations, and avoiding reliance on a pesticide-only approach by using rotation crops antagonistic to pest organisms.

Enicocephalidae

A family of bugs (order Hemiptera). They sometimes are called gnat bugs or unique-headed bugs.

► Bugs

Ensiform

This term is usually applied to structures that are sword-like in appearance. They are flattened with thin edges and taper to a point distally. Most often this term is applied to antennal structures.

Ensign Coccids

Members of the family Ortheziidae, superfamily Coccoidae (order Hemiptera).

► Bugs

Ensign Wasps

Members of the family Evaniidae (order Hymenoptera).

► Wasps, Ants, Bees and Sawflies

Enteric

This term refers to the digestive system or alimentary canal.

Entognatha

This is a taxon of superclass Hexapoda containing the primitive arthropods closely related to insects. Entognatha is usually considered to be a class, corresponding to the class Insecta, and consisting of the orders Collembola, Protura, and Diplura

(Entotrophi). However, these orders are sometimes considered to be classes, or orders within Insecta.

Entognathous

Mouthparts that are sunk into the head. This is also known as entotrophous. Such mouthparts are found generally in hexapod organisms that are close relatives of insects, such as Collembola, Diplura, and Protura. This is a major feature differentiating these insect-like groups from true insects, which have ectognathous (extruded) mouthparts.

Entomobryidae

A family of springtails in the order Collembola. They commonly are known as slender springtails.

► Springtails

Entomodeltiology

DALE H. HABECK
University of Florida, Gainesville, FL, USA

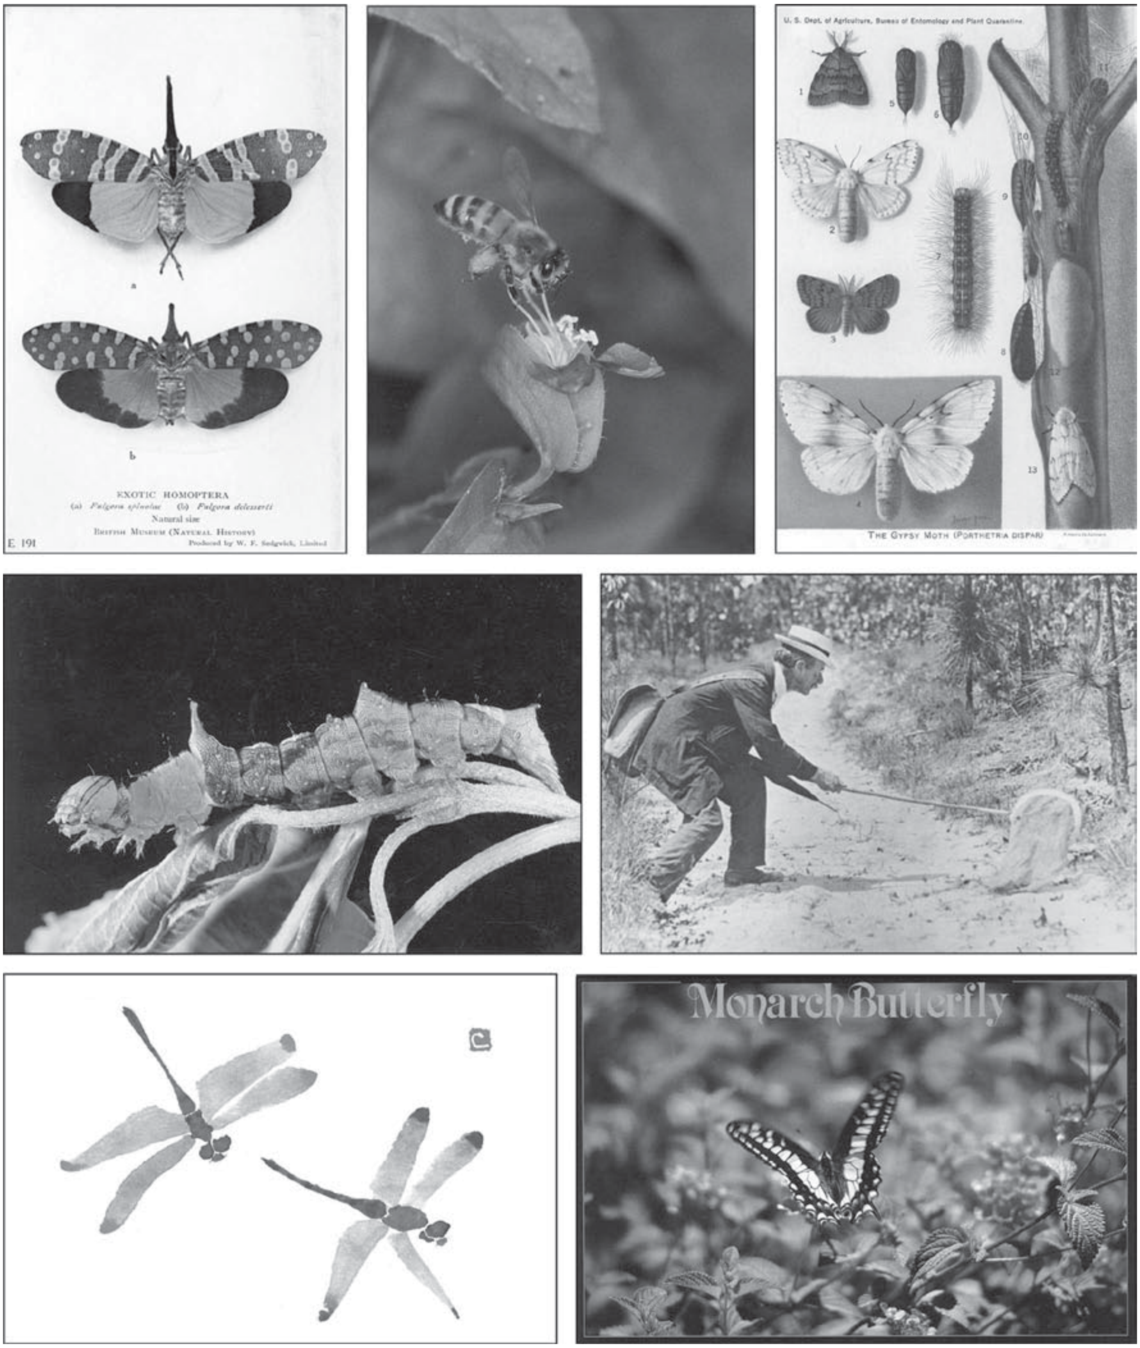
Many entomologists, ecologists, naturalists and amateurs collect insects because they find insects fascinating. Entomodeltiology, a combination of entomo = insect and deltiology = the hobby of collecting postcards, is another way to collect insects. Just as catching rare or unusual insects is challenging, finding postcards is equally challenging. Insects can be found on regular postcards and even on postcards made of leather, wood or ceramic.

Picture postcards were placed on sale at the Columbian Exposition in Chicago, Illinois, on May 1, 1893. Although there were earlier scattered issues, this was the real beginning of the postcard. Illustrations were placed on government printed cards or privately printed souvenir cards. The back of the card was for address only. In 1898, private printers in the U.S. were allowed to print and sell cards with the inscription "Private Mailing Card," and in 1901, private printers were granted permission to use the words "Post Card." Writing on the back was still limited to the address.

Postcards as we know them, with a vertical line down the middle of the back side with a space for the address on the right and a message on the left, were permitted beginning March 1, 1907. Millions of cards were printed from 1907 to 1915, mostly in Germany, where lithographic processes were far superior to those in America. The First World War stopped the printing and importation of post cards from Germany. Most cards were printed in England and the United States. Several other eras followed including the white border era (1915–1930). Printers saved ink by leaving a white border around the picture or illustration. These cards were of poor quality and many publishers went out of business. This was followed by the linen era (1930–1944) where cards with a high rag content caused the cards to have a linen-like finish. Many historical events were depicted on these cards. Finally (1945 to the present), the photochrome era. These color photographs are very appealing to the collectors and some postcard dealers specialize only in chromes.

Deltiology from 1915 to 1970 was not a popular hobby. Around 1970, interest began to grow. At present there are over 100 postcard clubs worldwide. Numerous postcard shows are held each year where collectors can peruse hundreds of thousands of postcards. Two magazines, Barr's Post Card News and Postcard Collector, are published. Subject interest is highest in geographic areas (cities, counties, states). Others limit their collecting to churches, schools, hotels, etc., in a particular area. There is hardly a topic that someone doesn't collect and that includes animals from the largest mammals to insects as diverse as butterflies and fleas.

Interest in insect postcards appears to be increasing as more and more dealers have an insect category in their topical offerings. A few years ago, if you inquired about insects on postcards, you would probably be referred to the animal category. The number of dealers who have a butterfly



Entomodeltiology, Figure 32 **Some postcards depicting insects: top row and second row left, educational postcards showing important or particularly interesting insects; second row right, postcards showing the "art" of capturing tiger beetles; bottom row, portrayal of insects for aesthetic value in oriental art (left) or photography (right). Note that the bottom right postcard is incorrectly labeled; this is a swallowtail rather than a monarch.**

Entomodeltiology, Figure 33 Additional postcards depicting insects: top two rows show humor, which often is associated with mosquitoes, particularly oversized mosquitoes; third row left, insects attired as humans; third row right, a "giant" grasshopper, a common source of humor in areas commonly infested with grasshoppers; bottom left, ladybeetles harnessed, another example of humor; bottom right, a colorful holiday greeting.

category has increased in recent years and it is unusual to find a dealer without such a category.

Considering the beauty of butterflies and moths, it is not surprising that they are favorites among insect postcard collectors. Examples range from chromes of live butterflies and sometimes their larvae, to artistic renderings of butterflies to the inclusion of small non-descript butterflies added to scenery pictures. Monarch butterflies are a favorite subject, especially on the newer chrome cards.

Butterflies and other insects (especially lady beetles and various bees and wasps) may be depicted on general greeting postcards (Fig. 32, Fig. 33) as well as birthday, Easter, Valentines, with only a few on Christmas, Thanksgiving, New Years, and St. Patrick' s Day.

Mosquitoes are frequently found on postcards in areas where tourists abound. A fairly common card has a giant stylized mosquito labeled as the state bird of (insert any state or province). Amazingly, these are usually labeled as *Aedes vexans*, apparently the only species known to postcard illustrators. Other old cards depict mosquitoes attacking people. Honey bees are not left out. Most are humorous with someone being attacked by a swarm of angry bees. Another comic card shows a man fighting bed bugs. Germany produced many postcards with scarab beetles performing as people.

Other themes found among insect postcards include fantasy (e.g., children with butterfly wings), exaggeration (e.g., giant grasshoppers), stamps, Asian art (insects are nearly as common as flowers), humor, and education (e.g., series of images produced by scientific institutes, government, and agrochemical companies).

New postcards may be found in any store that sells cards. Another good source is in the gift shops in natural history museums and butterfly houses. The British Museum of Natural History has issued over two dozen sets of insect postcards based on their vast worldwide collection of insects. Old postcards are often found in antique shops or at postcard shows. Postcard prices range from 25 cents up to hundreds of dollars depending on rarity, condition, topic and age.

Collecting postcards with insects is a challenging hobby. Unlike collecting insects on stamps, where catalogs are available listing every issue, the insect postcard collector is on his own.

Entomogenous

Refers to microbes or nematodes growing in or on the bodies of insects. This term connotes parasitic or other intimate symbiotic relationship, but not necessarily a pathogenic one. Though popular in recent history, this term is now rarely used, and is best considered obsolete (contrast with entomophilous and entomopathogenic).

Entomoparasitic

This term denotes a parasitic relationship between an insect and a parasite, though it usually is used to describe the relationship with insect parasitoids. Although entomoparasitic insects kill their hosts (i.e., they are pathogenic), they are never referred to as entomopathogenic. Some nematodes (the ones that do not kill quickly, instead functioning more like insect parasitoids) are correctly referred to as entomoparasitic (contrast with entomopathogenic, entomophilic).

Entomopathogenic

A relationship between an insect and a microbe, or an insect and a nematode, that results in the death of the insect. It is best considered a subset of entomophilic organisms. Some prefer to limit this term to insect-killing nematodes which harbor and release a pathogenic bacterium: nematodes in the families Steinernematidae and Heterorhabditidae. Although entomoparasitic insects kill their hosts (i.e., they are pathogenic), they are never referred to as entomopathogenic (contrast with and entomophilic).

Entomopathogenic Fungi and their Host Cuticle

NICOLAS PEDRINI, M. PATRICIA JUAREZ
Instituto de Investigaciones Bioquimicas de La Plata, CONICET, National University of La Plata, La Plata, Argentina

Entomopathogenic fungi are a very diverse group of insect pathogens that include approximately 700 species in almost 100 genera. They occur in most fungal taxonomic groups, with an ample variation in host range, thus providing a large number of microorganisms potentially useful as control agents against different insect orders. Insect pests infesting areas where it is difficult or unsafe to implement control using currently available insecticides are particularly good targets for mycoinsecticides. Among them, there is interest in targeting disease vectors that co-habit with humans (mosquitoes, flies and kissing bugs), mostly due to the health risk of toxic chemical use in human dwellings. There also is growing interest in use of mycoinsecticides to control pests affecting greenhouses, small orchards and organic farms (particularly aphids, whiteflies, a variety of beetles and caterpillars). Unlike other insect-pathogenic microorganisms that must be ingested to initiate the disease (virus, bacteria, nematodes and protozoa), entomopathogenic fungi normally invade by penetrating through the host cuticle. Surface structure and the chemical composition of the cuticle are both believed to affect the attachment of fungal propagules. Initial events can be divided into three successive stages:

(i) Adsorption at the interface between the propagules and the insect epicuticle. This first step involves physical and chemical characteristics of both propagules and host surfaces. The process may involve specific receptor-ligand and/or nonspecific hydrophobic and electrostatic mechanisms. This stage is characterized by the secretion of mucus by fungal cells and the initial dissolution of the surrounding epicuticle by this mucoid substance. Ungerminated conidia deposited on the cuticular surface are able to produce esterases, lipases, and N-acetylglycosaminidase. Thus, enzymatic activities might be implicated early in adhesion processes.

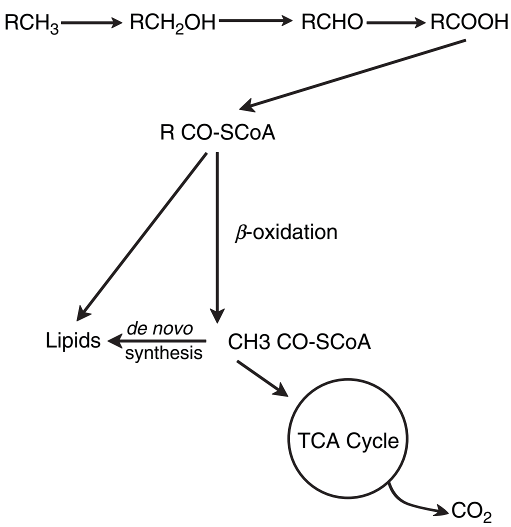
(ii) Fungal germination and development on the insect cuticle. Early events in spore germination require an exogenous carbon source. Both germination stimulators and inhibitors have been detected on the cuticle. In general, high relative humidity (over 90%) is needed for germination. However, an adequate microclimate to promote infection can be found on the intersegmental membranes of the insect's cuticle.

Both adsorption and germination must occur, but success here does not guarantee successful fungal infection. Fungal germination on non-host cuticle, without further penetration into the insect internal tissues, has been reported.

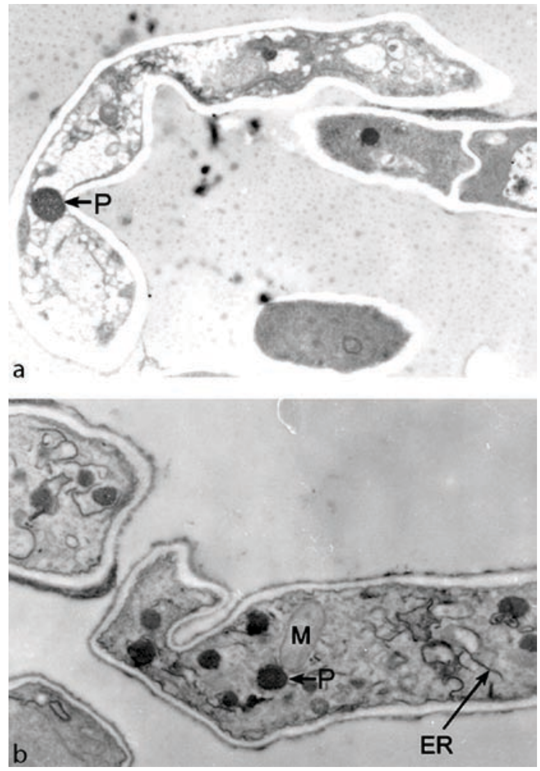
(iii) Fungal penetration. Germ tubes must pass through the different cuticular layers. This process depends both on the intrinsic properties of the germ tube and on the physiological state of the host and is essential for infection occurrence. The most common cuticular reaction to fungal penetration is a localized melanization around and in front of the penetration peg. Successful pathogens overcome any defensive reaction and penetrate into the hemocoel. Finally, the fungus replicates as budding hyphal bodies invading the entire cavity; insect death takes place shortly after.

Fungal Enzymes Involved in Cuticle Degradation

Although the major bulk components of the insect cuticle are protein and chitin, the outermost epicuticular surface layer comprises a complex mixture of non polar lipids, mainly composed by very long chain hydrocarbons (20 to more than 40 carbons). Entomopathogenic fungi are also able to degrade insect epicuticular hydrocarbons, incorporating them into cellular components (Fig. 34) as well as utilizing them for energy



Entomopathogenic Fungi and their Host Cuticle, Figure 34 Proposed pathway for hydrocarbon degradation by entomopathogenic fungi. RCH3: hydrocarbon, RCH2OH: fatty alcohol, RCHO: fatty aldehyde, RCOOH: fatty acid, RCO-SCoA: fatty acyl-CoA, CH3CO-CoA: acetyl-CoA, TCA: tricarboxylic acid.

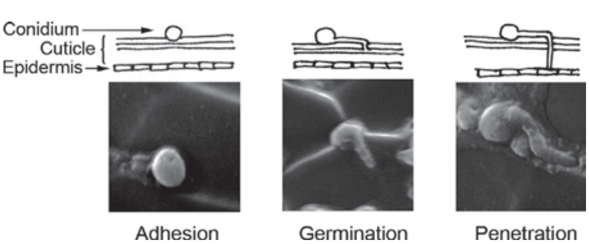


Entomopathogenic Fungi and their Host Cuticle, Figure 35 Electron micrographs of *Beauveria bassiana* comparing fungi grown either in an easily usable carbon source (glucose) or in insect-like hydrocarbon as the sole carbon source. Diaminobenzidine was used to stain peroxisomes. (a) Glucose-grown cells show scarce peroxisomes; (b) Hydrocarbon-grown cells show a large number of small size peroxisomes. P: peroxisomes, M: mitochondrion, ER: endoplasmic reticulum.

production. Insect hydrocarbons were shown to be the preferred cuticular lipid fraction for fungal growth. Employing radiolabeled analogues of insect hydrocarbons, they were shown to be incorporated into a variety of fungal lipid components. Depending on the substrate assayed, complete oxidation (CO_2 production) was also detected. The fungal enzymes involved in insect-like hydrocarbon breakdown have not yet been identified and characterized. In analogy to yeast systems, the first oxidation round is presumably carried out by a microsomal cytochrome P450 enzyme system, producing a fatty alcohol as the primary oxidation product. The alcohol, or eventually the fatty acid, will traverse the peroxisomal membrane, and after successive transformations by the concerted action of alcohol dehydrogenase, aldehyde dehydrogenase, and acyl-CoA synthetases, will eventually provide the appropriate fatty acyl-CoA for degradation in the peroxisomes, the site of β-oxidation in fungi. In *Beauveria bassiana*, development of peroxisomes is clearly stimulated in alkane-grown fungi; electron micrographs (Fig. 35) show diaminobenzidine-stained peroxisomal particles closely associated to endoplasmic reticulum. Furthermore, peroxisomal marker enzymes (i.e., catalase and acyl CoA oxidase) are induced in fungi grown on media containing insect-like hydrocarbons as the sole carbon source.

Penetration of exocuticle and endocuticle involves both physical and enzymatic activities.

The lack of data on the former makes it difficult to envisage its precise role in the whole process. To study enzyme production, fungal preparations are incubated either with insect cuticle or with chemical analogues, thus providing the required carbon and/or nitrogen sources. A variety of hydrolytic enzymes responsible for the degradation of the major cuticular components are induced sequentially: proteases and esterases are produced within the first day, whereas chitinase and lipase activities appear substantially later (4–5 d). Some of them act synergistically during degradation events. First, proteases hydrolyze most of the protein crosslinkages of the procuticle; afterwards, the chitinolytic complex is activated. A number of proteases and chitinases have been identified after expressed sequence tag (EST) analyses of cDNA libraries obtained from fungal cultures incubated with insect cuticle. In this growth condition, at least three kinds of proteases are expressed: subtilisin-like proteases, trypsin-like serine proteases and thermolysin-like metalloproteases. Subtilisin-related enzymes show the greatest activity against insect cuticle, having a crucial role in pathogenesis. Trypsin-related proteases have no ability to degrade intact cuticle, but act on partially hydrolyzed cuticular proteins. Their association with (Fig. 36) appressoria suggests they might be available during early stages of cuticle colonization. Both types of proteases might be part of a cascade of pathogen reactions facilitating the penetration of host cuticles. A similar situation is found with the complex mixture of endo- and exo-chitinases produced by entomopathogenic fungi during growth on the insect cuticle. Helping penetration, endo-chitinases are likely to be the most effective degrading cuticle polymers. Oligomers released by the endoacting enzymes might be further degraded by exo-chitinases resulting in small molecules (i.e., N-acetylglycosamine) usable for nutrition.



Entomopathogenic Fungi and their Host Cuticle, Figure 36 **Initial events of the interaction between entomopathogenic fungi and insect cuticle.**

Mycoinsecticide Improvement

Fungal virulence can be understood as the degree of pathogenicity against a potential insect host. Variation in fungal virulence toward a variety of insect hosts is related to enzyme production, growth conditions, temperature, relative humidity, and the presence of other microorganisms, among other factors. Insect mortality, the time period required achieving this goal, or fungal dose are frequently used as virulence parameters. The potential to enhance virulence has been addressed either by fungal adaptation to grow on a cuticle-like medium, or in a more sophisticated way, by adding insecticidal genes encoding specific cuticle-degrading enzymes (chitinases and proteases). These approaches resulted in 25–50% reduction in the time to kill and/or a similar percentage reduction in other mortality parameters.

The major barrier role of the cuticle in insect survival is well known; furthermore, the ability of fungal degrading enzymes to breach the insect cuticle is already recognized. Improving this set of tools by favoring the initial steps of fungal penetration will help increase mycoinsecticide performance. This goal may be attained through genetic modification, in addition to formulation optimization. Several methods can be applied for genetically improving strains, and recently, transformation methods have been used for the insertion of homologous or heterologous genes in fungal biocontrol agents. Overexpression of virulence-related fungal enzymes will be advantageous, since no safety concern to using genetically modified fungi has been provided, and hence it is an ecologically safe alternative to chemical pesticides.

Entomopathogenic Nematodes and Insect Management

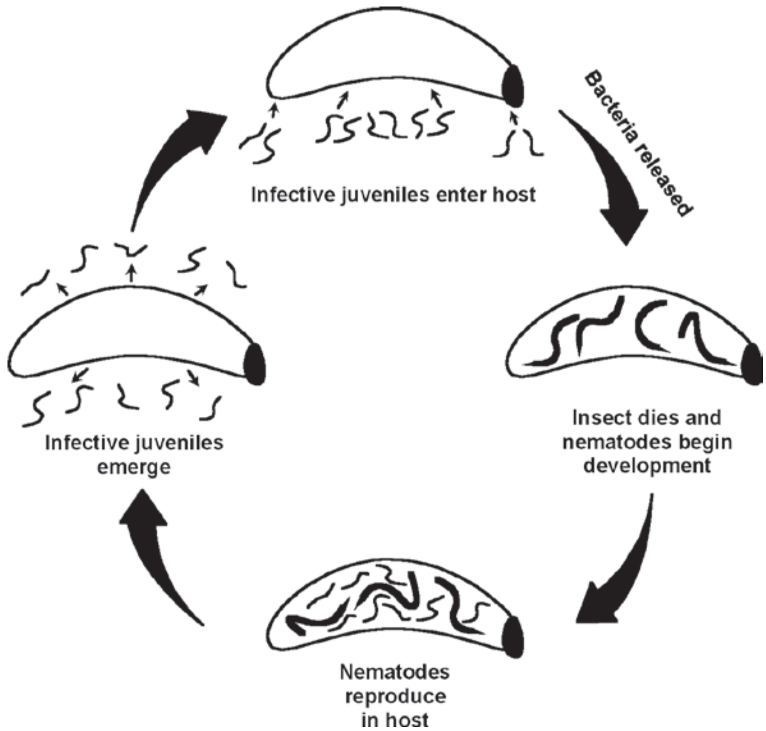
DAVID I. SHAPIRO-ILAN, [1] PARWINDER S. GREWAL, [2]
[1]United States Department of Agriculture, Agricultural Research Service, Byron, GA, USA
[2]The Ohio State University, Columbus, OH, USA

Entomopathogenic nematodes are small round worms comprising three genera in the order Rhabditida: *Heterorhabditis* Poinar, *Steinernema* Travassos, and *Neosteinernema* Nguyen and Smart. More than 35 species of entomopathogenic nematodes have been described. These nematodes are widespread and have been isolated from soil or natural hosts in every continent except Antarctica. In nature, these nematodes are obligate pathogens of insects, and thus have been developed as bioinsecticides to suppress arthropod pests. Entomopathogenic nematodes kill their hosts with the aid of a symbiotic bacterium. Heterorhabditid nematodes are associated with the bacteria *Photorhabdus* spp. And steinernematids are associated with *Xenorhabdus* spp. The bacterial symbiont associated with neosteinernematids has yet to be described.

Biology

A generalized life cycle of entomopathogenic nematodes is depicted in the accompanying figure (Fig. 37). The infective (Fig. 38) juvenile nematode, which is the only free-living stage, enters the host via natural openings, i.e., mouth, anus, spiracles, or occasionally through the insect cuticle. Once the nematodes penetrate into the host' s hemocoel, the symbiotic bacteria (carried in the infective juvenile' s intestine) are released and multiply rapidly, nematode development is initiated, and the host dies within 24–72 h. After the nematodes complete one to three generations within the insect cadaver, infective juveniles exit to find new hosts. The nematode life cycles differ among the genera in that the steinernematids contain only amphimictic forms (males and females), whereas the first generation of heterorhabditids (arising from infective juveniles) contain only hermaphrodites, and subsequent generations may contain amphimictic and hermaphroditic forms. Only one species of neosteinernematids has been described to date; their life cycle is similar to the steinernematids except that only one generation occurs in the host, and infective juveniles arise in female nematodes that have exited the host cadaver.

The relationship between the nematodes and their natural bacterial symbionts is mutualistic. The bacteria provide nutrients to the nematodes, produce antibiotics that inhibit competing microbes, and kill the host through septicemia (occasionally a bacterial toxemia precedes septicemia). Although the nematodes may also contribute to host death through suppression of the immune system and toxin production, the most important role they play in the mutualism is serving as vectors for the



Entomopathogenic Nematodes and Insect Management, Figure 37 **A generalized life cycle of entomopathogenic nematodes.**

Entomopathogenic Nematodes and Insect Management, Figure 38 **An infective juvenile steinernematid nematode.**

bacteria. Without the nematodes the bacteria cannot survive well outside of the host, e.g., in soil, and the nematodes are required for entry into the host hemocoel (few bacteria strains are pathogenic when ingested by a host). The relationship between nematode and bacterium is highly specific. Each steinernematid or heterorhabditid species is primarily associated with a single bacterial species, although some (Fig. 38) bacterial species can be associated with more than one nematode. The specificity of particular bacteria for growth and compatibility with nematodes can vary further on a strain level. The bacteria cells occur as two phenotypic variants: primary and secondary, which differ in dye absorption, response to biochemical tests, and antibiotic production. Although entomopathogenic nematodes have been reported to grow on secondary cells or even on certain non-symbiotic bacteria, the primary cells are most conducive to nematode growth. Infective juveniles only retain the primary cells.

Commerical Develoment and Efficacy

Entomopathogenic nematodes possess many positive attributes as biological control agents. They are safe to humans and are generally safe to other non-target organisms and the environment. Additionally, entomopathogenic nematodes have a wide host range, a durable infective stage, and can be applied using standard agricultural and horticultural equipment.

Another beneficial quality that entomopathogenic nematodes possess as biological control agents is amenability to mass production. The nematode-bacteria complex is mass-produced using *in vivo* (i.e., in insects) or *in vitro* methods (solid or liquid fermentation). *In vivo* production requires a low level of technology and relatively little capital outlay. However, cost efficiency using *in vivo* methodology is low due to space and labor requirements. Some of the factors that can affect nematode yield *in vivo* include choice of insect host and nematode species, nematode inoculum concentration, and environmental factors (humidity and temperature). The most common host used for in vivo production is the greater waxmoth, *Galleria mellonella* (L.); depending on nematode species, yields in *G. mellonella* vary from approximately 40,000 to 300,000 infective juveniles per insect. *In vitro* solid culture, i.e., growing the nematodes and bacteria on crumbled polyurethane foam infused with a liquid medium, offers an intermediate level of technology and costs between *in vivo* and liquid culture. Nematode yield using solid fermentation is affected by inoculum size, culture time, and media composition. Yields can vary from approximately 200,000 to 500,000 infective juveniles per gram of media. *In vitro* liquid culture is the most cost efficient production method but requires the largest startup capital outlay. Factors that affect nematode yields in liquid fermentation include nematode species, mixing (bioreactor design), aeration, and media. Entomopathogenic nematodes have been successfully cultured in bioreactors with capacities as large 80,000 liters, and yields of up to 300,000 infective juveniles per ml have been reported.

For small-scale or laboratory purposes, entomopathogenic nematodes are generally produced *in vivo* and stored in aqueous suspension (with sufficient exposure to oxygen) prior to use. Commercially produced nematodes, however, must be formulated prior to delivery and application. An effective formulation provides a suitable shelf life, stability of product from transport to application, and ease of handling. Increased shelf life, in most entomopathogenic nematode formulations, is obtained by reducing nematode metabolism and immobilization, which may be accomplished through refrigeration and partial desiccation. Optimum storage temperature for formulated nematodes varies according to species: generally, steinernematids tend to store best at 4–8°C whereas heterorhabditids have longer shelf life at 10–15°C. Various formulations for entomopathogenic nematodes have been reported, including activated charcoal, alginate and polyacrylamide gels, baits, clay, peat, polyurethane sponge, vermiculite, and water-dispersible granules. Depending on the formulation and nematode species, successful storage under refrigeration ranges from one to seven months.

The efficacy of entomopathogenic nematodes in suppressing insects depends on selection of the appropriate nematode for the target pest. A suitable nematode must possess a high degree of virulence (killing power) to the host. The nematode must be able to effectively invade and overcome the host immune system under field conditions (laboratory virulence does not necessarily predict field efficacy). Although many entomopathogenic nematodes possess a broad host range spanning several taxonomic orders, the nematode most suited to a particular pest will often be species and strain dependant. Not all entomopathogenic nematodes have broad host ranges, e.g., *S. kushidai* Mamiya appears to be specific for scarab beetles (Coleoptera: Scarabaeidae) and *S. scapterisci* Nguyen and Smart is most suitable to two-clawed mole cricket hosts (*Scapteriscus* spp.).

The ability of entomopathogenic nematodes to persist in the environment may also contribute to host suitability. Indeed, in some cases enhanced persistence may even compensate for lower virulence. Generally, high levels of efficacy persist for only two to six weeks following nematode application. However, there have been some reports of prolonged pest control over several seasons or years. Nematode persistence depends on the nematode species or strain, host density, and environmental factors (e.g., temperature, moisture, etc.).

Additionally, the suitability of an entomopathogenic nematode to control a particular pest depends on the nematode' s foraging strategy. Foraging strategies exhibited by entomopathogenic nematodes exist along a continuum from ambushers to cruisers. Ambushers use a sit and wait strategy; they usually stand on their tails (nictating) and wait until a host comes close before infecting. Cruisers actively seek out their hosts and cue into certain target volatiles (e.g., CO2) prior to contacting the host. Examples of nematodes that exhibit foraging behavior characteristic of ambushers include *S. carpocapsae* (Weiser) and *S. scapterisci*, those exhibiting behavior typical of cruisers include *H. bacteriophora* Poinar, *H. megidis* Poinar, Jackson, and Klein, and *S. glaseri* (Steiner), and those with intermediate search behavior include *S. feltiae* (Filipjev), and *S. riobrave* Cabanillas, Poinar, and Raulston. Ambushers tend to be most successful at infecting mobile insects on or near the soil surface, whereas cruisers tend to be most successful at infecting sessile insects below the soil surface.

Abiotic factors are critical in determining efficacy of entomopathogenic nematode applications. These nematodes are highly sensitive to desiccation and ultraviolet light. Thus, applications made to soil or other cryptic habitats (and made during the early morning or evening) tend to be most successful. Temperature extremes (e.g., below 20°C and above 30°C) can be detrimental to nematodes. The optimum temperature for maximum efficacy depends on nematode species or strain; some nematodes are relatively heat tolerant such as *H. indica* Poinar, Karunakar, and David, and *S. riobrave*, whereas others are relatively cold tolerant, e.g., *H. megidis* and *S. feltiae*. Soil characteristics can also be important in determining efficacy, e.g., coarse soils with high sand content facilitate nematode movement and allow for air exchange. Nematodes require oxygen for survival, and thus factors that reduce airflow such as compacted or water-saturated soil are detrimental. Other pesticides or fertilizers used in conjunction with entomopathogenic nematodes may affect efficacy antagonistically, additively, or synergistically, depending on the agent(s) involved.

Following is a list of some insect pests for which high levels of suppression (greater than or equal to 80%) were achieved under field conditions using entomopathogenic nematodes (Table 4). A high degree of efficacy in pest suppression, however, does not necessitate an opportunity for successful application on a commercial scale; economic factors are also important. Generally, to achieve a high degree of efficacy, at least 25 infective juveniles must be applied per cm^2 of treated area (= 2.5 × 109 per hectare). Based on the number of nematodes required for successful pest control, and current production methods, the cost of entomopathogenic nematodes tends to be relatively high compared with many chemical insecticides. Therefore, commercial use of entomopathogenic nematodes has been cost prohibitive in many low-value crops (e.g., row crops such as cotton and corn), and has been most successful in certain high value crops or niche markets. Some examples of pests and markets where entomopathogenic nematodes have been successfully commercialized include billbugs (*Sphenophorus* spp.) in turf, black vine weevil, *Otiorhynchus sulcatus* (F.), in cranberries and ornamental plants, diaprepes root weevil, *Diaprepes abbreviatus* (L.), in citrus, fungus gnats (Diptera: Sciaridae) in mushrooms, *Scapteriscus* mole crickets in turf, and white grubs (Coleoptera: Scarabaeidae) in turf and ornamental plants.

Several measures can improve entomopathogenic nematode efficacy. Advances in production, formulation, and application technology can enable more viable nematodes to be applied to the same area for an equal or lower cost. Discovery of new nematode strains or species with superior beneficial traits such as virulence, persistence, or environmental tolerance, can enhance the potential for successful pest suppression. Beneficial traits may also be developed in entomopathogenic nematodes through genetic methods, i.e., artificial selection, hybridization, mutagenesis, and genetic transformation.

Entomopathogenic Nematodes and Insect Management, Table 4 A list of some pests for which at least 80% suppression was reported using entomopathogenic nematodes under field conditions[a]

Pest common name	Pest scientific name	Nematode(s)[b]
Artichoke plume moth	*Platyptilia carduidactyla* (Riley)	Sc
Banana moth	*Opogona sachari Bojer*	Hb, Sc
Banana root borer	*Cosmopolites sordidus* (Gemar)	Sc, Sf, Sg
Black cutworm	*Agrotis ipsilon* (Hufnagel)	Sc
Black vine weevil	*Otiorhynchus sulcatus* (F.)	Hb, Hm
Borers	*Synanthedon* spp.	Hb, Sc, Sf
Codling moth	*Cydia pomonella* (L.)	Sc
Corn earworm	*Helicoverpa zea* (Boddie)	Sr
Diamondback moth	*Plutella xylostela* (L.)	Sc
Fungus gnats	Diptera: Sciaridae	Sf, Hb
Japanese beetle	*Popillia japonica* Newman	Hb, Sg
Leafminer	*Liriomyza* spp.	Sc
Mole crickets	*Scapteriscus* spp.	Sc, Sr, Ss
Root-knot nematodes	*Meloidogyne* spp.	Sc, Sf, Sr

[a]At least one scientific paper reported ≥80% suppression of these pests.
[b]Hb = *Heterorhabditis bacteriophora*, Hm = *H. marelatus*, Sc = *Steinernema carpocapsae*, Sf = *S. feltiae*, Sg = *S. glaseri*, Sr = *S. riobrave*, Ss = *S. scapterisci*.

Through continued research the use of entomopathogenic nematodes is expanding. In addition to controlling harmful insect pests, novel uses of entomopathogenic nematodes, and more so, their symbiotic bacteria or associated metabolites, are being pursued to suppress plant parasitic nematodes, and as anti-microbial agents in pesticide and pharmaceutical applications. Furthermore, toxins produced by the bacteria are being studied for their suitability as alternatives to other orally active insecticides such as toxins produced by *Bacillus thuringiensis*.

Entomophagous

Insectivorous; the consumption of insects or their parts. Though formerly used to describe a broad range of associations that resulted in insects being killed, it now is used mostly to indicate predation of insects. Parasitic relationships are best described as entomoparasitic (for parasitoids) or entomophilic/entomopathogenic (for nematodes and microbial pathogens).

Entomophagy

Consumption of insects by other animals and carnivorous plants.

Entomophagy: Human Consumption of Insects

JUN MITSUHASHI
Tokyo University of Agriculture, Tokyo, Japan

In ancient times, when humans first appeared on the earth, insects might have been important foods for them, because they had neither tools to hunt large animals, nor techniques for agriculture. Since then, entomophagy has continued up to the present time all over the world. Human coprolites, which were found in some caves in the USA and Mexico, give evidence to the above consideration. From the coprolites found in caves of the Ozark Mountains located between Arkansas and Missouri, ants, larvae of beetles, lice, ticks and mites were isolated. On the wall of a cave of Artamila in North Spain, a picture showing the collection of wild bee nests was found. It is said that the picture was drawn about 9,000 to 30,000 years B.C. At that time people might have eaten bee larvae and pupae together with the honey. In Shanxi Province, China, cocoons of a wild silkworm, *Theophila religiosae*, were found from the ruins of 2,000 to 2,500 years B.C. Each cocoon had a large hole on it, suggesting that people ate pupae of the silkworms. People ate various insects everywhere in the world, and this developed into traditional entomophagy. Some traditional entomophagy has been handed down to the present.

Most insect species are edible, but some are toxic. More than 1,000 species have been consumed as foods. However, identification of the species is difficult, because in many cases edible insects are given vernacular names. Some of more important groups include grasshoppers; caterpillars; beetles (larvae and adults); termites; bee, wasp and ant brood (larvae, pupae and sometimes winged adults); cicadas; and various aquatic insects.

Present entomophagy may be divided into two categories. One is consumption of insects as necessary nutrients, and the other is uptake of insects as a condiment. In the former case, insects are consumed as protein sources in the area where malnourished people live, or at the time of famine. For example, locust outbreaks are common in Africa and the Middle East, and edible plants are scarce after migration of locusts. Under these circumstances, people catch locusts for their food. However, sometimes local government sprays insecticides against locusts. The insecticide-sprayed locusts are no longer suitable for food. Then there will be conflicts between people and the government.

In the latter case, insects appear as cuisine in restaurants in big cities, and are also sold as processed food. In restaurants, insect dishes are always more expensive than beefsteak. The popular insects served in restaurants are maguey worms (*Cossus redtenbachi* and *Aegiale hesperiaris*), ants (*Liometopum apiculatum*) in Mexico; wasps (*Vespa sorror*), wild silkworm pupae (*Antheraea pernyi*), and pyralid moth larvae (*Chilo fuscidentalis*) in China; wasps (*Vespa* sp.), bees (*Apis dorsata*), giant water bugs (*Lethocerus* (*Belostoma*) *indicus*), pyralid moth larvae (*C. fuscidentalis*) in Thailand.

The processed insects also are expensive compared with other food. As processed insect foods, the followings are commercially available; canned rice grasshoppers (*Oxya yezoensis*), wasps (*Vespa lewisi*), silkworm pupae and adults (*Bombyx mori*), and larvae of Trichoptera from Japan; canned silkworm pupae (*B. mori*) from Korea; canned spice (namphric) containing giant water bugs (*L. indicus*) from Thailand; canned mopany worms (*Goninbrasia belina*) from South Africa; bottles of mezcal containing maguey worms (*C. redtenbachi*) from Mexico; canned soup containing witjuti (witchetty) grubs (larvae of large cossid moth) from Australia; candies containing mealworms (*Tenebrio molitor*) or crickets (*Acheta domesticus*) and fried snacks of some lepidopteran larvae from the USA.

Insects are eaten raw or cooked. In tropical regions where palm weevils (Coleoptera: Rhynchophoridae) are distributed, the larvae are eaten raw by native people joyfully at the moment when captured. In Papua New Guinea, children eat small grasshoppers as a favorite food. Many other species are consumed raw by people in developing countries.

The simplest and most primitive form of food preparation is roasting. It is common to roast insects in a fire or to throw them into hot ash. A more subtle way is to smother by burying insects in the soil with heated stones. Roasting insects by skewering them is popular too. Insects are also boiled or simmered in water or soup. They are often cooked with some vegetables and spices. Frying is also a popular cooking way of insects. Any species or any stage of edible insects can be eaten by frying. In many cases, fried insects with a bit of salt or spices are acceptable. Insects are also fried with vegetables. Some edible insects can be preserved by desiccation. In some places dried insects are commercially available in markets: e.g., mopany worms in South Africa, chipmi (*Gynanisa maja*, Saturniidae) in Zambia, small water bugs (ahuahutle) and their eggs in Mexico.

Although cooking methods for insects are similar in many places, traditions have developed in some areas. Some examples of traditional entomophagy follow. In Japan, rice grasshoppers, wasps (*V. lewisi*), silkworm pupae and trichopteran larvae have been consumed from old times. All these insects are cooked with soy sauce, sugar and rice wine. These insects were used as a protein source by people who lived in mountainous areas and had limited access to fish.

In Africa, termites are widely consumed. People collect termites when these insects swarm out of their nests at the first rain after the dry season. People eat them raw or fried. In Africa there are very many species of Saturniidae, whose larvae are large. Among these species, the mopany worm is famous. The mopany worm is distributed in southern Africa (i.e., South Africa, Botswana, Zimbabwe and Zambia). The worms are relished, and people collect them to a greater extent when the worms reach full-grown stage. In addition to the consumption by the collector themselves, many dried larvae are exported to neighboring areas where the mopany worm does not occur. The mopany worm is prepared mostly by stewing. In Lake Nyassa, when the midge *Chaoboris edulis* is very abundant, Tanzanians collect flies, press them into cakes, and dry them under the sun. The products are called "kungu," and are said to have taste of caviar. Also, Malawians collect ephemeropteran adults, and make cakes. This is also called kungu.

In Thailand and surrounding areas, giant water bugs have been consumed widely. People not only eat intact insects, but also make spices (namplaa sauce or namphric) from the scent glands of males.

In Australia, the aboriginal people still keep the custom of eating witjuty grubs (large cossid moth larvae) and a honey pot ant, *Camponotus inflatus*. People eat the witjuty grubs by roasting them, while the honey pot ants are consumed raw. The bogong moth, *Agrotis infusa*, is a well-known insect food for Aborigines. Every year, the adults migrate to the Australian Alps for summer estivation. Aborigines gather in the Alps to collect the estivating moths in interstices of rocks. They eat the moths by roasting them on heated ash.

In the USA, the Paiute Indians living in the Sierra and Cascade Mountains used to collect the pandora moth larvae, *Coloradia pandora lindseyi*, from conifer trees. Like mopany worms, pandora moth larvae are consumed by roasting or by boiling (the boiled larvae are called "pe-ag-gie" or "piuga"). Modoc Indians in California used to consume the adult of a fly, *Atherix* sp., which is easily collected along rivers. People eat them by making loaves and roasting them. It is said that the taste is similar to headcheese. In California, Mono Lake Indians who lives near alkaline and saline lakes used to consume pupae of a brine fly, *Ephydra hianus*. A colossal number of the pupae are thrown up on the shore of the lake in late summer. The Indians harvested the pupae, removed puparia by rubbing, and ate them. This food is called "koo-chah-bee."

In Thailand, especially in northern part of the country, many insect species are consumed as food. One weaver ant, *Oecophylla smaragdina*, is commonly eaten raw or rubbed with salt, chili or pepper. A grasshopper, *Patanga succincta*, is also a popular edible insect and consumed by frying. A cricket, *Brachytrupes portentosus* has been commonly consumed.

In China, cicadas, ants and wasps have been consumed since ancient times, and these insects are still served in restaurants.

Insect foods can generally be said to be nutritious, because insects are rich in protein, lipid and vitamin. Although the chemical composition of insects varies with developmental stages and sexes even in the same species, protein is about 30–75% and lipid 5–60% of dry weight of insects. Among amino acid constituting insect protein, leucine, lysine and aspartic acid are said to be rich, while cystine and tryptophan are poor. However, some insect protein (for example, that of the house fly, *Musca domestica*) is said to have similar amino acid composition to beef protein. Lipids contained in insects resemble the lipids we take from usual food. For examples, fatty acid composition of the house fly pupae is said similar to that of fish fat. Carbohydrate is minor component of the insect body and is not an important nutrient in insect food. In general, insects contain a few percent of ash. Among minerals, the content of phosphate is commonly high. Insects contain considerable amount of Na, but only a little NaCl. Insects are rich in vitamins A, B1, B2 and D. Larvae of the bee, *Apis mellifera*, are said to have vitamin D ten times of that of cod liver oil, and vitamin A several times of that of egg yolk. These facts suggest that insects will be considered as a source of protein in the future.

Most medicinal use of insects is a part of entomophagy. However, only a few substances have been identified as effective components of the insects used for medicines. Some insects are apparently used as medicines based on the superstition. Cantharidin from meloid beetles, and pederin from a staphilinid beetle, *Paederus paralelus*, are known to have fungistatic action. The former was once used as aphrodisiac, too. Crickets are said to contain a substance called grypin, which acts as antifebrile. A scale insect, *Dactylopius coccus*, contains red pigment called cochineal, which is used as cough medicine, and for trouble with nerves and kidneys. *Cordyceps* is not an insect but entomogenous fungus. It is used for various diseases; an effective substance, cordycepin, has been identified. There are many insect medicines based on superstition. For example, a cicada is used as a diuretic, because a cicada often excretes urine when it flies away, and people who have disuria might want to be able to urinate easily. Silkworm moths copulate soon after adult emergence, and for a long time. People used silkworm adults as an aphrodisiac, because impotent people envy their sexual strength.

Entomophilic

This term denotes an association of microbes or nematodes with insects (and also known as entomophilous). It is used to describe a phoretic or mutualistic association, but sometimes includes pathogenic associations. Thus, it is a very broad category that includes many types of associations, and for that reason, is not very descriptive. It is better to describe pathogenic associations as entomopathogenic rather than entomophilous or entomophilic.

Entomophobia

Abnormal fear of insects and mites. It may be manifested in dermatitis induced by physical irritants or allergens, but also may result in hysterical reactions caused by the sight of the actual or purported organisms. The occurrence of invisible "cable mites," "paper mites," and "computer mites," are sometimes associated with this affliction.

► Delusory Parasitosis

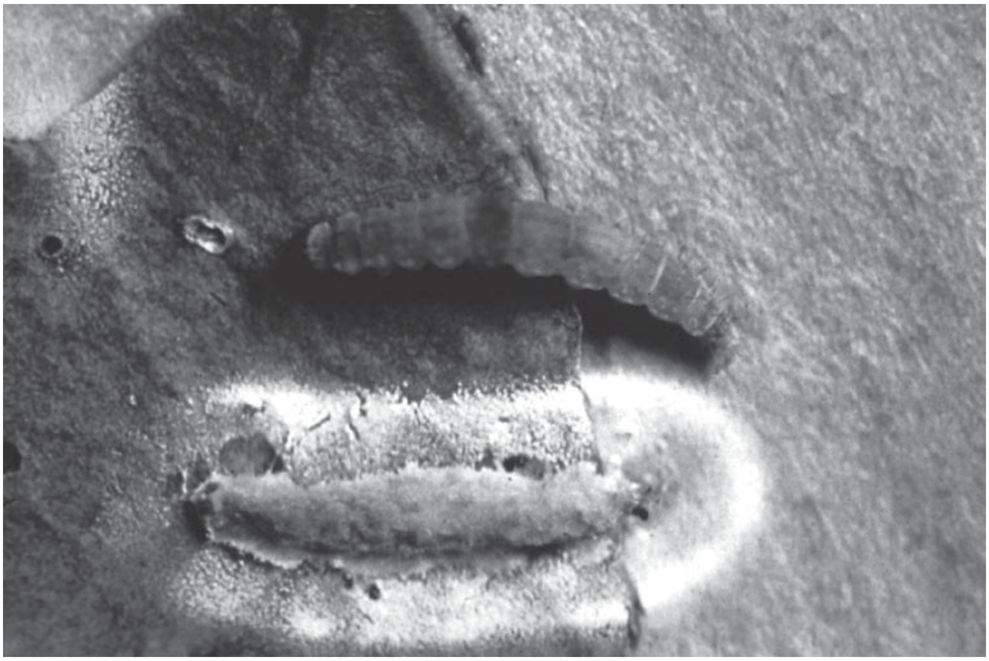
Entomophthorales

Most of the entomopathogenic genera within the Zygomycetes belong to a large order, the Entomophthorales. A second order in the Zygomycetes is the Mucorales, most of which are saprophytic; one genus, *Sporodiniella*, however, does infect membracids. Members of the Entomophthorales, with the exception of the genus *Massospora*, are characterized by the presence of forcibly discharged conidia; in *Massospora*, conidia are formed within the abdomens of periodical cicadas in the genus *Magicicada*. In addition to conidia, the Entomophthorales also produce zygospores (sexual) and azygospore-type resting spores, and mycelia are usually coenocytic, i.e., non-septate. The order is separated into six families depending upon nuclear cytology, characteristics of vegetative cells, and the modes of formation and germination of resting spores. Most notably, species in the genus *Entomophthora* (Entomophthoraceae), which was once the largest genus in the order, have been separated and moved into other genera.

Members of the Entomophthorales can attack a wide variety of insect hosts, including species from Hemiptera, Diptera, Lepidoptera, Coleoptera, Orthoptera and Hymenoptera. The host range of some fungal species may be limited to a specific host insect or may be broad enough to extend to non-target insects. A fungus tentatively identified as *Entomophthora* was found on a termite (Isoptera) embedded in 25 million-year-old amber. The Entomophthorales are especially important pathogens of aphids, grasshoppers, muscoid flies and lepidopteran larvae, and can function as biocontrol agents against these pests. Interestingly, one species of Entomophthorales, *Entomophaga maimaiga*, was introduced into New England from Japan in 1910–1911 in order to control the gypsy moth (*Lymantria dispar*). At this time, the fungus could not be grown in the lab, so researchers depended upon its overwintering in the field to produce new spores for inoculum. However, the fungus disappeared until 1989, when it was recovered from the field in areas with established gypsy moth populations. It is suggested that either the fungus introduced in 1910 developed into a more aggressive strain that has only recently caused obvious, widespread outbreaks, or that a more aggressive strain has been introduced at some point.

Some Entomophthorales will attack animals other than arthropods and can even infect mammals, including humans. Entomophthoromycosis in humans is caused by species of *Conidiobolus* or *Basidiobolus*, and occurs most often in tropical and subtropical regions. Infections usually are restricted to subcutaneous tissues such as those overlaying the paranasal sinuses, but it also has been reported to disseminate into the deep organs, i.e., lymph nodes, lungs, liver and intestines.

As entomopathogens, the Entomophthorales can infect larvae, pupae or adult hosts. Some species have broad host ranges while others, such as *Massospora*, can infect only one insect species. Insects attacked by some Entomophthorales may not show any symptoms until late in the infection process. Infected grasshoppers and Lepidopteran



Entomophthorales, Figure 39 **Entomophthorales infected *Plutella* larvae. Note the halo of primary conidia that have been actively discharged from conidiophores on the diseased insect. For comparison, see healthy insect above the cadaver surrounded by discharged conidia.**

larvae often display summit disease syndrome, meaning they have a tendency to climb to high positions, where they attach and die. Conidia from such cadavers then can disseminate easily to uninfected insects closer to the ground. The appearance of Entomophthorales-infected cadavers also depends upon whether they have surface conidia or internal resting spores. Insects from which conidia have been forcibly discharged may be surrounded by a halo of these propagules that forms as they settle on the substrate (Fig. 39). Diseased insects that produce the resting spore stage darken and liquefy internally.

Entomopoxvirus

At present, the family Poxviridae is divided into two subfamilies: the *Chordopoxvirinae*, composed of eight genera of vertebrate viruses, and the *Entomopoxvirinae*, containing three genera, A, B, and C, of insect poxviruses. Comparative analysis among the vertebrate and Entomopoxvirus groups has suggested low levels of genomic homology. To date, over 30 insect poxviruses have been detected in Coleoptera (A), Lepidoptera (B), Orthoptera (B), and Diptera (C), and have been placed in genera A, B, or C on the basis of virus morphology. Members within genus A are characterized by oval-shaped virus particles containing a unilateral concave core region and a single lateral body. Members of genus B, isolated from both lepidopteran and orthopteran hosts, have oval-shaped virus particles with a rectangular core region that lacks a discrete lateral body. Genus C members possess a cuboidal or cushion-shaped virus particle, a dumbbell-shaped core region, and two lateral regions.

Poxviruses are the largest and most complex viruses. Poxviruses encapsidate large (130–375 kbp) linear dsDNA molecules. The typical oval-shaped poxvirus measuring 200–400 nm in length may contain over 100 structural proteins. The biconcave or dumbbell-shaped core region contains tightly compressed nucleoprotein. The function of the lateral bodies is unknown. Surrounding the core and lateral body is a lipid bilayer referred to as the outer membrane. Extracellular poxviruses, released via budding, contain a second lipoprotein envelope. The majority of entomopoxviruses produce occlusion bodies at the late stage of infection. These Type B occlusions, also termed spheroids, are composed of the 115 kDa matrix protein spheroidin and numerous enveloped virus particles. The spheroidin component of the different entomopoxviruses appears to be conserved and all entomopoxviruses are sensitive to alkali treatment. It should be mentioned that the vertebrate poxviruses produce acid-sensitive Type A inclusions composed of individual viral particles encoated by a late viral protein. In addition to spheroids, members within genera A and B of the entomopoxviruses may produce virus-free, spindle-shaped inclusions. The 50 kDa protein fusolin (French fuseau = spindle) is the major component of spindles and represents, when present, one of the most abundant EPV proteins.

The entomopoxviruses, like other poxviruses, replicate in the cytoplasm of host cells. This property mandates that poxviruses encapsidate a complete transcriptional system capable of producing functional viral m-RNAs. Poxviruses contain a DNA-dependent RNA polymerase composed of multiple subunits which transcribes only ssDNA. Several of the subunits have been demonstrated to be homologous to eukaryotic RNA polymerases. A second enzyme is the multifunctional capping and methylation complex. This enzyme transfers guanosine and catalyzes the methylation of the terminal ribose molecules of the viral RNAs. The poly-A-polymerase, comprised of two subunits, adds adenylate residues (poly-A) to the 3′ end of the viral m-RNAs. Several encapsidated enzymes, including the monomeric DNA topoisomerase (333 aa), modify the topology via breaking and rejoining of DNA that allows the relaxation of the + and − strands of the supercoiled DNA. The topoisomerase of the AmEPV possesses structural features similar to the vaccinia virus enzyme. Various nucleotide triphosphate phosphohydrolases (NPH 1, 2), including a DNA-dependent ATPase (NPH1), are present in poxviruses. The NPH1 and NPH-II cleave the NTPs into NDPs and free phosphate. A virally encoded protein kinase functions to phosphorylate several virion-specific proteins. Additional enzymes affiliated with poxvirus particles include endoribonucleases, deoxyribonucleases, and alkaline proteases. The endogenous alkaline protease, associated with the entomopoxvirus viral inclusions (spheroids), is derived from host insects. This host-derived protease, activated by alkaline gut conditions, assists in the degradation of the spheroidin (115 kDa) and the subsequent release of virus particles. Tissue culture-produced spheroids lack such alkaline protease activity.

Entotrophi

An order of hexapods in the class Entognatha, but sometimes considered to be insects. This is an alternate name for the order Diplura. They commonly are called diplurans.

► Diplurans

Enumeration Sampling

Sampling based on the complete counting of all individuals in the sample unit (contrast with binomial sampling).

► Sampling Arthropods

Envelope

A covering of carton or wax around the nest of a social insect, especially a social wasp.

Envenomization

The toxic effects caused by stings, secretions, bites, stinging (urticating) hairs or other effects of poisonous arthropods. The same term is used to describe poisoning by other animals, including vertebrates.

Environmental Sex Determination

A method of sex deternmination in which the environment, such as temperature, has a significant effect on the developmental process leading to one or the other sex.

Environmental Influences on Behavioral Development in Insects

HELMUT V. B. HIRSCH[1], HELEN GHIRADELLA[2], MARTIN BARTH[2]

Information stored in the genome cannot be altered over the course of a lifetime, but only across a multitude of generations. Thus, the genome can give rise to developmental programs that will result in an organism, but it cannot optimize this organism for the conditions it may meet during its particular lifetime. It has long been assumed that if that lifetime is short, such optimization may not be necessary and that such short-lived animals as insects are developmentally inflexible, ensuring genetic survival by fecundity, rather than by investment in the perfection of individuals. As we shall see, this is not the case; like vertebrates, insects steer, rather than aim, development, even of behavior, which will be our special focus here. Developmental plasticity of behavior is especially significant to the organism, indeed to the whole community, since even subtle changes in behavior can have significant effects on an animal's success in obtaining food, escaping predation, or finding a mate. And we are now coming to realize that in insects, even as in vertebrates, behavioral development is the result of a series of "dialogs" between the nervous system and the outside world.

Background

In vertebrates, early experience is known to affect development of brain and behavior; impoverishment of stimulation generally diminishes performance of the adult, while enhanced stimulation can be beneficial. "Normal" early experience is important for normal vision, social interaction, homing, development of song… the list is very long. But what of the invertebrates, especially the small, short-lived ones? Because of the above mentioned assumption of inflexibility, they have received little study; indeed they represent a new and hitherto unexplored world, one holding immense promise for broadening our understanding of the development of behavior.

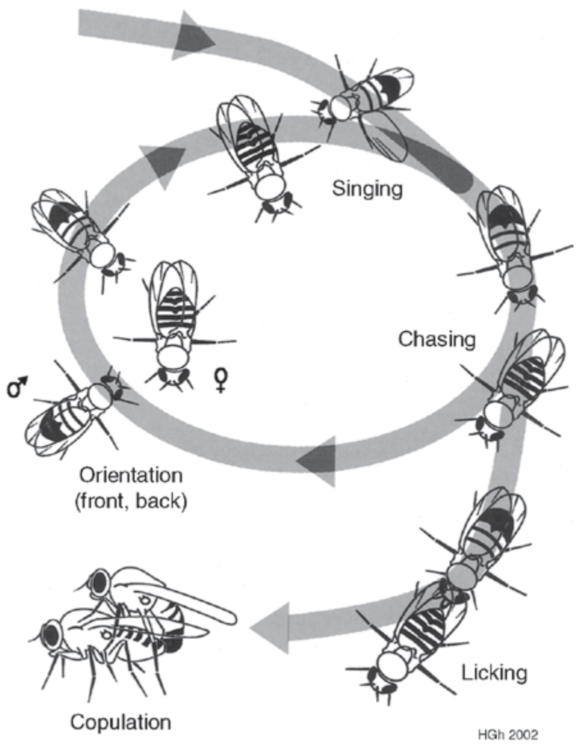
The common laboratory fruit fly, *Drosophila melanogaster*, is a wonderful starting point for such a journey of discovery and will allow us to explore the importance of environmental factors – sensory, social and chemical – in guiding development. *Drosophila* has many advantages as a model system for an analysis of developmental plasticity. First it has a rich and varied repertoire of behaviors that are both reproducible and quantifiable. Second, its short generation time (~10 days at 25°C), the ease with which it can be cultured and the large numbers of individuals that can be maintained under the same environmental conditions at different stages of the life cycle, help pinpoint the nature of the inputs needed for optimum development and the timeframes within which they are effective (the so-called sensitive or critical periods). Third, there are numerous *Drosophila* nervous system mutants, many affecting vision and learning, which are useful tools in determining the mechanisms of experience-dependent development. Fourth, the *Drosophila* nervous system consists of a relatively small number (perhaps a few hundred thousand) of neurons many of which are identifiable and can be compared across individuals raised in different environments. Finally, we "higher animals" share many genes with *Drosophila* – for example genes critical to visual development in *Drosophila* have similar function in mice, zebra fish, frogs, turtles, quail, rats, squid, and even nematodes, so that it is not unlikely that genes involved in developmental plasticity in *Drosophila* are conserved. For these reasons, we propose that *Drosophila* can make yet another contribution to biology by serving as a model of experience-dependent plasticity of brain and behavior.

In *Drosophila*, courtship seems particularly appropriate for the study of developmental plasticity. It has obvious significance in the organism's life history, it is easily studied in the laboratory and, because of its complexity, there is a good chance that even relatively subtle environmental variations may alter its expression. And, of course, what we are studying in the laboratory are manifestations of a neural plasticity that has long been selected for because it is advantageous in the flies' natural habitat.

Courtship matures gradually during the first few days of the adult stage; flies do not become fully competent to court or to be receptive to copulation until several days after they eclose from their pupal cases. This makes it possible that experience before and during the appearance of these behaviors could play a role in their development, much as it does for singing and mate choice in birds. Let us now look at the actual behaviors involved in *Drosophila* courtship.

Courtship Behavior in *Drosophila*

Courtship of *Drosophila* can easily be studied under a dissecting microscope by placing two or more flies into a small (0.2 cm^3) chamber. Shortly after being placed into the chamber, the male approaches the female, chases her, maintains his focus on her if she moves about, and orients his body so that he is facing her abdomen. He taps her abdomen with one of his foretarsi and (Fig. 40) vibrates the wing closest to her to produce a courtship song. After a few minutes, he may lick the female's genitalia, attempt to copulate, or suddenly move in a semicircle to wind up in front of her, "eye-to-eye." If his courtship stimulates her to become receptive, she slows down and eventually permits copulation by opening her vaginal plates.



Environmental Influences on Behavioral Development in Insects, Figure 40 **Diagrammatic representation of some common male courtship behaviors in *Drosophila melanogaster*. Early stages are characterized by chasing, orientation-back, and singing by the male; if the female becomes more receptive and slows down, the male will engage in orientation-front, licking, and making repeated copulation attempts until the female finally opens her vaginal plates, permitting him to mate.**

We can view these behaviors, which involve visual, auditory, chemical and tactile stimulation, as an exchange of sensory information. Males use visual, and to a lesser extent chemical, information to identify and to orient to the female; the absence of this information (as in a male with mutation-induced sensory losses) reduces the likelihood of copulation. Female receptivity is also influenced by such visual cues as the reflection from, and shape of, the male's eyes. Obviously, in a complex environment many agents may modify the development of courtship behaviors. We will look at three: effects on a newly emerged male of the presence of adult males, effects of the presence or absence of early visual stimulation on courtship effectiveness, and effects of low levels of the neurotoxin lead on courtship behavior.

Effects of Homosexual Courtship During the First Hours of Adult Life on the Male

Drosophila melanogaster males do not court only virgin females, they also court newly eclosed males (The young males do gradually lose their "sex appeal" and by the time they are sexually mature are no longer attractive to other males.) One obvious question is why this behavior exists; this "homosexual" courtship expends time and energy and renders the courting male more vulnerable to predation, so it must have some positive evolutionary significance. With such experience, immature males grow up to mate more quickly than do males without homosexual courtship experience. The courtship song, produced by vibration of the courting male' s wing, is one of the stimuli that affect the immature male, which suggests that early exposure to the visual and/or auditory stimuli associated with courtship song is important for development of effective courtship in males.

The observation that adult male flies that experience homosexual courtship during early adult life perform better when courting females has striking similarities to what others have observed studying the development of bird song. In both cases, the immature male receives the stimulation during early life (Fig. 41), before he expresses the behaviors that are influenced by the exposure. In birds, this has been explained by postulating that the young male lays down an auditory template and later compares his own output to that template, modifying the output until there is an adequate match. We suggest that male *Drosophila* may be engaged in a similar process. During the episodes of homosexual courtship, they may be storing something analogous to a neural template

Environmental Influences on Behavioral Development in Insects, Figure 41 **Latency to begin copulation with a female of males raised in the absence of older males, with older males that courted them but could not sing, with older males that courted them and could sing. Note that males copulate faster when they have been reared with older males that can sing while they court; other stimuli must also be important because being courted without singing is better than nothing (Data summarized in Hirsch and Tompkins, 1994).**

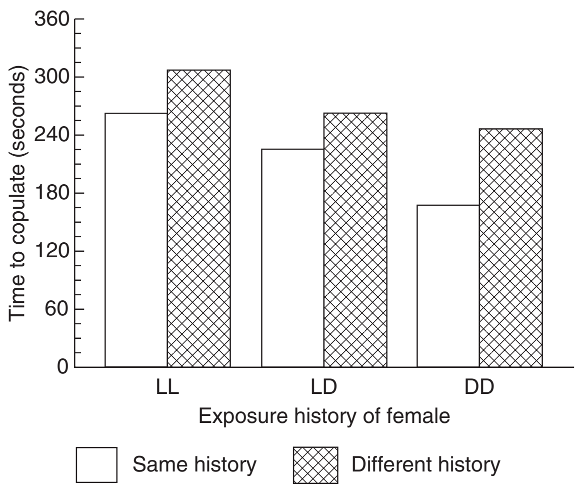
of courtship; when they mature, this template in some way facilitates their own behavior. This remains an open question, as the relevant experiments remain to be done.

Effects of Visual Experience During the First Days of Adult Life

Vision is important during courtship, and to determine whether early visual experience is important for the normal development of courtship behavior, during the first four days of adult life we kept flies either in total darkness (dark-rearing - DD), in constant illumination (light-rearing - LL), or as a control in normal cycling illumination (12 h light/12 h dark-LD). We subsequently scored (Fig. 42) them for copulation latency, i.e., the time taken from the initiation of courtship to copulation. Surprisingly, what affects this most is the similarity in the experience of both members of the pair. Pairs in which the male and the female received the same visual exposure (both LD, both LL, or both DD) mate more quickly than do those whose early experience differed, i.e., "culturally" similar flies mated more readily. Furthermore, these studies revealed the presence of a critical period during which alterations in normal exposure are particularly effective in causing behavioral changes.

Ecological Implications of Mate Choice

The influence of genotype on mate choice is well-documented, while that of early experience is less well understood, except for a few studies on effects of early social interactions on mate preferences of avian and mammalian females. From the studies discussed above, we conclude that otherwise normal *Drosophila* raised in any of our three light regimes (LL, LD, DD) prefer to mate with partners with similar experience. Since females typically copulate on their food source, and then lay eggs in it, their newly eclosed offspring will find themselves in the same environment in which their parents chose mates. Given that flies growing up in this environment are apparently well adapted to it, then perhaps preference for mates with similar backgrounds, including environmental exposure histories, will enhance the fitness of their offspring, assuming the environment has not changed drastically. Thus, what we have learned about developmental plasticity of mate choice may help us to better understand the mechanisms regulating fitness in this species.



Environmental Influences on Behavioral Development in Insects, Figure 42 **Latency to begin copulation with a male of females raised in constant light (LL), in normal cycling illumination (LD), and in total darkness (DD). Note that the less light exposure, the faster females tend to copulate, and that independent of exposure history females copulate faster with males sharing their "culture." (Redrawn from Hirsch et al., 2001.)**

Developmental Effects of Exposure to Low Levels of Lead

As a result of human activity, lead has become ubiquitous in the biosphere. At higher concentrations it can be very toxic, but even at very low concentrations chronic exposure during early life can have significant effects, including cognitive effects, in humans and in other mammals. Given that developmental plasticity is not exclusive to vertebrate animals, does developmental exposure to lead affect complex behaviors of *Drosophila*, in particular courtship?

We choose courtship because it may provide an assay of cognitive function for *Drosophila*, in effect a fly equivalent of an IQ test. Courtship requires that male and female assess one another and reach a decision about whether to mate. Since consequences of this decision can have important consequences for both participants, and especially for the female who does not mate very often in her lifetime, factors influencing the decision-making process can affect fitness of the male and the female.

The effects of lead exposure during development of *Drosophila* may be tested by exposing flies from egg stages until well into adulthood to a lead-contaminated food source. One then assays courtship by seeing how many flies will mate in a given time interval. The results are both striking and significant: the number of pairs mating after exposure to low concentrations of lead is greater than in controls, while after exposure to higher concentrations of lead it is lower. One possible explanation for the increase in mating speed after exposure to low concentrations of lead is that it reduces the female's selectivity in choosing a mate; she may mate more indiscriminately than do control females. Exposure to higher lead concentrations, on the other hand, may debilitate both sexes sufficiently that courtship is slowed down. Lead also has a non-linear (in this case biphasic) effect on fecundity of *Drosophila*, increasing it at low concentrations, and having no clear effect at higher concentrations.

The details of insect response to such toxicants as lead are as yet barely studied, but it is clear that insects such as *Drosophila* are indeed good model systems for the studies that need to be done.

Conclusions

We began by noting that developmental programs that are limited to information in the genome are limited in their ability to optimize the organism for the conditions prevailing during its particular lifetime. We argue that a first step in optimizing development is by providing it with sensitivity to environmental experience. Learning and sensory adaptation enable the process of optimization to continue throughout the organism's lifetime. In effect, these processes match the nervous system to those features of its environment which cannot be predicted far enough in advance to be incorporated into the genetic information base. Genetic information, which reflects adaptation to past conditions, is combined and integrated with epigenetic information, which is more immediately predictive of future conditions.

There are clear precedents for such interpretation of developmental processes. For example, it is known that in the cat, initial development of nerve cells responding to the orientation of a visual image is under genetic control, but completion of development requires visual experience, which fine-tunes the system to respond best to those orientations it saw during the first months of life. In effect, these cells become an internal model of the animal's early visual world. Because it was generated during a critical period after which it cannot be changed, this model has a life-long influence on the animal's behavior. In the fly, initial development of the photoreceptors and of their connections with a target structure, the lamina, is likely to be under control of intrinsic developmental programs, whereas experience modifies both the synapses from the photoreceptors onto special lamina cells, the monopolar cells, and the feedback synapses going back to the photoreceptors themselves. Thus, there is a flexible link between the sensor and the nervous system, a link that can be optimized on the basis of information about the prevailing environment. Consistent with this idea, some behavioral sensitivities are enhanced under test conditions that mimic those present during the animal's early life. Flies deprived of light exposure are more sensitive to light than controls, and the operating range of their visual systems is shifted to allow a better response at lower light levels. These effects are apparently long-term, being present three weeks later. The findings for both cat and fly support the hypothesis that during early stages of adult life the response properties of the visual system are adjusted to function optimally under the conditions prevailing in the animal's visual world; other sensory systems undoubtedly show similar tunability.

The last forty years, which have seen great changes in our understanding of how experience might affect the developing nervous system, have also witnessed the discovery of many model systems for the study of such development. These first included the retinogeniculocortical pathway in the cat, and to a lesser degree in the monkey. In the early 1980s it became clear that lower vertebrates, such as fish and frogs, also constituted good model systems for studying experience-dependent development, and now it is clear that invertebrates can also serve this role. Experience-dependent behavioral plasticity, once assumed to be a curiosity playing at most a minor role in the development of insect brain and behavior, is known to exist in many regions of the adult brain in *Drosophila* and in other invertebrates. Indeed, it seems to be the rule rather than the exception that in all animals experience is needed to complete development of adult brain structures. A corollary of this view is that the ability to undergo experience-dependent development is itself heritable, and that it should be possible to select strains of flies or other invertebrates that are more or less modifiable by early experience, thereby generating additional models for studying developmental plasticity.

One major task will now be to unravel the molecular mechanisms underlying the developmental adjustments in model systems such as *Drosophila*, and thereby to learn more about the often less accessible mechanisms underlying plastic processes in vertebrate brains. On a molecular level, there are likely to be several systems responsible for structural plasticity (for example, in *Drosophila* the cyclic AMP cascade seems to be involved in the central brain, but not in the optic lobes). There is a rich future for research in unraveling the genes involved in the plasticity of the visual system, and *Drosophila* is likely to continue to be a central figure in attempts to identify and characterize these genes. Among the many powerful techniques available with *Drosophila* is the capability of selectively expressing any cloned gene in specific regions of the fly, thus providing very fine "molecular scalpels." The usefulness of these lessons from the world of insects will underscore the basic unity of the mechanisms that appear to govern the link between brain and behavior in all organisms.

A very important lesson that we can learn as we come to understand more about brains and about what is needed to ensure their development, is that "higher" and "lower" animals have much more in common than had been thought possible 20 years ago. This commonality in our origins, and especially the realization that we are all affected by our environment during development, and that we update the information in the genome and enhance our ability to make accurate predictions about the world we live in, means that we have much to learn not only from our closest relatives, but from those who appear on the surface much more distant, and even alien. We hope it means also that our respect for these life forms – so like us in their vulnerability during development – will be enhanced, for in protecting and conserving them we are protecting and conserving ourselves.

Enzootic Disease

A disease (usually in low prevalence) which is constantly present in a population.

Enzyme

A protein catalyst that is not itself used up in a reaction. Enzymes are produced by living cells to catalyze specific biochemical reactions. Enzymes may also contain nonprotein components called coenzymes that are essential for catalytic activity.

Eomeropidae

A family of insects in the order Mecoptera.

► Scorpionflies

Eosentomidae

A family of proturans (order Protura).

► Proturans

Epermeniidae

A family of moths (order Lepidoptera). They commonly are known as fringe-tufted moths.

► Fringe-Tufted Moths
► Butterflies and Moths

Ephemerellidae

A family of mayflies (order Ephemeroptera).

► Mayflies

Ephemeridae

A family of mayflies (order Ephemeroptera).

► Mayflies

Ephemeroptera

An order of insects. They commonly are known as mayflies.

► Mayflies

Ephemerythidae

A family of mayflies (order Ephemeroptera).

► Mayflies

Ephydridae

A family of flies (order Diptera). They commonly are known as shore flies.

► Flies

Epicopeiidae

A family of moths (order Lepidoptera) also known as Oriental swallowtail moths.

► Oriental Swallowtail Moths

► Butterflies and Moths

Epicranial Suture

A Y-shaped suture on the upper surface of the head. The arms of the "Y" diverge toward the front of the head.

► Head of Hexapods

Epicranium

The upper portion of the head.

► Head of Hexapods

Epicuticle

The thin, outermost layer of cuticle. It is rich in lipid and protein but lacking in chitin. It consists of a shellac-like cement layer externally (Fig. 43, Fig 44) as well as a proteinaceous layer imbedded with lipids called the cuticulin layer.

► Cuticle

► Integument: Structure and Function

Epicuticular Filaments

Lipoprotein running from the epidermal cells through the pore canals and fusing with the inner edge of the cuticulin. The filaments (and the pore canal) can serve as a conduit for transport of materials such as wax from the epidermal cells to the procuticle and epicuticle.

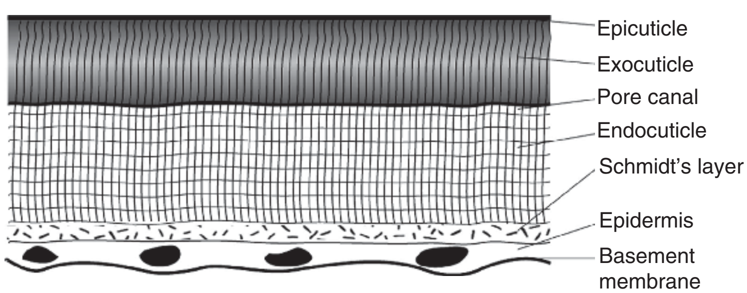
Epidemic

A period of unusually great abundance, especially of pests such as microbial disease agents.

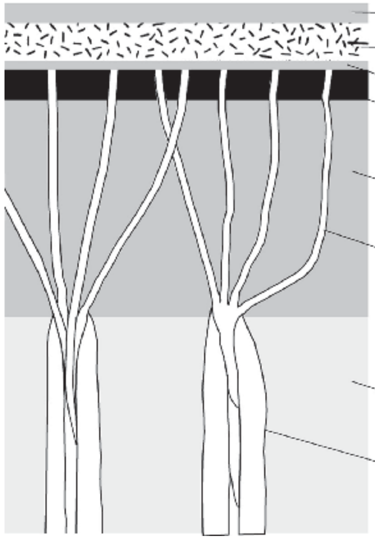
Epidemic Hemorrhagic Fever

A form of hemorrhagic fever endemic to northeastern Asia that is caused by a Hantavirus arbovirus transmitted by mites. It is characterized in its early stages by fever, sweating, thirst, abdominal pain, nausea, and vomiting, and in its later stages by hemorrhage, shock, and kidney failure. It is also called "Korean hemorrhagic fever."

► Mites



Epicuticle, Figure 43 Cross section of the insect cuticle and epidermis (adapted from Chapman, The insects: structure and function).



Epicuticle, Figure 44 Cross section of the insect epicuticle (adapted from Chapman, The insects: structure and function).

Epidemic Relapsing Fever

This disease is caused by a spirochete (*Borrelia recurrentis*) and is transmitted by human body lice. Once common in eastern Europe and Russia, it now occurs mostly in eastern Africa, China, and South America. An endemic form is caused by several forms of spirochete and is transmitted by *Ornithodorus* ticks. Symptoms include chills, fever, headache, muscle pain, nausea, vomiting, and weight loss.

► Chewing and Sucking Lice

Epidemic Typhus

A rickettsial disease (*Rickettsia prowazekii*) transmitted to humans by the human body louse. It occurs most frequently in cooler climates, where heavy clothing is commonly worn. It becomes epidemic during periods of strife, when warfare results in crowding and poor sanitation. It also can develop in prisons and on ships due to lack of sanitation and crowding, where it is known as "prison fever" and "ship fever." The disease is transmitted through the feces of the lice when humans scratch and rub the louse or louse feces into a wound. The lice are not affected by the *Rickettsia*. A variant of this is transmitted from flying squirrels to humans when squirrels take up residence in cabins or houses. Symptoms of epidemic typhus include chills, fever, headache, rash, stupor, and delirium.

► Chewing and Sucking Lice

Epidemiology

In entomology, the study of diseases affecting insects, especially the factors affecting outbreak and spread of the disease, or of diseases spread by insects to animals (humans, wildlife, livestock) or plants.

Epidermis

The layer of living cells (epidermal cells) of the integument, situated beneath the cuticle (Fig. 43), that secretes the cuticle at each molt. In addition, the epidermal cells secrete lipids (waxes), cement, and additional cuticular components.

► Cuticle
► Integument: Structure and Function

Epigaeic

Living, or at least foraging, primarily above-ground (contrast with hypogaeic).

Epigynum

In spiders, the external female genitalia.

Epimeron

The posterior portion of a thoracic pleuron. It is usually small, narrow, or triangular.

Epimorphosis

A type of development wherein the insect ecloses from the egg with a full complement of body segments (the opposite of anamorphosis).

Epipharynx

A mouthpart structure attached to the inner surface of the labrum or clypeus.

Epiphysis

A pad occurring on the inner aspect of the front tibiae in some Lepidoptera.

Epiplemidae

A family of moths (order Lepidoptera). They commonly are known as crenulate moths.

► Crenulate Moths
► Butterflies and Moths

Epipleura (pl. epipleurae)

The lateral margins of the eytra, which are bent downward.

Epiproct

The dorsal portion of the eleventh abdominal segment in insects. This is also known as the supraanal plate and the pygidium. This tergite often covers the anus.

Epipsocidae

A family of psocids (order Psocoptera).

► Bark-Lice, Book-Lice or Psocids

Epipyropidae

A family of moths (order Lepidoptera). They commonly are known as planthopper parasite moths.

► Planthopper Parasite Moths
► Butterflies and Moths

Episternum (pl. episterna)

The anterior-most sclerite of the thoracic pleuron.

► Thorax of Hexapods

Epistoma

The portion of the lower face between the eyes and the mouth.

Epizootic

An outbreak or widespread occurrence of disease in which there is an unusually large number of cases. A disease, or a phase of a disease, with high morbidity, and one that is only irregularly present in recognizable form.

Epizootic Bovine Abortion

A bacterial disease transmitted by ticks to cattle in the western USA.

► Ticks

Epizootiology

The field concerned with the study of diseases of animals and their pattern of occurrence.

Equilibrium Position (EP)

An expression used to describe the average density of pests relative to the economic injury level and economic threshold. Some insects have a low equilibrium position and rarely cause damage, whereas others have a high equilibrium position and regularly inflict injury if they are not managed. The concept of EP is most useful when considering insects that do not vary greatly in density or damage, but some insects display highly variable densities, and the equilibrium position is not very descriptive of their population tendencies.

Eradication

Elimination of an organism after it has become established.

Ergatogyne

Among social insects, a form that is intermediate between the worker and queen.

Eremiaphilidae

A family of praying mantids (Mantodea).
► Praying Mantids

Ergatoid Reproductive

Among termites, a supplementary reproductive that is larval in form, without any trace of wing buds, and with a distinctly rounded head.

Ergot of Cereals

A fungal disease of grains that can be transmitted by insects.
► Transmission of Plant Diseases by Insects

Erichson, Wilhelm Ferdinand

Wilhelm Erichson was born on November 26, 1809, in Stralsund, Germany, the son of a senator. After education at the Gymnasium ["high school"] of Stralsund, he entered the Universität zu Berlin in October 1928, obtaining by December 1832 a degree "Doktor der Medizin und Chirurgie" ["Doctor of Medicine and Surgery"]. By April 1834 he was licensed as a medical practitioner. During his university years, he was heavily involved in entomological studies, publishing (with J.F. Brant) in 1831 "Monographia generis Meloes" and then in 1832 "Genera Dyticeorum." In 1837 he obtained a degree "Doktor der Philosophie" from Universität Jena. In 1838, he was awarded the degree of "Privatdocent" [a degree permitting him to lecture at a university] from the philosophical faculty of the Universität zu Berlin, and in 1842 was appointed adjunct professor. The scholastic requirements at German and other European universities were much more rigorous at that time than in the USA. Then, leaving medicine behind, his lectures concentrated on entomology and helminthology. He has been acclaimed by Herman (2001) as a genius, the equivalent of a Mozart in music and, like Mozart, dying young, perhaps the most important entomologist of all time. Although he died before he was 40, his works were prodigious and profoundly important. He worked on Arachnida and Myriapoda as well as on the insect orders Coleoptera, Hymenoptera, Neuroptera, Hemiptera, Strepsiptera, Thysanoptera, Thysanura, and Siphonaptera. He published about 45 books and other papers. Two of them were "Die Käfer der Mark Brandenburg" (740 pages) and "Genera et species Staphylinorum" (954 pages) in which he proposed for the first time a classification that in general still stands of the huge family Staphylinidae. He died in Berlin on November 18, 1849.

Eri Silkworm, *philosamia ricini* (Lepidoptera: Saturniidae)

TIPVADEE ATTATHOM
Kasetsart University, Nakhon Pathom, Thailand

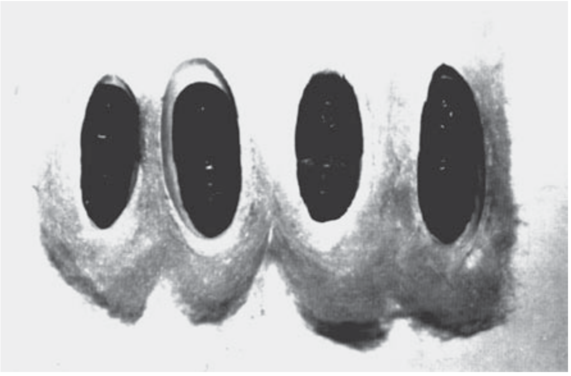
Silk is a smooth, shining, fabulous and unique natural fiber produced by several species of silkworm. Silk fiber generally is produced by the mulberry silkworm, *Bombyx mori*, which was domesticated nearly 2,000 years ago in China. Silkworm rearing and silk weaving, called sericulture, is an environmentally sustainable agro-industrial activity practiced in four major regions globally, with the highest production in Asia and the Pacific. Sericulture provides substantial contributions to a number of national economies while preserving the centuries-old history and tradition of many countries. It is beneficial to the rural population in climatically suitable agricultural sectors because it provides either a primary or secondary source of income for many workers, regardless of age and gender.

In addition to the renowned mulberry silkworm, Bombyx mori, there are at least eight species of wild silkworms that provide silk of high economic and commercial values. They are: *Antheraea pernyi*, *A. yamamai*, *A. proylei*, *A. assamensis*, *A. mylitta*, *A. proylei*, *Philosamia ricini* and *P. cynthia*. The eri silkworm, *P. ricini*, is the only completely domesticated silkworm that is not dependent on mulberry for food. This polyphagous insect feeds on several varieties of food plants in the family Euphorbiaeae, including castor (*Ricinus communis*), kesseru (*Heteropanax fragrans*), payam (*Evodia flaxinifolia*) and tapioca (*Manihot utilissima*). Castor is, by far, the best food plant to promote cocoons that are large in size and rich in silk content.

Eri silkworm has four stages: the egg, larva, pupa (encased in the cocoon), and the adult or moth. The moth lays white eggs which turn grey and then black just before hatching. Eggs hatch in seven days in hot weather, but may take as long as 24 days in cold weather. Female moths lay eggs in clusters that may contain as many as 100 or more eggs. The number of eggs per moth varies, however, the average for a well-fed, healthy moth is about 300.

Eri silkworm molts four times during its larval stage. When molting, the larvae stop eating and become motionless. This state may last for 24–48 h. Toward the end of this state, the larvae begin to cast their skins off by continued undulatory movements and wriggling. During the first to third larval stage, the head is black and shiny but eventually will turn greenish-yellow or yellow with a blackish patch on each cheek when they reach the fourth and fifth stages. On each thoracic and abdominal segment, there are four to six conspicuous tubercular spines mounted with a varying number of hairs and arranged in longitudinal rows. In the fifth stage, the larvae eat enormously and grow very quickly to reach their maximum stage of development. The well-fed (Fig. 45), full-grown

Eri Silkworm, *philosamia ricini* (Lepidoptera: Saturniidae), Figure 45 Larvae of eri silkworm, *Philosamia ricini* feed on cassava leaves.

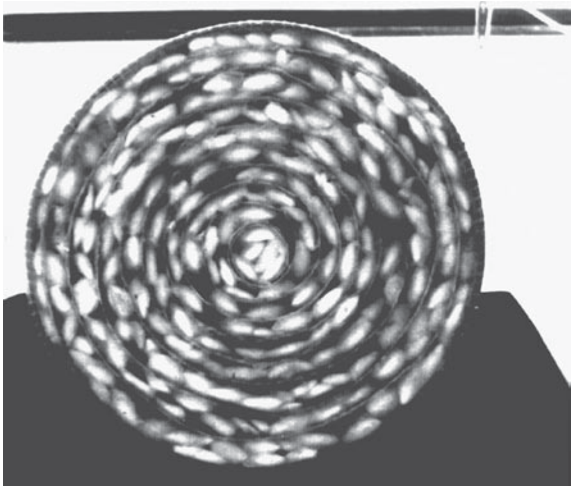


Eri Silkworm, *philosamia ricini* (Lepidoptera: Saturniidae), Figure 46 Cocoons of eri silkworm cut to show the pupae inside.

larvae are cylindrical and about 95–100 mm long. The general body color is white which turns yellow before spinning.

When the larvae get ready for spinning, they cease feeding and empty their digestive tract. The larvae then become active and roam about in search of a suitable place, and settle down to form cocoons. The cocoon is formed by exuding secretion from the silk gland through the spinneret which forms a fine filament of thread when it comes in contact with the air. The larvae finish spinning in about three days and rest inside the cocoon before turning into pupae (Fig. 46 and 47). The thread of the cocoon consists of a core of fibroin and a covering of sericin or gum. The eri cocoon is tapered at one end and is slightly flat and round at the other. It can not be reeled because the cocoon is not formed of a long continuous thread as in mulberry silk, but instead is spun by the larvae in layers. It is also an open cocoon in which the moth can push its way through one end without softening or cutting the fibers. Since eri cocoons are unreelable, they can only be spun by hand. They form a good and highly desirable raw material for millspun silk which is in high demand all over the world.

Moth emergence from the cocoon takes place after about two weeks from the cocoon formation. Male moths emerge earlier than female moths. The eri moth is a big moth with a wingspread of



Eri Silkworm, *philosamia ricini* (Lepidoptera: Saturniidae), Figure 47 Container provided to eri silkworm for cocoon formation.

100–125 mm. The wings are blackish-brown, crossed in the middle with a white band. In the middle of each wing is a crescent-shaped yellow and white spot bordered with a black line. The abdomen of the male is narrower than that of the female. After emergence, the males are more active. They flutter their wings rapidly and rest for an hour or two in a vertical position until their wings are dry. The male moths then start fluttering their wings again in search of female moths to mate with. Mating (Fig. 48) occurs a few hours after moth emergence and female moths lay eggs during the night. The oviposition

Eri Silkworm, *philosamia ricini* (Lepidoptera: Saturniidae), Figure 48 **Male and female eri silkworm shown mating. The female lays eggs on the wood stick.**

can go on for two or three nights. The moths do not fly away and do not eat.

The complete life cycle of the eri silkworm lasts about 44 days in the summer and 85 days in the winter. It is a multivoltine species which can be reared four to five generations all year round where the climatic conditions are favorable.

Eri silkworm cultivation has several profitable advantages. Since the worms feed on castor and tapioca or cassava leaves, eri silkworm cultivation can be practiced as a subsidiary cottage industry by the castor and cassava growers. With its excellent blending properties with both cotton and synthetics, the fabrics made from eri silk yarn are very soft and silky, far more durable than mulberry silk and far more resistant to perspiration and dust. Eri silk is also readily dyed with a large range of colors. All these unique characteristics make the cloths suited not only for dresses but also for shawls, cloaks, rugs, etc. In addition to finished fabrics, eri silk can also become the source of other essential products such as medicines and cosmetics.

Eri silkworms play a significant role in the research on the biological control of noxious insects. Eri egg and larva can be used to mass produce some parasitic and predatory insects. The predatory bug, *Eocanthecona furcellata*, which preys on several species of noxious lepidopteran insects, can be raised in laboratories using eri larvae as food. Furthermore, due to their high protein content, eri larva and pupa are eaten by people, especially those in the Asian countries. They also can be developed as animal feeds or food supplements for poultry, swine and fish which help to reduce production costs in these farms. The eri silkworm, therefore, can create several operations of high income potential. Many countries, therefore, are highly interested in the national industrialization of eri silkworm culture.

Ermine Moths (Lepidoptera: Yponomeutidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Ermine moths, family Yponomeutidae, total 395 species worldwide; actual fauna likely exceeds 500 species. Three subfamilies are recognized: Saridoscelinae, Yponomeutinae, and Cedestinae. The family is part of the superfamily Yponomeutoidea in the section Tineina, subsection Tineina, of the division Ditrysia. Adults small to medium size (8 to 31 mm wingspan), with head mostly smooth-scaled; haustellum naked; labial palpi upcurved; maxillary palpi 1 to 2-segmented (rarely reduced). Wings elongated, sometimes with long hindwing fringes (Fig. 49) in species with more lanceolate hindwings. Maculation is often white or gray with many small dark spots, or more monotone shades of brown or gray. Adults are mostly nocturnal. Larvae are leaf

Ermine Moths (Lepidoptera: Yponomeutidae), Figure 49 **Example of ermine moths (Yponomeutidae), *Yponomeuta cagnagella* (Hübner) from Italy.**

skeletonizers and leaf webbers, but some are leafminers or needleminers. Hosts include many different plant families. A few species are economic, particularly in the genus *Yponomeuta* (often misspelled as *Hyponomeuta* in older literature).

Erotylidae

A family of beetles (order Coleoptera). They commonly are known as pleasing fungus beetles.

► Beetles

Eruciform Larva

A larval body form with a cylindrical body, well developed head, and usually with thoracic legs and abdominal prolegs. Often they are sluggish, and found in the soil or living in burrows within fruit, seeds or wood. Caterpillars and white grubs are typical of eruciform larvae.

Esaki, Teiso

Teiso Esaki was born in Tokyo on July 15, 1899. His father was a government forestry official. Teiso grew up at first in Tokyo and then in Osaka. He published his first entomological note at the age of ten, in the journal Gifu ("Insect World"), which may be a record for young entomologists. He continued studying insects, especially Hemiptera, and publishing on them, while he was in middle school in Osaka. In 1920 he entered the Imperial University of Tokyo, and studied zoology. In 1923 he was appointed associate professor in Kyushu Imperial University, and in 1924–1927 was sent to Europe (especially Budapest and London) to study in the main museums and institutions. Then with his new, German, wife Charlotte, he returned to Japan via the USA. Eventually they had four children. He was elected to the council of the entomological society of Japan, and in 1951 was its president. In 1928, he was appointed chairman of entomology in Kyushu Imperial University, and in 1930 professor of entomology. He was appointed Japanese representative and commissioner to the International Commission of Zoological Nomenclature. He was interested in many aspects of natural history, and especially in zoogeography, zoological nomenclature, the history of biology, Hemiptera, Lepidoptera, and fossil insects, but his specialty was in aquatic Hemiptera, on which he became a world authority. He published about 130 important papers on Hemiptera. He died in Fukuoka, Japan, on December 14, 1957.

Esophagus

A portion of the foregut behind the pharynx and leading to the crop.

Essential Amino Acids

The amino acids that insects must have in their diet (i.e., they cannot synthesize these). They are the same as those required by rats: arginine, histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. However, some insects benefit from inclusion of so-called nonessential amino acids, which are actually essential for some species.

Essential Oils

These are terpenes distilled or pressed from plants. They are hydrophobic, and generally aromatic. Many repel insects, and some are insecticidal. In their unrefined state, they often are the basis for folk remedies for repelling insects. Examples include peppermint oil, white cedar oil, red thyme oil, bourbon geranium oil, and linalool.

Estimation

A sampling plan that numerically estimates population density or intensity. Commonly used for detailed population dynamic and experimental studies (contrast with classification) The term can also denote the process of calculating various statistical parameters such as variance.

► Sampling Arthropods

Estuarine Community

A group of organisms inhabiting an estuary (edge/inlet of the sea or juncture of a river and an ocean), as opposed to the open sea (called pelagic).

Ethiopian Realm

The zoogeographic region of Africa, though this does not include northernmost Africa, which is more similar to Europe (and considered to be part of the Palearctic realm). The Ethiopian realm is characterized by having antelopes, giraffes, elephants, rhinoceros, gorillas, dogs, and cats.

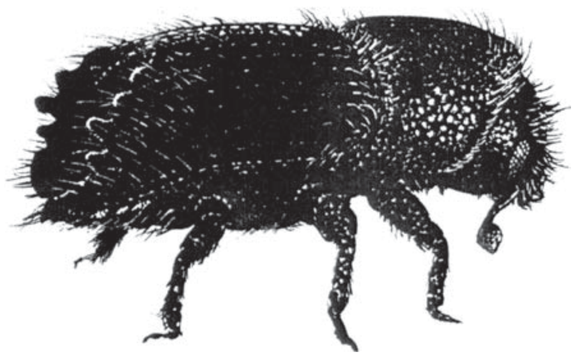
Eurasian Spruce Bark Beetle, *Ips typographus* Linnaeus (Coleoptera: Curculionidae, Scolytinae)

ERIK CHRISTIANSEN
Norwegian Forest Research Institute, Ås, Norway

Among thousands of bark beetle species worldwide, only a handful is able to attack and kill trees on a large scale. One of these is the 8-toothed spruce bark beetle, *Ips typographus* L., indigenous to the Palaearctic forests and recently introduced into North America (Fig. 50). In Europe, the main host is the Norway spruce, *Picea abies* (Linnaeus) Karsten; in Eastern Asia, including Japan, the main hosts are spruces of the *P. jezoensis* group. In unmanaged forests, these beetles play an important ecological role by killing old trees and stands, thus promoting biomass recycling and ecosystem rejuvenation. Foresters who are faced with extensive tree mortality do not, however, welcome this activity: managed forests of Europe have lost hundreds of millions of trees in recurring outbreaks.

Hibernation

In the colder areas, the beetles emerging from killed, standing trees most often hibernate in the



Eurasian Spruce Bark Beetle, *Ips typographus* Linneaus (Coleoptera: Curculionidae, Scolytinae), Figure 50 ***Ips typographus*** **adults are 5 to 6 mm long, hairy, and dark brown to black. The tip of each elytron has four teeth.**

litter of the forest floor where a good snow cover offers protection. Beetles hatching from grounded stems or logs more often remain under the bark during the winter. In warmer parts of its range, the spruce beetle is more prone to stay in standing trees. The adult beetles in Finland tolerate temperatures down to −30°C, while the larvae will die at temperatures around −15°C. The mortality rate during hibernation is generally not well known.

Voltinism

The beetles leave their winter quarters in early spring, but flight only occurs when maximum air temperatures exceed 20°C. In Central Europe where flight may occur as early as mid-April, a new generation of beetles may hatch by midsummer to start a second annual generation. A third generation may be initiated in unusually hot summers. In colder areas such as Fennoscandia, spring flight occurs in May and June and only one generation is produced per year. Here, an occasional second generation that remains in the larval stage at the onset of winter will die in the low temperatures.

Breeding

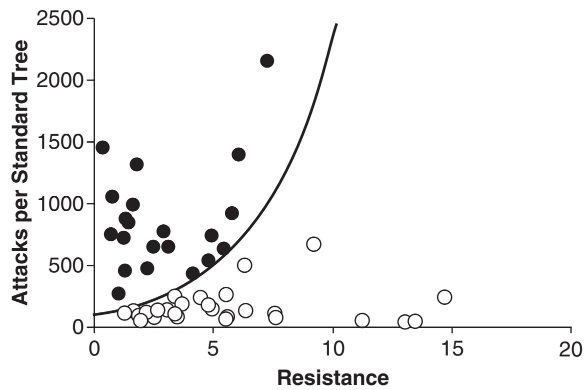
During the flight period, the beetles search for a breeding site. Flight distances are highly variable depending on energy reserves and the availability of fresh breeding substrate; i.e., timber with bark, logging debris, windfalls and live trees. Healthy trees have powerful defense mechanisms, but can be overcome when beetle populations reach epidemic levels.

In this polygamous species, gallery construction starts with the male excavating a nuptial chamber in the phloem, and is joined by one to four females. After mating, each female excavates a gallery and deposits her eggs singly in little niches as she moves along. Maternal galleries, running in the axial direction of the stem, are about 6–15 cm long, depending on attack density. The males remove frass from the galleries and also guard the entrance holes. Space permitting, a female may lay her full complement of about 100 eggs in one gallery. The 5–10 cm long larval mines start at right angles from the maternal gallery. The phloem, in which the larvae feed, is high in stored energy, and larval densities may exceed 500 galleries per square meter of bark surface. *I. typographus* often utilizes most of the stem, but shuns the lower 1–1.5 m as well as the top where the bark becomes too thin for gallery construction. In the upper stem, the galleries overlap with those of other bark beetles, particularly the smaller *Pityogenes chalcographus* (L.), which most often utilizes the thin-barked top section.

During an ongoing attack, parent beetles may be induced to re-emerge after a couple of weeks, particularly in warm weather and when crowding occurs. Males dominate among the re-emerging beetles. They may re-attack the tree from which they emerged, or fly to adjacent ones. Females are more prone to stay in their original host tree, but may also leave to construct new galleries, giving rise to “sister broods.” Occasionally, a second re-emergence may take place, resulting in a third sister brood. As a consequence, cohorts in different stages of development may occur simultaneously, even in areas with only one annual generation.

Pheromones Govern Beetle Attacks

During their initial search for a breeding site, volatile substances emanating from host material guide the beetles. However, upon successfully entering a suitable substrate, a "pioneer" male will emit a chemical bouquet of three volatiles, which act as population aggregation pheromones, summoning both sexes for a joint attack. At a later stage of the attack, two other substances with a repellent effect may be produced. This apparently contributes to the regulation of attack density by inducing latecomers to seek out other sites. The pheromones of the spruce bark beetle were isolated and identified in the 1970s, and have subsequently been used for bait in beetle traps. To some extent, they also attract other scolytids, and also act as kairomones for predators such as clerids.



Eurasian Spruce Bark Beetle, *Ips typographus* Linneaus (Coleoptera: Curculionidae, Scolytinae), Figure 51 **Threshold of successful attack on Norway spruce by *Ips typographus*. Black dots represent killed trees, white dots are surviving trees. A standard tree is 20 cm in diameter at breast height. Resistance is defined by growth efficiency, as measured at breast height, i.e., previous year's increment of stem cross-sectional area as a percentage of sapwood cross-sectional area. Redrawn by Alan A. Berryman after Mulock and Christiansen, 1986.**

The Epidemic Threshold

At low population levels, the beetles are unable to kill trees with intact defenses, and their breeding is therefore restricted to undefended substrates such as logging debris, windfalls and timber. High standards of forest hygiene may help to maintain this non-epidemic state. However, environmental calamities such as large-scale wind-felling and prolonged drought may upset even the best regime of hygiene (Fig. 51), boosting the beetle population to exceed the "Threshold of Successful Attack." Above this level, healthy trees can be overwhelmed in a mass-attack. The threshold is lowered when tree defenses are weakened by prolonged periods of drought, or when tree roots are damaged by strong winds.

When *Ips typographus* attacks a living tree, only two outcomes are possible: the tree is killed and the beetles produce a new generation, or the tree survives and no offspring are generated. In other words: if the number of assailants exceeds the "Threshold of Successful Attack," the beetles win, if not, they are driven away or die.

Fungal Associates

During attack and gallery construction, *Ips typographus* spreads spores of a variety of micro-organisms, among which, species of the fungal family Ophiostomataceae are particularly important. Because concentrations of hyphae often give a bluish stain to the wood, the fungi are referred to as "blue-stain fungi." When a new generation of beetles emerges, the sticky spores adhere to the body surface. Spores are also ingested by callow adults and carried in their guts. Some blue-stain fungi are capable of growing in fresh bark and wood and at least one species, *Ceratocystis polonica* (Siem.) C. Moreau, may kill healthy trees when artificially inoculated into the bark. Blue-stain fungi do not attack cell walls, but rather utilize the contents of bark and wood parenchyma cells, which are storage organs for starch, sugars and lipids and hence, the primary target for both beetles and fungi.

Host Tree Defense

Over the eons, conifers have developed elaborate defense mechanisms to cope with wounding and infection. Thick cork bark, often with abundant stone cells, is an obstacle to invasion. Also inside the living phloem, chemical defenses of both preformed and inducible nature await intruding organisms. An interconnected system of ducts stores constitutive resin, which may repel or immobilize attacking insects. Moreover, the phloem parenchyma cells, a primary energy source for both beetles an fungi, are active in synthesis, storage and modification of phenolics in response to wounding and infection. This renders the phloem inhospitable to intruders. Parenchyma cells may form new periderms including cork layers, thus compartmentalizing the infected area where they release fungistatic substances. Superficial wounds and infections, including aborted beetle attacks, are enveloped and rendered harmless by these reactions. Moreover, the underlying cambium produces numerous traumatic resin ducts in the xylem. Above the "Threshold of Successful Attack," the host defenses collapse. This critical level is defined by the host tree's genetic constitution and by the environment surrounding it. Sub-lethal beetle attacks may rise the threshold level thereby inducing local acquired resistance in attacked stems.

Control of Damage

By maintaining a high standard of forest hygiene, foresters attempt to keep beetle populations in a permanent non-epidemic state. Forest hygiene is generally dependent on the removal of potential breeding material. Ideally, no such material should be found in the forest when the beetles fly, and a minimum requirement is that any breeding substrate should be removed from the forest before the next generation emerges. However, even the most painstaking efforts may be in vain when a gale strikes, most often in winter, leaving large numbers of fallen trees. In rugged terrain with no roads, even dedicated managers may not be able to salvage all fallen trees before the onset of the beetles' flight season. Under such circumstances, downed breeding material may boost propagation, pushing the population across the "Threshold of Successful Attack." Trap trees and beetle traps may be useful for keeping non-epidemic populations down and for mopping up restricted, local populations of beetles, but in case of a full-fledged epidemic, these measures must be combined with large-scale salvage/sanitation cutting.

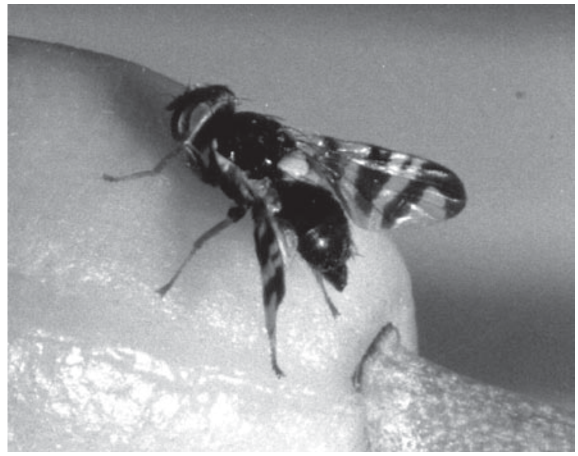
European Cherry Fruit Fly, *Rhagoletis cerasi* (L.) (Diptera: Tephritidae)

BYRON KATSOYANNOS
Aristotle University of Thessaloniki, Thessaloniki, Greece

The European cherry fruit fly is a univoltine, oligophagous, carpophagous species. Its larvae develop in the pulp of ripening or ripe wild and cultivated sweet (*Prunus avium* L.) and sour cherries (*P. cerasus* L.) (Rosaceae) as well as into honeysuckle berries (*Lonicera* spp. Caprifoliaceae), especially *L. xylosteum* L. and *L. tartarica*. L. This insect is native to the temperate West Palearctic Regions, including all European countries where its hosts occur (from southern parts, such as Cyprus, to as far North as Norway and Sweden) as well as in some Asian countries (such as Turkey and Iran). Races of the fly specializing in *Prunus* or *Lonicera* spp. may occur, and the existence of geographic races exhibiting unidirectional cytoplasmatic incompatibility has been demonstrated.

The adult is about 3–5 mm in body (Fig. 52) length, glossy black in color with characteristic patterned wings and a peculiar yellow scutellum (metathorax). The elongated larva (three instars) is



European Cherry Fruit Fly, *Rhagoletis cerasi* (L.) (Diptera: Tephritidae), Figure 52 ***Rhagoletis cerasi*** **female.**

typical of cyclorrhaphous Diptera. The last instar is about 5–6 mm long. The pupae are coarctate.

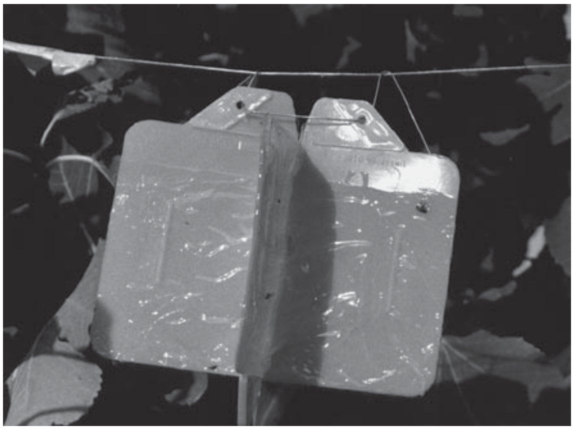
The fly overwinters in the pupal stage in the soil beneath its host plants. Adults emerge in spring and their appearance coincides with the presence of fruits suitable for oviposition. A few days after emergence, the males release a volatile sex pheromone to attract virgin females for mating. Adults feed upon plant exudates and honeydews from other insects. Mating occurs when females are about 5–10 days old. Visual stimuli are of predominant importance for host location. The shape, size and color of host fruits are important cues for their location by gravid females. Oviposition takes place into ripening host fruit. Usually only one egg is deposited into each fruit. After oviposition, the female deposits onto the fruit surface a non-volatile, long persisting, host marking pheromone, which discourages further egg laying into already oviposited fruits. Due to this pheromone, which also plays a role in the mating behavior by functioning as a male arrestant, a uniform distribution of eggs among available fruits in achieved and hence an optimal use of the resources available for larval development. The possibility of using natural or synthetic host marking pheromone for control purposes has been assessed with promising results.

Adults live about two months under optimal conditions (25°C) and each female lays about

200–250 eggs in her lifespan. Under field conditions, first instar larvae hatch in about 5–10 days after oviposition and larval development lasts two to three weeks. Developed larvae leave the fruit and drop to the soil where they pupate at a shallow depth. They undergo diapause and most adults emerge in the next spring. However, a small proportion may emerge after two or even three years, thus assuring persistence of the population during years of fruit scarcity or absence.

The European cherry fruit fly is the most important pest of cherries in Europe, causing fruit damage that may reach 100% of fruit production. Therefore, control measures are frequently required. Early ripening cherry varieties usually escape infestation. In late-ripening varieties, however, control measures are required frequently. This is usually made using insecticides either in the form of proteinaceous bait sprays or as a cover spray applied three weeks before harvest.

Based on the strong attraction of the fly to yellow panels reported, an effective, sticky-coated, 3-dimensional visual trap (the Rebell trap, Fig. 53) has been developed in Switzerland by E.F. Boller and his collaborators. The effectiveness of this trap can be enhanced by adding food attractants such as a dispenser containing ammonium acetate. The Rebell trap is widely used in Europe for adult population monitoring and mass trapping (in non commercial orchards). Intervention thresholds for late varieties are very low (one to two flies per trap or mere presence of flies).



European Cherry Fruit Fly, *Rhagoletis cerasi* (L.) (Diptera: Tephritidae), Figure 53 **Rebell visual trap.**

European Earwig, *Forficula auricularia* Linnaeus (Dermaptera: Forficulidae)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

European earwig is native to Europe, western Asia, and northern Africa, but also has been introduced to Australia, New Zealand, and North America. Once introduced, it can spread very rapidly. For example, European earwig was first observed in North America at Seattle, Washington, in 1907. It spread quickly across the United States, being discovered in Rhode Island in 1911, New York in 1912, and most other provinces of Canada and northern states in the USA in the 1930s and 1940s. Presently it occurs south to North Carolina, Arizona and southern California, but due to its preference for temperate climates it is unlikely to become abundant in the southeastern states. Also, it is not very tolerant of arid environments, but survives where irrigation is practiced.

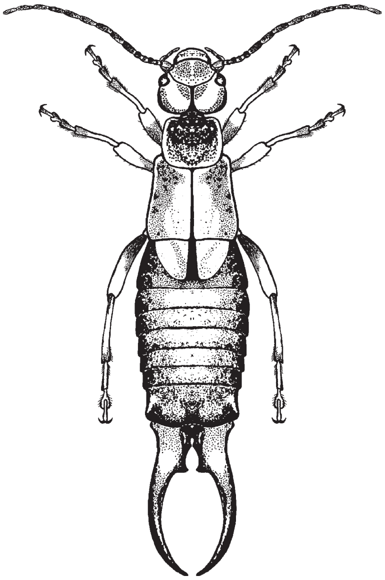
Life History

One generation is completed annually, and overwintering occurs in the adult stage. In British Columbia, Canada, eggs are deposited in late winter, hatch in May, and nymphs attain the adult stage in August. The overwintering females may also produce an additional brood; these eggs hatch in June and also mature by the end of August. In Washington, USA, these events occur about one month earlier. In colder climates such as Quebec, Canada, only a single brood of eggs is produced.

The egg is pearly white, and oval to elliptical. The egg measures 1.13 mm long and 0.85 mm wide when first deposited, but absorbs water, swells, and nearly doubles in volume before hatching. Eggs are deposited in a cell in the soil, in a single cluster, usually within 5 cm of the surface. Mean number of eggs per cluster is reported to range from 30 to 60 eggs in the first cluster. The second cluster, if produced, contains only half as many eggs. Duration of the egg stage under winter field conditions in British Columbia averages 72.8 days (range 56–85 days). The second or spring brood of eggs requires only 20 days to hatch. Eggs are attended by the female, which frequently moves the eggs around the cell, and apparently keeps mold from developing on the eggs. Females guard their eggs from other earwigs, and fight with any intruders.

The nymphal stages, which are four in number, have the same general form as adults except that the wings increase in size with maturity. The body color darkens, gradually changing from grayish brown to dark brown, as the nymph matures. The legs are pale throughout. The wing pads are first evident in the fourth instar. Mean head capsule width is 0.91, 1.14, 1.5, and 1.9 mm in instars 1–4, respectively. Mean body length is 4.2, 6.0, 9.0, and 9–11 mm, respectively. The number of antennal segments is 8, 10, 11, and 12 in instars one to four. Mean duration (range) of instars under laboratory temperatures of 15–21°C is 12.0 (11–15), 10.2 (8–14), 11.2 (9–15), and 16.2 (14–19) days for instars one to four. However, development time is considerably longer under field conditions, requiring 18–24, 14–21, 15–20, and about 21 days for the corresponding instars. Young nymphs are guarded by the mother earwig, which remains in or near the cell where the eggs are deposited until the nymph's second instar is attained.

The adult normally measures 13–14 mm in length, exclusive of the pincher-like cerci (forceps), though some individuals (Fig. 54) are markedly smaller. The head measures about 2.2 mm in width. Adults, including the legs, are dark brown or reddish brown in color, though paler ventrally. The antennae have 14 segments. The pronounced cerci are the most distinctive feature of earwigs; in the male the cerci are strongly curved whereas in the female they curve only slightly. Despite the appearance of being wingless, adults bear long hind wings folded beneath the abbreviated forewings. When ready to fly, adults usually climb and take off from an elevated object. The hind wings are opened



European Earwig, *Forficula auricularia* Linnaeus (Dermaptera: Forficulidae), Figure 54 **Adult male of European earwig, *Forficula auricularia* Linnaeus.**

and closed quickly, so it is difficult to observe the wings. Adults bear a set of cerci at the tip of the abdomen. Adults can use the cerci in defense, twisting the abdomen forward over the head or sideways to engage an enemy, often another earwig.

Earwigs are nocturnal, spending the day hidden under leaf debris, in cracks and crevices, and in other dark locations. Their nighttime activity is influenced by weather. Stable temperature encourages activity, and activity was favored by higher minimum temperatures but discouraged by higher maximum temperatures. High relative humidity seemed to suppress movement whereas higher wind velocities and greater cloud cover encouraged earwig activity. They produce an aggregation pheromone in their feces that is attractive to both sexes and to nymphs, and release quinones as defensive chemicals from abdominal glands.

Social behavior is weakly developed in the European earwig. Males and females mate in late summer or autumn, and then construct a subterranean tunnel (nest) in which they overwinter. The female drives the male from the nest at the time of oviposition. The eggs are manipulated frequently, apparently cleaning them to prevent growth of fungi. She will relocate the eggs in an attempt to provide optimal temperature and humidity for the eggs. Although the female normally keeps the eggs in a pile, as the time for hatching approaches she spreads the eggs in a single layer. After hatching, females continue to guard the nymphs and provide them with food. Food is provided by females carrying objects into the nest, and by regurgitation. Thus, there is parental care, but no cooperative brood care.

Several natural enemies are known, including some that were imported from Europe in an attempt to limit the destructive habits of this earwig in North America. Some authors have suggested that the most important natural enemy is the European parasitoid *Bigonicheta spinipennis* (Meigen) (Diptera: Tachinidae), which has been reported to parasitize 10–50% of the earwigs in British Columbia; others, however, report low incidence of parasitism. Another fly, *Ocytata pallipes* (Fallen) (Diptera: Tachinidae) also was successfully established, but causes little mortality. Under the cool, wet conditions of Oregon, Washington, and British Columbia, the fungi *Erynia forficulae* and *Metarhizium anisopliae* also infect earwigs. The nematode *Mermis nigrescens* appears to be an important mortality factor in Ontario, where 10–63% of earwigs were infected during a 2-year period; however, this nematode has not been reported from earwigs elsewhere. Avian predation can be significant.

Damage

This insect is omnivorous, feeding on a wide variety of plant and animal matter. Although its predatory habits do offset its phytophagous behavior to some degree, on occasion European earwig can inflict significant injury to vegetables, fruit, and flowers. Bean, beet, cabbage, celery, chard, cauliflower, cucumber, lettuce, pea, potato, rhubarb, and tomato are among the vegetable crops sometimes injured. Seedlings and plants providing the earwigs with good shelter, such as the heads of cauliflower, the stem bases of chard, and the ears of corn, are particularly likely to be eaten, and also to be contaminated with fecal material. Among the flowers most often injured are dahlia, carnation, pinks, sweet william, and zinnia. Ripe fruit such as apple, apricot, peach, plum, pear, and strawberry are sometimes reported to be damaged.

European earwig is reported to consume aphids, caterpillar pupae, scale insects, spiders, and springtails as well as vegetable matter. Aphid consumption is especially frequent and well documented. In addition to the higher plants mentioned above, earwigs consume algae and fungi, and often consume vegetable and animal matter in equal proportions.

The economic status of earwigs is subject to dispute. Undoubtedly earwigs sometimes damage vegetable and flower crops, both by leaf consumption and fruit injury. Foliage injury is usually in the form of numerous small holes. Tender foliage may be completely devoured except for major veins. However, the physical presence of earwigs as crop contaminants is perhaps even more important, because most people find their presence and odor to be repulsive. The annoyance associated with their presence is exacerbated by the tendency of earwigs to aggregate, often in association with human habitations; most people simply find them to be annoying. Their propensity to consume other insects, particularly aphids, is an important element in offsetting their reputation as a crop pest. However, augmenting the earwig population by field release, and providing them with additional shelter to enhance survival, have had mixed success in suppressing aphid populations.

Management

Population monitoring can be accomplished with baits and traps. Small piles of baits distributed in dense vegetation often attract large numbers of earwigs, which can be checked during the evening. Wheat bran or oatmeal can serve as bait. Traps take advantage of the natural tendency of earwigs to hide in crevices and dark spots, and can be used to detect presence of earwigs, and to estimate abundance.

Residual foliar insecticides and baits containing toxicants can be used to suppress earwigs. Of numerous baits evaluated, wheat bran flakes plus toxicant and a small amount of fish oil is reported to be optimal. However, others have suggested that fish oil is unnecessary but suggested addition of glycerin and molasses. Commercial products are rarely formulated specifically for earwigs because they rarely are a severe problem. Rather, products sold for grasshoppers, cutworms, slugs, and sowbugs are applied for earwig control. Bait is most effective if applied in the evening.

On residential property or in small gardens, persistent trapping can be used to reduce earwig abundance, though this approach is not likely to be effective if the initial earwig density is high. Boards placed on the soil will be attractive to earwigs seeking shelter. Even more earwigs will accumulate if there are narrow grooves or channels in the board. Moistened, rolled-up newspaper placed in the garden in the evening and disposed of in the morning makes a convenient earwig trap for home gardens. A particularly effective technique is to fill a flower pot with wood shavings and invert the pot over a short stake that has been driven into the soil. Traps can also be placed in trees because earwigs favor this habitat.

European Corn Borer, *Ostrinia nubilalis* (Hübner) (Lepidoptera: Crambidae)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

European corn borer is native to Europe, where it is widespread. It also occurs in northern Africa. In neither area is it a serious pest. However, it gained access to North America near Boston, Massachusetts, in 1917 where it quickly became troublesome. European corn borer quickly spread to the Great Lakes region. By 1948 it was established throughout the midwestern corn-growing region and eastern Canada. It now has spread as far west as the Rocky Mountains in both Canada and the United States, and south to the Gulf Coast states. The North American European corn borer population is thought to have resulted from multiple introductions from more than one area of Europe. Thus, there are at least two, and possibly more, strains present. The presence of an eastern or New York strain, and a mid western or Iowa strain, is evident because different pheromone blends are required to capture moths from each population. Both strains sometimes occur in the same area.

Host Plants

European corn borer has a very wide host range, attacking practically all herbaceous plants with a stem large enough for the larvae to enter. However, the eastern strain accounts for most of the wide host range, with the western strain feeding primarily on corn. Crops other than corn tend to be infested if they are abundant before corn is available, or late in the season when senescent corn becomes unattractive for oviposition; snap and lima beans, pepper, and potato are especially damaged. In North Carolina, for example, potato is more attractive than corn at peak emergence of the first moth flight, and more heavily damaged. Other crops sometimes attacked include buckwheat, grain corn, hop, oat, millet, and soybean, and such flowers as aster, cosmos, dahlia, gladiolus, hollyhock, and zinnia. Corn is the most preferred host, but many thick-stemmed weeds and grasses also will support European corn borer, especially if they are growing amongst, or adjacent to, corn. Some of the common weeds infested include barnyardgrass, *Echinochoa crusgalli*; beggarticks, *Bidens* spp.; cocklebur, *Xanthium* spp.; dock, *Rumex* spp.; jimsonweed, *Datura* spp.; panic grass, *Panicum* spp.; pigweed, *Amaranthus* spp.; smartweed, *Polygonum* spp.; and others.

Natural Enemies

Native predators and parasites exert some effect on European corn borer populations, but imported parasitoids seem to be more important. Native parasitoids include *Bracon caulicola* (Gahan), *B. gelechiae* Ashmead, *B. mellitor* Say, *Chelonus annulipes* Wesmael, *Macrocentrus delicatus* Cresson, and *Meteorus campestris* Viereck (all Hymenoptera: Braconidae); *Gambrus ultimus* (Cresson), *G. bituminosus* (Cushman), *Itoplectis conquisitor* (Say), *Campoletis flavicincta* (Ashmead), *Nepiera oblonga* (Viereck), *Rubicundiella perturbatrix* Heindrich, *Vulgichneumon brevicinctor* (Say) (all Hymenoptera: Ichneumonidae); *Dibrachys carus* (Walker) and *Eupteromalus tachinae* Gahan (both Hymenoptera: Pteromalidae); *Syntomosphyrum clisiocampe* (Ashmead) (Hymenoptera: Eulophidae); *Scambus pterophori* (Ashmead) (Hymenoptera: Hybrizontidae); *Trichogramma nubilale* Ertle and Davis and *T. minutum* Riley (both Hymenoptera: Trichogrammatidae); and *Archytas marmoratus* (Townsend) and *Lixophaga* sp. (both Diptera: Tachinidae). Although many species of native parasitoids are known, native parasitoids rarely cause high levels of corn borer mortality.

Exotic parasitoids numbering about 24 species have been imported and released to augment native parasitoids. About six species have successfully established. Among the potentially important species is *Lydella thompsoni* Herting (Diptera: Tachinidae), which may kill up to 30% of second generation borers in some areas, but has disappeared or gone into periods of low abundance in other areas. Other exotic parasitoids that sometimes account for more than trivial levels of parasitism are *Eriborus terebrans* Gravenhorst (Hymenoptera: Ichneumonidae), *Simpiesis viridula* (Hymenoptera: Eulophidae), and *Macrocentris grandii* Goidanich (Hymenoptera: Braconidae).

Avian predators such as downy woodpecker, *Dendrocopos pubescent* (Linnaeus); hairy woodpecker, *D. villosus* (Linnaeus); and yellow shafted flicker, *Colaptes auratus* (Linnaeus) have been known to eliminate 20–30% of overwintering larvae.

Several microbial disease agents are known from corn borer populations. The common fungi *Beauveria bassiana* and *Metarhizium anisopliae* are sometimes observed, especially in overwintering larvae. The most important pathogen seems to be the microsporidian *Nosema pyrausta*, which often attains 30% infection of larvae and sometimes 80–95% infection. It creates chronic, debilitating infections that reduce longevity and fecundity of adults, and reduces survival of larvae that are under environmental. Unfortunately, *N. pyrausta* also infects the parasitoid *M. grandii*.

Life table studies conducted on corn borer populations in Quebec with a single annual generation perhaps provide insight into the relative importance of mortality factors. These workers demonstrated that egg mortality (about 15%) was low, stable and due mostly to predators and parasites. Similarly, mortality of young larvae, due principally to dispersal, dislodgement, and plant resistance to feeding was fairly low (about 15%) but more variable. Mortality of large larvae during the autumn (about 22%) and following spring (about 42%) was due to a number of factors including frost, disease and parasitoids, but parasitism levels were low. Pupal mortality (about 10%) was low and stable among generations. The factor that best accounted for population trends was survival of adults. Dispersal of moths and disruption of moth emergence by heavy rainfall are thought to account for high and variable mortality (68–98%, with a mean of 95%), which largely determines population size of the subsequent generation. Overall generation mortality levels were high, averaging 98.7%.

Life Cycle and Description

The number of generations varies from 1 to 4, with only one generation occurring in northern New England and Minnesota and in northern areas of Canada, three to four generations in Virginia and other southern locations, and usually two generations in the northern United States and southern Canada. In many areas generation number varies depending on weather, and there is considerable adaptation for local climate conditions even within strains. For example, although the developmental rates of single-generation strains are lower than multiple-generation strains, at northern locations such as Prince Edward Island the single-generation strain develops quickly. European corn borer overwinters in the larval stage, with pupation and emergence of adults in early spring. Diapause apparently is induced by exposure of last instar larvae to long days, but there also is a genetic component. Moth flights and oviposition usually occur during June to July, and August to September, in areas with one to two generations annually. In southern locations with three generations, moth flights and oviposition typically occur in May, late June, and August. In locations with four generations, adults are active in April, June, July, and August-September.

Egg

Eggs are deposited in irregular clusters of about 15–20. The eggs are oval, flattened, and creamy white in color, usually with an iridescent appearance. The eggs darken to beige or orangeish tan. Eggs normally are deposited on the underside of leaves, and overlap like shingles on a roof or fish scales. Eggs measure about 1.0 mm in length and 0.75 m in width. The developmental threshold for eggs is about 15°C. Eggs hatch in four to nine days.

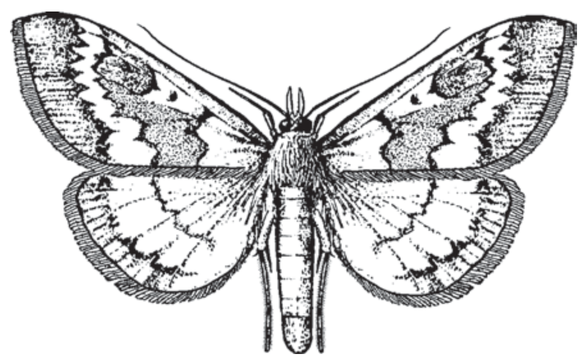
Larva

Larvae are light brown or pinkish gray in color dorsally, with a brown to black head capsule and a yellowish brown thoracic plate. The body is marked with round dark spots on each body segment. The developmental threshold for larvae is about 11°C. Larvae normally display six instars, but four to seven instars have been observed. Head capsule widths are about 0.30, 0.46, 0.68, 1.03, 1.66, and 2.19 mm in instars one to six, respectively. For populations with only five instars, mean head capsule widths are 0.29, 0.44, 0.80, 1.27, and 2.00 mm, respectively. Young larvae tend to feed initially within the whorl, especially on the tassel. When the tassel emerges from the whorl, larvae disperse downward where they burrow into the stalk and the ear. Mortality tends to be high during the first few days of life, but once larvae establish a feeding site within the plant survival rates improve. Larvae in the final instar overwinter within a tunnel in the stalk of corn, or in the stem of another suitable host. Duration of the instars varies with temperature. Under field conditions in New York, development time was estimated at 9.0, 7.8, 6.0, 8.8, 8.5, and 12.3 days for instars one to six, respectively, for a mean total development period of about 50 days. In contrast, during the next year development time at the same site was 4.4, 4.3, 4.6, 5.8, 8.5 and 9.0 days for the six instars, for a mean total larval development period of about 35 days.

European Corn Borer, *Ostrinia nubilalis* (Hübner) (Lepidoptera: Crambidae), Figure 55 **Adult male of European corn borer, *Ostrinia nubilalis*.**

Pupa

Pupae usually occur in April or May, and then later in the year if more than one generation occurs. The pupa is yellowish brown in color. The pupa measures 13–14 mm in length and 2–2.5 mm in width in males and 16–17 mm in length and 3.5–4 mm in width in females. The tip of the abdomen bears five to eight recurved spines that are used to anchor the pupa to its cocoon. The pupa is ordinarily, but not always, enveloped in a thin cocoon formed within the larval tunnel. Duration of the pupal stage under field conditions is usually about 12 days. The developmental threshold for pupae is about 13°C.



European Corn Borer, *Ostrinia nubilalis* (Hübner) (Lepidoptera: Crambidae), Figure 56 **Adult female of European corn borer, *Ostrinia nubilalis*.**

Adult

The moths are fairly small, with males measuring 20–26 mm in wingspan, and females 25–34 mm. Female moths (Fig. 56) are pale yellow to light brown in color, with both the forewing and hind wing crossed by dark zigzag lines and bearing pale, often yellowish, patches. The male (Fig. 55) is darker in color, usually pale brown or grayish brown, but also with dark zigzag lines and yellowish patches. Secondary host plants and adjacent grassy areas play a significant role in the mating behavior of adults, as adults rest and mating takes place in such areas of dense vegetation, called "action sites." Retention of droplets from rainfall and dew in this dense vegetation stimulates the sexual activity of females. Moths are most active during the first 3–5 h of darkness. The sex pheromone has been identified as 11-tetradecenyl acetate, but eastern and western strains differ in production of Z and E isomers. The western strain produces a blend that approximates 97:3 Z:E, whereas the eastern strain uses a blend of 3:97 Z:E. The preoviposition period averages about 3.5 days. Duration of oviposition is about 14 days, with oviposition averaging 20–50 eggs per day. The female often deposits 400–600 eggs during her life span, though there are also estimates of mean fecundity of about 150 eggs in some locations. Total adult longevity is normally 18–24 days.

Damage

This is a very serious pest of both sweet corn and grain corn, and before the availability of modern insecticides this insect caused very marked reductions in corn production. Young larvae feed on tassels, whorl and leaf sheath tissue; they also mine midribs and eat pollen that collects behind the leaf sheath. Sometimes they feed on silk, kernels, and cobs, or enter the stalk. Older larvae tend to burrow into the stalk and sometimes the base of the corn ear, or into the ear cob or kernels. Feeding by older larvae is usually considered to be most damaging, but tunneling by even young larvae can result in broken tassels. The presence of one to two larvae within a corn stalk is tolerable, but the presence of any larvae within the ear of sweet corn is considered intolerable by commercial growers, and is their major concern. European corn borer is considered to be the most important sweet corn pest in northern production areas of North America, and second-generation borers are the principal source of ear damage. Heavily tunneled stalks of grain corn suffer from lodging, reducing the capacity for machine harvesting. Lodging is not a serious threat to sweet corn. Boring by corn borers also allows several fungi to affect corn plants.

In crops other than corn, the pattern of damage is variable. European corn borer larvae damage both the stem and fruit of beans, pepper, and cowpea. The temporal occurrence of fruit affects susceptibility to injury, of course; in Wisconsin, snap beans 14–30 days from harvest were susceptible to damage by larvae, but young plants and fruit near harvest suffered little damage. In celery, potato, rhubarb, Swiss chard, and tomato, it is usually the stem tissue that is damaged. In beet, spinach, and rhubarb, leaf tissue may be injured. Entry of borers into plant tissue facilitates entry of plant pathogens. The incidence of potato blackleg caused by the bacterium *Erwinia carotovora atroseptica*, for example, is higher in potato fields with stems heavily infested by corn borers. Direct damage by corn borers to potato vines, however, results in negligible yield loss.

Management

Sampling

Moths can be sampled with blacklight and pheromone traps, and catches by these traps are correlated. Pheromone-baited water pan traps seem to be the most efficient method of adult. Trap catches are usually used to initiate intensive in-field scouting for egg masses, as moth catches are only roughly correlated with density. Thermal summations are also highly predictive. Moths seek shelter during the daylight hours in dense grass and weeds near corn fields. Flushing moths from such habitats gives an estimate of population densities. Eggs can be sampled by visual examination, but this is a very time-consuming effort.

Insecticides

Liquid formulations of insecticide are commonly applied to protect against damage to sweet corn, particularly from the period of early tassel formation until the corn silks are dry. Recommendations vary from a single application prior to silking, to weekly. Liquid applications are usually made to coincide with egg hatch in an effort to prevent infestation. If corn borers are present in a field, however, the critical treatment time is just before the tassels emerge, or at tassel emergence from the whorl. This plant growth period is significant because the larvae are active at this time and more likely to contact insecticide. A popular alternative to liquid insecticides is the use of granular formulations, which can be dropped into the whorl for effective control of first generation larvae because this is where young larvae tend to congregate. Insecticide is more persistent when applied in a granular formulation.

Cultural practices

Destruction of stalks, the overwintering site of larvae, has long been recognized as an important element of corn borer management. Disking is not adequate; plowing to a depth of 20 cm is necessary for destruction of larvae. Mowing of stalks close to the soil surface eliminates greater than 75% of larvae, and is especially effective when combined with. Minimum tillage procedures, which leave considerable crop residue on the surface, enhance borer survival.

Early planted corn is taller and attractive to ovipositing female moths, so late planting has been recommended, but this is useful mostly in areas with only a single generation per year. If a second generation occurs, such late-planted corn is heavily damaged. Planting border rows of a highly attractive variety of corn to surround a less attractive variety has been investigated in France. The attractive variety, especially if it is an early-flowering cultivar, receives most of the eggs of moths dispersing into the field. If treated with insecticide or destroyed, this border row trap could provide protection for the main corn crop.

Host plant resistance

Extensive breeding research has been conducted, and resistance has been incorporated into grain corn, especially against corn borer populations with only a single annual generation. A principal factor in seedling resistance to young larvae is a chemical known as DIMBOA, which functions as a repellent and feeding deterrent. It has proven difficult to incorporate the known resistance factors into sweet corn without degradation of quality. However, some progress has been made in producing commercially acceptable resistant cultivars, especially when host plant resistance is complemented by use of other suppressive tactics such as application of *Bacillus thuringiensis*.

Biological control

Biological control has been attempted repeatedly in sweet corn and other vegetables susceptible to European corn borer attack. *Bacillus thuringiensis* products can be as effective as many chemical insecticides, but often prove to be less effective. Most single-factor approaches, with the exception of newer formulations of *Bacillus thuringiensis*, have proven to be erratic.

European Honey Bee

This is *Apis mellifera mellifera* Linnaeus (Hymenoptera: Apidae), the common honey bee in most parts of the world. The species originated in the tropics of Africa, but the European strain, bred to be docile and an effective producer of honey, was developed in Europe. It is also known as the Italian honey bee. It has been replaced by the African strain (*Apis mellifera scutellata*) in South and Central America, and is now spreading in North America where it is replacing the European strain.

European Foulbrood

Unlike American foulbrood, European foulbrood is not considered to be a serious disease of honey bees. It is caused by the bacterium *Melissococcus pluton*, often appearing in the spring and early summer, then dissipating over the summer. It is found throughout the world. This disease affects very young larvae, and prevents the colonies from growing. It is initiated when the larvae feed on contaminated brood food, and by hive robbing. Infected bees are sometimes discarded by the nurse bees, but it is these nurses that also transmit the disease while feeding the larvae. Bacteria overwinter in the hives. The disease is also spread by contaminated equipment. It also tends to affect colonies that lack adequate nutrition.

Infected bees are discolored, but lack the distinct ropiness of bees infected with American foulbrood. The presence of a sour odor and damaged or uncapped cells is symptomatic, but does not serve to distinguish European foulbrood from American foulbrood. However, the dead bee larva forms a rubbery scale in the bottom of the cell, unlike the hard scale of American foulbrood. Often beekeepers do not treat European foulbrood, but antibiotics are curative.

Evans, Howard Ensign

Howard Evans was born in Hartford, Connecticut, on February 23, 1919. He received M.S. and Ph.D. degrees from Cornell University in 1941 and 1949, respectively, and served in the U.S. army from 1942 to 1945. He was a faculty member of Kansas State University (1949–1952), Cornell University (1952–1960), Harvard University (1960–1973), and Colorado State University (1973–1986). His awards included his appointment at Harvard University as Alexander Agassiz Professor of Zoology, his appointment at Colorado State University as Distinguished Professor, an award in 1976 of the Daniel Giraud Medal from the National Academy of Sciences for recognition of published work in zoology or paleontology, and his appointment as a fellow of the National Academy of Sciences (1977). His main research was on systematics and behavior of Hymenoptera, especially the families Sphecidae, Pompilidae, and Bethylidae, and he described one family (Scolebythidae), 31 genera, and almost 800 species. He published more than 255 scientific papers, 13 books and some dozens of popular articles. Two of his books, "Wasp farm" (1963) and "Life on a little-known planet" (1968) achieved popular acclaim. He died on July 18, 2002, survived by his wife, Mary Alice, and three children.

Eversible

Capable of being turned inside out, everted, or projected outward.

Excitorepellency

The tendency of some insecticides to excite insects so that they fly away prior to acquisition of a dose adequate for knockdown. This property is seen especially with DDT and some pyrethroids.

Ex Larva

A Latin phrase meaning out of the larva. It is normally encountered mostly on insect labels in museums, and is used to designate specimens that were reared from the larval stage of the host. The similar term "ex ovum" designates specimens reared from host eggs.

Eye-Cap Moths (Lepidoptera: Opostegidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

Eye-cap moths, family Opostegidae, are minute moths with a total of 122 known species, and known from all faunal regions but with many from the Australian region. The likely world total is over 175 species. The family, together with Nepticulidae, forms the superfamily Nepticuloidea, in the section Nepticulina of division Monotrysia, in the infraorder Heteroneura. Adults minute to small (3–16 mm wingspan), with head rough-scaled, with very large eye-caps on the antennal bases; haustellum short and naked (unscaled); labial palpi short and drooping and 3-segmented; maxillary palpi 5-segmented and folded. Wing venation is very reduced, with pseudofrenular bristles as the wing coupling. Maculation is generally white with bands or wing tip iridescences, although some species are dark. Adults are diurnally active. The few larvae known are leafminers, but some are stem borers.

Eye Gnats

These are *Hippelates* species (Diptera: Chloropidae) flies. They are found in the New World and as the name suggests, frequent the eyes (also sores and wounds) of mammals, where they feed at secretions. Their persistence makes them a nuisance, and they also have been implicated in the mechanical transmission of some diseases such as pinkeye.

► Flies
► Veterinary Pests and their Management

Exarate Pupa

A pupa in which the appendages are free, and not attached or adhering to the body (contrast with obtect pupa).

Excretion

The process of elimination of materials from the body. Excreted materials include metabolites and wastes, excessive and unnecessary nutrients, water, and allelochemicals. The principal organs of excretion are the Malpighian tubules and the hindgut.

Exocrine Gland

A gland that discharges its products to the outside of the insect (contrast with endocrine gland).

Exocuticle

The layer of sclerotized cuticle between the endocuticle and the epicuticle.

Exogenous

Originating outside an organism; extrinsic (contrast with endogenous).

Exogenous DNA

DNA from an outside source. In genetic engineering, DNA from one organism is often inserted into another by a variety of methods.

Exopeptidases

Protein digesting enzymes that attack small pieces of proteins by cutting off the terminal amino acid.

Exopterygota

A division of Insecta in which the wings develop externally during the immature stages. Hemimetabolous insects.

► Metamorphosis

Exoskeleton

A skeleton on the exterior of the body. The muscles are attached on the interior surfaces. A general term used to describe the hard body covering of insects, as is the term cuticle.

Exotic

Organisms that are native of elsewhere. Other terms used to describe this condition are alien and foreign.

Exotoxins

Poisonous substances produced by the microbial cell and liberated into the surrounding environment without destruction of the cell.

Exploratory Learning

Orientation behavior of social insects as they first leave the nest and become oriented to their surroundings.

Exploratory Trail

An odor trail produced continuously by advance workers from a foraging group (contrast with recruitment trail).

Exponential Growth

Population growth under ideal circumstances, without limitation. The population size increases at an increasing rate. The curve describing this relationship (number of individuals and time) is J-shaped.

Expression Vector

Vectors that are designed to promote the expression of gene inserts. Usually an expression vector has the regulatory sequence of a gene ligated into a plasmid that contains the gene of interest. This gene lacks its own regulatory sequence. The plasmid with this new combination (regulatory sequence + gene) is placed into a host cell such as *E. coli* or yeast, where the protein product is produced.

Extra-oral Digestion

Digestion of food before it is taken into the insect's body. This is accomplished by injection of hydrolytic enzymes into the food source, and then sucking up the digested products. Some insects continuously reflux the digestive enzymes by continuously re-injecting and sucking up the liquified juices.

Extrafloral Nectary

A nectar-producing gland found outside the flower.

► Plant Extrafloral Nectaries

Extrinsic Factors

Factors outside an organism, such as weather and other organisms. Exogenous elements.

Exuviae

The discarded or shed body covering after molting. Sometimes the terms “exuvium” or “exuvia” are used for the singular form, but this is not correct.

Eyes

The organs of sight in insects. The principal eyes of insects are (usually) large, multi-faceted “compound eyes.” Auxiliary organs of vision, with much less utility for the insect, are the “simple eyes”; these are more correctly called “ocelli.” Also, there are small, simple eyes found on the side of the head of larvae of holometabolous insects; these are more correctly called stemmata.

Eyes and Vision

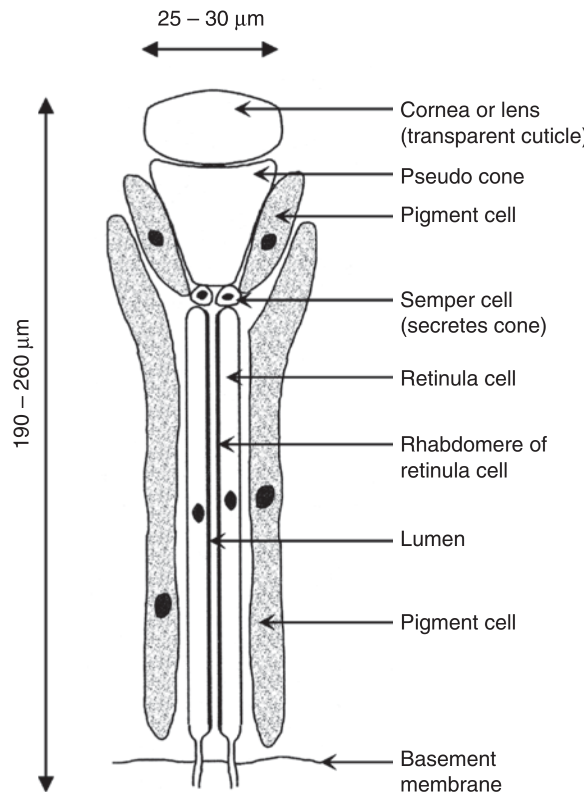
JAMES L. NATION
University of Florida, Gainesville, FL, USA

The ultimate source of light on earth is the sun, and both plants and animals evolved physical and biochemical mechanisms to capture light and make responses to its presence or absence. Light causes phototropic movements of leaves and stems and timing of flowering in many plants, and wavelengths in the 600–700 nm range promote photosynthesis. Light often influences sexual reproductive cycles, biological and seasonal rhythms, color changes in the skin, hormone secretion, and various chemical reactions (for example, synthesis of vitamin D in the skin of humans) in animals. Even the simplest plant and animal forms have pigments that enable them to respond to light. The electromagnetic radiation from the sun encompasses a wide spectrum from gamma rays and x-rays (<0.1 nm) to ultraviolet (UV), visible, infrared (IR), radio waves, and other longer wavelengths. Electromagnetic radiation from the sun that reaches the earth spans the range of about 300–900 nm, but the peak in intensity is near 500 nm wavelength. Wavelengths around this 500 nm peak are the only wavelengths that penetrate very deeply into water; even a few meters of water absorb most of the visible spectrum with the exception of wavelengths near 500 nm, which can penetrate clear water to about 100 m. Beyond this depth, little light penetrates. Ozone in the stratosphere strongly absorbs short wavelengths in the cosmic ray and UV range, which is very fortunate for all living things, because they cause chemical changes in DNA. Infrared radiation (IR) is strongly absorbed by water vapor, carbon dioxide, methane and other gases in our environment. Light that is visible to insects ranges from about 350 nm (UV) into the red range about 700 nm; this range is similar to human color vision, but humans do not have UV sensitive photoreceptors.

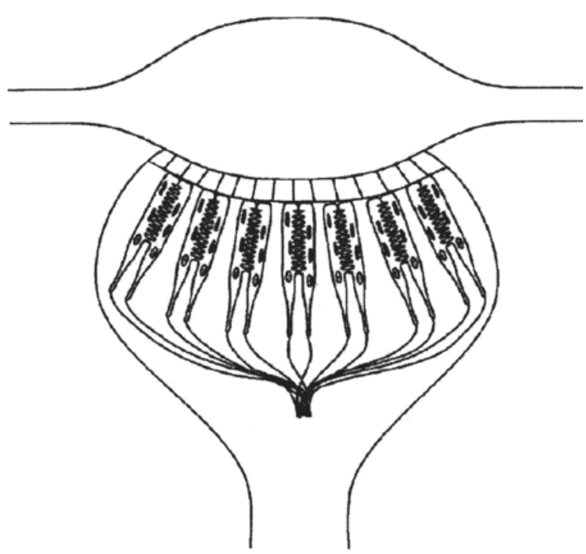
Although the main subject treated here will be insect eyes and vision, parallels and contrasts are noted with the eyes of other arthropods and vertebrates. Some extraordinary parallels in the independent development of visual systems occurred during the evolution of animals, with image-forming eyes evolving in flatworms, annelid polychaetes, coelenterates, echinoderms, insects, arachnids, crustaceans, cephalod molluscs, and vertebrates. Visual receptors, at least in terms of anatomy and structure, evolved independently in different groups of animals, possibly as many as seven times. However, all use the same chromophore, 11-*cis*-retinal or a very similar compound, and the transmembrane protein, opsin. Opsin and the chromophore combine to form rhodopsin, the visual pigment in invertebrate and vertebrate photoreceptors. Opsin is species-specific, as determined by its amino acid composition. Thus, even though the anatomical structure of eyes often evolved independently, it appears that some form of rhodopsin may have been present in very ancient organisms. The basic structure of compound eyes, in which a lens focuses light on photoreceptive cells, evolved 500–600 million years ago in trilobites in the Cambrian period. It is possible that UV, blue, and green photoreceptors existed in insects by the time of the Devonian period, about 300 million years ago.

Among the invertebrates, crustaceans have the most diversity in eye structure of any group of organisms, and at least one noted authority indicates that some of the eyes in crustaceans may have evolved several times independently. Some crustaceans have very simple eyes, but many have compound eyes very similar in structure and physiology to those in insects. Isopods, and some crabs, have apposition eyes (the eye restricts dispersal of light from one ommatidium to another due to a pigmented ommatidium wall) similar to the apposition compound eye in diurnal insects. Superposition eyes (the eye permits passage of light from one ommatidium to another through the unpigmented wall) occur in shrimp, crayfish, and lobster. Molluscs show a range of eyes from very simple eye-cups of limpets to image forming eyes with a lens in squid and octopus. Some scallops have compound eyes similar to apposition eyes in insects.

There are three types of visual receptors in insects: compound eyes, ocelli, and stemmata. Compound eyes are excellent (Fig. 57) motion detectors, responding to the movement of objects across the many small facets in the compound eyes, and in many insects this may be their most important function. Ocelli (Fig. 58) are found on immatures and adults of some insects. The cuticular covering forms a single lens over an ocellus. Beneath it are the photosensitive cells. Compound eyes, ocelli, and stemmata have the necessary structure to form an image. However, it is not



Eyes and Vision, Figure 57 A diagrammatical representation of a longitudinal view of a single facet in the compound eye of the Caribbean fruit fly, *Anastrepha suspensa*.

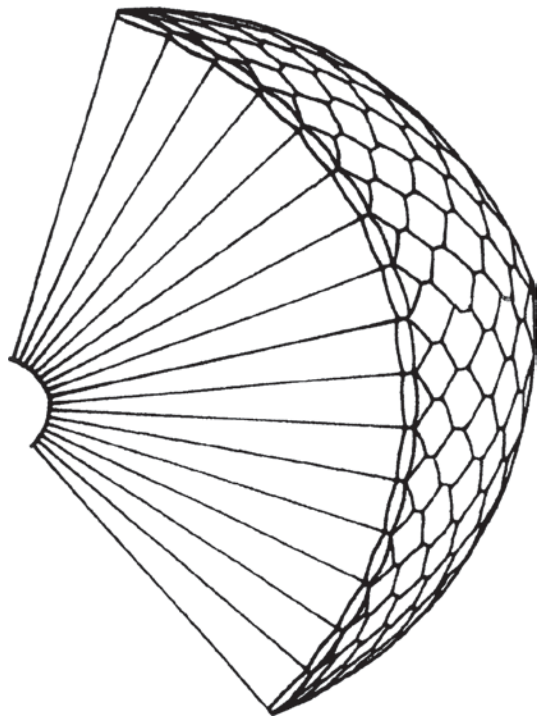


Eyes and Vision, Figure 58 A diagrammatical view of an ocellus showing a single lens, and pairs of retinula cells, each with a rhabdomere region.

possible to say what sort of image the insect sees, because it really sees with the integrative centers in the brain. Does the insect see dozens or perhaps hundreds of small images at once, or does the brain synthesize the incoming data into a single image? No one really knows. Ocelli have the necessary structure to form images, but in cases where detailed studies have been done, the images are focused below the level of the photosensitive cells, so it seems unlikely that insects actually receive an image in the brain from ocelli. Ocelli probably function mainly in detecting the quality and intensity of light, and its presence or absence. Stemmata, the visual receptors in larvae of many holometabolous insects, also can form an image, but stemmata are very small, and it is likely that any image is fuzzy and poorly resolved. The immature stage of grasshoppers, bugs, cockroaches, and other hemimetabolous insects have compound eyes similar to the adult compound eyes. Compound eyes, ocelli, and stemmata follow the same basic structural plan, with a lens to focus the light, light sensitive cells, and axons from the photoreceptive cells projecting to the brain. In all three types of eyes the photoreceptive cells have a rhabdomere region with many membrane layers that contain the visual pigment molecules.

Compound Eye Structure

Viewed from the surface, a compound eye has the appearance of being composed of hexagons. The hexagonal shape is created by the fitting together of multiple facets or units of the compound eyes called ommatidia. A single ommatidium is composed of the dioptric structures (cornea, lens, cone and sometimes other structures that bend and focus the light) the photoreceptor cells, and (Fig. 59) usually additional cells that contain shielding pigments that shield the photoreceptor cells from light entering adjacent facets. The photoreceptor cells actually are the cell bodies of specialized nerve cells, and their axons pass into the brain of the insects. The photoreceptor cells contain the photosensitive pigment, rhodopsin, which is synthesized from a chromophore and a protein (opsin). When light strikes the rhodopsin, it excites the chromophore, leading to a nerve impulse that is passed into the brain by the axons from the photoreceptor cells.



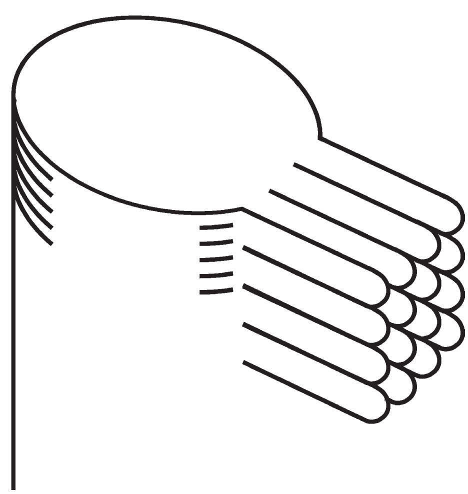
Eyes and Vision, Figure 59 A representation of a section through a compound eye showing multiple facets.

The size of the compound eyes and the number of facets or ommatidia in each eye are variable. A silverfish (*Lepisma* spp., order Zygentoma [Thysanura]) has only 12 ommatidia in each of its small eyes, but a dragonfly has big eyes, each containing thousands of ommatidia. Collembola, Zygentoma, Siphonaptera, and Strepsiptera do not have compound eyes, but they do have light-sensitive structures similar to ocelli.

Compound eye structure evolved adaptively in slightly different ways in diurnally active and nocturnally active insects. Diurnal insects are active during the day when light is bright, and have photopic or apposition eyes; those active in dim light, such as at dusk or at night, have scotopic or superposition eyes. In photopic eyes, the photoreceptor cells are located just below the dioptric structures and extend to the basement membrane. Pigment in accessory cells arranged in a circle around the photoreceptor cells shields the rhodopsin in the photoreceptor cells from light in adjacent facets, and ensures that only light that enters directly from above can strike the visual pigment in a given ommatidium. This arrangement is thought to make for a sharper image focused on the rhabdom of the photoreceptor cells in a particular ommatidium.

When light is very dim, sharpness of vision may not be as important as perception of form and movement. Scotopic eyes in nocturnal and crepuscular insects show light and dark adaptation. In dark adaptation, the pigment in shielding cells migrates or clumps in one end of the cells, leaving them more transparent to light from adjacent ommatidia, and allowing light from several ommatidia to strike the rhabdom of nearby photoreceptive cells. Thus, a particular photoreceptor cell may receive light and images superposed upon each other from nearby facets. Hence, the older name "superposition eye." This arrangement allows more light to enter each facet, but probably makes for a very fuzzy or blurred image because it is unlikely that all the images will be perfectly superimposed upon each other. Brighter light and higher temperatures (both typical of earlier in the evening for night active insects) cause the pigment in shielding cells to disperse throughout the shielding cells, thus shielding the photoreceptor cells from much or all light from adjacent facets. This converts the superposition eye into something that more nearly functions like a photopic eye, possibly with sharper images (as long as the light is brighter). Migration of the pigment to cause shielding of the photoreceptor cells may protect the visual pigment from being bleached by bright light. Nocturnally active insects usually have a network of tracheal tubes (called the "tapetum") beneath, and sometimes as a part of, the compound eyes, and the white, shiny tracheal tissue reflects light back up into the eye. This structural arrangement allows additional light to interact with the visual pigment in the photoreceptors, but also likely makes any image very fuzzy. The reflected light from the tapetum produces the eye shine seen when a light shines on a moth or other night active insect. The eye shine may be variously colored because of the shielding pigments in the eye.

The light-sensitive cells that contain the visual pigment are called "retinula cells" in the entomological literature. They are primary (Fig. 60) receptors, which simply means that their axons project into the optic lobe of the brain before synapsing. By way of contrast, the rods and cones in the human eyes are secondary receptors because their axons synapse several times before reaching the brain. Typically there are eight retinula cells arranged in a rough circle in each ommatidium, but some Lepidoptera have as many as 10–11; honeybees have nine. Sometimes the compound eye is divided into dorsal and ventral parts; adult dragonflies have four retinula cells in each ommatidium in the dorsal part of the eye, and six in the ventral part. Usually the eighth cell, or in honeybees the ninth cell, is short and extends only in the more proximal region (i.e., towards the brain) of an ommatidium. Retinula cells vary greatly in length. They are 60–100 μm long in *Drosophila melanogaster*, about 100 μm long in the American



Eyes and Vision, Figure 60 A representation of the microtubules composing the rhabdomere of a retinula cell.

cockroach, and from 150 to >200 μm long in the tephritid fruit fly *Anastrepha suspensa*.

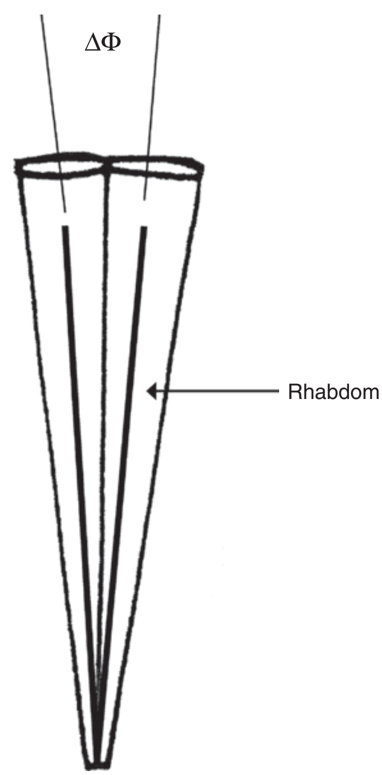
The visual pigment, rhodopsin, is contained in the rhabdomere, a special region of retinula cells that is convoluted into thousands of microvilli or microtubules ending blindly near the center of the circle formed by the retinula cells in a single ommatidium. The tubules typically are about 40–120 nm in diameter along all or part of the length of the cell. In *D. melanogaster*, there are about 60,000 microvilli along the length of each retinula cell, and about 80,000 in each rhabdomere of the American cockroach. A vast surface area is presented by these numerous folds of the cell membrane, and it is in the membrane of these tubules that the molecules of visual pigment, estimated by some researchers to be up to 100 million molecules of rhodopsin per cell, occur.

In some insects, the rhabdomeres of retinula cells in an ommatidium touch or fuse at the center of the circle to form a closed or fused rhabdom, as in honeybees, Lepidoptera, and many other insects. In Diptera and Hemiptera the rhabdomeres do not fuse, but face a central hollow cylinder in the ommatidium. When light strikes the visual pigment, the retinula cell undergoes a depolarization. The depolarizing effect of light is in contrast to the polarizing effect that light has upon the receptors in vertebrate eyes. Resting potentials ranging from 25 to 70 mv have been recorded across the membranes of retinula cells. The inside of the cell is negative relative to the outside during resting conditions in the dark. An electroretinogram (ERG) of electrical activity in response to stimuli can be recorded by placing one electrode on or into the eye and the reference electrode somewhere else in the head. An ERG is a summation of potentials from many retinula cells, and possibly of electrical activity within the optic lobe.

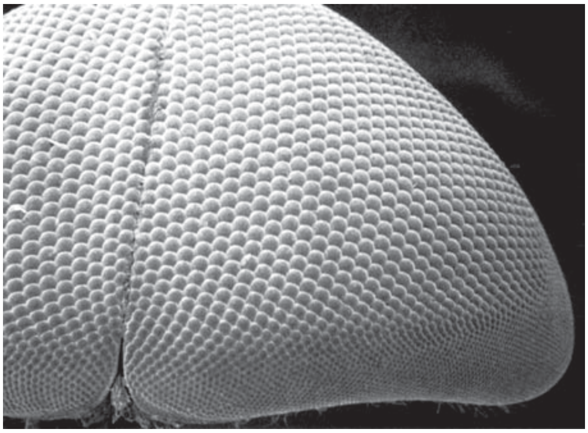
Visual Acuity

Visual acuity is a measure of how well objects can be resolved. Put simply, higher visual acuity means better ability to see objects in the environment and to navigate, capture prey, and chase a potential mate in flight. Insect eyes, however, do not even come close to having the acuity and resolving power of human eyes. The principal factors that determine visual acuity of compound eyes include the angle between two adjacent ommatidia, the optical quality of the dioptric structures that focus the light, dimensions of the rhabdom, the light level, and speed of movement across facets of the eye. The small size of facets of the compound eyes severely limits visual acuity, and larger facets increase visual acuity. The diameter of facets in compound eyes of many insects vary over different parts of the eyes.

The angle between two adjacent ommatidia (Fig. 61) is one important factor that determines acuity of vision. Dragonflies are among the insects that have the most acute vision, with an



Eyes and Vision, Figure 61 The interommatidial angle between two adjacent ommatidia or facets in the compound eye. Smaller values for the angle $\Delta\phi$ increase the possibility for greater visual acuity.



Eyes and Vision, Figure 62 **A scanning electron micrograph of the left compound eye, and a portion of the right eye, of a male horsefly *Tabanus lineola* showing the larger facets in front and extending to the top of the eye. Note smaller facets near the lower rim of the eye. Larger facets represent a fovea or area of the compound eyes with greater visual acuity. The eyes from each side of the head meet in males, but not in females (Photo courtesy of Dr. Jerry Butler, University of Florida.)**

interommatidial angle as small as 0.24°. Most insects have considerably larger interommatidial angles of several degrees up to tens of degrees. The smaller the interommatidial angle, all other factors being equal, the greater the distance at which objects such as prey, a predator, or the surrounding vegetation can be resolved. The very small nature of the lens in compound eyes severely limits resolving power because of diffraction. A human eye has much greater resolving power than a single facet of a compound eye because it is larger, has a larger opening to let light in, and has a single lens. Compound eyes are excellent motion detectors, but the fast movement of objects over the eyes causes any image to be blurred, just as movement of objects, or of the camera, causes blurring in photographs.

Insect compound eyes perform poorly in very dim light, but insects that are active at night or at dusk have special adaptations for vision in dim light. These may include wider facets and wider rhabdoms that increase sensitivity by up to 1–2 log units.

Some insects have variations that provide zones of greater acuity of vision (a "fovea") in certain parts of the eye than other parts. The fovea refers to the region in the human eye with the greatest density of cones (color and bright light sensitive) where resolution is greatest when the eyes are focused directly on the object. An "acute zone" has evolved in the forward facing, and sometimes upward looking, part of the compound eyes in some fast flying insects, particularly those that capture prey in flight, or chase flying potential mates. An insect in relatively straight line flight has a relatively stationary field of view straight in front, but highly blurred vision at the sides of the eyes as objects in the environment flash across the field of view. Bees, butterflies and some acridid grasshoppers have an acute zone in the front of the compound eyes, and better vertical acuity in a band around the equator of the eye. Male blowflies, drone honeybees, male hoverflies, some tabanid flies, and some other male insects that look for potential mates while flying have an acute zone that probably enables them to see the female better, particularly against the sky as a background. Both sexes of mantids, dragonflies, and robber-flies have higher visual acuity near the forward part of the eye that likely enable them to see and capture prey more effectively. The fast flying dragonfly *Anax junius* has 28,672 ommatidia per compound eye, with the smallest known interommatidial angles, and they have an acute zone in the dorsal part of the eye with relatively large facets as much as 62 μm across. This gives the dragonfly ability to catch mosquitoes and other small insects in flight.

Another insect with good vision is the praying mantis *Tenodera australasiae*. Facet diameters in the acute visual zone in the front of the eyes measures up to 50 μm across and they have overlapping acute zones in the large binocular looking eyes that enable them to determine distance of a prey object by binocular triangulation. They strike and capture the prey with the prothoracic pair of forelegs.

The Optic Lobe

The optic lobes extending out toward the compound eyes are large in those insects with large eyes. These optic lobes are part of the protocerebrum, the dorsal part of the brain. Three large neuropils in the optic lobes are sites of synaptic connections. The largest of the neuropils is the lamina ganglionaris, and it is the first synaptic region for incoming axons from the photoreceptors. There is a great deal of crossing of axons as they pass from the retinula cells to the lamina ganglionaris, so that axons from the same ommatidium do not converge upon a single monopolar interneuron. Additional crossing of axons occurs after synaptic connections in the next two neuropils, so that the signals from the individual ommatidia are not conveyed to the integrative centers of the brain as a direct representation of each ommatidium. Although we cannot know exactly what image an insect sees, it is reasonable to assume that its brain synthesizes the information into some sort of whole rather than seeing 28,672 little images (the number of ommatidia in each compound eye of the dragonfly *Anax junius*). The large amount of crossing of neural fibers in the optic lobe of insects is not peculiar to insects, but it is a general feature of visual systems in other animals including humans. Its function is not clearly understood, but it would appear to provide a great deal of back-up security if only some parts of either the external eye or brain receiving the input suffer damage.

Ocelli and Stemmata

Ocelli and stemmata share some similarities with a single ommatidium in a compound eye. The cuticle covering the ocelli and stemmata acts like a lens, focusing the light. Retinula cells below the cuticlar covering have a rhabdomere region of tubules where the visual pigment occurs. The axons from the retinula cells in an ocellus are gathered into the ocellar nerve that projects into the protocerebrum. The evidence suggests that any image formed is focused beneath the layer of retinula cells in an ocellus, and thus probably cannot be transmitted to the brain. Retinula cells show spontaneous electrical activity in the dark, and stimulation by a light beam leads to a more stable and increased transmembrane electrical potential rather than a depolarizing effect as shown by retinula cells in the compound eye. Ocelli likely function to signal light on-off information, intensity of illumination, and possibly in some insects they convey wavelength of stimulating light. The number of retinula cells in an ocellus is variable in different insects; honeybees, for example, have three ocelli and each contains about 800 retinula cells.

Stemmata are eyes in the larvae of some holometabolous insects, with one to six occurring on the head of different larvae. Stemmata have an overlying transparent cuticle and a few retinula cells with rhabdomere regions. Some stemmata have a crystalline lens, and some larvae have two separate rhabdoms, a distal one and a proximal one. An image that falls on the rhabdomere surfaces seems likely, but because of so few photosensitive cells, it is probably poorly, if at all, represented in the brain of the larva. Caterpillars frequently move the head from side to side, which may be a behavior that aids them in obtaining a wider field of view with small, multiple stemmata.

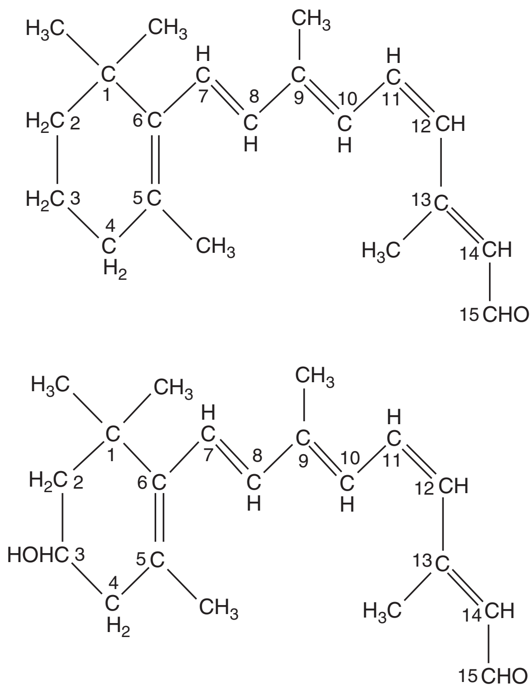
The Chemical Cascade Leading to Vision

The chromophore in insect eyes is 11-*cis*-retinal, or in some insects, 11-*cis*-3-hydroxyretinal. When a photon of light is absorbed by rhodopsin, 11-*cis*-retinal is isomerized to 11-*trans*-retinal. Contrary to the light absorbing reaction in vertebrate eyes, retinal and opsin do not separate from each other in light-activated insect eyes. Light stimulated rhodopsin in insects is called metarhodopsin, and it is a catalyst that activates a fast cascade of chemical reactions in the retinula cells, resulting in generation of a nerve impulse. This signaling pathway is extremely fast, and can be turned on and off, and repeated, many times per second. Measurements in *D. melanogaster* indicate that it takes only several tens of milliseconds to proceed from light activation of rhodopsin to the generation of a nerve impulse. The fact that portions of the visual cascade involves a number of enzyme reactions means that an initial stimulus is amplified as much as 100–1,000 times, turning a few photons of light into a barrage of nerve impulses to the optic lobe. In vertebrate eyes the 11-*trans*-retinal must be reconverted through a series of enzymatic steps in the dark part of the eye into 11-*cis*-retinal, which is combined with opsin to form a new molecule of rhodopsin. In insects, rhodopsin and metarhodopsin are in a dynamic state of equilibrium, and another photon of light can be absorbed by the metarhodopsin/11-*trans*-retinal complex and become converted into rhodopsin/11-*cis*-retinal, a process called photoisomerization. Although the anatomical structure of eyes seems to have evolved a number of times independently, the chemistry of vision is nearly the same in all organisms, and thus provides a link between invertebrates and vertebrates.

Color Vision

Color vision is the ability to discriminate between two wavelengths of light. Color vision may have existed in some insects since the Devonian period, about 300 million years ago. Many insects probably have color vision, but only a few have been studied enough to be certain. Behavior tests, electrophysiology, and molecular characterization of the visual pigment molecules have been used to characterize color vision.

Retinal is held to the opsin in a "pocket" by the ε-amino group of the amino acid lysine in the opsin molecule. The absorption maximum of 11-*cis*-retinal alone is at 380 nm and it absorbs little light longer than 400 nm. When complexed with opsin, however, the opsin tunes the absorption from 360 nm to about 640 nm. Certain amino acid substitutions in locations near the binding pocket for the chromophore influence the absorption spectrum as well, and screening pigments in the cells surrounding the circle of retinula cells in some insects seem to be able to alter the spectral sensitivity of rhodopsin. Insects usually have at least three, and sometimes more rhodopsins, each showing a different absorption maximum. All insect orders that have been tested have green-sensitive photoreceptor cells, and probably most have UV sensitive rhodopsin, which explains why entomologists can use UV lights to attract many kinds of insects. Most, but not all, insects also seem to have a blue-sensitive rhodopsin, but some appear to have lost the blue sensitive pigment over time. The painted lady butterfly, *Vanessa cardui*, has one rhodopsin that absorbs light maximally in the UV region at 360 nm, another absorbs in the blue region maximally at about 470 nm, and one is maximally sensitive in the green part of the spectrum at about 530 nm. The nymphalid butterfly *Heliconius erato* has three rhodopsins, with peak absorptions in the UV range, one in the blue-green range, and one absorbing maximally at long wavelengths between 590 and 640. Although the butterfly has only one rhodopsin for absorption in the red region, it has been shown experimentally that the butterfly can discriminate colored light at 590 nm, 620 nm, and 640 nm. This means it can distinguish yellow-orange from orange from orange-red with only one rhodospin, which would not be expected to give this ability to discriminate shades of red; *Vanessa atalanta*, another lady butterfly, can distinguish red color from green and blue, but cannot distinguish the differences in the red part of the spectrum as can *H. erato*. The Japanese yellow swallowtail butterfly, *Papilio xuthus*, has receptor cells in which rhodopsins are present that absorb maximally in the UV at 360 nm, violet range at 400 nm (sensitivity to violet color may be because the receptor pigment is being tuned by filtering pigments; a rhodopsin with a spectral peak at 400 nm is not common in insects), blue range at 460 nm, green range at 520 nm,



Eyes and Vision, Figure 63 **Chemical structure of 11-*cis*-retinal (above) and 11-*cis*-3-hydroxy retinal (below). When combined with the protein opsin, the visual pigment rhodopsin is formed.**

and red range at 600 nm. The butterflies were trained by Japanese workers to feed on sugar water from dishes placed on colored discs of paper in the laboratory. The butterflies most easily learned to look for food on red and yellow colors, but training to other colors required more training time, and they lost the ability to distinguish blue when the intensity of the color was reduced to 80% of the training intensity (intensity was reduced by placing neutral density filters over the color). Another swallowtail, *Papilio glaucus*, has rhodopsins with maximal absorption at approximately the same maxima as *P. xuthus*, except it does not have one absorbing in the violet range at 400 nm. Most moths are not sensitive to red. Sensitivity may not be very important in dim light because it cannot be distinguished from black; humans lose the ability to distinguish most colors in dim light because the cone cells in the retina that contain the rhodopsins sensitive to color do not work well in dim light. The tobacco hornworm, *Manduca sexta*, has UV, blue, and green receptors, but no red receptor.

Honeybees have color vision and were one of the first insects in which perception of color was demonstrated with behavioral tests. The German scientist and behaviorist Karl von Frisch (who received the Nobel prize for this and subsequent behavioral work with bees) trained honeybees to come to sugar water in a small dish placed on a sheet of blue paper lying on a table outdoors. After the bees had communicated the location to others in their hive (by the bee dance) and had recruited a regular stream of visitors to the dish, von Frisch replaced the blue paper with a clean one and an empty dish (the bees might have left an odor on the previous paper after alighting on it many times, and they might somehow smell the sugar solution or have added some olfactory cue to it by their feeding). He also made a checkerboard arrangement around the blue paper with gray papers of the same size as the blue one and graded in intensity from white to black. Each paper contained an empty dish. Von Frisch reasoned that color blind bees would confuse the blue paper with one or more of the gray papers, and probably would alight on the wrong dish or paper in their search for sugar solution. They were not confused, however, but flew directly to the dish (now without sugar water) on the blue paper. He performed many variations of this experiment, and found that the bees could be trained to come to sugar water on some other colored papers, but they could not distinguish red from black or dark gray colored papers. Subsequent work including electrophysiological analysis of the spectral sensitivity of the honeybee compound eye demonstrated that they have receptors that show maximum sensitivity at 344 nm (UV), 436 nm (blue), and 544 nm (green). They do not have a red-sensitive receptor, which explains why von Frisch could not train them to discriminate red papers containing sugar water.

Evolution of red receptors in insects has been relatively recent, and sporadic with respect to which groups have red receptors. Red receptors evolved at least four times in Lepidoptera, but some Lepidoptera may have subsequently lost the red receptor. Duplications of the green sensitive opsin, and occasional substitution of amino acids at crucial sites in some of the duplicates, probably led to the evolution of a red-sensitive rhodopsin in some insects.

Visual stimuli have been shown to be important to insects in various behavioral experiments. In flight tunnel tests, *M. sexta* moths responded best by flying up wind when visual cues (a white paper flower) were presented with an olfactory stimulus (oil of bergamot, a known attractant for the moths). When the two stimuli were presented spatially or temporally separate from each other, the moths showed a response to both, but less than to both presented together. The authors of the study concluded that the visual stimulus was the ultimate indicator of a nectar (food) source. The pine weevil, *Hylobius abietis*, when seeking an oviposition site, also showed the best (walking) response when a visual stimulus (a green wire with green plastic twigs to simulate a young pine seedling) was presented with pine odor. The response to the two together was additive, with reduced response to either stimulus presented alone. Attraction to the visual stimulus alone was clearly demonstrated, however.

Detection of Plane Polarized Light by Insects

Many invertebrates are able to detect plane polarized light, but humans can only detect it with instruments, not with their eyes. Most of the light from the sun is not polarized, and the waves vibrate in every conceivable direction, but a small percentage of the light becomes polarized by molecules and particles in the atmosphere. Light reflected from waxy and shiny surfaces, such as leaves, or other objects in the environment, also has a polarized component. Polarized waves vibrate in a specific plane, and the e-vector (vibration plane) and intensity of polarization vary with the position of the sun above the horizon, and consequently they change constantly. It is remarkable that so many invertebrates have evolved the ability to detect the plane of polarization, and some, such as honeybees, use a celestial (sun) clock to track both time and plane of polarization. When honeybees fly out from the hive to collect nectar, they often wander from site to site and spend considerable time away from the hive. The plane of polarization and the position of the sun above the horizon will have changed since their outbound flight, and they cannot find the hive again by following the old data from the outward flight. They update the data and fly back in the so-called "bee line" dictated by the new position of the sun and new plane of polarization. Houseflies, *Photurus pennsylvanicus*, fireflies, Japanese beetles, and several species of ants orient to plane polarized light under conditions that prevent them from using background reflections as orientation cues, but whether they use it in a sophisticated manner as do honeybees has not been demonstrated. Another insect that uses celestial navigation and polarization for homing after foraging is the ant *Cataglyphis bicolor*, which is found in North African deserts. It uses plane-polarized light to travel a direct path to its nest in the ground after having wandered, with many turns, up to 100 m in search of food. In most, if not all cases observed, it is the UV sensitive photoreceptor cells in the dorsal rim area of the compound eyes that seem to most often be the cells that detect the plane of polarization. When a UV absorbing shield was held over ants in the field, they began to wander aimlessly, unable to locate their underground nest. The red wood ant, *Formica polyctena*, of northern Europe uses polarized light as a compass. The precise way in which these insects determine the plane of polarization and how they measure time lapse is not known with certainty. The desert locust, *Schistocerca gregaria*, responds to polarized light, especially with two identified neurons named Tutu1 and LoTu1. These neurons respond to both polarized and ordinary light, and their response to plane polarized light is based on blue-sensitive photoreceptors in the dorsal rim area of the compound eyes. The LoTu1 neurons showed approximately two log units greater sensitivity to polarized light than to nonpolarized light.

In what ways other than homing could polarized light be useful to invertebrates? Desert locusts, for example, do not show homing behavior, but they might use polarized light during migrations, and reflected polarized light from plant food sources may be processed by the polarization receptors. The red swamp crayfish (not an insect of course), is sensitive to plane polarized light in behavioral tests. How the crayfish might benefit from detecting polarized light is not clear from experiments, but they may be able to detect transparent prey by the reflection of polarized light from their bodies, and may detect predator fish by reflection of polarized light from their silvery scales. Their compound eyes are similar to the compound eyes in insects, and the dorsal rim area of the eyes appears to be a site for detection of plane polarized light.

Monarch butterflies use a time-compensated sun compass during long migratory flights to Mexico, but behavioral experiments in a flight simulator that allowed the butterflies to take off in flight when exposed to patch of naturally polarized light from the sky, to artificial polarizers, or to the open sky did not indicate that the plane of polarization made any difference in their orientation. When the dorsal rim area of the compound eyes was painted with black paint, they still used their time-compensated sun compass in orientation, but presumably could not detect the plane of polarization. The authors of these experiments concluded that the butterflies do not need polarized light cues to orient in their flight, but the ability to detect the e-vector of polarization might still be useful in some ecological way that these experiments did not probe.

Neotropical butterflies (family Nymphalidae) in Costa Rican tropical forests appear to use polarized light reflected from the shiny surfaces of leaves and the surface of insects to detect forage and oviposition sites, and to identify conspecifics in the low light intensity of the forest foliage. Polarized light may be useful in motion detection, particularly in dim light. Mayflies (order Ephemeroptera) probably use reflected polarized light to identify water surfaces where they can lay their eggs. Unfortunately, they also can be fooled into laying them in the wrong place; mayflies in one location were discovered laying masses of eggs on asphalt road surfaces near the stream from which they emerged. Measurements with instruments designed to measure polarized light indicated that the asphalt surface with the sun shining on it reflected plane polarized light in much the same way that the sunlit water surface in their stream did. Thus, some mayflies were laying their eggs in an environment where they had no chance to hatch.

The dung beetle *Scarabaeus zambesianus* forages for fresh animal dung around sunset, a time when light intensity is low and the polarization pattern in the sky is the simplest of the day, with light of the entire sky polarized in one direction. When the beetles locate fresh dung, they quickly make a ball and roll it away in a straight line, apparently an adaptive mechanism to avoid competition and possible predator or parasite detection at the fresh dung. Experiments with polarization filters that change the e-vector of polarization, show that the beetles are sensitive to the e-vector and reorient their rolling behavior in response to an experimental change in the e-vector. The dorsal rim area of the compound eyes has photoreceptor cells with large rhabdom surfaces, a lack of screening pigments in surrounding cells, and the microvilli in the rhabdoms oriented orthogonal to each other (perpendicular to each other), all features providing the best arrangement for detecting the contrast in e-vector of polarized light. The beetles cease foraging about 40–50 min after sunset, when the degree of polarization at the zenith of the sky decreases from 45% to 5% within 15 min. The change in polarization, of course, might not be the sole factor involved in their behavior.

In the field cricket *Gryllus campestris*, photoreceptor cells have orthogonally oriented microvilli in the dorsal rim area of the compound eyes with a blue-sensitive rhodopsin (λmax about 440 nm).

The cells show strong sensitivity to the e-vector of polarized light, and their input converges on polarization sensitive neurons in the optic lobes of the brain. Inputs from about 200 ommatidia converge upon the optic lobe neurons, which increases the signal-to-noise ratio and sensitivity to the e-vector.

Fabre, Jean-Henri Casimir

Jean-Henri Fabre was born at Saint-Léons, southern France, on December 22, 1823. He received little education in school, and taught himself several subjects as a trainee teacher in Avignon. For this, he received a diploma, and found low-paying jobs as a schoolteacher. He married Marie Villard, another teacher. Now, he devoted his free time to studying insects. This gained him no recognition from his employers, but brought him attention from scientists. He was recognized in Paris, and given a high award: the Légion d' Honneur medal. Relations with his employers worsened and, in 1870, when he admitted girls to his science classes, he was fired. An English economist, philosopher and friend, John Stuart Mill, lent him money. Royalties from his numerous popular books on scientific subjects, and his teaching of evening classes, allowed him to live with his family, repay Mill, and even buy a small house on a plot of land. In 1879 he retired from teaching, and went to live in that house, and published the first of what became a series of works on entomology, called "Souvenirs entomologiques." But his wife Marie, who had borne five children, died. "Souvenirs entomologiques," which eventually ran to 10 volumes, contains careful accounts of insect behavior and life cycles, made from his field observations close to his home, and for that are admirable. At the age of 65, he married Marie-Joséphine Daudel, and they had three children. Unfortunately, his books were selling poorly, now because of his antievolutionary viewpoint. Then, in 1909, his fortunes changed. He was "discovered" by national writers and lauded. He was awarded a government pension, and his books began to sell again. But his second wife died in 1912, and he on October 11, 1915.

Fabricius, Johann Christian

Johann Fabricius (Fig. 1) was born in Tondern, Denmark, on January 7, 1745. He obtained his university education in Copenhagen and Uppsala, at the latter being a student of Linné. He worked as a professor at the universities of Copenhagen (1770) and Kiel (1775). These professorships (at both universities) were in natural history, economy and finance, evidencing the philosophy of the times. Whereas Linné had general interests in the description and classification of plants and animals, Fabricius specialized in insects. With this specialization, he described and named almost 10,000 species of insects contrasted with the 3,000 named by Linné. He also developed insect classification substantially; whereas Linné used characters provided by the wings, Fabricius added characters provided by the mouthparts to do this. He wrote several books, developing and expanding his

Fabricius, Johann Christian, Figure 1 **Johann C. Fabricius.**

classification of insects. They were (1775) "Systema entomologiae," (1776) "Genera insectorum," (1781) "Species insectorum," (1787) "Mantissa insectorum," (1792–1799) "Entomologia systematica" and "Supplementum," (1801) "Systema rhyngotorum" (Hemiptera), (1804) "Systema piezatorum" (Hymenoptera), (1805) "Systema antliatorum" (Diptera), and (1807) "Systema glossatorum" (Lepidoptera, which was never finished). They were written in Latin, which was then the international language of science. The major ones were published in Copenhagen, Kiel, and Leipzig, whose Latinized names are Hafnia, Kilia, and Lipsia. The title pages of the books, following names of the publishing companies, give these Latinized names in the genitive case, Hafniae (meaning "of Copenhagen"), Kiliae, and Lipsiae, a detail that eludes many modern bibliographers. In other words, a book may be said to have been published in Copenhagen (English spelling, used if you are writing in English) or København (Danish spelling, used if you write in a Scandinavian language) or even (if you must be incredibly pedantic this spelling is not wrong) "in Hafnia," but it is an error to say that it was published "in Hafniae."

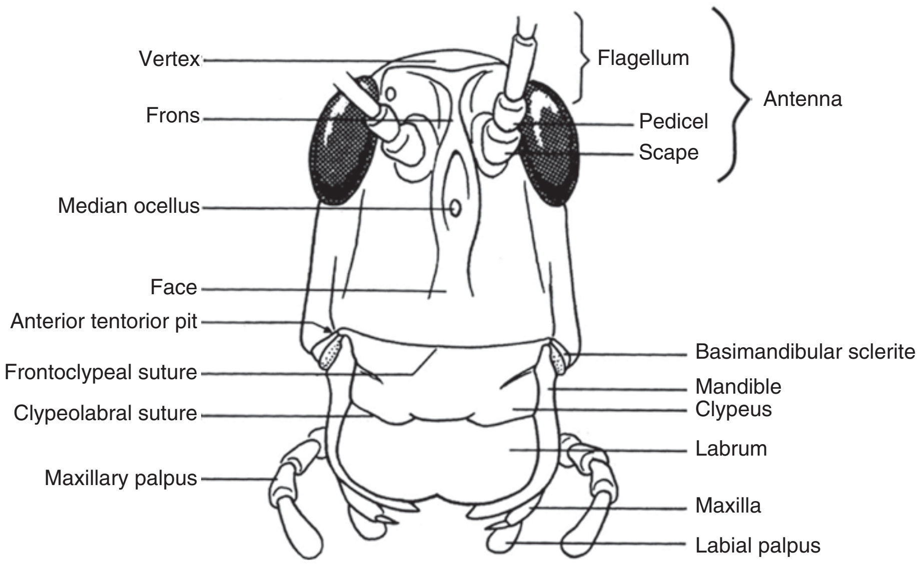
Face Fly, *Musca autumnalis* De Geer (Diptera: Muscidae)

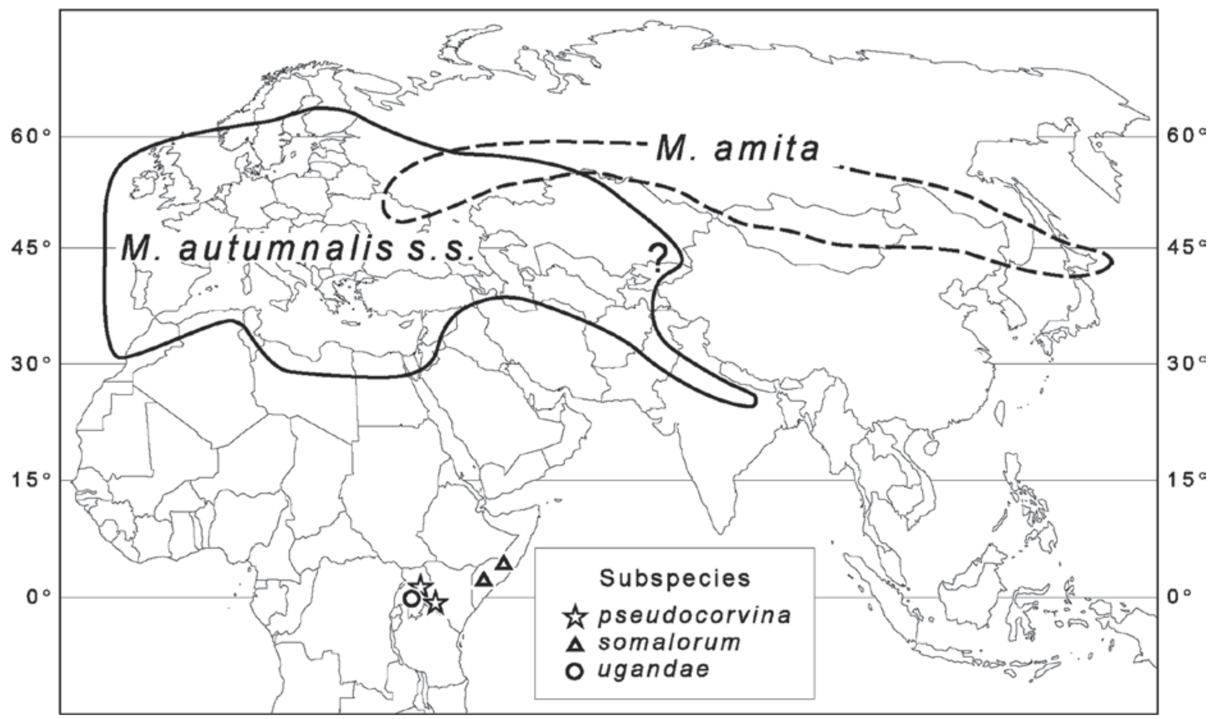
E. S. KRAFSUR[1], R. D. MOON[2]
[1]Iowa State University, Ames, IA, USA
University of Minnesota Saint Paul, MN, USA

Face fly, *Musca* (*Eumusca*) *autumnalis* De Geer, is one of only two *Musca* species recorded in North America, the other being the house fly, *M.* (*Musca*) *domestica* L. Three *M. autumnalis* subspecies have been described; two occur in Uganda and a third in Somalia (Fig. 3). We doubt their status because of the great distance from other conspecific populations, all of which occupy temperate regions and undergo a facultative reproductive diapause when daylengths approach 12 h. Recent genetic research utilizing mitochondrial nucleotide sequence variation suggests the occurrence of a morphologically indistinguishable sibling species in southeastern Kazakhstan.

In gross appearance, face flies look much like house flies but they tend to be larger and are found in different habitats. Eyes of female face flies are more completely holoptic than in house flies, and the male face flies are completely holoptic, unlike house flies. The basal abdominal pleuron of female



Face, Figure 2 **Front view of the head of an adult grasshopper, showing some major elements.**



Face Fly, *Musca autumnalis* De Geer (Diptera: Muscidae), Figure 3 **Old World distribution of *Musca autumnalis*. The occurrence of a presumptive sibling species to *M. autumnalis* is indicated by the question mark in Kazakhstan (modified after Krafsur and Moon, Annu. Rev. Entomol. 42).**

face flies is yellow, and succeeding pleura are gray-black, whereas the lateral pleura of house fly females more frequently are cream in color. The abdominal pleura of male face flies are bright yellow against a distinctly black dorsal stripe, a trait not commonly shown by male house flies.

Face flies differ greatly from house flies in habits and biology. Face flies are exophagic and exophilic, occurring around bison, pastured cattle and horses. They oviposit only in fresh bovine dung where larval development occurs. Only overwintering face flies in diapause may be found in human or livestock dwellings. In contrast, house flies are ubiquitous in and around human and animal habitations and oviposit and develop as larvae in many kinds of fermenting organic matter.

The veterinary and economic importance of face flies is related to the feeding habits of females, which seek protein from the eyes, noses and other orifices of cattle and horses. In so doing they can serve as vectors of eyeworms (*Thelazia* spp.), hemorrhagic bovine filariasis (*Parafilaria bovicola*), and the agents of "pinkeye" or infectious bovine keratoconjunctivitis (*Moraxella bovis*). When abundant, face flies annoy cattle and horses and are said to disrupt grazing patterns, but the economic significance of this remains to be demonstrated. Female face flies seek protein to support egg development and they do so in each successive gonotrophic cycle. Thus, the vectorial capacity of a face fly is related to her reproductive age. Sex ratios of adults around hosts are highly biased during the breeding season, from April to mid-September. Male face flies do not seek protein but can be found near animals albeit in much smaller numbers than the females. Males are found in much greater numbers perching at the margins of woods, on fences, and other sunlit surfaces. In these locations females are comparatively few and most are virgins. In very late summer, autumn, winter, and early spring, face flies may also be found on sunlit windows and walls in some human dwellings where diapausing flies are thought to have sought overwintering sites. Here the sexes occur in equal numbers.

Distribution and Colonization of North America

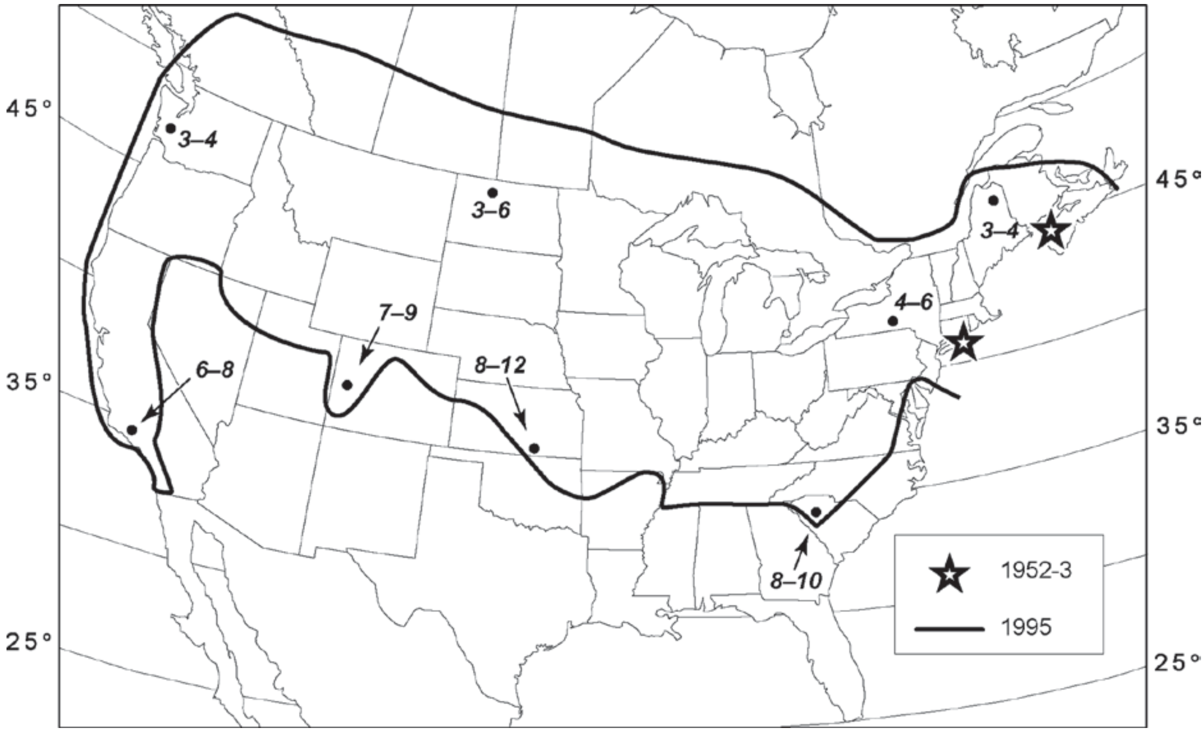
Musca autumnalis s.s. is Palearctic, occurring from the British Isles south to northern Africa and east to Pakistan, Kazakhstan, northern India, and Nepal. Face flies colonized North America only recently. They were first detected in Nova Scotia in 1952, and secondarily recorded in New York in 1953. They rapidly spread through the northern tier of states in North America and southern regions of Canada, to about 53°N and were detected in the Pacific Northwest in 1967, having spread westward at a yearly average rate of c. 250 km per year. Spread southward was much slower. Their current North American distribution extends as far south as about 35°N, including Georgia, Tennessee, Arkansas, Oklahoma, Utah, northern Nevada, and southern California (Fig. 4).

Genetic diversities in North American populations are substantial and indicate a large founding population of the order 10^2–10^3 or more reproducing females, a conclusion supported by the simultaneous introduction of the entomopathic nematode *Paraiotonchium autumnalis* (Tylenchida: Allantonematidae) that is found in about 2–4% of adult face flies. North American populations exhibit little genetic differentiation, testifying to their rapid spread from a likely single, genetically diverse population. Old World populations, however, showed much genetic diversity partitioned among English, Russian, and Kazakhstan populations. Mitochondrial sequence variation suggests the origin of New World face flies was the United Kingdom or Western Europe and a likely scenario is that a large cluster or clusters of diapausing flies were introduced via wartime or postwar shipping between the UK and maritime provinces of Canada.

Reproductive Biology

Face fly females become inseminated only once. Thereafter, females require exogenous protein to undergo vitellogenesis. Ovaries are paired, and average 12–13 ovarioles each. Hence, mean egg production per clutch is about 25, averaged over the breeding season.

Ovarioles develop in synchrony, and flies may undergo repeated cycles of vitellogenesis and oviposition. Ovariole number varies with body size



Face Fly, *Musca autumnalis* De Geer (Diptera: Muscidae), Figure 4 North American distribution of *Musca autumnalis*. The first detections of face flies are indicated. Seasonal numbers of generations are shown, estimated by calculating degree-day sums (modified after Krafsur and Moon, Annu. Rev. Entomol. 42).

and body size varies with the quality of larval nutrition. Late spring and early summer flies tend to be the largest and, therefore, have the most ovarioles.

Microscopic examination of female reproductive systems and chemical analysis of their heads provides the means to estimate reproductive ages and phenology. Because ovarian development is temperature dependent, it is possible to estimate, to a rough approximation, the calendar ages of flies in a sample if the temperature history of the sampling location is known. The first ovipositions in spring require about 77 degree-days (DD) above a threshold of 12°C. The previtellogenic phase requires 30 degree-days and vitellogenesis another 47 DD. Subsequent ovipositions require about 40 DD above the 12°C threshold. Calendar ages may be estimated more accurately by measuring spectrofluorometrically the concentration of pteridines in flies' head capsules. These substances accumulate in the eyes at a rate determined by temperature integrated over time. The pteridine method, applied to flies in the upper Midwestern states, indicated that during the main breeding season males lived an average of 10 days and females 11 days and completed two to three gonotrophic cycles. Development of eggs, larvae, and pupae also are temperature dependent, requiring 57 DD above a 10°C threshold for egg hatch and larval development and a further 134 DD for pupal development. Thus, egg to adult development requires an average 14 days at summer temperatures. Day degree summations indicate that the number of generations annually varies from about three to four in the northernmost part of the range to 8–12 in the south.

Phenology and Overwintering

Face flies overwinter as adults in reproductive diapause. In the field, short day lengths induce reproductive diapause. Both sexes develop hypertrophied fat bodies and do not demonstrate sexual behavior. They become increasingly photonegative and seek out hibernaculae, which may include human dwellings. It is unlikely, however, that many of the flies that enter buildings in autumn survive over winter, because they are unable to replace water and easily escape to the outdoors. Moreover, diapausing flies are killed by exposures to −10°C (14°F) for 7 h or longer. In much of their northern temperate range, temperatures often drop below −10°C for many hours to days. Thus, successful overwintering in heated or unheated structures seems unlikely in the northern regions of face fly distribution. It is more plausible that successful face fly overwintering in the cold climates occurs in subnivean environments or below ground where temperature extremes are much more moderate.

In late winter and early spring, diapausing flies can be found perching outdoors on sunny days when air temperatures approach 12°C. Spring warmth allows the flies to break diapause and seek mates. Females then obtain proteinacious meals from cattle and horses. Gravid flies oviposit on fresh bovine dung. These overwintered flies have survived approximately 7–8 months as adults. Larval and pupal development is temperature dependent. First generation flies then appear about a month later and undergo the same mating, feeding, and gonotrophic cycle, giving rise to overlapping generations. Repeated cycles occur until day lengths decline to 12.5 h in September. Then, newly eclosed flies undergo facultatively gonadotrophic dissociation and develop hypertrophied fat body. Annually replicated studies in Iowa have shown that sharp variations in prevailing daily temperatures have no detectable effects on the sudden switch to diapause development.

Veterinary Significance

The importance of face flies is related to the feeding habits of females on the eyes of cattle (Fig. 5) and horses. They will also imbibe saliva, blood from wounds, and discarded placenta and fetal membranes (afterbirth). Face flies are obligate developmental vectors of eyeworms *Thelazia gulosa*, *T. scrjabini*, and *T. lacrymalis*. The former two species occur in cattle, whereas the latter species

Face Fly, *Musca autumnalis* De Geer (Diptera: Muscidae), Figure 5 Face flies clustered around the head of a cow, where they feed on secretions of the eyes and nose.

occurs in horses. Adult nematodes reside in the lachrymal ducts of their hosts and shed eggs that develop to infective larvae that develop in the hemocoele of face flies. Third stage larvae migrate to the head of adult flies and depart when flies feed on cattle or horses. The clinical significance of *Thelazia* spp. is considered to be small. All three species are endemic in the Old World, and have been introduced into North America.

In Europe, the face fly is also the developmental host and vector for *Parafilaria bovicola* (Nematoda: Filaroidea). This nematode, detected in quarantined imported Charolais cattle in Ontario, causes cutaneous bleeding in cattle and lesions in the surfaces of carcasses, thereby reducing their value. *Parafilaria bovicola* has been recorded in France, Sweden, Eastern Europe, India, Pakistan, the Philippines, North, West and East Africa, and South Africa.

Reports in North America of increased pinkeye incidence after the appearance of face flies led to research focused on the causes and transmission of pinkeye, caused largely by the bacterium *Moraxella bovis*. Converging evidence is that *Moraxella* does not infect and replicate in face flies. Rather, the flies are readily contaminated with *Moraxella* from infected animals, and contaminated flies can assist in mechanical spread of the bacterium from infected to susceptible cattle. Similarly, the agent of bovine brucellosis, *Brucella abortis*, cannot replicate in face flies and ingested bacteria are rapidly degraded. Apart from causing annoyance when populations are dense, face flies do not seem to cause detectably significant economic damage.

Management

Extensive studies of ear tags of various formulations for face fly control have been carried out for 25 years. Backrubbers and dustbags charged with various insecticides have also been evaluated. Treatments are usually assessed by comparing visual counts of flies on animals' faces among treated and untreated herds. No treatment has proved particularly efficacious. It is probable that face fly populations were not effectively reduced largely because females spend little time directly on host animals, which minimizes exposure to insecticides on treated animals. The sterile insect technique (SIT) has been considered as a means of eradication. Treatment of puparia containing pharate adults to 21 Gy of ionizing radiation in an anoxic atmosphere induced 95% sterility in both sexes with minimal cost in reduced longevity and competitiveness compared with unirradiated flies. Although a release strategy has been developed, simulation modeling and methods for mass rearing and genetic sexing remain to be developed. The great propensity for dispersal demonstrated by face flies does not favor SIT as an efficacious way of eliminating face flies and the economic benefits of doing so are not likely to justify costs of the rearing, sterilization and release methods currently available.

Facet

The external surface of an individual ommatidium on a compound eye.

Factitious

An abnormal host for a parasitoid, specifically a non-normal host that biological control prac– titioners use to culture biological control agents in the laboratory because it is more convenient than the natural host.

Factitious Host

Abnormal host. Insects, and biological control agents of insects or plants, sometimes are produced on abnormal hosts due to ease or economy of culture.

Facultative Agents

A term used by Howard and Fiske to describe mortality factors that increase in intensity as population density rises; density-dependent mortality factors.

Facultative Diapause

Optional occurrence of diapause (arrested development), brought about by adverse conditions or conditions signifying the onset of adverse conditions. Facultative diapause occurs where adverse conditions do not occur regularly or predictably, or where insects have several generations per year and continue with their life cycle until some trigger stimulates induction of diapause.

► Diapause
► Obligatory Diapause

Facultative Myiasis

Myiasis in which the maggots dwell for some time in the gut or nasal passages of living animals if they are able to gain access.

► Myiasis

Facultative Parasitism

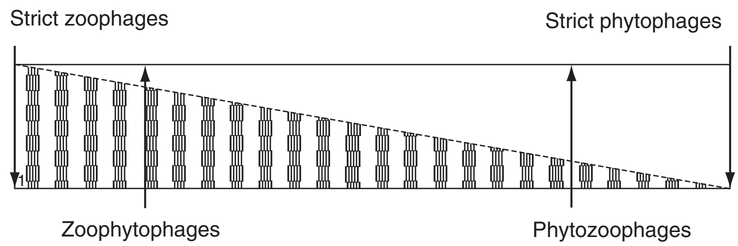
Optionally a parasite. A condition in which normally free-living organisms may become parasites.

Facultative Predators

R. ALBAJES[1], O. ALOMAR[2]
[1]Universitat de Lleida, Lleida, Catalonia, Spain
[2]IRTA, Cabrils, Catalonia, Spain

Omnivory, or trophic omnivory, is defined as the capacity of organisms to feed on more than one trophic level. True omnivory is a special case of trophic omnivory in which the consumer feeds on both plants and animal prey. The alternation of prey-feeding and plant-feeding stages during development is relatively common among animals. For example, many predatory insects feed upon plants at the adult stage by consuming floral or extra-floral nectar, pollen, seeds, plant saps and other plant materials, whereas they are carnivorous in juvenile stages. Less frequently, but not rarely, other insect predators may feed on plants and/or on prey at the same developmental stage; these are called facultative predators. The key feature that characterizes facultative predators is their capacity to feed on both plants and prey. Other closely related terms that are sometimes used to describe facultative predators are zoophytophages, phytozoophages, plant-feeding omnivores and opportunistic predators. More recently, omnivory has been structured into three types: life-history, temporal, and permanent omnivory.

The differences between these terms come from the prevalent feeding regime observed in each species. Thus, zoophytophages eat mostly prey, but also take vegetable resources. Conversely, in phytozoophages, the diet is mainly composed of plant materials to which prey are added. In practice, however, the relative amount of vegetable and animal consumption has rarely been determined, and the term applied to a species seems to reflect the perception of the observer rather than the real proportion of plant versus prey food ingested. In fact, species that may feed facultatively on both plants and prey are located in a continuum of feeding



Facultative Predators, Figure 6 **Trophic continuum of feeding habits by predators according to the relative consumption of animal and plant resources.**

habits (Fig. 6) between strict zoophagy and strict phytophagy.

Some authors use the term facultative predator to refer to predators that usually have a well-defined diet, but may also consume a broader range of prey. Parasitoids that are able to feed on the host may be regarded as facultative predators, as females can switch between predation and parasitism when a host is found.

Insect and Arachnid Groups Containing Facultative Predators

It is difficult to review the cases of facultative predation contained in the literature because many references report occasional observations of predators feeding on plants, or of phytophages feeding on animals, but rarely are there more continuous observations on the concurrence of plant and prey feeding at the same developmental stage. However, a list is provided of insect and arachnid groups containing at least one species with facultative predaceous habits (Table 1). Cases of cannibalism, hematophagy and host-feeding parasitoids have not been considered, whereas the cases of saprophagy are included. The list includes 18 orders and 84 families of mostly insects, but also arachnids. This would mean that facultative predation is more widespread among terrestrial insect predators than might be thought, due to the scarcity of studies on this feeding behavior.

Functions and Role of Facultative Predation

To understand functions of the capacity to feed on both plants and prey, it is important first to understand the benefits and costs derived from feeding on plants in facultative predators. At least some of the benefits confer adaptive advantages because a number of facultative predators have retained or acquired morphological (particularly mouth parts), or physiological (amylases, pectinases, symbiotes) traits of herbivores. Consequently, trophic switching capacity may itself constitute an adaptive strategy of some predators living in habitats with high variability in food type abundance.

Benefits may derive from nutritional considerations. Facultative predators may obtain complementary or supplementary nutrients, or other substances like vitamins, water, minerals, symbiotes, or enzymes from alternative plant or prey food. As a result of mixing prey and plant diets, facultative predators enhance one, or several, of their fitness components such as developmental rate, survival, fecundity, and longevity. These benefits in some fitness components, however, may be counterbalanced by costs in the decrease of other components as a result of the poorer quality of plant food. Another cost of facultative predation is a narrower range of prey as a consequence of their greater dependence on host plants than non-plant feeding predators (e.g., *Orius* species avoid foraging on tomato though it hosts suitable prey). The possibility of switching from prey to plant feeding may represent an additional benefit as it

diminishes competition among predators for prey. Other benefits come from the feature that most facultative predators are generalists and are better adapted to changing and ephemeral habitats.

The occurrence of facultative predation in food webs influences various interactions among components of the system. For instance, predator and prey may share a common resource and competition may thus occur (e.g., intraguild predation). Systems with facultative predators differ in four ways from those with strict predators: (i) it is unlikely that the relative sizes of prey and plants have a major effect on the tendency of a plant-feeding omnivore to switch between plant and prey feeding; (ii) unlike animal prey, plants are not usually removed after a feeding event, thus the probability of finding a plant does not change; (iii) the location of plant and prey sources is not independent: plants define the prey's habitat; and (iv) the chemical properties of plants and prey differ greatly, and their relative nutritional values for the facultative predator are likely to be a major determinate of the proportion of its plant and prey consumption in the continuum between herbivorous and predaceous habits.

Facultative predators may make different and contradictory contributions to the stability of food webs. As they can link species in the community that would otherwise be unconnected, the occurrence of facultative predators may stabilize systems. Their role in shortening food chains may also contribute to stability. The possibility of switching between prey and plant feeding may allow prey populations to escape predation at low density, resulting in a stabilizing mechanism for the prey population. Other stabilizing and destabilizing effects of facultative predators come from their characteristics as generalist predators.

Facultative Predators for Biological Pest Control

The potential of facultative predators for biological pest control has traditionally been neglected, mainly due to the risk that feeding on the crop may result in economic damage or because predation has been overlooked when compared to plant feeding. However, facultative predators have some advantages for use in biological control, so management programs must minimize their risks and maximize their benefits.

Facultative predators have two main advantages for their use in biological control. One is their capacity to establish themselves early in the crop fields and thus prevent pests from building up high populations. This is a particularly positive trait of biocontrol agents in ephemeral crops such as annual crops that have to be recolonized every season. A second advantage of facultative predators concerns their possibility of feeding on plants when prey are at low density, thus preventing predator extinction or migration. Most observations on the role of plant feeding in early predator establishment and persistence on the crop relate to pollen-feeding predators such as many phytoseiid mites or anthocorids and coccinellids. For instance, the establishment and persistence of *Orius insidiosus* at low prey densities may be due to the ability of the predator to feed on pollen. Similarly, the failure and success of establishing and maintaining *O. laevigatus* on cucumber and pepper has been attributed to the lack or presence of pollen in the flowers, respectively. However, such behavior has proved to be less evident in non-pollen feeding predators. For instance, the foraging times of adults of the facultative predator *Dicyphus tamaninii* in cucumber patches of low and high prey density were compared and no differences were found even though this predator spent some time feeding on the plant.

The main disadvantage of facultative predators for biological control stems from their capacity to damage crops during plant feeding. Such a risk depends on various factors such as the relative amount of plant vs. prey feeding, the host-plant species and cultivar, the time of plant feeding and crop phenology, and the plant tissue fed on by the predator. Relationships between the amount of plant and prey feeding are a function of the nature of nutrients derived from plants by facultative predators. When the nutrients derived from the plant are complementary to those obtained in the prey, plant feeding occurs independently of prey feeding, as has been found in *Campylomma verbasci*, which feeds on apple fruitlets regardless of the availability of prey. When predators switch between plant and prey as alternative sources, the relationship between the two types of feeding will be negative. If prey are preferred to plants, phytophagy will only occur when prey are scarce. This is the case for the mirid bug *D. tamaninii*, which only feeds on tomato fruit when its main prey, greenhouse whitefly, is not abundant. On the other hand, plant feeding may increase with prey feeding when plants provide an element (e.g., water) that is needed for prey consumption, as noted for *D. hesperus*. Consequences of plant feeding on pest suppression, and thus success of facultative predators in biological control, are difficult to predict. Positive effects of plant feeding on facultative predator performance do not necessarily lead to enhanced biological control because per capita prey consumption may be reduced by ingestion of plant food. On the other hand, reduced per-capita prey consumption can be balanced by improved numerical response. Further investigations should address relationships between plant feeding, prey consumption and pest suppression.

Some facultative predators show clear preferences to feed on some crop species and cultivars, which are thus more exposed to their injury than the less preferred ones. Such is the case for *D. tamaninii*, which may damage tomato, but rarely French cucumber varieties. Similarly, *C. verbasci* nymphs injure apples – differently according to the variety – by feeding on the flower parts and fruitlets, whereas injuries are rarely observed on pears. The influence of plant-feeding timing on crop damage can be exemplified by *C. verbasci*, which causes the greatest damage during the bloom period, whereas little or no damage occurs after the fruit reaches a certain size. Finally, risk of crop damage is determined by the plant tissue that is preferred by the facultative predator. Feeding on pollen or extra floral nectar, for example, will rarely lead to high crop damage, whereas damage will be high if fruit is the plant part preferred by the facultative predator, or moderate or even nil if leaves are preferred.

Most facultative predators that have been studied are also generalists regarding prey range. As such, they have traditionally been considered as unable to regulate pests and thus of little use in biological control. This belief, however, is not fully supported by the theory, and is refuted by detailed studies on the role of single species or assemblages of generalist predators. In contraposition with specific natural enemies, generalist predators have positive traits – e.g., quick response to sudden pest population increases, high dispersal capacity, aggregative responses to patched prey distribution, ability to survive at low target-prey density – in essence, for adaptation to changing environments and prey densities, such as those found in ephemeral crops.

Conclusions

Facultative predation is defined as a special case of true omnivory in which plant and prey feeding co-occur within the same developmental stage so that individuals may choose between the two types of food. Facultative predation is relatively common among terrestrial predaceous arthropods as it is found in at least 18 orders and 84 families. The functions of zoophytophagy are still poorly understood, but there are many examples of fitness enhancement in the literature when diets mix vegetable and animal resources. The occurrence of facultative predation in food webs influences various interactions among components of the system and its contribution to stability may be contradictory.

The role of facultative predation in biological control has been neglected mainly due to the risks of damage to the crop. These are functions of various factors that should be better known in order to develop programs for managing facultative predator populations in order to minimize risks and benefit from their advantages as agents of conservation biocontrol. In particular, understanding when facultative predators switch from prey to plant consumption, and how biological control is affected, are of crucial importance.

Fairchild, Alexander Graham Bell

Alexander Fairchild, known to family and friends as Sandy, was born in Washington, DC, on August 17, 1906. His father, David Fairchild, was a botanist with the U.S. Department of Agriculture, who was interested in many aspects of natural history and had even published a book of insect photographs. It was he who encouraged Sandy's interest in nature. In 1921 and again in 1924 he visited Panama, where his father was working. From September 1924 to 1926 he accompanied his parents on a voyage to England and thence to Indonesia, with many stops and side-trips to parts of western Europe, and northern Africa. His opportunities to collect insects were not wasted, and he knew by then that he wanted to become an entomologist. His education to this point had been slight, and in 1926 he entered a preparatory school to acquire enough education to enter university. In 1928 he entered Harvard University, and received a B.S. degree in biology in 1932. At Harvard he encountered Charles Brues, Frank Carpenter, and Joseph Bequaert. One of the latter's interests was Tabanidae, and it was this that inspired Sandy's decision to study tabanid taxonomy for his graduate research at Harvard. Requirements for his Ph.D. degree were completed in 1934, but the dissertation was not completed until 1941. In the intervening 6 years, he held several jobs, and he married Elva Whitman in 1938. The first job (1934–1935) at the University of Florida's Agricultural Experiment Station at Monticello, was as entomologist studying control of insect pests of pecan. In 1935–1937 he worked for the International Health Division of the Rockefeller Foundation, studying insect vectors of "jungle" yellow fever in Brazil. With his wife, in September 1938, he moved to Panama, and began a 32-year association with the Gorgas Memorial Laboratory. His work continued to be on the taxonomy of biting insects (and ticks). He worked on phlebotomine sand flies, simuliid black flies, and tabanids. During World War II he held a U.S. army commission, and he focused on control of mosquitoes, black flies, and sand flies. This took him to Peru and Guatemala as well as Panama. In 1949–1950 he took a leave of absence to teach medical entomology at the University of Minnesota. In 1953, his work on tabanids progressed with visits to examine type specimens in the museums of London and Paris, in 1959 to Rio de Janeiro, and in 1964 to Denmark, The Netherlands, Belgium, Germany, France, Austria and Italy. This work on the type specimens was published in several papers, and in 1971 was crowned with his catalog of Neotropical Tabanidae. He retired from Gorgas Memorial Laboratory in 1970 and moved to Gainesville, Florida, where he was given an office which he used until 1988 for further tabanid studies (and for guidance to graduate students). Then, in 1988 he moved some blocks away to the Florida State Collection of Arthropods in a building of the Florida Department of Agriculture's Division of Plant Industry. Here, his large collection is housed. He died on February 10, 1994, a few days before putting the finishing touches to a revised catalog of Neotropical Tabanidae which, coauthored with J. F. Burger, was published later that year. Elva and their two children survived him.

Fairmaire, Léon

Léon Fairmaire was born in Paris on June 20, 1820. He received training in law, but the 1848 war ruined his family financially, so he became a public servant, eventually retiring as a hospital administrator. He became an active member of the Société Entomologique de France, was president, and honorary president from 1893 to 1906. Most of his very numerous publications (more than 450) contained unintegrated species descriptions of beetles, not just from Europe but from worldwide localities. However, with Laboulbène he published in 1854 the Coleoptera section of "Faune entomologique française," which was a major analytical work. He collaborated with Jacquelin du Val in "Genera des coléoptères d' Europe" and with Germain in "Coléoptères du Chili." His collection is housed at the Muséum National d' Histoire Naturelle in Paris. He died in Paris on April 1, 1906.

Fairyflies (Hymenoptera: Mymaridae)

ELISABETTA CHIAPPINI[1], JOHN HUBER[2]
[1]Universita Cattolica del Sacro Cuore, Piacenza, Italy
[2]Canadian Forestry Service, Ottawa, ON, Canada

The family Mymaridae is cosmopolitan, occurring in all terrestrial habitats and also in freshwater ponds and streams. The greatest generic diversity occurs in Australia, New Zealand and South America, but the greatest number of species is probably in tropical forests. The northern hemisphere, particularly Europe, is relatively depauperate, with about one quarter of the genera. Mymarids form an important component of any chalcid fauna, making up at least 5–10% of the individuals of Chalcidoidea collected by methods such as Malaise traps or pan traps.

This family is one of the few chalcids groups with a common name – fairyflies – derived from the fact that individuals of most of the species are such small insects that most people have never seen them. Indeed, the family includes the smallest recorded insect: the wingless, eyeless males of *Dichopomorpha echmepterygis* Mockford, that live as parasites in barklouse (Psocoptera) eggs. Four males lined up end to end would extend the diameter of a period.

Diagnosis

Mymaridae are small to minute, mostly delicate wasps that are 0.13–5.4 mm long (average 0.5–1.0 mm), usually without metallic coloration, and usually winged but sometimes wingless. The antennae are usually at least as long as the body, those of the females have a distinct club, and those of the males are filiform. The most important diagnostic feature distinguishing mymarids from other Hymenoptera is the head structure. Dark bars of cuticle (trabeculae) and associated sutures arranged in an H-like pattern divide the vertex and the frons into two distinct sclerites. Mymarid wings are also characteristic, with long fringes of hairs. The forewing usually has a distinct, backward projecting seta (hypochaeta) on the ventral surface of the wing blade in front of the marginal vein. The hind wing is almost always very narrow and stalked, and the wing membrane does not extend the wing base.

Classification

The family contains about 1,400 described species, currently classified in about 100 genera. These have been grouped into tribes and subfamilies based upon either tarsal number or metasomal attachment. Depending on which character is used first, the five tribes and two subfamilies will contain different groupings of genera. A different classification, with three subfamilies, has also been proposed, based on male genitalia. One fossil subfamily was also described, based on a fossil genus in Canadian Cretaceous amber. Regardless of the system followed, the previously proposed tribes and subfamilies need to be critically reviewed to take into better account the diverse fauna from the Australian region, which includes the most primitive genera.

Keys to genera are given by Annecke & Doutt (1961) for the world (outdated), Yoshimoto (1990) for the Western Hemisphere, Schauff (1984) for the Holarctic Region, Subba Rao & Hayat (1983) for the Oriental Region, and Noyes & Valentine (1989) for New Zealand.

The largest and most common genera are *Anagrus*, *Anaphes*, *Gonatocerus*, and *Polynema*. These four account for over half of all the species. Another five, *Alaptus*, *Camptoptera*, *Erythmelus*, *Ooctonus*, and *Stethynium* make up another quarter of the species.

Life History and Habits

Mymarids are found in all terrestrial habitats from deserts to rainforests, and in most cultivated areas. Members of the genus *Caraphractus* live in ponds where the adults use their wings as paddles to swim under water. Many species can be collected in great numbers using Malaise traps or pan traps, but because of their small size, they are rarely seen and are difficult to study when alive. As a result, there is a tremendous amount of new information to be discovered about every aspect of their life history. The biology of very few species (in *Alaptus*, *Anagrus*, *Anaphes*, *Caraphractus*, *Gonatocerus*, and *Polynema*) has been studied in detail. Otherwise, most information on hosts, habits, or microhabitats occupied can be obtained only from the little biological information associated with specimens in museum collections. Hosts are known for species in only about one quarter of the genera, mainly in the four largest ones. Many host records need confirmation, however. Host records suggest that Hemiptera, especially Auchenorrhyncha, are the most commonly used hosts, but this could be because this group has been better studied than other hemimetabolous orders. Other host orders known for certain are Coleoptera, Diptera, Odonata, Psocoptera, and Thysanoptera.

All mymarids are internal, solitary or gregarious, egg parasitoids of other insects. Development is completed entirely within a host egg. There may be several generations per year, often on different hosts. As holometabolous insects, mymarids are unusual because they often have two different types of larval instars and two different kinds of preimaginal development. In *Anaphes*, a secondary immobile sacciform larva follows an active first instar "mymariform" larva. In *Anagrus*, the opposite occurs – an immobile first instar followed by a second, very active "hystriobdellid" instar.

Economic Importance

Most of the biological literature on mymarids focuses on *Anagrus* and *Anaphes* species because these two genera are the most used in biological control against economically important pests. About ten species of mymarids have been used in classical biological control attempts against insect pests such as Curculionidae, Chrysomelidae, Cicadellidae and Delphacidae. *Anagrus* is most important in vineyards against leafhoppers (Cicadellidae) in North America and Europe (where up to 90% egg parasitism may occur) and against planthoppers (Delphacidae) and leafhoppers of rice in Asia and Central America. *Anaphes* spp. are among the most effective parasitoids of leaf beetles (Chrysomelidae) in cereals and carrots in North America, often with 50–90% parasitism rates. The best-known example of successful biological control using mym arids is that of *Anaphes nitens* Girault) against the eucalyptus snout beetle, *Gonipterus scutellatus* Gyllenhal, in parts of Africa, South America and southern Europe. *Anaphes iole* Girault and *Anagrus atomus* L. are commercially reared for sale and mass release against Lygus bugs and leafhoppers in North America and Europe, respectively.

Falciform

This term is used to express a sickle-shaped appearance.

Fall Armyworm, *Spodoptera frugiperda* (J.E. Smith) (Lepidoptera: Noctuidae)

JOHN L. CAPINERA
University of Florida Gainesville, FL, USA

The fall armyworm is native to the tropical regions of the western hemisphere from the United States to Argentina. It normally overwinters successfully in tropical areas; in the United States overwintering occurs only in southern Florida and southern Texas. The fall armyworm is a strong flier, and disperses long distances annually during the summer months. Thus, in the USA it is recorded from virtually all states east of the Rocky Mountains. However, as a regular and serious pest, its range tends to be mostly the southeastern states.

Life Cycle and Description

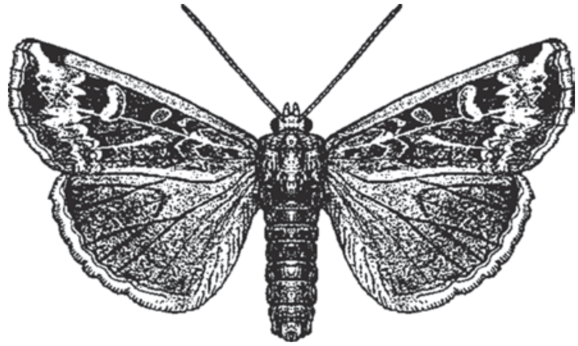
The life cycle is completed in about 30 days during the summer, but 60 days in the spring and autumn, and 80–90 days during the winter. The number of generations occurring in an area varies with the appearance of the dispersing adults. The ability to diapause is not present in this species. In northern areas, where fall armyworm moths do not appear until August, there may be but a single generation. The number of generations is reported to be one to two in Kansas, three in South Carolina, and four in Louisiana. In coastal areas of north Florida, moths are abundant from April to December, but some are found even during the winter months.

Egg

The egg is dome shaped; the base is flattened and the egg curves upward to a broadly rounded point at the apex. The egg measures about 0.4 mm in diameter and 0.3 m in height. The number of eggs per mass varies considerably but is often 100–200, and total egg production per female averages about 1,500. The eggs are sometimes deposited in layers, but most eggs are spread over a single layer attached to foliage. The female also deposits a layer of grayish scales between the eggs and over the egg mass, imparting a furry or moldy appearance. Duration of the egg stage is only 2–3 days during the summer months.

Larva

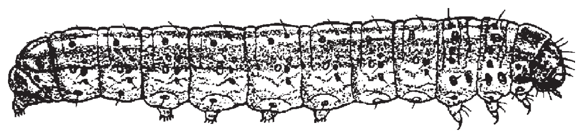
There usually are six instars in fall armyworm. Head capsule widths are about 0.35, 0.45, 0.75, 1.3, 2.0, and 2.6 mm, respectively, for instars 1–6. Larvae attain lengths of about 1.7, 3.5, 6.4, 10.0, 17.2, and 34.2 mm, respectively, during these instars. Young larvae are greenish with a blackhead, the head turning orangish in the second instar. In the second, but particularly the third instar, the dorsal surface of the body becomes brownish, and lateral white lines begin to form. In the fourth to the sixth instars the head is reddish brown, mottled with white, and the brownish body bears white subdorsal and lateral lines (Fig. 8). Elevated spots occur dorsally on the body; they are usually dark in color, and bear spines. The face of the mature larva is also marked with a white inverted "Y" and the epidermis of the larva is rough or granular in texture when examined closely. However, this larva does not feel rough to the touch, as does corn earworm, *Helicoverpa zea* (Boddie), because it lacks the microspines found in the similar appearing corn earworm. The appearance of this insect is quite variable. Duration of the larval stage tends to be about 14 days during the summer and 30 days during cool weather. Mean development time was determined to be 3.3, 1.7, 1.5, 1.5, 2.0, and 3.7 days for instars 1–6, respectively, when larvae were reared at 25°C.



Fall Armyworm, *Spodoptera frugiperda* (J.E. Smith) (Lepidoptera: Noctuidae), Figure 7 **Adult fall armyworm, *Spodoptera frugiperda*.**

Pupa

Pupation normally takes place in the soil, at a depth 2–8 cm. The larva constructs a loose cocoon, oval in shape and 20–30 mm in length, by tying together particles of soil with silk. If the soil is too hard, larvae may web together leaf debris and other material to form a cocoon on the soil surface. The pupa is reddish brown in color, and measures 14–18 mm in length and about 4.5 mm in width. Duration of the pupal stage is about 8–9 days during the summer.



Fall Armyworm, *Spodoptera frugiperda* (J.E. Smith) (Lepidoptera: Noctuidae), Figure 8 **Fall armyworm larva.**

Adult

The moths have a wingspan of 32–40 mm. In the male moth, the forewing generally is shaded gray and brown, with a triangular white spots at the tip and near the center of the wing (Fig. 7). The forewings of females are less distinctly marked, ranging from a uniform grayish brown to a fine mottling of gray and brown. The hind wing is iridescent silver-white with an narrow dark border in both sexes. Adults are nocturnal, and are most active during warm, humid evenings. After a preoviposition period of 3–4 days, the female normally deposits most of her eggs during the first 4–5 days of life, but some oviposition occurs for up to 3 weeks. Duration of adult life is estimated to average about 10 days.

Host Plants

This species seemingly displays a very wide host range, with over 80 plants recorded, but clearly prefers grasses. The most frequently consumed plants are field corn and sweet corn, sorghum, Bermudagrass, and grass weeds such as crabgrass, *Digitaria* spp. When the larvae are very numerous they defoliate the preferred plants, acquire an “armyworm” habit and disperse in large numbers, consuming nearly all vegetation in their path Field crops are frequently injured, including alfalfa, barley, Bermuda grass, buckwheat, cotton, clover, corn, oat, millet, peanut, rice, ryegrass, sorghum, sugarbeet, sudangrass, soybean, sugarcane, timothy, tobacco, and wheat. Among vegetable crops, only sweet corn is regularly damaged. Other crops sometimes injured are apple, grape, orange, papaya, peach, strawberry and a number of flowers. There is some evidence that fall armyworm strains exist, based primarily on their host plant preference. One strain feeds principally on corn, but also on sorghum, cotton and a few other hosts if they are found growing near the primary hosts. The other strain feeds principally on rice, Bermudagrass, and Johnson grass.

Damage

Larvae cause damage by consuming foliage. Young larvae initially consume leaf tissue from one side, leaving the opposite epidermal layer intact. By the second or third instar, larvae begin to make holes in leaves, and eat from the edge of the leaves inward. Feeding in the whorl of corn often produces a characteristic row of perforations in the leaves. Larval densities are usually reduced to one to two per plant when larvae feed in close proximity to one another, due to cannibalistic behavior. Older larvae cause extensive defoliation, often leaving only the ribs and stalks of cornplants, or a ragged, torn appearance. In corn, they sometimes burrow into the ear, feeding on kernels in the same manner as corn earworm, *Helicoverpa zea*. Unlike corn earworm, which tends to feed down through the silk before attacking the kernels at the tip of the ear, fall armyworm will feed by burrowing through the husk on the side of the ear.

Natural Enemies

Cool, wet springs followed by warm, humid weather in the overwintering areas favor survival and reproduction of fall armyworm, allowing it to escape suppression by natural enemies. Once dispersal northward begins, the natural enemies are left behind. Therefore, although fall armyworm has many natural enemies, few act effectively enough to prevent crop injury. Numerous species of parasitoids affect fall armyworm. The wasp parasitoids most frequently reared from larvae in the United States are *Cotesia marginiventris* (Cresson) and *Chelonus texanus* (Cresson) (both Hymenoptera: Braconidae), species that are also associated with other noctuid species. Among fly parasitoids, the most abundant is usually *Archytas marmoratus* (Townsend) (Diptera: Tachinidae). However, the dominant parasitoid often varies from place to place and from year to year.

Management

Sampling

Moth populations can be sampled with blacklight traps and pheromone traps; the latter are more efficient. Pheromone traps should be suspended at canopy height, preferably in corn during the whorl stage. Catches are not necessarily good indicators of density, but indicate the presence of moths in an area. Once moths are detected it is advisable to search for eggs and larvae.

Insecticides

Insecticides are usually applied to sweet corn in the southeastern USA to protect against damage by fall armyworm, sometimes as frequently as daily during the silking stage. In Florida, fall armyworm is the most important pest of corn. It is often necessary to protect both the early vegetative stages and reproductive stage of corn. Because larvae feed deep in the whorl of young corn plants, a high volume of liquid insecticide may be required to obtain adequate penetration.

Cultural Techniques

The most important cultural practice, employed widely in southern states, is early planting and/or early maturing varieties. Early harvest allows many corn ears to escape the higher armyworm densities that develop later in the season. Partial resistance is present in some sweet cornv arieties, but is inadequate for complete protection.

Biological Control

Although several pathogens have been shown experimentally to reduce the abundance of fall armyworm larvae in corn, only *Bacillus thuringiensis* presently is feasible, and success depends on having the product on the foliage when the larvae first appear.

Fall, Henry Clinton

Henry Fall was born in New Hampshire on December 25, 1862. In 1884 he received a B.S. degree from Dartmouth College, New Hampshire. For the next 5 years he taught physics and mathematics in Chicago schools, and for the 28 after that, physics and chemistry at schools in California. In 1917, he retired to New England. He had numerous hobbies, among which was collecting beetles. He accumulated about 250,000 specimens, described 1,484 species, and wrote 144 publications. He received an honorary Ph.D. degree from Dartmouth College in 1929 and died in Massachusetts in 1939. His insect collection and papers were left to the Museum of Comparative Zoology of Harvard University.

False Burnet Moths (Lepidptera: Urodidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

False burnet moths, family Urodidae, total only about 80 species, primarily Neotropical (mostly the genus *Urodus*), but with a few species in North America and in Eurasia (subfamily Galacticinae).

False Burnet Moths (Lepidptera: Urodidae), Figure 9 **Example of false burnet moths (Urodidae), *Urodus isthmiella* (Busck) from Panama.**

Only two subfamiles are named: Galacticinae and Urodinae. The family is in the superfamily Sesioidea in the section Tineina, subsection Sesiina, of the division Ditrysia. Adults small (10–37 mm wingspan), with head smooth-scaled; haustellum naked; labial palpi upcurved; maxillary palpi 1–2-segmented. Wings somewhat elongated (Fig. 9). Maculation mostly unicolorous in shades of gray, but a few with various spots; some with metallic-iridescence or lustrous scales. Adults may be crepuscular or mostly nocturnal, but a few possibly diurnal. Larvae are leaf webbers or skeletonizers, but few are known biologically. Pupation is in a specialized filigreed cocoon. Host plants known in Lauraceae, Leguminosae, Salicaceae, Sapotaceae, and Theaceae. A few are minor pests.

False Diamondback Moths (Lepidoptera: Acrolepiidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

False diamondback moths, family Acrolepiidae, include 96 species, mostly Palearctic. The family is part of the superfamily Yponomeutoidea in the section Tineina, subsection Tineina, of the division Ditrysia. Adults small (10–25 mm wingspan), with head smooth-scaled; haustellum naked; labial palpi upcurved; maxillary palpi 4-segmented. Wings elongated, with longer fringes (Fig. 10) on the pointed hindwings. Maculation various shades of brown with lighter markings. Adults are crepuscular or diurnal. Larvae mostly leafminers, but some are borers in seeds, stems and flower buds. Several hostplant groups are used, but mostly on Compositae. Very few are economic.

False Owlet Moths (Lepidoptera: Thyatiridae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

False owlet moths, family Thyatiridae, comprise 224 species from all regions (absent in Australia), but most are tropical Oriental (199 sp.); the actual fauna probably exceeds 275 species. Two subfamilies are recognized: Thyatirinae and Polyplocinae. The family is in the superfamily Drepanoidea, in the section Cossina, subsection Bombycina, of the division Ditrysia. Adults medium size (28–52 mm wingspan), with head scaling normal; maxillary palpi vestigial; antennae serrate or filiform; body robust. Wings elongate-triangular, mostly with acute forewing apex; hindwings subtriangular and rounded. Maculation varies but mostly (Fig. 11) shades of brown and gray, with various spotting and striae; sometimes more colorful and with

False Owlet Moths (Lepidoptera: Thyatiridae), Figure 11 **Example of false owlet moths (Thyatiridae), *Thyatira batis* (Linnaeus) from Taiwan.**

lustrous color patches or iridescence; hindwings mostly unicolorous and pale or dark. Superficially, the moths appear similar to owlet moths, thus the derivation of their common name. Adults are nocturnal. Larvae are mostly nocturnal leaf feeders. Host plants are recorded in a number of plant groups with forest trees, including Betulaceae, Caprifoliaceae, Cornaceae, Ebenaceae, Fagaceae, Juglandaceae, Rosaceae, and Salicaceae.

False Plume Moths (Lepidoptera: Tineodidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

False plume moths, family Tineodidae, include only 11 species, all from Australia. The family is in the superfamily Pterophoroidea in the section Tineina, subsection Tineina, of the division Ditrysia. Adults small (15–34 mm wingspan), with head scaling average; haustellum naked; labial palpi porrect; maxillary palpi 4-segmented. Forewings elongate (Fig. 12) and pointed termens can be falcate. Maculation mostly mottled shades of tan and gray. Adults possibly diurnal or crepuscular. Larvae are leaftiers, but most are not known biologically. Only recorded host plants are in Euphorbiaceae and Oleaceae.

Fat Body

An aggregation of large cells in the body cavity that stores metabolites (Fig. 13) and is a center of intermediary metabolism.

► Internal Anatomy

Fatty Acid Binding Proteins

NORBERT H. HAUNERLAND
Simon Fraser University, Burnaby, BC, Canada

The flight muscles of insects usually depend on fatty acids to fuel migratory flight. These fatty acids are obtained prior to migration from the diet and stored as triacylglycerol in the fat body. During flight, the lipids are converted to diacylglycerol that is released into the hemolymph and transported by the lipoprotein lipophorin to the flight muscle. There, diacylglycerol is hydrolyzed, and free fatty acids enter the muscle cell. Once fatty acids have crossed the plasma membrane, they need to move through the hydrophilic cytosol to the mitochondria where β-oxidation takes place. Because fatty acids are only poorly soluble in water, an intracellular mechanism in needed for their transport through the cytosol. Similarly, a transport process is required in the midgut cells, to facilitate the uptake of fatty acids from the diet and their subsequent delivery to the fat body. The intracellular transport of fatty acids is mediated by fatty acid binding proteins (FABPs).

FABPs are ubiquitous proteins in many vertebrate and invertebrate tissues, with separate genes encoding the FABPs found in various tissues. In insects, distinct FABPs have been identified and characterized in midgut cells and in flight muscle cells. Two midgut FABPs have been isolated from *Manduca sexta,* and their amino acid sequence and tertiary structure have been determined. Best characterized of the muscle FABPs is the FABP from flight muscles of locusts (*Schistocerca gregaria* and *Locusta migratoria*), but analogous proteins have also been found in Lepidoptera (*Helicoverpa zea*, *Acherontia atropos*), Hymenoptera (*Apis mellifera*), and Heteroptera (*Dipetalogaster maximus*). Their structures and function in insect metabolism are described below.

Locust muscle FABPs are very similar in their characteristics to mammalian FABPs. They are small, acidic proteins (Mr 15,000; pI 5.2–5.8) with a single binding site for fatty acids. Locust FABP was crystallized and its structure solved at 2.1 Å resolution. The protein displays the characteristic β-barrel motif common to all FABP. Two perpendicularly oriented β-sheets form a barrel-like structure; within this barrel the fatty acid binding site is located. The β-barrel itself is open to one side, but this (Fig. 14) opening is closed off by a helix-turn-helix motif. The overall structure is similar to the midgut FABPs from *Manduca sexta*, and their mammalian counterparts.

Locusts metabolize fatty acids at extremely high levels during migratory flight, and FABP is required for their rapid transport. Indeed, FABP is the most prominent flight muscle protein in mature adult locusts, amounting to as much as 20% of all cytosolic proteins. Yet, it is completely absent in immature locusts and in newly emerged adults. FABP expression commences immediately after adult ecdysis, and continues at high rates for almost 2 weeks. During this period, the FABP concentration gradually increases to its final concentration. This increase in the FABP concentration is concomitant with the

Fatty Acid Binding Proteins, Figure 14 Structure of locust muscle FABP. All FABPs have a typical beta-barrel structure. The binding site for a single fatty acid molecule is in the cavity formed by the beta-strands; the site is closed by a helix-turn-helix motif. Structure drawn from Brookhaven Protein Data Bank file ftp1.

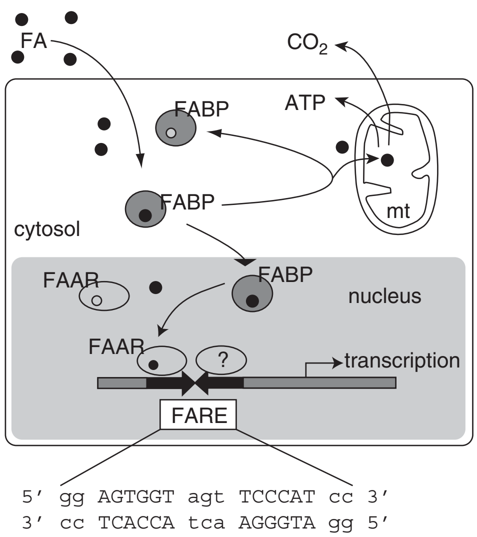
flight ability of the insect. Locusts cannot fly for longer time periods during the first 10 days of adult life, and one of the reasons for this may be the lack of an efficient intracellular fatty acid transport mechanism. Once FABP reaches a significant concentration, it becomes possible to use large amounts of fatty acids and hence to fly for long time periods. In mature adults, flight activity for periods exceeding 2 h further increases FABP expression. When 20 day-old locusts were exercised in tethered flight, the levels of FABP mRNA increased more than 12-fold. Flight times shorter than 1 h, however, had no influence on FABP expression. The latter flights are fueled by carbohydrates, while longer flight periods depend on the β-oxidation of lipids, and hence an efficient fatty acid transport. It was shown that a similar, strong accumulation of FABP mRNA could be induced by adipokinetic hormone, which mobilizes fatty acid from the fat body and stimulates their transport to the flight muscle, and even by an increased lipid supply alone. Thus, it appears that FABP expression is stimulated when the concentration of free fatty acid in the cell exceeds the amount of available FABP.

The molecular mechanisms by which this activation occurs have been partially elucidated.

The promoter of the FABP gene of the locust contains a fatty acid response element that is necessary for the induction of gene expression by fatty acids. The fatty acid response element is a 19 basepair inverted repeat with two hexanucleotide halfsites interspersed by three nucleotides, similar to steroid hormone response elements. It is likely that two different factors bind to the fatty acid response element, at least one of these is activated by the binding of long chain fatty acids. Fatty acids (Fig. 15) are required for full activity, and their availability to nuclear proteins depends on the intracellular concentration of FABP. FABP appears to have free access to the nuclear lumen, and thus this proteins contribution must be considered.

While for many FABP-types the exact functions have not been elucidated, it is generally accepted that muscle FABP serves the following three purposes: FABP increases the solubility of fatty acids and thus lead to a more rapid transport through the cytosol. Moreover, it serves as an intracellular acceptor for free fatty acids that have passed through the plasma membrane. Without such an acceptor, fatty acids would mostly remain in the membrane and not dissolve in the aqueous cytosol. Finally, the binding protein acts as a buffer for free fatty acids, both to assure the presence of fuel molecules prior to muscle activity, and to prevent the build-up of high concentrations of unbound fatty acids afterwards. With their hydrophilic carboxy-group and the hydrophobic tail, free fatty acids are amphiphilic molecules that, by detergent-like interactions, could destroy membrane structures within a muscle cell. The extremely high concentrations of FABP found in locust flight muscle support these functions, and the up-regulation of FABP gene expression by fatty acids represents an elegant physiological mechanism to handle high fatty acid fluxes safely and efficiently.

► Locomotion and Muscles



Fatty Acid Binding Proteins, Figure 15 Regulation of the locust muscle FABP gene. Shown is a schematic drawing of a muscle cell. Most of the fatty acid is bound by FABP and delivered to the mitochondrion for beta-oxidation. FABP also acts as a sensor of the fatty acid concentration in the nucleus. In the presence of an excess of fatty acid, nuclear transcription factors are activated, and the FABP gene is expressed. Abbreviations: FA = Fatty acid, FAAR = fatty acid activated receptor, FARE = fatty acid response element, mt = mitochondrion.

A family of thrips (order Thysanoptera).

► Thrips

Fauvel, Charles Adolphe Albert

Charles Adolphe Albert Fauvel was born in Caën, France, in 1840 and died there on January 4, 1921. A lawyer by profession, he was a prolific describer of insects, founding the journal "Revue d' Entomologie" as an outlet for many of his works. By 1900, under the name Albert Fauvel, he had published at least 246 papers, mostly on Coleoptera, and on Staphylinidae in particular. His major book was "Faune gallo-rhénane," in several volumes, which, unfortunately, was never completed. Other major works are on the staphylinid faunas of northwestern Africa, Australia and Polynesia, the Moluccas and New Guinea, and New Caledonia, material for which he obtained from collectors in those areas. In 1910, he abruptly stopped publication of Revue d' Entomologie, withdrew from scientific contacts, and remained secluded until his death. He described 96 genera and 1,851 species of Staphylinidae. His collection is now in the Institut Royal des Sciences Naturelles de Belgique.

Feather-Winged Beetles

Members of the family Ptilinidae (order Coleoptera).

► Beetles

Feces

The excrement of insects produced by the digestive system and passed out the anus. It is also known as excreta. When it is mixed with an abundance of indigestable plant fragments it is commonly called frass.

► Frass
► Alimentary Canal
► Digestion

Fecundity

The reproductive capacity of an organism, often taken to mean the number of eggs produced by a female during her lifetime (contrast with fertility).

Feeding Deterrents

Chemicals that inhibit feeding but do not necessarily repel insects

► Host Plant Selection by Insects

Felt, Ephraim Porter

Ephraim Felt was born in Massachusetts on January 7, 1868. He graduated from Massachusetts State Agricultural College with a B.Sc. degree in 1891 and then became assistant to Fernald and studied the gypsy moth. In 1892 he was awarded a fellowship to Cornell University, studied with Comstock, and received a D.Sc. in 1894. From 1893 to 1895 he taught natural science at the Clinton Liberal Institute, and then worked in the office of the State Entomologist (Fig. 16) of New York, becoming State Entomologist (a job he held for 30 years) when the incumbent, J.A. Lintner, died in 1898. In 1904 appeared in print his "The mosquitoes or Culicidae of New York State" and in 1906 his two-volume "Insect affecting park and woodland trees." His work on gall midges (Cecidomyiidae) was copious, and in his life he described 1,060 species of them, publishing in 1940 "Plant galls and gall makers." Additionally, he wrote several books on trees, and worked on wind-borne insects, the role of insects as vectors of human diseases, and gypsy moth. He was editor of Journal of Economic Entomology from 1908 to 1935, an active member of the New York Entomological Society, a frequent contributor to the New York Times, and

Felt, Ephraim Porter, Figure 16 **Ephraim P. Felt.**

entomological editor of "Country Gentleman." He married in 1908 and had four children. He died on December 14, 1943.

Femur (pl., femora)

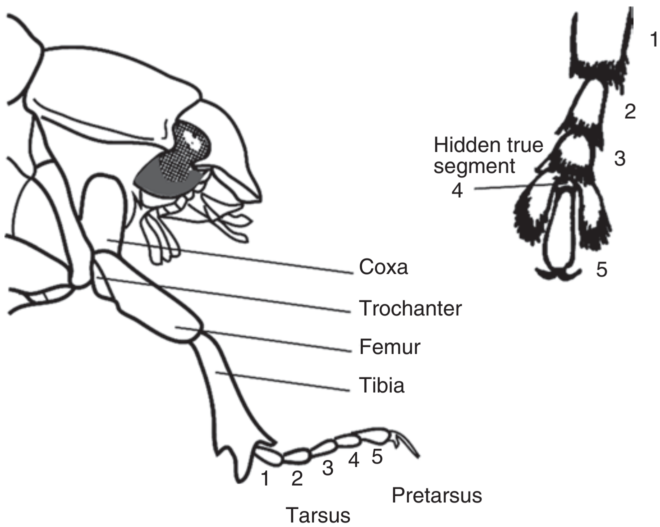
A segment of the leg between the trochanter and tibia. The third leg segment and one of the two largest portions (Fig. 17) of the insect leg, often expanded to enhance leaping or prey capture.

► Legs of Hexapods

Fenichel, Sámuel

GEORGE HANGAY
Narrabeen, NSW, Australia

Sámuel Fenichel was born on the 25th of August 1868 in Nagyenyed, Alsó-Fehér Shire, in Transylvania, then Hungary, now Romania. He received excellent education in natural history in the highly respected Bethlen College of his hometown. In 1888, he was invited to join the Museum of Archaeology in Bucharest, Romania. For 2 years he lead the excavations and research of the ruins of Tropea, a fortress and settlement built by the Romans in Dobrudja (Romania). During this work he met Albert Grubauer, a naturalist from Munich, who was planning a zoological expedition to New Guinea. Fenichel was young, with a keen interest of natural history and an expert preparator of zoological specimens; therefore, he seemed to be an ideal companion to Grubauer, who consequently asked him to join his expedition. Fenichel resigned from his museum post and travelled to Budapest (Hungary) where he received further training in the Hungarian National Museum. The museum also commissioned him to collect zoological and ethnographical material for its collections. Grubauer and Fenichel arrived to German New Guinea (Kaiser Wilhelmsland) in December 1891. Fenichel started to work immediately by collecting zoological specimens, mainly insects, but Grubauer fell ill and left the island. He also took with him the 200,000 Marks, which were to support the expedition, leaving only 100 Marks for Fenichel. Despite this setback, Fenichel stayed and continued his work alone. He concentrated on entomological work mainly, accumulating more than 25,000 specimens. He explored the country around Astrolabe Bay, Friedrich-Wilhelmshafen (today Madang), Konstantinhafen, Erima and Stephansort. He collected in the Finisterre Mountains, where only two other European naturalists worked before him, the Russian N.N. Mikhulo-Maklai (1846–1888) and the German Otto Finsch (1839–1917). As most field zoologists of that age, he also collected ethnographical objects, the number of items in his collection were over 3,000. Most of Fenichel's specimens reached the Hungarian National Museum and a few went to his Alma Mater in Nagyenyed. His promising carrier as an entomologist and



Femur (pl., femora), Figure 17 Leg of a beetle (Coleoptera: Scarabaeidae) leg showing its component parts, and a close-up of one type of beetle tarsus (foot).

naturalist was cut short by malaria. Fenichel died in Stephansort on the March 12, 1893. A memorial plaque on the wall of the Port Moresby University commemorates the life and work of Sámuel Fenichel, the first Hungarian entomologist in New Guinea.

Fennah, Ronald Gordon

Ronald Fennah was born in Ludlow, England, in 1910. He graduated from Cambridge University in 1935 with a bachelor's degree and was appointed lecturer in zoology at the Imperial College of Tropical Agriculture, Trinidad. While employed there, he was seconded in 1937–1942 as citrus entomologist and in 1942–1948 as food crop pests entomologist to the Windward Islands, and then (1948–1951) entomologist to the Trinidad Department of Agriculture and (1951–1958) entomologist to the cocoa research scheme, Trinidad. These postings involved him in surveys for citrus pests, a (1947) book "The insect pests of food crops in the Lesser Antilles," trials of the resistance of sugarcane varieties to froghoppers (Cercopidae), and studies of the insect pests of cacao in relation to cacao physiology. In 1944, he tested DDT against insect pests of food crops. To test its safety to humans, he deliberately ingested DDT, and painted an emulsion on his skin, during a period of 13 months. He detected no effect. In Trinidad, he developed an interest in the taxonomy of Hemiptera and began publishing on this subject, ultimately producing over 120 papers on this subject, mostly on Fulgoroidea. In 1958 he was appointed assistant director of the Commonwealth Institute of Entomology in London, its director in 1969, and he retired in 1975. Retirement did not stop his taxonomic contributions. Cambridge University awarded him an Sc.D. degree in 1967. He died on August 19, 1987, survived by his wife, Louie May.

Feral

Animals or plants that have escaped domestication and reverted to natural behavior. In entomology, this is used most commonly in reference to swarms of honey bees that escape domestication.

Fergusoninidae

A family of flies (order Diptera).
► Flies

Fernald, Charles Henry

Fernald, Charles Henry, Figure 18 **Charles H. Fernald.**

Charles Fernald was born in Maine on March 16, 1838. At 21, he entered Maine Wesleyan Seminary with the intent of becoming a ship's captain. After 3 years of study he joined the Union Navy and served 3 years during the American Civil War. In the Navy, he also was able to take courses, completing the requirements of Bowdoin College for a B.A. degree, which he received. After the war he became principal of Litchfield Academy, then of Houlton Academy, both in Maine. In the last of the positions, he studied geology, botany, zoology and entomology on his own, and then received in 1871 a M.A. degree from Bowdoin College. That same year, he was made a professor of natural history in Maine State College. In addition to teaching, he studied and published on insects. In 1886 he moved to Massachusetts Agricultural College as professor of zoology and lecturer (Fig. 18) in veterinary science, and occupied this position until his retirement in 1910. The Hatch Act made Federal funds available to state agricultural colleges for experiment stations, and Charles was appointed entomologist to the Massachusetts station. This gave him responsibility for research in applied entomology. A main part of his research was aimed at the gypsy moth, whose presence in Massachusetts was due to its importation by Leopold Trouvelot and subsequent escape from confinement. This research, and Fernald's teaching of entomology made Massachusetts a center for the training of entomologists. His wife, Maria, made her own mark on entomology, with moths of the families Tortricidae and Tineidae, and especially by publication of "A catalogue of the Coccidae of the world." Their son, Henry Torsey Fernald, born on April 17, 1866, in Maine, became first head of the Department of Entomology at Massachusetts Agricultural College in 1899 while his father was professor of zoology. Charles Fernald died on February 22, 1921.

Fern Scale, *Pinnaspis aspidistrae* (Signoret) (Hemiptera: Diaspididae)

These scale insects affect the foliage and fruit of citrus.

► Citrus Pests and Their Management

Ferris, Gordon Floyd

Gordon Ferris was born in Kansas on January 2, 1893, then moved to Missouri with his family and four siblings. His mother died there in childbirth. Gordon moved at the age of 13 to live with his brother Leslie on a farm in Kansas. In 1909, he entered Ottawa University in Kansas but soon dropped out and went to work for a power company in Colorado. The power company funded education for its employees, and in 1912 sent Gordon to Stanford University in California. In 1917, he obtained the degree of M.A., became a teaching assistant there, and remained there for the rest of his 42-year academic career. He was a taxonomist and teacher. He worked on Anoplura, Mallophaga, Coccoidea, Diptera-Pupipara, Cimicidae, and Polyctenidae, being an excellent collector of the insects that he studied. His collecting trips took him throughout the southwest of the USA, and to Mexico and China, and his museum study trips took him to the Natural History Museum (London) and to Cambridge University. He published 275 works, of which his 4-volume "Atlas of the scale insects of North America" (1950–1953) is one of the most outstanding. He died on May 21, 1958.

Ferruginous

A rusty or reddish brown color.

Fertility

The number of offspring produced, often taken to mean the number of eggs that hatch (living offspring) during the lifetime of the female. (contrast with fecundity)

Fertilization

The union of the haploid male and female gametes to produce a diploid zygote, marking the start of the development of a new individual and the beginning of cell differentiation.

Festoons

Uniform rectangular regions, separated by sulci (grooves), and located on the posterior margin of most hard ticks.

Fetid

A disagreeable or offensive odor to humans, though such odors may be quite attractive to insects. Such odors are often associated with decaying animals or plant material, but some plants produce fetid odors to attract pollinators.

Fibroin

A proteinaceous component of insect silk. It usually is covered by seracin.

► Silk

Fideliidae

A family of wasps (order Hymenoptera).

► Wasps, Ants, Bees and Sawflies

Field Capacity

A property of soils. Soil that contains all the moisture it can retain after draining freely under gravity. Saturated soil.

Field Crickets

A subfamily of crickets (Gryllinae) in the order Orthoptera: Gryllidae.

► Grasshoppers, Katydids and Crickets

Fig Rots

Several fungi affect fig fruit, causing the fruit to rot. Insects are implicated in causing these diseases.

► Transmission of Plant Diseases by Insects

Fig Wasps

HANNAH NADEL
USDA-ARS, San Joaquin Valley Science Center, Parlier, CA, USA

Miniscule wasps (order Hymenoptera) that breed exclusively in association with the flask-shaped floral receptacle (fig, syconium) of fig plants (*Ficus* spp.). The group is composed of about 3,000 species of Chalcidoidea in the families Agaonidae, Pteromalidae, Torymidae, Ormyridae, Eurytomidae, and the unplaced subfamilies Epichrysomallinae and Sycophaginae. The Agaonidae are mutualistic partners of figs, pollinating the flowers while laying their eggs in the ovules inside the receptacle. The other species feed on syconial tissues, parasitize the Agaonidae or each other, or parasitize a small number of other insects developing in the syconia. Non-pollinators mostly oviposit from the exterior of the fig wall, and hence have long ovipositors that evolved in length to match the thickness of the fig wall. Some resemble pollinators in form and habit, entering the syconia to lay their eggs. Many have apterous or dimorphic males. Only 20–30% of fig wasp species have been described. A few species of Braconidae (Ichneumonoidea) have also been reared from syconia.

► Wasps, Ants, Bees and Sawflies
► Agaonidae

Filariasis

Disease caused by infection with nematodes (filarial worms), and transmitted by flies.

► Dirofi lariasis
► Onchocerciasis
► Human Lymphatic Filariasis (Elephantiasis)

File

A file-like ridge on the underside of the tegmina, near the base. The file is part of the stridulating mechanism in katydids and crickets.

Filiform

Thread-like, slender, and nearly uniform in diameter. A term usually used in reference to antennae.

► Antennae of Hexapods

Filter Chamber

A modification of the gut in sap-feeding insects that allows much of the water and some of the excess carbohydrate ingested by the insect to bypass the midgut, resulting in production of honeydew.

► Alimentary Canal and Digestion

Filter Feeders

Insects in aquatic communities that collect particulate matter from water with the aid of mouth brushes, leg brushes, or webs.

Filter Rearing System for Sterile Insect Technology

CARLOS CACERES
International Atomic Energy Agency, Seibersdorf, Austria

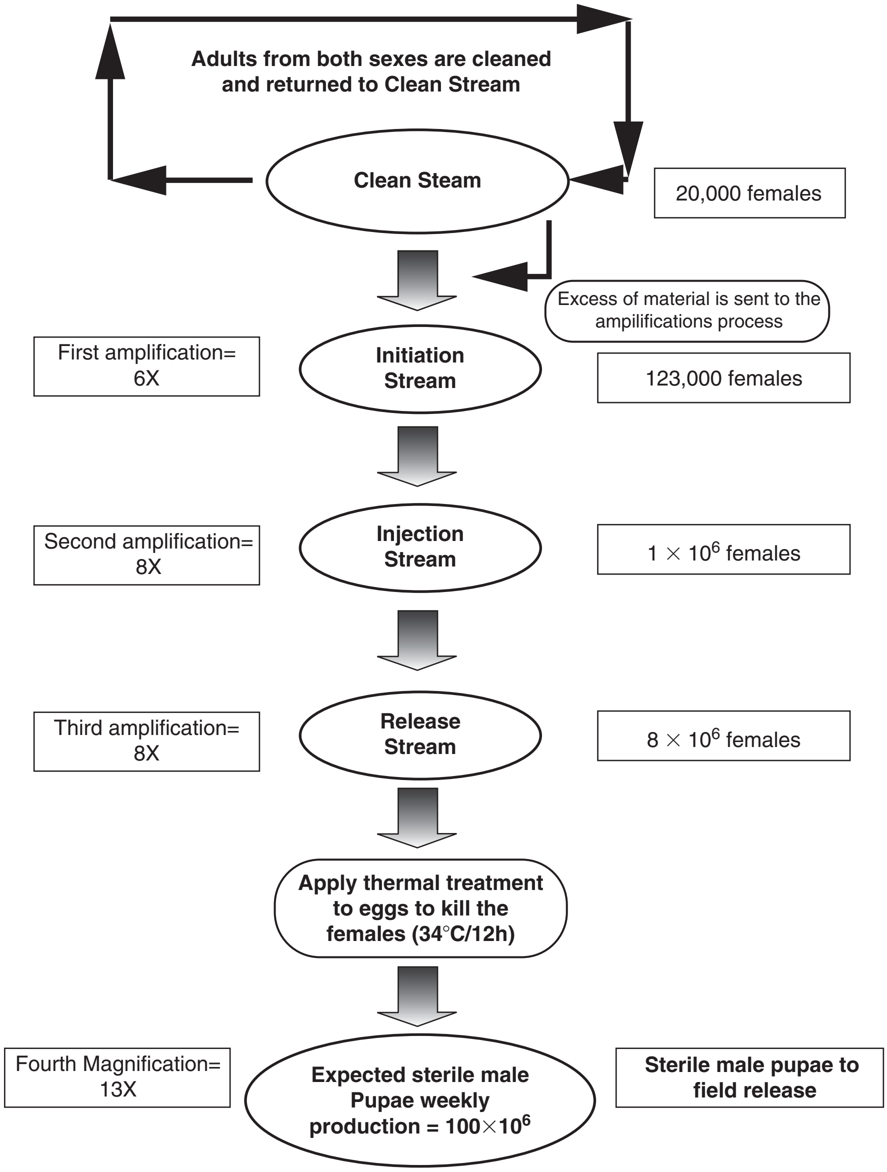
Genetic sexing strains (GSS), which produce only males, are now being used on a large scale for the control of the medfly, *Ceratitis capitata* using the sterile insect technique (SIT). The use of these strains has had a major impact on the overall efficiency of the technique by increasing significantly the amount of sterility induced in field populations and by reducing operational costs. GSS are based on the use of male linked chromosomal translocations, which make possible the linkage of selectable marker genes to the male sex. Two selectable genes have been incorporated into functional sexing strains specifically, *white pupae* (*wp*), which allows males and females to be discriminated based on pupal color, and *temperature sensitive lethal* (*tsl*), which allows the females to be killed by an increase in ambient temperature. GSS are not 100% stable due to the occurrence of a low level of genetic recombination between the selectable marker and the translocation breakpoint. This results in the loss of the sexing characteristics of the strain.

The Filter Rearing System (FRS) was designed to solve the problem of genetic recombination (Fig. 19) when GSS are mass reared for SIT programs. The principle of the FRS is to maintain a small colony of a GSS, with zero recombination, which can continually be amplified to rear a large colony from which males are produced for irradiation and release. In principle, the FRS creates a one-way system for production to ensure that any recombinants are not reintroduced into the colony. The FRS also has other applications for improving the quality of mass reared insects.

In a GSS, males emerge from brown pupae and females from white pupae. In the filter, any flies emerging from the wrong colored pupae are removed every generation. Pupae are separated by color 2–3 days before adult emergence and individual pupae are placed in plastic grids with 100 holes/grid. The holes are 1 cm^2. The grid is covered with a transparent plexiglass lid and the bottom of the grid is sealed with metal gauze. After adults have emerged, they are examined under a magnifying glass and recombinant individuals are killed with a burst of compressed air through the metallic grid. The adult flies emerging from the correct pupal color are transferred to a cage to start the amplification of the population for the subsequent release of sterilized males.

Since it is impossible to screen the very large colonies for operational programs the FRS is based on the sequential amplification of a relatively small backup colony which is cleaned of recombinant individuals. The backup colony (Clean Stream) must be cleaned each generation, but must be large enough to produce sufficient offspring to provide for itself and to initiate the colony amplification sequence. The number of amplifications (Initiation and Injection Streams) depends upon the size of the backup colony in relation to the size of the final colony (Release Stream) required to produce the desired number of males for release, and the rate at which recombinants accumulate at each amplification stage.

The FRS has now been introduced into all of the facilities rearing medfly GSS where it has been shown to be a viable and operational



Filter Rearing System for Sterile Insect Technology, Figure 19 **The continuous Filter Rearing System (FRS) for medfly male-only production.**

system to guarantee the accurate production of only males (> 99.5% males) during release operations.

Filth Fly Parasitoids (Hymenoptera: Pteromalidae) in North America

KEVIN D. FLOATE[1], GARY A. P. GIBSON[2]
[1]Agriculture and Agri-Food Canada Lethbridge Research Centre, Lethbridge, AB, Canada
[2]Agriculture and Agri-Food Canada Eastern Cereals and Oilseeds Research Centre, Ottawa, ON, Canada

Chalcidoid wasps (Hymenoptera: Chalcidoidea) of the family Pteromalidae comprise the principle parasitoids of pest flies (Diptera) associated with livestock. At least 15 native species of filth fly parasitoids have been identified and a few foreign species have been introduced into North America for classical biological control. Species reported to occur, or which may occur, in North America are listed in Table 2.

Several surveys have been conducted throughout North America to determine species compositions, which appear to be influenced by climatic conditions. Species of *Spalangia* typically are associated with warmer regions and, with species of *Muscidifurax*, dominate the parasitoid complexes in the United States and parts of Canada. The non-chalcidoid species, *Phygadeuon fumator* Gravenhorst (Hymenoptera: Ichneumonidae), also is important in northeastern United States and Canada, and *Trichomalopsis sarcophagae* (Gahan) is common in Alberta, Canada. Microhabitat conditions, such as type of substrate, moisture and light levels also influence species composition within different regions.

Natural levels of parasitism typically are low, with season-long values usually <5%. To enhance parasitism, several species have been commercialized for sale as biological control agents, primarily for the house fly, *Musca domestica* L. and the stable fly, *Stomoxys calcitrans* (L.) (Diptera: Muscidae). Commercialized species include *Muscidifurax raptor* Girault & Saunders, *M. raptorellus* Kogan & Legner, *Nasonia vitripennis* Walker, *Spalangia endius* Walker and *S. nigroaenea* Curtis. These species are mass-reared by insectaries in the United States and shipped to customers throughout North America. Parasitoids normally are packaged in units of 10,000 parasitized house fly pupae, which may contain up to 80,000 parasitoids depending on the species mix. *Muscidifurax raptorellus* and *N. vitripennis* are gregarious species that produce several offspring per parasitized pupae. A common mix includes species of *Muscidifurax* and *Spalangia*. *Spalangia* are reported to search deeper into the substrate for fly pupae than do *Muscidifurax*, but are less active at cooler temperatures than are *Muscidifurax*.

Purchased parasitized fly pupae are scattered in fly breeding sites, such as rotting piles of hay, straw or bedding, accumulations of manure, or spilled silage. Wasps emerging from the pupae then locate and parasitize natural fly pupae in the surrounding area. Release studies in feedlots show that *M. raptorellus* may disperse out to 100 or more meters to locate hosts. Because the flies have a shorter generation time and produce more eggs than the wasps, releases of the wasps are recommended every week or every second week throughout the fly season. Recommended release rates are based either on a per unit area, or on the number of animals in the livestock facility. Effective fly control relies upon a regular program of sanitation to remove fly breeding sites and possibly the occasional use of insecticides to target adult flies.

Research to improve the efficacy of these wasps as biological control agents of filth flies includes: (i) surveys to locate more effective species for commercialization, (ii) matching the release of commercialized species to regional climates, (iii) optimizing release rates and (iv) reducing the costs of mass-production. Research also is underway to increase the production of female wasps using infections of bacteria in the genus *Wolbachia*.

Finger-Net Caddisflies

Members of the family Philopotamidae (order Trichoptera).

► Caddisflies

Fingerprinting

DNA fingerprinting relies on the presence of simple tandem-repetitive sequences that are present throughout the genome. The regions show length polymorphisms, but share common sequences. DNA from different individuals is cut and separated by size on a gel. A probe containing the core sequence is used to label those fragments that contain the complementary DNA sequences. The pattern of each gel is specific for a given individual, and can be used to establish parentage.

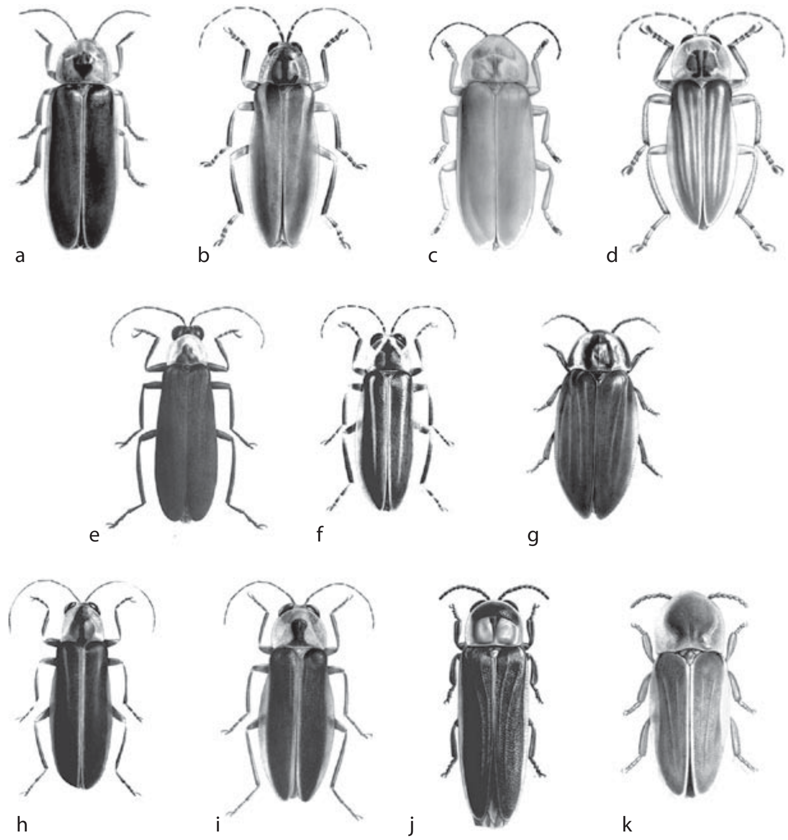
Fireflies (Coleoptera: Lampyridae)

JAMES E. LLOYD
University of Florida, Gainesville, FL, USA

Fireflies occur on all continents except Antarctica, and are best known for the biochemical light they emit. In some regions of North America the common flashing species are known as lightningbugs; in rural Jamaica fireflies are called blinkies but in Kingston they are peenywallies; in Latin America they are luciernaga; in Japan hotaru; in Great Britain and northern Europe, including Hamlet's Denmark (Act 1, Scene V), the single or more common resident species *Lampyris noctiluca* (L.) is known as "the glowworm" ("Glühwürmchen"); and in New Guinea pidgin they are "binatang em i gat lait bilong as." Fireflies appear in folk culture and tradition old and recent around the world: an Asian myth relates a burning grass origin, and one from Europe says that if a glowworm enters the house it warns of impending infant death; in colonial Hispanic America fireflies were used and subsequently outlawed as signals for romanti c trysts (this is more commonly told of luminescent click beetles, family Elateridae). North American children capture them at twilight and put them in jars for bedtime viewing, though some sell them to a company that extracts and processes their light-emitting chemicals for use in research and medicine. Another company transplanted the key gene (for the enzyme, luciferase) from the most common lawn firefly into a bacterium, simplifying commercial production and saving millions of fireflies – and hopefully returning childhood perspectives to the poetic value of fireflies. Children catching fireflies and looking at them in jars, and flying fireflies attracted to glowing time-pieces are TV images with commercial appeal.

With their presumptive kin (superfamily Cantharoidea) fireflies are sometimes informally referred to as leather-winged beetles, from the pliable texture of their wing-covers (forewings, elytra). This group includes soldier beetles, net-winged beetles, giant glowworm beetles, long-lipped beetles, false-fireflies (respectively, beetle families Cantharidae, Lycidae, Phengodidae, Telegeusidae, certain Omethidae), and a few additional rare and unfamiliar forms. Because ever more is learned of DNA content and patterns within and among these taxa, expect that significant changes in formal classification and theoretical framework may be forthcoming.



Fireflies (Coleoptera: Lampyridae), Figure 20 **Some fireflies: (a) *Photinus pyralis* (L.) is the best known firefly in eastern North America, and often appears in considerable numbers. It is the species children chase across lawns at twilight. Its distinctive dipping then rising yellow flashes earned it the appellation "Big Dipper Firefly." (b) *P. pennsylvanica* (DeGeer) was the name used for most North American *Photuris* species from early in the nineteenth century until 1951. Through studies of male flash patterns, several additional species were recognized. The firefly with a distinctive dot-long-dash pattern now claims the DeGeer name of 1774. (c) *Photinus pallens* (Fabricius), a common "blinky" in Jamaica, forms huge aggregations on Asian ginger lilies in fallow fields. (d) An unusual six-lined *Photuris* from Guatemala and southern Mexico. (e) An unnamed montane Photurinae from Colombia, South America, with wasp-like coloration suggesting it may be exposed to potential predators during daylight. (f) *Photuris lloydi* McDermott is presently known with certainty only from its type locality in a hydric hammock in the highlands of south-central Florida. (g) *Ellychnia corrusca* (L.) pupates in the fall and adults are found on tree trunks in the dead of winter, though mating occurs the following spring. (h) Several species with the general appearance of this Florida "variety" of *Photuris versicolor* (Fabricius) occur by the hundreds/thousands in various "grasslands" from the Atlantic to Kansas. (i) *Photuris frontalis* LeConte is one of the flash-synchronizing species in North America. Along with five other species, it forms a distinctive subset of North American *Photuris*. (j) *Photinus collustrans* LeConte, Florida's twilight lawn firefly, is identical in appearance to this one, except the yellow inner-margins of its elytra are continuous around the apices. This one, *P. tanytoxus* Lloyd, has green light and flies later in the evening. (k) *Pleotomodes knulli* Green, an ant-living firefly, occurs throughout peninsular Florida. A congener is found only in central Florida and another in Arizona.**

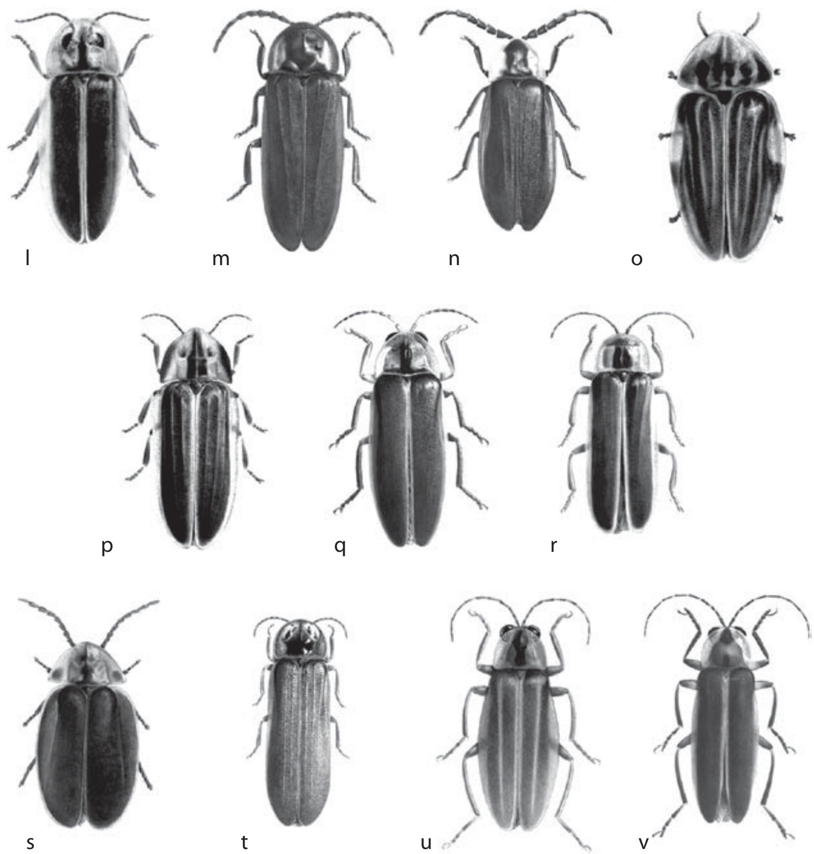
Worldwide, nearly 2,000 lampyrid species have been formally described and named in nearly 80 genera (Figs. 20 and 21). About half of these occur in tropical America and many also occur in tropical Asia, but, curiously, few are known from tropical Africa. The actual number of firefly species in the world, if competent museum naturalist/taxonomists had the opportunity to make a complete collection, might be nearly 8,000. About 120 species in 17 genera are presently named from North America, but in actuality, based on extensive field and bench study, there could be as many as 225 nameable entities in 19 genera, with several additional transitional and problematic populations and reports. The situation will be properly outlined only after their mating signals, ecology, and population inter-connections and genetics are studied in intimate detail. What is especially exciting about such research is that, because some species are so localized, a new (i.e., undescribed) species may be encountered at any time, as each unexplored valley or ancient lake bed is reconnoitered by a taxonomist-fireflyer (Fig. 22).

Carl Linnaeus, the Swedish originator of the basic system used for organismic classification, named the first North American species in 1758, and one of them was the ubiquitous *Photinus pyralis* (L.). The oldest actual firefly remnants presently known from North America are pronotal sclerites of specimens that are closely related to, if not actually, ancestors of today's day-active *Ellychnia corrusca* (L.). These fossils were found in post-glacial sphagnum bogs in southern Ontario, Canada, and dated at about 10,000 B.P. (before the present). Much older remnants of fireflies occur in amber from the Dominican Republic, including specimens that resemble *Robopus* species that now live on Caribbean islands, and a pair in a sexual coupling that has endured about 19 million years.

Although some Florida residents believe that fireflies don't occur in their state, more species are present in Florida than in the north, but conspicuous flashing displays that catch the human eye are rare. Georgia and Florida each have at least 56 species, and as easily seen from a good atlas (one with climate, vegetation, and topographic maps), these two states have a diversity of ecological situations. A 100-mile-wide swath along the border between the two states from the Atlantic to the Gulf may be the richest firefly space in North America. Northern and western states have fewer species. Fireflies in the central Atlantic and midwestern states get more attention because a few rather large species flourish in urban parkland, suburbs, farmland, and other disturbed grasslands, and these frequently flash in huge space-sweeping, eye-catching populations (Fig. 23).

The grandest of all flashing panoramas in the world occur in tidal swamps of mangrove and nippa palm in Southeast Asia, where species of the bentwinged fireflies (genus *Pteroptyx*) gather by the thousands, perhaps formerly in the millions, in broadleaved trees and bushes along brackish waterways and a little inland along canalways. Native boatmen once used 'firefly trees' as navigational beacons, but now there are industries and human habitations occupying the shorelines of many rivers. Such developments are sources of pollution, which flows downstream and sometimes returns on the incoming tide, and which can seep into and poison adjacent bentwing firefly habitat. In recent years, interest in preserving these fireflies has been expressed by local governments.

Some of these species, such as *Pteroptyx malaccae* (Gorham) and *P. tener* (E. Olivier) invite a 'beacon' appellation because perched males emit their flashes in precision synchrony – which western 'scientific' thought once considered to be 'unnatural,' hence not to be believed, and there is a considerable and occasionally silly literature on the subject. Visitors to Malaysia can take a tourist boat ride on the Kuala Selangor (River) and see synchronizers up close. Males of other tree-swarming southeast Asian species such as *Pteroptyx valida* E. Olivier and relatives in New Guinea emit more complex signals, and though they appear to flash independently, they are certainly influenced by near neighbors, which, of course,



Fireflies (Coleoptera: Lampyridae), Figure 21 **Some additional fireflies: (l) *Micronaspis floridana* Green occurs only in salt marshes along Florida's coasts and in the Keys. (m) *Pyropyga nigricans* (Say) occurs in wet grassy areas, and along streams and shorelines. Short-winged individuals occur at a few scattered localities, sometimes with the typical long-winged individuals. (n) *Lucidota atra* (G.A. Olivier) is the common large, black daytime firefly of midsummer in the eastern U.S. (o) *Aspisoma* fireflies are neotropical, but have been collected in extreme southern Texas and Florida. Some members of this genus may be semi-aquatic and pupate on emergent vegetation. (p) *Pyractomena angulata* (Say) sometimes is seen in numbers over marshes, but the amber candle-like flicker of this firefly is more often seen winding slowly around the boughs of treetops. (q) *Bicellonycha wickershamorum* Cicero in Arizona is the only member of this large neotropical genus known to occur north of Mexico. (r) *Photinus indictus* (LeConte) a daylight firefly is without a lantern, and virtually indistinguishable in dorsal view from the flashing species shown here, *P. macdermotti* Lloyd; it differs from all but one other daytime-dark species by having a pale border around each elytron. (s) *Tenaspis angularis* LeConte is a tropical firefly that is collected from time to time in North America, but rarely, and so far only singly judging from museum collections. Perhaps individuals occasionally arrive from Mexico, but they and progeny, if any, survive only a short time. (t) *Phausis reticulata* (Say) is known only from scattered localities across North America to Oklahoma, but can be seen in abundance in the Appalachian Mountains. (u) *Photuris lucicrescens* Barber is a very common firefly across much of eastern North America, and has a distinctive crescendo flash. This illustration is of a related though smaller Florida species that is virtually indistinguishable from "Big Lucy." (v) *Photuris lineaticollis* (Motschulsky) is one of several large species with a tawny rather than yellow trim and a broken pronotal vitta, and found in the southern U.S. from Florida to Texas.**

are rivals for females that approach and enter their illuminated arenas (leks?). There are a few species in North America in which males precisely synchronize their flashes, though these do it only while flying in especially close proximity, typically in open woodlands and hammocks. These include *Photuris congener* LeConte and *Photuris brunnipennis* Jacq.-DuV. in Florida, *Photuris frontalis* LeConte from Georgia north to Maryland and west into Tennessee, and *Photinus concisus* Lloyd in Texas.

Life history

Fireflies are holometabolous insects, and have four life stages: egg, larva, pupa, and adult.

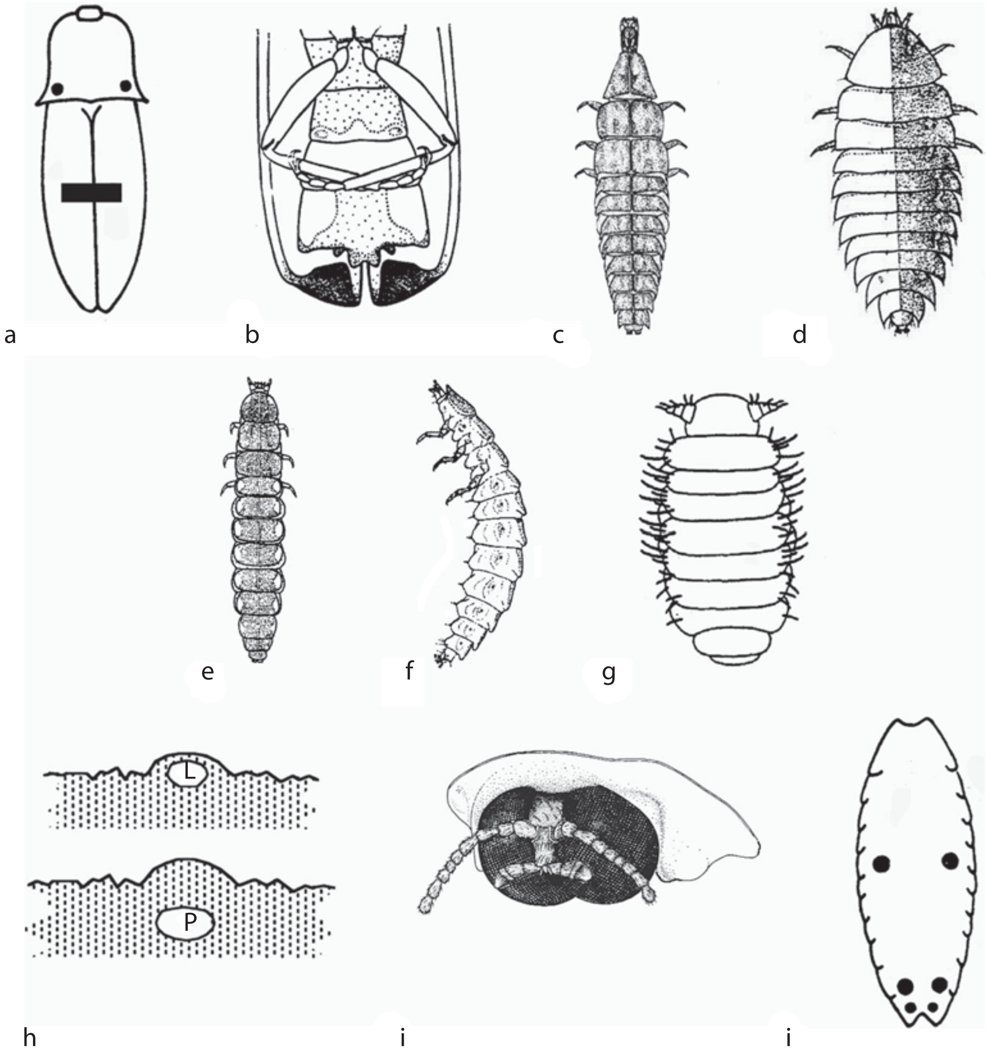
Eggs

In some lampyrid species eggs are deposited a few at a time over several days or weeks. This is probably the case in *Photuris* species in which adult females are hunters and travel among suitable locations seeking prey, and perhaps in early-successional (and ecologically tolerant) "weed" species such as *Photinus pyralis*. In some species, eggs are laid together at one time. Females of *Photinus collustrans* LeConte die in their burrows after ovipositing there. Unfortunately, no species in North America compares with certain Japanese species with respect to egg biology. In the stream-living Japanese Gengi firefly (*Luciola cruciata* Motschulsky), mated females fly upstream and lay their eggs communally in masses near the stream. When larvae hatch they fall, tumble and crawl into the stream, and during the next year, as they gradually are carried downstream, they eat snails and grow. In this firefly, which takes its common name from a samurai warrior family, the life cycle is thus intimately coupled with the hydrologic cycle. Ovipositing Gengi females locate the eggs of other females by the glow the "piles" emit. The eggs of some North American species also glow, but only dimly. In some cases, this glow comes from luminous material that is smeared on the eggs in the mother's egg canal, but later in development the light organs of developing embryos glow within the eggs.

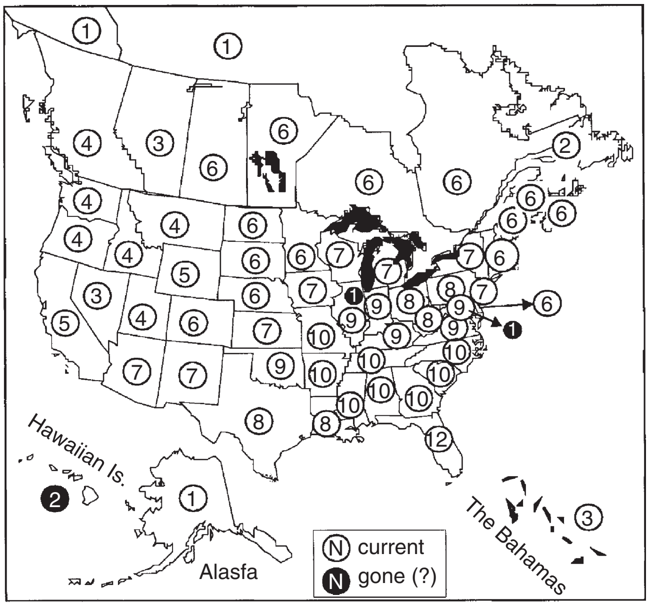
Larvae

Though larvae of only a few species have actually been observed, those of all fireflies are expected/presumed to be luminescent, even larvae of day-active species such as *E. corrusca*, in which the adults do not have lanterns, glow brightly from two points under the tail. The function of larval luminescence has been the source of human speculation for centuries, but now there is seemingly general agreement, and some experimental, comparative, and theoretical evidence as well, to indicate that it is a warning of unpleasant taste, with sometimes emetic or lethal consequences to prospective predators. Likewise, so far as is known, larvae of all fireflies are predaceous, and seek and subdue soft-bodied prey. The larvae of some, such as the European *L. noctiluca* and American *Pyractomena* species, are snail/slug specialists, such gastropods perhaps being the ancestral prey of the family. *Lampyris noctiluca* larvae are reported to follow 2-day-old slime-trails forward, tracking the snails, presumably and remarkably demonstrating that they are able to detect polarization in dry, if not stale, trails. *Photinus* species possibly are annelid specialists, and in captivity have been reared on minced earthworms. *Photuris* larvae are omnivores and scavengers, and reported to eat snails, worms, insect larvae, dead insects, and ripe berries (Fig. 27).

Larvae of a firefly from Sri Lanka (formerly Ceylon) was imported into New Britain (Solomon Islands) and Hawaii to prey upon and thus control the African snail, a pest of sugar cane. Also in the 1950s, two *Luciola* species from Japan were released in Hawaii for the control of fluke parasites of livestock. Because these flatworms (Platyhelmintheses,



Fireflies (Coleoptera: Lampyridae), Figure 22 **Attributes of "fireflies": (a) Outline of a click beetle (family Elateridae) with black dots showing positions of pronotal lanterns, which are visible above and below, and a black bar showing approximate position of the abdominal lantern which shines ventrally and is exposed only when in flight. (b) Ventral view of the abdomen of a male *Pteroptyx* firefly showing the bent elytral tips that form one jaw of a clamp that holds the female during copulation. (c) *Pyractomena borealis* larva, showing the distinctive canoe-like outline of larvae of this genus (from a study by M.A. Archangelsky and M. Branham). (d) *Photuris* sp. larva, showing the distinctively broad (sub-oval) outline of larvae of this genus (after A. Peterson). (e) *Pyropyga nigricans* larva, with a narrowly elongate form more suitable to a burrowing life (from a study by M.A. Archangelsky and M. Branham). (f) Side view of a *Lucidota atra* larva (after A. Peterson). (g) A rough sketch of a *Neanura barberi* collembolan (family Poduridae), about 0.9 mm in length; they occur in pale yellow and pink, and "milk-glass" white (diet?). (h) *Photuris* earthen chambers: top, larval molting chamber; bottom, pupation chamber (after L. Buschman). (i) Head of a *Microphotus angustus* LeConte male, the California pink-glowworm firefly, showing its huge eyes and small antennae and mouthparts. (j) Dorsal outline of female *Phausis reticulata* with dots showing positions of some lanterns; lanterns are variable and not visible unless illuminated.**



Fireflies (Coleoptera: Lampyridae), Figure 23 **Number of genera present in various states and provinces in North America, from current records and conservative interpolative, geographic assumptions. Exotic introductions, two into Hawaii from Asia in the 1950s and another to Maryland and Illinois from Europe before 1850, did not become established. West of the Rockies most species are day-active pheromone users (e.g., *Ellychnia*) or glowworm fireflies (e.g., *Phausis, Microphotus*); both types occur in the east with many lightningbug fireflies.**

Trematoda) spend part of their life cycle as internal parasites of snails, it was hoped that the larvae would eat these intermediate hosts. Apparently, none of the three exotic lampyrids survived in Hawaii. Larvae of Florida's *Pleotomodes* species live in ant nests and possibly feed on the food or young of the ants, or perhaps other nest visitors or inhabitants. Larvae of *Micronaspis floridana* Green live in salt marshes along coastal Florida, among the fiddler crabs and stranded, glowing comb-jellies (phylum Ctenophora). Generalizations on firefly life histories of American species are, with a few notable and noble exceptions, based on fragmentary and incidental observation because it is difficult and ultra-labor-intensive to rear them in captivity. In Japan, the success of hydroponically produced fireflies was critical to a national conservation program that restored vanishing stream species.

Photinus larvae of most species are subterranean and occasionally are dug up in gardens, but only rarely sighted above ground. Larvae of *Pyractomena* and *Photuris* species often are seen glowing. The former are sometimes arboreal, and on rainy nights can be found on twigs and branches of low woody plants. Larvae of marsh- and pond-inhabiting *Pyractomena* species are found on emergent vegetation, and occasionally are seen glowing underwater where they seek aquatic snails. *Photuris* larvae are the glowworms most commonly encountered by nocturnal sojourners in North America, along damp roadsides and paths, along streams and adjacent low wet meadows, and sometimes on lawns near lakes, streams, and ponds. Because adult *P. pennsylvanica* often are seen over marshes and soggy ground, near rivulets and around farm ponds, we can venture that when northeastern

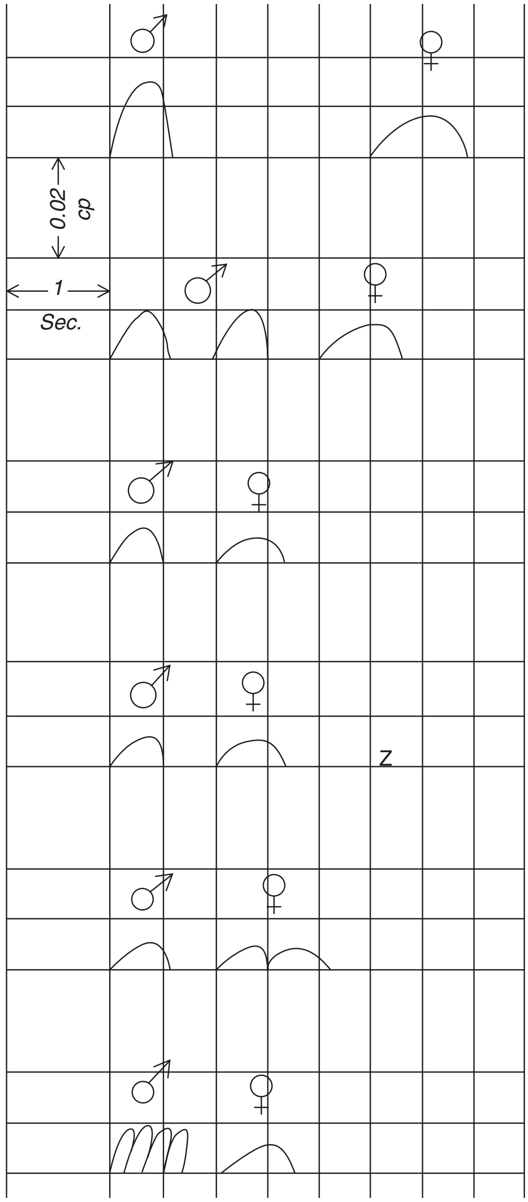
Fireflies (Coleoptera: Lampyridae), Table 3 Flightless females occur in several North American lampyrid species

Genus	Species	
	Flightless	Winged
Aspisoma (LB)	0	2
Bicellonycha (LB)	0	1
Brachylampis	0	2?
Ellychnia (DD)	0	12
Lucidota (DD)	1	2
Micronaspis (LB)	0	1
Microphotus (GW)	7	0
Paraphausis (GW?)	1?	0
Phausis (GW)	10	0
Phosphaenus (DD)	1	0
Photinus (LB)	12	34
Photuris (LB)	0	64
Pleotomodes (GW)	3	0
Pleotomus (GW)	3	0
Pollaclasis (DD)	0	1
Pyractomena (LB)	0	21
Pyropyga (DD)	1?	4
Tenaspis (DD)	0	1
Total	40	145

Sometimes the condition is obvious because the wings are shortened or absent: *Photinus scintillans* (Say), *Photinus collustrans* and others in its species group except *P. umbratus* LeConte, all those of the glowworm firefly genera, and *Lucidota luteicollis* LeConte, a daytime-dark firefly. Females of other species actually may be flightless but this has not been recognized because their wings are little reduced. Flightlessness often is associated with stabile habitats.
(DD = daytime-dark fireflies; GW = glowworm fireflies; LB = lightningbug fireflies)

North America was well-forested, this firefly often may have been associated with beaver dams and their wetlands.

Larvae of the three mentioned lightningbug genera, *Photinus*, *Photuris*, and *Pyractomena*, are the most commonly seen, but those of other genera can be found with some directed effort. Seek *Pyropyga nigricans* (Say) larvae along the shores of northern lakes and streams, on sandy strands and amongst and under stones; *Lucidota atra* (Fabricius) and *E. corrusca* juveniles occur in rotting logs, the latter perhaps especially in pine, and near the horizon with the forest soil (these genera are illustrated in the accompanying plates). When firefly larvae are sought at night in and under rotting logs, sometimes constellations of points of light will flash and quickly disappear. Not to be confused with lampyrids, these are the flashes of luminescent, springless springtails (Order Collembola), presently identified as *Neanura barberi* James, family Poduridae. It is possible that their flashes may mean something to the lampyrid larvae living there.



Fireflies (Coleoptera: Lampyridae), Figure 24 **The first known chart of firefly flashes, from the pioneering studies of Frank A. McDermott early in the twentieth century. While afield pursuing an interest in bioluminescence chemistry, he discovered that the flash patterns of male fireflies could be used to identify the species. For naturalist/taxonomists this compares with the discovery of the chemical nature of bioluminescence. Though some names "Mr. Mac" used in his chart were incorrect, this was because the taxonomy of North American fireflies was poorly known in 1914. McDermott later became a highly productive firefly taxonomist.**

Pupae

When ready to pupate, larvae seek or make sheltered places. During pupation the larva, a hunting/eating specialist, becomes the adult form and breeding specialist. Thus, pupation is not a resting stage, as sometimes stated, but a period of considerable phenotype reconstruction, a

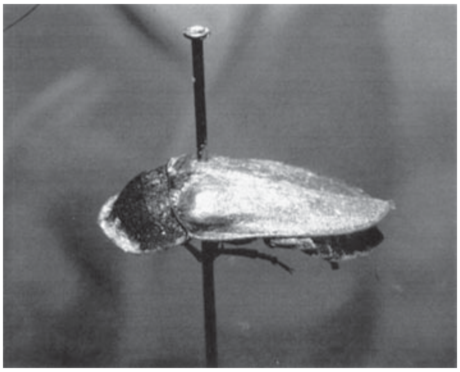
Fireflies (Coleoptera: Lampyridae), Figure 26 ***(top)*** **Male of a bent-wing firefly, *Pteroptyx valida* E. Olivier, perched at the edge of "his" leaf in a Thai swarm tree, aiming his lantern. His flashes attract females and may warn neighbors to stay off his leaf. (bottom) Copulating *P. valida*. The male (*left*) has pushed his elytral tips under those of the female and locked her genital region in the jaws of his clamp; his bent elytral tips form its upper jaw.**

process that results in a body form that is adapted to a completely different lifestyle and range of activities. Pupation lasts from 1 to 3 weeks, depending upon ambient temperature and species. *Photuris* and *Photinus* larvae, like most others that are known, pupate in chambers they make under or at the surface of soil. In contrast, *Pyractomena* larvae hang up in vegetation like chrysalids of some lepidopterans. Perhaps this is an adaptation for living in sites where rising water would flood chambers in the soil, as in river forests. Neotropical relatives of *Pyractomena* that live on emergent vegetation, and in marsh inhabiting *Pyractomena* in North America (*P. lucifera* Melsheimer, *P. linearis* LeConte, *P. dispersa* Green, *P. angulata* (Say)), this would avoid a difficult and perhaps dangerous walk to shore to dig an earthen chamber. In north-central Florida, larvae of *Pyractomena borealis* (Randall) pupate on the southern exposure of tree trunks in February. Development is accelerated by additional heat from the sun (insolation), and after sunset from sun-warmed tree-water, which allows them to become adults and reproduce before other species become active.

Adults

As far as is known from observation and can be predicted from present knowledge, adult fireflies

Fireflies (Coleoptera: Lampyridae), Figure 27 **Larva of *Pyractomena borealis* (Randall) attacking a snail. At this point, the larva is extended under the foot, with head reaching up to bite and inject poison. The snail has detected the larva and has turned its head slightly down and to its left, toward the larva's bite (note the turned position of the lower pair of tentacles). At the upper right, another larva is on the shell and barely visible around the contour of the shell.**



Fireflies (Coleoptera: Lampyridae), Figure 28 **Adult male of *Lamprigera tenebrosus* (Walker), a species introduced into Hawaii to control a snail pest of sugar cane. Apparently rare in collections, this museum specimen was probably collected from a spider web because it was wrapped in silk, which was removed for this photo (loaned by N. Ohba, Yokosuka City Museum, Japan).**

are concerned only with reproduction, including mate-finding and selection, copulation, oviposition, and dispersal, though egg dispersal is problematic in species that have short-winged, hence

Fireflies (Coleoptera: Lampyridae), Figure 29 **The larva of *Photinus pyralis* found glowing on a damp, dirt road in northern Virginia, and placed in a bed of moss to be photographed. Its curled-under tail shows a few fingers of the pygopodium, an eversible "rubber-glove"-like structure that is used for grooming and locomotion.**

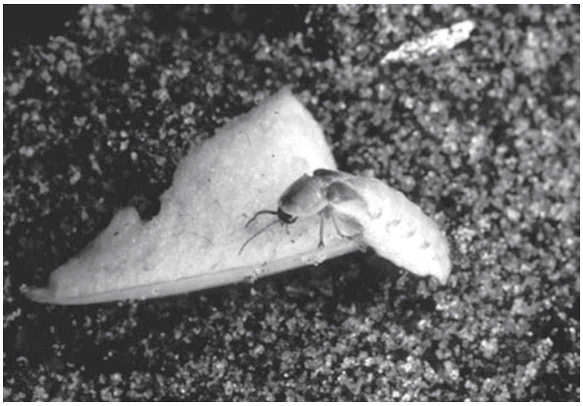
flightless, females. Only one species, *Pyropyga nigricans*, is known to have both short- and fully-winged females, but that this is a complex of species cannot be ruled out. In the case of *Photuris* fireflies, and neotropical relatives such as *Bicellonycha* spp., a singular dramatic exception to the "adult-fasting" rule is found: females of some Photurinae including most North American *Photuris* species augment the nutritional supplies they store as larvae by hunting, and are specialized predators of other fireflies. Some incorporate the protective poisons of their prey's blood into their own bodies and eggs for defense (Fig. 32).

Sexual Communication

Daytime-Dark Fireflies

In day-active species (for example, *Lucidota atra*, *Pyropyga nigricans*, *Photinus indictus* (LeConte)), males detect their females' pheromone, the chemical signal that drifts in a plume downwind, and fly upwind (anemotaxis), hence in the direction

Fireflies (Coleoptera: Lampyridae), Figure 30 **Pupal skin of *Pyractomena borealis* (Randall) hangs from its larval skin which is fastened to the tree bark. The recently eclosed adult is not yet tanned and is pearly white.**



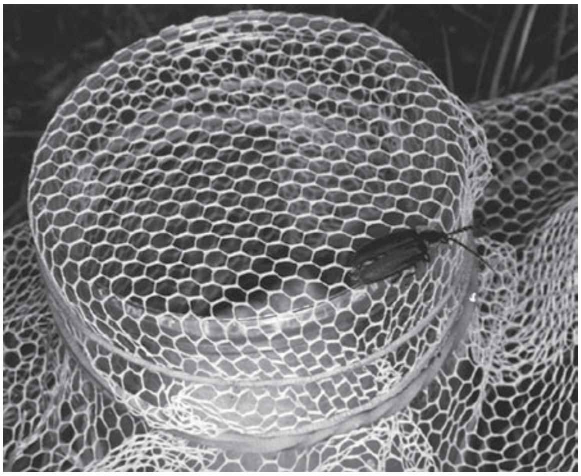
Fireflies (Coleoptera: Lampyridae), Figure 31 **Brachypterous (short-winged) female of *Photinus brimleyi* Green, showing the abbreviated elytra and wings found in a few North American *Photinus* species, including those of *P. collustrans*.**

Fireflies (Coleoptera: Lampyridae), Figure 32 **A female of *Photuris* unnamed-species "B" eating the male of *Pyractomena angulata*, near Lake Alice on the campus of the University of Florida.**

of the signal source. Some species probably use visual information when they near the pheromone emitter, such as a dark silhouette against a pale leaf background. The broad, black form of the rarest of all North American daytime fireflies, *Tenaspis angularis* LeConte is especially conspicuous whether on a leaf or on the wing. This cue was found to be important in the mate search of *P. pyralis* males during twilight. The chemical nature and structure of firefly pheromones has not been reported.

Glowworm Fireflies

In nocturnal species in which females emit light but mate-seeking males do not (for example, *Pleotomodes*, *Microphotus*, and most *Phausis* species), males fly about their habitat. The glowworm



Fireflies (Coleoptera: Lampyridae), Figure 33
A male *Lucidota atra* attracted out of a forest by the species' sexual pheromone and guided by the wind, walks on the netting over the emitting (calling) female.

Fireflies (Coleoptera: Lampyridae), Figure 34 Branched antennae and multifaceted and huge eyes of male *Pleotomus pallens* LeConte.

signal system is thus similar, even analogous to the daytime firefly pheromone system, except that in glowworms males orient to the actual signal, whereas daytime fireflies initially orient to the vehicle, the airflow. It is interesting and useful to consider the differences, the advantages, disadvantages, and consequences of signals that travel in straight lines but have a limited range (bioluminescence), and chemical signals that travel a long distance but only downwind, and in plumes composed of concentration filaments that stream on zephyrs, in spirals and twists up and down and around obstructions and stagnant air pockets (Fig. 33). *Pleotomus* species are glowworm fireflies, but perhaps use both of these signal channels: males may detect a female pheromone a long distance downwind with extensive arrays of sensors on their branched antennae, and at close range orient precisely to the female glow with their huge, abundantly-faceted and multi-directional eyes (Fig. 34). The glowworm fireflies *Microphotus*, *Phausis*, and *Pleotomodes* also may use pheromones, but their antennae are filamentous and do not give a hint of this. *Phausis reticulata* (Say) is an unusual glowworm in that searching males do emit light; their eerie green sparks are commonly seen gliding slowly and silently over the forest floor in the Appalachian Mountains. Sometimes the larva-like *Phausis* females are found glowing in the absence of male activity, but unlit females turn on their four or more tiny points of glow when a glowing male or penlight passes overhead. Perhaps the ability to douse their light permits females to hide from light-orienting predators until a legitimate receiver (a potential mate) is near. The "turn-on" response of these females, initiated upon detection of a male glow, is a key behavioral response that is highly developed in the lightningbug fireflies.

Lightningbug Fireflies

Males of many genera throughout the world emit their bioluminescence in patterns that require more complex lanterns and neural control than do the rather dim glows and slow ON-OFFs of glowworm fireflies. In North America, these species are in the genera *Photinus*, *Photuris*, *Pyractomena*, *Bicellonycha*, and *Micronaspis*.

In some species the male signal is a single flash, and in others it is a group of flashes. Such patterns are repeated at fairly regular "advertising" intervals by flying males. The male flash pattern is only one part of the signal code of such species. In the basic signaling system found in North American lightningbugs, when females see the flash pattern that is characteristic of their males, they flash an answer. During the ensuing dialogue, if the females choose to keep answering, the males fly, walk and climb toward, mount and touch/taste their respondents, and connect with them.

Signaling/courting behavior found in some flashing species in other parts of the world, in particular in certain paleotropic species of the subfamily Luciolinae, is quite different. In New Guinea forests, males and females of *Luciola obsoleta* (E. Olivier) gather in loose swarms beginning at dusk, and emit flickers and flashes for several hours. Finally, glowing females here and there take off and fly through or away from the swarm, and one or more flashing males take up pursuit. Aerial encounters with collisions between males ensue, and the female is repeatedly bumped in flight until she finally alights on a leaf with a male. After courtship dancing and chasing, they couple and remain connected tail-to-tail until the following evening. A great variety of mating behaviors and signal patterns has been described for Japanese and other Asian fireflies.

Flash Pattern Specificity

Because males of a lightningbug species emit a flash pattern that is characteristic of their species, as they fly about the habitat and activity space that is characteristic of their species, in their species' season and time of night, male flashing behavior can be used to identify species. For many in the genus *Photuris*, flash patterns provide the only reliable characters for identification. With practice, it is possible to identify local species from flashing behavior alone. But note that during the final approach of a male to a female, especially after touchdown, flash patterns sometimes become variable. Until the specifics of such pattern variations are known for a species, the flash patterns of perched or walking males cannot be used reliably for identification.

Female Flash Response

When a lightningbug female sees the flash pattern of a male of her species, she answers with a flash-response. Female signals are typically single flashes, and females of some species turn their lantern to face the approaching male. In many species, the answer is emitted within a second of the male signal, but in others there is a conspicuous delay. Females of *P. pyralis* delay 2–4 sec, and those of *Photinus ignitus* (Fig. 35) Fall delay 5–10 sec, depending upon temperature. Males can be attracted to a penlight by placing its tip against the ground and flashing a short flash after each pattern they emit; as a male approaches and flashes, answer each with the penlight tip pushed further into the soil to reduce its apparent brightness to the male.

Fireflies (Coleoptera: Lampyridae), Figure 35
A wolf spider in grass with firefly prey, a female *Photuris* that probably was blinking as she oviposited. A simple experiment is to bait pitfall traps with blinking, light-emitting diodes.

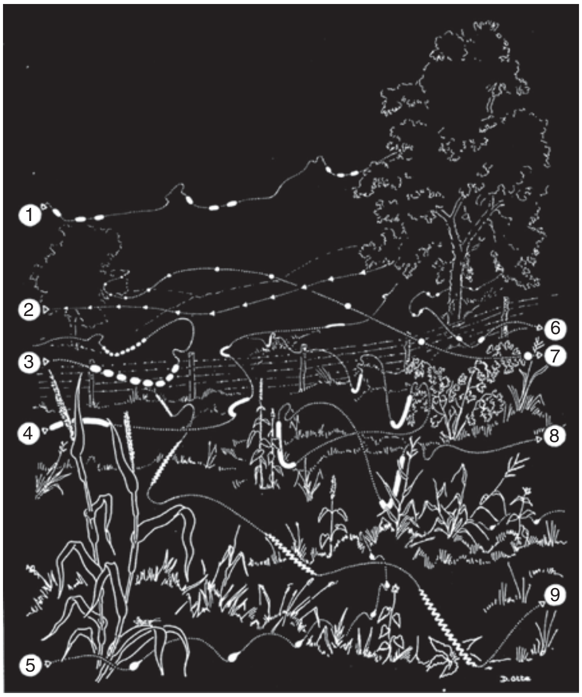
Females can be found by walking about their habitat flashing a penlight simulating the timing of the male flash pattern.

Supernumerary Flash Patterns, Pattern Change-Over and Defaulting

In his pioneering Photuris studies in the 1920s, H. S. Barber observed that males of *P. tremulans* Barber and *P. lucicrescens* Barber each emit two distinctive flash patterns. Since then, many other *Photuris* species have been found to use more than one pattern during mate search. For example, in some populations males of *P. pennsylvanica* emit a short flash for a few minutes after they begin evening activity, and then gradually change over until all are emitting the dot-long-dash pattern described by H. S. Barber. However, during early evening when a male receives an answer to his short flash he switches (defaults) to the dot-dash pattern during his approach to his respondent. Other species with this defaulting behavior include *P. quadrifulgens* Barber, *P. tremulans* Barber, and a New England relative in the same species group. When an observer sees a *Photuris* emitting a green flicker flash pattern, like the one described for *P. tremulans*, to identify the species the observer must become an experimenter and simulate a female answer with a penlight and thus elicit the default (species ID) flash pattern. In early spring in northwestern peninsular Florida, males of a variety of *Photuris lineaticollis* (Motschulsky) search with a continuous glow, presumably mimicking the signal of *Pyractomena angustata* LeConte males; when they are shown a female-like glow response, glowing *P. lineaticollis* males switch to their own short-flash pattern.

Miscellaneous Flashes

Firefly adults, especially those of *Photuris*, emit a variety of flashes (Fig. 36), glows, and twinkles under circumstances that are not connected with mate search, courtship, and rapprochement: from spider webs, puddles, tangles of grass and spanish moss, when encumbered with grasping pseudoscorpions, when held by spiders, when walking on the ground, when perched on wind-blown tips of vegetation, and when landing and taking off. The last mentioned seem to be used for illumination, but others are open for conjecture and study, for what now-hidden revelations they may avail us. In one other situation the meaning of the flashes is clear. *Photuris* females emit flashes as lures when hunting in what has been called "aggressive mimicry."



Fireflies (Coleoptera: Lampyridae), Figure 36 Diagrams of flashes of several species of *Photinus*. Not all of these species occur together. To identify a male from his signal, the observer must know where he is, and also, sometimes, the time of year. *P. pyralis* is number 8 and *P. collustrans* is number 4. Number 6 is a species in the *P. consanguineus* group, but identification is not possible because there is no precise clue to the timing of the two pulses in the pattern.

Aggressive Mimicry

Females of many *Photuris* species take perches in the activity spaces of other species and flash responses to passing males like those the males would receive from their own females. Duped males approach the *Photuris* females, are pounced on and eaten. *Photuris* females also attack flying male fireflies, using the emissions of the males to guide their attacks. Such predations by these females will have been a major influence on the signaling behavior of prey species: in aiming aerial attacks at flash patterns of flying males, predators have certainly influenced the patterns, particularly pattern duration, and flying behavior; with their signal mimicry they are inside their prey's coding system, forcing species to evolve deceptive codes or counter-measures. It was once thought that signaling evolved primarily in the context of avoiding mating mistakes, but a mating mistake is not lethal, and a predator attack can be. Since neither *Photuris* nor predator specialists like them occur in Asia, fireflies provide a natural intercontinental experiment to explore the impact such focused predation may have on signaling behavior.

What goes around comes around, and it would seem that just as prey species have been forced into changing, the communication of predator species also has been influenced by this turn of coevolutionary events, as suggested in the following section.

Flash Pattern Mimicry

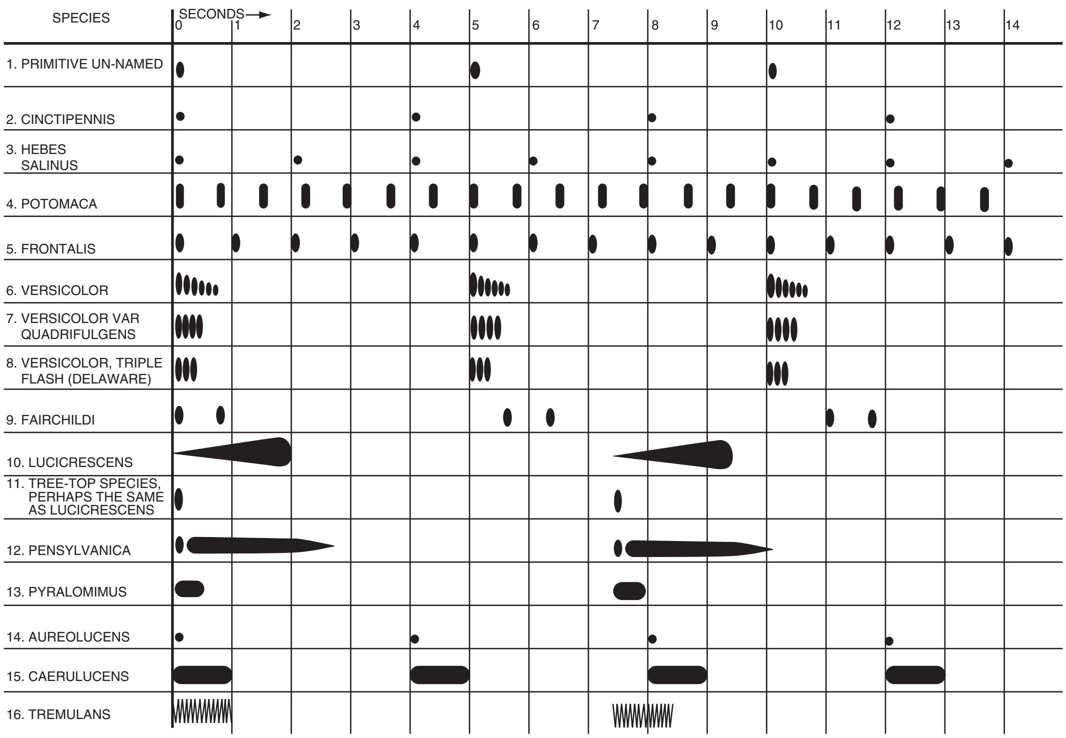
With this general discussion of female-response flashes, and specifically the aggressive mimicry of *Photuris* females, we now return to the supernumerary flash patterns of *Photuris* males. They clearly seem to be related to the aggressive mimicry of *Photuris* females. In several instances, the supernumerary patterns of *Photuris* males are nearly indistinguishable from the flash patterns of other firefly species. When *P. tremulans* and *P. quadrifulgens* males seek mates with the flicker pattern described for *P. tremulans*, they are using a flash pattern that is identical to that of *Pyractomena angulata*, except for its green color; *P. angulata* flickers are amber. The working explanation is this: when males default to their own pattern, they identify themselves to their own females, prospective mates that are hunting and narrowly tuned (gated) to a prey flash pattern. This system presents an interesting and educational, though difficult, problem in sexual selection. In seeming irony, when Barber chose the specific epithet for *Photuris tremulans*, he used not this species' own signal, but one it "borrowed," one being used by other *Photuris*, too, and perhaps one that they all acquired from the same ancestor (Figs. 37 and 38).

Conclusion

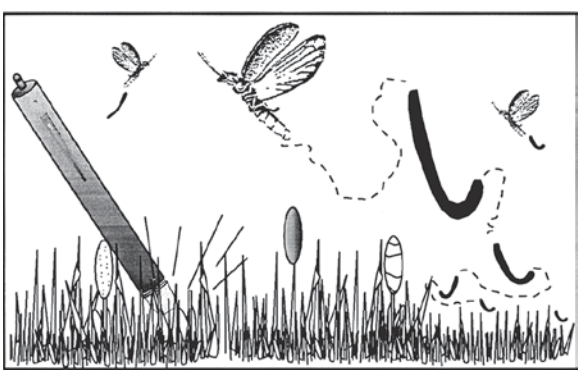
When considering environmental features that have influenced the signaling of fireflies, among the obvious are meteorological elements such as ambient temperature, ambient illumination, and wind; physical certainties, such as the fact that light travels in straight lines, will not pass through opaque objects, and rapidly decreases in visibility with (the square of) distance; and the biological certainty that most organisms and especially predators have photoreceptors. But the signals of other fireflies with which mating mistakes might be made, the signal mimicries of predaceous fireflies, and aerial attack certainly have been of major importance, too. The impact of these elements varies among sites, habitats, seasons, and population densities. When studying the natural history of animals, the naturalist is looking at a chronicle, and when the subjects are fireflies much is written in lights.

Fireflies and Intrusive Light

Suitable firefly habitats today are often bathed, if not drenched or washed out, in artificial light.



Fireflies (Coleoptera: Lampyridae), Figure 37 **Flash pattern chart accompanying Barber's *Photuris* study.**



Fireflies (Coleoptera: Lampyridae), Figure 38 **Method of attracting males to a penlight. Put the tip of the penlight against soft ground. As the male approaches, push the tip further into the ground, as a bright penlight will deter an approaching male.**

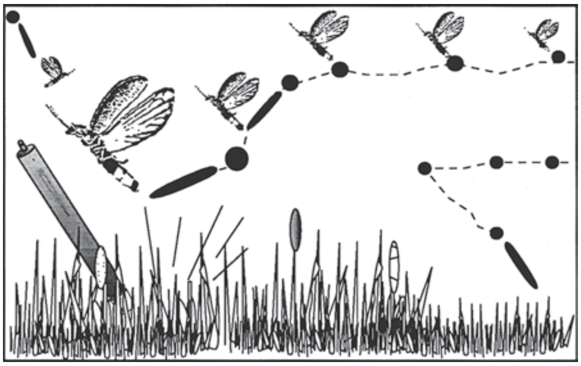
Because of the unique relationship that fireflies have with light, intrusive light may be expected to have especially serious consequences for them. There are several sources, but three main contexts of impact that foreign light can have: noise, illumination, and misinformation. When these combine with other environmental insults, the consequences can be deadly for the fireflies.

Noise

Intrusive illumination as from skyglow, especially that of clouds reflecting light from urbanization below, and direct illumination from streetlights, business or industrial lights, and residential lights make bioluminescent emissions less readily detected by intended (legitimate) receivers. Bioluminescence will be less efficient in mating signals, less attractive for predator-trappers, and less visible as aposematic warnings to attackers. The light intensity that fireflies normally emit is tuned to operate in darker surroundings, and though some may facultatively increase their luminous output to compensate, this decreases stored energy supplies (ATP, adenosine triphosphate), one molecule per emitted photon, that formerly was put more directly into gamete success. When females of the twilight firefly *Photinus collustrans* are delayed in mating and oviposition, it costs them about seven eggs per day of delay. A special consideration is the yellow light of recent, energy-efficient, sodium-vapor highway illumination; it may be of special concern because some fireflies have tuned their lights and eyes to operate in this range of frequencies. Also, if some of the subtle complexities of male signals are important in female mate choice (say, as they reveal good genes, health, and vigor), they could be obscured by intrusive light.

Illumination

Examples of intrusive light as a revealer of naturally hidden actors and activities is obvious to nocturnal naturalists who prowl woods and fields by moonlight and headlamp. Obviously, it will reveal targets to roving predators such as wolf spiders, but consider the attacks of *Photuris* females on other fireflies. These specialists attack flying, flashing males by aiming at their flash patterns and leaking glows from their lanterns. In particular, when attracting foreign males via mimicry, females sometimes leave their perches to attack. Increases in ambient light may shift the balance in these interactions, because it will reveal both perched respondents and approaching hawkers to the males, and also negate one of the few defenses that flying males have, that of hiding in the dark between flash emissions.



Fireflies (Coleoptera: Lampyridae), Figure 39
When early-flying, single-flashing males of *P. pennsylvanica* are answered, they default to their dot-dash (species ID) pattern. Knowing this, the naturalist can recognize at a distance what is happening (right). At the upper left, a distant and potentially interloping male, upon detecting the flash-response interaction, approaches.

Such illumination can have more subtle and obscure effects and results on firefly behavior. The onset of flight in twilight fireflies such as *P. pyralis* and *P. scintillans* (Say) is triggered by diminishing light intensity. Males of such species become active several minutes, even an hour earlier, in shady places and on cloudy days. Also, individual males of late-twilight species become active within shrubs and under herbaceous canopies, but land or return inward when their flight brings them out of the shade into the open. Adults of such species may be confused by intrusive light and initiate, continue, or terminate their evening mate search inappropriately. *Photinus collustrans* reveals another response to ambient light level that may be influenced by intrusions of stray light. Early in their 20-minute window of evening flight, which begins about 20 min after sunset, males fly <1 m above the ground, but as the light-level falls, they gradually fly higher and flight altitudes average above 1 m. This response can be seen when early-flying males pass through the shade of trees and adjust their altitude accordingly. Other manifestations and the significance and consequences of these responses invite fireflyer attention.

Misinformation

Natural light provides information to organisms as timing cues and triggers, and for orientation. Thus, artifical light can interfere with firefly life in several ways. Because light travels in straight lines, rays from celestial sources are used by various animals in their navigation over the earth. By maintaining a fixed angle on the parallel light rays arriving from remote ("infinite") sources, night flyers are able to steer and maintain straight flight over long distances. As an adaptation explanation (behavioral ecology), males could maximize their opportunity to intercept downwind-streaming female pheromone plumes by flying across the wind on star-oriented straight lines. Without a remote orientation reference, nocturnal flyers would tend to stray off course, perhaps fly in circles. When night flyers take a fixed bearing on a local light source with its diverging rays they will spiral into the light. Males of glowworm fireflies (e.g., *Pleotomus*, *Pleotomodes*) track pheromone plumes, and males sometimes are taken in light-traps in considerable numbers.

The orientation of the larvae of *P. borealis* on tree trunks is important for gaining heat from the sun (see above). If larvae use the visible light of the sun rather than, say, using the warmed bark of the trees to determine southern exposure, nearby streetlights may disorient them. A related species, *P. limbicollis* Green, occurs in many of the same forests, but pupates with a north-facing orientation and ecloses a few weeks later. Another potential source of photic misinformation for *P. borealis* was suggested when larvae were brought into the lab in early December and, by chance, were exposed to continuous room light connected with other research. The larvae climbed and pupated a few days after they were brought into the lab and soon eclosed as adults, 2–3 months too early! If continuous light triggered their metamorphosis, in other words caused them to break diapause, field populations exposed to continuous artificial illumination from skyglow or local lights may likewise eclose early or make other developmental miscalculations.

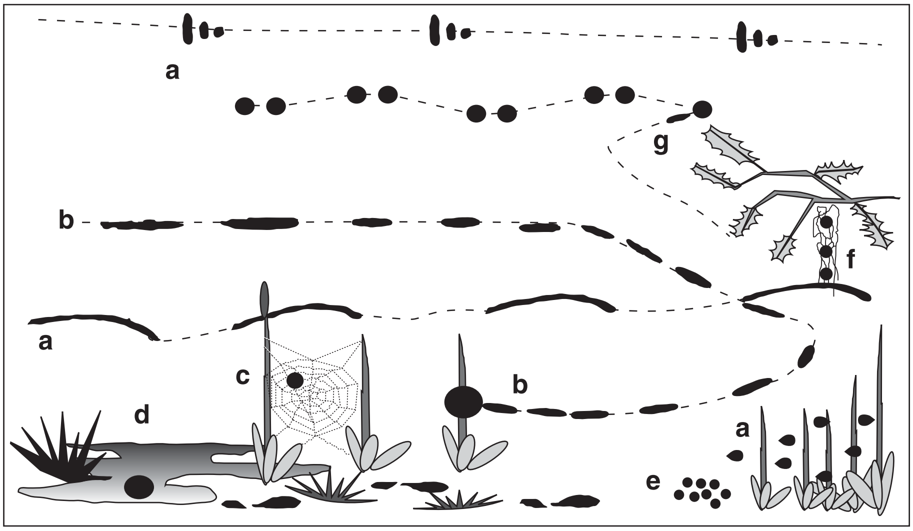
Artificial light sources may be attractive to colonizing and site-changing fireflies if it is mistaken as the glow of the collective emissions of fireflies in suitable habitats, "suitable" being defined as good for mate seeking by male and suitable for oviposition by female emigrants. This could be most significant and deadly for swarming *Pteroptyx* fireflies in Asia.

Intrusive Light as a Synergistic Aggravator

Two of the major ecological changes that have had an impact on firefly populations are: (i) the loss of suitable natural areas, including woodlands, meadows, and bottom-land near streams and rivers, and (ii) the lowering of water tables, resulting in fewer creeks and their floodplain forests, ponds and pond edges, marshes and wet meadows. To this we might add the trapping-out of beavers, if they indeed were once responsible for making firefly habitats in every place possible. This is really to say that the normal patchwork of populations of firefly species that existed in former times now has many holes in it. As more and more populations are lost, the holes get larger, and remaining local populations become less well connected by migrants. When local populations disappear, as they will naturally from time to time, neighbor populations that formerly would have reseeded empty sites are much further away. Thus, there is an ever larger separation of fewer and fewer suitable sites, with inhospitable spaces between remaining sites punctuated and bathed by noisy, revealing, and misinforming bright lights. This must present a formidable formula for extinction. A mathematical ecologist modeled the extinction of local populations and concluded that total extinction of species was retarded or prevented by the chaotic (in the formal, mathematical sense) nature of local extinction and the repopulation of suitable sites. I expect that formal chaos models for fireflies will now predict less optimistic outcomes.

Essences of Lumens

The nature of firefly light is misunderstood by many: laymen, journalists, and entomologists alike. Bioluminescence is the term given to chemiluminescence when it is produced by organisms, and is sometimes poetically referred to as "living light." It is but one of several forms of light emission collectively known as luminescence, which occurs when atoms of a

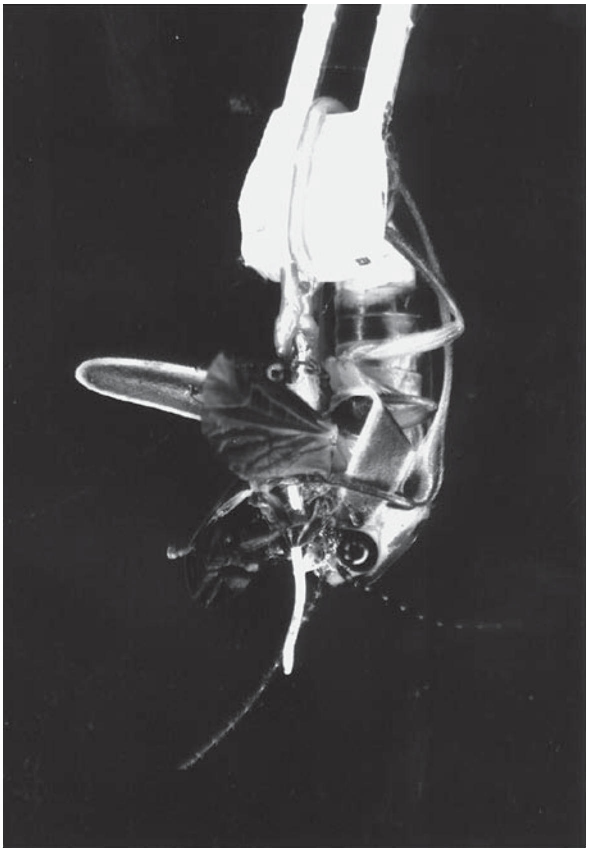


Fireflies (Coleoptera: Lampyridae), Figure 40 **Sampler of contexts in which adults flash. *Photuris* fireflies are responsible for most of the "odd" ones: (a) Male flash patterns, 4 species shown; (b) landing *Photuris* female; (c) ensnared in a spider web; (d) stuck in a water puddle; (e) walking, ovipositing; (f) in a tangle of Spanish moss; (g) female attacking an aerial target.**

Fireflies (Coleoptera: Lampyridae), Figure 41
A *Photuris* unnamed-species "C" female eating a *Photinus* male she has attracted by mimicking the sexual signals of his own females. Sometimes capturing females hang beneath leaves while eating, and hold their victims away from the perch, and sometimes they remain on their hunting platforms. Typically, they are so much larger than their prey that "they can eat anywhere they want."

substance emit photons (packets of light energy) as their electrons return to their stable state after having been lifted to a higher and unstable energy level by input energy. Chemiluminescence does not depend upon, nor come from, light or other electro-magnetic energy currently shining on, or that has previously shone upon, the emitter, as do luminescences such as fluorescence and phosphorescence, respectively. The physics of luminescence differs from that of incandescence, such as the glow of campfire coals and the yellow flame above them, in which molecules emit light because they have been heated to a high temperature and made to vibrate vigorously.

Terms for luminescences sometimes used in older texts and references have various historical and physical explanatory origins, with different terms sometimes having been applied to natural phenomena that have the same physical basis. For example, the sparks seen when certain hard candy is crushed between the teeth, and the sparkly glow observed along the line of separation when transparent tape is snatched from its roll (in the dark) are emitted by ionized atoms of nitrogen, though these two phenomena were once known by different names. The most common error in older biological and modern popular-press living-light literature is the use of the term phosphorescence when the term bioluminescence is correct.



Fireflies (Coleoptera: Lampyridae), Figure 42 **Flashing LED targets suspended from fishpoles by thin electrical wire elicit attacks from *Photuris* females. This one attacked the light (white rectangle at her tail), found an impaled male below, and is chewing on him. Note his elytra and flight wings, and one eye peering from behind the crumpled flight wing above.**

Fireflies (Coleoptera: Lampyridae), Figure 43 **Two *Photuris* females simultaneously attacked a flashing experimental target. The one on the right has severed the head and prothorax of the other. The impaled male hangs below. In this illustration, the macro-photo was superimposed on a time-lapse exposure that showed how the target was trolled and flashed along bushes at the edge of this sandy road; the image of the experimenter was not recorded because he was moving. Attacks were viewed in silhouette against the city skyglow in the background.**

Applications of Firefly Chemistry

The light-producing chemicals taken from the tails of fireflies, or mass-produced by organisms that have received firefly genes, have been used in a variety of ways. Here is a sampler, but new ones appear in cascade:

1. NASA has considered using firefly bioluminescence to search for life in space. Because light production requires luciferase, luciferin, ATP, and magnesium (a cofactor) in a water solution, if one ingredient is withheld no light is produced. If extraterrestrial life occurs, it may use a high-energy phosphate bond as in ATP. If, for example, a soil sample is scraped from the surface of Mars by a robot, mixed with firefly glow ingredients without ATP, and then light is detected, life may be present and the site should be given closer scrutiny.
2. Similarly, bacterial contamination of food can be quickly ascertained without the delay of culturing by swabbing a sample from meat in a packing plant, applying the firefly-test solution, and looking for a glow.

3. The photon-detection technique can find trace amounts of environmental pollution, such as ions of heavy metals. A luciferase gene is fused to the gene in a bacterium that provides specific resistance to the metal. A culture of the bacterium is immersed in a solution of luciferin and the environmental sample to be tested. If the ion is present, the resistance gene is activated, also activating the luciferase gene, and photons are emitted.
4. Animals with mutant genes for their circadian rhythm can be identified by observing their daily activity cycles. Detection of such mutants in plants is not accomplished as easily. To find plant mutants, the firefly luciferase gene is placed with a gene sequence that is turned on by the circadian rhythm gene. With luciferin available, mutant plants emit light out of the normal circadian phase for their species.
5. To determine whether genes can be picked up and coded into the genomes of mammalian tissue, because of the considerable potential of the technique in medicine, dog leg arteries were exposed then flushed (bathed) with genes for luciferase. After allowing time for the luciferase gene to be incorporated into the genome, luciferin was added to the solution. In brief, the leg glowed.
6. Tuberculosis is a serious, dreaded disease, caused by several strains of the bacterium *Mycobacterium tuberculosis*. Antibiotic medications are strain-specific, but diagnosis via culturing a sample from a patient can take 3 months, sometimes a lethal delay for the patient. Firefly solution: insert the luciferase gene into the genome of a bacterial sample from the patient (using a virus). After a short delay, add luciferin and get a glow; then apply various antibiotics to samples of the now-glowing infectious culture; the antibiotic that turns off the glow is the one to give to the patient. Time elapsed: 2–3 days.

Common Questions Asked About Fireflies

Here are answers to the most commonly asked questions about fireflies:

1. Why is firefly light said to be cold? Restatement: When the energy of ATP is converted to radiated electromagnetic energy, why is virtually all of it in the visible light range of wavelengths, and none outside this narrow window of the energy spectrum, including what would be felt as sensible heat? Natural selection has tuned the system of reacting molecules (perhaps in the context of conserving energy) to the wavelengths that are detected by the visual systems of significant receivers. Indirect support for such tuning comes from the finding that adults of early twilight species have made ecological adjustment and have yellow light and yellow-tuned eyes to better contrast with the abundant green in their environment.
2. Why are there no fireflies in California? Restatement: Why are there no lightningbug fireflies in California? The fact that California has other members of the family Lampyridae, glowworm and daytime-dark fireflies, with similar life histories and diets, is evidence that the region is not completely inhospitable to a lampyrid scheme of life. Since eggs, larvae, and adults of eastern U.S. lightningbug species certainly must arrive there from time to time (for example, in cyclonic storms, in root- and potting-soil with nursery stock, and with uninformed firefly enthusiasts), we must suspect that their absence is not because of perfect geographic isolation and such physical barriers as deserts and mountains. It is an interesting ecological puzzle that deserves attention. Perhaps the climate of California is generally too dry for the species that live in the east that are transported there, or the fireflies that presently occur there occupy and completely fill very narrow, highly specialized niches. There is one century-old record from southern California of an otherwise unknown *Photinus* firefly.
3. Why are fireflies disappearing? Restatement: Why do certain flashing fireflies that were formerly seen in eastern United States now appear to be much less abundant or absent altogether? There are standard answers that may be suggested, but there is no documentation or evidence in specific cases. Air, soil, water, and light pollution from a variety of

sources may affect them and their prey: earthworms, snails, slugs, etc. There is much less natural area available due to the ever-increasing amount of land development by humans. Lowered water tables, with the resulting loss of ponds and edges, marshes and general soil moisture, may be a factor in the loss of habitat. Increased sources of run-off such as highways, parking lots and rooftops, with increased volumes of water flowing over the ground causes surface contaminants, such as vehicle hydrocarbons, fertilizers, poisons and salt, to be carried and deposited in remaining natural areas. But we will continue to see certain fireflies for a long time to come, because a few species, such as *Photinus pyralis* and *Photuris tremulans*, are able to live, and apparently thrive, in sites that humans have altered, and these species have extensive geographic distributions. However, many North American species can be expected to become extinct during the next century.

4. How can I attract fireflies to my lawn and garden? Restatement: How can I increase the likelihood that mated firefly females will find and accept vegetation spaces around my home and lay eggs there, and that their progeny will survive, reach adulthood, and remain there for mate-seeking and oviposition? There are standard answers that may be suggested, but there are no specific studies to cite. To provide cues to attract and retain adults, prevent the intrusion of artificial light and enhance the growth of herbaceous vegetation to prevent the soil from becoming dry and hard-packed. Clues for success are provided by the abundance of fireflies in agricultural fields that have been abandoned. In such weedy-field spaces, which are termed old fields by classical ecologists, there has been pioneering by various herbaceous plants which form rich, damp, and sheltering habitats for a few years, with worms, snails, and other soft-bodied prey for firefly larvae. However, woody pioneers (sumac, aspen, locust) eventually invade, and in a few years they will exclude the herbs and grasses, and so on, through successional stages that are characteristic of the region. Encourage old fields in your spaces, and their continued existence where you see them now, by removing woody pioneers as they enter; mowing with the blade (cutter bar) set quite high, once or twice a year, should be sufficient. Occasional sprinkling of former gardens and lawns, and planting lush native herbs and grasses will encourage the development of suburban, experimental old fields. Then, plant some native annelid worms and terrestrial snails.

Fireflies and Human Culture

Emitters of living light, and in particular fireflies, are more than organisms, insects or beetles; they are a special part of human culture. The Japanese have for centuries used them as metaphors for emotional and personal experiences belonging to the human condition, and to punctuate subtle points of a reverent and shared natural philosophy. A firefly becomes a short poem, the keyword "Fireflies" may guide you to a book of short poems, and *A Net of Fireflies* is a collection of poems to be read before sleep, after the mosquito net is drawn up over the bed. It is an unworthy collection of summer haikus that does not have several firefly fireflies; the trick is to discover a meditative connection with the author. "Flash" may not translate directly, any more than a frog's "kerplunk" hits the mark in translation, according to some knowledgeable poetry critics. In pastoral North America of yesterday, FireflyFun was one operative word, but this now lives mostly in memory, with a country grandma and grandpa. Truly, fireflies go beyond science, and, in one of their incarnations, belong to the humanities.

Fireflies: Control of Flashing

HELEN GHIRADELLA, JOHN T. SCHMIDT
The University at Albany, Albany, NY, USA

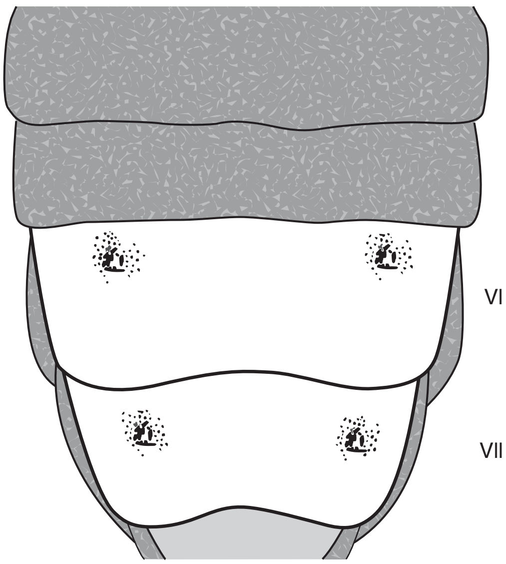
The remarkable ability of biological systems to control light is particularly evident in the phenomenon of bioluminescence, the production of light by living organisms. Many bioluminescent organisms "borrow" their light from luminescent bacteria that are cultured and maintained in special structures. Others produce their own light and in the insects, modulation of these lantern systems runs the control gamut from steady glows to the complex flash patterns of adult fireflies (see Buck, 1948, for a classic and authoritative review of firefly lantern capabilities, and Lloyd [this publication] for a taxonomic and behavioral review of firefly biology). Over literally centuries of study, especially of the lampyrid beetles *Photuris* and *Photinus*, scientists made great progress in working out the chemistry and neurobiology of the firefly light reaction. In basic chemical terms, a substrate, firefly luciferin, complexes with an enzyme, firefly luciferase, and ATP in the presence of Mg^{2+}; once oxygen is added, the system forms a cyclic peroxide which releases light as it decomposes. All ingredients can be mixed in a test tube and the system will stay lit until it runs out of a reactant. Adult fireflies, however, can turn the light both on and off; they can practice flash control.

Years of accumulated evidence suggest strongly that flash control is essentially oxygen control. Certainly insects appear for several reasons uniquely suited to have evolved the ability to use oxygen as a control mechanism. The light, strong and versatile exoskeleton that covers or lines all surfaces abutting on or interfacing with the environment enables their respiratory system to bring air directly to all tissues. The lantern nerves have their final synapses in the tracheal system rather than on the photocytes, the cells that actually produce the light. In the test tube, only addition of oxygen to a premixed "active intermediate" (that contains other ingredients of the flash reaction) initiates the flash rapidly enough (within msec) to approximate the flash *in vivo*. But until recently we have remained ignorant of any mechanism by which gaseous molecular oxygen could be controlled or gated by a biological system. But recent studies broke the log jam with two different but not mutually exclusive models for oxygen control. More recently, however, the current authors have realized that any oxygen control theory may be lacking an important link, and we have therefore developed yet a third model. This chapter will consider all three theories; in order to do so, we must start with a review of the distinctive anatomy of an adult lampyrid lantern (in this case that of *Photuris*). Along the way we will meet an unusual cell, and two respiratory organelles, one believed to be ancient (the peroxisome) and one that was perhaps more recently evolved (the mitochondrion). We will also consider the function of a signaling molecule (NO) relatively new to science for a purpose that may be very new to science. As usual, on considering and trying to answer old questions, we will be raising new ones.

Morphology and Physiology of the *Photuris* lantern

Adults of both *Photuris* sexes have lanterns located under windows of clear cuticle on the ventral layers of the sixth and seventh abdominal segments. Those of the male virtually fill the sterna of these segments (Fig. 44), while those of the female are smaller, but in ultrastructure and physiology they appear identical.

Each lantern is a flat slab of tissue that consists of a dorsal and a ventral layer. The dorsal layer, often referred to as the "reflective layer," consists of large cells filled with granules whose content and purpose are to our knowledge as yet undetermined, although many authors speak of them as urate crystals. The ventral "photogenic" layer consists of the photocytes and their tracheal and nerve supplies. The figure of the photogenic layer presents a view in frontal section (Fig. 45) of the adult lantern; it shows the concentric (rosette) arrangement of the photocytes around the channels, or cylinders, through which run the main tracheae, their finer branches, and (importantly) the closely associated nerve supply. Also shown is a figure presenting a diagrammatic representation of part of a cylinder and its associated structures. Let us now identify some of the cellular players in the system.

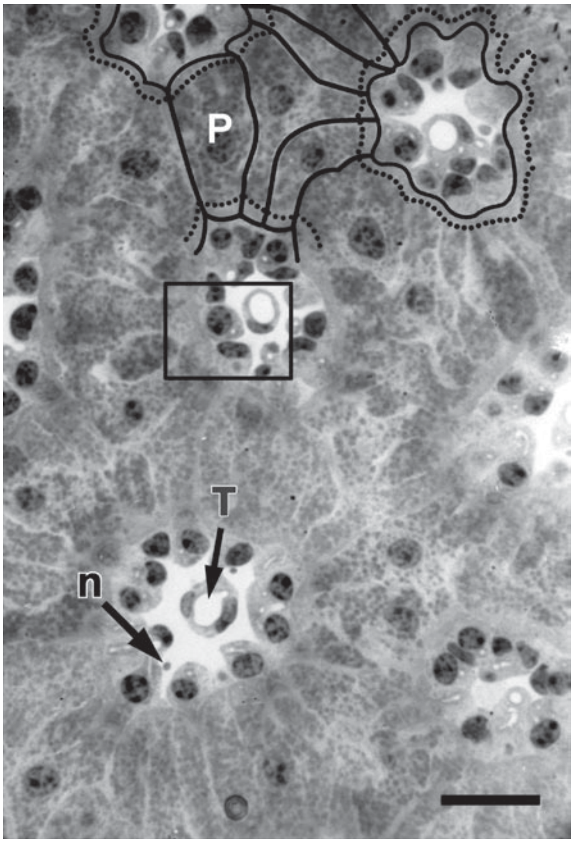


Fireflies: Control of Flashing, Figure 44 Diagrammatic ventral view of several abdominal segments of a male *Photuris*. The cream-colored lantern occupies the sternites of segments VI and VII, which have clear "windows" of cuticle. The depressions in each segment are external pits at the sites of internal attachment of respiratory muscles.

The light-emitting photocytes stretch from cylinder to cylinder so that they have access to tracheae at either end. They are unusual in that they are highly compartmentalized: the interior of each contains huge numbers of granular peroxisomes and little else other than the nucleus. Peroxisomes are cellular organelles that typically contain (among other things) catalases and peroxidases by which they can oxidize substrates by the use of peroxide intermediates. They are believed to have been important in the early development of biological mechanisms for detoxifying and eventually harnessing oxygen in respiration, which latter function was to be largely superceded by the rise of mitochondria and their attendant aerobic respiration. Where peroxisomes appear in contemporary eukaryotic cells, they may be involved in a host of functions, including lipid metabolism, generation of heat, and breakdown of amino acids (including D-amino acids, of which firefly luciferin is an analog). In the firefly photocyte, they contain the luciferin and luciferase and constitute the compartment of the cell that actually lights up.

As an aerobic cell, the photocyte also contains mitochondria, but these are restricted to so-called "differentiated zones" that line the cylinders, forming a "boundary" layer wherever the photocyte abuts on any part of the tracheal system. The photocytes also contain a type of granule, the so-called "differentiated zone granule," which remains to be characterized.

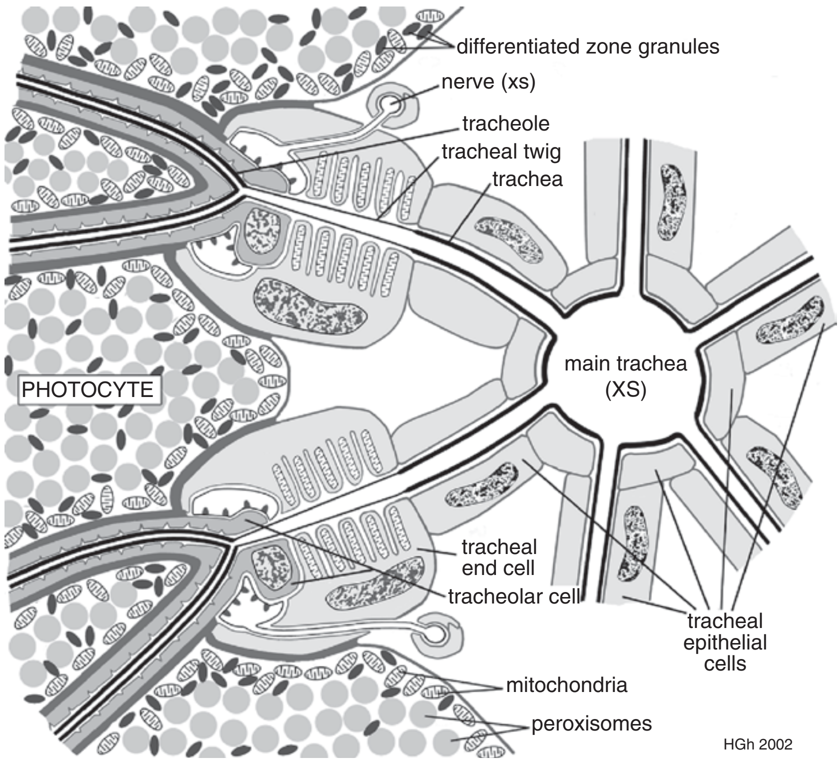
The standard insect tracheal system receives air through paired openings, the spiracles, that periodically open and close under neuromuscular control. From these extend inwards the



Fireflies: Control of Flashing, Figure 45 **Frontal (parallel to the lantern surface) section of the photogenic layer, showing several cylinders and their associated rosettes of peroxisome-laden photocytes. The borders of several photocytes (P) are outlined (solid lines); their collective borders also form the borders of the cylinders (the peripheral photocyte differentiated zones are set off by the dotted lines). The darker granules virtually filling the photocyte interiors are the peroxisomes. The cylinders contain the main tracheae (central signet-ring figures-T), nerves (n – small dot at end of arrow) and the tracheal end organs, which consist of tracheal end cells, tracheolar cells, and nerve endings. The rectangle shows an approximate location of the diagrammatic representation of a part of a cylinder and surrounding structures in the next figure. Bar = 10 μm.**

tracheae (here defined as the non-living cuticular intimae that actually carry the air – some authors use the term to include the attendant tracheal epithelial cells as well); these are sometimes elaborated into air sacs that aid in ventilation. The tracheae ramify throughout the interior, bringing the air directly to the tissues. As the system branches into finer and finer tubes, the number of tracheal cells associated with each tube is correspondingly reduced until at the narrow end of each trachea, each fine cuticular branch is wrapped in a single epidermal cell. Eventually each trachea gives rise to one or more tracheoles, the permeable "capillaries" of the system; these penetrate between the tissue cells to assure adequate ventilation. This transition point has associated with it a single tracheal end cell which is somewhat larger than the other tracheal cells and which hands the system off to a single tracheolar cell, which makes and maintains the tracheoles, All through the system, the cuticular tubes are usually wrapped in one or more spiral cuticular threads, the taenidia, which are presumed to provide reinforcement against distention or collapse.

The tracheal system in the adult lantern has these basic elements, but it is modified in four important ways. First, it is exceptionally richly and extensively branched. Second, the tracheal twig, the section of each trachea just proximal to the beginning of the tracheoles, lacks reinforcing taenidia; in whole mounts showing the cuticular elements alone, the twig appears flimsy and collapsable. However, in fixed and sectioned material, the tracheal twig invariably appears open and surrounded with what looks like a calyx of cuticular fibrils that extend back into crypts of the tracheal end cell (*vide infra*). Third, the tracheoles are also highly modified, but in the other direction, being stiff and resistant to bending or collapse. They (and the branches of their attendant tracheolar cells) penetrate between the photocytes and extend deep into the lantern, where their blind ends abut on those of their opposite numbers from the adjacent cylinders. Their course between the photocytes is matched by extensions of the differentiated zones of the photocytes, suggesting strongly that there is a functional importance for the juxtaposition of these two elements. Fourth, the tracheal



Fireflies: Control of Flashing, Figure 46 Diagrammatic representation of part of a cylinder and surrounding structures. The tracheae, surrounded by their epithelial cells, branch from the main trachea and approach the walls of the cylinder. As they reach the end cells, they shed their taenidia and become the thinner-walled and more flimsy tracheal twigs, which in turn branch into clusters of stout and reinforced tracheoles that penetrate between the photocytes. Each tracheal twig is surrounded by the distinctive tracheal end cell, whose luminal border contains mitochondria-lined folds separated by deep crypts. The tracheal end cell also envelops the body of the tracheolar cell, which makes and maintains the tracheoles. The nerve ending wraps around and appears to synapse (shaded semicircles) on the tracheolar cell. The photocyte is conspicuously compartmentalized: the surfaces abutting on the tracheal system contain the cell's mitochondria whereas the interior of the cell is filled with peroxisomes. The as-yet uncharacterized "differentiated zone granules" are more generally distributed.

end cell is large and specialized (v.i.); it wraps around and enfolds both the body of the tracheolar cell and the nerve ending, which latter synapses on the tracheolar cell. The complex of tracheal end cell, nerve ending and tracheolar cell body is referred to as the tracheal end organ.

The tracheal end cell is particularly specialized in that its luminal surfaces are thrown into deep crypts lined with mitochondria. This morphology is often referred to as "ion pump" morphology because it is commonly associated with such tissues as insect Malpighian tubules and rectal pads, tissues that are known to move ions, thereby moving fluid as well. This morphology is more faintly echoed in the proximal lumina of the tracheolar cells.

In sum, in the adult firefly an extensive and highly modified tracheal system penetrates deep into the lantern. Part (the tracheal twig) seems flimsy and collapsible, while other parts (the tracheoles) are stiffened and reinforced. The tracheal end cells and to a lesser extent the tracheolar cells have the deep mitochondria-lined infoldings that are usually associated with insect ion pumps. Let us now put the lantern nerves into the picture.

The lantern innervation *per se* is not remarkable; the patterning of the flashes apparently is controlled by a "pacemaker" that resides in the brain, and bursts of patterned impulses travel down the nerve cord to produce patterned flashes in the lantern. The lantern nerves travel alongside the tracheae, but they do not reach the photocytes (not in our North American species; although in some Asiatic fireflies, there may be limited contact between nerve endings and photocytes). The axons end not on the photocyte, as one would expect, but within the tracheal end organ, in calyces wrapped around the tracheolar cells. The transmitter that has been identified so far is octopamine, common in invertebrates, and application of octopamine can cause the lantern to glow.

The compartmentalized morphology of the photocyte and the location of nerve endings in the highly modified tracheal system suggested to many investigators that flash control must involve control of oxygen access to the photocyte. In other words, a lantern without these special features may glow, but it will not flash.

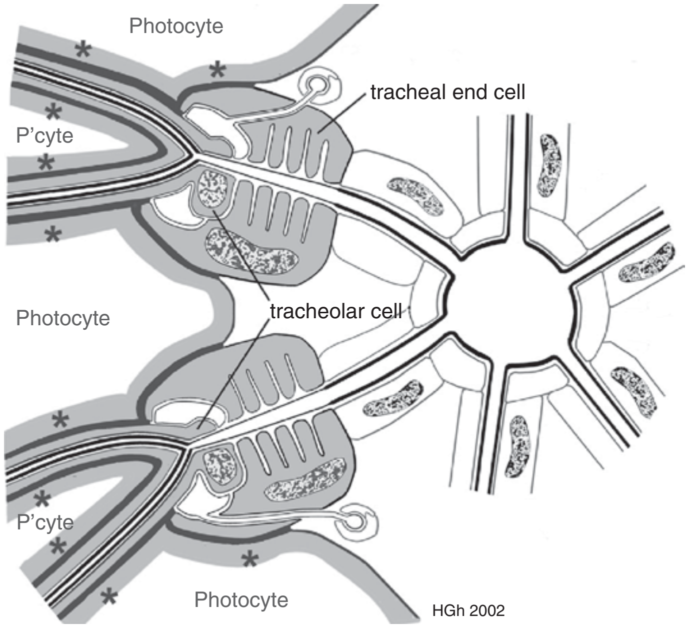
We find such a non-flashing lantern in larval *Photuris*. Like the adult lantern, it is bilayered. The dorsal layer is not that different from that in the adult, but the photogenic layer is. Its photocytes contain peroxisomes, mitochondria, and differentiated zone granules, but these are mixed in together, i.e., the cells are not compartmentalized. The nerves synapse directly on the photocytes rather than in the tracheal system, and the latter shows no particular specialization. Significantly, the larval lantern produces a less articulated signal, a simple glow that slowly rises and falls.

Firefly Flash Control

The increasing acceptance of oxygen as the key to flash control brought with it various suggestions as to mechanisms for this. All revolved around the possibility that a pulse of oxygen arriving via the tracheal system might reach the peroxisomes and set off the light reaction, either by directly providing an oxygen charge or possibly by causing the peroxisomes to make peroxide which in turn would complete the reaction. On the basis of the lantern morphology, Ghiradella pointed out that for oxygen to be the controlling factor, it itself must be controlled and kept from the peroxisome until flash time. The deployment of the mitochondria at the interface with the tracheal system suggested that they might serve as "gatekeepers," absorbing (and presumably using up) any incoming oxygen until the synaptic transmitter sets off a cascade of events that somehow opens the gate.

A mechanism for such a change was provided by Trimmer et al. who realized that the gaseous transmitter nitric oxide (NO) might be the "missing link." NO has several pertinent properties. It can be produced quickly by the enzyme nitric oxide synthetase (NOS) in response to calcium transients raised by the action of the transmitter at the cell surface, and it shuts down mitochondrial function by complexing with and inactivating the mitochondrial enzyme cytochrome c oxidase, without which a mitochondrion cannot bind and use oxygen. If, as it leaves the tracheole, the oxygen is not captured and used up by mitochondrial respiration within 1–2 μm of entering the photocyte, it should be free to diffuse further into the photocyte and reach the peroxisomes. In short, a gaseous transmitter would regulate transmission of another gas to control the flash. This action of NO is completely reversible; the gas degrades and diffuses away quickly, at which point mitochondrial respiration could immediately resume using up the oxygen supply. Trimmer et al. state that the time courses of all reactions are fast enough to account for the behavior of the intact lantern.

In several behavioral tests, Trimmer et al. confirmed that the lantern behaved as predicted with respect to NO manipulations (turned on in presence of NO gas and inhibited in presence of NO scavengers). They further showed via histochemical staining that NOS is roughly localized in the region of (Fig. 47) the tracheal end cells, the tracheolar cells, and the differentiated zones of the photocytes – the technique is not accurate enough



Fireflies: Control of Flashing, Figure 47 As in the preceding figure, part of a cylinder and its surround. Shaded regions show the approximate localization of the nitric oxide synthetase in the tracheal end organ and the differentiated zones (**) of the photocytes.

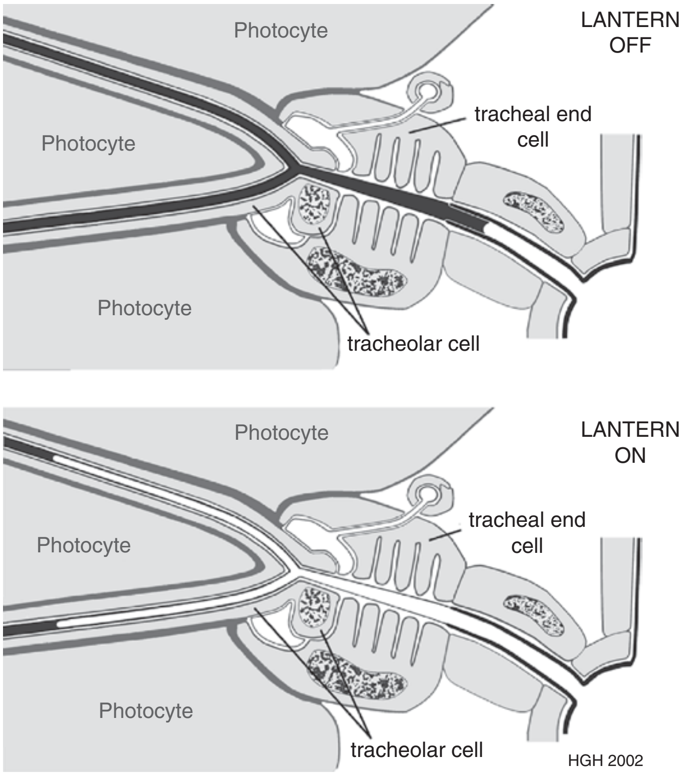
for precise subcellular localization. Trimmer et al. report that, given the abundant histochemical localization of the NOS, NO should be produced in "robust amounts."

Several pieces were now in place for these authors to model a mechanism. While the lantern is off, the mitochondria absorb and presumably utilize any entering oxygen to make ATP by oxidative phosphorylation. The crypts and mitochondria of the end cells and tracheolar cells present a large surface area that may provide an additional "outer gate," similarly absorbing and using any incoming oxygen. When the nerve fires, the transmitter activates the NOS to produce NO. The NO diffuses quickly into the mitochondrial regions of the end cells, tracheolar cells and photocytes. Here it complexes with and renders inactive the cytochrome c oxidase of the mitochondria, turning them "transparent" to the oxygen being delivered by the tracheal system. Oxygen can now diffuse through to the peroxisomes and initiate the flash.

The NO model also provided for flash termination, another hitherto troubling question. NO is labile and easily degraded. The elevated levels of oxygen that result from NO inhibition of cytochrome oxidase would help the process by negative feedback, both chemically and by competition with NO for the cytochrome c oxidase binding sites. Furthermore, studies with mammalian mitochondria suggest that light itself reverses the inhibitory action of the NO on the cytochrome c oxidase, so that the flash could function as a negative feedback system and actually contribute to its own termination. Studies on isolated firefly mitochondria suggest that the inhibitory effect of NO on respiration can be reversed by shining a bright light into the assay.

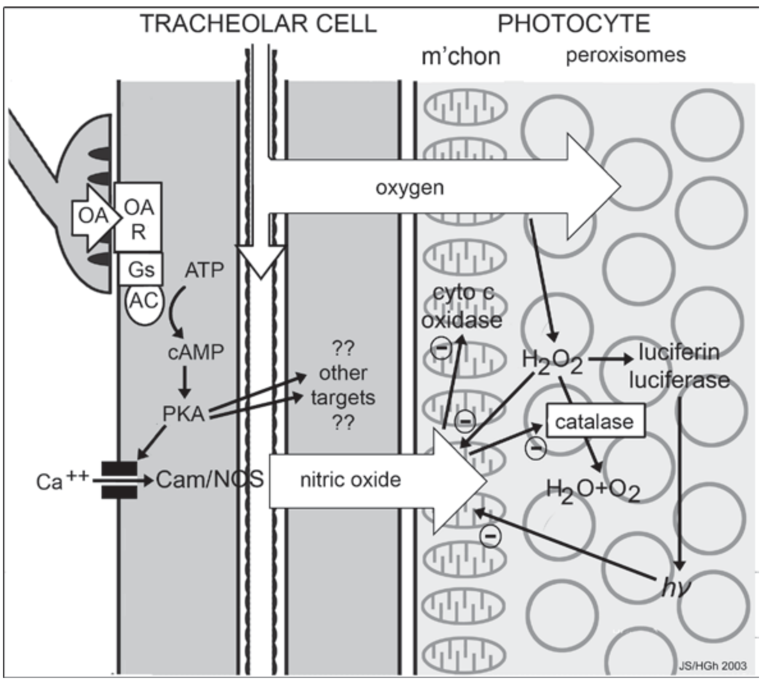
Robust as the model is, it doesn't take into account the putative ion pump morphology of the tracheal end and tracheolar cells and the collapsible nature of the tracheal twig. On the basis of this morphology, a different group of investigators (Timmins et al.) proposed an oxygen control model based on the higher (by a factor of 10^4) diffusion coefficient of oxygen in air than in water. These workers remind us that in any typical resting insect tissue the fine tracheoles are typically filled with fluid drawn from the tissue by capillary action. Anaerobic glycolysis causes the breakdown of glucose to more numerous end products, thereby raising the tissue osmotic pressure, which in turn draws the fluid out of the tracheoles. These then fill with air. In effect, anaerobic activity reduces the path length the oxygen must travel in liquid, greatly speeding up its access to the needy tissues. Timmins et al. extended this observation to the lantern by defining the kinetics of oxygen diffusion in the tracheoles under different conditions. For example, a switch from normal air to pure O_2 caused the lantern to light up continuously after a delay, and this delay was shorter if the firefly was already in flashing mode. Likewise changing from anoxic conditions (a stream of either pure N_2 or pure He) to an air stream caused a "pseudoflash" with different latencies for N_2 and He, which allowed the diffusion lengths in air and water to be calculated. The authors concluded that the O_2 diffusion data was consistent (Fig. 48) with an osmotic control mechanism, namely that tracheal end and tracheolar cells could be responding to the nerve action potentials by pumping ions and could thereby move the fluid out of the tracheoles to clear them for fast oxygen entry. By their calculations, the system should be able to perform this osmotic shift fast enough to account for the rise time of the flash, although the molecular details have not been given.

This proposal raises several questions about how such a model could work, of which speed is only the most prominent problem. Since any

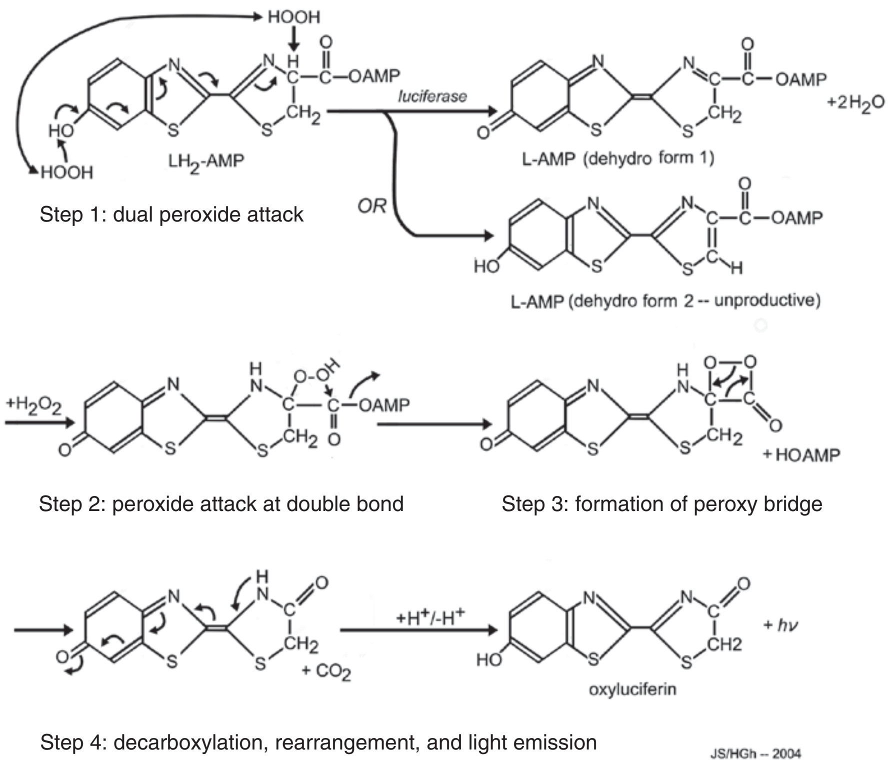


Fireflies: Control of Flashing, Figure 48 "Fluid switch" model for osmotic control of oxygen access to the photocyte. Top – inactive, dark lantern: The tracheae and tracheoles are filled by capillary action with tissue fluid, thereby creating a fluid barrier to the access of oxygen to the photocytes. Bottom – activated lantern: As a result of the nerve impulse, parts of the respiratory tubes are cleared of fluid, thereby permitting rapid diffusion of oxygen to the photocytes to initiate the production of light.

osmotic shift should generally be a relatively slow process (e.g., as in the original hypothesis of metabolic control), this mechanism would appear to be more suited to readying the lantern for flashing than to initiating and quenching each individual flash. Some features, in addition to the anatomical ones, actually fit well into this mechanism. Mosquito tracheolar cells, for instance have water channels called "aquaporins" which allow water to move through the membrane. The lantern is particularly rich in octopamine-sensitive adenyl cyclase and has high cAMP levels, which in mammalian kidney regulate water channel permeability as part of the AntiDiuretic Hormone (ADH) control. But cAMP production and cAMP kinase regulation are slow processes. What signal from the synapse would turn on the pumps (which are not known to be regulated in this



Fireflies: Control of Flashing, Figure 49 **The model mechanism for the control of the lantern flash. The nerve synapses onto the tracheolar cell, releasing octopamine (OA). Octopamine receptors (OAR) both depolarize tracheolar cells to fire spikes and also activate adenylate cyclase (AC), which makes cAMP from ATP. The activated cAMP-dependent kinase (PKA) can phosphorylate voltage dependent calcium channels to enhance Ca^{2+} to enter the cytoplasm (as well as other substrates that may enhance the excitability of this cell). The Ca^{2+} binds to calmodulin (Cam), activating nitric oxide synthetase (NOS) to release nitric oxide (NO), which can readily diffuse across cell membranes to carry the message into the photocytes. (Photocytes may also have calcium channels and NOS for their own NO synthesis as well.) NO binds to and inhibits cytochrome c oxidase, preventing its binding and use of oxygen; oxygen is then free to diffuse beyond the mitochondria to the peroxisomes, where it is converted into hydrogen peroxide. Hydrogen peroxide is normally quickly degraded by catalase, but NO also binds and inhibits catalase, further contributing to the rise in peroxide levels. We hypothesize that it is the fast rise in hydrogen peroxide, rather than a slow rise in oxygen, that activates the luciferin-luciferase to emit light. As time goes by, NO is degraded by light and by action of the catalase in the presence of peroxide, and rising oxygen. These changes terminate the action of the NO, the transient rise in peroxide, and the flash (from Ghiradella and Schmidt, 2004).**



Fireflies: Control of Flashing, Figure 50 **Proposed chemistry of the light reaction, starting with the luciferin-AMP intermediate that forms in the absence of oxygen. Hydrogen peroxide attacks both the 6´ OH and the C4 carbon, removing two hydrogens. No free radicals are left at each site because the double bonds rearrange (arrows) to produce a neutral conjugated dehydro form of L-AMP (form 1). An alternative dehydro form (classical dehydro form 2) does not result in light emission. After peroxide attack on the double bond (step 2), the peroxy-bridge structure forms by attack on the carbonyl, driving off AMP (step 3). This structure then disintegrates, releasing CO_2 and the ketone form of oxyluciferin, still in the rearranged form (C = O not conjugated with other double bonds). This spontaneously rearranges to give the original configuration (with the Ketone now included in the conjugated double bond system) and emits light (from Ghiradella and Schmidt, 2004).**

fashion elsewhere)? How would the pumps and channels be arranged for trans-tubular transport? In vertebrates such transport is accomplished by Na^+ channels on the luminal surface and Na^+ pumps on the external surface. In insect Malpighian tubules, transport is accomplished in the luminal surface using H^+ pumps to establish a gradient and H^+/Na^+ cotransport to utilize the resulting H^+ gradient (in addition to the Na/K pumps on the external surface) to complete the transport across the epithelium. This can account for the clustering of mitochondria at both luminal and external surfaces. It is doubtful, however, that a set of pumps limited essentially to the region of the tracheal twig can account for removal of tissue fluid from the entire length of the standard tracheoles (>100 mm of tubules) effectively enough to open an airway to the photocyte border within milliseconds.

The simplest way to combine the two models is to hypothesize that the osmotic control is the mechanism for readying the lantern for flashing and the NO production is the mechanism for actual flash control. Any such model also needs to explain the collapsible nature of the tracheal twig and the perversely reinforced nature of the tracheoles. We should like to look at that now. If the pumps in the tracheal end cell are in fact helping to move fluid out of the outer border of the cell, they would be reducing its turgor. If we assume that all tracheal elements upstream of the tracheoles themselves are impermeable (as suggested by osmium tetroxide penetration studies), the tracheal twig might very well be functioning as a mechanical valve (a suggestion raised almost a century ago by Dahlgren, 1917), perhaps involved in keeping the lantern dark while the animal is quiescent. If the calyx material seen around it in the sectioned material is in fact linking it with the crypts in the luminal border of the tracheal end cell, any shrinkage in the latter should open the twig. This is presumably what we see in the sectioned material, whose preparation usually causes some unavoidable tissue shrinkage and whose twigs are always wide open.

This ability to remain open or shut is exactly what we might predict of a system that has to change state at certain times of day, and the lantern certainly does this; during the first few minutes of active duty in the evening, it produces erratic and uncoordinated scintillation, almost as though the animal must wake and prime the system before it can start working.

We now return to the basic question we asked at the beginning: What really controls the flash? Any explanation needs to take into account the specialized morphology and the biochemical concomitants, including the NO. We here elaborate on a previous model. In the following discussion, we are assuming that all tracheoles deliver their oxygen efficiently to their tissues, i.e., that there is minimal "leaked" oxygen floating free in the hemolymph. We make the following observations:

- A cut lantern glows briefly at the cut surfaces and then quickly extinguishes. Oxygen must be diffusing in through the cut surfaces, but it does not raise a light response, suggesting that control must in fact be very local in the lantern tissue.
- Case and Strause report action potentials on the lantern surface, even though the nerves end within the tracheal end organs and not at the photocytes; the only other potential conductors are the branches of the tracheolar cells, which are certainly morphologically set up to spread the excitation deep within the lantern.
- The proximity of the photocyte differentiated zones to the air delivery system is exactly what we would expect if lantern mitochondria control lantern oxygen. But the flash does not rise in these regions but in the mysterious peroxisome-rich cell interior. Could there be yet another link in the flash process? Given the great concentration of peroxisomes, and the siting of the other flash ingredients on these, an obvious candidate is peroxide.

With these factors in mind, we proposed a model by which it is hydrogen peroxide, rather than oxygen, that completes the light reaction. As proposed by Trimmer et al., the NO would shut down mitochondrial function, allowing oxygen to reach the peroxisomes, where the oxidases that characterize these organelles would make hydrogen peroxide. The peroxisomal catalase, which would normally break down the peroxide, is also shut down by NO, and peroxide would accumulate explosively, completing the light reaction and raising the flash.

In more detail, our scenario is as follows (Fig. 49). Starting with flash onset:

- The transmitter depolarizes the tracheolar cell, which fires the afore-mentioned action potentials along its branches. This may require a second set of octopamine receptors, coupled to ionic channels, in contrast to those coupled to cAMP production; this is known to occur elsewhere in insects. The action potentials open calcium channels, and calcium enters the tracheolar cell and activates the NOS to produce NO.
- The NO shuts down the mitochondria, opening the photocyte to the entrance of the oxygen, which is in high supply because (we posit) both tracheal twigs and tracheoles are open and gas-filled. But at the same time, the NO reaches the peroxisomes and inhibits the peroxisomal catalase, the

combination of high oxygen and low catalase activity causes peroxide levels to skyrocket and peroxide completes the light reaction.

- As the light reaction runs its course, the NO diffuses out quickly and its inhibition of mitochondrial cytochrome c is reversed both by the high oxygen levels and by the light itself. Furthermore, in the presence of peroxide, NO is degraded by catalase. Thus, a series of feedback reactions undo what was done by the original entrance of NO and oxygen, and the system "tips back" to its interflash state.

This model is of course built around peroxide action and the question now is whether peroxide can also possibly complete the flash reaction, i.e., whether what is known about flash chemistry allows such a revision. We believe that it can: the final figure presents such a revision (details outlined in the caption).

We present this model as a next step, rather than a complete answer, especially since biological systems are rarely even this simple. It is becoming apparent that the oxygen not only travels as molecular O_2 but also as various free radicals and other highly reactive forms and, further, that cells can control and even use many of these. Furthermore, other questions still remain to be answered. Are we accurate in suggesting that the function of the tracheal end cell/tracheal twig complex is to ready the lantern for the night's activity by opening and holding open the tracheal twig to allow free access of oxygen to flash control machinery downstream? Precisely which oxidases are specific to firefly peroxisomes? Does the dorsal layer in fact contain urate, (which is characteristic of insect fat body, from which the lantern is believed to be derived, and if so, what part does the urate play in the flash chemistry? Where are the controls for multiple and flickering flashes? What can the larval lantern, which is developmentally distinct from that of the adult, tell us about the functioning of both types of lantern? And finally, how has this biological control of stored light evolved from what must have been antecedents common to most, or perhaps all, insects, and undoubtedly other organisms as well? We look forward to a bright future for firefly research as the firefly community continues to study this centuries-old mystery.

First Grub

The second phase of development in hymermetamorphic larvae of Meloidae. This generally corresponds to instars two to five. Such insects are scarabaeiform in appearance.

Fischer Von Waldheim, Gotthelf

Gotthelf Fischer von Waldheim was born in Lepzig, Germany, on October 3, 1771. He graduated from Universität Freiburg at the age of 26 with a doctoral degree. Then, in 1797, he accompanied von Humboldt to Vienna, intending to study medicine, but studied zoology instead. He then made a scientific journey through Germany and Switzerland, and moved to Paris, where he aided Cuvier. In 1804, he accepted a position as professor and director of the museum in Moscow, Russia. There, he was the leading entomologist and founded the Société Impériale des Naturalistes de Moscou. He described many of the insects collected in voyages by Russian explorers to North America. He published about 50 papers, mainly on Coleoptera and Orthoptera, but with some on Hymenoptera. He died in Moscow on October 18, 1853. His collection is mainly in Moscow, but with some materials in the hands of private collectors.

► Alderflies and Dobsonflies

Fitch, Asa

Asa Fitch was born on February 24, 1809, in the state of New York. At 17, he entered the Rensselaer School (now Rensselaer Polytechnic Institute) and graduated with honors in 1826. After this 1 year of college training, he entered the Vermont Academy of Medicine in 1827, receiving an M.D. degree in 1829. Next, he attended lectures at Rutgers Medical College in New York City, and then worked in the office of an established medical practitioner in the town of Albany. During the time of his medical studies and practice (1827–1838) he seems to have spent much time collecting insects and, in 1838 he abandoned medicine and returned to Salem, the town of his birth, to manage his father's business. He had married in 1832. In 1845 he published his first entomological paper, on *Cecidomyia*, in 1847 he was appointed as insect collector (Fig. 51) and identifier to the state of New York, and in 1854 his role was expanded to study "Insects injurious to vegetation." He was required to write annual reports on applied entomology, and these appeared in Transactions of the New York State Agricultural Society from 1855 through 1872. His title was not officially "State Entomologist of New York," but he was generally recognized as such. He died on April 8, 1879. His insect collection was in part sold to collectors or to the U.S. National Museum, and in part is deposited in the New York State Museum at Albany.

Fixed-Sample Size Sampling Plan

A sampling plan in which a predetermined number of sample units is collected based on a prescribed level of desired precision, classification accuracy, or level of confidence. (contrast with sequential sampling).

► Sampling Arthropods

Flabellate

A structure that has fan-like or lobe-like processes.

Flabellum

A fan or leafed structure. The lobe at the tip of the glossa in bees.

Fitness

The relative ability of an individual to contribute its genes to the next generation.

Flacherie

A term used to describe the flaccid condition (flaccidity) seen in silkworm larvae suffering from dysentery caused by bacteria, including *Bacillus thuringiensis*.

► Viral Flacherie

Flagellomere

One of the segments of the distal portion of the antenna. A portion of the flagellum.

► Antennae of Hexapods

Flagellum

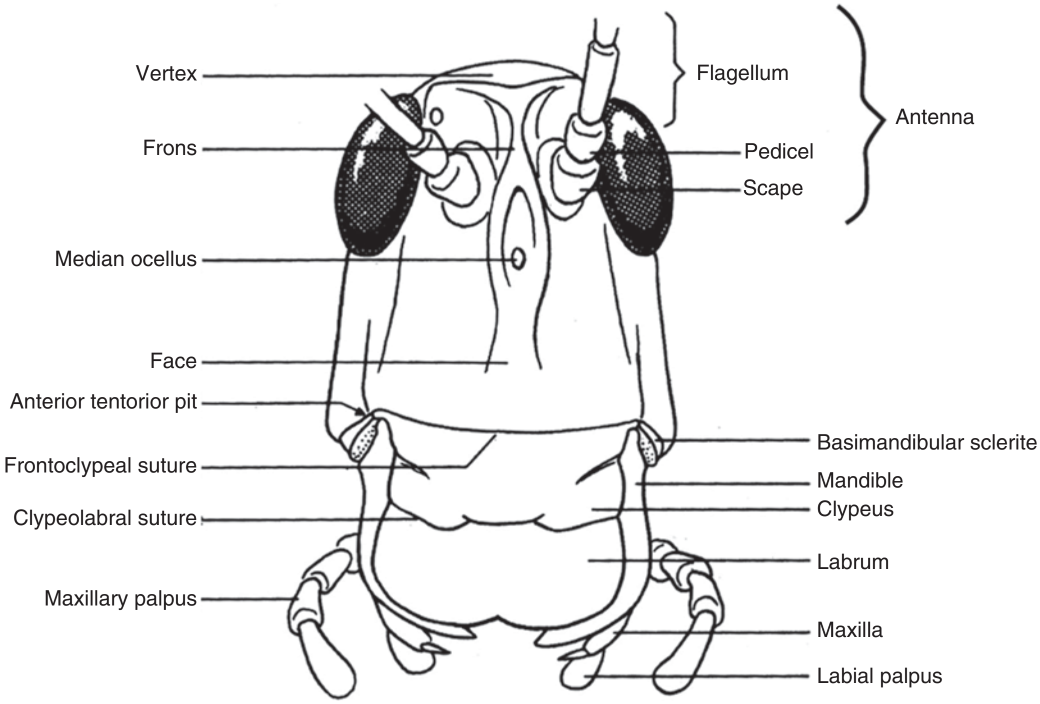
The outermost region of the antenna, beyond the (Fig. 52) scape and pedicel, and consisting of many segments or subdivisions (flagellomeres).

► Antennae of Hexapods

Flannel Moths (Lepidoptera: Megalopygidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

Flannel moths, family Megalopygidae, are a New World family of 263 species, mostly Neotropical; actual fauna likely exceeds 350 species. There are three subfamilies (sometimes elevated to separate families): Aidinae, Megalopyginae, and Trosiinae. The family is in the superfamily Sesioidea in the section Tineina, subsection Sesiina, of the division Ditrysia. Adults small to large (10–90 mm wingspan), with head rough scaled; haustellum vestigial; labial palpi minute; maxillary palpi absent; antennae bipectinate. Wings mostly rounded (Fig. 53) and quadrate; body robust. Maculation variable, with shades of brown and



Flagellum, Figure 52 **Front view of the head of an adult grasshopper, showing some major elements.**

Flannel Moths (Lepidoptera: Megalopygidae), Figure 53 **Example of flannel moths (Megalopygidae), *Edebessa purens* (Walker) from Brazil.**

gray, or white, but a few are colorful; scales often long and hair-like on some wing areas. Adults are nocturnal. Larvae are leaf feeders, usually communal in early instars; slug-like, with concealed head; with poison spines usually beneath long hair-like setae. A large number of host plants are recorded, and some species are polyphagous. A few are economic on forest trees and palms, but most are of medical importance due to urticating setae in adults and the poison spines in larvae.

Flapping Flight

The most common form of insect flight, wherein flapping movement of the wings generates thrust and movement. Insects can produce forward flight and hovering flight. They can also glide, which is called passive flight.

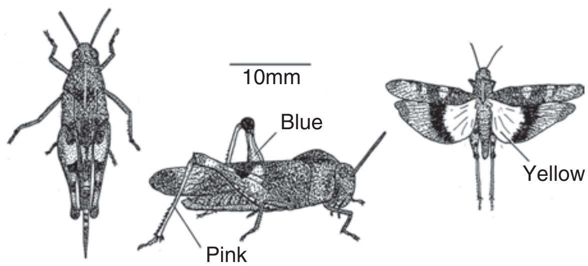
Flash Colors

MALCOLM EDMUNDS
University of Central Lancashire, Preston, United Kingdom

Flash colors are colors that are exposed when an animal moves but are hidden when it is at rest, e.g., the bright hind wings of underwing moths (*Catocala*, *Triphaena*), hawkmoths (*Macroglossum*), and grasshoppers (*Trilophidia*, *Oedipoda*) all make the insect conspicuous while it is flying but as soon as it comes to rest and folds its hind wings beneath the cryptic forewings, the color vanishes. It is thought that predators may initially be startled when a hitherto cryptic insect is disturbed and flies off, suddenly exposing bright colors. The predator may then follow the bright color as it flies, preparing to attack it, but when it lands and the color vanishes the predator is baffled because it was following the color rather than the insect. This is how flash colors are thought to work; they certainly deceive humans in this way, so it is reasonable to suppose that birds also may be deceived, but there has been no experimental demonstration that they reduce predation by natural predators.

Some butterflies have brightly colored upper sides to their fore wings which may be flash colors since these are hidden when the wings are folded together at rest. Other insects (e.g., some bugs and mantids) have bright colors (Fig. 54) on the dorsal surface of the abdomen which are hidden by the cryptically colored wings when at rest. These, too, may be flash colors.

Many grasshoppers stridulate as they jump or fly and then remain silent on landing. It is possible that predators follow the noise and are then baffled when the noise ceases and there is no sign of the insect. If this is indeed the function of stridulation in a flying grasshopper then, by analogy with flash coloration, it could be called flash behavior.



Flash Colors, Figure 54 The grasshopper *Trilophidia tenuicornis* is cryptically brown with disruptive markings when at rest (left and center). When it flies (right), bright colors are exposed on the hind wings which vanish when it lands (flash colors). The pink and blue marks on the hind legs may attract a predator to the most dangerous part of the insect; it can give a painful kick with these legs, which have sharp spines (reproduced from Edmunds, 1974, fig. 6.3).

► Beetles

Flea Beetles (Coleoptera: Chrysomelidae: Alticinae)

JULIANA J. SOROKA
Agriculture and Agri-Food Canada, Saskatoon, SK, Canada

Flea beetles are members of the subfamily Alticinae in the leaf beetle family Chrysomelidae, one of the most destructive of insect families. The Alticinae, the largest chrysomelid subfamily, has 6,000 species worldwide, most of which are phytophagous. Flea beetles are small, leaf-feeding beetles with greatly enlarged hind femora (thighs) and a propensity to jump when disturbed, from whence their common name originated. Many species of flea beetles are economic pests of vegetable and field crops, while some have been utilized as biological control agents of noxious weeds.

Although a few are generalist feeders on a wide range of host plants, most species of flea beetles are monophagous or oligophagous, feeding on plants in only one or a few related families. Thus, flea beetles in the genus *Chaetocnema* feed on sweet corn and grasses, others in the genus *Altica* feed on alder, dogwood, elm, grapevine, rose and willow, while another group feeds on potatoes, tomatoes, eggplant and pepper. Because of the variety of flea beetle species, host plants, and habitats, this entry will focus on one species, *Phyllotreta cruciferae* (Goeze), the crucifer flea beetle or cabbage flea beetle, which has many attributes of flea beetles in general.

Crucifer Flea Beetle, *Phyllotreta cruciferae* (Goeze)

The genus *Phyllotreta* Chevrolat is one of the largest alticine genera, with 250 species worldwide. *Phyllotreta* species are principally north temperate in distribution, occurring mostly in Eurasia and North America. Few species occur in tropical habitats. Along with the species in the genus *Psylliodes* Latreille, *Phyllotreta* encompasses the main flea beetle genus that feeds on crucifers. In addition to *P. cruciferae*, 14 other *Phyllotreta* species are injurious to cruciferous crops in Canada, with 12 of these distributed across North America. Many of the 150 Palearctic species of *Phyllotreta* are likewise economically important pests of crucifers. Several *Psylliodes* flea beetles are similar in appearance, biology, and crucifer damage patterns to *Phyllotreta cruciferae*. *Psylliodes crysocephala* (L.), the cabbage stem flea beetle, is one of the most injurious flea beetles to cultivated crucifers in the Palearctic region, while *P. punctulata* Melsh., the hop flea beetle, is commonly found in crucifer field crops in North America.

A native of Eurasia, the crucifer flea beetle, *P. cruciferae,* is the dominant flea beetle pest of oilseed crops in India and eastern Europe, although of sporadic occurrence in western Europe. It was first found in North America in 1923 near Agassiz, British Columbia, Canada. It spread rapidly, and is now distributed throughout the continent. Along with the striped flea beetle *P. striolata* (Fab.), *P. cruciferae* is the most economically important pest of crucifer vegetable and field crops in North America.

Morphology

Phyllotreta cruciferae adults are small, oblong-ovate or oval-shaped leaf-feeding beetles 2–3 mm long (Figs. 55a and 56). They are usually entirely black, or black with a bronze, metallic green or blue luster. Like other *Phyllotreta* species and unlike *Psylliodes*, which has 10, *P. cruciferae* has an 11-segmented, filiform-shaped antenna. The elytra are dorsally flat, and the punctae on them are not deep and arranged in rows as in *Psylliodes punctulata*, but are arranged randomly over the wings.

The creamy white to yellow eggs are oval in shape and about 0.35 mm by 0.20 mm in size. They are laid singly or in small numbers in the soil around the crown of host plants.

The three larval instars are creamy white, slender, cylindrical and worm-like in general appearance, with three pairs of very small legs, a brown head capsule and tan posterior segment (Fig. 55b). The third instar reaches a length of 3–5 mm. Just prior to pupation, third instar larvae form plump quiescent prepupae in an earthen cell in the soil near host roots. *Phyllotreta cruciferae* larvae, like most but not all *Phyllotreta* larvae, are root feeders and, as such, are rarely seen.

The whitish-yellow pupae are about 2.5 mm long, with free body appendages and dark-colored eyes. As they near eclosion to adult state, the pupae darken to black.

Host Range and Food Selection

Nearly all species of *Phyllotreta* feed on plants in the families Cruciferae, Resedaceae, or Capparidaceae. These plant families contain glucosinolates, sulfur-rich, anionic secondary plant compounds that produce several different products through hydrolysis by endogenous myrosinases. These hydrolysis products have different biological roles, acting as defense compounds in some instances and attractants in others. *Phyllotreta cruciferae* flea beetles are strongly attracted to allyl isothiocyanate, a volatile metabolite of the secondary plant compound allyl glucosinolate. The flea beetle feeds on cultivated and wild crucifers that contain glucosinolates, with host crops including the oilseed rapes, canolas, and mustards *Brassica rapa*, *B. napus*, *B. juncea*, *Crambe abyssinica*, *Camelina sativa*, *Eruca sativa*, *Sinapis alba*; host crucifer vegetables *B. chinensis*, *B. oleracea* including kale, Chinese cabbage, cauliflower, cabbage, Brussels sprouts, kohlrabi, broccoli, turnip, and radish; other host crops including *Alyssum*, *Hesperis matronalis*, *Cleome* spp., *Nasturtium officinale*, and *Tropaeolum minor*; and host wild species including *Arabis* spp., *Arabadopsis thaliana*, *Berberea vulgaris*, *Berteroa* sp., *Brassica amplexicaulis*, *B. balearica*, *B. barreliere*, *B. drepanensis*, *B. elongata*, *B. gravinae*, *B. incana*, *B. macrocarpa*, *B. maurorium*, *B. nigra*, *B. tournefotii*, *Cardamine* spp., *Diplotaxis* sp., *Descurainia* spp., *Erucastrum gallicum*, *Lepidium campestre*, *Neslia paniculata*, *Rorippa islandica*, *Sinapis allioni*, *S. ancheri*, *S. flexuosa*, *S. arvense*, and *S. pubescens*. The flea beetle does not feed readily on *Capsella*, *Erysimum*, *Iberis*, or *Thlaspi* species. In stress situations in the absence of suitable crucifer hosts *Phyllotreta* has been observed feeding on such diverse plants as garden peas *Pisum sativum* and red-root pigweed

Amaranthus retroflexus, but it is unlikely that *P. cruciferae* can survive and reproduce on such non-cruciferous hosts.

Biology

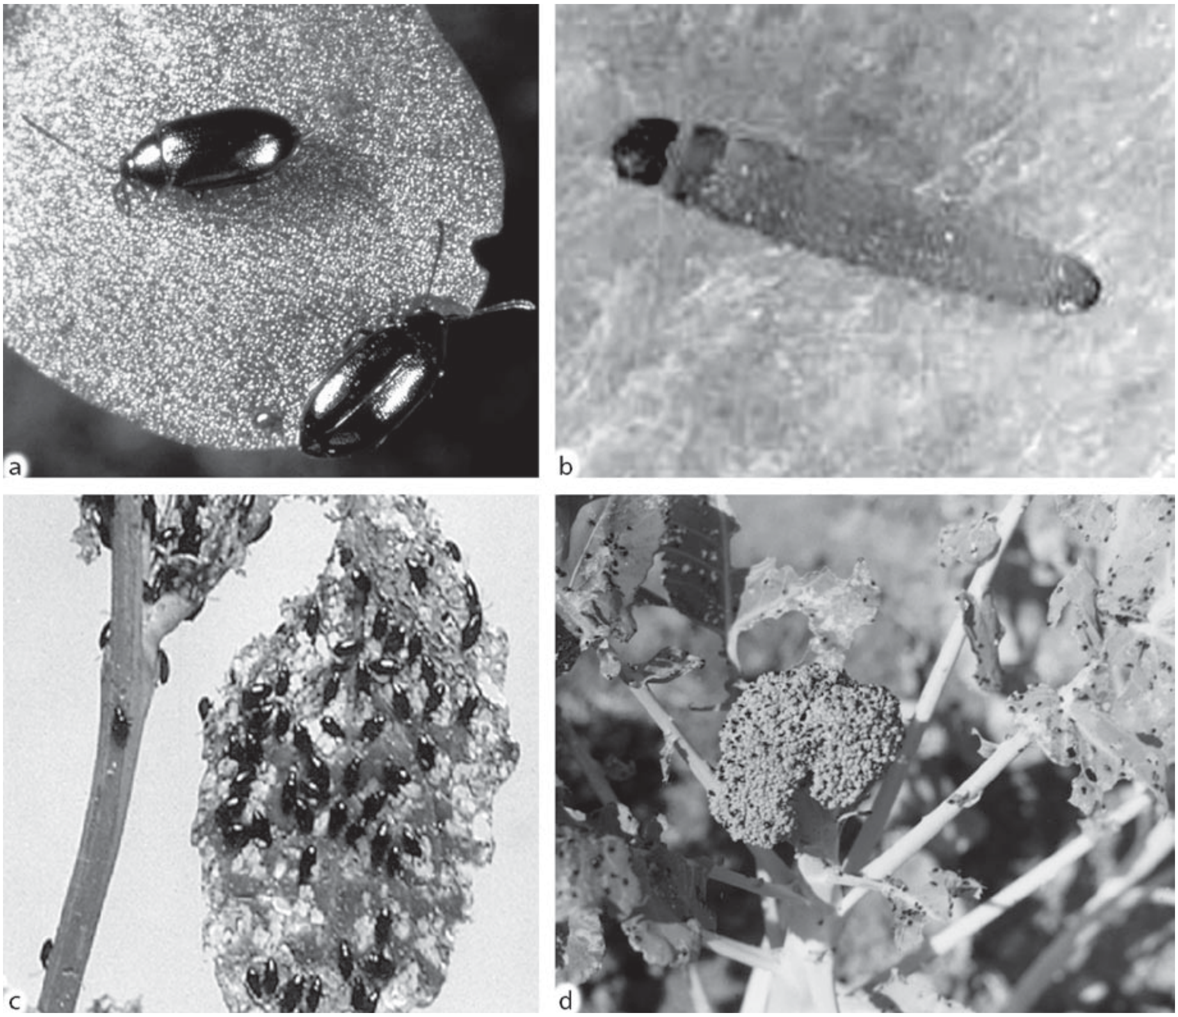
While some flea beetle species may have two to three generations per year, crucifer-feeding flea beetles have one complete generation a year in north temperate climates. *Phyllotreta cruciferae* overwinter as adults in leaf litter or occasionally in soil in protected places such as field margins, fence rows, hedges, tree rows or, less frequently, within cultivated fields. Winter mortality is generally very low, although populations can decline after several consecutive severe winters. Emergence from overwintering sites begins with the first extended period of warm weather in spring. In Alberta, Canada, peak emergence occurs near the end of May when ground temperatures reach 15°C. Overwintered *P. cruciferae* fly when daily maximum air temperatures exceed 14°C. Flea beetle emergence, movement, and feeding is maximized in periods of warm, sunny, dry and calm weather, and is curtailed in cold wet conditions. Flea beetles begin feeding on winter annual weeds or volunteer crucifers early in the spring. They move into fields of preferred host plants such as *Brassica napus* or cruciferous vegetables as these are seeded and germinate. After feeding for a period, each mated female will lay up to 25 eggs at the base of host plants or sometimes on plant roots from April to early July, whereupon the overwintered generation dies off. Larvae hatch in 10 days–2 weeks, and feed on root hairs and small roots, chewing circular pits or penetration holes into the root epidermis. The beetles develop through three larval instars. After feeding for a week to 10 days, the third instar larvae cease feeding and enter a quiescent prepupal resting stage in an earthen cell in the soil. After a pupal period of 1–2 weeks, adult beetles emerge from late July onward, and feed on green cruciferous plants until cold temperatures cause them to leave fields and seek overwintering sites. Univoltinism, one generation per year, appears to be facultative rather than obligate in flea beetle biology. With development from egg to adult being temperature dependent and occurring in as little as 7 weeks under favorable conditions, the event of a complete second generation may become more frequent with increasing global temperatures.

Damage

Phyllotreta cruciferae causes the greatest economic damage to cultivated crops through adult beetle feeding on the epidermis of cotyledons and young true leaves. Although each circular feeding pit is small and rarely perforates the leaves, tissue around each feeding lesion dies and, under heavy feeding pressure, the sheer number of feeding pits can give the fragile young leaves a sieve-like or shot-hole appearance (Fig. 55c). In large numbers, flea beetles can rapidly defoliate and kill seedling plants. During cold, inclement weather and periods of slow plant growth flea beetles can feed on seedlings at or below the soil surface as these emerge, destroying the apical meristem and, ultimately, the seedling. Light feeding on older leaves is often restricted to the leaf edges, where it causes browning and curling. Flea beetle feeding can result in decreased plant stand if meristems are severed or if foliar damage is extreme; if plants are not killed directly, flea beetle feeding can result in reduced vigor and delayed plant growth, stunted plants, uneven stands and protracted plant maturity. Under warm sunny conditions flea beetle movement into fields and feeding can be rapid and severe; under heavy flea beetle feeding, entire fields can be destroyed. Damage is often most severe along field edges, where the flea beetles are entering the field. Damage may be worse on light, sandy soils that exacerbate plant desiccation. Once past the three to fourth leaf stage, most crucifers are tolerant to flea beetle foliar feeding. Crucifer vegetable transplants are less affected than direct-seeded crucifer vegetable crops, but they, too, can be killed or severely stunted by heavy feeding during warm, dry weather. Once vegetables reach the six-leaf stage or are taller than 15 cm, only severe defoliation will affect head weight and quality.

Larvae of *P. cruciferae* and most cruciferous flea beetles feed on root hairs and small roots. By this time host plants can tolerate root pruning, and economic damage by *P. cruciferae* larvae to oilseed crops is considered negligible. However, in some cases the value of cruciferous vegetable crops such as radishes can be reduced because of cosmetic damage caused by flea beetle larvae. The larvae of a few species of European flea beetles such as *Phyllotreta nemorum* (L.) and *Psylliodes chrysocephala* (L.) bore into stem and leaf tissue, feeding on leaf mesophyll, petioles and stems. Thus, it is the larval stage of these species that is the most economically detrimental.

As adult populations of *P. cruciferae* emerge in summer, their debarking of the epidermis of green oilseed pods can cause increased chlorophyll content of seed, shriveled or "pepper seed," decreased seed weights, increased pod shattering, and fungal growth within pods in wet weather. Youngest pods and later-seeded crops are most affected. Feeding on heads of crucifer vegetables



Flea Beetles (Coleoptera: Chrysomelidae: Alticinae), Figure 55 **Crucifer flea beetle: (a) adult *Phyllotreta cruciferae* (Goeze); (b) *Phyllotreta cruciferae* larva (3 mm); (c) severe defoliation of crucifer leaves; (d) cosmetic damage to a broccoli head.**

(From Capinera 2001, Handbook of Vegetable Pests, Academic Press.)**

can result in brown flecks on curds or florets, creating cosmetic damage and downgrading in crops such as cabbage and broccoli (Fig. 55d). Although rare as a vector of disease in North America, the crucifer flea beetle has been reported to vector the bacterium that causes black rot in cabbage. In Europe flea beetles are known to transmit turnip mosaic.

Economic Impact

The cost of flea beetle damage to oilseed crucifer crops in North America exceeds $300 million annually. Direct losses to oilseed production average 8–10% of the annual crop yield. Because more than 90% of the 5 million ha sown to oilseed crucifer crops in Canada utilize insecticide-fungicide seed dressings, indirect costs include environmental and non-target exposure to pesticides for flea beetle control. Significant damage can occur to young cole crops, especially if these are direct-seeded rather than transplanted, and cosmetic damage by late season feeding can also reduce farm receipts appreciably.

Management

Economic Thresholds

Because of their propensity to move at the least disturbance, flea beetle numbers on plants are difficult to count accurately, and the impact of the number of feeding pits varies with the area of the leaf. Instead of numbers of beetles or feeding pits, economic thresholds in seedling oilseed crucifer crops in Canada are established as defoliation levels of >25% of the leaf area eaten at the cotyledon to third true leaf stage. Economic thresholds at crop maturity have not been determined, but if oilseed pods are still green, heavy feeding on them may decrease seed yields or quality. In cole crop production, late feeding can cause cosmetic damage that will downgrade head quality. An average of 75 beetles per plant can result in severe damage to a mature cabbage crop.

Monitoring

Crop monitoring is the first step in averting losses from flea beetle feeding. Often flea beetle infestations may be localized or sporadic. Examination of seedlings for the appearance of shot-hole feeding should be done daily from emergence until the crop reaches the three to four leaf stage, with special care taken to monitor field boundaries next to grassy or wooded areas. Yellow sticky cards can be used to monitor flea beetle presence, but they may not be suitable for estimating population levels or the need for control. A flea beetle aggregation pheromone has been developed that may allow for early detection of overwintering flea beetles, for population monitoring, and for estimating their densities. Crucifer crops should be monitored especially closely in hot, dry weather, when flea beetle numbers can increase exponentially, and feeding levels and plant stress are high.

Cultural Practices

Any practice that encourages rapid germination, increased seedling vigor and plant growth, and minimization of the seedling vulnerability period will aid in decreasing the susceptibility of young crucifer crops to flea beetle feeding. Thus, good seed bed preparation, proper fertilization, shallow seeding into warm soil with adequate moisture or irrigation will promote rapid seedling growth and lessen flea beetle damage to crucifer seedlings. Cruciferous weeds and volunteer crucifers should be controlled prior to seeding. Canola grown in a zero till cultivation regime with minimal soil disturbance, at high seeding rates and wide row spacings has been shown to suffer less flea beetle damage than crops grown under conventional tillage. Late planting can avoid the spring peak in flea beetle numbers, but may not be practical for agronomic reasons. Seeding rate and date does not significantly affect the abundance of new generation flea beetles. For cole vegetable and salad greens production, such cultural methods as the use of vigorous transplants, row covers, and exclusion fencing can protect seedlings physically until they become large enough to withstand feeding. Irrigation applied under warm, dry conditions may drown beetles when they are most active. Crop rotation and intercropping crucifers with plants from other families such as clovers, marigolds, or tomatoes may decrease flea beetle numbers. Protection of brassica greens such as arugula or bok choi from cosmetic damage may be necessary throughout the season, but is difficult by cultural means.

Host Plant Resistance

Host plant resistance holds potential as a means of effective flea beetle management. *Brassica napus* oilseed rape is less damaged by the crucifer flea beetle than is *B. rapa*, while yellow mustard *Sinapis alba* can outyield both *Brassica* species under heavy flea beetle feeding pressure. Intergeneric crosses between *B. napus* and *S. alba* are being undertaken to introduce mustard flea beetle resistance into oilseed rape. Transgenic *B. napus* with elevated levels of trichomes on the first true leaves also has potential for deterring flea beetles from feeding. Some cruciferous vegetable varieties are variable in susceptibility to flea beetle feeding. Red or purple colored cole varieties may be less preferred than green ones when mature. In general, there is less flea beetle feeding on vegetable cultivars with a heavy, waxy bloom on their leaves.

Biological Control

Three species of braconid parasitoid wasps, and an allantonematid and two mermithid nematodes have been recorded attacking eight *Phyllotreta* species in an intensive European study. The braconid wasp *Townselitis bicolour* (Wesm.) parasitized up to 50% of adult flea beetles in summer in Germany. Microsporidean, eugregarine, and nematode infections have been reported from *Phyllotreta* species in Sweden. In North America, crucifer flea beetles are attacked but not controlled by a suite of natural enemies, including predators such as lacewing (*Chrysopa*) larvae, big-eyed bug (*Geocoris*) sp., *Collops vittatus* Say beetles, and field crickets (*Gryllus* spp.). The native braconid wasp *Microctonus vittatus* Mues. normally parasitizes <5% of crucifer flea beetle populations. An attempt to introduce *T. bicolour* from Europe into western Canada in the 1980s was not successful.

Chemical Control

More than 90% of the oilseed rape crops in Canada are planted with seed that has been treated with an insecticide-fungicide combination. If flea beetles are not controlled by the seed dressings and feeding is severe, or in jurisdictions without registered seed treatments, various foliar insecticides are used for flea beetle control. Some new chemistry insecticides such as thiamethoxam and spinosad are effective in flea beetle control, but the plant-derived products azidiractin and pyrethrin, along with kaolin clay, may not provide adequate protection. New biological, botanical or reduced-risk synthetic insecticides are being investigated for efficacy of control of crucifer flea beetles.

Flea Collar

A collar containing slowly released fumigant insecticide that is worn by cats and dogs to prevent infestation by fleas. Once popular, though not entirely effective, it has largely been replaced by systemic products that are dabbed on the animal or fed to the animal periodically.

► Veterinary Pests and Their Management
► Cat Flea

Fleas (Siphonaptera)

The fleas are a well known order of blood feeding insects, attacking mammals and birds. They bear some similarities to Mecoptera and Diptera, but their relationship to other insects is uncertain. The order name is based on the Greek words *siphon* (tube), a (without), and *pteron* (wing).

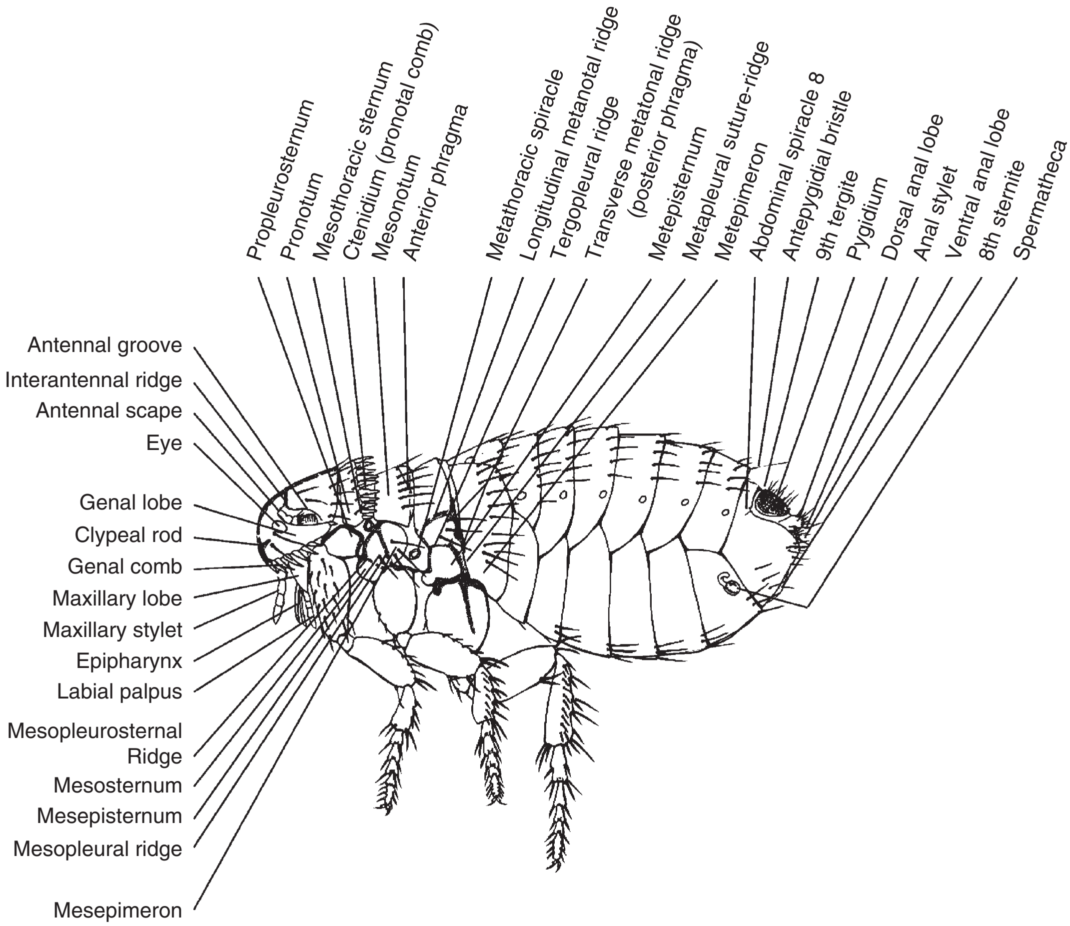
Classification

There are several classification systems available, with anywhere from five to ten superfamilies containing about 16 families. Following is a list of families containing about 2,300 species:

Class: Insecta
- Order: Siphonaptera
  - Family: Pulicidae – common fleas
  - Family: Tungidae
  - Family: Rhopalopsyllidae – club fleas
  - Family: Malacopsyllidae
  - Family: Vermipsyllidae – carnivore fleas
  - Family: Hystrichopsyllidae – rodent fleas
  - Family: Coptopsyllidae
  - Family: Pygiopsyllidae
  - Family: Stephanocircidae
  - Family: Macropsyllidae
  - Family: Xyphiopsyllidae
  - Family: Ancistropsyllidae
  - Family: Chimaeropsyllidae
  - Family: Ischnopsyllidae – bat fleas
  - Family: Leptopsyllidae – scaled fleas
  - Family: Ceratopsyllidae – bird and rodent fleas

Characteristics

Adult fleas are laterally compressed, wingless insects. They generally measure only 1–5 mm in length. They body is dark, normally brown or black, and well sclerotized. The antennae are short and held in grooves at the side of the head. The mouthparts are of the piercing-sucking type, but fairly short. The head often bears a row of large spines laterally; this is called the genal comb and the spines are called ctenidia. Fleas are adorned with numerous spines and setae. Fleas are renowned for their jumping ability, and some can leap up to 30 cm high and 20 cm distance in a single jump. Legs are of moderate size, though the coxae and the hind femora are enlarged. The abdomen consists of ten segments. Fleas display complete metamorphosis. Larvae are elongate (Fig. 57) and legless, resembling fly larvae, but they have a



Fleas (Siphonaptera), Figure 57 **Diagram of a flea showing a lateral view.**

distinct head capsule and moderately long setae. Larvae produce a small silken cocoon that often incorporates sand grains or other debris in its construction.

Biology

Adult fleas are obligate ectoparasites that feed on blood from birds and mammals; blood is required for development of eggs. They tend to be phototactic, and sometimes are attracted to shadows. In contrast, larvae often feed on organic debris, including the blood-containing feces of the adults. Both adults and larvae are often found principally in the nest of their host. The eggs are not normally glued to hair or feathers, and normally fall the nest of sleeping area of the host. Most species are quite specific, feeding on a single host species or related species of hosts. When lacking a preferred host, fleas may accept others, as is the case with rat fleas. Rats are quite susceptible to bubonic plague, and when the rats perish the fleas feed on other available hosts, including humans. Fleas infected with plague bacterial sometimes regurgitate into the host, thereby inoculating the (human) host with plague. Inoculation also is accomplished when the host scratches, and rubs feces containing bacteria into wounds. Rodents are the predominant host of fleas; 74% of fleas are known to feed on rodents. Fewer fleas attack birds. Only 6% of fleas feed on birds. Fleas have an unusual ability to remain for protracted periods of time in the pupal stage, and then to emerge quickly in response to mechanical stimulation. This is an excellent adaptation to conserve energy in the absence of hosts.

Problems Associated With Domestic Fleas

The primary importance of cat flea is its nuisance to humans and pets. They are not picky about their meals; they will feed on almost any warm-blooded animal. Bites usually cause minor itching, but may be more irritating to those with sensitive skin. Some people and pets suffer from flea allergy dermatitis, which can persist for up to 5 days and is characterized by intense itching, reddening at the sight of feeding, hair loss, and secondary infection. Cat fleas also serve as intermediate hosts of the dog tapeworm (*Dipylidium caninum*). This intestinal parasite is transmitted to the pet while grooming when it eats an adult flea carrying a tapeworm cyst. The flea is infected by ingestion of the cyst during its larval stage. The parasite segments resemble small pieces of rice and often are discovered around the anal region of the infected pet, though they may be elsewhere, and may drop from the animal.

Domestic Fleas

The most common domestic flea of both cats and dogs is the cat flea (*Ctenocephalides felis felis*). The dog flea (*Ctenocephalides canis*) appears similar to the cat flea, but is not common on household pets. The sticktight flea (*Echidnophaga gallinacea*) can become a problem if pets frequent areas associated with poultry.

The eggs of fleas are oval, and smooth. They are minute, measuring only about 0.5 mm in length, but visible to the naked eye. Their small size and white color may prevent them from being seen on lightly colored fabric. Small worm-like larvae, 1.5–5 mm in length, hatch from the eggs. Though they also are visible to the naked eye, they are not often observed. They are eyeless, legless and sparsely covered with hairs. The larval body is translucent white with a dark-colored digestive tract that can be seen through the skin. Eventually the larvae mature and spin silken cocoons in which they pupate, and develop into adult fleas. Cocoons are sticky, attracting dirt and debris. Adult fleas are 1–3 mm in length, reddish-brown to black, wingless, and laterally compressed They possess powerful hind legs, are well adapted for jumping onto hosts, and for running through hair and feathers.

Cat flea adults, unlike many other fleas, remain on their host. Females require a fresh blood meal in order to produce eggs. The eggs drop from the host. Adult fecal matter consists of relatively undigested blood. This dried blood falls from the pet and serves as food for the newly hatched larvae. The young fleas will hatch within 2 days and feed on dandruff, grain particles, and skin flakes found on the floor around them, in addition to the fecal matter provided by adult fleas. They develop best in areas protected from rainfall, irrigation, and sunlight, where the relative humidity is at least 75% and the temperature is 70–90°C. The larval stage lasts 5–15 days.

Larvae spin silken cocoons among carpet fibers, in floor crevices, or protected outdoor areas where they develop. Under optimal conditions, new adults are ready to emerge within 2 weeks. They develop faster at higher temperatures, but can remain in their cocoons up to 12 months. Vibrations and/or an increase in carbon dioxide stimulate adults to emerge. Adults live 4–25 days and are the only stage that lives on the pet and feeds on fresh blood.

Management of Fleas Affecting Household Pets

Effective control requires elimination of fleas from the pet, the home, the yard, and control of the flea life cycle. Removal of fleas from the pet alone is futile; immature fleas (eggs, larvae, pupae) develop off the pet and new adults quickly re-infest the animal. Historically, flea management was a very difficult problem in warm humid areas that favored their survival. However, new and safe chemical products are now available that can be used as part of a flea control program. There are three complimentary elements associated with flea management.

Treating the Pet

Removing fleas from pets may be done by a veterinarian, grooming parlor, or by the pet owner. A flea comb may be used, but is not very effective; only 10–60% will be collected. Fleas should be dropped in soapy water and then discarded. This method is very time consuming.

Shampooing the pet removes the dried blood and skin flakes that fall to the ground and serve as food for flea larvae. The animal's body must be thoroughly lathered, and it is recommended that the lather remain for up to 15 min before the pet is rinsed. Flea shampoos contain various insecticides. Some pets, however, may exhibit allergic reactions to these products.

The newest approach to topical flea control applications is spot treatment with products such as imidacloprid (Advantage) or fipronil (Frontline). Both are available as spot-on oils which are applied to the shoulder area of the pet and distribute over the body within a few hours. They are non-toxic to mammals and kill almost all fleas on the pet within 24 h of treatment, and provide effective suppression for 3–6 weeks. These products help reduce the symptoms of flea allergy dermatitis by killing fleas and reducing the number of flea bites on the animal, there may still be some allergic reaction because fleas are able to bite before they die.

Insect growth regulators (IGRs) and insect development inhibitors (IDIs) work by interfering with egg development, and molting of young fleas. They disrupt the flea life cycle but do not kill adult fleas. Methoprene (Precor) and pyriproxyfen (Nylar, Archer) are examples of IGRs available for pet treatment in sprays and flea collars. Lufenuron (Program), an IDI, is orally administered to the pet. The IGR and IDI products do not take immediate effect because they affect flea egg and larval development. Use of one of these products along with use of Advantage or Frontline will kill adults and prevent development of immature fleas.

Ultrasonic flea collars have also been proposed for use to keep fleas off pets, but are completely ineffective. Insecticidal flea collars also are not very effective.

Treating the Home

Indoor treatment should be concentrated on areas frequented by pets, as this is where most of the eggs and larvae will be located. Vacuuming the entire house and disposing of the vacuum bag will help eliminate fleas. Vacuuming will not only remove flea eggs, but may stimulate new adults to emerge from their cocoons, exposing them to any insecticide residue on the floor. Steam cleaning carpets is even more effective than normal vacuuming and should be considered if infestation is severe. In addition to sanitation, borate carpet treatment, applied either by the homeowner or a professional exterminator, works as intestinal poison when it is eaten by flea larvae. The powder is sprinkled and worked into the carpet. Overall risk of danger to pets and humans is unknown, but appears to be low. This treatment, however, is not recommended for homes with infants.

Treating the Yard

Flea larvae develop in shaded, humid areas, but will drown in a flooded environment. Rainfall is often enough to curb larval development outdoors. In addition to drowning, the fecal dried blood meal provided by adult fleas is no longer available if the lawn is wet. Sprays containing insecticides registered for outdoor use, such as pyrethroids, may be applied during dry seasons every 2–3 weeks to shaded areas where pets frequent, and flea larvae abound. Insect growth regulators are also available for outdoor use. If possible, control access of feral animals (opossums, skunks, etc.) to the yard as they bring new fleas with them. Sheds and dog houses should be treated the same as the house. Restricting pet access from areas that are difficult to treat (e.g., beneath porches, inside crowded sheds) may also help flea control.

Fletcher, James

James Fletcher was born on March 28, 1852, in the county of Kent, England. In 1874 he emigrated to Canada and worked for 2 years in the Bank of Montreal. He then became an assistant in the Library of Parliament in Ottawa. In this position he was able to continue his studies in botany and entomology, and he joined the Entomological Society of Canada in 1877. He married in 1879 and later had two daughters. In 1878 he published his first entomological paper, "An outline sketch of the Canadian Buprestidae" and in 1879–1880 a botanical paper "Flora Ottawaensis." His expertise in insects and plants was recognized in 1884 by his appointment as Dominion Entomologist (Fig. 58) to the Canadian Department of Agriculture. Then, he turned his attention to applied entomology, and published annual reports on this subject. His efforts persuaded the Committee of Agriculture of the Canadian House of Commons to establish Experimental Farms in 1887. He then received the title of Entomologist and Botanist, and was transferred from the Library of Parliament to the staff of the Experimental Farms. For the next 21 years his time was occupied with applied entomology and applied botany. In 1896, he received an honorary LL.D. degree from Queen's University, Ontario, for his contributions to agricultural science. He died in Montreal on November 8, 1908.

Flies (Diptera)

Flies are an order of fairly small, relatively frail, two-winged insects. Despite these characteristics, however, they are extremely important, both for their direct biting effects, and because they may transmit diseases to animals. The name of this order is based on the Greek words *di* (two) and *pteron* (wing).

Classification

About 100,000 species of flies are known. Various classification systems exist for this large and diverse order. Two suborders usually are presented: Nematocera with long, many-segmented antennae, and Brachycera with short, apparently 3-segmented antennae. The larvae of the Nematocera also are distinguished by possessing large heads with mandibles that move laterally. In contrast, the larvae of Brachycera tend to have small heads bearing mouth hooks that move vertically. Pupae of the Brachycera also differ in that the pupal stage is passed inside the hardened cuticle of the last larval instar; this is called a puparium. The numerous muscoid families are divided into those with lobes (calypteres) at the base of the wing, and those lacking them.

Class: Insecta
- Order: Diptera
  - Suborder: Nematocera
    - Infraorder: Tipulomorpha
      - Family: Tipulidae – crane flies
      - Family: Cylindrotomidae
      - Family: Limoniidae
      - Family: Trichoceridae – winter crane flies
    - Infraorder: Psychodomorpha
      - Family: Psychodidae – moth and sand flies
    - Infraorder: Ptychopteromorpha
      - Family: Tanyderidae – primitive crane flies
      - Family: Ptychopteridae – phantom crane flies
    - Infraorder: Culicomorpha
      - Family: Dixidae – dixid midges
      - Family: Corethrellidae
      - Family: Chaoboridae – phantom midges
      - Family: Culicidae – mosquitoes
      - Family: Thaumaleidae – solitary midges
      - Family: Simuliidae – black flies
      - Family: Ceratopogonidae – biting midges
      - Family: Chironomidae – midges
    - Infraorder: Blephariceromorpha
      - Family: Nymphomyiidae – nymphomyiid midges
      - Family: Deuterophlebiidae – mountain midges
      - Family: Blephariceridae – net–winged midges
    - Infraorder: Bibionomorpha
      - Family: Axymyiidae – axymyiid flies
      - Family: Bibionidae – March flies
      - Family: Hesperinidae
      - Family: Pachyneuridae – pachneurid gnats
      - Family: Ditomyiidae
      - Family: Diadocidiidae
      - Family: Bolitophilidae
      - Family: Lygistorrhinidae
      - Family: Manotidae
      - Family: Keroplatidae
      - Family: Mycetophilidae – fungus gnats
      - Family: Sciaridae – dark-winged fungus gnats
      - Family: Cecidomyiidae – gall midges
      - Family: Perissommatidae
      - Family: Scatopsidae – minute black scavenger flies
      - Family: Canthyloscelididae
      - Family: Anisopodidae
  - Suborder: Brachycera
    - Infraorder: Xylophagomorpha
      - Family: Xylophagidae – xylophagid flies
    - Infraorder: Stratiomyomorpha
      - Family: Panthophthalmidae
      - Family: Xylomyidae – xylomyid flies
      - Family: Stratiomyidae – soldier flies
    - Infraorder: Tabanomorpha
      - Family: Rhagionidae – snipe flies
      - Family: Pelecorhynchidae – pelecorhynchid flies
      - Family: Athericidae – athericid flies
      - Family: Tabanidae – horse flies and deer flies
      - Family: Vermileonidae
      - Family: Acroceridae – small–headed flies
      - Family: Nemestrinidae – tangle-veined flies

Family: Bombyliidae – bee flies
Family: Apystomyiidae
Family: Mythicomyiidae
Family: Hilarimorphidae – hilarimorphid flies
Family: Therevidae – stiletto flies
Family: Scenopinidae – window flies
Family: Apioceridae – flower flies
Family: Mydidae – mydas flies
Family: Asilidae – robber flies
Family: Empididae – dance flies
Family: Dolichopodidae – long-legged flies
Infraorder: Cyclorrhapha (Muscomorpha)
Division: Aschiza
Family: Lonchopteridae – pointed-winged flies
Family: Opetiidae
Family: Platypezidae – flat-footed flies
Family: Ironomyiidae
Family: Sciadoceridae
Family: Phoridae – hump-backed flies
Family: Pipunculidae – big-headed flies
Family: Syrphidae – flower flies
Division: Schizophora
Section: Calyptrate
Family: Mormotomyiidae
Family: Scathophagidae – dung flies
Family: Anthomyiidae – anthomyiid flies
Family: Fanniidae
Family: Muscidae – house flies
Family: Glossinidae – tsetse flies
Family: Hippoboscidae – louse flies
Family: Calliphoridae – blow flies
Family: Sarcophagidae – flesh flies
Family: Rhinophoridae – rhinophorid flies
Family: Tachinidae – tachinid flies
Family: Oestridae – bot and warble flies
Section: Acalyptratae
Family: Cypselosomatidae – cypselosomatid flies
Family: Megamerinidae
Family: Micropezidae – stilt-legged flies
Family: Neriidae – nerid flies
Family: Diopsidae – diopsid flies
Family: Gobryidae
Family: Nothybidae
Family: Psilidae – rust flies
Family: Somatiidae
Family: Syringogastridae
Family: Tanypezidae – tanypezid flies
Family: Conopidae – thick–headed flies
Family: Lonchaeidae – lonchaeid flies
Family: Pallopteridae – pallopterid flies
Family: Piophilidae – piophilid flies
Family: Platystomatidae – platystomatid flies
Family: Pyrgotidae – light flies
Family: Richardiidae – Richardiid flies
Family: Tachiniscidae
Family: Tephritidae – fruit flies
Family: Ulidiidae
Family: Ctenostylidae
Family: Celyphidae
Family: Chamaemyiidae – chamaemyiid flies
Family: Eurychoromyiidae
Family: Lauxaniidae – lauxaniid flies
Family: Coelopidae – seaweed flies
Family: Dryomyzidae – dryomyzid flies
Family: Helosciomyzidae
Family: Ropalomeridae – ropalomerid flies
Family: Sciomyzidae – marsh flies
Family: Sepsidae – sepsid flies
Family: Acartophthalmidae – acartophthalmid flies
Family: Agromyzidae – leaf miners
Family: Anthomyzidae – anthomyzid flies
Family: Asteiidae – asteiid flies
Family: Aulacigastridae – aulacigastrid flies
Family: Clusiidae – clusiid flies
Family: Fergusoninidae
Family: Marginidae
Family: Neminidae
Family: Neurochaetidae
Family: Odiniidae – odiniid flies
Family: Opomyzidae – opomyzid flies
Family: Periscelididae – periscelidid flies
Family: Teratomyzidae
Family: Xenasteiidae
Family: Australimyzidae
Family: Braulidae – bee lice
Family: Canacidae – canacid flies
Family: Carnidae – carnid flies
Family: Chloropidae – frit flies

Family: Cryptochetidae – cryptochetid flies
Family: Milichiidae – milichiid flies
Family: Tethinidae – tethinid flies
Family: Chyromyidae – chyromyid flies
Family: Heleomyzidae – heleomyzid flies
Family: Sphaeroceridae – small dung flies
Family: Camillidae – camillid flies
Family: Curtonotidae – curtonotid flies
Family: Diastatidae – diastatid flies
Family: Drosophilidae – small fruit flies
Family: Ephydridae – shore flies

Characteristics

Adult flies normally bear a single pair of membraneous wings, though some are brachypterous, and a few are wingless. The second pair of wings is reduced to stubby, knobbed balancing organs called halteres. The eyes are large, and three ocelli usually are present. The antennae are variable, though flies in the suborder Nematocera tend to have long, multi-segmented antennae whereas those in suborder Brachycera tend to have short antennae, often with the third (and final) segment bearing a process called an arista or style. The arista is variable in appearance, but usually hair-like or plume-like. The mouthparts generally are of the sucking type, but some are piercing-sucking whereas others are lapping or sponging. The legs tend not to be unusual or specialized in form, though some are quite long. The terminal tarsal segment often bears a structure called the empodium between the tarsal claws, or pads called pulvilli at the base of the claws. The wings, which number only two if present, often have reduced venation. Most often the wings are colorless. The base of the wing often bears a small lobe called the alula, and basal to the alula may be two lobes, the calypteres. Flies display complete metamorphosis (holometabolous development). Larvae of the Brachycera are often called maggots, and usually headless, legless and worm-like, though those of the Nematocera have head capsules. The pupae of Nematocera are obtect, while those of Brachycera are coarctate. The number of instars tends to be 4–9 in the Nematocera, but only three in Brachycera.

Biology and Importance

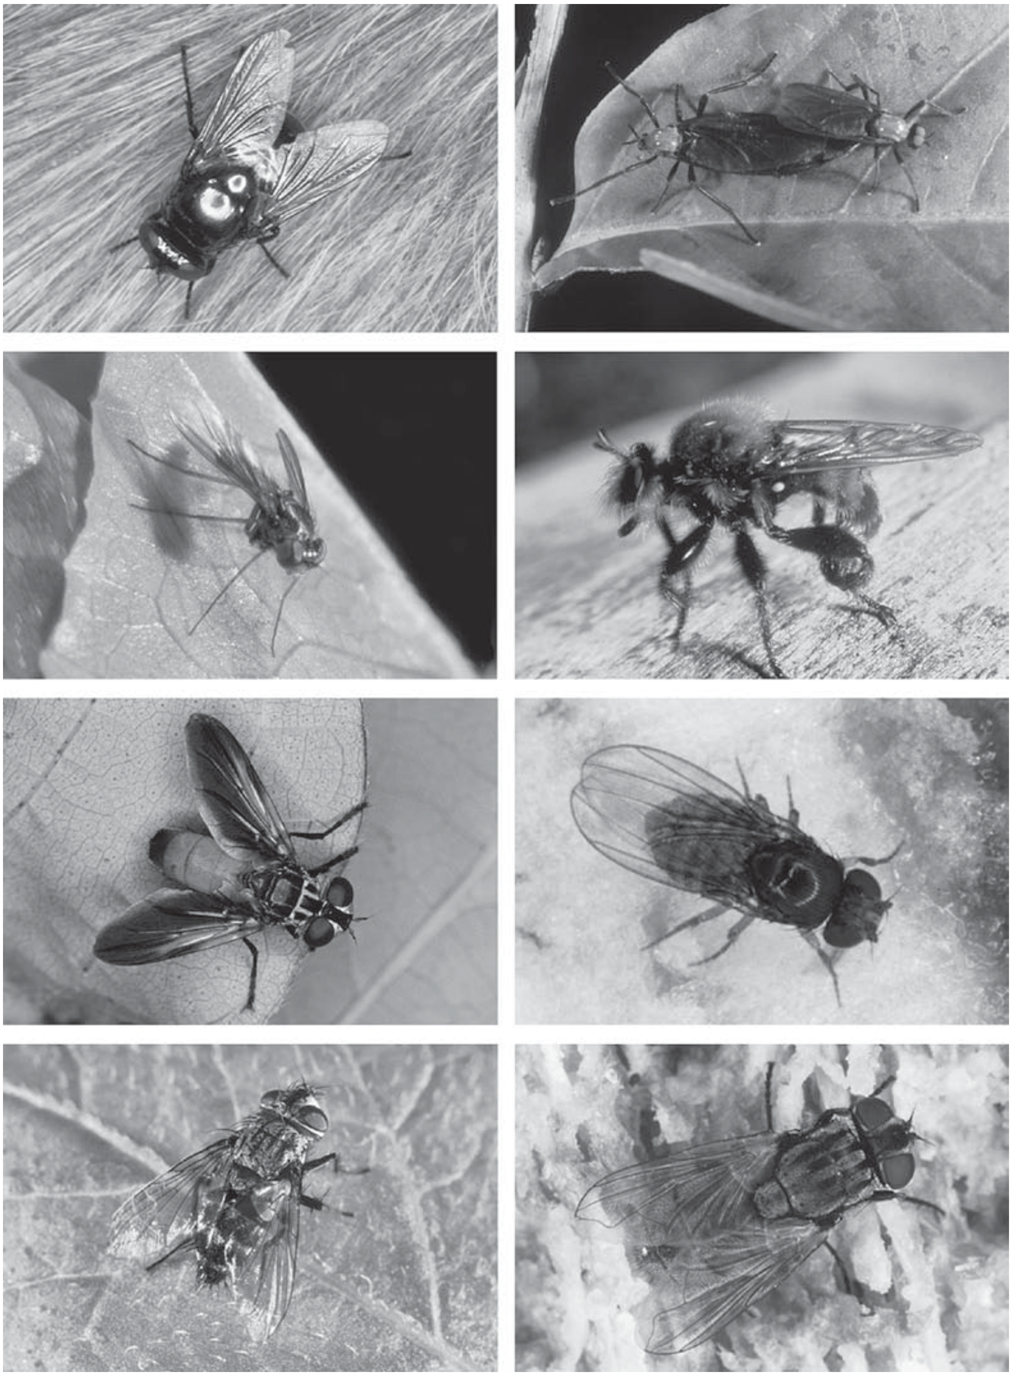
Adults flies generally are excellent fliers. Most of the adult flies feed on nectar or decaying organic matter. However, a considerable number are predatory or fed on blood of animals. Eggs are often deposited in wet habitats, though it ranges from aquatic to terrestrial. Soil and dung are often suitable. Larvae similarly are found in many habitats, and though many lack legs they may be quite mobile. Some attack living vertebrate animals, or recently killed animals.

Diptera is a very large and diverse group of insects, and many are of considerable importance. Some are beneficial, including the carrion and dung-feeding species (Figs. 59 and 60) such as blow flies (Calliphoridae) that quickly assist in the degradation of animal bodies and fecal matter, the predatory species such as flower flies (Syrphidae) that feed on other insects such as aphids, and the parasitoids such as tachinid flies (Tachinidae) that parasitize other insects such as caterpillars. Some flower-feeding species assist with pollination.

Flies are better known as pests, and often are associated with pestilence. Some feed directly on plants, including root maggots (Anthomyiidae), large fruit flies (Tephritidae), and leaf miners (Agromyzidae). Animal-biting flies include deer flies (Tabanidae), black flies (Simuliidae), tsetse flies (Glossinidae) and mosquitoes (Culicidae). The latter flies are the most important because they are widespread, and efficient vectors of many diseases to humans.

Important Taxa

Following are brief profiles of some of the largest and most important families of flies. Many additional taxa could be included.



Flies (Diptera), Figure 59 **Representatives of the order Diptera. *Top row, left*: green bottle fly, *Phaenica sericata* (family Calliphoridae) (photo, J.L. Castner); *top row, right*: lovebugs, *Plecia nearctica* (Bibionidae) (photo, J.L. Capinera); *second row*, *left:* a longlegged fly, (Dolicopodidae) (photo, J.L. Capinera); *second row*, *right*: a robber fly (Asilidae) (photo, Whitney Cranshaw); *third row*, *left*: feather-legged fly, *Trichopoda pennipes* (Tachinidae) (photo, J.L. Crane Flies (Tipulidae)

These long-legged flies are also called daddy-long-legs (some spiders also bear this common name), mosquito hawks and giant mosquitoes (both misnomers as they neither feed on mosquitoes nor feed like mosquitoes). They are some of the largest of the Nematocera, but usually quite harmless. The large size and long legs (easily detached by handling) usually distinguishes them immediately. The adults are not blood feeders. Some plant root and foliage-feeding feeding larvae, often called leatherjackets, are elongate, possess a sunken head, and are relatively amorphous. Few crane flies are damaging to plants. This is the largest family of flies, with about 15,000 species described from around the world.

Mosquitoes (Culicidae)

Mosquitoes are probably the most important insects. About 1,600 species are known. These slender flies possess long piercing-sucking mouthparts. Females, but not males, are commonly blood feeders. Both accept nectar. Larvae are aquatic filter-feeders, often feeding on algae and other particles, though some are carnivorous. Pupae also are aquatic, and are active. Water is the key to mosquito abundance. Temporary water, lacking predaceous insects and fish, is often a prerequisite for mosquito abundance. Eggs are deposited in the water, or on soil that is likely to be flooded. Snow melt, unusually heavy rainfall, and abnormally high tides often provide the temporary water that allows mosquitoes to breed and reach high numbers. Mosquitoes can cause injury by nuisance biting, by blood removal, and by transmission of diseases, particularly viruses and protozoa.. Insecticides have been used extensively to protect against mosquitoes and mosquito-transmitted diseases, and resistance to insecticides is a problem in some areas. Species richness is greatest in the tropics, but abundance is often greatest in arctic regions.

Black Flies (Simuliidae)

These are stout-bodied flies with short legs. They also are called buffalo gnats. The mandibles are a piercing type, but not as elongate as in mosquitoes. The females of some species are blood feeders, and sometimes black flies are a severe problem for people and animals. They are damaging because of their extremely high numbers, their tendency to bite viciously, and their tendency to penetrate orifices of the body such as nostrils, ears, and eye margins. Their feeding can cause the death of birds (especially poultry), and some transmit worms causing filariasis. The larvae are aquatic, and require swiftly flowing, clean water for their development. Ironically, when streams and rivers are cleansed of pollutants, frequently there is a upsurge of black fly problems, making the area less than pleasant during the spring months. About 1,500 species are known world-wide.

Biting Midges (Ceratopogonidae)

These small insects are also known as sand flies, no-see-ums and punkies. Despite their small size, they are vicious biters, often proving to be a serious nuisance along seashores, rivers, and lakes. Some areas are virtually uninhabitable during periods of the year if these midges are not managed. They feed on both vertebrate and invertebrate animals, including other insects. Larvae are semiaquatic, usually living in mud and decaying vegetation. The most important of these midges from the human perspective are in the genus *Culicoides*.

Fungus Gnats (Mycetophilidae)

Fungus gnats tend to be small insects, rather delicate, and widespread. About 3,000 species have been described. In adults, the antennae are long (12–17 segments) and the coxae are well developed. In larvae, the body is worm-like usually whitish with a small, dark sclerotized head, and relatively free of hairs and appendages. The larvae often live in damp places such as decaying organic matter or fungi; adults favor damp, shaded habitats. They tend to be gregarious, and unjustified damage to fruit and vegetables is sometimes attributed to these flies when, in fact, they are attracted to fungus-infected organic matter. Some fungus gnats are serious pests, however, and damage to mushrooms and the roots of potted plants is common. Fungus gnats are unremarkable in appearance, often muted in color

Gall Midges (Cecidomyiidae)

Gall midges are very small, delicate flies with long antennae. About 4,000 species are known. The wings have simplified venation. The larvae often feed on plants, inducing the formation of abnormal growth called galls. The galls provide shelter, and enhanced nutrition, for the larvae. These galls often are unique in shape, and symptomatic of the species. Some gall midges are very damaging, including Hessian fly, *Mayetiola destructor*, sorghum midge, *Contarinia sorghicola*, and chrysanthemum gall midge, *Diarthronomyia chrysanthemi*. Not all members of the family form galls, and some feed on detritus and a few are important predators of other insects.

Horse or Deer Flies (Tabanidae)

Tabanids have acquired many common names, including horse flies, deer flies, yellow flies, stouts, breezeflies, dunflies and clegs. They are heavy-bodied, flattened, and of moderate to large in size. The eyes are very large. The third antennal segment lacks an arista (style). The proboscis projects, and in the female it is used to pierce animal flesh and feed on blood. Males feed on honeydew and on flowers. Tabanids are swift flyers, and often trouble livestock and people. Though eggs are deposited on foliage, the larvae are found in moist soil and decaying debris, where they prey on small animals such as worms and other insects. About 3,500 species are known.

Robber Flies (Asilidae)

The flies of this large family are moderate to large-sized, bristly or densely hairy, and with long, stout legs. The proboscis protrudes, and is particularly hairy. Adults are predatory, sometimes capturing flying insects. The larvae live in the soil and feed on other insects, or are scavengers. Although often considered to be beneficial because they feed on other insects, sometimes they inflict heavy predation on other flies that are parasitoids of grasshoppers, thereby interfering with biological control. About 4,000 species are known.

Bee Flies (Bombyliidae)

Bee flies are often densely pubescent, with long, thin legs and a projecting proboscis. This appearance, plus the hovering behavior of the adults, accounts for the common name. The adults scatter their eggs about the soil. The larvae are parasitoids, attacking bees, wasps, some caterpillars, and grasshopper eggs. The young larvae display hypermetamorphosis, initially actively seeking prey, but then settling down once food is located. About 3,000 species have been described world-wide.

Flower or Hover Flies (Syrphidae)

These tend to be colorful flies, and moderate to large in size. The black and yellow coloration of many species causes them to be confused with bees or wasps. The adults are associated with flowers, where they hover in the air or feed, and they often are quite important as pollinators of flowers. The larvae are variable in their feeding habits; some feed on plants, others on detritus or in aquatic habitats, and many are important as predators of insects. Some are beneficial, feeding on aphids, scale insects and other pests, but others feed within the nests of social insects. A comprehensive treatment of this family has never been published, so although it is certainly one of the largest families of Diptera, with over 5,000 species described, their diversity remains uncertain.

Small Fruit Flies (Drosophilidae)

These small flies are also known as vinegar flies and pomace flies. About 2,800 species are known world-wide. They are often associated with decay, and apparently are attracted to the by-products of fermentation. Because they are easily reared, with rapid generation time, they (particularly *Drosophila melanogaster*) have become favorites for laboratory genetic studies. However, their biology is quite variable, and their feeding habits also include predation, sap and nectar feeding, and leaf mining in addition to feeding on decaying materials. Though commonly emerging from fruit and vegetables, few species are capable of direct damage to plants. Rather, most take advantage of openings or breaks in the fruit surface caused by physiological disorders, cultivation, and harvesting to gain entry. Most species are tropical.

Warble or Bot Flies (Oestridae)

This is a comparatively small family of flies, but it is important because larvae are endoparasites of animals, including humans and livestock. The larvae have swollen bodies and bear numerous stout spines encircling the body. The adults are stout and hover bee-like about their hosts, often causing great excitement or alarm among livestock. Some flies develop within the nasal and pharyngeal cavities, but others migrate through the body, completing their development on the back of the host. The human warble, *Dermatobia hominis*, seizes mosquitoes and deposits its egg on the mosquito; the egg hatches when the mosquito bites a human, and the warble fly larva then penetrates the host at the site of the mosquito bite.

Blow Flies (Calliphoridae)

Blow flies are medium to large in size, and usually metallic blue or green in color. This is a fairly large family, widely distributed, and often quite abundant. They often are scavengers, and become apparent when a freshly killed animal becomes available. Many species lay their eggs on fresh carcasses, with the larvae feeding on the decaying tissues, and contributing significantly to the rapid degradation of carrion. Some, such as the screwworm fly *Cochyliomyia hominivorax*, attack living tissue and can be serious livestock pests. In Australia, sheep blow flies in the genera *Calliphora* and *Lucilia* are severe problems for the livestock industry. Blow flies also are capable of causing cutaneous myiasis, and infesting the nasal cavity or the intestine of living animals. Others feed on animal excrement or similar materials. Some calliphorids are parasitoids of land snails, or predators of grasshopper eggs, and others attack frogs, toads and young birds. The cluster fly, *Pollenia rudis*, attacks earthworms and sometimes becomes so abundant as to be a nuisance in buildings where they collect on ceilings or at windows.

Tachinid Flies (Tachinidae)

This large family of about 8,200 species is relatively indistinct morphologically, but adults tends to be bristly. They are very important as endoparasitoids of other insects, particularly caterpillars, but also sawflies, beetle larvae, orthopterans, and hemipterans. Some species are specific, while others have a very broad host range. They scatter their eggs where they may be consumed, or deposit their eggs on their hosts. Some appear to deposit larvae, but these are actually eggs that hatch immediately upon deposition. Tachinids also attack silkworm larvae, so despite being largely beneficial, at least a few can be considered to be pest.

Leaf Miners (Agromyzidae)

This is a large family of small flies, consisting of about 2,500 flies world-wide. The larvae are miners of leaf tissue and stems, though some are gall formers. The larvae often are flattened, and create a mine of increasing size as they mature. Pupation can occur within the mine, on the leaf surface, or in the soil. Adults often feed at oviposition/feeding punctures. Some species, particularly those in the genus *Liriomyza*, have been the target of extensive insecticide use. As a result, they have evolved resistance to most insecticides. Such flies can become very numerous and damaging when insecticides are used inappropriately. Wasp parasitoids usually can keep leaf miners at low to moderate levels in the absence of insecticides, which disrupt the parasitoids more than the flies.

Large Fruit Flies (Tephritidae)

The large fruit flies often are colorful, and have well-marked wings; the pattern may be diagnostic. Many are important plant pests, most because the larvae burrow into fruit, flowers and stems. Among the damaging species are Mediterranean fruit fly, *Ceratis capitata*, melon fly, *Dacus cucurbitae*, and apple maggot, *Rhagoletis pomonella*. Some of these flies have been relocated accidentally to fruit-growing areas around the world, where they cause great damage to fruit. In other cases they cause loss indirectly because produce is quarantined and cannot be shipped to potential markets. Considerable success has been attained in the suppression and eradication of these fruit flies by using sterile male release techniques and area-wide management. Although the fruit-infesting flies are best known, they comprise only a small proportion of the tephritids, with the majority feeding on flowers. About 5,000 species are known.

Flower Moths (Lepidoptera: Scythrididae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Flower moths, family Scythrididae, total about 523 species worldwide, but mostly known from Europe. The family is part of the superfamily Gelechioidea in the section Tineina, subsection Tineina, of the division Ditrysia. Adults small (5–22 mm wingspan), with head smooth-scaled; haustellum scaled; labial palpi recurved; maxillary palpi 4-segmented. Wings (Fig. 61) elongated, with long fringes. Maculation usually rather dark with various spots; some have metallic-iridescence and a few are more colorful. Adults are diurnal but some may be crepuscular. Larvae are skeletonizers on leaves, buds, flowers, hiding under webbings. Brachypterous species are known which make long silken tubes. Many plant families are used as hosts, plus some on lichens and mosses, but particularly Chenopodiaceae, Crassulaceae, Compositae, and Gramineae.

Flower Strips as Ecological Compensation Areas for Pest Management

CYRUS ABIVARDI
Swiss Federal Institute of Technology, Zurich, Switzerland

There are many practices designed to make agriculture more sustainable, reduce agrochemical use, and enhance biodiversity in agricultural ecosystems. Organic farming, crop rotation, small-scale fields, and maintenance of natural areas between agroecosystems are some examples. The latter, sometimes referred to as ecological compensation areas, consists of separate or interconnected fields that form buffer zones. Ecological compensation zones act as refuge areas and/or dispersal centers and offer many species adequate niches, compensating, at least partly, for the negative effects of agriculture.

A significant decrease in the use of fertilizers and pesticides occurred as a result of ecological compensation areas in Europe. For example, under integrated production or organic farming systems in Switzerland, farmers have to set aside at least 7% of their farmland as ecological compensation areas (e.g., meadows, hedgerows, traditional orchards, and wild flower strips).

Ecological compensation areas in agriculture not only enhance biodiversity of rare and threatened species, but also support biological control of agricultural pests by increasing the diversity and abundance of beneficial arthropods. This is of particular importance for integrated production and biological farming because almost all spiders and predatory beetles active in crop fields in spring and summer depend on semi-natural habitats for overwintering.

Flower Strips

Flower strips (also known as wild flower strips, sown flower strips or sown weed strips) are a type of ecological compensation areas. Flower strips have found particular favor in central Europe, where they were introduced to increase biodiversity in intensively used arable land. Although flower strips, like the agricultural landscape, are artificial habitats, they have many advantages and offer good opportunities to combine agricultural use and nature conservation. These strips are highly attractive for many species of insects, and increase biodiversity. Even rare species can occur in intensively managed agricultural landscape if the minimum habitat area they require is available and their specific ecological requirements can be fulfilled using a strip-management program. Increasing biodiversity is the primary function of flower strips, and they are proven to enhance the species number of several beneficial arthropod groups. Flower strips, ideally, should occupy at least 5–10% of an agricultural landscape.

Establishment of Flower Strips

Flower strips usually are planted to a width of 3–8 m and sown with native weed-seed mixtures (Fig. 62). The strips are situated at a border of a

Flower Strips as Ecological Compensation Areas for Pest Management, Figure 62 **Photo showing a flower strip sown inside a wheat field in Switzerland (courtesy of Dr. Dieter Ramseier, Swiss Federal Institute of Technology, Zurich, Switzerland).**

field or divide large fields into small parts so that the distance between strips does not exceed 50–100 m. The length of the strip, however, depends on the field length and may be in the range of several hundred meters. Flower strips should start or end at other ecological compensation areas such as road sides, field margins, hedges, forest remnants, dry slopes, and so on. Thus, the total system of flower strips forms a network of ecological compensation areas which connects several types of natural, semi-natural, and artificial habitats. The fields are, therefore, embedded into this network and profit from its high diversity.

Seed Mixtures

The composition of the mixtures is based on the results of a long screening process in which specific characters of over 100 species of wild flowers and cultivated plants have been considered. Seed mixtures for flower strips should be chosen based on properties such as insect diversity and abundance of beneficial insect species in patches of the plant species, length of flowering period, survival capacity in agricultural soils, longevity in a complex plant mixture, the lesser tendency to dispersal into adjacent fields, and seed costs. A good technique to reduce the seed costs is by allowing a maximum amount of natural reseeding of weeds.

The recommended seed mixtures currently used for establishment of flower strips in Switzerland include a complex mixture of wild flowers and cultivated plants and are available from several commercial seed distributors (Table 4). The selected species cover a wide range of low, middle sized, and tall plants. They include early to late flowering plants as well as annuals, biennials, and perennials. Since the commercial production of wild flower seeds is not inexpensive there is a particular need to reduce the costs of the wild flower seed mixture. Much simpler seed mixtures also have been tested consisting of only one to four non-crop species (mixtures of clover and grass, *Phacelia*, sunflowers, etc.), but their usefulness is not yet established.

Maintenance

Maintenance of the vegetation mix, which consists of both the multispecies seed mixture and additional wild species initiated by the seed reservoir in the soil, is a difficult task. Sown strips maintain a high diversity at least in the first 3 years, but weedy grasses may become more common under some circumstances. Problem weeds (e.g., *Cirsium* sp., *Rumex* sp.) may need to be controlled by individual treatments of the plants. To slow down succession towards grasses and to prevent the dominance of only a few species or the appearance of woody plants, it may be desirable to alternate mowing half the strip every second year. In the United Kingdom, flower strips (used as field margin strips) are drilled with a mixture of wild flowers and managed using herbicide applications and by cutting to aid plant establishment. In Switzerland, however, herbicides are not often used.

When these habitats become less and less diverse some kind of regeneration technique must be applied. This may be accomplished by some kind of a minimum soil treatment or by complete plowing followed by additional, or new, sowing.

Flower Strips as Ecological Compensation Areas for Pest Management, Table 5 The extent of penetration of different carabid species into wheat field at different distances from the field margin (after Welling et al., 1994, integrierte Pflanzenproduktion II. Research Report)

Carabid species	No. collected from the field margin	No. collected in the field with regard to distance from the field margin			
		50 m	100 m	150 m	200 m
Carabus granulatus L.	234	12	17	6	5
Pterostichus melanarius Illiger	452	2	2	1	1
Platynus dorsalis Pont.	4497	11	5	1	1
Poecilus cupreus L.	947	32	16	1	0
Carabus auratus L.	47	3	8	0	0
Harpalus aeneus F.	522	3	0	0	0
Loricera pilicornis F.	268	4	0	0	0

The objective, in the long-term, is to attain a steady state between young and old sown weed strips within a landscape. This provides the type of mosaic in which landscapes naturally regenerate and represents an important feature which stabilizes agricultural landscapes.

Flower Strips and Farmers

Organic farmers of Switzerland consider the main advantage of ecological compensation areas (including flower strips) to be the increase in biodiversity. The main disadvantage is believed to be the increase in pests. Other farmers consider the main advantage to be protection against soil erosion and the disadvantages to be the loss of production area and the limitation of free management.

The concept of flower strips has been developed primarily for use where increase of productivity is not a major concern. Because agricultural yields in many areas already are high, actual efforts should aim not at increasing the production, but at stabilizing the yield with respect to an environmentally friendly and sustainable practice.

Weeds

In Switzerland, the density of sown plants often is not high enough to suppress problematic weeds (i.e., *Chenopodium album*, *C. polyspermum*, *Galium aparine*, *Galeopsis tetrahit*, *Polygonum lapathifolium*, *L. persicaria*, *Raphanus raphanistrum* and *Sinapis arvensis*). The suppression of root-propagated weeds (i.e., *Cirsium arvense*, *Convolvulus arvensis* and *Agropyron repens* [*Elymus repens*]) as well as *Rumex obtusifolius* and *Galium aparine* is generally insufficient. A continuous decline in the number of weed species from the 1st to the 4th year, a maximum diversity of flowers in the 2nd year and continuous increase in the percentage of grass occurs on the majority of sites. A dominance of *Anthemis tinctoria*, *Centaurea jacea* and *Leucanthemum vulgare* in the 2nd, and *Achillea millefolium* and *Tanacetum vulgare* in the 3rd year can be observed. In addition, yields in neighbouring crops may be reduced up to a total loss within 2 m distance of the strips due to bad fertilizer spread, insufficient herbicide efficacy, extensive tillage and slug damage. There is neither a positive nor negative yield effect measurable further away in the crop. Weed problems commonly noted by farmers include *Cirsium arvense* (the most serious weed). *Rumex obtusifolius*, *Agropyron repens* [*Elymus repens*] and *Convolvulus arvensis*. The sown flower species are not considered to be problems. The acceptance of ecological compensation area concept is reduced considerably when farmers encounter weed problems.

Slug species (such as *Arion lusitanicus* and *Deroceras reticulatum*) can cause damage adjacent to flower strips in Switzerland and France. Yield loss in the edge rows of the crop has been observed in maize, wheat, peas, and sugarbeet.

Response of Beneficial Insects to Flower Strips

Many weeds attract beneficial insects in high numbers, as pollinators, on green parts of the plants, and overwintering on or in dead plant structures or in the soil below the plants.

For instance, a study conducted in Germany revealed that the flower strips adjacent to wheat fields serve as habitats for several weeds and animals, including beneficial arthropods. Aphids were the most important pest in cereals, and carabids and epigeic spiders were important polyphagous predators. In boundary strips the spectrum of species of both carabids and spiders was more diverse compared to the adjacent wheat fields. In herbicide-free crop edges with a high amount of arable weeds, 10–60% more carabid and spider species were found as in the sprayed control edges. When comparing wheat fields with "rich" marginal structures on one side (broad, diverse boundary strips and hedges) and "poor" marginal structures on the opposite side (narrow, monotone boundary strips), the infestation with cereal aphids was up to 50% lower on the "rich" side. This reduction of aphids was not only at the edges, but also up to 10–20 m inside the fields. By means of mark/recapture-experiments it was shown that most of the carabid species could immigrate 100–150 m into the fields. However, a great number of carabids remained inside wild vegetation. Thus, carabids are mainly retained inside the strips and their penetration into field in a right time and in a sufficient number is doubtful (Table 5).

Similarly, the flower strips offer an haven for attraction and accumulation of syrphids and bees important in pollination of crop plants. For instance, Swiss researchers examined the attractiveness of flower strips towards hoverflies (Diptera: Syrphidae), butterflies (Lepidoptera: Rhopalocera), wild bees (Hymenoptera: Apoidea) and thread-waisted wasps (Hymenoptera: Sphecidae). Insects were quantified visually and/or caught with yellow pan traps. Visual observation indicated that the strips hosted the largest number of these species. In all groups of flower-visiting insects, numbers of species and individuals were higher in the flower strips than in the fields. Interestingly, twelve percent of all species of these insect groups belonged to endangered species. Thus, flower strips provided suitable shelter and nutritional conditions for flower-visiting insects and were therefore very attractive habitats for all insect groups investigated in this study.

Economic Impact of Flower Strips

Wingeier reporting on economic impact of flower strips sown into fields, considers the strips as a method of stabilizing agricultural ecosystems and of reducing the need for pesticides. These strips remain intact throughout the year whereas the crop is harvested at the usual time. His experiments on the economic impact of flower strips were conducted in the Swiss lakes regions (Grosses Moos) in 12 winter wheat, 6 winter barley, 4 winter oat and 4 rye fields in summer 1990. No significant correlations were found between the distance of the strip from the field border and crop yield for any of the cereals studied. Flower strips entailed both an increase and a reduction of field maintenance operations: on the one hand, the strips need to be managed (to prevent excess proliferation), but on the other, savings arise from the smaller field area for cultivation (an area reduction of about 1.2% for 5-ha fields and 2.1% for 1-ha fields with a single 1.5-m wide strip). No adverse effects of flower strips on the grain quality of adjacent wheat plants were noted and only a small increase was determined in the duration of cropping operations. Nevertheless, with ecologically desirable strip distances of 24 m and strip widths of 1.5 m, yield penalties of about 4.5% were recorded for both 1-ha and 5-ha fields with 2 and 4 strips, respectively. These yield reductions would have to be compensated by state subsidies.

Although the establishment of flower strips in an agricultural landscape acts as a haven for the natural enemies (as well as for the pests, e.g., slugs), we cannot overlook their great potential as a sink for accumulation of beneficial insects (e.g., ground beetles) as well as important pollinators. Therefore, these strips can only be of benefit to agroecosystems when they can enhance dispersal of beneficial agents, at the right time and at a significantly high number, into the field.

► Small Fruit Pests and their Management

Flower-Loving Flies

Members of the family Apioceridae (order Diptera).

► Flies

Flutter Flies

Members of the family Pallopteridae (order Diptera).

► Flies

Fly Paper

Sticky strips of paper use to capture flies. Adult flies tend to alight on elevated areas where they can obtain a good view of their surroundings. Use of fly paper takes advantage of this behavior; by hanging fly paper from the ceiling or other elevated locations, when flies land they adhere to the sticky paper. The fly paper is often yellow in color, which may provide a visual stimulus for landing, though this is not necessary. Once commonly used in both indoor and outdoor markets, barns, and milking parlors, they largely have been replaced by black-light, electrocuting grid traps where electric power is available.

► Traps for Capturing Insects

Focus (pl., foci)

In epidemiology, the area where the disease is prevalent.

Foliar Application

Application of a pesticide to leaves or plants.

Folivory

Arthropods that feed on foliage, though sometimes this is more narrowly defined to mean insects that chew on foliage, thereby excluding sap-sucking arthropods. Such arthropods are said to be folivorous or folivores.

► Phytophagy
► Herbivory

Follicular Epithelium

A layer of epithelial cells that surround the oocyte.

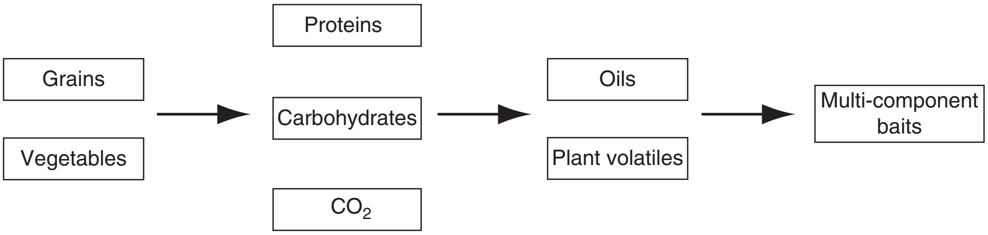
Food-Based Poisoned Baits for Insect Control

KATHRYN A. BARBARA, JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

Food-based baits are an effective and selective method of insect control. Typically, a bait consists of a base material called a carrier (often grain or animal protein) plus a toxicant (most often insecticides such as organophosphates, carbamates or pyrethroids) and sometimes an additive (usually oil, sugar or water) to increase attractiveness. The toxicant part of a bait can also be biological rather than chemical. Examples of biological toxicants are *Bacillus thuringiensis* (Bt), parasitic nematodes and fungi. Many baits are not highly attractive to the insect, but instead function as an arrestant. The insect is not attracted to the base material, but finds it palatable and will eat it when encountered. Therefore, baits are distributed by either ground or aerial broadcast application in order to ensure broad dispersion. Toxic baits are often environmentally friendly, inexpensive methods of insect control. Little or no insecticide drift is associated with baits, and there is minimal insecticide residue on crops being attacked by the pest insect. Baits are beneficial because the reduction of pesticide use provides more safety to the pesticide applicator and to the environment.

History

The evolution of bait technology shows a trend (Fig. 63) over time of increased complexity. Simple products such as grains and vegetables comprise the early baits. Grains and vegetables were



Food-Based Poisoned Baits for Insect Control, Figure 63 **Evolution of bait technology, showing the trend of increasing complexity of baits over time.**

Food-Based Poisoned Baits for Insect Control, Figure 64 **For suppression of insects with food-based bait, the volume of bait can be a logistical problem. Shown here is wheat bran-based bait, mixed by hand and machine, and prepared for a grasshopper suppression effort in Colorado, USA, in 1937.**

eventually refined to their specific attractive components such as proteins, carbohydrates, and carbon dioxide. As science and technology advanced, oils and plant volatiles could be extracted and identified from whole plants. Grain (Figs. 64–66) and vegetable bait types present a low cost method of insect control while multi-component baits are more costly, technologically advanced baits. Baits that are made of basic grains and vegetables would be appropriate in situations where cost is a concern such as in low value crops or in less developed countries. Conversely, bait types that are made of plant volatiles and multi-component baits would be more appropriate in high value crops, or in more technologically advanced societies where cost is less of an issue. Nevertheless, relatively simple bait systems tend to predominate throughout the world.

The result of years of research, many modern-day baits are made with synthetic attractants such as pheromones (which are chemical substances

Food-Based Poisoned Baits for Insect Control, Figure 65 **Bait can be distributed by hand, as shown here in the Colorado grasshopper suppression effort of 1937, but it is a formidable task if large areas are involved.**

Food-Based Poisoned Baits for Insect Control, Figure 66 **If bait distribution is to be accomplished on a large scale, some type of machinery is usually needed. Shown here is a primitive (but effective) bait spreader used in the 1937 grasshopper suppression effort in Colorado. Ground distribution of bait was soon replaced by aerial application, and both solid and liquid baits are now generally applied by air if the land area to be treated is extensive.**

used for communication between insects), or kairomones (host plant extracts). Bait carriers used for the formulation of insect control agents can include baits that encourage insect feeding, or inert particles that help carry the insecticide to the target site. Different combinations of bait carriers and attractants are successful on certain insects and not on others.

Food-Based Poisoned Baits for Insect Control, Figure 67 **An assortment of modern food-based bait formulations. The mole cricket and slug/snail baits are an old but effective approach using relatively simple grain or oil-based baits. The ant and cockroach baits involve more complex formulations (the "ant bait system" has separate baits that attract sugar feeding or oil feeding ants; the "roach killing gel" allows placement in hard-to-reach places; and the "roach controller" keeps the bait away from children and pets). The Amdro® fire ant bait ant and the unlabeled, plastic Sentricon® termite bait holder are examples of products that contain slow-acting toxicants that are transported back to the queen.**

Different Types of Baits

The proper bait to use on a specific insect is based on the behavior of the insect and the type of hosts that it finds attractive. Most insect baits are based on one of three categories: food, sex, or shelter. Food baits often use the properties of odor, color, taste, shape, or moisture as the basis of attraction. Sex-based baits utilize odor, color, shape and oviposition behavior as attractants, while baits where shelter is the basis often use visual and tactile stimulation to attract the targeted insect. Because insect behavior is quite different when seeking food, sex, or shelter, these different baits are not usually combined. There are exceptions however. For example, plant volatiles (food) and pheromones (sex) are combined to attract elm bark beetle and Japanese beetle to sticky traps.

Baits used for insect control are usually made of materials that are inexpensive and readily available. The most common baits are those containing grain as the attractant, and some type of toxicant. The composition of baits may contain common household items such as Doritos®, peanut butter, sugar and milk or ingredients as simple as carbon dioxide, a natural by-product of humans and animals. Baits are sometimes specific to the species of insect that they are intended to control. For example, wood is used to monitor for termites in the Sentricon® termite colony elimination system and other similar products. Sentricon® stations are placed in the ground around a building and are baited with untreated wood. If termites are found in the stations, the untreated wood is then replaced with a Baitube™ containing the active ingredient hexaflumuron. The termites feed on the treated wood, tunnel out and send other termite colony members back to feed on the bait. Once the colony is eliminated, the untreated wood is replaced and the process begins again. Slow-acting insecticides are an important component of the bait systems for termites and many other social insects. Slow kill allows the toxicant to be transported back to the queen, thereby eliminating the entire colony. With non-social insects, rapid mortality is usually desirable.

Advantages of Baits

There are several advantages to using dry baits over liquid insecticide formulations. The potential of chemical exposure by direct contact or inhalation of pesticides by non-target organisms is small. When dry baits are used, many beneficial species are not affected directly because the bait is eaten only by a subset of arthropod species. The amount of insecticide active ingredient applied per unit area in dry baits is lower than in liquid sprays. Dry baits may also reduce negative, indirect effects on non-target insectivores (insects that feed on other

Food-Based Poisoned Baits for Insect Control, Table 6 **Examples of food-based bait and the insects they attract**

Bait Type	Insect	Scientific Name	(Order: Family)	Life Stage
Grain baits				
distiller's grain and cat chow	cockroach	various	(Blattodea)	adult/nymph

insects) by preserving their food supply because fewer arthropod groups are affected.

The benefits of baits are clearly demonstrated by a mathematical model developed by USDA researchers. The model developed predicts the dose of bait that would likely provide the desired degree of initial kill in grasshopper populations. Bait treatments can be made more economical by increasing the efficiency of individual flakes and by reducing the rate of application. In this study, the model predicted that six flakes of 1.96% carbaryl wheat would kill one grasshopper.

Baits are often necessary when insect control programs are conducted near water, where threatened and endangered species occur, or where preservation of a beneficial species of arthropod is important. Baits reduce the problems encountered when applied pesticides drift. When baits are applied, they fall straight down and little dispersion is encountered, unlike liquid or dust insecticides. Considerably less toxic chemicals per unit area is needed as a bait compared with sprays to reduce pest populations to non-economic levels, and baits can be less expensive. Baits often target a particular pest species; therefore, environmental hazards are reduced.

Food Canal

A longitudinal groove found in the maxillary stylets of Hemiptera. The groove forms a tube for passage of plant sap from the plant to the head. Also found in the stylets of Hemiptera (but not Thysanoptera) is a smaller salivary canal for secretion of saliva as an aid to digestion. Some types of plant viruses are injected into plants through this latter canal.

Food Chain

A pyramid of numbers among species in a community. Species in the community differ in their niche parameters. Members of the lowest level (producers) are most abundant and are consumed by a less abundant higher level (primary consumers), which are in turn consumed by an even less abundant higher level (secondary consumers), etc. Insects typically comprise the primary and secondary consumer levels.

Food Habits of Insects

STAN K. GANGWERE
Wayne State University, Detroit, MI, USA

The million or so insects that occur in nature come in an astounding array of sizes, shapes and colors and exhibit a wealth of adaptations. They are found virtually everywhere, and some reach staggering numbers of individuals. Their exceptional variability, ubiquity and great numbers, in combination with the wide assortment of plant and animal foods that nature makes available to them, contribute to an almost infinite variety in feeding. Nevertheless, one can sort out a few of their generalized feeding trends, or food habits, as outlined below.

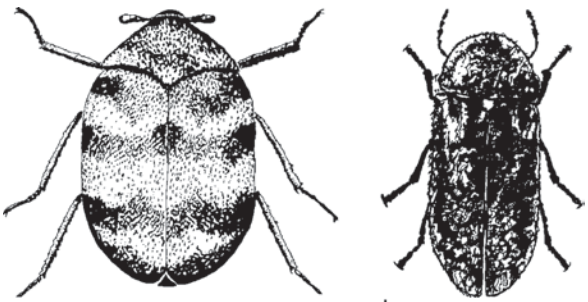
What do Insects Eat?

Insects eat an astonishingly wide array of materials, a few extreme examples of which are worth mentioning. Adult carpet beetles of the genus *Anthrenus* (Fig. 68), are innocuous pollen feeders generally found out-of-doors on flowers, yet they enter homes and lay eggs that soon hatch into larvae. These voracious juveniles eat wool, feathers and hair and, in the process, ruin expensive carpets, upholstery and clothing. Clothes moths including *Tineola bisselliella* (Hummel) and *Tinea pellionella*, L. the skin and larder beetles of *Dermestes* spp., and biting lice also eat hair, wool, feathers, epidermal scales and horn, which all contain the remarkably indigestible substance keratin, a material that does not otherwise form the basis of the diet in animals. Certain larger skin beetles frequent tanneries where they eat skin, hoofs and hair, and vertebrate zoologists rear cultures of the hide beetle, *Dermestes maculatus*, De Geer to clean the bones of museum specimens for study and exhibition. The smaller dermestid, *Anthrenus verbasci*, L. is the acknowledged scourge of entomological collections because of its destructiveness to pinned, dried, unprotected museum specimens.

The cigarette beetle, *Lasioderma serricorne* (Fabricius), is one of a number of common household pests that infest spices including pepper, paprika and chili powder, as well as cereals and pet foods, but it is best known for its consumption of dry, cured tobacco, often in fully formed cigarettes and cigars, which are rendered unusable. This food habit is remarkable in that nicotine, the tobacco plant's secondary substance, is so effective in thwarting insect attack that, in the early twentieth century, it was a commonly used insecticide.

The lead-cable borer, *Scobicia declivis* (Le Conte), and certain other powderpost beetles damage metals causing short-circuiting and service interruption as they bore through oak, maple and other woods. Other members of this heterogeneous group of beetles, the powderpost beetles, infest dry, seasoned wood that is not in contact with the soil. They pose a special problem in barns, cabins and older homes with hardwood flooring, beams, sills, studs, siding and rafters, and they damage lumber, tool handles, furniture, etc., unless the wood has been previously painted or varnished. The beetles drill through the wood, peppering it with pin- or pencil-sized tunnels, and unceremoniously heap the powdery residues outside the exit holes. Those powderpost beetles called deathwatch beetles, especially *Xestobium rufovillosum* (De Geer), make a gnawing or ticking sound as they bore through wood. This sound is audible during periods of (Fig. 68) quiet, especially at night during a wake, from which the name "deathwatch" is derived.

The large milkweed bug, *Oncopeltus fasciatus* (Dallas), the milkweed beetle, *Tetraopes femoratus* Le Conte, and the monarch butterfly, *Danaus*



Food Habits of Insects, Figure 68 (a) *Anthrenus verbasci,* one of the destructive carpet beetles often found in houses where its larvae attack carpets, upholstery, clothing and other fabrics; (b) the deathwatch beetle, *Xestobium rufovillosum*, one of the powderpost beetles that makes a ticking sound as it damages the dry, seasoned wood of old houses, barns, etc. (a is modified and redrawn from Arnett; b is modified and redrawn from Ohio Biological Survey.)

plexippus (L.), are colorful aposematic insects that not only frequent, but actually eat, plants of the poisonous milkweed family Asclepiadaceae and gain a measure of protection thereby. Milkweeds have a milky sap containing cardiac glycosides that these feeders not only tolerate but sequester, rendering them unpalatable to potential predators, most of which find the glycosides emetic. Not only the milkweed-feeding larvae, but also the adults that arise from them, are protected by the glycosides that concentrate particularly on the wings so that birds attempting to eat them vomit violently. Though they do not die, the birds learn to avoid monarchs and other butterflies that resemble monarchs. For example, the viceroy butterfly, *Basilarchia archippus* (Cramen), mimics the distasteful monarch and is protected by its monarch-like appearance though its body fluids lack the offensive glycosides.

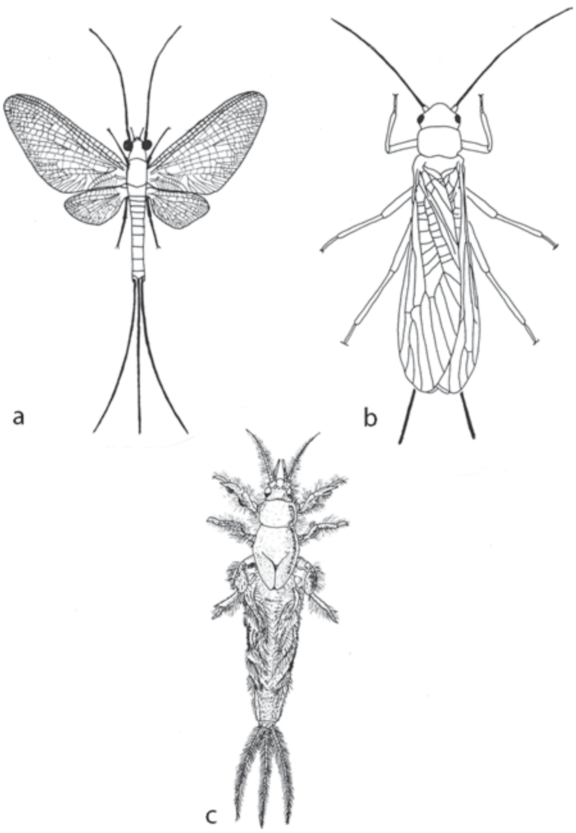
Tumblebugs, or dung beetles, especially of the genus *Canthon*, are among the insect scavengers of feces, and cockroaches such as *Periplaneta americana*, (L.), and the field crickets of genus *Gryllus*, consume feces, mucus and dead animals in varying stages of decomposition, as well as fresh and decayed vegetation. These and other insect scavengers play an important role in nature's decomposition process without which, the world would be a far different, much more loathsome place than that about us today.

Pygmy grasshoppers, or grouse locusts, of the genera *Tettigidea* and *Tetrix*, literally eat dirt. They ingest rich, moist pond and lake soil and the algae, lichens and plant constituents found in it, thereby nourishing themselves on the organic component as they egest the sand and other non-organic components.

Insects That do not Eat

Several kinds of adult insects are aphagous; they do not eat. Mayflies of the genus *Ephemera*, and certain stoneflies with reduced, non-functional mouthparts in the adult stage are examples of aphagous insects (Fig. 69). Their sole purpose in life is to procreate. The naiads, or juveniles, of mayflies such as *Hexagenia limbata* (Serville) eat heartily of algae and aquatic debris found in the clear, unpolluted lakes, ponds and streams, but cease feeding upon reaching maturity. Their adult life is necessarily short because they are obliged to live off the limited food reserves stored during the juvenile stage. Mayfly naiads are easily recognized by their usual three feathery caudal gills as well as plumose gills along the sides of the abdomen. Stonefly naiads superficially resemble mayfly naiads, but have two caudal gills as well as branched gills on the thorax and about the leg bases. Stonefly naiads are plant feeders, predators, or omnivores in cool, rocky stream and lake habitats. Those stonefly adults that eat, consume algae, but other stoneflies resemble mayfly adults in their inability to feed.

The feeding habits of some adult insects are like that of their juveniles, whereas other insects take on completely different food habits upon (Fig. 69) reaching maturity. The change in food habits is correlated with their development. More primitive insects, such as orthopteroids and most hemipteroids, undergo a gradual metamorphosis involving juveniles called nymphs that resemble



Food Habits of Insects, Figure 69 (a) *Ephemera* sp., an adult mayfly, (b) *Isoperla confusa*, an adult stonefly. Although mayflies and certain stoneflies do not eat as adults, their naiads eat heartily and (c) *Hexagenia limbata*, a juvenile mayfly (a is modified and redrawn from Needham; b is modified and redrawn from Frison; c is modified and redrawn from Burks.)

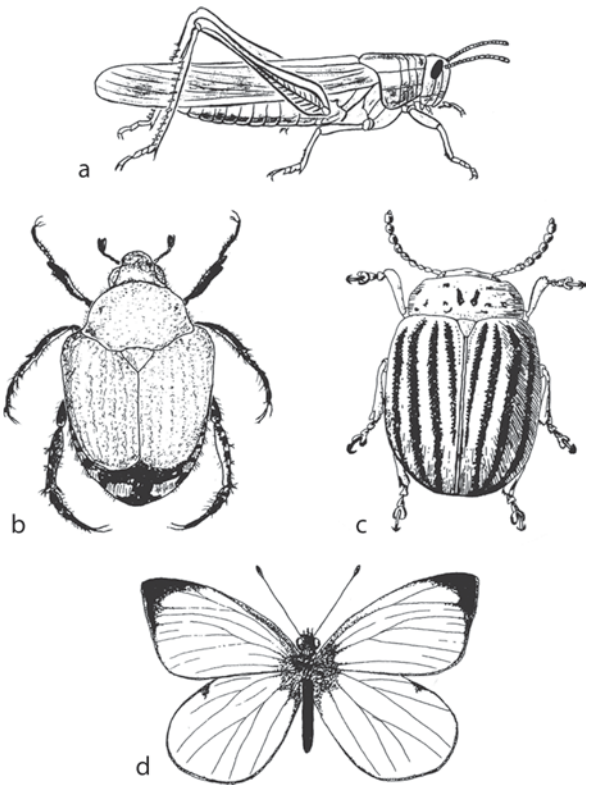
one another and also the adult, differing mainly in size, body proportions and incompletely developed genitalia and wings. These nymphs and the adults into which they grow occupy a similar environmental niche in which the available foods do not change appreciably, even with the season. Moreover, the nymphal mouthparts and digestive tracts are little different from those of the adults and are well adapted for handling a similar kind of food.

In contrast to the above generalized insects are the more advanced insects such as beetles, neuropterans, moths and butterflies, bees, wasps, true flies and certain others. They undergo a complete metamorphosis characterized by dissimilar larval, pupal and adult stages. The larva is essentially a feeding and growing stage often characterized by reduced eyes, antennae and body sclerotization. Its suppression of adult characteristics imparts to it a complete dissimilarity from the structure, physiology and behavior of the adult. The larvae often occupy a different environmental niche and use a different kind of mouthpart and a different digestive tract to take advantage of foods other than those that the adults eat. The adult stage is a dispersal and reproductive stage where adults often select foods that are different from those eaten by the larvae and, occasionally, do not even eat. So dissimilar are the larva and the adult in these advanced insects that a pupal stage has evolved to bridge the structural and physiological transition between them.

One might surmise from the preceding that insect food habits are almost as varied as are the creatures themselves. Fortunately, the picture can be simplified by breaking insect foods into three basic categories: living plants, living animals and dead plants and animals.

Insects That Eat Living Plants

Herbivory or phytophagy, i.e., plant-feeding, is one of the most common food habits among insects. Perhaps half of the living insect species eat vegetation, though their selectivity among the innumerable available host plants varies widely. Plague locusts, their grasshopper relatives, gypsy moth caterpillars, the Japanese beetle and many leaf beetles are examples of polyphagous plant feeders (Fig. 70). Polyphagous species eat plants belonging to widely divergent taxonomic groups, both related and unrelated. They select host plants largely on the basis of availability, abundance, texture, succulence and other physical and chemical attributes. The desert locust, *Schistocerca gregaria* (Forskal), other plague locusts and certain related North American grasshoppers are examples. The desert locust (Fig. 70) sometimes reaches outbreak populations



Food Habits of Insects, Figure 70 **(a) The grasshopper *Schistocerca* sp., a North American relative of the Old World desert locust *Schistocerca gregaria*, and (b) the Japanese beetle, *Popillia japonica*. These two insects are polyphagous. They consume plants belonging to numerous host groups, both related and unrelated.**
(c) The Colorado potato beetle, *Leptinotarsa decemlineata*, which eats members of the potato family and (d) the cabbage butterfly, *Artogeia* (formerly *Pieris*) *rapae*, which eats cruciferous plants. These two insects are oligophagous. They eat host plants belonging either to a single taxonomic group or to several closely related groups. (a is redrawn from Riley; b is modified and redrawn from Essig; c is modified and redrawn from USDA; d is modified and redrawn from Viedma et al.)

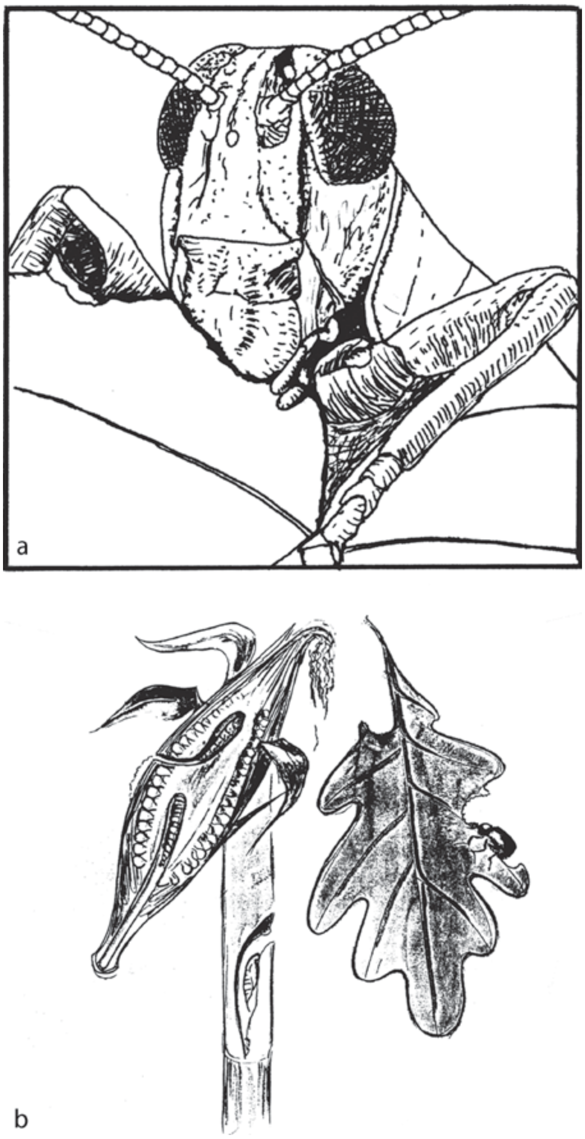
in which it becomes cannibalistic and almost indiscriminately attacks grains, garden crops, trees, native grasses, forbs, dung, dead animal carcasses, and, under starvation pressure, it even turns to perspiration-stained cloth, rake handles, wooden fences and other non-food items. The gypsy moth, *Lymantria dispar* (L.), a well-known pest of shade trees in Europe, was introduced into Massachusetts in the late 1800s in an ill-conceived attempt to cross-breed it with several other silk producers. It accidentally escaped captivity and soon spread throughout New England and westward thereafter until today it is distributed throughout much of northeastern United States. Female gypsy moths are flightless and lay their eggs in silken masses on tree trunks. They die shortly afterward without having traveled far, so most dispersal is by the larvae, which have become one of our most serious pests of oak, birch, ash, and other shade trees. The attractively colored Japanese beetle, *Popillia japonica* Newman, is another introduced pest insect, in this case, one that was accidentally imported on nursery stock from Japan. The larvae eat roots of grass and other herbs until, by midsummer, the adults emerge and begin attacking the foliage and flowers of more than 250 plant species, including roses and many other economically important plants.

Oligophagous insects are more selective and less common than the polyphagous ones just described. They select host plants belonging either to a single taxonomic group, or to several closely related groups. Examples include the monarch butterflies mentioned earlier with respect to milkweeds (their sole source of food), the Colorado potato beetle that is restricted to eating members of the potato family and the imported cabbageworm, which consumes only mustards. The Colorado potato beetle, *Leptinotarsa decemlineata* (Say), a handsome yellow beetle striped with black, is a serious pests of cultivated potato. Originally from Mexico, it was an innocuous member of the Rocky Mountain fauna and attracted little attention eating only a few species of nightshade, which are wild members of the Solanaceae, or potato family. With the advent of railroads and other advances in transportation and communication, the American west came under heavy settlement following the Civil War, whereupon the beetle began invading local gardens to attack potatoes, tomatoes, eggplant and a few other solanaceous plants that it found attractive.

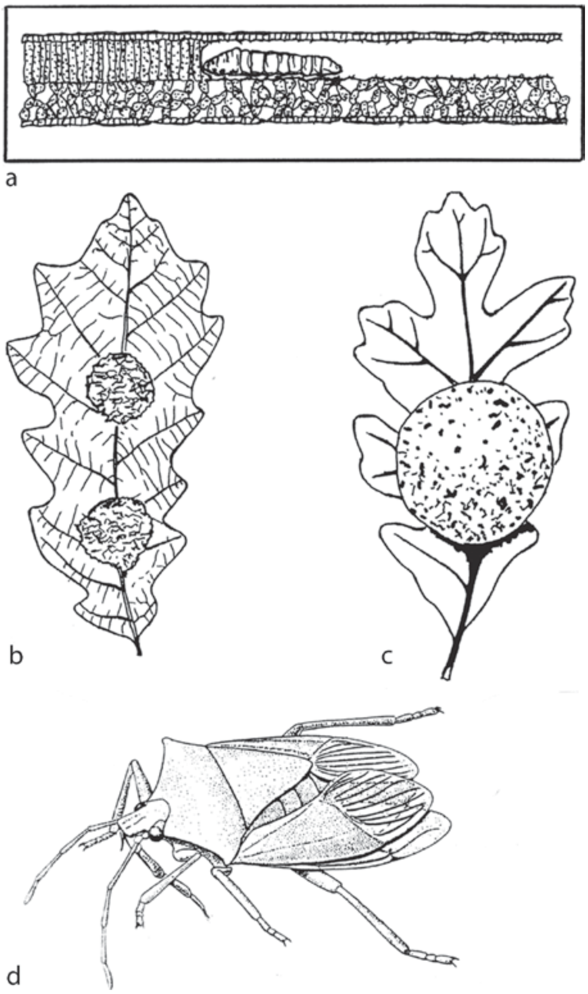
It quickly spread from potato patch to potato patch, reaching the east coast of the United States before the turn of the century and invading Europe afterward. The imported cabbage butterfly, *Artogeia* (formerly *Pieris*) *rapae* (L.), is one of our most common whites. Its larvae eat members of the family Cruciferae, particularly cabbage, riddling the outer leaves of the head. The several cultivated crucifers (cabbage, brussels sprouts, cauliflower, etc.) contain mustard oils with a distinctive, pungent odor and taste that most potential feeders find repulsive. The cycle begins when the female butterfly seeks out and oviposits in a cabbage patch. The larvae hatch, eat and grow to maturity on the particular host species that the parent selected. They refuse plants to which they are not accustomed, and starve in absence of the preferred host. Interestingly, however, they accept the foliage of certain non-host plants if the accustomed mustard oil is first smeared on the strange foliage.

Only a few insects are monophagous, i.e., restricted to a single host. An example is the silkworm moth; its natural food is mulberry. The silkworm moth, *Bombyx mori* (L.), is an Asian native that was introduced into Europe in the sixth century and into the Americas in the eighteenth century. Through the years, this domestic insect has been used in sericulture, and is commercially reared for silk. The larvae eat mulberry leaves until grown and able to spin their cocoons, the strands of which, when unwound, may be used to provide silk. Adult silkworm moths rarely fly and, like mayflies, live only a few days as they are unable to eat.

Insects eat roots, stems, leaves, flowers, fruits, pollen, spores, sap and other plant parts or plant secretions in a manner that varies widely (Figs. 71 and 72). Many beetles, most butterfly and moth caterpillars, grasshoppers, many katydids and some other insects excavate morsels from the edges or center of their chosen foliage or flowers; larval long-horned beetles and other borers tunnel deep within their host plants consuming tissues, fungi, or wood fragments; certain larval caterpillars and flies mine within the upper and/or lower surfaces of the host leaves consuming palisade tissue and/or parenchymatous cells; gall midges and gall gnats stimulate their host to form distinctive, tumor-like plant growths, or galls, in which they sequester themselves and feed; and



Food Habits of Insects, Figure 71 Different types of feeding by insects: (a) the grasshopper, *Melanoplus femur-rubrum*, excavating escalloped morsels from a leaf edge; (b, right leaf) a scarab beetle excavating the leaf edge of an oak and (b, left) larval corn borers attacking an ear and a stalk of corn. (a is modified and redrawn from the Illinois Natural History Survey; b is modified and redrawn from USDA.)



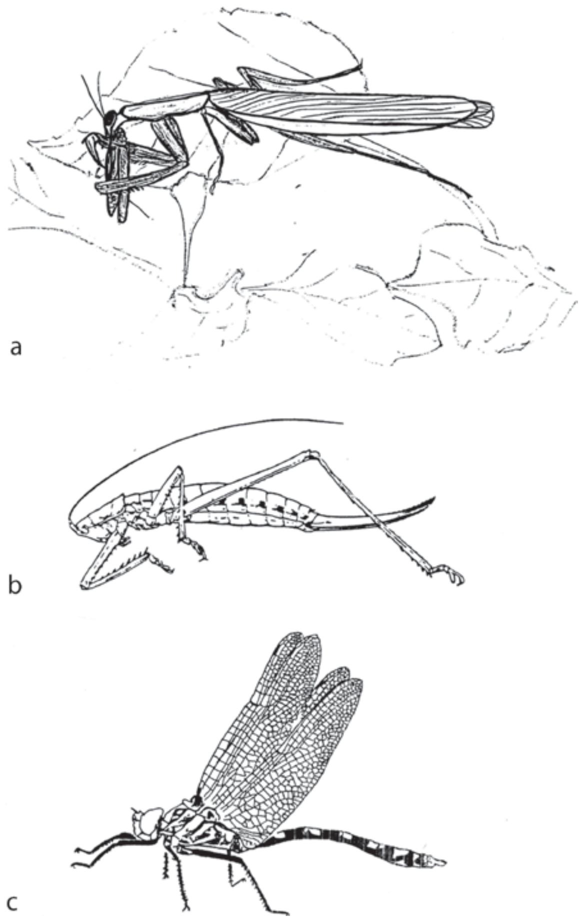
Food Habits of Insects, Figure 72 Different types of feeding, continued: (a) a leaf miner coursing through the interior of a leaf, consuming cells as it goes, but leaving intact the upper and lower leaf surfaces; (b, c) two kinds of galls in which live and feed the respective insect occupants whose influence has stimulated the plants' tumor-like growth; (d) a stink bug showing the typical hemipteran suctorial beak between the fore legs. (a is modified and redrawn from Evans; b and c are modified and redrawn from Atkins; d is by courtesy of the Illinois Natural History Survey.)

aphids, leafhoppers, scale insects, stink bugs and other true bugs are among the phytoparasitic insects that suck plant fluids using their elongate beak in much the same manner as do many blood-feeding animal parasites in their attacks on animal hosts.

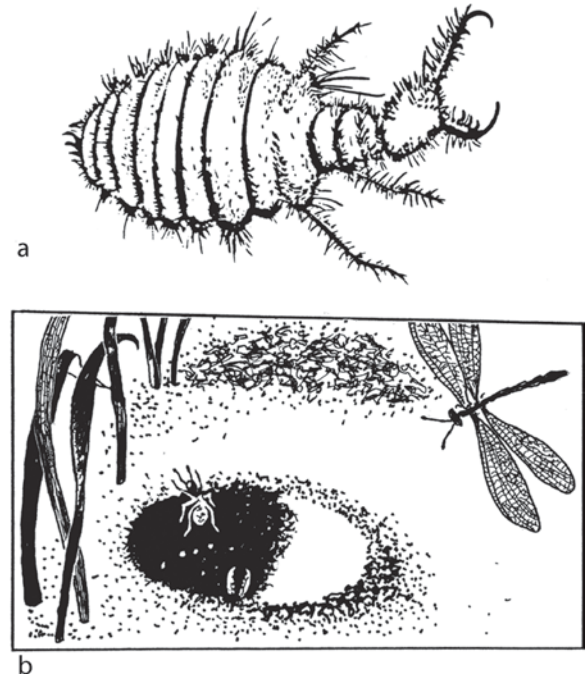
Insects That Eat Living Animals

A number of aggressive, relatively powerful or specialized insect predators attack, overpower and eat other animals (called prey), generally resulting in the latters' death. The prey usually consists of species other than that of the predator, although some strongly predacious insects also feed on their own species, the act of cannibalism. Rapacious katydids such as *Saga pedo*, *Macromia magnifica* MacLachlan and other dragonflies, robber flies, ladybird beetles and mantises are representative predators. Mantises such as *Tenodera* sp., use stealth and (Figs. 73 and 74) ambush to attack, capture and eat, alive and kicking, practically any moving animal of the right size that they can catch and overpower and are even cannibalistic on their own species. Older, larger mantises often devour newly hatched young mantises when given the opportunity, and the larger, stronger adult female mantises may consume the smaller adult males attempting to mate with them. Dragonflies prey on their animal hosts in much the same manner as mantises and carnivorous katydids except they pursue their prey on the wing. Both larval and adult ladybirds are rapacious hunters of aphids and scale insects. *Myrmeleon* sp. and certain other antlions entrap their prey by excavating a pitfall in loose, sandy soil where they bury themselves, with only the rapier-like jaws exposed. In this position, they are able to fall upon and suck dry any ants that blunder into the trap.

Parasites are another kind of animal feeder. Insect parasites differ from insect predators in that they are usually smaller and less powerful than their hosts, and the predator-host relationship usually does not involve the latter's death. *Anopheles maculipennis* Meigen (Fig. 75) and certain other mosquitoes, the females of which may be responsible for the transmission of malaria, yellow fever and other important human diseases, are ectoparasites that live apart from the host except to feed. They are little specialized for their parasitic existence aside from possession of an elongate beak used to suck blood. The human louse, *Pediculus humanus* L., and other sucking lice and



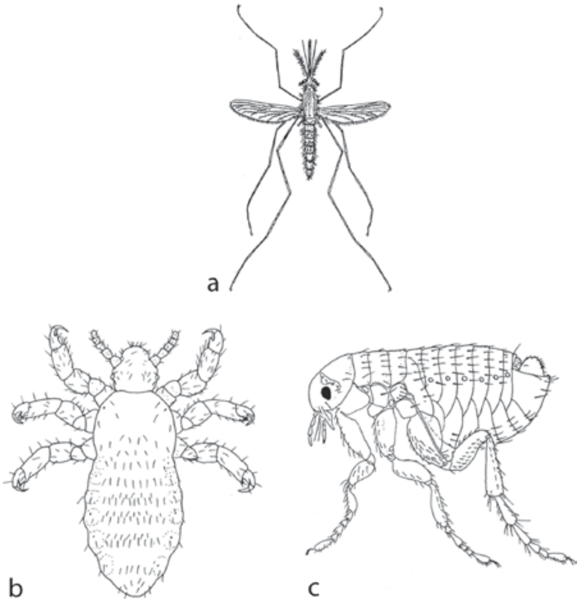
Food Habits of Insects, Figure 73 **(a) The mantis, *Tenodera* sp., eating a prey insect that it has ambushed and is holding by its raptorial fore legs; (b) *Saga pedo*, a predacious Mediterranean katydid that pursues and catches its prey by powerful armed legs; (c) the dragonfly, *Macromia magnifica*, which captures its prey on the wing. (a is modified and redrawn from various sources; b is modified and redrawn from Chopard; c is modified and redrawn from Kennedy.)**



Food Habits of Insects, Figure 74 **(a) *Myrmeleon* sp., an antlion larva, and (b) an overall view of its pitfall. (Figures are modified and redrawn from Buchsbaum.)**

the human flea, *Pulex irritans* L., and other fleas represent another kind of ectoparasite. Unlike mosquitoes, this kind of ectoparasite lives on or near the chosen mammalian host and may require close, continued association with its body warmth. This more intimate parasitism typically involves a highly specialized, wingless, flattened insect with a suctorial beak. The host-parasite relationship is often so specific that, for example, a monkey-feeding louse given access only to a human host starves to death, being unable to accept human food.

Parasitism grades into predation in a number of other insects called parasitoids, of which tachina flies and *Lysiphlebus testaceipes* (Cresson) and (Fig. 76) other parasitic wasps are representative. Parasitoidism is characteristic of larval stages only, not of adults. It is a relationship in which, unlike true parasitism, the larva eventually kills the host. The parasitoid is also relatively large-bodied, sometimes almost as large as the host that it attacks. (It cannot be larger, of course, because it must be able to complete development on the tissues of that single individual). Adult parasitoids lay their eggs on or within the prospective host, and the newly hatched young then eat tissues of their hosts' body cavity, bloodstream or digestive

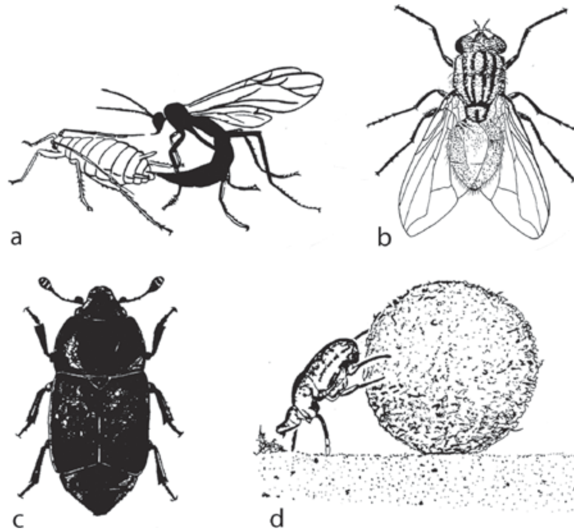


Food Habits of Insects, Figure 75 **(a) The adult mosquito, *Anopheles maculipennis*, an ectoparasite that lives apart from its host, which it approaches only to feed; (b) the human louse, *Pediculus humanus*; (c) the human flea, *Pulex irritans*. (a is modified and redrawn from Nuttall and Shipley; b and c are modified and redrawn from Essig.)**

tract. They feed on non-vital parts at first before turning to vital ones, eventually killing the host.

Insects That Eat Dead Plants and Animals

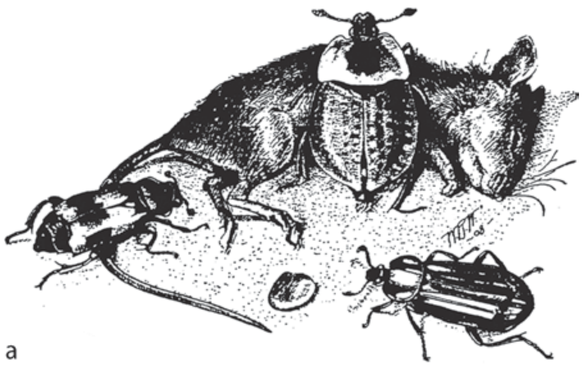
Sap beetles, such as *Carpophilus lugubris* Murray, a serious pest of corn, and certain members of the genus *Glischrochilus*, are likely found in putrefying watermelon rind, fruits or other garbage. These attractive little black insects that are spotted with yellow, as well as the house fly, *Musca domestica* L., and other insect scavengers, may frequent tables at local picnic grounds. Maybe their antics are amusing, but they likely have come from their most recent repast at adjacent garbage dumps, piles of feces, or other equally loathsome waste deposits.



Food Habits of Insects, Figure 76 **At the top is (a) an adult of the parasitoid, *Lysiphlebus testaceipes*, ovipositing in an aphid; in the middle are two scavengers, (b) the house fly, *Musca domestica,* a medically important pest distributed virtually worldwide, and (c) the sap beetle, *Carpophilus lugubris*; and at the bottom is (d) *Kheper aegyptiorum*, a tumblebug using its legs to roll its carefully molded ball of dung to a suitable oviposition and feeding site. (a is modified and redrawn from Crossman; b is modified and redrawn from Turtox Key Cards; c is modified and redrawn from Borror et al.; d is modified and redrawn from Heinrich & Bartholomew.)**

The tumblebug, *Kheper aegyptiorum*, and other dung beetles and carrion beetles including the genera *Silpha* and *Nicrophorus*, are scavengers (Fig. 77) of even more specialized habit than sap beetles and house flies. They are able to eat and develop only when provided their respective food, either dung or carrion. So closely associated are they with their particular food that entomologists who wish to collect them do not look for them directly, but seek out the stools or carrion in which they are likely to be found.

Periplaneta americana (L.) and other cockroaches are insect omnivores par excellence. The American, German, Oriental and other domestic cockroaches are cosmopolites whose individuals



a

Food Habits of Insects, Figure 77 **(a) At left (resting on the host tail) is the carrion beetle, *Nicrophorus* sp., and at right (both on the body and below it) are two different species of the carrion beetle genus, *Silpha*, eating a dead mouse; (b) the domestic cockroach, *Periplaneta americana*. Carrion beetles are carrion specialists, eating only carcasses; cockroaches are generalists, being scavengers that eat most any available living or dead plant or animal or the tissues thereof. (a is after Walton; b is by courtesy of M. Dababneh.)**

frequent kitchens, restaurants, bakeries, grocery stores, hospitals and other places with warmth, humidity and organic debris to eat. They prefer soft, starchy foods but eat a vast array of other substances, fresh or decayed, animal or plant in origin. They even gnaw cardboard, glue, paste, clothing, book bindings, hair, leather, garbage and the secretions and wastes of vertebrates. Their wild cockroach relatives, seldom seen in human dwellings, are secretive nocturnal insects found under bark or leaves, or within woodland debris. These wild cockroaches attack roots, stems, foliage, flowers and fruits both of living and of dead plants, but apparently prefer living to dead tissues. They also prey on small, weak insects, are occasionally cannibalistic, and are attracted to all types of vertebrate wastes and secretions.

Foote, Richard H.

Richard Foote is remembered as an authority on the taxonomy of fruit flies (Diptera: Tephritidae). He was born on May 2, 1918 in Bozeman, Montana, and graduated from Montana State University in 1941 before serving in the armed forces during World War II. He earned a Sc.D. in parasitology from Johns Hopkins University in 1952 and immediately joined the United States Department of Agriculture in what was to become the Systematic Entomology Laboratory. Although initially working on mosquitoes, he soon devoted himself to tephritid fruit flies. He devoted his entire career to this agency, and is perhaps best known for his 1993 publication, "Handbook of the Fruit Flies of America North of Mexico." Foote is also known for his early acceptance and promotion of computers for entomological data retrieval. He was active in society activities, particularly in journal editing, and served as president of several scientific societies. He died on February 9, 2002.

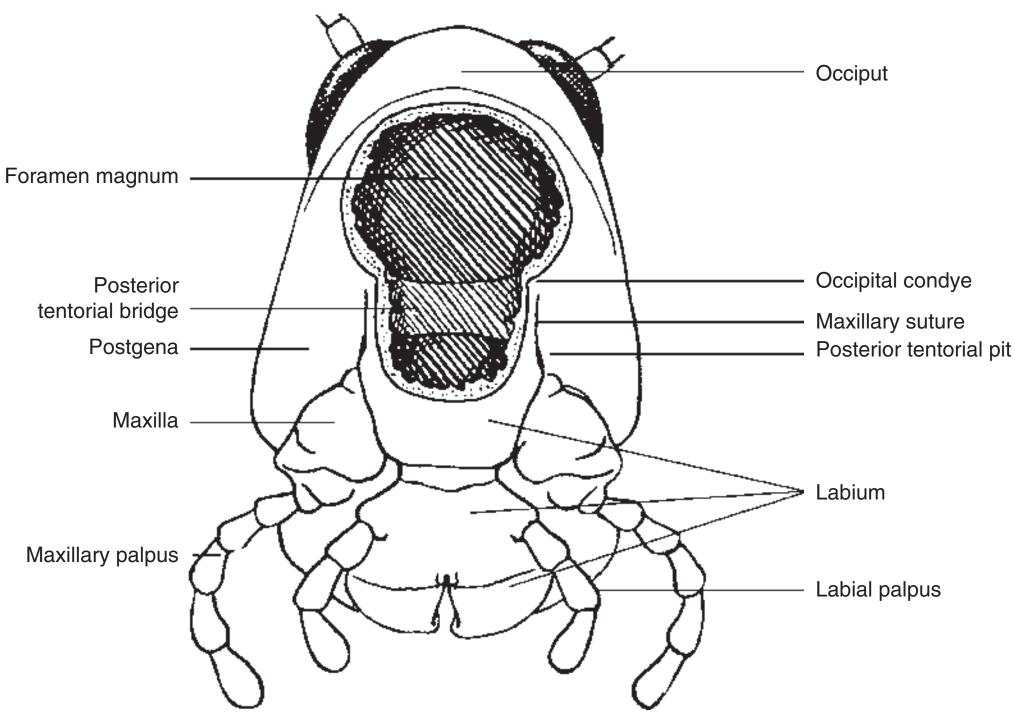
Forbes, Stephen Alfred

Stephen Forbes was born in Illinois on a small pioneer farm on May 29, 1844, one of six children.



Foramen Magnum, Figure 78 **The posterior view of the head of a grasshopper (Orthoptera).**

His father died when Stephen was ten, and it was Stephen's older bother, Henry, who sacrificed his own education to send Stephen to Beloit Academy in 1860, a short-lived endeavor because the funds could not be continued. Henry and Stephen served as soldiers in the American Civil War (during which Henry died) and, afterwards, in 1865, Stephen went to study medicine at Rush College in Chicago, but dropped out because of shortage of funds and an aversion to conducting surgery without anaesthetics. He then became infatuated with botany and other aspects of natural history, and worked for some time as a schoolteacher. When J.W. Powell resigned as curator of the Illinois Natural History Society in 1872, Stephen succeeded him. He was appointed in 1877 Director of the State Laboratory of Natural History, a position that he held for the next 40 years, at which time he was made head of the Illinois Natural History Survey, a newly-organized entity. Additionally, he was appointed professor of zoology at the Normal University in 1875–1878, and in 1882 Illinois State Entomologist. But in 1884 he became Dean of the College of Science at the University of Illinois (Fig. 79) and in the same year Indiana University bestowed upon him the title of doctor of philosophy. His interests were not just in entomology, but extended to birds, fishes, crustaceans, leeches, bacteria, rotifers, the parasites of swine, museum methods, and teaching. He was one of those rare individuals who can survive on few hours (five in his case) of sleep each night. His entomological efforts were applied especially to applied entomology, and he worked on Hessian fly, and pests of maize ("corn"), strawberries, sugarbeet, the chinch bug, white grubs, San Jose scale, armyworms, codling moth, black flies, and diseases of insects. He was twice (1893 and 1908) president of the American Association of Economic Entomologists, and also served as president of the Ecological Society of America and of the Entomological Society of America. He died on March 13, 1930, surviving his wife Clara (with whom he had five children) by a few weeks.

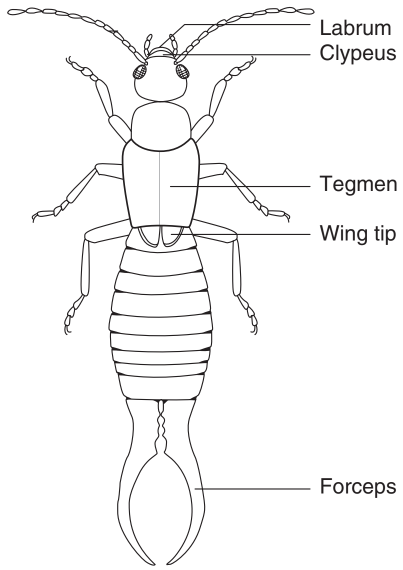
Forceps

These are pincer-like processes found at the tip of the abdomen. They are particularly well developed in earwigs (Fig. 80), where they are used in defense, but also occur in some other insects where they are less noticeable and aid in clasping during copulation.

Ford, Edmund Brisco

Edmund Ford was born in the county of Cumbria, England, on April 23, 1901. In 1920 he entered Oxford University as an undergraduate. He never left, and after his degrees became lecturer in zoology and comparative anatomy. His interests turned toward genetics, he became director of the genetics laboratory within the Zoology Department and, from 1963 to 1969, professor of ecological genetics. One of his interests was in archaeology. A second interest, in wildlife conservation, led to establishment in England of the Nature Conservancy



Forceps, Figure 80 **Dorsal view of an adult earwig (Dermaptera), showing the forceps.**

Council, on which he served from 1949 to 1959. His special contribution in genetics was as "inventor" of ecological genetics, but his contributions to medical genetics led to his nomination as an honorary fellow of the Royal College of Physicians in 1974. Already in 1946 he had been elected a fellow of The Royal Society. His work in ecological genetics involved especially numerical fluctuations in populations of butterflies, and the concurrent changes in genetic structure. Some of his books are (1945) "Butterflies," (1955) "Moths," (1964) "Ecological genetics," (1965) "Genetic polymorphism," (1976) "Genetics and adaptation," and (1984) "The biology of butterflies." [His work on population genetics is mirrored in the work of Theodosius Dobzhansky, see above]. He died in Oxford on January 21, 1988.

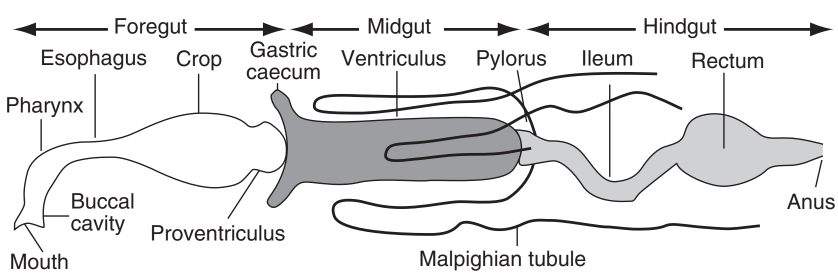
► Alimentary System

Foreign Exploration for Insects that Feed on Weeds

LUCA FORNASARI
Montpellier, France

The principal reason to conduct foreign exploration for insects that feed on weeds is to identify exotic natural enemies for their prospective use in biological control programs. Indeed, importation of natural enemies is the most common approach to the biological control of pests, and is often called "classical" biological control. This type of pest control requires exploration for beneficial organisms in the home country of the pest to be controlled, with the intent of introducing the beneficial organism to the country where the plant has become a weed. It should be noted that in this case we consider the target plants – the weeds – to be the pests, and phytophagous insects to be



Foregut, Figure 81 **Generalized insect alimentary system (adapted from Chapman, The insects: structure and function).**

beneficial organisms (not pests, as commonly perceived). So we are reversing the way we usually consider insects and plants as pests and crops in agriculture.

Criteria for Successful Exploration

The target plant usually is not a problem in its area of origin and in its natural area of distribution, where as a matter of fact it may even be beneficial and very important for local ecosystems. The goal of biological control of weeds is to reproduce, in the new environment, a natural balance among the plant and its natural enemies. If successful, this process will reduce the populations of the weed to below the injury level, or minimize their impact on the environment. Foreign exploration is the first, and one of the most critical, steps for the success of any introductory biological control program. The exploratory entomologist should possess multidisciplinary expertise, especially in entomology (various fields), plant and insect pathology, field biology, botany and ecology. In addition, the explorer needs foreign language skills, field and travel experience, organizational ability, tact, self-reliance, stamina and resourcefulness, because exploration is often conducted under difficult conditions.

Plant Ecology

The nature of the weed problem, and the ecological basis for the spread of the plant in the new environment, provide the background for subsequent studies. The plant may have been introduced accidentally, or intentionally (as, for example, an ornamental that spread to become a noxious weed). The mode of introduction of the plant, the mode of spread, size of the area infested, type of habitats invaded and their soil and climate, the species of plants displaced, and impact on native flora and fauna, all contribute to defining the ecology of the target plant and its aggressiveness in its introduced range. One crucial aspect is the exact characterization of the taxonomy of the target plant. It is important to consider the existence of hybrids, biotypes, and other variations in the genetics, morphology, or biochemical traits of the plant. This is essential to obtain the desired effective biological agents for the target plant. Also, all information available from taxonomy of the insect can provide an important contribution to assess the potential as biological control agents of the organisms discovered during the survey. In all cases, a high level of host specificity is required to prevent damage to other species of plants.

Geographic Origin and Climate

Determination of the area to explore is dependent on the information available before starting such exploration. The plan for the survey should be designed on a case by case basis, based on the biology of the plant and its natural enemies, once they are known. The area for exploration should be within the native range of distribution of the target plant, and usually the center (or centers) of origin of the plant is considered the most promising area to explore, because it normally represents the main source of diverse and better adapted natural enemies. However, depending on the nature of the weed problem, evolutionary history and characteristics of the plant, geographical range, and the existence of distinct populations, it may be more important to consider the possible area from which the plant was originally introduced into the new environment. Also, effective natural enemies may occur in other parts of the range of distribution of the plant, as new parasite-host associations. The area explored should be large enough to offer considerable ecological and genetic variation, and therefore a diversity of natural enemies. Careful consideration should be given to the climates in the range of distribution of the plant, as well. The climate or physical environment at the source of biological control agents should be similar, as far as possible, to those of the areas where the plant is a weed problem. Generally speaking, climate matching is a good predictor of successful establishment of biological control agents. Nevertheless, there are cases of successful biological control agents that have been effective in controlling weeds in areas that were not ecoclimatically homologous; the new habitats did not match with the environmental characteristics of their area of origin. Also, it is possible to conduct foreign exploration for insects whose native area of distribution is not in the same hemisphere in which they should be released for biological control. In this case, it is necessary to synchronize their life cycle with the season in the area of introduction.

In conclusion, the identification of the geographical area where it will be more likely to find effective natural enemies is a major step for the success of the exploration. The study of the ecological relationships between the plant and its natural enemies and the importance of other biotic and abiotic factors helps to understand the role and potential effectiveness of the weed-feeding insects discovered during the exploration. The taxonomic position of the plant, along with its relatives and its evolutionary patterns, are important elements to consider during the survey and when evaluating the natural enemies associated with the plant. The exploration may be extended to plant species related to the target plant, since this can provide important information about the degree of specificity and potential of the insects associated to the plant as candidate agents for biological control. Also, in some cases, insects attacking other species of plants that are close relatives of the target weed, may prove to be suitable and successful biological control agents.

Forel, Auguste Henri

Auguste Forel was born in 1848 at Morges on Lake Geneva in Switzerland. As a boy, he became interested in insect natural history, influenced by his entomologist great uncle. At the age of 11, his special interest in ants developed as a result of his reading an old book by Pierre Huber. By the age of 12, he had begun to investigate thievery (later called by him lestobiosis) in the little ant *Solenopsis fugax*. After leaving school, he went to study medicine in Zurich and became interested in neurology and psychopathology. Thereupon he went to Vienna and worked on a doctoral dissertation on the morphology of the optic thalamus. Next, he went to Munich and worked for 5 years as assistant in psychology, being much involved in the development of microscopy. Meanwhile, his studies of ants continued, and in 1869 he published his first entomological paper on the behavior of *Solenopsis fugax*. This was followed in 1874 by a groundbreaking book on Swiss ants, "Les fourmis de la Suisse." In 1879 he was appointed professor of psychiatry in Zurich and his career in psychiatry continued to develop with numerous publications. However, it was not surprising that he, a neurologist, should also have studied neurology and sensory perception in ants. His work on chemosensory perception by the antennae of ants was published in 1902, and he worked on the development of castes (polymorphism), the organization of social instincts and their morphological basis, colony development, slavery, and parabiosis in ants. He also worked on collections of tropical ants and phylogeny of ants, and succeeded in describing 3,500 new taxa of ants. He espoused pacificism during World War I, and then socialism. He died in Yvorne, Switzerland, on July 27, 1931.

Forensic Entomology

ROBERT D. HALL
University of Missouri, Columbia, MI, USA

Forensic entomology is the intersection between insect science and the legal system. Although most recent attention has focused on the subspecialty known as "medicocriminal entomology," where insect development and succession on a corpse are used to estimate how long the decedent has been dead, there are additional areas where entomology is of legal interest.

Urban entomology includes a variety of important insects with legal implications. Obviously, termites and the damage they cause are at the center of many legal controversies. Other wood-destroying insects, such as powder post beetles, can have similar effects. Dermestid larvae can damage or destroy hides, animal specimens, and furs. Clothes moth larvae can damage stored garments. All of these situations may result in lawsuits.

Another legal implication under the rubric of urban entomology is nuisance. Although often paradoxically rural in nature, flies and other insects emanating from livestock or poultry facilities can annoy nearby residents and result in claims for damages or to enjoin further livestock operations.

Insecticide applications against pest insects can result in drift, run-off or unanticipated outcomes and therefore claims for negligence or recklessness. Cockroaches or flies can adversely affect infants in nurseries or the elderly in nursing homes and result in claims of neglect. Poisonous spiders, especially the brown recluse, are frequently the focus of lawsuits brought under landlord-tenant, worker's compensation or invitee theories.

Insects, insect parts or insect debris in food or similar materials fall under the category of stored products entomology. The typical case involves beetles or moths in flour, cereals or other foodstuff; however, products such as herbal pharmaceuticals may also be involved. Much litigation involves insects associated with restaurants and especially fast-food establishments. Customers finding insects in hamburgers or other foods may sue under various legal theories, but the rigid procedures followed by most national chains typically offer thermal protection against insect and microbial contamination. Not infrequently, customers may try to defraud restaurants or markets by deliberately putting insects into food purchases. These attempts are typically identified by inconsistencies in behavior or biology between the species chosen and the facts of the case.

Medicocriminal entomology is the principal forensic emphasis of insect science. Two major approaches are typically employed to facilitate estimates of postmortem interval or situs (place) of death. Insects are cold-blooded, or poikilothermic, animals that develop, within limits, proportionately more rapidly as temperatures increase. The biologies of most common necrophilous species of flies have been well studied and developmental data are readily available. As the insect "buzzards" of decomposition, female blow flies (Diptera: Calliphoridae) oviposit on carrion in a predictable manner. Many species appear at dead bodies within a few minutes after death has occurred; others exhibit delays in appearance. Therefore, if certain conditions are met, these flies can reflect the length of time someone has been dead. Obviously, the method is best applied during the season of the year when flies are active, and the flies must have access to the corpse. Corpses inside automobile trunks, inside buildings, wrapped in plastic, or in other unique circumstances may be totally or partially protected from flies. Most common blow flies cease oviposition during nighttime hours. Thus, in a straightforward application where a decedent is found outdoors during summer, the procedure is to collect representative samples of the insects present and to assess the most mature stages present. If the species are known, the measured rates of development can be compared to retrospective temperatures obtained from proximate weather stations and the amount of time required to progress from the stage deposited on the decedent by the female fly to the stage collected can be estimated. This period is known as the "minimum postmortem interval," because the decedent in question had to be dead for at least that period.

It is well established that insects and other arthropods appear at dead animals and humans in a predictable succession of species, depending on how long the decedent has been dead. Local studies of the succession of necrophilous arthropods can facilitate mostmortem estimates.

Medicocriminal entomology has enjoyed more than a century of judicial acceptance. It has a solid foundation of insect taxonomy, physiology and behavior and thus passes the "good science" test that is part of evidentiary admissibility. The same is true of the other fields in forensic entomology, and these techniques are often useful as controversies are resolved within the judicial system.

Formosan Subterranean Termite, *Coptotermes formosanus* Shiraki (Isoptera: Rhinotermitidae)

ASHOK K. RAINA
U.S. Department of Agriculture, Agricultural Research Service, SRRC, FSTRU, New Orleans, LO, USA

Termites are primarily wood feeding insects, and occur throughout the world. Out of about 2,300 known species, 183 are responsible for significant economic damage. The subterranean termites, as the name suggests, live mostly underground and are major pests of wood and wood products. Most of the destructive species belong to the family Rhinotermitidae, with their center of origin and dispersal primarily in the Oriental region. In this family three genera, *Coptotermes*, *Reticulitermes* and *Heterotermes* are of enormous significance because of the damage they cause. *Coptotermes*, essentially a tropical and subtropical genus, is distributed in the Far East, South Asia, Australia, parts of southern Africa, southern regions of the U.S. (Fig. 82) and Hawaii. Some of the most destructive species include *C. formosanus* (Far East and USA), *C. parvulus* (Indian subcontinent), *C. havilandi* (Thailand, Indonesia and Malaysia) and *C. frenchi* (Australia). In the continental USA, the Formosan termite, *C. formosanus*, was first detected in 1965

Formosan Subterranean Termite, *Coptotermes formosanus* Shiraki (Isoptera: Rhinotermitidae), Figure 82 World distribution of *Coptotermes* spp.

Formosan Subterranean Termite, *Coptotermes formosanus* Shiraki (Isoptera: Rhinotermitidae), Figure 83 A 1-year-old incipient colony of *Coptotermes formosanus,* with the primary reproductives, a soldier, workers and eggs.

around Houston, Texas, and was probably introduced between 1944–1946 in ships returning from the Pacific arena.

The Formosan termite, being a social insect, has a complex caste system. A mature colony comprises a queen and a king, eggs, larvae, workers, soldiers (Fig. 83) and brachypterous nymphs. Each year, for a period of about 6–8 weeks, the mature colonies produce huge swarms of winged adults or primary reproductives. After a short flight to the nearest source of light, the alates land on the ground, shed their wings and form tandem pairs with males closely following the females. The link between the sexes is facilitated by a contact sex pheromone produced by the female. Most of these adults are killed by predators or die of other natural causes. Surviving pairs find a suitable place (need wood and moisture) and form fully enclosed nuptial chambers. Mating takes place within these chambers. There are no external genitalia and the tail to tail mating lasts only about 30 s. Sperm are circular in shape and lack the characteristic tail. Each reproductive pair can mate repeatedly and egg laying follows within a couple of days. After laying 30–40 eggs over a period of about 2 months the pair spends the next 2–3 months feeding and grooming the young larvae. Egg-laying is then resumed and the cycle is repeated about four times over a period of 2 years. After this period, egg-laying is almost continuous and the female grows to an enormous size. Such a female is called a physogastric queen and is essentially a bag of eggs. Various estimates suggest that a physogastric queen may lay over 1,000 eggs/day. The larvae, after molting three times, become either workers or pre-soldiers, the latter molting to soldiers. Typically, a Formosan termite colony has about 5% soldiers, whose primary function is to protect the colony from invaders. The workers build galleries and forage for food. They also feed and groom the newly hatched larvae. Once a colony is 8–10 years old, it starts producing brachypterous nymphs which have small wing pads. After several molts, the brachypterous nymphs give rise to the alates. The factors that regulate formation of various castes, particularly brachypterous nymphs, are not fully understood. Termites are unable to digest wood on their own, and require the help of flagellates and spirochetes present in large numbers in their gut to digest cellulose to usable sugars.

The Formosan subterranean termite, with very high reproductive capacity and resulting colony size (1–4 million termites/mature colony), has tremendous potential for destroying wooden structures, live trees and selected crops. Damage due to subterranean termites in the U.S. is estimated at around $1 billion and the control measures could easily add another $1.5 billion annually. In heavily infested areas, *C. formosanus* can cause major structural damage to an unprotected home in 6 months and almost complete destruction within 2 years.

Detection of termite infestations is the first step in the war against this menacing pest, and remains a critical issue for pest control operators and homeowners alike. As cryptic organisms, subterranean termite infestations remain hidden below the ground, inside trees and within building structures. Traditional methods of detecting infestations of subterranean termites include the use of a flashlight and a sharp probe to determine whether termites are present, but this is useful only in areas accessible to inspection. Other methods that have been studied for detection of termites include use of acoustic signals, odor detection using electronic devices, video probes and infrared imagery. In addition, light and/or sticky traps are used to monitor alates that can suggest the presence of termites in a general area. In-ground monitors, usually in the form of wooden stakes or plastic stations containing wood placed at regular intervals around structures to be protected, have been used to detect infestations. Discovery of termites in the monitors, with regular monitoring, indicates their presence in the structures or surrounding soil; however, the converse is not necessarily true.

Subterranean termites have been around for millions of years and are well adapted to environmental stresses. Being underground, they are fairly well protected from common hazards and the possibility of direct pesticide application. Until recently, termite management practices had focused on protecting individual structures through application of physical or chemical barriers to exclude termites from the structure, while doing little to mitigate populations of the termites in the surrounding area. Present management paradigms have changed with the advent of new termite control methods to that of reducing termite populations below economic threshold while protecting houses, wood products and trees. The new management paradigm can only be achieved through a combination of existing technologies and continued development of new technologies and integrated pest management concepts.

Anything non-chemical that would stop foraging termites from getting to a potential host is a physical barrier. Physical barriers are primarily used to protect buildings and involve the use of particulate matter or metal screens. Pre- and post-construction soil treatment with persistent chemicals such as cyclodienes (aldrin, dieldrin, etc.) was fairly effective against subterranean termites. Some of these chemicals had residual lives of 25–35 years in the soil. However, environmental and health concerns led to the cancellation of their use in mid-1980s. The newer chemicals besides being less mobile in the soil than the organochlorine pesticides require greater precision and frequent application to provide a uniform barrier to termite penetration.

Because of the short life of currently used liquid termiticides, the relative difficulty of providing a complete chemical barrier, and because of continuing health and environmental reasons, monitoring/baiting technologies have been developed to detect the presence of termites and deploy insecticide only when termites are present. Termite presence is monitored using cellulose substrates examined on a regular basis. Several monitoring/baiting systems are commercially available for both in ground and above ground use. Soil monitoring stations are regularly spaced around the structure to be protected. Once termite activity is detected in a monitoring station, the bait is replaced with a toxin-laced substrate. To effectively use baiting technology as a control, the toxicant must be non-repellent and a slow-acting toxin so that termites do not die at the site of treatment and become secondarily repellent. Further, such a slow-acting toxin allows termites to distribute the toxin more widely throughout the colony before they die by grooming and trophollaxis. One group of such chemicals includes the chitin synthesis inhibitors (CSI). The CSIs disrupt ecdysis resulting in the death of the colony.

The subterranean termites live in warm and damp habitats which can be very conducive to the establishment of pathogenic bacteria, fungi and nematodes. However, none of these organisms have proven effective in controlling the termite infestations under field conditions.

Contrary to the practice of treating buildings, chemical treatment of trees is a more recent phenomenon. This is particularly important in the attempt to save valuable trees in urban landscapes. Holes are drilled into a tree trunk and termiticides injected into the termite galleries, usually formulated into a foam to allow movement of the pressurized stream both upward and downward within tree hollows and the termite galleries.

Wood and moisture are two primary requisites for successful establishment of subterranean termite infestations. Sanitation, associated with termite control is a special case in which removal of one or more factors required for termite survival can provide protection by limiting their ability to colonize the area.

Fossil Record of Insects

MARJORIE A. HOY
University of Florida, Gainesville, FL, USA

Insects have a relatively extensive fossil record, with approximately 1,263 families in 30 commonly recognized orders having been identified. Although only a few fossil insects (such as Collembola) are known from the lower Devonian, a massive radiation began sometime during the early Carboniferous, more than 325 million years ago (mya). The first insects lack wings, but winged insects (the pterygotes) soon radiated into stem groups of all major lineages, including ephemeroids, odonatoids, plecopteroids, orthopteroids, blattoids, hemipteroids, and endopterygotes. The number of orders present by the upper Permian was similar to that today although some of the orders are now extinct and new orders have evolved. Insects, as measured by the number of families, increased in diversity during the late Carboniferous and middle Permian (Table 7).

Insects are highly diverse and ancient arthropods. For example, within the phylum Arthropoda the subphylum Crustacea was present in the Cambrian (about 600 million years ago, mya). A bristletail (Archaeognatha) from the Early Devonian resembles modern archaeognathans. Clear remains of a Collembolan have been found in Devonian deposits and arthropods have apparently been found on land since Devonian times. Two Collembola species were found in the lower Devonian (400 mya) that resemble recent extant Isotomidae and Neanuridae, suggesting that terrestrial arthropods already had radiated in the Ordovician (ca. 500 mya).

A number of extinct and extant orders of primitive insects have been found in a diverse late Paleozoic fauna. During the Carboniferous (which began 360 mya) a diverse array of extinct (in italics) and extant insects were present, including the: Diplura, Monura, Diaphanopterodea, Palaeodictyoptera, Megasecoptera, Permothemistida, Ephemoptera (mayflies), Protodonata, Paraplecoptera, Plecoptera (stoneflies), Orthoptera (grasshoppers

Fossil Record of Insects, Table 7 **Geological time scale in millions of years and types of fossil insects found**

Era	Period	Epoch	Began mya	Extinct and extant fossil insect orders first found
Cenozoic	Quaternary	Recent		Protura, Zoraptera, and Phthiraptera first appeared in fossil record.
		Pleistocene	1.6	
	Tertiary	Pliocene	5	
		Miocene	25	
		Oligocene	35	
		Eocene	60	Mantodea first appeared in fossil record.
		Paleocene	65	
Mesozoic	Cretaceous		145	Isoptera first appeared in fossil record.
	Jurassic		210	Dermaptera first appeared in fossil record.
	Triassic		245	Odonata, Titanoptera, Grylloblattodea, Trichoptera, Lepidoptera and Hymenoptera first appeared in the fossil record.
Paleozoic	Permian		285	Permothemistida, Plecoptera, Embioptera, Protelytroptera, Glosselytrodea, Psocoptera, Thysanoptera, Hemiptera, Antliophora, Mecoptera, Diptera, Amphiesmenoptera, Neuroptera, Megaloptera, and Coleoptera first appeared in the fossil record.
	Carboniferous		360	Pterygotes radiated into stem groups of all major lineages, with seven surviving to modern times (ephemeroids, odonatoids, plecopteroids, orthopteroids, blattoids, hemipteroids, and endopterygotes). Diplura, Monura, Thysanura, Diaphanopterodea, Megasecoptera, Permothemistida, Protodonata, Paraplecoptera, Orthoptera, Blattodea, Caloneurodea, Blattinopsodea, and Miomoptera were present.
	Devonian		400	Collembola (*Rhyniella praecursor*) and Archaeognatha
	Silurian		440	Mites, opilionids, scorpions, pseudoscorpions, centipedes, spiders found in preDevonian strata.
	Ordovician		500	
	Cambrian		600	

and crickets), Blattodea (cockroaches), Caloneurodea, Blattinopsodea and Miomoptera.

During the Permian (which began 285 mya), additional extinct and extant insect groups are found in the fossil record, including Plecoptera (stoneflies), Embioptera (webspinners), Protelytroptera, Glosselytrodea, Thysanoptera (thrips), Hemiptera (true bugs and leafhoppers), Antliophora, Mecoptera (scorpionflies), Diptera (true flies), Asmphiesmenoptera, Neuroptera (lacewings, antlions), Megaloptera (dobsonflies), and Coleoptera (beetles).

By the Triassic (245 mya), nearly all modern orders of insects are found in the fossil record, including Lepidoptera (butterflies and moths), Trichoptera (caddisflies), and Hymenoptera (bees and wasps). By the Jurassic (210 mya), many current families were present. Tertiary insects (65 mya) are essentially modern and include genera nearly indistinguishable from living fauna.

The great diversity of insects was achieved by low extinction rates rather than by high origination rates. The great radiation of modern insects began 245 million years ago and was not accelerated by the expansion of the angiosperm plants during the Cretaceous period.

There are more than 700,000 living species of living insects classified in at least 29 orders and more than 750 families, with the orders Coleoptera (>300,000 named species), Lepidoptera (>120,000 species), Hymenoptera (>120,000 species), and Diptera (>150,000 species) containing the most species. Insects are diverse, numerous, and ancient. An understanding of their systematics and phylogeny will require the combined use of the fossil record, traditional morphological data, and molecular methods.

Fossorial

Adapted for digging; usually used in reference to legs.

Founder Effect

The genetic pattern resulting from introduction of a small population into a new area, and the subsequent divergence from the parental stock. The new population, after a period of time, may no longer be compatible with the original population and is incapable of interbreeding.

Foundress

Among social insects, a fertilized female that founds a new colony. All the offspring in the colony are the sons and daughters of the foundress.

Fourcroy, Antoine-François (Comte De)

Antoine-François Fourcroy was born in France in 1755 and grew up in poverty. He studied medicine, assisted financially by a benefactor, and received a medical degree in 1780. He was appointed professor of chemistry in 1784 at the Jardin du Roi, later Jardin des Plantes, and still later Museum National d' Histoire Naturelle in Paris. He worked with Lavoisier and others in studying chemicals of animal and plant products, classifying them, and reforming the system of chemical nomenclature. He published major works on chemistry in 1792 and 1801. He also was interested in the classification of animals, and published (1785)

"Entomologia Parisiensis; sive catalogus insectorum quae in agro Parisiensi reperiuntur; secundum method Geoffraeanam…" in two volumes; Geoffroy contributed descriptions of new species in pages 1–231 of the first volume. He was a strong supporter of the French revolution, held public offices in it, and became director-general of public education in 1901. In 1908, he was made a count, and became known as Antoine-François de Fourcroy. He died in 1809.

Four-Legged Mites (Eriophyoidea or Tetrapodili)

MARJORIE A. HOY
University of Florida, Gainesville, FL, USA

The Eriophyoidea or Tetrapodili are unusual mites because they have only two pairs of legs as adults instead of the normal four pairs. Eriophyoid mites are second only to the spider mites in their economic importance as plant pests around the world. Eriophyoid mites are minute, and highly specialized to feed on plants. They are the smallest arthropods that feed on plants, averaging 100–500 μm in length and, despite their very small size which could lead to rapid water loss, some can survive in relatively exposed environments on leaves. The mouthparts of eriophyoids consist of a pair of stylet-like chelicerae and a pair of accessory stylets which are modified palps. The small size of the stylets allows eriophyids to penetrate only about 5 μm into the leaf, so feeding occurs in the plant epidermis (Fig. 84).

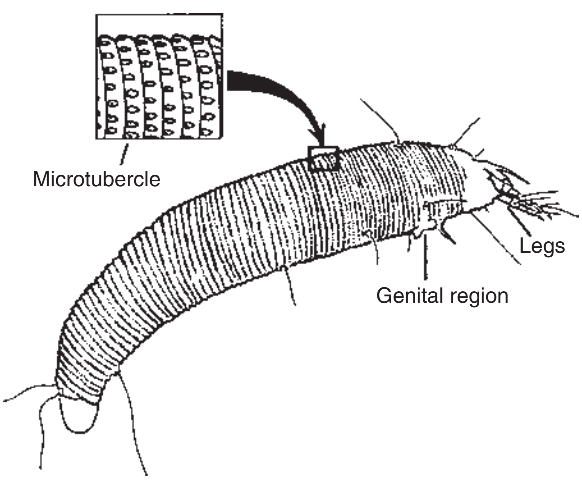
The Eriophyoidea contain three families, the Phytoptidae (consisting of about 20 species of primitive forms often found on conifers), the Eriophyidae (consisting of about 85% of the known species) and the Diptilomiopidae (consisting of about 16 species that are vagrants on leaves). Approximately 3,000 species in 230 genera of eriophyoid mites have been described, yet the biology of many remains relatively unknown.

Most eriophyoid females deposit eggs, from which larvae hatch. After larvae feed they enter a quiescent resting stage from which a nymph emerges and feeds. After another resting stage, adults emerge. The spheroid eggs are laid on leaves or on buds and very small (about 20–60 μm in diameter), but large in comparison to the size of the female depositing them. Immatures are similar to adults in appearance, but smaller and lacking external genitalia. The immatures of many species have never been studied. Adults consist of females and males, but females are more numerous and males of some species have not been found. Males are usually similar to females, although smaller. The basic life cycle consists of egg, larva, nymph, adult, but eriophyoids may have more complex life cycles, with two different types of adult females.

Females of species in which there are two types of adult females are called protogyne and deutogyne. The protogyne female form usually is similar to that of the male. The second type of adult female is the deutogyne, and she often looks very different from the protogyne. This has created taxonomic confusion. This type of life cycle was discovered in the plum nursery mite, *Aculus foceui*; the deutogyne female is the overwintering or hibernating form of *A. foceui*, developing when the foliage begins to harden in the hottest part of the summer. Deutogynes do not deposit eggs prior to overwintering and have a different body form than the protogynes. In the buckeye rust mite, *Tegonotus aesculifoliae*, the two forms were sufficiently different that they were given different genus names. In general, the main differences between proto- and deutogynes is in the microtuberculation (shape of micro ridges on the exoskeleton, which are important taxonomic characters); deutogynes have a reduced microtuberculation, or the microtubercles are a different shape. Deutogynes appear to be adapted to survive adverse conditions perhaps because the reduced microtubercles limit water loss.

Leaf hardening, particularly in the case of eriophyoid species that are leaf vagrants or rust mites, triggers the production of deutogynes in late spring or summer, usually in association with rising temperatures. In some species, particularly those in erinea or galls, the trigger is the onset of cool conditions in the fall of the year and the deutogynes appear later in the year. Deutogynes move off leaves into sheltered crevices on twigs, under bud scales, or other protected sites where they hibernate or aestivate. The deutogyne females mate prior to entering the protected sites and the males don' t go with them. If females fail to mate, they produce only male progeny, indicating that they are arrhenotokous.

Initially, it was assumed that deutogynes were produced only in those species that lived on deciduous host plants. Later, however, it was discovered that deuterogyny occurs in species on evergreen plants and in species on tropical plants. The deutogynes in the tropical or subtropical species differ from the deutogynes in temperate climates. For example the mango-leaf-coating eriophyid, *Cisaberoptus kenyae*, is found on mango leaves and is widespread in the tropics; in *C. kenyae*, however, the deutogynes deposit eggs. In this species, the deutogyne is the commonest form seen and seems to tend the white coating, keeping the coating raised enough to provide space for other colony members. Finally, some species have less distinctive forms of deutogynes, making it difficult to resolve whether there are actually two types of females. It is possible that the less-distinctive deutogynes are suited for dispersal rather than hibernation or aestivation. Only a relatively few eriophyoid species have been studied in sufficient detail that their biology and ecology is well known.



Four-Legged Mites (Eriophyoidea or Tetrapodili), Figure 84 **Eriophyoid mites are wormlike, with only two pair of legs (*right*) close to the chelicerae, the piercing mouthparts. The posterior of the mite has anal pads that allow the mites to adhere to the leaf surface. The exoskeleton has distinctive microtubercles that are useful in identifying eriophyoids. The size and shape of these tubercles may differ between the two types of females, called protogynes and deutogynes, found in some species.**

Eriophyoids disperse by walking, or are wind distributed. At least one, *Aceria litchii*, can be moved about on the bodies of honeybees after the bees forage in infested flower panicles of lychees in Australia. Eriophyoid mites can be transported easily on plant materials, as well. Wind dispersal in some species appears to be a matter of choice with mites assuming a distinctive upright posture to facilitate their aerial dispersal.

Eriophyoids are called blister mites, rust mites, bud mites or gall mites because their feeding causes distinctive damage to plants (Table 8). Fusiform eriophyoids are found wandering on the leaf or bud surfaces of their hosts and are classified as rust mites or leaf vagrants. Examples include the citrus rust mite, a pest of citrus in many parts of the world. Soft bodied worm-like eriophyoids also are found within buds, in blisters, or in galls, and are called bud or gall mites. They are most often found on perennial plants and are generally quite host specific. In fact, eriophyoids are sufficiently host specific that a key is available that shows photographs of the damage on each host plant; this key allows one to identify the species in North

Four-Legged Mites (Eriophyoidea or Tetrapodili), Table 8 Some eriophyoid mite species, their hosts, and damage in North America

Host plant species	Mite species	Damage
Acer campestre, hedge maple	*Eriophyes macrochelus*	Leaf gall
Acer rubrum, red maple	*Eriophyes major*	Erineum, or hairy growth on leaf surface
Avena sativa, oats and other grasses	*Eriophyes tulipae*	Wheat-streak-mosaic virus disease
Carya illinoinensis, pecan	*Eriophyes caryae*	Leaf edge, spotting
Citrus spp., citrus	*Phyllocoptruta oleivora*	Bronzing, russeting of fruit, leaves and twigs
	Eriophyes sheldoni	Deformed buds, flowers, fruit and leaves
Corylus avellana, hazelnut	*Phytocoptella avellanae*	Big bud or bud gall
Cynodon dactylon, Bermuda grass	*Eriophyes cynodonis*	Leaf blade and terminal shoot distortion
	Eriophyes cynodoniensis	Leaf sheath and stem gall
Fagus grandifolia, American beech	*Acalitus fagerinea*	Erineum
Ficus carica, fig	*Eriophyes ficus*	Mosaic-virus disease
Fraxinus americana, white ash	*Eriophyes chondriphora*	Leaf gall
Gossypium spp., wild and cultivated cotton	*Acalitus gossypii*	Bud injury, foliage deformation, leaf blister
Juglans californica, California walnut	*Eriophyes neobeevori*	Catkin gall
	Eriophyes brachytarsus	Leaf gall
Juglans nigra, black walnut	*Eriophyes caulis*	Petiole gall
Juglans regia, English walnut	*Eriophyes erineus*	Erineum
Lycopersicon lycopersicum, tomato also *Datura*, *Petunia*, nightshade and potato	*Aculops lycopersici*	Foliage browning, withering and fruit russeting
Malus pumila, apple	*Calepitrimerus baileyi*	Browning underside of leaves
	Aculus schlechtendali	Injured terminal growth, leaf curl, russeting
Medicago sativa, alfalfa	*Eriophyes medicaginis*	Witch's broom
Pinus clausa, sand pine	*Trisetacus floridanus*	Aborted buds, rosette gall, stunted needles
Pinus monticola, Western white pine	*Trisetacus alborum*	ditto
Prunus domestica, plum	*Acalitus phloeocoptes*	Bud gall
	Phytoptus emarginatae	Leaf gall
Quercus agrifolia, California live oak	*Eriophyes paramackiei*	Brooming at lower tree level
	Eriophyes mackiei	Erineum
Rhus radicans, poison ivy	*Aculops toxicophagus*	Leaf gall
Tulipa sp., tulip	*Eriophyes tulipae*	Bulb damage

Four-Legged Mites (Eriophyoidea or Tetrapodili), Table 8 Some eriophyoid mite species, their hosts, and damage in North America (Continued)

Host plant species	Mite species	Damage
Vaccinium spp., blueberry	*Acalitus vaccinii*	Bud blister, rosette fruit deformation
Vitus spp., grape	*Calepitrimerus vitus*	Abnormal growth, bunched foliage, injured flowers, short internodes
	Colmerus vitus	Deformed bud clusters and leaves, erineum

America (unless the mite is a new invasive pest). Even where two eriophyoids occur on a plant, their feeding damage and location on the plant usually is so distinctive that the different species can be discriminated easily. These very tiny mites cannot be seen readily on leaf surfaces without magnification, however. Because galls or blisters remain on leaves even after the mites have died or dispersed, feeding damage can be seen until the deciduous plant defoliates.

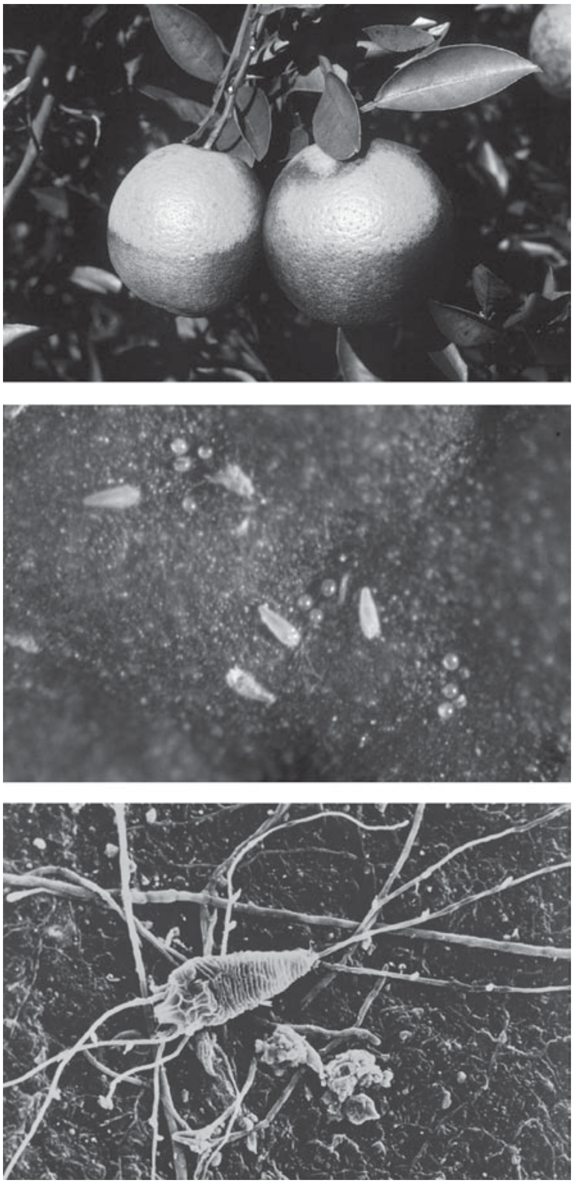
Leaf injury

Injury caused by eriophyoid feeding affects the surface (epidermis) of the leaf because the stylets (modified chelicerae) of these mites are short. Damage to foliage may be quite specific to the mite and host plant: the peach rust mite, *Vasates cornutus*, causes browning or silvering of the peach leaf surfaces by its feeding. *Aceria brachytarsus* causes pocketing of leaf tissues (purse galls) on walnut leaves. *Eriophyes pyri*, the pear blister mite, invades the mesophyll of pear leaves and causes serious injury. Hairy patches, called erinea, on the underside of grape leaves infested with *Eriophyes vitis* represent open galls in which the pocketing of the leaf tissue is minimal. Eriophyoids also injure buds by feeding on their surface and can cause gall formation. The citrus bud mite, *Aceria sheldoni*, causes fruit and leaf malformation in California citrus groves. Eriophyoids also cause "witches broom" of twigs, flower galls, shortening of internodes, or secondary development of leaf hairs.

Vectors of Plant Disease

Eriophyoids are vectors of plant viruses (potyviruses from the genus *Rymovirus*). Each virus has a limited host plant range and a single mite vector species usually is known for each virus. The best studied eriophyoid-virus relationship is the wheat-streak-mosaic virus and the wheat-spot-mosaic viruslike pathogen, both of which are transmitted by *Eriophyes* (= *Aceria*) *tulipae*. These viruses can be acquired after a few minutes of feeding, but longer access to plants results in higher transmission rates. Viruses are retained by the mites following a molt, but are not transovarially transmitted. The virus persists (Fig. 85) about one week at room temperature or for several weeks at lower temperatures in the vectors and must be acquired by one of the two nymphal stages if subsequent transmission by adults is to occur. Because adults cannot acquire and transmit virus, spread of the virus must originate from the original host of the individual mite. Dispersal of eriophyoids, and thus spread of virus, depends on temperature and wind. Although eriophyoids are wingless, during daylight hours they "stand up" on their anal papilla and allow themselves to be distributed by wind. *Aceria tulipae* transmits kernel-red streak of corn as well as wheat-spot, and wheat-streak mosaic viruses.

Other important plant-disease vectors include: *Aceria ficus* transmits fig-mosaic virus; currant-reversion virus is transmitted by *Phytoptus ribis*; peach-mosaic virus is transmitted by *Eriophyes insidiosus;* and ryegrass-mosaic virus is transmitted by *Abacarus hystrix*. The disease called "High Plains



Four-Legged Mites (Eriophyoidea or Tetrapodili), Figure 85 **Citrus rust mite and damage. (*above*) Discoloration of oranges caused by citrus rust mite feeding. (*middle*) Citrus rust mites as seen under a light microscope. (*below*) Citrus rust mite killed by *Hirsutella* fungus as seen under a scanning electron microscope.**

disease" is now known to be consistently associated with a virus and an eriophyoid mite, *Aceria tosichella*. Prior to 1993, no corn virus diseases were found in Colorado but a disease, initially diagnosed as wheat-streak mosaic, was found. The host range of the virus appears to include corn, wheat, barley, rye and oats, as well as cheat grass (*Bromus secalinus*) and yellow foxtail (*Setaria glauca*). The virus can be seedborne. Resistant cultivars have been identified and integrated pest management is possible using host plant resistance, elimination of volunteer plants, isolation from small grains (sources of the virus and vector), and modification of planting date.

Some Major Pests

Phyllocoptruta oleivora (Citrus Rust Mite)

The citrus rust mite is one of the most important and widespread citrus pests in the world. It reproduces rapidly and causes damage to the exterior of the fruit, which causes fresh market fruit to be downgraded. The interior quality of the fruit is not affected, so if the fruit is grown for juice, mite densities are less important.

Citrus rust mite eggs are laid in groups in indentations on fruits and on the ventral surfaces of leaves. The life cycle requires about 7–10 days in summer and females live about 20 days, depositing 20–30 eggs. The mites do well in warm, humid conditions. Severely infested fruits have a powdery appearance as a result of the exuviae left behind by the molting immatures. Mites do not tolerate bright sunlight well, so they choose undersurfaces of leaves and shaded areas of the fruit, which can result in a typical damage pattern in these areas. Feeding damage affects only the surface of the fruit and damaged fruits become silver, reddish brown or purplish black depending on the mite density. The rust mite is able to colonize very young fruit and, thus, control measures should be applied early, if natural enemies such as predator mites or the fungal pathogen *Hirsutella* is not suppressing populations sufficiently. In South Africa, the predatory mite *Amblyseius citri* feeds on rust mite, although it is not fully effective. In Florida, the rust mite is controlled in part by the fungus *Hirsutella thompsoni*. Unfortunately, the fungus often is eliminated if sprays are applied to control fungal pathogens of citrus. The rust mite is thought to have originated in southeast Asia, but little information is available on the natural enemies of this pest there.

Aculus cornutus (Peach Silver Mite)

This mite attacks peaches and almonds. The mites are found on leaves and their feeding causes the leaf surface to appear silvery when high populations are found. High densities can reduce tree growth and reduce fruit size. These mites can serve as prey for phytoseiid predators, such as the phytoseiid *Metaseiulus occidentalis* in California almond orchards, and thus rarely becomes a pest in almond orchards where these predators are abundant.

Aculops lycopersici (Tomato Rust Mite)

Tomato rust mites are pests of tomatoes around the world. Unlike many other eriophyoid mite species, the tomato rust mite attacks various plant species in the family Solanaceae. It can easily kill tomato plants and damages peppers, potatoes, egg plants, tobacco, and petunias. It is often found on *Ipomoea purpurea* (morning glory) in field margins. The morning glory is a natural host and these weeds can serve as a reservoir of the pest.

Tomato rust mites are dispersed by the wind and also by farm workers and agricultural tools. When the tomato plant begins to die, the rust mites migrate to the top of the plant, holding their bodies perpendicular to the leaf surface and adhering to the surface by the anal lobes. In this posture, they are more likely to be blown off the leaf surface. On occasion they form chains by crawling up each other to disperse. Tomato rust mites prefer warm weather and are able to feed on the upper surfaces of leaves in direct sunlight. Symptoms of rust mite damage on tomatoes include: bronzing of leaves, withering, and change of stem color from green to brown. Defoliation takes place, so eventually only young growth remains. The fruits are then sunburned, plant growth is slowed, and fruit production is reduced. If the fruits are attacked, the skin becomes brown. On potatoes, the tomato rust mite does not cause browning, but the leaves may become dry and the whole plant can die. Sulfur dusts or oils can be used to control the tomato rust mite.

Aculus schlechtendali (Apple Rust Mite)

These mites feed on flowers, fruits and leaves of apple. It causes apple leaves to roll up longitudinally and become rusty brown on the lower side and russeting of fruit. Aculus schlechtendali is considered a beneficial species in Washington apple orchards under an integrated mite management program because these mites serve as prey for the predatory phytoseiid *Metaseiulus* (= *Typhlodromus* or *Galendromus*) *occidentalis*. Apple rust mites provide alternative food for these important and effective predators early in the growing season and allow predator populations to increase so they can suppress the spider mite pests (*Panonychus ulmi* and *Tetranychus* spp.) on apples later in the growing season. Apple rust mite populations must become relatively large before they cause significant damage. Likewise, in the northeastern USA, *A. schlechtendali* is an alternative food source for the phytoseiid *Typhlodromus pyri* early in the growing season; this phytoseiid is an important predator of European red mite, *Panonychus ulmi*, in this apple-growing area.

Pesticides and Pesticide Resistance

Various insecticides, fungicides and miticides (acaricides) can be used to control eriophyoid mite pests. Generally, oils and sulfur are effective and have been used against eriophyoid mites for many years, although care must be taken to avoid phytotoxicity from both products.

Eriophyoid mite populations that are exposed to repeated and consistent applications of pesticides can develop a genetically based resistance to particular products. For example, some populations of the peach silver mite (*Aculus cornutus*) in

North America have become resistant to organophosphorous insecticides, and the apple rust mite (*Aculus schlechtendali*) in British Columbia and Washington state in the USA has become resistant to a variety of pesticides used in apple orchards. Likewise, the pear rust mite (*Epitrimerus pyri*) in Washington state is resistant to various pesticides. In citrus groves around the world, the citrus rust mite (*Phyllocoptruta oleivora*) has become resistant to several pesticides, including zineb, dicofol and chlorobenzilate, making control difficult. Developing effective management programs for these agricultural pests may require several tactics in order to delay the development of resistance in eriophyoid pest populations.

Invasive Species

The small size of eriophyoids makes them easy to transport on fruits and foliage without detection and eriophyoids can invade new geographic regions regularly. For example, the eriophyoid *Tegolophus perseaflorae* was found recently in flowers and fruits of avocado in Dade County, Florida. The mites feed on buds, causing necrotic spots on apical leaves and subcircular, irregular openings on mature leaves. Mites are also found on petioles and the undersides of leaves and fruitlets. The feeding causes fruit deformation and discoloration. It was speculated that avocado grafting material was the source of this new pest.

Biological Control of Weeds by Eriophyoids

Not all eriophyoids are considered pests. Many species remain unnoticed, while others are used for biological control of weeds. Attributes that contribute to their success as natural enemies of weeds include: eriophyoids are often host-specific, even to the level of race of plant and host tissue they attack. They are easily distributed by the wind; they can be used with other biological control agents; and some species are able to transmit specific plant viruses to the weed. Negative aspects include the fact that they are relatively slow-acting and must often be used in conjunction with other natural enemies. They are also quite sensitive to low relative humidities because of their small size.

The eriophyoid *Aceria chrondrillae* has been used in the biological control of the Eurasian rush skeleton weed, *Chrondrilla juncea*, in Australia and in the USA. Feeding on skeleton weed induces gall formation in the vegetative and flower buds, causing plant stunting, reduction in seed formation and weakness. Mites appear to be very specific to particular geographic races of the weed; a strain originating from Greece was most suitable against the weed in Australia, but this strain did not perform well in the USA. An Italian strain has been introduced to control the weed population in the USA.

Other eriophyoids have been considered as control agents of weeds, including *Aceria acroptiloni* which suppressed Russian knapweed (*Centaurea repens*) and was introduced into the Crimea from Central Asia. *Aceria centaureae* and *A. thessalonicae* have been evaluated for control of diffuse knapweed (*Centaurea diffusa*) in the USA and Canada. *Eriophyes boycei* was shipped from the USA to Russia for ragweed (*Ambrosia* spp.) control and *Aceria convolvuli* has been released for control of field bindweed (*Convolvulus arvensis*) in the USA. The European St. John's wort, *Hypericum perforatum*, is a weed in eastern Australia and, although the defoliating beetle *Chrysolina quadrigeminata* has become established and provides substantial control, the mite *Aculus hyperici* has been evaluated as an additional natural enemy. Host specificity trials indicate that *A. hyperici* is specific to the genus *Hypericum*.

Other species of eriophyoid mites could become useful natural enemies of weeds once additional information on their taxonomy, host range, and detrimental effects on target weeds have been obtained. In addition, the combination of a host-specific eriophyoid mite as a vector of a specific viral disease of the weed could result in enhanced biological control of weeds.

Identification of Eriophyoids

If you know the plant species and the location of the mite on the plant, you are likely to be able to identify the eriophyoid mite to species. For example, it is usually possible to identify North American eriophyoids without having to use a key because a list of host plants, symptoms of injury, and mite species in North America is available. Of course, this method won't work if the eriophyoid you are trying to identify is a new pest in the USA.

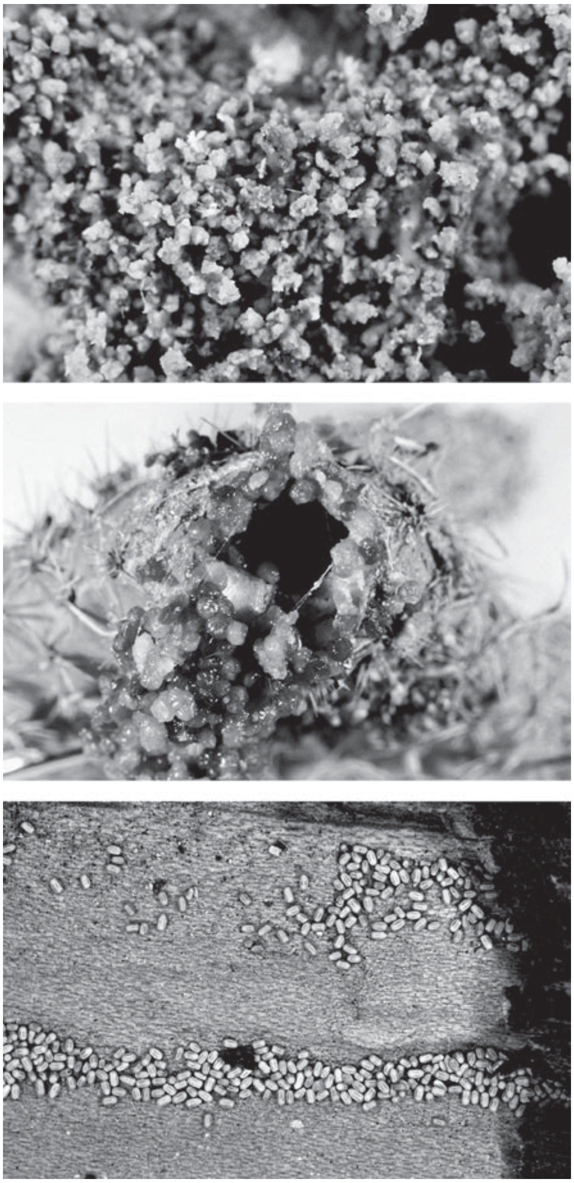
Fovea

A deep pit or depression on the integument of insects. A small pit is called a "foveola." Surfaces bearing fovea or foveola are said to be "foveolate."

Frass

WHITNEY CRANSHAW
Colorado State University, Ft. Collins, CO, USA

Frass is the solid excrement (fecal material) produced by various insects that feed on wood, foliage and other solid materials. Frass is produced in various shapes (Fig. 86), and moisture content varies with the diet. It is commonly produced in pellet form by various leaf-feeding caterpillars, sawflies



Frass, Figure 86 Frass, or excrement, can be of diagnostic value. Above is termite frass produced by subterranean termites; note that it has irregular edges and is dry. Middle image is moist frass produced by the blue cactus borer, and extruded from the tunnel by the larva; it is very moist. Bottom image is frass from drywood termites; it is produced in smooth-edged pellets and is very dry. (Termite frass photos by J.L. Castner, University of Florida; cactus borer frass photo by J.L. Capinera, University of Florida.)

and beetles, and the shape can be diagnostic of certain genera. The term is probably more widely used to describe excrement produced by various wood boring beetles and certain termites.

Frenate

Bearing a frenulum.

Frenular Hook

A hook or fold into which the frenulum is fitted. This structure occurs in the males of some Lepidoptera.

► Wings of Insects

Frenulum

A spine-like process in Lepidoptera in which the spine arises from the base of the hind wing, protrudes beneath the forewing, and serves to couple the fore- and hind wings during flight.

Fringe-Tufted Moths (Lepidoptera: Epermeniidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Fringe-tufted moths, family Epermeniidae, total 102 species, with many being Palearctic (36 sp.) and Australian (23 sp.). There are two subfamilies: Epermeniinae and Ochromolopinae. The family is part of the superfamily Copromorphoidea in the section Tineina, subsection Tineina, of the division Ditrysia. Adults small (8–20 mm wingspan), with head smooth-scaled; haustellum naked; labial palpi upturned; maxillary palpi 3-segmented. Wings narrow, with fringes longer on hindwings and scale tufts on forewing margin (Fig. 87). Maculation rather somber shades of brown, with various mostly darker markings. Adults are diurnal or crepuscular. Larvae are leafminers, leaf skeletonizers, or borers of seeds, fruits, or buds; a few are gall makers. Host records include several plant families.

Frisch, K. Von

Karl von Frisch was born in Vienna on November 20, 1886. After his schooling, he entered Universität Wien to study medicine, at the insistence of his father, although he preferred zoology. After 3 years of study in Vienna, his father relented and allowed him to transfer to Munich to study zoology. Now with a degree, he returned to Vienna in 1909 as a graduate student. In 1910 he was awarded a Ph.D. for a thesis on color changes in fishes. He returned to Munich as assistant professor of zoology, was promoted to associate professor by 1912. During World War I he worked at a Red Cross hospital in Vienna. In 1921 he became professor and director of the zoological institute of Universität Rostock, in 1923 he moved to a similar position at Breslau (now Wroclaw in Poland), and in 1925 he returned to Munich. That last city was heavily damaged in World War II, and he transferred to Graz in Austria. However, in 1950 he returned to Munich to help reconstruct the institute. His official retirement was in 1958, but he continued to publish research results until shortly before he died. He performed research and published on sensory physiology and animal behavior, producing 158 papers and 16 books. His best-known work is on the means by which bees navigate and communicate. His book (English edition 1966), "The dancing bee" and (English edition 1967) "Dance language and the orientation of bees" gained him much acclaim. His awards included a Nobel prize, six honorary doctorates, the Austrian medal of honor, and many others. He died on June 12, 1982.

Frivaldszky, Imre

GEORGE HANGAY
Narrabeen, NSW, Australia

Imre Frivaldszky was born on the 6th of February 1799 at Bacskó, in Zemplén Shire, Hungary. He began his studies in the highly regarded Piarist College in Sátoraljaújhely where he met the greatest Hungarian botanists of the time. During the many botanical excursions his interest toward natural history deepened and although in 1816 he enrolled as a student in the Budapest University of Medical Sciences, he spent most of his spare time outdoors, studying plants and animals. In 1823, he was awarded with the Doctor of Medicine degree, but he never became a practitioner. Instead, he devoted his life to natural history, especially to the study of Coleoptera. He became a curator of the Hungarian National Museum's natural history section, and he spent the first 10 years in this office by surveying the flora of the country. The resulting collection was outstanding by European standards, but Frivaldszky – and consequently Hungarian science - benefited even more from this work, as during the years of plant collecting, he gradually became a committed entomologist. In 1838 he was admitted into the Hungarian Academy of Science. His achievements in entomology were awarded by many learned societies in Hungary and abroad, and in 1847 he became the Director of the Hungarian National Museum. He expanded his sphere of interest to other countries as well. He organised a number of collecting expeditions to the Balkans, the Near East, the Mediterranean region and the neighbouring lands. His last expedition, at the age of 74, took him to Turkey. Shortly after this journey, on the 19th of October 1870, he passed away. Frivaldszky's life achievement was not only a huge natural history collection that formed the backbone of the museum, but also his tremendous fundamental work, which established entomology as a science in his country. His impetus to Hungarian entomology was so great that it was unparalleled for almost a century, until Zoltán Kaszab's directorship begun in the Hungarian Natural History Museum.

Frivaldszky, János

George Hangay
Narrabeen, NSW, Australia

János Frivaldszky was born on the 17th of June 1822, at Rajec, in Trencsén Shire, Hungary. He was introduced to natural history at an early age by his uncle, Imre Frivaldszky. He completed his formal studies at the University of Technology and received his diploma of engineering. But, he didn't become an engineer, instead choosing the study of zoology as his life-long career. He assisted his uncle in the processing and researching of the various collections brought back from his expeditions and became an expert entomologist and conservator. From 1850 onwards he often acted in his frequently sick uncle's museum position. Upon Imre Frivaldszky's retirement, in 1852 he became the assistant director of the Hungarian National Museum's Zoological Collections. János Frivaldszky was especially interested in the arthropods of Hungary and he set out to survey the country's fauna, with special attention to cave dwelling organisms. Due to his labors the museum's collections and entomological knowledge of the Hungarian fauna increased considerably. When the great collections of János Xántus arrived at the museum, Frivaldszky curated them and published the results (*Rövid vázlata azon szerzeményeknek, melyekkel Xántus János az MNM állattani osztályát gazdagította*. Pest, 1865.). Later in his life he studied ornithology and produced a concise work on the avifauna of Hungary (*Aves Hungariae* (*Magyarország madarai*). Budapest, 1891.). In recognition of his life-time achievements in zoology he was admitted in to the Hungarian Academy of Science, first as a corresponding member in 1865 and finally in 1875 as full member. He passed away on the 29th of March 1895 in Budapest.

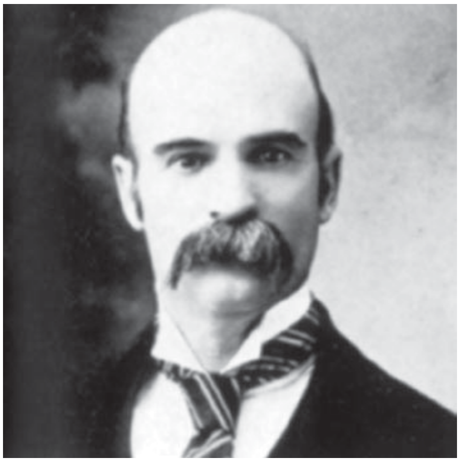
Froggatt, Walter Wilson

George Hangay
Narrabeen, NSW, Australia

Walter Wilson Froggatt was born in 1858 in Melbourne, Australia. He had a keen interest in natural history, especially entomology, and led the adventurous life of a professional collector. In 1885 he joined the Royal Geographical Society's New Guinea Expedition and not much after that he was employed by Sir William John Macleay as a collector. Beginning in April 1887 he spent more than a year in the wildest parts of northwest Australia, working for Macleay. He spent most of his life in the field, either as a free-lance entomologist or in the service of institutes, museums or private collectors. Usually he traveled alone either by horse or on foot, carrying his equipment and supplies. He collected an enormous number of specimens, which are distributed amongst the many collections in Australia and overseas. In 1907, he published a popular book, the "*Australian Insects*" and in 1923 another on "*Forest Insects of Australia*." He was an avid writer, producing a record number of published entomological articles. From 1923 until 1927



Froggatt, Walter Wilson, Figure 88 **William Froggatt.**

he was Forest Entomologist (Fig. 88) of the New South Wales Forestry Commission. He passed away in 1937 in Croydon, New South Wales, Australia. Froggatt had a remarkably adventuresome life and he is remembered as a pioneer of Australian Entomology.

Feeding on fruit. Such arthropods are said to be frugivorous or frugivores.

► Food Habits of Insects

Fruit Flies (Diptera: Tephritidae)

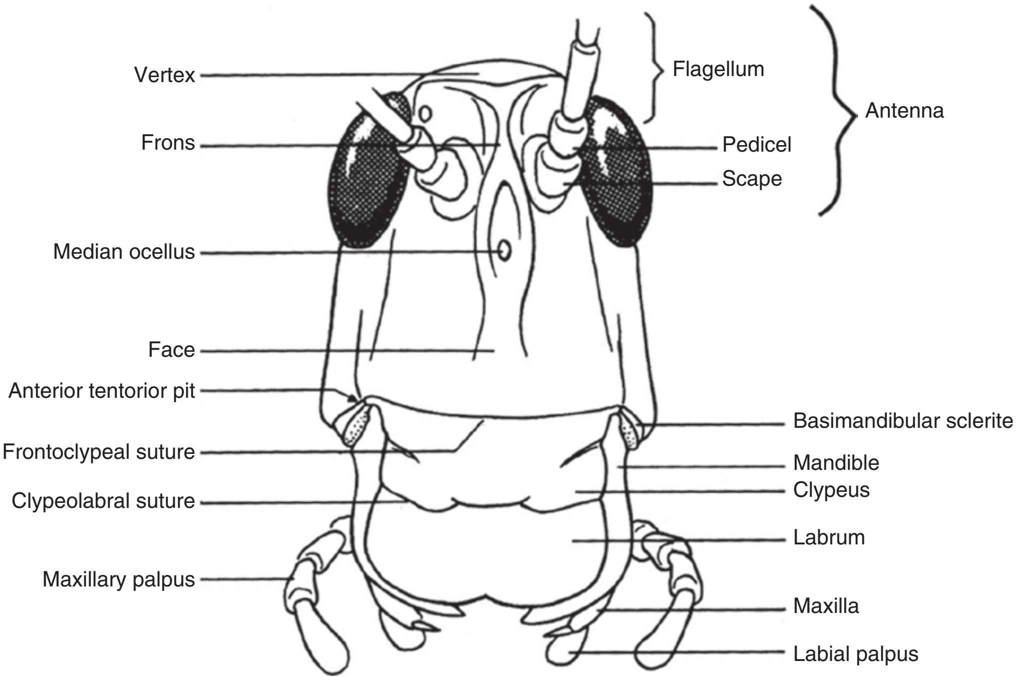
GARY J. STECK
Florida State Collection of Arthropods,
Gainesville, FL, USA

The family Tephritidae is a member of the large and phylogenetically complicated group known as acalyptrate flies.

Order: Diptera
  Suborder: Brachycera
    Infraorder: Muscomorpha
      Section: Schizophora
        Subsection: Acalyptratae
          Superfamily: Tephritoidea

Other families included in the same superfamily are Lonchaeidae, Pallopteridae, Piophilidae, Platystomatidae, Pyrgotidae, Richardiidae, and Ulidiidae (= Otitidae).

The family comprises over 4,300 described species, which are distributed throughout temperate and tropical regions of the world. The Tephritidae may be further subdivided into six subfamilies,



Frons, Figure 89 **Front view of the head of an adult grasshopper, showing some major elements.**

Tachiniscinae, Blepharoneurinae, Phytalmiinae, Trypetinae, Dacinae, and Tephritinae. Only the subfamilies Trypetinae and Tephritinae are represented in all of the major biogeographic regions.

Other insects are sometimes called "fruit flies," particularly the Drosophilidae, but they are not closely related.

Adult

One of the prominent features of the family is the presence in females of a chitinized ovipositor sheath and a needle-like ovipositor that allows them to oviposit into healthy plant tissues. Most species have "picture wings" that are prominently patterned with stripes or spots, and bodies with strongly contrasting colors, such as yellow stripes or spots on a dark background, as in species of *Toxotrypana*, which likely mimic wasps, or bold black stripes on the wings, as in some species of *Rhagoletis* and *Zonosemata*, that mimic jumping spiders. Identification to species level in some groups, including important pest groups such as *Anastrepha*, relies on features specific to the female sex (ovipositor). Sexual dimorphism is common, in which males may be ornamented with specialized combs or bristles on the legs (e.g., some *Ceratitis* species) or elaborate antler-like projections on the head (e.g., some *Phytalmia* species). Adult size varies from about 2–25 mm in length.

Immature stages

Eggs are typically white and elongate-cylindrical, sometimes with long, tail-like extensions. The egg stage lasts only a few days for most species. Active feeding and growth occurs during three larval instars inside the host plant tissues. Body shapes range from vermiform in stem-mining species to globose in gall-makers. Identification to genus or species level usually requires knowledge of the host and may be possible using characteristics of the spiracles, the cephalic segment and various surface features. Larvae may pupate inside the host plant, as is common in many flower infesters and gall makers, or they may exit the host to pupate in the soil, as is typical for most fruit infesters.

Plant Relationships

The family Tephritidae is best known for its pest species that attack a wide array of commercial and wild fruits and vegetables in many different plant families (Figs. 90 and 91). However, the great majority of species are not pests, and the majority are not even fruit infesters. Over half of the members of the family use non-fruit plant tissues as larval feeding sites. These include a large number of flower and seed feeders, and also gall-makers, and stem- and leaf-miners that infest members of the plant family Asteraceae. Members of the tribe Gastrozonini breed in bamboo stems. A few saprophagous and parasitic species are also known.

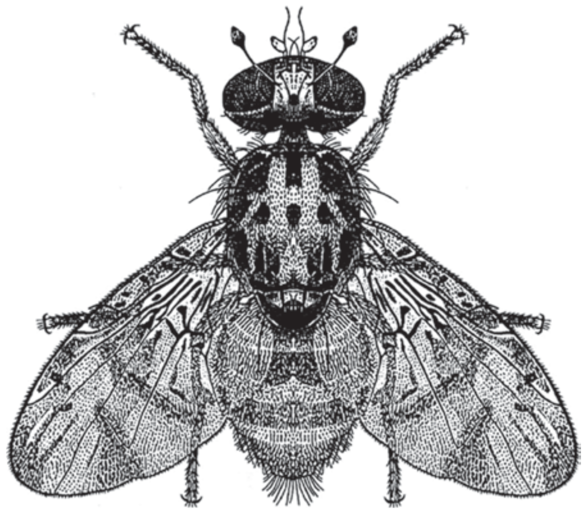
Life History

The duration and timing of the various life stages of tephritid flies depend on their host plant relationships. Many polyphagous, tropical fruit infesters, for example, breed year round, and have long-lived (several months) adults that are able to use a series of different host fruits for oviposition; their egg to pupa stages last only a few weeks, and all life stages are present simultaneously and throughout the year. Other species, both temperate and tropical, are restricted to a single host plant, they are univoltine, and most of their developmental stages are of short duration and synchronized. The adult flight period lasts only a few weeks during the period when the appropriate developmental stage of its host plant is available for oviposition. For most such species, most of the year is passed in the pupal stage. Some temperate species undergo obligatory diapause in the pupal stage that may last for several years.

Behavior

Courtship and mating behavior are very complex and elaborate in some species and may continue for hours. The behavior of many species is linked to the host plant, which may be used as a meeting site for males and females and may be a defendable resource for males. Males of many species display territorial behavior on the host plants and some engage in "boxing" matches to defend them. Lek-like mating aggregations, in which males compete for females, have been described for a number of fruit infesters including the Mediterranean fruit fly, *Ceratitis capitata* (Figs. 90 and 91). Many other aspects of fly behavior are also tightly linked to their host plants, for example, dispersal, feeding, pheromone release and response,

Fruit Flies (Diptera: Tephritidae), Figure 90
Oriental fruit fly, *Bactrocera dorsalis*.



Fruit Flies (Diptera: Tephritidae), Figure 91
Mediterranean fruit fly, *Ceratitis capitata*.

oviposition, and co-occurrence of other tephritid species that utilize the same host plant.

Control

Because of their economic importance, a great deal of effort has gone into study of the biology, genetics and control of pest species. The sterile insect technique (SIT) is widely used in population suppression and eradication programs, especially for the Mediterranean fruit fly. This involves mass rearing of fruit flies, sometimes by the hundreds of millions and sometimes using genetically modified all-male strains, followed by irradiation during the pupal stage to induce sterility. These flies are released into infested areas where sterile males outnumber their wild, fertile counterparts, thus reducing the number of successful matings and limiting population growth or even driving the population to extinction. Another control/eradication technique, known as "male annihilation," is based on attraction of males to highly potent parapheromones, such as methyl eugenol. "Bait stations" using a mixture of the attractant and an insecticide can quickly remove most or all males from a population and drive it to extinction. This technique has been used very successfully against the Oriental fruit fly, *Bactrocera dorsalis*. Classical biological control using hymenopteran parasitoids that attack the immature stages of fruit flies has been used with varying degrees of success.

Evolutionary Studies

The genus *Rhagoletis* has figured prominently in studies of evolutionary biology as a possible model of sympatric speciation. Because the mating, phenology, and biology of tephritid flies is so tightly linked to their host plants, it has been proposed that a shift in host-plant relationships could effectively isolate subpopulations even within a geographic area and lead to genetically distinct host races and ultimately to separate species.

Importance to Humans

Nearly all known members of the family are intimately associated with their host plant taxa, which serve as a feeding substrate for the larval stages. For this reason, many species of Tephritidae are highly damaging plant pests, and are widely known as "fruit flies." Some of the most important genera and examples of fruit and vegetable pest species are: *Anastrepha* with over 200 species occurring in the Americas, including *A. fraterculus*, the South American fruit fly, and *A. ludens*, the Mexican fruit fly; *Bactrocera* with over 500 species mostly in tropical Asia, Australia and islands of the Pacific Ocean, including *B. dorsalis*, the Oriental fruit fly, *B. cucurbitae*, the melon fly, and *B. oleae*, the olive fly; *Ceratitis* with about 80 species, all African in origin, including *C. capitata*, the Mediterranean fruit fly; *Dacus* with about 250 species, mostly African, including *D. bivittatus*, the pumpkin fly; *Rhagoletis* with more than 60 species, mostly Holarctic, but also present in Central and South America, including *R. pomonella*, the apple maggot; and *Toxotrypana* with 13 or more species in tropical America, including *T. curvicauda*, the papaya fruit fly.

Some tephritid host plants are invasive weeds with severe impact especially in pasture and rangelands. Various tephritid flies whose larvae feed on buds or seeds or produce galls have been intentionally promulgated into these weed populations as biological control agents, for example various *Urophora* species that attack thistles.

Fruit Stalk Borer, *Oryectes elegans* Prell (Coleoptera: Scarabaeidae)

YOUSIF ALDRYHIM
King Saud University, Riyadh, Saudi Arabia

The fruit stalk borer is found in the Arabian Peninsula as well as in Iraq and Iran. The adult is a stoutly built rhinoceros beetle that is shiny and reddish brown in color. The body length is about 34–36 mm in the female and 28–34 mm in the male. Adults have a horn-like structure on the head which is longer in females. The dorsum of the first thoracic segment has a depression that is deep and large in the female and shallow and small in the male. Mature larvae are about 55–65 mm in length, creamy white in color with brown heads, curved in shape and the last three abdominal segments are thicker than the remaining segments. Two cellulose destroying fungi, *Chaetomium elatum* and *C. murorum*, are found in the frass of fruit stalk borer larvae. The adults hide during the day in damp, organic soils. The adults are attracted to light from April to September and do great damage by boring through the leaf-bases and stems of inflorescences in the crown of the tree.

Importance and Damage

The importance of the fruit stalk borer as a pest varies from year to year. It causes severe damage in damp and neglected fields. The adults cause more damage than the larvae. However, the larvae may cause a huge cavity in the infested trunk that will ultimately cause its collapse. The adults make surface mines in the midrib of the fronds and the fruit stalks. Attacked fruit stalks may be broken or the fruits may be small and droop and shrivel. The adults also make holes at the base of the growing heart leaves and enter the stem.

The larvae do not cause real damage unless they are numerous in one trunk. The larvae also feed on decomposing materials in the soil.

There are other problems that the stalk borer might cause. The most common one is the tapered cut (crosscut) at the lower part of the fruit stalk fruit. However, it was reported from the United States of America, Pakistan, Iraq and a few other countries in the Middle East that these cuts are due to a physiological disorder. Another problem is the detachment of the fruit stalk from the growing point of the tree. There is no strong evidence that such damage is caused by the fruit stalk borer.

Biology

The life-cycle of the fruit stalk borer may require more than 1 year. Females start laying eggs a week after emergence. The eggs are laid singly in wet soil around the roots of date palm trees or on rotten trunks. The eggs that are laid in early spring may reach the adult stage in autumn, while those laid later may reach the adult stage the following spring. The larval stage may take up to 10 months. Pupal longevity is up to three weeks.

Control

In most cases, there is no need for control. But under certain conditions such as high humidity due to rainfall, the fruit stalk borer may cause serious damage. Also, damage by the fruit stalk borer facilitates entry by the red palm weevil, *Rhynchophorus ferrugineus*.

A light trap can be used to reduce the number of flying adults, and to predict the occurrence of the fruit stalk borer outbreak. Most captures usually occur in April, a time when the greatest damage occurs. Food or shelter traps also can be used. These traps consist of wet organic materials mixed with wet, small pieces of date palm trunk covered by fronds. The adults are attracted to this trap in the early morning as a hiding place during the day, and females may even lay eggs in these traps. Pesticides may be added to the traps to kill the attracted adults.

Fruitworm Beetles

Members of the family Byturidae (order Coleoptera).

► Beetles

Fruitworm Moths (Lepidoptera: Carposinidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Fruitworm moths, family Carposinidae, total about 279 species from all regions, but most are Australian and South Pacific. The family is part of the superfamily Copromorphoidea in the section Tineina, subsection Tineina, of the division Ditrysia. Adults small to medium (10–40 mm wingspan), with head smooth-scaled; haustellum naked; labial palpi porrect; maxillary palpi 1-segmented. Wing venation has reduction of two median veins in the hindwings and hindwings somewhat pointed apically. Maculation shades of gray and brown on forewings, plus some scale tufts; hindwings mostly pale. Adults are nocturnal or crepuscular. Larvae are borers in fruits, seeds, buds, or trunks and limbs, but a few are leafminers. Hosts include a variety of plants. A few species are economic.

► Bugs

Fulgoroidea

A superfamily of insects in the order Hemiptera. Included in this superfamily are families such as Delphacidae, Derbidae, Cixiidae, Kinnaridae, Dictyopharidae, Fulgoridae, Acilidae, Tropiduchidae, Flatidae, Acanalonidae, and Issidae. They sometimes are called planthoppers.

► Bugs

Fuller Rose Beetle, *Asynonychus godmani* (Crotch) (Coleoptera: Curculionidae)

Though not a serious pest, this species affects the ability of North American citrus producers to ship their products.

► Citrus Pests and Their Management

Fumigant

A liquid or solid chemical that forms toxic gas or vapor upon exposure to air, and is used to disperse insecticide in difficult-to-penetrate substrates such as stored grain and soil.

Fumigation

Treatment that uses a pesticide applied in a gaseous form.

Functional Genomics

Study of what traits/functions are conferred on an organism by specific DNA sequences. Typically functional genomics occurs after the DNA sequences have been identified.

Functional Response

A behavioral response of predators or parasitoids to the presence of prey. Searching and prey handling behavior is modified, resulting in increased efficiency of prey destruction. Learning, and more active search in the presence of prey, are implicated in functional responses. (contrast with numerical response)

Fundatrix (pl., fundatrigeniae)

In aphids, the stem mother or first viviparous parthenogenetic generation developing from the fertilized egg.

► Aphids

Fungal Pathogens of Insects

DONALD C. STEINKRAUS
University of Arkansas, Fayetteville, AR, USA

Fungi are eukaryotic, heterotrophic, absorptive organisms. Most grow vegetatively as fine hyphal filaments and reproduce by means of spores. Fungi are vital parts of ecosystems, often playing a valuable role in decomposition. They include common important organisms such as bread and wine yeasts, edible mushrooms, the causative agents of ringworm and athlete's foot, and fungi which produce antibiotics such as penicillin.

The classification of fungi is complicated and still imperfectly understood. Many different classifications and names have been proposed. Current authorities place the fungi in their own Kingdom, the Fungi or Eumycota. There are more than 56,000 described species placed in four phyla: the Ascomycota, Basidiomycota, the Chytridiomycota, and the Zygomycota. The Deuteromycota is an additional informal polyphyletic phylum. Aquatic entomopathogenic fungi, such as *Lagenidium* (Oomycota) that infect aquatic insects, are no longer considered fungi by some mycologists and are placed in the Kingdom Chromista.

Modern classification schemes no longer consider the Oomycota to be a phylum in the Fungi, but instead members of the Kingdom Chromista.

Fungi and insects interact symbiotically in many ways including mutualism, parasitism, commensalism, and predation. Some insects are totally dependent on fungi for their food. For instance, the leaf-cutting ants *Acromyrmex* and *Atta* spp., and termites in the Macrotermitinae, are mutualists with the fungi *Attamyces* and *Termitomyces*, respectively. These important groups of insects are utterly dependent on fungi for their survival, and similarly, these fungal species are found only in association with their insect "farmers." On the other hand, many fungi exploit and "feed" on insects. Such fungi are called pathogens and are the subject of this section (Table 9).

Fungal entomopathogens are microorganisms that are capable of causing disease in otherwise healthy host insects. They possess the ability to invade, reproduce in, and escape from a host, while overcoming or avoiding the host's defenses. In order to do this, fungal pathogens have spores that are able to mechanically and enzymatically penetrate an insect's exoskeleton, and vegetative hyphae that can survive and grow within a host. After killing a host, the fungus produces spores that are dispersed to new hosts. Often fungi that have little or no ability to infect living healthy insects are found growing on dead insects. These are called

Fungal Pathogens of Insects, Table 9 Simplified classification of entomopathogenic fungi and their arthropod hosts

Phylum/Order	Genus	Hosts
Oomycota		
Lagenidiales	*Lagenidium*	mosquito larvae
Saprolegniales	*Leptolegnia*	mosquito larvae
Chytridiomycota		
Blastocladiales	*Coelomomyces*	mosquito larvae
	Coelomycidium	black fly larvae
Zygomycota		
Entomophthorales	*Conidiobolus*	aphids and others
	Entomophaga	moths, grasshoppers
	Entomophthora	adult flies, aphids
	Erynia	many insects
	Massospora	periodical cicadas
	Neozygites	aphids, thrips, mites
	Strongwellsea	adult flies
	Zoophthora	many insects
Basidiomycota		
Septobasidiales	*Septobasidium*	scales
Ascomycota		
Laboulbeniales	many genera	many insects
Ascosphaerales	*Ascosphaera*	bee larvae
Sphaeriales	*Cordyceps*	many insects
Deuteromycota		
Sphaeropsidales	*Aschersonia*	scales and whiteflies
Moniliales	*Beauveria*	many insects
	Hirsutella	mites and scales
	Metarhizium	many insects
	Nomuraea	Lepidoptera larvae
	Paecilomyces	many insects
	Verticillium	aphids, whiteflies

saprophytic fungi. Most microbial pathogens, such as viruses, protozoa and bacteria, enter the host via the mouth during ingestion, an entry method called *per os*. Fungi, along with certain nematodes, have the ability to directly penetrate the exoskeleton of an arthropod. This makes the fungi particularly important pathogens of insects such as aphids, cicadas, and other sucking insects that do not chew leaves and other substrates, and are, therefore, unlikely to ingest microbial pathogens.

Life Cycle and Invasion of the Host

The life cycle of fungal pathogens begins with a spore. Spores vary in size and shape, and these characteristics are important in determining the species of a fungus. When a spore contacts a suitable host, it attaches to the host integument, forms an appressorium, and penetrates the insect's integument via a germ tube or penetration peg. Usually, enzymes are produced by the spore to soften or dissolve the insect's cuticle, then a germ tube mechanically penetrates the host's exoskeleton. This can be a complicated process. In some fungal species, adhesion of spores is non-specific, while in others the spores "recognize" an appropriate host's integument and begin the germination process. Once inside the host, the fungus grows vegetatively as filaments, called hyphae, or as yeast-like hyphal bodies. Within 3–7 days, the fungus has filled the host's body cavity (hemocoel), resulting in the host's death. Fungal toxins are sometimes involved, particularly with *Beauveria* and *Metarhizium*. *Beauveria* produces a number of toxic metabolites: beauvericin, a cyclic depsipeptide which is toxic to mosquito larvae; bassianolide, which is toxic to lepidopteran larvae; and cyclosporin, an immunosuppressant. *Metarhizium* produces toxins called *destruxins* that can paralyze insect larvae.

Usually after the host's death, the fungus produces spore-bearing hyphae called conidiophores that grow out of the host. Depending on the fungal species, spores are either explosively discharged (as in the Zygomycota: Entomophthorales) or are passively discharged (as in the Deuteromycota and Ascomycota). In some genera, such as *Massospora* in periodical cicadas and *Strongwellsea* in various adult flies, conidia (spores) are produced while the host is still living and mobile. The host in such cases helps disseminate the pathogen.

Epizootics, Biological Control, and Population Regulation

Fungal pathogens that prey on insects often cause readily observed epizootics. An epizootic is defined as an unexpectedly large proportion of diseased insects in a population. Fungal epizootics are often spectacular because: (i) large numbers of insects may be killed; (ii) insects killed by fungi are frequently held in elevated sites by fungal holdfasts; (iii) fungi sporulating on insect hosts are often colorful (white, green, or other colors); and (iv) because insects killed by fungi are usually firm, mummified, and persist for days to months.

Because fungal pathogens kill large numbers of many insect pests, they are frequently important regulators of insect populations and are valuable biological control agents. Fungi are among the most important natural enemies of arthropods such as gypsy moth larvae, periodical cicadas, whiteflies, aphids, spider mites, and many others (Table 10).

Why are fungi so efficient at causing epizootics? First, because their life cycles are usually relatively short compared to the host; sometimes, as is the case with *Neozygites fresenii*, a pathogen of aphids, they kill the host within 3–4 days. Second, many spores, thousands to millions, are produced from each infected host. Third, because many entomopathogenic fungi have developed specialized structures, such as rhizoids, that fasten a host where the opportunities are maximized for spores to contact new hosts. Fourth, spores of many fungi are rapidly spread by air or water to new hosts.

Importantly, many fungal pathogens (Figs. 92 and 93) of insects have a narrow host range, infecting insects in only a limited number of insect species. A limited host range is beneficial because

Fungal Pathogens of Insects, Table 10 Examples of fungi that cause natural epizootics in important insects and mites

Host	Host name	Fungal species
Twospotted spider mite	*Tetranychus urticae*	*Neozygites floridana*
Citrus rust mite	*Phyllocoptruta*	*Hirsutella thompsonii*
Caddisfly adults	Trichoptera	*Erynia rhizospora*

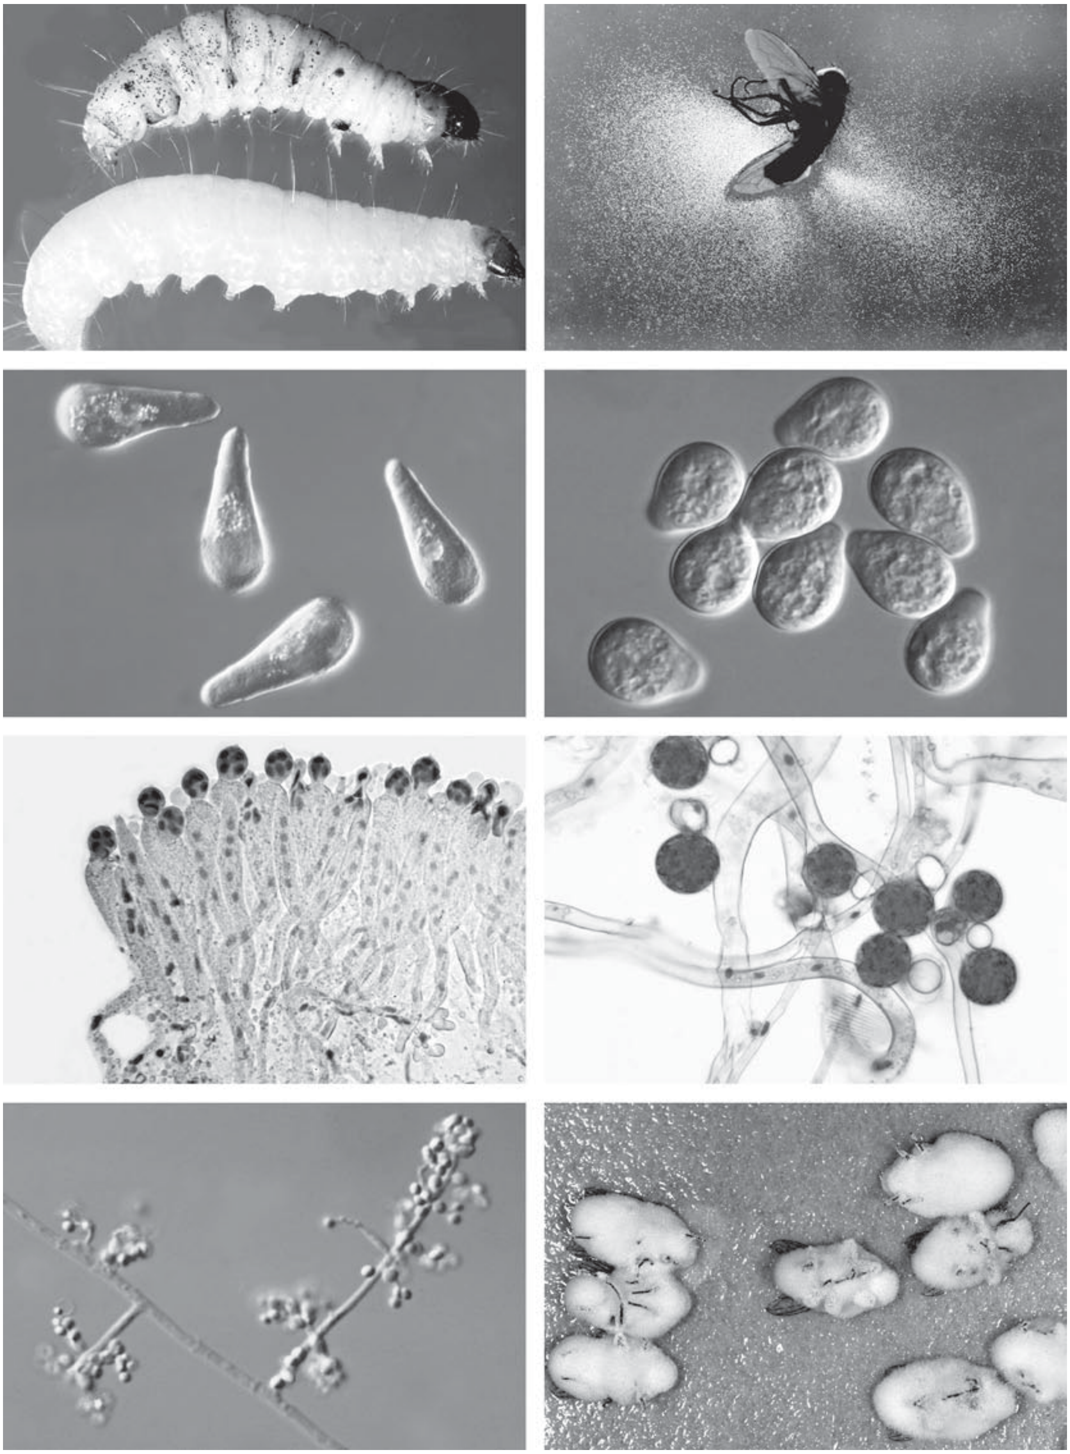
Grasshoppers	Acrididae	*Entomophaga grylli*
Aphids	Aphididae	*Neozygites fresenii*
Aphids	Aphididae	*Erynia neoaphidis*
Aphids	Aphididae	*Condiobolus obscurus*
Aphids	Aphididae	*Entomophthora planchoniana*
Periodical cicadas	*Magicicada* spp.	*Massospora cicadina*
House fly	*Musca domestica*	*Entomophthora muscae*
Mosquito larvae	Culicidae	*Erynia aquatica*
Mosquito larvae	Culicidae	*Coelomomyces* spp.
Mosquito larvae	Culicidae	*Lagenidium* spp.
Black fly larvae	Simuliidae	*Coelomycidium* spp.
Noctuid moths	Noctuidae	*Nomuraea rileyi*
Whiteflies	Aleyrodidae	*Aschersonia aleyrodis*
Diverse insects	Lepidoptera, Aleyrodidae	*Paecilomyces* spp.
Aphids, Whiteflies	Aphididae, Aleyrodidae	*Verticillium lecanii*
Honey bees	*Apis mellifera*	*Ascosphaera apis*
Solitary bees	Megachilidae	*Ascosphaera aggregate*
Diverse insects	Scarabaeidae, Formicidae	*Cordyceps* spp.
Alfalfa weevil	*Hypera postica*	*Zoophthora phytonomi*

non-target organisms such as plants, beneficial insects, and vertebrates are not harmed. Nearly all fungal pathogens of insects are safe for man, his animals and plants. For instance, *Neozygites floridana* and *Hirsutella thompsonii* have a host range limited to mites, *Neozygites fresenii* is limited to aphids, and *Nomuraea rileyi* is limited to lepidopteran larvae. However, fungal entomopathogens are not risk free. There are rare reports of *Beauveria* causing fatal respiratory infections in cold-blooded animals such as alligators and crocodiles, causing allergic reactions in people, and infections in the nasal passages of mammals. *Beauveria* does not grow well at temperatures above 37°C, which limits its dangers to mammals and birds. Strains of entomopathogenic fungi that grow well at 37°C or above could pose risks and probably should not be used in biological control programs.

Fungal species and structures within a species vary widely in their sensitivity to, and ability to survive, environmental conditions such as temperature, relative humidity, and sunlight. Conidia are relatively short-lived in the environment. Therefore, many fungi have the capability to produce longer-lived, environmentally resistant spores, called resting spores. In some cases these can remain viable for years before infecting a host. Fungal pathogens also can survive in the mummified bodies of their hosts (Fig. 92).



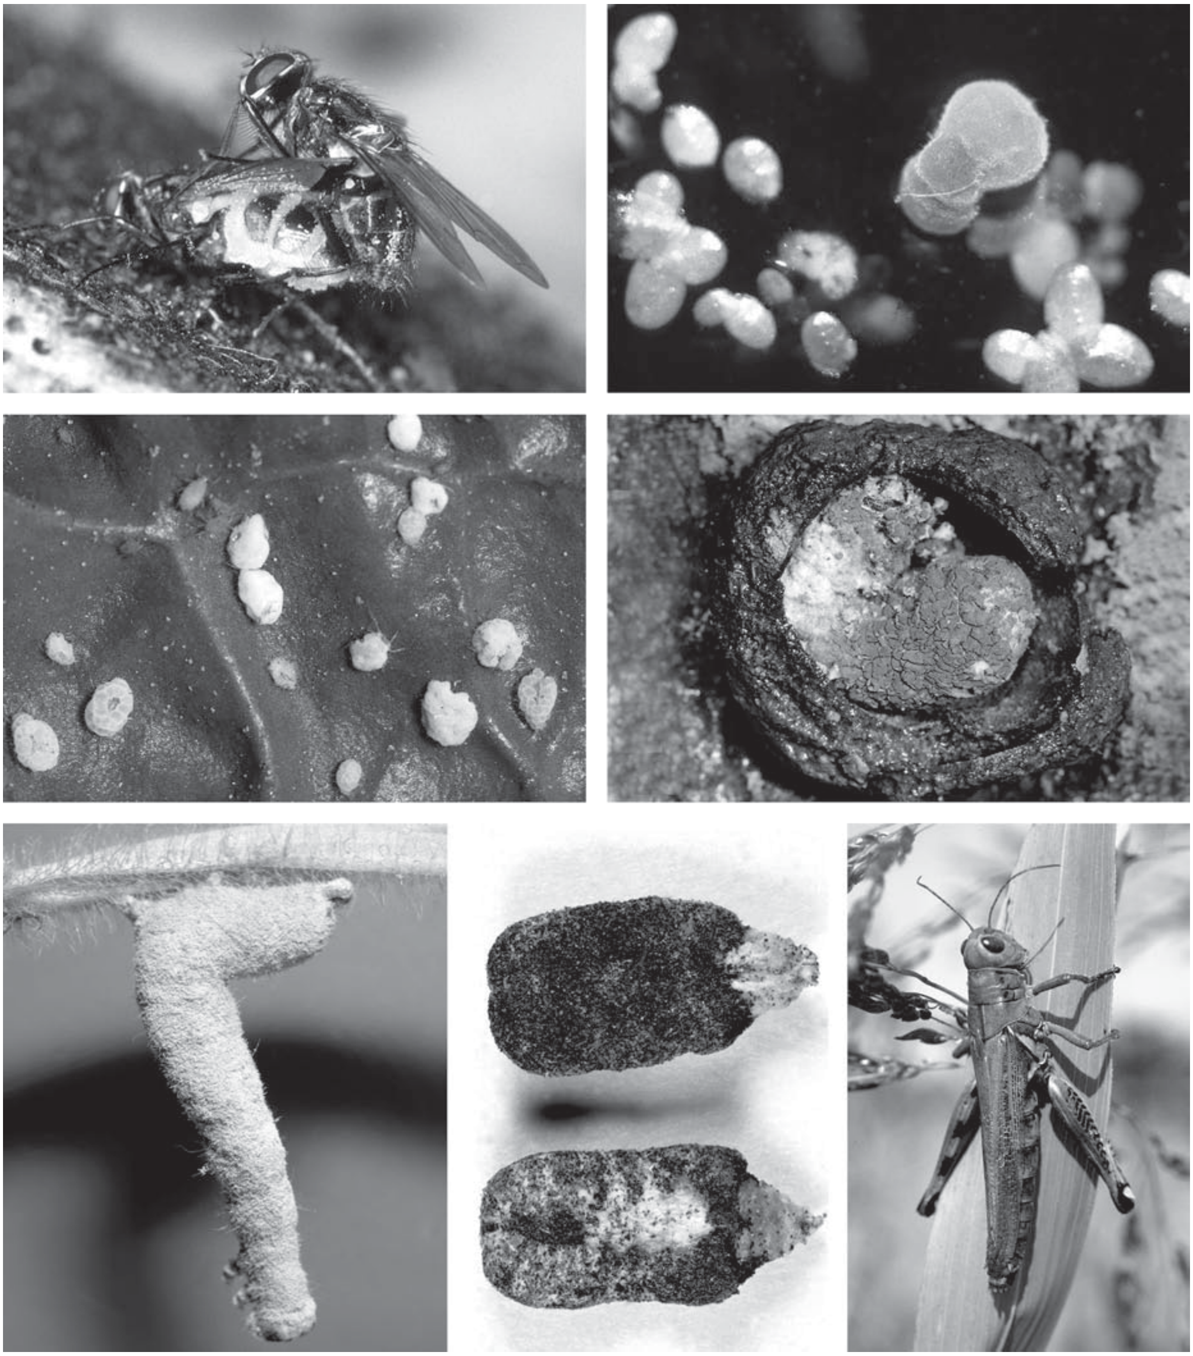
Fungal Pathogens of Insects, Figure 92 **Some insect pathogens: (*upper left*) Larvae of the Indian meal moth, *Plodia interpunctella* (Pyralidae). The top larva was inoculated with spores of *Paecilomyces* sp. (Deuteromycota: Hyphomycetes) and the lower larva was not inoculated. Note the black spots on the integument of the inoculated larva. Each spot represents a melanization defense response of the host to the penetration activity of a *Paecilomyces* spore. This is one example of host defenses against infection;**

Ecology

Entomopathogenic fungi occur in many habitats, including lakes, streams, ponds, snowpools, woodlands, tropical rain forests, agricultural landscapes, and the soil. *Lagenidium giganteum* (Oomycota) is highly pathogenic to mosquito larvae. *Lagenidium* produces motile zoospores that encyst on the cuticle of young mosquito larvae, and penetrate mechanically and enzymatically into the host hemocoel. Mosquito larvae defend themselves by producing melanin at the encystment sites. Mycelia of *Lagenidium* fills the body of the mosquito larva, breaking down the host tissues with fungal protease enzymes. No toxins are thought to be involved. Other fungal pathogens occur adjacent to aquatic habitats. *Erynia rhizospora* is a pathogen of adult Trichoptera; *Erynia conica* attacks various adult Tipulids and Chironomids; *Erynia curvispora* attacks black fly adults; and *E. aquatica* is a pathogen of mosquito pupae and adults. Frequently, infected insects can be discovered attached to rocks and logs near streams, waterfalls, and lakes (Fig. 93).

Forests, both tropical and temperate, are habitats for a variety of entomopathogenic fungi. *Cordyceps* spp. are fascinating pathogens of many insects in tropical and subtropical forests. These Ascomycota produce interesting club-like fruiting bodies (stromata) that emerge from infected hosts (often larvae or pupae of

(*upper right*) A house fly, *Musca domestica* (Muscidae), killed by and held to a window by the fungus, *Entomophthora schizophorae* (Zygomycota: Entomophthorales). When the fly died, specialized hyphal rhizoids (fungal holdfasts) grew out of the mouthparts of the fly and glued it to the glass. Then spore-bearing hyphae grew out of the host and produced thousands of spores (primary conidia) that were explosively discharged and are visible as a white halo around the dead fly. Fungal-mediated changes in host behavior and structures, such as holding the host in an elevated position, improve the odds of spores contacting new hosts; (second row left) Conidia of *Erynia aquatica* (Zygomycota: Entomophthorales), a pathogen of mosquitoes. Each spore is about 35 μm long. Note the difference in size and shape compared to the conidia of *Entomophaga grylli;* (second row right) Primary conidia of the grasshopper pathogen, *Entomophaga grylli* (Zygomycota: Entomophthorales). These spores are about 30 μm long. The shape and size of fungal spores are important characters used in their identification; (third row left) Photomicrograph of spore-bearing hyphae (conidiophores) of *E. schizophorae*. At the tips of the conidiophores the primary conidia are formed and then explosively discharged into the air. Each conidium contains 5 nuclei and is about 23 μm long. Nuclei, visible within the conidiophore, move into the developing conidium, prior to conidial discharge; (third row right) Resting spores of *E. aquatica*. Thick-walled resting spores can remain viable in mud and debris near mosquito breeding sites during the winter, then germinate and infect mosquito larvae in the spring; (bottom left) Spores of *Beauveria bassiana* and other Deuteromycota tend to be smaller than those of the Entomophthorales. These conidia, still attached to their conidiophores, are about 2–4 μm and are globose in shape. The spores of the Deuteromycota, unlike the Entomophthorales, are not explosively discharged from the host into the air; (bottom right) *Beauveria bassiana* (Deuteromycota) is one of the most commonly encountered entomopathogenic fungi, particularly in soil insects. This fungus has a very wide host range (several hundred species of insects at least) and there are several commercial products based on it. Commercialization of *B. bassiana* is possible because it is easily cultured in vitro, its spores are relatively small and easily formulated, and it has a wide host range. The dead hosts, in this case house flies, are covered by a white layer of fungal spores and mycelium. Note the similar appearance of these infected flies. Host insects killed by entomopathogenic fungi usually do not present a shaggy appearance, like saprophytic fungi do.



Fungal Pathogens of Insects, Figure 93 **Some additional insect pathogens: (*upper left*) *Entomophthora schizophorae* causes epizootics in muscoid flies, especially the house fly. Like the grasshopper killed by *E. grylli*, hosts killed by *E. schizophorae* are held to substrates, in this case by fungal rhizoids that grow out of the mouthparts (the lobes of the labellum) of the fly. In addition, dead infected flies appear life-like, have raised wings, and the infected females are attractive to males, who will sometimes engage in copulation with dead females, with obvious implications for the spread of the pathogen. Here you see a male house fly copulating with a dead infected female; (*upper right*) Entomophthoralean fungi in the genus *Erynia* are commonly found infecting insects that occur in moist situations, such as along stream**

Lepidoptera or Coleoptera) in the soil. In China, larvae of hepialid moths infected with *Cordyceps sinensis* have been collected and used medicinally for thousands of years. Especially important in the temperate forests of North America is the fungus *Entomophaga maimaiga*, which causes large-scale epizootics in larval populations of the gypsy moth, *Lymantria dispar*. This fungus is one of the most valuable natural enemies of this pest. Various other Entomophthorales cause epizootics in tent caterpillars, aphids, and other forest pests.

In agricultural habitats, fungi play an important role in regulating populations of various pests: whiteflies are attacked by *Aschersonia* spp.; spider mites are attacked by *Neozygites floridana*; and citrus rust mites by *Hirsutella thompsonii*. Various lepidopteran larvae are frequently decimated on soybean by *Nomuraea rileyi*, while the alfalfa weevil, *Hypera postica*, is heavily attacked by *Erynia phytonomi*.

Techniques for Studying Fungal Pathogens of Insects

Identification of entomopathogenic fungi is best accomplished when the host species is known, the gross signs of the fungus on the host (such as color, texture, attachment structures) are noted, and when microscopic fungal structures (spores, rhizoids, hyphae, cystidia) are examined with a phase microscope. Small amounts of fungal material are removed from the host, using an insect pin or minuten mounted in a wooden dowel, placed in a mounting medium (such as lactophenol) on a glass slide under a coverslip. The coverslip may be sealed with nailpolish to make it semi-permanent. Phase microscopes (usually at 100–400x) are used to examine the spores (conidia), conidiophores (spore-bearing hyphae), rhizoids, hyphae or hyphal bodies, and other structures. The size, shape, and color of spores are particularly important in identification using appropriate keys.

banks, waterfalls, and lakes. *Erynia aquatica* infects mosquitoes (Culicidae) that breed in snow pools. Here you see a mosquito that died in the pupal stage from this fungus. The dead mosquito pupa floats on the water surface, the spores are discharged from the dead host, and infect newly emerged mosquito adults; (second row left) *Pandora neoaphidis* (Zygomycota: Entomophthorales) is one of the most important pathogens of aphids. These are green peach aphids, *Myzus persicae*, killed during an epizootic of *P. neoaphidis*, in a spinach field. The infected aphids are held firmly to the leaf by fungal rhizoid holdfasts; (second row right) *Metarhizium anisopliae* (Deuteromycota) is a very common pathogen of soil insects and has a wide host range. The photograph shows a green June beetle larva, *Cotinus nitida* (Scarabaeidae), in its pupation chamber, killed by *M. anisopliae*. Note the white areas of hyphae where the fungus has not yet sporulated. The mature spores cover the host with millions of green spores; (bottom left) *Nomuraea rileyi* (Deuteromycota: Hyphomycetes) is a common pathogen of Lepidoptera larvae in southern field crops. Host larvae are covered with pale green spores. Note that this host larva, a soybean looper, is attached to a leaf, is firm, is covered with powdery light green masses of spores; (bottom center) *Ascosphaera apis* (Ascomycota: Ascosphaerales) causes chalkbrood in honey bee larvae (brood). The mummified bee larvae resemble pieces of chalk in front of the hive, hence the name chalkbrood. Note the firm, "preserved" appearance of the dead insect. Other diseases of bee larvae, such as American foulbrood, caused by a bacterium, result in the larva becoming "gooey" and having a foul smell; (bottom right) *Entomophaga grylli* attacks grasshoppers. Infected hosts often are found clinging to the tops of grasses, and the dead hosts appear to be alive. There are no fungal holdfasts produced. However, the fungus mysteriously makes its grasshopper victim tightly grasp a plant with its legs before it dies. Upon dissection, large numbers of resting spores were found within the host's abdomen. Another *Entomophaga* sp., *E. maimaiga*, is the cause of major epizootics in gypsy moth larvae and is considered one of the most important natural enemies of this pest.

Many entomopathogenic fungi can be cultured *in vitro* on mycological media, such as Sabouraud dextrose agar. Some such as *Beauveria*, *Metarhizium*, and *Paecilomyces* grow readily on media. Others such as *Pandora neoaphidis* and *Erynia curvispora* can be grown relatively easily *in vitro*, while others such as *Entomophthora muscae* are difficult to culture, and yet others, such as *Neozygites fresenii* are almost impossible to culture in vitro.

Isolating pure cultures of entomopathogenic fungi can be difficult depending on the species of fungus involved and the state of the host. Contamination of cultures by bacteria or unwanted fungi is a frequent problem. Selective media, such as oatmeal agar amended with dodine, are frequently used to isolate fungi such as *Beauveria*, while Entomophthorales are frequently isolated on coagulated egg yolk media. Most media used for isolation include broad spectrum antibiotics such as tetracycline and streptomycin to reduce the chance for bacteria to contaminate the culture. Fungal spores can be transferred from the host to the culture media using a needle. One of the best methods to isolate Entomophthorales is to place the sterile isolation media above the host cadaver, so that conidia are discharged from the host onto the media surface above.

Cultures can be preserved by regular serial transfers onto fresh media, by storing culture slants under a layer of sterile mineral oil, by freeze-drying, or in ultra cold freezers. The USDA maintains a collection of entomopathogenic fungal cultures called the USDA-ARS Collection of Entomopathogenic Fungal Cultures, in Ithaca, New York.

Fungus Gnats (Diptera: Mycetophilidae and Others)

PETER H. KERR
California Department of Food and Agriculture, Sacramento, CA, USA

Fungus gnats (Mycetophilidae, Bolitophilidae, Ditomyiidae, Diadocidiidae, Keroplatidae, and Lygistorrhinidae) are a diverse and abundant group of insects in the order Diptera, suborder Nematocera. Adults are usually recognized by their hump-backed appearance, stout and elongate coxae and well-developed tibial spurs (Figs. 94–98). Fungus gnats are primarily forest dwellers but can be found in a variety of ecosystems, often in association with fungal habitats, although most of their natural history secrets remain untold. They occur on all continents except Antarctica. The adults often attain large populations and play an important role in the food web of forest environments.

Traditionally, fungus gnats have been treated as a single family, the Mycetophilidae, and along with Sciaridae (dark-winged fung,us gnats) and Cecidomyiidae (gall midges), make up the superfamily Sciaroidea, within the infraorder Bibionomorpha. Fungus gnats formerly placed in Mycetophilidae, however, have been shown to be composed of several distinct lineages that are now treated as six separate families: Mycetophilidae, Bolitophilidae, Ditomyiidae, Diadocidiidae, Keroplatidae, and Lygistorrhinidae. More families may be recognized in the near future as more study and greater understanding of the *Heterotricha*-group taxa is developed. The *Heterotricha*-group is a heterogeneous assemblage of at least 12 genera

Family: Mycetophilidae
Family: Bolitophilidae
Family: Ditomyiidae
Family: Diadocidiidae
Family: Keroplatidae
Family: Lygistorrhinidae

In total, approximately 5,000 species of fungus gnats have been formally named and described. Mycetophilidae remains the largest family in terms of species number with approximately 3,500 species worldwide, in approximately 136 genera. Undoubtedly the number of fungus gnat species will increase significantly as more study is devoted to the family. The number of genera is also expected to increase. Currently, there are at least several genera that are widely suspected to be artificial groupings of two or more disparate lineages (e.g., *Boletina*, *Dziedzickia*, *Sciophila*). These genera are in need of systematic revision. The largest genus, *Mycetophila*, contains over 700 species and is distributed worldwide. The Palearctic Region is the area of greatest fungus gnat diversity. This may be a result of heightened local interest and expertise in the group more than actual taxonomic diversity but it is interesting to note that in Europe, fungus gnat diversity does not increase as one approaches lower latitudes (a typical pattern for many groups) and it may be that in general, the temperate regions are more diverse for fungus gnats than the tropics. Currently, Finland has the richest fauna of Mycetophilidae recorded among the nations of Europe.

In forested areas throughout the world, fungus gnats are both abundant and diverse. Even in North America, it is not uncommon for two dozen or more fungus gnat genera to be collected over the course of a season from a single Malaise trap. In Finland, one survey effort captured 209 different species of mycetophilid gnats in a single trap in one season. This represents over 30% of the entire mycetophilid species total recorded for Finland. Fungus gnats are sensitive to forestry practices however, and the diversity of gnats may be suppressed for many decades or even permanently after clear-cutting forests.

As their name implies, most fungus gnats are dependent on fungi for their development, either in mushroom fruiting bodies themselves, in the ground on mycorrhizae, or in or on wood or decomposing hummus where they feed on fungal mycelia. Many species appear restricted to certain ecological or systematic groups of fungi. Furthermore, within a particular host fungus, there may be a succession of fungus gnat species that specialize in particular decomposition stages. However, fungus gnats are not restricted to fungal environments. Larvae have also reportedly been found in birds' nests and mammals' burrows (where they may be mycetophagous), and on algae, mosses, liverworts and possibly on lichens. Curiously, field mushrooms (*Agaricus* spp.) do not serve as hosts. Some larvae, such as members of the genus *Leptomorphus* (Mycetophilidae), spin webs underneath bracket fungi where fungal spores are caught and eaten. Some members of Keroplatidae (e.g., *Asindulum* and others) take this one step further and also spin webs to capture small living invertebrate prey. Possibly the most famous of all fungus gnat larvae, the New Zealand glow worm, *Arachnocampa luminosa*, is predaceous and uses its own bioluminescence to lure midges and other small flies into a sticky silk thread that the larva spins and hangs from overhanging rocks (e.g., in caves and hollows). The glow worm silk strands may be up to 50 cm long and are coated with sticky poisonous droplets that paralyze trapped prey so that the surrounding snares remain intact. Other keroplatids, such as some *Orfelia* spp. also have predaceous, bioluminescent larvae and may be found in caves in North America. Still other keroplatid larvae are associated with ant-plants. Perhaps most outlandish of all fungus gnat lifestyles is exhibited by the larva of *Planarivora insignis* (Keroplatidae), a Tasmanian species that lives endoparasitically in land planarians. Approximately 80% of fungus gnat hosts are still unknown.

Fungus gnat larvae are usually slender and white, with ventral welts and a dark head capsule. Larvae pass through five instars. Development time for larvae may be rapid and passed in as little time as a week if the host fungus is ephemeral or in as long as 8–9 months for some keroplatids.

Pupation usually takes place in the ground but may be within the host fungus or hanging from the host fungus in a web of salivary threads. The form of the cocoon is generally dependent on the pupal environment; the pupa is enclosed in a dense or weak cocoon or may be encased within a web, without a cocoon. Many cocoons may be found together within the tissue of non-deliquescent fungi. Fungus gnats may have several generations in summer and fall and generally overwinter in the larval or pupal stage, although some troglophilic species may overwinter as adults.

Adults are slender to moderately robust flies that are black, brown, orange, yellow or a combination of these colors, and may have dark markings on the wings. Some are quite showy and probably mimic Hymenoptera (e.g., *Platyura*, Keroplatidae).

They range in size from 2 to 13.5 mm. Most are crepuscular. During the day, many species prefer moist dark places such as caves, overhanging stream banks, or cavities under tree roots. These areas often support dancing swarms of gnats. Sometimes species of several genera, in one or more families appear to swarm together and can be swept up in one motion with a collecting net. The adults of some genera, especially those with elongate mouthparts (e.g., *Antlemon* and *Asindulum*, Keroplatidae; *Gnoriste*, Mycetophilidae; *Lygistorrhina*, Lygistorrhinidae), presumably visit flowers to feed on nectar. Fungus gnats may be drawn to red or yellow pan traps and/or to light traps (mercury vapor or blacklight) by night. They may also be readily collected by sweeping in the appropriate habitat with an insect collecting net. However, the best way to collect high numbers of fungus gnats is by Malaise trapping.

In the fossil record, the earliest fungus gnats appear in the late Jurassic, at least 150 million years ago. Fungus gnats are rare but already well diversified in Cretaceous ambers, and by the Eocene it appears they were quite abundant. Fungus gnats belonging to recent genera are relatively common in Baltic amber.

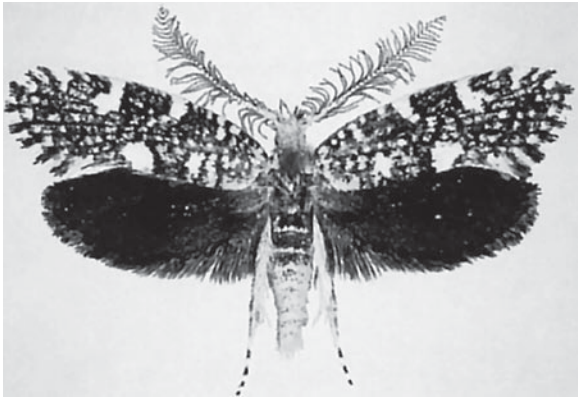
Fungus Moths (Lepidoptera: Tineidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Fungus moths (Fig. 99), family Tineidae, comprise the first very large family of Lepidoptera, with about 2,160 described species; actual world fauna probably exceeds 4,000 species. The family is part of the superfamily Tineoidea, in the section Tineina, subsection Tineina, of the division Ditrysia. The family is divided into 16 subfamilies (many have been considered as separate families by some specialists in the past): Euplocaminae, Myrmecozelinae, Harmacloninae, Meessiinae, Dryadaulinae, Scardiinae, Nemapogoninae, Tineinae, Setomorphinae, Perissomasticinae, Hapsiferinae, Hieroxestinae, Erechthiinae, Siloscinae, Stathmopolitinae, and Teichobiinae. Adults minute to medium size (5–54 mm wingspan), usually with rough head scaling (a few have smooth-scaled heads); haustellum naked (unscaled); maxillary palpi long, 5-segmented (rarely 3-segmented). Maculation mostly somber grays or brown shades, with various speckling spots, but some tropical species colorful (e.g., genus *Coryptilum* from Southeast Asia). Adults are nocturnal or crepuscular; rarely diurnal. Larval habits vary greatly, but most are detritus feeders, some making cases, tunnels, or silken tubes; also, odd groups are coprophagous, keratophagous, woolen feeders, and even myrmecophilous and termitophilous larvae are known. The smooth-headed and more colorful Hieroxestinae and related groups are leafminers. Included among Tineidae are some of the most well



Fungus Moths (Lepidoptera: Tineidae), Figure 99 **Example of fungus moths (Tineidae), *Euplocamus ophisa* (Cramer) from Albania.**

known household pest species, such as clothes moths and grain moths.

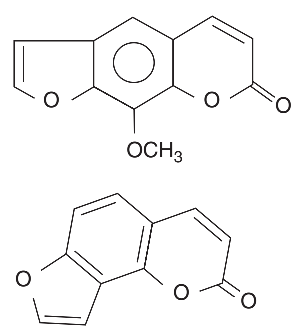
Furanocoumarins

CYRUS ABIVARDI
Swiss Federal Institute of Technology,
Zurich, Switzerland

Furanocoumarins (or furocoumarins) are known to exert photodynamic action. Furanocoumarins are of special interest from entomological, medicinal, public health, and environmental viewpoints because of their high photobiological activity. Wavelengths in the near ultraviolet (i.e., UV-A: 320–380 nm) are the most effective spectra, even though furanocoumarins absorb relatively poorly in this region. Although plants containing photosensitizing furanocoumarins have been used by Indian and Egyptian civilizations for more than 3,000 years to treat certain skin disorders, it was only in the middle of the last century (late 1940s) that the photosensitizing and pigment-stimulating agents in these plants were identified. Extensive research on different aspects of furanocoumarins has been conducted since this discovery.

Furanocoumarins are a group of heterocyclic compounds in which the furan ring is fused with coumarin. They arise in nature from two configurations of the basic tricyclic ring structure, e.g., linear (psoralen: e.g., xanthotoxin) and angular (isopsoralen: e.g., angelicin) (Fig. 100). Based on available data, the linear furanocoumarins are more biologically active than their angular analogs. Furthermore, substitutions that increase polarity of the molecules usually decrease the activity. Naturally occurring phototoxins are an integrated part of our environment and they are apparently used by plants as defense mechanisms against herbivores. For instance, the biosynthesis of furanocoumarins and polyacetylenes, which are well established as phytoalexins, are drastically enhanced following plant infection with pathogens.



Furanocoumarins, Figure 100 **Chemical structure of two classes of furanocoumarins: above, linear (e.g., 8-methoxypsoralen, known as 8-MOP or xanthotoxin); below, angular (e.g., angelicin).**

Occurrence in Plants

Photoactive furanocoumarins have been isolated from at least a hundred plant species from eight families, including Apiaceae (Umbelliferae), Rutaceae, Leguminose (Papilionaceae), Moraceae, and Orchidaceae, but find their greatest diversity in the Apiaceae and Rutaceae. The seeds and roots are major sources of furanocoumarins in some of the clinically important plants species that are cultivated solely to obtain these photosensitizers.

Effects of Furanocoumarins

Since the discovery of the photosensitizing and the pigment-stimulating activities of furanocoumarins in 1940, entomological, medicinal and veterinary medicinal aspects have been the focus of different investigations.

Insects

Xanthotoxin, a linear furanocoumarin also known as 8-methoxypsoralen (or 8-MOP), was the first natural phototoxin that was shown to have insecticidal properties in 1978. When this compound was administered at a rate of 0.1% to the larvae of the southern armyworm (*Spodoptera eridania*), a low level of toxicity was observed. The activity was, however, greatly enhanced when the larvae were irradiated with near UV light. It also was shown that the southern armyworm will feed on carrot which does not contain furanocoumarins. It will not, however, feed on parsnip that does contain these compounds. A very low concentration of 8-methoxypsoralen has ovicidal activity against *Drosophila melanogaster* when exposed to light, but much higher concentrations are inactive in darkness.

Studies on insects also have determined how furanocoumarin-tolerant species avoid phototoxicity. There are several mechanisms for the resistance of insects to photosensitizers. While dark coloration due to the deposition of melanin is suggested to govern the resistance of *Papilio machaon* and *Manducta sexta* to phototoxic furanocoumarins, rapid metabolism of these toxins is considered to be the biochemical reason for *Papilio machaon*, *P. polyxenes*, *Depressaria pastinacella* and *Pastinaca sativa* to feed on umbelliferous host plants known to contain furanocoumarins. Nevertheless, the larvae of the furanocoumarin-sensitive fall armyworm (*Spodoptera frugiperda*) which also metabolize linear furanocoumarins by similar pathways, fail to avoid the toxicity due to a slower metabolism.

Domestic Animals

As early as 1946, it was suggested that ingestion of furanocoumarin-containing plants was a significant cause of photosensitization in domestic animals. For example, the furanocoumarin-containing plant spring parsley, *Cymopterus watsonii*, is a serious problem to domestic animals in the western USA, and *Ammi majus* is an important photosensitization source in cattle in the USA. While both cases involve severe blistering, the latter case also may lead to blindness.

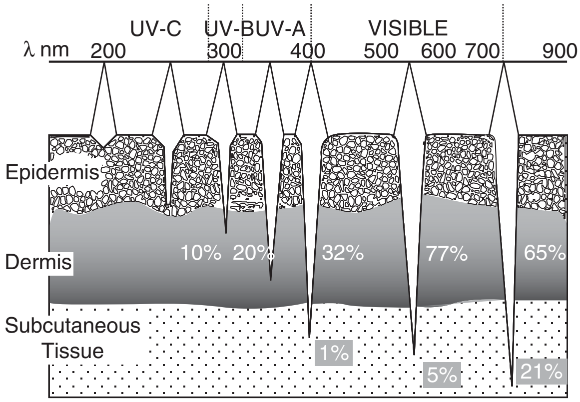
It is likely that most wildlife species have adapted through evolutionary pressures to avoid such plants. Nevertheless, it has been demonstrated that furanocoumarins, upon activation by light, are powerful antimicrobial agents, nematicides, molluscicides, piscicides, and powerful skin photosensitizers against humans and animals.

Photodynamic Therapy

The various photobiological actions exhibited by furanocoumarins have contributed to their extensive range of actual and potential uses in human medicine. Xanthotoxin (8-MOP) plus UV light, known as PUVA therapy, is now the treatment of choice for severe psoriasis. PUVA therapy has also been potentially beneficial for treatment of numerous human disorders including mycosis, atopic dermatisis, herpes simplex and lymphoma. Studies have shown that DNA and RNA viruses, both enveloped and non-enveloped, in nearly all major virus families have been successfully inactivated by psoralen derivatives in tissue culture medium and in blood products such as serum. The only viruses resistant to psoralen inactivation observed to date are picornaviruses. There is evidence to suggest that this resistance is due to the failure of psoralen to penetrate the exceptionally dense coat of this virus. Inactivation of human hepatitis viruses (B and non-A and non-B: i.e., C) by 8-MOP was successful in an in vivo chimpanzee infectivity model (Fig. 101).

Mode of Action

Although furanocoumarins are primarily known for their light-dependent activity, their biological activities in the absence of light, even though moderate, have also been demonstrated. They are, however, of special interest from agricultural, medicinal, public health, and environmental viewpoints for their highly photobiological activity.



Furanocoumarins, Figure 101 Extent of penetration of ultraviolet (UV) and visible light into human skin. (Drawing from the late B.E. Johnson, Department of Dermatology, University of Dundee, Scotland, U.K., courtesy of Springer-Verlag and G. Moreno, R.H. Pottier, T.G. Truscott (eds.), 1988, Photosensitisation: molecular, cellular and medical aspects.)

Wavelengths in the near ultraviolet (320–360 nm) range are the most effective ones, even though the absorption of these compounds in this region is relatively poor.

Psoralens readily pass through membrane structure (e.g., cell wall and virus coats), to photoreact preferentially with nucleic acids. Studies have shown that diadducts and mono-adducts (bound to a single pyrimidine) block nucleic acid replication and transcription. Consequently, the infectious quality of the virus is lot, while the surface and structure of the virus may remain largely unmodified.

At least a major part of the photobiological actions of furanocoumarins results from their intercalation into the double helix of DNA where, upon light activation, they form cyclobutane adducts with pyrimidine bases. Although there is clearly no direct involvement of oxygen in this interaction, which is governed by the Type I reaction, photogeneration of singlet oxygen by furanocoumarins has also been well demonstrated. The latter reaction (Type II) which involves singlet oxygen, may potentially be responsible for enzyme inactivation and membrane disruption.

Risks and Benefits Associated With Furanocoumarins

Photodynamic agents demonstrate a drastic increase in toxicity (usually 2–3 orders of magnitude) in the presence of UV-A or visible light. This is a property which should not be overlooked in assessment of toxicological data for the safety of these compounds. Although in the absence of light the oral LD_{50} for a furanocoumarin [i.e., xanthotoxin (8-MOP)] ranges between 300and 600 mg/kg body weight in rats, an oral dose of only about 1 mg/kg of body weight can be dangerous for humans with as little as 1 h of subsequent sunlight exposure. Phototoxicity symptoms include severe erythema followed by blistering and peeling of the skin. Fair-skinned individuals are much more likely to suffer sunburn and blistering reactions from furanocoumarin exposure than are more pigmented individuals.

The level of furanocoumarins in celery (originally 1 mg/kg) can increase about 100-fold if the celery is stressed or diseased. Many cases of contact photodermatitis have been reported in humans who have had dermal contact with furanocoumarin-containing plants. For example, celery pickers and handlers suffer from periodic outbreaks of celery dermatitis by the appearance of skin rashes on their arms when exposed to diseased celery. The causative agents have been identified as xanthotoxin (8-MOP) and trisoralen, which celery produces in response to "pink rot" infection with *Sclerotina sclerotiorum*.

There is up to 25-fold increase of several photocarcinogenic furanocoumarins (including 8-MOP and psoralen used in PUVA therapy) in the roots of diseased parsnips when compared with those isolated from the roots of healthy plants. In some instances, the amounts are so high that mixed crystals of furanocoumarins can be detected on the surface of parsnip roots by light microscopy. Linear furanocoumarins such as psoralen derivatives, which are widespread in plants of the Umbelliferae family, are potent light-activated carcinogens and mutagens. Skin cancer in animals and probably in humans are known consequences of photosensitization with furanocoumarins. Xanthotoxin (8-MOP), as well as other naturally occurring photosensitizers such as cercosporin, hypericin, polyacetylenes and their thiophenes, may represent a hazard to health as they possess the ability to induce genetic damage and mutations.

Side Effects of Photodynamic Therapy

Patients treated by photodynamic therapy normally suffer from different side effects of phototoxicity, such as nausea, hair loss, erythema, etc. In addition, numerous types of damage at the cellular level have been observed. For example, nuclear aberrations, single-strand breaks, interference with repair processes, DNA-protein cross-links, and injury to cell membrane, mitochondria and the nucleus have been documented.

Naturally occurring photosensitizers, such as 8-MOP, currently used in the treatment of psoriasis (PUVA therapy) also may represent a hazard to health as they possess the ability to induce genetic damage and mutations. Low concentrations of 8-MOP, mediated by UV-A, were sufficient to induce an increase in the frequency of chromosome aberrations in Syrian hamsters. There is no question that major changes occur to both tumor and surrounding normal microvasculature during and following photodynamic therapy. Changes to the endothelium, smooth muscle contraction and increased capillary permeability also have been observed during therapy. Thus, PUVA therapy should be used with caution.

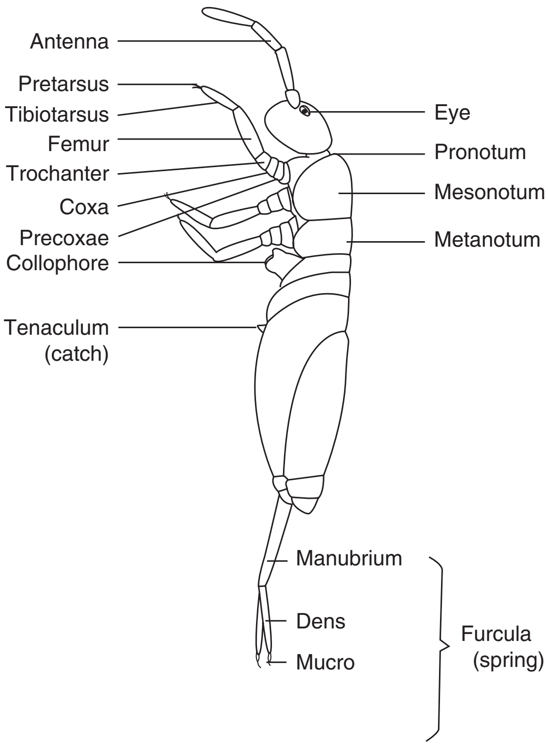
Furcate

Having a forked appearance.

Furcula

A forked structure found beneath the abdomen of springtails (Collembola), attached apically, and used for leaping (Fig. 102).

► Abdomen of Hexapods



Furcula, Figure 102 **Lateral view of a springtail (Collembola).**

Furniture Beetles

An alternative name for beetles of the family Anobiidae, or death-watch beetles. They feed on dry substances such as cereal grains or wood, including furniture.

► Beetles

► Food Habits of Insects

Fused

This term usually is used to indicate structures that were once (in an evolutionary sense) separate, but are now joined, and lack indication of former separation.

Fusiform

This term describes a structure that is widest at the midpoint, and narrowed at both ends.

G

Gahan, Arthur Burton

Arthur Gahan was born into a large farm family in Kansas on December 9, 1880. He attended Kansas State College, graduating in 1903. Then in 1904 he became assistant in the Department of Entomology of Maryland Agricultural College, and received an M.S. from that institution in 1906. He remained there as Assistant Entomologist, becoming interested in "parasitic" Hymenoptera in general and braconid parasitoids of aphids in particular. In 1913 he accepted a position with the U.S. Department of Agriculture, to work as a taxonomist at the U.S. National Museum. There, he worked on various groups of "parasitic" Hymenoptera, but ultimately concentrated on Chalcidoidea and became a leading authority of them and publishing copiously. He married in 1908, was active in civic affairs and the Entomological Society of Washington, becoming its president in 1922. He died on May 23, 1960, and was survived by his wife and two children.

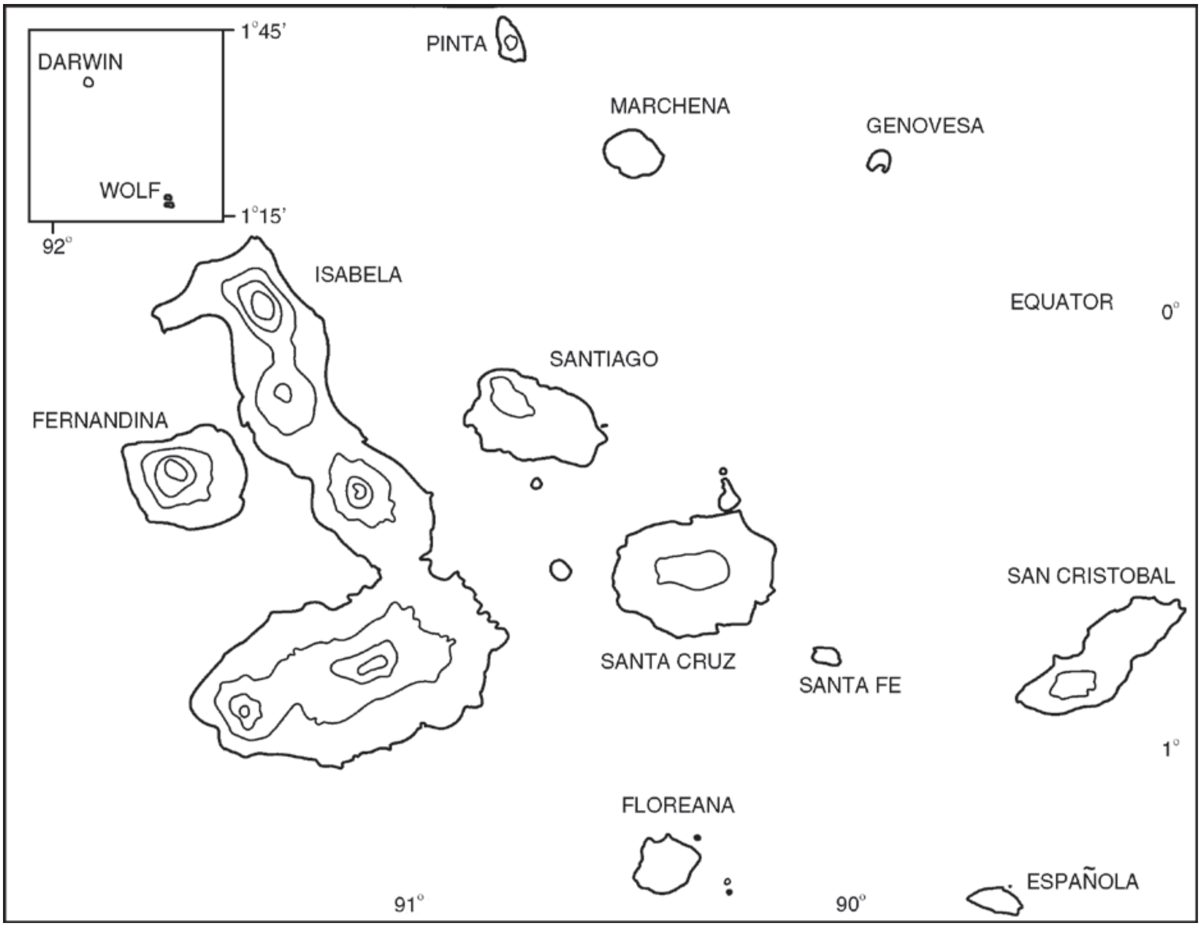
Galápagos Islands Insects: Colonization, Structure, and Evolution

STEWART B. PECK
Carleton University, Ottawa, ON, Canada

The Galápagos archipelago of Ecuador has an interesting insect fauna that is now rather well known. The archipelago is composed of 19 islands larger than 1 km^2, with a total land area of 7,882 km^2. It is the world's only remaining tropical oceanic archipelago that is little altered by humans. The present islands, 800–1,000 km west of the Pacific coast of Ecuador, have been available for terrestrial colonization for 3–4 million years. The archipelago is a model system for assessing the dynamics of biotic dispersal to, and differentiation on, oceanic islands. They are a natural experiment which has been running in oceanic near-isolation for about 3 Ma. Each island (Fig. 1) is a replicate of an experiment in biotic dispersal, colonization, and differentiation. The present plants and animals can be seen to be a record of the successes in dispersal to the islands, and of the dynamics of their subsequent evolution in isolation. The story has been well (or even exhaustively) reported for many of the larger plants and vertebrates. This story, however, has not been well studied for the vast majority of insects and other terrestrial invertebrates.



Galápagos Islands Insects: Colonization, Structure, and Evolution, Figure 1 **Map of Galápagos Archipelago.**

The insect fauna (Tables 1 and 2) is now known to contain 23 of the world's 31 orders of insects, with at least 255 families, 1,057 genera, and 1,853 species, of which 736+ are endemic, 818+ are indigenous, and 295+ are introduced. Within the beetles (Coleoptera), the islands have 56 families, 297 genera, and 486 species (266 endemics, 110 indigenous, and 110 introduced species). The 376 native beetle species (indigenous and endemics combined) represent a rate of species accumulation of about one every 9,260 years (through successful colonization plus speciation through about 3.5 million years).

Charles Darwin is known to have been a keen collector of insects and especially beetles. However, as he wrote in his 1845 book "Voyage of the Beagle," he was not impressed by the abundance or diversity of the insects of the Galápagos Archipelago. In fact, the entire biota of the Galápagos is generally not very impressive in appearance. But there are a few exceptions and these have received exceptional publicity. Most of the organisms are, however, small or drab when compared with those of the luxuriant tropical forests of mainland South America. This is partly a reflection of the isolation of the islands (800–1,000 km west of the coast of Ecuador), their youth (only 3–4 million years), the difficulty of dispersing to them, their seasonally harsh and semi-arid tropical climate, and the difficulty of establishment by colonizing species.

Galápagos Islands Insects: Colonization, Structure, and Evolution, Table 1 Numbers of native (endemics plus indigenous) genera, species, and single-island endemic beetle diversity, arranged by increasing island size . The larger islands have more genera, more species, more single-island endemics, and more species per genus. These generalizations also occur in the rest of the native insects fauna

Colonization Processes

How do insects get to oceanic islands? The processes of colonization and any subsequent evolution on islands can seldom be directly observed. Usually, they are deduced from an analysis of the distributional and ecological patterns of the organisms in conjunction with evolutionary and ecological theory.

There are two general groups of hypotheses about processes which place biotas on islands. One of these, the "Continental Drift" process of distribution of ancient biotas, is irrelevant for the Galapágos because of their geological youth and oceanic origin.

Galápagos Islands Insects: Colonization, Structure, and Evolution, Table 2 Summary of numbers of species and native genera of the insect orders of the Galápagos islands. Some orders have a disproportionate number of introduced species, especially on the islands with human settlement. A figure of 1.00 in the column of native species/native genus ratios shows that there has been no speciation in many insect orders after the natural colonization event of a single species in each genus, and comparatively little in the other orders

Order	Introduced Species	Native species	Native Genera	Species/Genus Ratio
Collembola	3	35	22	1.57
Diplura	1	2	2	1.00
Archeognatha	0	1	1	1.00
Thysanura	1	2	2	1.00
Odonata	0	8	7	1.14
Orthoptera	4	29	13	2.23
Mantodea	0	1	1	1.00
Blattodea	11	7	3	2.33
Isoptera	0	4	3	1.33
Dermaptera	4	3	2	1.50
Embioptera	1	1	1	1.00
Zoraptera	0	1	1	1.00
Psocoptera	14	26	22	1.18
Thysanoptera	8	42	42?	1.00?
Hemiptera	118	198	86	2.30
Phthiraptera	8	80?	40?	2.00?
Neuroptera	0	8	5	1.6
Strepsiptera	0	1	1	1.00
Siphonaptera	3	1	1	1.00
Coleoptera	111	378	226	1.67
Lepidoptera	64	±300?	160?	1.88?
Diptera	66	±200?	150?	1.33?
Hymenoptera	46	±250?	160?	1.56?

Thus, all terrestrial colonists have crossed the oceanic water gap by one of four general dispersal mechanisms. The method of dispersal is a property of all the ecological, behavioral, and physiological characteristics of the species and of its mode and frequency of transport opportunity. Colonization is a property of both the life history requirements of the species and the characteristics of the new environment.

Aerial Transport (Actively by Flight and/or Passively by Wind)

This probably accounts for about half of the insects of the Galápagos. The mean body size of Galápagos insects appears to be smaller than for a mainland Ecuadorian fauna (but measurements are available for neither). Darwin first noted the small size of the insect fauna. The smaller body size would support the idea that the majority of the insect colonists were carried as flying individuals by winds. In contrast to its importance for insects, it may seem surprising that wind transport may account for only 9% of natural seed-plant colonizations of the Galápagos.

Marine Transport

A significant component of the total insect fauna probably arrived on the sea surface, either on rafts of vegetation and flotsam or by floating themselves (as pleuston). This may be the most important mode for most of the flightless terrestrial arthropods. For the insects themselves, it is estimated that marine transport may also account for about half of the original colonists. Flightless or poorly flying groups of large-bodied beetles such as weevils and darkling beetles probably used this mode, as did millipedes, centipedes, terrestrial isopods, oribatid mites and others. Bostrichids, cerambycids and various other wood-boring and wood-associated beetles probably arrived by rafting in wood as adults or immatures. Flightless *Gerstaeckeria* weevils may have arrived on rafting pieces of their *Opuntia* cactus host plants.

Several groups of large-bodied wingless beetles such as endemic *Galapaganus* weevils and the three genera of Darwin's darkling beetles (genera of Tenebrionidae containing nine species that were first collected by Darwin: *Stomion*, *Ammophorus*, and *Blapstinus*) are represented by species that occur on more than one island. Such cases are usually within the older eastern and central group of islands. It is logical that these species originated (speciated) on one island and that they have then moved from this to another island, probably after being washed to sea during heavy El Niño rainstorms and floods.

Transport on or in Other Animals

Insect ectoparasites, such as all of the 80 species of Phthiraptera (chewing bird-lice) and the 8 species of Hippoboscidae (louse flies, Diptera), as well as bird ticks, reptile ticks and chigger mites, undoubtedly arrived on their vertebrate hosts. Bird transport has also been important for seed-plants, because it is estimated that 79% of the angiosperms arrived as propagules with birds, either on or in their feathers or in their digestive tracts. Rafting terrestrial mammals and reptiles seem to have carried a few arachnid and insect ectoparasites. And invertebrate colonists themselves have also carried some of their own arthropod parasites. Examples are one strepsipteran (in leafhoppers), several dryinid wasps and some pipunculid flies (in leafhoppers). Among the beetles, there are two examples: one meloid blister beetle (on *Xylocopa* carpenter bees), and two rhipiphorid beetles (in wood-boring beetle larvae) probably arrived as parasitic immatures on or in their host insects. The parasitized bee hosts themselves probably arrived by rafting on floating wood and the hosts of the rhipiphorids in lumber imported for construction of buildings.

Human Mediated Transport

Humans have intentionally introduced many domestic animals and agricultural or horticultural plants to the Galápagos. Some of these have escaped and become feral. But there is only one example of the intentional introduction of an arthropod: the vedalia beetle (Coccinellidae) for the bio-control of the cottony cushion scale (*Icerya purchasi*, Hemiptera), an introduced pest. By 1998 there were at least 292 recognized examples of unintentional introductions of insect species and the number in 2004 was at 450 species of introduced insects. Such species are here called introduced species, but the term "adventive" has also been used for these. The first such introduced insect may have arrived with the first European landings of Bishop Tomas de Berlanga and his party in 1535, as *Dermestes* (dermestid) and *Necrobia* (clerid) beetles and cockroaches. These were all commonly associated with humans and stored products in their sailing ships. Pirates, who used the islands from shortly after the time of their discovery until the early 1700s, and whalers and sealers, from the mid 1700s to mid 1800s, may have brought an alleculid beetle (and other dry-wood insects such as bark-beetles) in logs or firewood from the mainland.

Ships transporting both supplies and tourists have taken insects attracted to ships' lights to and between the islands. The orders with the largest number of introduced species are Coleoptera, Hemiptera, Lepidoptera, and Diptera. Some 111 beetle species are among the more commonly encountered species of insects introduced to date. Not all of the introduced species seem to have become permanently established; some long-horned beetles have not been found since their original collection. The introduced species occur in greatest diversity on the four large islands with permanent human settlements. There is now a program of agricultural quarantine control and inspection of goods and materials coming into the Galápagos in an attempt to limit future introductions of alien arthropods.

Sources of the Colonists

There is limited detailed data on the mainland distributions of either indigenous Galápagos insects or mainland sister species of the endemic species. The data now available seem to indicate that only a few of the Galápagos colonist insects came from southern South America (arid coastal Peru or Chile). Most of the faunal relationships are with the lowland semi-arid and seasonal Neotropics, along the Pacific coast from Mexico to Ecuador. The best phylogenetic and biogeographic analyses show a general biogeographic pattern of a western Neotropical source area and that the Galápagos species are relatively recently derived species.

Stochastic (Random) Processes in Colonization and Distribution

Colonization is seldom strictly predictable or linear even if the islands themselves are relatively linear in age or geography. As an example, one would predict that insect colonization was first to San Cristóbal and Española, which are the oldest and most easterly islands, and that the other islands were colonized sequentially northwestward as stepping stones as they formed through time. Exceptions to these predicted patterns do exist. This shows the lack of absolute predictability in present distributions through the randomness of the processes of either past dispersal, or colonization success, or extinction. For instance, the carabid beetle genera *Platynus* and *Scarites* are on Isabela and San Cristóbal islands, and not on Santa Cruz, which lies between them. The indigenous carabid *Halocoryza acapuliana* Whitehead is known only from small and central Rabida Island.

Neighbor islands are more likely to share endemic species. This is clear in a number of shared beetle species limited to island pairs such as Darwin and Wolf (the tenebrionid *Stomion cribicollis* Van Dyke and the weevil *Galapaganus darwini* Lanteri), and Marchena and Pinta (the tenebrionid *Stomion rugosum* Van Dyke). The isolation of Genovesa is evident in its failure to be colonized by flightless *Ammophorus* beetles and other insect groups. Flightless *Galapaganus* weevils are seemingly absent from Pinta and Marchena. Pinzón is famous for not having the widespread palo santo tree (*Bursera graveolens*), but this island's insects are not well enough known to evaluate a pattern of absence of insect species there.

Randomness is evident in the fact that some colonizations have been across the archipelago (from one side of the archipelago to the other). Molecular data suggest that Pinta Island was colonized by tortoises by oceanic transport from Española, and cladistic analysis suggests the same pattern in flightless *Stomion* beetles.

Structure of the Insect Fauna

An Unbalanced Fauna

Insect representation at the family level in the Galápagos is vastly different from that in the Neotropical fauna. The cause is the inequality of families in their ability to successfully complete both the sequential processes of dispersal and then colonization. When compared to the fauna of the Neotropical continental source area, it is evident that the Galápagos fauna is unbalanced (or disharmonic) and impoverished. This means that the taxonomic composition of the archipelago is significantly different in its makeup and proportions from that of the mainland.

The probable reasons for the absence of many insect families, subfamilies, and tribes are diverse. Difficulties of long-distance over-water dispersal and colonization must lie at the core of the reasons. Long distance dispersal is unlikely for many taxa and the lack of diverse and suitable habitats in the Galápagos is of undoubted importance. The absence of suitable food plants or prey items is involved. The taxa which are present can be viewed as able dispersalists, rugged colonists, and adaptable in acceptance of available microhabitats and food materials.

Trophic Generalists

Colonization is probably easier for trophic generalists (scavengers and predators) than for herbivores which are more likely to be specialist feeders. Island insect faunas in general tend not to be as rich in herbivores as the faunas on continents. In Galápagos beetles there are more trophic generalists (scavengers and predators) than herbivores. However, in Heteropteran bugs, colonization of islands by herbivores seems to be more successful than by predators.

Trophic Specialists

There is little evidence that Galápagos insects have narrow or restricted feeding niches. The few examples are *Gerstaeckeria* weevils which feed only on the tissues of *Opuntia* cactus, and some host specific seed feeding bruchids and scolytids. *Ataenius* scarabs, usually associated with herbivorous mammal dung, feed on the dung of the herbivorous giant tortoises and land iguanas. This may or may not represent a shift to a new food type. Tortoise and land iguana dung appears similar to that of ungulates because it is mostly composed of poorly digested plant materials.

Ecological Escape

Plant or animal colonists on islands may be ecologically "released" through escape from their continental herbivores, parasites, predators, and competitors. Many cases of escape from insect herbivores or predators must exist, but few are recognized. One example is the seed-producing legume plants which have escaped many (but not all) of their seed predator bruchid beetles. The bruchid *Megacerus leucospilus* (Sharp) feeds on the seeds of the widespread beach morning-glory *Ipomoea pes-caprae* in Central America, but the plant seems not to have this seed predator on the Galápagos.

Parthenogenesis

If females of a species can reproduce without the presence of individuals of the male sex, the species is more likely to establish itself as a colonist. Several of the Galápagos insects are known to be parthenogenetic. But there is no apparent evidence that this has been disproportionately important in the colonization of the Galápagos.

Vegetational Zonation and Diversity

Terrestrial communities in the Galápagos are usually characterized according to the elevation-related (precipitation and temperature controlled) zonation of the flora. The archipelago may possess the strongest or most compressed floristic zonation to be found anywhere in the world, passing through its six major vegetation zones in an elevational rise of only about 700 m; the littoral, arid, transition, humid forest, evergreen shrub, and above-treeline fern-sedge ("pampa") zones.

Insect diversity also seems to display some zonation, with fewer species being known from the higher elevations. The arid zone has the largest area in the islands and the most native insect species. The other zones, at higher altitudes, have progressively less area and proportionally fewer species, but sampling has not been equivalent. This probably indicates that the arid zone has been a bigger target for colonization for a longer period of time. The introduced species are more evenly distributed in all zones. This might be a reflection of the more eurytopic (adaptable) nature of the introduced species.

Plants also support diversity in that they provide various structural parts that may be fed upon by feeding specialists. Host-specific plant-feeding insects could be expected to exhibit the same zonation as their hosts, but almost all Galápagos phytophagous insects seem to feed on several species of host plant. Data for genus and family-level host-plant diversity are not available. Host specificity, to be expected in groups which elsewhere are usually monophagous or stenophagous plant-feeders, such as chrysomelids, is slight in Galápagos phytophagous beetles. There is no additional evidence for host specificity in indigenous phytophagous insects other than in *Gerstaeckeria* weevils on *Opuntia* cactus and some bruchids and scolytids. Thus, phytophagous species are in the minority, few are host specific, and none seem to have co-evolved with the endemic vegetation.

Seasonality

Environmental conditions regulate periods of insect activity. Most adult insect species are present or active during the rainy months of January to June. With the arrival of the Galápagos rainy season, insect activity increases and there are large and noteworthy outbreaks of beetles and other insects, which seem to be short-lived. These include *Calosoma* ground beetles, *Camponotus* ants, *Disclisioprocta stellata* Guenée (a geometrid moth), various sphinx moths, and other insects. These mass emergences are best noticed at lights at night and are environmentally triggered, but they also occur annually in coastal mainland Ecuador and seasonal forests elsewhere in Central and South America, so they are not a unique island feature.

Evolutionary Dynamics

Genus Level Endemism

Endemics are taxa limited to the geographic area under discussion. Genera endemic to the Galápagos probably represent an earlier time of colonization and a more prolonged period of isolation. Galápagos endemic genera are proportionally more frequent in the vertebrates and less frequent in the insects. This could mean that vertebrates differentiate at a faster rate or under stronger selective pressures, but more probably is a reflection of the more finely divided subjective criteria for what defines a vertebrate genus. Some endemic insect genera do exist. Among these endemics are some which can be called phylogenetic relicts or paleoendemics and which have no close relatives, such as the eyeless cave staphylinid *Pinostygus* of Isla Santa Cruz, and the *Neoryctes* dynastine scarabs which occur as four species on four islands. Some genera, once thought to be Galápagos endemics, have since been found in mainland Neotropical localities and others may yet be detected.

Species Level Endemism

Most insect colonization has not been followed by much species multiplication; the mean for the native beetle fauna is about 1.35 species per colonizing ancestor. About half the naturally occurring species are endemic, depending on the insect order. These evolved to endemic status following the colonization event of the ancestral species. The factors suppressing speciation in general in the Galápagos (as compared with other archipelagos) seem to be, in probable order of importance: lack of great ecological diversity, closeness to mainland source areas, and geological youth of the islands.

Different groups of organisms need not present equivalent amounts of endemism. This is obviously a result of differences in their vagility and the amount of gene flow between continental and island populations. In beetles, the good dispersers have lower levels of endemism, while poorer dispersers have higher levels. Comparison of the Galápagos and Hawaiian archipelagos shows a much larger mean number of speciation events from a single colonist ancestor in Hawaii. This is probably the result of Hawaii's greater age, area, ecological diversity, and isolation (this is to say that colonist arrival is less frequent, and that genetic dilution of island populations by mainland genomes is also less frequent).

Speciation

Most insect genera in the Galápagos are represented by only a single species. This shows that most colonization of the islands has usually been by only one species in a genus. This pattern was first noted by Darwin. Only a minority of the native insect genera which are present contain more than one species, either through multiple colonization, or species multiplication on the islands. The process of forming several species by allopatric speciation on a single individual island has not been a dominant evolutionary process in Galápagos beetles, while it has been a spectacularly exuberant process in the Hawaiian Archipelago.

Nevertheless, there are several insect genera which have undergone appreciable subspeciation or speciation in the Galápagos but none of these approach the dramatic swarms of species (descended from a single ancestor species) of insects, snails, or birds that have evolved in Hawaii. For instance, while hundreds of species of *Drosophila* occur in Hawaii, there are only 13 species (many cosmopolitan) of in these in Galápagos.

Winged Endemic Species

In the winged insects the most common pattern of distribution is for a species to occur on more than one island. This is easy to understand. It is most likely that these evolved on a single island and then dispersed to other islands, usually by flight.

Loss of Wings

Loss of flight ability is one of the more pronounced phenomena associated with island insects. This is seemingly not a property of island life itself, but of habitat stability and homogeneity. Flightlessness also frequently occurs in insects in desert and semi-arid habitats. This last is the best single characterization of Galápagos environments, and beetles are prime examples. Flightlessness in some South African desert dwelling scarab beetles is a morphological correlate with water conservation capabilities. This may also be true and part of the adaptive strategies of such flightless Galápagos beetles as tenebrionids, carabids, and weevils. Beetle examples of more speciation in less vagile groups are in flightless carabids, weevils, and Darwin's darkling beetles (*Stomion*, *Ammophorus*, and *Blapstinus*). Interestingly, even within flightless genera in the arid lowlands, many species do occur on more than one island, and these are probably evidence of inter-island oceanic transport following the origin of the species on one island.

The single island endemics are usually restricted to either the arid lowlands or the moist uplands (of high islands). Groups that are actively in the process of losing flight ability, such as *Ataenius* and *Neoryctes* scarabs, show discrete polymorphic stages in reduction of hind wings. So, loss of flight ability in Galápagos insects is a significant evolutionary theme. This has not always sponsored a major burst of species multiplication, but it has happened more often in groups that lost their flight ability on the Galápagos as a convergence rather than in groups that arrived already in a flightless condition. There is a parallel in birds: rails have reached many oceanic islands and then convergently experienced a reduction in wings and loss of flight ability.

Speciation and Flightlessness

Flightless terrestrial arthropods would certainly appear to have less dispersal potential than winged ones, and most species proliferation has occurred in the Galápagos beetles that are secondarily wingless. Nine genera of beetles probably colonized in a flightless condition, but only four of these have undergone island multiplication to three or more species. These groups have produced an average of 3.0 species per colonization event. Another 14 genera appear to have become flightless after colonization and these show even more species proliferation, with a mean of 3.6 species per colonization event.

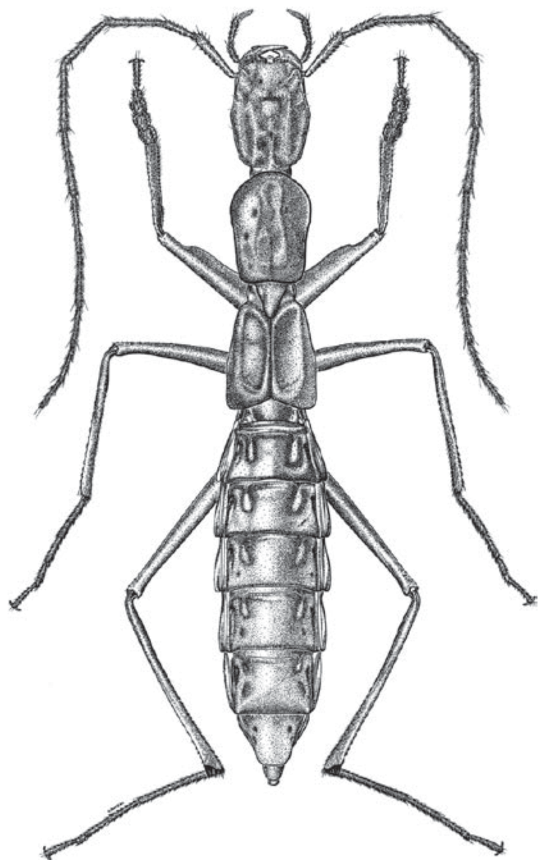
Adaptive Radiation

Adaptive radiation is a common phenomenon on islands. But it is important to note that adaptive radiation is much more than just the simple allopatric species multiplication that follows genetic isolation on separate islands. It is here defined as the set of evolutionary changes which occur in the diversification of a lineage that facilitate the exploitation of new resource types with different morphological or physiological traits. Thus, along with the morphological, physiological, and/or behavioral changes accompanying speciation must also come changes in either or both niche and habitat use. This is what has happened in the famous textbook example of Darwin's finches. Other examples can include the striking adaptive radiation in *Scalesia* trees and shrubs, and perhaps arguably in *Opuntia* cactus. In contrast, the famous giant tortoises and less famous lava lizards have undergone much speciation or subspeciation, but there is little evidence for true adaptive radiation in these examples. Adaptive radiation is probably enhanced by competition for limited resources, as in the case of the finches, especially in times of drought. But, it is difficult to envision intense competition between generalist scavenger or generalist predator insects.

Are the few examples of adaptive radiation indicative of a generalization, or are they exceptions? How many of the monophyletic species swarms in the insects of the archipelago have undergone significant ecological, morphological, or behavioral differentiation that promotes life in a new niche or new habitat? In short, there seem to be very few examples within the insects in general. In the three genera of Darwin's darkling beetles (*Ammophorus*, *Stomion*, *Blapstinus*) there are some cases of congeneric species sympatry and there is some habitat separation between species based on preferences for different substrate types (sand versus volcanic ash), habitat distance from the seacoast, and elevation. Most *Ammophorus* species inhabit the arid zone, but two are restricted to the moist highlands of San Cristóbal and Santa Cruz Islands. The same occurs in *Galapaganus* weevils. Thus, while the Galápagos are famous for having provided a classic example of the process and results of adaptive radiation in Darwin's finches, this is an exception. It is only a very infrequent or arguable result in Galápagos insects.

Subterranean Arthropods

A diverse assemblage of many eyeless arthropods occurs in the extensive systems of caves and rock crevices in the volcanic basalt bedrock of the Galápagos. Some ten species of arthropods such as geophilomorph centipedes, polydesmoid millipedes, soil dwelling earwigs, and darkling and carabid beetles are in eyeless (Fig. 2) genera which must have colonized the Archipelago in an already-eyeless condition. But at least another 23 species of



Galápagos Islands Insects: Colonization, Structure, and Evolution, Figure 2 **The staphylinid beetle *Pinostygus galapagoensis* Campbell and Peck from a lava tube cave on Santa Cruz island. This eyeless and flightless subterranean endemic genus and species has probably changed more from its ancestral colonizing species than any other Galápagos animal. The beetle belongs to a group of visually hunting and flying arboreal predators which live in the canopy of tropical South American rainforests. No other members of its tribe occur in the Galápagos. The body length is about 2.5 cm, and this is the world's largest eyeless-wingless staphylinid beetle.**

eyeless terrestrial arthropods, including seven beetle genera, are in normally eyed groups. These must have lost their eyes after colonizing the islands, and during the process of adapting to soil, litter or subterranean habitats.

Extinction

Extinction through time is a natural process and is to be expected. But extinction caused by human action is different and should be of great concern in the Galápagos. Insect species extinction through human causes is probable, but no documented individual examples are known. Some of the introduced insects, such as *Wasmannia* fire ants and *Polistes* wasps, are preying on or competing with indigenous and endemic insects.

Feral vertebrates have had a two-fold effect on beetles and other insects. (i) The vertebrates have caused the near or complete loss of insect host plants, such as *Opuntia* cactus on most of Floreana and San Cristóbal (eaten by feral goats and donkeys). This has led to the concomitant loss of host-specific insects such as *Gerstaeckaria* weevils. (ii) The vertebrates have also had an effect by being predators, such as mice or rats or pigs, feeding on *Neoryctes* scarab beetles or other large-bodied insects. Despite these examples, there is presently no strong or direct evidence of the actual archipelago-wide extinction of an insect species on the Galápagos through an action ultimately caused by human activity.

Human-caused habitat alteration has had a significant, but unmeasured effect on the native insect populations. The clearing of large areas of *Scalesia* forest for agriculture and pastures and the replacement of large areas of native vegetation by introduced crop plants, grasses and weeds on Floreana, Santa Cruz, San Cristóbal, and Isabela must have had some impact. The importance of all of these introductions and alterations has not been measured or even estimated for the beetles or other insects.

Future Research

Although much is now known about Galápagos insects, there is still much to learn, especially about the life histories and evolutionary relationships of the species and in comparing them with the continental South American insect fauna. The Galápagos National Park Service and Charles Darwin Research

Station invite international research proposals and scientific collaboration with Ecuadorian personnel, students, and researchers. Information on past and present entomology research programs and details for scientific research permit applications can be found at http://www.darwinfoundation.org/terrest/entomology.html Research proposals of an applied and conservation orientation are especially welcome. General collecting without a research purpose is not permitted.

Gall

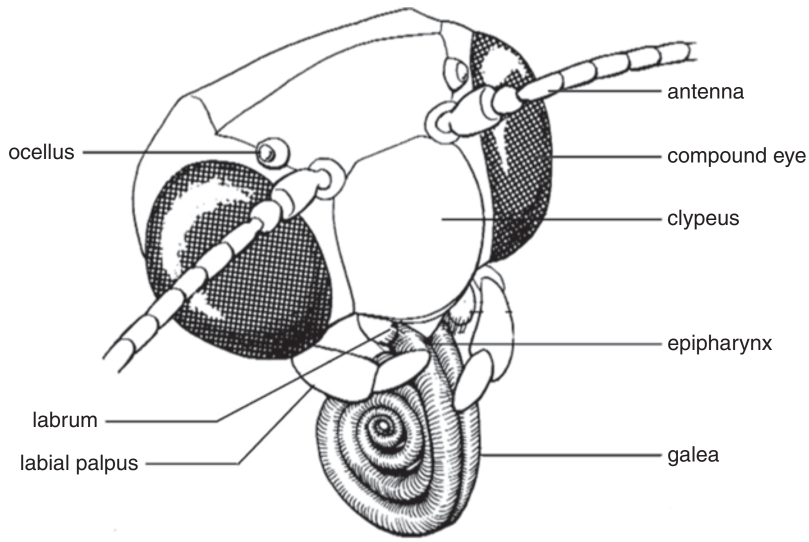
An abnormal growth on a plant induced by insect or mite feeding, or a plant pathogen.

Gall Formation

CAROL C. MAPES
Kutztown University of Pennsylvania, Kutztown, PA, USA

Galls are structures that form as a result of the abnormal growth activities of plants in response to gall-inducing organisms. Most galls are caused by nematodes, insects and mites, while a very small percentage are caused by bacteria, fungi and viruses. There are thousands of species of insects in the world that induce gall formation on the roots, stems, leaves, buds, flowers and fruits of plants in a wide variety of plant families. Insect galls range in complexity from simple outgrowths to more highly differentiated structures such as those typified by many of the cynipid wasp galls. Despite the large numbers and types of insect-induced galls, very little is known regarding the underlying mechanism or mechanisms of insect gall formation. In contrast, the mechanism of crown gall formation by the bacterium *Agrobacterium tumefaciens*, has been well characterized. An understanding of the mechanism of crown gall formation may provide some clues to the mechanism or mechanisms of insect gall formation.

Crown galls form as a result of wound inoculation on many species of plants by the soil dwelling bacterium *Agrobacterium tumefaciens*. Early studies showed that crown gall tissues exhibit autonomous growth and retain their tumorous



Galea (pl. galeae), Figure 4 **The head of a moth (Lepidoptera) showing some components.**

characteristics in the absence of the inducing bacterium. The ability of the bacterium to induce gall formation subsequently has been shown to be encoded by a tumor-inducing (Ti) plasmid that is transferred into the plant tissue. A small fragment (the T-DNA) of the Ti plasmid is integrated into the plant cell genome within the nucleus and is stably maintained and transcribed. It has been shown that the T-DNA contains genes that code for the production of plant hormones, the auxin indole-3-acetic acid (IAA) and for cytokinins. Cytokinins promote cell division in plant cells while auxins play a role in cell enlargement. Both of these hormones also affect tissue differentiation in plants as well as many other processes. Cytokinins have been shown to be produced by additional species of gall forming bacteria including *Erwinia herbicola* pv. *gysophilae*, *Pseudomonas savastonoi* and *Rhodococcus fascians*. A linear plasmid with a cytokinin synthesis gene has been found in *R. fascians*, a bacterium that induces leafy galls.

While an understanding of the mechanism of crown gall formation may provide some clues to the mechanism of insect gall formation, it should be noted that insect galls have some important differences compared to crown galls. Unlike crown galls, insect galls are organized structures, often with very complex morphologies. In addition, early studies have shown that unlike crown galls, insect-induced galls do not exhibit the autonomous growth that is characteristic of crown galls. Gall growth does not continue indefinitely once the gall-inducing insect is no longer present. The physical presence of the insect within the gall tissue is another unique factor that may play a role in the mechanism of insect gall formation, but the role of mechanical tissue disruption in the process of insect-induced gall formation has not been well studied. Instead, studies have focused on the role of chemicals in insect-induced gall formation.

Studies of Insect Extracts and Secretions

A number of studies have been undertaken to test insect extracts and secretions for gall inducing chemicals. Larvae of *Mikiola fagi*, a midge that forms leaf galls (Fig. 5) on the European beech (*Fagus sylvatica*), have been tested to determine if they secrete cecidogenetic (gall-forming) chemicals. When the larvae were placed on a lanolin

Gall Formation, Figure 5 **Leaf gall caused by *Mikiola fagi* on the European beech (*Fagus sylvatica*).**

Gall Formation, Figure 6 **The eastern spruce gall caused by *Adelges abietes* on Norway spruce (*Picea excelsa*).**

paste on leaves of beech and when a paste that larvae had previously been on, was repeatedly applied to leaves, changes involving cell division and cell elongation resulted, but galls did not form.

Studies of the eastern spruce gall on Norway spruce (*Picea excelsa*) have provided evidence for the presence of cecidogenetic activity associated with the salivary glands of the gall-forming adelgid *Adelges abietes*. The characteristic needle swelling associated with the early stages of gall formation (Fig. 6) has been mimicked by injecting spruce buds with a solution containing macerated adelgid salivary glands.

The willow leaf gall, caused by *Pontania pacifica*, is initiated by the accessory gland secretions of the ovipositing female sawfly while further development of the gall is dependent on the presence and activity of the larvae. When gland sacs were placed in developing galls from which larvae had been removed, galls continued to grow. If the glandular material was repeatedly injected over a period of several days, the galls continued to develop to normal size. Extracts of young *Pontania* larvae and extracts of female accessory glands were able to promote the continued growth of galls from which the larvae had been removed. Mixtures of chemicals were tested to see if they played a role in willow leaf gall formation. Rapid and sustained growth of galls was obtained with a periodic injection of a mixture containing a synthetic cytokinin kinetin, a naturally occurring auxin indole-3-acetic acid and adenine.

While the examples noted above provide evidence for gall-inducing factors associated with extracts and secretions, the specific cecidogenetic chemicals have not yet been identified. In addition, while there is evidence for cecidogenetic properties associated with glandular extracts and secretions, no one has been able to mimic the entire process of gall formation with an extract or secretion. This is not surprising given the difficulties associated with attempting to simulate the continual release of a gall-inducing stimulus from the precise location where the insect is normally active within the plant tissue.

Studies of Auxin and Cytokinin Involvement in Insect Gall Formation

Given the importance of plant hormones in plant development as well as in the mechanism of crown gall formation, a number of studies have focused on the roles of the plant hormones auxins and cytokinins in insect gall formation.

There were some early reports that applications of auxins to plant tissues resulted in structures similar to galls, while others reported failure in their attempts to induce galls with auxin. Applications of auxins to plant tissues have not resulted in the formation of structures that exhibited the complexity and the degree of hyperplasia of insect galls. Extracts of the saliva of gall-inducing aphid species have provided evidence for the presence of the auxin indole-3-acetic acid (IAA) and some have concluded that IAA was the active cecidogenetic factor in the aphid species studied. However, it was not determined whether the aphids produced the auxin, or whether they accumulated it from the plant tissue.

IAA has been detected and analyzed in other galls and gall formers. Oak apple galls caused by *Cynips quercusfolii* on *Quercus robur* and *Quercus sessiliflora* were shown to contain twice as much auxin activity as normal leaf tissues, while *Pinus edulis* needles with galls induced by larvae of the midge *Janetiella* sp. near *J. coloradensis* were found to contain 3.7 times higher concentrations of auxin bioactivity compared to needles lacking galls on a fresh tissue weight basis, and 17 times more auxin activity per needle. IAA was detected in *Cynips quercusfolii*, but was not detected in the larvae of the midge *Janetiella* sp. near *J. coloradensis*. In a study of the goldenrod ball gall induced by larvae of the dipteran *Eurosta solidaginis*, the gall-forming larvae were shown to contain high levels of IAA with detection by gas chromatography-mass spectrometry (GCMS). Concentrations of IAA in the gall tissues were higher than in the stem tissues on a weight per stem length basis, but not on a weight per weight basis.

Some studies have shown high levels of cytokinins in gall tissues. Levels of four cytokinins were shown to be higher in developing galls induced by *Pontania proxima* compared to levels in leaf tissue. Levels of the cytokinin isopentenyladenosine were shown to be much higher in hackberry (*Celtis occidentalis*) gall tissues than in control leaf tissues. However, others have not found higher levels of cytokinins in gall tissues compared to normal tissues. Levels of cytokinin bioactivity found in galls formed by *Mikiola fagi* were not elevated when compared to healthy leaves, while cytokinin concentrations in gall tissues formed by a chalcid wasp on *Erythrina latissima* were lower than those in surrounding leaf tissues. Levels of four cytokinins were shown to be higher on a weight per stem length basis in goldenrod ball galls compared to normal stem tissues, but were not higher on a weight per weight basis.

Studies have also shown evidence for cytokinins associated with gall-inducing insects. Cytokinins have been detected in the oriental chestnut gall wasp (*Dryocosmus kuriphilus*) and in the larvae of a chalcid wasp that forms leaf galls on *E. latissima*. The high concentration of cytokinins in the larvae of the chalcid wasp could be responsible for nutrient mobilization by the larvae within the galls, and may also be responsible for the fact that galls containing larvae remain as green islands on senescing leaves, while those without larvae, senesce rapidly. Four different cytokinins have been detected by GCMS in the larvae of *Eurosta solidaginis*, the dipteran responsible for the formation of goldenrod ball galls (Fig. 7). The cytokinin isopentenyladenine was shown to be present at much higher concentrations in first instar larvae than in normal stem tissues. In contrast, in a study of willow galls induced by *Pontania pacifica*, growth promotion was found to be associated with two unidentified adenine derivatives in the female accessory glands of the sawfly, but no significant cytokinin bioactivity of gland extracts was detected.

In summary, studies have provided evidence for yet-to-be-identified gall-inducing factors associated with extracts and secretions of gall-inducing insects. In addition, there have been numerous reports of the presence of plant hormones in gall-inducing insects and gall tissues with detection not only by bioassay, but also by sophisticated state-of-the-art techniques. However, it remains to be seen whether gall-inducing insects have the ability to synthesize plant hormones such as auxins and/or

Gall Formation, Figure 7 **The goldenrod ball gall caused by *Eurosta solidaginis* on *Solidago altissima*.**

cytokinins, whether the gall-formers induce synthesis of the hormones in the surrounding plant tissue, or whether the hormones that have been detected in the gall-formers have just been accumulated from the plant tissue. The high levels that have been found in some species of gall-inducing insects are suggestive of synthetic capabilities. Despite the evidence for plant hormones in galls and gall-inducing insects, the specific role of plant hormones in the development of insect galls has not been determined. Given the important role that auxins and cytokinins play in normal developmental processes in plants as well as their well- characterized role in crown gall formation, it seems likely that they play an important role in insect gall development as well. As the evidence for the involvement of auxins and cytokinins in insect gall formation is more convincing for some of the gall systems that have been studied than for others, it is most probably the case that other yet-to-be-determined cecidogenetic agents will be identified as playing important roles in the mechanism of gall formation for certain types of insect galls.

Gall Midges (Diptera: Cecidomyiidae)

Netta Dorchin
Museum Koenig, Bonn, Germany

Cecidomyiidae are one of the largest families in the order Diptera, with more than 5,700 described species and many more undescribed and unknown species worldwide. The family belongs to the suborder Nematocera, and its closest relatives within it are the fungus-feeding gnats in the families Sciaridae and Mycetophilidae (in the broad sense). According to fossils from the Jurassic period, the family is at least 150 million years old, but has apparently experienced explosive speciation during the Cretaceous, with the appearance of flowering plants. Cecidomyiidae have a cosmopolitan distribution, although only the faunas of Europe and North America are fairly well known. This situation makes it impossible to estimate the actual number of species in the family. The common name "gall midges" refers to the gall-inducing habit of most species, which constitute the largest group of gall-inducing organisms. However, the family also contains many species that are fungus-feeders, predators, or feed on plants without inducing galls.

Classification

The Cecidomyiidae are divided into four subfamilies:

The Catotrichinae constitute the oldest subfamily and are considered ancestral to all other subfamilies. This group contains one genus (*Catotricha*) and seven species, which are known from the Holarctic region and from Australia.

The Lestremiinae are a diverse group of about 630 species that is ancestral to the remaining two subfamilies. Although many genera and species in this group are common and widespread, it is still largely unknown, and dozens of species belonging to it are yet to be described from the

Holarctic and the Australasian regions. Faunas of other parts of the world are poorly known. Lestremiinae are fungus or detritus feeders, and their larvae are found in decaying organic matter.

The Porricondylinae constitute a diverse, paraphyletic group of 635 species that are similar in habits to the Lestremiinae. A few species are consistently found in association with plants, such as in already infested fruit or in conifer cones, but are assumed to feed on decaying organic matter in these niches. Several species are known as fossils from the upper and lower Cretaceous. The subfamily is poorly known outside the Palearctic region, and relationships among its tribes are unclear.

The Cecidomyiinae are the youngest, largest, and most diverse subfamily of gall midges, with more than 4,400 described species worldwide. This is a monophyletic group that includes all the plant-feeding species in the family, as well as several unrelated groups of fungus feeders and predators. The Cecidomyiinae are divided into four supertribes: the species-poor Stomatosematidi and Brachineuridi, whose biology is largely unknown, and the very large and biologically diverse Cecidomyiidi and Lasiopteridi.

Morphology

Adult gall midges are tiny, fragile flies, usually 2–5 mm in length. Most species are inconspicuously colored, but some groups have color patterns, especially black and white, resulting from dense covering of scales and hairs. The head is made up largely of compound eyes that often touch at the vertex. The antennae usually number 12 flagellomeres, but their number vary among groups and sometimes also within the same species and even the same individual. Male flagellomeres are often composed of a large node and a long narrow neck, whereas female flagellomeres are mostly cylindrical with much shorter necks. Males of many species have two nodes on each flagellomere, each bearing sensory setae and circumfila – sensory hairs that girdle the flagellomere and sometimes form very long loops. Male antennae of some groups in the family resemble those of the female. Mouthparts are usually greatly reduced and are only capable of liquid consumption; the adults of most plant-feeding species may not feed at all. The wing is usually transparent and has greatly reduced venation in most groups, with only 2–5 long veins, and long hairs along its margin. The legs are usually long and slender and comprise five tarsomeres. In the subfamilies Porricondylinae and Cecidomyiinae, the first tarsomere is considerably shorter than the second, and legs are easily broken beyond it. Tarsal claws are variably shaped, some with 1–2 additional teeth at their base. The ovipositor varies in length and is usually retracted inside the abdomen. Different groups have developed various modifications of the ovipositor, including conspicuous setation, or needle-like or sword-like parts to aid in oviposition. The male genitalia include gonopods that clasp the female during mating.

Larvae pass through three instars. They are legless and have a greatly reduced head capsule with no eyes, very short antennae, and mouthparts that are suited for piercing and sucking liquids. They are often bright yellow, orange, or red, but they may also be white, depending on the species. The third instar larva usually has a spatula, a dark, sclerotized structure on the ventral side of the prothorax, which is unique to the Cecidomyiidae. The spatula, which varies in shape and size among species, is used for digging in the soil or cutting through plant tissue, but many taxa have lost it altogether. Pupae may have diagnostic characters on their head and abdomen in the form of horns and spines that aid in cutting through plant material prior to adult emergence.

Biology

The gall-inducing guild within the Cecidomyiidae has received more attention than any other group in the family due to the large number of species and the remarkable diversity of host plants, gall structures, and life-history strategies exhibited by its members (Fig. 8). Roughly 70% of the known species in the family are gall inducers, most of which are monophagous (restricted to a single host), or oligophagous (feeding on a few related plant species). A few species are known to use a larger number of hosts that belong to several different families, either simultaneously or at different stages of their life cycle. Gall midges are found on hundreds of plant families all over the world, but certain families, such as the Asteraceae, Chenopodiaceae, Fabaceae, and Salicaceae, support especially high numbers of species. Galls range from simple leaf swellings, leaf curls, and unopened flowers to complex stem and bud galls that may comprise from one to many larval chambers and vary in the extent of tissue differentiation. Galls may be tiny or very conspicuous, green to bright red, hairy or smooth, and they may resemble the original structure of the affected plant organ or greatly deviate from it. The only other group of gall inducers exhibiting similar diversity in gall shapes and forms is the gall wasps (Cynipidae), but these are less species-rich and, as a group, are associated with much fewer plant taxa.

Although plant-feeding is by far the most common strategy in the family, feeding habits among cecidomyiid larvae are extremely diverse. Larvae of all Catotrichinae, Lestremiinae, and Porricondylinae, as well as some of the Cecidomyiinae, feed on fungi or decaying organic matter, while all plant feeders and predators belong to the Cecidomyiinae. Some species feed on or in plants without gall induction, or develop as inquilines, invading galls of other arthropods and feeding on gall tissues at the expense of the gall inducer. Inquilinism has evolved independently many times in the family, and while some genera are entirely or mostly composed of inquilinous species, others include both gall-inducers and inquilines. Predatory larvae occur in many unrelated groups within the Cecidomyiinae and are either specialists or generalists that feed on various arthropods, particularly Homoptera and mites. Certain groups within the subfamily are secondarily associated with symbiotic fungi that develop in their galls (e.g., many species in the tribes Asphondyliini and Lasiopterini), but larvae in these galls seem to feed on plant tissues rather than on the fungus, and the nature of this association is still unclear.

The life cycle of phytophagous gall midges is closely associated with that of their host plants. Species that are associated with trees are usually univoltine, whereas those that are associated with shrubs and herbaceous plants are often bivoltine or multivoltine, since these plants may continuously offer tissues that are suitable for galling. Females usually emerge from the pupae with their eggs fully mature and mate directly or after some courtship with males that wait for them on the host plant or on the ground. Sex ratios among emerging adults are often skewed towards females, and females of some species produce strictly unisexual (all male or all female) progeny throughout their lifetime, a phenomenon known as monogeny. While all Cecidomyiidae reproduce sexually, a few species in the Porricondylinae that feed on fungi may also reproduce by paedogenesis, a much shortened and simplified parthenogenetic life cycle during which larvae or pupae give rise to daughter larvae. This situation has evolved at least twice in the family and seems to be regulated by the availability of food; when food becomes scarce the population switches to normal, sexual reproduction through the development of adults.

Mated females cease to attract males and immediately engage in host seeking for oviposition. In most phytophagous species, the eggs are laid on the surface of plants or in between their scales or leaves. Some species in the tribe Asphondyliini have evolved a piercing ovipositor and insert the eggs directly into plant tissues. Whether eggs are laid individually or in batches is a species-specific trait, as is the morphogenesis of the resulting gall and its final shape and structure. Larval feeding cause modification of plant tissues around them to produce the gall, which often

reaches its final size when the larvae are still first instars. Both the physical and the chemical stimulation applied by the larvae are necessary for gall induction, and galls will cease to develop if the larvae are killed. Mature larvae either pupate in the gall or drop to the ground and pupate in the soil, depending on the species, and in some multivoltine species also on the time of year. Larvae of many species, especially in temperate areas, enter diapause in the soil or inside the plant for a certain part of the year until suitable plant tissues become available again. In multivoltine species, larvae of the last generation, and/or a certain proportion of the larvae in each generation, may enter diapause until the following year, and in some species dormancy may last several years.

Economic Importance

Many gall midges are pests of agricultural and food crops, ornamental plants, and forest trees. One of the most serious pests in the family is the Hessian fly, *Mayetiola destructor* (Say), whose larvae feed in the stems of wheat, and kill the plants or severely reduce their productivity. This species was introduced from Europe to North America during the Revolutionary War, presumably in Hessian soldiers' mattresses that contained infested wheat stems. Another serious European pest that was introduced into North America is the sorghum midge, *Contarinia sorghicola* (Coquillet), one of the most important pests of grains in the world, whose larvae feed in seeds and hinder their development. Gall midges from the genus *Orseolia* that develop in buds and stems of rice plants are serious pests of this crop in Asia and Africa. Control of pest species may be achieved by using natural enemies or chemicals, but control has been most efficient with the use of resistant plant strains and modifications of management practices.

Certain predatory gall midges are considered beneficial because they prey on agricultural pests. *Aphidoletes aphidimyza* (Rondani), for example, is a biological control agent that is available commercially against numerous aphid pests. Adults of this species efficiently locate aphid infestations where females lay their eggs, and individual larvae may each consume dozens of aphids throughout their lifetime. Some phytophagous gall midges are successfully used as biological control agents of invasive weeds, although their impact is often too weak when not combined with other agents. Successful weed control projects involving cecidomyiid agents include the bud galler *Spurgia esulae* Gagné against leafy spurge in North America, and the flower-galling *Dasineura dielsi* Rübsaamen against the Australian wattle *Acacia cyclops* in South Africa.

Gall Moths (Lepidoptera: Cecidosidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Gall moths, family Cecidosidae, total only seven species, with five species from southern South

America and two from South Africa. The family is in the superfamily Incurvarioidea, in the section Incurvariina, of division Monotrysia, infraorder Heteroneura. Adults small (7– 26 mm wingspan), with rough head scaling; haustellum reduced, scaled; labial palpi short; maxillary palpi vestigial, 1- segmented. Maculation is somber, usually without spots but often with iridescence. Adults are probably diurnal. Larvae are gall makers on *Schinus* (Anacradiaceae) in Argentina.

Gall Wasps (Hymenoptera: Cynipidae)

EILEEN A. BUSS
University of Florida, Gainesville, FL, USA

The Cynipoidea [Hymenoptera: Apocrita (Parasitica)] superfamily contains plant-feeding (phytophagous) and parasitic wasp species, but is best known for the gall wasps (family Cynipidae). The superfamily includes about 3,000 described species. The number of families within the Cynipoidea is a matter of debate. Some researchers subdivide the group into six families: Cynipidae, Ibaliidae, Liopteridae, Figitidae, Charipidae, and Eucoilidae. Others use different classifications, including four families (Cynipidae, Ibaliidae, Figitidae, and Himalocynipidae), or five families (Austrocynipidae, Ibaliidae, Liopteridae, Cynipidae, and Figitidae).

Order: Hymenoptera
Suborder: Apocrita (Parasitica)
Superfamily: Cynipoidea
Family: Cynipidae

In general, cynipids are either gall-makers or inquilines in galls made by other species. About 1,360 species have been described, but it is estimated that 3,000–6,000 species actually exist. Gall-making cynipids (Cynipinae) are similar to true parasitoids in that they inject a kind of venom with their eggs into plant tissue. A gall forms because of the plant's response to the wasp's egg laying, presence of the egg, and/or feeding stimulation by the larva. Plant cells are usually modified and enlarged, the plant tissue surrounds the egg or larva, and the gall protects and provides nutritive cells for the gall-maker. Inquilines (e.g., Synerginae) cannot make their own galls on plants. Females lay eggs into other galls, and their larvae feed on gall tissue, sometimes changing the normal shape or size of the gall.

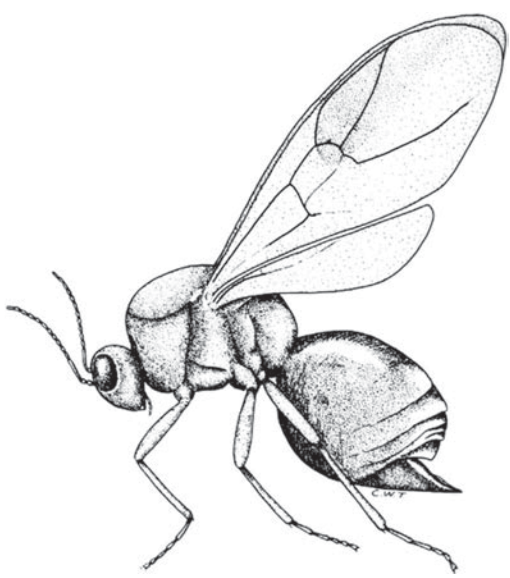
Gall Diversity

Cynipid galls come in a wide variety of forms, the shape and complexity being determined by the species of gall wasp that feeds within. Commonly attacked structures include catkins, seeds, flowers, petioles, branches, stems, and roots, but most galls occur on leaves and buds. The galls that cynipids make are generally described as blister, bud, bullet, oak apple, roly-poly, rosette, twig or stem galls. More than one gall species may also occupy a leaf or other structure. Some galls are single-chambered (monothalamous) and contain only one gall-maker, and others are multi-chambered (polythalamous) and contain many gall-makers. Those plants most often infested by cynipids are in the families Rosaceae, Asteraceae, Salicaceae, and Fagaceae. Oaks (Fagaceae: *Quercus* spp.), however, support the greatest diversity of gall-makers in North America, numbering at least 717 cynipid species.

Biology

Cynipid adults are small (1–6 mm), hard-bodied insects, with compressed abdomen, reduced wing venation, and simple, filiform antennae (Fig. 9). Most are drab-colored (e.g., black, brown, dark red, amber, or straw yellow), and may be either dull or shiny, but never metallic. Antennae of females are usually 13-segmented and males have 14 or 15 segments with the third often elongated and bent. The larvae are about 1-4 mm long, white, lack legs, and have distinct head and chewing mouthparts. Each larva develops within a discrete chamber of a gall, even when multiple gall-maker larvae develop in the same, polythalamous gall. Larvae apparently feed continuously, but do not produce fecal matter until pupation. Pupation always occurs in the gall, wherever the gall is located (e.g., on the plant or in the litter layer). Adults usually chew a circular hole upon exiting the gall.

The life cycle of many cynipids is complex, and involves heterogeny or alternation of generations. As such, a bisexual generation (both males and females) alternates with a unisexual generation (all females). The female generation reproduces by parthenogenesis, and the unfertilized eggs develop into sexual offspring. Because of the haplo-diploid genetics of wasps, all males can develop from unfertilized eggs. However, females result from the replication of chromosomes inside an unfertilized egg' s nucleus. The wasps of the two generations often look morphologically different and may attack the same or different plant structures and make very different galls. As a result, the insects of both generations have occasionally been falsely described as separate species.



Gall Wasps (Hymenoptera: Cynipidae), Figure 9
Adult *Diplolepis rosae*, which develops in the mossy rose gall.

Gall Inhabitants

Galls are good nutrient sources, and can be inhabited by other insects that feed on gall tissues or use the gall for shelter. Some of these insects can kill some or all of the gall-making larvae, either directly or indirectly by competition for resources. In addition to inquilines (e.g., *Synergus* spp. and *Ceroptres* spp. in oak galls), other insects feed opportunistically on gall tissue, including clearwing borers, longhorned beetles, metallic wood-boring beetles, weevils, gall midges, and others. Some of these opportunistic insects may have broad host ranges and also be pests on other plant species (e.g., dogwood borer). Some additional arthropods live externally on gall surfaces (e.g., mites, collembola), or in old, dry galls (e.g., ants). Natural enemies, especially parasitoid complexes, also inhabit galls and increase gall-maker mortality.

Abundance and Distribution

Populations of cynipids are sometimes greater on certain plants within a species than others, and several reasons why this occurs have been proposed. One possibility involves the adult female' s choice of ovipositional sites and her ability to distinguish between host plants or structures that vary in size, nutritional quality, or defensive capability. Because her offspring are embedded in plant tissue, her "choices" determine where eggs and subsequent offspring are dispersed. Especially important for those species that oviposit into buds before leaf flush is synchrony between insect hatch or emergence and plant budburst or leaf and shoot elongation. However, the plant' s genotype and ability to form a gall may still limit its use as a host for gall-makers. Thus, an egg may be laid into a bud, but the plant may not react to the stimulus to make a gall. In addition, because cynipids have limited sexual reproduction and dispersal ability, genetic variation within the population may be reduced, resulting in less adaptation to a variety of hosts and greater specialization on isolated host plants.

Economic Importance

Some galls and gall-makers are beneficial, and are used in biological control programs for weeds. And, historically, those galls containing tannic acid (e.g., oak galls) were used to make inks and dyes, and to tan leather.

Although galling insects are usually not considered pests, certain species can reach outbreak levels and cause either physical or aesthetic damage to high-value plants. Galling insects have been known to reduce photosynthesis and acorn production, discolor foliage, cause defoliation, branch dieback, and plant death. For example, the jumping oak gall wasp, *Neuroterus saltatorius* (Edwards) attacks Garry oak (*Q. garryana* Douglas) in the western United States and Canada, and causes severe and chronic mid-summer leaf scorching and partial defoliation. The rough oak bulletgall wasp, *Disholcaspis quercusmamma* (Walsh), forms galls on bur oak (*Q. macrocarpa* Michaux) and swamp white oak (*Q. bicolor* Willd) that disfigure trees and produce a sticky exudate, which attracts stinging insects. Other galls may host inquilines that are pests of other plants. In addition, aesthetic disfigurement can be enough to prevent the sale of infested nursery stock. At present, little information exists on the effective management of galling insect pests; pruning is labor-intensive and insecticide use may disrupt the natural enemy population, potentially leading to additional outbreaks.

Gamagrass Leafhopper, *Dalbulus quinquenotatus* Delong & Nault (Hemiptera: Cicadellidae)

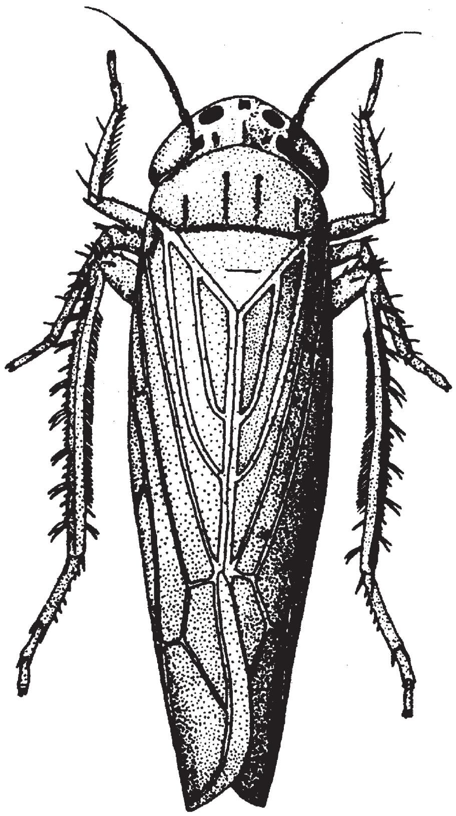
GUSTAVO MOYA-RAYGOZA

University of Guadalajara, Jalisco, Mexico

The gamagrass leafhopper is a small (length 3.0–4.3 mm) deltocephaline, brownish orange in color, with five black spots on the head (Fig. 10). This species is found at low elevations (125–1,975 m) and occurs in central and southern Mexico and in Costa Rica.

Its developmental time from egg to adult eclosion is about 34 days at 24°C. Nymphs begin hatching on day 12 and peak nymphal abundance is reached on day 16. Generations develop continuously through the year on perennial gamagrasses (*Tripsacum* spp.).

This leafhopper has particular behavioral and ecological importance because it is among the few leafhopper species tended by ants. Unlike its non-tended congeners, *D. quinquenotatus* responds to

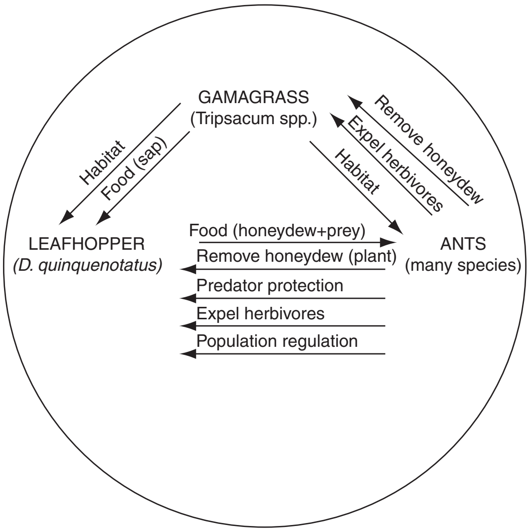


Gamagrass Leafhopper *Dalbulus quinquenotatus* Delong & Nault (Hemiptera: Cicadellidae), Figure 10 *Dalbulus quinquenotatus*.

stroking of the abdomen by ants' antennae by excreting and holding honeydew droplets until droplets are removed by ants. *Dalbulus quinquenotatus* excretes three to six times the volume of honeydew as do non-tended species. Moreover, droplets of *D. quinquenotatus* are about 23% larger in diameter and are excreted two to four times more frequently than its non-tended sister species. Nymphs and adults are sedentary and gregarious. They aggregate within leaves at the bases of *Tripsacum* spp. Sedentary and gregarious behaviors are typical in other hemipterans tended by ants such as aphids (Aphididae), treehoppers (Membracidae), and scales (Coccidae), but rare in leafhoppers. Because it has been broadly investigated, the gamagrass leafhopper can serve as model in the study of other hoppers tended by ants in the tropical and temperate regions.

The gamagrass leafhopper is tended by 18 ant species from four different subfamilies; however, the two most commonly associated ant species are *Brachymyrmex obscurior* Forel and *Solenopsis geminata* (F.). Other insects also inhabit the leaves at the bases of *Tripsacum* spp. where *D. quinquenotatus* is tended by ants. These include the decomposers *Coproporus* sp. (Staphylinidae), *Carpophilus* sp. (Nitidulidae), and *Haptoncus* sp. (Nitidulidae). These taxa occur during the wet season, and of these *Carpophilus* sp. is the most abundant. This species feeds mainly on the fermenting fluid of plants. The source of fermentation in this case is the carbohydrate contained in the honeydew excreted by *D. quinquenotatus*.

The mutualistic association (Fig. 11) between *D. quinquenotatus* and ants occurs because both receive benefits. The gamagrass offers habitat and food in the form of sap for the leafhopper most of the time, except at the end of the dry season, when gamagrass populations dry up. The sap is transformed by the leafhopper into honeydew and prey. The honeydew provides water, sugars, amino acids, lipids, and vitamins to ants. Moreover, ants consume some nymphs and adults thereby obtaining



Gamagrass Leafhopper *Dalbulus quinquenotatus* Delong & Nault (Hemiptera: Cicadellidae), Figure 11 Beneficial effects of the *D. quinquenotatus*- ants-gamagrass relationship.

protein and reducing the leafhopper population. Ants remove the honeydew produced by the gamagrass leafhopper. This leafhopper oviposits its eggs in clusters on the upper surface of midribs of basal leaves; therefore, removal of honeydew by ants reduces the death of leafhopper eggs by suffocation from accumulated honeydew and the formation of sooty mold on host leaves. Also, when the honeydew is removed the sooty mold is eliminated, facilitating plant photosynthesis. Ants protect *D. quinquenotatus* from arthropod predators such as spiders and nabids (Nabidae). Predators not only are expelled by ants when they try to approach *D. quinquenotatus*, but also are captured and transported to the ant nest and presumably used as food. Ants tending *D. quinquenotatus* also expel the related leafhoppers *D. gelbus* and *D. guzmani* that inhabit the canopy of *Tripsacum* spp. Adults of these two species respond readily to mechanical stimuli and avoid capture and predation by ants, especially on large gamagrasses.

The mutualistic association between *D. quinquenotatus* and ants on gamagrasses is affected by biotic and abiotic factors. Under greenhouse conditions, diet influences the response of ants to population of *D. quinquenotatus*. When ants are denied food, they prey upon and extinguish populations of *D. quinquenotatus*, but when supplied with prey (dead yellowjackets), large numbers of ants tend leafhopper populations that grow in size. Few ants tend leafhoppers when supplied with insect prey and honey. In natural conditions ants exploit other food resources to replace *D. quinquenotatus* honeydew during the driest months, when *D. quinquenotatus* populations are lower. That resource is nectar produced in extrafloral nectaries by the plants *Acacia pennatula*, *Leucaena esculenta*, *Lobelia laxiflora*, and *Lysilona* sp. that grow in the gamagrass community. In the wet season, when the host plants contain abundant green foliage, *D. quinquenotatus* and ants are most abundant on *Tripsacum* spp. The gamagrass populations, which grow in open areas in patches alongside herbaceous plants, shrubs, and trees, tend to be maintained in an early state of succession because of frequently occurring fires during the dry winter months in Mexico. Burned gamagrass populations are colonized better than unburned gamagrasses by the gamagrass leafhopper and tending ants. Five months after fire, the mutualistic association is higher in burned than unburned gamagrass populations. Populations of leafhopper adults and ants are equal on gamagrass plants given extra doses of phosphorous, nitrogen, or potassium. This suggests that the mutualistic association between ants and gamagrass leafhoppers is not affected by plant nutrients.

Gallinipper

This name is sometimes applied to any large mosquito, but it is more correctly applied to *Psorophora* *ciliata*, a large and ferocious mosquito inhabiting most of the New World. Apparently it is America's largest mosquito. It is distinguished not only by its large size and painful bite, but by its hairy or shaggy legs. Interestingly, an American warship was named Gallinipper. It was part of a "mosquito fleet," a group of small boats, equipped with both sails and oars, which operated from Florida and patrolled the Caribbean in pursuit of pirates in the 1820s.

Gamete

A germ or reproductive cell, i.e., the sperm and ovum or egg.

Ganglbauer, Ludwig

Ludwig Ganglbauer was born in Vienna on October 1, 1856. By the age of six, he had become interested in plants and beetles. He was educated at the Schottengymnasium in Vienna, obtained a teaching diploma in zoology and botany from Universität Wien, and taught for a few years at a high school. He accepted a position at the Wiener Hofmuseum (which later was renamed Naturhistorisches Museum) and by 1881 had begun publishing on the taxonomy of Coleoptera. These early publications gained him acclaim, and in 1898 he was named Kustos in the zoology department, in 1904 head of the zoology department, and in 1906 director. In 1881 he became one of the founders of the journal Wiener Entomologische Zeitung, and served as one of the editors for three years. His major work, a four-volume book "Die Käfer von Mitteleuropa" (1892–1905), was unfinished because of his early death, in Vienna on June 5, 1912. The published volumes are still widely used.

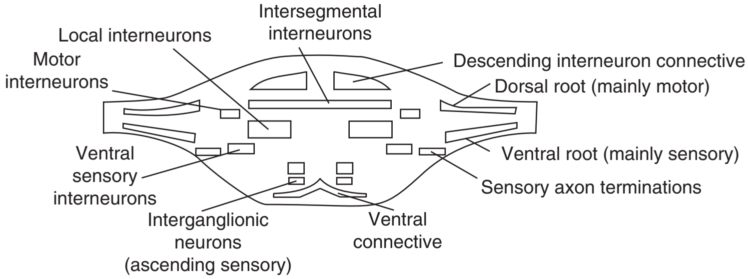
Ganglion (pl. ganglia)

A mass of nervous tissue, and the basic functional unit of the central nervous system. Many insects have three thoracic ganglia (the pro-, meso-, and metathoracic ganglia) in the thoracic region, though in others the meso- and metathoracic ganglia are fused. Each thoracic ganglion (Fig. 12) sends motor axons to the leg muscles of its respective segment, and receives input from sensor receptors in the legs. The meso- and metathoracic ganglia innervate the wing muscles. Ganglia also are found in the abdominal segments, though fusion of ganglia occurs here also. Nearly all ganglia support nerves carrying



Ganglion (pl. ganglia), Figure 12 **Diagram showing the position of nervous tracts within a ventral ganglion.**

both sensory and motor neurons laterally in the insect's body.

Garden Symphylan, *Scutigerella immaculata* (Newport) (Symphyla: Scutigerellidae)

► Potato Pests and their Management
► Symphylans

Gaster

The swollen, terminal abdominal segments of Hymenoptera; the region behind the constriction or pedicel.
► Abdomen of Hexapods

Gasteruptiidae

A family of wasps (order Hymenoptera).
► Wasps, Ants, Bees, and Sawflies

Gastric Caecum (pl. gastric caeca)

Bladder-like extensions of the midgut that function in food absorption.
► Alimentary Canal and Digestion

Gause's Principle

The principle that no two competing organisms can coexist in a stable environment without one species replacing the other. If seemingly equivalent species do co-exist, this implies that there are differences in their niches.

Gelastocoridae

A family of bugs (order Hemiptera). They sometimes are called toad bugs.
► Bugs

Gelechiidae

A family of moths (order Lepidoptera). They commonly are known as twirler moths.
► Twirler Moths
► Butterflies and Moths

Gel Electrophoresis

The separation of molecules on the basis of size and electrical charge.

Gena

The side of the head (Fig. 13) beneath the compound eyes. The "cheek."
► Head of Hexapods

Gene Amplification

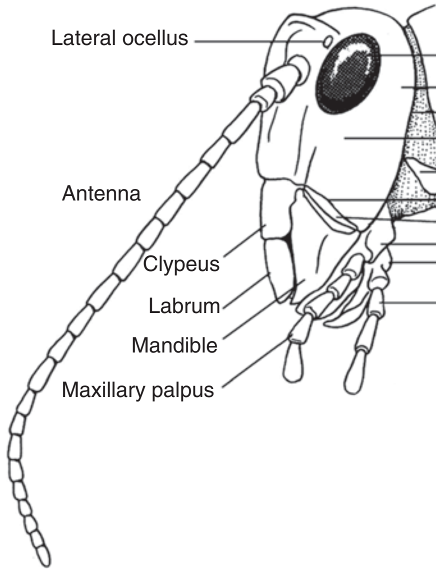
The production of multiple copies of genes in order to increase the rate of expression of a gene. Numerous genes are amplified in the developing oocyte of the mothers ovaries, providing for rapid translation of the genetic message into proteins for rapid embryonic development.

Gene Cloning

Insertion of a fragment of DNA containing a gene into a cloning vector and subsequent propagation of the recombinant DNA molecule in a host organism. Recently, cloning of a DNA fragment by the polymerase chain reaction has simplified the technology.

Gene Duplication

The duplication of a DNA segment coding for a gene; gene duplication produces two identical



Gena, Figure 13 Side view of the head of an adult grasshopper, showing some major elements.

copies which may retain their original function allowing the organism to produce larger amounts of a specific protein. Alternatively, one of the gene copies may be lost by mutation and become a pseudogene or a duplicated gene can evolve to perform a different task.

Gene Expression

The process by which the information carried by a gene is made available to the organism through transcription and translation.

Gene Flow

The movement of genes within and among populations as a result of cross fertilization.

Gene Gun

A method of propelling microscopic particles coated with DNA into cells, tissues, and organelles to produce transformation of the recipients.

Gene Library

A collection of recombinant clones derived from genomic DNA or from the cDNA transcript of an mRNA preparation. A complete genetic library is sufficiently large to have a high probability of containing every gene in the genome.

Gene Regulation

The mechanisms that determine the level and timing of gene expression.

General-Use Pesticide

This terminology was developed by the US Environmental Protection Agency to describe pesticides that are considered to be sufficiently safe that they can be used by the public without special training. Pesticides in this class can be purchased and used without license or permit. In contrast, more toxic or hazardous material are classified as "restricted-use pesticides" and can be purchased and used only by persons who are certified by the appropriate regulatory agency in the state in which they work.

► Insecticides
► Regulations Affecting Use of Pesticides

Generalist

An insect that occupies a broad niche, or consumes a wide range of food.

Generation

The length of time from any given life stage to the same stage in its offspring, though it is usually considered to be egg to egg or adult to adult.

Genetic Modification of *Drosophila* by *P* Elements

MARJORIE A. HOY
University of Florida, Gainesville, FL, USA

It became possible to genetically modify *Drosophila melanogaster* using recombinant DNA methods in 1982 when *P* elements (described below) were identified and genetically altered to serve as mechanisms (vectors) for inserting genes into the nuclear genome of *Drosophila*. The use of *P*-element vectors provides a powerful tool that has modernized *Drosophila* genetics and made it possible to study the role of many genes important in development and behavior. In addition, the *P*-element system has served as a model for scientists wanting to genetically modify other insects for use in pest management programs (Transgenic Insects).

P Elements are Disposable Elements

P elements are transposable (movable) elements that have been harnessed as a tool for genetically modifying the fruitfly *Drosophila melanogaster* in a consistent manner. Transposable elements are independent genetic elements that can move within and between genomes; some call them selfish genetic elements. The development of *P* elements as tools (vectors) for inserting genes into *D. melanogaster* has revolutionized research on this important model insect, allowing fundamental studies of development and evolution.

Intact *P* elements are 2,907 bp long and encode a single polypeptide that has transposase (an enzyme that facilitates the movement of the element from one chromosome to another) activity. There are four exons (DNA sequences that are transcribed into protein, numbered from 0 to 3) flanked by inverted repeats 31 bp long. The presence of intact inverted repeats is required if the *P* element is to transpose (move).

Multiple copies of *P* elements (30–60) are dispersed throughout the genome of certain strains (called P) of *D. melanogaster*, but are not active because transposition is suppressed by factors in the *P* cytotype. Many *P* elements in *D. melanogaster*, and other *Drosophila* species, have some sequences deleted (are mutated), which also makes them incapable of transposing.

Movements of *P* elements cause mutations by inactivating genes, altering rates of transcription, or developmental- or tissue-specific gene expression. *P*-element movements can break chromosomes and cause chromosome rearrangements and germ cell (oocyte or sperm) death. Transposition of *P* elements in somatic cells reduces the life span of *D. melanogaster* males, as well as reducing fitness, mating activity and locomotion.

Hybrid Dysgenesis

P elements initiate a syndrome called hybrid dysgenesis in *D. melanogaster*. Hybrid dysgenesis occurs when males from a strain that contains *P* elements (P males) are mated with females lacking P (M females). Their progeny have high rates of mutation, chromosomal abnormalities and, sometimes, are completely sterile. These abnormalities are caused by movement of *P* elements in the chromosomes of the ovaries or testes. The reciprocal cross does not generate hybrid dysgenesis because the P female' s cytotype suppresses movement of the *P* elements.

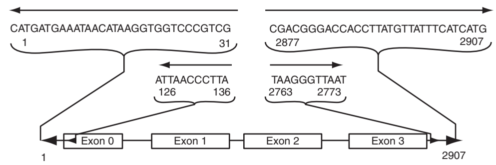
P Element Structure Varies

Many *P* elements in the *Drosophila* genome are defective. Some have internal deletions and are unable to produce their own transposase but, if they retain their 31 bp terminal repeats, they can move if supplied with transposase by intact *P* elements. *P* elements with defective 31 bp terminal repeats are unable to move because these repeats are the site of action of the transposase enzyme and important in movement and insertion of the elements into the chromosomes.

Transposition Method

P elements move from site to site in the genome (jump) by a "cut and paste" method. When a *P* jumps, it leaves behind a double-stranded gap in the DNA. The gap is repaired by using a matching sequence as a template. This matching sequence can occur on the sister chromatid or elsewhere in the genome. If the transposition occurs in an individual that is heterozygous for the *P* insertion, and the matching site on the homologous chromosome is used as the template for DNA replication and repair, there can be a precise loss of the *P* element sequence in the original site. There is no net loss in the genome because the *P* element has simply changed locations.

If a *P* jumps after the chromosomes have duplicated, but before the cell divides, one of the sister chromatids will still have a *P* in its original position. In this situation, the homologous *P* may serve as the template for filling in the (Fig. 14) hole left when the *P* moved to a new position elsewhere in the genome. Under these circumstances, the number of *P* elements in the genome is increased by one. The *P* element is replaced in its original site



Genetic Modification of *Drosophila* by *P* Elements, Figure 14 ***P*-element vector diagram.**

by gap repair and now is present in a new site in the genome, as well.

The cut and paste mechanism of transposition implies that *P* elements don' t have to confer an advantage on the organism to invade and persist in the genome. In fact, a mathematical simulation model indicates that *P* elements can become fixed in populations even when fitness is reduced by 50% and many laboratory studies have shown that colonies can change from M to P strains relatively rapidly.

The location of the *P*-element in the chromosome is important in determining the frequency of transposition. Although transposition is more-or-less at random, P-element vectors containing specific gene sequences-show some specificity by frequently inserting near the parent gene (which is called homing). *P* elements also tend to insert into upstream promoter regions of genes.

How Did *P* Elements Invade *D. melanogaster*?

P elements are relatively new to *D. melanogaster* populations. Surveys indicate laboratory strains of *D. melanogaster* collected before 1950 lack *P* elements, but most colonies collected from the wild within approximately the past 50 years have *P* elements. By contrast, *P* elements are relatively common in many other species of *Drosophila*. Surveys indicate that very closely-related, full sized and potentially active *P* elements are in *D. willistoni*, *D. guanche*, *D. bifasciata* and *Scaptomyza pallida*. *P* elements have been found in other dipteran families, including Opomizydae and Trixoscelididae. Inactive *P* elements were found in the sheep blowfly *Lucilia cuprina* (Calliphoridae) and the housefly *Musca domestica* (Muscidae). The presence of *P* elements in families other than Drosophilidae suggests that *P* elements may be more widely distributed than currently thought.

Phylogenetic analyses of DNA sequences from *P* elements in 17 *Drosophila* species in the *melanogaster* species group show that sequences from the *P* element family fall into distinct subfamilies or clades which are characteristic for particular species subgroups. These clades indicate that vertical transmission of *P* elements has occurred, but in some cases the P phylogeny is not congruent with the species phylogeny. More than one subfamily of *P* elements may exist within a group, with DNA sequences differing by as much as 36%, suggesting that horizontal transfer (movement between species) has occurred. In fact, horizontal transfer may be essential to the long-term survival of transposable elements.

P elements invaded *D. melanogaster* within the past 50 years. The donor species that provided a *P* element to *D. melanogaster* is thought to be in the willistoni group, which is not closely related to *D. melanogaster*. Because these species diverged from each other about 60 million years ago, there should have been sufficient time for considerable sequence divergence in the *P* elements if they had been present in both genomes prior to divergence (and transmitted vertically). However, DNA sequences of the *P* elements from *melanogaster* and *willistoni* are nearly identical, supporting the hypothesis of horizontal transfer. It is thought that the invasion of *D. melanogaster* by *P* occurred after *D. melanogaster* was introduced into the Americas.

Two mechanisms have been proposed to explain how the *P* element could have infected *D. melanogaster*. One involves horizontal transfer and the other involves interspecific crosses. Both *D. melanogaster* and *D. willistoni* now overlap in their geographical ranges in Florida and in Central and South America, but they apparently are unable to interbreed. Horizontal transfer could have been effected by a viral, bacterial, fungal, protozoan, spiroplasmal, mycoplasmal, or a small arthropod vector (perhaps a hymenopteran parasitoid or predatory mites). One candidate for horizontal vector may be the mite *Proctolaelaps regalis*. *P. regalis* is associated with both *Drosophila* species; it has been found in laboratory colonies and in the field associated with fallen or rotting fruit, which is the natural habitat for *Drosophila*. Laboratory observations indicate that *P. regalis* feeds on fly eggs and can make rapid thrusts of its mouth parts into a series of adjacent eggs. This brief feeding on multiple hosts might allow it to pick up DNA from one egg and inject it into another. Mites from colonies of *Drosophila* with *P* elements in their genome were analyzed with several molecular methods that indicated the mites carried both *P* element and *Drosophila* ribosomal DNA sequences. Mites isolated from M colonies (which lack *P* elements) lacked *P* sequences.

For the mite *P. regalis* to have transferred *P* elements to *D. melanogaster* from *D. willistoni*, a number of events had to occur in the proper sequence. Females of *D. melanogaster* and *D. willistoni* had to deposit their eggs in close proximity and mites had to feed sequentially on one and then the other, in the correct order. The recipient egg had to be less than 3 h old, the germ line of the recipient embryo had to incorporate a complete copy of the *P*, the transformed individual had to survive to adulthood, and the adult had to reproduce.

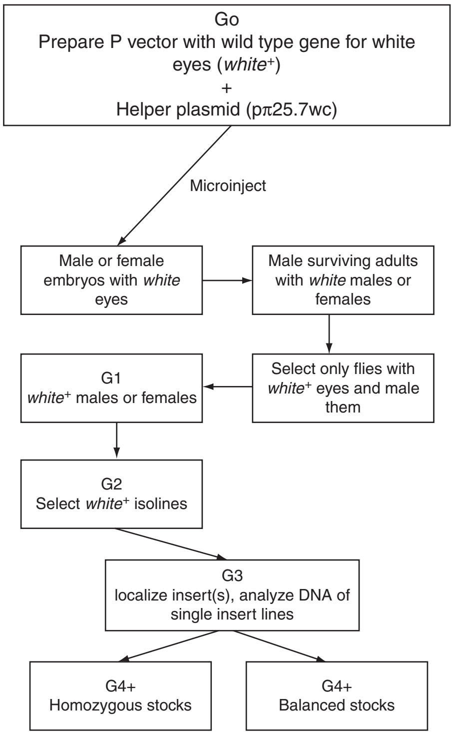
Another potential mechanism for horizontal transfer of *P* involves interspecific crosses. Crosses between the sibling species *D. simulans* and *D. mauritiana* produce sterile males, but fertile females. When F_1 females are backcrossed to males of either species, a few fertile males are produced. Hybridization, although rare, occurs between some *Drosophila* species. Although *D. melanogaster* and *D. willistoni* are unable to cross, interspecific crosses may have allowed the transfer of other types of TEs between *Drosophila* species.

P Element Vectors and Genetic Modification of *D. melanogaster*

P-elements have been genetically engineered to serve as vectors to insert genes into the germ line of *D. melanogaster*. A number of (Fig. 15) different vectors with different genetic characteristics have been produced subsequently.

Isolating pure *Drosophila* lines containing a single *P*-element insertion with a gene(s) of interest requires a sequence of steps over several generations. A *P*-element vector containing the gene(s) of interest inserted into it are microinjected into dechorionated eggs along with a helper plasmid that contains a complete DNA sequence coding for the transposase. The helper vector is unable to insert into *Drosophila* chromosomes by normal transposition methods because it lacks part of one inverted terminal repeat and lacks transposase (the gene of interest is typically inserted into the location of the transposase gene).

Embryos used for injection should be in the preblastoderm (an early embryonic stage prior to the development of the ectoderm, endoderm and mesoderm), when the embryo is still a syncytium



Genetic Modification of *Drosophila* by *P* Elements, Figure 15 Steps in transformation of *D. melanogaster* with a *P*-element vector.

(the nuclei have divided rapidly but cell walls have not formed between them yet). Some of the injected eggs die, but those that survive to produce adults may contain some individuals that contain the introduced gene(s) of interest.

These adults (called G_0) are mated individually to uninjected males or females and their progeny are reared and evaluated to determine if they carry the injected gene, or any injected "marker" genes designed to allow discrimination between genetically modified and unmodified flies. The resulting G_1 progeny will be screened to determine if they carry the gene(s) of interest and the marker genes. Because insertion of the transgenes into the chromosome occurs nearly at random, multiple individual lines of transformed flies will need to be evaluated for fitness and level of expression of the inserted DNA as well as their stability.

Insertion of the genes into germ line chromosomes is enhanced if preblastoderm embryos are microinjected. At that stage, the cleavage nuclei are in asyncytium (lacking nuclear membranes) and exogenous DNA can more easily be inserted into the chromosomes. The preblastoderm embryos are in the process of forming the pole cells (cells that will give rise to the ovaries and testes). Insertion of exogenous DNA into the chromosomes of the germ line results in stable transformation, meaning that the transgenes are likely to be transmitted each generation. If only somatic cells contain the introduced genes, the flies cannot transmit the new trait to their progeny. Such adult flies may exhibit the trait, but are only transiently transformed.

Only a portion of the *P*-element vector inserts into the chromosome. The DNA inserted consists of the *P* sequences contained within the inverted terminal repeats. The plasmid DNA outside the inverted repeats should not insert and is lost during subsequent development.

Once transformed fly lines are obtained, the transgenic fly lines should be stable unless transposase is provided in some manner. Sometimes an experimenter wants to induce movements of the inserted DNA, and secondary transpositions can be induced if transposase is introduced by injecting helper elements containing the transposase gene into preblastoderm embryos.

Transformation success rates vary from experiment to experiment and experimenter to experimenter. Usually, it is important to obtain at least ten lines containing the gene(s) of interest. This may require microinjecting 600 or more embryos, because survival of embryos after microinjection averages 30–70% and, of these, only 50–60% survive to adulthood (G_0). Even after G_0 adults are obtained, damage caused by microinjection may result in early death or sterility in 30–50% of the adults.

Transformation may not take place in all germ line cells in an injected embryo. Usually only a small fraction of the germ line cells of a G_0 individual produces transformed G_1 progeny. Thus, it is important to maximize the recovery of G_1 progeny from each G_0 individual to increase the probability of detecting progeny in which integration of *P* elements occurred. The size of the introduced *P* element is another factor that may influence transformation success; the larger the construct, the less frequent the insertion.

Detailed information on the life history and culture of *Drosophila* are available in a variety of references, as are detailed protocols for transforming *Drosophila* with *P*-element vectors. The protocols provide complete information on the appropriate equipment for microinjection, how to prepare the embryos for injection, align them on slides, desiccate them, and inject them in the region that contains the pole cells. Directions are available for preparing the DNA for injection and for pulling the very fine glass needles required. *P* elements have been engineered to provide an array of vectors with different characteristics and functions.

Uses for *P* Element Vectors

When a *P*-element vector inserts into a nuclear gene, it has been tagged. This allows the researcher to isolate and clone specific genes if the altered gene exhibits an altered phenotype in *D. melanogaster*. This process is called transposon tagging. Genetic engineering with *P*-element vectors in *D. melanogaster* also permit the expression of foreign genes from a variety of organisms.

P-element vectors also can be used to evaluate the effects of position on expression of a transgene by moving stably-inserted transgenes to other sites within the genome. The ability to replace or modify genes in their normal chromosomal locations in *D. melanogaster* is a very valuable genetic tool.

Transformation of Other Insects by *P* Elements

DNA from *D. melanogaster* has been introduced into other species of *Drosophila* with *P*-element vectors. Unfortunately, efforts to use *P*-element vectors to transform arthropod species outside the genus *Drosophila* have failed and research has shifted to the use of other types of transposable element vectors for this purpose. See the entry on Transgenic Arthropods for additional information on this topic.

Evolution of Resistance to *P* Elements

The spread of *P* elements throughout populations of *D. melanogaster* during the past 50 years has been remarkable, particularly since intact *P* elements can induce a variety of severe disadvantages in individuals in newly invaded populations. If *P* elements invade a small population, that population usually goes extinct. If evolution of repression systems (resistance to transposition) fail to occur quickly enough, larger populations also can go extinct.

In fact, several types of *P* repressor systems (resistance mechanisms) have been identified; they either are transmitted cytoplasmically (maternally inherited) or through the nuclear genome, in which case the transmission is biparental. The repressor systems have been classified as P, M′ or Q.

P fly strains have a strong maternally inherited system called P cytotype. P cytotype is mediated by a protein produced by differential splicing of the transcript of the complete element. When P females are crossed to a strong P line, less than 10% of the ovaries in their progeny become dysgenic, indicating that P strains strongly repress hybrid dysgenesis. By contrast, if P males are crossed to M females, more than 90% of the ovaries in their progeny are dysgenic. M′ strains contain repressor elements of P, as well. Transposition repression in M′ strains is due to the KP element. M′ strains display intermediate levels of repression of dysgenesis when crossed to P males. Both males and females from M′ strains are able to pass the repressing factor to their progeny. Q strains can strongly repress transposition and also display a low induction of transposition. Some Q strains show a maternal mode of inheritance of repression while others have biparental mode of inheritance. It thought that a repressor (SR) results from a deletion in the *P* element. The SR repressor cannot produce functional transposase but can produce the repressor protein and a novel protein, both of which may be involved in Q type repression.

Evolution of P, Q and M′ repression systems was evaluated during two surveys of *D. melanogaster* populations conducted along a 2,900 km cline along the eastern coast of Australia. The first survey was conducted in 1983 and the second in 1993. In 1983, P populations were found in the north, Q populations at central locations, and M′ populations in the south. After 10 years, Q and M′ populations had increased their range at the expense of P lines. The surveyors speculated that the P and M′ mechanisms of repression may be early, emergency responses to the harmful effects of transposition by *P*. The surviving *D. melanogaster* populations then may have the opportunity to evolve a superior mechanism to improve fitness by acquiring the biparentally transmitted Q repression system.

In many species of *Drosophila*, in which *P* elements have been present for a longer time than in *D. melanogaster*, no complete functional *P* elements have been found. Instead, many populations contain mutated elements which might encode repressor activity. These results reinforce the notion that active transposition of *P* is highly detrimental to species of *Drosophila* in the wild.

Using *P* Elements to Drive Genes into Populations

The interest in using transposable elements, such as *P*, as drivers for inserting engineered genes into natural populations for insect pest control has led to some computer simulation and empirical studies using *D. melanogaster* as a model system. Several different computer simulations suggest that transposable elements may be used successfully to drive specific genes into pest populations, including populations with different sizes, reproductive rates, density dependence and transposition frequency. Typically an equilibrium was reached quickly (usually within 50 generations), especially if 5 or 10% of the population carried the transposable element. However, if the "sweep" of elements does not occur rapidly, resistance mechanisms might develop that could reduce the effectiveness of the pest management program.

Genetic Code

The rules that determine which triplet of nucleotides code for which amino acid during translation. There are more than 20 different amino acids and four bases (adenine, thymine, cytosine and guanine). There are 64 potential combinations of the four bases in triplets (4 × 4 × 4). A doublet code would only be able to code for 16 (4 × 4) amino acids. Since only 20 amino acids exist, there is redundancy in the system so that some amino acids are coded for by two or more different triplets (codons).

Genetic Control

A method of pest control that uses strains of insects with genetic mutations rendering them sterile or disadvantaged. When released into the natural populations of the target insect, the sterile insects mate with wild insects and produce sterile or disadvantaged offspring.

Genetic Distance

A measure of the evolutionary divergence of different populations of a species, as indicated by the number of allelic substitutions that have occurred per locus in the two populations. The most widely used measure of genetic distance is that of Nei (1972), $D = -\ln(I)$.

Genetic Engineering

The deliberate modification of genes by man. Also called gene splicing, gene manipulation, recombinant DNA technology.

Genetic Linkage

Genes are located together on the same chromosome.

Genetic Marker

An allele whose phenotype is recognized and which can be used to monitor the inheritance of its gene during genetic crosses between organisms with different alleles.

Genetic Sexing

GERALD FRANZ
International Atomic Energy Agency, Seibersdorf, Austria

Genetic sexing refers to the methodologies enabling the separation of large numbers of insects according to sex (e.g., the separation or killing of females so that an all male population is produced). It is especially relevant for the Sterile Insect Technique (SIT) which is used to control or eradicate key insect pests by introducing genetic sterility into the target population. The primary active agent in the SIT is the sterile male, although in practice, both sexes have been released. A role for the sterile female in the SIT was sometimes debated, but direct evidence shows that females do not contribute significantly to the sterility induced in the wild population. In fact, releasing both sexes together at the high overflooding ratios required for the SIT to be effective leads to assortative mating among the released flies and, consequently, dilutes their effectiveness.

Genetic sexing can be achieved by utilizing natural differences between males and females (e.g., the time of emergence of tsetse flies, or the size of the pupae of certain Lepidoptera and mosquitoes). If such differences do not exist, then specific strains have to be developed using classical Mendelian genetic techniques. Two independent genetic modifications are required, the induction of a mutation that can be used as a selectable marker (e.g., affecting pupal color, or temperature dependent viability), and a chromosome re-arrangement (reciprocal Y-autosome translocation) that links the selectable marker to the male-determining Y chromosome. The most advanced and operational genetic sexing strains (GSS) are available for the Mediterranean fruit fly, *Ceratitis capitata* (medfly). In this species, two mutations, white pupae (*wp*) and a temperature sensitive lethal (*tsl*), are used either to separate the sexes at the pupal stage using optical sorting machines, or to kill the females at the embryo stage by incubating the eggs at slightly elevated temperatures. Both mutations are found on chromosome 5. In the males of a GSS, the wild type alleles of these selectable markers, wp^+ and tsl^+, are linked to the Y chromosome.

Structure of GSS Based on the Selectable Markers *wp* and *tsl*

The structure of this Y-autosome translocation determines the stability of the GSS over time. Genetic recombination in the male between the selectable marker and the translocation breakpoint, leads to a reversal of the male and female phenotypes. Over several generations, such recombinants can accumulate and the GSS reverts to a standard bi-sexual strain. By choosing translocations where the selectable marker and the breakpoint are close together, and by incorporating recombination suppressors (inversions), GSS can be generated that are stable enough for large scale rearing as required for the SIT. The inclusion of a Filter Rearing System greatly increases the useful life of a GSS in mass rearing factories. The structure of the translocation also determines the rearing efficiency. Ideally, the sterility linked to such chromosome re-arrangements occurs as early as possible with minimal affect on the rearing process/quality. The choice of the most appropriate selectable marker influences the cost effectiveness and the accuracy of the sexing procedure. The *tsl*-based strains currently in use in most medfly facilities allow females to be killed with an accuracy of 99.5% even at production levels of over 500 million males per week, and only inexpensive equipment (a water bath) is needed.

For the application of the SIT, the use of GSS offers the following advantages:

- Sterility is introduced more efficiently into the target population. Data show that 3 to 4 times more sterility can be induced if only sterile males are released.
- Production, handling and release costs are reduced. Only the active agents, the males, in the SIT have to be dealt with.
- Monitoring costs, in combination with female specific traps, are reduced, as only wild females are trapped and not sterile males.
- The males can be aged before release without mating, and as a consequence, they are released closer to sexual maturity.
- Sterile stings by females are eliminated, and SIT can be used for control as well as eradication.

GSS for the medfly are now used in most of the mass rearing facilities worldwide. In 2001, the overall production capacity was 1,400 million males per week. Research is ongoing to generate improved GSS (e.g., by introducing a marker for the discrimination of wild and released flies). In the future, it may be possible to use genetic transformation techniques to produce GSS for SIT programs. In addition, efforts have begun to construct GSS for other key pest species such as the screwworm fly.

Genetic Transformation

ALFRED M. HANDLER
USDA, Agricultural Research Service, Gainesville, FL, USA

Genetic transformation is a process that involves the introduction and expression of foreign genes in a host organism. This expression can result from the extrachromosomal, or episomal, presence of genes in nuclei that may persist if the introduced DNA has a mechanism for replication. Extrachromosomal expression, however, is most often transient as the DNA becomes diluted with cell division. Expression also can result from the integration of foreign DNA into somatic chromosomes that can persist through the lifetime of the organism, but not be inherited. Alternatively, foreign genes may be stably inherited if incorporated into the genome of the germ-line, known as germ-line transformation. This is the most common type of genetic transformation in insects.

Transient or somatic transformation can be achieved in several ways, and most often is used for testing promoter regulatory sequences. Most simply, DNA, usually in the form of circular plasmid molecules, is introduced into tissue by microinjection, biolistic bombardment, or electroporation. The DNA within those plasmids that is taken up into nuclei usually are subject to transcription similar to chromosomal DNA. DNA also can be integrated into viral vectors that may persist extrachromosomally or integrate into somatic chromosomes, and this presents an effective means of transient gene expression. Viral vectors for this purpose include densoviruses, subgenomic Sindbis virus, and pantropic Moloney murine leukemia virus (MoMLV). Transient expression in a foreign host also is possible by gene expression from bacterial symbionts in what is called "paratransgenesis." This may be inheritable if the genes of interest are stably incorporated into the symbiont, and if the symbiont population is inherited. Examples of paratransgenesis include the expression of foreign genes in the bug, *Rhodnius prolixis*, via the bacterial symbiont *Rhodococcus rhodnii*, and the potential for foreign gene expression in *Wolbachia*.

Germ-line transformation that is stable and inheritable most commonly is achieved using transposable element, or transposon, based vector systems. This was first developed for *Drosophila melanogaster* using the *P* element transposon discovered in the same species. The *P* element belongs to a class of transposons that transpose in a precise or nearly precise fashion by using a DNA intermediate. These elements share general structural features including inverted terminal repeat sequences that surround a transcriptional unit that encodes a transposase enzyme. Transposases act at or near the terminal sequences to catalyze the transposition process that includes excision of the entire element from one chromosomal site and insertion into another site. All of the transposons currently in use for germ-line transformation belong to this general class of elements, and are used in a binary vector-transposase helper system. In this system the transposon vector plasmid includes the inverted terminal repeat sequences and subterminal sequences required for mobility that surround a selectable marker gene and other sequences of interest. The transposase gene within the vector is either deleted or made defective, and vector transposition depends upon a separate helper plasmid that includes the complete transposase gene but not the terminal sequences necessary for integration. Thus, when transiently expressed in the germ cells, the helper transposase can catalyze chromosomal integration of the vector, but is lost in subsequent cell divisions allowing the vector integration to remain stable.

Currently, the two transposon systems developed for *Drosophila melanogaster* transformation, based on the *P* and *hobo* elements, do not function or are highly inefficient in other insect species. Four other transposon systems, discovered in other *Drosophila* species or other insects, function in a wide range of insects including *Drosophila*. These include the *Hermes* element from *Musca domestica*, the *mariner* Mos1 element from *Drosophila mauritiana*, *Minos* from *Drosophila hydei*, and *piggyBac* from *Trichoplusia ni*. Together, these systems currently have been used for germ-line transformation of more than 20 species within the Diptera, Lepidoptera, Coleoptera, and most recently, the Hymenoptera.

A critical component of transformation is the use of selectable marker systems used to identify transformed, or transgenic, individuals. Eye color markers are used routinely in *Drosophila*, and similar markers were used in the first transformation of tephritid fruit flies and mosquitoes. This was possible owing to the existence of mutant eye color strains and their wild type alleles cloned as recombinant DNA. Vectors carrying the wild type marker gene integrated into a mutant host strain allow transformed insects to be identified by visible detection of their wild type eye-color phenotype. Later transformations in species not amenable to such "mutant rescue" selections relied on the use of dominant-acting visible marker genes. These include the green fluorescent protein (GFP) from the jellyfish, *Aequora victoria*, and variants of this gene that emit blue (BFP), yellow (YFP), and cyan (CYP) light under epifluorescence optics. The most recent fluorescent protein in use is the DsRed fluorescent protein from the coral *Discosoma striata*. Chemical and drug-resistance genes also have been used as dominant-acting selections, but these often have proven to be unreliable owing to natural resistance mechanisms resulting in the selection of non-transformed individuals.

In addition to the initial selection of transformant insects by marker detection or selection, transformation must be verified by molecular tests that include DNA Southern hybridization, DNA sequencing of the chromosomal integration site, and chromosomal in situ hybridization. These tests confirm chromosomal integration, determine the number of integrations, and assess whether integration has occurred by a transposon-mediated process. The latter confirmation is possible since most transposons duplicate their insertion site sequence, with some transposons integrating solely into a defined nucleotide sequence such as TA or TTAA. In some instances vectors integrate by a random or fortuitous recombination event resulting in integration of the entire vector plasmid, and often in a rearranged fashion. Such integrations can be useful, but may be problematic since rearrangements can disrupt genes within the vector, and in some cases the selection marker may remain intact while other genes of interest become nonfunctional. The potential for vector integration by recombination exists for all insect species, but thus far it is most prevalent in mosquitoes.

Transgenic insects have a wide potential of uses for basic biological analysis and practical application for pest and beneficial species. Transposon-mediated germ-line transformation is especially useful for insertional mutagenesis for functional genomics analysis. Transposon vectors are mutagenic since they can disrupt gene function as a result of chromosomal insertion. Genes and regulatory sequences of interest that are interrupted in this way can be identified by a mutant phenotype or reporter gene expression, and isolated by probing for or amplifying the transposon vector sequences. Numerous genes and genetic pathways involved in development and behavior have been investigated in this way in *Drosophila*, and the availability of transformation vectors for nondrosophilid species now makes the use of these methods, and sophisticated genetic analysis, possible for a wide range of insects.

In addition to further investigating insect genetics and biology by functional genomics studies, strategies also are being modeled and tested in *Drosophila* for the use of transgenic insects for biological control. The first of these will improve existing programs such as the sterile insect technique (SIT) by creating strains that are genetically marked, and allow for genetic-sexing (due to female lethality) or male sterility. Sexing and male sterility should occur in response to a conditional or suppressible gene expression system so that the strain could breed normally under permissive conditions. Of considerable interest is the possibility for new strategies for biocontrol, also based on conditional systems integrated into transgenic strains, that result in the death of the released insects and their offspring in response to changes in diet or environmental conditions. The most common strategies at present include those utilizing a lethal gene expression system that is suppressed by the antibiotic tetracycline, or its analogs, which can be provided in diet but is not present in the field. Other strategies include use of temperature sensitive lethal genes that result in death of host insects at elevated field temperatures, but where strains can survive at lower laboratory rearing temperatures.

The greatest challenge for the effective use of transgenic insects in such highly promising strategies will be the comprehensive ecological risk assessment necessary for the field release of such strains. Transposons that are used as vectors are naturally mobile genetic elements, and many have become distributed among insects and other species by horizontal transfer. Thus, a primary concern for their use in practical application will be the potential for vector movement into unintended host organisms. Vector mobilization or instability also will have serious consequences relating to the effectiveness of the transgenic strain, since the desired traits will be lost with the vector. These concerns for vector stability are diminished by use of vectors that are defective, so that they can be mobilized only by an exogenous source of transposase, or helper plasmid, such as that used for the transformation event. While the helper transposase should not persist in the host, the same or related transposon system may exist in the host or a symbiont or infectious organism resulting in mobilization, or instability, of the vector. Methods to more thoroughly evaluate vector stability, and the creation of new vectors that cannot be re-mobilized, will be our greatest challenge for the effective use of genetic transformation techniques to control pests and improve beneficial insect species.

Gene Transfer

The movement of a gene or group of genes from a donor to a recipient.

Gengidae

A family of bugs (order Hemiptera, suborder Fulgoromorpha). All members of the suborder are referred to as planthoppers.

► Bugs

Geniculate

Elbowed or abruptly bent. When used with antennae it is equivalent to elbowed antennae.

Genitalia

The modified abdominal segments used in copulation and release of sperm or eggs.

Genome

The total complement of DNA in an organism. The total genetic composition of the chromosomes.

Genomes of Insects

MARJORIE A. HOY
University of Florida, Gainesville, FL, USA

The total complement of DNA in an insect is the genome. Nuclear genomes in insects consist of the chromosomes, consisting of DNA and proteins. The nuclear genome is the largest contributor of genetic information within an insect. However, mitochondria, which are organelles in the cytoplasm, also are components of the genome. Mitochondria are derived from bacteria that became essential symbionts of eukaryotic organisms and contain a number of genes essential to the insect. Finally, in addition to the nucleus and mitochondria, many insects contain intracellular and extracellular microorganisms that provide essential services to the insect. Symbionts may be bacteria, viruses, fungi or spiroplasmas that live in or on their insect hosts. Many insect symbionts are unable to survive outside their host and many insects cannot survive without the services of their symbionts. Thus, insects contain genetic information from several sources.

Nuclear Genome Size and Content

The nuclear genome is the most important and largest source of genetic information in the insect. However, the nuclear genome size in arthropods seems to bear little relationship to the complexity of arthropod morphology or to the number of genes encoded. Nuclear genome size varies widely among insects, with up to 250-fold differences in C values known. C stands for constant or characteristic and denotes the fact that the DNA content (size) of the haploid nuclear genome is fairly constant within a species.

C values vary widely among insect species. Size is usually measured in picograms (pg) of DNA or in kilobases (kb) of DNA sequence. For example, the locust *Schistocerca gregaria* has a C value of 9,300,000 kb, 52-fold more than that of the fruitfly *Drosophila melanogaster* yet it is unlikely that the locust is more complex genetically. Likewise, nuclear DNA content varies by five-fold among tenebrionid beetle species.

Genome size also can vary within insect species; diploid cells in the mosquito *Aedes albopictus* contain 0.18–6 pg of DNA and C values vary by three-fold (0.62–1.6 pg) among different populations. The amount of DNA in insect cells is difficult to measure because many tissues are polyploid (containing more than the normal two copies of each chromosome), with different tissues having different degrees of ploidy.

DNA consists of four types of nucleotides containing the bases guanine (G), cytosine (C), thymine (T) and adenine (A). The base ratios in insect DNA are lower than those found in vertebrates, with guanine + cytosine bases (G + C) comprising from 32 to 42% of the DNA bases, compared to 45% for vertebrates. If DNA base composition were random, 50% of arthropod DNA would be G + C.

Sequencing Nuclear Genomes

The entire nuclear genomes of several model species, including humans, the mouse, the fruitfly *Drosophila melanogaster* and the nematode *Caenorhabditis elegans*, have been sequenced in an effort to understand the evolution of genes and genome function. To make the immense amounts of DNA sequence data available to scientists, databanks for depositing the sequences are expanding rapidly. There are three major database sites on the world wide web: the DNA Data Bank of Japan (DDBJ), the European Molecular Biology Laboratory Nucleotide Sequence Data Library (EMBL) and the GenBank Genetic Sequence Data Bank (GenBank). Subsets of the databases also have been organized. For example, there is a database of mitochondrial DNA sequences, a eukaryotic promoter database, a database of restriction enzymes, a database for intron sequences and a database for homeodomains.

The nuclear genome of only one insect, *Drosophila melanogaster*, had been sequenced completely by the date of this writing (2002). The genomes of other species may be sequenced in the future when costs for sequencing decline. The *D. melanogaster* genome contains approximately 180 megabases (Mb or million bases) of DNA located on four chromosomes. A third of the DNA is noncoding heterochromatin, meaning that it does not code for a protein. Heterochromatin typically is found in the centromeres, telomeres and other regions of the chromosomes that do not contain functional genes. Heterochromatin was named this because it stains differently than euchromatin, which is DNA that contains coding sequences. The 120 Mb of coding DNA is on the two large autosomes and the X chromosome; the fourth chromosome is mostly heterochromatin, with only about 1 Mb of coding DNA.

Prior to the start of the *Drosophila* Genome Project, approximately 3,800 different *D. melanogaster* genes had been mapped and many had been associated cytogenetically with one of the 5,000 bands visible on stained polytene salivary gland chromosomes. Approximately 3,000 transcription units (DNA sequences that are transcribed into messenger RNA) had been placed on the cytogenetic map by localizing the DNA on specific polytene chromosomes by a molecular process called *in situ* hybridization. Nearly 10% of the total, 1,300 genes, already had been cloned and sequenced by individual laboratories.

The Genome Project initially was controversial because some feared that it would take funding away from individual research projects, would cost too much, and take too long. Despite this controversy, a *Drosophila* Genome Project was initiated as a collaborative effort among academic and government scientists with public funding. Later, a commercial company (Celera) initiated its own *Drosophila* Genome Project using a different approach.

The actual sequencing of the *Drosophila* genome by Celera began in May 1999. By late fall of 1999, sequencing was completed and multiple computers had assembled the DNA sequences in order! This amazingly rapid conclusion to the project was facilitated by the availability of the sequences produced by the public consortium. The genome sequences were published in the journal Science in March of 2000 and the project represents a major scientific milestone. The entire *Drosophila* sequence is available in GenBank and at FlyBase on the worldwide web. FlyBase is a database of genetic and molecular information and includes information on genes, alleles (variations of genes), phenotypes, transposons (movable genetic elements present in the genome), clones, stock lists, the locations of *Drosophila* workers, and bibliographic references (Table 3).

Several unexpected results were found in the *Drosophila* genome. Early analyses of the *Drosophila* genome suggest that there are only 13,600 genes, which is slightly fewer than the number found in the nematode *Caenorhabditis elegans*. This number (13,600) is far fewer than the 30,000 originally estimated for *D. melanogaster*. However, *Drosophila* has a relatively large number of overlapping genes, so additions eventually may be made to the total.

Immediately after obtaining the *D. melanogaster*-genome sequences, a comparison was made to the genomes of *C. elegans* and the yeast *S. cerevisiae* in the context of cellular, developmental and evolutionary processes. These comparisons indicated there are many genes left to be studied in *Drosophila*.

Analysis of the *Drosophila* sequences also indicated this insect is surprisingly relevant to the study of genes and metabolic pathways involved in tumor formation and development in humans. Many of the well-studied signal pathways in tumor development in humans are conserved between flies and humans: at least 76 *Drosophila* genes are-homologs to mammalian cancer genes and are under intensive study. Furthermore, 178 (62%) of the 287 known human disease genes can be found in *Drosophila*, including genes causing neurological problems (Alzheimer' s disease, Huntington' s disease, Duchenne muscular dystrophy, juvenile-onset Parkinson' s disease). In addition, analysis of the *D. melanogaster* genome may prove useful in the study of renal, cardiovascular, metabolic and immune diseases, malformation syndromes, and cancer. The *D. melanogaster* genome represents a treasure trove of information that can be mined for years to come.

Chromosome Systems in Arthropods

Many insects are diploid (2n) in their somatic cells and haploid (n) in their gametes (eggs or sperm). Diploidy means that each chromosome type is represented twice. Diploid insects undergo meiosis prior to producing haploid eggs and sperm.

Some insect groups are parthenogenetic (females are able to reproduce without mating) and may be polyploid. Species in the Orthoptera (Blaberidae, Tettigoniidae), Hemiptera (Coccidae Delphacidae), Embioptera (Oligotomidae), Lepidoptera (Psychidae), Diptera (Chamaemyiidae, Chironomidae, Psychodidae, Simuliidae), Coleoptera (Ptinidae, Chrysomelidae, Curculionidae), and Hymenoptera (Diprionidae, Apidae) may be parthenogenetic. Polyploid insects usually are 3n or 4n, but exceptions include curculionid weevil species that are 5n and 6n. Parthenogenesis has not been found in the Diplura, Protura, Odonata, Plecoptera, Dermaptera, Grylloblattodea, Zoraptera, Megaloptera, Mecoptera and Siphonaptera, although it is not clear that species in these groups have been examined carefully for this attribute.

Parthenogenesis

Parthenogenesis is reproduction in which progeny are produced by unfertilized females. The mechanisms involved in parthenogenesis are diverse but can be divided into three major types: arrhenotoky, thelytoky, deuterotoky. Deuterotoky involves the development of unfertilized eggs into either males or females, and at least one insect, a mayfly, is reported to exhibit facultative deuterotoky. In the more common arrhenotoky, insects are haplo-diploid, with males developing from unfertilized eggs and females developing from fertilized eggs. The entire order Hymenoptera and many species in the Hemiptera, Thysanoptera, and Coleoptera are arrhenotokous. When the male of a species is haploid, its germ line nuclei contain half the number of chromosomes present in the corresponding diploid nuclei of the female and meiosis is modified so that the sperm remain haploid and do not undergo the typical reductional division.

Insects that exhibit thelytoky have females only. Thelytoky has arisen repeatedly in evolution and consists of several types. Thelytoky can be induced experimentally in a number of ways. In some cases of thelytoky, eggs only develop after penetration by a sperm (pseudogamy or gynogenesis), but the sperm nucleus degenerates without fusing with the egg nucleus so that the sperm makes no genetic contribution to the embryo. The sperm may be derived from the testis or ovotestis of a hermaphrodite or from a male of a different, but closely related, species.

Thelytoky may be the sole mode of reproduction in a species or it may alternate with sexual reproduction in regular manner (cyclical thelytoky). Cyclical thelytoky is found in aphids, gall wasps and some cecidomyiids. In species that reproduce by cyclical thelytoky, genetic recombination is possible. In species with complete thelytoky, there is no way in which mutations that have occurred in two unrelated individuals can be combined in a third. Thelytokous reproduction can be induced in the eggs of many insect species by pricking the egg, or by exposing it to chemical agents or heat. In a number of normally bisexual insects, a few eggs deposited by virgin females can hatch spontaneously; the incidence of such egg hatch can be increased by artificial selection. The capacity for artificial parthenogenesis, induced thelytoky, or facultative thelytoky indicates that some capacity for parthenogenesis is probably present in all eggs. Thelytokous species or thelytokous populations of bisexual species have been found in the Diptera, Hymenoptera, Lepidoptera, Orthoptera and Coleoptera.

In the Hemiptera, both arrhenotoky and thelytoky occur, but even more complex genetic systems are found. For example, in mealybugs (Pseudococcidae), both males and females develop from fertilized eggs but, in the embryos that develop into males, the paternally derived chromosomes become heterochromatic (stain differently with a dye), are genetically inactive and not transmitted to male progeny. This genetic system has been called parahaploidy. Some method of chromosome imprinting is probably involved to ensure that the paternally derived chromosomes are eliminated in parahaploidy and not the maternally derived ones.

Endopolyploidy in Arthropods

Cells within insects may contain the typical diploid (2n) number of chromosomes or may contain multiples of the haploid (n) number. The discussion of chromosome number (ploidy) is confusing because, in most insects, some of the somatic tissues exhibit high levels of endopolyploidy (multiple copies, greater than 2n, of chromosomes may be present in some cells) while other cells may be diploid.

For example, haploid male honeybees (which have one copy of each chromosome in their testes cells) have about the same amount of DNA as diploid females (which are 2n in the ovaries) in some of their other tissues. This increase in chromosome number occurs because nuclei in some of the tissues of the male undergo repeated cell divisions so that equal amounts of DNA are present compared to the diploid (2n) females. In some cases, haploid insect males exhibit higher levels of endopolyploidy than the females of the same species.

Polyploidy of all cells in the body occurs when the chromosome number in an organism increases over the usual diploid (2n) amount, usually by duplicating the number of chromosomes to 3n or 4n. Thus, polyploidy can occur in all cells of an insect or in just some tissues (endopolyploidy). A few insects are polyploid in all tissues, but many have polyploid tissues. For example, the diploid blood cells of the silkworm *Bombyx mori* contain 1 pg of DNA per blood cell, but a polyploid silk gland cell, which is metabolically much more active, in the same individual contains 170,000 pg of DNA. DNA content within cells also varies with developmental stage. At metamorphosis, the amount of DNA in *B. mori* declines by 81% after adults emerge from the pupal stage, which is probably due to histolysis of the polyploid larval silk glands and other polyploid cells that are not needed by the adult moth.

Noncoding DNA

DNA in the nuclear genome can be coding or noncoding. Coding DNA sequences code for enzymes (proteins that facilitate metabolic processes) and structural proteins. Coding DNA is transcribed into messenger RNA and then translated into proteins. In addition, the coding DNA is transcribed and the resulting RNA is used directly (without translation into a protein) as transfer RNAs or ribosomal RNAs.

Noncoding DNA does not code for any known product, although it may have a function or functions. Noncoding DNA can constitute 30% to more than 90% of the insect nuclear genome. Noncoding DNA has been called junk or parasitic or selfish. There are several hypotheses to explain its persistence in nuclear genomes. One suggests that the noncoding DNA performs essential functions, such as regulating gene expression. A second hypothesis is that the noncoding DNA is maintained because it is linked physically to functional genes; the excess DNA is not eliminated because it does not affect fitness of the organism. A third hypothesis suggests that noncoding DNA is a functionless parasite that accumulates and is actively maintained by selection. A fourth hypothesis is that noncoding DNA has a structural function, perhaps for compartmentalizing genes within the nucleus, or for maintaining a structural organization (nucleoskeleton) within the nucleus. The lack of correlation between genome size, complexity and gene number remains a puzzle. Unless the noncoding DNA has a function, it should constitute a load upon the insect and be lost over evolutionary time.

Much of the noncoding heterochromatic DNA in insects is repetitive DNA, DNA sequences that are repeated several times to millions of times. Repetitive DNA is found in heterochromatin near centromeres (regions of the chromosomes to which spindle fibers attach so that chromosomes can be distributed to the daughter cells during mitosis or meiosis), telomeres (the ends of chromosomes) and other heterochromatic regions. Some repetitive DNA sequences are repeated 100 to 10,000 times and include genes that code for ribosomal RNA and transfer RNA.

Species vary in the amount of repetitive DNA in their genome. For example, *Drosophila melanogaster* has about 30% of its genome as heterochromatic DNA, but about 60% of the genome of *Drosophila nasutoides* is repetitive DNA. Aphids have small amounts of repetitive DNA, and scientists have speculated that this reduced amount of repetitive DNA could be associated with a faster development time.

Satellite DNA is a type of highly repetitive DNA that differs sufficiently in its base composition from the majority of DNA in an insect that it separates out as one or more distinct bands when DNA is isolated by centrifugation with cesium chloride. Satellite DNA is rich in either A + T or in G + C sequences, and is found in long tandem arrays within the heterochromatic regions of chromosomes.

Even within an insect family, genome organization can vary. Total DNA in the genome of four mosquito species (*Anopheles quadrimaculatus*, *Culex pipiens*, *Aedes albopictus* and *A. triseriatus*) varies from 0.19 to 0.90 pg with the amount of repetitive elements varying from 0.01 to 0.15 pg. Generally, the amounts of repetitive DNA increase linearly with genome size in these mosquitoes. Intraspecific variation in the amount of highly repetitive DNA was found in *A. albopictus* colonies and may be due to differences in the number or type of transposable elements. Transposable elements are independent DNA or RNA elements that can move from one site to another in the genome and between genomes. The amounts of repetitive DNA in mosquitoes varies from 20% in *An. quadrimaculatus* to 84% in *A. triseriatus*. Because genome organization of relatively few insect species has been studied, it is difficult to determine the significance of these patterns.

Mitochondria

In addition to the nuclear genome, insects contain mitochondria in the cytoplasm. Mitochondrial chromosomes are circular, supercoiled, double-stranded DNA molecules. The mitochondrial chromosome of *Drosophila* contains approximately 18.5 kb of DNA and each mitochondrion contains several copies of the chromosome. Mitochondrial genes in insects lack introns (segments of DNA in the middle of coding regions that are normally removed prior to translation into proteins) and intergenic regions (noncoding regions between coding regions) are small or absent. The ribosomes found in the mitochondria are smaller than the ribosomes in the cytoplasm. Mitochondria contain distinctive ribosomes, transfer RNAs, and aminoacyl-tRNA synthetases. Mitochondria have their own genetic code that differs slightly from the universal genetic code.

The complete sequences of a number of insect mitochondria are known, which allows comparisons of the organization and evolution of insect mitochondrial genomes. These complete mitochondrial genome sequences can be found in GenBank. One of the first mitochondria to be completely sequences was that of *Drosophila yakuba* which was found to have 37 genes: 2 are ribosomal RNA genes, 22 are transfer RNA genes, and 13 are protein genes that code for subunits of enzymes functioning in electron transport or ATP synthesis. Partial DNA sequences of mitochondria have been obtained from many insects and also can be found in GenBank (Table 3).

Mitochondrial DNA is thought to be inherited only through the mother (in the oocyte) and males are not expected to transmit mitochondria to their progeny via the sperm. However, two studies have shown incomplete maternal inheritance of mitochondrial DNA occurs in *Drosophila simulans*. Most eggs and somatic cells contain hundreds or thousands of mitochondria, so a new mutation can result in a situation in which two or more mitochondrial genotypes coexist within an individual (heteroplasmy). Heteroplasmy, however, is apparently a transitory state. Thus, the majority of individuals are effectively haploid with regard to the number of types of mitochondria transmitted to the next generation.

Mitochondrial DNA evolves faster than single copy nuclear DNA because mitochondria are relatively inefficient in repairing errors during DNA replication or after DNA damage. In Hawaiian *Drosophila*, mitochondrial DNA appears to evolve about three times faster than coding sequences in nuclear DNA. Because mitochondrial DNA does not code for proteins involved directly in its own replication, transcription or translation, it often contains a large number of mutations.

Mitochondrial DNA has been extensively used for systematics or population genetic studies. Genes can be amplified easily from mitochondria by the polymerase chain reaction (PCR) because there are multiple copies in each cell. Mitochondria are easier to purify than a specific segment of nuclear DNA.

Transposable Elements

Every genome probably contains several types of transposable elements. Transposable elements are genetic elements that can move from one site to another in the genome. Transposable elements have been divided into two classes, those that transpose with an RNA intermediate and those that transpose as DNA. Transposable elements have been found in the genomes of most organisms, including humans, bacteria, frogs, mice, maize, nematodes, protozoans and insects. An

organism may contain multiple types of transposable elements. Most of them may be inactive because they have been mutated or suppressed by the host.

Highly mutated transposable elements probably are the source of much of the noncoding repetitive DNA. There are numerous types of transposable elements in insects. The ubiquity of transposable elements in the genomes of organisms has raised a number of unanswered questions about their evolutionary effects. Examples are still being discovered in which new transposable elements are in the process of invading and spreading within insect populations.

Symbionts of Arthropods

As noted above, mitochondria are derived from a microbial intracellular symbiont that became dependent upon its host cell early in the evolution of eukaryotes (organisms with a defined nucleus and cytoplasm). The relationship between mitochondria and the eukaryotic cell is now mutualistic and obligatory. Other organisms (viruses, bacteria, rickettsia, spirochaetes) also may have long evolutionary relationships with arthropods. Some are gut symbionts, while others are associated with the salivary glands and reproductive tracts. Some relationships are obligatory, others are not.

For additional details about the relationship between microbial genomes (contained within symbionts) and the insect genome.

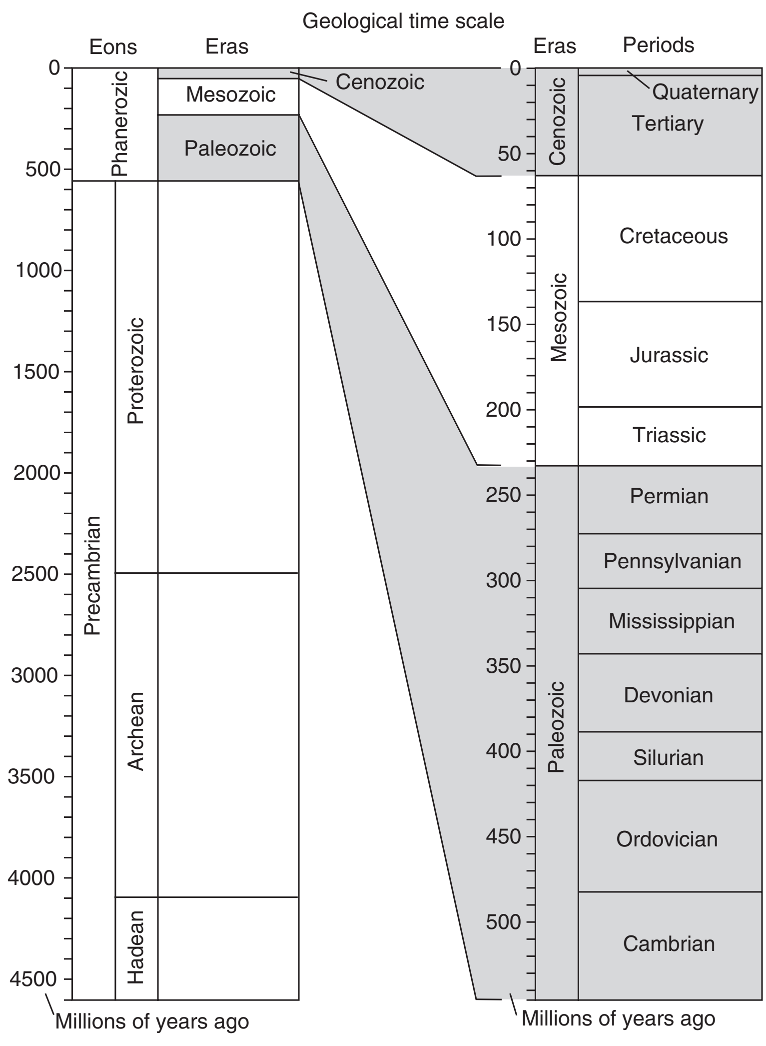
A management system for data associated with precise locations.

Geological Time

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

The time line that describes the history of the earth has been divided into large blocks of time, but each large block is normally subdivided, and subdivided again, for convenience (Fig. 16). The generally accepted divisions are eon, era, period, epoch, and age. The names given the block of time often have historical significance, and may be associated with occurrence of different fossils. For example, the Phanerozoic eon also consists of three major divisions: the Cenozoic, the Mesozoic, and the Paleozoic eras. The "zoic" part of the word comes from the root "zoo," meaning animal. "Cen" means recent, "Meso" means middle, and "Paleo" means ancient. These divisions reflect major changes in the composition of ancient faunas, with each era associated with domination by a particular group of animals. The Cenozoic has sometimes been called the "Age of Mammals," the Mesozoic, the "Age of Dinosaurs," and the Paleozoic the "Age of Fishes." This is not entirely accurate, though there is some basis for these designations. Also, unlike most time lines, the time is expressed not only by date, but from the present. Thus, periods or events are commonly described in millions of years ago (mya). Different spans of time on the geological time scale are usually delimited by major geological or paleontological events, such as mass extinctions. For example, the end of the



Geological Time, Figure 16 A graphical depiction of the geological history of earth (adapted from the Geological Society of America).

Cretaceous period of the Mesozoic era is marked by the demise of the dinosaurs and of many marine species.

The oldest known meteorites and lunar rocks are about 4.5 billion years old, but the oldest portions of Earth currently known are 3.8 billion years old. Sometime during the first 800 million or so years of its history, the surface of the Earth changed from liquid to solid. Once solid rock formed on the Earth, its geological history began. This most likely happened to 3.8–4 billion years ago, but firm evidence is lacking. The oldest time period, the Hadean eon, is not a geological period *per se*. No rocks on the Earth are this old, except for meteorites. During the Hadean time, the Solar System was forming, probably within a large cloud of gas and dust around the sun. The Archean eon was marked by formation of land masses as the earth's crust cooled and plates began to form. The atmosphere was hostile to life as we know it today, consisting mostly of methane, ammonia, and other toxic gases. The only life known from this early period are bacteria and bacteria-like archaea, commencing about 3.5 billion years ago. Things got interesting only in the Proterozoic eon, when life became more plentiful and the first more advanced life (eukaryotic) forms began to appear and oxygen began to accumulate. Eukaryotic life forms, including some animals, began to appear perhaps as long ago as one billion years ago, but certainly by 500 mya.

The Paleozoic era was interesting because well-preserved fossils document this period. The seas were dominated by trilobites, brachiopods, corals, echinoderms, mollusks, and others, and toward the end of this period life appeared on land. On land, the cycads, primitive conifers, and ferns were abundant. The Mesozoic saw the radiation and disappearance of dinosaurs, mammals appeared, while more advanced land plants such as ginkgos, ferns, more modern conifers, and eventually the angiosperms began to appear.

The Cenozoic, the most recent era, is divided into two main sub-divisions: the quaternary and the tertiary periods. Most of the Cenozoic is the Tertiary, from 65 million years ago to 1.8 million years ago. The Quaternary includes only the last 1.8 million years. The Cenozoic is particularly interesting to biologists because most of the life forms we see today developed in this period. It has been called the "age of insects" due to the development of great diversity, but could also be known as the age of flowering plants, birds, etc.; most of the flora and fauna we see today evolved during this period. The last 10,000 years (the Holocene) is sometimes known as the "age of man" and is also the time period since the last major ice age. The time period before the Holocene, the Pleistocene, is interesting because though much of the recent flora and fauna is the same as today, some interesting and now extinct megafauna were present, including mastodons, mammoths, saber-toothed cats, and giant ground sloths. The human species, *Homo sapiens*, also expanded during this time period, and as mentioned previously, there was a significant ice age period.

From an entomological perspective, the Phanerozoic eon (Table 4) was an exciting time. Arthropods ventured onto land during the Paleozoic, perhaps 400 mya, though the Silurian entomofauna consisted of primitive myriapods and arachnids. Fossil hexapods have been recovered from the Devonian, most notably springtails from chert. Insects proliferated rapidly during the remainder of the Paleozoic and thereafter. Interestingly, during the Mississippian (also called the Early Carboniferous) we have no fossil evidence of insects, whereas in the Pennsylvanian (also called late Carboniferous) we have numerous records of early (mostly now extinct) insect groups (e.g., protodonata and protorthopterans from deposits in France). At the close of the Paleozoic, the Permian period, the environment of earth was undergoing significant change, most notably a less tropical climate. Numerous insects from many deposits around the world document over a dozen orders of insects, including the occurrence of "giant" insects.

Geological Time, Table 4 Important time periods of the Phanerozoic eon (543 million years ago to present)

Cenozoic era (65 mya to today)	Quaternary period (1.8 mya to today)
	Holocene Epoch (10,000 years to today)
	Pleistocene Epoch (1.8 mya to 10,000 yrs)
	Tertiary Period (65 to 1.8 mya)
	Pliocene Epoch (5.3 to 1.8 mya)
	Miocene Epoch (23.8 to 5.3 mya)
	Oligocene Epoch (33.7 to 23.8 mya)
	Eocene Epoch (54.8 to 33.7 mya)
	Paleocene Epoch (65 to 54.8 mya)
Mesozoic Era (248 to 65 mya)	Cretaceous Period (144 to 65 mya)
	Jurassic Period (206 to 144 mya)
	Triassic Period (248 to 206 mya)
Paleozoic Era (543 to 248 mya)	Permian Period (290 to 248 mya)
	Carboniferous Period (354 to 290 mya)
	Pennsylvanian Epoch (323 to 290 mya)
	Mississippian Epoch (354 to 323 mya)
	Devonian Period (417 to 354 mya)
	Silurian Period (443 to 417 mya)
	Ordovician Period (490 to 443 mya)
	Cambrian Period (543 to 490 mya)
	Tommotian Epoch (530 to 527 mya)

The Triassic period of the Mesozoic era saw a warming of the earth, and fossil deposits document the occurrence of early insects such as Blattaria and some Orthoptera, Coleoptera, Odonata, Plecoptera, Neuroptera and Grylloblattodea. Transition into the Jurassic was not abrupt for insects, and the fossil record documents few marked changes, but increased radiation.

The Cretaceous period is notable for the radiation of angiosperms that took place. Because many insects are intimately associated with plants through phytophagy and pollination, they were profoundly affected by the availability of these new resources. Many of the modern taxa became established during this period, though more modern taxa such as some Diptera and Lepidoptera radiated later, in the Cenozoic. One very noteworthy feature of the Cretaceous is the great availability of amber. The spread of resin-producing trees through this period and into the Tertiary provided an excellent preservation medium for insects. Thousands of species and perhaps 30 orders have been recovered from amber deposits around the world. As insects transitioned from the Cretaceous to the Cenozoic era, the earth witnessed the appearance of "modern" insect groups such as termites, scale insects, fleas, lice, batbugs, flies, bees, and ants.

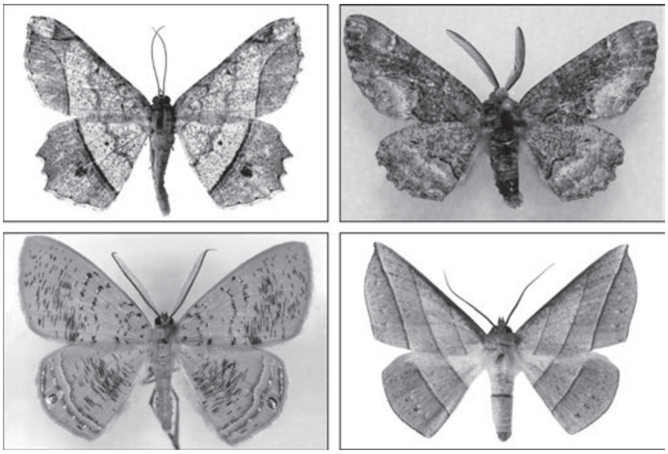
Geometer Moths (Lepidoptera: Geometridae)

John B. Heppner
Florida State Collection of Arthropods,
Gainesville, FL, USA

Geometer moths, family Geometridae, also called inch worms, are the second largest family of Lepidoptea, with about 21,150 described species from all faunal regions; the actual fauna probably exceeds 26,500 species. The major biodiversity is in the Neotropics, with over 6,500 species described, and the Indo-Australian region with about 6,670 species. The family is in the superfamily Geometroidea, in the section Cossina, subsection Bombycina, of the division Ditrysia. The family is divided into eight subfamilies (recent past classifications mainly used only 6 subfamilies): Archiearinae, Oenochrominae, Orthostixinae, Ennominae, Desmobathrinae, Geometrinae, Sterrhinae, and Larentiinae. There are a very large number of tribal names used and much study and consolidation of overlapping groups is still needed in order to sort out all the valid tribes among the different faunal regions. Adults small to large (8–120 mm) (most range 20–45 mm), with head scaling normal; haustellum naked; labial palpi upcurved; maxillary palpi small, 1 to 2-segmented; antennae various but mostly filiform (males usually with thicker antennae then females). Wings triangular, usually with somewhat pointed forewings (sometimes rounded), but sometimes emarginate or with falcate apex; hindwings more rounded in most species (rarely tailed); a number of genera have brachypterous or apterous females (Fig. 17). Body usually slender and delicate, but robust in some genera. Maculation extremely varied, but most species with somber hues of brown or gray; occasionally green (especially among Geometrinae) or very colorful among many tropical genera (especially in Ennominae). Adults mostly nocturnal, but also some crepuscular and diurnal groups. Larvae mostly leaf feeders, typically moving in looping fashion due to reductions in proleg numbers, and many remain motionless when disturbed and resemble small sticks or twigs. Some larvae deposit debris on their bodies to camouflage even further (Geometrinae); also known are attacking predaceous larvae (*Semiothisa* sp.) in Hawaii. Host plants include most all plant families. Some major defoliating pests are known in this family.



Geometer Moths (Lepidoptera: Geometridae), Figure 17 **Examples of geometer moths (Geometridae): *top left*, (subfamily Ennominae), *Macaria monticolaria* (Leech) from Taiwan; *top right*, *Nacophora quernaria* (J. E. Smith) from Florida, USA; *bottom row left*, *Palyas auriferaria* (Hulst) from Florida, USA; *bottom row right* (subfamily Oenochrominae), *Sarcinodes aequilinearis* (Walker) from Taiwan.**

Geometridae

A family of moths (order Lepidoptera). They commonly are known as measuring worm moths or geometer moths.

► Geometer Moths
► Butterflies and Moths

Geophilous

This term, which literally means "ground-loving" is applied to organisms that live on the soil, or favor this habitat.

Georeference

Reference to the location on the earth' s surface based on latitude and longitude coordinates.

Geotaxis

Taxis response with respect to gravity.

Geotrupidae

A family of beetles (order Coleoptera). They commonly are known as earth- boring dung beetles.

► Beetles

Geridae

A family of bugs (order Hemiptera). They sometimes are called water striders.

► Bugs

German Cockroach, *Blattella germanica* (Linnaeus) (Blattodea: Blattelidae)

Blattella germanica is one of the most important nuisance species of cockroaches.

Germar, Ernst Friedrich

Ernst Germar was born in Germany on November 3, 1786. At 21 he moved to Leipzig and bought Hübner' s insect collection. In 1810 he obtained a doctorate in philosophy from Universität Halle. That was the year when the first part of his (1810–1812) work "Dissertatio sistens Bombycum species…" was published. In 1911, he traveled to Dalmatia, resulting in a (1817) book "Reise nach Dalmatien." In 1813 he founded an entomological journal "Magazin der Entomologie" which ran for six years, was interrupted, and resumed publication in 1839–1845, at which time it was merged into "Linnaea Entomologica." He married

Wilhelmine Keferstein in 1815. In 1817, he was appointed (at first without tenure) professor of mineralogy in Universität Halle. His other great entomological works were (1817–1847) “Fauna insectorum europae” and (1824) “Insectorum species novae…” He died in July 1853.

Germarium

An area at the tip of the ovarioles (in females) or sperm follicles (in males) where egg or sperm formation is initiated.

Germ Band

During the blastoderm stage of embryogenesis a region of thickened cells called the germ band forms on the ventral side and elongates. Eventually in differentiates and invaginates.

► Embryogenesis

Ghilarov, Mercury Sergeevich

BELLA R. STRIGANOVA
A.N. Severtsov Institute of Ecology and Evolution, Moscow, Russia

M.S. Ghilarov was born on February 22, 1912, in Kiev (Russian Empire, now the capital of the Ukraine). He was educated at the State University of Kiev (1929–1933) where he specialized in entomology. After graduation from the University, he worked as an entomologist in the Ukrainian Station of Plant Protection. In 1936 he accepted the position of the senior scientific worker in the State Research Institute of Rubber-bearing Plants in Moscow. He studied ecology of soil insects and influence of soil conditions on the fauna of pests in arable soils. In 1938 he obtained a Ph.D. degree. His further scientific interests turned into studies of general problems of insect adaptations to soil environment. In 1944 he moved to the Institute of Evolutionary Morphology, USSR Academy of Sciences (now the Institute of Ecology and Evolution, Russian Academy of Sciences) in Moscow where he remained until the end of his life. In the 1940s he developed the concept of the evolutionary role of soil as an intermediate environment in the course of transition of animals from the aquatic to terrestrial life. For this work he gained the degree of Doctor of Biological Sciences. His monograph “The specificity of soil as insect habitat and its role in insect evolution” (1949) served as the theoretical basis of soil zoology, the modern branch of soil natural history. In 1956 he founded the Laboratory of Soil Zoology in the Institute, and in the 1950–1960s he organized the broad comparative study of soil entomofauna in different regions of the Northern Palearctic. He found that the ranges of a number of soil-dwelling insects coincide with the particular types of the soil (“Zoological method of the soil diagnostics,” 1965). He headed the taxonomic study of soil insects and mites which were resulted in “Key of soil-dwelling insect larvae” (1964), and “Key of soil-dwelling mites” (Sarcoptiformes, 1975; Mesostigmata, 1977; Trombidiformes, 1978). He published more than 500 scientific papers devoted to various aspects of entomology. From 1973 he was the President of the USSR Entomological Society. In 1974 he was elected as a member of the USSR Academy of Sciences and in 1975 he was appointed the Academician-Secretary of the Division of General Biology of the Academy. Beginning in 1978 he also headed the Department of Invertebrate Zoology in the State University of Moscow. He was engaged in a broad range of international activities. He was a member (starting in 1956) and the Vice-president (1967) of the Permanent Committee of International Entomological Congresses, and from 1976–1982 he was the vice-president of the International Union of Biological Sciences. His scientific awards include three USSR State Prizes (1951, 1967, 1980), the Philippo Sylvestry Golden Medal (1965), the Gustav Kraatz Medal of the German Agricultural Academy (1966), a medal of the International Committee on the entomofauna of Middle Europe (1975), a medal of the Zoological Society of France (1976), a medal of the German Academy "Leopoldina" (1977), the I. Mechnikov Golden Medal of the USSR Academy of Sciences (1978) and honorary memberships in entomological societies and academies of sciences of a number of countries. He passed away in Moscow, USSR, on March 6, 1985.

Ghost Moths (Lepidoptera: Hepialidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Ghost moths (sometimes also called swifts), family Hepialidae, comprise about 496 species and occur in all faunal regions, although most species are in the ancient refugia regions of Australia, South Africa and Chile. The family is the main component of the superfamily Hepialoidea, in the infraorder Exoporia. Adults small to very large (20–250 mm wingspan), with head roughened; haustellum absent or vestigial and no mandibles are evident; labial palpi small and 2- or 3-segmented; maxillary palpi are minute and 1 to 5-segmented; antennae are very short. Maculation is usually dull with light (Fig. 18) spotting, but can include some green or gold iridescent markings or other light spots or bands. The

Ghost Moths (Lepidoptera: Hepialidae), Figure 18 **Example of ghost moths (Hepialidae), *Zelotypia stacyi* Scott from Australia.**

hindwings tend to be large and overall the adults have large bodies. Adults are typically crepuscular or nocturnal, but a few are diurnally active. Larvae feed as borers on roots, trunks or under bark of trees, various bushes, or grasses, or even leaf litter. A few species are considered pests in Europe, Asia and Australia. This family has the record for egg deposition by a single female, of about 50,000 eggs, which are scattered over potential Host plants during flight. A few are economic. The largest species are the Australian *Zelotypia stacyi* Scott and the Amazonian *Trichophassus giganteus* (Herrich–Schäffer).

Giant Axons

Very large neurons running through the abdominal ganglia of insects, and connecting by electrical rather than chemical synapses. Giant axons promote the rapid transmission of impulses.

Giant Coccids

Some members of the family Margarodidae, superfamily Coccoidae (order Hemiptera).

► Bugs

Giant Butterfly Moths (Lepidoptera: Castniidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Giant butterfly moths, family Castniidae, total 170 known species, mostly Neotropical but with some species also in the Indo-Australian region; likely world total may exceed 180 species. Three subfamilies are known, with the more unusual groups being from Australia and Southeast Asia: Synemoninae, Neocastniinae, and Castniinae. The family is its own monobasic superfamily, Castnioidea, in the section Cossina, subsection Cossina, of the division Ditrysia. Adults medium to large size (24–190 mm wingspan), with head smooth scaled and eyes large; haustellum naked (rarely vestigial); labial palpi often with distal segment erect; maxillary palpi 2 to 4-segmented; antennae clubbed. Body robust. Wings quadratic and broad (Fig. 19); hindwings rounded. Maculation variable but often dark browns with lighter bands or other markings; often colorful with variously colored patches and markings, especially on the hindwings. Adults diurnal or crepuscular. Larvae are borers of monocot plants, including grasses (Gramineae), Cyperaceae, Bromeliaceae, Marantaceae, Musaceae, and Palmae, among others.

Giant Butterfly Moths (Lepidoptera: Castniidae), Figure 19 Example of giant butterfly moths (Castniidae), *Castnia licus* Fabricius from Peru.

A few are economic on banana plants, various palms, and sugarcane. One palm pest from Argentina has become established in southern Spain in recent years.

Giant Hooktip Moths (Lepidoptera: Cyclidiidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Giant hooktip moths, family Cyclidiidae, are a small family of 14 described species, all Oriental plus one species in the southern Palearctic. The family is in the superfamily Drepanoidea, in the section Cossina, subsection Bombycina, of the division Ditrysia. Adults medium to large size (56–85 mm wingspan), with head scaling normal; maxillary palpi small, 3-segmented; antennae serrate or filiform; body slender. Wings broad and triangular, with somewhat acute forewing apex; hindwings rounded (Fig. 20). Maculation mostly pale with gray striae or other markings; dark spot on hindwings in some species, otherwise similar to forewings. Adults are nocturnal. Larvae are leaf feeders. Host plants recorded so far only in Alangiaceae.

Giant Lacewings

Members of the family Polystoechotidae (order Neuroptera).

► Lacewings, Antlions, and Mantidflies

Giant Lappet Moths (Lepidoptera: Eupterotidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Giant lappet moths, family Eupterotidae, total 325 species worldwide (except the Nearctic), but most are Oriental (238 sp.); only four species are recorded in the Neotropics. Three subfamilies are recognized: Janinae (in Africa), Eupterotinae, and Panacelinae (in Australia). Some specialists now include Hibrildinae (plus Tissanginae) in Eupterotidae. The family is in the superfamily Bombycoidea (series Bombyciformes), in the section Cossina, subsection Bombycina, of the division Ditrysia. Adults small to large (23–140 mm wingspan), with head scaling roughened; haustellum (Fig. 21) absent (rarely vestigial); maxillary palpi absent; antennae bipectinate (sometimes tripectinate or serrate); body robust. Wings mostly broad and rounded. Maculation varies but mostly shades of brown or gray with few markings. Adults are nocturnal. Larvae are leaf feeders, usually with many secondary setae. Host plants among numerous different plants, including Acanthaceae, Boraginaceae, Gramineae, Leguminosae, Myrtaceae, Pinaceae, and Rubiaceae, among others. Few species are economic (e.g., rice or forest pests).

Giant Water Bugs (Hemiptera: Prosorrhyncha Belostomatidae)

MARTA GOULA
Universitat de Barcelona, Barcelona, Spain

These aquatic insects are also known as giant fish killers, electric light bugs, and toe biters. They are predators of insects and other small organisms up to the size of tadpoles, small water birds or even fish, and occasionally are known to inflict injury to humans. In humans, a belostomatid bite produces a painful burning sensation that lasts several hours.

Morphology

Belostomatidae are large-sized (up to about 110 mm), ovoid to elongate aquatic bugs. They are brownish, dorsoventrally flattened while ventrally convex. The head extends triangularly in front of the large eyes. They have a stout syringe-like rostrum or beak, which is the result of the pair of mandibles and the two pairs of maxillae evolved in long piercing stylets. The beak is three segmented. A pair of short, 4-segmented antennae are concealed in grooves beneath the head. Segments 2 and 3 have lateral projections. Belostomatidae possess a pair of large compound eyes, but lack ocelli. The head does not overlap the pronotum. The front wings are in the form of hemelytra, with a sclerotized basal region (corium) and a membranous apical region (membrane) with reticulate venation. The hind wings are completely membranous.

The front legs usually are raptorial. They are at least dexterous, as in the genus *Limnogeton*, but in most cases they act as a vice-like grip. Very dense short setae on the under surface of most front leg segments help the insect grasp. Front femora are expanded to contain a powerful musculature that allows the tibia and tarsi to seize the prey. Except in the case of *Limnogeton*, the middle and hind legs are paddle-shaped, and well suited for swimming. They are flattened and broadened, and doubled-fringed with long, fine setae that increase the effective swimming surface. The tarsi may be 2-, 3- or more rarely 1-segmented. There may be a single claw, slightly or greatly reduced, or paired claws, like in the front legs of Horvathiniinae. A metathoracic scent gland system (MSGS) has been reported only in Lethocerinae. In nymphs, the dorsal abdominal scent glands are not functional.

In the apex of the abdomen (tergum 8), the Belostomatidae have a pair of retractable, strap-like appendages that allow snorkeling while the insect is under water. These special respiratory structures are the most distinctive feature of the group. Belostomatidae also are provided with static sense organs, associated with spiracles 2–7.

Giant Water Bugs (Hemiptera: Prosorrhyncha Belostomatidae), Figure 22 Adult giant waterbug, *Lethocerus* sp. (photo courtesy of Dave Almquist, University of Florida).

Taxonomy

Belostomatidae, as Belostomida, were recognized as a group by Leach in 1815. This family presently is arranged in three subfamilies: Lethocerinae, Horvathiniinae and Belostomatinae. Currently, 11 genera and approximately 150 species are recognized. The antennal and spiracular characteristics are most often used to identify subfamilies.

The Lethocerinae are 37–150 mm in length. Formerly it contained a single genus, *Lethocerus*, that was recently divided into three genera: *Benacus*, with a single species *B. griseus*; *Kirkaldyia* also with a single species *K. deyrolli*; and *Lethocerus* with the remaining 22 species. *Lethocerus maximus* (Fig. 22) is the largest true bug and is among the largest insects. Males of Lethocerinae perform emergent-brooding, attending clutches glued to vegetation at the shore.

The Belostomatinae are between 9 and 70 mm in length. They are found worldwide, and contain most of the genera of Belostomatidae, and about a hundred species. *Belostoma*, with approximately 60 species, is the most species-rich genus. Other quite species-rich genera are *Diplonychus* (approximately 6 species), *Abedus* (10 species) and *Apassus* (17 species), while *Sphaerodema*, *Hydrocyrius* and *Limnogeton*, among others, comprise very few species each. *Limnogeton*, with its unspecialized legs and its diet restricted to water-snails, is the most primitive genus. *Poissonia* and *Weberiella*, two monospecific genera, are poorly known. Belostomatinae males perform back-brooding.

Horvathiniinae, which measure 25–30 mm in length, are the least known belostomatid subfamily. In the unique genus *Horvathinia*, nine species were described, but recent revision (2005) left only two species: *H. pelocoroides* and *H. lenti*. Generally, only specimens attracted to light are known. However, recently two adults were collected for the first time in their natural habitat, but nymphs have never been observed. The real position of

Horvathiniinae is uncertain. Egg color is as in Lethocerinae, and the eggs are buried as in Nepidae (water scorpions), but those eggs lack the respiratory horn-like structures typically found in water scorpions.

Biology

Giant water bugs live in many freshwater environments. In Japan, rice fields have been reported to function as alternative wetlands for many aquatic insects, including belostomatids. Overwintering occurs in the mud at the bottom of the rice field. Giant water bugs in the subfamily Lethocerinae inhabit ponds, lakes and slow waters of streams and rivers. Belostomatinae prefer lentic waters, from small puddles to margins of large lakes. *Horvathinia pelocoroides* (Horvathiniinae) has been captured in the province of Corrientes, Argentina, in a permanent shallow pond of about 1 ha surface and 2.1 m depth; during the rainy season, the water level is high enough to drain into a stream. The pond was densely filled with floating hydrophytes dominated by water hyacinth, *Eicchornia crassipes*, and water lettuce, *Pistia stratiotes*. Other belostomatids shared the habitat with *H. pelocorides*. Other fauna, including tadpoles and snails were reported to live in the area. Belostomatids are quite easily reared, so their biology has been extensively studied in laboratory trials.

Belostomatids are good flyers, and this ability is needed to escape (migrate) from drying ponds or streams, or due to shortage of prey. Migration may be related to the lunar cycle, as is the case in *Diplonychus rusticus* or *Lethocerus* sp. (in the latter case, during the full moon). Heavy rains also induce flight activity (called “rainfall response behavior”), primarily as an adaptation to migrate to breeding sites. However, the rainfall response behavior also ameliorates the risk of extinction due to flash floods. For *Abedus aberti*, there is a report that a torrential rainfall threshold of 8.0 min caused one-third of the adults to abandon a rapidly flowing stream; immatures respond more slowly to the flooding cue, usually requiring about 30 min of torrential rainfall. In this species, flash flood mortality normally causes less than 15% mortality because they can perceive danger through rainfall rate, while for most freshwater invertebrates exposed to such flooding the mortality may be more than 90%. Belostomatids are good swimmers, but in the case of *Limnogeton* and in Horvathiniinae, they are less efficient than the rest of the group. Positive phototropism (attraction to light, especially to mercury vapor lamps) of giant water bugs is the basis for their common name “electric light bugs.” Such lights interfere with their normal nighttime navigation as they normally navigate using star light.

Giant water bugs are carnivorous, and either ambush or actively pursue and capture the prey (foraging). They attack moving prey, but not still or immobile objects. Once grasped by the front legs with lightning speed, the prey is pierced with the robust rostrum. The bug then injects venomous saliva containing proteases, hyaluronidases, phospholipases, hemolythic enzymes and heart-stopping neurotoxins. This mixture, similar to that in snake venom, easily subdues (paralyzes and kills) the prey. As a result, the prey’s tissues are liquefied by external digestion, and the bug sucks out that liquid using a cybarial pump. Once grasped, the prey is never released, however it struggles to escape from the predator. The size of prey tends to match that of the predatory bug. The smallest belostomatids prey on water snails, which seems to be an ancient trait of the group. Increasing size allows them to prey on crustaceans, dragonfly nymphs, vertebrate larvae, small fish, and even frogs, salamanders, water-birds, larger fish, and snakes. Except for *Limnogeton*, a specialist in water-snails, the rest of the Belostomatidae have a diversified diet, always including vertebrates. It is hypothesized that the ancestral snail consumption, which requires quite precise movements and tight grasping, is a pre-adaptive trait (a trait evolved for one function but later co-opted for another) that allows the insect to handle more demanding prey such as vertebrates. Some species catch more prey than they can eat, a hoarding behavior. Cannibalism is sometimes reported.

Although living in water, belostomatids need to breath air. Breathing is mediated by the special abdominal airstraps, which are protruded to the surface while lying motionless in the water. They transmit the air to the subhemelytral airstore by a channel, formed by the setae, which converge mesioventrally. Air finally passes to the tracheal system mainly through the dorsal first abdominal spiracle. In nymphs, respiration occurs from the airstore on the ventral surface of the abdomen, and cuticular breathing also plays a key role.

Defensive behavior is well developed in this group. The first reaction to a threat is the motion of the front legs as if to grasp the aggressor. Also, a foul-smelling liquid may be ejected from the anus for more than a meter. In Lethocerinae, the metathoracic scent gland does not play any defensive role, but seems to be essential in marking the trail to the clutch laid on the shore vegetation. The odor of the metathoracic gland does not prevent *Lethocerus* specimens from being eaten by humans in several parts of Asia.

Reproductive behavior of giant water bugs is unique among insects, as paternal care is the rule in most of them. Lethocerinae are emergent-brooders, while Belostomatinae are back-brooders. Only Horvathiniinae seem not to perform brood-caring, and eggs are half-buried in small groups in the wet sand of the shore. When paternal care occurs, a reversal of the typical sexual competition occurs, as the females fight for mates. Most probably, the big size of Belostomatidae, a primary trait, promoted ancillary selection of paternal care. Hatching occurs one or two weeks after egg laying, and nymphal development occurs in one or two months, requiring five molts.

Natural Enemies

Predation of eggs of *Belostoma* by water scorpions, *Notonecta*, has been reported. Also, young nymphs of *Kirkaldyia* are preyed upon by the water scorpions *Laccotrephes*, *Notonecta*, and *Ranatra*, the giant water bug *Appasus*, and dragonflies of the family Aeschnidae.

Belostomatids such as *Belostoma* (Fig. 23) may serve as hosts of ectosymbiont platyhelminths such as *Temnocephala*. Also, *Bodo* kinetoplastid flagellates were isolated from the hindgut of *Lethocerus indicus*. Some belostomatid species have been reported as intermediate hosts for metacercariae of digenetic trematodes; this is the case for several *Belostoma* spp. that are parasitized by the trematode *Stomylotrema* in Brazil and Argentina. Trematode metacercariae lodge in the abdominal cavity of both male and female bugs.

Distribution

Although distributed worldwide, Belostomatidae are most diverse in the tropics. Lethocerinae have a pantropical distribution, with a few temperate representatives. *Benachus* lives in North America and the Caribbean regions, *Kirkaldyia* is distributed in East and Southeast Asia, and *Lethocerus* is a cosmopolitan genus. Belostomatinae genera differ in their distribution. For example, *Belostoma* is known from the Americas, while *Abedus* is restricted to the southwestern USA and to Central America. *Diplonychus* lives in Asia, India, China, and probably Malaysia. *Appasus* lives in Africa and Asia, *Hydrocyrius* is present in Saudi Arabia, Africa and Madagascar, and *Limnogeton* is found exclusively in Africa. Horvathiniinae have been recorded in Central and South America (northeastern Argentina, Uruguay, Paraguay, Bolivia and southeastern Brazil).

Ecological and Economic Significance

Belostomatids play a key role in freshwater ecosystems, where they perform as intermediate-stage predators in the food chain. Their control over invertebrate populations is greater in the absence of fish. *Belostoma* and *Lethocerus* species, among others, may be efficient controllers of freshwater snail populations. As a consequence, they may play a useful role in preventing human and veterinary schistosomiasis, as snails are an intermediate host. *Lethocerus* may be of concern in fisheries, as it may prey on specimens up to 20 cm long. Mosquito and/or chironomid larvae and/or pupae are actively preyed upon, and controlled to some extent, by *Belostoma*, *Diplonychus*, *Spherodema* and *Lethocerus* species. However, pesticide treatments targeted at mosquito larvae, or other biocide treatments for agricultural purposes, may poison water and prove harmful to giant water bugs. *Kirkaldyia deyrolli* is reported to be a threatened-vulnerable species in the Read Data Book of Japan, most probably due to water pollution. Interestingly, *Bacillus* sp. spread to control larval mosquitoes may remain in belotomatid feces and dead bodies, acting as a mosquito-killing microbe repository.

Relative to humans, the main role of these insects is as a food source in several Asian countries where adults of *Lethocerus* are considered a delicacy, and are eaten both fresh and cooked. In Southeast Asia, some species are highly valued for extraction of a very expensive essence from the essence-producing glands. The "essence" is a sex-pheromone, and is produced by males to attract females. It is used by humans in cooking (dipping sauce).

Belostomatids may also be a nuisance because they are attracted to lights, especially when attracted to lighted pools where they might bite swimmers. The role of some giant water bugs as second intermediate hosts of digenetic trematodes may result in medical importance of giant water bugs in some regions. Thus, like many insects, belostomatids display several behaviors that could result in them being classified as either useful or harmful insects.

Evolution

In past times, giant water bugs likely took advantage of shallow waters teeming with small vertebrates or invertebrate larvae, an empty niche unavailable to large predatory fish, which need deeper water. The individuals best adapted to feed on larger prey succeeded over the predators taking smaller prey, in a feed-back cycle whose only limit was egg size and embryo nutrition. Thus, it appears that large body size, a primary trait under natural selection because it allows feeding on bigger prey, has shifted the evolution of Belostomatidae to their current large body size.

Gill

A respiratory structure found in immature aquatic insects, through which they obtain dissolved oxygen. Gills take various forms, and are found at various locations.

Girault, Alexandre Arsène

Alexandre Girault was born in the state of Maryland, USA, on January 9, 1884. He earned a B.S. degree from Virginia Polytechnic Institute in 1903, and then in 1904 became employed by the U.S. Department of Agriculture. During that employment he worked as an applied entomologist on the plum curculio, Colorado potato beetle, and lesser peach borer. In 1908 he moved to Illinois as assistant to the State entomologist and then as assistant in entomology at the University of Illinois. There he worked on insects of stored products, the Colorado potato beetle, and Cimex bed bugs. In 1911, he moved to Australia, as entomologist to the Bureau of Sugar Experiment Stations in Queensland. There, he worked on taxonomy of "parasitic" Hymenoptera. He also studied thrips. Three years later, he returned to the USA to work again for the U.S. Department of Agriculture, but this time in Washington, DC, on the classification of Chalcidoidea. He moved back to Australia in 1917, this time as assistant entomologist to the Queensland Department of Agriculture and Stock. His major work was a monograph (1912–1915) "Australian Hymenoptera Chalcidoidea" of over 900 pages. Many others of his over 300 papers were small notes, some of them badly printed on a small press of his own, and distributed to few institutions and hymenopterists, thus not readily available. He died in Brisbane, Australia, on May 2, 1941.

Gladiators (Mantophasmatodea)

In 2002, German researchers announced the discovery of a new insect order, Mantophasmatodea. The order name is based on the names of their close relatives, the Mantodea (praying mantids) and the Phasmatodea (walking sticks). This was a significant find because a new order had not been discovered since 1915. Indeed, it remains to be seen whether the entomological community accepts the report that this is a new order. It has been a controversial topic since the initial discovery. Some have argued that Mantophasmatodea is a sister group of Grylloblattodea, and that they should be treated as suborders in the order Notoptera. Further, two of the three families were relegated to subfamily status in this system, and the insects were named "rock crawlers," whereas the members of the sister taxon, were called "ice crawlers."

Characteristics

Mantophasmatodea was first found in the Brandenberg Mountains of Namibia in southwestern Africa (since then they have been found widely in the western regions of South Africa, and in Tanzania). They were found at the base of grass clumps growing in rock crevices. In most respects these insects resemble stick insects (Phasmatodea), but have characteristics of praying mantids (Mantodea), and some unique attributes. Superficially, they resemble immature mantids, which are wingless like gladiators, but the gladiators lack the well-developed raptorial front legs of mantids. They differ from stick insects in that the head is hypognathous (pointing downward), the first thoracic segment is the largest, the first and second pairs of legs are raptorial, and the insects are carnivorous. Unlike mantids, the second pair of legs is used in feeding. The thorax appears to be armored, hence the name "gladiators." They are also known as "heelwalkers" because they tend to elevate their tarsi when walking.

Gladiator insects are hemimetabolous, like other orthopteroids. The antennae are long and filiform, the head hypognathous. The thoracic segments decrease in size from anterior to posterior. The femora of the first and second pairs of legs are broadened and armed with spines. The tarsi have five segments. There is slight sexual dimorphism. In males, the subgenital plate has a median projection. The cerci are one-segmented, prominent and clasping. In females, the ovipositor projects markedly beyond the short subgenital lobe. The female abdomen is widest in the middle, whereas in the male it is widest apically. Males are smaller than females. All insects are apterous. They generally are under one cm in length. They are brown or green, and may be uniform or mottled in color, often with a dorsal stripe or stripes. Polymorphism is common.

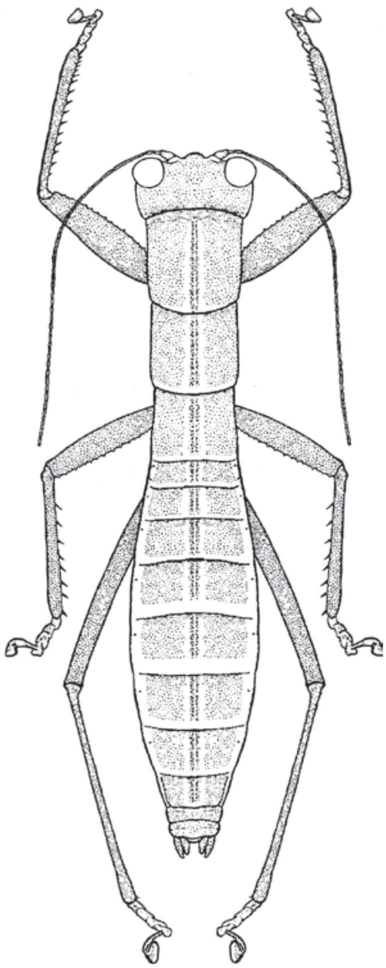
Biology

The eggs of gladiators hatch after the seasonal rains commence, with the nymphs developing during the wet months and the adults maturing at the end of the rainy season. The adults mate, lay eggs and die within two weeks. Mating can be protracted, lasting for 1–3 days. The eggs persist through the arid period in an egg pod in the soil. The pod is composed of sand granules glued together with an exudate. Each pod contains about 12 eggs, and females (Fig. 24) produce several pods.

Gladiators feed on small insects such as flies and bark lice. They may be nocturnal or diurnal. They frequent low vegetation such as tufts of grass. Apparently they communicate vibrationally, as they have been observed taping their abdomen on the substrate.

Taxonomy

The order presently consists of three or more families, several genera (some have yet to be placed in families) and perhaps 12 species. One genus, *Raptophasma*, is known from Baltic amber, dating back



Gladiators (Mantophasmatodea), Figure 24 **Female *Austrophasma* sp. (Mantophasmatodea: Austrophasmatidae) (adapted from Klass et al. 2003).**

about 45 million years. These extinct insects differ from the modern forms in lacking the spines on the femora and tibiae of the first and second sets of legs.

Order Mantophasmatodea
- Family Tanzaniophasmatidae

Glassy-Winged Sharpshooter, *Homalodisca vitripennis* (Hemiptera: Cicadellidae)

TOBIN D. NORTHFIELD, RUSSELL F. MIZELL III
University of Florida, Quincy, FL, USA

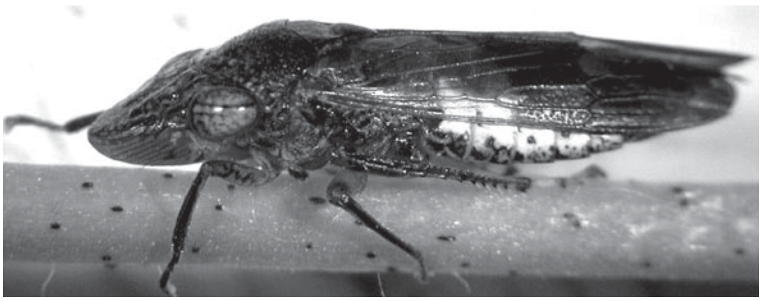
The glassy-winged sharpshooter, *Homalodisca vitripennis* (Germar) feeds on xylem fluid and is damaging to crops and ornamentals through the transmission of *Xylella fastidiosa*, a bacterium that causes phony peach disease, Pierce's disease in grapes, and leaf scorch in almond, plum, elm and oak. In Brazil, a strain of *X. fastidiosa* causes citrus variegated chlorosis, but the current geographic range of the strain does not overlap that of

H. vitripennis. *Homalodisca vitripennis* is native to the southeastern United States, and in the late 1980s or early 1990s spread from Texas to southern California, where Pierce's disease caused $30 million in damage to California vineyards from 1994 to 2000. In California, *H. vitripennis* is a more important vector than the native species because it spreads the disease further into vineyards from surrounding vegetation. Furthermore, in the southeastern United States only muscadine grapes are grown successfully, because only the muscadine varieties are resistant to Pierce's disease. The range of *H. vitripennis* is restricted to areas with mild winters. However, *H. vitripennis* has been accidentally introduced to Hawaii, Tahiti, and Easter Island, Chile. Also, climatological models predict that *H. vitripennis* and *X. fastidiosa* could become established in Central and South America, southern Europe and Asia, Africa, Australia, and northern California.

The "sharpshooter" name refers to leafhoppers in the tribes Proconiini and Cicadellini (Hemiptera: Cicadellidae), and the name has two possible derivations. One reason for the name sharpshooter is the tiny "bullet holes" in branches and stems that are caused by the piercing-sucking behavior. In addition, adults and nymphs quickly move to the opposite side of a branch when startled, and this behavior is similar to the way a military sniper moves to the far side of a tree to avoid detection. The Proconiini tribe comprises 350 species in 56 genera, including *H. vitripennis*, and the range of the tribe includes the Americas and Tahiti.

Homalodisca vitripennis adults (Fig. 25) are generally light brown with black and red wings, and are 11–13 mm in length. Adults usually align head to tail with their heads facing down when feeding, and feed on a wide range of host plants (>100 species), including hardwoods, softwoods, fruit trees, herbaceous crops, and grasses. Some preferred hosts include plum, holly, crape myrtle, citrus, grape and sunflower.

Feeding on xylem may limit the number of competitive interactions *H. vitripennis* encounters, as few insects feed on xylem fluid and there is little or no degradation of xylem quality with insect feeding. In addition, xylem fluid has little or no chemical defensive compounds, which may enable *H. vitripennis* to feed on such a broad host range. However, there are some disadvantages associated with xylem feeding, and *H. vitripennis* has developed some important adaptations to feeding on xylem fluid. To overcome the strong negative pressure associated with xylem tissue, *H. vitripennis* uses a large cibarial pump in the anterior portion of the head to extract the xylem fluid. Furthermore, xylem fluid is approximately 99% water, so a portion of the gut and the Malpighian tubules form a filter chamber that is designed to extract most of the water from the ingested xylem fluid. This process allows nutrients to be absorbed from a more concentrated solution. In addition, *H. vitripennis* feeds for long periods in order to



Glassy-Winged Sharpshooter, *Homalodisca vitripennis* (Hemiptera: Cicadellidae), Figure 25 Adult of glassy-winged sharpshooter, *Homalodisca vitripennis* (Germar).

gain adequate nutrients. Hourly consumption of xylem is often 10–100 times greater than the dry body weight of the individual, so they must produce large amounts of waste. *Homalodisca vitripennis* has become a pest to the tourist industry in Tahiti due to the dense populations of adults and nymphs and the "rain" they excrete that falls on tourists. *Homalodisca vitripennis* excreta consist of a dilute mixture of water and ammonia, which is much less physiologically expensive than urea or uric acid. Most animals do not use ammonia as a waste product, due to the chemical's toxic nature, but *H. vitripennis* waste products are too dilute to cause ammonia poisoning.

Glassy-winged sharpshooters have adapted high assimilation efficiency (about 99%) of amino acids, organic acids and sugars. This assimilation may be due in part to two species of endosymbiotic bacteria that live in the cytosol of *H. vitripennis* cells and aid in attaining the adequate nutritional requirements. Each species of bacteria complements the nutritional advantages of the other and is passed by females to offspring from generation to generation. One species, *Baumania cicadellinicola*, is related to endosymbionts of aphids, tsetse flies, and ants, but is a more primitive species and synthesizes most vitamins and cofactors. The other species, *Sulcia muelleri*, produces many of the essential amino acids that are not abundant in xylem fluid.

Adults often fly from plant to plant, sampling xylem fluid to find optimal hosts and adjust feeding rates to correlate with xylem nutrition. Flight behavior usually consists of short flights from plant to plant and *H. vitripennis* generally flies 2–3 m high, depending on the height of the surrounding vegetation. Dispersal rates vary with available host plants and seasonal conditions, but a single *H. vitripennis* can travel up to 100 m in a matter of minutes. Daily foraging usually occurs between 10 am and 2 pm, during peak xylem flow and this behavior allows adults to attain the best sample of a host in order to make a decision to stay and feed or move on. In addition, *H. vitripennis* may feed on different plants at different times of the day to correlate feeding with maximum xylem flow in the plants. Foraging adults and nymphs are attracted to the color yellow, which may resemble new growth occurring in host plants. *Homalodisca vitripennis* also uses plant volatiles to locate host plants, but olfactory cues appear to be secondary to visual stimuli. Adults do not appear to use pheromones as aggregation cues or to locate mates.

When mating occurs, females line up head to tail on branches, while males fly from branch to branch looking for aggregations of females. Once the male selects a branch to land on, it walks down the branch in a spiral formation and looks for an accepting mate. If the female is not ready to mate, she will stick her legs and abdomen in the air and block off any potential suitors. Mating occurs in the morning or evening, and females deposit eggs at night. Eggs are inserted under the leaf epidermis on the underside of the leaf in groups of 3–28, although eggs are occasionally deposited in fruits or herbaceous stems. A single female can lay up to 1,000 eggs, and eggs hatch approximately 7 days after oviposition. Nymphs are gray and develop through five instars, usually lasting about two months.

Nymphs have different nutritional preferences than adults. Adults prefer to feed on xylem fluid that is high in amides (glutamine and asparagine), and nymphs prefer to feed on xylem fluid with a more balanced spectrum of amino acids. In addition, adults can feed on stems with thicker epidermis than nymphs, due to the adult's thicker proboscis. Pubescent leaves and stems also deter nymphs from feeding, as first and second instars often feed on xylem in leaf veins, and have difficulty reaching the plant through the trichomes. Often eggs are laid on hosts that are acceptable to adults but do not support the development of nymphs, so the nymphs must disperse to find new hosts. However, nymphs have developed excellent dispersal abilities, and third and fifth instars can jump up to 68 and 79 cm, respectively. In addition, nymphs can traverse up to 10 m across a grassy field in three days, and neonates survive an average of 84 h without a host plant.

Nymphs and adults cover themselves in a light coating of lipid-protein molecules called brochosomes, which are produced by special cells in the Malpighian tubules. *Homalodisca vitripennis* secrete brochosomes from the hindgut after each molt and spread them over the integument with their hind legs. In addition, adult females often have conspicuous, white spots of brochosomes on their wings. Females cover their egg masses with these brochosomes by using their hind legs to brush the powdery substance from the forewing patch to the egg mass. All Cicadellidae species cover their integument with brochosomes, but only Proconiini species cover egg masses as well. The structure of brochosomes varies between species, and brochosomes that cover egg masses are structurally different than those that cover the integument. Brochosomes have repellant properties and probably aid adults, nymphs and eggs in the repellency of water and sticky substances, as well as protect against infections. In addition, brochosomes on egg masses may inhibit parasitism by egg parasitoids. Brochosomes may also protect against desiccation and UV light in some instances, as well as aid in thermoregulation.

In northern Florida and southern Georgia there are one or two generations per year. The first generation emerges from eggs laid by overwintered adults in forest edges, and migrates as adults to summer hosts and cropping systems in late May. The second generation migrates back to the forest in August and September, where they spend the winter in reproductive diapause and feed only during warm spells. There are two or three generations per year in California, with the highest oviposition periods in early spring and mid to late summer. During winter months in California adults actively feed on citrus, but do not reproduce. The close proximity of vineyards to these citrus orchards often increases the ease of movement between winter and spring hosts, and can increase the spread of *H. vitripennis* and Pierce's disease into vineyards.

Late in the summer in their native range most *H. vitripennis* eggs are parasitized by mymarid (Hymenoptera: Mymaridae) parasitoids. These parasitoids include *Anagrus stethynioides* and several *Gonatocerus* species, most of which have been evaluated and/or used as biological control agents in California as part of a Pierce's disease management program. The most common parasitoids in the native range are *G. ashmeadi*, *G. triguttatus*, *G. morrilli*, and *G. fasciatus*. Eggs are susceptible to the different parasitoid species at different stages, but generally eggs older than 6 days are not susceptible. Once parasitized, eggs turn black as the parasitoid develops, and eventually the parasitoid chews a distinctive, circular exit hole and emerges. Parasitism often reaches close to 100% in the southeastern United States, but in California parasitism rates rarely exceed 19%. In addition to high mortality from parasitism, *H. vitripennis* populations suffer predation from several generalist predators, including spiders, anoles, dragonflies, and birds.

An entomopathogenic fungus, *Hirsutella homalodiscae*, often infects nymphs and adults, and is most common in mid to late summer. Infected *H. vitripennis* can be recognized by the fuzzy, white fungus growing on the exoskeleton. The generalist fungus *Beauveria bassiana* also infects *H. vitripennis*, but infection rates vary by strain and are generally low. Strains from natural populations in the southeastern United States and Texas are more efficient than commercially available strains. In addition, there are several chemical controls available that have strong effects on *H. vitripennis* nymphs and adults, but low effects on associated egg parasitoids.

The main focus in the control of *H. vitripennis* populations is on limiting the geographic spread of *H. vitripennis*. If *H. vitripennis* populations spread to the north from southern California, the damage to central California vineyards could be devastating. In addition, limiting the international spread is very important to the economic stability of vineyards in Europe and Australia and to the control of citrus variegated chlorosis in South America. The most important method to contain *H. vitripennis* is through the monitoring of horticultural shipments. This is a daunting task, due to the wide range of food and oviposition hosts used by

H. vitripennis. However, if this monitoring is not conducted there could be worldwide consequences.

Glory Moths (Lepidoptera: Endromidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Glory moths, family Endromidae, are a monobasic family of four species, with *Endromis* (one sp.) from Europe, *Dalailama* (one sp.) from Tibet, and *Mirina* (two sp.) from Central Asia. There are two subfamilies: Endrominae and Mirininae. The family is in the superfamily Bombycoidea (series Saturniiformes), in the section Cossina, subsection Bombycina, of the division Ditrysia. Adults medium size (29–74 mm wingspan), with head vertex rough-scaled; haustellum absent (or vestigial); labial palpi short, dropping (2 to 3-segmented); maxillary palpi vestigial; antennae bipectinate; body robust with very long hair-like setae. Wings broadly rounded with somewhat acute apex; hindwings rounded. Maculation dark orange brown, with various white spots and darker striae, or lighter and spotted (Fig. 26). Adult males are diurnal but females are nocturnal. Larvae are leaf feeders. Host plants recorded in Betulaceae, Caprifoliaceae, Salicaceae, Tiliaceae, and Ulmaceae.

Glover, Townend

Townend Glover was born in Rio de Janeiro on February 20, 1813. His parents were English, and it to was Leeds, England, that Townend was sent on his mother's death when he was only six weeks old. He became interested in natural history and enjoyed drawing. He was left an inheritance by his father, and this became available to him at the age of 21. He traveled to visit Munich, studied painting, and visited other European cities before returning to Leeds. His paintings, perhaps because he was shortsighted, were meticulous in detail. In 1836 he sailed for the USA to visit relatives, and traveled widely, especially in the South. In 1838 he moved to the state of New York, married in 1840, spent his time on natural history in the widest sense, and in 1846 bought his father-in-law's country estate. In 1854 he joined the "Bureau of Agriculture" which had just been established in the U.S. Patent Office; his job was to collect information about insects. In 1856–1857 he was sent to British Guiana and Venezuela to collect new planting stock of sugarcane for Louisiana. Next, he worked on insect pests of citrus in Florida. He also studied plant diseases, soils, birds, mammals, reptiles, Indian mounds, and even human nature. In 1859 he resigned from the Patent Office and joined the faculty of the Maryland Agricultural College. In 1862 a new U.S. Department of Agriculture was established, independent of the Patent Office, and Glover was appointed United States Entomologist to it. He became a one-man Department of Agriculture, occupied with projects far

Glover, Townend, Figure 27 **Townend Glover.**

broader than entomology. He recommended fumigation of insect-infested shipments from abroad, a clairvoyant policy which has never been followed totally and adequately. He also was occupied with the biological collections of the (Fig. 27) Department of Agriculture. Ill and with failed vision, he resigned in 1878 and went to live in Baltimore with his adopted daughter. The copper plates that he assembled (273 of them) of his drawings of insects were never used to illustrate a major text on entomology but eventually, after his retirement, were bought by the U.S. Government Committee of Agriculture. He was succeeded as U.S. Entomologist by Charles Riley, another Englishman. He died in Baltimore on September 7, 1883, survived by his wife and adopted daughter.

Glowworms

Although this term is sometimes applied to any insect that produces light, it is more correctly applied to *Arachnocampa* spp. (Diptera: Keroplatidae). These insects live in New Zealand and Australia, often in caves or other dark shelters. The best known are *A. luminosa* of New Zealand, and *A. richardsae*, *A. flava* and *A. tasmaniensis* of Australia. The larvae have organs that produce blue-green light. The light is used to attract prey, which are then ensnared in vertical silk threads coated with sticky mucous material that the larvae dangle from the ceiling of the cave or shelter. They are most frequent along streams, and suffer if exposed to low humidity.

Elsewhere, other light-producing flies include *Keroplates sesioides* in Sweden, *K. testaceus* in Germany, *K. nipponicus* in Japan, and *Orelia fultoni* in the Appalachian Mountains of the USA. Several relatives of these insects produce long sticky threads for prey capture but are not luminescent. Fireflies or lightningbugs (Coleoptera: Lampyridae) are sometimes called glowworms, but it is best not to apply this term to lampyrids.

Glowworms produce about 130 spherical eggs that measure about 0.75 mm in diameter. They hatch in 1–3 weeks depending on temperature. The larvae construct a hollow, tubular nest of silk and mucus, release sticky threads and begin light production. There are five instars, with the larva attaining a length of about 30–40 cm in about nine months. This is the only stage that feeds. The pupa is suspended by two silk strands, and in some species the pupal stage is luminescent. Pupation requires about two weeks. Upon emergence, the adults are quite different in appearance, the female being much larger and heavier. The adults live briefly, not more than one week, and the adult males are more active fliers. The adult females of some species luminance intermittently. Mating occurs upon emergence and females mate only once. Females, being poor fliers, tend to lay their eggs near where they emerged.

Glowworms are not selective in their feeding behavior, taking anything that is captured on their sticky threads.

Glycogen

A polysaccharide found in insects that is one of the two most common carbohydrate stored reserves (the other is trehalose) for insect flight. It occurs principally in the glycogen, fat body, and gut tissues. Glucose is released for metabolism from glycogen. Glucose usually is transported by the hemolymph as trehalose.

GLP

An acronym for "Good Laboratory Practice," representing internationally recognized, sound standards of conduct and procedures. The objective of GLP is to ensure the generation of high quality and reliable test data. In entomology, GLP is usually reference to the context of pesticide assessment, but has broad application to laboratory-based science, and has a corresponding protocol for field research, "Good Field Practice" (GFP).

Glyphipterigidae

A family of moths (order Lepidoptera). They commonly are known as sedge moths.

► Sedge Moths
► Butterflies
► Moths

Gmelin, Johann Friedrich

Johann Gmelin was born in Tübingen, Germany, in 1748, the son of a professor of medicine. In 1768, at the age of 20, he took a three-year journey through Holland, England, and Austria. In 1771, he became an untenured professor of medicine at Universität Tübingen, and three years later a tenured professor at Universität Göttingen. His (1787) treatise "Abhandlung über die Wurmtroknis," which described effects of *Ips typographus*, was a major contribution for forest entomology. He contributed pages 1517–2224 to the 13th edition (1790) of Linné' s "Systema naturae…" He died in 1804 at the age of 56.

Goeldi, Emil (Emilio) August

Emil Goeldi was born in Ennetbühl im Obertoggenburg, Switzerland, on August 28, 1859. His schooling was in Switzerland until in 1882 he entered Universität Jena in Germany and studied zoology and anatomy. After he was awarded a doctoral degree, he was offered three job possibilities overseas, and of these he chose to become a professor in Rio de Janeiro. There, he worked in the Museu Nacional under the auspices of Brazil's emperor, Dom Pedro II. When a republic was proclaimed in 1889, he lost his job and went to live in the montane Colonia Alpina of Serra dos Órgãos. Later, the new Brazilian government offered him the job of founding a new museum at the mouth of the Amazon, so in 1894 he traveled to Belém, and in a few years had built a large institution, the Museu Paraense. He began two scientific journals, the Boletím and the Memórias of that museum which became known, even in his lifetime, as Museu Goeldi. His first name is usually written in Brazil as Emilio, in keeping with Portuguese spelling. He collected extensively and published numerous papers on various animal groups. Some of those works were on insects, including Coleoptera and Diptera (a major work on the mosquitoes of the state of Pará). In 1907 he returned to Switzerland to teach at Universität Bern. He published (1913) a book on medical zoology, "Die sanitarischpathologische Bedeutung der Insekten und Verwandten Gliedertiere, namentlich als Krankheits-Erreger und Krankheits Ubertrager" drawing upon his experiences in Brazil. He died in Zurich on July 5, 1917.

Gold Moths (Lepidoptera: Axiidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Gold moths, family Axiidae, are a very small family of only six Palearctic species in the Mediterranean region, mostly in the genus *Axia*. The family is in the superfamily Drepanoidea, in the section Cossina, subsection Bombycina, of the division Ditrysia. Adults medium size (23–30 mm wingspan), with head scaling normal; labial palpi slightly porrect but very short; maxillary palpi vestigial; antennae bipectinate. Wings elongated and triangular, with relatively acute forewing apex; hindwings triangular and rounded (Fig. 28). Maculation mostly shades of brown to pink, but with at least one bright iridescent mark (often golden color); hindwings unicolorous. Adults nocturnal. Larvae are leaf feeders. Host plants all are in Euphorbiaceae.

Gondwanaland Moths (Lepidoptera: Palaephatidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

Gondwanaland moths, family Palaephatidae, total only 31 known species, with 28 from Chile and Argentina and three from Australia. The family forms a monobasic superfamily, Palaephatoidea, in the section Nepticulina, of the division Monotrysia, infraorder Heteroneura. Adults small to medium (8–36 mm wingspan), with head roughened; haustellum is average length and naked (unscaled); labial palpi short and porrect, and 3-segmented; maxillary palpi 5-segmented (rarely 4-segmented and short), long and folded; antennae rather short. Wing venation is heteroneurous, with frenulate wing coupling, and usually with somewhat falcate forewing tips. Maculation is variable, usually with various spots; without large fringes (Fig. 29). Adults are thought to be diurnally active. Biologies are little known and the single known species has larvae that tie twigs together on its host plants (Verbenaceae and Proteaceae).

Gonopod

An appendage of the genital segment modified for copulation, insemination or oviposition.

Gonopore

The external opening of the ejaculatory duct (in males) or oviduct (in females).

Gorgas, William Crawford

William Gorgas was born on October 3, 1854, near Mobile, Alabama. The son of General Josiah Gorgas, William graduated from the University of the South in 1875. General Josiah Gorgas was an officer in the Confederacy during the American Civil War, so it is perhaps not surprising that William was denied entrance to the premier American military college, the United States Military Academy at West Point, New York. William was determined to have a military career, a prestigious career in earlier days, so he entered the military by way of a medical degree. In 1880 he entered the U.S. Army Medical Corps as an assistant surgeon.

William Gorgas' life was fairly average for about two decades after entering the military. However, he was stricken by yellow fever early in his career, and thereafter he was immune, so was frequently drafted for service wherever yellow fever was a problem. Yellow fever was an enigma at that time, and its appearance, impact, and the inability to control the disease were quite puzzling. Gorgas was dispatched to Cuba during the Spanish-American War, in 1898, when yellow fever was seriously affecting American troops. The prevailing approach for the management of the disease at that time was fire, and the village and hospital to which Gorgas was assigned were torched in September of that year.

In 1898, Gorgas was made chief surgeon of Havana, Cuba, and he followed the generally accepted methods of yellow fever management, relying primarily on sanitation and isolation. However, it was not until the Cuban doctor Carlos Finlay, the English scientist Ronald Ross, and the U.S. Army doctor Major Walter Reed identified the *Aedes aegypti* mosquito as the vector of yellow fever that truly effective practices of management could be implemented. Prior to this time, yellow fever was thought to be transmitted from person to person via personal belongings or merchandise on which the organism was carried, and attempts to prove that mosquitoes could transmit the disease had been futile. Indeed, the earliest attempts to clean up Havana were unsuccessful because although the sanitation efforts cleaned up the water and debris, the relevant vector was favored by clean water and so prospered. However, once all mosquito breeding sites in the city of Havana were eliminated by either preventing mosquitoes from accessing water, or by oiling the surface of water where mosquitoes were likely to breed, yellow fever was effectively suppressed. Thus, Gorgas came to believe that environmental sanitation, and particularly mosquito management, could be used to reduce or eliminate yellow fever.

At the turn of the century, the development of the Panama Canal was in progress. The French were stymied in their efforts to complete the project due to yellow fever and malaria, losing 20,000 lives in an eight year effort to construct the canal. Ironically, the U.S. government seemed similarly inclined to ignore taking adequate measures to prevent workers from contracting the disease. The Canal Commission considered health measures to be extravagant expenditures, but as disease extracted a lethal toll on workers, Gorgas' ideas on sanitation received a better reception. He promoted the draining of swamps in Panama, thereby mitigating malaria and yellow fever and greatly prolonging the life of workers involved in the construction project. Even after conditions improved, Gorgas' enemies were quite effective in discrediting him and his mosquito control policies, and it took the intervention of President Theodore Roosevelt to assure that his procedures would be implemented. Even then, the U.S. military attacked Gorgas' sanitary service. Gorgas prevailed, however, and made the Panamanian cities of Panama and Colon as safe as any city in the United States.

In 1914, based on his successes in Panama, Gorgas was appointed Surgeon General in the U.S. Army. He retired in 1918, but was commissioned to investigate the yellow fever situation in western Africa. Unfortunately, he experienced a stroke in 1920, and died a month later in London on July 4, 1920.

William Gorgas is remembered as the person whose sanitation skills allowed construction of the Panama Canal, a monumental achievement. His achievements at managing yellow fever in Havana are overshadowed by the Panamanian successes, but even the Cuban successes would accord him considerable recognition.

Gossamer-Winged Butterflies (Lepidoptera: Lycaenidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Gossamer-winged butterflies, family Lycaenidae (including blues, coppers, elfins, hairstreaks, and harvesters), total about 5,955 species worldwide; the actual fauna probably exceeds 7,000 species. About 1,125 species are Neotropical. The family is in the superfamily Papilionoidea (series Papilioniformes), in the section Cossina, subsection Bombycina, of the division Ditrysia. Most of the relictual groups are Southeast Asian and African, such as the subfamilies Lipteninae, Poritiinae, Liphyrinae, Miletinae, and Curetinae. The family has eight subfamilies: those just noted, plus Lycaeninae, Theclinae, and Polyommatinae. North temperate species are only found in the latter three subfamilies. Some specialists include Riodinidae as another lycaenid subfamily, and also reduce the subfamily number to five (including the Riodininae), thus the classification is still in flux. Adults small to medium size (6 to 92 mm wingspan) (most average 20 to 39 mm), with body usually slender (rarely robust). Wings mostly rounded, but some with acute forewing apex; hindwings sometimes with tails (usually very narrow tails) (Fig. 30). Maculation varied but often with blues, greens or other bright colors, and with iridescence or lustrous shine, and often without many dorsal spots (more spotting usually on ventral sides of both wings); hindwings often with color spots near tails at the tornal corner of the wing margin (so-called "false heads"); and fringes short but often white or lustrous. Adults diurnal, but a few of the relict genera possibly crepuscular or only in dark forests. Larvae mostly somewhat slug-like, with tubercles and short setae; head usually retractable into thorax. Larvae feed as leaf feeders (some on other plant parts), but many are myrmecophilous and some even are carnivorous on ant larvae or hemipterans (especially Liphyrinae and Miletinae).

Gossamer-Winged Butterflies (Lepidoptera: Lycaenidae), Figure 30 **Example of gossamer-winged butterflies (Lycaenidae), *Hypaurotis crysalus* (W. H. Edwards) from New Mexico, USA.**

Some of the relict groups feed on lichens (Lipteninae). Host plants are in a wide variety of plant families, particularly Fagaceae and Leguminosae. A few economic species are known.

Gradual Metamorphosis

This is a type of incomplete metamorphosis (hemimetabolous development) found in some aquatic insects (Odonata, Ephemeroptera, Plecoptera). Unlike insects displaying the typical form of incomplete metamorphosis, in which the immature and adult stages are substantially the same in body form (differing principally in the presence of fully formed wings among the adults), immature and adult stages of these aquatic insects differ slightly to significantly in appearance as compared to their adults. However, they lack a pupal stage, which is characteristic of insects with complete metamorphosis (holometabolous development). Because these insects depart from the typical pattern of hemimetabolous development, they sometimes are said to have gradual metamorphosis or paurometabolous development. Consistent with this differentiation, the immature are sometimes called naiads rather than nymphs (contrast with incomplete metamorphosis, complete metamorphosis).

► Metamorphosis

Graham, Marcus William Robert De Vere

Marcus Graham was born in the county of Durham, England, on March 25, 1915. As a boy, he became intrigued with natural history. At the start of World War II, he enlisted in the British army, and served in India from 1942 to the end of

1945. But he had begun to publish entomological papers in 1941. At the end of 1945, he entered Trinity College, Dublin, and graduated in 1950 with a B.A. degree and a B.Sc. degree. In Dublin, he studied the taxonomy of Braconidae, then turned to Chalcidoidea. He was soon appointed to the post of curator of the insect collections of the Hope Department of Entomology, Oxford University. He married in 1953. In 1955, he was awarded the degree of D.Phil. from Oxford University. He taught, took part in administration, and conducted taxonomic research on Hymenoptera until his retirement in 1981. His research was meticulous, he solved many puzzles resulting from inadequate descriptions by early taxonomists of Hymenoptera, and became the foremost authority on European Chalcidoidea. He produced major contributions on the European Pteromalidae, Tetrastichinae (Eulophidae), Encyrtidae, and Myrmaridae. He described 60 genera and 475 species of Hymenoptera. Apart from insect taxonomy and botany, he was interested in Romance languages and medieval literature, painting, and naval history. After retirement, he continued to work (his total production was some 200 papers) and was working on a revision of the genus *Torymus* (Torymidae) when he died, on March 27, 1995. He was survived by his wife, Nora, and son.

Gramineous Lepidopteran Stem Borders in Africa

RAMI KFIR
ARC-Plant Protection Research Institute, Pretoria, South Africa

Cereals, especially maize and sorghum, are the most important field crops grown in Africa by commercial and small-scale farmers. Sugar cane is also an important cash crop in many countries on the continent. Although maize and sorghum are grown primarily for human consumption, surpluses are used as fodder for livestock. Among the insect pests found attacking these crops in Africa, lepidopteran stem borers are by far the most injurious.

Given their great economic importance, an enormous amount of literature has accumulated during the past century. The aim of the following sections is to briefly summarize the current state of knowledge on these stem borer pests of cereals. Special attention is given to *Busseola fusca* and *Chilo partellus*, which are the principal borer pests of maize and grain sorghum in Africa, and to *Chilo sacchariphagus*, a serious pest of sugar cane on the Indian Ocean islands, which has recently invaded Mozambique.

Distribution of Major Stem Borers of Maize, Sorghum, Rice and Pearl Millet

WILLIAM A. OVERHOLT
ARC-Plant Protection Research Institute, Pretoria, South Africa

Lepidopteran cereal stem borers in Africa typically occur as complexes of species, with notable regional variation in their distributions. The noctuids *Busseola fusca* Fuller and *Sesamia calamistis* Hampson, and the pyralid *Eldana saccharina* (Walker), are present throughout most of sub-Saharan Africa, but there are important regional differences in the ecozones they inhabit, and their pest status. In eastern and southern Africa, *B. fusca* is a major pest of maize and sorghum at medium and high elevations (greater than 1,000 m), while in West Africa, it is considered to be important from sea level to 2,000 m. *Sesamia calamistis* generally is not a major pest in eastern and southern Africa, whereas in West Africa, this species is one of the most damaging to maize, sorghum and rice. *Eldana saccharina* is primarily a pest of sugar cane in South Africa, while in West Africa, *E. saccharina* is a major pest of maize, and attacks sugar cane to a lesser degree. In some areas of East Africa, *E. saccharina* attacks maize, but tends to arrive late in the season when the crop is less susceptible to yield loss.

Other important stem borers have more limited distributions. *Coniesta ignefusalis* (Hampson) (Crambidae) is the dominant stem borer of pearl millet in the Sahelian region of West Africa, but only a minor pest in other crops and other regions. It also has been recorded from Sudan, Ethiopia and Angola, and thus probably has a fairly wide distribution. *Chilo orichalcociliellus* (Strand) occurs in eastern Africa, mainly in lowland coastal zones, where it once was considered to be a major pest of maize and sorghum. However, recent studies suggest that densities of *C. orichalcociliellus* have decreased due to competition with *Chilo partellus*, an invasive Asian borer. *Chilo partellus* is thought to have arrived in eastern Africa in the early part of the twentieth century, and has since spread to all countries in the eastern and southern parts of the continent. It seems likely that its distribution will continue to expand westward. *C. partellus* is generally the most damaging stem borer of maize and sorghum at elevations below about 1,000 m in eastern and southern Africa. *Sesamia cretica* Lederer, which occurs in Somalia, Sudan, Egypt, and Ethiopia, and *S. nonagrioides botanephaga* Lefebvre, which is found in both East and West Africa, are both important locally. *Chilo aleniellus* (Strand) has been reported as an important pest of maize in Ivory Coast. In addition to stem borers, there are several lepidopteran cob borers in Africa, one of which, *Mussidia nigrivenella* Ragonot (Pyralidae), is an important pest in West Africa. This species is discussed in a later section. The important stem borers of maize, sorghum and millet are listed below (Table 5), along with an approximation of their relative importance in different regions.

Information on rice stem borers is primarily from West Africa, and the Indian Ocean Islands, as these are the areas where rice is an important food crop. *Chilo zacconius* Bleszynski is considered to be the most important stem borer of rice throughout West Africa. *Maliarpha separatella* and *S. calamistis* also are of economic importance in the region. *M. separatella* is the only rice borer that has a widespread distribution in sub-Saharan Africa, and also occurs in the Comoro Islands and Madagascar. Other stem borers in rice in West Africa include *Scirpophaga* spp., *Chilo diffusilineus* (de Joannis), and *S. nonagrioïdes botanephaga* Lefebvre. Additionally, *Chilo aleniellus* (Strand) is mentioned as a rice stem borer in Ivory Coast.

Distribution and Pest Status of African Sugarcane Stem Borers

purposes. Commercial sugar cane production, however, has an interesting history in Africa. Many countries had very strong industries in the early 1900s, which collapsed during various civil wars and for other reasons through the years. Some of these countries now are rehabilitating their industries. A few still have very strong industries, which have withstood the vagaries of time. This section deals only with the commercial sugar industries known to occur in Africa, as it is only from reports and papers emanating from these that pest records are known. Also, for the purposes of this section, Africa is divided into southern, eastern, northern and western regions. The countries known to have, or have had, viable sugar cane industries in southern Africa include South Africa, Swaziland, Zimbabwe, Malawi, Mozambique and Zambia. In east Africa, they are Tanzania, Kenya, Uganda and Ethiopia. In north Africa, these are limited to Egypt, the Sudan and possibly Libya. West African countries producing, or known to have produced, sugar on a commercial scale include Sierra Leone, Ivory Coast, Burkino Faso, Ghana, Nigeria, Cameroon, Gabon, Mali, Senegal, Guinea Bissau and, more recently, Angola.

In Africa, only lepidopteran larvae have been recorded as borers of sugar cane. These can attack the youngest shoots, causing dead hearts, through to the most mature sugar cane stalks. In severe infestations, the rootstock of ratooning sugar cane can harbor developing larvae, which can severely affect the regrowth of the crop. In addition, larvae of some species of Lepidoptera develop in the whole stalk when the cane is mature, others only in the top third, and still others in the bottom third. In different parts of Africa, the same species may develop in the bottom third of mature sugar cane plants, while in other parts, they may develop in the top third of the stalk.

Oviposition by different species of Lepidoptera attacking sugar cane also may vary. Some species prefer to oviposit on the green leaves of sugar cane, either on the abaxial and/or adaxial surfaces of leaf blades, and in sugar cane from one month old to maturity, which may be up to 24 or 30 months old. Other species oviposit in cryptic positions, in older sugar cane behind dead leaf sheaths, in folded dead leaf blades, or even in decaying dead leaf material around the bases of mature sugar cane stalks.

Until 1992, fourteen species of Lepidoptera had been recorded as attacking sugar cane in Africa. The majority of these are indigenous to the African continent. In 1999, a fifteenth species, *Chilo sacchariphagus* (Bojer) (Pyralidae), was confirmed as attacking sugar cane in Mozambique. This is the first record of an exotic lepidopteran establishing on sugar cane in economic proportions in Africa. Prior to this, the only other exotic reported to occasionally attack African sugar cane has been *Chilo partellus* (Swinhoe) (Crambidae).

Most of the boring lepidopteran pests of sugar cane belong to the families Crambidae, Pyralidae, and Noctuidae, and a ranking, in 1994, of these species (using the number of citations in Review of Applied Entomology, 1972 to 1992 to each on sugar cane) has revealed that only four are regarded as major pests in Africa. These are *Eldana saccharina* Walker (Pyralidae), *Chilo agamemnon* Bleszynski (Crambidae), *Sesamia cretica* Lederer and *S. calamistis* Hampson (both Noctuidae) (Table 6). More recently, *Busseola fusca* (Fuller) has been recorded occasionally from sugar cane in West Africa. The following table outlines the distribution of the stem borers regarded as major pests in African sugar cane, and their severity in south, east, north and west Africa.

Eldana saccharina is by far the most injurious stalk boring pest in Africa. It is also one of the few attacking mature (or older) sugar cane stalks. In southern Africa is has been the subject of much research in plant resistance, biological control, insecticide and cultural means in attempts to control it. In southern and coastal eastern Africa, it attacks the lower portion of sugar cane stalks. However, in the Kenyan and Ugandan industries around Lakes Victoria and Albert, respectively, and in West Africa, it attacks the upper third of mature stalks. In many of the more tropical countries, sugar cane is cut at too early a stage for *E. saccharina* to become a pest, although if the cane is not harvested at this early age for some reason, then this borer can affect it seriously.

Chilo agamemnon has received much attention in Egypt, where it is classed as an internode borer, thus attacking the more mature cane stalks. However, it also attacks young plants, causing dead hearts. Researchers in Egypt are working on plant resistance, as well as inoculative biological control using egg parasitoids.

The *Sesamia* species are generally pests of young cane, causing dead hearts. By the time the sugar cane is mature though, these borers have been brought under control by parasitoids, and thus do not become major pests.

Pest Status of *Mussidia nigrivenella* Ragonot, a Cob-borer of Maize in Western Africa

MAMOUDOU SÉTAMOU
Texas A&M Research Center, Texas, USA
and
FRITZ SCHULTHESS
IITA, Cotonou, Republic of Benin,

In West Africa, five borer species are commonly found feeding in maize cobs, but *Mussidia nigrivenella* Ragonot (Lepidoptera: Pyralidae) is by far the most important across all zones. Grain yield losses are relatively low and range from 2 to 25%. Percentage of grain infected by the toxic fungus *Aspergillus flavus* as well as mean aflatoxin content of samples, however, increases exponentially with grain damage. Cob damage by *M. nigrivenella* also promotes the infestation of storage beetles such as *Sitophilus zeamais* Motschulsky, *Carpophilus* spp. and *Cathartus quadricollis* Guérin. Furthermore, damaged cobs cannot be sold as green maize, an important source of cash in the vicinity of centers of population. Thus, in addition to the direct damage, *M. nigrivenella* induces indirect qualitative and quantitative losses in the field and store.

Mussidia nigrivenella is highly polyphagous, and is found on 20 plant species from 11 different plant families, among them cotton, *Phaseolus* bean and cover-crops such as the velvet and Jack-bean. In West Africa, no parasitoids were ever obtained from annual crops, and most alternate host plants. The solitary chalcidid pupal parasitoid, *Antrocephalus crassipes* Masi, was the predominant species with highest and stable parasitism on *Gardenia* spp.

Mussidia nigrivenella has never been described from annual crops in eastern Africa, but according to some anecdotal reports is found on wild host plants. This opens the opportunity of the novel association biological control or expanding the geographic range of a natural enemy species.

Displacement of Native Stem Borers by *Chilo partellus*

WILLIAM A. OVERHOLT
ARC-Plant Protection Research Institute,
Pretoria, South Africa

The invasive stem borer, *Chilo partellus*, has proved to be a highly competitive colonizer in many of the areas it has invaded in eastern and southern Africa, often becoming the most injurious stem borer, and displacing native species. In coastal Kenya, there is evidence that *C. partellus* has partially displaced the indigenous borer, *Chilo orichalcociliellus*. Whether the displacement of *C. orichalcociliellus* will proceed toward complete extirpation in the southern coastal area of Kenya seems unlikely. Recent sampling has shown that *C. orichalcociliellus* continues to persist, and laboratory studies have found that *C. orichalcociliellus* was able to complete development in two native grasses in which *C. partellus* could not develop. This difference in niche breadths of the two species may account for the continued occurrence of the native species. Additionally, a parasitoid of *C. partellus* from Asia, *Cotesia flavipes* (Cameron), has been introduced and established in several countries in Africa. Evidence from coastal Kenya suggests that the introduction of *C. flavipes* has resulted in a marked population decrease of *C. partellus*, but that populations of two native borers, *C. orichalcociliellus* and *Sesamia calamistis*, have slightly increased.

In addition to the work in coastal Kenya, there is evidence of displacement of native stem borers in two other areas in Africa. In the Eastern Province of Kenya, work conducted in the 1980s found that *C. partellus* was present, but less abundant than *Busseola fusca*. However, in the same area in the late 1990s, *B. fusca* was rare and *C. partellus* was dominant. Similarly, in the Highveld region of South Africa, *C. partellus* has partially displaced *B. fusca*.

Several factors may be responsible for the competitive superiority of *C. partellus* over the native stem borers. Various studies have shown that *C. partellus* completes a generation in less time than *C. orichalcociliellus*. As fecundities of both species are similar, the shorter generation time is likely to lead to higher population levels, which may give the alien species a numerical advantage. A more rapid diapause termination compared to both *C. orichalcociliellus* and *B. fusca* has also been shown, which may allow *C. partellus* females to colonize host plants before the two native species, which would be particularly important if the native species avoid previously infested plants.

Damage and Pest Status

RAMI KFIR
ARC-Plant Protection Research Institute,
Pretoria, South Africa

Feeding and tunneling by stem borers can result in serious damage and crop losses. Damage is caused by the larvae, which at first feed on the young leaf funnels at the growing point and then later by tunneling into the stems. Apart from leaf damage, growing points may be killed, leading to stunting and deadhearts or to early senescence of plants. Stem tunneling may cause lodging, but also secondary and insidious effects, such as interference with translocation of metabolites and nutrients, resulting in malformation and loss of grain. There can also be a sharp increase in the incidence of stalk rot. Feeding in ears has been associated with fungal infection and elevated levels of mycotoxins.

Busseola Fusca

In South Africa, crop loss assessments in cereal crops from *B. fusca* attack ranged from 10 to 100%. Although much of this was due to leaf damage in maize, the most severe loss was from stem-boring activity. In Lesotho, seasonal variation in maize yields due to *B. fusca* ranged from 0.4 to 37%.

In Tanzania, 40–100% of the sorghum crop can become infested with *B. fusca*. Together with Kenya, loss of about 12% maize yield for every 10% of plants infested with B. fusca has been documented. In Ethiopia, movement of *B. fusca* larvae into the base of the sorghum panicle resulted in undersized panicles and a 15% yield reduction. In Burundi, using insecticides and exclusion cages, 30–50% of the maize harvest was shown to be lost to *B. fusca*.

In the Northern Guinea savanna of Nigeria, where *B. fusca* is the dominant stem borer, 49% loss of sorghum was reported. Comparative yields on 22 farmers' sorghum fields in Nigeria, sprayed and unsprayed with insecticide, showed a 21% mean loss in yield due to this borer. Losses to *B. fusca* in sorghum crops in Nigeria are very much dependent on the time of initial infestation. Thus, sorghum infested prior to the booting stage suffered the greatest yield losses. The proportion of internodes bored in the lower part of the stalks had a more consistent negative correlation with harvested grain than did the proportion of stalks tunneled. A recent study in Cameroon showed that stem borers, primarily *B. fusca*, were responsible for a 9 g loss in sorghum yield per plant per borer. There was also an 11% crop loss through deadheart.

Chilo Spp

The estimated yield losses in maize and sorghum in South Africa due to *C. partellus* exceeded 50%. A negative correlation between the level of *C. partellus* infestation and yield has been demonstrated. Comparative trials in separate and mixed stem borer populations, using artificial infestation techniques, indicated that *C. partellus* was more injurious to sorghum than *B. fusca*. More damage also was caused by *C. partellus* to long-season sorghum cultivars, mainly due to their longer exposure to stem borer attack while in the susceptible pre-flowering stage.

In Mozambique, the third generation of *C. partellus*, the most important stem borer occurring in the country, was reported to infest 87% of cobs of late planted maize and to cause 70% loss of grain. Infestations of up to 100% of the crop, with considerable yield losses, were recorded in the Maputo and Gaza Provinces and in the Limpopo Valley, in southern Mozambique.

In Zimbabwe, *C. partellus* caused sorghum yields to drop by 50–60%, while in maize up to 70% damage was reported from the fields of resource-poor farmers. However, in the commercial farming areas, where insecticides are routinely applied, maize damage was less than 30%.

In Kenya, 18% loss of maize was attributed to *C. partellus* and *C. orichalcociliellus*, while 88% loss of sorghum crop to *C. partellus* was reported. Heavy stalk damage to maize, and up to 80% of the sorghum harvest, was lost to the latter borer on 20-day-old crops. *Chilo partellus* infestations caused insignificant crop loss when 60-day-old plants became infested. Similar observations were reported from Uganda.

Sesamia spp

In Ghana, a positive relationship between the number of *Sesamia* sp. larvae and the extent of damage to maize stalks, and a negative relationship between damage to maize stems and maize yields were demonstrated. The calculated losses caused by *Sesamia* sp. to maize in the rain forest, coastal, derived and Guinea ecological zones were 27, 15, 18 and 14%, respectively. Chemical control of stem borers in sorghum in the Southern Guinea savanna of Nigeria, where *S. calamistis* predominates, increased yields by 16–19%.

Eldana Saccharina

In West Africa, natural infestations by *E. saccharina* decreased maize yields by 16, 15 and 28%, respectively, in the dry season and the first and second rainy seasons. Infested maize plots had significantly lower grain weight, indicating that *E. saccharina* damage to the stems affected grain filling.

In Burundi, insecticides and exclusion cage trials indicated diminished maize yields of 12–15% by *E. saccharina*. Curiously, in southern Africa, *E. saccharina* is not known as a pest of either maize or sorghum, but is a serious pest of sugar cane.

Stem Borer–Fungal Interactions

KITTY F. CARDWELL
USDA, CSREES, Washington, DC, USA
and
FRITZ SCHULTHESS
IITA, Cotonou, Republic of Benin

Both fungi and insects possess chitin-based exteriors. Also, both are heterotrophic, i.e., acquire nutrients by feeding on other organisms. It is at this nutritional interface where fungi and insects often intersect, giving rise to many different types of insect-fungus relationships, which can be neutral, mutually beneficial, exploitative, or antagonistic. Some relationships are merely opportunistic, while others are co-evolved and have become obligatory. Direct mycophagy, or fungivory, occurs when insects preferentially select fungi as a food source. Alternatively, many fungi require insects as a food source and become pathogens. Insects that feed on plants often encounter fungi that either live within the plant as endophytes or in association with plant tissues, resulting in an indirect effect on insect fitness. Often, insects are the vehicle by which fungi gain ingress into a plant or disperse throughout a habitat.

Fusarium verticillioides is an endophyte of wild and cultivated grasses. It produces mycotoxins such as fumonisin, which promotes esophageal cancer in humans and leucoencephalomalacia in horses. The fungus may attack at all growth stages of the plant and move from seed to stem into the cob. Similarly, variants of *F. moniliforme* have been found to produce the compound beauvericin, which was originally isolated from the entomopathogenic fungus *Beauveria bassiana*. In a survey in southern Benin, *F. verticillioides* was the most common endophytic fungus inhabiting maize stalks. Incidence was higher in plants damaged by insect pests, and was cultured from stems of 71–80% of plants damaged by stem borers. It was found that ovipositing adult lepidopteran stem and cob borers such as *E. saccharina*, *S. calamistis* and *Mussidia nigrivenella* not only preferred infected plants, but that offspring had higher survival and fecundity. This relationship is completely mutualistic because the insects feeding on infected plants may also vector the fungus from soil to plant and from plant to plant. Furthermore, lepidopteran pests feeding in the ear produce exit holes before pupating, which then are used as entry holes by storage beetles, which may be grain or fungal feeders. They, in turn, vector the mycotoxic fungus *Aspergillus flavus*, which has been shown to be suppressive to *S. calamistis*, *E. saccharina* and *C. partellus*; *M. nigrivenella*, on the other hand, was not sensitive to aflatoxin or *A. flavus* in the diet, which makes it a perfect vector; thus, aflatoxin content in grain increase exponentially with grain damage caused by *M. nigrivenella* or resulting increased beetle infestations. Control programs at the International Institute of Tropical Agriculture in Nigeria aim at both the fungi and the insects, and include biological control (e.g., *Trichoderma* sp.) and seed treatment against *F. verticillioides*, cultural control (sorting of infected ears), host plant resistance, competitive niche displacement (the use of atoxigenic, competitive races) against *A. flavus,* and host plant resistance, biological control and habitat management against stem and ear borers.

Larval Diapause

RAMI KFIR
ARC-Plant Protection Research Institute,
Pretoria, South Africa

Many cereal stem borers undergo a resting period toward the end of the cropping season in response to cold and/or dry conditions. The resting period is spent as mature larvae within dry crop residues and stubble in the fields.

In the elevated regions of southern Africa, *B. fusca* and *C. partellus* pass winter (May to September), which is the cold dry season, in diapause in the lower portions of the dry stalks of their host plants, where they are well protected from adverse climatic conditions. In West Africa, *B. fusca* also enters a prolonged diapause during the dry season, which takes up to six months to complete. With the start of the rains, the larvae pupate within the stems and 10–12 days later emerge as adult moths.

While *B. fusca* diapauses throughout its distribution range in Africa, the larvae of *C. partellus* do not undergo diapause in the warmer low-lying South African provinces of Kwazulu-Natal and Mpumalanga, Swaziland and southern Mozambique. Likewise, while *C. partellus* is known to diapause in the dry season in India and on several islands off the coast of Africa, non-diapausing larval populations occur along the coast of Kenya. In periods between cropping seasons, some *C. partellus* larvae enter diapause within maize stubble, whereas other larvae remain actively feeding on alternative host plants, such as Napier grass growing in the proximity of the cultivated areas.

Thus, in coastal regions where there is an abundance of host plants and where the climate remains favorable, *C. partellus* normally exhibits continuous development. Whereas inland, on the upland plateau, which experiences a long dry or cold season, larvae enter a diapause. Similarly, *C. ignefusalis* in West Africa exhibits a facultative diapause within dry millet stems.

In the interior of Kenya, the larvae of *C. partellus* and *C. orichalcociliellus*, together with *S. calamistis*, enter diapause for several months in the dry season. However, *S. calamistis* was reported not to enter diapause in Uganda nor in Nigeria.

An increase in carbohydrates and a decrease in protein and water content of the host plant are the principal factors inducing diapause in *B. fusca*. Drying out of the host plant, and a general deterioration in the nutritive environment, were found to induce diapause in *C. partellus* larvae, even when climatic conditions remained favorable for development. Diapause also could be "artificially" induced in non-diapausing larvae by introducing them into aging maize stems.

During diapause, larvae of *B. fusca* and *C. partellus* both showed a progressive decrease in weight and an increase of up to seven additional molts. The longer the larvae remained in diapause, the smaller the resultant moths became. Such female moths showed impaired ovarian development with fewer oocytes, and also laid fewer eggs. After eight months in diapause, the emerging moths weighed about half as much and produced half as many eggs as those moths emerging from non-diapausing larvae.

Diapausing larvae of *B. fusca* collected in South Africa in the field during winter emerged as moths in mid-October, regardless of the date of collection and the length of time they were kept at 21°C and 60% RH in the laboratory. However, larvae of *C. partellus* collected during April to June from the field emerged in November, while those collected in July emerged as moths in October. Those collected in August emerged in September. Regardless of collection date, *C. partellus* started to emerge from diapause earlier and the emergence period of the moths was up to twice as long as that found for *B. fusca*. In the field, *C. partellus* moths emerged from diapause in the second half of August and continued doing so until the first week of November, emergence thus lasting a total of 12 weeks. In contrast, *B. fusca* only pupated during October to November.

B. fusca hence had an obligatory larval diapause, whereas *C. partellus* had a facultative diapause. These differences in the pattern of moth emergence following diapause explain the distinct annual generations occurring in *B. fusca* and the continuous overlapping generations of *C. partellus* observed in South Africa.

Conditions of continuous moisture during the long rainy season in Kenya played a significant role in the termination of diapause in *B. fusca*. However, rainfall alone did not appear to be the main cause. Contact with free water was of more significance in breaking diapause than water uptake. In Ethiopia, as well as in the Ivory Coast, provision of water played an important role in promoting pupation during post-diapause dormancy of *B. fusca*. Any delay in wetting of larvae after diapause, and access to water early in diapause, had an adverse effect on the larvae. The key factor enabling diapausing *B. fusca* larvae to survive adverse conditions appears to be efficient water conservation.

A combination of temperature and photoperiod also played an important role in termination of diapause of *B. fusca* in South Africa. Water was important in stimulating morphogenesis following larval diapause. Long days accelerated termination of diapause in *C. partellus*, but under a 16 h daylight regime, termination of diapause was faster than under constant illumination. In contrast, temperature, relative humidity and day length did not affect diapause of *C. partellus* and *C. orichalcociliellus* larvae in Kenya.

It appears that *C. partellus* larvae collected in South Africa at 25°38′ latitude are more affected by day length than Kenyan borer populations located near the equator. It has been suggested that the right combination of day length and temperature could be used for breaking diapause in order to rear large numbers of larvae for experimental use in plant resistance trials. Simpler and cheaper facilities could hence be used for maintaining continuous laboratory cultures of these stem borers.

Pest Management

Use of Synthetic Sex Pheromones

Pheromone-baited traps are useful devices for monitoring stem borer moth populations. Trap catches of male moths provide useful information for quantifying moth abundance and for alerting and timing of spray applications. From the advances made in the identification and the use of sex pheromones in stem borer monitoring, it was concluded that trapping alone was unlikely to provide effective control; mating disruption was a more likely control option. Synthetic pheromone blends for *Chilo suppressalis*, *C. sacchariphagus*, *C. indicus*, *C. auricilius* and *C. zacconius* have been shown to be attractive to male moths in the field. Sex pheromones for *B. fusca*, *C. partellus*, *S. calamistis*, *S. cretica*, *S. nonagrioides* and *Coniesta ignefusalis* have been identified and are now commercially available.

Several years of monitoring *B. fusca* moths in South Africa with the aid of sex pheromone traps have revealed that the first flight of moths, emerging from overwintering larvae, peaked about mid-November. A second, larger flight then occurred in the latter half of February, while a third flight peaked around mid-April. No moths were trapped during winter (June to September). In the field, larval peaks of *B. fusca* lagged from 4 to 6 weeks behind the corresponding moth flight peaks. Omni-directional traps were found to be superior to delta traps for quantitative and qualitative estimation of *B. fusca* moth populations. More research into trap design and the correlation between trap catches and subsequent field infestations are required before trapping of *C. partellus* moths can be used in predicting economic threshold levels.

A slow-release pheromone formulation produced high levels of mating disruption in *B. fusca* when applied at 40 g a.i. per hectare at 250–500 release points per hectare. This effect persisted for at least 18 weeks and, based on release rate studies, was predicted to last for six months. In field trials in Kenya, some reduction in damage levels was observed, suggesting that mating disruption had indeed occurred.

Cultural Control

Cultural control is probably still the most relevant and economical method of stem borer control available to farmers in Africa. Other control methods are less practical. For example, pesticides often are unavailable or are too expensive for resource-poor farmers. Resistant cultivars are likewise not easily available, nor can biological control of stem borers be completely relied upon.

Cultural control is amongst the oldest, traditional, farming practice known. It is considered the first line of defense against stem borer pests and includes methods such as removal and destruction of old crop residues, intercropping, crop rotation, manipulation of planting dates and use of different tillage methods. The latter three cultural practices are of particular importance and can directly benefit crop yields. Though many of these cultural practices are very labor intensive, they do have the advantage of having minimal environmental impact and also can be readily implemented without extra capital investment.

However, adequate knowledge of stem borer biology and phenology, together with a close working relationship with the crop through all its growth stages, are essential for the development of efficient cultural control strategies. The differences found in the behavior of *E. saccharina* in South Africa and in East Africa affords an example of the importance of pest knowledge in making the right control decision. In South Africa, larvae of *E. saccharina* mainly infest the lower part of sugar cane stalks and farmers therefore cut off the tops of the cane, which are simply left lying as crop residues in cane fields. In contrast, the same larvae in East Africa largely occur in the upper cane, and any tops of plants left as residues would therefore provide a further source of infection and exacerbate the carry-over of the pest population.

Although cultural control options for stem borer management appear promising and offer relief, many African farmers have not adopted them. Cultural control is still severely constrained by a lack of management capability of farmers, especially in areas where agricultural extension services are inadequate.

Managing Crop Residues

Crop residues are especially important for the carry-over of stem borer larval populations from one growing season to the next. In Nigeria, larvae of *B. fusca*, *E. saccharina* and *S. calamistis* were found in crop residues below the soil surface, and higher incidences of these borers always occurred in no-tillage plots. In Kenya, *C. orichalcociliellus*, *C. partellus*, *E. saccharina* and *S. calamistis* were observed in stalks after harvest. In Ethiopia, a considerable proportion of *B. fusca* larvae survived in the stubble. In Uganda, untreated crop residues often were used to mulch the next crop. Under these conditions, moths emerging from the previous crop constantly reinfest newly planted crops.

An effective control option would thus be to reduce the first generation moth populations by destroying the bulk of the mature larvae overwintering in the old stalks. Plowing, in order to bury the maize stubble, proved an effective measure for controlling *B. fusca* infestations as far back as the 1920s in South Africa.

In Zimbabwe, it was observed that *B. fusca* moths experienced difficulty in emerging through 5 cm of soil and that deep burial under 10–15 cm of soil could totally prevent moth emergence. Deep plowing tillage in South Africa, where large areas are under maize or sorghum and where densities of up to 226,000 borer larvae per hectare have been estimated, is thus a viable control option for *B. fusca* and *C. partellus*.

Slashing of maize and sorghum stubble to expose overwintering larvae to the elements and natural enemies destroyed 70% of *C. partellus* and *B. fusca* populations, while additional plowing and disking destroyed a further 24% of the pest population in sorghum and 19% in maize.

However, for these cultural control measures to be really effective, the close cooperation of all farmers in a particular region is required because moths emerging from untreated fields will readily infest neighboring crops. Currently, this cultural control strategy is no longer so widely practiced in South Africa, owing to the advent of minimum tillage and to the importance of providing winter grazing on old maize fields for beef cattle.

In rural Africa, farmers often use the dry stalks of maize, sorghum and millet as building construction material in their houses and fences, in contour terracing and for use as stakes. Stalks also are kept for fuel and for use as bedding for livestock. Farmers often stack the dry stalks in the field, where they are kept until the start of the rainy season, thus creating ideal reservoirs of stem borer infection. To solve this problem, early cutting of stalks and horizontal placement on the soil surface have been recommended. This was found to cause 97% mortality of stem borers in maize and 100% in sorghum in Ethiopia. This practice also has reduced the residual population of borers in uncut millet stems from 16% to 3%. The high levels of mortality of *C. partellus*, *C. orichalcociliellus* and *S. calamistis* larvae observed in horizontally placed stalks was ascribed to the combined effects of radiant heating and high temperatures on the thermal tolerance of borer larvae. On the other hand, in Nigeria, the control of *S. calamistis*, *B. fusca*, *C. ignefusalis* and *E. saccharina*, through removal of maize stalks and stubble after harvest, did not reduce stem-borer populations significantly, apparently because of immigration of moths into the crop.

Control of *B. fusca* and *C. partellus* by burning old stalks and other crop residues after harvest also has been recommended. For example, almost complete eradication of *C. partellus* was achieved on maize and sorghum in Tanzania after setting fire to old crop residues. However, in Nigeria where the majority of farmers make use of their old sorghum stalks and do not normally burn them after harvest, a partial burn when the leaves were dry and the stalks still green gave up to 95% control of *C. partellus* larvae. The heat generated from burning the leaves apparently killed the larvae inside their tunnels. At the same time this cured the stalks, which not only improved their strength for building purposes, but also made them more resistant to termite attack. On the other hand, crop residues are the only organic matter that is added to the soil on many small scale cultivations in Africa. Burning of old crop residues can thus deprive the soil of organic matter and also result in increased soil degradation due to wind and water erosion.

Manipulation of Sowing Dates and Plant Densities

Planting crops when the pest is least abundant ensures that the more susceptible early growth stages escape becoming infested. In Kenya, an attempt to legislate this principle was made for controlling *B. fusca* on maize during the 1920s and 1930s. The aim was to restrict maize plantings to the February to May period, a time when moth infestations were normally low. Unfortunately, there is no available information on the efficacy of these measures, and the last attempt at implementing such legislation was in 1937–1938, after which it fell into disuse.

In West and Central Africa, early planting has been found to reduce *B. fusca* and *S. calamistis* infestations. Reports of increased stem borer damage to late maize plantings, as compared to early plantings, have come from Benin, Cameroon, Ghana, Nigeria, Burundi and Zaire. In some areas of West Africa, farmers also do not plant maize during the second rainy season because of the risk of severe infestation. This also influenced the borer populations found in the rain forest zone, where alternative wild host plants in the dry season are scarce.

Early planting of cereals also is practiced in the semi-arid tropics, where rainfall is variable and unpredictable. Late sowing, however, is also unpopular because of poor yields, even in the absence of stem borer damage.

On the Highveld region of South Africa, the second generation of *B. fusca* in mid-summer is larger and causes more damage than the first spring generation. The best control strategy is hence to plant early in the season. Similar conditions apply to Lesotho, Zimbabwe and Ethiopia, where second generation larvae caused crop losses of 23–100% as compared to 0–23% by first generation larvae.

At lower elevations in South Africa, it is recommended that sorghum be planted after mid-October to avoid infestation from the first moth peak of *C. partellus*. In Tanzania, it was shown that maize planted early in the season was more liable to severe infestation by *B. fusca* than later maize plantings. In Malawi, planting date also influenced pest levels of *B. fusca* and *C. partellus* on sorghum. However, the choice of optimum sowing date also depended on the sorghum cultivar planted. In contrast, in the Sahelian region, manipulating the planting dates of millet was not an effective option against infestation by *C. ignefusalis*.

Sowing density may also affect crop growth and thereby influence pest population levels. The behavior of the pest in its search for food or for oviposition sites may well be adversely affected by plant density. Young *C. partellus* larvae need to migrate from their hatching site to the leaf funnels or to reach adjacent plants within their immediate vicinity. During this critical migration period, up to 100% mortality of the first instar larvae may occur. The lowest incidence of deadheart was caused by *B. fusca* at low plant densities of sorghum in South Africa and from maize in Nigeria. Conversely, a reduction in row width increased the number of stem borer larvae infesting adjacent crop rows through migration, and this in turn resulted in greater crop damage. *B. fusca* larvae can migrate up to a distance of 2.4 m from their eclosion site. At the standard 90 cm inter-row planting distance used in commercial maize production in South Africa, lateral transmission over ±4 rows of maize is thus possible.

Rather than reducing plant densities within individual rows, wider row spacings also have been used in the Ivory Coast in an attempt to reduce *B. fusca* and *E. saccharina* damage to maize. However, studies on *C. partellus* in maize and on *C. ignefusalis* in millet, planted at different crop densities, showed no significant differences in stem borer incidence.

In subsistence farming systems in Africa, where farmers normally intercrop cereals with other crops, and where lack of water is an overriding constraint, manipulation of sowing dates and plant densities is not always possible. Farmers generally must plow and plant after the first rains have fallen, rendering some of these cultural control alternatives impractical.

Fertilizers

Providing fertilizer to cereal crops has been shown to increase stem borer infestation and survival of borer larvae. For example, damage to rice by *Maliarpha separatella* in Nigeria increased with fertilizer application, while sorghum plants with no fertilizer supplied were less preferred for oviposition by *C. partellus* moths in South Africa. However, no such differences were observed in similar oviposition behavior trials with *B. fusca*. However, in South Africa, where *E. saccharina* is a problem on sugar cane, a reduction in nitrogen fertilizer rates from 50 kg to 30 kg per hectare proved beneficial.

Increased survival of *S. calamistis* larvae and accelerated larval development occur with increased nitrogen content of maize resulting from fertilizer treatment. It also was suggested that addition of fertilizer might stimulate additional annual generations of stem borers.

Although nitrogen fertilizer enhanced borer development, it also had a positive effect of increasing host plant tolerance to borer attack. Yield losses decreased linearly from 20% with no fertilizer, to 11% with 120 kg nitrogen added per hectare. It also has been reported that timing of nitrogen fertilizer application influenced the incidence of *C. ignefusalis* on millet. The suggestion has been made that by manipulating the timing and quantity of nitrogen fertilizer, a compromise between using low fertilizer levels to dampen stem borer infestation, and high fertilizer levels to stimulate better yields, might be achievable.

Intercropping and Habitat Management

ZEYAUR R. KHAN
ICIPE, Nairobi, Kenya

Small-scale farmers in Africa practice intercropping or mixed cropping to reduce risk of crop failure, attain higher yields, and improve soil fertility. Although no studies have shown that farmers grow specific intercrops to reduce insect pests, some of these practices also lead to suppression of cereal stem borer populations. Studies in Kenya have concentrated both on the practice of intercropping cowpea with maize and sorghum, and on the ways in which these systems could be adopted by small-scale farmers in the region. Most studies on intercropping have shown a reduction in the incidence of stem borers. Maize/cassava intercropping systems in Nigeria were found to reduce by half larval numbers of stem borer populations. Unfortunately, many of these intercropping studies did not seek to determine the underlying mechanisms behind the effect of intercropping on stem borer populations. Intercropping maize with cowpea was an effective way of reducing damage caused by *C. partellus*, because 30% of *C. partellus* oviposition was on cowpea.

Planting an outer encircling row of a highly preferred host to act as a trap plant is a useful diversionary tactic to control stem borers. Napier grass, *Pennisetum purpureum*, and Sudan grass, *Sorghum vulgare sudanense,* common fodder plants in Africa, are reported to provide natural control of stem borers by acting as trap plants. Although the stem borers oviposit heavily on the attractive Napier grass, only very few larvae are able to complete their life cycles. In on-farm trials in Kenya, planting Napier grass around maize fields has been shown to significantly increase crop yields by reducing the stem borer population in maize. Sudan grass provided natural control of stem borers by acting as a trap plant, and as a reservoir for its natural enemies.

A recent study from Kenya has reported the effectiveness of intercropping maize with a non-host grass, *Melinis minutiflora*. In field trials, *M. minutiflora* showed no colonization by stem borers, and when used as an intercrop with maize, significantly reduced stem borer infestation in the main crop. A significant increase in parasitism of stem borers by the larval parasitoid *Cotesia sesamiae* was also observed. Volatile agents produced by *M. minutiflora* repelled stem borers but attracted *C. sesamiae*. Female *C. sesamiae* were attracted to (E)-4,8-dimethyl-1,3,7-nonatriene, one of the volatile components released by intact molasses grass. While serving as an effective cover crop, *M. minutiflora* at the same time provides good fodder for livestock. The grass is now being tested in on-farm trials in Kenya to control stem borers on maize.

For the control of stem borers in resource-poor maize farming systems in eastern Africa, "push-pull" or stimulo-deterrent diversionary tactics have been developed. These strategies involve combined intercropping and trap crops. Stem borers are trapped on highly susceptible trap plants (pull) and are driven away from the maize crop by repellent intercrops (push). The plants that are used as trap or repellent plants in a push-pull strategy are Napier grass, Sudan grass, *M. minutiflora* and silverleaf desmodium, *Desmodium uncinatum*. Napier grass and Sudan grass are used as trap plants, whereas *M. minutiflora* and silverleaf desmodium repel ovipositing stem borers. All four plants are of economic importance to farmers in eastern Africa as livestock fodder.

Before making decisions on the use of intercrops and trap plants for stem borer control, it would be important to assess economic impact as well as the biological effects. The economic gain from the use of intercrops usually depends on the balance between a lowered cost of stem borers control and the increased cost of maintaining an intercropped field, along with any decrease in yield of the main crop from greater plant competition. Net profit can be increased if the intercrop favorably changes the balance between income and costs.

Host Plant Resistance

Host plant resistance as an approach to pest management in gramineous crops confers many advantages. Resistant crop varieties provide an inherent control that involves no environmental problems, and are generally compatible with other insect control methods. Major emphasis on the host plant resistance work in Africa has been on screening maize and sorghum crops against *Chilo partellus* and *Busseola fusca*. Attempts have been made to understand the nature of *C. partellus* and *B. fusca* resistance in maize and sorghum. A general association between plant phenology and resistance to stem borers has been established. A wide range of mechanisms are involved in *C. partellus* and *B. fusca* resistance in maize and sorghum, including non-preference for oviposition, reduced larval settling, reduced larval feeding and food utilization, and reduced larval survival and development. The cause of ovipositional antixenosis mechanism in maize against *C. partellus* was found to be a high number of trichomes on the lower leaf surface.

Information on the mode of inheritance and the number of genes involved in the resistance of plants to particular insect species, although not essential for breeding plants, has great practical significance for identifying donors for resistance, developing isogenic lines, and breeding broad-based resistant varieties. In maize and sorghum, resistance to *C. partellus*, measured in terms of leaf-feeding, deadhearts and stem-tunneling, is polygenic. Polygenic resistance is moderate, but more stable and longer lasting than monogenic or oligogenic resistance. In sorghum, an additive gene effect was important in the inheritance of *C. partellus* resistance.

Efforts are underway in Africa to identify sources of stem borer resistance in cereal crops, but high levels of resistance have not been found. Crop varieties resistant to one stem borer species are not necessarily resistant to others. Therefore, it is important that sources with multiple resistance to stem borers are selected for breeding for durable resistance. During the last two decades, several national and international programs have been attempting to incorporate resistance to *C. partellus* into a good agronomic background of maize and sorghum, and many genotypes are already in national yield trials. Resistant lines/hybrids with good general combining ability have been identified. Several hybrid sorghums bred in South Africa exhibited tolerance to stem borer damage, and therefore suffered low yield losses.

Introduction of Biological Control of *Chilo partellus* in Africa

WILLIAM A. OVERHOLT
ARC-Plant Protection Research Institute,
Pretoria, South Africa

Because *C. partellus* is an exotic stem borer in Africa, there have been several attempts to introduce exotic parasitoids for its control. The first was in East Africa, where eight species of parasitoids, mostly from India, were released from 1968 to 1972 by the Commonwealth Institute of Biological Control. There were no reports of establishment. In South Africa, there were a series of introductions of 11 parasitoids from various locations from 1980 to 1993, but again, none established.

In 1993, a program was initiated in Kenya to introduce the gregarious larval endoparasitoid, *Cotesia flavipes*, from Pakistan for biological control of *C. partellus*. Releases were made in 1993 at three locations in the southern coastal area of Kenya, and the parasitoid was recovered during the season of release from *C. partellus* and two native stem borers, *C. orichalcociliellus* and *S. calamistis*. *Cotesia flavipes* was released at a fourth site in coastal Kenya during the non-cropping season of 1994 in an area where the vegetation was dominated by a wild grass, *Sorghum arundinaceum* (Desv.) Stapf. Recoveries in the wild habitat, and in a nearby maize field during the following cropping season, indicated that the parasitoid could sustain its population during the dry season in wild grasses and then colonize maize fields during cropping seasons.

Other than recoveries at the wild sorghum site, only one stem borer parasitized by *C. flavipes* was found in 1994, despite intensive sampling. In 1995 and 1996, a few recoveries were made, but parasitism was low. In 1997, the number of recoveries increased dramatically and parasitism at 30 sites averaged about 6%. Parasitism continued to increase during the next two years with average parasitism of about 13% at 67 sites in 1999.

Surveys in other maize growing areas of Kenya in the mid to late 1990s showed that *C. flavipes* was present in the Eastern Province and in the area bordering Lake Victoria in western Kenya. In the Eastern Province, which borders the Coast Province, *C. flavipes* was found in low densities in 1996 and then released at three sites in 1997. Parasitism during the season following the releases was about 14%. Parasitism in western Kenya did not increase to the levels observed in coastal Kenya or the Eastern Province, which may be due to the composition of the stem borer complex. In western Kenya, four stem borers are common: *C. partellus*, *S. calamistis*, *B. fusca* and *E. saccharina*. All of these are attractive and acceptable hosts for *C. flavipes*, but two of them, *B. fusca* and *E. saccharina*, are not suitable for its development. The presence of acceptable, but unsuitable, hosts in an area appears to act as a sink which depresses population growth of *C. flavipes*.

The impact of *C. flavipes* on stem borer populations in coastal Kenya was recently investigated. A host-parasitoid model was used to estimate the stem borer density with and without the parasitoid. A reduction of 1.1 to 1.6 stem borers/plant, equivalent to a 32–55% decrease in the stem borer density, was shown. As there is not yet any evidence that the *C. flavipes* density has reached an equilibrium, it may continue to increase and provide greater suppression of stem borers in the future.

In addition to the work in Kenya, *C. flavipes* was found in northwestern Tanzania in 1995. Based on surveys conducted prior to 1994, and on electrophoretic evidence, it was concluded that the most likely explanation was that *C. flavipes* moved into Tanzania from Kenya. Likewise, surveys in 1999 and 2000 revealed that *C. flavipes* had moved into Ethiopia.

Releases of *C. flavipes* have now been made in several other countries including Mozambique, Uganda, Somalia, Malawi, Zambia, Zanzibar and Zimbabwe. Establishment has been confirmed in Mozambique, Uganda, Malawi and Zanzibar. In Uganda, *C. flavipes* was found to be the most common larval parasitoid of stem borers one year after its release.

Biological Control of *Chilo saccharriphagus* on the Indian Ocean Islands and Africa

RÉGIS GOEBEL
CIRAD-CA, SASEX, Mount Edgecomb,
South Africa

Over 150 years ago, *C. sacchariphagus* was introduced from Java to the Indian Ocean islands of

Mauritius, Réunion and Madagascar in cane cuttings. The biology of this insect is similar to that of other sugarcane borers like *Eldana saccharina* in Africa or *Diatraea saccharalis* in the Americas. Damage is caused by the larvae, which penetrate into the stalk internodes where they feed until pupation. In terms of economic losses, damage results in a significant lowering of cane tonnage and, to a lesser extent, in a loss of sugar due to the inversion of saccharose, and to impurities in the juice. On a susceptible variety, the loss in cane weight is estimated to range from 10 to 30 tons per hectare, depending on the growing conditions. This pest has been increasing in some cane producing areas of the island due to the adoption of new varieties, and since 1994 it has been the subject of research to devise an integrated control program. Recent results from field experiments suggest new strategies for minimizing borer attack using predators, parasitoids and varietal resistance.

Biological Control Attempts: Lessons from the Past

In the Indian Ocean islands, attempts to control *C. sacchariphagus* with exotic parasitoids started in the 1940s. However, variable results were obtained. In Mauritius and Réunion, introduction and large scale releases of parasitoids, mainly originating from India, did not control *C. sacchariphagus*, despite the successful establishment of species like *Trichogramma chilonis* Ishii and *Cotesia flavipes* in sugar cane fields. In Réunion, several attempts at biological control in the 1970s by introducing and releasing tachinid flies also failed to control the pest.

Paradoxically, during the years of mass-releases, there were few ecological studies on *C. sacchariphagus* and its indigenous parasitoids and predators. Moreover, no accurate information was available concerning the parasitization rate of borer eggs by *Trichogramma* spp. and other egg parasitoids. However, in Réunion, Mauritius and Madagascar, natural parasitism of *C. sacchariphagus* eggs was generally high and ranged from 80 to 90%.

The Imoprtance of Predation by Ants

Predation of *C. sacchariphagus* eggs in Réunion was assessed on sugar cane fields in 1996–1997 by placing fresh eggs on the top leaves through the cane cycle. In two experiments conducted at different localities, 70–100% of the eggs were attacked by ants when sugar cane was six months old. The level of predation remained very high until the harvesting period (12 months). Trap catches and regular observations in the plots revealed that *Pheidole megacephala* F. (Hymenoptera: Formicidae) was the major predatory species.

However, predation by ants on eggs interfered with a major parasitoid, *Trichogramma* sp. Observations of parasitized eggs in clutches spared by the ants indicated that the ants destroyed the eggs whether they were parasitized or not. Despite this, natural control of the stem borer is a reality in sugar cane fields, and efforts should be focused on conserving natural enemies. This can be done by ceasing certain cultural practices such as burning at harvest, which is totally incompatible with the conservation of predatory insects.

Revised Biological Control with the Use of Trichogramma sp

A new biological control program using *Trichogramma* spp. is currently being implemented in Réunion Island. This program encompasses different steps, from field and lab research to technology transfer. It includes the choice of suitable species and the selection of strains to improve field performance (higher fecundity, survivorship and more efficient parasitism). One of the most important steps was to identify the *Trichogramma* strains and set up different studies on biology and population dynamics. Morphological and molecular characterization of numerous strains collected form different sites around the island led to the identification of *Trichogramma chilonis* Ishii. This species, previously named *T. australicum*, probably originated from Southeast Asia, the native home of *C. sacchariphagus*. All biotypes identified were evaluated for parasitism and the most suitable one will be mass-reared for inundative releases in the field. Further studies on population dynamics of *T. chilonis* are currently being conducted on a susceptible cane variety. The main objective of this study is to investigate the response of *T. chilonis* to different densities of *C. sacchariphagus* eggs. This information is essential to determine the ability of *T. chilonis* to control the borer in the field.

The technology for mass rearing of *Galleria* moths to produce high quality *Trichogramma* has been transferred to an organization in Réunion, which has many contacts with farmers. The method will be improved for eventual mass-releases. Nevertheless, small scale production of *Trichogramma* will allow the testing of different factors linked to the methods of release, quantity of *Trichogramma* per hectare, time of releases, packaging of the parasitoids, and indicators to assess efficacy of the releases. These practical studies will be conducted in partnership with farmers.

Predation by ants, as mentioned previously, also should be considered in the timing of *Trichogramma* releases. Therefore, to ensure the highest efficiency, these releases should be conducted during the period when predation is low and sporadic, which is also the egg laying period for *C. sacchariphagus*. After this period and until maturity of the cane, predation should assure the destruction of most of the borer eggs.

C. sacchapriphagus in Mozambique: a Threat to the South African Sugar Industry

In 1998, the presence of *C. sacchariphagus* in sugar cane in Mozambique was confirmed. Prior to that, its presence was suspected and was mentioned in various unpublished reports as early as the 1970s. Subsequent to its positive identification, a biological control program has been initiated with the collaboration of the sugar estate management. An ichneumonid pupal parasitoid, *Xanthopimpla stemmator*, which is a parasitoid of *C. sacchariphagus* in Sri Lanka, and which had been introduced and established in Mauritius and Réunion, was chosen as the first biocontrol candidate.

Methods to detect the presence of *C. sacchariphagus* in the South African sugar industry are already organized. During the last two years, a series of insect pheromones traps have been in operation in strategic locations along the border of South Africa with Mozambique. However, traps cannot detect the presence of borers in sugar cane stalks transported across the border. It is suspected that the first introduction of this pest into the Indian Ocean islands and Mozambique was made in this way. Presently, the risk of invasion of *C. sacchariphagus* is high for countries that have a common border with Mozambique (particularly Zimbabwe and Tanzania). Continued vigilance along the common borders will minimize the possibility of the importation of infested sugar cane stalks. Appropriate control measures can be applied immediately should an infestation in sugar cane farms be detected.

Graminivory

Eating or feeding on grasses (the plant family Graminae or Poaceae). Arthropods that feed on grasses are said to be graminivorous or graminivores. Grasses are sometimes said not to be particularly well defended biochemically against insect feeding, depending instead on silicification, lignification, trichomes, and a basal meristem for defense against herbivory. However, secondary plant compounds are also abundant in grasses.

Granary Weevil, *Sitophilus granarius* (Linnaeus) (Coleoptera: Curculionidae)

This is an important pest of Stored grain.

► Stored Grain and Flour Insects

Granivory

Seed feeding. Such arthropods are said to be granivorous or granivores. This is distinct from graminivorous (graminivores), or grass feeding, though animals that feed on grass seeds can be said to be both granivorous and graminivorous.

► Food Habits of Insects
► Phytophagy
► Herbivory

Granular Formulation

A dry formulation of pesticides that is substantially larger and heavier than dust, and applied with a granule applicator, not a duster.

Granule

The individual particles that are used in a granular formulation of pesticide.

Granulocyte

A type of hemocyte that is important in encapsulation of foreign objects found in the hemolymph.

► Hemocytes of Insects: their Morphology and Function

Granulosis

A disease of certain insects caused by granulosis virus (granulovirus) and characterized by the presence of minute granular inclusions in infected cells.

► Granulovirus

Granulovirus

KIA RASHIDAN[1], CLAUDE GUERTIN[2], JEAN CABANA[2]
[1]INRS-Institut Armand-Frappier (INRS-IAF), Laval, Qc, Canada
[2]AFA Environment Inc., Montreal, PQ, Canada

There are an increasing number of problems associated with the use of chemical pesticides, including emergence of resistant insects, elimination of non-target insects, and environmental contamination. Thus, the need for alternative biological insecticides that are cost-effective and environmentally safe is greater than ever. As a result, interest in microbial insecticides is increasing. Microbiological pathogens include various species of bacteria, fungi, nematodes, and viruses. The best-known example of a microbiological insecticide, which is used in large scale against agriculture and forest pests, is the bacterium, *Bacillus thuringiensis* (commercially known as Bt).

Viruses comprise another important class of insect pathogens that are being considered as good alternative biological insecticides due to their specificity for insect hosts. At least eight families of insect viruses are known, but the viruses most commonly used as viral bioinsecticides are those from Baculoviridae family.

Baculoviruses are a group of viruses that are specific to arthropods. Unlike other insect viruses, no morphologically similar counterpart to baculoviruses has been detected in vertebrates. Baculoviruses are characterized by the presence of a large protein matrix or occlusion body which encase the viral particles. Baculoviruses are classified in two genera: the nucleopolyhedroviruses (NPVs), and the granuloviruses (GVs). Safety testing of non-target organisms including mammals, fish, and birds has shown baculoviruses to have a very limited host range and to be safe to non-target organisms. Of the insect viruses, only baculoviruses have been recommended for field use.

Although baculoviruses have been isolated from different orders of insects, they have been used mostly to control pest species from the orders Lepidoptera, Hymenoptera, and Coleoptera. Overall, the most successful examples of baculovirus usage can be found in forestry. For instance, in the U.S.A. and Canada, baculoviruses have been used successfully in large-scale against the Douglas fir tussock moth (*Orgyia pseudosugata*), pine sawfly (*Neodiprion sertifer*), red headed sawfly (*Neodiprion lecontei*) and gypsy moth (*Lymantria dispar*).

Granulovirus Infection (Granulosis)

Granulovirus (GV) infection, known as granulosis, was first detected by Paillot, in 1926, in the larvae of *Pieris brassicae* (the large white butterfly). At that time he called this disease pseudograsserie. Later he described a similar disease in *Agrotis segetum* (a cutworm). In 1947, Steinhaus rediscovered the disease in *Peridroma saucia* (variegated cutworm), and he called the disease granulosis because he observed some tiny granules in affected tissues when observed with light microscopy. In 1948, a similar disease in *Choristoneura muriana* (pine shoot roller) was described by Bergold. Bergold was the first to demonstrate the viral nature of granulosis with electron microscopy; he described the virus as rod-shaped particles.

Infection begins when larvae ingest the occlusion body. Several days after infection, larvae begin to display unusual characteristics such as sluggishness, loss of appetite, followed by color change from the light brown to pink or white. For example, *Choristoneura fumiferana* (spruce budworm) and *Pieris rapae* larvae become pink, and *Cydia pomonella* (codling moth) larvae become white in very late stages of infection. The organ of the insect that is principally affected is the fat body, but virus also replicates in other tissues such as the epidermis, hemocytes, tracheal matrix cells, and Malpighian tubules.

The high pathogenicity of GVs toward different insect pests of agricultural crops and forests make this group of viruses a very attractive candidate to be used as biological insecticides. Since the 1950s, different GVs have been used as a biological insecticide in different parts of the world. One of the first countries to use GVs against *Hadena sordida* and *Trichoplusia ni* was the former Soviet Union. In Canada, GVs are mostly used in forestry against spruce budworm (*C. fumiferana*), and fir budworm (*C. muriana*). In the U.S.A., GVs have been used against *Cydia pomonella* (codling moth) and *Plodia interpunctella* (Indian meal moth).

General Aspects of Granulovirus

GVs are rod-shaped enveloped virions that contain one molecule of circular (super coiled) double stranded DNA. Nucleocapsids, which consist of proteinaceous capsid and DNA-protein core, are relatively large, 200–450 nm long and 30–100 nm in diameter. Nucleocapsids are cylindrical structures in which subunits of capsid are assembled in rings stacked one on top of another. Each turn of the helix consist of 12 copies of the capsid protein. The two ends of the nucleocapsid are different in shape and have been described as "nipple and claw." One end (nipple end) has the appearance of stacked rings of decreasing diameter.

GVs produce two different phenotypes, termed budded virions and occlusion-derived virions. Distinct viral structures are visible in thin sections of infected tissue. These two phenotypes are produced at different times and locations in the infected larvae. Budded virions are produced in the late phase of the infection cycle, when nucleocapsids bud from the surface of infected cells. Occlusion-derived virions, on the other hand, are produced very late in infection; they become enveloped and subsequently occluded within an occlusion body within the infected cell. Enveloped nucleocapsids are individually encased in occlusion bodies. Occlusion body is a protein matrix, termed granulin, which protect the viral DNA against the UV radiation of sunlight. Each phenotype has different functional roles. Occlusion-derived virion is the phenotype that is released in the environment after the death of the infected insect, it has a great infectious potential toward other susceptible insects.

Molecular Biology of Granulovirus

Genome

Granuloviruses have large genomes (80–180 kbp) that have the potential to encode about 100 genes. On the contrary, other viruses with big genomes like poxvirus that carry an extensive array of enzyme which are essential for early gene transcription, granuloviruses (like other baculoviruses) carry no virion-associated proteins that are essential for virus early gene transcription on their genome. The genome of granuloviruses is composed almost entirely of unique DNA sequence, though several small repeated sequences known as homologous regions are known in the DNA. The homologous regions have roles as enhancers for early genes, and also as origin of DNA replication. The activation property of an early gene known as *ie*-1 is enhanced when the genes are linked to homologous region sequences.

Open reading frames (ORFs) are located on either strand of the DNA. Most ORFs are separated by 2–200 bps of DNA rich in A + T. There are also some overlapping ORFs in granulovirus genome, usually termination codon UAA overlaps with the primary polyadenylation signal AAUAAA. Some promoters are located within the neighboring ORFs.

Frequently, transcripts of one gene initiate within, into, or through neighboring ORFs. Beside partial clustering of genes which have assigned roles in early gene regulation (e.g., *ie*-1, *ie*-2, and pe-38), genes in the genome of granulovirus, like other baculoviruses, do not appear to be clustered. Genes encoding structural proteins are distributed throughout the genome with no obvious pattern to the location.

Structural Proteins

Granulin is the major protein in SDS-polyacrylamide gel electrophoresis (SDS-PAGE). Studies on alkaline solubilized granulin of different GVs show that matrix protein of GVs has a molecular weight equal to approximately 30 kDa. Analysis of the nucleotide and amino acid composition of granulin in different GVs show a high degree of similarity. Amino acid sequence analysis of granulin in different granuloviruses showed conserved amino acid residues, which is likely due to "evolutionary memory," which maintains the secondary structure of granulin in all GVs.

The presence of 12–20 proteins has been shown in enveloped nucleocapsids of different GVs by SDS-PAGE analysis. Molecular weight of these polypeptides ranges from 12 to 160 kDa.

Cycle of GV Infection in Susceptible Insects

The infection cycle of granulovirus has two distinct phases: primary and secondary cycle.

Primary Cycle of Infection

The primary phase of infection is initiated by ingestion of virus by larvae, followed by dissolution of granulin (matrix protein of occlusion body) in the midgut of the insect, and liberation of the enveloped nucleocapsids. Granulin dissolved due to the alkaline environment of the insect' s midgut. Occlusion-derived virion infectivity is boosted by a protein present in occlusion body, termed Enhancin, which is a proteolytic compound with structural and functional characteristics of metaloproteases. Enhancin seems to have a direct effect on degradation of the peritrophic membrane in insect midgut.

Enveloped nucleocapsids attach to the surface of microvilli of columnar cells, and nucleocapsids enter the cytoplasm of cells following fusion of the viral envelope with plasma membrane. Nucleocapsids move toward the nucleus of the cell by polymerizing the actin filaments and release their DNA into the nucleus.

Replication and transcription of viral DNA take place in the nucleus of infected cells, and progeny nucleocapsids are formed in the nucleus of columnar cells. Nucleocapsids acquire their envelope by budding through the modified plasma membrane. This modification is due to the transportation of virus-made proteins into the plasma membrane of the infected cells. The primary phase of infection terminates when these enveloped nucleocapsids, known as budded virion phenotype, are released from infected cells. Budded virions are potentially infectious for tissues within the hemocoel. The mechanism by which the budded virion traverses the basal lamina of the midgut epithelium is not completely known. Some researchers suggest this possibility that budded virions may directly traverse the basal lamina of the midgut epithelium during budding. There is also another possibility that budded virions may use the tracheal system as a conduit to cross the basal lamina of the midgut epithelium.

Secondary Cycle of Infection

The secondary phase of granulovirus infection is different from the primary phase in several ways: (i) budded virions enter these cells by a receptor-mediated endocytosis in contrast to the occlusion-derived virion, which enter by fusion, (ii) more cells are infected, (iii) the yield of progeny virus per cell is much higher, (iv) progeny nucleocapsid acquire envelope inside the cell (instead of budding through the plasma membrane), (v) enveloped nucleocapsids encased inside the proteinaceous matrix, and (vi) the occluded progeny (termed occlusion-derived virion phenotype)are released upon cell lysis.

Viral entry by endocytosis is a process that usually consist of six steps: (i) virion attachment to a receptor on the surface of host cell, (ii) invagination of host plasma membrane in the viral attachment site, (iii) formation of a vesicle containing the enveloped virion (endosom), (iv) acidification of the endosom, (v) fusion of the viral envelope and endosomal membrane, and (vi) release of the nucleocapsid into the cytoplasm.

Following the release of nucleocapsid into the cytoplasm, they are transported toward the nucleus. Studies that concentrate on the mechanism of the transportation in NPVs showed that actin cables might play a major role in this movement. These studies also suggest that a structural protein in the nucleocapsid triggers the polymerization of actin cables. After nucleocapsid reach the nucleus, viral DNA is directly released into the nucleus through the nuclear pores. It seems that a phosporylated capsid protein (P78/83), which is localized at one end of the nucleocapsid, plays a role in the interaction of nucleocapsid and nuclear pores. The mechanism of uncoating of DNA in another baculovirus genus, NPVs, is different than GVs. Nucleocapsids of NPVs enter host cell nuclei and uncoat within the nucleus.

Upon uncoating of granulovirus DNA in the nucleus, early genes are transcribed by a host RNA polymerase. Early viral products are mostly regulatory proteins that activate transcription from other early genes. The transition from early to late phase is characterized by inhibition of host transcription and replication of viral DNA. Replication of viral DNA seems to be a crucial step prior to late phase transcription. Late genes are transcribed by a viral RNA polymerase. At least 18 baculovirus genes have been shown to control the late gene expression; these genes are identified as late expression factors genes (*lef* genes). All structural proteins are expressed in late and very late gene expression.

Nucleocapsid assembly begins after synthesis of late proteins. Electron microscopy studies demonstrate that initially a virogenic stroma appears within nuclei, and empty capsids assemble within this stroma. These capsids then fill with DNA. A basic DNA binding protein in the capsid (P7/12) may play a role in packaging of viral DNA. This protein has similarity to cellular protamines, the basic proteins that substitute for histones in the packaging of DNA within the sperm of many species. Both proteins (i) are rich in arginine residues which lead to a high basic charge, (ii) have the ability bind zinc (Zn^{+2}), and (iii) are a substrate for kinase activity.

After the process of packaging viral DNA, nucleocapsids are ready for envelopment followed by occlusion. The mechanism for envelopment is not known, but some researchers suggest that budding through the nuclear membrane fragments is a possible way for envelopment. The very late phase of infection starts by hyperexpression of very late genes such as granulin (the occlusion body protein). Granulin crystallizes around the enveloped nucleocapsids and encases the virions. Following the occlusion process, an envelope-like structure (calyx) covers the occlusion body.

At the final stage of granulovirus infection, cells become packed with occluded virions that cause cell lysis and liberation of virus into the hemocoelum followed by death of the insect.

Use of Baculovirus against Lepidoptera

Baculoviruses have been used to control different lepidopterous pests in agriculture and forestry. Historically, the first attempt to use viruses as a bioinsecticide date back to 1892. In this year, a baculovirus was used to control *Lymantria monacha* population in pine forests in Germany. The United States was the first country in North America to use a baculovirus against *Lymantria dispar*.

There is no record of large scale use of baculoviruses in agriculture in United States before the late 1940s. In this year, aerial application of NPV against *C. eurytheme* (alfalfa caterpillar) were attempted in California. The use of *Helicoverpa zea* NPV in the 1970s showed promising results in soybean and maize agriculture. Between 1975 and 1980, over one million hectares were treated by HzNPV. Introduction of synthetic pyrethroids in the early 1980s decrease the use of HzNPV, but the emergence of a worldwide resistance against pyrethroids during the 1990s promoted the use of the HzNPV. In 1996, HzNPVwere again used in large scale in the cotton industry in the United States. Currently, China is one of the countries that use HzNPV and *H. armigera* NPV in cotton industry. Annually, 100,000 ha of cotton fields in China is treated by HaNPV. Thailand and Vietnam are two other countries, among others, that use HaNPV on a large scale.

One of the best examples of using baculovirus in fruit crops is the use of a granulovirus against *Cydia pomonella* (codling moth: a pest of apples, pears and walnuts). *Cydia pomonella* granulovirus (CpGV) demonstrates a high pathogenicity against the larva and kills the insect very quickly. Field tests with CpGV in North America demonstrated that CpGV is a highly virulent and selective control agent against codling moth. CpGV is currently in use in different European countries. France, Switzerland, Germany, and Russia are the major consumers.

Records of using baculoviruses in forestry show that the following insects were the most important Lepidopera that were subjected to applications of baculoviruses: *C. fumiferana* (spruce budworm), *C. occidentalis* (western spruce budworm), *C. pinus* (jackpine budworm), *L. dispar* (gypsy moth) and *O. pseudotsugata* (Douglas-fir tussock moth). A NPV for *O. pseudotsugata* was registered and used in United States in 1976. This virus has been used during the last three decades in different parts of the United States and Canada. *Lymantria dispar* NPV is another baculovirus that has been used widely since its registration in 1978.

The first baculovirus used against spruce budworm was CfMNPV. The most important problem related to CfMNPV is its low pathogenicity. The other baculovirus that has a great potential to be used as a microbiological insecticide against spruce budworm is *C. fumiferana* granulovirus (ChfuGV).

A Case Study: Use of *Choristoneura fumiferana* Granulovirus (ChfuGV) in Canada

In eastern North America, spruce budworm is considered the most destructive insect of coniferous trees. The spruce budworm is a huge economic threat to vast forest areas (60 million ha) in Canada and eastern United States. The Maritime Provinces (New Brunswick, Nova Scotia, Newfoundland), Quebec, Ontario, and the Great Lake states are the areas that are affected by spruce budworm outbreaks most extensively. Spruce budworm larvae feed on a number of conifers, but balsam fir (*Abies balsamea* [L.] Mill.), and white spruce (*Picea glauca* [Moench] Voss) are the major hosts in eastern North America. Species occasionally attacked include black spruce (*Picea mariana* [Mill.] B.S.P.), red spruce (*Picea rubens* Sarg.), eastern hemlock (*Tsuga canadensis* [L.] Carr.), tamarack (*Larixlaricina* [Du Roi] K. Koch), and white pine (*Pinus strobus* L.).

In Quebec, Canada the outbreak of *C. fumiferana* usually affects huge forest areas. For example, the infested area in 1999 was estimated more than 23,000 hectares. This figure was twice as large as the infested area in 1998. Defoliation, inhibition of seed production, cone mortality, root mortality and tree mortality are the most important impacts of spruce budworm on trees. Defoliation caused by spruce budworm decreases the growth rates of trees; this decline can last several years. When outbreaks occur, the affected trees usually die after three to four years of heavy defoliation, and most of the trees die between six and ten years after the first attack. Even when the spruce budworm population returns to its endemic level, the damaged trees continue to die.

Chemical insecticides were the most common method of protecting spruce-fir forests from spruce budworm from 1927 up to the 1970s. DDT and Phosphophamidon were used mostly during the period from 1944 to 1970. In the 1970s and 1980s organophosphates and carbamates replaced DDT. Most of these compounds are toxic to humans and other warm-blooded animals. The concern about finding an alternative for chemicals started during the 1960s and among the candidates were biological insecticides. Also, as insects continue to gain resistance to chemical pesticides, industrial interest in commercial development of biological pesticides increases.

Natural predators, parasites, competitors and pathogenic microorganisms like fungi, bacteria and viruses have been used as biological agents. In eastern Canada *Bacillus thuringiensis* var. *kurstaki* (Btk) is used in insect control programs against spruce budworm. No major resistance against Btk in natural population of spruce budworm has been reported. However, laboratory results demonstrated that several insect species are able to develop resistance against the Btk toxin. The risk of appearance of resistance against Btk obligates the researchers to quest for new alternatives.

ChfuGV has been isolated from infected spruce budworm in several part of eastern Canada. This virus is considered a very attractive and powerful candidate to be used instead of, or along with, Btk in the case of the emergence of resistant spruce budworm larvae.

Laboratory bioassays with ChfuGV demonstrated its high pathogenicity for spruce budworm population ($LD_{50} = 5.72 \times 10^5$ viruses/larvae). The development and implementation of ChfuGV as a microbial insecticide were carried out during a pilot project on 100 ha of forests in Quebec, Canada. The results of these field experiments demonstrated that two weeks after treatment with ChfuGV a considerable reduction (40%) of defoliation was observed in treated areas as compared to control areas. Also, the number of *C. fumiferana* larvae was reduced by over 35% in treated areas. One of the most interesting results, from an economical perspective, is that when ChfuGV was used in a lower rate volume applied per ha, the same level of protection was observed.

Production of Granulovirus-based Insecticides

Currently, most granuloviruses are produced in vivo. The reason is due either to the absence of cell lines for some granuloviruses, or low yield of virus production for the others. One of the most important drawbacks concerning the in vitro production is that the viruses often lose infectivity after several passages through cell culture. The most important aspect of the virus production process is: (i) choice of the host. (ii) rearing conditions. (iii) virus purification. (iv) formulation.

Usually, a natural virus host is the best choice in virus production, but in the cases that the natural host is not suitable for laboratory rearing, and alternative hosts must be considered. The following cases are examples of unsuitable hosts: (i) when the natural host has a special dietary requirement, or (ii) when long obligatory diapause is required.

Temperature and humidity are the most important aspects in insect rearing. The other key factor for in vivo virus production is the number of larvae per each diet container and the size of container. The use of large containers is not recommended for species with a cannibalistic nature.

Formulation of granulovirus-based insecticides is a very important part in production. For large-scale applications, different aspects such as storage stability and UV protection must be considered in order to have a stable and high quality product. The formulation also must provide good residual activity in field. The formulation must not contain any additive with negative effects on virus activity.

Standardization and Quantification of Granulovirus-based Insecticides

One of the most important requirements for the production and use of GVs is the availability of bioassays. With bioassays, GV producers can determine the potency and virulence of an industrial product or preparation. On the other hand, bioassays can be also used: (i) to determine the biological activity of GVs for different insect species, (ii) to determine the relative biological activity of several viruses against one or more insect hosts.

Bioassays ensure the activity of the product prior to field use. In each bioassay there are some facts that should be respected to ensure the quality of the bioassay: (i) the purity of the virus preparation should be established by electron microscopy or other analytical procedures, (ii) presence of contaminating micro organisms such as bacteria and mycets should be checked, (iii) the assay must be reproducible for the same strain of insect species under similar conditions. Different methods of bioassays, such as bioassays by injection, bioassay by contaminated leaf disks, and finally bioassays by contaminated artificial diet have been suggested by different workers.

Injection methods have been used for establishment of activity of non-occluded virus obtained from alkaline-dissolved granules (granule: a complete granuloviral particle contain nucleocapsid, envelope and occlusion body). This method is very tedious and time consuming, but the primary advantages of this type of assay are (i) the amount of inoculums per insect is known, and (ii) the time of the beginning of infection is known.

Another time consuming method of bioassay is using leaf disks contaminated by with known quantities of GV preparation. Bioassays using contaminated artificial diets are the most commonly used assays for many insect viruses including GVs. In this method, known quantities of GVs are incorporated into, or layered on, the surface of artificial diets, which allows the evaluation of the LC_{50}. There are two very important advantages related to this method: (i) early stages of insect larvae, which are generally the most susceptible to viral infection, can be used in large numbers, (ii) insect handling is minimized since the stay in the same container throughout the bioassay. The disadvantage of this method is that the dose of the virus ingested by each insect is not known. There are always problems that could arise in different types of bioassays, but these problems can be avoided if certain precautions are taken.

Methods of Application of Granuloviruss-based Insecticides

An effective application should distribute virus to the insect' s feeding sites in a way that the probability of acquiring a lethal dose of virus is maximized. Granuloviruses, like most other baculoviruses, are applied by spraying the viral product to the target site. Ground application is mostly used for agricultural crops, but aerial application is the common method in forestry. There also are other application techniques that have been demonstrated, such as release of infected insects, though these have some limitations.

The Future of Granulovirus

Baculoviruses and among them granulovirus, can be considered to be major elements in biological control programs in the next 10 years. On the other hand, considering the fact that a great deal of effort has been directed toward the development of recombinant baculoviruses, it also is probable that recombinant viral insecticides will be used on a large scale against insects pests of forests and crops in near future. The most important issue concerning the use of genetically modified baculoviruses is the safety issue. Therefore, to be safe, it is important to prepare comprehensive risk assessment protocols for genetically modified baculoviruses.

Grape Phylloxera, *Daktulosphaira vitifoliae* (Fitch) (Hemiptera: Aphidoidea: Phylloxeridae)

DOUG DOWNIE
Rhodes University, Grahamstown, South Africa

Grape phylloxera is a primitive aphid that feeds and develops on grapevines (*Vitis* species). It is notorious for the damage it caused to viticulture first in France, then globally as it was introduced and spread into vineyards in nearly every grape-growing region of the world in the middle to latter part of the nineteenth century. Its native range is North America east of the Rocky Mountains, the southwestern USA, and well into Mexico and Central America to as far south as Venezuela. Grape phylloxera has had a checkered nomenclatural history, and the genus names *Pemphigus*, *Rhizaphis*, *Peritymbia*, *Viteus*, and *Daktulosphaira* as well as *Phylloxera* have been applied to it. For many years, *Phylloxera* was the most commonly applied name so the common name and Latin genus name were one and the same. This name was subsiding from use after 1952, however, and Russell cleared up the nomenclatural mess more than thirty years ago. However, there is no phylogenetic hypothesis for the Phylloxeridae so nothing is known about the relationship of *D. vitifoliae* to the approximately 41 described species of *Phylloxera* and it may still turn out, once such a hypothesis is in hand, that erecting a new genus for grape phylloxera was unjustified. There is an unfortunate prevalence in both entomological and viticultural circles to use the name phylloxera as the common name. Because a large number of other species in the family have this as their Latin name, it is desirable to specify "grape" phylloxera when discussing this insect.

Life Cycle and Biology

Grape phylloxera is a gall forming insect (as are the majority of species in the Phylloxeridae) causing galls on leaves and young roots on native vines and on hardened roots of susceptible cultivars. It has been stated that grape phylloxera may form galls on vine tendrils, but this is not true under natural conditions. Its host range appears to be restricted to about six to eight (depending on taxonomic concepts) of the some 20 or so *Vitis* species in the Americas and a number of cultivars, most notably the wine grape *V. vinifera* L. The distribution of grape phylloxera in Mexico and Central America is uncertain at this time. On leaves, pouch galls are formed that completely enclose the gall-former and her eggs. Galls on young roots (typically called nodosities) have a characteristic hook shape as cells distal to the insect feeding site become hypertrophied. The gall-former may be partially hidden in the elbow of the hook, but is otherwise exposed. Galls on hardened roots (tuberosities) appear as bumps on the surface of the root, with the gall-former and her eggs exposed on the surface. There is currently no evidence to suggest that the mechanism of gall induction differs on the three different plant organs or tissue types attacked; the different morphology is due to the different substrates galled (i.e., a pouch gall cannot form on a cylindrical and hardened root).

The life cycle differs in the native range and under most vineyard conditions and these will be discussed separately:

Native Range

As with the majority of Aphidoidea, grape phylloxera is a cyclic parthenogen in its native range. That is, one to multiple generations pass by apomictic parthenogenesis followed by a single generation of sexual reproduction each year. Sexually produced eggs are cold-resistant and are the overwintering stage. Individuals hatching in the spring from these zygotic eggs are called fundatrices. As first instar crawlers, fundatrices initiate galls on newly forming leaves in which they will mature in 2–3 weeks, laying upwards of 300 eggs as adults. Galls can only form on the newly expanding leaves. Fundatrices and all subsequent gall mothers (gallicolae) generally do not leave their gall after gall initiation. As eggs hatch, the crawlers leave the galls and move up the shoots to newly forming leaves where they in turn make their galls. A variable number of generations may pass this way. New leaf growth tends to slow or cease as summer progresses, meaning there is no longer any leaf resource for grape phylloxera. In the southwestern USA, and perhaps Mexico and Central America, it appears that this is when sexual forms (sexuales) are induced and overwintering eggs produced, ending the life cycle. There is evidence that gallicolae will sometimes secondarily occupy already-formed galls. There are no winged forms (alatae). In eastern North America the life cycle is prolonged by crawlers moving to the roots where they (called radicicolae) form galls on new, unhardened rootlets. Analogous to host alternation in aphids, it is here that alatae are produced that ascend into the canopy to lay a small number of male and female eggs. Induction of alatae may be influenced by density dependence, deterioration of the resource, or temperature. The neotenic sexual morphs have no mouthparts and live only a few days. Following mating these females lay a single zygotic egg each. It is often said that the overwintering eggs are laid in crevices in the bark on the trunks of vines but there have been too few observations to convincingly say how these eggs are distributed.

Vineyards

Vineyards in the eastern part of North America appear to be attacked by the local populations of grape phylloxera, and the life cycle on these cultivated vines does not differ. Elsewhere, except in cases where rootstocks are allowed to sucker or grow from cut down vines, the life cycle has been modified by elimination of the leaf galling phase, and with it production of sexual forms. Overwintering occurs as first or second instars. There is now good evidence that most populations of grape phylloxera, in vineyards of Australia and California at least, reproduce only asexually. Alate individuals are common, however, and have been observed at various times of the year. Apparently they are either infertile, their eggs are inviable, or sexuales do not survive to adulthood. Both nodosities and tuberosities are formed, with some cultivars resistant to tuberosity formation but susceptible to nodosity formation.

Dispersal of grape phylloxera occurs by flight of alatae and by blowing of crawlers by wind, and may also occur by windblown or water-carried galled leaves that harbor eggs or live individuals. In vineyards, all stages could be moved by agricultural equipment and activities.

Damage and Management

There are no data directly relevant to how damaging grape phylloxera is to wild grapevines and what effect on fitness, if any, is incurred. It has commonly been assumed that these vines are tolerant, but this is not likely to be strictly true because extensive galling must divert resources away from seed production. More study of this plant-insect interaction on wild grapevines is needed and would aid in understanding the evolution of resistance in grapevines.

In vineyards, damage is most severe when tuberosities are formed, vines being able to withstand the damage from nodosity formation. Tuberosities tend to occlude the vascular system, and a heavy infestation high up in the root system will effectively remove a substantial proportion of the translocation to and from the root system. This effect is exacerbated significantly by entrance of fungal pathogens through the cracked surface of the galled portion of the roots, resulting in necrosis and loss of root area. Ultimately, attacked vines die.

Management tactics have varied over the years and have included spraying of copper bisulphide in the early days to more modern insecticides (especially against leaf galling forms), and even flooding vineyards. The cryptic and protected habitat of root galling individuals makes use of conventional insecticides problematic. Systemic insecticides have found some use, but have not been widely applied. The use of natural enemies has not been thoroughly explored. Because fungal pathogens play an important role in damage, efforts are underway to control these. Finally, grape phylloxera has been effectively excluded from some wine regions in Australia by enforcing strict quarantine measures.

The only effective and durable management tactic has been the development and use of host plant resistance. Resistant cultivars have been developed directly from vine collections from the native range or, more often, from breeding programs, often leading to complex hybrids. The dominant *Vitis* species that have been used in these breeding programs have been *V. riparia*, *V. rupestris*, and *V. berlandieri*. Once developed, these cultivars are used as rootstocks for scions of the wine grape, *V. vinifera* L. The mechanisms of resistance are not well understood but there is evidence for antixenosis (insect avoidance), antibiosis (death or poor development of the insect) as well as tolerance (plant can suffer large numbers of herbivores without succumbing). Phenolic compounds may play a role in inhibiting development, and a hardened periderm beneath the feeding site has been observed, which would inhibit gall formation and isolate the insect from its nourishment.

Host plant resistance has been an effective strategy for managing grape phylloxera since it was introduced in the late 1800s, with only a few examples of failure. A notable example of a failure of what was previously considered to be a resistant rootstock is that of the rootstock AXR#1 in California in the 1980s. This rootstock was widely planted in California vineyards in the 1960s and 1970s but began declining under grape phylloxera attack in the 1980s, leading to large scale replanting to other rootstocks and massive economic outlays. It is likely, however, that this rootstock was never sufficiently resistant to grape phylloxera under California conditions, and the failure of resistance in this case may be more a failure of implementation than a failure of resistance.

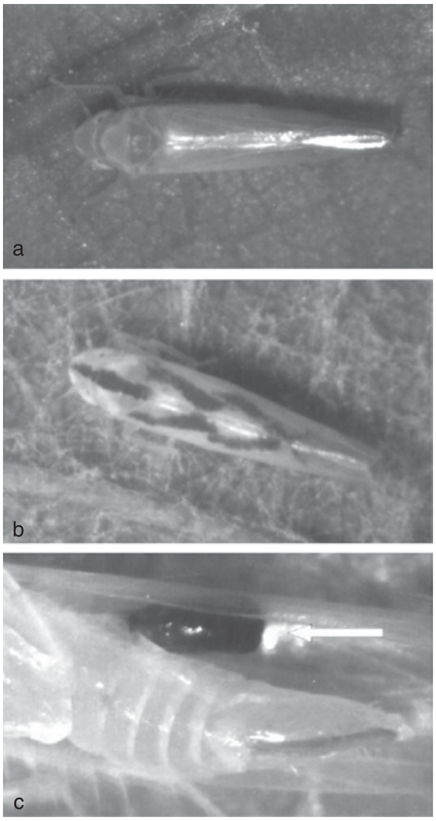
Various species of leafhoppers attack grapevines throughout the world. In Cyprus, the grapevine leafhopper complex consists of three species that have been identified by C.A.B. International Institute of Entomology (London) as *Zygina rhamni* (Ferrari), *Jacobiasca lybica* (Bergevin & Zanon), and *Asymmetrasca decedens* (Paoli). Assessment of population density through D-vac samples and insect counts directly on the plants showed an overall prevalence of *Zygina* over the other two. *Zygina* and *Jacobiasca* prevailed in areas with drier microclimatic conditions (Avdhimou and Pakhna) where the overall relevant populations were 52% and 45%, respectively. At Phassouri, though, a much less drier area, 45% of the leafhopper population was *Asymmetrasca*. This pest prevailed from April to early August and then its populations dropped significantly as it moved to other host-plants. Minor differences have so far been found in the within-plant distribution of the two principal species. At low population levels, these cicadellids had the tendency to live on different leaves, but at higher populations they could also be found on a same leaf, almost exclusively on the lower leaf surface. More insects were found on the basal than on the apical half of the vines.

The adult females lay their eggs singly in the epidermal tissue of the leaves and appear like tiny bean-shaped blisters. The young leafhoppers that emerge (nymphs), and the adults, are found almost exclusively on the lower leaf surface. They feed by sucking out the sap from the leaf cells or veins causing discoloration, deformation and in cases of heavy infestation, drying and shedding of leaves. Although *Zygina* is more widespread, it is not so harmful to the plants because it sucks the sap from the leaf cells, causing only leaf discoloration. The other two leafhopper species are more harmful because they suck the sap from the leaf veins, causing leaf deformation and drying. Yellow sticky trap catches showed increased populations of *Zygina* only from the end of July to the end of November, while those of *Jacobiasca* followed the same trend with about a three-week delay. Considering this population behavior, and the insect count on the grapevine leaves that were much lower than those reported as economically significant elsewhere, the pest status of the leafhopper complex was questionable.

Adults of *Z. rhamni* overwinter on *Rubus* sp. and *Sarcopoterium spinosum* (L.) Spach. They present a reddish pigmentation on their head and front wings, which in grapevines with poor growth starts appearing gradually from mid-August onwards, while in those with rich and tender growth, 15 days later. This gradual change of adult pigmentation is completed generally by mid-November. Adult migration to the winter quarters may start as early as September with a gradual infestation of *Rubus*, which is an evergreen bush. *Sarcopoterium* is available for infestation from around mid-November. This cicadellid develops (Fig. 31) one generation on these plants in early spring, and then it moves to grapevines where it stays for as long as there are green leaves, developing a maximum of 4 more generations.

Jacobiasca lybica overwinters as adult on *Rubus*, and then it develops only on grapevines, completing a maximum of six generations per year. *Asymmetrasca decedens* overwinters on citrus and on several weeds without interrupting its development, although it slows down because of the lower temperatures. In spring it moves to several vegetables and to grapevines where it prevails until the end of July. It then develops on various vegetables until winter, completing a maximum of eight generations per year.

Aphelopus orphanidesi Olmi (Hymenoptera Dryinidae), a new species, was the only parasite of *Z. rhamni* found so far in Cyprus. Adult females oviposit in the body of the leafhopper nymphs



Grapevine Leafhopper Complex (Hemiptera: Cicadellidae) in Cyprus, Figure 31 ***Zygina rhamni*: (a) adult of summer generations, (b) adult of overwintering generation, (c) adult female parasitized by *Aphelopus orphanidesi*.**

only and larval development extends in the adult stage of the host. The older nymphal stages seem to be preferred. Adult leafhoppers exposed to parasitoid females have never been attacked. The parasitoid female grasps the cicadellid nymph with her mandibles, holds it in position with her legs, and oviposits in its body. Parasitized leafhoppers, noticed by the unaided eye only at the adult stage, bear a sac on either side of the fore parts of the cicadellid gaster in a dorso-lateral position under the wings that contains the parasitoid larva. No leafhopper nymphs have been found to carry any larval sac of the parasitoid. On the overwintering leafhoppers, the sac darkens gradually as the parasitoid larva grows, and becomes shining black. It then becomes white after the larva abandons it. On adults reared in the laboratory at 25°C and in the field during the summer, the sac remains white throughout the entire larval development. Upon completion of its development, the parasitic larva leaves its moribund host, and drops to the soil where it becomes pupa and then adult.

The parasitoid completes five generations in one year. Emergence of adult parasitoids from the overwintering generation occurs in March and coincides with the appearance of first generation host nymphs, which are available for parasitization. Adults of the following parasitoid generations appear in May, July, August, and September. Parasitization rates are relatively high (75%) only on the overwintering leafhopper generation. In this generation, oviposition starts from September, but parasitized leafhoppers are noticed by the unaided eye from January onwards.

Grasshopper and Locust Pests in Africa

JOHN L. CAPINERA
University of Florida, Gainesville, Florida, USA

Africa has an exceedingly rich fauna of Orthoptera, including several families and well over 1,000 species, that could be considered to be grasshoppers or locusts. In Africa (also in Asia, Australia, and South and Central America), some grasshoppers are called "locusts." This term is applied to species of grasshoppers that display phase polymorphism. Phase polymorphism is largely a behavioral change between different states: gregarious and solitary forms, with intermediate forms called "transiens." During the gregarious phase, which is induced by high densities, locusts tend to disperse long distances in groups (during the nymphal stage the groups are called bands, during the adult stage they are called swarms). These same species are not very dispersive, nor gregarious, during the solitary phase. Physical changes in appearance may also occur during the change in phase, and of course physiological changes underlie the behavioral and morphological shifts. Transition between the solitary and gregarious phase takes more than one generation. In contrast, grasshoppers tend not to disperse long distances, tend not to aggregate during dispersal, and their appearance remains about the same regardless of density conditions. Thus, "grasshoppers" do not display phase change. Africa suffers from both grasshopper and locust infestations, but is best known for locust problems. The Arabic phrase for locusts translates to "teeth of the wind," providing some indication of the severity of the problem. As is the case elsewhere in the world, most of the orthopteran pests are in the family Acrididae, but other families of the order Orthoptera, particularly Pyrgomorphidae, are present as pests.

Locusts and grasshoppers sometimes, but not always, conform to the "typical" phase pattern suggested by the common name of these insects. As expected, when comparing the gregarious and solitary phases of desert locust, *Schistocerca gregaria* (Forskål), and migratory locust, *Locusta migratoria migratorioides* (Reiche & Fairmaire), the different phases can be quite distinctive. The behavior, coloration and size differ markedly between the gregarious and solitary phases. A common measure of the gregarious phase is the ratio of wing length to the width of the head; the gregarious phase has relatively longer wings. However, in some other species such as the Moroccan locust, *Dociastaurus maroccanus* (Thunberg), there is little or no change in color, though the relative size of body parts does change. The Senegalese grasshopper, despite not being called a locust, displays some morphological differences between the swarming and non-swarming populations, including longer wings. Thus, it is a good idea not to dwell on the common name of orthopterans, but to look critically at the biology of species individually. Other species are more typically grasshopper-like. Africa has a few spectacular species of "locusts" that command most of the attention and notoriety (as is largely the case in Australia), but some regions also suffer from a large assemblage of grasshoppers (as is largely the case in North America). Some of the more important species are shown in Table 7 and Fig. 32.

In Africa, and generally elsewhere in the world, grasshopper and locust populations in arid regions tend to grow in response to increased rainfall, and increased availability of host plants brought about by the precipitation. Annually, favorable habitats result from the belt of rain that

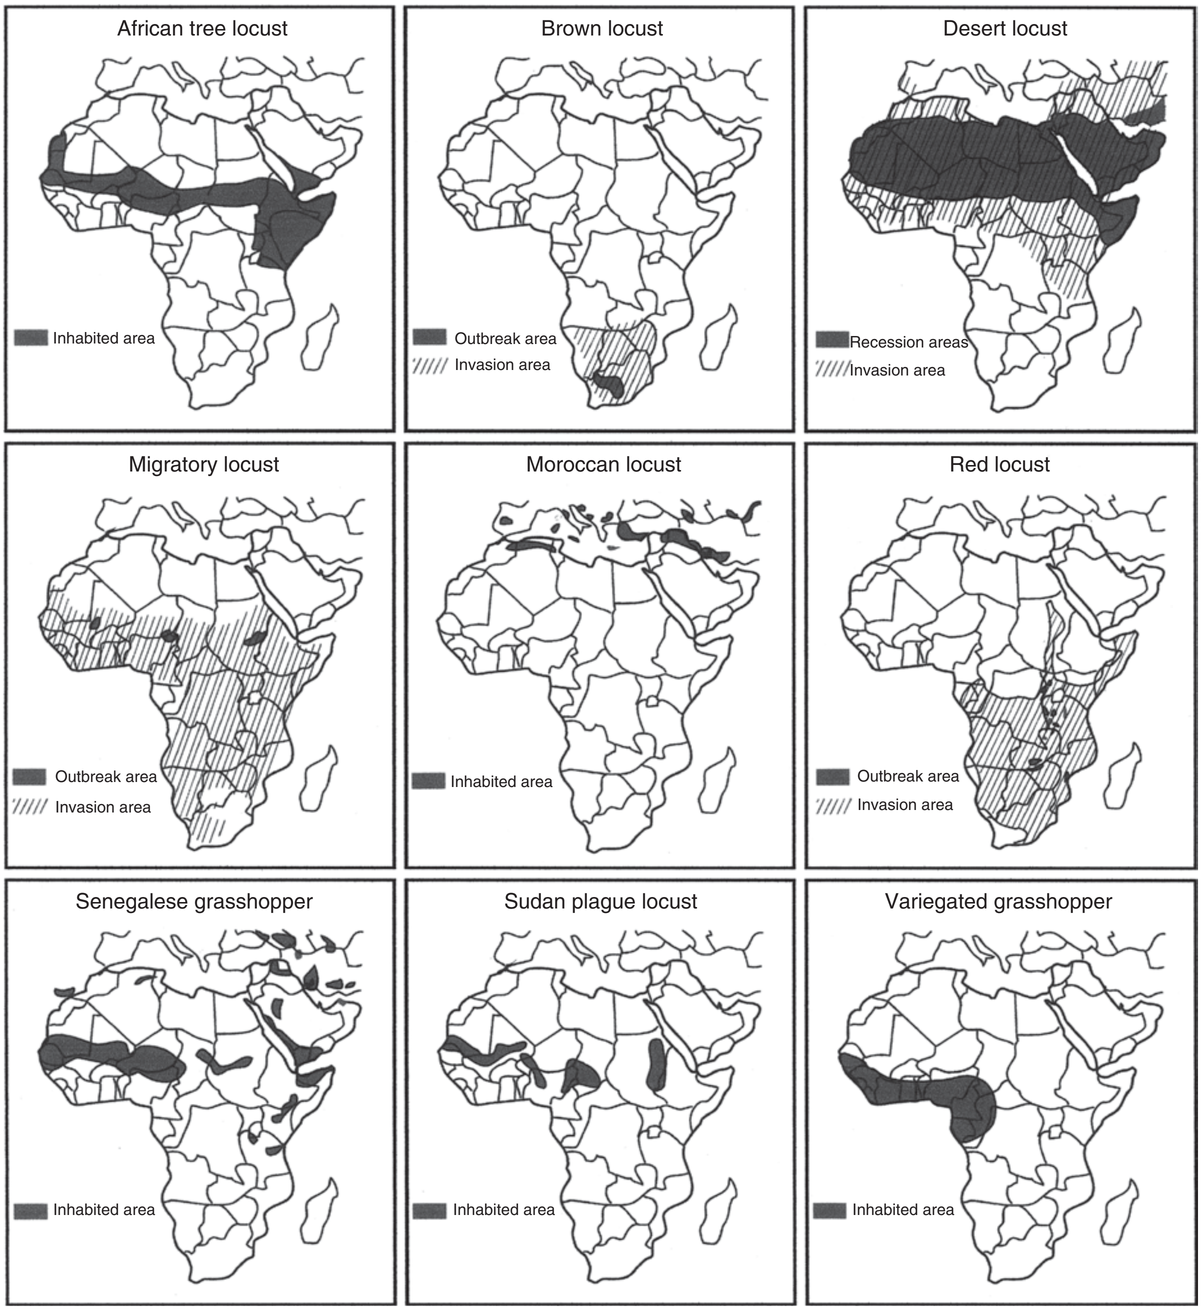
N, S, E, and W indicate northern, southern, eastern and western Africa, respectively

follows the movement of the intertropical convergence, the pattern of prevailing winds that sweeps southward toward the equator from the northern hemisphere, and northward to the equator from the southern hemisphere. Higher than normal levels of precipitation in the arid regions tends to result in population upsurges, but population decrease can be brought about by losses due to dispersal, competition for food, reduction in food due to decrease in precipitation, and the actions of



Grasshopper and Locust Pests in Africa, Figure 32 **The distribution of some important grasshoppers and locusts in Africa. The regularly inhabited areas are dark-shaded. For the dispersive species, the areas inhabited occasionally (during periods of outbreak) are shown as cross-hatched.**

natural enemies. However, as is often the case in biology, not always does this simple pattern of seasonal rainfall leading to population increase occur. This is due partly to the vagaries of weather, which are quite complex, and regionally and temporally subject to variation. Also, the different grasshopper and locust species have evolved different survival strategies. Species like the desert locust, especially when in the gregarious phase, are capable of long distance dispersal, and contrary to expectations, may seemingly disperse against the prevailing winds or disperse to areas where rainfall has not recently occurred.

Temperature is as important as rainfall and food in governing grasshopper and locust populations. Temperature affects nearly all biological activities, and when grasshoppers are outside their relatively narrow optimal temperature zone, they do not thrive. Optimal body temperature for most species is 35–42°C. To some degree, grasshoppers can modify their internal temperatures by changing their behavior, a process called thermoregulation. By basking in the sun, they can raise their body temperature by several degrees, and by moving into the shade or elevating themselves away from the hot soil surface, they can reduce their temperature. However, they remain substantially at the mercy of ambient weather conditions. In northernmost and southernmost Africa, weather is predictably limiting during the cool periods of the year. However, even in the warmer regions, temperature can be limiting, and grasshoppers engage in basking behavior and suffer metabolically during periods of heavy cloud cover or rain.

Desert Locust, *Schistocera gregaria* (Forskål)

Not only is desert locust a devastating pest in Africa, but worldwide it is the most dangerous locust species. It has the capacity to produce very large, long-lasting, and dispersive swarms. This insect is graminivorous, but during outbreaks it feeds on a large number of plants, including all the important grain crops, cotton, and fruit of the region. It occurs in a persistent form within a large area of northern Africa, Saudi Arabia, and east to India. Only small areas of this area of persistence, called a recession area, typically produce the locusts leading to swarms that spread more widely, to regions called invasion areas. Even portions of Europe and the former Soviet Union are invaded on occasion, and invasion of over 60 nations in the area has been recorded. Within the recession area are sites where locusts feed, breed and become gregarious; these can be called outbreak areas. These outbreak areas are characterized by having sandy or silty soils and being in arid or semi-arid regions. They are not always the same sites, however, because rainfall and vegetation are prerequisites to population increase.

Rainfall is required for oviposition, and females produce 20–100 eggs per pod, and two to three pods per female. On average, the solitary form produces about 95 eggs in the first pod, the gregarious form about 75. Subsequent pods have fewer eggs. The eggs complete their development in 11–75 days, fastest at about 32–34°C. The ensuing nymphs develop in about 38 days (range of 20–66 days), undergoing five instars. The molt to the adult is called fledging, and the young adult a fledgling. The adults require weeks to months to mature reproductively, but once mature persist for only about 30 days. Once they are ready to oviposit, they have only a few days to find a suitable site. Eggs do not undergo diapause. One to three generations are completed per year, depending on conditions.

Crowding for more than one generation is required for development of fully gregarious characteristics. Reduction in plant material within the outbreak sites sometimes forces the insects into closer proximity and stimulates gregarization. Alternately, repeated rains can produce several generations in the same area, allowing population increase and crowding. Sometimes partially gregarized populations move to another site that fosters further gregarization. Hoppers spend most of the day marching, and then roost at night on vegetation. Much of the feeding occurs while roosting. Once hoppers reach the adult stage, they are soon capable of flight, but do not always do so. Solitary locusts fly at night, gregarious locusts during the day. During swarms, locusts can fly for up to 17 hr per day, and travel for 5,000 km during their lifetime. Breeding can occur in the winter months in the Somali peninsula and along the Red Sea, some of the Saharan summer breeding areas and southeast Africa, and some of Pakistan and India.

Migratory Locust, *Locusta migratoria migratorioides* (Reiche & Fairmaire)

There are several named subspecies of migratory locust found in the eastern hemisphere. In Africa, the *migratorioides* subspecies is by far the dominant race. Migratory locust traditionally has been more of an issue in the southern half of Africa. It occurs in varied habitats, including dunes with open tussock vegetation, man-made habitat including fallow fields, and flooded areas. Its areas of outbreak normally are limited to small areas just south of the Sahara Desert where grass plains flood during summer rains, providing ample food. In more recent times, migratory locust has benefited from the expansion of irrigated agriculture in the Sahara region, and northern Africa is now realizing migratory locust problems. It is graminivorous. Migratory locust has two to four generations per year, and females produce one to five egg pods with up to 65 eggs per pod. Eggs normally hatch in 10–50 days, but sometimes persist for up to 100 days. There are five to seven instars, requiring a total of 21–40 days. The adults remain immature for 10–14 days, but persist for up to 70 days.

Unlike most locusts and grasshoppers, migratory locust lacks a stage that can tolerate long periods in unfavorable conditions. They must breed continuously or they die out. On the other hand, favorable conditions allow them to increase in number rapidly. The locusts migrate from the flood plains to the surrounding Sahelian areas where they oviposit, but then migrate back to the flood plain and reproduce further. The offspring of this generation again migrate to the Sahel, and return, as did their parents, to the flood plains.

Red Locust, *Nomadacris septemfasciata* (Serville)

Red locust occurs widely in southern Africa during periods of swarming, but the areas of outbreak are limited to several small regions along the Rift Valley in eastern Africa. Outbreak areas are wet lowland regions dominated by grasses and characterized by extreme conditions of flooding and drought. The outbreak areas comprise only 1/1,000 of the invasion area. This locust has only one generation per year, and eggs complete their development in 30 days. The female deposits about 100 eggs in each pod (more in the solitary form), with up to five pods produced per female at 10–15 day intervals. Six to seven instars are completed in about 60–70 days. The pre-reproductive adults persist through the dry season in regions called retention areas; these are principally in eastern Zimbabwe, southern Malawi, southwest Uganda, and northern Tanzania. They persist in this stage for over eight to nine months, and then at the start of the rainy season they mature and lay eggs, but adults live for only about a month. Eggs are deposited in areas of bare soil or sparse vegetation.

Young hoppers initially remain clumped in family groups, then disperse and re-group in about the second or third instar. The tendency to concentrate is highest in dense vegetation. About the third instar, nymphs begin to form into hopper bands. They shelter at night beneath vegetation and then climb upward to bask in the sun in the morning. As ambient temperatures reach 23°C the nymphs commence feeding and disperse, only to reassemble into bands for evening roosting. This species is graminivorous, and there always seems to be plenty of grass in the outbreak areas, so formation of swarms cannot be ascribed to lack of food. Swarms persist for long periods within their favored habitats, but when they disperse to other areas that are less favorable for reproduction the population declines.

Brown Locust, *Locustana pardalina* (Walker)

Brown locust occurs only in southern Africa, and its outbreak area is found in the southernmost part of the continent. Like most locusts, its preferred habitat is semi-arid and desert. It is graminivorous, feeding on grain crops and pastures. There are two to four generations per year. The female deposits four to five egg pods with about 40 eggs per pod at 7–8 day intervals. Oviposition occurs in dry soil but eggs require moisture to hatch. They can persist for up to 15 months without rain. These locusts tend to oviposit communally. Some eggs display delayed hatch of 1–3 months, even though they may be in the same pod as eggs hatching quickly. The rapidly developing eggs require only about 10 days to develop, and hatch when 10 mm or more of precipitation occurs. The nymphal stage has 4–5 instars, and requires 20–40 days to develop. Solitary hoppers complete development in as few as 20 days whereas gregarious hoppers tend to require 40 days, and transient forms intermediate in development time. The adults are short-lived, persisting for 2–3 weeks in the pre-reproductive stage and then 1–2 months in the reproductive stage.

Moroccan Locust, *Dociostaurus maroccanus* (Thunberg)

Moroccan locust occurs throughout the Mediterranean region on semi-arid steppe and semi-arid desert with grasses, particularly *Poa bulbosa*. It is found in northern Africa in Morocco, Algeria, and Tunisia, but is also found in southern Europe and east to Iran and central Asia in a discontinuous pattern. Formerly a minor pest, it has assumed greater importance due to destruction of forests and overgrazing, which provide additional habitat for this insect. This graminivorous species thrives in regions with winter rains and untilled soil for oviposition. Tilled soil is unsuitable, but fallow or abandoned crop land becomes suitable again. Moroccan locust has only one generation per year, and persists during the dry season, about nine months, in the egg stage. The female produces 2–5 pods, each containing 20–30 eggs. Pods tend to be grouped in clusters of 5–6 pods with several such clusters in a one meter square area. The nymphs have fives instars, and develop in 30–45 days. They form narrow bands when marching, often only 2 m deep, but a single band may extend for several km. Bands usually march during the day, but sometimes extend into the night. The adult persists for 2–4 months. The adult is gregarious, but not migratory.

Tree Locust, *Anacridium melanorhodon* (Walker)

Tree locust generally is considered to be inconsequential except in Sudan, where it defoliates *Acacia senegal*, the tree used to produce gum arabic. It feeds preferentially on trees, and is found in the Sahelian region, south of the Sahara desert, from coast to coast. Despite this preference for *Acacia*, there are reports of it attacking fruit trees, cotton, tobacco, and millet. Outbreaks occur in semi-arid areas, within natural thickets of *Acacia* spp. Normally, a single generation occurs annually, sometimes a second. Egg pods contain about 150 eggs per pod, and the eggs require 1–2 months before hatching. The nymphs undergo 5–8 instars and complete their development in 2–3 months. Immatures are found throughout the dry season, and adulthood is attained with the onset of rains (usually May-June). Oviposition begins in June-July, and young hoppers appear in August-October. Despite numerous attempts to differentiate between swarming and non-swarming populations on the basis of morphometrics, there is little difference to be found. Swarms and bands, when they occur, are relatively small. Both adults and immature forms tend to roost high in trees during the day, descending and feeding at night or early in the morning. They also fly at night.

Senegalese Grasshopper, *Oedaleus senegalensis* (Krauss)

The Senegalese grasshopper is graminivorous, and is associated with sandy soils and open steppe vegetation, predominately grasses. Found mostly in Sahelian central Africa, its distribution also extends to North Africa, the Arabian peninsula, and beyond into southwest Asia. It occurs principally in lightly wooded or open savanna, and steppe or ephemeral prairies with sandy soil. It often is associated with *Aristada pallida*, a perennial tussock grass, and *Cenchrus biflorus*, an annual grass. This species has 2–4 generations per year, and the female produces 1–2 pods with only 20–30 eggs. Eggs are deposited in moist, sandy soil. The eggs resist desiccation, and enter a period of quiescence if adequate moisture is not available. Eggs laid after late August enter obligatory diapause, which can continue for two or more years if adequate moisture is not available. The young hoppers develop quickly, progressing through fives instars in 17–20 days. The interval between hatch and first oviposition is about 35 days. The adults can live for 1–4 months. Like some other grasshoppers, this species shows some of the characteristics of locusts, displaying changes in morphology, marching by hoppers, limited swarming by adults, and long distance migration. Flight occurs mostly at night.

Sudan Plague Locust, *Aiolopus simulatrix* (Walker)

Sudan plague locust occurs in a broad band across Central Africa, and also in Asia. It is most abundant, and damaging, in the Nile Valley of Sudan. It is graminivorous and has two generations per year. Breeding begins soon after the start of rains. The female produces 2–3 pods containing 20–30 eggs per pod, which require less than a month for development. The nymphs undergo five instars, and complete their development in less than a month. The adults are long-lived, persisting for 6–9 months. Adults disperse when they are unable to find suitable breeding sites, which are normally the clay soils of flood plains.

The first generation adults migrate north, where the second generation is produced. In turn, the adults from the second generation migrate southward. Flight occurs at night. Second generation adults survive the dry season hidden deeply within the cracks in the parched soil. As temperatures and humidity rise, signaling the beginning of the rainy season, the adults emerge from the soil cracks, but return during the heat of the day. The populations inhabiting the Nile Valley, which is oriented north and south, generally have higher densities than other inhabited areas, which are smaller and not so oriented. The north-south orientation of the Nile Valley allows the locusts to remain within suitable habitat during their migrations, resulting in lower mortality.

Variegated Grasshopper, *Zonocerus variegatus* (Linnaeus)

Variegated grasshopper is found in west-central Africa. Unlike most African grasshopper and locust pests, it is found in humid and sub-humid area, inhabiting openings in the forest zone. It occupies both natural clearings and deforested, cultivated areas. This species has only one generation per year. In the mid-March to May period, females produce 2–3 pods, each containing 50–60 eggs. Egg pods tend to be clustered, often in groups of hundreds or thousands. The eggs enter diapause, and require 6–7 months for development. Hatch occurs in October or November. The nymphs require a fairly long time, 75–90 days, to undergo 5–6 instars. The nymphs tend to remain clustered into dense groups, and emit foul-smelling liquids from the first abdominal segment. They disperse relative short distances.

The adults emerge in February and persist for 60–90 days. They are dimorphic for wing length, and the long-winged forms are capable of short flights. This species is also unusual in that it prefers broadleaf plants rather than grasses.

It damages herbs, flowers, citrus, and coffee. To a lesser extent it feeds on banana, cassava, and cotton. They are most abundant, and damaging, in the dry season.

Damage

Most of the African grasshopper and locust pests feed on grasses, and it is the cultivated grasses, the grain crops, that are most damaged. The grain seedlings and immature seed heads are most susceptible to damage. Although rangeland grasses are injured, they usually recover quickly, unlike crops. However, many rangelands, particularly in the Sahel region, are being overgrazed by livestock. The additional loss of forage to locusts on such rangelands can have long-term implications for the health of this ecosystem.

Damage to both crops and rangeland is often greatest along the margins of deserts. However, when locusts swarm they can affect crops nearly anywhere. Insect damage, when taken on a regional or national basis, often seems relatively insignificant, or difficult to justify when compared to the costs of pest suppression. However, to an individual farmer or pastoralist, the losses can be devastating, and sometimes fairly large regions suffer severe losses simultaneously. Particularly in Africa, the losses caused by grasshoppers and locusts are not easily rectified due to poor infrastructure for reallocation of food, poor communication, or political turmoil. Thus, locust and grasshopper problems can have surprisingly severe consequences, and suppression programs can provide significant benefit.

The severity of the issue in Africa can be seen by examining Table 8, which shows the frequency and distribution of locust and grasshopper problems in northern Africa and adjacent areas of the Middle East for the 20-year period of 1963–1982. This example shows only countries experiencing large-scale problems that resulted in organized suppression campaigns, not smaller or localized problems. Nevertheless, the scale of the problem is apparent, and in each year there was need for organized suppression in at least one country. Also, it is apparent that some countries experienced locust or grasshopper problems almost annually, whereas for others it was an infrequent issue. Lastly, an element of area-wide population increase and decrease is evident, with many countries experiencing problems nearly simultaneously, and then release from locust and grasshopper problems at about the same time.

Management

Technologies for population assessment have improved, eliminating some of the element of surprise from locust and grasshopper outbreaks. Weather monitoring and modeling are often very useful for forecasting the potential for problems, and vegetation can be assessed with remote sensing technology. However, insect populations are normally confirmed by ground survey personnel via site visits, although swarming populations are sometimes monitored by observers in aircraft. The most important benefit of newer (remote) assessment technologies is that ground survey personnel are able to focus their visits and insect sampling to areas and times where they are likely to detect the pests. This improved efficiency translates into considerable financial savings. The locust outbreak areas are often targeted for more intensive monitoring and control efforts because costs are greatly reduced by treating pests while they are confined to these relatively small areas.

Although it is possible to recommend cultural and physical management techniques to help suppress grasshoppers and locusts, implementation is often difficult. Over the last 50 years, chemical insecticides have proven to be the management technique of choice, and a considerable amount of effort has been dedicated to improving the application techniques or otherwise affecting the killing power of the insecticides. Generally, application of liquid, residual insecticides to plants, by use of both ground application equipment and aircraft,

Grasshopper and Locust Pests in Africa, Table 8 North African and Middle Eastern countries in which large-scale locust/grasshopper suppression occurred during the 20 year period of 1963–1982 and the total number of years the suppression programs were instituted

has been effective. On a much more restricted scale, poison bait applications have been used, especially for the treatment of bands of the gregarious, wingless stages of locusts. More recently, flying swarms have been sprayed with insecticides, or even better, swarms that have alighted. For both ground and air application of liquid insecticides, ultra low volume (ULV) techniques are preferred because mixing and dilution with water is unnecessary, and applicators can spray more land area with each load of insecticide.

Bioinsecticides have recently been developed as an alternative to chemical insecticides. In particular, identification of a relatively fast-acting fungal pathogen, *Metarhizium anisopliae* var. *acridum* (formerly known as *M. flavoviridae*), and the formulation of this in oil, have greatly improved the ability to implement non-chemical suppression. Other bioinsecticides, such as *Beauveria bassiana* and *Nosema locustae*, have proven to be less efficacious, as has the botanical insecticide neem. Insect growth regulators have been shown to disrupt the development of grasshoppers, but this requires that the product be applied to the immature stages, and will not protect against winged swarms.

Grasshopper and Locust Pests in Australia

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

In Australia (also in Asia, Africa, and South and Central America), some grasshoppers (Orthoptera: Acrididae) are called "locusts." This designation is applied to species of grasshoppers that display phase change. Phase change is largely a behavioral change between different states, gregarious and solitary forms. During the gregarious phase, which is induced by high densities, locusts tend to disperse long distances as groups (during the nymphal stage, the aggregations are called bands, during the adult stage, they are called swarms). These same species are not very dispersive or gregarious during the solitary phase. Physical changes in appearance may also occur during the change in phase, and of course physiological changes underlie the behavioral and morphological shifts. Transition between the solitary and gregarious phase takes more than one generation. In contrast, grasshoppers tend not to disperse long distances, tend not to aggregate during dispersal, and their appearance remains about the same regardless of density conditions. Thus, "grasshoppers" do not display phase change.

The distinction between grasshoppers and locusts is not clear-cut. At low densities, locusts are not gregarious, nor highly dispersive, but they are still called locusts. Some species that occasionally form aggregations, even forming bands, are called grasshoppers, not locusts, because they do not disperse long distances. In Australia, migratory locusts have all the features associated with phase change: change in body shape and color, and formation of dense swarms during dispersal. The Australian plague locust displays a tendency to become gregarious and to swarm, but lacks a change in appearance during the transition between phases. The spur-throated locust rarely forms bands, though it does form swarms. The small plague grasshopper forms aggregations, but does not undergo long distance dispersal in swarms. So the "locusts" of Australia display a wide range of behaviors, from very locust-like to not so typically locust-like.

Australia is known for frequent and severe problems with locusts, but grasshoppers also are implicated. The severity of the problem is due principally to the fact that Australia is largely an arid country (about 80% is arid or semi-arid), and in this environment not only do grasshoppers tend to thrive, but the effects of their herbivory are amplified by the sparse grass and other herbage available to livestock in this climate. During periods of drought, forage plants are especially valuable, and vital for livestock grazing; thus, conflict with humans is inevitable. However, the relationship of grasshoppers with moisture is not simple. In the more arid, ephemeral grasslands, high levels of summer moisture provide an abundance of food, allowing grasshoppers to maximize their reproductive potential and build to high numbers, usually over three to four generations. As the vegetation dries, the grasshoppers disperse (migrate) until they find areas with green vegetation.

In regions with more rainfall during the summer breeding season (formerly forested but cleared by humans for grazing or crops), however, biotic factors that suppress grasshopper numbers are more effective during wet seasons, so population outbreaks are associated with drought. In some areas, clearing of forest, expansion of improved pasture, and the introduction of irrigation have created environments conducive to grasshopper outbreaks. In these areas, species not formerly causing problems have emerged as pests.

Pest Species of Grasshoppers in Australia

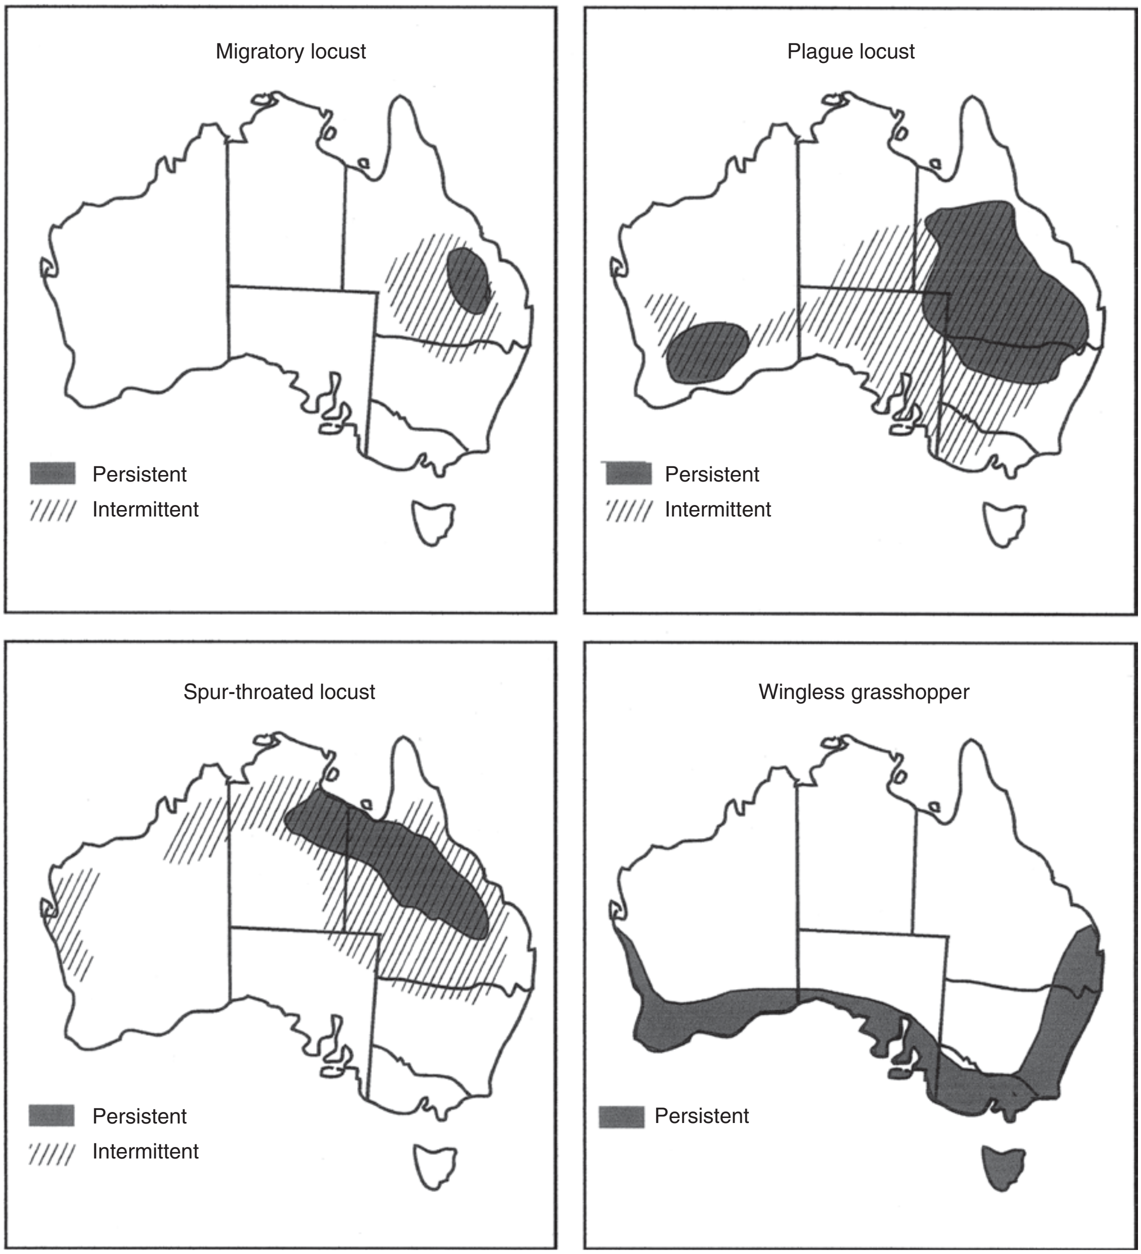
Despite that fact that about 275 species of grasshoppers are known from Australia, only a few are serious pests, and most are indigenous to Australia. However, most of the damage is caused by only four species: Australian plague locust, *Chortoicetes terminifera* (Walker); spur-throated locust, *Austracris guttulosa* (Walker); migratory locust, *Locusta migratoria migratorioides* (Reiche & Fairmaire), and wingless grasshopper, *Phaulacridium vittatum* (Sjöstedt), and of these, two are rather widespread in Southeast Asia (Fig. 33). The important species are given in (Table 9).

Spur-throated locust and migratory locusts sometimes cause severe damage on a localized basis, but the frequency of this is low. Wingless grasshopper has emerged as a chronic pest of improved pastures in southeastern Australia. Small plague grasshopper was formerly a serious pest in Australia during the 1930s and 1940s on cereal crops grown in southern and western Australia, but has diminished in importance. Giant grasshopper is pestiferous only occasionally, and this species is limited to northern and eastern Australia. Yellow-winged locust feeds only on grasses, and though irregularly important, seems to be favored by drought.

Australian Plague Locust, *Chortoicetes terminifera* (Walker)

The Australian plague locust is the most important grasshopper pest in Australia due to the high frequency of outbreaks and the widespread nature of the problem. For example, during the period of 1976–2001, Australian plague locust required control in eastern Australia in 18 of the 27 years. The number of generations ranges from one per year in arid, interior regions, to three per year in the more favorable regions of eastern Australia. Outbreaks normally originate in the arid zone of southeastern Australia, and to a lesser degree southwestern Australia, but they can disperse into adjacent but much larger areas during periods of outbreak.

Australian plague locust normally inhabits areas containing Mitchell grass, *Astrebla* spp., species that remain green for several months after rain, thus providing a relatively constant



Grasshopper and Locust Pests in Australia, Figure 33 **The distribution of some important grasshoppers and locusts in Australia. The regularly inhabited areas are dark-shaded. For the dispersive species, the areas inhabited occasionally (during periods of outbreak) are shown as cross-hatched.**

food supply. If multiple rainfall events occur, populations build rapidly, and migrate if rain does not continue. The direction of dispersal is determined by the pattern of weather; in eastern Australia, those moving in southerly or easterly directions pose a serious threat to crops. Long-distance dispersal occurs when nighttime temperatures (above 25°C) are warm, and strong winds are present at high altitudes. These locusts typically remain airborne for 8–9 h, descending

Grasshopper and Locust Pests in Australia, Table 9 **The most important grasshopper pests in Australia**

Scientific name	Common name	Occurrence
Chortoicetes terminifera (Walker)	Australian plague locust	Semi-arid interior of Australia
Austracris guttulosa (Walker)	Spur-throated locust	Northern and northeastern Australia, and elsewhere in Southeast Asia; adapted to seasonally dry regions
Locusta migratoria migratorioides (Reiche & Fairmaire)	Migratory locust	Adapted to continuous moist tropical and subtropical conditions, especially coastal regions of northern and eastern Australia, but widespread in the Pacific Region
Phaulacridium vittatum (Sjöstedt)	Wingless grasshopper	Moist uplands of temperate regions of Australia
Austroicetes cruciata (Saussure)	Small plague grasshopper	Limited to southern fringe of arid zone in Australia
Gastrimargus musicus (Fabricius)	Yellow-winged locust	Moist subcoastal regions of Australia
Valanga irregularis (Walker)	Giant grasshopper	Eastern Australia
Oedaleus australis Saussure	Eastern plague locust	Eastern interior Australia
Aiolopus thalassinus Fabricius	Clearwinged grasshopper	Coastal and subcoastal eastern Australia
Praxibulus spp.	Yellow-bellied grasshoppers	Southeastern Australia
Fipurga crassa Sjöstedt	Dimorphic grasshopper	Southeastern Australia
Urnesia guttulosa Walker	Salt and pepper grasshopper	Semi-arid interior of Australia

at daybreak. Emigrants may breed successfully and continue the outbreak, but Australian plague locust outbreaks typically dissipate within a few generations. Thus, its notoriety is based more on the frequency of occurrence than the length of the plague. Sometimes migration proves to be deadly for locusts, as their dispersal is largely determined by strong winds associated with weather fronts or low pressure systems. Low pressure is often indicative of rain, which works to the advantage of insects requiring green grass for breeding, but sometimes locusts are deposited in lakes or the ocean, causing massive mortality. Also, though it is less evident, the progeny of some migratory locusts return from the invaded areas to their regions of persistence, helping to re-establish the potential for new outbreaks.

In the south, the cool winters inhibit development and no egg laying occurs for about three months. Egg deposition typically occurs in hard, packed soil or stony areas. In the warmer north, the interruption in reproduction is shorter. Irrespective of location, however, at the start of the spring the majority of the population is usually in the egg stage, and some diapause occurs. This locust has five or six nymphal instars after hatching, which requires (in total) 3–5 weeks. Males of Australian plague locust measure about 25–30 mm long, females 30–42 mm. Adults of this species are distinguished from other common locusts by the presence of a dark spot at the tip of the hind wing. The adult requires only about 2 weeks to mature, and then deposit eggs. Eggs are deposited in the soil at a depth of 6–8 cm. If the weather is favorable and no diapause occurs, eggs can hatch in as little as 2 weeks. Females deposit two to three egg pods, each containing about 50 eggs. Often females lay large numbers of pods in the same area (egg beds), probably because soil moisture conditions are appropriate. If the rainfall is concentrated into a brief period (typically summer, but winter in some locations) the population is limited to a single generation, but if rainfall continues (e.g., spring and autumn), up to four generations may occur. It is these multiple generations per year that can result in rapid population increase and development of a plague.

Spur-Throated Locust, *Austracris guttulosa* (Walker)

This tropical species occurs widely in Australia and nearby islands, north to the Philippines. Unlike most of Australia's locust and grasshoppers, which survive the inclement periods in the egg stage, this species undergoes reproductive diapause. Thus, it fails to reproduce during the dry season, but commences egg production with the onset of the monsoons in the spring. Additional rain is needed for good egg and nymph survival. As noted previously, the egg stage does not undergo diapause and requires warm conditions in order to develop. A period of quiescence is possible, however, and egg hatch can be delayed for a month if moisture is absent.

This species is distinguished by the presence of a large spine between the front legs, and its large size. Males are 55–65 mm in length, females 70–80 mm long. This species lays up to 160 eggs in a pod, and up to five pods within its life span. It does not favor oviposition in egg beds, though barren areas are favored. Areas along roadways and irrigation ditches often are favored oviposition sites. Eggs require 18–30 days to hatch. Nymphs can be found at high densities, but they do not form marching bands. Duration of the nymphal stage is 1–2 months. There are 6–8 instars. The adults mature at the end of summer. Only one generation develops per year.

Outbreaks of spur-throated locust are infrequent, and initially are quite confined in area. Population dynamics are not well understood, but abnormally high summer rainfall is thought to precede population increases. If vegetation becomes dry, adults are more likely to migrate. After spending the dry winter months in a rather sedentary manner, roosting in trees or other tall vegetation, the adults become active in the spring and may disperse and expand the outbreaks. The populations cannot thrive without wet conditions, however, so except during outbreaks it is largely confined to the wet northern regions. Grasses are the principal host during the early instars. As summer habitats dry up, swarms disperse to winter habitats, which are woodlands and cultivated crops. Because the adult stage persists through the winter until mid summer, it can easily damage a wide range of winter crops (wheat, barley, millet) and summer crops (sunflower, soybean, cotton, sorghum), and others. The adults tend to feed during the day, and roost in trees at night.

Control of this species is directed at the adult stage, which is sedentary in winter and therefore easy to assess and treat with insecticides. Once the adults disperse, egg laying is scattered, so treatment of nymphs is difficult.

Migratory Locust, *Locusta migratoria migratorioides* (Reiche & Fairmaire)

Widely distributed in the Australasian region, this is a diapause-free insect that inhabits the mild, mostly coastal and subcoastal regions of Australia, and cannot survive the colder regions of southern Australia. Two (in temperate areas) to four (in tropical areas) generations are produced per year. They are primarily grass feeders, attacking grass pastures and grass crops such as sugarcane, sorghum, maize, and wheat.

This large, heavy-bodied species measures about 45–55 mm in length for males, and 55–65 mm for females. Females commonly oviposit in groups, resulting in "egg beds" that contain numerous egg pods. A pod contains about 50–60 eggs, with females producing 3–5 pods. Eggs require 11–15 days to hatch. There are about six instars, and this insect requires approximately 30 days to attain maturity.

Changes in weather precipitate outbreaks of this species, resulting in gregarization. Increases in winter rainfall and decreases in summer rain are the normal triggers. However, forest removal and pasture improvement has fostered winter breeding in some areas, and provided good sites for oviposition. It was not until the extensive clearing of native vegetation of the central highlands of Queensland that migratory locust became a pest, as pastures and crops have become important food resources.

Migratory locust is less dispersive than many other locusts, and nighttime flights are lacking, so development of outbreaks proceeds slowly. The swarms are unusually cohesive, however, and characterized by a low, tumbling or rolling progression. Once the swarms leave habitat suitable for breeding, they collapse. Duration of outbreaks is 10–20 generations over 4–5 years, which is longer than some other locusts but shorter than exhibited by the same species in Africa and the Philippines (7–13 years). A wide range of crops are damaged by migratory locust, and damage can be quite severe, but due to the limited dispersiveness it tends to be a regional concern rather than a national problem.

Control of migratory locust is feasible if properly timed because, during the period of gregarization, the populations are confined to relatively small areas. If detected during the period of gregarization, suppression with chemical insecticides, using aerial or ground application technology, is quite efficient and economical.

Wingless Grasshopper, *Phaulacridium vittatum* (Sjöstedt)

Wingless grasshopper is actually a species complex, consisting of *Phaulacridium crassum* Key (though much less important and confined to southwestern Australia) in addition to *P. vittatum*, though the presence of *P. crassum* is often overlooked. It is found in the cooler, temperate areas of Australia. Wingless grasshopper has only one generation per year. Eggs are deposited in the fall, undergo diapause and hatch in the spring. Egg pods contain only about 12 eggs per pod, considerably less than the aforementioned locusts, which usually produce pods of 50 or more eggs. However, they may produce 12–16 pods. There are five instars during the summer months.

Males of wingless grasshopper are about 8–12 mm in length; females are 12–18 long. Despite the name given these grasshoppers, wingless grasshopper is short-winged under most pasture conditions and often long-winged in woodland and garden conditions.

Wingless grasshopper problems were not known in Australia until about 1935, and were not recorded as a severe problem until 1979, but are increasing in severity. This grasshopper normally feeds on broadleaf plants in woodlands and pastures, and though present, is not common in natural woodlands, probably due to shortage of suitable food. With European settlement came land clearing and introduction of grazing animals that depleted the native grasses. Accidentally introduced and deliberately introduced broadleaf plants soon replaced native grasses; the broadleaf plants proved to be very suitable food for wingless grasshoppers. However, it was not until about 1945, when subterranean clover (a winter-active plant) was planted into pastureland, and fertilized, that wingless grasshopper became a regular problem. Addition of other legumes (perennial clover in southeastern Australia and alfalfa [lucerne] in southwestern Australia) during the summer exacerbated the grasshopper problem by providing a continuous suitable food supply. It also attacks crops such as sunflowers, sweet corn, potatoes, grapes, ornamentals, and trees. Movement of these grasshoppers is unlike that of most locusts. The dispersing assemblages are described as streaming, and as formation of loose bands. They occur when food is depleted, which often is associated with hot weather.

The continuous availability of food predisposes improved pastures to wingless grasshopper problems, but outbreaks also involve drought, overgrazing, and insect parasitic nematodes. When droughts occur, the carrying capacity of pastures is exceeded, and overgrazing occurs. Overgrazing, and opening of the canopy, initially favors grasshopper survival, and drought inhibits mermithid nematodes (*Amphimermis acridiorum*, *Agamermis catadecaudata*, *Mermis quirindiensis*, *Hexamermis* spp.) from parasitizing wingless grasshoppers. When rainfall again increases, the activity of the nematodes increases correspondingly, resulting in grasshopper suppression.

Wingless grasshoppers can be managed if continuous vegetative cover is maintained, particularly an increase in grasses at the expense of legumes. Natural enemies, particularly mermithid nematodes, are important and favored by good vegetative cover and high moisture. Reforestation, especially of ridge lines where grasshopper survival is favored, will reduce grasshopper numbers. Overgrazing should be avoided.

Management Strategies

Many of Australia's locust problems result from changes in precipitation, and there is little to be done about weather other than careful weather monitoring. However, it is imperative to understand how different species respond to precipitation, and to be alert for impending problems. Population monitoring can be difficult when dealing with swarming insects, as it is easy to overlook mobile swarms until they move to cultivated areas. Once increasing populations are detected, it is advisable to decrease the threat of economic loss from migrating swarms by eliminating the problem before it fully develops. This usually requires decreasing the pest population by 50% in each generation, even when the pests are limited to waste areas and not immediately threatening. This is a departure from past practices, when populations were treated primarily when they moved into crop or pasture areas. The reasoning behind not treating locusts until the threat was imminent was that many swarms would collapse due to changes in weather without ever doing damage to crops. However, to allow the populations to develop unimpeded meant that the resultant populations could be quite large and difficult to control. Locust and grasshoppers are treated with liquid insecticides by air and ground; poison baits also are used, especially for wingless grasshopper. As noted above, some species become problems following changes in land management, mostly land clearing for crops or replacing grasses with more susceptible plants. Thus, some problems can be alleviated by wise land use.

Grasshopper Pests in North America

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

In North America, there is not much effort to label grasshopper species as "locusts," as is done elsewhere in the world, though the Central American locust, *Schistocerca piceifrons* (Walker), occurring in Mexico and southward into South America, is a notable exception. At least one additional species (*Melanoplus sanguinipes* [Fabricius]), perhaps others, would qualify as locusts using the standards of orthopterists elsewhere (see "Grasshopper and locust pests in Australia" for discussion of this topic). Also, the crop-damaging shieldback katydids or long-horned grasshoppers (Orthoptera: Tettigoniidae) are often called crickets, but functionally affect crops and rangeland like grasshoppers, or maybe even locusts, so they are mentioned below even though they are technically neither grasshoppers nor crickets. With few exceptions, North American grasshoppers considered to be pests are in the order Orthoptera and family Acrididae; the exceptions are lubber grasshoppers (Romaleidae) and the aforementioned tettigoniids.

Grasshoppers attack nearly all grain, forage, field, fruit, and vegetable crops. Ornamental plant crops are also damaged in both nurseries and the landscape when grasshoppers are especially abundant, but less often than other crops due to their common location in or near urban and suburban areas, away from habitats conducive to grasshopper outbreaks. Rangeland is the natural habitat of an immense assemblage of grasshoppers, and more than any cultivated crop, it is affected by grasshoppers. Sometimes the grasshoppers cause injury when the plants are quite small and easily defoliated, or stressed by lack of precipitation. However, mature or nearly mature crops are commonly damaged when grasshoppers enter crops along the field margins, feeding on the foliar or reproductive structures. Unhindered, they may eventually spread over the entire field. On rangeland, grasshoppers are often found throughout the environment, though the elements of the species assemblage vary according to topographic and host plant characteristics.

Ragged leaf tissue or complete defoliation of plants along field margins is suggestive of grasshopper problems. Normally the grasshoppers are readily visible, though the adults of some species sometimes disperse to distant areas with good cover, re-invading the crop daily.

Identity of Crop-Feeding Grasshoppers (Families Acrididae, Romaleidae, Tettigoniidae)

Melanoplus spp. (family Acrididae) grasshoppers are the most important grasshopper pests of crops in North America. The principal pests in North America are two-striped grasshopper, *Melanoplus bivittatus* (Say); differential grasshopper, *M. differentialis* (Thomas); red-legged grasshopper, *M. femurrubrum* (De Geer); and migratory grasshopper, *M. sanguinipes* (Fabricius) (Fig. 34). In northernmost states of the United States and the Prairie Provinces of Canada, Packard's grasshopper, *M. packardi* Scudder, can be locally important, as can other species including some band-winged species, particularly the clear-winged grasshopper, *Camnula pellucida* (Scudder). In southeastern North America, eastern lubber grasshopper, *Romalea microptera* (Beauvois) (family Romaleidae) and American grasshopper, *Schistocerca americana* (Drury) (Acrididae) are locally important. In Mexico and Central America, the Central American locust, *Schistocerca piceifrons* Walker displays locust-like behavior. Overall, migratory grasshopper is the most damaging species, and though not usually called a "locust," nonetheless it is a strong flier and has gregarious tendencies. Other species can surpass the abundance of *M. sanguinipes* locally, and others display gregarious and dispersive tendencies, but none compare on a regional basis to this widespread grasshopper. In the mountain and intermountain areas of western North America, certain shieldbacked katydids (family

Capinera).**

Tettigoniidae) are grasshopper- or locust-like, though flightless. The most important is Mormon cricket, *Anabrus simplex* Haldeman, but sometimes coulee cricket, *Peranabrus scabricolis* (Thomas) is abundant enough to be damaging to crops.

Life Cycle of Crop-Feeding Grasshoppers

Most grasshoppers pass the winter in the egg stage and have a single generation per year, but in southern areas *M. sanguinipes* and *S. americana* may have additional generations, and *S. piceifrons* has two generations. Grasshoppers typically hatch from eggs in the spring or early summer. The species differ slightly in the timing of their hatch, and the hatching is not synchronous, so different stages may be found throughout the summer. Grasshoppers usually molt five or six times and require about 5–6 weeks to reach maturity. About two weeks later they commence egg laying, and continue to deposit eggs, in clusters called pods, containing 20–100 eggs per pod until they are killed by cold weather. Eggs, which are deposited in the soil, are not normally affected by weather, but are susceptible to damage by tillage and certain predatory insects. When the young grasshoppers hatch in the spring they are susceptible to inclement weather (low temperatures and rainfall). Throughout their lives, grasshoppers are attacked by parasitic insects, diseases, and insect and vertebrate predators. These natural enemies can suppress grasshoppers locally, but often only after the grasshoppers attain very high and damaging densities. Plants differ greatly in suitability for grasshopper survival and growth. In general, these pests prefer broad-leaf plants, not grasses, but the cultivated grains, especially wheat and corn, are highly attractive and suitable for grasshopper survival.

Management of Crop-Feeding Grasshoppers

The need for management is most directly related to grasshopper density. As a general rule, when grasshopper densities are 15 or more per square yard (18 per square meter) within a grain field or more than 40 per square yard (48 per square meter) along field borders, economic damage will ensue. With densities of 8–14 per square yard (10–17 per square meter) within a field, or 20–40 per square yard (24–48 per square meter) along field borders, the crop is at risk. These lower densities can prove damaging when the grasshoppers are more mature (larger), the crop is young, or the crop is stressed by lack of soil moisture. Thus, for winter wheat culture (the crop is planted in the late summer, becomes dormant in the winter, and completes its growth in the spring), the lower thresholds for treatment are used because the grasshoppers are mature in the autumn when the wheat is young.

Grasshopper problems most often originate outside the crop field (though planting into wheat stubble or fields that were previously weedy can be exceptions), so treatment of weedy or waste areas (sometimes rangeland) surrounding a field with an insecticide can be an effective approach to prevent invasion of the crop (Fig. 36). Liquid formulations of contact insecticides are usually used for this approach. Alternatively, treatment of the crop margin (about 150 feet [47 m] of the border areas) will kill most grasshoppers as they disperse into a crop. Fast-acting contact insecticides applied to foliage or soil, contact insecticides applied to wheat bran bait, and systemic insecticides applied to the foliage or seed are some approaches used to deliver toxicants to grasshoppers. In some areas, farmers commonly plant higher densities of grains along the field margins if they anticipate grasshopper problems, to allow for some crop loss.

Identity of Rangeland Grasshoppers

Rangeland occurs mostly in arid and semi-arid regions, which corresponds roughly with the western half of the United States and Canada. This habitat consists of grasses and broadleaf plants (forbs), and sometimes shrubs, but not usually trees. The North American grasshoppers affecting rangeland sometimes are the same as those affecting crops, particularly *Melanoplus sanguinipes*, and to a lesser degree *Camnula pellucida* and *Anabus simplex*, which can be abundant and damaging in both environments. Most often, however, the abundant species on rangeland are not the same as those affecting crops (Fig. 35), even when irrigated crops are surrounded by rangeland, providing good opportunity for rangeland species to disperse into crops. Often when the crop-feeding

Grasshopper Pests in North America, Figure 36 **Damage to the edge of a winter wheat field caused by grasshoppers. Grasshoppers dispersed from the residue of a previous weedy wheat crop (designated "a"), to the margin of a young wheat crop, where they destroyed the seedlings (location "b"). The undamaged wheat is in the foreground (location "c").**

species are present on rangeland, it is due to disturbance and growth of weedy vegetation instead of native grasses or forbs. Floral disturbance can occur following overgrazing, excessive trampling of the soil (a common occurrence around livestock water tanks), or other factors such as outbreaks of white grubs (Coleoptera: Scarabaeidae) which kill the grasses, allowing weeds to invade. The species most commonly associated with rangeland damage are listed in the table.

North America has a surprisingly rich fauna on rangeland, with a large number of species contributing to "grasshopper" population outbreaks (Table 10). About 375 species of grasshoppers are found inhabiting North American rangeland. About a third are considered to be pests, but nearly all the rest are innocuous, either due to their dietary habits or their lack of abundance. Most outbreaks on rangeland consist of an assemblage of species, with the species varying from place to place, and some peaking early in the outbreak cycle, and others later. Another interesting aspect of rangeland grasshopper problems is that some species have proven to be destructive at one time or another, only to fade into oblivion for many years (e.g., high plains grasshopper, *Dissosteira longipennis* Thomas).

Interestingly, not all rangeland-dwelling grasshoppers are pests. Many species do not feed on grasses or other important livestock food (the "grass" hopper designation, like many common names, is not entirely accurate). More importantly, some species feed selectively on rangeland plants that are considered to be toxic to livestock (e.g., *Hesperotettix viridis* [Scudder] on snakeweed, *Gutierrezia sarothrae* and *microcephala*) or competitors for moisture or light with more nutritious species (e.g., *Hypochlora alba* Dodge on sagebrush, *Artemisia* spp.). Even *Anabrus simplex*, long viewed as a scourge of farmers and ranchers in the Rocky Mountain region, has been shown to be relatively innocuous on rangeland under normal conditions. It avoids grasses, except for seed heads, preferring to feed on flowers and foliage of low-value broadleaf weeds. Only under severe drought conditions, when there is almost no forage available for livestock, is this insect a pest of rangeland.

Life Cycle of Rangeland Grasshoppers

The biology of rangeland grasshoppers and crop-feeding grasshoppers is, in most cases, about the same. However, a few rangeland species overwinter as nymphs, and in southernmost areas adults are sometimes found in the winter. Natural enemies are more important in the survival of rangeland grasshoppers because insecticides are rarely used, and therefore beneficial insects are more abundant. Tillage is not normally practiced on

rangeland, so there is less soil disturbance that might result in destruction of egg pods. In contrast to crop environments, egg pods in rangeland are less likely to be concentrated along field margins, as often occurs with crops that have weedy margins along fences and irrigation ditches, which are favored by grasshoppers for oviposition.

A notable aspect of rangeland grasshopper biology is the relatively synchronous increase or decrease in abundance of different species in the grasshopper species assemblage. Population cycles are related to weather, host plant abundance, and natural enemy abundance. Generally, hot and dry weather are responsible for increase in population density in northern areas, where grasshoppers are limited by inadequate daily warmth during the summer days, or a short summer season. In southern regions, however, warmth is not so limiting, and the lack of abundant nutritious vegetation is more constraining, so rainfall during the spring (which determines the availability of host plants) is a controlling variable.

Grasshoppers need to control their body temperature if they are to feed, develop, and reproduce optimally. Patches of bare soil allow grasshoppers a site to elevate their body temperatures by basking in the sunshine, and so many species thrive where the vegetation density is low enough to allow basking. However, if there is too much vegetation-free space they cannot meet their nutritional needs. Thus, there are trade-offs between not enough and too much vegetation, and this is made more complex by the differing dietary needs (different host preferences and amount of vegetation required) of different species of grasshoppers. Competition for the most suitable food resources is more frequent and important than generally acknowledged. Many observers fail to recognize that grasshopper populations can be under nutritional stress when there is still relatively abundant vegetation on rangeland because it may be difficult to discern that the most favored plant species have already been consumed.

Rangeland differs greatly in suitability for plants and grasshoppers. Precipitation is the major determinant of plant species occurrence and in plant size, but temperature effects, due both to altitude and latitude, are important. The dominant species of grasses, and their biomass, change with location. For example, the dominant grasses are various *Adropogon*, *Agropyron*, *Stipa*, *Panicum*, and *Calamovilfa* spp. in the eastern areas of the Great Plains of North America, but are replaced by *Bouteloua* and *Stipa* spp., *Koleria scoparius*, and *Agropyron smithii* centrally, and *Bouteloua gracilis*, *Agropyron smithii*, and *Buchloe dactyloides* in more western regions. There is also a general decrease in the average height of vegetation as one moves from east to west in the Plains region, so these regions are denoted as tallgrass, mixedgrass and shortgrass regions, respectively. In the intermountain region, bunchgrasses such as *Agropyron spicatum* and *Bromus* spp. predominate. As noted in the table, species from three subfamilies, Melanoplinae, Gomphocerinae, and Oedopodinae, are important rangeland grasshoppers. Generally, members of each subfamily occur together, but the proportion in each subfamily is not constant among different localities. Though tallgrass and mixedgrass environments are dominated by grasshoppers in the subfamily Melanoplinae (spurthroated grasshoppers), shortgrass sites are dominated by grasshoppers in the subfamily Gomphocerinae (stridulating slantfaced grasshoppers).

Management of Rangeland Grasshoppers

The principal challenges confronting rangeland grasshopper management are the extensive areas to be managed, and the low value of the forage. Both factors limit the amount of money that can be expended per unit area, and preclude using anything but the most economic pest suppression measures in most instances.

Insecticides are generally used for suppression of grasshoppers, and usually area-wide campaigns are instituted with the help of government agencies because when a problem develops, it normally occurs over a large geographic area. Large, specially equipped aircraft often are used to treat large land areas with liquid insecticide, and sometimes ultra low volume (ULV) insecticides are applied because they are applied undiluted and at very low application rates, which means that more land area can be treated between refills of the spray tanks. This reduces time and labor costs considerably. A common alternative to liquid insecticide application is to apply insecticide-treated bran bait using aircraft. This has the advantage of being more selective, because although many species of grasshoppers will feed on bait and perish, many other insects are unaffected.

When initiating grasshopper suppression on rangeland, the common biological considerations are the grasshopper species involved, their density, and the stage of development. Not all grasshoppers are damaging, and some are quite a lot more damaging than others. A density of 10–15 grasshoppers per square yard (12–18 per square meter) is normally needed to justify treatment (hopefully adjusted for the species involved). Not all grasshoppers hatch synchronously, and applications are timed to allow for all, or at least most, of the hoppers to hatch and thus come into contact with the insecticide. Waiting too long, however, is counterproductive because they will have already consumed a significant amount of livestock forage.

Grasshopper suppression operational considerations are as important as biological considerations in determining the feasibility of area-wide grasshopper suppression. Operational considerations usually involve population sampling to delineate areas that need treatment over an extensive area, including areas that are "sensitive" and cannot be treated; obtaining and scheduling the aircraft and toxicants; organizing ranchers to obtain funds and permission for treatment; and establishing a mechanism of effective mapping, communication, and rancher and public information, including news releases.

Livestock grazing pressure is often suggested as an element that affects grasshopper abundance. Historically, overgrazing by livestock disrupted the native flora, especially in the eastern regions of the Great Plains, allowing invasion of weeds more suitable for grasshoppers. Also, grazing can result in more barren soil, which is attractive to grasshoppers for thermoregulation and oviposition. Thus, grasshopper problems are sometimes attributed to overstocking of livestock. While overgrazing should be avoided for several reasons, including the ability to cause grasshopper problems under certain conditions, some rangeland can tolerate quite a lot of grazing pressure, and even benefit from grazing by livestock. Extensive research has demonstrated a positive correlation between vegetation abundance and grasshopper abundance in the arid regions of the Great Plains where vegetation is shorter or less abundant, and grasshoppers tend to be food-limited. As noted previously, these areas are dominated by gomphocerine species, whereas other areas have proportionally more melanoplines and oedopodines. Where gomphocerine grasshoppers predominate, moderate or heavy grazing can reduce the abundance of grasshoppers relative to ungrazed or lightly grazed areas.

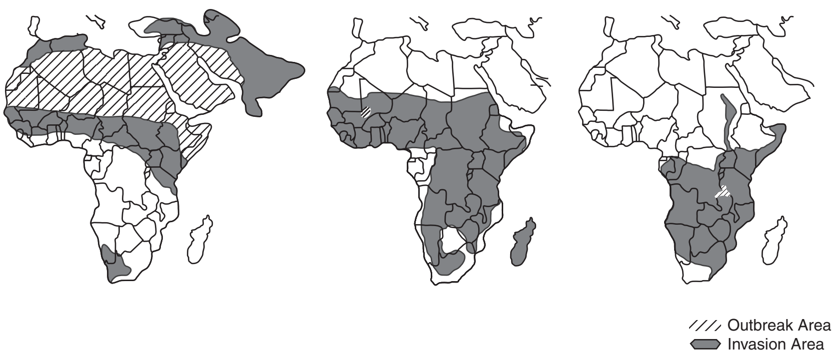
Grasshoppers and Locusts as Agricultural Pests

STEVEN ARTHURS
Texas A&M University, College Station, TX, USA

Orthoptera represent a large insect order with a worldwide distribution. Taxa in the superfamily Acridoidea are commonly either called grasshoppers or locusts. This division separates insects that readily aggregate in persistent bands or swarms in response to increases in intra-specific density ("locusts") from those that show no such change in behavior ("grasshoppers").

Economically, socially and historically, locusts and grasshoppers are one of the most destructive pests. This century alone, there have been eight major plagues of the desert locust *Schistocerca gregaria* Forskål. Agricultural production across 29 million km^2 in Africa and south-western Asia is threatened during plague periods.

Although the desert locust is probably the most infamous of all acridoid pests, a suite of other locust and grasshopper species and species assemblages cause more frequent and cumulatively far more significant damage (Fig. 37) throughout Africa, Australia, the middle East and parts of Asia and North and South America. In Southern Africa, the Brown Locust, *Locustana pardalina* Walker, has necessitated frequent widespread control measures over the last 45 years. In central and southern Africa, the Red locust, *Nomadacris septemfasciata* Serville; in Sudan, the tree locust, *Anacridium melanorhodon* Walker; in Madagascar, the migratory locust, *Locusta migratoria migratoriodes* Reiche and Fairmaire; and in semi-arid territories around the Mediterranean, the Moroccan locust, *Dociostaurus maroccanus* Thunburg, all require regular control measures to prevent the formation of migratory swarms. Although less mobile, grasshoppers such as *Melanoplus sanguinipes* Fabricius within North America, and *Phaulacridium vittatumeastern* Sjöstedt within Australian grasslands also require frequent control measures. Grasshopper complexes within the semi-arid African Sahelian belt such as *Aiolopus simulatrix* Walker, *Kraussaria angulifera* Krauss, *Acrotylus* spp. and *Oedaleus senegalensis* Krauss, as well as those from the more humid West Africa zone, notably *Hieroglyphus daganensis* Krauss and *Zonocerus variegatus* L., represent a continuing threat to the food security of many rural communities. Even today, locusts and grasshopper outbreaks cause problems in every major continent of the world.



Grasshoppers and Locusts as Agricultural Pests, Figure 37 Outbreak and invasion areas of some African locusts. The locusts tend to persist in the outbreak areas, and when conditions for reproduction are favorable the locusts multiply and spread to invasion areas. Desert locust, *Schistocerca gregaria* (*left map*), has a relatively large area of persistent habitation, consisting of most of northern Africa and the Arabian Peninsula, whereas African migratory locust, *Locusta migratoria migratorioides* (*center map*), and red locust, *Nomadacris septemfasciata* (*right map*) have small areas of origin in northwest and south central Africa, respectively.

Grasshopper and Locust Control

The task of combating locust and grasshopper plagues usually falls to the national crop protection services in cooperation with regional control organizations such as the Desert Locust Control Organisation for Eastern Africa (DLCO-EA). In recent years, this challenge has largely relied on the application of synthetic chemical insecticides applied as baits or dusts, and more recently and more commonly, sprayed as ultra low volume (ULV) oil formulations. The adoption of recent environmental monitoring technologies means the breeding habitats of some migratory locusts and grasshoppers can be monitored using satellite imagery as well as aerial and ground surveys. Prevention of upsurges by early intervention is now normally the preferred approach. Modeling and recent improvements in forecasting have helped some governments, donors, researchers and locust officers predict potential outbreak periods and contain the problem of outbreaks at the source level. For example, the goal of the FAO's Emergency Prevention System (EMPRES) for Transboundary Animals and Plant Pests and Diseases is to minimize the risk of locust plagues emanating from the central region of the desert locust distribution area through timely, environmentally sound interventions. However, in many rural areas, such as the Sahel, where access to pesticides is limited, traditional methods such as using smoke to repel arriving swarms or driving migrating hopper bands (immature locusts) into steep-sided ditches from which they cannot escape continue to be employed.

Chemical Control

Locust and grasshopper control has evolved since the middle of the twentieth century. Until the 1970s, most control operations used persistent organochlorine insecticides, with dieldrin favored for desert locust control due to its effectiveness at low doses and in barrier sprays. There is circumstantial evidence supporting the effectiveness of such insecticides in suppressing plagues, with the period 1930 to 1960 representing the longest known interplague period for the desert locust. Dieldrin, however, is now banned in most countries due to environmental damage, negative effects on human and animal health and legislation originating in the USA concerning the stockpiling of toxic wastes. The use of carbamate and organophosphorous such as bendiocarb, malathion and fenitrothion began in the 80s, and more recently pyrethroid insecticide compounds such as deltamethrin have been used. However, although these products have a lower mammalian toxicity (most insecticides currently used for locust control are classified as "moderately hazardous" to human health based on acute oral and dermal toxicity studies in rats) their reduced persistence makes them less effective than dieldrin, and repeated applications are often necessary to achieve the same level of control. This is of particular importance in recession (permanent sites of locust breeding) areas where the requirements for repeat applications have resulted in increased control costs and amounts of pesticides used. Most recently, the phenylpyrazole compound fipronil has been promoted as a significant break-through in locust control, since it is effective and persistent at low doses. Fipronil was largely used in the half-million hectares treated against migratory locusts in Madagascar in recent years.

The most recent desert locust upsurge (1986–1989) and a simultaneous grasshopper outbreak in the West African Sahel triggered a massive emergency response from the international community. The problem was again countered by large-scale spraying of swarms as well as feeding and breeding sites. Nearly 14 million hectares in Africa alone were sprayed for locusts while additional millions of hectares were sprayed in the Sahel for grasshopper control. Total donor assistance was approximately $250 million (U.S. dollars) and total costs including contributions from afflicted countries exceeded $295 million (U.S. dollars). However, the value of recent desert locust control campaigns has been called into question. While crop losses caused by swarms during plague conditions may be high (national pre-harvest losses due to grasshoppers in the Sahel have been estimated at 30% or more), overall yields may not be affected, as plague years are normally rainy and thus associated with better than average harvests.

As well as concerns over economic viability, the environmental and human health consequences of large-scale control campaigns using synthetic broad-spectrum insecticides in sensitive ecological areas (often representing breeding sources for many migratory acridid pests) has come under increasing scrutiny. For example, at the recommended rates for locusts and grasshoppers, fenitrothion is near the threshold where it can cause immediate death among birds. Chlorpyriphos and pyrethroids may reduce the biodiversity of honeybees, spiders and aquatic insects. Fipronil is highly toxic to certain birds, fish, terrestrial and freshwater invertebrates. Human exposure to pesticides during control operations can present problems during handling, or as a result of spray drift from operations, especially where protective clothing is not available or there is an unwillingness to wear it under hot field conditions. Local residents and nomadic pastoralists may also be affected directly through spray drift or through contamination of livestock, water or foodstocks.

Biological Control

There are numerous reports of natural enemies of grasshoppers and locusts. The principle groups consist of vertebrate and invertebrate predators which attack eggs, nymphs and adult insect, as well as insect parasitoids, parasitic nematodes and pathogens. In addition to natural control, recent research has led to the development of biopesticides based on entomopathogenic fungi.

Most locusts and grasshopper predators are generalists, and will attack a range of species, rather than any single host. Both nymphs and adults are attacked by various arthropods such as scorpions, spiders and solifugids and predaceous insects like asilid flies, sphecid wasps, ants, mantids and ant lions, and also by many species of lizards, snakes and birds. Eggs are also attacked by larvae of bombyliid flies and various Coleoptera, chiefly tenebrionid larvae. Additionally, a number of naturally occurring diseases also suppress locust and grasshopper populations worldwide, including descriptions of spectacular epizootics by the *Entomophaga grylli* complex of fungal pathogens. There are, however, relatively few in-depth studies on the impact of grasshopper and locust natural enemies, especially for tropical species.

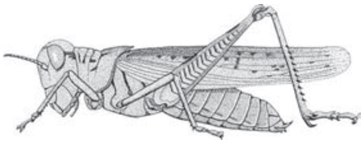
Although they merit conservation, indigenous natural enemies are often killed by nonselective chemical insecticides. This aspect, plus the concerns over the human health consequences of large-scale applications of chemical pesticides during recent locust campaigns, has led to recommendations by the World Bank and others to place locust and grasshopper control within the context of integrated pest management (IPM) programs. This has increased pressures to introduce biological control.

Although arthropod predators and parasitoids may hasten the end of plagues, apart from possibly controlling static grasshopper populations they cannot be manipulated, and migratory pests such as the desert locust are poor targets for classical biological control. However, pathogens can be manipulated for use as biological pesticides. Many locusts and grasshoppers are migratory pests and have characteristics amenable for control with microbial agents, (i) feeding and breeding take place outside the crop, often in conservation areas where high natural mortality can be expected to occur; (ii) as there is often public funding for control, high environmental values are involved in the purchasing decisions.

The major pathogen groups that have received interest as biological control agents of locusts and grasshoppers are bacteria, protozoa, entomopox viruses and fungi. The characteristics needed for a good agent include cheap and easy production, toxicological safety, host specificity and (given the existence of highly developed application technology) the ability to be formulated and applied using currently available equipment. Commercial formulations of entomophilic nematodes are available, but their high cost and water requirements during application and infection restrict their use in most regions against locusts and grasshoppers.

The use of entomopathogenic bacteria against locusts and grasshoppers has received some attention. The non-sporeforming *Serratia marcescens* Bizio and *Pseudomonas aeruginosa* (Schroeter) Migula have high pathogenicity in laboratory cultures. However, disappointing field results and concerns over mammalian safety have precluded further investigation. Though it has a well-developed production technology, efforts to find strains of *Bacillus thuringiensis* that produce endotoxins with pathogenicity against locusts or grasshoppers have not yet been successful. Various protozoa are known to infect locusts or grasshoppers. Among the Microsporidia (Phylum Microspora), *Nosema locusta* Canning has received the most attention, possibly due to its easy and efficient in vivo production characteristics. *N. locusta* has been the subject of a number of inundative field trials against grasshoppers where its spores are typically incorporated into bait carriers. However, the release of such pathogens generally only causes modest reductions. Nevertheless, because *N. locusta* may reduce the rates of host development, fecundity and feeding, it is considered by some to be a candidate for long-term population suppression and low impact maintenance in IPM strategies. *N. locusta* is registered for grasshopper control within conservation rangeland areas in the USA.

The use of entomopox viruses (EPVs) against locusts and grasshoppers is also receiving attention. The most extensively studied is the rangeland grasshopper *Melanoplus sanguinipes* (Fig. 38) virus (MsEPV), which is considered to have some potential as a biocontrol agent on Canadian rangelands. However, field studies demonstrating effective control are limited and restrictions to their production *in vitro* and ability to be formulated in spray carriers suggest that using EPVs against locusts and grasshoppers currently



Grasshoppers and Locusts as Agricultural Pests, Figure 38 **Migratory grasshopper, *Melanoplus sanguinipes* (Fabricius), an American grasshopper with locust-like dispersive behavior. (artwork, J. Mottern)**

remains unlikely. Further investigations into the infectivity of the baculoviruses, such as the nuclear polyhedrosis viruses (NPVs), which have better production characteristics, may open up new opportunities.

Among pathogens, the entomopathogenic fungi are the easiest to be manipulated as biopesticides. They have the advantage over other pathogens because they are able to infect through the insect cuticle, thus avoiding the necessity of providing bait. Spores (conidia) of fungal pathogens are also lipophilic, favoring their formulation in the oil-based carriers that are typically applied as a low volume spray in locust and grasshopper control campaigns.

Over 700 species of fungi from approximately 90 genera are pathogenic to insects; however, only the deuteromycetes *Metarhizium* spp. and *Beauveria* spp. (class Hyphomycetes) currently fulfill the criteria required for a successful inundative biological control agent. The entomophthoralean fungi, in particular members of the *Entomophaga grylli* (Fres.) Batko species complex, represent a group of obligate pathogens found in most areas of the world that have frequently been recorded decimating populations following epizootics. Although species in the *E. grylli* complex have been used successfully in some classical biocontrol introductions in the USA, difficulties with host specificity and *in vitro* mass production limit their application for inundative release.

Recent research programs have developed the fungal pathogen *Metarhizium anisopliae* var. acridum for the control of locusts and grasshoppers in Africa and Australia, and *Beauveria bassiana* for grasshopper control in Canada. Currently the development of microbial-based pesticides follows the same procedures of testing and registration as the chemical ones. Ongoing technological research in these programs has resulted in significant advances in the *in vitro* production, storage and formulation characteristics of such pathogens and recently has been the focus of commercial scale efforts to produce available mycopesticide products. Accordingly, applied using conventional spraying equipment at rates of 0.5–5 l per hectare, mycopesticides have proven at least as effective as chemical insecticides against locusts and grasshoppers in a variety of ecological zones.

Grasshoppers, Katydids and Crickets (Orthoptera)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

Members of the order Orthoptera are found at nearly all latitudes, though they are primarily tropical insects as judged by species diversity, which is greatest in warm areas. Most are known for their well-developed hind legs and jumping abilities, but many are noteworthy because they "sing," particularly at night. Orthopterans, or at least the grasshoppers and locusts, are often considered synonymous with "plagues" due to the devastating damage they inflict during periods of abundance.

Orthopterans are usually medium-sized to large insects. Not surprising for a large taxon, the wing condition varies considerably. They may be apterous (wingless), micropterous (short-winged and incapable of flight), or macropterous (long-winged and capable of flight). When bearing wings, which is the usual condition, they usually bear two pairs, and sometimes are capable of very strong flight. The name Orthoptera means "straight-winged" and refers to the thickened front wings or tegmina. The front wings bear numerous veins, and function more for protection than as an aid for flight. The front wings often are pigmented with a color or pattern that provides camouflage. Sometimes the front wings are quite broad and modified to resemble leaves. The hind wings usually are broader, folded like a fan, and though sometimes brightly colored, often are unpigmented. The wings, even if short, are often involved in sound production. Species inhabiting open desert and grasslands tend to be strong fliers, those inhabiting woodlands, islands and mountaintops tend to be flightless. In a few taxa, the second pair of wings is absent. In several groups, including many crickets, katydids and pygmy grasshoppers, the front wings are shorter than the hind wings.

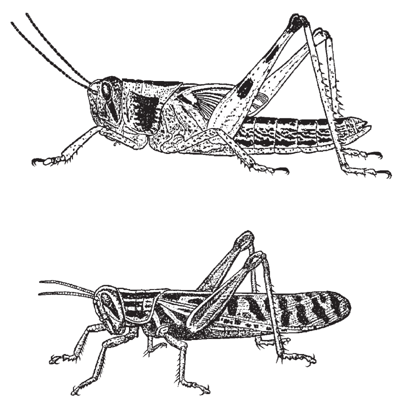
Orthopterans possess chewing mouthparts. Their eyes are large, and ocelli are usually present and three in number. The antennae usually are narrow, but vary in length: short in suborder Caelifera and long in suborder Ensifera. The thorax is large, and the saddle-shaped pronotum bears large lateral lobes that serve as the sides of the thorax. The legs are long. The hind legs are most often enlarged, especially the hind femora, and allow the insects to jump when alarmed. The tarsi have 1–4 segments and normally end with a pair of claws. Contrary to popular belief, normal locomotion is by walking, not jumping. Sometimes the front legs are enlarged, either for digging or for prey capture. The abdomen consists of about 11 segments and usually is free of notable structures other than the cerci and the ovipositor. Tympana, or hearing organs, are commonly present in these insects. In the suborder Caelifera, they are located on the side of the first abdominal segment. In the suborder Ensifera, they are found on the front tibiae.

Orthopterans display gradual metamorphosis. After hatching from the egg, the immature stage (nymph) feeds and grows, molting four or more times before reaching the adult stage. The number of molts varies considerably among taxa, and is commonly 4 or 5 in grasshoppers, but generally more than 10 in crickets. As in all exopterygote (wings developing externally) insects, the nymphs greatly resemble the adults, both in appearance and in mode of life. There is an exception, however. Grasshoppers and katydids hatching in the soil actually have a pronymphal stage preceding the first instar. This initial form is called the vermiform (worm-like) larva, and consists of the young nymph encased in a cuticular covering. The vermiform larva wriggles through the soil to the surface, and then the nymph escapes the covering, beginning its above-ground existence as a young hopper. The vermiform stage is not counted in the instar numbering system because it is just the first instar within a sheath.

Nymphs and adults can be difficult to distinguish (Fig. 39). The principal differences in appearance are the imperfectly developed wings and genitalia of nymphs. Nymphs have external wings pads that enlarge with each molt. Their shape is useful for determining the instar. In Acrididae, Tettigoniidae and Gryllidae, the wing pads initially point downward, but part-way through nymphal development, the orientation switches and the wing pads point upward or backward. With wingless or short-winged species, distinguishing the instar is more difficult. At maturity, the males court the females (rarely the roles are reversed) and copulate. In the suborder Caelifera, the male deposits the sperm internally. In the suborder Ensifera, the males of some taxa attach a spermatophore (packet containing sperm) externally at the female' s genital opening, whereas others display the internal sperm deposition system. In both cases, the female stores sperm until oviposition (egg deposition), when fertilization occurs.

Insects with gradual metamorphosis have the ability to regenerate lost limbs. If a grasshopper loses an antenna or leg as a young nymph, the missing appendage is regrown, in part, at the next molt. If the damage occurs early enough in the development of the insect, the lost appendages may be completely regenerated. These insects also shed limbs readily, a process called autonomy. If a leg is grasped by a predator or caught in a spider web, the leg may be shed, allowing the insect to escape.

The order Orthoptera is usually divided into two suborders: Caelifera and Ensifera. The suborder Caelifera consists of the grasshoppers and locusts (including the deceptively named pygmy



Grasshoppers, Katydids and Crickets (Orthoptera), Figure 39 Typical nymphal and adult stages of a grasshopper, *Schistocerca americana* (Thomas). Note that they are similar in body form, with the primary distinguishing factor the abbreviated wings of the nymph (*top*). Shown is the sixth instar, which bears the largest wings prior to the molt to the adult. Unfortunately, many grasshopper species possess such abbreviated wings as adults, making age determination difficult. Some possess both short-winged and long-winged forms. A few species show no development of wings. (images from United States Department of Agriculture).

mole "crickets," which are now recognized to be derived from grasshoppers, not crickets). The suborder Ensifera consists of the katydids and crickets (including the true crickets, mole crickets, camel crickets and Jerusalem crickets). There are many easily-recognizable groups within the order, and there is little dispute about most of these divisions and their phylogenetic relationships. However, there is considerable disagreement over the placement of the groups within the taxonomic hierarchy, i.e., whether or not they should be regarded as superfamilies, families or subfamilies. There are more than 25,000 species of Orthoptera in the world and, depending on the author of the classification system, up to about 35 families within the order.

Suborder Caelifera

The Caelifera usually have enlarged hind femora, short antennae, and tarsi with three or fewer segments. The antennae are normally threadlike, sometimes flattened, and occasionally enlarged at the tip. Tympana are often present, and are located on the sides of the first abdominal segment. Wing length is variable, but the cerci and the ovipositor are always short. Most species are diurnal, and phytophagous. Some primitive caeliferans, such as Eumastacidae, Tetrigidae and Tridactylidae, feed on more primitive plants, such as ferns and algae. Some Caelifera species inhabit areas of bare soil, many are associated specifically with grasses or broadleaf plants, while others dwell in trees. Visual and acoustic displays are part of the mating ritual of many species, and one or both sexes may produce sound. Sound production usually results from rubbing the hind legs against the front wings (called stridulation), although some groups stridulate by rubbing the front wings against the hind wings. Wing snapping in flight (called crepitation) also can occur. Eggs are normally deposited in the soil in clusters, and usually within a protective foamy structure called an egg pod. Univoltine and multivoltine species occur, with a tendency for greater multivoltinism in the warmer latitudes.

Following is one possible classification system for Caelifera, which basically follows Otte' s Orthoptera Species File. Subfamilies are not given in the following list except in the case of Acrididae, the largest and most important family.

Suborder: Caelifera
- Superfamily: Acridoidea
  - Family: Acrididae
    - Subfamily: Acridinae
    - Subfamily: Calliptaminae
    - Subfamily: Catantopinae
    - Subfamily: Conophyminae
    - Subfamily: Coptacridinae
    - Subfamily: Cyrtacanthacridinae
    - Subfamily: Dericorythinae
    - Subfamily: Egnatiinae
    - Subfamily: Eremogryllinae
    - Subfamily: Euryphyminae
    - Subfamily: Eyprepocnemidinae
    - Subfamily: Gomphocerinae
    - Subfamily: Hemiacridinae
    - Subfamily: Illapeliinae
    - Subfamily: Lithidiinae
    - Subfamily: Melanoplinae
    - Subfamily: Oedopodinae
    - Subfamily: Ommatolampinae
    - Subfamily: Oxyinae
    - Subfamily: Podisminae
    - Subfamily: Proctolabinae
    - Subfamily: Rhytidochrotinae
    - Subfamily: Spathosterninae
    - Subfamily: Teratodinae
    - Subfamily: Tropidopolinae
    - Subfamily: Trybliophorinae
  - Family: Charilaidae
  - Family: Lathiceridae
  - Family: Lentulidae
  - Family: Ommexechidae
  - Family: Pamphagidae
  - Family: Pauliniidae
  - Family: Pyrgomorphidae
  - Family: Romaleidae
  - Family: Tristiridae
- Superfamily: Eumastacoidea
  - Family: Eumastacidae

Family: Proscopiidae
Superfamily: Pneumoroidea
Family: Pneumoridae
Family: Tanaoceridae
Family: Xyronotidae
Superfamily: Trigonopterygoidea
Family: Trigonopterygidae
Superfamily: Tetrigoidea
Family: Tetrigidae
Superfamily: Tridactyloidea
Family: Cylindrachetidae
Family: Regiatidae
Family: Ripipterygidae
Family: Tridactylidae

Following is information on some of the important families and subfamilies within the suborder Caelifera:

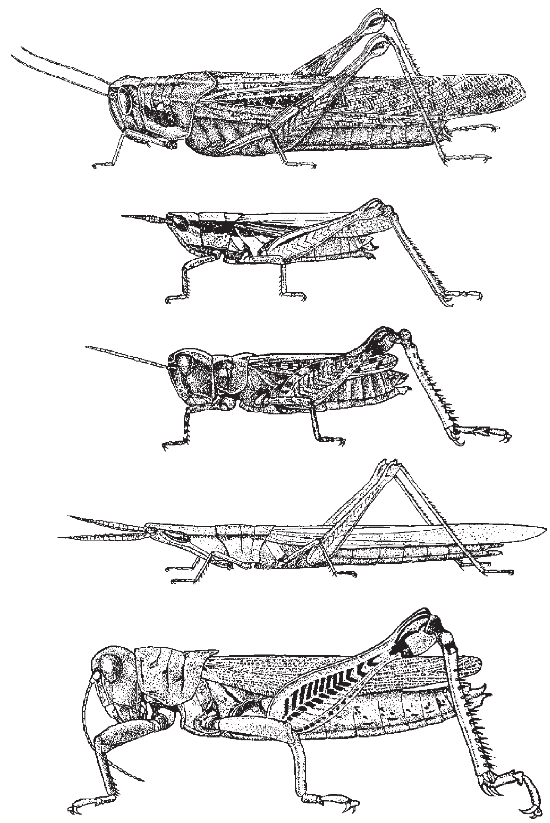
Family Acrididae

This is the largest family of the Orthoptera, and consists of the "true" grasshoppers and locusts. It is not uncommon to see other approaches to the classification of this family. The acridids are small to large in size, and stout to slender in general appearance. Their color is variable, but green and brown are common. The antennae and the pronotum are elongate and distinct. The legs are long, the hind legs are especially long and the femora is stout. The wings are variable in length, but often long. Acridids possess tympana, and sometimes produce sound. They are found in nearly all habitats. They are generally phytophagous, but vary in specificity. Eggs are deposited within pods in the soil; pods may contain three to 200 eggs, depending on the species.

Some subfamilies, such as Catantopinae, Gomphocerinae, Melanoplinae and Oedopodinae, are large and contain 500 or more species. Other subfamilies possess as few as one to five species. Some subfamilies are quite limited geographically and are found only on a single continent. Other taxa are found across Africa, Europe, Asia and Australia, or even more broadly (though they are absent from Antarctica).

Subfamily Acridinae (Silent Slantfaced Grasshoppers)

Grasshoppers in this subfamily have a slanted face and flattened, sword-shaped antennae (Fig. 40). Acridines lack a spine (the prosternal spine) between the front legs. The hind wings are colorless or nearly so. Acridinae are very similar in appearance to the



Grasshoppers, Katydids and Crickets (Orthoptera), Figure 40 Representative grasshoppers in the family Acrididae (*top to bottom*): a birdwing grasshopper, *Schistocerca nitens* Thunberg (subfamily Cyrtacanthacridinae); stridulating slantfaced grasshoppers, *Opeia obscura* (Thomas), *Psoloessa texana* (Scudder), and *Achurum sumichrasti* Saussure (subfamily Gomphocerinae); a New World spurthroated grasshopper, *Melanoplus differentialis* Thomas (subfamily Melanoplinae). (images from Arizona Agricultural Experiment Station).

stridulating slantfaced grasshoppers (subfamily Gomphocerinae), but as the common name suggests, members of this subfamily lack stridulatory pegs on the hind femora of males and thus do not produce sound. This subfamily is most abundant in Africa and Eurasia, though it occurs widely. Over 400 species are known.

Subfamily Calliptamine

These small to medium-sized grasshoppers are fairly typical in most respects, but the males are distinguished by their large, forceps-like cerci. The antennae are threadlike. The face is vertical or curved, but not strongly angled. The wing length is variable. Tympana are present, though sound production is limited to mandibular stridulation. They occur in Europe, Africa and Southeast Asia. About 100 species are known.

Subfamily Catantopinae (Old World Spurthroated Grasshoppers)

These typical-appearing grasshoppers vary considerably in size, and in wing structure. Their antennae are threadlike. The tympana generally are present though sound production is unknown. A prosternal spine is present. They greatly resemble Melanoplinae, and are separated mostly on the basis of geography. Cantantopines occur in Europe, Asia and Africa. Over 1,000 species are known.

Subfamily Cyrtacanthacridinae

The treatment of this subfamily varies greatly among authors. Sometimes the subfamily name Cyrtacanthacridinae is used to include a great number of genera and species. Here, it is restricted to about 75 genera, the most important of which is *Schistocerca*, the birdwing grasshoppers.

These grasshoppers bear a prosternal spine ventrally between the front legs (on the prosternum). The antennae usually are threadlike. The head is not especially large in size, and these grasshoppers do not appear to be especially heavy-bodied. In most genera, the head has a vertical orientation. These grasshoppers generally have long wings. The genus *Schistocerca* contains especially long-winged, strong fliers. Cyrtacanthacridine grasshoppers do not make sounds during flight; nor do they stridulate.

The habitat preferences of these grasshoppers are highly variable. Dietary habits also vary, but generally these insects are polyphagous. This group contains many important pests. Many of the grasshoppers are called "locusts" because of the swarming behavior found in this group. These grasshoppers are found throughout the world, but the greatest diversity occurs in Africa. In *Schistocerca*, however, the greatest diversity is in Central and South America.

Subfamily Eyprepocnemidinae

These insects are fairly typical in appearance, and variable in size. The antennal shape also varies. They possess a prosternal spine. The wing length is variable. The typana are present, though sound production is limited to mandibular stridulation. These insects are found principally in Africa, but also in southern Europe and Southeast Asia. About 175 species are known.

Subfamily Gomphocerinae (Stridulating Slantfaced Grasshoppers)

Grasshoppers in this subfamily tend to have slender bodies and long, slender legs. Their heads are elongate and often cone-shaped, usually with a highly slanted face. The hindwings are not colorful. Gomphocerines often have relatively short wings, rendering them incapable of sustained flight. When disturbed, these grasshoppers leap and use their wings, but their wings often do little more than increase the distance jumped. They do not make sounds during flight. This does not mean that these grasshoppers are silent. They can stridulate by rubbing the inner surface of the hind femur on the edges of the forewing while resting. Because the males of this subfamily usually have a row of stridulatory pegs on the inner surface of the hind femora, they are also known as toothlegged grasshoppers.

The habitat of gomphocerines tends to be tall grasses in open fields. The form and color of many species allows them to blend in with stems and blades of grass, making them difficult to detect until they move. Most species feed predominantly on grasses. They are found throughout the world, and species number nearly 1,000.

Subfamily Melanoplinae (New World Spurthroated Grasshoppers)

These grasshoppers bear a prosternal spine, the basis for their common name. For this reason, they are often grouped into the Cyrtacanthacridinae. The antennae usually are threadlike. The head is not especially large, and they do not appear to be especially heavy-bodied. In most genera, the head has a vertical orientation. The wing length is variable. Melanoplines do not make sounds during flight; nor do they stridulate. The habitat of these grasshoppers is highly variable. Thus, their dietary habits vary. This group contains many important crop and pasture pests. During periods of drought, they often attain high densities and cause considerable damage. They are found in North, Central and South America. Over 600 species are known.

Subfamily Oedipodinae (Bandwinged Grasshoppers)

The bandwinged grasshoppers are usually heavy bodied, and bear enlarged hind legs. The head of these grasshoppers often appears enlarged and broadly rounded. The orientation of the face is nearly vertical. Bandwinged grasshoppers lack a spine between the front legs. The bandwinged grasshoppers tend to be gray or brown in color, and often are mottled with darker spots. The forewings frequently bear distinct or indistinct transverse bands. The bandwinged grasshoppers usually bear bright colors, but this may not be obvious. The hindwings are often yellow, orange, or reddish basally, with a broad black band crossing near the center of the wing. The colorful hindwings are hidden by the front wings except when in flight. The males produce sound in flight.

The oedipodine grasshoppers normally are associated with open, sunny areas, and particularly with bare soil where their coloration provides excellent camouflage. About 800 species are known throughout the world.

Subfamily Oxyinae

These are small to medium-sized grasshoppers, and their body has a smooth integument. They do not stridulate, and they lack tympana. The wing length is variable. The antennae are threadlike. An interesting characteristic of these grasshoppers is that the hind tibiae usually are expanded distally, which is thought to be an adaptation for swimming. The female' s ovipositor valves are serrate or spined. Oxyinids are found in Africa, Europe, Southeast Asia and Australia, but are most abundant in humid, tropical habitats, especially wet environments. About 175 species are known.

Family Eumastacidae

This is one of the more primitive forms of grasshoppers, and they are sometimes referred to as monkey grasshoppers. The common name is derived from their agility when moving through vegetation. They tend to be small to medium in size. These insects lack tympana. They may bear wings, or be wingless. The legs, when the insect is at rest, are often held away from the body. The tarsi are three-segmented. The antennae usually are variable in shape, unusually short, and often bear a small tubercle on an apical segment, called the antennal organ. They lack a prosternal spine. These are tropical insects, and are absent from Europe and northern Asia. In North America, they are found only in the warm-weather Southwest. They feed on ferns, algae and gymnosperms. Most of the approximately 750 known species occur in the Old World.

Family Pamphagidae

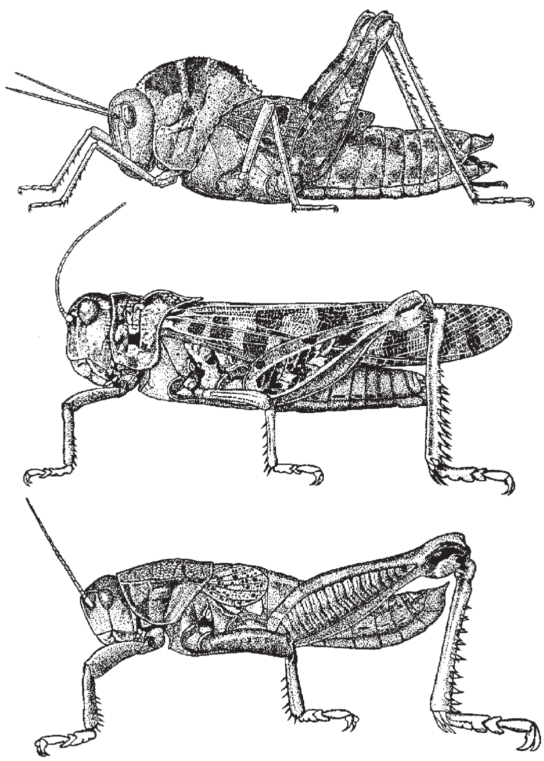
Generally medium or large in size, these grasshoppers possess a prosternal spine or elevated process. The pronotum is often elevated, sometimes forming a distinct crest. The wing development is variable. The tympana are either present or absent, and stridulation occurs. These grasshoppers often are cryptically colored, allowing them to blend with rocky soil and sand. These grasshoppers are found in Africa, southern Europe and Asia. Over 300 species are known.

Family Pyrgomorphidae

These insects have a conical head, usually with a very slanted face. They have a relatively soft body and weak integument. The antennae are threadlike or flattened. A prosternal spine or elevated process on the prosternum is present. Often brightly colored, they also excrete body fluids from between the first and second abdominal segments that provides a form of chemical protection that is variously repellent or poisonous. Wing length varies in this group. These grasshoppers usually are associated with grass vegetation in tropical and subtropical areas. They are known mostly from eastern Africa, Southeast Asia, Australia, and Central and northern South America – basically everywhere except North America. Over 400 species are known in this family.

Family Romaleidae

This group, also known as lubber grasshoppers, is sometimes considered to be a subfamily of Acrididae. It is distinguished, in part, by having a spine on both the inner and outer surface at the tip of the hind tibiae. Other grasshoppers (Fig. 41) may have moveable spurs, which resemble spines, but lubbers also have immovable spines at this location. Lubber grasshoppers also bear a prosternal spine. Lubber grasshoppers often are large, robust, colorful and usually bear short wings. The name "lubber" is derived from the heavy-bodied appearance and clumsy behavior of these insects. The shape of the



Grasshoppers, Katydids and Crickets (Orthoptera), Figure 41 Representative grasshoppers in the family Acrididae (*top to bottom*): bandwinged grasshopper, *Tropidolophus formosus* (Say) and *Xanthippus corallipes* Haldeman (subfamily Oedipodinae). Representative grasshopper in the family Romaleidae: a lubber grasshopper, *Brachystola magna* Girard. (images from Arizona Agricultural Experiment Station).

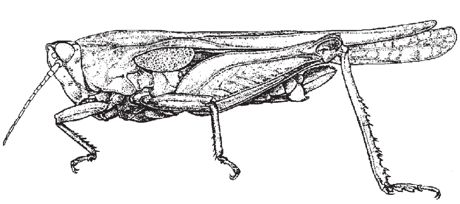
head, though variable, is usually broadly rounded. The hind femora are enlarged. When disturbed, lubber grasshoppers may hiss and spread their wings. The males also may use their wings to stridulate. The forewings and hindwings sometimes are brightly colored. The lubber grasshoppers are found in North, Central and South America, with their abundance greater in the southern latitudes. About 500 species of Romaleidae are known.

Family Tanoceridae

These grasshoppers, known also as desert long-horned grasshoppers, are medium in size and wingless. The threadlike antennae are relatively long in males and shorter in females. They are nocturnal, and are not often found by collectors. They are known only in the southwestern region of North America. Only four species from this family have been described thus far.

Family Tetrigidae

The pygmy grasshoppers (Fig. 42) are also known as groundhoppers and grouse grasshoppers. They are distinguished by their small size, usually 6–16 mm in length; their dull, cryptic coloration, usually brownish gray, gray, or black or mottled, but never green; their prominent eyes; and especially their greatly elongated pronotum, which often extends backward to the tip of the abdomen and ends in a sharp point. The antennae are relatively short. They may be long- or short-winged, or wingless. Like other grasshoppers, their hind femora are enlarged. Both sexes stridulate, and mating is a very brief process. They apparently feed on algae and possibly other organic matter in the soil. They often are found in marshy areas and at the margins of water, or in moss covered habitats. Some can descend into water, carrying an air bubble with them. They deposit loose clusters of eggs in wet soil. They tend to live in small groups in a more or less gregarious condition. They are difficult to collect unless special effort is made to sweep close to the soil. In some environments, they may be common. Tetrigids are found throughout the world, but they are most abundant in Southeast Asia. About 1,200 species are known.



Grasshoppers, Katydids and Crickets (Orthoptera), Figure 42 Representative of the family Tetrigidae: (*top*) a pygmy grasshopper, *Tetrix subulata* (Linnaeus).

Family Tridactylidae

These very small insects, usually measuring only 4–10 mm in length, are grasshoppers despite their common name: pygmy mole crickets. The antennae are relatively short, as with acridid grasshoppers. However, they possess some unusual features that differentiate them from other grasshoppers. They resemble mole crickets because they have front legs that are adapted for digging in soil and an arched pronotum. The tip of the abdomen bears a set of bristly appendages that resemble cerci, so they appear to have two sets of cerci. The hind tarsi possess plates that help them move on water, an important feature because they frequent the sandy edges of streams and ponds. They are quite good at walking on the water surface. Their diet consists mostly of organic material such as algae, possibly fungi, nematodes and bacteria, often ingested along with sand particles. Tridactylids are found throughout the world, but seem to flourish in tropical and subtropical locations. Nearly 200 species are known.

Suborder Ensifera

The ensiferans, like the caeliferans, are jumping insects. However, their legs tend to be longer, and the hind femora less enlarged, than the caeliferans. Their most distinctive feature is their long, threadlike antennae, which normally exceed the length of the body. The tarsi are three or four-segmented. The tympana, when present, are located on the front tibiae. Stridulation is common, and normally is caused by rubbing one front wing against the other. Sometimes the wings are slightly elevated when singing, but this behavior varies among taxa. Females bear a long sword-shaped or cylindrical ovipositor. The wing length is variable, but often even the long-winged species are weak fliers. Most species are nocturnal, and dietary habits vary from carnivory to phytophagy, but omnivory is common. Ensiferans often are associated with thick vegetation, and are most common in mesic areas. The superfamily Tettigonioidae, in particular, frequent vegetation almost exclusively. The Gryllacridoidea and Grylloidea, in contrast, often seek shelter in crevices, tunnels beneath the soil, or tree holes. Acoustic displays are an important part of the mating ritual of many species. Eggs are deposited singly, though several may be laid at the same location. Unlike grasshoppers, katydids and crickets do not produce egg pods. Some crickets and katydids deposit eggs on or in vegetation, others in soil.

Following is one possible classification system for Ensifera, based on that found in Otte's Orthoptera Species File. Subfamilies are not given, except in the case of the Tettigoniidae and Gryllidae, the most important groups.

- Suborder: Ensifera
  - Superfamily: Tettigonioidea
    - Family: Haglidae
    - Family: Tettigoniidae
      - Subfamily: Austrosaginae
      - Subfamily: Bradyporinae
      - Subfamily: Conocephalinae
      - Subfamily: Hetrodinae
      - Subfamily: Lipotactinae
      - Subfamily: Listroscelidinae
      - Subfamily: Meconematinae
      - Subfamily: Microtettigoniinae
      - Subfamily: Phaneropterinae
      - Subfamily: Phasmodinae
      - Subfamily: Phyllophorinae
      - Subfamily: Pseudophyllinae
      - Subfamily: Saginae
      - Subfamily: Tettigoniinae
      - Subfamily: Tympanophrinae
      - Subfamily: Zaprochilinae
    - Family: Prophalangopsidae
  - Superfamily: Gryllacridoidea
    - Family: Gryllacrididae
    - Family: Cooloolidae
    - Family: Anostostomatidae
    - Family: Stenopelmatidae
    - Family: Schizodactylidae
    - Family: Rhaphidophoridae
  - Superfamily: Grylloidea
    - Family: Gryllidae
      - Subfamily: Brachytrupinae
      - Subfamily: Cachoplistinae
      - Subfamily: Eneopterinae
      - Subfamily: Euscyrtinae
      - Subfamily: Gryllinae
      - Subfamily: Gryllomiminae
      - Subfamily: Itarinae
      - Subfamily: Malgasiinae
      - Subfamily: Nemobiinae
      - Subfamily: Oecanthinae
      - Subfamily: Pentacentrinae
      - Subfamily: Podoscirtinae
      - Subfamily: Pteroplistinae
      - Subfamily: Sclerogryllinae
      - Subfamily: Trigonidiinae
    - Family: Gryllotalpidae
    - Family: Mogoplistidae
    - Family: Myrmecophilidae

Following is information on some of the important families and subfamilies within the suborder Ensifera.

Family Anostostomatidae

This unusual group is known as king crickets and wetas. They are large, stout, and have oversized heads. Nearly all are wingless, but a few have fully formed wings. The mandibles and hind legs are sometimes enlarged. they are nocturnal. King crickets seem to be omnivores, though wetas are herbivores. To deter avian and reptilian predation, wetas raise their hind legs, exposing long spines. However, hiding below-ground is the principal defense. Wetas possess large tympana on their front legs. wetas and king crickets stridulate, though their sound production is a relatively primitive, intermediate stage in the evolution of acoustic signaling. They also transmit vibratory signals through their substrate. Tree wetas, but not king crickets, maintain harems of females and possess enormous mandibles that they use for fighting with competing males, whereas giant weta males freely compete for females without aggression. The king crickets and wetas occur in a variety of habitats. About 40 king crickets are known from southern africa, and 60 from australia and New Zealand. Wetas occur in Australia and New Zealand. Wetas are at risk of extinction because they are relatively defenseless against imported animals such as rats.

Family Cooloolidae

The cooloolids are called cooloola monsters due to their unusual appearance. These insects, though considered to be ensiferans, have short (10-segmented) antennae. They possess a large abdomen, and relatively short legs and with a muscular, hump-backed appearance. They resemble king crickets and wetas (Anastostomatidae) and to a lesser degree Jerusalem crickets (Stenopelmatidae). These are not leaping insects. Also, they do not tunnel, rather, living below ground where they "swim" through sandy soil. This very small (three species) and unusual family is known only in Australia.

Family Gryllacrididae

Some gryllacridids are known as leaf-rolling crickets, but not all species exhibit this behavior. They produce silk from glands in their mouthparts, and use it to tie leaves. The leaf rolls provide daytime shelters, but some species inhabit burrows in soil. The common name raspy crickets has also been suggested. This name stems from a raspy sound produced during defense. These are robust crickets, and can be fairly large, attaining 15 cm in length. They may be winged or wingless. The antennae are as long as or longer than the body. They are distinguished by the lateral lobes of the tarsi, and the presence of pegs on the inner surface of the hind femora that rub against the abdomen. They are not as long-legged as the cave and camel crickets (Rhaphidophoridae), and are soft bodied as compared to the king crickets and wetas (Anastostomatidae). This group is not well known, but all are thought to be nocturnal. They occupy varied habitats, and their dietary habits include herbivory, omnivory and carnivory. They are found widely in southern Africa, southwestern Asia, Australia, the Pacific region and South America. Few species are known from the northern hemisphere. Over 600 species are known around the world.

Family Gryllidae

Most crickets are compact and large-headed insects. Their antennae are long, usually reaching the tip of the abdomen or beyond. The forewings, when fully formed, are relatively broad, and flattened over the abdomen. Many species are wingless or short-winged. The front wings may be shorter than the hind wings, and in males, may function principally as acoustic devices. Many species can only be recognized by their calling behavior. Some species are mute. Tympana are found on the front tibiae. The ovipositor is long, thin and tubular. The body color is dull, usually pale, brownish or black. Long cerci are found near the tip of the abdomen and are similar in both sexes. Gryllids are often considered to be omnivorous, which is largely true, though individual species vary from herbivorous to nearly carnivorous. About 3,000 species occur in this large family.

Subfamily Eneopterinae (Bush Crickets)

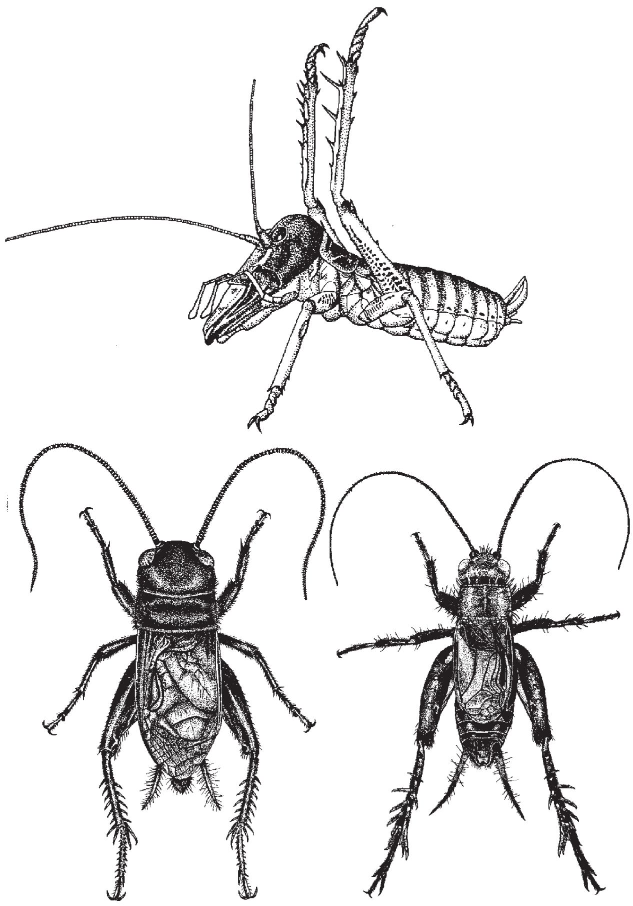
The bush crickets are medium sized and slender. The body usually has a fine covering of hairs. They frequent vegetation rather than soil. About 200 species are known from this subfamily.

Subfamily Gryllinae (Field Crickets)

These common crickets (Fig. 43) are similar to the ground crickets (Nemobiinae), but usually are medium in size rather than small. They tend to be heavy-bodied and brown or black in color. Their wing length varies considerably. They can call during the day and night, and tend to dwell belowground. Many species are similar morphologically and are distinguished by their calling behavior. They are omnivorous. About 500 species are known and are distributed widely in the world. A few species are considered to be crop pests.

Subfamily Nemobiinae (Ground Crickets)

The ground crickets tend to be small, and often bear a sparse covering of hairs. Tympana are present on the front tibiae. The wing length is variable. They often are uniformly brown, which



Grasshoppers, Katydids and Crickets (Orthoptera), Figure 43 **Representative of the family Anostostomatidae (*top*) a weta, *Hemideina crassidens* (Blanchard) (image from Larry Field); the family Gryllidae: (*bottom left*) a field cricket, *Gryllus veletis* (Alexander and Bigelow) (subfamily Gryllinae); and (*bottom right*) a ground cricket, *Allonemobius griseus* E.M. Walker (subfamily Nemobiinae) (images from Lyman Entomological Museum).**

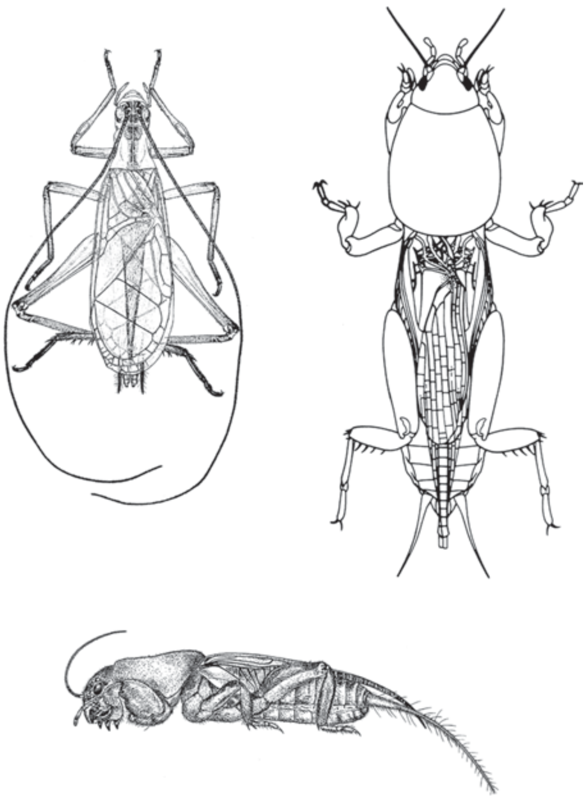
allows them to blend in well with their terrestrial environment. These insects can be quite numerous in pastures and woodlands, and can be active during the daylight hours. They are omnivorous. About 200 species are known around the world.

Subfamily Oecanthinae (Tree Crickets)

The tree crickets (Fig. 44) are slender and pale colored, often greenish or whitish. The males tend to have broad front wings. Most are quite vocal. They inhabit trees, shrubs and weedy fields. Some cause injury to trees and shrubs by depositing their eggs within twigs. Tree crickets tend to be predatory. They are found throughout the world, but are most numerous in Africa and South America. About 175 species occur in this subfamily.

Subfamily Trigoniinae (Sword-Tail Crickets)

These insects tend to be small, and pale in color. The wing length is variable, though the wings can be quite long when present. Tympana are present. Sword-tail crickets often are found in vegetation adjacent to water, and do not normally frequent the soil surface. About 275 species are known throughout the world.



Grasshoppers, Katydids and Crickets (Orthoptera), Figure 44 Representative of the family Gryllidae, (*top left*) a tree cricket, *Oecanthus nigricornis* (subfamily Oecanthinae); the family Gryllotalpidae, (*top right*) a mole cricket, *Scapteriscus* sp.; and (*bottom*) a mole cricket, *Neocurtilla hexadactyla* (images Lyman Entomological Musuem except *Scapteriscus* from Florida Division of Plant Industry).

Family Gryllotalpidae

Among the most easily distinguished orthopterans, the mole crickets bear wide forelegs modified for digging. Both the femora and tibiae are flattened, with the tibiae bearing enlarged teeth or "dactyls." The hind legs are not markedly enlarged. The antennae are shorter and thicker than in many ensiferans. The oval pronotum is disproportionately large and sturdy. They are often, but not always, long-winged. The ovipositor is not apparent. These insects dwell below-ground during the day, often emerging in the evening to sing or eat. They sing from specially constructed acoustical chambers, constructed in the soil, that expand as they open to the outside like the end of a trumpet. This design serves to amplify their call. Some species are mute. Mole crickets create deep permanent burrows, but also superficial foraging tunnels. The eggs are deposited in special egg chambers within the burrows. Their dietary habits range from carnivorous to phytophagous, but some are important vegetable and pasture pests. Three species of *Scapteriscus* from South America were accidentally introduced into southeastern North America and have caused considerable damage. Less than 100 species are known from this family.

Family Mogopistinae

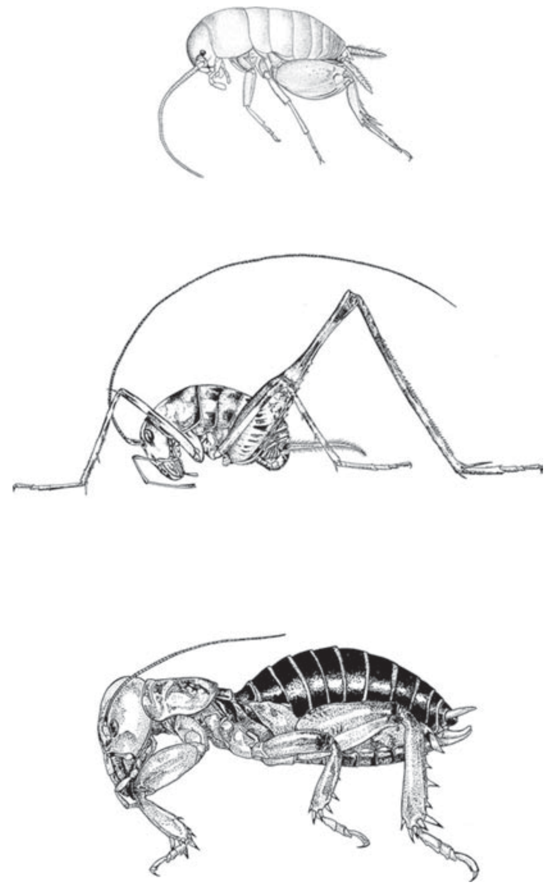
These insects are called scaly crickets. Resembling silverfish, these small crickets tend to be short-winged, flat and slender. Their name is derived from the presence of translucent scales covering most of their body. They are mostly tropical in distribution and seem to favor areas near water. Over 350 species are known.

Family Myrmecophilidae

This is a small family of very small, wingless, oval and flattened crickets that inhabit ant nests. They cannot live independently from the ants. The eyes are reduced, though the cerci are pronounced. The tympana are lacking. The ovipositor is shortened and stout. The hind femora are broad. These unusual insects feed on secretions produced by ants. Apparently, they are taken to be ants by their hosts. Some species are parthenogenetic. Only about 50 species are known.

Family Rhaphidophoridae

The camel crickets (Fig. 45) are similar to the Tettigoniidae, but wingless. They bear long, thread-like antennae, usually longer than in Tettigoniidae. Their legs also are quite long. The pronotum is smoothly rounded and lacks ridges. Unlike most of their close relatives, they do not have a hearing organ on the front tibia. They are not usually considered to be singers, though some are capable of making some sounds, and some species have stridulatory pegs. Because they lack wings, it is difficult to distinguish adults from nymphs except by the developing ovipositor, or fully developed male genitalia. They are dull colored insects, usually some shade of brown or gray. Camel crickets are nocturnal. About 250 species are known around the world.



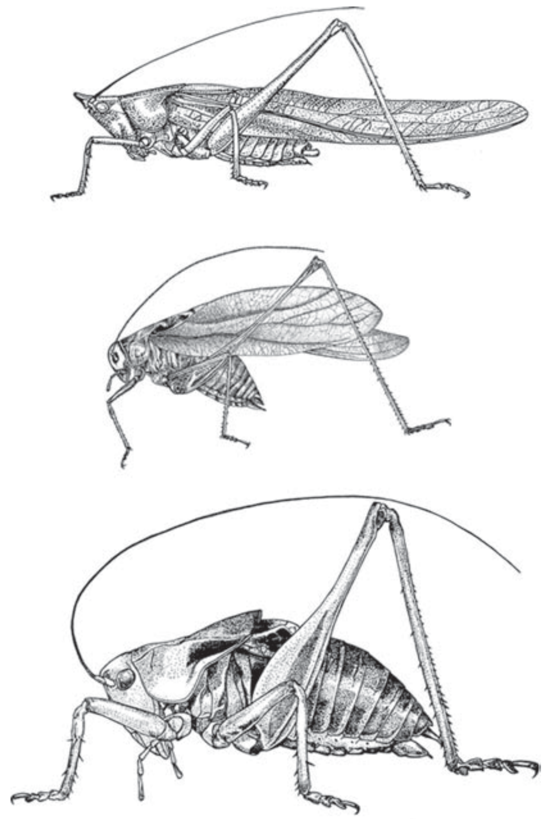
Grasshoppers, Katydids and Crickets (Orthoptera), Figure 45 **Representatives of the family Myrmecophilidae, (*top*) an ant nest-inhabiting cricket, *Myrmecophilus oregonensis* Bruner; the family Rhaphidophoridae, (*center*) a camel cricket, *Tachycines asynamorus* Adelung; and the family Stenopelmatidae, (*bottom*) a Jerusalem cricket, *Stenopelmatus fuscus* Haldeman (images from Lyman Entomological Museum).**

Family Stenopelmatidae

This group consists of cricket-like insects known as Jerusalem crickets. They are flightless, nocturnal and infrequently encountered. Thus, they are poorly known. Jerusalem crickets are large, somewhat hump-backed, with large heads resembling anastostomatids. Their legs bear stout spines. They have large mandibles and bite readily. When disturbed, Jerusalem crickets will flip onto their backs, exposing their mandibles in a defensive posture. They seem to be omnivores, and they benefit from animal protein. Most occupy arid western North America, often resting below-ground or beneath objects, but surfacing at night to feed. In Central America, however, some inhabit rotting logs and stumps. Jerusalem crickets can be large, some species weighing as much as 8 g, but others weigh less than 1 g. They transmit vibratory signals through the substrate. The males are sometimes eaten by the females after copulating. At least 80 species are known to occur in North America, but most are undescribed.

Family Tettigoniidae

This is a large and important family that is variously known as katydids in North America and Australia, or bush crickets in other English-speaking areas. These species tend to be medium-sized or large in size, often 35–50 mm in length. The antennae are longer than the body. These insects bear tympana on the front tibiae. The pronotum only rarely bears a ridge. A large, sword-shaped ovipositor is usually present in the females. Although some katydids oviposit in soil, they also deposit eggs in leaf tissue, stem tissue and even bark crevices. Some oviposit flattened, overlapping eggs like roof shingles on leaf and stem tissue. A small number construct "nests" of chewed plant material and mud. Katydids (Fig. 46) are usually green or brown in color, and though some species are active during the day, most are largely nocturnal. The males stridulate freely, and in many environments, these insects are an important element of night-time sounds. They are largely phytophagous, but are also omnivorous and a few feed on other insects. They prefer proteinaceous food, and even the phytophagous species often select blossoms and fruit for their higher protein content. The males tend to produce a large edible spermatophylax, a structure containing the spermatophore. The spermatophylax is passed on to the female as a nuptial gift, and is also a means of providing a protein supplement to the female when she is producing eggs. Tettigoniids are found throughout the world, and number nearly 400 species.



Grasshoppers, Katydids and Crickets (Orthoptera), Figure 46 Representatives of the family Tettigoniidae: (*top*) a coneheaded katydid, *Neoconocephalus ensiger* (Harris) (subfamily Conocephalinae); (*center*) a false katydid, *Amblycorypha oblongifolia* (De Geer) (subfamily Phanopterinae); and (*bottom*) a shield-backed katydid, *Atlanticus monticola* Davis (subfamily Tettigoniinae) (images from Lyman Entomological Museum).

Subfamily Conocephalinae (Meadow and Coneheaded Katydids)

These katydids are small to medium in size. They are long, thin insects and some have a conical head. The ovipositor may be long and sword-shaped. The antennae are long. They are green or brown, blending well with vegetation. The preferred habitat is short or tall grasses and broadleaf plants, normally in fields and swamps, but sometimes in forests. They sing mostly at night, and are found throughout most of the world. Nearly 1,000 species are known. One tribe, the copiphorini, is sometimes treated as a subfamily.

Subfamily Meconematinae (Quiet-Calling Katydids)

These are small, diurnal insects. They are found in Africa, Europe and northern Asia. Over 400 species are known in the subfamily.

Subfamily Phaneropterinae (False Katydids)

This group of katydids is distinguished by the absence of spines on the prosternum and by the wing length; the hind wings are longer than the front wings. These insects are noted songsters, and they vocalize late in the day and during the evening. They normally are brown, but pink forms are known. About 2,000 species are known.

Subfamily Phyllophorinae (Giant Leaf Katydids)

These leaf feeders are the largest of the tettigonids. Their wing spans attain 25 cm. They bear a very heavy pronotum, and the males have lost the ability to stridulate using the tegmina. There are about 70 known species, all from Australia and nearby areas.

Subfamily Pseudophyllinae (True Katydids)

These are broad-winged insects that commonly inhabit trees and shrubs. The subfamily is quite diverse in the tropics of both the New World and the Old World, and different species often mimic different natural elements of their habitat such as leaves and bark. About 1,000 species are known.

Subfamily Saginae (Stick Katydids)

These flightless insects occur in Africa, Europe and Asia. One species, of European origin, has established in North America. This flightless species, *Saga pedo*, reproduces parthenogenetically, a rare occurrence among katydids. Sagines are predators, and quite aggressive about grasping prey with their spined forelegs. About 50 species are known.

Subfamily Tettigoniinae (Shield-Backed Katydids)

Many large, ground-dwelling, flightless species are found in this subfamily. They tend to be shortwinged, and are sometimes dark in color, often brown or black. Other species in this same subfamily are long-winged and good fliers. They occupy a diversity of habitats. Some, such as the Mormon cricket, *Anabrus simplex* Haldeman, are crop pests in western North America. Omnivory and carnivory are common in this group. Nearly 900 species are known from this group. They are found throughout the world.

Evolution of Orthoptera

The evolution of Orthoptera can be traced back to the Protorthoptera of the Upper Carboniferous-Permian period some 300 million years ago. The

Protorthoptera gave rise to several primitive groups that eventually gave rise to the ancestors of the most recent orthopteroid orders. The order Orthoptera probably underwent an early split to give rise to the two major lines of evolution now recognized as Caelifera and Ensifera. Ensifera is considered to be more primitive than Caelifera.

The orthopterans are closely related to the mantids, walkingsticks, cockroaches and rock crawlers. They are less closely related to earwigs, webspinners and termites. Collectively, these taxa are referred to as the orthopteroid orders. All are thought to be descended from a common neopteran ancestor that predated the Protorthoptera.

Not everyone agrees with this interpretation, however. It is also possible that Caelifera and Ensifera evolved independently from different protorthoperan ancestors. It has even been suggested that the Orthoptera could be an artificial group (Caelifera plus Ensifera) that appears united mostly because they have enlarged hind legs for leaping. Consider that although the orthopterans produce sound, the two suborders differ in how they produce and hear sound. However, most available evidence, and most orthopterists, support the idea of a single order.

Natural Enemies of Orthoptera

There are numerous natural enemies of orthopterans, and the same types of natural enemies generally affect the several taxa of Orthoptera. However, the relative importance of the natural enemies varies among orthopterans, among different periods of the orthopteran population cycle, in different regions of the world, according to the weather and according to the soil type.

Natural enemies of orthopterans include predators (which kill and eat their prey), parasitoids (parasitic insects that develop in or on the host orthopteran and kill the host only when the parasite reaches maturity), and pathogens (microbial diseases that kill the host after the host' s nutrients are exhausted).

Important egg predators include bee flies (Diptera: Bombyliidae), ground beetles (Coleoptera: Carabidae) and blister beetles (Coleoptera: Meloidae). Nymphs and adults are captured and eaten by spiders, birds, small mammals and rodents, ants (Hymenoptera: Formicidae), sphecids (Hymenoptera: Sphecidae) and robber flies (Diptera: Assilidae). Among the important parasitoids of nymphs and adults are blow flies (Diptera: Calliphoridae), sarcophagids (Diptera: Sarcophagidae), nemestrinids (Diptera: Nemestrinidae) and tachinids (Diptera: Tachinidae). Mites (Acari) are commonly found clinging to orthopterans, and some feed on the blood of their host. Although mites weaken their host, they are not thought to be important mortality agents. Pathogens affect all stages of orthopteran development, and among the most important are nematodes, fungi, viruses and microsporidians. Nematodes and fungi are readily affected by soil and weather conditions, so their occurrence is inconsistent. However, these pathogens can have dramatic effects on orthopteran populations when conditions favor their virulence. Viruses and microsproridians are found widely, though they often are not especially virulent. The impact of pathogens is often overlooked relative to predators and parasitoids because their effect may be expressed as a shortening of the life span or as a reduction in reproduction, rather than in direct mortality.

The importance of natural enemies is difficult to measure, and the action of these beneficial organisms may come too late in a population outbreak to prevent damage. Sometimes they may interfere with one another, as when robber flies capture insect parasitoids as well as grasshoppers, or when fungal diseases kill a host insect prematurely, causing the death of the parasitoid contained in the host orthopteran. Nevertheless, there are many striking examples of natural enemies suppressing orthopteran populations. Examples of natural enemy effects include: parasitism of grasshoppers by the nematode *Mermis nigrescens* killed 71% of *Melanoplus femurrubrum* grasshoppers in Michigan, USA; mermithids infected 69% of

Locusta migratoria in wet areas of Papua New Guinea, but only 15% in dry areas; 30–70% of field crickets were infected with microsporidians in Michigan, USA; grasshoppers comprised 94% of the diet of the robber fly *Proctacanthus milbertii*, a generalist predator, in studies conducted in Montana, USA, and this fly consumed about 25% of all hoppers present; birds ate about 27% of adult grasshoppers during the summer in Nebraska, USA; over 200 species of birds in Nebraska feed on grasshoppers, and during the summer months, the average bird's stomach contains at least 25 grasshoppers at any time; parasitism of *Zonocerus* locusts exceeded 40% by a calliphorid in Africa; and the combined effects of natural enemies accounted for about 50% mortality in desert locust, *Schistocerca gregaria*, populations in Africa.

Importance of Orthoptera to Humans

Grasshoppers, katydids, crickets and other orthopterans vary considerably in their importance to humans. In some societies, grasshoppers are a minor source of food, and katydids and crickets are kept as pets for their acoustical abilities. However, these beneficial aspects are minor compared to their destructive attributes. Grasshoppers are widely recognized to be serious pests of arid-land or prairie agriculture, and to a lesser degree, in mesic areas. Katydids, crickets and allied insects usually have minor effects on agriculture, though a few species are quite damaging. Grasshoppers, katydids and sometimes other orthopterans consume considerable amounts of foliage during their nymphal development, and also as adults. Occasionally, other insect activities such as tunneling (by mole crickets) or oviposition (by tree crickets) may be the basis for injury. Pasture, forage, grain, vegetable, and even fruit and ornamental crops can be affected. Historically, grasshoppers and locusts have been very disruptive to civilizations in Africa, the Middle East, India, China and North America. However, Australia, Europe and South America also have witnessed serious problems, so, virtually no area of the globe is immune to attack by grasshoppers. However, except in areas where access to technology and funds are limited, the tools are now available to manage these pests and to prevent them from excessive destruction.

Abnormally high densities of grasshoppers are called outbreaks or plagues. Regardless of the terminology applied, the phenomenon occurs throughout the world, and its origin is invariably related to food and weather. Grasshoppers that tend to attain high densities periodically, especially those that tend to become gregarious and move together as groups or swarms, are sometimes called locusts. Locusts do not really differ from grasshoppers, other than displaying a greater degree of gregarious behavior. Even species known as locusts periodically experience periods when they are not numerous, not gregarious, and do not cause much injury.

Grasshoppers require warm and sunny conditions for optimal growth and reproduction. Warmth alone seems to be inadequate, and grasshoppers often bask in the sun to raise their body temperatures. Thus, drought stimulates grasshopper population increase, apparently because there is less rainfall and cloudy weather to interfere with grasshopper activity. A single season of such weather is not adequate to stimulate massive population increase; rather, 2–3 years of drought usually precede grasshopper plagues. Warm winter temperatures also seem to be beneficial, because less mortality occurs by overwintering nymphs and adults. This scenario explains outbreaks that occur in temperate climates, where food is not limited, but heat may be inadequate. However, it does not explain all grasshopper outbreaks.

Food is a necessary prerequisite for grasshopper success, and optimal weather alone, in the absence of adequate food supply, will prove insufficient for rapid grasshopper population growth. For outbreaks or plagues to occur, both requisites must be satisfied. Thus, some precipitation must be present at the appropriate time to stimulate plant growth, but an over-abundance results in too much cloud cover. In tropical or subtropical climates, especially warm but arid regions, precipitation is an important stimulus that increases grasshopper breeding and causes outbreaks to develop.

Management of Orthoptera Pests

The ideal way to manage orthopteran pests is to manage the environment to prevent them from attaining pest status. One example of how this can be accomplished is with weed management in fallow fields, and along roadsides and irrigation ditches. Luxurious growth of weedy vegetation often favors the survival of grasshoppers, which then can spread to adjacent crops. If this land is instead tilled or planted with short grass, fewer grasshoppers will breed there and the damage potential is greatly reduced. Unfortunately, many environments cannot be manipulated easily, and when weather or other factors favor population increase, a suppressive action must be initiated. Another example of how problems can be prevented is by introducing natural enemies of grasshoppers that have invaded a new area, and have therefore left their natural enemies behind. The introduction of a parasitic fly, *Ormia depleta*, and an entomopathogenic nematode, *Steinernema scapterisci*, for the suppression of *Scapteriscus* mole crickets in Florida, illustrates how this method can be applied effectively to invaders. However, most orthopteran pests are native, and there is little opportunity to identify natural enemies from elsewhere.

Biological suppression of orthopteran populations is difficult to achieve once they have attained damaging levels. Natural enemies sometimes eventually build to high enough levels to help decrease pest abundance. For example, wild birds will sometimes switch their feeding to take advantage of an abundance of grasshoppers, but this is effective only on a local scale, not a regional scale. Domestic fowl, especially turkeys, readily consume vast quantities of grasshoppers, and can be used for small-scale suppression. There also are grasshopper disease agents that are under investigation, and even some that are sold commercially, but so far, none has been shown to provide adequate suppression. Entomopathogenic nematodes are used for mole cricket suppression in some environments. Biological control remains a promising area for research, and the search continues for more effective products, but thus far, there are few practical options. For some people, neem products are attractive. Neem products are botanical derivatives that, when applied to plants, act as a feeding deterrent, reducing damage. Also, if applied to grasshopper nymphs, neem can act as a growth regulator, disrupting the normal growth and development, and sometimes resulting in the death or sterilization of grasshoppers. Although neem products are chemicals, many people take comfort in knowing that they are derived from plants, and are therefore somewhat "natural." Like many natural controls, effectiveness is not always consistent.

In some situations, physical barriers can provide some protection from damage. It is possible to screen or cover valuable plants with netting, floating row cover, or similar material to deny grasshoppers access to susceptible plants. This is suitable for small gardens, and is even applied commercially for ornamental plant production, wherein shade houses are sealed tightly to deny access to orthopterans. The potential for this approach is limited in scale due to the cost. For flightless species such as lubber grasshoppers or Mormon crickets, physical barriers such as a ditch with steep sides, or a short metal or plastic "wall," can prove to be effective impediments to grasshopper dispersal. If such a wall is contemplated, however, consider that orthopterans have sharp claws and can ascend vertical surfaces with amazing agility, so the top of a barrier should end in a 45 degree angle, forcing the insects to fall back.

As mentioned above, cultural management of crop- and pasture-land can sometimes be used to manipulate orthopteran abundance. The habitats most favorable for grasshopper population growth and survival are open, sunny habitats containing mixed, early to mid-successional plants. Land with trees providing moderate to deep shade rarely produce large numbers of grasshoppers. Also, land that is kept mowed, either mechanically or by livestock grazing, tends not to produce grasshoppers unless grass pasture-land is damaged by overgrazing and broadleaf weeds invade.

If natural enemies and cultural manipulations have failed to keep orthopteran pests in check, chemical insecticides are most often used to prevent excessive damage. Chemical insecticides can be applied in liquid form, by application directly to the grasshoppers, or to the plants they will walk or feed upon. Insecticides can also be applied to food bait, usually bran flakes, and distributed in the pest's environment. If insecticides are to be used, it is advisable to apply the chemicals when the pests are young. Small insects are much easier to kill than large ones, and grasshoppers and crickets are notoriously difficult to kill under any conditions. Also, because the grasshoppers usually develop in surrounding vegetation, it is usually best to take the "battle" there, and apply insecticides to the young grasshoppers before they disperse into crops and cause damage.

Grasshoppers of the Argentine Pampas

NORMA E. SÁNCHEZ, MARÍA. L. DE WYSIECKI
Universidad Nacional de La Plata, La Plata, Argentina

The Pampas, which occupies the Province of Buenos Aires and parts of the Provinces of Entre Ríos, Santa Fe, Córdoba, La Pampa and San Luis, are temperate subhumid grasslands. Mesothermic grasses dominate in this region of mild climate with mean annual temperature ranging from 10 to 20°C, and annual rainfall between 400 and 1600 mm. There is a general decrease southwestward in annual precipitation, soil organic matter and grassland productivity.

The landscape has been altered markedly during the last century due to agricultural and grazing activities, and pristine grasslands have been drastically modified. Most of the land has been converted to cropland, mainly soybean, corn, sunflower and wheat.

Among the most important native herbivores are grasshoppers, which are a recurrent pest of the agro ecosystems of this area. These insects may cause, in some years, forage and crop losses of considerable magnitude.

The Pampas and the Great Plains of North America have some ecological similarities in grasshopper fauna. However, species richness and diversity are higher in the US grasslands, while the Pampas have a greater diversity of higher acridid taxa, three families (Acrididae, Romaleidae and Ommexechidae) and nine subfamilies (Melanoplinae, Gomphocerinae, Copiocerinae, Leptysminae, Cyrtacanthacridinae, Acridinae, Romaleinae, Ommexechinae and Aucacrinae)

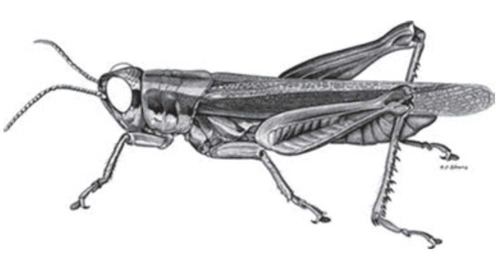
versus two families (Acrididae and Romaleidae) and six subfamilies (Oedipodinae, Melanoplinae, Gomphocerinae, Acridinae, Cyrtacanthacridinae and Romaleinae). The Melanoplinae is the main subfamily in both regions and the genus *Melanoplus* of North American is considered to be the ecological equivalent to the South American genus *Dichroplus* (Table 11).

There exists a large-scale association between grasshopper and plant communities along the Pampas. Indeed, assemblages may differ in density, dominance, and species composition because of differences in vegetation and climatic conditions. Total species richness is thirty nine, ranging from four to sixteen at different sites. *Dichroplus pratensis* and *D. elongatus* (Fig. 47) are clearly the most common and widely distributed species in this region. Both are polyphagous species, eating grasses and forbs. Eggs hatch in November and, after passing through 5 nymphal instars, reach the adult stage in January. They have an obligatory embryonic diapause and one generation a year.



Grasshoppers of the Argentine Pampas, Figure 47
***Dichroplus elongatus* G. Tos. Another species of this genus, *D. maculipennis*, one of the most harmful species of this area thirty years ago, has exhibited very low populations during the last decade.**

In relation to damage, a population of *D. pratensis* with a peak of 22.19 individual/m^2 may cause a forage loss of approximately 274.32 kg/ha.

Another species of this genus, *D. maculipennis*, one of the most harmful species of this area thirty years ago, has exhibited very low populations duringthe last decade.

Other common species are *Laplatacris dispar*, *Amblytropidia australis*, and *Scotussa lemniscata* in the humid northeastern grasslands. The central grasslands are dominated by *D. pratensis*, *D. elongates*, *Staurorhectus longicornis*, *Leiotettix pulcher* and *D. vittatus*. *Borellia brunneri*, *Covasacris albitarsis* and *S. lemniscata* are common in the southeastern habitats. Grasshopper assemblages of the xeric western grasslands are dominated by *D. pratensis* and *Neopedies brunneri*, and among common species are *Rhammatocerus pictus*, *S. longicornis*, *D. vittatus* and the Romaleidae *Zoniopoda tarsata*.

Most species in the Pampas are rare. Some are registered every year from most sites, but in low numbers (e.g., *Baeacris punctulatus*), whereas others are found in many years but only in some sites (e.g., *Xyleus laevipes* and *Z. omnicolor*).

At present, the only control measure against these insects is the use of chemical pesticides. The microsporidian pathogen *Nosema locustae* Canning was introduced between 1978 and 1982 to control pest grasshoppers, and became established in some areas. However, no surveys to evaluate the effectiveness as a biological control agent has been conducted. Only one native microsporidian pathogen, *Perezia dichroplusae* Lange, is currently known in argentine grasshoppers. Other pathogens, like the amoeba *Malameba locustae* King & Taylor (Protozoa: Rhizopoda), the virus *Entomopox* (Poxviridae: Entomopoxvirinae) and the fungus *Entomophaga grylli* (Fresenius) (Zygomycetes: Entomophtorales) also are recorded.

Grassi, Giovanni Battista

Giovanni Grassi (Fig. 48) was born in the province of Como, Italy, on March 27, 1854. He was educated at the universities of Pavia and Messina (Italy) and Heidelberg and Würzburg (Germany). In 1883 he was appointed professor of zoology, anatomy, and comparative zoology at Università di Catania, and in 1895 he was appointed to a similar position at Università di Roma. His works began on intestinal worms, proceeded to Protozoa (especially of termites), continued with flies (1883, "Malefizi delle mosche") as vectors of eggs of nematodes and spores of fungi, on embryology of the honey bee, morphology and phylogeny of arthropods, the biology of termites, the transmission of malaria by *Anopheles* mosquitoes, the life history of *Phlebotomus*, on the grapevine pest *Phylloxera*, and on chaetognaths, marine eels, and development of the vertebral column. In 1908 he was made a member of the Italian senate. In 1884–1889 he studied Thysanura, *Scolopendrella*, and *Koenema mirabilis*, the last being an arachnid that he discovered. For his collaborative work with Sandias on termites, and for his studies of muraenoid eels, he was awarded the Darwin gold medal of The Royal Society. In 1898–1900, he concentrated on malaria, finding that all Italian species of *Anopheles* can transmit *Plasmodium*, and that *Plasmodium* is the same parasite that Ross described under the name

Grassi, Giovanni Battista, Figure 48 **Giovanni Batista.**

Proteosoma (1900, Studi di uno zoologo sulla malaria). He continued his studies of malaria in 1917, continued to publish, but died on May 5, 1925.

Grass Miner Moths (Lepidoptera: Elachistidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Grass miner moths, family Elachistidae, comprise about 723 species worldwide, but most are Palearctic (472 sp.), and many are in the genus *Elachista*. Two subfamilies are used, or only tribes: Perittiinae and Elachistinae. The family is part of the superfamily Gelechioidea in the section Tineina, subsection Tineina, of the division Ditrysia. Adults small (5–23 mm wingspan), with head smooth-scaled; haustellum scaled; labial palpi upcurved but sometimes porrect; maxillary palpi minute, 1 to 2-segmented. Wings narrow and lanceolate, with reduced venation, but with large hindwing fringes (Fig. 49). Maculation often white with various markings or bands, or darker, sometimes with iridescence. Adults are often crespuscular or nocturnal, but some are diurnal. Larvae are leafminers (sometimes gregarious) or stem miners, especially on grasses (Gramineae) and related plant groups like Juncaceae and Cyperaceae, but other plant families are also utilized.

Grass Miner Moths (Lepidoptera: Elachistidae), Figure 49 **Example of grass miner moths (Elachistidae), *Biselachista cucullata* (Braun) from Florida, USA.**

Gravenhorst, Johan Ludwig Christian

Johan Ludwig Gravenhorst was born in Braunschweig [Brunswick], Germany, on November 14, 1777. He was educated at the Katharinen Gymnasium in Braunschweig. Despite an early interest in natural history, he decided on a career in law, and entered Universität Helmstadt to study law. However, in 1790 he entered Universität Göttingen to study zoology, mineralogy, and botany. In 1801 he returned to Helmstadt and defended his dissertation "Conspectus historiae entomologiae" and was awarded the title of "Doctor philosophiae et magister liberalium artium." Then he returned to Braunschweig and spent all his time on entomology. His first major publication (1802) was "Coleoptera Microptera Brunsvicensia," after which he journeyed to Paris to study insect collections, and meet entomologists. On return to Braunschweig, he bought entomological collections, became a "Privatdocent" at Universität Göttingen, and published (1906) "Monographia Coleopterorum Micropterorum," which expanded his recognition among entomologists. He worked on an expanded edition of this work until Erichson' s (1840) "Genera et species Staphylinorum" made it redundant. In 1810 he accepted a position of professor of natural history and second director of the botanical garden at Frankfurt an der Oder. In 1811, this university was transferred to Breslau (now Wroclaw in Poland), and Gravenhorst followed. In 1814 he sold his insect collection to the university in return for a guaranteed annual income transferable to his widow, and he founded the zoological museum there. He began to work on Ichneumonidae (Hymenoptera) on which he published intensively to 1829. In 1830 he travelled to Prague, Vienna, and Trieste to study marine animals, on which he published. He was a member of at least 21 natural history societies in Germany, France, Italy and England. He died in Breslau on January 17, 1857, after a very lengthy illness.

Greater Date Moth, *Arenipses sabella* Hmps. (Lepidoptera: Pyralidae)

YOUSIF ALDRYHIM
King Saud University Riyadh, Saudi Arabia

The importance of the greater date moth as a date pest seems to be increasing. It is known from India, Iran, Iraq, Saudi Arabia, Oman, Egypt and Algeria.

Description

The adult greater date moth is 18–22 mm long, with a wing span of 33–35 mm in males and 40–42 mm in females. They are light brown to yellowish. The head and thorax are light brown and the abdomen is silvery white, the front wings are brownish to yellowish with black scales and the hind wings are light brown. The eggs generally are laid singly, but also have been observed in clusters. They are creamy-white in color and spherical in shape. The larvae of the greater date moth are 28–35 mm in length and are dark pink in color. The pupae are elongated, about 18 mm in length, and are light brown.

Behavior

The adult greater date moths are nocturnal, but attracted to artificial light. They hide in the inner side of the bases of the palm petioles during the daytime. The larvae are also nocturnal at high temperatures, but have been seen active during the daytime at moderate temperatures. The hiding places of the larvae are at the inner bases of the split spathes, between the base of strands, in the inner base of the palm petioles. The larvae are quite mobile and can hide easily when threatened.

Biology and Damage

The biology of this pest is not well understood. The adults are active most of the year in warm areas and are not seen in the winter months in cold areas. The pest spends the winter in the larval stage in coccons under the fibers of the tree cabbage (head of the tree). The number of generations per year is uncertain, but there are at least two generations per year. In February in warm areas, larvae feed on the inner base of the petioles. The females lay eggs on the external tips of the unopened spathes, on strands and on fruit clusters. Hatched larvae feed on the tips of unopened spathes, which become black because of the clustering of black frass and silken threads. The larvae penetrate the sheath of the unopened spathes and feed on the strand mainly on tips. The tips of the strands become light gray to silver in color and devoid of flowers. When the spathes open, the larvae may remove the flowers and young fruits from the strands. The larvae also feed on the base of the main axis of the fruit cluster and make longitudinal tunnels and holes, both filled with black frass, coarse silks and plant fragments. The larvae feed in September on the ripened fruits. The infested dates become filled with black frass tied by silks. The infested dates may be inadvertently harvested and transferred to stores where consumers unfortunately encounter the larvae and adults.

Control

No definitive studies have been done to control this pest. The adult greater date moths were observed to be attracted to light traps with high rates of attracting from March to May. Pruning of the palm fronds may eliminate the hiding places of the larvae and adults. The current general practices to control this pest are dusting the cabbage of the tree with organophosphorus or pyrethriod insecticides in the autumn after harvesting, and dusting the strands and the bases of the fruit clusters with an insecticide at the time of pollination. If the problem persists, sprays also should be applied on the young fruits. No active and promising natural enemies have been recorded for this pest. The pheromone of this pest has not yet been identified, therefore, it is important that new research focus on this aspect.

Greater Fritillaries or Silverspots, *Speyeria* [=*Argynnis*] (Lepidoptera: Nymphalidae)

JAMES C. DUNFORD, KELLY R. SIMS
University of Florida, Gainesville, FL, USA

Speyeria scudder (Nymphalidae: Heliconiinae: Argynnini), commonly known as greater fritillaries or silverspots, are medium to large butterflies (wingspans of 40–90 mm) that represent conspicuous members of North American Lepidoptera. The genus was named in honor of a German entomologist, Adolph Speyer, who specialized in butterfly studies. The origin of the common name "fritillaries" is obscure, and one explanation is that these butterflies resemble the lily genus *Fritillaria*. Typically orange and black or brown in color, most are recognized by distinctive black spots and bars on the dorsal wing surface and silvery or cream-colored spots located on the ventral surface of the hind wings.

Speyeria fritillaries are restricted to North America (absent in southeastern regions of the United States and all but northern Mexico), although morphologically similar genera exist in other temperate parts of the world and together may be considered the temperate-zone counterpart to tropical Heliconiini (i.e., passion-vine butterflies). Long included in the Old World genus *Argynnis* Fabricius, they differ from their Eurasian relatives primarily in genitalic structure and were thus considered generically distinct from *Argynnis* by dos Passos and Grey; all North American taxa named since that time have been described within *Speyeria*. Recent workers, however, have treated *Speyeria* as a subgenus of the primarily Palearctic *Argynnis* fritillaries.

Speyeria species and associated geographical forms have been collected and examined in great detail in the past and continue to be a target for professional and amateur butterfly enthusiasts. The early works on *Speyeria* listed over 100 "species" names, but subsequent workers realized that most of these "species" were no more than geographical forms or races associated with a few polytypic species. Since then, several additional subspecies have been described, three subspecies have been elevated to full species status, and some taxon names have been declared synonyms.

Speyeria is presently comprised of 16 species Table 12), and according to some authors, over 100 subspecific, geographical forms. *Speyeria cybele* (Fabricius), *S. aphrodite* (Fabricius), *S. idalia* (Drury), and *S. atlantis* (Edwards) occur east of the Mississippi River, each with distributions or subspecies occurring in western North America, while *S. diana* (Cramer) is restricted to the eastern United States (in Appalachian and Ozark Mountain ecosystems). The remaining species occur in the western regions of North America, some as far north as Alaska. All but three *Speyeria* species are extremely variable [exceptions include *S. diana*, *S. idalia*, and *S. edwardsii* (Reakirt)], with the western North American species, in particular, fragmenting into numerous geographic forms that are often clinally joined with considerable intergradation occurring.

Species and subspecies determinations are made primarily using wing patterns, wing coloration, and geographical location; because of this, specific and subspecific identification is difficult in many taxa due to subtle pattern (Fig. 50) and color variations. Generally, adult morphological variation between species and subspecies is based on overall size, varying degrees of sexual dimorphism, and the wings. Important wing characteristics found dorsally are ground color, intensity of black markings, degree of dark basal suffusion, prominence of marginal band, and thickness of veins on the wings. Ventrally the important characteristics are the general ground color of the discal area on the hindwings, the size, shape, color and position of spots on the hindwings, and color and width of the submarginal band between the two outer rows of spots on the hindwings (Fig. 52).

Life History

Adults frequent open fields, moist meadows, and open woodlands near streams, or are restricted

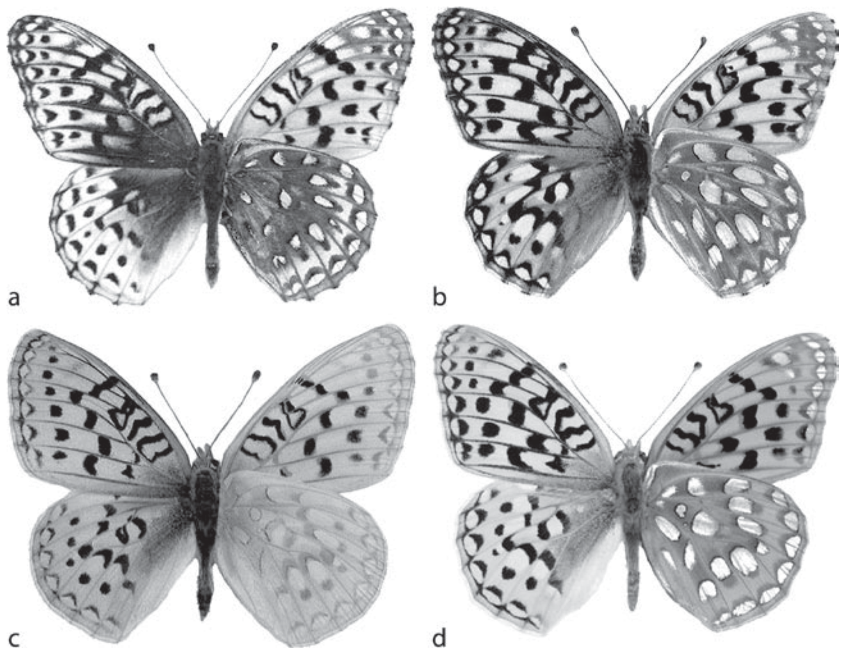
Speyeria mormonia (Boisduval) – Mormon Fritillary

to coastal dunes, tallgrass prairies, or mountains. During the summer months they may be abundant in forest clearings, by roadsides, and along flower rich slopes and meadows in mountainous regions. *Speyeria* often prefer tall nectar sources such as thistles, wild asters, sunflowers, penstemons, mint, and dogbane. Males are often found congregating in large numbers at seeps and roadside puddles. Adults are strong fliers and can fly many kms, especially in late summer. They are rather long lived (several weeks to 2–3 months from May-September) and all members of the genus are univoltine.

Adult males typically emerge a week before females and patrol for potential mates. Courtship is rather elaborate, and pheromone cues from both sexes may be a reproductive barrier between species. *Speyeria* adults (Fig. 51) bear scent scales that lie along the veins on the upper side of the wings. Males pursue females, draw their forewings forward, and flick the closed wings slightly open in quick bursts. Each burst of two to five flicks lasts less than a second, wafting pheromones up to the female's antennae. The tips of the abdomens of male Argynnini (including *Speyeria*) contain paired glands normally hidden in the abdomen that aid in courtship. Courting males keep their forewings in a forward position and open and close them near the resting female to waft pheromones. Unreceptive females will flutter their wings to reject males.

Fritillaries are fecund butterflies, with some species laying over 2,000 eggs. Females delay egg-laying until late summer and usually oviposit rather haphazardly near their host plants rather than carefully placing them on the plant as most butterflies do. They are known to deposit eggs on twigs, leaves, stones and other debris. Eggs bear a tannish, camouflage coloration and are slightly rounded, tapering toward the apex. They are highly sculptured and likely adapted to withstand considerable environmental pressures including submergence, frost, and ground dwelling predators and microbes.

Larvae usually pass through six instars, overwintering as first instars and breaking diapause to complete development the following season. They are generally secretive and feed primarily at night, returning to hiding places under host leaves or



Greater Fritillaries or Silverspots, *Speyeria* [=*Argynnis*] (Lepidoptera: Nymphalidae), Figure 50 **Dorsal (*left*) and ventral (*right*) wing patterning of some *Speyeria* species: (a) *Speyeria hesperis* (New Mexico); (b) *Speyeria callippe* (Nevada); (c) *Speyeria mormonia* (Nevada); (d) *Speyeria zerene* (Nevada) (images by James C. Dunford).**

nearby vegetation during the day. Most species are black with lighter markings and bear three rows of branching spines on either side of the body. Some species exhibit spots of red/orange or other colors. Larvae feed on various violet species (*Viola*), and in laboratory conditions they are known to feed on every American violet species tested. *Viola* species range widely across temperate habitats of the Northern Hemisphere and into higher elevations of mountain systems towards the equator. *Speyeria* pupae are generally tan or brown with a few markings and hang freely from the cremastral end.

Speyeria individuals likely gain protection from potential predators in a variety of ways. *Speyeria diana* females (Fig. 52) are sexually dimorphic from *S. diana* males and, unlike the typical orange and black patterning of most *Speyeria* species, have been implicated in a Batesian mimicry complex with the distasteful, similarly colored pipevine swallowtail butterfly. In some *Speyeria* species, an eversible gland, capable of producing an unpleasant odor, is located on the dorsum of the female abdomen. Larvae also bear a gland located ventrally just behind the head that is likely used for defense against predators. Other avoidance measures during the larval stages include taking refuge under leaves during the day and feeding at night. First instars will also often hibernate inside grass stems. Eggs in some species may also contain phytochemicals used to deter potential predators.

Conservation

A few *Speyeria* species have been declining over the past 200 years and have been listed as either federally/state endangered or threatened [e.g., *S. idalia*, *S. diana*, *S. zerene hippolyta* (Edwards)]. *Speyeria* and their larval host plants (*Viola*) are among the best indicator organisms of native, undisturbed ecological communities in North America. They are also among the first organisms to be eliminated from such communities as a result of human-caused disturbances.

Wagner; images a and f by James C. Dunford).**

Speyeria idalia populations have been extirpated in much of the northeastern United States and have declined precipitously in other parts of its range. They inhabit native tallgrass prairies in the Midwest, an ecosystem that is shrinking due to development and agricultural activities. *Speyeria diana* disappeared from southeastern Virginia in about 1951 and is considered uncommon or extirpated in many other parts of its range. Historical populations in the Midwest and the Virginia Piedmont were extirpated in the 1800s, and most occurrence records (except in the Appalachians and Ozarks) are more than 50 years old. Coastal subspecies, such as the Oregon Silverspot (*S. z. hippolyta*), have been federally listed and depend on vanishing salt-spray meadows along the Oregon coast. Research on *Speyeria* butterflies continues to focus on various conservation and management measures required to maintain and protect threatened or endangered species.

Greenhouse Whitefly, *Trialeurodes vaporariorum* (Westwood) (Hemiptera: Aleyrodidae)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

Greenhouse whitefly is found widely around the world, including most of the temperate and subtropical regions of North America, South America, Europe, Central Asia and India, northern and eastern Africa, New Zealand and southern Australia. It does not thrive in most tropical locations, and occurs in colder regions only by virtue of its ability to survive winter in greenhouses. It often overwinters only in such protected locations, but in mild-winter areas it survives outdoors throughout the year. The origin of this species is not certain, but is thought to be Mexico or the southwestern United States.

Life History

The development period from egg to adult requires about 25–30 days at 21°C, and 22–25 days at 24°C. Thus, because the preoviposition period of adults also is short, less than two days above 20°C, a complete life cycle is possible within a month. Greenhouse whitefly can live for months, and oviposition time can exceed the development time of immatures; this results in overlapping generations. Optimal relative humidity is 75–80%. The developmental threshold for all stages is about 8.5°C.

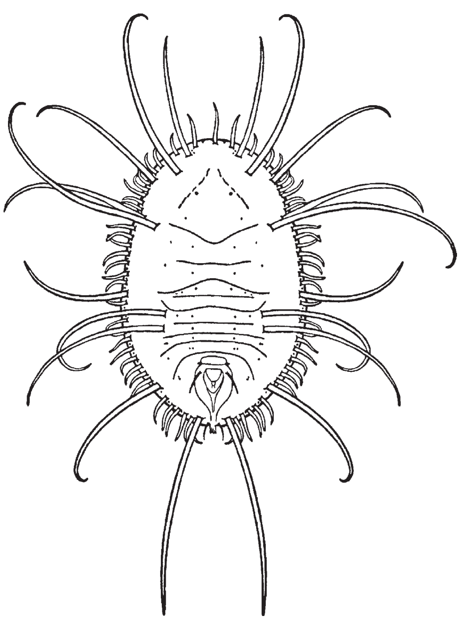
Eggs are oval in shape, and suspended from the leaf by a short, narrow stalk. The eggs initially are green in color and dusted with white powdery wax, but turn brown or black as they mature. The eggs are about 0.24 mm long and 0.07 mm wide. Eggs are deposited on the youngest plant tissue, usually on the underside of leaves in an incomplete circular pattern. Up to 15 eggs may be deposited in a circle measuring about 1.5 mm in diameter. This pattern results from the female moving in a circle while she remains with her mouthparts inserted into the plant. This pattern is less likely on plants with a high density of trichomes because plant hairs interfere with the oviposition behavior. Duration of the eggs stage is often 10–12 days, but eggs may persist for over 100 days under cool conditions. When cultured at 18, 22.5, and 27°C, egg development requires an average of 15, 9.8, and 7.6 days, respectively. Maximum fecundity varies according to temperature; optimal temperature is 20–25°C regardless of host plant. When feeding on eggplant, greenhouse whitefly produces over 500 eggs, on cucumber and tomato about 175–200 eggs.

The newly hatched whitefly nymph is flattened, oval in outline, and bears functional legs and antennae. The perimeter is equipped with waxy filaments. The first instar measures about 0.3 mm in length. It is translucent, usually appearing to be pale green in color but with red eyes. After crawling one cm or so from the egg, it settles to feed and molt. Development in the first instar requires 6.5, 4.2, and 2.9 days, respectively, when cultured at 18, 22.5, and 27°C. The second and

Greenhouse Whitefly, *Trialeurodes vaporariorum* (Westwood) (Hemiptera: Aleyrodidae), Figure 53 **Adult of greenhouse whitefly, *Trialeurodes vaporariorum* (Westwood).**

third nymphal stages are similar in form and larger in size, though the legs and antennae become reduced and nonfunctional. They measure about 0.38 and 0.52 mm in length, respectively. Duration of the second instar requires about 4.3, 3.2, and 1.9 days whereas third instars require 4.5, 3.2, and 2.5 days, respectively, when cultured at 18, 22.5, and 27°C. The fourth nymphal stage, which is usually called the "pupa," differs in appearance from the preceding stages. The fourth instar measures about 0.75 mm in length, is thicker and more opaque in appearance, and is equipped with long waxy filaments. The pupal stage actually consists of the fourth nymphal instar period, which is a period of feeding, plus the period of pupation, which is a time of transformation to the adult stage. Thus, pupation occurs within the cuticle of the fourth instar. Duration of the fourth instar period and pupal period are 8.7 and 5.9, 5.9 and 4.0, and 4.5 and 2.8 days, respectively, at 18, 22.5, and 27°C.

The form of the pupa is used to distinguish among whitefly species (Fig. 54), and can be used to separate greenhouse whitefly from the similar-appearing *Bemisia* spp. Greenhouse whitefly is straight-sided when viewed laterally, ovoid, and lacks a distinct groove near the anal end of the body. In contrast, the *Bemisia* spp. are oblique-sided, irregularly oval, and possess a distinct groove in the anal region.



Greenhouse Whitefly, *Trialeurodes vaporariorum* (Westwood) (Hemiptera: Aleyrodidae), Figure 54 **Pupa of greenhouse whitefly, *Trialeurodes vaporariorum* (Westwood).**

Individuals of greenhouse whitefly which develop on lightly or moderately pubescent leaves tend to be relatively large and to have four pairs of well developed dorsal waxy filaments. In contrast, whiteflies developing on densely pubescent leaves tend to be smaller, and to bear more that four pairs of dorsal filaments. These morphological variations are not entirely consistent, and have led to considerable taxonomic confusion.

Adults (Fig. 53), are small, measuring 1.0–2.0 mm long. They are white in color, with the color derived from the presence of white waxy or mealy material, and have reddish eyes. They bear four wings, with the hind wings nearly as long as the forewings. The antennae are evident. In general form, viewed from above, this insect is triangular in shape because the distal portions of the wings are wider than the basal sections. The wings are held horizontally when at rest; this characteristic is useful for distinguishing this species from the similar-appearing *Bemisia* spp. whiteflies, which hold their wings angled or roof-like when at rest. Mating may occur repeatedly, though females can also produce eggs without mating.

This species has a very wide host range, with over 300 species recorded as hosts. However, some hosts are more suitable. Vegetable plants often serving as good hosts are bean, cantaloupe, cucumber, lettuce, squash, tomato, eggplant, and occasionally cabbage, sweet potato, pepper, and potato. Among greenhouse-grown vegetables, the most common hosts are tomato, eggplant, and cucumber. Many ornamental plants serve as good hosts, including ageratum, aster, chrysanthemum, coleus, gardenia, gerbera, lantana, poinsettia, salvia, verbena, zinnia and many others.

Natural enemies of greenhouse whitefly are numerous, but few are consistently effective, especially under greenhouse conditions. Greenhouse whitefly is attacked by the common predators of small insects, including minute pirate bugs (Hemiptera: Anthocoridae), some plant bugs (Hemiptera: Miridae), green lacewings (Neuroptera: Chrysopidae), brown lacewings (Neuroptera: Hemerobiidae), and ladybirds (Coleoptera: Coccinellidae). Parasitic wasps attacking greenhouse whitefly are largely confined to the family Aphelinidae, but many species are involved and they vary regionally. Some of the important parasitoids are *Encarsia formosa* Gahan, *Aleurodophilus pergandiella* (Howard), *Eretmocerus haldemani* Howard, *Prospaltella transvena* Timberlake, and *Aphidencyrtus aphidivorus* (Mayr). Although these agents exercise considerable control on whitefly populations in weedy areas or on crops where insecticide use is minimal or absent, they do not survive well in the presence of most insecticides. *Encarsia formosa* has been used successfully under greenhouse conditions, and to a lesser extent field conditions, to affect biological suppression.

The pathogens of greenhouse whitefly are principally fungi, particularly *Aschersonia aleyrodis*, *Paecilomyces fumosoroseus*, and *Verticillium lecanii*. All occur naturally and can cause epizootics in greenhouses and fields, and also have been promoted for use in greenhouses as bioinsecticides. *Aschersonia* is specific to whiteflies, *Verticillium* has a moderately wide host range, and *Paecilomyces* has a broad host range. For optimal development of disease, high humidity is required. *Aschersonia* is spread principally by rainfall, so often fares poorly in greenhouse environments.

Damage

Adult and nymphal whiteflies use their piercing-sucking mouthparts to feed on the phloem of host plants. This results in direct damage, resulting in localized spotting, yellowing, or leaf drop. Under heavy feeding pressure, wilting and severe growth reduction may occur. Whiteflies also secrete large amounts of sugary honeydew, which coats the plants with sticky material, and must be removed from fruit before it is marketed. The honeydew also provides a substrate for growth of sooty mold, a black fungus that interferes with the photosynthesis and transpiration of plants.

Greenhouse whitefly is, as the common name suggests, primarily a pest in greenhouses, and is a serious limitation to the production of vegetables grown in such structures. However, it can also be a field pest, often in warmer climates but also in cool climates when seedlings contaminated with whiteflies are transplanted into the field.

Greenhouse whitefly is capable of transmitting viruses to plants, but is not considered to be a serious vector, particularly relative to the *Bemisia* spp. However, greenhouse whitefly transmits beet pseudo-yellow virus to cucumber in greenhouse culture.

Management

Although whitefly nymphs and adults can be detected readily by visual examination of foliage, most monitoring systems take advantage of the attraction of adults to yellow, and use yellow sticky traps to capture flying insects. Sticky cards or ribbons are suspended at about the height of the crop for optimal monitoring. Traps must be placed close to plants or close to the ground or population densities will be underestimated. Traps should be dispersed widely because whitefly distribution is not uniform within a crop. Whitefly flight peaks at about noon, but under greenhouse conditions is independent of temperature if the basal flight temperature of 16–17°C is exceeded.

Applications of insecticides are often made to minimize the effects of whitefly feeding on crops in greenhouses. Greenhouse whitefly feeds on the lower surface of foliage and is sessile throughout most of its life, habits that minimize contact with insecticides, and resulting in frequent applications and effectiveness mostly against the adult stage. In greenhouse culture, application intervals of only 4–5 days are common, and systemic insecticides are often used to increase the likelihood of insect contact with toxins. Thus, whitefly resistance to nearly all classes of insecticides is known, and rotation of insecticide classes is encouraged. Mixtures of insecticides are often used, which is indicative of high levels of resistance among whiteflies to insecticides. Field populations of greenhouse whitefly invariably are derived from greenhouse populations, and possess similar resistance to many insecticides. Applications of petroleum oils and biological control agents help to avoid difficulties with insecticide resistance.

Some insecticidal materials can be integrated into biologically based whitefly management systems. Selective materials that affect only adult and nymphal whiteflies, insect growth regulators, and insecticidal soaps are somewhat compatible with parasitoids and can be used when parasitoids are failing.

Few cultural practices are available, but disruption of the whitefly population with host-free periods is important. Continuous culture of plants allows whiteflies to move from older to younger plants. Similarly, weeds may allow whiteflies to bridge crop-free periods, and should be eliminated. Culture of plants over white reflective mulch also reduces whitefly densities. Yellow sticky traps can be hung in greenhouses to capture adult whiteflies, thereby reducing whitefly density.

Seasonal inoculative release of the parasitoid *Encarsia formosa* Gahan into crops infested with greenhouse whitefly has been used extensively for suppression of whiteflies on greenhouse-grown vegetable crops. Excellent suppression of whiteflies is attainable, but on host plants such as cucumber and eggplant, which are very favorable for whitefly reproduction and have hairy leaves that interfere with parasitoid searching, frequent releases must be made. Alternatively, cucumber varieties with reduced trichome density have been developed, and which favor parasitism. Another critical factor is temperature, because low greenhouse temperatures are more suitable for whitefly activity than parasitoid activity. Daytime temperatures of about 24°C seem to be optimal; temperatures of 18°C or less suppress parasitoid searching. A cold-tolerant *Encarsia* strain that is active at 13–17°C has also been used to overcome this temperature problem. Interference from pesticides can markedly affect parasitoid survival, so other pests such as mites must be managed biologically also. Lastly, release rates are important because if too many parasitoids are released the host whiteflies are driven nearly to extinction, leading to disappearance of the parasitoids; this is most likely to occur in small greenhouses. Alternatively, parasitoid releases can be made throughout the season, irrespective of whitefly presence. Although the protocols and technologies for whitefly management using *E. formosa* have been perfected for use in greenhouses, management under outdoor conditions awaits further research.

The fungus *Verticillium lecanii* is sometimes used commercially in Europe for whitefly and thrips suppression in greenhouses, though its success is strongly affected by humidity. Where humidity can be raised to a high level, epizootics can be induced in 1–2 weeks. Both young and adult stages are susceptible to infection.

Green Peach Aphid, *Myzus persicae* (Sulzer) (Hemiptera: Aphididae)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

Green peach aphid is found throughout the world, including both tropics and temperate latitudes. It is considered to be a pest nearly everywhere, often due to its ability to transmit plant viruses. In addition to attacking plants in the field, green peach aphid readily infests vegetables and ornamental plants grown in greenhouses. This allows high levels of survival in areas with inclement weather, and favors ready transport on plant material. When young plants are infested in the greenhouse and then transplanted into the field, fields will not only be inoculated with aphids but insecticide resistance may be introduced. These aphids are also reported to be transported long distances by wind and storms.

Life History

The life cycle varies considerably, depending on the presence of cold winters. Development can be rapid, often 10–12 days for a complete generation, and with over 20 annual generations reported in mild climates. Where suitable host plants cannot persist, the aphid overwinters in the egg stage. In the spring, soon after the plant breaks dormancy and begins to grow, the eggs hatch and the nymphs feed on flowers, young foliage, and stems. After several generation on *Prunus* spp., dispersants from overwintering hosts deposit nymphs on summer hosts. In cold climates, adults return to *Prunus* spp. in the autumn, where mating occurs, and eggs are deposited. All generations except the autumn generation culminating in egg production are parthenogenetic.

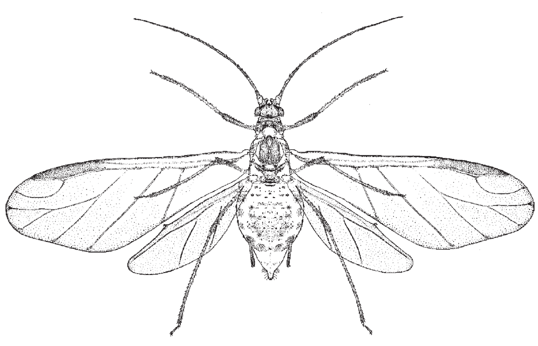
Eggs are deposited on *Prunus* spp. trees. The eggs measure about 0.6 mm long and 0.3 mm wide, and are elliptical in shape. Eggs initially are yellow or green, but soon turn black. Mortality in the egg stage sometimes is quite high.

Nymphs initially are greenish, but soon turn yellowish, greatly resembling viviparous adults. There may be four instars in this aphid, with the duration of each averaging 2.0, 2.1, 2.3, and 2.0 days, respectively. Alternatively, five instars also have been reported, with a mean development time of 2.4, 1.8, 2.0, 2.1, and 0.7 days, respectively. Parthenogenetic females give birth to offspring 6–17 days after birth, with an average age of 10.8 days at first birth. The length of reproduction varies considerably, but averages 14.8 days. The average length of life is about 23 days under caged conditions where predators are excluded. The daily rate of reproduction averages 1.6 nymphs per female, with about 75 offspring produced. The maximum number of generations occurring annually is 20–21, depending on the year.

Up to eight generations may occur on *Prunus*, but as aphid densities increase winged forms are produced, which then disperse to summer hosts. Winged (alate) aphids have a black head and thorax, and a yellowish green abdomen with a large dark patch dorsally. They measure 1.8–2.1 mm in length. Winged green peach aphids seemingly attempt to colonize nearly all plants available. They often deposit a few young and then again take flight. This highly dispersive nature contributes significantly to their effectiveness as vectors of plant viruses.

The offspring of the dispersants from the overwintering hosts are wingless, and each produce 30–80 young. The wingless (apterous) aphids are yellowish or greenish in color. They measure about 1.7–2.0 mm in long. A medial and lateral green stripes may be present. The cornicles are moderately long, unevenly swollen along their length, and match the body in color. The appendages are pale. The rate of reproduction is positively correlated with temperature, with the developmental threshold estimated to be about 4.3°C. As aphid densities increase or plant condition deteriorates, winged forms are again produced to aid dispersal. The nymphs that give rise to winged females may be pinkish. The dispersants typically produce about 20 offspring, which are always wingless. This cycle is repeated throughout the period of favorable weather.

In the autumn, in response to change in day length or temperature, winged male and female aphids are produced which disperse in search of *Prunus* (Fig. 55). Timing is important, as foliage on the *Prunus* hosts is physiologically optimal as leaves begin to senesce. Females arrive first, and give birth to wingless (apterous) egg-laying forms (oviparae). Males are attracted to oviparae by a pheromone, capable of mating with several females, and eggs are produced. The oviparous female deposits 4–13 eggs, usually in crevices in and near buds of *Prunus* spp. The oviparous female is 1.5–2.0 mm long, and pinkish.



Green Peach Aphid, *Myzus persicae* (Sulzer) (Hemiptera: Aphididae), Figure 55 Adult of green peach aphid, *Myzus persicae* (Sulzer).

Parthenogenic reproduction is favored in the many parts of the world where continuous production of crops provides suitable host plants throughout the year, or where weather allows survival on natural (noncrop) hosts. The average temperature necessary for survival of active forms of green peach aphid is estimated at 4–10°C. Plants in the families Cruciferae and Chenopodiaceae, both crops and weeds, readily support aphids through the winter months.

Green peach aphid feeds on hundreds of host plants in over 40 plant families. However, it is only the viviparous summer stages that feed so widely; the oviparous winter stages are much more restrictive in their diet choice. In temperate latitudes the primary or overwintering hosts are trees of the genus *Prunus*, particularly peach and peach hybrids, but also apricot and plum. During the summer months the aphids abandon their woody hosts for secondary or herbaceous hosts, including ornamental, vegetable and field crops. Crops differ in their susceptibility to green peach aphid, but it is actively growing plants, or the youngest plant tissue, that most often harbors large aphid populations. In warmer climates the aphids do not seek out overwintering hosts, but persist as active nymphs and adults on hardy crops and weeds.

Broadleaf weeds can be very suitable host plants for green peach aphid, thereby creating pest problems in nearby crops. Common and widespread weeds such as field bindweed, *Convolvulus arvensis*; lambsquarters, *Chenopodium album*; and redroot pigweed, *Amaranthus retroflexus*, are often cited as important aphid hosts, and plant viruses may be acquired from these hosts.

Natural Enemies

Hundreds of natural enemies have been recorded, principally ladybirds (Coleoptera: Coccinellidae), flower flies (Diptera: Syrphidae), lacewings (Neuroptera: mainly Chrysopidae), parasitic wasps (Hymenoptera: Braconidae), and entomopathogenic fungi (mainly Entomophthorales). Most are general predators, moving freely among green peach aphid, other aphids, and even other insects. Quantitative data generally are lacking for the influence of most natural enemies. Weather also reportedly contributes to significant change in aphid numbers, including direct mortality, but this also is poorly documented.

The ephemeral nature of aphid infestation in many crops is believed to prevent the beneficial organisms from consistently locating the aphids and reproducing in a timely manner. Nevertheless, anyone who has frequently observed green peach aphid at high densities probably has observed sudden population decreases following the appearance of ladybirds, wasp parasitoids, or entomopathogenic fungi such as *Erynia neoaphidis*. Unfortunately, the disease epizootic often occurs too late to keep aphids from attaining high numbers. Various studies that selectively excluded or killed beneficial organisms have demonstrated the explosive reproductive potential of these aphids in the absence of biological control agents, thus demonstrating their value in reducing damage potential. In greenhouse crops, where environmental conditions and predator, parasitoid, and pathogen densities can be manipulated, biological suppression can be effective and consistent.

Damage

Green peach aphids can attain very high densities on young plant tissue, causing water stress, wilting, and reduced growth rate of the plant. Prolonged aphid infestation can cause appreciable reduction in yield of root crops and foliage crops. Contamination of harvestable plant material with aphids, or with aphid honeydew, also causes loss. Where mild winters allow good overwintering survival of green peach aphid on spinach, crop value is affected by insect presence. Blemishes to the plant tissue, usually in the form of yellow spots, may result from aphid feeding. Leaf distortions are not common except on the primary host. Contamination of vegetables by aphids sometimes presents quarantine problems and fumigation techniques have been developed that kill the insects without causing harm to the vegetables.

The major damage caused by green peach aphid is through transmission of plant viruses. Indeed, this aphid is considered by many to be the most important vector of plant viruses throughout the world. Nymphs and adults are equally capable of virus transmission, but adults, by virtue of being so mobile, probably have greater opportunity for transmission. Both persistent viruses, which move through the feeding secretions of the aphid, and non-persistent viruses, which are only temporary contaminants of aphid mouthparts, are effectively transmitted. Over 100 viruses are transmitted by this species. Some of the particularly damaging diseases include potato leafroll virus and potato virus Y to Solanaceae, beet western yellows and beet yellows viruses to Chenopodiaceae, lettuce mosaic virus to Compositae, cauliflower mosaic and turnip mosaic viruses to Cruciferae, and cucumber mosaic and watermelon mosaic viruses to Cucurbitaceae. A discoloration in potato tubers, called net necrosis, occurs in some potato varieties following transmission of potato leafroll.

Management

Day-degree models using a developmental threshold of 4°C can be used to predict various phenological events such as egg hatch and immigration of alate aphids. Yellow traps, particularly water pan traps, are commonly used for population monitoring.

Despite the numerous options potentially available, many crop producers are dependent on insecticides for suppression of green peach aphid abundance. Systemic insecticide applications are especially popular at planting time, most of which provide long-lasting protection against aphid population buildup during the critical and susceptible early stages of plant growth, and some of which provide protection for months.

Green peach aphid is able to develop at lower temperatures than its parasitoids, so the wasps are beneficial only in benign climates or where temperature can be controlled, as in some greenhouses. Indeed, there has been considerable success using parasitoids, the entomopathogenic fungus *Verticillium lecanii*, and the predatory midge *Aphidoletes aphidimyza* (Diptera: Cecidomyiidae) for greenhouse-grown vegetables in Europe.

The overwintering behavior of green peach aphid, which in many areas is restricted to *Prunus* or other relatively restricted sites, has fostered research on techniques to reduce aphid abundance and disease transmission to other crops, by either removing the overwintering site or by eliminating the aphids before they disperse. Destruction of peach and apricot trees, and treatment of trees with dormant oil and insecticide, have been used effectively to disrupt aphid population increase. Similarly, vegetable and flower plants grown in greenhouses during the winter months have been shown to be an excellent source of infestation during the following spring, and incidence of leafroll in potatoes can be directly related to the abundance of aphids in home gardens. Inspection of garden centers and treatment of seedlings found infested with aphids can be important elements of the overall potato leafroll reduction effort. As is usually the case with aphids, green peach aphid populations tend to be higher when plants are fertilized liberally with nitrogen fertilizers.

Because some of the virus diseases transmitted by green peach aphid are persistent viruses, which typically require considerable time for acquisition and transmission, insecticides can be effective in preventing disease spread in some crops. For example, potato leafroll virus is transmitted within the potato crop principally by wingless aphids moving from plant to plant. Infected seed potatoes are the principal source of leafroll in most potato crops, so planting disease-free seed is obviously an important step in minimizing the incidence of the disease. Insecticides may not keep winged aphids from alighting in a crop and quickly transmitting non-persistent virus, but they can certainly prevent the secondary spread of virus within a crop by colonizing aphids. However, insecticide resistance is a severe problem in many areas. Application of mineral oil and use of aluminum or white plastic mulch reduces virus transmission. Aphids that are not effectively repelled by reflective mulch seem to thrive on mulched crops and exhibit high rates of reproduction. Therefore, even in mulched crops some aphid control is necessary.

Gregarines of Insects

The subclass Gregarinasina currently encompasses about 220 genera and 1,500 named species. The modern day gregarines are a monophyletic group associated with invertebrates, including various polychaetes (marine worms), oligochaetes (earthworms), and arthropods. The majority of the gregarines have been described from insect hosts, including a wide variety of aquatic insects and many coleopterans. Normally, these organisms are capable of infecting a certain group of hosts without the involvement of a vector or secondary host. It is likely that the current list of gregarine species represents only a small percentage of the gregarines existing in nature. Gregarines display a high degree of host specificity, and may be restricted to a particular tissue (or site) of a specific life stage of a single insect species. However, certain neogregarines (*Mattesia* spp.) have been experimentally transmitted to insects of different orders. In many cases, insects may harbor a gregarine complex. Gregarines, lacking the virulence of other insect disease agents and not possessing a vertebrate counterpart, have not received much attention from pathologists during the past several decades.

Morphologically, the gregarines produce mature gamonts which have the conoid structure modified into an epimerite or mucron. The epimerite, often containing attachment hooks, mediates gregarine attachment to the host cell. This anucleated segment, separated from the main cell by a septum, often is lost when the gamont detaches from the host cell. The mucron, unlike the epimerite, lacks the septal structure. Gregarines are divided into four major groups: the Archigregarines, Blastogregarines, septate Eugregarines, and Neogregarines. The primitive archigregarines and blastogregarines are parasites of the digestive tracts of marine worms and annelids. The life cycle of these latter gregarines includes three schizogonies: merogony, gametogony, and sporogony.

The Eugregarine group, believed to arise from an ancestral archigregarine, contains the vast majority of the described gregarines (1,300 species). Most eugregarines that are detrimental to the host insect are found within the genus *Ascogregarina*. The life cycle of the eugregarines, unlike the archigregarines or neogregarines, lacks the merogony phase. Host insects ingest the dormant oocyst stage that is activated to release infectious sporozoites that exit through the polar canals. Excystation is a pH-sensitive event and, therefore, may be regulated by the pH gradient existing in the insect's digestive tract. Excysted sporozoites (4–8 per oocyst) migrate to the midgut epithelium and undergo both intracellular and extracellular growth phases. Upon attaching to the midgut epithelia, sporozoites differentiate and produce either epimerite (septate gregarine) or mucron (aseptate gregarines) attachment structures. These cells, referred to as trophozoites or gamonts (Fig. 56), may penetrate the midgut or remain attached to the microvillar surface. Individual gamonts undergo extensive growth, reaching a size that may be measured in millimeters. Normally, the fully mature detached gamont is the stage that is detected in infected insects. Mature gamonts detach themselves from the midgut and pair off in the lumen, forming a prenuptial association known as syzygy. A membrane is formed around the paired gamonts, forming the gametocysts that are expelled in feces. Within the gametocyst one of the gamonts produces microgametes and the second gamont develops macrogametes. Alternatively, both gamonts may produce isogametes. The gametes fuse, producing a diploid zygote that undergoes successive meiotic and mitotic divisions, resulting in a thick-walled oocyst filled with haploid sporozoites.

Gregarines of Insects, Figure 56 **Light micrograph of septate gamonts of *Gregarina blatteria* attached to cockroach midgut surface.**

Eugregarines lacking the merogonic cycle are unable to multiply and spread within host insects. The number of gamonts found in the host is a direct reflection of the number of sporozoites released from the ingested oocysts. The impact of gregarines inhabiting the digestive tract is often negligible; damaged host cells are replaced without a noticeable impact on the host insect. For example, the mealworm *Tenebrio molitor* is host to *Gregarina polymorpha*, and can harbor up to 6,000 gamonts in its digestive tract without any pathological effect. In certain cases, these organisms are considered commensals. However, in other cases, the presence of these gregarines results in a measurable impact on the host. Large numbers of gregarines often damage the gut barrier and allow opportunistic microbes to invade and kill the host. This is especially true for the coelomic gregarines that penetrate the midgut and develop in the hemocoel. Normally, the impact of these organisms is subtle and cannot be measured simply in terms of insect mortality. For example, *Ascogregarina barretti* does not kill infected *Aedes triseriatus*, but results in the production of short winged adults. Similarly, under appropriate environmental conditions, infection by the aseptate gregarine *Ascogregarina culicis* alters the developmental kinetics and reduces the survival fitness of the host mosquito *Aedes aegypti*. A second aseptate gregarine, *Ascogregarina chagasi*, has been reported to cause population declines in laboratory colonies of the dipteran *Lutzomyia longipalpus*.

The order Neogregarinida includes the neogregarines characterized by their additional merogonic life stage. Neogregarines are found commonly in members in the orders Lepidoptera, Coleoptera, Hemiptera, Diptera, and Orthoptera and include the well-studied genus *Mattesia*. Neogregarines are transmitted orally and display a high level of host specificity. These gregarines usually are smaller than the eugregarines and possess a nonsegmented body plan. The oocyst stage of neogregarines is ingested and the digestive fluids act on polar caps (plugs), allowing for the release of the infectious sporozoites. The sporozoite penetrates the midgut and invades the fat body. Within this tissue, the sporozoites develop and give rise to micronucleate meronts. These meronts grow, producing multinucleate cells that measure 20–30 μm in length, and contain 30–200 nuclei. The nuclei move to the peripheral region and bud from the meront, releasing motile, elongate merozoites. These motile merozoites, released from infected cells, infect other healthy cells, spreading the infection through the target tissue(s). The merozoites, after undergoing one or more cycles, eventually undergo macronuclear merogony. The exocellular budded macronuclear merozoites round up and transform into gamonts, thus initiating the sexual phase. The gametocytes form pairs that synthesize an envelope and transform into the gametocyst. The gamonts within the cyst each produce a set of gametes that fuse to form the zygote. The zygotes develop a spore wall forming the oocyst. The zygote undergoes division, producing a set of sporozoites within the oocyst or spore.

The best-studied genus of insect neogregarines is *Mattesia*. The species *M. grandis*, pathogenic to the cotton boll weevil, *Anthonomous grandis*, has been examined as a microbial control agent. Under insectary conditions, *M. grandis* was found to cause epizootics and to decimate laboratory colonies. In the mid-1960s, this pathogen was mass-produced in host weevils. Spores harvested from infected adults were bait formulated and tested against weevil populations. Field-cage experiments demonstrated that spores delivered as baits could infect weevils. The high cost of production and erratic field performance has limited subsequent interest in this pathogen.

Gregarious Behavior

The tendency of organisms to stay in groups.

Gregarious Behavior in Insects

GREGORY A. SWORD
University of Sydney, Sydney, NSW, Australia

Many insects spend time in a group of conspecifics at some point during their lives. Insect groups can form passively, for example, through the common use of feeding, mating, oviposition, basking or shelter sites. Alternatively, insect aggregations may arise through the detection and active movement toward conspecifics or their associated cues. Cues used to detect the presence of conspecifics can be tactile, visual, auditory, olfactory or pheromonal, and may act alone or in combination.

Gregarious behavior is commonly associated with social insects that live in communal colonies (see Sociality of Insects), but it is also widespread among the non-social insects considered here. In these cases, insect groups of various sizes form under a myriad of conditions and are often interchangeably referred to as aggregations, associations, clumps and other such terms. Importantly, gregariousness is not limited solely to insects, but rather is widespread throughout the animal kingdom (e.g., fish schools and bird flocks). As such, the study of group living and its population level consequences are active areas of behavioral, ecological and evolutionary research. Entomological studies have played important roles in all of these disciplines.

In general terms, insect groups are considered as associations among multiple conspecifics at some point in space and time. Although a precise definition of groups and their respective sizes that might be appropriate for all non-social insects is lacking, this omission is largely irrelevant to the study of gregariousness. The conditions under which insects aggregate, the developmental stages during which aggregation occurs, as well as the physiological and behavioral mechanisms that underlie their formation have all been found to vary among and even within species (Fig. 57).

The evolution and maintenance of gregariousness necessarily requires the benefits of group formation to outweigh the corresponding costs in terms of individual fitness consequences. Empirical and theoretical studies investigating the benefits of grouping have historically outnumbered those concerned with measuring its costs. Even more rare are integrative empirical studies that have attempted to examine both the costs and benefits of gregariousness within single species. Comparative phylogenetic analyses that seek to examine the evolutionary relationships between gregariousness and other ecological, morphological and behavioral traits are similarly rare, but have provided important insights and will likely increase as phylogenetic frameworks become available for a variety of different insect lineages.

Some of the many examples of the costs and benefits of gregariousness in insects are provided below. When considering these examples, it is important to keep in mind that they are by no means mutually exclusive. Multiple benefits, as well as costs, may be at play and those benefits that initially favor the evolution of gregariousness need not be the same ones responsible for its maintenance. Indeed, a broad consensus has emerged that no single factor likely serves as a general explanation for the evolution and maintenance of gregarious behavior, or the lack thereof, among insect species.

Gregarious Behavior in Insects, Figure 57 **A dense aggregation of *Doratifera casta* caterpillars. *Doratifera casta* expresses ontogenetic variation in gregariousness. Larvae are gregarious during the early instars, but become solitary in later stages. Gregariousness confers at least two advantages during early stages of development, facilitation of feeding and functioning as part of an aposematic anti-predator strategy. Their subsequent switch to a solitary lifestyle suggests that these advantages disappear or are outweighed by costs associated with intraspecific competition during the final instars. (Photo by Dieter Hochuli.)**

Benefits of Gregarious Behavior

Mate Finding

Many insects that are otherwise solitary-living form groups during the process of finding a mate. In acoustically signalling insects such as crickets and some grasshoppers, males can be attracted to the calls of conspecific males, resulting in local aggregations. Males in these groups often have a higher probability of securing a mate than their solitary counterparts. Among desert clicker grasshoppers, *Ligurotettix coquilletti*, which tend to aggregate in this manner, males selectively chose the highest quality food plants from which to call. Thus, a male's call may also serve as an indicator of host plant quality to females. Insects in a variety of orders also form leks in which males aggregate and display to attract mates. Females visit these sites only to mate and typically gain no other resources. The advantage to females afforded by leks appears to be the choice of a large number of potential mates and the opportunity to simultaneously assess the quality of multiple males. The advantage to males of participating in leks is less clear, but is likely related to the prediction that the rates of female visiting and mating should increase with lek size, thereby increasing the average number of matings per male participant in the lek.

Facilitation of Feeding

Gregarious insects are often able to obtain food resources that they would otherwise be unable to consume as solitary individuals. Nymphs of the two-spotted stinkbug, *Perillus bioculatus*, feed together on caterpillars and beetle larvae. Older and larger nymphs are better able to overcome prey defenses than are the smaller and younger nymphs that often join them in feeding. Older nymphs likely benefit from the assistance provided by younger nymphs in subduing larger prey, whereas the younger nymphs gain access to otherwise unobtainable prey items.

Among herbivorous insects, there are many examples in which individuals in larger groups develop at an increased rate compared to smaller groups or lone individuals. Grouped larvae of the neotropical nymphalid *Chlosyne janais* achieve this benefit either by inducing a nutrient sink in the damaged leaf or by overcoming an induced defensive response on the part of their host plant. In the eucalyptus-feeding beetle *Chrysophtharta agricola*, neonate survivorship increases with group size because feeding sites on tough leaves initiated by larvae with larger mandibles provide smaller individuals with access to feeding sites. Milkweed bugs, *Oncopeltus fasciata*, feed on seedpods and also survive better in larger groups. In this case, the joint secretion of lytic enzymes by multiple individuals facilitates the ingestion of nutrients from the seeds within the pod.

Microhabitat Modification

Insect aggregations can serve to buffer group members from harsh environmental conditions. Aggregations of *Blattella germanica* cockroach nymphs enable group members to better survive under dry conditions. The diffusion fields of water vapor overlap among group members and reduce individual evaporative water loss to the air. Anti-desiccant effects have also been observed in aggregations of other insects such as woodlice, stinkbugs and beetles. Clustering of eggs by ovipositing females similarly functions to prevent water loss by reducing the amount of exposed surface area. Importantly, this strategy of egg clustering may serve as one of the principle mechanisms underlying the initial formation of many larval insect groups.

Grouping has also been shown to play an important role in thermoregulation. Higher body temperatures in grouped versus solitary caterpillars have been observed in a number of different lepidopterans. These higher temperatures result in faster growth rates and reduced development times that in turn can reduce the risk of exposure to predators, parasitoids or pathogens, and possibly allow the insects to outpace a decline in host plant quality. Some gregarious insects even build structures within which their microhabitat is modified. For example, temperatures inside the tent shelters constructed by eastern tent caterpillars, *Malacosoma americanum*, have been shown to be higher than outside air temperatures.

Protection from Natural Enemies

By far the most commonly invoked benefit of gregarious behavior is protection from natural enemies such as predators and parasitoids. The notion that individual attack risk declines as group size increases has been widely referred to as the "selfish herd" effect. In other words, the reduction in attack risk provides individuals with a selfish motive to join a group. However, a number of different underlying mechanisms, both passive and active, may be responsible for conferring protection to individual group members. Similarly, as evidenced by the other benefits described above, instances in which the improved survivorship of insects in groups was assumed to be due to protection from natural enemies may actually have been due to other unrecognized benefits of group living.

The simplest scenario for protection in a group is a dilution effect in which the risk of attack to an individual group member is inversely proportional to the size of the group. However, few if any insects rely solely on a dilution effect for protection. They often also have some means of active defense such as early detection, evasion, chemical defense and warning coloration (aposematism).

Groups of sea-skaters, *Halobates robustus*, detect and respond to predators from a greater distance than do solitary individuals. Once a predator attack has been initiated, insects in dense groups will often flee in erratic patterns that are assumed to either startle or confuse predators, or reduce the predictability of prey locations.

Given that individual predators have an upper limit to the number of prey they can consume, sufficiently high numbers of insects in aggregations may effectively swamp or satiate local predators and confer the benefit of reduced predation on surviving group members. Predator swamping has been proposed for mass emerging insects such as mayflies and periodical cicadas, and likely operates during outbreak periods in insects such as locusts (e.g., *Schistocerca* spp.) and Mormon crickets (*Anabrus simplex*) that exhibit widely fluctuating local population dynamics.

Many gregarious insects are also aposematic. These insects utilize conspicuous warning coloration as a signal to potential predators that they are deterrent or unpalatable by virtue of possessing some form of defense, usually chemical. The relationship between insect gregariousness and the evolution of both unpalatability and warning coloration has been the source of long running debate. Theoretical and empirical evidence suggest that grouping can facilitate the evolution of chemical defenses, as well as enhance predator learning of warning coloration. Based on this, it has been hypothesized that gregariousness initially promotes the evolution of unpalatability, followed by the evolution of conspicuous warning coloration. Despite the seeming logic behind this argument, a series of phylogenetic analyses using lepidopteran larvae suggest a different polarity for the evolution of these traits. These analyses indicate that gregariousness has repeatedly evolved after, rather than before, unpalatability and warning coloration. Thus, although it seems likely that defenses have evolved prior to warning coloration and gregariousness, the precise polarity of events could feasibly vary among taxa depending on the specific ecological circumstances. Additional phylogenetic analyses in other insect lineages will be critical in resolving this issue.

Costs of Gregarious Behavior

Intraspecific Competition

One of the most obvious and widely documented costs of gregariousness is intraspecific competition. As more individuals share a limited resource, the amount available per individual decreases. Food, mates, and sites for shelter, basking or oviposition can all be limiting resources. Some insects such as bark beetle larvae may deplete their food sources and die before reaching the more mobile adult stage. In others such as aphids, the effects of competition may be less severe but still result in restricted access to nutrients, smaller adult size and reduced fecundity. Perhaps the most extreme form of intraspecific competition is cannibalism, the threat of which can be particularly severe among larval forms of insects that feed in enclosed environments such seeds, fruit, stems, and stored products. Cannibalism can also serve as an important mechanism by which individual insects redress nutritional imbalances brought on by increased competition for resources at high population densities.

Pathogen Transmission

Another clear cost of living in a group is the increased risk of becoming infected with a pathogen or parasite. An increased probability of fungal pathogen infection among group members has been shown in a variety of insects such as aphids, cicadas, caterpillars, and beetle larvae. Both pathogens and parasites can be spread by direct contact with infected individuals as well as their excrement and saliva. Alternatively, propagules from infected individuals may be rapidly dispersed locally among group members through the air or across the substrate surface where they can be secondarily encountered. Some insects have evolved an elegant solution to the increased risk of pathogen infection in crowds by incurring the metabolic cost associated with pathogen resistance only under high population density conditions. This form of density-dependent pathogen resistance or prophylaxis has been demonstrated across insect orders in taxa such as *Tenebrio molitor* beetles, *Spodoptera exempta* caterpillars, and *Schistocerca gregaria* locusts.

Increased Conspicuousness to Predators

A group of insects should simultaneously be more apparent to predators and more worthwhile as a source of potential food than solitary prey. The cost of increased conspicuousness in a group should be even greater for aposematic insects that are themselves conspicuously colored. That so many gregarious insects exist in the first place suggests that this cost is routinely surmounted by at least one of the benefits described above. In addition to providing a larger visual stimulus to predators, aggregations may also result in the local concentration of other cues used by natural enemies to find insect prey. Predators and parasitoids can locate their prey directly by orientation toward cues such as aggregation pheromones or the sound of calling males, as well as indirectly through cues such as volatile compounds emanating from frass or plant tissues exposed by feeding damage.

Physiological Costs

Among insects that use aggregation pheromones for group formation, pheromone production necessarily involves a metabolic cost. For example, these costs may range from minimal when pheromones are by-products of existing metabolic pathways and structures as they appear to be in *Phylotretta cruciferae* flea beetles, to more substantial when pheromone production requires the development and maintenance of specialized glands or organs as in the triatomine bugs. Furthermore, aggregation pheromone production has been shown in some beetles to be regulated and can be reduced under crowded conditions. However, it is not yet known if this facultative response serves to reduce metabolic costs or is perhaps an adaptation that reduces some other cost associated with crowding.

Population Level Consequences of Gregarious Behavior

Gregariousness not only affects the performance and survivorship of individual insects, but can also have important population level consequences. The expression of gregarious behavior can interact with other ecological processes to influence a species' population dynamics, dispersal or migration, and spatial distribution patterns. Gregarious behavior in insects can sometimes lead to devastating consequences for humans, as evidenced by its central role in the biology of two major pest species, the desert locust, *Schistocerca gregaria*, and the Mormon cricket, *Anabrus simplex*.

The Desert Locust

Under outbreak conditions, locusts form huge groups in which millions of insects can travel en masse on the ground in migratory bands as juveniles and in the air as characteristic swarms of flying adults. Unlike other grasshoppers, locusts can express an extreme form of density-dependent phenotypic plasticity known as "phase polyphenism." Individuals reared under low population densities (the harmless, non-migratory "solitarious" phase) differ markedly in behavior, physiology, color and morphology from locusts reared under crowded conditions during outbreaks (the migratory swarming "gregarious" phase) (Fig. 58). A shift to the expression of gregarious behavior at high population density is central to the process of locust phase change. This form of behavioral phenotypic

Gregarious Behavior in Insects, Figure 58 **Gregarious behavior in locusts is environmentally determined and mediated by changes in local population density. Examples of the alternative density-dependent phenotypes of final instar desert locust nymphs, *Schistocerca gregaria*, are pictured. The non-migratory and cryptic "solitarious" phase produced at low population density is on the left. The migratory and aposematic "gregarious" phase induced by high population density is on the right. (Photo by Greg Sword.)**

plasticity suggests that natural selection has favored, within the same individual, the ability to lead a solitary lifestyle when it is advantageous at low population densities, as well as the ability to take advantage of gregariousness under high population density conditions.

At the heart of locust swarm formation and migration is the shift from the shy, cryptic behavior of solitarious phase locusts, which are relatively sedentary and avoid one another, to the highly active behavior and tendency to aggregate typical of gregarious phase insects. Nymphs of the desert locust, *Schistocerca gregaria*, can become behaviorally gregarious after just 1 h of crowding. This behavioral transition to gregariousness is soon followed by changes in other traits. One such change is a shift in feeding behavior in which the newly crowded insects become willing to feed on noxious plants that cause the locusts to be toxic to their predators. In turn, these behavioral changes are followed at the next nymphal molt by a density-dependent change in coloration from crypsis to warning coloration that enables the nymphs to advertise their recently acquired unpalatability to predators. Predator learning and subsequent avoidance of aposematic gregarious phase locust nymphs can reduce the per capita predation risk and facilitate additional population growth.

In addition to functioning as part of an aposematic anti-predator strategy, gregariousness in desert locusts also interacts with local habitat structure resulting in some habitats being more likely than others to generate locust swarms. Individual locusts are more likely to come in contact with each other and change into the migratory gregarious phase when the resources they utilize, such as host plants or roosting sites, are distributed in an aggregated as opposed to dispersed manner. As more and more locusts become gregarious, they also become locally concentrated, and once a critical population density is reached, mass migration is triggered. Recent evidence suggests that mass movement among juvenile locusts in migratory bands is mechanistically linked to the risk of cannibalism in high-density groups, a process first identified in Mormon crickets and described below.

The Mormon Cricket

Mormon crickets are flightless tettigoniids from western North America that also form huge migratory bands during outbreaks. Although Mormon cricket and locust migratory bands share many similar characteristics, Mormon crickets do not appear to express the density-dependent phase changes in gregariousness or other traits as do locusts. Thus, the phenomenon of migratory band formation (Fig. 59) and movement appears to have convergently evolved in these two groups via different underlying behavioral mechanisms.

Mormon crickets constitute a unique model system in which understanding the costs and benefits of gregariousness has provided a unifying framework that explains both how and why inter-individual interactions can lead to landscape-scale mass movement. In terms of benefits, a radiotelemetry-based mark recapture study revealed that migratory bands form as part of an anti-predator strategy. Individual band members are much less likely to be killed by predators than are insects that have been separated from the group. As predicted, once migratory bands have formed, individual band members are subject to increased intraspecifc competition for nutritional resources. Individual crickets within migratory bands have been shown to be deprived of specific nutritional resources, namely protein and salt. When provided with augmented dietary protein, individual crickets spent less time walking, a response that was not

Gregarious Behavior in Insects, Figure 59 **A migratory band of Mormon crickets, *Anabrus simplex*, crossing a dirt road in NE Utah, USA. Migratory bands can contain millions of insects that walk up to 2 km/day. Gregariousness confers protection from predators. However, band members suffer from intraspecific competition and must keep moving to encounter new nutritional resources as well as to avoid being cannibalized by other hungry insects in the band. (Photo by Greg Sword.)**

found when crickets had ample carbohydrate. Thus, group movement results in part from locomotion induced by protein deprivation and should act to increase the probability that individual band members will encounter new resources and redress their nutritional imbalances.

An additional cost of group formation is that Mormon crickets are notoriously cannibalistic. Their propensity to cannibalize is a function of the extent to which they are nutritionally deprived. Given that Mormon crickets are walking packages of protein and salt, the insects themselves are often the most abundant source of these nutrients in the habitat. As a result, individuals within the band that fail to move risk being attacked and cannibalized by nutritionally deprived insects approaching from the rear. Thus, the mass movement of individuals in migratory bands is a forced march driven by cannibalism due to individuals responding to their endogenous nutritional state. The fact that migratory bands are maintained as cohesive groups despite these conditions suggests that the risk of predation upon leaving the band must outweigh the combined costs of intraspecific competition for resources and cannibalism.

Parasitoids than can co-exist with others of the same species within the body of a host insect.

Gressitt, Judson Linsley

Judson Linsley Gressitt was born in Tokyo in 1914 to an American family. He grew up in Tokyo and was educated at an American school. On finishing school, he traveled alone at age 18 to Taiwan and collected insects in much of the island, including the highest mountains. His first degrees were in entomology at the University of California, after which he accepted a position at Lingnan University in Guangzhou, China. He continued fieldwork, and he married Margaret Kriete. The family was interned in 1941–1943 by Japanese forces in China. After the war, Lin returned to Berkeley and earned a doctorate in entomology. Then he returned to Lingnan University as Associate Professor until 1951. In 1949 the family was interned again, this time by Chinese forces as the Chinese revolution raged and the Korean War was imminent. His involvement with Pacific entomology and especially with the Bernice

P. Bishop Museum in Honolulu followed. In 1955, he began an association with New Guinea, which led in 1961 to establishment of what is now the Wau Ecology Institute. His research interests covered biogeographic and ecological questions in plants, vertebrates, and invertebrates. His particular taxonomic interests were in the beetle families Cerambycidae and Chrysomelidae. But his work included many other projects such as insect disease carriers, Antarctic entomology, transoceanic dispersal, and insect conservation. He was editor of four serial publications. He and his wife, Margaret, died in an air crash in China on April 26, 1982.

► Stoneflies

Grooming

Cleaning of the body using the mouthparts or legs. In solitary insects, it is a self-cleaning process, but in social insects individuals groom one another.

Grote, Augustus Radcliffe

Augustus Grote (Fig. 60) was born in Liverpool, England on February 7, 1841, of a Welsh mother and German father who moved with him to a farm in New York when he was seven. As a schoolboy he spent much time collecting insects. His hopes of attending Harvard University were dashed when his father's investments failed and the family was left in straitened circumstances. He did, however, receive an A.M. degree from Lafayette College, Pennsylvania, after studies in Europe. In Alabama in the early 1870s, he studied the cottonworm, *Alabama argillacea*, eventually publishing five papers on it. On the death of his wife in 1873, he moved to Buffalo, New York, and worked as museum director. He was publisher of the Bulletin of the Buffalo Society of Natural History and of a short-lived journal called "The North American Entomologist." He wrote many articles on Lepidoptera, and produced with Coleman Robinson "A synonymical catalog of North American Sphingidae, with notes and descriptions" and a "List of the Lepidoptera of North America." In 1884 he moved to Germany, first to Bremen and then to Hildesheim, but continued writing for North American journals. For the last nine years of his life, he was honorary assistant at the Roemer Museum in Hildesheim, in which city he died on September 12, 1903. His large insect collection was offered

Grote, Augustus Radcliffe, Figure 60 **Augustus Grote.**

for sale in the USA, but when there were no buyers it was sold to the British Museum (Natural History).

Ground Beetle (Coleoptera: Carabidae) Feeding Ecology

ERIC W. RIDDICK
U.S. Department of Agriculture, Agricultural Research Service, MS, USA

The Carabidae, or ground beetles, represent approximately 40,000 described species found throughout the world, with most species present in the tropics. There are nearly 2,700 described species in Europe and over 2,000 species in North America. Detailed biological descriptions are available for fewer than 100 species (mostly western European species). Many carabids are easily recognized at the family level. Adults are well-proportioned beetles with pronounced mandibles and palps, long slender legs, striate elytra, and sets of punctures with tactile setae. Many possess an antenna-cleaning organ and mostly pubescent antennae. Many are dark colored, shiny or dull. Some have bright or metallic colors and some are pubescent.

Although carabids possess an easy-to-recognize general body form, they have undergone morphological adaptations to suit the habitat in which they are found. Such modifications have permitted running, burrowing in soil and sand, living under tree bark, climbing plants, and swimming in water. Consequently, some species are found in very unique places. For example, some inhabit the edges of ice glaciers, others live in caves, others along stream banks. Others are found in woodlands, or are found in deserts. Most species reside on the ground (epigeic), but some species are plant-dwelling (arboreal) during the adult stage. Others live in self-constructed tunnels in sand or fine soil.

Based upon research in Britain (in Europe), carabid genera are found typically in certain habitats: species of *Bembidion* are common amongst vegetation alongside rivers and lakes; species of *Acupalpus*, *Agonum*, *Stenolophus*, and smaller-sized *Pterostichus* are present in litter on the soil surface in marshy (fresh water) habitats. The genera *Dicheirotrichus*, *Dyschirius*, and *Pogonus* are found in salt marshes. Larger-bodied genera such as *Calathus*, *Carabus*, *Harpalus*, *Nebria*, or *Pterostichus* can be found in rough grass, or in gardens. In drier habitats, especially exposed to sun, *Amara*, *Badister*, some *Harpalus* and *Notiophilus* can be found. The location of the preferred habitat (and microhabitat) can be influenced by season, temperature and humidity extremes, life history pattern, competitors, and food availability.

General Feeding Ecology

Feeding Preferences

Carabid beetles can be categorized as carnivores, herbivores, or omnivores. A recent survey of 1,290 literature references indicated that 775 species were partially or exclusively carnivorous, 85 species were exclusively herbivorous, and 206 species were omnivorous. Some carnivorous species opportunistically feed on a diversity of prey. For example, the diet of numerous species in the genera *Agonum*, *Calathus*, *Chlaenius*, *Poecilus*, or *Pterostichus* is most often dependent on the season and availability of specific prey. Other carnivorous species are more selective. Some oligophagous species such as those in the genera *Cychrus* and *Scaphinotus* are predators of snails and slugs. Others in the genus *Calosoma* prey upon caterpillars. Species of *Loricera* and *Notiophilus* are predators of springtails (Collembola). Species in the genus *Promecognathus* specialize upon millipedes. Some species are parasitoids in the larval stage, but are predators in the adult stage. For example, the larvae of *Lebia* spp. are ectoparasitoids of pupae of leaf beetles (Chrysomelidae), whereas the adults attack egg and larval stages. The larvae of *Brachinus* spp. (bombardier beetles) are ectoparasitoids of pupae of water scavenger beetles (Hydrophilidae) and whirligig beetles (Gyrinidae).

Herbivorous carabids may consume plant seeds, ripe fruit, and foliage. *Zabrus* adults and larvae consume ripe grains and sprouting leaves of cereal plants. Many *Harpalus* and *Amara* adults feed on germinating weed seeds. The diet of the larvae, however, is unknown for the majority of species. Several *Harpalus* species collect and cache seeds of grasses in burrows.

Omnivorous carabids are apparently opportunists that feed upon the food items most readily available in their immediate habitat. Many carabid species are likely omnivorous. In fact, predominantly carnivorous species probably consume pollen, fungi, and other plant materials during periods of prey shortage to avoid starvation.

Searching for Food

Carabid beetles are known to search actively for food by means of random search, vision, or chemical cues. Most adults rely on random search, in which the beetle contacts the prey with its mouthparts, antennae, or setae on some body part or appendage. This strategy is common to nocturnal species. Very little is known about the searching behavior of carabid larvae. Presumably, the larvae of most nocturnal species rely on random search and then physical contact with prey. Some carabid larvae do not actively search for prey. Instead, they deploy an ambush strategy. They remain concealed inside burrows or tunnels and only attack prey that come too close to their burrows. This strategy is typical of tiger beetle larvae (tribe Cicindelini; e.g., *Amblycheila*, *Cicindela*, *Megacephala*, and *Omus*).

Diurnal species rely upon short-range vision to locate prey. For example, *Notiophilus biguttatus* adults and larvae feed extensively on springtails (Collembola). Adults are aided by their large compound eyes to hunt their prey. This predator may intensify its search for prey in relation to light intensity. Greater light intensity usually results in an increased search rate. The *N. biguttatus* larvae rely more on physical contact for detection of prey.

Several carabids respond to the odor of their prey to facilitate detection. Adults of *Pterostichus melanarius* and *Harpalus rufipes* were attracted to an aphid alarm substance released by aphids under attack by predators, such as ladybird beetles. In contrast, *Nebria brevicollis* adults were attracted to the odor of live springtails, but not to aphid alarm substance. Note that *P. melanarius* was also attracted to the odor of live aphids, but the other two species were not. Larvae of *N. biguttatus* are guided by chemical cues to the aggregation sites of springtails. Reliance upon chemical cues from prey (or hosts in the case of parasitoids searching for concealed prey) is probably more widespread than currently reported.

Although most carabids search for prey on the ground, some species seek prey on plants. *Calleida*, *Cymindis*, *Dromius*, *Lebia*, *Parena*, *Pinacodera*, and *Plochionus* adults have been found foraging on plants during the day. More than 30% of tropical carabid species (e.g., *Agra*, *Lebia*) forage on plants. Adults of a few species of *Agonum*, *Amara*, *Chlaenius*, *Harpalus*, and *Pterostichus* are occasionally found foraging on plants. Both adults and larvae of *Calosoma sycophanta* (and other species of *Calosoma*) forage for prey on the trunks of forest trees.

Prey Capture

Once prey is located, some species lunge toward it with their mandibles agape. Most adult carabids use their well-developed mandibles to subdue and kill prey. Morphological and behavioral adaptations can be involved in capturing prey, particularly for the species with specialized feeding habits. *Cychrus caraboides* and *Carabus violaceous* successfully subdue slugs (gastropods) by biting them at specific locations on the body, which may paralyze prey. This could prevent the production and secretion of mucus by the slugs, a mechanism of defense against predation.

Species that specialize on snails are not deterred by the shell. Some *Cychrus* and *Scaphinotus* adults readily capture and consume large-sized snails by inserting their slender, elongate head and prothorax into the opening, then proceed to kill and consume the prey. *Cychrus* larvae crawl inside the shell and feed, in spite of the mucus secretions of the prey. Some generalists such as *Pterostichus* species can crush shells with their mandibles. Shell thickness could influence the vulnerability of snails to attack from generalist carabids.

Prey capture behavior has been described for several species that hunt springtails. Adults and larvae of *N. biguttatus* rely on vision to capture elusive springtails. Prey capture occurs when the predator rapidly lunges toward the springtail and grasps it within the mandibles. Adults of *Loricera pilicornis* capture springtails at night. Physical contact, rather than sight, is a prerequisite to prey capture. Adults lunge toward prey during the attack and bring their antennae together to entrap the springtail. Long, strong setae on the antennae enclose the prey and draw it toward the gaping mandibles. The prey capture behavior of *L. pilicornis* larvae differs from that of adults. Although prey are located by physical contact, the larvae do not lunge toward prey. Instead, larvae turn in the direction of contact while opening their mouthparts. The setae on the maxillae and an adhesive secretion coating the proximal end of each maxilla function to entrap the prey. The springtail is ultimately grasped by the mandibles.

Digestion

The adults of most carabids ingest and digest prey fragments, after mastication, with little or no extra-intestinal (i.e., pre-oral) digestion. The mandibles are used for crushing or tearing off fragments of food, which then are ingested. Enzymes involved in digestion are copious once food enters the foregut. In contrast, the adults of other species, particularly in tribes Carabini (e.g., *Calosoma*, *Carabus*), Cicindelini (e.g., *Cicindela*, *Omus*), and Cychrini (e.g., *Cychrus*, *Scaphinotus*, *Sphaeroderus*) masticate their prey only to lubricate it and extract the fluid contents from it. Extra-intestinal digestion commences after adults discharge a fluid from their buccal cavity (mouth) onto the prey or prey fragments. This fluid contains enzymes (proteases, carboxylases, amylases, etc.) that liquefy tissues. These enzymes are synthesized in the midgut, but are stored in the crop, from whence they are regurgitated onto the food prior to feeding. Only very fine particles and liquefied remains of prey are ingested. Digestion proceeds within the foregut, including the crop. Absorption of nutrients occurs primarily in the midgut. As far as is known, carabid larvae digest their food extra-intestinally. Once liquified food is ingested, the digestion process continues in the foregut, with absorption occurring primarily in the midgut. Carabid larvae that are ectoparasitoids (e.g., *Brachinus*, *Graphipterus*, *Lebia*) may rely almost exclusively on extra-intestinal digestion of host tissues.

Applied Feeding Ecology

Predation of Aphids and Leafhoppers

In sugar beet fields, carabid adults (especially *Pterostichus dorsalis*) were capable of reducing aphid (*Aphis fabae*) population densities in field cages. Carabids, even when at relatively low densities, were able to locate low density populations of aphids.

The impact of carabids and wolf spiders (Class Arachnida, Order Araneae, Lycosidae) on leafhopper (Cicadellidae) and aphid populations was assessed in maize fields. The abundance of both predator groups was manipulated by removing or adding individuals within field enclosures during mid-season and end-of-season. Although the impact of carabid predation could not be differentiated from spider predation, the combined action of both predator groups reduced populations of leafhoppers. In addition, the combined predators were capable of reducing aphid populations during mid-season.

Research in cereal fields indicated that the rate at which aphids (*Sitobion avenae*) dropped from plants to escape predators on the plants was critical to the efficacy of carabid predation on the ground. Carabids intercepted many aphids before they could climb back up on the plants. The effect of generalist predators functioning in-concert to impact aphid populations was investigated in experiments deploying carabids and lady beetles (Coccinellidae) in alfalfa fields. Positive predator-predator interactions occurred between the lady beetle *Coccinella septempunctata*, and the carabid *Harpalus pensylvanicus*. In laboratory arenas and in field cages, both predators fed on pea aphids, *Acyrthosiphon pisum*. Predation rates were greater than expected for the combined action of both predators. Thus, synergism occurred as *C. septempunctata* foraged on plants and *H. pensylvanicus* foraged at the base of the plants.

Predation of Flies

Predation of gall midge (Cecidomyiidae) larvae on the soil surface was found to be considerable, since polyphagous predators were responsible for 43–58% reduction of wheat gall midges (*Contarinia tritici*). Predation caused an 81% decrease in adult emergence of the midge Sitodiplosis mossellana. Feeding bioassays in the laboratory indicated that the carabids *P. melanarius* and *Platynus dorsalis* were primarily responsible for the decline of *S. mossellana* populations.

Carabid predation of the cabbage root fly (*Delia radicum*) and other anthomyiid species has been examined. Carabids (especially *Bembidion lampros* and *Trechus quadristriatus*) caused approximately 30% mortality of *D. radicum* by predation of eggs and first instar larvae in the soil. In a greenhouse experiment, a predator density of two *Bembidion tetracolum* adults per plant prevented an infestation of *D. radicum* in the spring season. Carabid predation caused an 82% reduction of the pest population, when *D. radicum* eggs were exposed on the soil surface. But, other carabid species (*B. tetracolum*) had difficulty locating eggs that were buried just beneath the surface.

Bembidion quadrimaculatum adults located onion maggot (*Delia antiqua*) eggs that were buried 1 cm deep in the soil. Up to 25 eggs were consumed daily under laboratory conditions and onion maggot numbers were reduced by up to 57% in field cages. Another study investigated the impact of predation on *D. antiqua* pupae exposed on the soil surface in corn fields. Carabid beetle abundance was manipulated so that the rate of removal of pupae from field exclosures (excluding vertebrates but not invertebrates) was determined during the growing season. Significantly more onion maggot pupae were removed from the cages that excluded vertebrates than from the cages that excluded both vertebrates and invertebrates. Carabid abundance correlated positively with predation rates. Feeding trials in the laboratory indicated that the four most abundant carabids (*Pterostichus* and *Poecilus* species) in corn fields readily consumed *D. antiqua* pupae.

Predation of Beetles

Carabids can be significant predators of the Colorado potato beetle *Leptinotarsa decemlineata* (Chrysomelidae), a pest of cultivated potato. In Bavaria (Germany), predation of larvae by *Carabus* spp. reduced the yield damage from this pest by approximately 33% in experimental plots compared to infested control plots that did not contain *Carabus* adults. *Carabus* consumed from 8 to 10 *L. decemlineata* larvae (third and fourth instars) per day in the laboratory.

In the United States, *Lebia grandis* larvae are confirmed ectoparasitoids and adults are specialist predators of *L. decemlineata* on cultivated potato. In the late 1930s, several years after the inadvertent introduction of *L. decemlineata* into

France, *L. grandis* was imported from the United States and a mass rearing program was initiated. The rearing technique was capable of generating large quantities of *L. grandis*, but was too labor intensive. Released adults had little demonstrable impact on *L. decemlineata* populations and failed to become established in France.

Carabid predation of weevils (Curculionidae) was documented. One study revealed that 28% of *Sitona hispidulus* eggs were removed by carabids when placed in experimental cages in alfalfa fields. Of the carabid species tested, *Amara aenea* was the most efficient predator. Carabid predation resulted in greater than 30% reduction of larvae and overwintering adults of *Sitona lineatus* in field beans. *Bembidion properans* adults consumed *S. lineatus* eggs and young larvae.

Predation of the rape blossom beetle, *Meligethes aeneus* (Nitidulidae) by the carabid *Clivina fossor* was documented. In a two-week period *C. fossor* adults consumed 65% of *M. aeneus* larvae and pupae that had been introduced into an arena containing soil at a depth of 6–7 cm. Another investigation indicated that *M. aeneus* experienced a 39% population decline, perhaps, during the time that mature larvae had left the crop plants (rape) and wandered on the soil surface, prior to pupation. Predation by polyphagous predators was thought to be responsible for the decline of the pest population. Research is ongoing to determine the contribution of different species to the mortality of *Meligethes* spp.

Predation of Moths

In the early 1900s, *Calosoma sycophanta* was introduced into northeastern United States to control the gypsy moth *Lymantria dispar* (Lymantriidae), an inadvertently introduced pest of forest and shade trees. The beetle is well-established in most areas where gypsy moth is distributed, and is an important arthropod natural enemy of larval and pupal stages. Adult C. sycophanta are long-lived (2–4 yr) and even a low density of beetles can have considerable impact on L. dispar populations. A single *C. sycophanta* larva can kill more than 50 late instar *L. dispar* larvae during a two-week time span, whereas, an adult can kill an average of 150 late instar larvae. Unfortunately, this carabid has a slow numerical response to pest population densities and has not been able to prevent gypsy moth outbreaks.

In apple orchards, carabids are important predators of codling moth, *Cydia pomonella* (Tortricidae), a worldwide pest of pome fruit, including apple. Carabids can forage on the ground during the season when mature larvae are wandering on the soil surface before pupation in leaf litter or under loose tree bark. Several carabid species from an apple orchard in Canada gave positive serological reactions to antiserum against *C. pomonella* larvae. *Pterosticus* species consumed *C. pomonella* mature larvae in experimental arenas in the laboratory. In the field, tethered mature larvae were located and then killed by carabids; 60% predation by carabids per night was estimated during the first generation of codling moth in the spring in an apple orchard in northern California, USA. *Pterostichus californicus*, *Pterostichus cursitor*, and *Pterostichus lustrans* dominated the carabid assemblage in an unsprayed orchard in northern California.

Maize plants suffered significantly less damage from armyworms *Pseudaletia unipuncta* (Noctuidae) when ground-foraging predators were included in experimental arenas rather than excluded from arenas. Carabid predation of armyworms was thought to be responsible for the reduction. *Pterostichus chalcites*, *Pterostichus lucublandus*, and *Scarites subterraneus* adults readily consumed second and fourth instar *P. unipuncta* larvae in the laboratory.

A laboratory and field investigation assessed the impact of carabid predation on diamondback moth *Plutella xylostella* (Yponomeutidae) larvae on seedling cabbage plants in Japan. The highest consumption rate (of 24 carabid species tested) was 23 larvae (fourth instars) per day by *Chlaenius* *posticalis* adults. Note that *C. posticalis* and *Chlaenius micans* larvae consumed approximately 92 and 191 early fourth instar *P. xylostella* larvae, respectively.

Conclusion

Despite their generally accepted role as natural enemies, detailed information on the feeding ecology of carabids is not available for many species. More research is needed to clarify the trophic relations of carabid larvae. Carabids appear to affect the populations of some crop pests. Carabids may have their greatest impact when operating in concurrence with other natural enemies.

Ground Beetle (Coleoptera: Carabidae) Taxonomy

PAUL M. CHOATE
University of Florida, Gainesville, FL, USA

There are approximately 110 families of beetles found worldwide. The order Coleoptera is subdivided into two major sub-orders, Adephaga and Polyphaga. Polyphaga contains most beetle species. Ground beetles are placed in the sub-order Adephaga. This sub-order contains relatively few families of beetles, most families belonging to the much larger sub-order Polyphaga. As now defined, Adephaga contains the families Gyrinidae, Haliplidae, Trachypachidae, Noteridae, Amphizoidae, Dytiscidae, Hygrobiidae, and Carabidae. Adult Adephaga are separated from all other beetle families by the presence of a visible notopleural suture on the prothorax; six visible abdominal sterna; with the first 3 segments fused and divided by hind coxae (Figs. 61–64). Many species are capable of flight and possess fully developed flight wings. Ground beetles range in size from less than 1 mm to more than 60 mm in length. Most ground beetles are uniformly dark in color, but some species are brightly colored (especially tropical species). Carabids occur throughout the world, and may be found from sea level to altitudes of above 5,000 m in the Himalayas. Although there is diversity of form among carabid tribes (Figs. 65–74), the large number of species in

some genera makes separation of specimens difficult at the species level. In spite of the abundant number of species, the tribal classification is fairly well established. Because there are no rules for assignment of categories above the species level, grouping of taxa above tribes is very much unsettled, and vary according to author and region. What follows here is a current arrangement of the higher taxa of ground beetles with representative illustrations of adults of several tribes.

Identification of ground beetles includes analysis of external morphological characters, and frequently comparison of genitalic structures. The latter requires dissection of specimens and is used less commonly than external morphological characters. Species definitions for ground beetles are varied, dependent upon the group and diagnostic characters defined by that group' s expert.

Literature dealing with the identification of ground beetle species is voluminous. Maddison (1995) listed the world higher classification of ground beetles. His classification differed somewhat from Ball and Bousquet (2001), who presented a comprehensive outline of higher classification of the Nearctic ground beetles based on the classification scheme of Lawrence and Newton (1995). In their classification scheme the wrinkled bark beetles are treated as the family Rhysodidae. Madison (1995) cited disagreement over placement of several Adephaga families, namely the tiger beetles (family Cicindelidae or supertribe Cicindelitae) and the wrinkled bark beetles (family Rhysodidae or tribe Rhysodini). I follow the classification scheme of Lawrence and Newton (1995) here. Tribes are listed in phylogenetic order (according to degree of relatedness) beginning with what are considered the most primitive groups.

The following abbreviations are used in the listing of ground beetle taxa (f = family; s.f. = subfamily; t = tribe; ** = with representatives in North America). Approximate distributions are listed for those taxa that are sufficiently well known and defined.

Family: Carabidae
- Subfamily: Paussinae
  - Tribe: Metriini ** – 2 species restricted to western North America
  - Tribe: Ozaenini ** – Pantropical, occurring in Oriental, Afrotropical, Australian, and Neotropical regions
  - Tribe: Paussini – myrmecophilous, restricted to tropics in southern Hemisphere
- Subfamily: Gehringiinae
  - Tribe: Gehringiini** – a single Pacific Northwest species in North America
- Subfamily: Nebriinae
  - Tribe: Notiophilini** – Palearctic, Oriental, Nearctic, Neotropical regions
  - Tribe: Notiokasini – Neotropical
  - Tribe: Pelophilini** – Arctic and subarctic regions
  - Tribe: Opisthini** – Nearctic and China, India, Bhutan, Nepal, and Taiwan
  - Tribe: Nebriini** – Holarctic and north Oriental
- Subfamily: Carabinae –
  - Tribe: Carabini** – worldwide distribution
  - Tribe: Ceroglossini – Chile
  - Tribe: Pamborini – Australia
  - Tribe: Cychrini** – Holarctic, and China, Tibet, and Sikkim, Himalaya
- Subfamily: Cicindelinae (tiger beetles)
  - Tribe: Omini** – western US
  - Tribe: Collyridini – Pantropical
  - Tribe: Megacephalini** – Nearctic, Palearctic
  - Tribe: Ctenostomatini – Neotropical
  - Tribe: Manticorini – South Africa
  - Tribe: Cicindelini** – worldwide
- Subfamily: Loricerinae –
  - Tribe: Loricerini** – Holarctic – Oriental regions
- Subfamily: Omophroninae – found in all major zoogeographical regions except Australia
  - Tribe: Omophronini**
- Subfamily: Elaphrini – Holarctic
  - Tribe: Cicindini – Kuwait
  - Tribe: Elaphrini** – Holarctic
  - Tribe: Migadopini – Chile
  - Tribe: Amarotypini – distribution uncertain
- Subfamily: Promecognathinae –
  - Tribe: Promecognathini** – Nearctic and South Africa
- Subfamily: Scaritini – all major zoogeographical regions
  - Tribe: Siagonini – Palearctic
  - Tribe: Hiletini – Peru, tropical Africa, Southeast Asia, Indonesia
  - Tribe: Clivinini** – all major zoogeographical regions
  - Tribe: Scaritini** – all major zoogeographical regions
- Subfamily: Rhysodinae – worldwide
  - Tribe: Rhysodini** – wrinkled bark beetles, sometimes placed in family Rhysodidae
- Subfamily: Trechinae – worldwide, mostly in temperate regions
  - Tribe: Psydrini** – Holarctic and Australia
  - Tribe: Melaenini – South India
  - Tribe: Cymbionotini – South India
  - Tribe: Broscini** – temperature portions of all major zoogeographical regions
  - Tribe: Apotomini – South India
  - Tribe: Trechini** – worldwide distribution
  - Tribe: Zolini – Chile
  - Tribe: Pogonini** – all zoogeographical regions
  - Tribe: Bembidiini** – all zoogeographical regions
  - Tribe: Patrobini** – Oriental, Palearctic, and Nearctic regions
  - Tribe: Amblytelini – Australia
- Subfamily: Harpalinae
  - Tribe: Pterostichini** – all major regions
  - Tribe: Morionini** – Nearctic and pantropical regions
  - Tribe: Cnemalobini – Argentina
  - Tribe: Catapieseini – Neotropics
  - Tribe: Platynini** – all major zoogeographical regions
  - Tribe: Zabrini** – Holarctic, Oriental, Ethiopian, and Neotropical regions
  - Tribe: Bascanini – sub-Saharan Africa

Tribe: Peleciini – Neotropics, Oriental, Africotropical regions
Tribe: Cuneipectini – western Australia
Tribe: Chaetogenyini – distribution uncertain
Tribe: Licinini** – all major zoogeographical regions
Tribe: Oodini** – all major zoogeographical regions
Tribe: Panagaeini** – Nearctic, Neotropics
Tribe: Chlaeniini** – worldwide
Tribe: Harpalini** – all major zoogeographical regions
Tribe: Dryptini** – all major zoogeographical regions
Tribe: Zuphiini** – all major zoogeographical regions
Tribe: Galeritini** – Pantropical, Holarctic
Tribe: Physocrotaphini – distribution uncertain
Tribe: Anthiini – eastern Hemisphere tropics
Tribe: Helluonini** – most zoogeographic region
Tribe: Idiomorphini – India
Tribe: Orthogoniini – eastern Hemisphere
Tribe: Hexagoniini – Afrotropical, Oriental regions
Tribe: Ctenodactylini** – Neotropical
Tribe: Amorphomerini – distribution uncertain
Tribe: Lachnophorini** – Western hemisphere
Tribe: Pentagonicini** – all major zoogeographical regions
Tribe: Odacanthini** – all major zoogeographical regions
Tribe: Calophaenini – distribution uncertain
Tribe: Perigonini** – Pantropical
Tribe: Graphipterini – Afrotropical
Tribe: Cyclosomini** – primarily tropical, Oriental, Afrotropical, Neotropical
Tribe: Masoreini – Afrotropical
Tribe: Lebiini** – all major zoogeographical regions
Subfamily: Pseudomorphinae
Tribe: Pseudomorphini** – Nearctic, Neotropical, and Australian regions
Subfamily: Brachininae (bombardier beetles) – all major zoogeographical regions
Tribe: Crepidogastrini – eastern Hemisphere
Tribe: Brachinini** – all major zoogeographical regions, largely tropical

Ground Beetles

Members of the family Carabidae (order Coleoptera).

► Ground Beetle Taxonomy
► Ground Beetle Feeding Ecology
► Beetles

Ground Crickets

A subfamily of crickets (Nemobiinae) in the order Orthoptera: Gryllidae.

► Grasshoppers, Katydids and Crickets

Ground Pearls

Some members of the family Margarodidae, superfamily Coccoidae (order Hemiptera).

► Bugs
► Turfgrass Insects and their Management

Group Predation

Hunting and retrieving of prey by groups of cooperating individuals. Among insects, this is well developed in ants.

Group Selection

An evolutionary process functioning through the effects of different numbers of descendents left by groups rather than by individuals.

Grouse Locusts

A family of grasshoppers Tetrigidae) in the order Orthoptera.

► Grasshoppers, Katydids and Crickets

Grub

A thick-bodied larva with well-developed head and thoracic legs, but without abdominal prolegs. At rest, the body is curved, and often is described as C-shaped. A scarabaeiform larva (Scarabaeidae). This term also is sometimes applied to larval wasps (Hymenoptera).

► Beetles

► Scarab Beetles

► Hymenoptera

Gryllacrididae

A family of crickets (order Orthoptera). They commonly are known as leaf-rolling crickets.

► Grasshoppers, Katydids and Crickets

Gryllacridoids

Certain members (suborder Ensifera, superfamily Gryllacridoidae) of the order Orthoptera.

► Grasshoppers, Katydids and Crickets

Gryllidae

A family of crickets (order Orthoptera). They commonly are known as crickets.

► Grasshoppers, Katydids and Crickets

Grylloblattodea

An order of insects. They commonly are known as rock crawlers.

► Rock Crawlers

Gryllotalpidae

A family of crickets (order Orthoptera). They commonly are known as mole crickets.

► Grasshoppers, Katydids and Crickets

Gryropidae

A family of chewing lice (order Phthiraptera). They sometimes are called guinea pig lice.

► Chewing and Sucking Lice

Guenée, Achille

Achille Guenée was born in Chartres, France, on January 1, 1809. He began to study Lepidoptera as a boy. His first university education was at Chartres, and then he studied law in Paris. Of a wealthy family, he married and had a son and two daughters, of whom the son died young. He lived at his country residence at Châteaudun for the remainder of his life and contributed 63 papers on Lepidoptera. A major contribution was his six volumes in the series "Suites à Buffon" [a supplement to Buffon's series on "Histoire naturelle"], "Spécies général des lepidoptères" (1852–1857). Another was "Essai sur une nouvelle classification des microlepidoptères" (1845), a major classificatory work. He died at Châteaudun on December 30, 1880.

Guérin-Méneville, Félix Edouard

Félix Guérin-Méneville was born in Toulon, France, on October 12, 1799, named Félix Edouard Guérin. He produced taxonomic works on most orders of insects, but later wrote on applied entomology, including sericulture and pests of grapevines. In 1836 he changed his surname to Guérin-Méneville. In 1831 he founded and edited "Magasin de Zoologie," and when it was merged with "Revue Zoologique" in 1849 as "Revue et Magasin de Zoologie," he continued as editor until 1873. His own output of publications was over 400, of which his encyclopedic "Iconographie de règne animal de G. Cuvier" in seven volumes brought him the most recognition. France's "Legion d'Honneur" was the most prestigious of his many awards. He died in Paris on January 26, 1874.

Guest

Among social insects, this term is used to indicate a social symbiont.

Guild

A group of species that exploits the same resource in a similar manner. Examples of a guild are the various insects that are responsible for decomposition of cow dung, or the various insects that attack the flower head of sunflower.

Guinea Pig Lice

Members of the family Gryropidae (order Phthiraptera).

► Chewing and Sucking Lice

Gula

A sclerite found centrally beneath the head, in the position of the "throat." It also is called the gular plate.

Gundlach, Johannes (Juan) Christopher

Johannes Gundlach was born in Marburg, Germany, on July 17, 1810. His father, a university professor there, died young, leaving his widow and their five children with inadequate income. Johannes became interested in natural history, and began to collect birds by shooting them in preparation for taxidermy. An early accident with a gun left him with an injured palate and nose, and loss of his senses of smell and taste. His mother wanted him to study religion, and he began to do so, but he obtained a job as conservator of the university museum and put aside his religious training to study zoology. He obtained free tuition as son of a faculty member, a master of arts degree in 1837, and a doctorate in philosophy in 1838. He was offered accommodation in Surinam by a friend who was a military doctor there, and began to seek funding for his trip, the funds to be repaid by the sale of specimens collected. While organizing this funding, he spent six months studying specimens in the zoological museum at Frankfurt am Main, southern Germany. His sea voyage to Surinam took him first to Cuba, where he spent from Christmas 1838 through early January 1839 collecting before learning that his friend in Surinam had died. Johannes decided to remain in Cuba and to repay his loan with specimens collected in Cuba. He received much hospitality in Cuba from landowners, even to the extent in 1846 of establishing a museum of his collections at a farm called "El Refugio" near to Cárdenas. This museum received thousands of visitors. In 1864 the collection was moved to a building on the farm of the Cárdenas family. He collected in all parts of Cuba with enthusiasts and sponsors or alone. The Cuban insurrection against Spanish rule began in 1868 and made fieldwork dangerous because of roving bands of rebels and Spanish soldiers, so Johannes collected intensively on the Cárdenas farm and made three visits to Puerto Rico, in 1873, 1875–1876, and 1881. His hosts, the Cárdenas family, had meanwhile encountered great financial difficulty. In 1892, after approval from Spain, Johannes sold his collections to the Instituto de Segunda Enseñanza de la Habana ("Institute of Havana"), and gave all the proceeds to the Cárdenas family. However, the transaction also allowed a small salary as curator to Johannes. The collections were installed in Havana in 1895, and Johannes (known in Cuba as Juan) died on March 17, 1896. He published on numerous aspects of Cuban and Puerto Rican zoology. His major works on insects were (1881, 1886, 1891) "Contribución a la entomología cubana" in three volumes, and (1887, 1891, 1893) "Apuntes para la fauna puerto-riqueña" (a series published in Anales de la Sociedad Española de Historia Natural, of which the parts in volumes 16, 20 and 22 of that journal concern insects). He never married, lived very frugally, and dedicated his life to Cuban zoology.

Gustatory

This is used to describe features related to the sense of taste such as gustatory sensilla or gustatory behavior.

Gut pH

The pH of the insect gut is variable, and has significant influence on the actions of enzymes secreted in the midgut, and solubility of the food. Different enzymes function optimally at different pH levels. Though the gut tends to be slightly acidic in most species (about pH 4–6), the gut pH is related to host plant chemistry. Insects that feed on trees, which typically possess high levels of tannins, have higher pH levels, around 8.6, apparently because this reduces the effects of ingested tannins. The hindgut regions of insects ingesting cellulose, such as termites and crickets, tend to be acidic due to anaerobic fermentation of glucose derived from cellulose digestion.

► Alimentary Canal and Digestion

Gyllenhal, Leonhard

Leonhard Gyllenhal was born in Algusthorp, Sweden, on December 3, 1752. At the age of 17 he entered the University of Uppsala, and studied natural history with Linnaeus, being influenced by the latter to specialize in entomology. However, after three years he entered the Swedish army and served for 27 years. Upon retirement as a major from the army, he met Gustav Paykull and helped the latter with his "Fauna svecica" (1798–1800), and collaborated with Carl Johann Schönherr in production of the latter' s "Synonymia insectorum" (1806, 1808). Only then did he start his own work, "Insecta Svecica," of which four volumes were published (1810–1827) on Coleoptera. In the 1830s he also contributed heavily to Schönherr's "Genera et species curculionidum" He died on May 13, 1840, in Hoeberg, Sweden.

Gynandromorph

An individual that contains structural characteristics of both sexes, often with one sex on one side and the other sex on the other side. This is an abnormal condition in insects, occurring infrequently.

Gyne

A female of the reproductive caste in social Hymenoptera. It is applied to potential or actual queens of ants, bees and wasps.

Gynopara (pl. gynoparae)

In aphids, viviparous females that are produced on the secondary host in the autumn, and then fly to the primary host to produce new females that mate and deposit eggs.

► Aphids

Gypsy Moth, *Lymantria dispar* Linnaeus (Lepidoptera: Lymantriidae)

WAYNE BREWER
Auburn University, Auburn, AL, USA

Gypsy Moth, *Lymantria dispar* Linnaeus (Lepidoptera: Lymantriidae), Figure 75 Etienne Leopold Trouvelot, a French naturalist who accidentally introduced gypsy moth into the field at Medford, Massachusetts, in 1869 (courtesy of USDA).

The gypsy moth, *Lymantria dispar* L., is recognized as one of the most serious insect defoliators of North American forests and urban landscapes. Since its introduction, the gypsy moth has spread to all or part of 17 states and the District of Columbia. Yearly defoliation often reaches into the millions of acres, and the costs of damage and control run into tens of millions of dollars. The moth is a native of Europe and Asia where it is a sporadic pest. It was introduced into the U.S. in 1869 by a French naturalist, Etienne Leopold Trouvelot (Fig. 75), who brought the moths to his home in Medford, Massachusetts. He apparently intended to cross them with other moths to create a prolific and hardy strain of silkworms. The experiment failed, the moths escaped and spread to the surrounding area.

The first outbreaks of the gypsy moth began in Trouvelot's neighborhood about 10 years after their introduction and, in 1890, the State and Federal Government began attempts to eradicate the moth. These efforts ultimately failed and the gypsy moth has continued to spread since that time. Currently established populations occur throughout the northeastern U.S. and the moth is spreading south and west across the U.S. The moth often "hitchhikes" to new areas on the camper trailers and motor homes of northern residents vacationing in uninfested areas. The result is that every year isolated populations are discovered beyond the contiguous range of the gypsy moth, but these are usually eradicated or disappear without intervention. However, it is inevitable that the gypsy moth will continue to expand its range in the future.

Biology

The gypsy moth (Fig. 76) has one generation per year. The adults emerge in midsummer, usually in July but variations occur depending on local or regional conditions. Although winged, the females cannot fly and usually remain near the pupal case from which they emerged. Soon after emerging, the females release a sex pheromone that attracts the males, which do fly; they mate and she begins to lay eggs. The females normally produce one egg mass in which the number of eggs may range from fewer than 100 to over 1,000. The eggs are covered by a dense coating of hairs that are sloughed from the abdomen of the female as she oviposits. It is thought that these hairs provide a form of insulation that helps protect them from low temperatures. Gypsy moths overwinter in the egg stage which lasts 8–9 months. The following spring, the eggs hatch and the larvae emerge. The date of larval emergence is strongly influenced by temperature. Larval feeding continues through four instars with the last instar doing most of the damage to foliage. It has been estimated that a single larva consumes about one square meter of foliage during its development. Pupation occurs about eight weeks after egg hatch. The pupae are usually located in cryptic locations such as cracks or crevices of the bark, in the leaf litter, or in other protected places. This stage lasts about two weeks and then adults emerge to continue the cycle.

Gypsy Moth, *Lymantria dispar* Linnaeus (Lepidoptera: Lymantriidae), Figure 76 Some stages of the gypsy moth life cycle: *top*, a mature larva; *center*, female moths (adults) with egg masses protruding from beneath; *bottom*, a male moth (adult photos courtesy of John Ghent, U.S. Forest Service).

Dispersal

The newly hatched, small and hairy larvae move to the tops of trees and feed on new foliage. Some may be blown by the wind to new locations. The long larval hairs of the early instars and the strands of silk they produce from special glands in their heads are conducive to this type of transport. This "ballooning" is a major means of natural dispersal. However, most long distance spread to new locations occurs as result of the transport of infested items by humans. The larvae may pupate, or females may lay egg masses, on almost any object left outside. These include campers, mobile homes, packing crates, pallets and other items. If infested items are moved to a new location, a new infestation may become established.

Hosts

The gypsy moth is known to feed on the foliage of over 300 species of trees and shrubs with species of oaks ranked among the most preferred hosts. Oaks are common in much of the forested and urban areas of the U.S. and their wide distribution will be a major factor in the ultimate distribution of the moth. Where oaks are less common, however, the gypsy moth has maintained populations on other tree species including aspen and other hardwoods. A few species, including tulip poplar and dogwood, appear to be immune to feeding and other species, especially conifers, are not acceptable to very young gypsy moth larvae, but older instars feed readily on them.

Damage

When the gypsy moth first moves into a new area, tree mortality is often extensive. Species of oaks, especially white and chestnut oaks, appear to be most susceptible with mortality often exceeding 50 %. The effects of repeated defoliation can be very serious. Coniferous trees often die after a single defoliation. Deciduous trees can withstand one or two defoliations but the mortality level rises sharply after the third. Other stresses, such as drought or poor site conditions, may increase the risk of mortality. Much tree mortality is actually caused by pathogens or insects, such as wood borers that attack and kill weakened trees. In areas where the gypsy moth has existed for some time, such as New England, the moth is more notorious as a nuisance rather than for killing large numbers of trees. This may be a result of gypsy moth populations eventually coming under control by natural enemies, or the change in forest composition due to favored hosts being killed and the remaining trees being less suitable as sources of nutrition.

Nuisance Factors

At low population levels, gypsy moth larvae remain inactive and secluded in resting places during the day, but when populations are high, their behavior changes dramatically. Larvae in dense populations become hyperactive during the day. Infested areas are literally crawling with larvae as they move incessantly up and down trees and travel along the ground. These larvae are attracted to and climb any object in their path including trees, telephone poles, cars and people. They are not harmful, but the presence and activity of such large numbers of these larvae create a nuisance. In addition, when outbreaks occur, many larvae die from various mortality factors. The unpleasant odor of decaying larvae is often evident throughout the defoliated area. Outdoor activities, such as picnics and barbeques, are often disrupted by larvae, or their frass (excrement) dropping from infested trees onto patios, decks and picnic tables.

Natural Enemies

Various biological control agents have been collected from Asia and Europe and introduced into infested areas of the U.S. over the last 100 years. These include over 20 insect parasitoids and predators that are natural enemies of the gypsy moth. Small mammals, like the white-footed mouse, and other rodents such as shrews, are perhaps the most important gypsy moth predators, especially at low population densities. Birds are also known to prey on gypsy moths, but do not seem to cause any substantial reduction in moth populations. A nucleopolyhedrosis virus usually causes the collapse of outbreak populations, and recently an entomopathogenic fungus species has caused considerable mortality of gypsy moth populations in North America.

Control

In addition to the introduction of natural enemies, several million acres of forest land have been aerially sprayed with pesticides over the last 20 years to suppress gypsy moth populations. Though some areas are treated by private companies under contract with land owners, most areas are sprayed under joint programs of state governments and the USDA Forest Service. The USDA, state and local governments also jointly participate in programs to identify and eradicate new gypsy moth populations in currently uninfested areas. These survey programs involve the use of small triangular-shaped traps baited with a synthesized female sex pheromone. In addition, the USDA Forest Service, working with state and federal cooperators, began a Gypsy Moth Slow the Spread (STS) project in 1999. The project covers the 1,200 mile gypsy moth frontier from North Carolina through the Upper Peninsula of Michigan. The project goal is to use novel integrated pest management strategies to reduce the rate of moth spread.

H

Habitat

The place where an organism dwells. This is a less inclusive term than "niche."

Habitat Diversity

The range of habitats present in an area. Because insects often have preferred habitats, there usually is a strong correlation between habitat and insect diversity.

Habituation

Failure to elicit normal response after repeated stimuli. Often the organism gradually decreases it response to the stimulus, and the organism may not respond even after the stimulus is discontinued for a protracted period. All insects are thought to be capable of habituation to some stimuli, and it is considered to be the simplest form of learning.

Haddow, Alexander John

Alex Haddow was born in Scotland in December 1912, and as a boy showed intense interest in insects. His first degree was in zoology, from Glasgow University in 1934. He took another 4 years to complete an M.D. degree. Next, he studied at the London School of Tropical Medicine for a diploma in tropical medicine. In 1941 he traveled to Kenya and studied biting cycles of mosquitoes under conditions of a 24-h continuous catch, developing and standardizing methods for collecting and analyzing the data. Other work in Africa was on the epidemiology of yellow fever, and it involved collecting and sampling from monkeys. After 24 years in Africa, he returned to Britain in 1965, to become Administrative Dean of the Faculty of Medicine at Glasgow University. His honors include election to the fellowship of The Royal Society as well as the Royal Society of Edinburgh. He died in Glasgow on December 26, 1978, survived by his wife, Peggy, and two sons.

Haematopinidae

A family of sucking lice (order Phthiraptera). They sometimes are called ungulate lice.

► Chewing and Sucking Lice

Hagen, Hermann August

Hermann Hagen (Fig. 1) was born in Königsberg (now Kaliningrad), then in German East Prussia (now in Russia), on May 30, 1817. He was educated at Universität Königsberg, and became a physician in that city. He studied extant insects (Odonata, Neuroptera, Isoptera, Psocoptera, Plecoptera, and Trichoptera) and fossil insects. Some of his major works were "Monographie der Termiten" (1855–1860) and "Bibliotheca Entomologica" (1862–1863) [for a subsequent bibliography of the world's entomological literature, see: Horn, Walther]. In 1867 he was invited to the USA to take charge of the entomological section of the Museum of Comparative Zoology at Harvard University in Massachusetts. He accepted, organized and built that collection, and greatly influenced taxonomic entomologists in the USA. In 1890–1891 he was afflicted with paralysis and influenza, and died in Massachusetts in 1893.

Hagen, Kenneth Sverre

Ken Hagen was born in the state of California, USA, on November 26, 1919. He displayed an early interest in insects and formed a collection. He earned a B.S. degree from the University of California at Berkeley in 1943. After service in the U.S. navy in World War II (landings at Normandy and Okinawa), he returned to the graduate school of the same institution, earning degrees of M.S. in 1948 and Ph.D. in 1952. While he was a graduate student he worked as a technician, but after his Ph.D. he was hired as junior entomologist in the Division of Biological Control, of the University of California's Agricultural Experiment Station at Albany. He became entomologist in 1965 and professor of entomology in 1969. His areas of research interest included the behavior of coccinellids, highlighted in a (1970) article in National Geographic called "The high-flying ladybug." He was the leader of projects that resulted in introduction of 25 species of biocontrol agents against 17 economically important pests. He had a pioneering role in the nutrition of biocontrol agents, with proof in the field that manipulative techniques using artificial nutrition could work. He authored more than 160 scientific publications and received numerous awards. He was also a gifted teacher. He died on January 10, 1997, survived by his wife, Maxine, and one son.

Hahn, Carl Wilhelm

Carl Hahn was born on December 16, 1786, and lived mainly in Nürnberg (Nuremberg), Germany. He studied the spiders of his country, which he described and illustrated in two major works, "Monographie der Spinnen" and "Die Arachniden". His premature death in 1836 interrupted publication of the latter, of which he completed only two volumes. It was then completed, in a further 14 volumes, by C. L. Koch between 1836 and 1849.

Hair Pencil

Clusters of long setae on the body of certain insect (particularly male Lepidoptera and some Neuroptera). They occur on various parts of the body, but usually on the abdomen. They are associated with exocrine glands, and usually used during courtship to disperse sex pheromones. This term is synonymous with "brush organ."

Hair Plate

A sensor structure found at the leg joints and at other limb articulations. They respond to touch, bending and joint flexing by emitting nervous stimuli, and adapt slowly. They allow the insect to know the orientation of the head and appendages. A more complex version of the hair plate is the chordotonal sensillum.

Hairstreaks

Some members of the family Lycaenidae (order Lepidoptera).

Hale Carpenter, Geoffrey Douglas

Geoffrey Hale Carpenter was born in Eton College, England, on October 26, 1882. His undergraduate studies were at Oxford University, and then in 1908 he qualified in medicine and took a D.M. degree in 1913. But by 1911, interested in tropical medicine and natural history, he was studying the bionomics of *Glossina palpalis* and its relation to sleeping sickness in Uganda. His research was published in reports of The Royal Society in 1912, 1913, and 1919. In Uganda, too, he studied mimicry in butterflies, and through rearing experiments solved problems of relationships. He viewed mimicry among butterflies as a result of natural selection by predatory birds, mammals, and reptiles. His butterfly studies are published mainly in journals of the Royal Entomological Society. In 1933 he was appointed Hope Professor at Oxford University, succeeding Sir Edward Poulton. He retired in 1948 and died in Oxford on January 30, 1953.

Haliday, Alexander Henry

Alexander Haliday (Fig. 2) was born in Belfast in 1807. At the age of 15, he entered Trinity College, Dublin, remaining there 5 years and obtaining an M.A. degree. Next, he studied law, and apparently was successful, although it is not clear that he ever practiced this profession. Returning to the north of Ireland, he devoted his time to the study of literature and natural history. He was appointed High Sheriff of the county of Antrim in 1843, a political position rather than one in law-enforcement. Beginning in 1828, he published a long series of papers on the Irish insect fauna, especially Diptera. He also published extensively on Chalcidoidea and other "parasitic" Hymenoptera, and on Thysanoptera. Due to poor health, he emigrated to Lucca, Italy, about 1860. There, he continued collecting insects and helped to found the Società Entomologica Italiana. He died on July 12, 1870.

Handling Time

The time a predator spends pursuing, subduing, and consuming prey (a meal).

Handlirsch, Anton

Anton Handlirsch was born in Vienna on January 20, 1865. He studied pharmacy, and in 1883 received a master's degree in that subject. Then, he became scientific helper, assistant (1892), adjunct custodian (1899), second-class custodian (1906), first-class custodian (1918) and director (1922) of the Naturhistorisches Hofmuseum of Vienna. His earliest entomological work was on Hymenoptera, reaching a climax (1887–1894) with a monograph of wasps related to *Bembex* and *Nysson*. He took charge of Hemiptera at the museum, purchased the Signoret collection for it, and wrote a monograph on Phymatidae (1897). Next, he turned his attention to fossil insects. His (1906–1908) book "Die fossilen Insekten und die Phylogenie der rezenten Formen" enumerated or described all known fossil insects. It included a new classification with discussion. In his contributions to Schroeder's (1925) "Handbuch der Entomologie" and Kükenthal's (1926–1935) "Handbuch der Zoologie," he modified the classification. He also published about 100 other titles. He died in Vienna on August 28, 1935.

Hansen, Viktor

Viktor Hansen was born in Copenhagen on August 29, 1889. In 1907 he entered the Metropolitanskolen and in 1913 obtained his law degree. He worked in the Justitsministeriet from 1915, became a superior judge in 1941, and worked in that capacity until he retired in 1959. However, he began to collect beetles as a teenager, and in 1905 joined the Entomologisk Forening [entomological society]. His first paper was published in 1907 in Entomologiske Mededelser. His lifetime total was more than 100 papers on the Danish beetle fauna. His major production was 23 volumes on beetles in the series Danmarks Fauna. For this, he was awarded an honorary doctoral degree from Københavns Universitet in 1950, and medals from entomological societies in Denmark and Sweden, and from a natural history society in Denmark. He died on March 6, 1974.

Haplodiploidy

A type of parthenogenetic reproduction in which males are produced from unfertilized eggs and are haploid, while the females are diploid. In Hymenoptera, females can control the release of sperm, and regulate the sex ratio of offspring.

Haploid

Cells or organisms that contain a single copy of each chromosome.

Hardy-Weinberg Equilibrium

An equilibrium of genotypes achieved in populations of infinite size in which there is no migration, selection, or mutation after at least one generation of panmictic mating. With two alleles, *A* and *a*, of frequency *p* and *q*, the Hardy-Weinberg equilibrium frequencies of the genotypes *AA*, *Aa* and *aa* are p^2, $2pq$ and q^2, respectively.

Harlequin Bug

► Crucifer Pests and their management

Harlequin Bug, *Murgantia histrionica* (Hahn) (Hemiptera: Pentatomidae)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

Indigenous to Mexico and Central America, harlequin bug has dispersed north into the United States. Its appearance in Texas, USA, in 1864 coincided with the occurrence of Union troops during the American Civil War, and in parts of the South earned it the name "Sherman-bug" after the northern General Sherman, and "Lincolnite" after President Abraham Lincoln. It rapidly spread throughout the southern states, and eventually reached northern locales such as Colorado, Iowa, southern Michigan, Pennsylvania, and Massachusetts. It is considered to be a serious pest only in southern states, however, and is not regarded as a problem in California. It has also dispersed to the Hawaiian Islands.

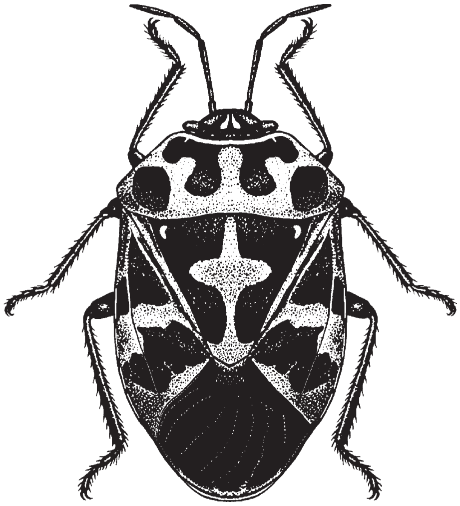
Life History

Harlequin bug breeds continuously in the southern portions of its range. During mild winters all stages have been observed as far north as Virginia. In colder climates only the adults survive the winter in sheltered locations. They seek shelter in and near fields, among overwintering crop plants, and in other organic debris such as dead leaves and bunches of grass. Two or three generations per year seem to be normal, but there appears to be four generations in south Texas.

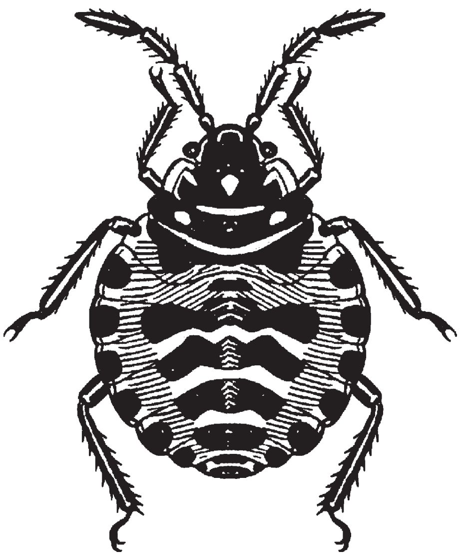
Adults begin depositing eggs about 2 weeks after becoming active in the spring. Eggs are deposited beneath leaves, usually in clusters of 12 arranged in two rows of six, at intervals of 5–6 days. As the female nears the end of her life, the egg batches get slightly smaller and the egg arrangement less regular. The eggs are barrel-shaped, and measure about 1.30–1.38 mm long and 0.90–0.92 mm in diameter. They are light gray or pale yellow in color, and generally are circled by two black bands. They may also bear small black dots or spots, and the top has a semicircular black marking. The average number of eggs is reported to be 115 per female. Egg deposition may occur over a period of 40–80 days. Eggs hatch in about 4–5 days during warm weather, while 15–20 days may be required during cool weather.

Upon hatching, young nymphs stay clustered near the old eggs for 1 or 2 days. The newly hatched nymphs are pale green with black markings, but soon become brightly colored: black or blue, with red and yellow or orange markings. Reportedly there are six instars in Texas, and nymphal development can be completed in as little as 30 days. There, average development times are 3.4, 3.2, 4.7, 4.7, 7.0, and 4.3 days, respectively, for the six instars developing under summer conditions. Under spring conditions, development times were increased by about 30%. Studies in Virginia suggest only five instars, however, and a development time requirement of 40–60 days during the summer, and slightly longer, perhaps 70 days, during cool weather.

The adults usually live about 60 days, but may live considerably longer during the winter. They measure about 8.0–11.5 mm in length. The adults are brightly colored, similar to the large nymphs, principally black and yellow or black and red. The color pattern varies (Figs. 3 and 4), with the spring and summer bugs being more brightly colored



Harlequin Bug, *Murgantia histrionica* (Hahn) (Hemiptera: Pentatomidae), Figure 3 **Adult of harlequin bug, *Murgantia histrionica* (Hahn).**



Harlequin Bug, *Murgantia histrionica* (Hahn) (Hemiptera: Pentatomidae), Figure 4 **Third instar of harlequin bug, *Murgantia histrionica* (Hahn).**

than the overwintering insects. As with many stink bugs, harlequin bugs produce a disagreeable odor if disturbed, and birds avoid eating them.

Harlequin bug is principally a pest of crucifers, attacking broccoli, Brussels sprout, cabbage, cauliflower, Chinese cabbage, collard, kale, kohlrabi, mustard, radish, rutabaga, turnip, and watercress. Harlequin bug is reported to be especially fond of horseradish. In the southernmost states, crucifers do not thrive during the summer months, and the bugs are forced onto other plants. Thus, they are sometimes found feeding on asparagus, beans, okra, squash, tomato and many other vegetables, but this is usually due to lack of normal food. Harlequin bug feeds readily on cruciferous weeds such as wild mustard, *Brassica* spp.; shepherds purse, *Capsella bursa-pastoris*; and pepperweed, *Lepidium* spp.; and related mustard oil-containing plants such as members of the family Capparaceae. Other weeds common in crops, such as pigweed, *Amaranthus* spp., and lambsquarter, *Chenopodium album*, are also fed upon, and reproduction occurs on these plants.

Harlequin bug appears to be relatively free of natural enemies, other than for egg parasites and general predators. The egg parasitoids are *Oencyryus johnsoni* (Howard) (Hymenoptera: Encyrtidae), *Trissolcus murgantiae* Ashmead, and *T. podisi* Ashmead (both Hymenoptera: Scelionidae). The species that is best known is *O. johnsoni*, which has been reported frequently from harlequin bug eggs, and has caused up to 50% mortality during a harlequin bug outbreak in Virginia. This parasite is widely distributed, and apparently has other hosts. It attacks eggs in all stages of embryonic development, and prevents the eggs from hatching. However, *O. johnsoni* is not the only effective parasite, as *T. murgantiae* was observed to parasitize 45% of harlequin bug eggs in North Carolina, at locations where *O. johnsoni* parasitized only 30% of eggs. Because of its effectiveness, *T. murgantiae* was introduced into California.

Damage

The piercing-sucking feeding behavior of this insect results in white blotches at the site of feeding. Wilting, deformity, and plant death may occur if insects are abundant. Mild winters are said to favor survival, and subsequent damage. Once considered the most serious crucifer pest in the south, this insect has been relegated to minor status in commercial production and persists mostly as a home-garden pest.

Management

Insecticides are applied to the foliage for suppression of harlequin bug. Harlequin bug can be difficult to control with insecticides; targeting the young bugs and thorough coverage are recommended. Soap applied alone or in combination with rotenone has provided good control.

Trap crops, usually consisting of early-planted mustard, rape, or kale are sometimes recommended to divert the overwintering bugs from the principal crop. Such trap crops must be sprayed or destroyed, however, or the adults will soon move to the main crop. Destruction of crop residues, on which the insect may overwinter in the north or oversummer in the south, is an important cultural practice to alleviate harlequin bug damage.

Susceptibility to damage varies among crucifer crops. Mustard and Chinese cabbage are quite susceptible; turnip, kale, rutabaga, and some radishes are intermediate; and cauliflower, cabbage, broccoli, collard, Brussels sprout, kohlrabi, and most radish varieties are fairly resistant. Cabbages are the most resistant crop, but considerable variation among cultivars is evident.

Harris, Thaddeus William

Thaddeus Harris (Fig. 5) was born in Massachusetts on November 12, 1795. He obtained a first degree from Harvard University in 1815 and then a medical degree in 1820, after which he practiced medicine and married. In 1823 he published his first entomological paper. In 1831 he published a catalogue of insects and became librarian at Harvard University. Teaching of courses in natural history and entomology followed. His 1841 "Report on insects injurious to vegetation" became a classic and was reprinted several times. He also published some descriptions of new species of insects that were of economic importance. He died in Massachusetts on January 16, 1856.

Harvester Ants

Ant species that store seeds in their nests. This behavior occurs in many ant taxa, including some that are not closely related.

► Harvester Ants, *Pogonomyrmex*

Harris, Thaddeus William, Figure 5 **Thaddeus Harris.**

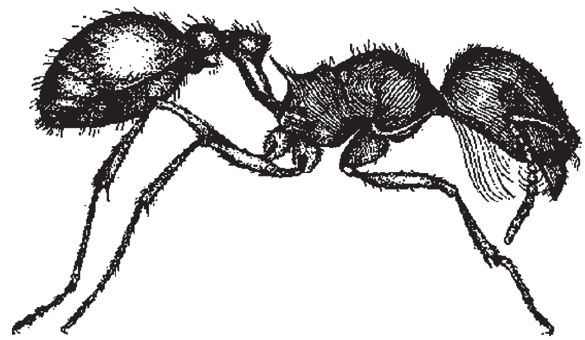
Harvester Ants, *Pogonomyrmex* Mayr (Hymenoptera: Formicidae)

THOMAS O. CRIST
Miami University, Oxford, OH, USA

Harvester ants are so named because they collect and store seeds in their nests for later consumption. The seed-harvesting habits of ants are noted in several historical accounts and are the subject of numerous scientific studies. Over 150 species of seed-harvesting ants occur worldwide. In the New World, harvester ants comprise 60 species belonging to two closely related genera, *Pogonomyrmex* Mayr ("bearded ant") and *Ephebomyrmex* Wheeler ("youthful ant"). The beard, or psammophore, refers to the tuft of hairs that extend below the head on the workers of nearly all 45 species of *Pogonomyrmex*. This distinctive trait corresponds to the ground-nesting habits of harvester ants because the psammophore is used to move particles of soil. Some harvester ants build large mounds or craters of soil and gravel on the soil surface while others have more inconspicuous nests under rocks.

Most *Pogonomyrmex* occur in deserts and grasslands where seeds are abundant, but a few species are found in forest and montane environments. Harvester ants (Fig. 6) range throughout South America, portions of Central America and the Caribbean, and virtually all of western North America and the southeastern Coastal Plain. The geographic ranges of most species, however, are found within southwestern North America and northern South America, the latter of which is likely the evolutionary origin of *Pogonomyrmex*.

The mating behavior and life cycle is generally similar among *Pogonomyrmex* species. During spring or summer, ant colonies produce numerous winged males and females ("alates") that are reproductively viable and larger than the sterile workers. Alate flight activity is synchronous among colonies, usually occurring in the late morning on 2 or 3 days following a significant rainfall. Mating flights can occur several times a year, but are usually restricted to a 2 or 3-week period. After leaving the nest, alates



Harvester Ants, *Pogonomyrmex* Mayr (Hymenoptera: Formicidae), Figure 6 A worker harvester ant. The genus *Pogonomyrmex* is named after the prominent beard (the psammophore) on the lower side of the head. Drawing is by Ruth Ann DeNicola, published in Cole, A. C., Jr. (1968) *Pogonomyrmex* harvester ants: a study of the genus in North America. Reproduced with permission from The University of Tennessee Press, Knoxville, Tennessee.

aggregate on hills or cliffs and in the uppermost portions of shrubs, trees, or structures such as fence posts, windmills, or buildings. Males often "lek" (form mating aggregations) together in groups of 5–20 individuals, and females are attracted to male aggregations by a pheromone. Females typically mate with several males, a behavior that results in genetically variable workers after the queen begins reproduction. In some species, such as *P. badius* (the Florida harvester ant), lekking does not occur and males fly to another nest to mate with females, or mating might take place between males and females of the same colony, which can result in inbreeding and a loss of genetic variability over time.

After mating, the fertilized female sheds her wings and begins excavating a nest in the soil. Most "foundress queens" die before successfully establishing a colony. The queen must carry out all of the worker tasks – foraging, nest maintenance, and brood care – for 2 or 3 weeks until her first brood matures into adult workers. The mortality of young colonies continues to be high until the next year when the size of the worker population may increase substantially. *Pogonomyrmex* colonies have variable numbers of workers: *P. laticeps* and *P. magnacanthus* have only 50–250, whereas *P. rugosus* (the rough harvester ant) and *P. barbatus* (the red harvester ant) may boast up to 15,000. Most species have a worker force of 500–5,000 ants. Two species, the slavemaking *P. anergismus* and *P. colei*, have no workers at all; instead, they live in the nests of *P. rugosus* or *P. barbatus* and enslave workers to raise reproductive males and females for them. It appears that all *Pogonomyrmex* species are monogynous (have one queen) during the life of a colony, which may persist for 10–50 years in some species such as *P. occidentalis* (the western harvester ant) and *P. owyheei* [*salinus*] (the Owyhee harvester ant).

Workers perform a variety of tasks. Nest workers take care of the queen and developing larvae and pupae. They also create and maintain a variety of nest chambers for seed storage, brood development and discarded refuse. Storage chambers are connected by networks of tunnels, which may extend 2–3 m vertically below ground in some species. The queen and workers usually overwinter more than a meter below ground in colder climates. Worker tasks vary according to the age of the worker and the needs of the colony. After emerging from pupae, ants work mostly within the nest. Then, as workers get older, they shift to exterior maintenance of the nest, and finally to patrolling, scouting, or foraging, which may entail venturing up to 20 m from the nest in some species. Workers also switch tasks according to the needs of the colony. For example, if a nest is damaged by heavy rain, foraging workers might switch to nest maintenance. Similarly, a nest intruder may elicit an alarm pheromone that rapidly employs a substantial number of workers to defend the nest. Harvester ants are well-equipped for nest defense, as the workers of many species will deliver a painful sting.

A number of scientific studies have examined the foraging and seed-harvesting behavior of *Pogonomyrmex* ants. Foraging workers search for seeds in an individualistic manner, specializing on particular seed species or locations near the nest. Although this is the primary foraging strategy in some species (e.g., *P. desertorum*, *P. maricopa*, and *P. californicus*, the California harvester ant), several harvester ants also show group foraging tactics. These involve the use of permanent pathways (trunk trails) that orient workers to different foraging areas, and pheromone trails that chemically recruit workers to areas of high-food density (e.g., *P. rugosus*, *P. barbatus*, and *P. occidentalis*). Recruitment pheromones are volatile compounds that dissipate rapidly if workers do not reinforce them by laying additional pheromones along the recruitment trail. Ants usually harvest <10% of the total seeds available in their foraging areas, but they often remove a much larger fraction of the seed species they prefer – grasses and small-seeded forbs – and consequently, influence the types of plants that are found near nests. A significant part of the harvester ant diet is arthropods, especially in some species found at higher elevations (e.g., *P. montanus* and *P. mayri*). A variety of other materials are also returned to the nest by workers, including twigs, leaves, flowers and feces.

Several vertebrates and arthropods prey on harvester ants. Most commonly, these are birds, lizards and spiders. Horned lizards (*Phrynosoma* spp.) are specialist predators of harvester ants and have evolved a resistance to the toxic compounds in the venom delivered by the sting of worker ants. Predation by horned lizards can substantially reduce the number of workers in a nest. Ants respond to lizard predation by reducing their foraging activity, or closing their nests entirely. The storage of seeds in harvester ant nests is thought to provide a food source when foraging activity is decreased in response to predation. Other seed-eating animals, such as kangaroo rats (*Dipodomys* spp.), may also compete with harvester ants for food.

The large nest size and colony longevity of many *Pogonomyrmex* species have important consequences to soils and plants. Ants change the physical and chemical characteristics of soil by increasing the porosity, organic matter and nutrient levels. The alteration of nest soils and the removal of plants and seeds by ants result in different plant species near nests compared to surrounding areas. Therefore, in deserts and grasslands where colony densities are high, harvester ants influence plant species diversity and composition. Recently, however, the native *Pogonomyrmex* ants have been displaced in several areas by more aggressive, invasive species such as the red imported fire ant (*Solenopsis invicta*), or the Argentine ant (*Linepithema humile*). A loss of harvester ants from these ecosystems may have several consequences to the constituent soils, plants and animals.

The biology and behavior of *Pogonomyrmex* ants continues to fascinate scientists and amateurs alike. Most studies of harvester ants are from relatively few of the 60 species; future investigations of lesser-known species will further our understanding of these remarkable insects.

Hatch, Melville Harrison

Melville Hatch was born in Detroit, Michigan, USA, on November 25, 1898. An early interest in biology led to his seeking and obtaining a university education in the subject, culminating in a Ph.D. from the University of Michigan in 1925. He became a teaching assistant at the University of Michigan in 1926, then an instructor at the University of Minnesota, and next an assistant professor at the University of Washington. Promotions followed, and he became professor in 1941 and chairman of the Zoology Department, and Curator of Entomology at the university's Burke Museum in 1962. He retired from teaching in 1969. Meanwhile he had begun to write and publish his greatest work, "The beetles of the Pacific Northwest," which appeared in five volumes, the last in 1971. His other publications numbered more than 170, and he served as editor of "The Biologist" from 1959 through 1967. His Coleoptera collection was moved to the University of Oregon after he had ceased to work on it. He died near Seattle, Washington, on January 19, 1988.

Hawk Moths (Lepidoptera: Sphingidae)

JOHN B. HEPPNER
Florida State Collection of Anthropods, Gainesville, FL, USA

Hawk moths, family Sphingidae (also called sphinx moths, bee moths and hummingbird moths), total 1,230 species worldwide. Tropical regions of the New World, Africa and Asia have the most biodiversity. There are three subfamilies: Smerinthinae, Sphinginae, and Macroglossinae (sometimes only two subfamilies are used). The family comprises the monobasic superfamily Sphingoidea, in the section Cossina, subsection Bombycina, of the division Ditrysia. Adults (Fig. 7) medium size to very large (23–200 mm wingspan), with head vertex scaling mostly normal but sometimes roughened; haustellum usually very long, to 30 cm (rarely vestigial); labial palpi mostly upcurved (sometimes porrect), with small third segment; maxillary palpi small; antennae mostly clavate or lamellate and thickened; body very robust (sometimes with longer hair-like setae); some genera with long needle-like spines on hind tibiae (e.g., *Oxyambulyx* species from Southeast Asia). Wings elongated and usually with acute apex; hindwings usually elongated but basally rounded, and much smaller than forewings. Maculation varied but many with shades of brown and gray, often with few markings, but also very colorful species; some with hyaline wings and mimicking wasps. Adults nocturnal or crepuscular but some a diurnal. Larvae are leaf feeders, usually with a posterior tail-like scolus; many larvae extremely large. Host plants recorded in numerous plant families. A few are economic. Among the largest species in the family are females of *Clanis titan* Rothschild & Jordan, of Southeast Asia, and *Coequosa triangularis* Donovan, of Australia, both also with massive bodies, while the smallest is *Sphingonaepiopsis obscurus* Mabille, from Madagascar.

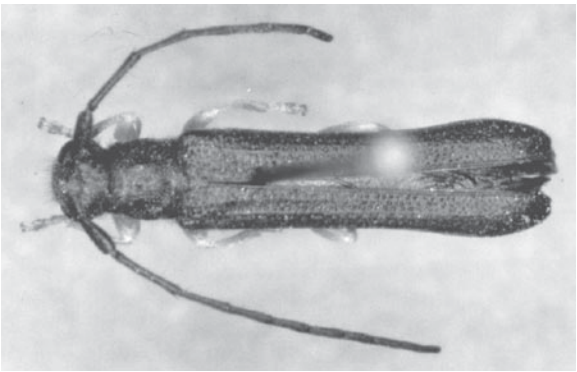
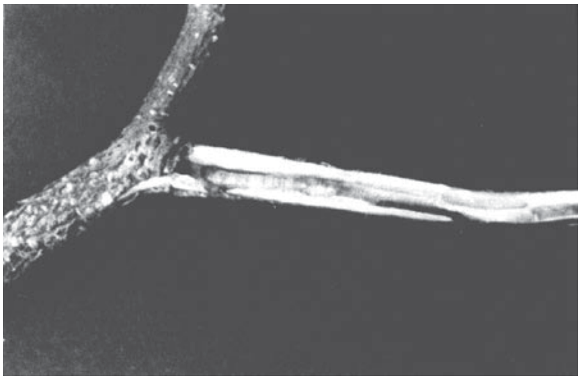
Hazelnut and Walnut Twig Borer, *Oberea linearis* L. (Coleoptera: Cerambycidae)

MINOS E. TZANAKAKIS
Aristotle University of Thessaloniki, Thessaloniki, Greece

The adult (Fig. 8) of this hazelnut and walnut twig borer is long and slender, measuring 11–16 mm long and 2 mm wide. The body is black and the legs yellowish. The antennae do not reach the tip of the elytra. The pronotum and the elytra are covered



Hazelnut and Walnut Twig Borer, *Oberea linearis* L. (Coleoptera: Cerambycidae), Figure 8 *Oberea linearis* adult.



Hazelnut and Walnut Twig Borer, *Oberea linearis* L. (Coleoptera: Cerambycidae), Figure 9 *Oberea linearis* larva in its gallery in a hazelnut twig.

by fine dark brown hairs. The larva (Fig. 9) is apodous, yellowish or light brown with a brown prothoracic shield, and has the characteristic form of cerambycid larvae. Its final length is 20–25 mm.

On hazelnut, in southern and central Europe, *Oberea linearis* completes one generation every 2 years, whereas in colder regions one in every 3 years. There is a report that on walnut, in Greece, it completes one generation per year, but this needs confirmation. On hazelnut, this borer spends the first winter as a relatively young larva and the second winter as a fully-grown larva at the end of its gallery in a twig. It pupates in spring. The female lays an egg in a slit she gnaws in the bark of a shoot, 10–15 cm from its tip. The first-instar larva bores a gallery which is first semicircular and perpendicular to the longitudinal axis of the shoot. This causes the ultimate death of the apical part of the shoot which often breaks off. Subsequently, the gallery goes deeper, and is directed towards the base of the shoot. The larval excrement is pushed out through small holes the larva opens along its gallery. After its first overwintering, the larva continues boring its gallery during spring and summer of the second year, reaches full growth in autumn and overwinters. On hazelnut, the larval gallery reaches 40–60 cm the first year and is directed towards the base, whereas in the second year it is directed towards the apex of the twig.

On walnut, in southern Europe, according to Anagnostopoulos, the adults emerge from the twigs in May or early June. After feeding on new growth for a few days and mating, the female lays an egg on the bark of a shoot a few cm from the tip, or on the pedicel of a fruit. She prefers shoots bearing fruits, and shoots not very turgid. If the shoot is turgid, the female gnaws a semicircular to circular groove in the bark. This weakens the shoot and seems to favor the development and survival of the young larva. When the egg is deposited on the fruit pedicel, the gallery is bored first in the pedicel, then extended in the shoot. Sometimes the gallery goes to the mesocarp of the walnut. On walnut, galleries are shorter than on hazelnut. Galleries in the fruit pedicels cause early drying and early drop of walnuts, while galleries in the shoots cause the death of the eroded part of the shoot and of the fruits it bears. Therefore, on walnut, there may be loss of fruits, loss of dormant floral buds, and of some parts of the foliage. The damage may be serious if the insect's population density is high. In hazelnuts, the damage is limited to shoots and twigs and usually is not such as to justify control measures. Yet, even on hazelnut economic damage may occur under excessive population densities of the insect.

On hazelnut, the best method of control is the removal and destruction of infested dry twigs from late autumn to early spring, before the adults come out of them. Another measure is spraying with an organic contact insecticide of long residual action when the period the adults come out in spring. On walnut, where cutting off infested twigs is usually not practical because of the height of the trees, insecticidal sprays are usually recommended. Sprays applied against the codling moth may suffice. Where pruning is feasible, Anagnostopoulos recommends that it be done in July, to prevent further injury, or in spring, when new growth has started and infested twigs having no leaves can easily be distinguished.

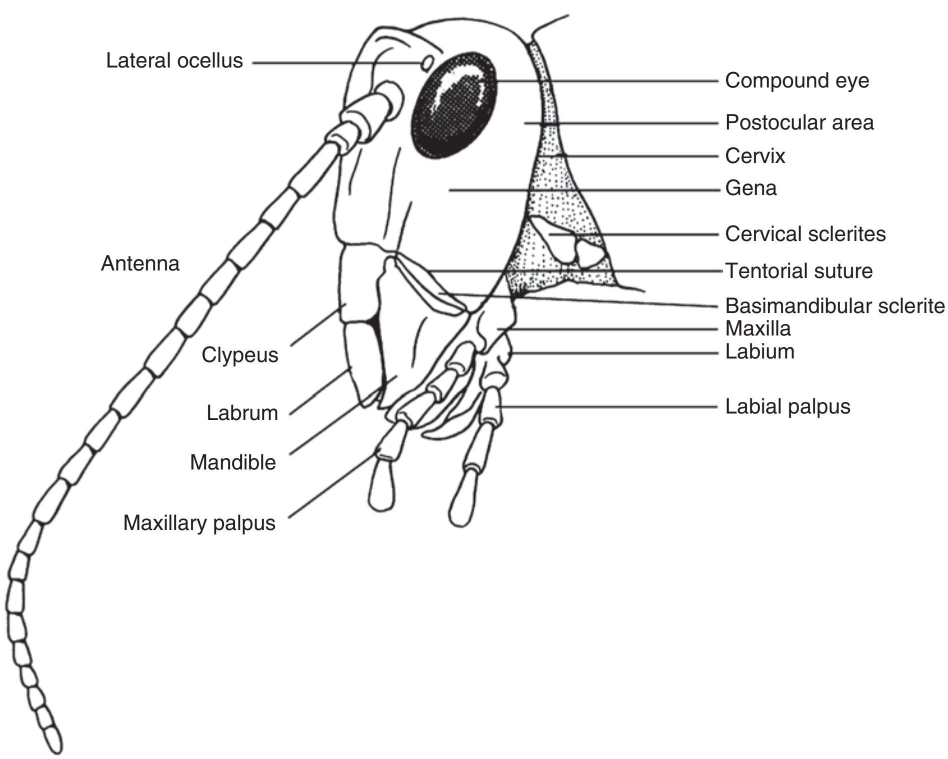
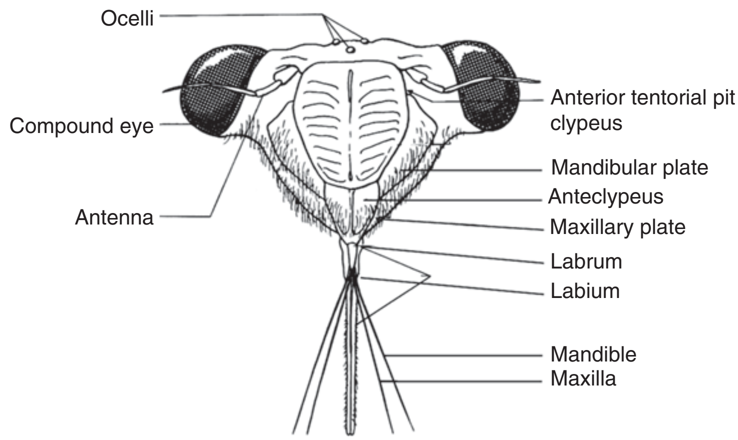
Head of Hexapods

SEVERIANO F. GAYUBO
Universidad de Salamanca, Salamanca, Spain

In the insects, the head is the tagma in the cephalic or anterior position. Structures related to two vital functions are situated in this tagma: feeding (mouthparts) and sensory function (organs like the antennae and visual organs: two compound eyes in the lateral position and three ocelli). The



Head, Figure 10 **Side view of the head of an adult grasshopper, showing some major elements.**



Head, Figure 11 **Anterior aspect of the head and mouthparts of a cicada (Hemiptera).**

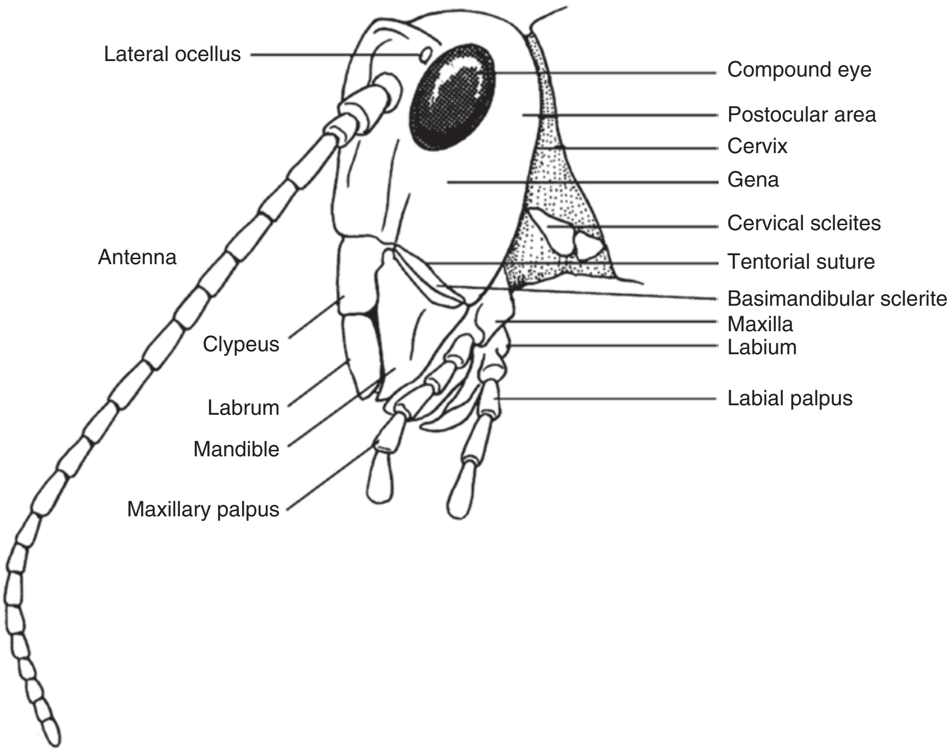
insertion of the antennae in the head capsule (Figs. 12 and 14) can vary from the median frontal area to a more or less ventral position. The compound eyes are situated laterally and generally occupy an ample surface area. The ocelli are situated between the compound eyes, arranged like an isosceles triangle; of the three, the most anterior (median position) seems to be conserved like a well-differentiated lens, while the two posterior ones (lateral position) tend to be reduced or modified, as occurs in some genera of Hymenoptera.

The foramen magnum (Fig. 13) is found in the posterior part of the head, connecting the head and the thorax, and on its ventral border is situated the oral cavity, from which the mouthparts articulate. It is formed by the acron and the preantennal segment (some consider one labral segment), the antennal segment, the intercalary or premandibular segment (some consider a postantennal fused to the antennal segment), the mandibular segment, the maxillary segment, and the labial segment. Externally, this segmentation is not visible due to the existence of the head capsule, formed by the strong sclerotization of the integument. However, this scelerotization is not homogeneous, being differentiated into sutures and grooves that separate sclerites. Among these sutures are found the epistomal or frontoclypeal that unites the anterior tentorial pits and separates the labroclypeal (preoral) region from the frontal region (postoral); likewise, it separates the frons from the clypeus. The clypeus is separated from the labrum by the labroclypeal suture. In certain species the clypeus is differentiated into an anteclypeus and a postclypeus.

The posterior limit of the frons (Fig. 14) is marked by the branches of the epicranial suture (in the form of a Y). This suture represents the ecdysial line of the preimaginal stages, and its trajectory can vary; thus, postfrontal sutures appear (delimiting a postfrons) situated externally at the antennal sockets, and frontal sutures that are internal to those sockets (delimiting the frons). Both sutures can coexist, or only one of them may be present. This generalized arrangement of sclerites and sutures may exhibit numerous modifications, depending on the group of insects in question.

The odd branch of the epicranial suture, known as the coronal suture, separates two parietal sclerites that constitute the laterodorsal regions of the head capsule. The most dorsal zone is called the vertex (Figs. 14 and 15). Each parietal sclerite continues ventrally, forming the postocular area and the gena (areas situated ventrally and posteriorly to the compound eye).

Two transverse sutures are generally differentiated in the posterior part of the head capsule: the occipital and the postoccipital, between which are found the occiput (dorsal) and the postgenae



Head of Hexapods, Figure 12 **Side view of grasshopper head (Orthoptera: Romaleidae).**

Head of Hexapods, Figure 15 **Front (*left half*) and rear (*right half*) view of scorpionfly head (Mecoptera).**

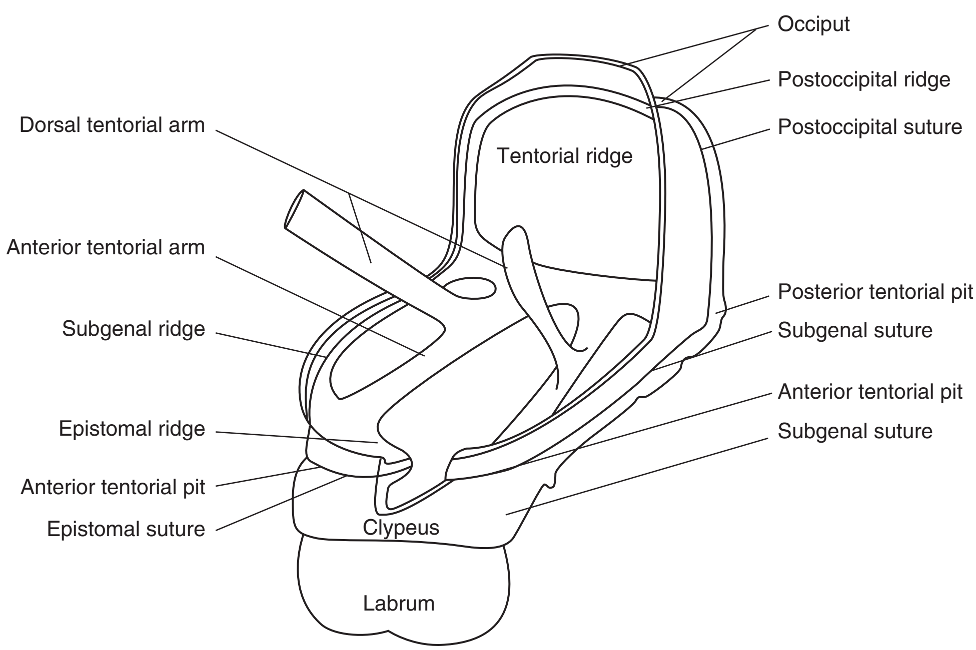
(lateral). The postocciput forms the posterior margin of the cranium by way of a narrow band posterior to the postoccipital suture.

The subgenal suture separates the gena and postgena from a well sclerotized band in the ventral position, the subgena. The subgenal suture consists of two parts, an anterior (pleurostomal suture) and a posterior (hypostomal suture), which delimit the pleurostoma (in which are found the mandibular articulations) and the hypostoma (where the maxilla articulates). The joining of the pleurostoma and hypostoma forms the subgena. Certain authors utilize the term epicranium to denote what together is formed by the occiput (posterior), vertex (dorsal), frontoclypeus (anterior) and genae (lateral).

Internally, the head has some endoskeletal structures, the occipital phragma and the tentorium. The occipital phragma corresponds to an internal ridge or phragma of the postoccipital suture. This phragma normally is formed by a pair of laterodorsal plates, in which the gnathal muscles and the prothoracic motor muscles of the head are inserted. The tentorium is a complex structure that has two fundamental functions; it serves as the area of muscular insertion and reinforces the head capsule. The number and type of muscles that are inserted into the tentorium varies depending on the hexapod group. In primitive groups of hexapods like the Machilidae it consists of three parts, the anterior and posterior tentoria and the tentorial-neck plate.

In the Pterygota, the tentorium is an odd structure (Fig. 16) formed by the tentorial body, from which are differentiated three pairs of extensions, one pair in the anterior position (anterior arms or pretentorium), another posterior (posterior arms or metatentorium) and a third dorsal (dorsal arms or supratentorium). Anterior and posterior arms result from anterior invaginations (pretentorinae) and posterior invaginations (metatentorinae), respectively. They are apodemal structures. These invaginations constitute important morphological reference points. The pair of dorsal arms is directed toward the antennal region. Their union with the cuticle is through naturally fibrous connective structures. Those dorsal arms constitute evaginations of the anterior arms.

Two types of head capsules are distinguished, depending on whether the mouthparts are positioned externally (ectotrophous or ectognathous) or



Head of Hexapods, Figure 16 **Internal structures of the insect cranium (after Snodgrass).**

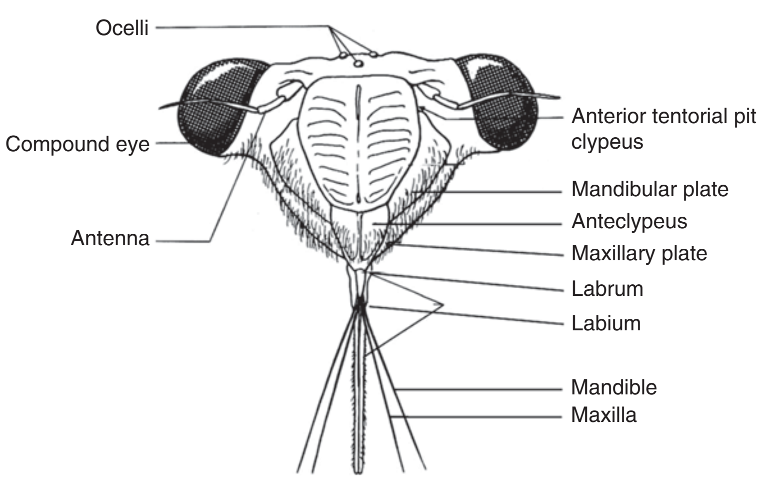
internally (entotrophous or entognathous). These terms can also be applied to the mouthparts themselves. In the first case, both the mouthparts and their articulations with the head are visible externally. In the case of the entognathous insects, the mouthparts are withdrawn into the head, in internal cavities, and are not visible externally when the insect is at rest. Clear examples of this type of head capsule are found in Collembola, Protura and Diplura, and to a lesser extent in Thysanoptera (Fig. 20), Phthiraptera (Anoplura) and some Hemiptera (Fig. 17).

If we consider the position of the oral cavity and consequently of the mouthparts with respect to the cephalocaudal axis, three fundamental types of head capsules (Fig. 21) are distinguished: orthognathous or hypognathous; prognathous; and opisthognathous or opisthorhynchous (these names can also be applied to the mouthparts).

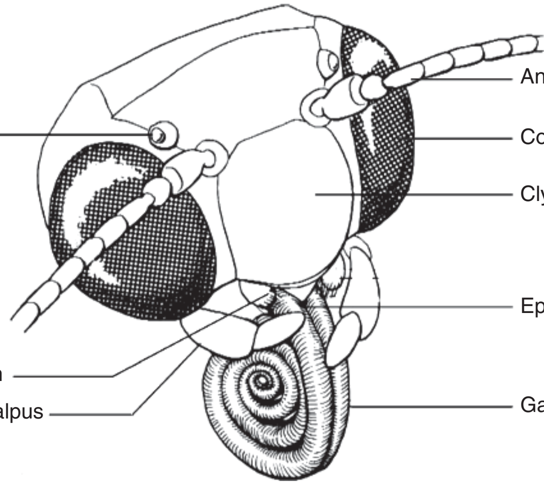
In the orthognathous or hypognathous condition, the mouthparts are situated more or less perpendicular to the cephalocaudal axis. This model is differentiated in phytophagous insects that feed on solid particles and in some predators. In the prognathous condition the oral cavity is situated in the anterior ventral part of the head, and the mouthparts are directed forward. Modifications of certain parts of the head capsule result, such as a tendency to incorporate the clypeus into the frons, a shortening of the occipital areas, and a lengthening of the structures that form the ventral closure of the head. The prognathous condition is represented in many hexapod orders, being considered a primitive condition (for example, Embiidina, Isoptera and Dermaptera) or secondarily acquired (larvae of Neuroptera, mining caterpillars and certain beetle larvae). The prognathous condition is characterized by the predatory species, whose adults actively hunt their prey. The condition is also found in some larval forms (particularly in Coleoptera) that use their mandibles for burrowing.

The opisthognathous condition is characterized by the oral cavity being (Fig. 17) situated in the posterior ventral part of the head and the mouthparts directed toward the back, being held at rest between the anterior legs (Hemiptera).

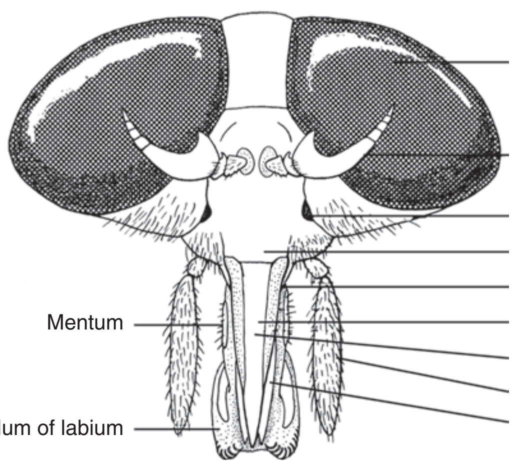
There exists a tendency for the ventral closure of the head to be differentiated into two types of head or cranial capsules: open and closed. In the first case, the foramen magnum is bordered ventrally by the proximal margin of the submentum, having the metatentorinae in the inferior extremes of the occipital suture, near the foramen magnum. Nevertheless, the most frequent case is where the labium is separated from the foramen magnum by a more or less wide, sclerotized band. This band can be situated anteriorly to the metatentorinae,



Head of Hexapods, Figure 17 **Front view of cicada head (Hemiptera: Cicadidae).**



Head of Hexapods, Figure 18 **Dorsolateral view of a moth head (Lepidoptera).**



Head of Hexapods, Figure 19 **Front view of a horse fly head (Diptera: Tabanidae).**

forming the hypostomal or postgenal bridge, or it can be posterior to the metatentorinae, forming the gula. These sclerotized formations can occupy a great part of the ventral zone of the head, with the consequent displacement of the mouthparts (Fig. 21) toward the front. The prognathous condition discussed earlier originated in this manner.

The hypostomal bridge is formed by the union of two lobes that are of mixed origin (each one is formed beginning from the hypostoma and the postgena). Clear examples of this bridge exist in advanced Hymenoptera and Diptera.

The gula constitutes a sclerotized zone that prolongs the submentum behind the metatentorinae, which are advanced, and it is separated from the postgenae by the gular sutures. The origin of the gula is disputable, and although it probably pertains to what is called labial, some attribute its origin starting from the neck and including the prothoracic region. Clear examples of the presence of the gula are found in certain beetles.

Heer, Oswald

Oswald Heer was born in Matt, a mountain village in Switzerland, on August 31, 1809. His interest in natural history was aroused there. In 1828, he went to Universität Halle in Germany to study theology (his father was a priest) and there met several renowned naturalists. He was ordained in St. Gallen, Switzerland, but also pursued natural history. In 1832, he obtained the post of curator of the Escher-Zollikofer natural history collection in Zurich. Two years later he became docent of botany and zoology of Universität Zurich, and in 1835 professor of botany there. His work on paleobotany and paleozoology was perhaps his most notable research contribution. Nevertheless, his multi-part "Fauna Coleopterorum Helvetica" was seminal for Swiss

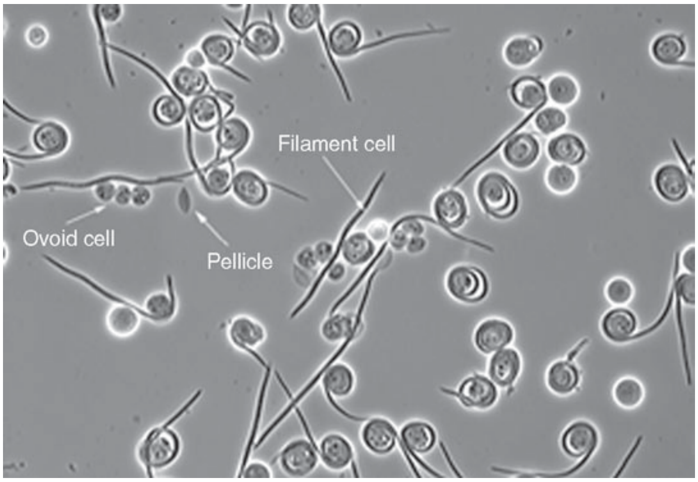
Helicosporidium

AURÉLIEN TARTAR
University of Florida, Gainesville, FL, USA

To date, there is only one named species of Helicosporidia: *Helicosporidium parasiticum*. It was initially described and named by Keilin in 1921, who detected this protist in larvae of *Dasyhelea obscura* Winnertz (Diptera: Ceratopogonidae) collected in England. He examined the new parasite thoroughly and attempted to infer its life history from his observations. He described a vegetative growth characterized by very active multiplications of helicosporidial cells inside the body cavity of the host, and noticed that these "schizogonic multiplications" were followed by the formation of what he called spores. Keilin noted that the spores are very easily recognized; they consist of the assembly, inside an external membrane, of three ovoid cells (named by Keilin "sporozoites") and one peripheral, spiral, filamentous cell. These features, especially the highly characteristic filamentous cell, have since remained the principal diagnostic for identification of a *Helicosporidium* sp. Keilin was able to describe and characterize structurally the new genus *Helicosporidium*, and the new species *H. parasiticum*. He also was able to present a hypothetical life cycle of this protist based on his microscopy observations. He suggested that the spores (or cysts) break open in the host hemocoel, releasing the filamentous cell and the three "sporozoites," which he proposed are the infective forms of *H. parasiticum* (Fig. 24). Keilin believed that *H. parasiticum* belonged to the Protozoa, and compared this isolate with members of various clades: Cnidiosporidia (which, at that time, included Microsporidia such as *Nosema bombicis*), Haplosporidia, Serumsporidia, and Mycetozoa. He concluded that the genus *Helicosporidium* differed markedly not only from all these groups, but also from all the protists known at that time. He finally proposed that *Helicosporidium* "forms a new group, which may be temporarily be included in the group of the Sporozoa."



***Helicosporidium*, Figure 24** **Light micrograph of dehisced *Helicosporidium* sp. cysts. Following rupture of the pellicle, one filamentous cell and three ovoid cells are released from each cyst.**

Following the discovery of another isolate of *Helicosporidium parasiticum* in a larva of *Hepialis pallens* (Lepidoptera: Hepialidae), another taxonomic position was proposed for the group Helicosporidia. Based on observation of this new isolate as well as the original specimen described by Keilin, Weiser claimed that the Helicosporidia are best placed among the lower Fungi. He argued that the spore characteristics are much too different from what is found in Protozoa, but are similar in some aspects to primitive Fungi, such as insect pathogens of the genus *Monosporella*, classified as Nematosporoideae inside the Saccharomycetaceae (primitive Ascomycetes).

In the early 1970s, *Helicosporidium parasiticum* was isolated from larvae and adults of the beetle *Carpophilus mutilatus* (Coleoptera: Nitidulidae). This isolate was infectious per os to 18 species of arthropods, including three orders of insects (Lepidoptera, Coleoptera, Diptera) and one family of mites. In contrast, species of Orthoptera, Hymenoptera, and Diptera were not susceptible to this isolate. The spores (cysts) present in the host artificial diet were ingested and released the three round cells and the filamentous cells in the host midgut. After 24 h, helicosporidial cells appeared in the host hemolymph and grew vegetatively. The vegetative growth is characterized by cell division that occurs within a pellicle. After division, the pellicle ruptures and releases the daughter cells (4 or 8). Empty pellicles and daughter cells eventually fill the entire host hemocoel. Daughter cells then develop into spores, in which the filamentous cell differentiates and encircles the three round cells. Additional studies reported the presence of *Helicosporidium* sp. in new host species such as crustaceans, mites, collembolans, and trematodes.

In 1999, a *Helicosporidium* sp. was discovered in larvae of the black fly *Simulium jonesi* Stone & Snoddy (Diptera: Simuliidae). This isolate was demonstrated to grow under both in vitro and in vivo conditions. In vivo, the ingested helicosporidial cysts dehisced and released the three ovoid cells and the filamentous cells. The filamentous cells attached to the peritrophic membrane and penetrated the midgut epithelium initiating infection. The in vitro growth of *Helicosporidium* sp. was reminiscent of that reported for unicellular, achlorophytic algae belonging to the genus *Prototheca*. Both the genera *Helicosporidium* and *Prototheca* are characterized by a vegetative growth that consists of cell divisions inside a membrane. Four, eight, or sixteen daughter cells are produced inside this pellicle and eventually are released. Such cell divisions result in the accumulation of both round daughter cells and empty pellicles. The suggestion that *Helicosporidium* was related to algae has been confirmed by molecular analysis. The 18S, 26S, 5.8S regions of the *Helicosporidium* ribosomal DNA, as well as some partial sequences of the actin and tubulin genes, were sequenced. Comparative analyses of these nucleotide sequences were performed in order to evaluate the position of *Helicosporidium* sp. within the phylogeny of eukaryotes. All trees depicted *Helicosporidium* sp. as a green alga (Chlorophyta), and as sister taxon to the genus *Prototheca* (class Trebouxiophyceae). This association always was supported by significant bootstrap values. On the basis of this phylogenetic analysis, *Helicosporidium* sp. is clearly neither a protozoan nor a fungus, but represents the first described algal invertebrate pathogen.

A family of bugs (order Hemiptera).

► Bugs

Hematophagous

(haematophagous) Insects that feed on blood.

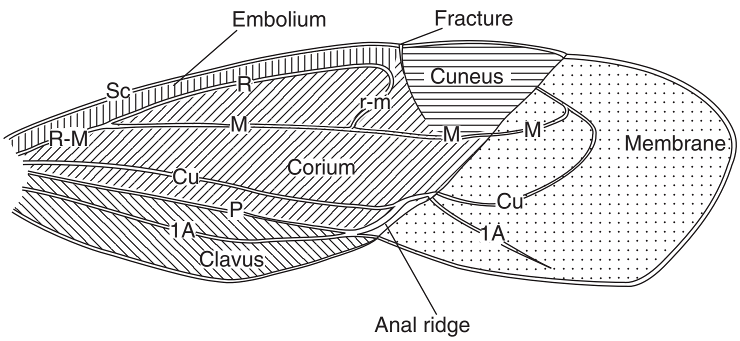
Hematophagy

(haematophagy) Feeding on blood. Usually this refers to arthropods that bite to obtain blood, but secondary hematophagy also is possible, wherein arthropods feed at a bleeding wound, with the wound accidental or inflicted by another organism.

Hemelytron (pl. hemelytra)

The front wing of insects in which the basal portion in thickened and the distal portion membranous (Fig. 25), usually Hemiptera.

► Wings of Insects



Hemelytron (pl. hemelytra), Figure 25 **Front wing of a bug (Hemiptera: suborder Heteroptera), thickened basally and membranous distally.**

Hemerobiidae

A family of insects in the order Neuroptera. They commonly are known as brown lacewings.

► Lacewings, Antlions and Mantidflies

Hemipsocidae

A family of psocids (order Psocoptera).

► Bark-Lice, Book-Lice or Psocids

Hemiptera

An order of insects. Many of these insects are called bugs, or true bugs, but this is a very diverse assemblage, and includes leafhoppers, treehoppers, cicada, scales, aphids, whiteflies, and many others. Hemiptera is sometimes treated as two orders: Hemiptera and Homoptera.

► Bugs

Hemimetabolous Development

Insects having incomplete metamorphosis, or a gradual change in body form with each molt, and wings developing externally. A subset of insects (Odonata, Ephermeroptera, Plecoptera) with a modified form of hemimetabolous development are said to have paurometabolous development. The hemimetabolous insects (including paurometabolous insects) lack the pupal stage that is found among insects with holometabolous development. The immature forms of hemimetabolous insects are called nymphs, though some entomologists call all immature insects larvae, regardless of developmental pattern. (contrast with holometabolous development)

► Metamorphosis
► Complete Metamorphosis
► Incomplete Metamorphosis

Hemocoel

(haemocoel) The hemolymph (blood)- filled body cavity of arthropods.

Hemocoelic Insemination

Female bed bugs (Hemiptera: Cimicidae) are inseminated by the male's needle-like penis, which can be inserted in many locations in the female's body, because the sperm migrate through the hemolymph to the ovary. This process may provide additional nutrients to the female, but certainly other insects do this in less traumatic ways. This process is also called "traumatic insemination."

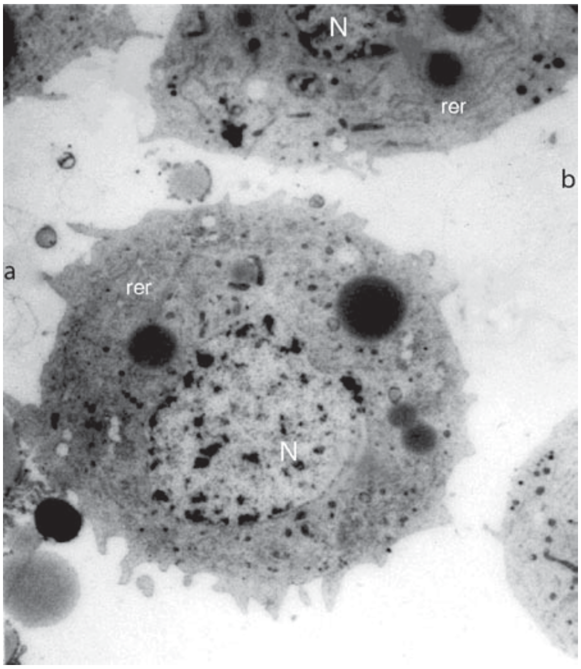
► Bed Bugs

Hemocytes of Insects: Their Morphology and Function

PAULINE O. LAWRENCE
University of Florida, Gainesville, FL, USA

Hemocytes are blood cells that circulate in a clear fluid, the plasma, within the hemocele (body cavity) of insects. The hemocytes, plasma, and dissolved inorganic and organic molecules constitute the hemolymph. Nutrients, nitrogenous waste products, hormones, and a variety of other substances also are transported in the hemolymph for distribution to various tissues. In most insect larvae, the hemocytes are produced within hematopoietic (hemopoietic) organs (blood cell producing factories) where they replicate and differentiate. The number and types of hemocytes vary with insect species, developmental stage, and physiological state. In general, total hemocyte count (the number of hemocytes per unit volume) increases throughout larval development, reaching a maximum at each larval ecydsis but probably not during pupal/adult ecdysis. Qualitative and quantitative fluctuations in hemocyte populations also may be influenced by endocrine events as well as by wounding and microbial and parasitic infections.

The classification of insect hemocytes has been based primarily on the morphology of cells observed under the light and electron microscopes. While all hemocyte types described to date do not occur in all insects, the six recognized and most common types are: adipohemocytes, granulocytes, oenocytoids, plasmatocytes, prohemocytes, and spherule cells. Adipohemocytes vary in size and are ovoid with well-defined lipid droplets and granular cytoplasm with rough endoplasmic reticula (RER) and Golgi complexes, indicative of synthetic and secretory functions. Granulocytes vary in size and shape and have a small nucleus: cytoplasm ratio and small, uniform acidophilic cytoplasmic inclusions. Their cytoplasm is richly supplied with an elaborate network of RER, Golgi vesicles and other organelles. In studies of the encapsulation process in Lepidoptera, granulocytes were determined to attach to, and release their contents (degranulate) on, the surface of a foreign object during the initial phase of capsule formation, and to release cytokines that recruit plasmatocytes (Fig. 26) to the site. The innermost cells of the capsule then flatten and develop desmosomes that hold the cells together. Gap-junctions develop between cells of the external and internal layers of the capsule, providing an intercellular pathway presumably for nutrients, hormones, and probably cytokines for intercellular signaling, and for other factors needed to maintain the integrity of the capsule. Granulocytes are presumed to arise from plasmatocytes, and their



Hemocytes of Insects: Their Morphology and Function, Figure 26 Transmission electron micrograph of a spherical (discoid) plasmatocyte (a) from the third instar of the Caribbean fruit fly, *Anastrepha suspensa* (Diptera: Tephritidae). Three populations of discoid plasmatocytes occur in *A. suspensa*, ranging from 10–25 μm in diameter. (b) Portion of a lamellocyte showing rough endoplasmic reticula (RER). Lamellocytes are 15–20 μm long and 6–10 μm wide. N = nucleus. (Micrograph by P.O. Lawrence.)

population ranges from 30 to 65% of the total hemocyte count. Some authors consider cystocytes (also called coagulocytes) to be a small form of granulocytes because they are presumed to participate in the coagulation process. Like granulocytes, cystocytes have acidic cytoplasmic inclusions and a small nucleus. Because their cell cytoplasm is translucent, cystocytes sometimes are called hyaline cells. To date, cystocytes have not been identified in lepidopterans, dipterans or hymenopterans.

Oenocytoids are large (18–38 μm in diameter), sometimes with two eccentric nuclei and an acidophilic cytoplasm. They have numerous microtubules and few synthetic organelles. They also exhibit endogenous phenoloxidase activity and are presumed to participate in the process of melanization (melanosis), often associated with wound healing and encapsulation. Plasmatocytes usually represent more than 28% of the total hemocyte population in most insects. They are pleiomorphic, varying in size and shape from round (discoid), to spindle-shaped (lamellocytes) and have a single nucleus that occupies about 40–50% of the granular, basophilic cytoplasm. They possess RER and Golgi organelles, indicative of a synthetic function. They are motile and phagocytic, with lysosomal vesicles, and are the primary line of defense in the insects' cellular response to microbial infection. Indeed, they release substances that induce degranulation of the granular hemocytes during the final stage of encapsulation. They also participate in other defense-related processes such as nodulation and, along with cystocytes, in plasma coagulation. Podocytesare considered by some authors to either arise from, or be a form of, plasmatocyte. Prohemocytes are thought to be the smallest blood cells. They are round with a large nucleus:cytoplasm ratio, and basophilic, but are devoid of synthetic organelles (e.g., endoplasmic reticula, etc). They undergo mitosis, presumably giving rise to prohemocytes, plasmatocytes, and probably to granulocytes. Thus, they are considered the hemocyte stem cells. Spherulocytes (spherule cells) are ovoid and usually are larger than prohemocytes, but smaller than some plasmatocytes. In some cases, spherulocytes represent about 4% of the total hemocyte population. Their cytoplasm appears to contain large acidophilic inclusions. Other hemocytes such as podocytes and vermiform cells could be forms of plasmatocytes, but neither their origins nor specific functions are known.

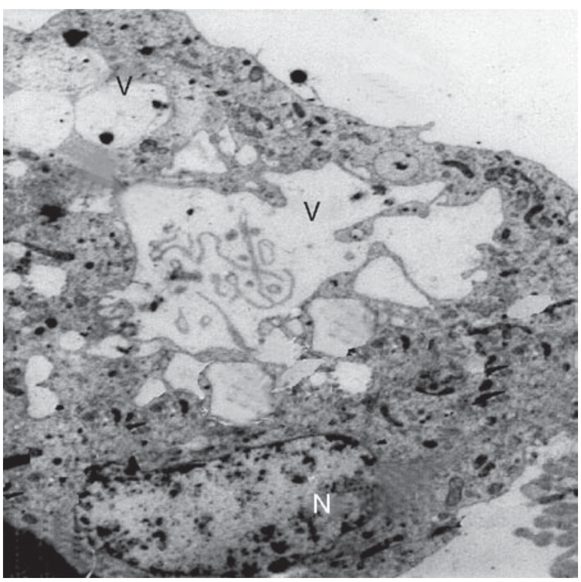
Larval dipterans have hemocytes (e.g., prohemocytes, plasmatocytes, and oenocytoids) similar to some found in other insects. However, they are thought to lack true granulocytes and spherule cells. Indeed, some authors consider previously described "spherule cells" and "granulocytes" of some Diptera (e.g., *Calliphora erythrocephala*) to be plasmatocytes and thrombocytoids, respectively. True spherule cells are thought to be absent in dipterans while thrombocytoids, crystal cells, and vacuolated cells are presumed to be unique to dipterans, although they do not occur in all species.

Crystal cells, unique to drosophilids, are 10–12.2 μm with a nucleus of 3.5–5 μm in diameter and comprise 5–10% of the total hemocyte count. They characteristically have large cytoplasmic paracrystalline inclusions that are presumed to contain tyrosine, a substrate of phenol oxidase. Consequently, upon disruption, these cells release their contents, causing melanosis which is important in wound healing and other defense responses. Since oenocytoids of other dipterans, and indeed other insects, are known to have endogenous phenol oxidase activity and are involved in wound healing, it is likely that the crystal cells of *Drosophila* are at least analogous, if not homologous to them.

Thrombocytoids are round cells with numerous invaginations of the plasma membrane that penetrate deep into the cytoplasm close to the nucleus. Based on in vitro studies, thrombocytoids are presumed to phagocytose bacteria, and to participate in encapsulation and wound healing. They disintegrate within the hemolymph to give rise to cytoplasmic fragments and naked nuclei. Thrombocytoids are absent from *Drosophila* sp.

and culicid mosquitoes, but occur in calliphorids and tipulids.

Vacuolated cells (Fig. 27) are 14–23 μm in diameter and are characterized by extensive vacuolation of the cytoplasm, presumably the result of invaginations of the cell membrane. Numerous free ribosomes, RER, Golgi bodies, and mitochondria are dispersed throughout the cytoplasm. Vacuolated cells are <20% of the total hemocyte count. These cells are presumed to be unique to the Diptera, although do not occur in all species. They have been reported from larval sciarids, the fruit fly *Anastrepha suspensa*, and from mutant *Drosophila melanogaster* that have a lethal malignant blood neoplasm (lmbn) (i.e., melanotic tumors of the hemocytes). These tumerous blood cells [l(2)mbn] when cultured in vitro, readily differentiate into hemocyte morphotypes that correspond to plasmatocytes, lamellocytes, podocytes, and vacuolated cells of the wild type (normal) larvae. Lamellocytoids (apparent homologs of the lamellocytes in vivo) were transformed to vacuolated-like cells in vitro upon treatment with the insect molting hormone 20-hydroxyecdysone (20-OHE). Interestingly, the combined application of juvenile hormone III (the predominant juvenile hormone found in dipterans) and related JH agonists, along with 20-OHE, counteracted the effects of 20-OHE alone. Given the respective roles of JH and 20-OHE in the maintenance of larval characteristics and induction of metamorphosis, it is likely that the incidence of vacuolated cells in dipterans may be influenced by hormonal and/or related developmental events, as is apparently the case with certain other hemocytes.



Hemocytes of Insects: Their Morphology and Function, Figure 27 **Transmission electron micrograph of a portion of a vacuolated hemocyte from the third instar of the Caribbean fruit fly, *Anastrepha suspensa*. These vacuolated cells are 25–30 μm in diameter (compared to 14–23 μm in other dipterans). N = nucleus, V = vacuoles. (Micrograph by P.O. Lawrence.)**

The behavior and function of hemocytes are influenced by the release of humoral factors such as cytokines, cell adhesion molecules, lectins, and agglutinins that mediate intercellular communication. The receptors for these factors have not been fully characterized, and neither is their distribution among the different hemocytes.

Overall, it appears that certain hemocytes, such as the plasmatocytes, have similar morphology and ultrastructure across the various insect families. Indeed, techniques have been used to establish criteria that facilitate interspecies comparisons and classification of some hemocytes. These include the use of electron microscopy, the development of monoclonal antibodies for specific hemocytes, and histochemistry. Nevertheless, additional approaches are needed to identify unique characteristics of hemocyte types and facilitate meaningful interspecies and within species comparisons. The plasticity in hemocyte morphology as a result of normal ontogeny, stage specific factors, and hormonal or environmental events demands additional approaches to provide insights into hemocyte identity within and between species and families. Likely technologies include differential display, microarrays and glycobiology.

Henneguy, Louis Félix

Félix Henneguy was born in Paris on March 18, 1850. He studied medicine, was an assistant in physiology in Montpellier (1871–1875) and earned a doctorate in medicine there. He moved to Paris in 1881 and became a preparator in comparative embryology at the Collège de France. He earned a doctorate in science in 1888. In 1900 he became a professor of comparative embryology. In 1907 he was elected member of the Academie de Médecine, and in 1908 of the Academie des Sciences. His other interest, in entomology, led to his (1904) book "Les insectes" which emphasizes morphology and embryology. He also contributed some shorter entomological papers. He died on January 28, 1928.

Hennig, Willi

Willi Hennig was born in Durhennersdorf, Germany, on April 20, 1913. As a youth, he collected beetles and butterflies, was interested in birds and reptiles, started a herbarium, and liked to visit the zoological museum in Dresden. In 1932, he entered Universität Leipzig to study zoology, botany and geology. He graduated in 1936, having written a thesis on the copulatory organ of cyclorraphous Diptera, and also having published eight papers. He trained briefly at the zoological museum in Dresden, then went to the Deutsche Entomologische Institut in January 1937. By 1939 he had published some 41 papers, most of them on flies. But, in the spring of 1939, he was drafted into the German army, in which he served as infantryman and was wounded. Next, he was sent by the German army to northern Italy, to work in malaria control. Captured by British troops, he continued to work in malaria control. Before he was sent home to Germany, he drafted a manuscript under the title "Grundzüge einer Theorie der phylogenetischen Systematik." Even during the war he published, including about his work in malaria control. After returning to Germany, he spent some months in several cities, including 13 months at Universität Leipzig, until in April 1947 he was able to return to the Deutsche Entomologische Institut in Berlin. He continued to work on his manuscript on larval forms of Diptera, which eventually was published (beginning in 1948, in three volumes) as "Die Larvenformen der Dipteren." He worked some more on his "Grundzüge einer Theorie…" and then published it in 1950. Numerous other publications followed, but then the government of East Germany in 1961 built a wall across the city of Berlin. Hennig could no longer travel from his home in West Berlin to the institute in East Berlin. Instead of emigrating to what was then the communist country of East Germany, he resigned from his job, and taught for 2 years at the Technische Universität in Berlin. Then, he moved with his family to Ludwigsburg (West Germany) in 1963. He resumed an earlier interest in fossil insects, and published (1964–1972) 17 papers on Diptera from Baltic amber and three on fossils from Lebanese amber. The insight this gave him resulted in his (1969) book "Die Stammesgeschichte der Insekten," translated (1981) to English as "Insect phylogeny." Meanwhile, his "Grundzuge…" had been translated to English as (1966) "Phylogenetic systematics," whose translation and concomitant editing did not please Willi. A German edition, truer to its author' s intent, was published (1982) as "Phylogenetische Systematik." He continued working on taxonomic revisions of flies of the palearctic region, and published works on the families Muscidae (1955–1964) and Anthomyiidae (1966–1976) in Lindner's multivolume work "Die Fliegen der palaearktischen Region," which were his 13th and 14th contributions to this work. He was appointed associate professor at Universität Tübingen in 1970, and gave lectures there, and he was co-editor of the journal Zeitschrift für Morphologie der Tiere/Zoomorphologie. In his last year, he was working on a revised edition of "Die Larvenformen der Dipteren." He had a very important influence on biology as a whole because of his phylogenetic theory, even taking into account his dissatisfaction at its translation into English. He died on November 4, 1976, survived by his always-supportive wife and their three sons.

Herman, Ottó

GEORGE HANGAY
Narrabeen, NSW, Australia

Ottó Herman was born on June 26, 1835 at Reznóbánya, in Zólyom Shire, Hungary. He was introduced to natural sciences, especially the study of birds, at an early age, as his father was a medical practitioner and keen amateur ornithologist. However, the 1848 Hungarian Revolution and freedom fight against the Austrian Empire interrupted young Ottó's formal studies. Probably he wasn't the best of students anyway, because shortly after the revolution, his father decided that scholastic life wasn't the way for his son, who continued his career as a locksmith's apprentice. Later he went to

Vienna and enrolled in the polytechnic college, but upon the death of his father, once again he discontinued his formal studies. This didn't mean that his interest in natural history dwindled, rather the contrary, he begun to educate himself by autodidactic methods and soon built up a reputation as an outstanding naturalist, versed in many aspects of zoology, botany and ethnography. In 1875 he was appointed as assistant curator of the Hungarian National Museum's zoological collections. By then he was immersed in the research of spiders, and between 1876 and 1879 he published his major entomological work: "The Spider Fauna of Hungary," in three volumes. In 1877 he founded a journal entitled "Natural History Notebooks" (Természetrajzi Füzetek). He remained the editor of this journal for 10 years, during which it became one of the most popular scientific publications of the country. In 1888 he embarked on a North European and Sub-Arctic expedition, following the route of migratory birds. He passed away on December 27, 1914. Ottó Herman produced eminent works in a number of scientific disciplines. Beside entomology, he explored the bird and fish fauna of Hungary, conducted ethnographical studies, directed palaeontologic and historical excavations, and initiated the establishment of nature reserves and the protection of the natural environment. He produced 14 books and a great number of scientific articles. He is regarded as one of the most outstanding pioneers of natural history studies in Hungary.

Herrich-Schäffer, Gottlieb August

Gottlieb Herrich-Schäffer, son of a medical doctor, was born in Regensburg, Germany, on December 17, 1799. He was influenced in his early interest in natural history by his great uncle. By 1817 he had formed a collection of Lepidoptera and other insects. In 1818 he entered Universität Würzburg, and obtained a medical degree in 1821. However, he used his holidays to travel to Erlangen in 1919, to Heidelberg in 1820, to Berlin in 1821, and to Munich in 1822 to further his entomological interests with time spent in the field. In 1824 he began practicing as a medical doctor in public service and, at the retirement of his father from such service in Regensburg, he returned there in 1828 to take the vacant position. He occupied this position until his retirement in 1856. In 1832 he befriended C.L. Koch, who was a forestry official for the Regensburg region (and entomologist), learned to engrave, and provided 960 engraved plates for a supplement to Panzer's "Faunae insectorum germaniae initia." He continued Hübner's "Sammlung europäischer Schmetterlinge." In 1835 he published the first part of his own "Nomenclator entomologicus." In 1843 he published the first part of his greatest work, "Systematische Bearbeitung der Schmetterlinge von Europa," with Geyer as its illustrator, completed in 1856 in six volumes. Other works followed, including works on exotic species such as "Die Schmetterlinge der Insel Cuba." He used to lead insect-collecting expeditions composed of family members and friends in the countryside surrounding Regensburg. He died in Regensburg on April 14, 1874, leaving a son and four daughters.

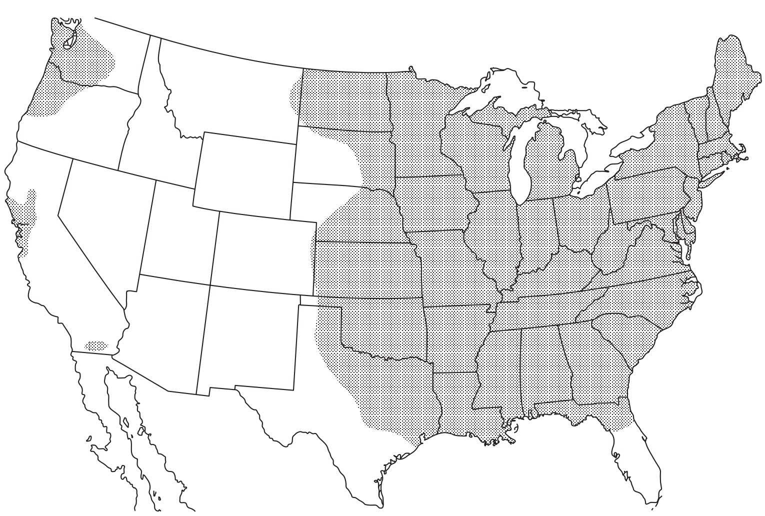
Hessian Fly, *Mayetiola destructor* (Say) (Diptera: Cecidomyiidae)

RICHARD H. SHUKLE
U.S. Department of Agriculture, Agricultural Research Service, West Lafayette, IN, USA

The Hessian fly, *Mayetiola destructor*, is a destructive pest of wheat and occurs in most wheat-growing areas of the United States (Fig. 29) and most other production areas of the world. It is thought to be endemic to the southern Caucasus and southwest Asia, the center of origin of the genus *Triticum* L., and to have dispersed to Europe, North Africa and North America. While chiefly injurious to wheat, at times it causes some damage to barley, rye and triticale. It also can be found on wild grasses such as *Agropyron repens* (L.), *Elmus virginicus* L., *Hordeum pusillum* Nutt., and *Aegilops* sp., which may serve as hosts when wheat is not available. The insect received its common name from Americans when it was found infesting wheat on Long Island, New York, in 1779, and it was believed Hessian mercenaries serving with Lord Howe's army 3 years earlier had brought the pest from Europe in bedding straw.



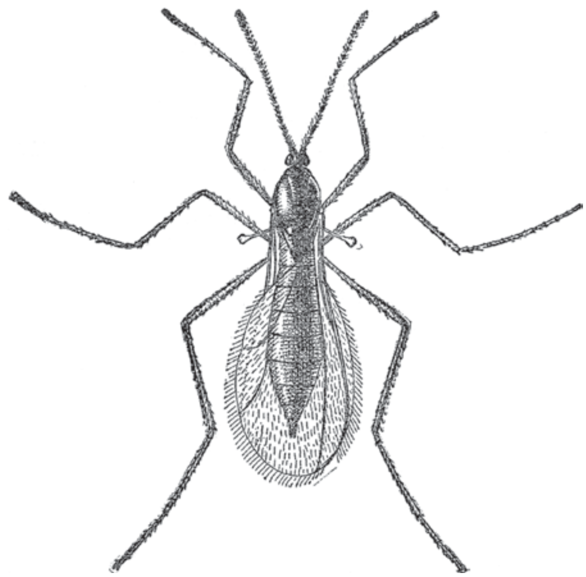
Hessian Fly, *Mayetiola destructor* (Say) (Diptera: Cecidomyiidae), Figure 29 Distribution of the Hessian fly within the United States. (from Foster, J. E., P. L. Taylor, and J. E. Araya. 1986. The Hessian fly. Department of Entomology Agricultural Experiment Station Bulletin 502, Purdue University, West Lafayette, Indiana.)

Interestingly, the insect was not reported in England until 1886. It has been recorded in Russia from 1847 onward, especially in the Ukraine, and has been recognized as a serious pest of wheat in Morocco, Algeria and Tunisia since the early 1900s.

Life History

As with other flies, development in the Hessian fly has four life stages: egg, larva, pupa and adult. Adults are small dark to black midges about 3 mm long and live for 2–3 days after they emerge. Females emit a sex pheromone to attract males with mating taking place soon after emergence. As in other members of the Cecidomyiidae, individual Hessian fly females generally produce all male or all female progenies, with the sex of a progeny determined by the female. Shortly after mating, females begin to deposit eggs in the grooves along the veins on the upper surface of the leaves of wheat. The eggs are glistening-red, cylindrical and about 0.5 mm long. They hatch in 3–7 days depending on temperature, and the larvae crawl down the leaves to feed near the crown in seedlings or at the nodes during culm elongation. First-instar larvae also are red but begin to turn white within a few days. Second-instar larvae are white, cylindrical and about 4 mm long when mature. The cuticle of the mature larva hardens and turns a dark brown forming a puparium, which is commonly called a "flaxseed" because it resembles the seed of flax. Pupation occurs within the puparium.

In northern winter wheat areas, there are typically two generations a year. In the fall, adults (Fig. 30) that emerge from infested wheat stubble infest volunteer wheat or early fall-seeded fields. Larvae in the fall generation are found in the leaf sheath at, or near, the crown. With the onset of cold weather, the mature larva forms a protective puparium in which it over-winters. In the spring, these larvae pupate within the puparium and adults emerge and infest wheat plants about the time they begin to joint. Larvae in the spring generation are found above the nodes (frequently the second node) under the leaf sheaths. Larvae pass the summer within the puparia in dry wheat stubble. In late summer or fall, the larvae pupate and adults emerge to infest volunteer or early-seeded wheat. In southern winter wheat areas, supplementary broods can develop either before or after the main fall generation, or after the main spring generation. In Canada and the northern spring wheat areas of the United States, only one annual spring generation occurs.



Hessian Fly, *Mayetiola destructor* (Say) (Diptera: Cecidomyiidae), Figure 30 **Hessian fly: adult female. (from Webster, F. M. 1915. The Hessian fly. USDA Farmers' Bulletin 640 – author's illustration.)**

Injury to Wheat

Damage in wheat is due entirely to feeding by larvae. In fall infestations, larval feeding results in stunting (Fig. 31) and development of a dark green color in infested primary culms or tillers and can lead to the death of seedling plants. In spring infestations, larval feeding prevents normal elongation of internodes, transport of nutrients to developing grain and results in lodging at the nodes. The mouthparts of larvae are highly specialized mandibles that are thought to inject salivary secretions into the plant. These secretions are believed to contain enzymes that inhibit plant growth, increase the permeability of cell membranes, and soften cell walls.

Hessian Fly, *Mayetiola destructor* (Say) (Diptera: Cecidomyiidae), Figure 31 **Fall-infested wheat seedling showing typical stunting. A non-infested tiller is shown on the left for comparison. (from Foster, J. E., P. L. Taylor, and J. E. Araya. 1986. The Hessian fly. Department of Entomology Agricultural Experiment Station Bulletin 502, Purdue University, West Lafayette, Indiana – illustrator G. Safranski.)**

While economic threshold levels have not been established for Hessian fly infestations, evaluation of injury and loss of winter wheat grain yield indicates significant damage occurs when fall infestations exceed 5–8% of tillers, or when spring infestations exceed 13–20% of stems. When 10% of tillers are infested in the fall or 20% of stems in the spring, grain yield loss is estimated at about 250 kg/ha. Historically, the Hessian fly has caused losses estimated at $100 million in a single year. Recently, losses in Georgia were estimated at $4 million in 1986, and at $28 million in 1989. Damage from Hessian fly also has been reported in other southern states; in Texas, losses estimated at $5 million were reported in 1984.

Control

Because many biotic and abiotic factors regulate the abundance of the Hessian fly, when and where economic infestations may occur is not easily predictable. Thus, control measures for Hessian fly are primarily preventive rather than remedial. Prevention of infestation is achieved through (i) planting resistant wheat varieties, (ii) delaying seeding of winter wheat to escape fall infestation, (iii) destruction of volunteer wheat. The use of resistant varieties is the most economically and environmentally sound method of control, and has been employed for the past 50 years. Insecticides are seldom used for control of Hessian fly. Once larvae have entered the leaf sheath, a systemic insecticide is required, and research has demonstrated that resistant wheat varieties are as effective in controlling damage as application of systemic insecticide at seeding. If resistant varieties are not seeded, infestations can be reduced by cultural practices (i.e., delayed planting and destruction of volunteer wheat). In much of the United States cultural practices are effective in reducing infestations in winter wheat. However, in the southern United States, delayed planting is not as effective as it is in northern winter wheat areas because oviposition and development of larvae can occur throughout the winter.

Hessian fly Resistance in Wheat

Resistance to Hessian fly has been identified in common and durum wheat, wild wheat and rye. Resistance in these sources is expressed as larval antibiosis; larvae die within 3 days and do not injure the wheat. Resistance generally is controlled by single genes that are partially to completely dominant. To date, twenty-nine major genes controlling Hessian fly resistance in wheat, designated *H1* through *H29*, have been described. Other genetic factors for resistance are those derived from Kawvale and Marquillo wheat. The genetic control of resistance in Kawvale has not been determined. Several recessive genes might control the resistance in Marquillo. However, recent work has suggested the resistance is controlled by a temperature-sensitive, partially dominant gene designated *H18*. The molecular/biochemical basis of resistance in wheat to the Hessian fly has not been determined for any gene. However, cytological studies support the hypothesis that a hypersensitive reaction is the phenotypic basis of resistance in the Hessian fly/wheat interaction and involves "recognition" of an avirulence gene product or process.

Hessian fly Biotypes

The existence of life types or "biotypes" of Hessian fly, capable of infesting resistant wheat, has been known for many years. These biotypes describe populations that vary in host-adapted alleles. Virulence, the ability of Hessian fly larvae to survive on and stunt plants, is controlled by recessive genes at single loci and operates on a gene-for-gene basis with resistance. Presently, sixteen defined biotypes, Great Plains (GP) and A through O, have been identified in field populations by their reaction in a differential set of four wheat genes for resistance *H3*, *H5*, *H6* and *H7/8*. The Great Plains Biotype is avirulent with respect to each of these genes for resistance, while Biotype L is virulent on each of these genes.

Management and durability of resistance

The development of virulent biotypes of the Hessian fly capable of surviving on and stunting formerly resistant wheat is the greatest threat to the durability of resistance. Several factors in the biology of the Hessian fly can affect the development of virulent biotypes. Dispersal by adults is limited; adults are short-lived (2–3 days) and oviposition by females begins one to three hours after mating, limiting time spent in dispersal. These factors restrict local gene flow, which can increase the probability of recessive mutations for virulence becoming homozygous in a population. In opposition to this are the observations that virulent larvae can affect the expression of resistance in wheat and allow avirulent larvae that co-infest to survive. Survival of avirulent larvae would reduce selection pressure for virulence in populations and slow the increase in frequency of virulence alleles associated with selection from resistant cultivars.

The deployment strategy implemented also can affect the durability of resistance genes to Hessian fly in wheat. A sequential release program has been utilized to date. Under this regime, a single gene is released in cultivars and used until it begins to lose effectiveness in the field (generally 6–10 years), at which time new biotype specific resistance genes are released. Another strategy is to stack or pyramid multiple resistance genes. This strategy has not been utilized to date because of a lack of suitable markers to monitor incorporation of multiple resistance genes; however, the development of molecular markers will allow implementation of this strategy.

Heterobathmiidae

A family of moths (order Lepidoptera). They commonly are known as Valdivian archaic moths.

► Valdivian Archaic Moths

► Butterflies and Moths

Heteroceridae

A family of beetles (order Coleoptera). They commonly are known as variegated mud-loving beetles.

► Beetles

Heteroecious Life Cycle

A life cycle where there is alternation of host plants by insects (generally aphids) through the season. In species with this type of life cycle, typically the autumn, winter and spring are spent on a woody (primary) host plant and summer is spent on an unrelated herbaceous (secondary) plant. (contrast with autoecious life cycle)

► Aphids

Heterogamy

Alternation of bisexual and parthenogenetic reproduction.

Heterogastridae

A family of bugs (order Hemiptera, suborder Pentamorpha).

► Bugs

Heterogynaidae

A family of wasps (order Hymenoptera).

► Wasps, Ants, Bees and Sawflies

Heterogynidae

A family of moths (order Lepidoptera) also known as Mediterranean burnet moths.

► Mediterranean Burnet Moths

► Butterflies and Moths

Heteronemiidae

A family of walkingsticks (order Phasmatodea). They commonly are known as common walkingsticks.

► Walkingsticks and Leaf Insects

Heteroptera

Sometimes considered to be suborder of Hemiptera, containing the "true bugs."

► Bugs

Heterosis

Also known as hybrid vigor.

Heterotroph

An organism that obtains energy and other materials by eating other organisms. (contrast with autotroph)

Heterothripidae

A family of thrips (order Thysanoptera).

► Thrips

Heterozygosity

Having a pair of dissimilar alleles at a locus; a measure of genetic variation in a population estimated by a single locus or an average over several loci.

Heterozygous

A diploid cell or organism that contains two different alleles of a particular gene.

Hewitt, Charles Gordon

Charles G. Hewitt was born near Macclesfield, England, on February 23, 1885. He obtained a B.Sc. from Manchester University in 1902, a M.Sc. in 1903, and then worked at that university as a lecturer until 1909, when he received a D.Sc. degree and emigrated to Canada. His move to Canada was well timed, as the position of Dominion Entomologist was vacant. Hewitt had demonstrated considerable potential while in England, and despite considerable misgivings about his level of experience, he was named Dominion Entomologist of Canada in 1909, and served in this capacity until 1916. Along they way, he played a key role in passage of the "Destructive Insect and Pest Act" of 1910, which allowed Hewitt to add staff in the form of inspectors and field officers, and to establish entomological field stations at nine points from coast to coast. He also published an important treatise on "House flies and how they spread disease" in 1912, and "The house fly, *Musca domestica* Linn." in 1914, and served as an officer in several scientific societies. His position was enlarged to "Dominion Entomologist and Consulting Zoologist of Canada" in 1916, and he continued in this capacity until 1920. His interests and expertise extended well beyond insects, and he also was active in natural history and ornithology organizations. He died prematurely at Ottawa, Canada, on February 29, 1920. In 1921, his book titled "Conservation of the wild life of Canada" was published posthumously, which proved to be his most renowned contribution to science. Most importantly, during his brief tenure Hewitt had developed economic entomology from a small division to an important branch of the Department of Agriculture.

Hexapoda

A superclass in the phylum Arthropoda containing animals with three major body segments and three pairs of walking legs. Hexapoda consists of the class Insecta, the insects, and the class Entognatha, the collembolans, diplurans, and proturans.

Hibernaculum

An overwintering retreat in which an early-instar larva retreats or diapauses during the winter. It is usually made of silk, but may consist of other materials as well.

Hilarimorphid Flies

Members of the family Hilarimorphidae (order Diptera).

► Flies

Hilarimorphidae

A family of flies (order Diptera). They commonly are known as hilarimorphid flies.

► Flies

Hilltopping

JEFFREY H. SKEVINGTON
Agriculture and Agri-Food Canada, Ottawa, ON, Canada

When you are small, locating a potential mate can be a challenge. Insects employ many strategies of mate finding, from swarms to individual territories to specific landmark mating strategies. Landmark mating strategies involve species setting up mating aggregations over any conspicuous marker. This can range from a rock to a tuft of grass, a road, a stream course, a canyon, a bog, an emergent tree (taller than the others) or a hilltop. Although this article focuses on the latter, this phenomenon is essentially a continuum. The difference between simple landmarks and hilltops is that simple landmarks typically support only a single species. However, emergent trees in rainforests are likely immensely important for landmark mating species. Unfortunately, few data are available on this. Hilltops are significant landmarks in that they support many species, often hundreds or in rare cases even thousands. Hilltops range from massive rocky mountain tops over 4,000 m high to small hummocks in flat country. These hummocks can function as full-fledged hilltops, particularly if they have some conspicuous landmark on top. A small rise of land in an otherwise flat area in Western Australia exemplifies this (Fig. 32); a shelter at the top of the rise serves as a major hilltopping site for many species and families of flies, wasps and butterflies.

Arguably the best hilltop (most diverse) anywhere in the world is in Queensland, Australia. Mount Moffatt (1,097 m, 25°03’35” S, 148°02’38” E) is a distinctive, conical hilltop, rising about 350 m above the surrounding land (Fig. 32). It is somewhat of a mystery what makes one hilltop better than another. Despite this, Mount Moffatt gives us some clues.

The height above the surrounding land is not too intimidating to exclude many species, while the hilltop is distinctive and visible for large distances. The summit is focused and not very large (about 100 m by 20 m), is variably vegetated (with a rocky open north end, and shaded south end) and the habitat around the hilltop is excellent (in Carnarvon National Park). Further, no other high points compete for hilltopping insects within a several kilometer radius. Hilltops covered entirely by tall trees may also be important but it is difficult for entomologists to access these habitats.

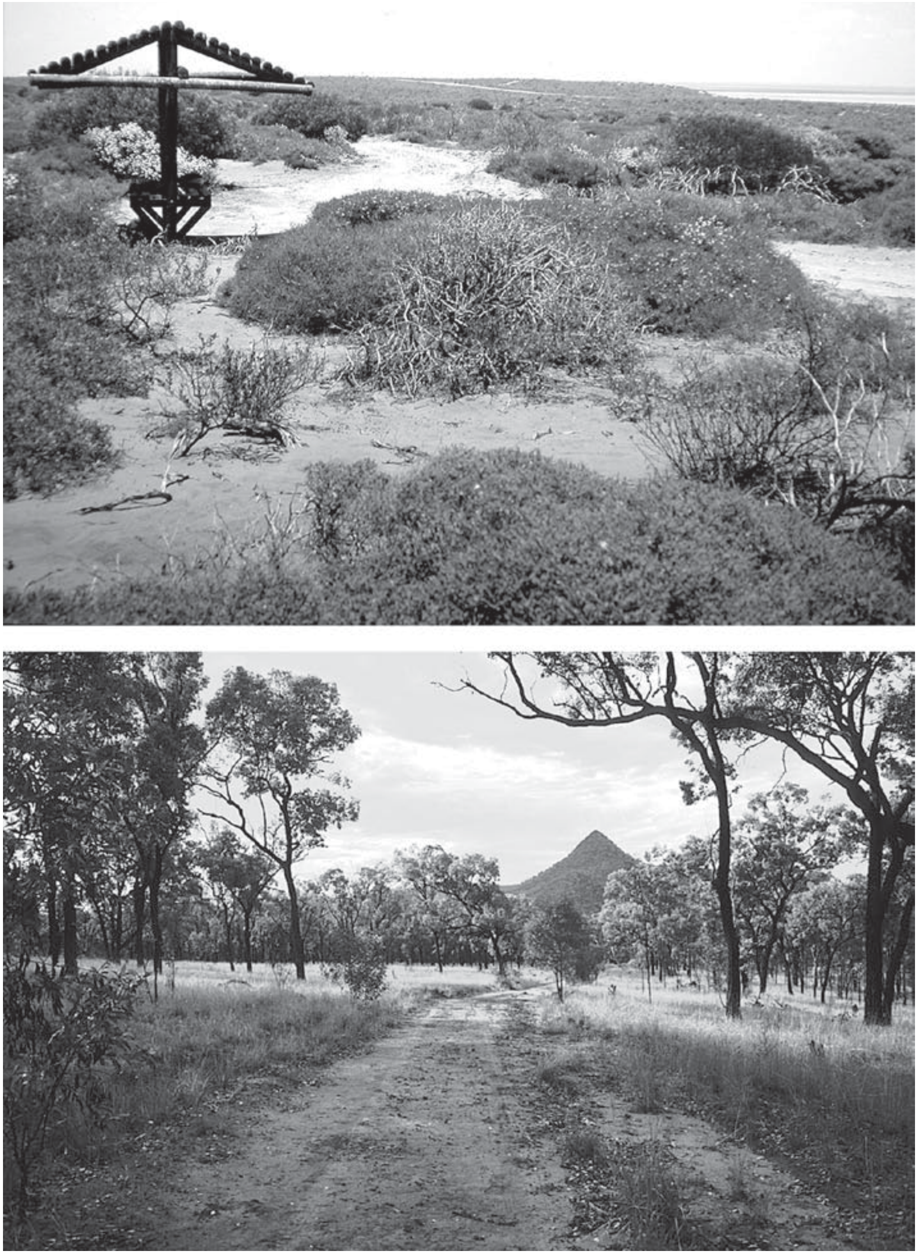
The diversity of insects using Mount Moffatt as an aggregation site almost certainly numbers well over 1,000 species. Over the course of 3 days between October 10 and 13, 2002 (early in the austral spring), three entomologists collected 104 species of hilltopping Tachinidae (Diptera) on Mount Moffatt. Based on this, there are almost certainly over 200 species of this family alone using Mount Moffatt as a hilltopping aggregation site. Pipunculidae (Diptera) diversity is also high on Moffatt and exceeds 50 species (Fig. 33). No other groups have been inventoried, but other abundant and diverse groups using Mount Moffatt include: Diptera: Anthomyiidae, Bombyliidae, Calliphoridae, Muscidae, Pipunculidae, Sarcophagidae, Syrphidae, Tabanidae and Tachinidae; Hymenoptera: Ichneumonidae; and Lepidoptera: Nymphalidae. More information on hilltopping taxa is included below.

Hilltopping Taxa

The dominant orders of insects represented on hilltops are Diptera, Hymenoptera, and Lepidoptera. Within Diptera, the following families have been found to have hilltopping species: Acroceridae, Agromyzidae, Anthomyiidae, Anthomyzidae, Apioceridae, Athericidae, Bibionidae, Bombyliidae, Calliphoridae, Conopidae, Culicidae, Empididae s.l., Fanniidae, Ironomyiidae, Lonchaeidae, Muscidae, Mydidae, Nemestrinidae, Oestridae, Pelecorhynchidae, Phoridae, Pipunculidae, Platypezidae, Rhagionidae, Sarcophagidae, Scenopinidae, Sepsidae, Simuliidae, Sphaeroceridae, Stratiomyidae, Syrphidae, Tabanidae, Tachinidae, and Therevidae (Fig. 33). Most work on hilltopping of Lepidoptera has focused on butterflies in the following families: Hesperiidae, Lycaenidae, Nymphalidae, Papilionidae, and Pieridae. Within Hymenoptera, all families of sawflies appear to hilltop. Braconidae, Formicidae, Ichneumonidae and some Sphecidae are also important components of the hilltopping diversity.

Definition of Hilltopping

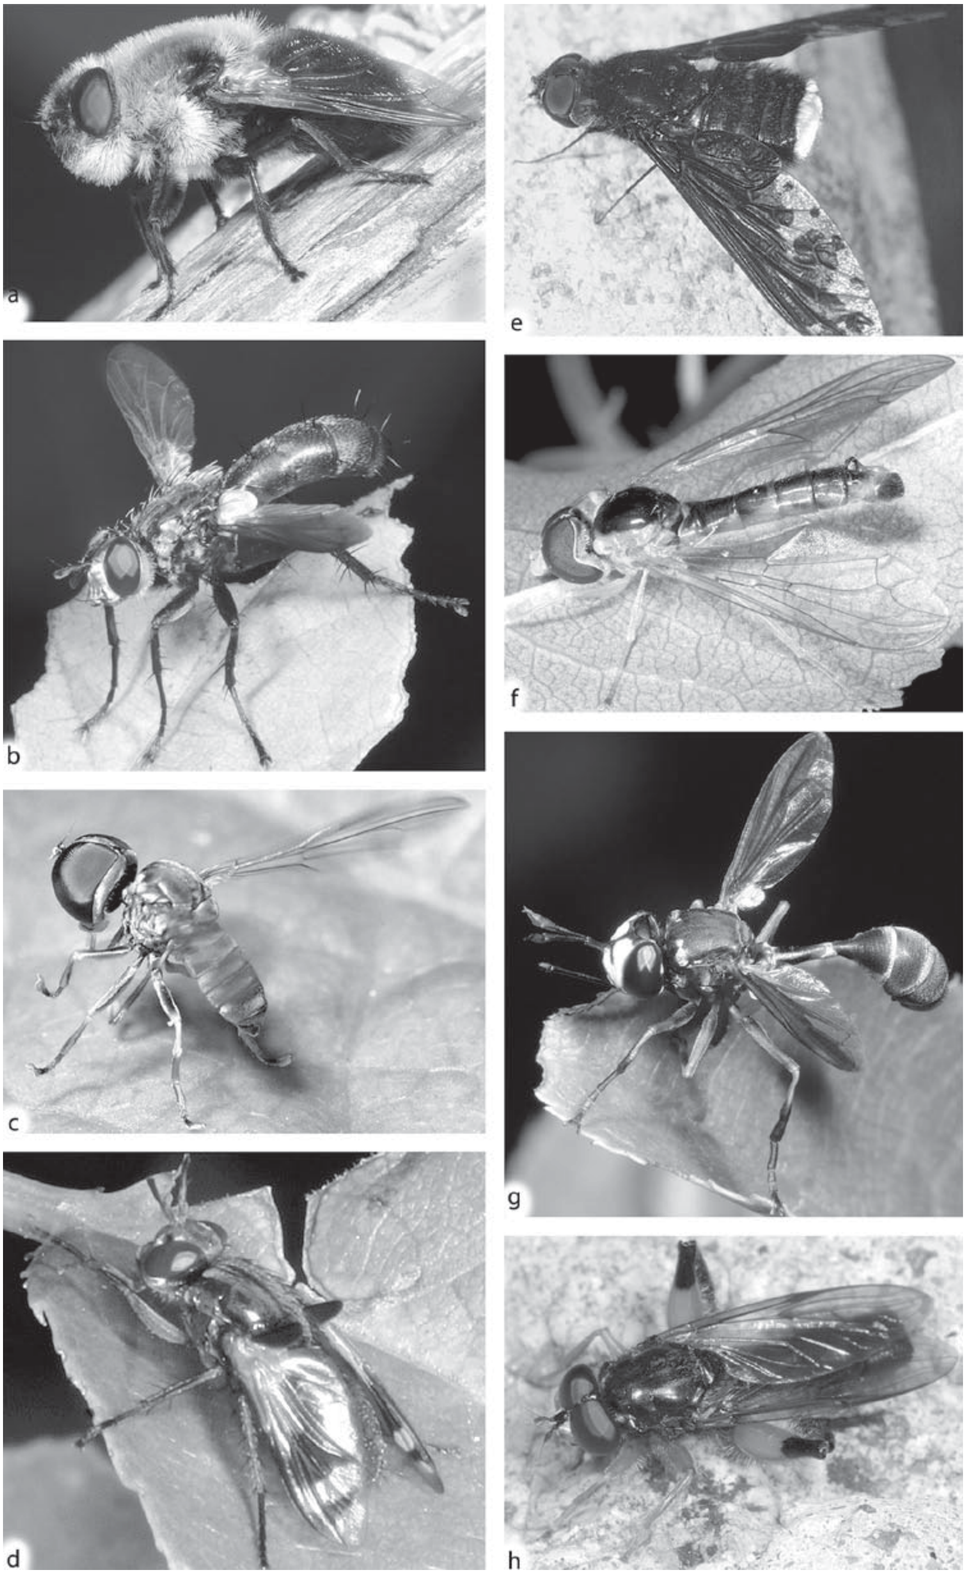
Hilltopping is a phenomenon apparently restricted to insects in which males and virgin or multiple-mating females instinctively seek a topographic summit to mate. Larval foodplants or hosts are typically not present on the hilltop and may be a



Hilltopping, Figure 32 (*above*) **A shelter at the top of a small rise of land in an otherwise flat area in Western Australia serves as a major hilltopping site for many species and families of flies, wasps and butterflies (Denham, Western Australia (25°54′33″ S, 113°31′54″ E). (*below*) Arguably the best hilltop in the world is Mount Moffatt in Queensland, Australia (1,097 m, 25°03′35″ S, 148°02′38″ E). This distinctive, conical hilltop, rising about 350 m above the surrounding land is a model hilltop in terms of shape, vegetation and proximity to other hilltops.**

considerable distance away. Hilltopping is a widespread mating system among insects and is focused on groups that are rare, parasitic, predaceous on ephemeral prey, or whose larval foodplants are scattered or rare. Mate-finding is difficult under these conditions.

Note that some species that form behavioral aggregations do so at hilltops (e.g. *Forficula lurida*



Hilltopping, Figure 33 **(Continued)**

Fischer (Dermaptera) and some species of Coccinellidae (Coleoptera)). This prelude to communal hibernation is not considered hilltopping as defined here as in such cases sex ratios are typically 1:1 and no mating or feeding activity typically occurs.

Hilltopping Behavior

General

Typically, there is a very high proportion of male insects on hilltops. This is explained by the persistence of males in such areas (see below) and the brief visits by females. Arriving females typically quickly select a mate and leave the summit. Once they have mated, males return to the summit while mated females typically never return. Males often select bare or open areas from which they can see approaching females best.

Studies of butterflies reared and released in different sites suggest that hilltopping species are genetically programmed to seek out hilltops. Once there, many species seem to be similarly predisposed to seek out very specific places on the hilltop or otherwise partition the hilltop by their behaviors. For example, three similar species of *Chalcosyrphus* (Diptera, Syrphidae) occur on a hilltop in Rigaud, Quebec, Canada (45°27'59" N, 74°19'35" W). These species partition the hilltop by their different behaviours. *Chalcosyrphus plesia* (Curran) hovers low over rocks near the summit, *C. curvaria* (Curran) typically sits on rocks around the summit and *C. vecors* (Osten Sacken) perches on the leaves of Serviceberry (*Amalanchier* sp.) or Red Oak (*Quercus rubra*) near the summit.

Hilltopping, Figure 33 **Collage of hilltopping flies (Insecta, Diptera): (a) *Cephenemyia phobifer* (Clark) (Oestridae). Voucher #CNCD144 (Canadian National Collection of Insects-CNC, Ottawa). This rarely observed fly is common on Mount Rigaud (Quebec, Canada) where this photo was taken. Bot flies are often found on hilltops despite being found rarely elsewhere (unless they are reared from their hosts). (b) *Cylindromyia* sp. (Tachinidae). Voucher #CNCD354. Tachinidae form a major component of most hilltopping insects. This species is common on Mount Rigaud. (c) *Eudorylas* sp. (Pipunculidae). Voucher in University of Guelph Insect Collection (no unique number) (photo by S.A. Marshall). Big-headed flies are often abundant on hilltops. (d) *Euthera tentatrix* Loew (Tachinidae). Voucher in CNC (no unique number). This attractive little fly is rarely collected away from hilltops such as Mount Rigaud (where this one was photographed). (e) *Anthrax maculatus* Macquart, (Bombyliidae). Voucher in University of Queensland Insect Collection (no unique number). Common on hilltops in Eastern Australia. This specimen was photographed on Mount Wellington in Tasmania. (f) *Nephrocerus acanthostylus* Skevington (Pipunculidae). Voucher #JSS16983 (in CNC). This enigmatic genus of big-headed flies is rarely collected anywhere. Mount Rigaud has hosted three of the six Nearctic species, including the specimen in the photo. Two additional species have been found at a nearby hilltop in Gatineau. This illustrates how effective hilltop collecting can be to survey many groups of insects, particularly parasitoids such as Conopidae, Pipunculidae and Tachinidae. (g) *Physocephala marginata* (Say) (Conopidae). Voucher #CNCD347. This is another family of flies that can often be found most readily on hilltops. Photograph taken on Mount Rigaud. (h) *Chalcosyrphus curvaria* (Curran) (Insecta, Diptera, Syrphidae) is one of three closely related flower fly species that partition hilltops in northeastern North America by subtle choices in habitat and differences in behavior. *Chalcosyrphus curvaria* (Curran) typically sits on rocks around the summit as in this photo taken at Mount Rigaud, Quebec, Canada (45°27'59" N, 74°19'35" W). *Chalcosyrphus plesia* (Curran) hovers low over nearby rocks and *C. vecors* (Osten Sacken) perches on the leaves of serviceberry (*Amalanchier* sp.) and red oak (*Quercus rubra*) in the same vicinity near the summit.**

Effectiveness of Hilltopping for Males Seeking Mates

In theory, if virgin females move randomly upslope, males patrolling or perching near the summit should have a higher probability of mating success than those dispersed throughout the vegetation below. In years of low population density it should be adaptive if both sexes tend to move uphill toward landmarks. However, in years of high population density the numerous males that find their way to the ridge would compete heavily for a few females since most would be mated on their uphill flight. Thus the smaller the population, the lower the chance of virgin females encountering males before reaching the hilltop and the more adaptive the behavior becomes for the males that join the hilltopping aggregation.

Measuring the adaptive advantage of hilltopping is difficult as males on summits likely face considerable additional pressures. The energy allocated to hilltopping is likely higher than that required by individuals remaining off the summit. Predation rates may also be higher as many predatory insects and birds take advantage of the abundance of prey on hilltops. For example, aerial foraging birds such as swifts and swallows clearly focus on hilltop feeding and many large predatory insects, such as dragonflies (Odonata, Anisoptera) and robber flies (Diptera, Asilidae), also congregate there to feed. However, given that this may be the only way for some insects to find a mate, it is clearly beneficial and has been adopted by a wide variety of insects.

Evidence for Hilltopping

Mark-recapture studies, particularly using butterflies, have garnered considerable evidence supporting a hilltopping strategy as defined here. In one study, about half of the unmated, reared females released 610 m (117 vertical meters) away from a summit, were found on the hilltop within 1 day. Mated females did not go to the summit. In fact, an abnormally high percentage of female butterflies collected on the summit were virgin when compared to those captured elsewhere. The percent virginity for non-hilltop sites was mostly under 10% in contrast to 35–97% of females at the summit which were virgin upon arrival. The apparent scarcity of females at hilltops was due to inconspicuousness of mating pairs and due to the fact that virgins stayed only long enough to mate and non-virgins rarely approached the summit. When arriving at or released on summit, males strongly adhered to it. After copulating, females showed little response to topography.

Mark-release of males of the butterfly *Papilio zelicaon* Lucas away from the hilltop resulted in about 33% returning from varying distances (similar to the rate of recovery of specimens released directly on the hilltop). These males returned from multiple directions and one returned from five km away and flew into a wind to return. When transported further away, they would go to another closer hill; however, there is some evidence that they prefer their own hill when two are similar distances apart (even though both are used by the species). The return speed for four *P. zelicaon* recaptured the same day varied from 14 (no wind) to 42 (strong wind at right angle to motion) meters per minute.

In one study, butterflies were found to fly toward the highest point available. Uphill movement was directed by two cues, the highest location within a distance of 50 m, and the immediate slopes available to the butterfly. This suggests that the highest landmark available in an area is likely to be used for hilltopping, but this is clearly not always the case. For example, in an area of high rocky hills in Tasmania, Australia, the best (most diverse) hilltop was a partly vegetated hill that was hundreds of meters lower than the many surrounding hills (Donaghy's Hill, 42°11'52" S, 145°55'55" E). More work is clearly needed to understand how insects choose specific hilltops and navigate to these summits.

Differences in behavior between males and virgin females have been hypothesized to represent asymmetry in the mate-searching strategy between genders. This may improve the mate-searching algorithm by increasing an insect's chances of meeting the opposite sex of another of its species along the way. In butterfly studies, virgin females were found to perform little searching for males when not on summits whereas males searched for conspecifics everywhere.

Timing and Weather

Hilltopping activity is highest in the morning on sunny, warm days with relatively little wind. Peak flight times are clearly correlated with temperature and humidity. Early morning activity (before 8 am) is marked in very hot, dry climates. Even in moderate climates, the intensity and diversity of hilltoppers declines rapidly after mid-day. A resurgence of activity occurs in some species in the evening although most species do not appear to have daily bimodal activity patterns. Crepuscular and nocturnal species such as *Ormia* (Diptera, Tachinidae) and many moths (Lepidoptera) start to appear at dusk and some may fly all night. Very little research has been conducted on nocturnal hilltopping species. One note describes the observations of someone carrying a lantern up a mountain. No moths were observed except at the very summit where hundreds of moths of many species were sitting everywhere. These insects were there when the observer arrived and were not attracted to his light. This clearly illustrates the unexplored potential of studying nocturnal hilltopping patterns.

The effect of clouds on insect behavior is extremely pronounced on hilltops. Thousands of insects can be flying one minute in the sun, producing a loud hum, when suddenly with the passing of a cloud over the sun, the insects land and the humming stops. As the cloud passes, it is as if the entire hill erupts at once as everything takes to the air simultaneously. The effect of wind and reduced temperature are similar but not as dramatic because of the slower shifts. As wind speed increases, activity moves to the leeward side of the hilltop and remains focused there until the wind reaches too high a speed and all activity ceases.

Some species are active throughout the entire period of peak activity while others have clear arrival and departure times throughout the day. Research on the diversity of hilltopping taxa thus necessitates long hours over many days. Individual species abundance, particularly of parasitoids, also varies considerably from year to year. Studies that span several years may give a much more representative picture of diversity at a particular summit.

Distances Covered

A few mark-recapture studies have attempted to determine how far hilltopping individuals travel. Much remains to be learned here, but it appears that some species travel considerable distances to suitable hilltops. Two species of ants, *Formica subnuda* Emery and *Leptothorax muscorum* (Nylander), captured at a hilltop in British Columbia, Canada returned (even against or across the wind) from distances up to 760 m away (the farthest tested). Over 20% of the winged ants released returned to the hilltop from 760 m away.

Minimum distances traveled by hilltopping butterflies from the nearest areas of their foodplants were several thousand vertical feet for *Papilio indra kaibabensis* in Arizona and 1,700 vertical meters for *Pieris callidice* in France.

It is presumed that once animals initiate a hilltopping movement they may persistently fly upwards and cover distances of several kilometers or even tens of kilometers. This remains to be tested.

Site Tenacity

A substantial number of hilltopping males remain for periods of time on a summit on a given day. There is some evidence that some males of some species may spend their entire lives at a particular summit. Mark-release and re-sighting studies have shown that males remain at aggregation sites for life and that there is a shifting of territories from day to day. Roosting males of several species have been found at or near the summit of hills, also supporting the notion that they stay there all of their lives once they have arrived. One marked *Papilio zelicaon* male was seen on a summit on eight different days over a 20-day period. The longest period recorded for an individual was 29 days of one *P. zelicaon* specimen.

Despite the discovery that male insects of some species spend most of their lives on a particular hilltop, it seems unlikely that most species are this sedentary in their behaviors. At night, during hot parts of the day, and on days with poor weather, few diurnal insects can be found anywhere near the summit. Most presumably leave during these times to feed or take shelter somewhere below.

Multiple day site fidelity has been demonstrated in many studies but the reduction in returns over several days always appears to be steep. The fact that even successful territory holders rarely spend more than a single day at a site suggests that males rapidly deplete their energy reserves, experience a very high rate of mortality and/or regularly disperse to different landmark sites. A sex ratio of 2:1 in favor of males reported for *Cuterebra approxima* is hypothesized to offset high male mortality at aggregation sites.

One study conducted more than 20 years after the initial study found individuals of *Cuterebra austeni* occupying the same landmark site. This species used the same perching areas for over two decades. Other unpublished research on tachinid flies has found that this is the case for hundreds of species. This supports the notion that these behaviors are hardwired by instincts that have evolved over millennia.

Survey of Hilltopping Insects

Capture of hilltopping insects typically requires a focused effort at hand netting. This can be difficult because of the high degree of habitat partitioning shown by the species. Three systematists concurrently focusing on Diptera collecting on Mount Moffatt had surprisingly little overlap in 3 days of collecting Tachinidae. This is presumably due to the different search strategies employed by these dipterists. To sample the diversity of a particular group, an effort should thus be made to vary the collecting technique. Trapping is typically ineffective, at least for males. Malaise and pan traps positioned on hilltops catch a very unrepresentative sample of the species present. Presumably this is because males are focused on the task of finding a mate and are not moving far from their chosen sites. Females tend to be picked up in these Malaise traps, likely because they are commuting through the area more than males. Sugaring (spraying a mixture of artificial honeydew (honey, Coca-Cola™ and water) on the leaves of plants) is sometimes effective at attracting the attention of parasitoid flies on hilltops.

Conservation

The contribution of hilltopping to genetic mixing between populations may be of great ecological importance. These aggregation sites may be crucial to the maintenance of populations of many species and their identification could aid in attempts to protect threatened populations. Conversely, efforts to eradicate pests made sparse by control measures could be focused on hilltops but the potential effects on other species would have to be evaluated before attempting such measures.

Very little effort has been focused on conservation of hilltops, even in parks. Microwave towers and other communication devices are often installed even in protected areas on hilltops. Critical evaluation of these sites is needed before their development proceeds. The loss of any hilltop could endanger a particular, or even numerous, species. The loss of a significant hilltop such as Mount Moffatt that supports over 1,000 species of hilltopping insects could have tremendous impacts on the insect fauna of an area.

Integrated pest management often explores habitat matrices available in agricultural settings with the intention of increasing habitat for beneficial insects; however, these strategies have not explored the importance of hilltops. Given the critical importance of this mating strategy to many parasitoid insects, more attention should be given to these structures in the future.

Himantopteridae

A family of moths (order Lepidoptera). They also are known as long-tailed burnet moths.

► Butterflies and Moths

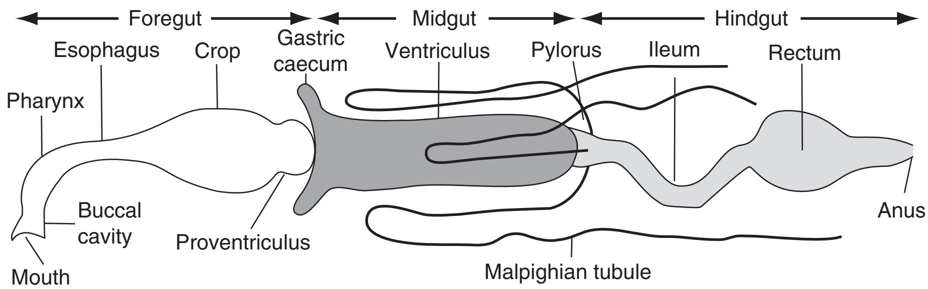
Hindgut

The third or posterior section of the gut. The hindgut receives products from the midgut at the juncture of the Malpighian tubules, and consists of the ileum and/or colon, and the rectum (Fig. 34). The waste products exit the hindgut from the anus.

► Alimentary System
► Alimentary Canal and Digestion

Hinton, Howard Everest

Howard Hinton was born August 24, 1912, in Mexico of American parents, but attended high school and university in Berkeley, California. Then he entered Cambridge University in 1934 to study for a Ph.D. Between 1939 and 1949 he worked as a taxonomist in the Department of Entomology of the British Museum (Natural History) in London. He published copiously, including a 350-page work (1945) "A monograph of the beetles associated with stored products." In 1945 he moved to Bristol University as Reader in Entomology, later being given a professorial chair and then becoming head of the Zoology Department. He was elected a fellow of The Royal Society in 1961 and was president of the



Hindgut, Figure 34 Generalized insect alimentary system (adapted from Chapman, The insects: structure and function).

Royal Entomological Society of London in 1969–1970. His research covered many areas of insect anatomy, physiology, biochemistry and behavior. But he found time to publish (1967) "Mongooses; their natural history and behavior" and to found and edit two journals: "Journal of Insect Physiology" and "Insect Biochemistry." He died in Bristol on August 2, 1977. The 3-volume book "Biology of insect eggs" on which he had been working just before his death was published in 1981.

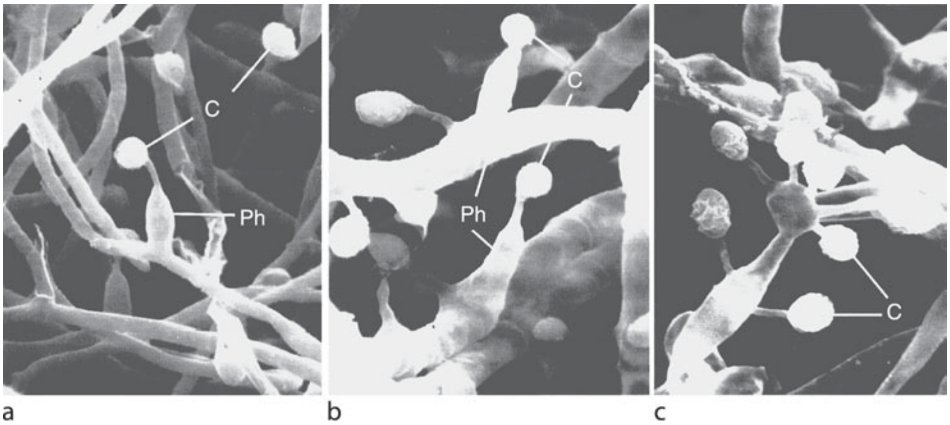
Hirsutella

SAOWANIT MAIMALA[1], DRION G. BOUCIAS[2]
[1]Department of Agriculture, Ministry of Agriculture and Cooperation, Chatuchak, Bangkok, Thailand
[2]University of Florida, Gainesville, FL, USA

The genus *Hirsutella* infects a number of different types of insects as well as mites and nematodes. Most of the species (about 50) that infect insects produce synnemata, i.e., structures composed of a compact group of erect conidiophores. The most common species, *H. thompsonii*, is pleomorphic and has been separated into three morphologically distinct groups. *Hirsutella thompsonii* variety synnematosa occurs in the tropics, whereas varieties *vinacea* and *thompsonii* occur in subtropical and temperate zones, respectively. All three varieties can produce conidiogenous structures that are solitary, proliferating phialides that generate one or more globose, verrucose (warty) conidia, or polyblastic conidia that generate subglobose to ellipsoidal conidia with smooth walls. In addition, variety *vinacea* produces vinaceous (purple) colonies on agar, and variety *thompsonii* characteristically produces gray-green colonies in culture. Under *in vitro* conditions (Ridell mounts), different *H. thompsonii* isolates have shown extensive variation in the length of the phialide, the length of interval between phialides, the rate of linear growth along substrate, and in the relative degree of mycelial branching.

The *in vivo* life cycle of *H. thompsonii* in host mites takes only 60–72 h. The conidia invade hosts (e.g., mites) through the integument. It should be noted that these short-lived conidia germinate within minutes after being placed in water. Additionally, these propagules, unlike the hydrophobic conidia of many Hyphomycetes, are hydrophilic, and they possess a mucus coat that facilitates adhesion to the mite cuticle. It is presumed that these conidia produce penetrant germ tubes that gain ingress through the



Hirsutella, Figure 35 **Scanning electron micrograph of the conidiophores of *Hirsutella thompsonii* (A), and (B) represent phialides producing solitary conidia, and (C) phialides producing polybastic conidia.**

cuticle. Internalized hyphae break up and form round, multinucleate chlamydospores, which then germinate and produce aerial mycelia with conidiophores; initially, the mycelia may emerge only through oral, anal, or genital openings. These observations suggest that the pathogens may be ingested and grow out from the gut lumen. *In vivo*-produced phialides (Fig. 35) are solitary and arise from mites attached to plant substrates. Conidiogenesis occurs within 9–24 h after host death and requires at least 98% relative humidity (RH) and optimal temperatures (about 25–30°C). In hot, humid weather, *H. thompsonii* can cause spectacular natural epizootics among mite populations (citrus rust, blueberry, coconut, tomato mites, etc.) and is considered to be a key natural enemy of various mite pests.

In vitro, this fungus displays a simple growth cycle. Conidia germinate and produce the mycelial phase that gives rise to conidiophores and/or chlamydospores. Shake flask cultures of several strains of *H. thompsonii* var. *thompsonii* (strain HTF-87, HtF JAB) produce toxic metabolites including the protein toxins, Hirsutellin A (HtA) and B (HtB) and the phomalactones, 6-(1-propenyl)-5,6-dihydro-5-hydroxypyran-2-one. The gene encoding for HtA (GenBank U86836) has been cloned and sequenced. This gene codes for a precursor of 164 aa which includes a 34 aa leader sequence that contains both a signal and a pro-sequence. This monomeric cationic protein undergoes post-translational modification, producing a mature 130 aa HtA toxin which has a calculated M_r=14,159 and pI = 9.21. HtA has been reported to possess consensus sequences similar to those found in various microbial exocellular ribonucleases. Crude filtrates of mycelial cultures containing HtA were found to be toxic to wax moth, *Galleria mellonella*, larvae and *Drosophila melanogaster* (Meigen) adults via injection and per os applications, respectively. In addition, culture filtrates were active against the citrus rust mite, *Phyllocoptruta oleivora*, and the common two-spotted spider mite, *Tetranychus urticae* (order Prostigmata).

History and Insects

THOMAS R. FASULO
University of Florida, Gainesville, FL, USA

It is impossible to list the number of times insects affected the course of history, mostly because historians and physicians, during much of our history, were not aware that many of the diseases that caused such loss of human life were transmitted by insects. Even today, medical scientists speculate over the identity and causes of the "plagues" that devastated armies and civilian populations in our early history. While scientists feel confident in attributing some of these plagues to specific diseases, many of which are vectored by insects, they cannot be certain.

America, the French and Yellow Fever

In 1803, Thomas Jefferson, president of the United States, negotiated one of the greatest land deals in history. He did so by buying from the French Emperor Napoleon a vast tract of land known as Louisiana for the then great sum of $15 million. This transaction is forever remembered in history as the Louisiana Purchase. At that time, control of the city of New Orleans was strategically important to the growing United States, as the nation that controlled New Orleans controlled the Mississippi River. The United States desperately needed control of the Mississippi so that western farmers could ship their grain, hogs, cattle and other produce to market by flatboats that floated down the river.

Early in Jefferson's first administration the Spanish, who then controlled Louisiana, had closed the port at New Orleans to the United States' western settlers and caused them great hardship. Jefferson knew he needed to secure for his country a quick and dependable way to transport bulky goods to market cheaply. But France was then the most powerful country in the world, and there was no hope of forcing any privileges from it.

So, in 1802, Jefferson sent James Monroe to France with an offer to buy New Orleans, and if possible West Florida, for $2 million. Napoleon countered with an offer to sell all of Louisiana for $15 million. Jefferson accepted, doubled the size of the United States, and ensured that there would eventually be just one nation spanning the center of the North American continent. History books teach us that Napoleon's primary reason for selling Louisiana was that he needed the money to pay for his new war against Great Britain, but this is incorrect. The real reason Napoleon sold Louisiana had to do with mosquitoes.

In January 1802, a flotilla of French transports carrying 35,000 soldiers commanded by Captain-General Victor-Emmanuel Charles Leclerc, escorted by 62 warships, arrived at the island of Hispaniola in the Greater Antilles. (Today it is divided into the Republic of Haiti in the west and the Dominican Republic in the east.) The mission of the force was to reestablish direct control over the colony of Saint Domingue (now Haiti and then one of the richest colonies in the world) as the colony's leaders were behaving as if it were an independent republic. The former black slaves put up a spirited and well-led defense, but they also had help. By July, more than 10,000 French troops were dead, mostly due to yellow fever, a disease transmitted by mosquitoes. Leclerc himself died of the fever. His successor requested another 35,000 troops as reinforcements. Estimates vary as to the number of French troops Napoleon sent to the island, but the best recent study suggests that the total exceeded 60,000 men and women. By November, only 7,000 starving, sickly troops remained. Four-fifths of the French had died of yellow fever, including 18 generals. By mid-March 1803, France was once again at war with Great Britain. With his need for troops to fight the British in Europe, and with little hope of victory over yellow fever, Napoleon decided that he could not maintain a strong military force in the Americas. He abandoned his idea to secure Saint Domingue and to reestablish French power on the North American continent. On April 30, 1803, he completed the accords that sold Louisiana to the United States.

Yellow Fever and the Transatlantic Slave Trade

The victory of yellow fever, and the mosquitoes that transmitted it, over the French had far greater consequences. The collapse of French power in the West Indies, as their other Caribbean colonies fell to Britain, negated the argument British slave holders had that abolishing slavery would not diminish the transatlantic slave trade, but only turn it over to the French. In 1807 Britain outlawed slavery for its own flag vessels. During the late Napoleonic Wars, Britain began boarding the ships of other nations and freeing slaves. By the early 1820s, the British had set their sights on slavery's abolition around the world. Due to their efforts, the transatlantic slave trade came to an end. With the importation of inexpensive slaves at an end, the value of slaves in the southern United States grew, and they became important enough economic assets that their owners would eventually resort to war to protect them. Additionally, in 1818, the restored French monarchy under Louis XVIII considered an attempt to recover Haiti for France by force. Survivors of the Leclerc expedition, relating their experiences with yellow fever, helped talk the French government out of it and possibly prevented a war between France and the United States.

James Monroe, president of the United States from 1817 to 1825, introduced the Monroe Doctrine (although it was not called that until 20 years after his death) in December 1823. The Monroe Doctrine basically stated that the United States would resist any attempts of "colonization by any European Powers" in the Western Hemisphere. When the French later seized control of the Mexican government during the American Civil War of the early 1860s, the United States was too deeply committed to interfere. However, immediately at the end of that conflict a large American army was sent to the Texas-Mexican border. The French understood the gesture and withdrew their economic and military support of the government, which soon fell. A French-American War in the Western Hemisphere during the nineteenth century would have been a real possibility, if France had maintained colonies there as Spain did. In the late 1890s American public opinion was directed against Spain's remaining colonies in the New World, and in 1898 The Spanish-American War took place.

Insects, Greece, Rome and the Mongols

More than once a powerful army or nation was defeated or reduced in stature due to insect-vectored diseases. For example, many suggest that Alexander the Great's death was most likely due to malaria, which is transmitted by mosquitoes. When Alexander died, his driving force died with him and his empire broke up. Who knows what might have happened had Alexander lived, to expand his empire and establish a dynasty that would have maintained that empire?

Malaria both hurt and aided the ancient Romans, who dedicated a temple honoring the fever goddess. They prayed for mercy from the mysterious illness that appeared every summer and made life and travel dangerous. That illness was malaria, and it both helped and harmed the Romans. Occasionally barbarian hordes would descend on mighty Rome during its times of ebbing power, only to find themselves dying more rapidly from malaria than from the famous Roman short sword. Visigoths, Vandals, Ostrogoths and Huns would temporarily seize control of the Italian countryside but, lacking immunity to the local strain of malaria, would soon die by the thousands. As the poet Godfrey of Viterbo wrote in 1167, "When unable to defend herself by the sword,/Rome could defend herself by means of the fever".

Rome's legions also suffered when they ventured into newly conquered areas. Perhaps one reason the Roman Empire built Hadrian's Wall in northern England was to keep out the strain of malaria that killed half of an 80,000-man army that tried to conquer Scotland. During the Dark and Middle Ages, malaria strains to which the soldiers weren't immune decimated entire invading armies. Death from mosquito-transmitted malaria has even been suggested as one of the reasons the Mongols decided not to continue their invasion of Western Europe after their subjection of much of Russia and the Balkans. Their raids deep into Western Europe brought back slaves and loot, but part of that loot was death to many of the raiders from the European strains of malaria.

Great epidemics are recorded throughout history as either having laid waste to great empires or saving them from invading armies. The oldest recorded epidemic occurred during the Second Peloponnesian War in Greece. Large armies camped in Attica, and refugees crowded the cities. Diseases spread, but which diseases were involved isn't certain. The choices seem to be typhus, bubonic and pneumonic plague, and smallpox, with typhus having the most supporters. Typhus is transmitted by both fleas and human lice, and has been associated with war for so long that it is also known as "war fever." In any case, Athens was defeated and the Golden Age of Greece came to a close.

Bubonic Plague

Diseases, especially bubonic plague transmitted by fleas, also helped bring about the decline of the still strong Eastern Roman Empire. Edward Gibbon, in his "The Decline and Fall of the Roman Empire," states that "during 3 months, five and at length ten thousand persons died each day at Constantinople; and many cities of the East were left vacant, and that in several districts of Italy the harvest and vintage withered on the ground." Thus did insects and disease cooperate with wars and political corruption to finally bring the Roman Empire to its knees. The Roman administrators died, and their talents died with them. Barbarians laid waste to civilization and its trappings, and the Dark Ages settled over much of Europe.

William McNeill, in "Plagues and Peoples," states that bubonic plague epidemics occurred in the eastern Mediterranean region several times during the late Roman empire. Outbreaks of this disease were a major factor in preventing Justinian, emperor of the Byzantine empire, from finding the required resources needed to restore imperial unity to the region. Furthermore, flea-transmitted bubonic plague significantly contributed to the failure of the Byzantine and Persian empires to offer effective resistance to the Moslem armies that swarmed out of Arabia in the middle of the seventh century.

In China, the first descriptions of the bubonic plague date from the year 610, or two generations after its first appearance in the eastern Mediterranean. A series of devastating epidemics began in 762, and the records relate that entire provinces lost 50% or more of their populations. These catastrophes resulted in a weakening of the existing Chinese empire, major revolts and an influx of barbarian influence. China took hundreds of years to regain pre-plague population levels.

Diseases were even used as an early method of biological warfare that often spread far beyond the battlefield and had consequences beyond the immediate goals of the armies that used them. In 1347, when the Mongols used catapults to hurl decaying corpses of plague victims over the walls of Kaffa, a city they were besieging on the shores of the Crimea, they had no idea that the end result would be a complete transformation of European social, educational, religious and political infrastructures. The bodies carried with them what we know today as the Black Death, a bacterium that causes plague in both its bubonic and pneumonic forms. It is initially spread by fleas, then by fleas and airborne bacteria after an epidemic starts. The Black Death, or Black Plague, was one of the major calamities in history. In Europe alone, it caused 25–75 million deaths in <40 years, depending on the authority quoted. Most revised estimates place the total closer to the lower estimate than the higher.

As Genoese traders fled Kaffa and sailed to Sicily, they carried with them rats and fleas that carried the plague. When ships docked at Messina, most aboard were dead or dying. Soon local inhabitants also began to die from the plague. Other ships carried the Black Death to Italy, where the results were the same. Tens of thousands died in the major cities, and many smaller towns and villages lost all their inhabitants. By the spring of 1349 the Black Death had reached as far as Ireland, and in 1350 it passed through Scandinavia. Along its way, it caused moral, religious and political disintegration, as well as cruelty. For example, in many European countries, thousands of Jews were accused of poisoning the wells, tortured and killed.

In Europe, there were four major bubonic plague epidemics in the fourteenth century, with the last three having significantly declining death rates as the population developed immunity. When the first onslaught of the plague was over, one out of every three Europeans was dead. This was the reason the Black Death had such an effect on Europe at that time. Imagine a society in which one out of every three workers, craftsmen, teachers, religious and political leaders, and others died in such a short period. With people believing that they were soon to die, law and order broke down in many areas and chaos reigned for a time. The very fabric of society was torn apart. The Black Death established a dividing line between the central Middle Ages, with medieval culture in full bloom and at its greatest strength, and the later Middle Ages. The later period was one of a significantly reduced population which required hundreds of years to attain its pre-Black Death density.

The Black Death Changes Europe

The Black Death is often credited with bringing an end to the feudal system in Europe. However, that system was already in decline, although the Black Death hastened its end. Strong city states and nations were already emerging, but that process was drawn out as a result of the Black Death. Urban populations recovered quickly, in some cases within a few years, as peasants left the countryside for better opportunities in the cities. As the other three epidemics occurred, city dwellers (many of them former peasants) died, only to be replaced by more peasants who left the land. But the Black Death killed many in rural areas, and this left large areas of farmland without sufficient workers. With a decreased work force, local lords either lost wealth and influence or simply went bankrupt, if they didn't die of the plague themselves. By the fifteenth century, feudalism was in the past. The surviving workers demanded and received higher wages and more rights, and many historians believe that this new sense of freedom and self-worth led to the Peasants' Revolt of 1381.

This severe population loss is considered the main or sole reason for the rise of a monetary economy and increased technological development. When debtors died, their creditors could not collect as the debtors' families quite often died with them. This helped create a monetary economy as it allowed immediate payment for many goods or services. Surprisingly, so many deaths also led to a better standard of living. Fewer people meant a decreased demand for goods. This led to price reductions, which allowed people, now earning higher wages, to purchase items they could not have afforded before. In addition, the local lords, with more land to care for than their work force allowed, sold off parcels to peasants and townspeople who never dreamed they would have a chance to own property. The middle class grew in size and influence. All this happened because fleas were busily transmitting the plague.

The fourteenth century was not a good time for Europe, as it had problems before the arrival of the Black Death. The economy was in decline. The rise of the Mongol and Ottoman empires disrupted important trade routes, and areas of Europe with seafaring economies were already experiencing some economic depression. In the interior of Europe, the overall climate was changing, and the cooler and wetter weather resulted in lower crop yields even as the population increased. By the early 1300s, some parts of Europe were already experiencing famines. Plus, it didn't help that The Hundred Years' War (1337–1453) added war to plague and famine. In fact, if the Black Plague had a beneficial effect, it was that the four epidemics produced periods of peace in The Hundred Years' War.

While the breakdown of class relationships due to the effects of the Black Death led to a massive restructuring of society, it also had a lasting effect on art, literature and religious thought. Certain professions suffered a higher mortality rate from the Black Death, especially those whose duties required them to administer to the sick, such as doctors and clergy. When the priests died and no one could hear confession, people learned that they could live without the church forgiving their sins. The Black Death is a particularly gruesome disease, and it caused despair throughout Christianity. First, people wondered if they had angered God, and many looked to the church for guidance. Then they wondered why His chosen servants in the church were not able to do something to mitigate the disease and why so many of the clerics died from it. This caused the Catholic church to lose much of its prestige, breaking down blind allegiance to that church and setting the stage for the Protestant Reformation.

Education of the elite suffered as universities and schools, usually located in urban areas, were closed or even abandoned. Up to that time, most books had been written in either Latin or Greek, which required rigorous study to learn. But the Black Death killed many educators and left students uneducated or undereducated in Latin and Greek. This led to a temporary decline in universities and a long-term decline in the knowledge of classical languages. The result was a drastic change in the entire educational system as new professors and students used the language of the region instead of Latin or Greek. As a consequence, authors wrote books directly in, and scholars translated directly to, the vernacular. Without the need to learn Latin or Greek, more of the common people could achieve some level of education.

Due to the death of so many priests and monks, scribes were authorized to make copies of manuscripts. This not only greatly increased the number of people copying manuscripts and books produced, but it also decreased the price of those books. During this time the printing press was invented, which allowed for faster and cheaper duplication of books. Books, and the knowledge they contained, were no longer the domain of the wealthy.

The Black Death even became a part of our literature. A common children's nursery rhyme of that time survives to this day: Ring a-round the rosy/Pocket full of posies/Ashes, ashes!/We all fall down! (Ring a-round the rosy – use your rosary beads to implore God's help. A pocket full of posies – posies were used to hide the odor of rotting bodies which was also thought to cause the plague, so doctors used posies to protect themselves from infected plague patients. Ashes,

ashes – the church sanctioned burning the dead when burying them became too time consuming. We all fall down – dead.) In Shakespeare's "Romeo and Juliet," a friar is sent to inform Romeo that Juliet's apparent suicide was a fake. When the friar stops to help a family infected with the plague, he is boarded up in the house with them by their frightened neighbors. When the friar finally emerges, he is too late to reach Romeo to tell him the truth, and both lovers kill themselves over the other's apparent and real suicides.

After the four great epidemics in Europe, the Black Death returned often, but usually only for a short time and even then in smaller areas. However, Spain suffered three major outbreaks of plague during the end of the sixteenth and in the middle seventeenth centuries. More than half a million died in the first outbreak and probably as many in the next two. Together the three epidemics count as one of the significant factors contributing to Spain's decline in economic and political power.

As time passed, people learned how to deal with the plague, and the mortality rate decreased sharply as the population gained immunity. One way people avoided the plague was to leave the infected area if they could afford it. During the last big outbreak in Europe, which occurred in London in 1665, one university professor did just that and retired to his home in the country. This was fortunate as it gave him time to compose his thoughts concerning some theories he held. It was during this unscheduled vacation that Isaac Newton worked out the mathematics for his theory of gravity. Popular history tells us that Newton developed the theory of gravity because an apple dropped on his head. We see now that it was because of a flea.

Although the Black Death finally left Europe in peace, it continued to plague other areas. Egypt also experienced a major outbreak of the plague at the same time it first ravaged Europe, in 1347–1349. Approximately a third of the population died at that time, and smaller outbreaks continued to plague that region over the centuries. During the fourteenth century many areas of China experienced the plague, and records indicate that up to "two thirds of the population" died. During the nineteenth century, most of the Ottoman governors and administrators in the Turkish-occupied Balkans lived in the cities and towns where disease, especially bubonic plague, was common. As they died they were replaced by more administrators from Turkey, who also did not have an immunity to local strains of malaria and other diseases. Meanwhile, the local Christian populations, most of whom lived in the rural areas and did not convert to Islam, grew in size as the numbers of Turks declined. Eventually the Christian populations revolted, and Ottoman rule was overthrown in the Balkans.

Just because Europe was no longer ravaged by the Black Death did not mean that it was free from the effects of other insect-transmitted diseases. For example, in 1643, Charles I of England had to give up his attempt to seize London during the English Civil War because typhus ravaged his army, and he missed his chance to quell Parliament's revolt. Typhus was originally transmitted from rats to humans by fleas, but later was most frequently spread by body lice. But the Class Insecta does not play favorites and Charles got his revenge, years after being beheaded, when Oliver Cromwell died from malaria in 1658. However, at least one historian presents the case that Oliver Cromwell was actually poisoned by his enemies, who used his illness from malaria to disguise his murder. Even if true, a mosquito still contributed to Cromwell's death by assisting in the coverup of the crime.

Insects and Armies

Diseases have always been closely associated with large gatherings of armed men and have influenced the outcomes of wars and invasions many times. Even the greatest of military commanders were often helpless against disease-transmitting insects. For example, early in his career, insects dealt Napoleon a defeat in his Syrian campaign in the Middle

East as he boldly attacked into what is now Israel and Palestine, striking northeast from Egypt. Many of his troops fell ill from bubonic plague, transmitted by fleas. While total casualties to the plague were not excessive, the mortality rate was almost 92%. The morale of Napoleon's soldiers suffered greatly, and some even committed suicide when they contracted symptoms.

But even Napoleon eventually learned how to use insects to win battles. When England landed 25,000 troops on the Dutch island of Walcheren during a campaign in the Netherlands, Napoleon relied on malaria-transmitting mosquitoes to defeat this threat to his flank. Of course, at that time, neither he nor anyone else knew that mosquitoes were responsible for spreading malaria. The malaria was there and that was all that mattered.

Napoleon in Russia

Napoleon, defeated in the West Indies by the mosquito and in the Middle East by the flea, suffered another stunning setback due to an insect – the human body louse. When he assembled his armies for the invasion of Russia in June 1812, they numbered almost a half million men as they left their staging centers in Germany and Italy. As the armies converged and moved through Poland, many of the soldiers appropriated the insect-infested hovels of the peasants. Sleeping on the straw mats, the soldiers were infested with the body lice living there, many of which were carrying typhus. Countless thousands were left in makeshift hospitals or by the wayside and never made it to Russia. By August 25, Napoleon's main army had lost 105,000 men out of an original 265,000. By September, typhus, the prominent disease, and dysentery had ravaged Napoleon's armies and some corps were only half their original size. In October, when the French entered Moscow, Napoleon's armies totaled only 100,000 men, an 80% reduction in strength. By November, pneumonia had joined typhus and dysentery in ravaging the Grand Army. For example, by December only 20 men remained in the Third Army Corps commanded by Marshal Ney. When the Grand Army completed its retreat from Russia, it could muster only about 7,000–10,000 men fit for duty. This was not the last of Napoleon's problems with diseases. In 1814 he raised another army of 500,000 men only to see it reduced to 170,000 by the Battle of Waterloo. Of the 330,000 casualties, two-thirds were caused by disease, mostly typhus.

The Mexican War of 1847

But insects also could help an army win great victories on the field of battle even without causing significant casualties to the opposing force. During the Mexican War of 1847, General Winfield Scott, the commander of a small American army, led his forces to victory after victory over much larger Mexican forces, which were often in highly defensive positions. He did this because mosquitoes forced him to take risks. In March of that year, the American army under Scott's command seized Vera Cruz on the Mexican coast. Scott knew that he had to move into the interior without waiting for reinforcements, as the malaria season was soon to begin. In this case, moving into the interior also meant gaining considerable altitude and leaving the mosquito-infested coast behind. Another general might have waited for reinforcements and watched his army die from malaria. But Scott chose to do otherwise, leaving his supply line hanging in the air, and the result was a brilliant military campaign.

The Crimean War

The lice and typhus that helped defeat Napoleon remained a problem in later wars. During the Crimean War of the late 1850s, the Allies and the opposing Russians were sometimes suffering 12,000 casualties a month from diseases, mostly typhus, which occurred in two major outbreaks. During the war, the French suffered 200,000 casualties out of an army of 309,000. Only 50,000 of the casualties were from wounds received in battle; the other 150,000 were hospitalized by disease. Many of these men were sent to the hospitals because they were infected with typhus but then died from other diseases, like cholera, that they contracted in the filthy hospitals. These terrible deaths continued until Florence Nightingale arrived, reorganized the Allied military hospitals and reduced the death rate from 45 to 2%. It is unknown to the author how many casualties the Russians suffered from typhus.

The American Civil War

Lice played no favorites during the American Civil War, as they infested Federal and Confederate soldiers alike. The armies of both sides were heavily infested as soldiers often wore and slept in the same clothes for months. Fortunately, the lice did not have a typhus reservoir to draw upon as they fed on Blue and Grey combatants. Although two-thirds of the 622,000 military deaths during the American Civil War were caused by disease, typhus was not a significant cause. According to medical records, only about 820 deaths were attributed to typhus. Instead, lice were just an irritant that the soldiers learned to live with. Federals called the lice "greybacks," a name they also used for the Confederates. And both sides helped pass the time in camp by playing a gambling game with lice. Soldiers placed a tin plate issued for meals over a candle. As the flame heated the center to the point where it was just uncomfortable for lice, but not deadly, the men would place bets and release several lice in the center of the plate. The first to scramble over the edge won money, coffee, tobacco or fewer hours on guard duty for its recent host. Today, Civil War reenactors often joke that the true test of authenticity in a reenactor is when he does not have to buy his lice from the sutlers (period merchants), but grows his own.

Dysentery was probably the major non-combat killer of American Civil War soldiers. Of the approximately 410,000 deaths due to disease, it is estimated that 40,000–100,000 died from dysentery. Dysentery is caused by unclean conditions, and the American Civil War armies were just as unclean as any mass army at that time. People, even medical personnel, had little awareness of the good effects a little sanitation would bring. Latrines were ignored just as often as they were used. Consider the filth that an army of 75,000–150,000 men, along with tens of thousands of horses and mules, creates daily. One month after General Sherman captured Savannah he began to ask the government to give him another mission so he could move his troops from their bivouacs, which were beginning to accumulate filth. He knew what disease could do to what was then one of the finest fighting armies in the world. After a while he stopped just asking and began to beg. Eventually, the government allowed him to move his armies north into the Carolinas. Dysentery was such a constant companion to the Civil War soldiers that today's reenactors sometimes tell spectators their unit is so authentic that when they camp they assign a man to defecate upstream from where they draw their drinking water. Other armies in other wars also fought battles against General Dysentery, and the combined casualty lists were enormous.

Certainly humans can spread filth, but filth-feeding flies are also a great help. Civil War letters and diaries are filled with tales of soldiers who fought the flies more often than they fought the enemy. With sanitary conditions in a poor state, and open kitchens as the rule, flies who fed on filth one minute might be feeding on the armies' rations the next. The flies also fed on the dead soldiers and their horses and mules. During the American Civil War, as with many wars, General Dysentery had an aide-de-camp, and his name was Colonel Fly.

Filth-feeding flies weren't the only members of that insect order that helped make life miserable for the Federals and Confederates (Fig. 36). An examination of medical records revealed that during the American Civil War over 1.3 million

History and Insects, Figure 36 **Confederate soldiers from the American Civil War cover themselves with sand to avoid mosquitoes (courtesy of the Florida State Archives).**

cases of malaria, and 10,000 deaths from that disease, were reported just in the Union Army. While medical records for the Confederates are nowhere near complete, it is known that in the first 2 years of the war alone, more than one-seventh of all cases of sickness reported by Confederates stationed east of the Mississippi River were due to malaria. Mosquito-transmitted malaria even helped stop one of the first attempts by Union forces to capture Vicksburg.

Many Civil War historians maintain that the Confederacy lost the Civil War in the West, and not in the campaigns in Virginia. The loss of Vicksburg was the beginning of the end for the Confederacy, and an early victory there would have hastened the end of the war. A shorter war, without the horrendous casualties suffered in mid-1864 and later, might have resulted in a more lenient attitude toward the South after the war. This in turn might have helped avoid so many of the problems the United States endured over the next 100 years, problems created by a harsh Reconstruction that the winners forced on the South. An early victory might also have left President Lincoln alive at the end of the war. Only he had the political influence to counter the political clique known as the Black Republicans, who dictated policy after the Civil War. We know from his writings that Lincoln intended to be very lenient toward those who had fought against the Federal government. What the history of the United States might have been had he lived is something we can dream of only wistfully.

World War I

Lice may have played a role in allowing the Allies to eventually win World War I. As a result of the early battles of the war, when the Austrians invaded Serbia and were eventually driven out, northern Serbia was devastated. Then typhus began to appear in the Serbian armies in November 1914. There were fewer than 400 doctors in the country, most of whom caught the disease, and 126 died. The country was in ruins: it had almost no experienced nurses, relatively few hospitals for the flow of wounded, inadequate prisoner-of-war camps and appalling sanitary conditions. In early 1915, a typhus epidemic flared up that outpaced any other recorded typhus epidemic. By April, new cases numbered in the thousands per day. The mortality rate among infected patients rose from 20% early in the disease outbreak, to 60–70% at the height of the epidemic. Hans Zinsser reports, in his book "Rats, Lice and History," that 150,000 people died in 6 months, Austrian prisoners included. Although Germany mobilized and went to the aid of Austria on the Serbian front, there was no troop movement. With the Serbian armies smitten by disease, the Austrian and German armies stayed put. The last thing their high commands wanted was a typhus epidemic destroying their armies. For almost 6 months, the front was quiet. This delayed the timetable for the German-Austrian advance all along the Eastern Front, kept the Russians in the war longer and may possibly have saved the Middle East for Britain.

During World War II, the Germans would transfer units swiftly between the Western and Eastern fronts, as necessity demanded. However, during World War I this was not done. For some reason, although lice were just as common in the trenches of the Western Front as they were on the Eastern Front, typhus wasn't. The battlegrounds of France and Belgium never experienced the typhus epidemics of the Eastern Front. As a result, German and Austrian units were transferred only after they had undergone a lengthy delousing program. Generals Louse and Typhus robbed the Germans and Austrians of the military advantage of interior lines during World War I.

The Russian Revolution

During the period after the Russian Revolution, from 1917 through 1923, one Russian scientist estimated that there were 30 million cases of typhus, resulting in 3 million deaths, in European Russia alone. How this might have affected the political turmoil of this period, when Reds and Whites were locked in battle for ownership of Mother Russia, is unknown, but interesting to speculate about. Even Lenin is supposed to have said, "Either socialism will defeat the louse, or the louse will defeat socialism."

Lice

Lice have been our constant companions for most of history. Only in recent times have many come to believe that just the poor and uneducated are infected. In Sweden during the Middle Ages, the mayor of Hurdenburg was even chosen by a louse. The eligible elders sat around a table with a louse in the center and spread their beards. The one whose beard the louse climbed into was mayor for the next year. Thomas Becket, the murdered Archbishop of Canterbury, suffered even further distress after his death. As he was laid out for viewing in all his woolen clothes, his body cooled and the parasites began to depart. As one chronicler reports, "The vermin boiled over like water in a simmering cauldron, and the onlookers burst into alternate weeping and laughter." Lice have even entered our literature. For example, one of Scottish poet Robert Burns' more famous works is entitled, "To A Louse, On Seeing One On A Lady's Bonnet At Church."

And for all those who wondered why for centuries Europeans insisted on shaving off their hair only to cover their heads with elaborate wigs, I give you this simple answer – head lice. (Actually, head lice were probably only part of the reason for wearing wigs.) Unfortunately, while an interesting attempt at cultural control, because you could wash or change most wigs easier than hair, the fad quickly gained a life of its own. Some wigs were so elaborate that upper-class women had to sleep sitting up in bed to prevent destroying what a hairdresser had spent hours creating. Eventually people lost track of why wigs were initially worn, and the wigs were just as infested with head lice as hair once was. In addition to lice there is one report of a mouse family setting up housekeeping in one lady's elaborate hairpiece. And at least one noblewoman actually had a bird's nest woven into her wig. Eventually wigs were slowly replaced by powdered hair. I' m not sure why this fashion came about (cheaper than wigs?), but the white powder (usually flour) might have served as a mechanical control for lice.

Mosquitoes

During the Spanish-American War of 1898, the United States suffered far more casualties from malaria and yellow fever, transmitted by mosquitoes, than it did fighting the Spanish. These casualties occurred just as often in the camps around Tampa, Florida, as they did in Cuba, Puerto Rico and the Philippines. Approximately 80% of the American soldiers in Cuba came down with yellow fever. Fortunately, the death rate, while high, was nothing like that suffered by the French in Hispaniola at the beginning of the eighteenth century.

Both before and after the Spanish-American War, mosquitoes played a major role in preventing the successful completion of the Panama Canal, first by a French corporation, then by the Americans. During these attempts, thousands of workers died, and tens of thousands of investors lost more than $3 billion in the French attempt alone, an extremely large sum at the time. It was only after medical scientists realized that malaria and yellow fever were transmitted by mosquitoes and ordered that housing conditions be improved (with screening) and containers of standing water (in which the mosquito larvae developed) be emptied or destroyed that the workers stopped dying like flies.

The French seemed to have a continual problem with disease-transmitting mosquitoes. During World War I, a French general in Macedonia told his government that he had to disobey his orders to attack as his army was in the hospital with malaria. Fortunately for him, his German opponents were telling the same thing to their government.

The American military would have other encounters with malaria transmitted by mosquitoes. During World War II, American forces in the southwest Pacific and southeast Asia suffered 500,000 cases of malaria. General Douglas MacArthur once complained that two-thirds of his army was either suffering from malaria or recovering from it and therefore useless to the war effort. It was only when he consulted with a malaria-prevention team, and then commanded that their efforts be given much higher priority, that the tide of battle against malaria turned and the Army could then concentrate on defeating the Japanese. The Allies also had a secret weapon that came into use during 1943 – DDT. Used in all theaters of war, in bases far behind the lines and in newly liberated cities and towns, DDT was instrumental in reducing louse-borne disease and malaria. And during the Viet Nam War, the author remembers regularly forming up his Marine Corps platoon and walking the line with a Navy corpsman to ensure every marine swallowed his malaria prevention tablet.

Tsetse Fly

Outside of Africa, most people encounter tsetse fly only when reading about the African adventures of European explorers of the nineteenth century. But for inhabitants of sub-Saharan Africa, tsetse fly is much more than an interesting insect from the history books. Nearly 100 years ago, the tsetse was identified as the vector of sleeping sickness, a deadly disease that still has a stranglehold on a vast area larger than the United States. Tsetse fly, and the disease it transmits, is the reason why the ungulate herds of the African savanna have survived to the present day. This is because, without modern prophylaxis, livestock cannot live in regions where the tsetse fly flourishes, and significant human losses occur as well. As a result, economic development or exploitation of this region, although attempted many times by African and European concerns, was never successful. The tsetse fly has even been viewed as a beneficial insect in that it protected central Africa and the huge ungulate herds from those rapacious European governments of the nineteenth century that were busy looting the resources of the rest of the world. According to the World Heath Organization, human sleeping sickness threatens more than 60 million people in 36 countries. Without treatment, the disease is fatal. In the last century, there have been three major epidemics of sleeping sickness in Africa. The last one began in 1970 and is still in progress as of 2002. The tsetse fly may have protected central Africa from exploitation, but it had help from other flies. Even before venturing into central Africa, European powers had difficulty penetrating the wall created by malaria- and yellow fever-transmitting mosquitoes.

In cattle, sleeping sickness is called Nagana, and it is found in an area over 6 million square miles (or 10 million square kilometers) in Africa. It affects an estimated 46 million cattle in Africa alone and causes 3 million cattle deaths annually. Ninety percent of Africa's livestock consists of herds in small villages where maintaining healthy animals can be the difference between subsistence misery and a tolerable life for herders and their families. Other species have also suffered indirectly from this disease. Just in the country of Zimbabwe alone, more than 2,900 tons of DDT have been used in an attempt to control the tsetse fly. The effects of DDT on many vertebrate and beneficial insect species are too well-known to mention here. Fortunately, scientists developed new baiting methods that resulted in a dramatic decrease in pesticide use.

Black Flies

River blindness, or onchocerciasis, made parts of Africa and Latin America virtually unlivable. This disease, caused by a filarial worm, is transmitted by black flies. The worms migrate from the initial infection under the surface of the skin throughout the body and eventually to the surface of the eye, causing intolerable itching and scarring that results in a progressive loss of vision. Fortunately, medical science has developed treatments that are extremely effective. Recently completed multinational control programs coordinated by the World Health Organization have effectively eliminated this disease from large parts of West and Central Africa. This has been accomplished by temporarily (for about 20 years) eliminating the immature vectors from the breeding sites in rivers with insecticides, while at the same time therapeutically controlling the disease in humans. New programs are being mounted with the hope of continuing these exciting successes.

Mosquitoes, Disease and Society

Mosquito-transmitted malaria and yellow fever have also influenced economic and social conditions. To appreciate this you must first understand how the mosquitoes acquire and then transmit the diseases. You have probably been wondering, while reading this article, how these diseases can cause severe casualties among invading armies but leave the local residents still standing. Here is a very simplified explanation of a complex process. There are many strains of malaria and yellow fever, each of which is endemic to a region. When children are born in a region they are usually infected with the local strain. In children, the diseases may produce mild reactions, often confined to flulike symptoms. In many cases, their parents are not even aware the children have been infected. Sadly, this is not true for all children, as will be related later. Children who survive infection by the local strains may acquire partial immunity to those strains. However, as people travel to a different region, they encounter different strains to which they may not be immune. If they are adults, the new strains now infecting them can be life-threatening.

A female mosquito must first bite an infected person to acquire the disease. After a short period for the disease organism to complete the next portion of its life cycle, the female mosquito is now ready to pass it on to another person the next time it feeds. Many of the more common mosquitoes that transmit malaria and yellow fever have relatively short flight ranges, often less than a mile.

Therefore, a female mosquito that acquires the disease organism from an infected person will not normally travel great distances to spread that strain to new areas hundreds or thousands of miles away. (Unfortunately, modern methods of transportation have helped mosquitoes and disease strains to overcome these natural barriers.) It is especially important to know that the mosquitoes that transmit malaria and yellow fever are either dawn and dusk feeders and/or night feeders. If you are new to an area where malaria or yellow fever is common but take care to protect yourself from dusk to dawn from biting mosquitoes, then the chances of becoming infected with and dying from the local strains of malaria or yellow fever are greatly decreased. However, there are also at least two species of yellow fever-transmitting mosquitoes that also feed during daylight hours.

One of the lessons learned in Panama was that an area could be created that was relatively free of mosquito-borne infections. This area could then be inhabited by foreign troops, workers, administrators and their families. The French began to advocate separate communities for natives and Europeans. British medical scientists endorsed this concept by insisting that only natives carried the disease organisms in their blood. As a result, representatives of these governments in many colonies issued regulations against Europeans socializing or living near local populations. Some called this segregation, others called it apartheid. In some countries it eventually took on a social meaning of its own that was no longer related to disease transmission.

After the American Civil War, the southern states were devastated and needed capital investment to return the region to its former prosperity. Unfortunately, for most regions in the South, capital investment never arrived in the amounts necessary. As a result, the southern states would not achieve economic parity with most northern states until well into the twentieth century. One of the reasons for the lack of capital investment was very simple. The listlessness associated with malaria-infected workers, as well as the ever-present threats of malaria and yellow fever epidemics, kept many northern and European investors from risking their capital in the South. Workers infected with malaria may not have died, but the recurring illness contributed to a significant amount of missed work days and reduced productivity even when at work. It was estimated that one-third of all work missed by southern railroad workers was due to malaria. Other sectors of the economy also reported reduced productivity during those months when malaria was most pronounced.

The Continuing Effects of Insects on Society

Plagues, famine, social upheaval and conflict, and the insects that cause them, are easy to write about. Not as easy to understand and weigh are the everyday situations we live with that are also influenced or caused by insects. Numerous insect species continue to have a direct or indirect effect on the world economy. Here are a very few examples.

First, there is their entertainment value. Just as with our ancestors, insects are a part of our literature. Locust swarms, as depicted in Pearl Buck's "The Good Earth" which was also made into a very good movie, are still very much a threat for farmers in many regions of the world. "Leiningen Versus The Ants," an excellent fictional short story of one man's battle against army ants, has been adapted for many movies and TV dramas. Japanese film-makers used immense caterpillars and moths to destroy Tokyo many times. The 1950s saw Hollywood produce many films in which insects were threats to humanity, the author's personal favorite being "Them," a movie about giant ants. Even the least threatening of insects have been used to frighten theatergoers. For example, in "Damnation Alley," hordes of Madagascar hissing cockroaches were supposed to have eaten the entire population of Salt Lake City. The different ways in which insects have been featured in articles, books, films and TV shows is beyond counting. Aside from being entertaining, all of these have provided jobs and revenue to the countless people who wrote, directed or otherwise worked on them. And probably the world's shortest poem is even about an insect. Ogden Nash, the poet laureate of Maryland until his death in 1971, wrote "Fleas," which consists entirely of Adam/Had'm.

In a more serious vein, screwworms, the maggots of some fly species, feed on the flesh of living mammals. In the early part of the twentieth century, these pests cost the United States and Central American cattle industries millions of dollars in losses each year. A major effort using sterile flies has eliminated the primary screwworm from the United States all the way to southern Panama, where a barrier is maintained by quarantine and sterile fly releases to prevent reinfestation from South America. In 1996, the benefits to the various cattle industries were estimated at: USA – $796 million, Mexico – $292 million, Central America – $77.9 million. Before the primary screwworm threat was eliminated from these regions, many pet owners accepted that their dogs and cats would only live with them for a few years. Superficial cuts suffered by these cherished family members often resulted in a screwworm infestation, and the pets would wander off to die.

The urban pest-control industry in the United States provides hundreds of thousands of jobs and annually generates more than $5 billion in income. Termites alone are responsible for more than $1 billion in damage each year. The amount of wood used to replace such damage is considerable. Its harvest often generates bad feelings between the timber industry and environmentalists. Not only are millions of dollars spent on lawsuits by and against the timber industry, but the amounts spent on termiticides and new termite-proof construction practices take their toll on our economy.

In the United States, the major reason for most urban children missing school is asthma. And the major cause of asthma for these children is an allergic reaction to airborne cockroach feces and body parts. The social cost of these missed school days cannot be measured.

The urban pest-control industry formerly was the primary industry responsible for flea control in the United States. This is no longer true as the veterinary industry now markets several systemic insecticides to pet owners to the tune of more than $250 million dollars a year. This does not include the amount spent to prevent or cure heartworm, another mosquito-transmitted disease in dogs and cats.

And let us not forget the red imported fire ant (RIFA), which has become such a costly nuisance in the southern United States. As this ant expanded its range in the middle of the last century, the United States spent more than $270 million in an attempt to destroy it with airborne application of insecticides. That did not work, and it killed a lot of the native ant species and allowed the most aggressive RIFA to move into the vacant niches. Meanwhile, we continue to spend huge amounts every year in an attempt to control RIFA, which has an economic impact on the ornamental, agricultural and livestock industries, as well as others. In 2002, Congress funded a 5-year, multimillion dollar program to demonstrate RIFA management in pastures. Fruit pickers demand extra wages to work in infested citrus groves. And the amount spent by homeowners on RIFA insecticides, much of it wasted as they do not understand how to apply the baits properly, can only be guessed at.

Visit any hardware/garden store or supermarket and count the number of products specifically designed to control or manage insects. Scan any garden or home catalog to see the numerous products, many of which work and others of which do not, for eliminating insects from your home, garden or life. While many people believe that these problems and products cost our economy more than they benefit it, other people believe that they create even more jobs and strengthen the economy. Insecticides allow us to feed billions, but they also generate a cost to human health and the environment. And these problems are worldwide in scope. Whether you are growing corn in the American Midwest or tomatoes in a backyard in Italy, your insect problems are similar to farmers in Central Africa fighting whiteflies on cassava or rice farmers in the Philippines trying to control leafminers.

Of course, we now live in the twenty-first century, and we expect that the great insect-caused plagues of the past will not occur again because we have the technology to control them. Tell that to the government of Brazil, which employs 50,000 people to go into neighborhoods and empty out water-filled containers that serve as breeding areas for disease-vectoring mosquitoes. During late 2001 and early 2002 in Brazil, one out of every 10 workers just in the Brazilian state of Rio de Janeiro missed work due to being ill with dengue fever, another mosquito-borne disease. The region's association of merchants estimated that 30% of workers had contracted the disease. Dengue fever is characterized by severe headache, pain behind the eyes, high fever, backache, pain in the joints and a severe rash, with convalescence that may require several weeks.

Four strains of dengue virus have been identified, each of which produces lifelong immunity against the infecting virus. However, exposure to infection by a second strain of dengue virus in an already immune individual may result in a more severe form of dengue known as dengue hemorrhagic fever (DHF), with accompanying dengue shock syndrome. Death is then common, particularly when the Type 2 virus infects children who had previously been infected with another strain. Increased incidence of DHF has been experienced in the Western Hemisphere in the last 20 years, with outbreaks occurring in the Caribbean region. About 205,000 cases of dengue fever were reported annually in Brazil before the recent 2001–2002 season. In 1998, an epidemic in that country caused 540,000 cases. Worldwide, dengue is one of the most important arthropod-transmitted human viral diseases, and about 50 million 100 million cases of DHF are reported annually. On many Caribbean islands, residents are forbidden to have bird baths in their yards, and government employees perform the same function as those in Brazil, searching for and emptying water containers on private property. Although it has not experienced a dengue epidemic in decades, Florida began surveillance for dengue fever in 2002 and by October had reported nine confirmed and nine probable cases, all incurred from outside the United States. Texas occasionally reports cases of dengue fever. Currently, there is no vaccine available for dengue.

Malaria is also a major problem in Brazil, with 600,000 cases reported annually. Worldwide, 10% of the world's population suffers from malaria, and this mosquito-transmitted disease continues to kill up to 3 million people every year, including one child every 30 sec (another authority estimates one child every 12 sec). Today, malaria is so uncommon in most industrialized countries that people think it is a tropical disease. This is not true. Malaria was once common even in Scandinavia, and, as previously stated, malaria played a role in defeating the Roman invasion of Scotland and the Mongol invasion of western Europe. On the North American continent the Missouri and Mississippi watersheds were once major reservoirs for the disease, as was Canada. Malaria epidemics were once common on the East Coast, and Staten Island in New York only experienced heavy development when extensive draining of marshes occurred after 1900. Today, improvements in housing (screening, air conditioning, etc.) in many countries make the severe malaria epidemics of the past unlikely. However, the malaria virus strains and their vectors continue to evolve, and scientists are concerned that the newer, hardier breeds will one day make us pay greatly for thinking that it "can't happen again."

Encephalitis viruses are spread by mosquitoes. Eastern equine encephalitis (EEE) is the most lethal of the mosquito-borne encephalitides. Originally isolated from horses, this virus can also infect humans. The profitable race-horse industry can suffer large losses with just the death of a few highly-valued animals. However, when humans contract the disease, the cost is far worse. Older victims usually die, and Florida lost several elderly adults in 2001, when mosquito populations were low. When children are infected the cost is particularly high, not even counting the suffering among families. It is estimated that survivors of EEE each cost society $2.8 million in health care costs, long-term care and lost productivity.

The West Nile virus, which surfaced in New York in 1999, moved more quickly across the United States than many scientists estimated. By late-2002, it was present in more than 40 states. Yet with all the publicity surrounding this new disease to the North American continent, most people have still not changed their cultural behavior. Perhaps because, unlike dengue and malaria, not enough people are dying from it. Parents still take their children for walks at dusk, mostly shirtless, in areas where West Nile and other mosquito-transmitted diseases have been confirmed. Bird baths are a popular item in many backyards and are seldom emptied and the water changed. Other water-filled containers, mostly trash, are commonly found in yards and lots and serve as breeding grounds for untold billions of mosquitoes. At least two primary mosquito vectors of yellow fever and dengue fever breed in these containers, and both feed during daylight hours. One, the Asian tiger mosquito, is an introduced species that is now firmly established in the southern United States and is increasing its range.

Will Americans change their cultural habits only when many of them are sick and dying as the result of mosquito-transmitted diseases? Probably not. In South and Central America, and on many Caribbean islands, where governments often have more forceful methods of ensuring citizen cooperation, many residents still are strong believers in the right of property and resist government intrusion into their yards. As a result, people still die. The World Health Organization reports that worldwide there are still 2.5–3 million deaths a year from malaria, after decades and billions of dollars spent on educational outreach. And do not think that West Nile virus is a worst-scenario disease. There are other mosquito-transmitted diseases in other regions of the world that are just waiting for the opportunity to immigrate to North America, Europe and other continents.

For example, the Indian subcontinent, like the rest of Asia, has never experienced a yellow fever epidemic. What might happen if yellow fever were to be unleashed on this huge population that has no immunity to the disease? Andrew Spielman and Michael D'Antonio in "Mosquito," an excellent book detailing the natural history of this group, state that "If yellow fever broke out in India, for example, where vector mosquitoes and their human hosts are exceptionally abundant, the loss of human life would be cataclysmic." If you believe this to be an exaggeration, then consider that in the first half of the twentieth century, India had an average of 75 million people infected with malaria at any given time and that the death rate from malaria was 800,000 a year.

Mosquitoes are such a scourge in India that they sometimes can accomplish what modern armies cannot. During mid-2002, swarms of malaria-bearing mosquitoes along India's border with Bhutan were able to drive guerilla insurgents from their jungle hideouts in search of medical treatment. The mosquitoes accomplished something that Indian security forces have been unable to do for years.

Based on the above, it might seem that humanity would be better off if all insects were eliminated. Fortunately, entomologists, as well as scientists in many other disciplines, and a growing number of politicians realize that this is not the case. With well over a million identified species of insects, only a few hundred species are listed as serious pests of humans and their crops, animals and structures. A few thousand more species can be considered minor pests. But all the rest are considered directly or indirectly beneficial to humans. Just in the United States alone, insects annually pollinate more than $15 billion worth of fruit and vegetables. This does not include insects that pollinate flowering ornamentals which bring so much joy to our lives and provide employment in a huge industry. Plus, the insects themselves are responsible for destroying a thousand times more pest insects than we are able to with our feeble "advanced technologies." As a result, governments, universities and private concerns are expanding their funding for research and implementation of cultural and biological control techniques that are successfully managing insect and other pest populations. Without insects and other arthropods killing other insects and pollinating plants, the human species probably would have died out, either through disease or lack of food, even before leaving the trees.

The next time you swat at a mosquito, or flea, or other pest, try to remember that its ancestors did more to change human history than anything your ancestors ever did. For only when we recognize the tremendous influences insects have had on the history of our civilization can we begin to appreciate the adjustments in human behavior that will be necessary to live acceptably with them in the future.

History of Biological Control of Wheat Stem Sawflies (Hymenoptera: Cephidae)

THOMAS G. SHANOWER
USDA-Agricultural Research Service,
Sidney, MT, USA

Wheat stem sawflies (Hymenoptera: Cephidae) are important pests of wheat and other grain crops in the northern hemisphere. The egg, larval, and pupal stages are spent inside the wheat stem, while the adult is mobile but short-lived. Sawfly larvae feed inside the stem and the damage they cause reduces the number and weight of the kernels. The sawfly larva also cuts the stem at the base of the plant as it constructs a pupation chamber. The weakened stem breaks and the grain lodges or falls to the ground, adding to yield losses and making harvesting difficult. Yield losses of more than 20% have been reported for different sawfly species from North America, Europe, North Africa and Asia. The value of these losses may reach $100 million annually.

Management of wheat stem sawflies has focused on three strategies: the development of resistant wheat cultivars, relying primarily on solid-stems as a resistance mechanism; various tillage operations to destroy larvae and/or pupae in the wheat stubble; and biological control. Pesticides are generally ineffective because the larvae are hidden within the stem and are too costly for a relatively low value crop such as wheat. Efforts to develop solid-stemmed wheat cultivars began in the 1930s. The first solid-stemmed cultivar was released in 1946, and more than 20 cultivars have been released since then. Unfortunately the performance of these cultivars has been variable, and yields in the absence of sawflies are lower than hollow-stemmed cultivars. Tillage, either in the spring or fall, has also been somewhat successful in reducing sawfly populations but has important limitations. Tillage requires an additional field operation, increasing wheat production costs and reducing profitability, and can also increase soil erosion rates. The third strategy used to manage sawflies is biological control using exotic parasitoids. Three cephids, *Cephus cinctus*, *C. pygmaeus*, and *Trachelus tabidus*, have been targets of biological control programs in Canada and the USA. These efforts have been extensive, though only partially successful. The remainder of this section reviews previous biological control efforts against these pests, beginning with the biology of sawfly natural enemies (the parasites, predators and pathogens that attack these pests).

Sawfly Natural Enemies

The most important sawfly natural enemies are parasitic Hymenoptera. A small number of pathogens and predators are known to attack sawflies but have relatively little impact on sawfly population dynamics compared to parasitoids. More than 40 parasitoids are reported to attack sawflies, though little is known about most species; fewer than ten have a significant impact on sawfly populations. Many species attack other hosts found in grasses or other parasitoids (these are then called hyperparasitoids). The most important primary parasitoids of grass-feeding sawflies are in the Braconidae, Ichneumonidae, and Eulophidae families. Before discussing sawfly biological control programs, it is important to understand the biology and ecology of the key natural enemies.

Several species of braconid attack sawflies in different regions of the world. All of these braconids are larval ectoparasitoids, living and feeding on the outside of the host larva's body. The most important are *Bracon cephi* and *Bracon lissogaster* that attack *Cephus cinctus*, and *Bracon terebella* and *Heterospilus cephi* that attack *Cephus pygmaeus*. In general, braconid parasitoids have more impact on sawfly populations in the New World than in the Old World. This may be due to the absence of ichneumonid parasitoids in North America. In other parts of the world, ichneumonids dominate sawfly parasitoid complexes. Parasitism levels by braconids range from 20 to more than 90% of available hosts in North America, while in Europe and the Mediterranean region a considerably lower percentage, often <5%, of hosts are parasitized. The biology of the braconids is similar among species. Females locate sawfly larvae inside the stems from the vibrations produced by the feeding larva. She inserts the ovipositor and paralyzes the larva before laying one or more eggs. Eggs hatch within a few days and the braconid larvae begin feeding on the sawfly larva. Depending on the braconid species, more than one parasitoid may develop on a host larva. The braconid larvae consume the entire host except for the head capsule and epidermis. Larval development is completed in 2–3 weeks, and the parasitoid larva usually overwinters in the stem of the host plant. There may be one or two generations per year.

More than ten species of *Ichneumonidae* attack sawflies, though most are rare or are present at very low levels. The most important are species of *Collyria*. This group is egg-larval endoparasitoids, meaning they live and feed from inside the body of the host. In Europe, *Collyria coxator* is the dominant primary parasitoid of the European wheat stem sawfly (*Cephus pygmaeus*). Parasitism levels of 20–76% have been reported from England, Belgium, France, Switzerland, Germany, Russia, and Bulgaria. *Collyria coxator* females locate and oviposit into sawfly eggs inside the plant stem. Up to eight *Collyria* eggs and/or larvae have been found within a single sawfly (known as superparasitism), though it is not known whether these eggs are from the same or different females. Despite the presence of more than one *Collyria* larva, only a single adult parasitoid will emerge from a parasitized sawfly larva. Unlike the braconid parasitoids, *Collyria* does not paralyze the sawfly larva. The parasitized sawfly larva continues to feed within the stem throughout the season, and moves to the base of the plant and cuts the stem in a manner similar to an unparasitized sawfly larva. The *Collyria* larva remains within the host body until spring when it emerges and pupates. The adult then chews through the plugged end of the stub and emerges prior to the emergence of the unparasitized sawfly adults.

The third and least common group of primary parasitoids are several species of Eulophidae. The impact of these species is very low, and only two species (*Pediobius* spp.) have been studied in any detail. These two are found throughout the northern hemisphere, and are internal larval parasitoids. In addition to attacking sawfly larvae, they also attack other phytophagous Hymenoptera and Diptera found in grass stems. Parasitism of more than 50% of sawfly larvae in grasses has been observed, while in wheat, parasitism levels rarely exceed 5%. The reasons for the low attack rate in wheat are unknown.

Previous Biological Control Programs

Cephus cinctus was the first sawfly targeted for biological control. This work was initiated in Canada, and used parasitoids collected in the United Kingdom. Three parasitoids were selected for introduction into Canada, two from England (*Collyria coxator* and *Pediobius nigritarsus*), and one from the eastern United States (*Heterospilus cephi*). The three species were not collected from *C. cinctus* but rather from the related sawfly species, *Cephus pygmaeus*. From 1930 to 1938, when the program was discontinued due to the onset of World War II, more than 450,000 *C. coxator* and 120,000 *P. nigritarsus* individuals were released at sites in Saskatchewan and Alberta. Relatively few *H. cephi* adults were released, approximately 1,500, at one site in Alberta, and in only 1 year. None of the three released parasitoids became permanently established, though recoveries of *C. coxator* were made up to 2 years after release, with parasitism up to 9% at some sites.

A second biological control attempt against *Cephus cinctus* was undertaken in the western USA between 1952 and 1955. This program also used parasitoids obtained from *C. pygmaeus*, but this time collections were made in France instead of England. The predominant parasitoid collected was again the ichneumonid *Collyria coxator*, which parasitized 25–90% of the *C. pygmaeus* hosts. A second parasitoid, *Bracon terebella*, was also collected. Parasitized *C. pygmaeus* cocoons were collected and shipped to Moorestown, New Jersey, where they were held for adult emergence. After emerging, parasitoid adults were flown to release sites in Montana and North Dakota. Nearly 40,000 *C. coxator* and 3200 *Bracon terebella* were released over 4 years. Release sites were sampled for 6 years beginning in 1953. No recoveries were made of *B. terebella* in either Montana or North Dakota. Low numbers of *C. coxator* were recovered at some sites, but never more than 2 years after release. The last recovery was in 1957.

The third and smallest biological control program against *Cephus cinctus* began in the late 1950s, when it was recognized that parasitoids collected from England and France might be poorly adapted to climatic conditions in western North America. Parasitoids were collected, again from the related host *C. pygmaeus*, in the Ukraine, the Caucasus region of Russia, and from Sweden. As in the two previous attempts, the most common parasitoid collected was *Collyria coxator*. However, in laboratory studies, *Collyria coxator* suffered high mortality in *C. cinctus*. Nonetheless, a small quantity (119) of *Collyria coxator* from the Ukraine was released in Alberta. There is no report of establishment.

The biological control efforts directed at *Cephus cinctus* are examples of an approach that has been called "new associations" or neoclassical biological control. This approach utilizes natural enemies from a different but closely related species to the target host. The target host and natural enemy thus form a new association, and according to the theory, establish a lower equilibrium population level for the target host. In this instance, four parasitoid species, *Collyria coxator*, *Pediobius nigritarsus*, *Bracon terebella* and *Heterospilus cephi*, were released against *C. cinctus* in North America. Despite a sustained effort, particularly for *Collyria coxator*, none of these species was successfully established. The lack of establishment was likely due to the use of poorly adapted parasitoids. The parasitoids were collected from a different sawfly species and the locations where they were collected, predominantly England and France, are climatically and agronomically very different from the North American Great Plains. Host suitability studies conducted early in the program could have saved considerable time and effort by identifying the lack of compatibility between the target host and the natural enemies. In hindsight, these studies could have avoided the needless release of an inappropriate parasitoid.

In contrast to the program for *Cephus cinctus*, biological control of *C. pygmaeus* was very successful. These efforts, carried out from 1935 to 1938 in the USA and 1937–1940 in Canada, resulted in the successful establishment of a parasitoid and a reduction in sawfly population levels. Because both *C. pygmaeus* and *T. tabidus* were attacked in Europe by many of the same parasitoid species, the release program in the US was intended to address both pest species (*Trachelus tabidus* has not been reported from Canada). These programs utilized *Collyria coxator* which Canada had arranged to obtain from England for use against *Cephus cinctus* in the western Prairie Provinces (described above). More than 28,000 *C. coxator* adults were released in the US, and more than 24,000 *C. coxator* females were released in Canada. *Collyria coxator* was successfully established in both the US and Canada, and based on the levels of parasitism observed in the field, it appears to play an important role in regulating *C. pygmaeus* populations. By the mid-1980s, *C. coxator* parasitized up to 80% of *C. pygmaeus* larvae in the field.

This program is an example of classical biological control, where an introduced pest is controlled by collecting natural enemies from the target pest's area of origin, and releasing them into the new habitat. Once established, the introduced natural enemies can lower the target pest's population to sub- economic levels.

Summary

Wheat stem sawflies are important pests of wheat in the northern hemisphere, particularly in North America. Host plant resistance and cultural control strategies offer partial control, though both have significant drawbacks. Attempts at biological control using exotic parasitoids have been variably successful. For *Cephus pygmaeus* and *Trachelus tabidus* in eastern North America, an ichneumonid parasitoid (*Collyria coxator*) was successfully established and contributes to reduced population levels now observed in these two sawflies. In contrast, biological control for *Cephus cintus* has been attempted unsuccessfully three times. Several factors may have contributed to the lack of establishment of natural enemies in the western US and Canada. A key factor may have been that the parasitoids selected for release were collected from a different sawfly host and perhaps they were unable to complete development in this new host. A second problem may have been that the parasitoids were not adapted to the colder, drier climate they were released into. The release protocol may also have contributed to the lack of establishment. Adults were transported across the country (Canada or the US) and released immediately into the field. This may have resulted in injury or death to the adult parasitoids due to shipping and handling, and poor timing and/or synchronization between C. cinctus populations and the parasitoids.

Hobby, Bertram Maurice

Maurice Hobby was born in Southampton, England, on October 23, 1905. As a schoolboy living in Southampton, he developed an early interest in insects and lived close enough to the New Forest that frequent collecting trips there were possible. In 1925 he became a student at Oxford University, gaining his first degree in zoology in 1929. As a graduate student at Oxford, he worked on "Predaceous insects and their prey," and gained a D.Phil. degree in 1934, whereupon he was awarded a Junior Research Fellowship and, the following year, was appointed assistant to the chairman of the entomology department (the Hope Department of Entomology). Other positions and promotions followed at Oxford University, until he retired in 1972. But, in 1938 he was appointed examiner to the Oxford Delegacy of Local Examinations, and later a delegate of that organization, as well later still as a Delegate of Oxford University Department for External Studies. Thus, he served as a teacher and tutor within the university and outside it. His research was mainly on predatory insects, especially Asilidae and Empididae, and included analyses of insect diets and taxonomy. In 1932, while still a student, he took part in an Oxford University expedition to Sarawak, bringing back large collections of insects, which were described in part by him and in part by others. In 1937, he married Marcia Prestidge and, the same year, joined the editorial board of the Entomologist's Monthly Magazine. He and Marcia had a 45-year association with the editing of that journal, and it was in this capacity that they had contact with so many entomologist authors. He was the editor, and a very patient one; she handled much of the correspondence. He was a member of entomological societies, president of the Society for British Entomology in 1937, elected an honorary fellow of the Royal Entomological Society of London in 1982, and elected a fellow of the Linnean Society in 1948, became a fellow of the Zoological Society of London, and was secretary of The Entomological Club (an exclusive organization) and secretary of the Ashmolean Natural History Society. His ability at swimming led not only to his participation in swimming and water polo teams but as Examiner for the Royal Life-Saving Society, Treasurer of the Oxford University Swimming Club, and President of the Oxfordshire Swimming Association. He also represented Oxford University as a chess player. He died at his home in Oxford on July 19, 1983, survived by Marcia and their one son.

Hocking, Brian

Brian Hocking was born in London on September 22, 1914. With a bachelor's degree and supportive wife, Jocelyn, he served as an entomologist in the Indian army in World War II. In 1946, he was appointed a faculty member of the Department of Entomology, University of Alberta, and eventually became professor and head. His interests were in insect flight, behavior, migration, and physiology, especially of Diptera of medical importance, the diseases transmitted by biting flies, and he studied the biting flies of Churchill, Manitoba, and means of their control. He published 110 papers and supervised research of 30 graduate students. He was president of the Entomological Society of Alberta in 1967, and was awarded the Gold Medal of the Entomological Society of Canada in 1973. He died on May 23, 1974.

Hodotermitidae

A family of termites (order Isoptera). They commonly are known as Old World harvester termites.

► Termites

Holarctic Realm (Nearctic and Palearctic Realms)

The holarctic realm is a large zoogeographic region encompassing most of North America, Europe, and northern Asia. It often is subdivided into the Nearctic realm (North America south to central Mexico) and Palearctic realm (Europe and Asia except for Southeast Asia), but the faunas are really quite similar, and characterized by such fauna as vireos, wood warblers, deer, bison and wolves.

► Zoogeographic Realms

Holcopogonidae

A family of moths (order Lepidoptera).

► Butterflies and Moths

Holdfast

A structure that functions to attach an insect to a substrate (e.g., the anal tube of some beetle larvae).

Holidic Diet

A chemically defined diet. A diet in which all the components added to the diet are precisely known. There may be chemical reactions that occur after mixing, however, that change the nature of the diet. This type of diet is important for determining the effects of various nutrients on insect biology. (contrast with meridic and oligidic diets)

Holland, William Jacob

William Holland was born in Bethany, Jamaica, on August 16, 1848, and his parents returned with him to the USA in 1851. His father, a pastor of the Moravian church, was very interested in natural history and brought collected items to Ohio, USA, from Jamaica. In 1858 the family moved again, to North Carolina, and in 1863, during the American Civil War, to Pennsylvania. In 1867 he completed studies at Moravian College, and in 1869 entered Amherst College, Massachusetts, and studied chemistry, physics, geology, astronomy, paleontology, and philosophy. After graduation he became a school principal. However, in 1871 he entered Princeton Theological Seminary at his father's request, in preparation for a church ministry. In 1874 he became pastor of a church in Pittsburgh, Pennsylvania, and worked in this position until 1891, when he became Chancellor of the Western University of Pennsylvania. While still occupying the last position, he also became in 1898 Director of the Carnegie Museum (in Pittsburgh). His great entomological contributions were his (1898) "The butterfly book…" and (1903) "The moth book…" which were affordable illustrated works on the butterflies and moths of the USA and Canada. His research was on the Lepidoptera of equatorial Africa and of Central and South America. His collection was rich in lepidopterous specimens from those places, Asia, and the USA. His interests extended also to fossil reptiles. He died on December 13, 1932.

Holocyclic Life Cycle

A life cycle in which a viviparous parthenogenetic female produces live nymphs without mating during some time of the year, but cyclically produces males and females that mate and produce eggs. (contrast with anholocyclic life cycle)

Holometabolous Development

A type of development, also known as complete or complex metamorphosis, characterized by the occurrence of the egg, larval, pupal, and adult stages during the life cycle. This is considered to be a more evolutionarily advanced form of development than hemimetabolous development (incomplete or simple metamorphosis).

► Metamorphosis
► Hemimetabolous Development

Holoptic

A term used to describe flies in which the compound eyes meet dorsally.

Holotype

The original specimen from which a new species description is created. Also referred to as the "type" specimen.

Homeostasis

Stability or steady state in an ecological community or in physiological functions.

Homeothermic

An organism capable of maintaining a relatively constant body temperature, usually elevated above the ambient temperature. Although some insects are capable of limited temperature regulation, they are poikilotherms, not homeotherms.

► Poikilothermic

Homeotic Gene

Genes that determine the identification and sequence of segments during embryonic development in insects.

Homeotic Genes in Coleoptera

SUSAN J. BROWN[1,2], TERESA D. SHIPPY[1,2], ROBIN E. DENELL[1,2], RICHARD W. BEEMAN[1,2]
[1]Kansas State University, Manhattan, KS, USA
[2]USDA-ARS-GMPRC, Manhattan, KS, USA

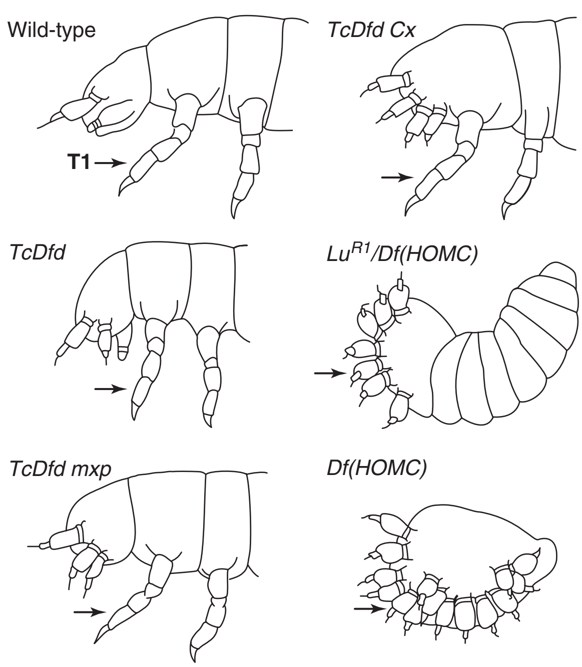
Ever since W. Bateson coined the term "homeotic" in the late nineteenth century to describe arthropod and vertebrate variants in which one body part is transformed into the likeness of another, scientists have been intrigued by the underlying implication that single genes may have large effects on the morphological development of individual segments. Indeed, during the last half-century, eight homeotic genes located in two clusters (Antennapedia Complex = ANTC and Bithorax Complex = BXC) have been identified by genetic and molecular analysis in the fruit fly *Drosophila melanogaster*. These genes encode structurally similar transcription factors that regulate many other genes to control regional identity along the anterior-to-posterior axis during embryogenesis in arthropods and virtually all other animals. A. Sokoloff and others described several homeotic mutants in the beetle, *Tribolium castaneum*, as early as 1960 in the *Tribolium* Information Bulletin. In 1987, R. Beeman determined that, similar to homeotic mutations in flies, *Tribolium* homeotic mutations display colinearity in that their order on the chromosome reflects the order of their functional domains along the anterior-to-posterior axis of the insect. In addition, he demonstrated that they are located in a single homeotic complex (HOMC) rather than in two separate clusters, as in flies. This information allowed M. Akam and others to infer the ancestral state of the homeotic complex (single and contiguous) by comparing insect and vertebrate "Hox" genes.

Genetic and molecular analyses have been exploited to elucidate the structure and function of homeotic genes in *Tribolium*. The evolutionary counterparts (orthologs) of all eight *Drosophila* homeotic genes have been cloned and characterized. In addition, the region of the *Tribolium* HOMC corresponding to the *Drosophila* ANTC has been sequenced. The expression patterns of the *Tribolium* homeotic genes are similar to those of their *Drosophila* orthologs. The genetic tractability of *Tribolium* makes it the most useful non-Drosophilid arthropod for the study of homeotic genes. Mutations in all but one of the *Tribolium* homeotic genes are now available, and comparison of mutant phenotypes between *Tribolium* and *Drosophila* orthologs has yielded several important insights into how homeotic gene function may have evolved in these two insect lineages. Many phenotypic differences may reflect the highly derived morphology of *Drosophila* larvae, which has internalized head structures and no external limbs.

Perhaps the most striking case of functional difference is that of the *Tribolium* gene, *maxillopedia* (mxp), and its *Drosophila* counterpart, proboscipedia (pb). In *Drosophila*, *pb* specifies the identity of the adult maxillary and labial appendages. In *pb* mutants, maxillary appendages are abnormal, while labial appendages are transformed to legs. However, *pb* has no apparent embryonic function, because larvae lacking *pb* function are completely normal. In beetles, *mxp* is required for proper maxillary and labial appendage identity in both larvae and adults. In individuals completely lacking *mxp* function, the maxillary and labial palps are transformed to legs. Individuals with reduced mxp function survive to adulthood and show the transformation of the adult maxillary and labial palps to legs. These observations suggest that an ancestral *pb* gene may have had an embryonic function that was lost along the lineage leading to *Drosophila*, and subsequent analysis of pb orthologs in other insects supports this conclusion.

Mutations in the *Drosophila Deformed* (*Dfd*) gene cause abnormal head development in both embryos and adults (Fig. 37), but do not produce homeotic transformations. In *Tribolium*, embryos lacking function of the corresponding gene, *Tribolium castaneum Deformed* (*TcDfd*), the mandibles are transformed to antennae and the endite lobes of the maxillary appendages are missing. This phenotype suggests that an ancestral *Dfd* gene had a homeotic function.

The embryonic phenotype of *Drosophila Sex combs reduced* (*Scr*) mutants is somewhat controversial. The first thoracic segment (T1) is unambiguously transformed toward second thoracic segment (T2) identity, but the effect on the



Homeotic Genes in Coleoptera, Figure 37 **Mutations caused by expression of homeotic genes.**

labial segment has been interpreted as either a transformation to maxillary identity, or merely a loss of labial identity. In adults, weak Scr alleles cause T1 to T2, as well as labial to maxillary, transformations. In *Tribolium*, the embryonic mutant phenotype of *Cephalothorax* (*Cx*) (the ortholog of *Scr*) is quite different from that of Scr. In larvae completely lacking *Cx*, the labial appendages are transformed to antennae, and there is no segmental groove between the T1 segment and the head, such that the T1 segment is cephalized.

Drosophila mutants lacking *Antennapedia* (*Antp*) function die as larvae and display transformations of all three thoracic segments toward more anterior segments. The posterior portion of T1 is transformed toward posterior labial identity, and T2 and the anterior portion of T3 are transformed toward T1. During adult development, patches of T2 leg tissue that lack *Antp* function are transformed toward antennal identity. However, in *Tribolium* larvae lacking function of prothoraxless (the *Antp* ortholog), all three legs are transformed to antennae.

Null mutants of *Drosophila Ultrabithorax* (*Ubx*) affect segments in the posterior thorax and the anterior abdomen. One notable effect is the appearance of a rudimentary thoracic limb (Keilin's organ) on the first abdominal segment (A1) of *Ubx* mutant larvae. Further studies have demonstrated that *Ubx* normally represses expression of *Distalless* (*Dll*) in this segment, and thus prevents Keilin's organ formation. In contrast, during embryonic development in *Tribolium*, a pair of modified appendages, called pleuropodia, transiently appears on A1. *Ultrathorax* (*Utx*), the *Tribolium* ortholog of *Ubx*, and *Dll* are co-expressed in the pleuropodia. In mutants lacking Utx, the pleuropodia are transformed toward legs. Thus, in *Tribolium*, *Utx* modifies appendage identity rather than repressing appendage formation.

The *Drosophila abdominal-A* (*abd-A*) gene is expressed throughout most of the abdomen, but *abd-A* mutations cause only the anterior abdominal segments to be transformed. In contrast, *Tribolium* mutants lacking function of *Abdominal* (*A*) (the beetle ortholog of *abd-A*) develop appendages with mixed leg/pleuropodia identity on A1–A8. Thus, the Tribolium *abd-A* ortholog (A) is responsible for the limbless abdomen in Tribolium.

The *Drosophila Abdominal-B* (*Abd-B*) gene specifies the identity of the posterior abdomen and the post-abdomen. These functions are performed by two protein isoforms, M (expressed in the posterior abdomen) and R (expressed in the post-abdomen). In *Tribolium*, expression of the *Abd-B* ortholog is limited to the post-abdomen, and mutant effects are confined to this region as well. Thus, the Tribolium ortholog seems to lack the M function. This restriction of the Abd-B domain also accounts for the expanded region affected by *A* mutants.

An overarching theme of the *Tribolium* homeotic mutant phenotypes is that removal of all homeotic genes from a segment results in the transformation of the appendages on that segment to antennae (diagrammed in the accompanying figure, first thoracic appendage indicated by arrow). This is dramatically demonstrated by a deficiency mutation, (*Df*(*HOMC*)), that deletes most of the *Tribolium* homeotic genes (*TcDfd* through *A*). Embryos homozygous for Df(HOMC) have antennae on every segment from anterior head through posterior abdomen. Another deficiency, (Lu^{R1}), which removes all HOMC genes except *A* and the *Abd-B* ortholog, as well as genes outside the HOMC, has been identified. Although, individuals homozygous for Lu^{R1} die early in embryogenesis, embryos carrying one copy of *Df*(*HOMC*) and one copy of Lu^{R1} survive to hatching. These larvae have normal abdomens, but they also have antennae on all thoracic and head segments. These results suggest that the default appendage state in the absence of homeotic genes is antenna, and that the presence of homeotic genes is required to specify other appendage types, either directly or indirectly.

In *Drosophila*, artificially induced expression of most homeotic genes transforms antennae toward legs. This transformation is apparently caused by repression of *homothorax* (*hth*), a gene required for antennal development. In the absence of *hth* and homeotic gene expression, the antennae are transformed toward legs. Thus, it appears that homeotic gene repression of *hth* causes transformation of antenna to leg by uncovering an even lower default state of appendage identity. Limited data from *Drosophila* suggest that homeotic genes also may repress antennal development within their normal expression domains. The phenotypes of the *Tribolium* homeotic mutants demonstrate that this is a conserved, global property of homeotic genes in insects, and that these genes have dual roles: the specification of regional identity and the repression of antennal identity.

Homologous Chromosomes

Two or more identical chromosomes.

Homologous Genes

Two genes from different organisms and therefore of different sequence that code for the same gene product.

Homology

Homology has been defined as "having a common evolutionary origin," but also is often used to mean "possessing similarity or being matched." At the genetic level, it means that organisms have two or more gene products in common.

Homoplasy

The resemblance of organisms due to convergent evolution or parallelism, rather than to common ancestry.

Homoptera

Sometimes considered to be a suborder of Hemiptera, containing the aphids, whiteflies, scale insects, leafhoppers, and many other small insects with piercing-sucking mouthparts.

► Bugs

Homotomidae

A family of bugs (order Hemiptera, superfamily Psylloidea).

► Bugs

Homozygous

Diploid cells or organisms that contain two identical alleles of a particular gene.

Honey Bee, *Apis mellifera* (Hymenoptera: Apidae)

Thomas C. Webster

Kentucky State University, Frankfort, KY, USA

The genus *Apis* in the family Apidae consists of at least nine species. This genus is distinguished from other bee genera by a combination of eusocial behavior, construction of vertical sheets of beeswax comb, communication and recruiting by a dance language, and a barbed stinger in the worker bee. Unlike some other bees, *Apis* species do not construct material to surround their nests.

The honey bee kept by most beekeepers, *Apis mellifera* L., is native to Europe, Africa and Asia west of the Caspian Sea. Approximately 20 subspecies are distributed across this very large range. The other *Apis* species are all native to southern and eastern Asia. *Apis cerana*, the species most closely related to *A. mellifera*, is also managed by beekeepers in China and other Asian countries.

Anatomy

The honey bee conforms to the general Hymenopteran morphology. The mandibles are developed for biting and chewing, and the proboscis for sucking liquids. Like nearly all apids, *Apis* species are adapted to collect and consume nectar and pollen from flowering plants. Branched hairs facilitate pollen collection and the pollination of plants they visit.

The queen bee is the primary reproductive female. Glands that produce pheromones are in the mandibles, tergites, rectum and tarsi. Her abdomen is noticeably enlarged when actively laying eggs, as her ovaries fill most of her abdomen. She can extend a curved, unbarbed stinger from the tip of her abdomen.

The drone is designed entirely for reproduction. He is easily recognized by his robust thorax and abdomen, and large compound eyes which touch each other dorsally and cover most his head. Most of the abdominal cavity is filled with the reproductive organs.

The worker bee is a female derived from the queen form. She is usually sterile, although she has several small ovarioles in each ovary. A few individuals in a typical colony are inclined to become "laying" workers with developed ovaries.

The worker is enabled in her many tasks by several modifications. Many of the youngest workers become nurse bees, with enlarged hypopharyngeal, salivary and mandibular glands which secrete food for larvae and the adult queen. Eight wax glands in the underside of the abdomen are activated when the colony needs to build comb. The crop is large enough for the bee to carry nearly its own weight in nectar or honey. A segment of each hind tarsus, concave and fringed with hairs, holds the pollen loads of returning forager bees. These are corbiculae, or pollen baskets. A straight, barbed stinger at the tip of the abdomen is used against intruders, including worker bees from other hives. The barbs keep it embedded in a large intruder. When the stinging bee breaks away from the intruding animal, she leaves the venom sac attached to the stinger where it continues to pulse and inject venom. The venom contains a potent mix of proteins and peptides.

Life History

The egg, larval and pupal stages of each bee are spent inside of a beeswax cell. The cells are built by worker bees according to the needs of the colony. In this way, the workers direct much of colony growth and reproduction (Fig. 38).

Honey Bee, *Apis mellifera* (Hymenoptera: Apidae), Figure 38 **Comb with adult bees, brood cells and stored honey.**

The queen cell begins as an inverted, thimble-shaped cup. Nurse worker bees add a glandular secretion, royal jelly, to the cup as the larva grows inside of the queen cell. Worker bees extend the cell walls as the larva grows. Soon the cell takes on a peanut shape, hanging down across the face of comb. The highly nutritious royal jelly allows the queen to reach adulthood only 16 days after being laid as an egg. Within a week or two of emerging from the cell, the queen takes a mating flight, returns to the hive, and begins to lay eggs. In the course of one or several flights, she will mate with 15–20 drones. After mating, her ovaries will enlarge greatly. She may lay as many as 2,000 eggs daily during late spring. In temperate climates she will cease oviposition during winter. The queen rarely lives more than 2 years. When she begins to fail due to age or disease, the workers rear a replacement queen, a process called supersedure.

Drone cells are hexagonal and horizontal, usually built along the bottom and edges of the comb. Drone larvae are fed a mix of glandular secretions and honey. The drone emerges as an adult after 24 days of development. He is fertile and prepared for mating flights within several weeks of adult life. He may fly a kilometer or more to a drone congregation area where he may mate on the wing with a young queen. If he is successful in mating, he then falls away from the queen, leaving his genitalia inside of her, and dies soon afterward. In temperate climates, any drones that survive until autumn are evicted from their hive by worker bees and die soon afterward.

Most of the cells in the hive are worker cells. They are hexagonal and horizontal like drone cells, but smaller. Worker larvae, like drones, consume glandular secretions and honey. A worker bee takes 21 days to mature in the cell, and emerges as an adult. She then takes on a complex series of tasks that collectively maintain the colony. A worker lives 1 or 2 months during the very active period of spring and summer. Workers winter with their queen in a quiet cluster in temperate regions.

As a highly eusocial insect, the honey bee is always colonial. The colony will overwinter with as few as 10,000 workers and a single queen. Colony population grows rapidly in spring, often to over 50,000 workers, several thousand drones and a queen. Colony fission, or swarming, is normal in spring. One or more queens are reared in preparation for this event. The original queen leaves the hive with a fraction of the colony's workers and drones to found a new nest. A daughter queen remains and inherits her mother's hive. One or two afterswarms may leave with other daughter queens and part of the remaining colony population.

In many regions, honey hoarding ends in early summer. Late summer and autumn are spent in reduced foraging, nest maintenance and winter preparations. In a cold winter, brood rearing and foraging will cease. The colony clusters tightly to conserve heat. A healthy, populous colony with sufficient stored honey will survive until spring, when it begins again to forage and rear brood.

One honey bee subspecies from southern Africa, *A. mellifera scutellata*, was brought to Brazil in 1956 and was later released. It reproduced and spread rapidly, as it is well adapted to the New World tropics. Over the following four decades *A. m. scutellata* displaced most of the European race bees from northern Argentina through Mexico, except where beekeepers maintained European stock. In the United States it is now established in many southern states. This African, or Africanized, bee is undesirable in most countries because of its extreme tendency to sting, swarm and abscond. However, it is a much better honey producer in the tropical countries such as Brazil, where beekeepers have learned to manage it effectively.

Another subspecies, *A. m. capensis*, is notable for its ability to produce females from unfertilized eggs. By this trait the colony can create a new queen long after its original queen has disappeared. This bee is native to a small area of South Africa. However, it has recently begun to colonize the region further north where it interbreeds with, and replaces, the colonies of *A. m. scutellata* kept by South African beekeepers. *Apis mellifera capensis* is a poor honey producer, and very difficult to exclude from hives. This bee has created a crisis in South African beekeeping.

Behavior and Physiology

During the first days of adult life, the worker bee cleans cells. Care for larvae follows, including the production of glandular secretions. Some workers will secrete beeswax, build comb, circulate air through the hive by fanning their wings, ripen honey, guard the hive entrance, and attend the queen according to the needs of the colony. The oldest bees forage for nectar, pollen and water. This progression creates a division of labor based on the ages of worker bees in the colony: age polyethism. The transition is regulated in part by juvenile hormone secreted by the corpora allata.

The honey bee colony has sophisticated mechanisms which allow it to respond appropriately to needs and opportunities. One is the flexibility in the workers' division of labor. The proportion of the workers in a colony which attend to a task changes quickly when need arises. The number of nurses, beeswax producers, guard bees, water collectors, or foragers increases if more larvae are reared, new comb must be constructed, enemies threaten, the hive overheats, or flora become available, respectively.

Another mechanism is the communication of floral food sources among foragers. A fraction of the forager bees are scouts, searching for new nectar and pollen sources. Successful scouts communicate the direction, distance and quality of food sources to other foragers inside the hive. A waggle dance in a figure-8 pattern gives this information. Direction is given by the angle of the dance on the comb, distance by the duration of the waggling, and quality by its vigor. Recruit workers that attend the dance are then able to find the flora, even kilometers from the hive.

The discovery and assessment of potential nest sites by scout bees is comparable to the cooperative search for forage. This occurs soon after a swarm has left its original hive. Individual bees search for cavities and assess them according to size, location, dryness and other criteria. These scouts communicate the location and desirability of each site to the others, by waggle dancing on the surface of the swarm. This assessment and communication behavior is analogous to that for food sources.

The queen bee's presence in the colony and her condition are communicated to the workers by pheromones. These pheromones inhibit the construction of queen cells and ovarian development in workers. On a queen's mating flight, they attract drones.

Worker bee pheromones play critical roles in colony life. One comes from the Nasanov gland at the dorsal tip of the abdomen. Workers release volatile chemicals from this gland to draw others to a particular site. When a colony must aggregate at a new nest site, or unite after a disruptive event, workers releasing Nasanov pheromone attract the other colony members. A second pheromone is a volatile mix at the stinger. When a stinger embeds in a hive intruder and breaks free of the stinging worker bee, the sting pheromone is released. This encourages other bees to sting near the same spot. By this chemical communication, a quick and painful defense is mounted against the intruder. Also, worker and queen bees produce pheromones that allow them to identify kin and nestmates.

The brood is also a source of pheromone that inhibits the development of worker ovaries and stimulates workers to forage. Beeswax stimulates foraging, apparently due to volatile chemicals in the wax secreted by the workers' wax glands.

Honey bees, like all eusocial insects, share food by passing it directly from one individual to another. This process, trophallaxis, involves the entire colony. Trophallaxis informs all colony members of the availability of food and allows the efficient transfer of food to storage cells or to those individuals that most require it.

The temperature of the colony is carefully regulated. During cold weather, the bees coalesce into a ball with their branched hairs interwoven. By rapidly contracting their flight muscles the workers generate enough heat to maintain the core of the cluster at around 35°C. In hot weather, water foragers place droplets of water on the cell walls of the comb. Other workers perch at the hive entrance and inside the hive where they pull air through the hive by fanning their wings. This evaporative cooling keeps the hive at the critical 35°C.

Honey and pollen hoarding is behavior adaptive for long periods without forage, especially winters in cold climates. Honey is made from nectar gathered from the nectaries of many types of flowering plants. A foraging worker bee carries the nectar from the flower to another worker waiting in the hive, which in turn deposits the nectar in a wax cell. Other workers then ripen the nectar into honey by adding enzymes and evaporating much of the water by fanning their wings to circulate air through the hive. Ripe honey contains glucose, fructose, approximately 18% water, a small amount of hydrogen peroxide, and is slightly acidic. Microbes will not grow in ripe honey. Small amounts of minerals, amino acids and other nutrients vary in honey according to the floral source. Pollen is also stored in wax cells, with honey and glandular secretions added.

Honey is primarily an energy source for adult bees. Pollen contains protein, vitamins, lipids and minerals to support brood rearing and the queen when she is laying eggs. Pollen is not directly consumed by larvae and the queen, however. Nurse bees feed glandular secretions to them after digesting large amounts of pollen.

Genetics and Breeding

Like all hymenopterans and some insects of other orders, honey bees are haplodiploid. Females have two sets of 16 chromosomes, while drones have one set. When the queen is about to lay an egg she may apply a bit of semen from that stored in her spermatheca, as the egg passes through her reproductive tract. This egg is thereby fertilized, and in most cases becomes diploid and a female. Alternatively, the queen may withhold semen from the egg. It is then laid as a male, retaining its haploidy. The development of individuals, in this case males, from unfertilized eggs, is termed parthenogenesis.

The queen's ability to control the sex of her offspring is critical to social life. The rearing of drones, which are unable to perform the tasks necessary to colony maintenance, is relegated to mating season.

Honey bees differ from many hymenopterans in their sex determination mechanism. A single locus controls the sex of the individual bee. A diploid bee that is heterozygous at this "sex locus" is female. A haploid bee has only one allele at the locus and hence develops as a male, or drone. Most populations of honey bee colonies include many alleles for this locus. Consequently, most fertilized eggs will be heterozygous and female. However, some fraction of the diploids will be homozygous, depending on the number of alleles in the population and the degree of inbreeding. These individuals become "diploid drones." They are routinely cannibalized as very young larvae shortly after they hatch.

The queen bee's habit of mating far from her hive and with many drones has important implications for the colony. It promotes outbreeding and ensures that most of her diploid offspring will be heterozygous at the sex locus, hence female. Also, multiple mating creates multiple subfamilies of workers within the colony. Worker bees with the same queen mother and drone father share 75% of their genes by common descent. Workers from the same mother and different fathers share only 25% of their genes by common descent. These relationships are the basis of cooperation and rivalry among colony members. Much of our understanding of insect sociality is derived from the genetic systems of honey bees and other social Hymenopterans.

Honey bee breeding has been fairly successful in many respects. Bees can be bred for gentle behavior, disease and mite resistance, honey production, pollen hoarding and color. However, breeding is complicated by two factors. One is the bees' habit of mating in flight, far from the hive. Attempts to control mating within an enclosed structure or on isolated islands have been unpractical or unsuccessful. Complete control over breeding relies on instrumental insemination. This technique works well, but is laborious when practiced for a large scale operation. The second factor is the production of diploid drones as lines are inbred to select for a desired trait. Inbred colonies with queens producing many diploid drone larvae suffer badly. A closed breeding population must be maintained carefully to retain sufficient sex alleles.

The honey bee genome was sequenced in 2004. This allows close inspection of the bee's traits and also illuminates comparisons with other species.

Honey Bee Sexuality: An Historical Perspective

Cyrus Abivardi
Swiss Federal Institute of Technology Zurich, Zurich, Switzerland

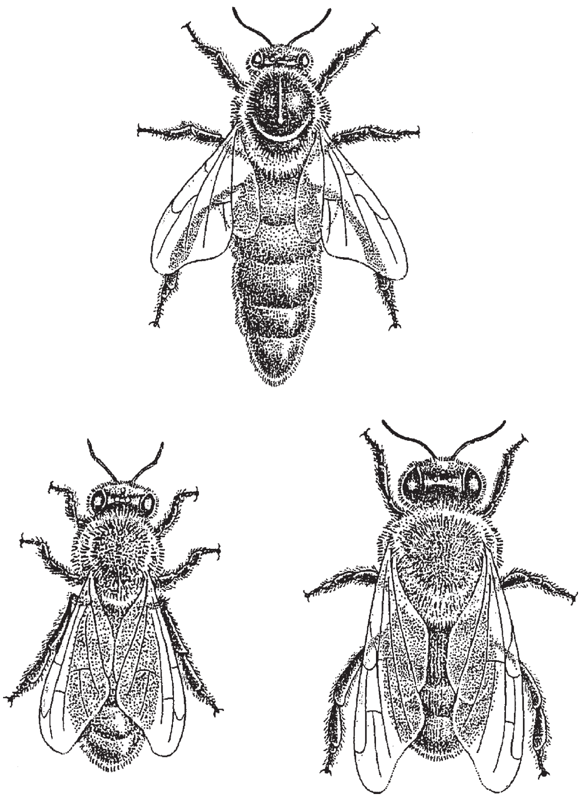
Before honey bees (*Apis mellifera* L. and other *Apis* species) were domesticated, honey was gathered from wild hives. Rock painting dating from 8,000 to 15,000 years ago depict a fascinating history of this process. The earliest recorded hives, which signify domestication, are about 5,000 years old, and are seen in paintings and drawings on tombs and other monuments in Egypt. However, the traditional hives of Iran and Turkey may provide a clue to the question of the origin of the hives that were depicted in Ancient Egypt.

Despite a long history of beekeeping, the first report on the sexuality of the queen honey bee is relatively new. Although Aristotle (384–322 B.C.) noted that some authorities referred to the large ruler bee as the hive's mother, he found the hypothesis unlikely, as "nature only arms males." Because the hive's ruler has a sting, Aristotle concluded that it must be the king and the defenseless drones were, therefore, the females (Fig. 39). Although erroneous, Aristotle's word was taken as virtual law for the next 1,800 years.

It was not until 1609 that Charles Butler (an English beekeeper) in his famous book titled "The Feminine Monarchie," challenged the idea of king bees. Thereafter, in 1670, a Dutch scientist (Jan Swammerdam) proved this hypothesis through dissection, accompanied by his full anatomical drawings of queen, drone and worker. He died in 1680, but his work was not published until 1737–1738.

"The Feminine Monarchie" consists of over 230 pages in ten chapters. The introductory chapter (Cap. I.), titled "Of the nature and properties of Bees, and of their Queene," contains information on the benefits and behavior of honey bees in general and a description of the Queen bee in particular.

"*Among all the creatures which our bountifull GOD hath [has] made for the use and service of man, in respect of (1) great profit with small cost (2) of their ubiquity or beeing [being] in al [all] countries, and (3) of their continual labour and consenting order, the Bees are most to be admired. For first with the provision of a hive and some little care and attendance, which need be no hinderance to other busines [business], but rather a delightful recreatio*



Honeybee Sexuality: An Historical Perspective, Figure 39 **Three castes of adult honey bees: *above*, the queen; *below left*, the worker, and *below right*, the drone.**

amid the same, they bring in store of sweete delicates most holesome both for meate and medicine…

"For their order it is such that they may wel [well] be said to have a comon wealth, since al that they do is in como [community] without any privat [private]… They work for al, they watch for al, they fight for al. In their private quarrels when they are from the hive or common treasury howsoever you use them they wil not resist it by any meanes they can get away. Their dwelling and diet are common to al alike: they have like commo [common] care both of their wealth and young ones. And al this under the government of one Monarch, of whom above al things they have a principal care & respect, loving, reverencing, and obeying her in al things.

"If she goe [goes] forth to solace [rescue] her selfe (as sometime she wil) many of them attend upon her, garding her person before and behind; they which come forth before her ever now & the returning, and looking back, and making with all and extraordinarie noise, as if they spake [speak] the language of the knight. Marshalls men, & so away they fly together, and anon [immediately] in like manner they attend her back againe [again]. This I may say because I have seene [seen] it: although the Philosopher be of another minde [mind].

"If by hir [her] voice she bid them goe [go], they swarme [swarm]; if being abroad she dislike the weather, or lighting place, they quickly returne [return] home again; while she cheereth [cheers] thé [them] to battaile [battle] they fight; when she is silent they cease, while she is well, they are cheerfull about their worke [work], if she droope [droops], they faint also; if she dy [dies], they will never after prosper, but thenceforth languish till they bee [be] dead too.

"If they have many Princes, as when two fly away with one swarme, or when two swarmes are hived to gether [together]: they strike one of them presently, and sometime they bring her down that evening to the matle [battle?], where you may find hir covered with a little heape [heap] of Bees, otherwise the next day they carie [carry] her forth either dead or deadly wounded. Likewise if the olde [old] Queene [Queen] bring forth many Princes (as she may have six or seaven [seven], yea sometime halfe [half] a skore or more which superfluitie [superfluity] nature affordeth [affords] for more suretie [security], in case some miscarrie [miscarry]) then lest [in order to avoid] the multitude of rulers should distract the unstable commons into factions, within two daies [days] after the last swarme, you shall finde [find] them that remained, dead before the hive. I have taken eight of thé [them] up [above-mentioned] together brought out of one hive, when two were already gon [gone] forth with the swarmes.……

"The Queene-bee is a Bee of a comely and stately shape, browne [brown] of colour as other Bees, but that her belly is more bright: she is longer thé [than] honi-bee [honey-bee], by one third part, that is almost an inch long: she is also bigger then [than] a honi-bee [i.e., the Worker] but not so big as a drone, although somewhat longer: hir head

proportionable, but that it is more roud [round] thé [than] the little Bees, by reason hir fanges [fangs] be shorter; hir tonge [tongue] not halfe so long as the little Bees: for whereas they gather with one nectar, with the other ambrosia, shee [she] hath no need to use either, beeing to bee [be] maintained, as other Princes, by the labor of hir subicects [subjects]; hir wings of the same size with a smal [small] Bee, & therefore in respect of hir long body, they seeme [seem] very short, for they reach but to the middle of hir nether [lower] part: hir legges [legs], proportionable, and of the colour of hir belly, but hir two hinlegges more yellowe: hir nether part so long, and halfe so long as hir upper part, more picked thé [than] smale Bees, and without such three whitish ringes [rings] as other Bees have at the three partitions: the speere [spear] she hath is but little, and not halfe so long as the other bees: which, like a kings sword, is borne rather for shewe [show] and authoritie [authority], then [than] for any other use: For it belongeth [belongs] to her subiects as well as to fight for her, as to provide for her."

The year 1609 A.D. (i.e., the date of publication of "The Feminine Monarchie") is considered by some to mark the beginning of our knowledge about the sexuality of the ruler of the hive (the Queen). However, the first person to understand the sex of the queen probably was Luis Méndez de Torres in Spain who published a book in 1586 titled "*Tractado breve de la cultivacion y cura de las colmenas*." In this book, he stated clearly that the leader bee in the hive laid the eggs, from which all workers, drones and future queens developed. In addition to de Torres, the knowledge of several Persian scientists about the queen bee may be traced back to a much earlier period.

Ikhawân-ul-Safâ (or The Brethren of Purity), who flourished in A.D. 950–1000 at Basra, composed a series of tracts in Arabic language known as the "Epistles of the Brethren of Purity," (also reported as "Epistles of the Brethren of Sincerity") in the latter half of the tenth century (A.D. 950–1000). The authors of these series were six encyclopaedists, with at least three of them from Persia. Among their work, the "Dispute Between Man and the Animals" is of zoological interest. The following citation from this work refers to the sexuality of the ruler of the hive:

"*There, the king of the hasharât [insects], Ja'sub [i.e., the bee queen], rules over the wasps, the flies, the bugs, the mosquitoes, the dung beetles, the spanish flies, the butterflies and moths and over the locusts, i.e., over all small animals which fly by wings, have no feathers, no bones, no soft hair and no fur.*"

The above statement, which uses the Arabic word of *Ja'sub* [the bee queen], clearly refers to the sexuality of the hive ruler. It is also the first attempt to define an insect. After about three centuries, al-Qazwini (the author of "*Ajâ' ib al-Makhluqât*," composed in A.D. 1263) clearly speaks of the role of the king of honey bees (the queen) in the production of a new king. Despite this report, the sexuality of the queen as well as the definition of the insect were overlooked by other scholars for a long time. While the sexuality of the "King" remained unnamed until publication of "The Feminine Monarchie" by Charles Butler in 1609 A.D. (or the publication of the book of Luis Méndez de Torres in 1586 A.D.), the definition of insect was ignored until the seventeenth century.

Some citations from al-Qazwini (1263) follow:

"*Honeybee is a nice, pleasant animal with fine body structures…*"

"*A king has been established to give orders. He has inherited his honour from his ancestors, since it is the king who produces again a new king.*"

"*The king is twice as large as the others and leads the work…*"

Although the word "King" used in the former sentences may indicate the ignorance of al-Qazwini about the sexuality of the "Queen," the second phrase (i.e., "since it is the king who produces again a new king"), leaves no doubt on the awareness of this author about the sex of the "Queen."

Honeydew

WHITNEY CRANSHAW
Colorado State University, Ft. Collins, CO, USA

Honeydew is the liquid excrement produced by certain insects in the order Hemiptera that feed on the phloem of plants. It is an often highly concentrated, sugary fluid mixed with some nitrogenous compounds. Honeydew is primarily produced by aphids, certain "soft scales," mealybugs, whiteflies, some leafhoppers and some treehoppers. Honeydew is sometimes used to describe the sugary-rich materials exuded from certain plant structures and some insect galls.

The sugars found in honeydew are a complex of simple plant-derived sugars (e.g., glucose, fructose) and more complex sugars (e.g., melezitose) that have usually been derived by the insect using enzymes. Various nitrogenous materials are found in honeydew that primarily reflect plant products of the host plant, but also includes waste products of the insect. Nitrogenous materials may occur in concentrations typically ranging 1–2% in honeydew.

Excreted honeydew is sometimes described as "dripping sap" or "ghost rain," particularly when it drops from shade trees. Some honeydew-producing insects may excrete several times their weight per day. It is sticky and can foul surfaces where it lands, producing significant nuisance problems. Surfaces on which honeydew persists also allow growth of sooty mold fungi.

The high sugar content of honeydew may also attract wasps and bees. This can create nuisance problems with these insects aggregating as they forage on shade trees, shrubs and ornamental plants. However, honeydew is sometimes a valued resource for honey bees, particularly in Europe where honey dew-derived honey may be described as "forest honey," usually collected when normal nectar sources are limited and honeydew-producing insects are common.

Honeydew and other exudates of phloem-feeding hemipterans have also been used as sweet materials in the human diet, sometimes described as manna. The most notable description of this material is from the Biblical chapter Exodus, and likely involved a honeydew-producing local scale insect (*Trabutina mannipara*) associated with tamarisk.

Honey Pot

A container constructed from cerumen by stingless bees and bumblebees and used to store honey.

Hood

A structure found in soft ticks that projects over, and covers, the mouthparts.

Hoogstraal, Harry

EMMETT R. EASTON
University of Hawaii, Honolulu, HI, USA

Harry Hoogstraal was born on February 24, 1917 in Chicago, Illinois. As a young man he and his sister Catherine were taken by their mother to the Chicago Natural History Museum on Lake Shore Drive to attend Saturday morning lectures for children on natural history. Mrs. Hoogstraal then convinced museum administrators to allow Harry to listen also to Saturday afternoon lectures for adults. Here they were exposed to fascinating adventures by speakers such as Admiral Byrd and makers of wildlife films, and Harry was allowed into the research area of the museum. This exposure kindled a passion for natural history that Harry maintained for the rest of his life.

He went on to receive the B.A. degree from the University of Illinois and, while working on a M.S. degree from the same university, conducted four expeditions (1938–41) exploring the distribution of animals and plants (first on reptiles and amphibians) and later with the late Robert Traub and Kenneth L. Knight (fellow student) collecting invertebrates, mammals and birds. During the second year, the brakes failed on a truck that Harry was driving on June 20, 1940, while on a remote mountain road in the Sierra Madre mountains, in the central highlands of Mexico. Harry was caught beneath the truck's frame when it rolled, while his associates in the back were thrown clear. His back was broken and he suffered other injuries and was taken to the hospital in Mexico City where physicians predicted he would never walk again. However, two physicians from the University of Chicago were visiting and they just happened to have a new sulfa drug, sulfonilimide, that had been recently developed. He was treated with this drug, making him one of the first persons to receive it.

After receiving the M.S. degree in 1942 he joined the U.S. Army and worked on mosquito taxonomy in New Guinea and in the Philippines. During wartime he developed plans for a Philippine expedition with Donald Heyneman, Floyd Werner and Philippine colleagues by convincing the herpetologist, Karl Schmidt, Curator of Zoology, Field Museum to join with the Philippine National Museum in conducting a faunal survey.

Later, in 1948–49, he conducted surveys in East Africa and Madagascar under the U.S. Navy and the University of California African expedition and became head of the Sudan sub-unit of Naval Medical Research Unit #3, where he conducted host-parasite studies in the equatorial province of the Sudan. This resulted in his 1,099 page monograph on the "Ticks of the Sudan" (1956), which continues to be cited today. In 1950 he became Head of the Medical Zoology Department at NAMRU #3 in Cairo, a post that he held until his death. He received the Ph.D. from the London School of Hygiene and Tropical Medicine in 1959, with the D.Sc. from the same institution in 1971. He also received a doctorate (honoris causa) in 1978 from Ain Shams University, Cairo and an honorary D.Sc. from the University of Khartoum in 1983.

Starting in the late 1940s, Harry pursued the study of ticks with a single-minded dedication, producing over 500 research papers, an 8-volume bibliography of ticks and tick-borne diseases, and over 1,750 translations of Russian and Chinese articles. Harry was interested in ticks on a world-wide basis, not just in Africa, and few scientists outside of Russia or China could read these languages. When Madam Pospelova-Shtrom published her paper on a new *Argas* tick from a vulture in Turkmenia (former USSR) (previously known as the fowl tick, *Argas persicus*), Harry made the translation (T89) available to anyone working on ticks. He would routinely send his publications to anyone interested in ticks, as well as copies of his bibliography, and he cooperated with Rocky Mountain Laboratory scientists in Montana (USA) as well as tick authorities in England, and in South Africa. He and Makram Kaiser then reviewed the *Argas persicus* problem by re-examining as many ticks as possible from museums and collections that had previously been misidentified as *persicus*, resulting in several new species being described such as *Argas arboreus* from heron and cattle egret rookeries in Cairo, *Argas africolumbae* from swallows in South and East Africa, *A. zumpti* from a vulture in South Africa, and *A. walkerae* from domestic poultry in southern Africa. In the Americas, persicus were also re-examined as it was originally believed this tick occurred world-wide between 40° N and 40° S latitude. Glen Kohls and C. Clifford then reported *A. sanchezi* in southwestern USA and Mexico, *A. radiatus* in central and southern USA, and *A. miniatus* in Panama and South America; all had previously been misidentified as *persicus*.
